Abstract
This paper considers correlation clustering on unweighted complete graphs. We give a combinatorial algorithm that returns a single clustering solution that is simultaneously $O(1)$-approximate for all $\ell_p$-norms of the disagreement vector; in other words, a combinatorial $O(1)$-approximation of the all-norms objective for correlation clustering. This is the first proof that minimal sacrifice is needed in order to optimize different norms of the disagreement vector. In addition, our algorithm is the first combinatorial approximation algorithm for the $\ell_2$-norm objective, and more generally the first combinatorial algorithm for the $\ell_p$-norm objective when $1 < p < \infty$. It is also faster than all previous algorithms that minimize the $\ell_p$-norm of the disagreement vector, with run-time $O(n^\omega)$, where $O(n^\omega)$ is the time for matrix multiplication on $n \times n$ matrices. When the maximum positive degree in the graph is at most $\Delta$, this can be improved to a run-time of $O(n\Delta^2 \log n)$.

1 Introduction
Correlation clustering is one of the most prominent problems in clustering, as it cleanly models community detection problems [38, 36] and provides a way to decompose complex network structures [39, 32]. The input to the unweighted correlation clustering problem is a complete graph $G = (V,E)$, where $|V| = n$ and each edge $e \in E$ is labeled positive (+) or negative (−). If the edge $(u,v)$ is positive, this indicates that $u$ and $v$ are similar, and analogously if the edge $(u,v)$ is negative, this indicates that $u$ and $v$ are dissimilar. The output of the problem is a partition of the vertex set into parts $C_1, C_2, \ldots$, where each part represents a cluster.
Simultaneously Approximating All $\ell_p$-Norms in Correlation Clustering

The output should cluster similar vertices together and separate dissimilar vertices. Specifically, for a fixed clustering (i.e., partition of the vertices), a positive edge $(u, v)$ is a disagreement with respect to the clustering if $u$ and $v$ are in different clusters and an agreement if $u$ and $v$ are in the same cluster. Similarly, a negative edge $(u, v)$ is a disagreement with respect to the clustering if $u$ and $v$ are in the same cluster and an agreement if $u$ and $v$ are in different clusters. The goal is to find a clustering that minimizes some objective that is a function of the disagreements.\footnote{Note that the sizes and number of clusters are unspecified.} For example, the most commonly studied objective minimizes the total number of disagreements.

As an easy example to illustrate the problem, consider a social network. Every pair of people has an edge between them, and the edge is positive if the two people have ever met before, and negative otherwise. The goal of correlation clustering translates to partitioning all the people into clusters so that people are in the same cluster as their friends/acquaintances and in different clusters than strangers. The difficulty in constructing a clustering is that the labels may not be consistent, making disagreements unavoidable. Consider in the social network what happens when there is one person with two friends who have never met each other $(u, v, w)$ with $(u, v)$ and $(u, w)$ positive but $(v, w)$ negative. The choice of objective matters in determining the best clustering.

For a given clustering $C$, let $y_C(u)$ denote the number of edges incident to $u$ that are disagreements with respect to $C$ (we drop $C$ and write $y$ when it is clear from context). The most commonly considered objectives are $\|y_C\|_p = \sqrt[p]{\sum_{u \in V} y_C(u)^p}$ for $p \in \mathbb{R}_{\geq 1} \cup \{\infty\}$, the $\ell_p$-norms of the disagreement vector $y$. Note that the optimal objective values may drastically vary for different norms too. (For instance, in the example in Appendix A of [35], $V = A \cup B^2$, where $|A| = |B| = n/2$, and all edges are positive except for a negative matching between $A$ and $B$. The optimal $\ell_\infty$-norm objective value is 1 whereas the optimal for $\ell_1$ is $\Theta(n)$.) When $p = 1$, this objective minimizes the total number of disagreements. Setting $p = \infty$ minimizes the maximum number of disagreements incident to any node, ensuring a type of worst-case fairness.\footnote{\textcopyright denotes disjoint union.} Balancing these two extremes – average welfare on one hand and fairness on the other – is the $\ell_2$-norm, which minimizes the variance of the disagreements at each node.

Correlation clustering was proposed by Bansal, Blum, and Chawla [7] with the objective of minimizing the $\ell_1$-norm of the disagreement vector. The problem is NP-hard and several approximation algorithms have been proposed [7, 4, 16, 18]. Puleo and Milenkovic [35] proposed studying $\ell_p$-norms of the disagreement vector for $p > 1$, and they give a 48-approximation for any fixed $p$. Charikar, Gupta, and Schwartz [15] introduced an improved 7-approximation, which Kalhan, Makarychev, and Zhou [29] further improved to a 5-approximation. When $p > 1$, up until recently, the only strategies were LP or SDP rounding, and it has been of interest to develop fast combinatorial algorithms [37]. Davies, Moseley, and Newman [19] introduced a combinatorial $O(1)$-approximation algorithm for $p = \infty$ (see also [25] for a different combinatorial algorithm), and leave open the question of discovering a combinatorial $O(1)$-approximation algorithm for $1 < p < \infty$.

In all prior work, solutions obtained for $\ell_p$-norms are tailored to each norm (i.e., $p$ is part of the input to the algorithm), and it was not well-understood what the trade-offs were between solutions that optimize different norms. Solutions naively optimizing one norm can be arbitrarily bad for other norms (see Figure 1). A natural question is whether this loss from using a solution to one objective for another is avoidable. More specifically:

\footnote{In the social network example, minimizing the $\ell_1$-norm corresponds to finding a clustering that minimizes the total number of friends who are separated plus the total number of strangers who are in the same cluster. The $\ell_\infty$-norm corresponds to finding a clustering minimizing the number of friends any person is separated from plus the number of strangers in that person’s same cluster.}
For any graph input to unweighted, complete correlation clustering, does there exist a partition (clustering) that is simultaneously $O(1)$-approximate for all $\ell_p$-norm objectives?

Phrased another way, does there exist a universal algorithm for $\ell_p$-norm correlation clustering – one which is guaranteed to produce a solution that well-approximates many objectives at once? When the goal is to simultaneously optimize every $\ell_p$-norm, this is known as the all-norms objective. Universal algorithms and the all-norms objective are well-studied in combinatorial optimization problems, such as load balancing and set cover (see Section 1.2 for more discussion). In the context of correlation clustering, such an algorithm outputs a partition that has good global performance (i.e. $\ell_1$-norm) and also has no individual node with too many adjacent disagreements (i.e. $\ell_\infty$-norm). Universal algorithms exist for some problems and are provably impossible for others. The question looms, what can be said about universal algorithms for correlation clustering?

As far as we are aware, there are no known results for the all-norms objective in other clustering problems. In fact, for the popular $k$-median and $k$-center problems, it is actually impossible to $O(1)$-approximate (or even $o(\sqrt{n})$-approximate) these two objectives simultaneously [5].

1.1 Results

This paper is focused on optimizing all $\ell_p$-norms ($p \geq 1$) for correlation clustering at the same time. The main result of the paper answers the previous question positively: perhaps surprisingly, there is a single clustering that simultaneously $O(1)$-approximates the optimal for all $\ell_p$-norm objectives, and more generally $\ell_p$-norm objective for fixed $2 \leq p < \infty$.

In what follows, let $O(n^\omega)$ denote the run-time of $n \times n$ matrix multiplication.

\textbf{Theorem 1.} Let $G = (V,E)$ be an instance of unweighted, complete correlation clustering on $|V| = n$ nodes. There exists a combinatorial algorithm returning a single clustering that is simultaneously an $O(1)$-approximation for all $\ell_p$-norm objectives, for all $p \in \mathbb{R}_{\geq 1} \cup \{\infty\}$, and its run-time is $O(n^\omega)$.

\footnote{In some of the literature, for instance that of Golovin et al. [24], it is called the all-$\ell_p$-norms objective.}

\footnote{Note this is independent of $p$.}
The algorithm gives the fastest run-time of any \(O(1)\)-approximation algorithm for the \(\ell_p\)-norm objective when \(p \in \mathbb{R}_{>1}\). Further, the run-time can be improved when the positive degree of the graph is bounded, as shown in the following corollary.

**Corollary 2.** Let \(\Delta\) denote the maximum positive degree in an instance \(G = (V, E)\) of unweighted, complete correlation clustering on \(|V| = n\) nodes. Suppose \(G\) is given as an adjacency list representation of its positive edges. There exists a combinatorial algorithm returning a single clustering that is simultaneously an \(O(1)\)-approximation for all \(\ell_p\)-norm objectives, for all \(p \in \mathbb{R}_{>1} \cup \{\infty\}\), and its run-time is \(O(n\Delta^2 \log n)\).

The run-time of the algorithm matches the fastest known algorithm for the \(\ell_\infty\)-norm objective \([19]\), in both the general case and when the maximum positive degree is bounded. The best-known algorithm before our work relied on solving a convex relaxation on \(|V|^2\) variables and \(|V|^3\) constraints. We improve the run-time by avoiding this bottleneck.

In the setting when the positive edges form a regular graph, the interested reader may also find a clean proof (which is much simpler than that of Theorem 1) in Section 3 showing there is a solution that is simultaneously \(O(1)\)-approximate for the \(\ell_1\)-norm and \(\ell_\infty\)-norm objectives.

### 1.2 Related work

Correlation clustering was introduced by Bansal, Blum, and Chawla \([7]\). The version they introduced also studies the problem on unweighted, complete graphs, but is concerned with minimizing the \(\ell_1\)-norm of the disagreement vector. For this problem, Ailon, Charikar, and Newman \([4]\) designed the Pivot algorithm, which is a randomized algorithm that in expectation obtains a 3-approximation. While we know algorithms with better approximations for \(\ell_1\) correlation clustering than Pivot \([16, 18]\), the algorithm remains a baseline in correlation clustering due to its simplicity. (However, Pivot can perform arbitrarily badly -- i.e., give \(\Omega(n)\) approximation ratios -- for other \(\ell_p\)-norms; see again the example in Appendix A of \([35]\).) It is an active area of research to develop algorithms for the \(\ell_1\)-norm that focus on practical scalability \([11, 17, 33, 36, 14]\). Correlation clustering has also been studied on non-complete, weighted graphs \([15, 29]\), with conditions on the cluster sizes \([34]\), and with asymmetric errors \([26]\). In fact, in recent work Veldt \([37]\) highlighted the need for deterministic techniques in correlation clustering that do not use linear programming. Much interest in correlation clustering stems from its connections to applications, including community detection, natural language processing, location area planning, and gene expression \([38, 36, 39, 32, 9, 21]\).

Puleo and Milenkovic \([35]\) introduced correlation clustering with the goal of minimizing the \(\ell_p\)-norm of the disagreement vector. They show that even for minimizing the \(\ell_\infty\)-norm on complete, unweighted graphs, the problem is \(\text{NP}\)-hard (Appendix C in \([35]\)). Several groups found \(O(1)\)-approximation algorithms for minimizing the \(\ell_p\)-norm on complete, unweighted graphs \([35, 15, 29]\), the best of which is currently the 5-approximation of Kalhan, Makarychev, and Zhou \([29]\). Many other interesting objectives for correlation clustering focus on finding solutions that are (in some sense) fair or locally desirable \([3, 8, 1, 22, 27, 2]\). All of these previous works that study general \(\ell_p\)-norms or other notions of fairness or locality rely on solving a convex relaxation. This has two downsides: (1) the run-time of the algorithms are bottle-necked by the time it takes to solve the relaxation with at least \(\Omega(n^2)\) many variables and \(\Omega(n^3)\) constraints; in fact, it is time-consuming to even enumerate the \(\Omega(n^2)\) variables and \(\Omega(n^3)\) constraints; and (2) the solution is only guaranteed to be good for one particular value of \(p\).
Several problems have been studied with the goal of finding a solution that is a good approximation for several objectives simultaneously. The all-norms objective was introduced by Azar et al. [6], where the goal is to design a $\rho$-approximation algorithm for all $\ell_p$-norm objectives of a problem. They originally introduced the objective for the restricted assignment load balancing problem and showed an all-norms $2$-approximation. Further follow-up on the all-norms objective has been done for load balancing [30, 10, 31], and for set cover [24]. The term “universal” algorithm has also been used for Steiner tree [12, 13], TSP [28], and clustering [23], though in these settings the goal is different, namely, to find a solution that is good for any potential input; e.g., in Universal Steiner Tree, the goal is to find a spanning tree where for any set of terminals, the sub-tree connecting the root to the terminals is a good approximation of the optimal.

2 Preliminaries

We will introduce notation, and then we will discuss two relevant works – the papers by Kalhan, Makarychev, and Zhou [29] and Davies, Moseley, and Newman [19].

2.1 Notation

Recall our input to the correlation clustering problem is $G = (V,E)$, an unweighted, complete graph on $n$ vertices, and every edge is assigned a label of either positive ($+$) or negative ($-$). Let the set of positive edges be denoted $E^+$ and the set of negative edges $E^-$. Then, we can define the positive neighborhood and negative neighborhood of a vertex $u$ as $N_u^+ = \{v \in V \mid (u,v) \in E^+\}$ and $N_u^- = \{v \in V \mid (u,v) \in E^-\}$, respectively. We further assume without loss of generality that every vertex has a positive self-loop to itself.

A clustering $\mathcal{C}$ is a partition of $V$ into clusters $C_1, \ldots, C_k$ (but recall that $k$ is not pre-specified). Let $C(u)$ denote the cluster that vertex $u$ is in, i.e., if $\mathcal{C}$ has $k$ clusters, there exists exactly one $i \in [k]$ such that $C(u) = C_i$. It is also helpful to consider the vertices in a different cluster than $u$, and so we let $\overline{C}(u) = V \setminus C(u)$ denote this. We say that a positive edge $e = (u,v) \in E^+$ is a disagreement with respect to $\mathcal{C}$ if $v \in \overline{C}(u)$. On the other hand, we say that a negative edge $e = (u,v) \in E^-$ is a disagreement with respect to $\mathcal{C}$ if $v \in C(u)$. For a fixed clustering $\mathcal{C}$, we denote the disagreement vector of $\mathcal{C}$ as $y_\mathcal{C} \in \mathbb{Z}_{\geq 0}^n$, where for $u \in V$, $y_\mathcal{C}(u)$ is the number of edges incident to $u$ that are disagreements with respect to $\mathcal{C}$. We omit the subscript throughout the proofs when a clustering is clear.

Throughout, we let $\text{OPT}$ be the optimal objective value, and the $\ell_p$-norm to which it corresponds will be clear from context. The next fact follows from the definitions seen so far (recalling also the positive self-loops).

Fact 3. For any $u,v \in V$, $n = |N_u^+ \cap N_v^+| + |N_u^- \cap N_v^-| + |N_u^+ \cap N_v^-| + |N_u^- \cap N_v^+|.$

2.2 Summary of work by Kalhan, Makarychev, and Zhou

The standard linear program relaxation for correlation clustering is given in (P) below.\(^6\) In the integer LP, the variable $x_{uv}$ indicates whether vertices $u$ and $v$ will be in the same cluster (0 for yes, 1 for no), and the disagreement vector is $y$; the optimal solution to the integer LP has value $\text{OPT}$, while the optimal solution to the relaxation gives a lower bound on $\text{OPT}$. Note the triangle inequality is enforced on all triples of vertices, inducing a semi-metric space

\(^6\) Technically this is a convex program as the objective is convex; we say LP as the constraints are linear.
on $V$. Throughout this paper, as in [19], we refer to the algorithm by Kalhan, Makarychev, and Zhou as the KMZ algorithm. The KMZ algorithm has two phases: it solves (P), and then uses the KMZ rounding algorithm to obtain an integral assignment of vertices to clusters. At a high-level, the KMZ rounding algorithm is an iterative, ball-growing algorithm that uses the semi-metric to guide its choices. Their algorithm is a 5-approximation, and produces different clusterings for different $p$, since the optimal solution $x^*$ to (P) depends on $p$.

$$\min ||y||_p$$

s.t. $y_u = \sum_{v \in N^+_u} x_{uv} + \sum_{v \in N^-_u} (1 - x_{uv}) \quad \forall u \in V$ \hspace{1cm} (P)

$x_{uv} \leq x_{uw} + x_{vw} \quad \forall u, v, w \in V$

$0 \leq x_{uv} \leq 1 \quad \forall u, v \in V.$

Definition 4. Let $f$ be a semi-metric on $V$, i.e., taking $x = f$ gives a feasible solution to (P). The fractional cost of $f$ in the $\ell_p$-norm objective is the value of (P) that results from setting $x = f$. When $p$ is clear from context, we will simply call this the fractional cost of $f$.

2.3 Summary of work by Davies, Moseley, and Newman

The main take-away from the work of Kalhan, Makarychev, and Zhou [29] is that one only requires a semi-metric on the set of vertices, whose cost is comparable to the cost of an optimal solution, as input to the KMZ rounding algorithm. Thus, the insight of Davies, Moseley, and Newman [19] for the $\ell_\infty$-norm objective is that one can combinatorially construct such a semi-metric without solving an LP, and at small loss in the quality of the fractional solution. They do this by introducing the correlation metric.

Definition 5 ([19]). For all $u, v \in V$, the correlation metric defines the distance between $u$ and $v$ as

$$d_{uv} = 1 - \frac{|N^+_u \cap N^+_v|}{|N^+_u \cup N^+_v|} = \frac{|N^+_u \cap N^-_v| + |N^-_u \cap N^+_v|}{|N^+_u \cap N^-_v| + |N^-_u \cap N^+_v| + |N^-_u \cap N^-_v|}.$$  

Note that the rewrite in the second equality is apparent from Fact 3.

The correlation metric captures useful information succinctly. Intuitively, if $u$ and $v$ have relatively large positive intersection, i.e., $N^+_u \cap N^+_v$ is large compared to their other relevant joint neighborhoods $(N^+_u \cap N^-_v) \cup (N^-_u \cap N^+_v)$, then from the perspective of $u$ and $v$, fewer disagreements are incurred by putting $u$ and $v$ in the same cluster than by putting them in different clusters. This is because if $u$ and $v$ are in the same cluster, then they have disagreements on edges $(u, w)$ and $(v, w)$ for $w \in (N^+_u \cap N^-_v) \cup (N^-_u \cap N^+_v)$, but if they are in different clusters, then $u$ and $v$ have disagreements on edges $(u, w)$ and $(v, w)$ for $w \in N^+_u \cap N^+_v$. For more on intuition behind the correlation metric, see Section 2 in [19].

Davies, Moseley, and Newman [19] prove that the correlation metric $d$ can be used as input to the KMZ rounding algorithm by showing that (1) $d$ satisfies the triangle inequality and (2) the fractional cost of $d$ in the $\ell_\infty$-norm (recall Definition 4) is no more than 8 times the value of the optimal integral solution (OPT). Since the KMZ rounding algorithm loses a factor of at most 5, inputting $d$ to that algorithm returns a 40-approximation algorithm. A benefit of the correlation metric is that it can be computed in time $O(n^2)$, and even faster when the subgraph on positive edges is sparse.
2.4 Technical overview

It is not hard to see that the correlation metric cannot be used as input to the KMZ algorithm for $\ell_p$-norms other than $p = \infty$, as one cannot bound the fractional cost of the correlation metric against the optimal with only an $O(1)$-factor loss. To see why, consider the star again, as in Figure 1. Here, for all $u, v \in \{v_1, \ldots, v_{n-1}\}$, $d_{uv} = 1 - 1/(n - (n - 3)) = 2/3$, but for the $\ell_1$-norm, we need the semi-metric to have the value $1 - d_{uv}$ be close to 0, i.e. $O(1/n)$, for such $u, v$, in order for the fractional cost to be comparable to the value of OPT for $p = 1$.

There are several possible fixes one could try to make to the correlation metric. One idea is that since one can interpret the correlation metric as a coarse approximation of the probability the Pivot algorithm\(^7\) separates $u$ and $v$, one could try to adapt the correlation metric to more accurately approximate this probability.\(^8\) Another idea, inspired by an observation below, is that one could define a semi-metric for edges in $E^+$ and another semi-metric for edges in $E^-$, but then there is the difficulty of showing the triangle inequality holds when positive and negative edges are mixed. Both of these ideas were, for us, unsuccessful.

Instead, the following two observations of how the correlation metric works with respect to the $\ell_1$-norm led us to an effective adaptation:

1. One can bound the fractional cost, restricted to positive edges, of the correlation metric in the $\ell_1$-norm by an $O(1)$-factor times the optimal solution's cost (see Claim 1 in Appendix C of the full version \[20\]). Negative edges still pose a challenge.

2. If the subgraph of positive edges is regular, then we can actually bound the fractional cost of the correlation metric in the $\ell_1$-norm on negative edges as well.\(^9\) See Section 3.

These observations led us to ask whether some adjustments to the correlation metric might yield a semi-metric with bounded fractional cost in the $\ell_1$-norm or even the $\ell_p$-norm more generally (while still remaining bounded in the $\ell_\infty$-norm). Moreover, since the KMZ rounding algorithm does not depend on $p$ (whereas in the KMZ algorithm, the solution to the LP does depend on $p$), inputting the same semi-metric to the rounding algorithm produces the same clustering for all $\ell_p$-norms!

We are ready to define the adjusted correlation metric. Let $\Delta_u$ denote the positive degree of $u$ (the degree of $u$ in the subgraph of positive edges).

\begin{definition}
Define the adjusted correlation metric $f : E \to [0, 1]$ as follows:

1. For $d$ the correlation metric, i.e., $d_{uv} = 1 - |N_u^+ \cap N_v^-| / |N_u^- \cup N_v^+|$, initially set $f = d$.

2. If $e \in E^-$ and $d_e > 0.7$, set $f_e = 1$ (round up).

3. For $u \in V$ such that $|N_u^- \cap \{ v : d_{uv} \leq 0.7 \}| \geq 10 \Delta_u$, set $f_{uv} = 1$ for all $v \in V \setminus \{ u \}$.
\end{definition}

The idea in Step 3 is that if the fractional cost of negative edges incident to $u$ is sufficiently large, we instead trade this for the cost of positive disagreements, as the rounding algorithm will now put $u$ in its own cluster. For the $\ell_\infty$-norm, this trade-off is innocuous. For $\ell_p$-norms in general, a refined charging argument is needed to show that post-processing $d$ in this way sufficiently curbs the (too large) fractional cost of $d$.

In Section 3, we start with a warm-up exercise and show that if the graph on positive edges is regular, then the (original) correlation metric $d$ has $O(1)$-approximate fractional cost. Note this section is not necessary to understanding the rest of the paper, but we...
Simultaneously Approximating All $\ell_p$-Norms in Correlation Clustering

include it in the main body because we find the proof here is clean and lends insight into the challenges for the irregular case. The main technical result of the paper is Section 4, where we prove Theorem 1 by showing that the adjusted correlation metric can be input to the KMZ rounding algorithm. Namely, we will first show (quite easily) that the adjusted correlation metric satisfies an approximate triangle inequality. Then, it remains to upper bound the fractional cost of the adjusted correlation metric against $\text{OPT}$. We tackle this with a combinatorial charging argument. This argument leverages a somewhat different approach from that used in [19] and is simpler than their proof for only the $\ell_\infty$-norm. The constant approximation factor obtained from inputting the adjusted correlation metric to the KMZ rounding algorithm is bounded above (and below) by universal constants for all $p$ (this is the worst case and one can get better constants for each $p$).

3 A Special Case: Regular Graphs

In general, the original correlation metric $d$ (Definition 5) does not necessarily have bounded fractional cost for the $\ell_1$-norm objective (or more generally for $\ell_p$-norm objectives). So, we use the adjusted correlation metric $f$ (Definition 6) as input to the KMZ rounding algorithm. In this section, we show that if the subgraph of positive edges is regular, then the correlation metric $d$ can be used as is (i.e., without the adjustments in Steps 2 and 3 of Definition 6) to yield a clustering that is constant approximate for the $\ell_1$-norm and $\ell_\infty$-norm simultaneously:

▶ Theorem 7. Let $G = (V, E)$ be an instance of unweighted, complete correlation clustering, and let $E^+$ denote the set of positive edges. Suppose that the subgraph induced by $E^+$ is regular. The fractional cost of $d$ in the $\ell_1$-norm objective is within a constant factor of $\text{OPT}$:

$$\sum_{u \in V} \sum_{v \in N_u^+} d_{uv} + \sum_{u \in V} \sum_{v \in N_u^-} (1 - d_{uv}) = O(\text{OPT}).$$

Therefore, the clustering produced by inputting $d$ to the KMZ rounding algorithm is a constant-factor approximation simultaneously for the $\ell_1$-norm and $\ell_\infty$-norm objectives.

Proof. Let $\Delta$ be the (common) degree of the positive subgraph. To show that the fractional cost of $d$ in the $\ell_1$-norm objective is $O(\text{OPT})$ for regular graphs, we will use a dual fitting argument. The LP relaxation we consider is from [4], which uses a dual fitting argument to show constant approximation guarantees for Pivot (although the proof here does not otherwise resemble the proof for Pivot). The primal is given by

$$\min \left\{ \sum_{e \in E} x_e \mid x_{ij} + x_{jk} + x_{ki} \geq 1, \forall ij \in \mathcal{T}, x \geq 0 \right\} \quad (P')$$

where $\mathcal{T}$ is the set of bad triangles (i.e. triangles with exactly two positive edges and one negative edge). For $x \in \{0, 1\}^{|E|}$, $x$ corresponds to disagreements in a clustering: we set $x_e = 1$ if $e$ is a disagreement and $x_e = 0$ otherwise. The constraints state that every clustering must make a disagreement on every bad triangle. Thus, $(P')$ is a relaxation for the $\ell_1$-norm objective. In fact, we will prove the stronger statement that the fractional cost is $O(\text{OPT}_{P'})$, where $\text{OPT}_{P'}$ is the optimal objective value of $(P')$.

The dual is given by

$$\max \left\{ \sum_{T \in \mathcal{T}} y_T \mid \sum_{T \in \mathcal{T} : T \ni e} y_T \leq 1, \forall e \in E, y \geq 0 \right\}. \quad (D')$$
We show that by setting $y_T = \frac{1}{2\Delta}$ for all $T \in \mathcal{T}$, $y$ satisfies the following properties:
1. $y$ is feasible in $(D')$.
2. The fractional cost of $d$ is at most $6 \cdot \sum_{T \in \mathcal{T}} y_T$.

Letting $\text{OPT}_{D'}$ be the optimal objective value of $(D')$, we have $6 \cdot \sum_{T \in \mathcal{T}} y_T \leq 6 \cdot \text{OPT}_{D'} = 6 \cdot \text{OPT}$, which will conclude the proof.

To prove feasibility, we case on whether $e$ is positive or negative.

If $e \in E^-$, then $|\{T \in \mathcal{T} : T \ni e\}| = |N_u^+ \cap N_v^+| \leq \Delta$, where equality is by the definition of a bad triangle. So $\sum_{T \in \mathcal{T} : T \ni e} y_T \leq \frac{\Delta}{\Delta} \leq 1$.

If $e \in E^+$, then $|\{T : T \ni e\}| = |N_u^+ \cap N_v^+| \leq 2\Delta$. We conclude $y$ is feasible, since $\sum_{T \in \mathcal{T} : T \ni e} y_T \leq \frac{2\Delta}{\Delta} = 1$.

Now we need to show that the fractional cost of $d$ is bounded in terms of the objective value of $(D')$. First we bound the fractional cost of the negative edges:

$$\sum_{(u,v) \in E^-} (1 - d_{uv}) \leq \sum_{(u,v) \in E^-} \frac{|N_u^+ \cap N_v^+|}{\Delta} = \sum_{e \in E^-} \sum_{T \in \mathcal{T} : T \ni e} 1/\Delta = \sum_{e \in E^-} \sum_{T \in \mathcal{T} : T \ni e} 2y_T,$$

where in the first inequality we have used that $|N_u^+ \cap N_v^+| \geq \Delta$. Next we bound the fractional cost of the positive edges:

$$\sum_{(u,v) \in E^+} d_{uv} \leq \sum_{(u,v) \in E^+} (|N_u^+ \cap N_v^-| + |N_u^- \cap N_v^+|)/\Delta = \sum_{e \in E^+} \sum_{T \in \mathcal{T} : T \ni e} 1/\Delta = \sum_{e \in E^+} \sum_{T \in \mathcal{T} : T \ni e} 2y_T.$$

So the total fractional cost is bounded by $\sum_{e \in E} \sum_{T \in \mathcal{T} : T \ni e} 2y_T = 6 \cdot \sum_{T \in \mathcal{T}} y_T$, since each triangle contains three edges. This is what we sought to show. Since the fractional cost of $d$ is bounded for the $\ell_1$-norm objective (and the $\ell_\infty$-norm objective by [19]), using $d$ as input to KMZ rounding algorithm produces a clustering that is simultaneously $O(1)$-approximate for the $\ell_1$- and $\ell_\infty$-norm objectives.

# 4 Proof of Theorem 1

The goal of this section is to prove Theorem 1 and the subsequent Corollary 2. We begin by outlining that the adjusted correlation metric satisfies an approximate triangle inequality in Subsection 4.1. Then in Subsection 4.2, we prove the fractional cost of the adjusted correlation metric in any $\ell_p$-norm objective is an $O(1)$ factor away from the optimal solution’s value. We tie it all together to prove Theorem 1 and Corollary 2 in Subsection 4.3.

We start with an easy but key proposition. Loosely, it states that if two vertices are close to each other according to $d$, then they have a large shared positive neighborhood.

Proposition 8. Fix vertices $u, v \in V$ and a clustering $C$ on $V$ such that $d_{uv} \leq 0.7$ and $|N_u^+ \cap C(u)| / |N_u^+| \geq 0.85$. Then $|N_u^+ \cap N_v^+ \cap C(u)| \geq 0.15 \cdot |N_u^+|$.

## 4.1 Triangle Inequality

Recall that the correlation metric $d$ satisfies the triangle inequality (see Section 4.2 in [19]). We will show that the adjusted correlation metric $f$ satisfies an approximate triangle inequality, which is sufficient for the KMZ rounding algorithm. Formally, we say that a function $g$ is a $\delta$-semi-metric on some set $S$ if it is a semi-metric on $S$, except instead of satisfying the triangle inequality, $g$ satisfies $g(u,v) \leq \delta \cdot (g(u,w) + g(v,w))$ for all $u, v, w \in S$.

Lemma 9 (Triangle Inequality). The adjusted correlation metric $f$ is a $\frac{10}{\delta}$-semi-metric.
52:10 Simultaneously Approximating All $\ell_p$-Norms in Correlation Clustering

The proof of Lemma 9 is straightforward given that $d$ satisfies the triangle inequality.

Lemma 3 in [19] proves that one can input a semi-metric that satisfies an approximate triangle inequality (instead of the exact triangle inequality) to the KMZ rounding algorithm (with some loss in the approximation factor). We summarize the main take-away below.

▶ Lemma 10 ([19]). If $g$ is a $\delta$-semi-metric on the set $V$, instead of a true semi-metric (i.e., 1-semi-metric), then the KMZ algorithm loses a factor of $1 + \delta + \delta^2 + \delta^3 + \delta^4$.

Since we show in Lemma 9 that $f$ is a $\frac{10}{7} \delta$-semi-metric, we lose a factor of 12 in inputting $f$ to the KMZ algorithm (along with the factor loss from the fractional cost).

4.2 Bounding the fractional cost of $\ell_p$-norms

This section bounds the fractional cost of the adjusted correlation metric for the $\ell_p$-norms. The following lemma considers the case where $p = \infty$. The general case is handled after.

▶ Lemma 11. The fractional cost of the adjusted correlation metric $f$ in the $\ell_{\infty}$-norm objective is at most $56 \cdot \text{OPT}$, where $\text{OPT}$ is the cost of the optimal integral solution.

The lemma follows from the fact that the fractional cost of the correlation metric $d$ in the $\ell_{\infty}$-norm is known to be bounded by [19], and that it only decreases when $d$ is replaced by $f$ due to Definition 6. See Appendix B in the full version [20] for a proof.

We use two primary lemmas – one for the positive edge fractional cost and one for the negative edge fractional cost – to show that the adjusted correlation metric well approximates the optimal for general $\ell_p$-norms.

▶ Lemma 12. The fractional cost of the adjusted correlation metric $f$ in the $\ell_p$-norm objective is a constant factor (independent of $p$) away from the cost of the optimal integral $\ell_p$ solution.

Proof. Let $y$ be the disagreement vector for an optimal clustering $C$ in the $\ell_p$-norm, for any $p \in \mathbb{R}_{\geq 1} \cup \{\infty\}$. When $p = \infty$, see Lemma 11. For $p \in \mathbb{R}_{\geq 1}$, by definition $\text{OPT}^p = \sum_{u \in V} (y(u))^p$, and the $p$th power of the fractional cost of $f$ is given by

$$
\text{cost}(f)^p = \sum_{u \in V} \left( \sum_{v \in N_u^+} f_{uv} + \sum_{v \in N_u^-} (1 - f_{uv}) \right)^p.
$$

Observe that

$$
\text{cost}(f)^p \leq 2^p \sum_{u \in V} \left( \sum_{v \in N_u^+} f_{uv} \right)^p + 2^p \sum_{u \in V} \left( \sum_{v \in N_u^-} (1 - f_{uv}) \right)^p.
$$

We refer to bounding $(S^+)^p$ as bounding the fractional cost of the positive edges, and likewise $(S^-)^p$ for the negative edges. The first sum, $(S^+)^p$, is bounded in Lemma 13 and the second sum, $(S^-)^p$, is bounded in Lemma 16. Using those two bounds, together we have $\text{cost}(f) \leq 2^p ((S^+)^p + (S^-)^p)^{1/p} \leq 529$, for $p \in [1, \infty)$. Specifically, the middle term is maximized at $p = 1$, giving the bound of 529, and tends to below 214 as $p \to \infty$. (A more tailored analysis gives a constant of 74 for $p = 1$; see Appendix C in the full version [20].) ▶

We note that, as our main interest is determining whether a simultaneous constant approximation is even possible (and a combinatorial one, at that), we did not pay particular attention to optimizing constants, but suspect these could be greatly reduced.

---

10When $\delta = 1$, this factor equals 5, which is the loss in the KMZ algorithm.
4.2.1 Fractional cost of positive edges in $\ell_p$-norms

We first bound the fractional cost of the positive edges.

Lemma 13. For $p \in \mathbb{R}_{\geq 1}$, the fractional cost of the adjusted correlation metric $f$ in the $\ell_p$-norm objective for the set of positive edges is a constant factor approximation to the optimal, i.e.,

$$(S^+)^p = \sum_{u \in V} \left( \sum_{v \in N^+_u} f_{uv} \right)^p \leq 2^p \cdot \left[ (8^p/2 + 1)((20/3)^p + 2 + 4^p) + 8^p + 1 \right] \cdot \text{OPT}^p.$$

One of the challenges in bounding the cost of $f$ is that disagreements in the $\ell_p$-norm objective for $p \neq 1$ are asymmetric, in that a disagreeing edge charges $y(u)$ and $y(v)$ (whereas for $p = 1$ we can just sum the number of disagreeing edges). Step 3 rounds up the edges incident to $u$ when the tradeoff is good from $u$’s perspective. However, an edge $(u, v)$ may be rounded up to 1 when this tradeoff is good from $v$’s perspective, but not from $u$’s perspective. The high-level idea for why this is fine is that if $u$ and $v$ are close under $d$, their positive neighborhoods overlap significantly and, in some average sense, $u$ can charge to $v$. Proving this requires a double counting argument using a bipartite auxiliary graph. If $u$ and $v$ are far under $d$, on the other hand, we can charge to the cost of the correlation metric, which will be bounded on an appropriate subgraph. The second challenge is showing that the $\ell_p$-norm of the disagreement vector, restricted to vertices $u$ that are made singletons in Step 3, is bounded. This again requires a double counting argument.

Proof. Fix an optimal clustering $C$. We partition vertices based on membership in $C(u)$ or $C(u)$ (as defined in Subsection 2.1). Let $y$ denote the disagreement vector of $C$. We have

$$(S^+)^p = \sum_{u \in V} \left( \sum_{v \in N^+_u \cap C(u)} f_{uv} \right)^p \leq 2^p \sum_{u \in V} \left( \sum_{v \in N^+_u \cap C(u)} f_{uv} \right)^p + 2^p \sum_{u \in V} \left( \sum_{v \in N^+_u \cap \bar{C}(u)} f_{uv} \right)^p.$$

It is easy to bound $S^+_2$ by using the trivial upper bound $f_{uv} \leq 1$:

$$S^+_2 = \sum_{u \in V} \left( \sum_{v \in N^+_u \cap \bar{C}(u)} f_{uv} \right)^p \leq \sum_{u \in V} \left( \sum_{v \in N^+_u \cap \bar{C}(u)} 1 \right)^p \leq \sum_{u \in V} (y(u))^p = \text{OPT}^p,$$

where we used that every edge $(u, v) \in E^+$ with $v \notin C(u)$ is a disagreement incident to $u$.

Next, we bound $S^+_1$. Let $R_1$ be the set of $u$ for which Step 3 of Definition 6 applies. For these $u$, we have $f_{uv} = 1$ for all $v \in V \setminus \{u\}$. Let $R_2 = V \setminus R_1$. For $u \in R_2$ and $v \in N^+_u$, we have that either $v \in R_2$, in which case $f_{uv} = d_{uv}$; or $v \in R_1$, in which case $f_{uv} = 1$. (Note that $V$ is the disjoint union of $R_1$ and $R_2$.) So

$$S^+_1 = \sum_{u \in R_1} \left( \sum_{v \in N^+_u \cap C(u), v \neq u} 1 \right)^p + \sum_{u \in R_2} \left( \sum_{v \in N^+_u \cap C(u)} f_{uv} \right)^p,$$
and in particular
\[
S_{12}^+ = \sum_{u \in R_2} \left( \sum_{v \in N_u^+ \cap C(u) \cap R_1} 1 + \sum_{v \in N_u^+ \cap C(u) \cap R_2} d_{uv} \right)^p
\]
\[
= \sum_{u \in R_2} \left( \sum_{v \in N_u^+ \cap C(u) \cap R_1} 1 + \sum_{v \in N_u^+ \cap C(u) \cap R_2} d_{uv} \right)^p
\]
\[
\leq \sum_{u \in R_2} \left( \sum_{v \in N_u^+ \cap C(u) \cap R_1} 1 + \sum_{v \in N_u^+ \cap C(u) \cap R_2} 4 \cdot d_{uv} \right)^p
\]
\[
\leq \sum_{u \in R_2} \left( \sum_{v \in N_u^+ \cap C(u) \cap R_1} 1 + \sum_{v \in N_u^+ \cap C(u)} 4 \cdot d_{uv} \right)^p
\]
\[
\leq 2^p \sum_{u \in R_2} \left( \sum_{v \in N_u^+ \cap R_1} 1 \right)^p + 8^p \cdot \sum_{u \in R_2} \left( \sum_{v \in N_u^+ \cap C(u) \cap R_2} d_{uv} \right)^p.
\]

First we bound \(S_{13}^+\). We will strongly use that \(d_{uv} \leq 1/4\) in the inner sum. Observe:

\[\blacktriangledown\textbf{Proposition 14.} \ Long d \ be \ the \ correlation \ metric, \ and \ d_{uv} \leq 1/4. \ Then \ |N_u^+| \leq \frac{7}{3} \cdot |N_u^+|.\]

Next, we will need to create a bipartite auxiliary graph \(H = (R_2, R_1, F)\) with \(R_2\) and \(R_1\) being the sides of the partition, and \(F\) being the edge set. We will then use a double counting argument. Place an edge between \(u \in R_2\) and \(v \in R_1\) if \(uv \in E^+\) and \(d_{uv} \leq 1/4\). Then we have precisely that \(S_{13}^+ = \sum_{u \in R_2} \deg_H(u)^p\). We will show that

\[
S_{13}^+ = \sum_{u \in R_2} \deg_H(u)^p \leq 4^{p-1} \cdot \sum_{v \in R_1} |N_v^+|^p \leq 4^{p-1} \cdot ((20/3)^p + 2 + 2 \cdot 4^p) \cdot \OPT^p \tag{1}
\]

where the last bound follows from Proposition 15, which we establish separately below. We will bound via double counting the quantity \(L\), defined below. Let \(N_H(\cdot)\) denote the neighborhoods in \(H\) of the vertices.

\[
L := \sum_{f=uv \in F} (\deg_H(u) + \deg_H(v))^{p-1} \leq \sum_{v \in R_1} \sum_{u \in N_H(v)} (\deg_H(v) + \deg_H(u))^{p-1}
\]
\[
\leq \sum_{v \in R_1} \sum_{u \in N_H(v)} \left(|N_u^+| + |N_v^+|\right)^{p-1} \leq \sum_{v \in R_1} \sum_{u \in N_H(v)} 4^{p-1} \cdot |N_u^+|^{p-1} \tag{2}
\]
\[
\leq 4^{p-1} \cdot \sum_{v \in R_1} |N_v^+|^p \cdot |N_v^+|^{p-1} = 4^{p-1} \cdot \sum_{v \in R_1} |N_v^+|^p
\]

where in (2) we’ve used Proposition 14. Note that \(L\) is upper bounded by the right-hand side in (1). Now it just remains to show that \(L\) is lower bounded by the left-hand side in (1).

\[
L = \sum_{f=uv \in F} (\deg_H(u) + \deg_H(v))^{p-1} \geq \sum_{u \in R_2} \sum_{v \in N_H(u)} \deg_H(u) \cdot \deg_H(v)^{p-1} = \sum_{u \in R_2} \deg_H(u)^p,
\]

\[
\sum_{u \in R_2} \deg_H(u)^p = \sum_{u \in R_2} \deg_H(u) \cdot \deg_H(u)^{p-1} = \sum_{u \in R_2} \deg_H(u)^p,
\]
which is what we sought to show. Now we bound $S_{14}^+$.

$$S_{14}^+ \leq \sum_{u \in V} \left( \sum_{v \in N_u^+ \cap C(u)} \frac{|N_u^+ \cap N_v^-| + |N_u^- \cap N_v^+|}{|N_u^+ \cup N_v^-|} \right)^p \leq \sum_{u \in V} \left( \sum_{v \in N_u^+} \frac{y(u) + y(v)}{|N_u^+ \cup N_v^-|} \right)^p \leq 2^p \sum_{u \in V} \sum_{v \in N_u^+} |N_u^+|^{p-1} \cdot \frac{y(u)p}{|N_u^+ \cup N_v^-|^p} + 2^p \sum_{u \in V} \sum_{v \in N_u^+} |N_u^+|^{p-1} \cdot \frac{y(v)p}{|N_u^+ \cup N_v^-|^p}.$$ 

In the second line, the first inequality uses the fact that for $w \in (N_u^+ \cap N_v^-) \cup (N_u^- \cap N_v^+)$, then at least one of $(u, w), (v, w)$ is a disagreement, since $v \in C(u)$ in the inner summation of the first line. The second inequality in the second line uses Jensen’s inequality.

To bound the first double sum above, we use an averaging argument:

$$\sum_{u \in V} \sum_{v \in N_u^+} |N_u^+|^{p-1} \cdot \frac{y(u)p}{|N_u^+ \cup N_v^-|^p} \leq \sum_{u \in V} \sum_{v \in N_u^+} \frac{y(u)p}{|N_u^+ |^p} = \sum_{u \in V} y(u)p = \text{OPT}^p.$$ 

To bound the second double sum, we first have to flip it:

$$\sum_{u \in V} \sum_{v \in N_u^+} |N_u^+|^{p-1} \cdot \frac{y(v)p}{|N_u^+ \cup N_v^-|^p} \leq \sum_{v \in V} \sum_{u \in N_v^+} |N_u^+|^{p-1} \cdot \frac{y(v)p}{|N_u^+ |^p} = \sum_{v \in V} y(v)p = \text{OPT}^p.$$ 

In total, we have

$$S_{14}^+ \leq 2 \cdot 2^p \cdot \text{OPT}^p = 2^{p+1} \cdot \text{OPT}^p$$

and

$$S_{12}^+ \leq 2^p \cdot S_{11}^+ + 8^p \cdot S_{14}^+ \leq 2^p \cdot 4^{p-1} \cdot ((20/3)^p + 2 + 2 \cdot 4^p) \cdot \text{OPT}^p + 8^p \cdot \text{OPT}^p.$$ 

Next we turn to bounding $S_{11}^+$. Recall that $R_3 = \{u : |N_u^- \cap \{v : d_{uv} \leq 0.7\}| \geq \frac{10}{3} \cdot \Delta_u\}$ and

$$S_{11}^+ \leq \sum_{u \in R_1} |N_u^+ \cap C(u)|^p \leq \sum_{u \in R_1} |N_u^+|^p.$$ 

So it suffices to bound the right-hand side, which we do in the following proposition.

**Proposition 15.** Let $R_1$ be the set of $u$ for which Step 3 of Definition 6 applies. Then

$$\sum_{u \in R_1} |N_u^+|^p \leq ((20/3)^p + 2 + 2 \cdot 4^p) \cdot \text{OPT}^p.$$ 

**Proof of Proposition 15.** For $u \in R_1$, define $R_1(u) = N_u^- \cap \{v : d_{uv} \leq 0.7\}$, so in particular $|R_1(u)| \geq \frac{10}{3} \cdot \Delta_u$. Fix a vertex $u \in R_1$. We consider a few cases. The crux is Case 2a(ii).

**Case 1.** At least a 0.15 fraction of $N_u^+$ is in clusters other than $C(u)$. Let $u \in V^1$ be the vertices in this case. This means that $0.15 \cdot |N_u^+| \leq y(u)$, so

$$\sum_{u \in V^1} |N_u^+|^p \leq \sum_{u \in V^1} \frac{1}{0.15^p} y(u)^p \leq (20/3)^p \cdot \text{OPT}^p.$$
We further partition the cases based on how much $w$ intersects $C(u)$.

**Case 2.** At least a 0.85 fraction of $N_u^+$ is in $C(u)$.

We further partition the cases based on how much $R_1(u)$ intersects $C(u)$.

**Case 2a:** At least half of $R_1(u)$ is in clusters other than $C(u)$.

We partition into cases (just one more time!) based on the size of $N_u^- \cap C(u)$. See Figure 2.

**Case 2a(i):** At least half of $R_1(u)$ is in clusters other than $C(u)$ and $|N_u^- \cap C(u)| \geq \Delta_u$.

Let $u \in V^{2a(i)}$ be the vertices in this case. Note that $y(u) \geq |N_u^- \cap C(u)|$. Then

$$\sum_{u \in V^{2a(i)}} |N_u^+|^p = \sum_{u \in V^{2a(i)}} \Delta_u^p \leq \sum_{u \in V^{2a(i)}} |N_u^- \cap C(u)|^p \leq \sum_{u \in V^{2a(i)}} y(u)^p \leq \text{OPT}^p.$$ 

**Case 2a(ii):** At least half of $R_1(u)$ is in clusters other than $C(u)$ and $|N_u^- \cap C(u)| \leq \Delta_u$.

Let $u \in V^{2a(ii)}$ be the vertices in this case. Denote the vertices in $R_1(u)$ that are in clusters other than $C(u)$ by $R'_1(u)$. By definition of Case 2a(ii), $|R'_1(u)| \geq \frac{5}{3} \cdot \Delta_u$. A key fact we will use is that $|C(u)| \leq 2 \cdot \Delta_u$:

$$|C(u)| = |N_u^- \cap C(u)| + |N_u^+ \cap C(u)| \leq \Delta_u + \Delta_u = 2 \cdot \Delta_u.$$ 

For $u \in V^{2a(ii)}$ and $w \in N_u^+ \cap C(u)$, define $\varphi(u, w) = |R'_1(u) \cap N_w^+|$.

Each $w \in N_u^+ \cap C(u)$ dispenses $\varphi(u, w)^p/|C(u)|$ charge to $u$. Also, observe that for $v \in R'_1(u)$, we have that $d_{uv} \leq 0.7$, so we know by Proposition 8 that $|N_u^+ \cap N_v^+ \cap C(u)| \geq 0.15 \cdot |N_u^+|$. This implies that

$$\sum_{w \in N_u^+ \cap C(u)} |R'_1(u) \cap N_w^+| = \sum_{w \in N_u^+ \cap C(u)} \sum_{v \in R'_1(u) \cap N_w^+} 1 = \sum_{v \in R'_1(u) \cap C(u) \cap N_u^+} 1$$

$$= \sum_{v \in R'_1(u)} |C(u) \cap N_u^+ \cap N_v^+| \geq \sum_{v \in R'_1(u)} 0.15 \cdot |N_u^+|$$

$$= 0.15 \cdot |N_u^+| \cdot |R'_1(u)| \geq 0.15 \cdot \Delta_u \cdot \frac{5}{3} \Delta_u = 0.25 \cdot \Delta_u^2.$$ 

By Jensen’s inequality, the amount of charge each $u$ satisfying Case 2a(ii) receives is at least

$$\frac{1}{|C(u)|} \sum_{w \in N_u^+ \cap C(u)} \varphi(u, w)^p \geq \frac{1}{|C(u)|} \cdot \frac{1}{|N_u^+ \cap C(u)|^{p-1}} \cdot \left( \sum_{w \in N_u^+ \cap C(u)} \varphi(u, w) \right)^p$$

$$\geq \frac{1}{2 \Delta_u} \cdot \frac{1}{\Delta_u^{p-1}} \cdot \left( 0.25 \cdot \Delta_u^2 \right)^p \geq \frac{1}{2} \cdot 0.25^p \cdot |N_u^+|^p,$$
Next we need to upper bound the amount of charge dispensed in total to all \( u \) satisfying Case 2a(ii). Note by definition that \( \varphi(u, w) \leq y(w) \). Each vertex \( w \in V \) dispenses at most \( y(w)^p / |C(u)| = y(w)^p / |C(w)| \) charge to each \( u \in C(w) \cap N_u^+ \). So in total each \( w \) dispenses at most \( |C(w)| \cdot y(w)^p / |C(w)| = y(w)^p \) charge to all \( u \) satisfying Case 2a(ii).

Now we put together the lower and upper bounds on the total charge dispensed:

\[
\sum_{w \in V} y(w)^p \geq \text{charge dispensed} \geq \sum_{u \in V^{2s(iii)}} \frac{1}{|C(u)|} \sum_{w \in N_u^+ \cap C(u)} \varphi(u, w)^p \\
\geq \sum_{u \in V^{2s(iii)}} \frac{1}{2} \cdot 0.25^p \cdot |N_u^+|^p.
\]

In all, \( \sum_{u \in V^{2s(iii)}} |N_u^+|^p \leq 2 \cdot 4^p \cdot \sum_{w \in V} y(w)^p \leq 2 \cdot 4^p \cdot \text{OPT}^p \).

Case 2b: At least half of \( R_u \) is in \( C(u) \).

Let \( u \in V^{2b} \) be the vertices in this case. Denote the vertices in \( R_i(u) \) that are in \( C(u) \) by \( R_i''(u) \). By definition of Case 2b, \( |R_i''(u)| \geq \frac{5}{4} \cdot \Delta_u \). Since every vertex in \( R''(u) \) is in \( N_u^- \), there are at least \( |R''(u)| \) disagreements incident to \( u \). So \( y(u) \geq |R''(u)| \geq \frac{5}{4} \cdot \Delta_u \), giving

\[
\sum_{u \in V^{2b}} |N_u^+|^p = \sum_{u \in V^{2b}} \Delta_u^p \leq \sum_{u \in V^{2b}} y(u)^p \leq \text{OPT}^p.
\]

Adding the terms in the boxed expressions across all cases, the proposition follows. ▶

So we have

\[
S_{11}^+ \leq \sum_{u \in R_1} |N_u^+|^p \leq ((20/3)^p + 2 + 4^p) \cdot \text{OPT}^p.
\]

Adding together all the cases, we conclude that

\[
(S^+)^p \leq 2^p \cdot (S_1^+ + S_2^+) \leq 2^p \cdot (S_{11}^+ S_{12^+} + S_v^+) \leq 2^p \cdot [8^p/2 + 1](20/3)^p + 2 \cdot (20/3)^p \cdot \text{OPT}^p.
\]

4.2.2 Fractional cost of negative edges in \( \ell_p \)-norms

This section bounds the cost of negative edges. The meanings of \( C, C(\cdot), \) and \( y \) are as before.

▶ Lemma 16. For \( p \in \mathbb{R}_{\geq 1} \), the fractional cost of the adjusted correlation metric \( f \) in the \( \ell_p \)-norm objective for the set of negative edges is a constant factor away from optimal:

\[
(S^-)^p = \sum_{u \in V} \left( \sum_{v \in N_u^-} (1 - f_{uv}) \right)^p \leq 2^p((200/9)^p + 1 + (10/3)^p + 2 \cdot (20/3)^p) \cdot \text{OPT}^p.
\]

Proof. We have

\[
(S^-)^p = \sum_{u \in V} \left( \sum_{v \in N_u^-} (1 - f_{uv}) \right)^p \leq 2^p \sum_{u \in V} \left( \sum_{v \in N_u^- \cap C(u)} (1 - f_{uv}) \right)^p \\
+ 2^p \sum_{u \in V} \left( \sum_{v \in N_u^- \cap C(u)} (1 - f_{uv}) \right)^p.
\]
Simultaneously Approximating All $\ell_p$-Norms in Correlation Clustering

It is easy to bound $S_1^-$ by using the trivial upper bound $1 - f_{uv} \leq 1$:

$$S_1^- = \sum_{u \in V} \left( \sum_{v \in N^-_u \cap C(u)} (1 - f_{uv}) \right)^p \leq \sum_{u \in V} \left( \sum_{v \in N^-_u \cap C(u)} 1 \right)^p \leq \sum_{u \in V} y(u)^p = \text{OPT}^p,$$

where we have used that every edge $(u, v) \in E^-$ with $v \in C(u)$ is a disagreement incident to $u$. Next, we bound $S_2^-$. Let $R_1$ and $R_2$ be as in the previous subsection: $R_1 = \{u : |N^-_u \cap \{v : d_{uv} \leq 0.7\}| \geq \frac{10}{3} \cdot \Delta_u\}$ and $R_2 = V \setminus R_1$. For $u \in R_2$, define

$$V_u = \{v : v \in N^-_u \cap \overline{C(u)}, d_{uv} \leq 0.7\}.$$

Note that the definition of $V_u$ is the same as $R'_1(u)$ in the previous subsection, but here $V_u$ is only defined for $u \in R_2$, while $R'_1(u)$ was defined for $u \in R_1$. For $u \in R_1$, we have $1 - f_{uv} = 0$ for every $v \in V \setminus \{u\}$. So the outer sum in $S_2^-$ only need be taken over $u \in R_2$:

$$S_2^- = \sum_{u \in R_2} \left( \sum_{v \in N^-_u \cap C(u)} (1 - f_{uv}) \right)^p \leq \sum_{u \in R_2} \left( \sum_{v \in \overline{C(u)}, d_{uv} \leq 0.7} (1 - d_{uv}) \right)^p \leq \sum_{u \in R_2} |V_u|^p,$$

In the second equality, we have used that if $u \in R_2$ and $v \in N^-_u$, then $f_{uv} = d_{uv}$, unless $f_{uv}$ was rounded up to 1 in Step 2 of Definition 6 (which happens when $d_{uv} > 0.7$), or $f_{uv}$ was rounded up to 1 in Step 3 (in which case $1 - f_{uv} = 0 \leq 1 - d_{uv}$).

A key observation is that since $u \in R_2$, it is the case that $|V_u| \leq \frac{10}{3} \cdot \Delta_u$. Fix a vertex $u \in R_2$. We consider a few cases.

**Case 1.** At least a 0.15 fraction of $N^+_u$ is in clusters other than $C(u)$.

Define $V^1$ to be the set of $u \in R_2$ satisfying Case 1. Then for $u \in V^1$, $0.15 \cdot |N^+_u| \leq y(u)$, and

$$|V_u| \leq \frac{10}{3} \cdot \Delta_u \leq \frac{10}{3} y(u) = \frac{200}{9} y(u).$$

so

$$\sum_{u \in V^1} |V_u|^p \leq \frac{(200/9)^p}{\sum_{u \in V^1} y(u)^p} \cdot \sum_{u \in V^1} y(u)^p \leq \frac{(200/9)^p \cdot \text{OPT}^p}{\sum_{u \in V^1} y(u)^p}.$$  

**Case 2.** At least a 0.85 fraction of $N^+_u$ is in $C(u)$.

Define $V^2$ to be the set of $u \in R_2$ that satisfy Case 2. Fix $u \in V^2$ and $v \in V_u$. Define $N_{u,v} = N^+_u \cap N^+_v \cap C(u)$. Since $d_{uv} \leq 0.7$ and by the assumption of this case, using Proposition 8 we have

$$|N_{u,v}| = |N^+_u \cap N^+_v \cap C(u)| \geq 0.15 \cdot \Delta_u.$$  

Observe that since $v \notin C(u)$ for $v \in V_u$, $(v, w)$ is a (positive) disagreement for all $w \in N_{u,v}$.

**Case 2a:** $|N^-_u \cap C(u)| \geq \Delta_u$.

Define $V^{2a}$ to be the set of $u \in V^2$ that satisfy Case 2a. Since all edges $(u, v)$ with $v \in N^-_u \cap C(u)$ are disagreements, we have $y(u) \geq \Delta_u$. Recalling that $|V_u| \leq \frac{10}{3} \cdot \Delta_u$ for $u \in R_2$, we have

$$\sum_{u \in V^{2a}} |V_u|^p \leq \sum_{u \in V^{2a}} (10/3 \cdot \Delta_u)^p \leq (10/3)^p \cdot \sum_{u \in V^{2a}} y(u)^p \leq (10/3)^p \cdot \text{OPT}^p.$$
Case 2b: $|C(u)| \leq 2\Delta_u$.
Define $V^{2b}$ to be the $u \in V^2$ satisfying Case 2b. Fix $w \in N^+_u \cap C(u)$ and $u \in V^{2b}$. Define
\[ \varphi(u, w) = |V_u \cap N^+_w|, \]
i.e. $\varphi(u, w)$ is the number of $v \in V_u$ with $w \in N_{u,v}$. Each $w \in N^+_u \cap C(u)$ dispenses $\varphi(u,w)^p \over |C(u)|$ charge to $u$. Also,
\[
\sum_{w \in N^+_u \cap C(u)} \varphi(u, w) = \sum_{w \in N^+_u \cap C(u)} |V_u \cap N^+_w| = \sum_{w \in N^+_u \cap C(u)} \sum_{v \in V_u \cap N^+_v} 1
\]
\[
= \sum_{v \in V_u} \sum_{w \in N_{u,v}} 1 = \sum_{v \in V_u} |N_{u,v}| \geq |V_u| \cdot 0.15 \cdot \Delta_u.
\]
By Jensen’s inequality, the amount of charge each $u$ satisfying Case 2b receives is at least
\[
\frac{1}{|C(u)|} \sum_{w \in N^+_u \cap C(u)} \varphi(u, w)^p \geq \frac{1}{|C(u)|} |N^+_u \cap C(u)|^{p-1} \left( \sum_{w \in N^+_u \cap C(u)} \varphi(u, w) \right)^p
\]
\[
\geq \frac{1}{2\Delta_u} \cdot \frac{1}{|C(u)|^{p-1}} \left( |V_u| \cdot 0.15 \cdot \Delta_u \right)^p = \frac{1}{2} \cdot 0.15^p \cdot |V_u|^p.
\]
To upper bound the amount of charge dispensed in total to all $u$ satisfying Case 2b, first note that $\varphi(u, w) \leq y(w)$. Also, each vertex $w \in V$ only distributes charge to $u \in C(w) \cap N^+_u$, and the amount of charge distributed to each such $u$ is
\[
\frac{\varphi(u, w)^p}{|C(u)|} = \frac{\varphi(u, w)^p}{|C(u)|} \leq \frac{y(w)^p}{|C(w)|},
\]
so that in total each $w$ dispenses at most $y(w)^p \cdot |C(w)| \leq y(w)^p$ charge. Putting together the lower and upper bounds on the amount of charge dispensed:
\[
\sum_{w \in V^+} y(w)^p \geq \text{total charge dispensed} \geq \sum_{u \in V^{2b}} \frac{1}{|C(u)|} \sum_{w \in N^+_u \cap C(u)} \varphi(u, w)^p
\]
\[
\geq \sum_{u \in V^{2b}} \frac{1}{2} \cdot 0.15^p \cdot |V_u|^p.
\]
In all,\[
\sum_{u \in V^{2b}} |V_u|^p \leq 2 \cdot (20/3)^p \cdot \sum_{w \in V} y(w)^p = 2 \cdot (20/3)^p \cdot \text{OPT}^p.
\]
Combining the cases, we see that $(S^-)^p \leq 2^p(200/9)^p + 1 + (10/3)^p + 2 \cdot (20/3)^p) \cdot \text{OPT}^p$. ▷

4.3 Proofs of Theorem 1 and Corollary 2

Here we show that Theorem 1 follows directly from the preceding lemmas. We defer the proof of Corollary 2 to the full version [20].

Proof of Theorem 1. First we show that Lemma 12 implies that the clustering resulting from inputting $f$ into the KMZ rounding algorithm is $O(1)$-approximate in any $\ell_p$-norm. Since the rounding algorithm does not depend on $p$, the clustering will be the same for all $p$. Let $C^*$ be the clustering produced by running the KMZ rounding algorithm with the adjusted correlation metric $f$ as input. Let $\text{ALG}(u)$ be the number of edges incident to $u$ that are disagreements with respect to $C^*$. From [29] and Lemmas 9 and 10, we have that
Simultaneously Approximating All $\ell_p$-Norms in Correlation Clustering

for every $u \in V$, $\text{ALG}(u) \leq 12 \cdot y_u$ where $y_u$ is as in LP $P$ when taking $x = f$. So $||y||_p$ is the fractional cost of $f$ in the $\ell_p$-norm. In what follows, $||\text{ALG}||_p$ is the objective value of $C^*$ in the $\ell_p$-norm and $\text{OPT}(p)$ is the optimal objective value in the $\ell_p$-norm. Thus using Lemma 12 in the last inequality, we have

$$||\text{ALG}||_p \leq 12 \cdot ||y||_p \leq 12 \cdot 529 \cdot \text{OPT}(p) = 6348 \cdot \text{OPT}(p).$$

The overall run-time is $O(n^\omega)$. From the analysis in [19], computing the correlation metric takes time $O(n^\omega)$, and the KMZ rounding algorithm takes time $O(n^2)$. We just have to show the post-processing of $d$ in Steps 2 and 3 of Definition 6 that were done in order to obtain the adjusted correlation metric $f$ can be done quickly. Indeed, Step 2 takes $O(n^2)$ time as it simply iterates through the edges. Step 3 also takes $O(n^2)$ time, since it visits each vertex and iterates through the neighbors. Thus, the run-time remains $O(n^\omega)$.

5 Conclusion

This paper considered correlation clustering on unweighted, complete graphs, a problem that arises in many settings including community detection and the study of large networks. All previous works that study minimizing the $\ell_p$-norm (for $p \in \mathbb{R}_>1$) of the disagreement vector rely on solving a large, convex relaxation (which is costly to the algorithm’s run-time) and produce a solution that is only $O(1)$-approximate for one specific value of $p$. We innovate upon this rich line of work by (1) giving the first combinatorial algorithm for the $\ell_p$-norms for $p \in \mathbb{R}_>1$, (2) designing scalable algorithms for this practical problem, and (3) obtaining solutions that are $O(1)$-approximate for all $\ell_p$-norms (for $p \in \mathbb{R}_>1 \cup \{\infty\}$) simultaneously. We emphasize this last point, as such solutions are good in both global and local senses, and thus may be more desirable than typical optimal or approximate solutions. The existence of these solutions reveals a surprising structural property of correlation clustering.

One question is whether there is a simpler existential (not necessarily algorithmic) proof that there exists an $O(1)$-approximation for the all-norm objective for correlation clustering.

It is also of interest to implement the KMZ algorithm with the adjusted correlation metric as input, and empirically gain an understanding of how good the adjusted correlation metric is for different $\ell_p$-norms. We suspect that our analysis is lossy (we did not focus on optimizing constants), and that the approximation obtained would be of much better quality.
