Preface

The series of International Symposia on Mathematical Foundations of Computer Science (MFCS), organized since 1972, invites high-quality contributions in all branches of theoretical computer science. The broad scope of MFCS provides an opportunity to bring together researchers who do not usually meet at specialized conferences.

In the year 2024, the 49th edition of MFCS was held in Bratislava, on August 26–30. This volume contains 80 contributions selected out of 239 full submissions. The programme was further enriched by five invited talks given by Wojciech Czerwiński (University of Warsaw), Jarkko Kari (University of Turku), Kasper Green Larsen (Aarhus University), Rupak Majumdar (Max Planck Institute for Software Systems), and David Peleg (Weizmann Institude of Science).

We express our deep gratitude to all the members of the program committee and the reviewers. Due the the high number of submissions, the load of work was higher than anticipated. Still, the merits of all papers were considered very carefully not only in the reviews but also in subsequent discussions. We also warmly thank the invited speakers, as well as the authors of the submitted papers. We also thank the local organizing team chaired by Dana Pardubská.

MFCS proceedings have been published in the Dagstuhl/LIPIcs series since 2016. We thank Michael Wagner and the LIPIcs team for their kind help and support.

Abstract

Call a sequence $d = (d_1, d_2, \ldots, d_n)$ of positive integers *graphic*, *planaric*, *outer-planaric*, or *forestic* if it is the degree sequence of some arbitrary, planar, outer-planar, or cycle-free graph G, respectively. The two extreme classes of graphic and forestic sequences were given full characterizations. (The latter has a particularly simple criterion: d is forestic if and only if its *volume*, $\sum d \equiv \sum_i d_i$, satisfies $\sum d \leq 2n - 2$.) In contrast, the problems of fully characterizing planaric and outer-planaric degree sequences are still open.

In this paper, we discuss the parameters affecting the realizability of degree sequences by restricted classes of sparse graph, including planar graphs, outerplanar graphs, and some of their subclasses (e.g., 2-trees and cactus graphs). A key parameter is the *volume* of the sequence d, namely, $\sum d$ which is twice the number of edges in the realizing graph. For planar graphs, for example, an obvious consequence of Euler's theorem is that an n-element sequence d satisfying $\sum d > 4n - 6$ cannot be planaric. Hence, $\sum d \leq 4n - 6$ is a necessary condition for d to be planaric. What about the opposite direction? Is there an *upper* bound on $\sum d$ that guarantees that if d is graphic then it is also planaric. Does the answer depend on additional parameters? The same questions apply also to sub-classes of the planar graphs.

A concrete example that is illustrated in the technical part of the paper is the class of outer-planaric degree sequences. Denoting the number of 1's in d by ω_1, we show that for a graphic sequence d, if $\omega_1 = 0$ then d is outer-planaric when $\sum d \leq 3n - 3$, and if $\omega_1 > 0$ then d is outer-planaric when $\sum d \leq 3n - \omega_1 - 2$. Conversely, we show that there are graphic sequences that are not outer-planaric with $\omega_1 = 0$ and $\sum d = 3n - 2$, as well as ones with $\omega_1 > 0$ and $\sum d = 3n - \omega_1 - 1$.

1 Introduction

Background. Throughout, we consider a a nonincreasing sequence $d = (d_1, \ldots, d_n)$ of n nonnegative integers. The sequence d is *graphic* if it is the degree sequence of some graph G. The graph realization problem concerns deciding, for a given d, if it is graphic, and if so -

constructing a realizing graph for it. The problem has been studied extensively over the past 60 years, and was given both combinatorial characterizations and construction algorithms, cf. [9, 13, 14]. In particular, by [9], a nonincreasing sequence d is graphic if and only if

$$\sum_{i=1}^{\ell} d_i \le \ell(\ell-1) + \sum_{i=\ell+1}^{n} \min\{\ell, d_i\}, \qquad \text{for } \ell = 1, \ldots, n. \tag{1}$$

Beyond its theoretical interest, realization questions are also relevant in the context of specification-based network design, where the users specify the desired network properties, as well as in some scientific contexts where it is required to discover the unknown structure of a network based on measurements on its various parameters.

The question can be asked also in the context of special graph families. In particular, the realizability of a given sequence d by a *planar* graph was studied in [23] and some of the sequences whose status was left undetermined in [23] were later resolved in [10, 11]. In addition, regular planar graphic sequences were classified in [15], and planar bipartite biregular degree sequences were studied in [1]. Still, the realizability of a given sequence d by a planar graph was not given a complete solution so far.

The same question can be asked with respect to other restricted classes of graphs. One extreme example is that of *trees* and more generally *forests*. Whereas the characterization (1) for graphic degree sequences (realizable by general graphs) is somewhat involved, composed of n different conditions and affected individually by each of the degrees in the sequence, the characterization for *forestic* sequences (namely, ones realizable by a forest) is very simple: an n-element sequence d is forestic if and only if its *volume*, defined as $\sum d \equiv \sum_{i=1}^{n} d_i$, satisfies $\sum d \le 2n-2$ (with equality if and only if the sequence is realizable by a tree). One might conjecture that restricted graph classes should tend to have simpler characterizations, or ones that depend on fewer parameters.

The current paper is motivated by the (intuitively clear) fact that the volume parameter of the sequence d plays a significant role in its realizability by classes of *sparse* graphs. One direction is easy: if the class $\mathcal{G}$ contains only graphs of M or fewer edges, then clearly, sequences of volume larger than $2M$ cannot have a realization from $\mathcal{G}$. Hence $\sum d \le 2M$ is a *necessary* condition for realizability by a graph from $\mathcal{G}$. Here, we discuss the converse question: Can one derive *sufficient* conditions for realizability by $\mathcal{G}$ based on the volume parameter?

Indeed, for various low-volume graph classes $\mathcal{G}$, there are known results, guaranteeing that if d is graphic and $\sum d$ is sufficiently small, then d has a realizing graph in $\mathcal{G}$. In particular, consider the following hierarchy of graph classes and corresponding hierarchy of volume bounds.

- Forests [12]: A sequence d is forestic if and only if $\sum d \le 2n-2$ and $\sum d$ is even.
- Uni-cyclic graphs [6]: These are connected graphs with precisely one cycle. A sequence d is uni-cyclic if and only if $\sum d = 2n$ and $d_1 \le n-1$.
- Bi-cactus graphs [2]: Here, there is a full characterization that involves two additional parameters, ω_1 and ω_{odd}, where ω_i is the number of i's in d and ω_{odd} is the number of odd degrees in d. In particular, a necessary condition for a sequence d to be realizable by a bi-cactus is that $\sum d < 8n/3$. The sufficient condition is more complex, utilizing also ω_1 and ω_{odd}.
- Cactus graphs [20]: Here, again, there is a full characterization that involves ω_1 and ω_{odd}. In particular, a necessary condition for a sequence d to be realizable by a cactus graph is that $\sum d \le 3(n-1)$, and the sufficient condition utilizes also ω_1 and ω_{odd}.
- Outer-planar graphs: This is the main technical contribution of the current paper, to be described shortly.

- 2-trees [7]: This class was given a full characterization, where the volume requirement is $\sum d = 4n - 6$ but the precise conditions depend also on ω_1 and ω_2, and involve also some exceptions.
- Planar graphs [4]: Full characterization is still out of reach. The natural necessary condition based on volume is $\sum d \leq 6n - 12$. The sufficient condition given in [4] depends also on ω_1.

Our main technical contribution concerns sequences that can be realized by outer-planar graphs. A graph is *outer-planar* if it can be embedded in the plane such that edges do not intersect each other and additionally, each vertex lies on the outer face of the embedding, i.e., no vertex is fully surrounded inside an internal face (cf. [24]). Call a sequence d *planaric* (respectively, *outer-planaric*) if it is the degree sequence of some planar (resp., outer-planar) graph G.

Since it is known that every outer-planar graph has at most $2n - 3$ edges, it follows that every sequence d with $\sum d > 4n - 6$ cannot be outer-planaric. In fact, as claimed in [3], this bound can be improved if ω_1, the multiplicity of degree 1, is taken into consideration. Specifically, if the sequence d satisfies $\sum d > 4n - 6 - 2\omega_1$ and $d \neq (n - 1, 1, \ldots, 1)$, then it is not outer-planaric (the exceptional sequence has $n - 1$ leaves and volume $2n - 2$, and is realizable by a star graph). It is also easy to show that this bound is tight, in the sense that there are outerplanar sequences d with $\sum d = 4n - 6 - 2\omega_1$, for ω_1 values in the range $[1, n - 2]$.

Focusing on the converse question, we look for a function $f(n, \omega_1)$ guaranteeing that if d is graphic and $\sum d \leq f(n, \omega_1)$, then d is *always* outer-planaric. A straightforward such bound is $f(n, \omega_1) = 2n - 2$, since as mentioned above, if $\sum d \leq 2n - 2$ then d has a realization by a forest, hence it is trivially outer-planaric. Here, we present a tight answer to the question, separated into two cases, depending on whether or not the sequence d contains 1's. Specifically, we show that if $\omega_1 = 0$ then the desired property holds when $\sum d \leq 3n - 3$, and if $\omega_1 > 0$ then the desired property holds when $\sum d \leq 3n - \omega_1 - 2$. Conversely, we show that the set of graphic sequences that are not outer-planaric includes:

(1) sequences with $\omega_1 = 0$ and $\sum d = 3n - 2$;

(2) sequences with $\omega_1 > 0$ and $\sum d = 3n - \omega_1 - 1$.

Related Work. A number of papers studied the outerplanar degree realization problem in the past. *Forcibly* outerplanar graphic sequences, i.e., sequences *all* of whose realizations are outerplanar, were given a full characterization in [8]. The degree sequences of maximal outerplanar graphs with exactly two 2-degree nodes were characterized in [19]. This was also mentioned in [7] independently. The degree sequences of maximal outerplanar graphs with at most four vertices of degree 2 were characterized in [17].

The special class *2-trees* has also received some attention. A graph G is a 2-tree if $G = K_3$ or G has a vertex v with degree 2, whose neighbors are adjacent and $G[V \setminus \{v\}]$ is a 2-tree. Sufficient conditions for a sequence d to have a realization by a 2-tree were given in [18]. The degree sequences of 2-trees were fully characterized in [7]. (The conditions are surprisingly rather involved, and include a number of specific exceptions.) Note that 2-trees have $\sum d = 4n - 6$. This implies, using Theorem 1 of [7], that if a sequence d satisfies some specific conditions, then d has a realizing 2-tree. Rengarajan and Veni Madhavan [22] have shown that every 2-tree has a 2-page book embedding. Unfortunately, the class of 2-trees is not hereditary (meaning that a subgraph of a 2-tree is not necessarily a 2-tree), so the result of [7] does not extend to non-maximal degree sequences.

The planar degree realization problem also has a long history. Regular planar graphic sequences and planar bipartite biregular degree sequences were given a classification in [15] and [1] respectively. Schmeichel and Hakimi [23] identified the graphic sequences with $d_1 - d_n = 1$ that are planaric, and did the same for $d_1 - d_n = 2$ with a small number of unresolved exceptions, some of which were later resolved in [10, 11]. Additional studies on special cases of the planaric degree realization problem are discussed in [21].

In [4] it is shown that for every sequence d with $\sum d \leq 4n - 4 - 2\omega_1$, if d is graphic then it is also planaric. Conversely, there are graphic sequences with $\sum d = 4n - 2\omega_1$ that are non-planaric. For the case $\omega_1 = 0$, it is shown therein that d is planaric when $\sum d \leq 4n - 4$, and conversely, there is a graphic sequence with $\sum d = 4n - 2$ that is non-planaric.

A cactus graph is a connected graph in which any edge may be a member of at most one cycle, which means that different cycles do not share edges, but may share one vertex. Rao [20] provided a full characterization for degree sequences realizable by cactus graphs, and also gave a characterization for degree sequences realizable by cactus graphs whose cycles are triangles and for degree sequences realizable by connected graphs whose blocks are cycles of k vertices. Beineke and Schmeichel [5] characterized cacti degree sequences with up to four cycles and also provided a sufficient condition for cactus realization. A characterization for degree sequences realizable by bipartite cactus graphs was shown in [2].

2 Preliminaries and Known Results

Some Terminology. Two necessary (but not sufficient) conditions for a non-increasing sequence $d = (d_1, \ldots, d_n)$ to be graphic are that $\sum d$ is even and $d_1 \leq n - 1$. We refer to sequences that satisfy these two conditions as *standard* sequences. Hereafter, we consider only standard sequences.

For a nonincreasing sequence d of n nonnegative integers, let $\mathsf{pos}(d)$ denote the prefix consisting of the positive integers of d. We use the shorthand a^k to denote a subsequence of k consecutive a's. Denote the *volume* of sequence $d = (d_1, \ldots, d_n)$ by $\sum d \equiv \sum_{i=1}^{n} d_i$.

Trees and Forests. Consider a sequence $d = (d_1, \ldots, d_n)$ of positive integers such that $\sum d$ is an even number. It is known that if $\sum d \leq 2n - 2$, then d is graphic and moreover, $\mathcal{G}(d)$ contains an acyclic graph (forest). In this case, we say that d is *forestic*. If $\sum d = 2n - 2$, then d can be realized by a tree and we say that d is *treeic*. We refer to a vertex of degree one as a *leaf*.

We make use of a special type of realizations for treeic and forestic sequences, known as *caterpillar graphs*. In a caterpillar graph $G = (V, E)$, all non-leaves are arranged on a path which we call the *spine* of G, i.e., the spine $S = (x_1, \ldots, x_s) \subset V$ is an ordered sequence where $(x_i, x_{i+1}) \in E$, for $i = 1, \ldots, s - 1$ (see Figure 1 for an example).

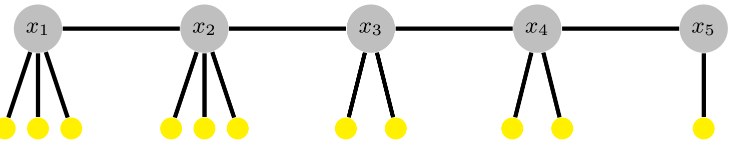

Figure 1 Caterpillar graph with degree sequence $(5, 4^3, 2, 1^{11})$. Leaves are depicted in yellow.

The following (possibly folklore) observation appears in [3]. We provide a proof, since its method will be instrumental in what follows.

▶ **Observation 1** ([3])**.** *Any forestic sequence d can be realized by a forest composed of the union of a caterpillar graph and a matching.*

Proof. First consider a treeic sequence d (such that $\sum d = 2n - 2$). Assume there are $n - s$ vertices of degree 1 in d. Denote by d^* the prefix of d that contains all the degrees $d_i > 1$. It follows that $\sum d^* + (n - s) = \sum d = 2n - 2$, or equivalently $\sum d^* - 2s + 2 = n - s$. To get the caterpillar realization of d, first arrange s vertices corresponding to the degrees of d^* in a path. The path edges contribute $2s - 2$ to the volume $\sum d^*$. The missing $\sum d^* - 2s + 2 = n - s$ degrees are satisfied by attaching the $n - s$ leaves to the path, which now forms the spine of the caterpillar realization. Note that the order of the vertices on the spine can be arbitrary.

Now assume that d is forestic but not treeic, i.e., $\sum d < 2n - 2$. In this case, remove pairs of 1 degrees from d until the volume of the reaming sequence d' with n' vertices is $2(n' - 2)$. This must happen because each pair removal reduces the volume by 2 while $2n - 2$ decreases by 4. Let G' be the caterpilar realization of d' as implied by the first part of the proof. To get the realization of d, add $(n - n')/2$ edges to G' to satisfy the $n - n'$ removed 1 degrees by a matching. ◀

Necessary Conditions for Outer-Planaric Sequences.

▶ **Lemma 2** ([25])**.** *If $d = (d_1, \ldots, d_n)$ is an outer-planaric degree sequence where $n \geq 2$, then $\sum d \leq 4n - 6$.*

It is known that every outer-planar graph has at least two vertices of degree two or less, and at least three vertices of degree three or less, see for example Sysło [24]. This implies the following necessary condition for outer-planaric sequences.

▶ **Lemma 3** ([24])**.** *If $d = (d_1, \ldots, d_n)$ is an outer-planaric degree sequence, then*
(i) $d_{n-1} \leq 2$, *and*
(ii) $d_{n-2} \leq 3$.

The Havel-Hakimi Algorithm and Outer-planaric Sequences. The lay-off techniques developed by Havel and Hakimi, and subsequently extended by Kleitmann and Wang, are among the fundamental tools for constructing realizations for degree sequences. One might hope to be able to use such techniques for finding (outer-)planar realizations as well. Unfortunately, it turns out that the lay-off operation does not, in general, preserve planarity or outer-planarity (only graphicity), hence it cannot be applied directly to generate a realizing outer-planar graph for a given outer-planaric sequence.

Nevertheless, we do make use of the lay-off technique, and specifically the *minimum pivot* version of the Havel-Hakimi algorithm [13, 14]. It is used for realizing a nonincreasing degree sequence $d = (d_1, d_2, \cdots, d_n)$ associated with the vertices $v_1, v_2, \ldots, v_n$, and is based on repeatedly performing the following operation, hereafter referred to as the *MP-step*, until all the vertices reach their required degree. Suppose the current sequence of residual nonzero degrees is $d' = (d'_1 \geq d'_2 \geq \cdots \geq d'_h)$ and the corresponding vertices are $v_{i_1}, v_{i_2}, \ldots, v_{i_h}$.

- Pick the vertex $v = v_{i_h}$ with degree d'_h as pivot.
- Set v's neighbors to be the d'_h vertices $v_{i_1}, v_{i_2}, \ldots, v_{i_{d'_h}}$.
- Delete the pivot from d', reduce by 1 the residual degrees of its selected neighbors, and delete from d every vertex whose residual degree became zero.

The key observation is that, in case the MP-step transforms the residual degree sequence d into d', the following holds: d is graphic if and only if d' is graphic.

3 Outer-Planaric Degree Sequences

3.1 Necessary conditions

We first recall that Lemma 2 can be improved if ω_1, the multiplicity of degree 1, is taken into consideration. We add the proof for completeness.

▶ **Lemma 4** ([3]). *If d is an outer-planaric sequence such that $\sum d > 2n - 2$, then $\sum d \leq 4n - 6 - 2\omega_1$.*

Proof. Let d be as in the lemma and let $G = (V, E)$ be an outerplanar graph realizing d. Construct a graph G' by deleting from G all the ω_1 vertices of degree 1 together with their incident edges, and subsequently deleting the vertices whose degree was reduced to zero. Notice that the graph G' may contain vertices whose degree became 1. Observe that G' is outerplanar, and let $d' = \deg(G')$. Note that $n' \leq n - \omega_1$, where n' the number of vertices in G'. We have that $\sum d' \leq 4n' - 6$ due to Lemma 2. Hence,

$$\sum d = \sum d' + 2\omega_1 \leq 4(n - \omega_1) - 6 + 2\omega_1 = 4n - 6 - 2\omega_1 \ ,$$

where the first equality comes from the fact that ω_1 vertices of degree 1 together with their incident edges are deleted. ◀

We remark that Lemma 4 is false if we drop the assumption $2n - 2 < \sum d$. To see this, consider the sequence $d = (a, 1^a)$ which is (uniquely) realized by a star graph and therefore outer-planaric. The construction of G' in the proof above, applied to d, yields an isolated vertex. Note that Lemma 2 cannot be applied in this case. Indeed, we have that

$$\sum d = 2a > 2a - 2 = 4(a + 1) - 6 - 2a = 4n - 6 - 2\omega_1.$$

Observe that sequences of the form $d = (a, 1^{a+t})$ are the only sequences where G' has order one or less. If $t \geq 2$ (note that t must be even), the bound can be shown directly with the above calculation. We state the following corollary.

▶ **Corollary 5.** *If $d = (d_1, \ldots, d_n)$ is an outer-planaric sequence such that $d \neq (a, 1^a)$, then $\sum d \leq 4n - 6 - 2\omega_1$.*

The next corollary gives us a useful necessary condition for outer-planaric sequences.

▶ **Corollary 6** ([16]). *If $d = (d_1, \ldots, d_n)$ is an outer-planaric sequences, then $d_1 + d_2 \leq n + 2$.*

3.2 Sufficient Conditions

In this section, we show sufficient condition for outer-planaric sequences.

The collection of *low-volume* (standard) sequences is defined as

$$LV \ = \ LV_1 \cup LV_2 \ ,$$

where

$$LV_1 = \left\{ d \mid \sum d \leq 3n - \omega_1 - 2, \ \ d_n = 1, \ \ d \text{ is graphic} \right\}$$
$$LV_2 = \left\{ d \mid \sum d \leq 3n - 3, \ \ d_n = 2 \right\}$$

Notice that by assuming that the sequences are standard, we implicitly require that $\sum d$ is even and that $d_1 \leq n - 1$.

We now show that all sequences in LV are outer-planaric. For the proof we analyze a slightly large collection than LV_2, namely,

$$LV_2' = \left\{ d \mid \sum d \leq 3n-2, \quad d_n = 2 \right\},$$

Notice that $LV_2 \subset LV_2'$. We prove that all the sequences in LV_2' except for a small set EX are outer-planaric. As $LV_2 \subset LV_2' \setminus EX$, we get that all the sequences in LV_2 are outer-planaric. Moreover, we also use LV_2' to prove that all the sequences in LV_1 are outer-planaric.

In order to analyze the collection LV_2', we break it into four sub-collections A, B, C, D, and handle each of them separately. Specifically, we define the following sets.

$$\begin{aligned}
A &= \left\{ (3^s, 2^{n-s}) \mid n \geq 3, \quad 0 \leq s \leq n-2, \quad \text{and } s \text{ is even} \right\}, \\
B &= \left\{ (d_1, 2^{n-1}) \mid d_1 \geq 4 \quad \text{and} \quad d_1 \text{ is even} \right\}, \\
C^M_{even} &= \left\{ (d_1, d_2, 2^{n-2}) \mid d_1, d_2 \geq 4, \quad d_1 + d_2 = M \quad \text{and} \quad d_1, d_2 \text{ are even} \right\}, \\
C^M_{odd} &= \left\{ (d_1, d_2, 2^{n-2}) \mid d_1 \geq 5, \quad d_2 \geq 3, \quad d_1 + d_2 = M \quad \text{and} \quad d_1, d_2 \text{ are odd} \right\}, \\
C_{even} &= \bigcup_{M \leq n+2} C^M_{even}, \\
C_{odd} &= \bigcup_{M \leq n+2} C^M_{odd}, \\
C &= C_{even} \cup C_{odd}, \\
D &= \left\{ d \mid d_1 \geq 4, \quad d_3 \geq 3, \quad d_n = 2, \quad \sum d \leq 3n-2 \right\}.
\end{aligned}$$

Note that all sequences in A, B, C, D are standard.

▶ **Observation 7.** *$LV_2' = A \cup B \cup C \cup D$.*

Proof. One can check directly that $A, B, C, D \subseteq LV_2'$, and hence $A \cup B \cup C \cup D \subseteq LV_2'$. For the converse, consider some $d \in LV_2'$. If $d \in LV_2' \setminus D$, then $d_3 = 2$ or $d_1 \leq 3$, so d has the form $(d_1, d_2, 2^{n-2})$ or $(3^s, 2^{n-s})$. First assume that $d_3 = 2$ and consider d of the form $(d_1, d_2, 2^{n-2})$. If $d_2 = 2$, then $d \in B$. If $d_1 = d_2 = 3$, then $d \in A$. Otherwise $d_1 \geq 4$ and $d_2 \geq 3$, we have $d_1 + d_2 \leq n + 2$ since $\sum d \leq 3n-2$. In this case, $d \in C$. Next consider d of the form $(3^s, 2^{n-s})$. Since $\sum d \leq 3n-2$, $s \leq n-2$. In this case, $d \in A$. Combining these cases, we have $LV_2' \subseteq A \cup B \cup C \cup D$. The observation follows. ◀

▶ **Lemma 8.** *Every sequence $d \in A$ is outer-planaric.*

Proof. Let d be as in the lemma. By the definition of A, $d = (3^s, 2^{n-s})$ where s is even and $0 \leq s \leq n-2$. We construct an outer-planar realization G of d as follows. First, arrange n vertices in a cycle, i.e., let $G = C_n$. If $s = 0$, then G is a valid realization of d (noting that $n \geq 3$ so G is a simple graph). Now suppose $s > 0$. Select one vertex y on the cycle and denote its clockwise (respectively, counter-clockwise) neighbor of distance x by u_x (resp., v_x), for $x = 1, \ldots, s/2$. Observe that the vertices $u_{s/2}$ and $v_{s/2}$ cannot be connected by an edge in C_n, since $s \leq n-2$. To complete our construction, we add to $E(G)$ a matching consisting of the edges (v_x, u_x), for $x = 1, \ldots, s/2$ Since these new edges can be placed *inside* the cycle, G has an outer-planar embedding as shown in Figure 2. Verifying that $\deg(G) = d$, the claim follows. ◀

▶ **Lemma 9.** *Every sequence $d \in B$ is outer-planaric.*

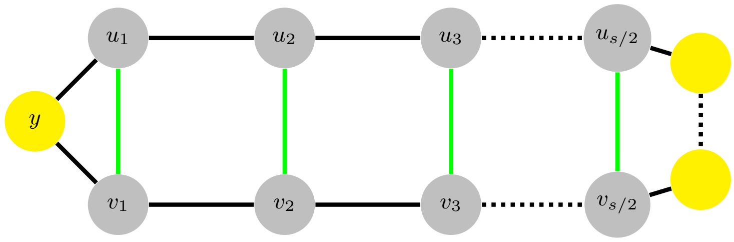

Figure 2 Schematic outer-planar realization of a sequence $d = (3^s, 2^{n-s})$ where s is even and $0 \le s \le n-2$. The yellow vertices have degree two and the gray vertices have degree three. Cycle edges are drawn in black and matching edges are drawn in green.

Proof. Since d_1 is even, d can be realized by the graph $G = (V, E)$ where $V = \{v_1, \ldots, v_n\}$ and the edge set E is constructed by the following steps:

(1) $E_1 \leftarrow \{(v_1, v_i) \mid i = 2, \ldots, d_1 + 1\}$ connects v_1 to d_1 other vertices.

(2) $E_2 \leftarrow \{(v_{2j}, v_{2j+1}) \mid j = 2, \ldots, d_1/2\}$ is a perfect matching among the neighbors of v_1.

(3) Let $W \leftarrow V \setminus \{v_1, \ldots, v_{d_1+1}\}$ be the set of remaining vertices. If $W = \emptyset$, then set $E_3 \leftarrow \{(v_2, v_3)\}$. Otherwise (i.e., if $W = \{v_j \mid j = d_1 + 2, \ldots, n\}$ where $d_1 + 2 \le n$), $E_3 \leftarrow \{(v_2, v_{d_1+2}), (v_{d_1+2}, v_{d_1+3}), \ldots, (v_n, v_3)\}$.

(4) Set $E \leftarrow E_1 \cup E_2 \cup E_3$.

Note that Steps (1) and (3) can be performed based on d since $d_1 \le n-1$. More specifically, Step (1) yields well-defined edges, i.e., $E_1 \subseteq V \times V$, and in Step (3), W is well-defined. Step (2) can be performed based on d i.e., $E_2 \subseteq V \times V$, since d_1 is even. Figure 3 illustrates these steps. Note that every vertex is located on the outer face, so G is outerplanar. As G realizes the degree sequence d, it follows that d is outer-planaric. ◀

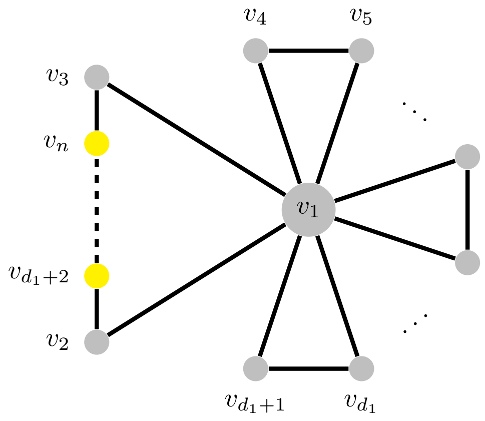

Figure 3 An illustration of the graph G constructed in the proof of Lemma 9 where the set W (vertices in yellow) is not empty.

Define $EX = C^{n+2}_{even} = \{(d_1, d_2, 2^{n-2}) \mid d_1, d_2 \ge 4, \;\; d_1 + d_2 = n+2 \;\text{ and }\; d_1, d_2 \text{ are even}\}$.

▶ **Lemma 10.** *Let $d \in C \setminus EX$. Then d is outer-planaric.*

Proof. Suppose $d \in C \setminus EX$. Since $\sum d \le 3n-2$, necessarily $d_1 + d_2 \le n+2$.

First suppose $d \in C_{odd}$. Construct a realizing graph G on the vertex set $V = \{v_1, \ldots, v_n\}$ by taking the following steps. Let v_1 and v_2 be the vertices with degree d_1 and d_2 respectively.

(1) $E_1 = \{(v_1, v_2), (v_1, v_3), (v_1, v_4), (v_2, v_3), (v_2, v_4)\}$. These edges connect v_1 to v_2 and also connect v_1 and v_2 to two common neighbors, v_3 and v_4.

(2) $E_2 \leftarrow \{(v_1, v_i) \mid i = 5, \ldots, d_1 + 1\}$ connects $d_1 - 3$ extra neighbors from the remaining vertices to v_1, and $E_3 \leftarrow \{(v_{5+2j}, v_{6+2j}) \mid j = 0, \ldots, \frac{d_1-5}{2}\}$ sets a perfect matching among the vertices $\{v_i \mid i = 5, \ldots, d_1 + 1\}$.

(3) If $d_2 = 3$, then $E_4, E_5 \leftarrow \emptyset$.
Otherwise, $E_4 \leftarrow \{(v_2, v_i) \mid i = d_1 + 2, \ldots, d_1 + d_2 - 2\}$ connects $d_2 - 3$ extra neighbors from the remaining vertices to v_2, and $E_5 \leftarrow \{(v_{d_1+2+2j}, v_{d_1+3+2j}) \mid j = 0, \ldots, \frac{d_2-5}{2}\}$ is a perfect matching among the vertices $\{v_i \mid i = d_1 + 2, \ldots, d_1 + d_2 - 2\}$.

(4) Let $W \leftarrow V \setminus \{v_1, \ldots, v_{d_1+d_2-2}\}$ be the set of remaining vertices. If $W = \emptyset$, then set $E_6 \leftarrow \{(v_1, v_3)\}$
Otherwise, plant the vertices of W on the edge (v_1, v_3), or more formally, replace (v_1, v_3) with the edges in the path $(v_1, v_{d_1+d_2-1}, \ldots, v_n, v_3)$, namely with the edge set $E_6 \leftarrow \{(v_1, v_{d_1+d_2-1}), (v_{d_1+d_2-1}, v_{d_1+d_2}), \ldots, (v_n, v_3)\}$

(5) Set $E \leftarrow (E_1 \setminus \{(v_1, v_3)\} \cup E_2 \cup E_3 \cup E_4 \cup E_5 \cup E_6$.

Note that Step (1) can be performed based on d, in the sense that no vertex is assigned more edges than its degree, since $d_1, d_2 \geq 3$ and $d_3 = d_4 = 2$. Steps (2) and (3) use $d_1 + d_2 - 6$ distinct vertices (from v_5 to $v_{d_1+d_2-2}$) to serve as the remaining neighbors of v_1 and v_2. Since $d_1 + d_2 \leq n + 2$, Steps (2) and (3) can be performed based on d, i.e., $d_1 + d_2 - 2 \leq n$ so $E_2 \cup E_3 \subseteq V \times V$. Besides, the matchings in Steps (2) and (3) can be performed based on d, i.e., $E_4 \subseteq V \times V$, since d_1 and d_2 are both odd. Figure 4 illustrates the steps of the construction. One can check that constructed graph G realizes d and is outer-planaric, since all vertices are located on the outer face.

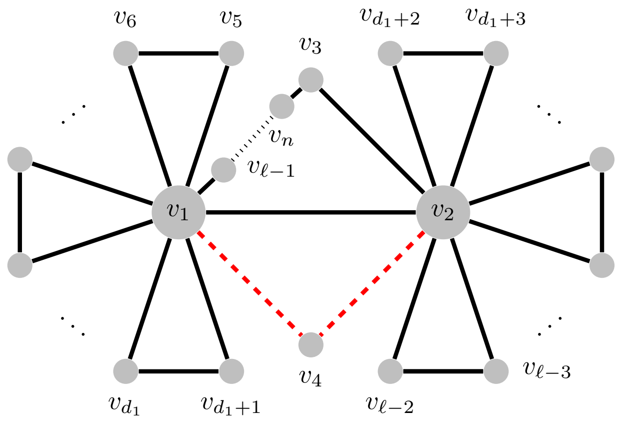

Figure 4 An illustration of the graph G constructed in the proof of Lemma 10 for the case where $d \in C_{odd}$. Let $\ell = d_1 + d_2$. The graph for the case where $d \in C_{even}$ is obtained by removing the red dashed edges.

Now suppose $d \in C_{even} \setminus EX$. Hence, $d_1 + d_2 \leq n + 1$. Let $d' = (d_1 + 1, d_2 + 1, 2^{n-1})$. Notice that $n' = n + 1$ and that $d'_1 + d'_2 = d_1 + d_2 + 2 \leq n + 1 + 2 = n' + 2$. Hence, $d' \in C_{odd}$. Construct a realizing outerplanar graph G' for the sequence d'. Let G be the graph we get by removing v_4 and its two edges the edges (v_1, v_4) and (v_2, v_4) from G'. (The dashed red edges in Figure 4.) Observe that G realizes d and it is outer-planar. ◀

▶ **Lemma 11.** *Let $d \in EX$. Then d is not outer-planaric.*

Proof. Recall that $d = (d_1, d_2, 2^{n-2})$, where $4 \le d_1 \le n-1$, $d_2 \ge 3$, $d_1 + d_2 = n+2$, and both d_1 and d_2 are even. Assume towards contradiction that d is outer-planaric, and let $G = (V, E)$ be a realizing outerplanar graph for it. Let v_1 and v_2 be the vertices of degree d_1 and d_2 in G, respectively.

Let $k \le d_2$ be the number of common neighbors of v_1 and v_2. If v_1 and v_2 are not adjacent, then

$$n - 2 = (d_1 - k) + (d_2 - k) + k = d_1 + d_2 - k = n + 2 - k \; .$$

Hence, $k = 4$. In this case, G contains a subgraph homeomorphic to $K_{2,3}$, and therefore it is not outer-planar [24], leading to a contradiction.

Otherwise, if v_1 and v_2 are adjacent, then

$$n - 2 = (d_1 - k - 1) + (d_2 - k - 1) + k = d_1 + d_2 - 2 - k = n - k \; .$$

Hence, $k = 2$. Consequently, denoting the two common neighbors of v_1 and v_2 in G by v_3 and v_4, let $N'[v_1]$ (respectively, $N'[v_2]$) be the set of neighbours of v_1 (resp., v_2) except for v_3, v_4 and v_2 (resp., v_1). See Figure 5. $|N'[v_1]|$ and $|N'[v_2]|$ are odd, since d_1, d_2 are even. Since the vertices in $N'[v_1] \cup N'[v_2]$ all have degree 2, there must exist (at least) one vertex in $N'[v_1]$ and one vertex in $N'[v_2]$ that are connected. (In Figure 5, these are marked as v_5 and v_6.) It follows that there are three paths from v_1 to v_2, the first contains v_3, the second contains v_4, and the third contains v_5 and v_6. In this situation, in any planar embedding of G, at least one of the common neighbors v_3 or v_4 or the pair v_5 and v_6 is not in the outer face. (In Figure 5, the vertex v_3 is blocked.) This leads to a contradiction. ◀

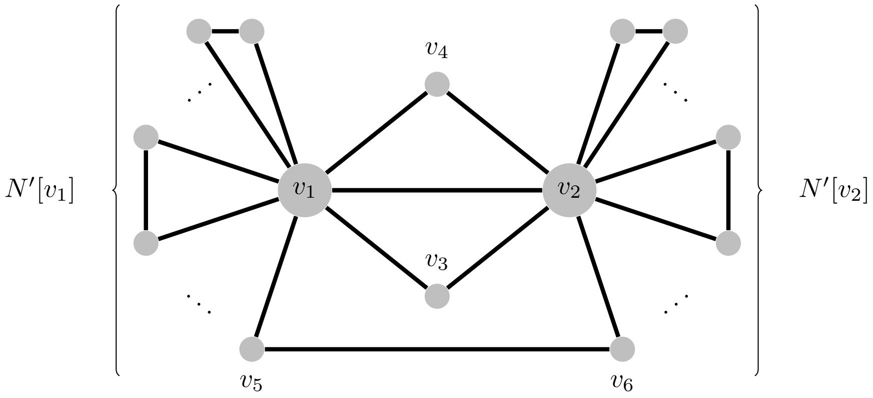

Figure 5 The non outer-planar graph G constructed in the proof of Lemma 11. $N'[v_1]$ and $N'[v_2]$ are, respectively, the vertex sets to the left of v_1 and to the right of v_2.

To prove the next lemma, we construct an outer-planar graph by starting from a caterpillar graph and adding a matching, increasing the degree of each vertex by one. The next observation describes a part of the construction used repetitively.

▶ **Observation 12.** *Let $G = (V, E)$ be a caterpillar graph with an outer-planar embedding as depicted in Figure 1. If $L \subseteq V$ is an even set of leaf vertices that appear consecutively in the embedding, then one can add a matching between the vertices of L such that the resulting graph has an outer-planar embedding.*

Proof. Let $L = \{\ell_1, \ldots, \ell_h\}$ be the leaf vertices in consecutive order, for even h. Note that vertices in L are pairwise non-adjacent. We add the matching edges (ℓ_{2i-1}, ℓ_{2i}), for $i = 1, \ldots, h/2$, i.e., we add every second edge of the path $(\ell_1, \ldots, \ell_h)$. ◀

The next lemma proves the most general case where $d_n \geq 2$.

▶ **Lemma 13.** *Every sequence $d \in D$ is outer-planaric.*

Proof. Consider $d \in D$. Denote $k = \sum d - (2n-2)$. Observe that k is even and that $k \geq 2$, since $\sum d \geq 2n$. Also, $k \leq 3n - 2 - (2n-2) = n$.

Our proof consists of two major steps:

(1) Create a treeic sequence d' from d and find an (outer-planar) caterpillar realization G of d' as described in Observation 1.

(2) Modify G by adding edges such that $\deg(G) = d$ and G remains outer-planar.

For step (1), construct the sequence $d' = (d'_1, d'_2, \ldots, d'_n)$ as follows:

$$d'_i = \begin{cases} d_i, & i \leq n-k, \\ d_i - 1, & i > n-k. \end{cases}$$

d' is well defined since $k \leq n$, and also note that $\sum d' = \sum d - k = 2n - 2$.

We first assume that $\omega'_2 \leq 2$.

Relying on Observation 1, we find a caterpillar realization $G = (V, E)$ of d'. Let $S = \{v_1, \ldots, v_s\} \subseteq V$ be the vertices on the spine of G. Note that $|S| \geq 3$ since $d_3 \geq 3$, implying that (at least) the three highest-degree vertices are non-leaves. Let ℓ denote the number of leaves in the caterpillar. Notice that $\ell + s = n$. Also, observe that $k \geq \ell$. Out goal is to increase the degree of all leaves and of $k - \ell$ vertices in the spine by 1 while maintaining outer-planarity.

As a preliminary step we rearrange the spine such that vertices high degree vertices are closer to the center of the spine. Specifically, if s is even, the order is $v_{s-1}, \ldots, v_3, v_1, v_2, \ldots, v_s$, and if s is odd, the order is $v_{s-1}, \ldots, v_2, v_1, v_3, \ldots, v_s$. Notice that only v_s and v_{s-1} may be of degree 2. We refer to such a construction as an *ordered caterpillar.*

For step (2), we consider two cases:

Case A: $k < n$.

Case A.1: ℓ and $k - \ell$ are even.

We add a perfect matching of consecutive leaves as described in Observation 12. We also add the (matching) edges (v_i, v_{i-1}), for $i = s, s-2, \ldots, s-(k-\ell)+2$ between the vertices on the spine. The latter is feasible since $k < n$ (or $k - \ell < s$).

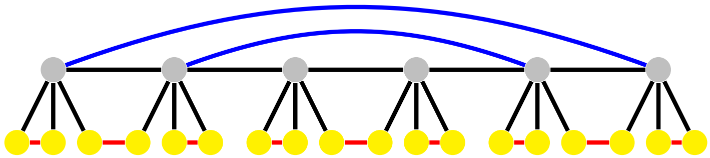

Figure 6 Illustration of the construction in Case A.1.

Case A.2: If ℓ and $k - \ell$ are odd, we add one leaf of v_{s-1} to the spine. Since $\ell - 1$ is even, we can add edges as in case A.1.

Case B: $k = n$.

Observe that n must be even, since k is even. Also, in this case, $s = k - \ell$. Let m be the number of leaves connected to spine vertices to the left of v_1 up to v_1 (including v_1).

Case B.1: s and ℓ are odd.

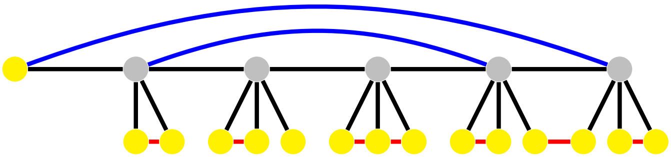

Figure 7 Illustration of the construction in Case A.2.

Case B.1(i): m is even.
Add a perfect matching of the consecutive leaves connected to $v_{s-1}, v_{s-3}, \ldots, v_1$ as described in Observation 12, add an edge connecting v_1 to the leftmost leaf of the vertex to its right (v_2 or v_3), and then add perfect matching of the rest of the leaves. In addition, add the (matching) edges (v_i, v_{i-1}), for $i = s, s-2, \ldots, 3$ between the vertices on the spine.

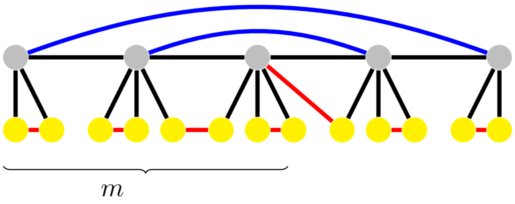

Figure 8 Illustration of the construction in Case B.1(i).

Case B.1(ii): m is odd.
Add the leftmost leaf of v_{s-1} and the rightmost leaf of v_s to the spine. Now use the same construction as in the case B.1(i).

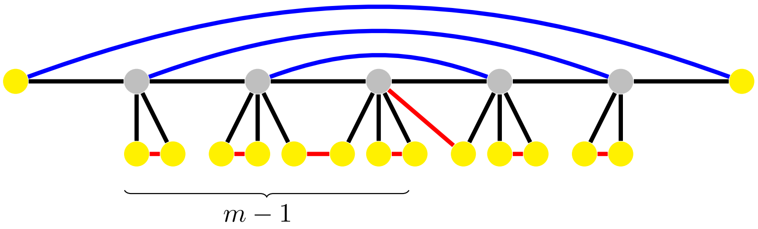

Figure 9 Illustration of the construction in Case B.1(ii).

Case B.2: s and ℓ are even.

Case B.2(i): m is odd.
Add the leftmost leaf of v_{s-1} to the spine, and use the construction of case B.1(i).

Case B.2(ii): m is even.
Add the edges (v_i, v_{i-1}), for $i = s-1, s-3, \ldots, 3$ between the vertices on the spine. Also, add the edge (v_{s-1}, v_s). In addition, replace the edge (v_{s-1}, u) with the edge (v_1, u), where u be the leftmost leaf of v_{s-1}. Add a perfect matching of consecutive leaves as described in Observation 12.

It remains to consider the case where $\omega'_2 > 2$. There are two options regarding the 2's in d'. Either all of them appear in d, or all of them originate from 3's in d.

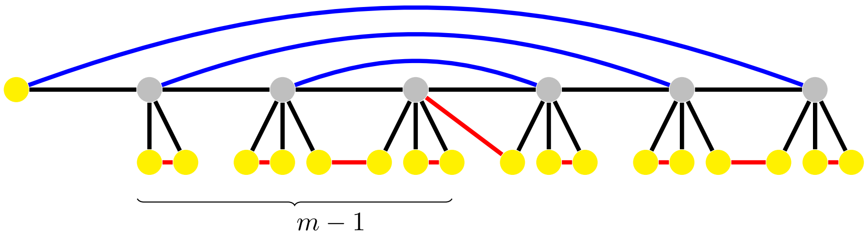

Figure 10 Illustration of the construction in Case B.2(i).

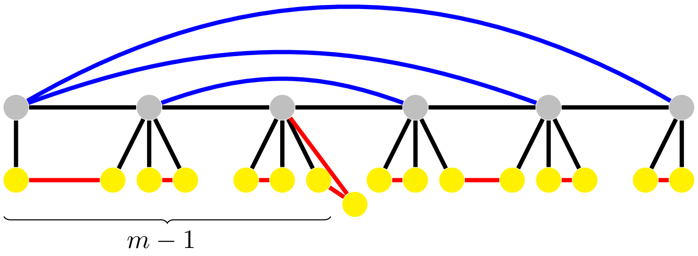

Figure 11 Illustration of the construction in Case B.2(ii).

In the first case, we obtain a sequence d'' by removing all 2's from d', and construct an outer-planar embedding for the first n'' entries by using the construction for case where $\omega_2'' \leq 2$. Consider any edge (x, y) connecting two former leaves in the above construction. We replace the edge with a path of length $\omega_2' + 1$.

In the second case, we remove $t = 2\lfloor\omega_2'/2\rfloor$ 2's from d', and construct an outer-planar embedding for the first n'' entries by using the construction for case where $\omega_2'' \leq 2$. Consider any edge (x, y) connecting two former leaves in the above construction. We replace (x, y) with a path $(x = u_0, u_1, \ldots, u_t, u_{t+1} = y)$. Then, we add the edges $\{(u_i, u_{t+1-i}) : i = 0, 1, \ldots, t/2 - 1\}$, but not in the outer-face. ◀

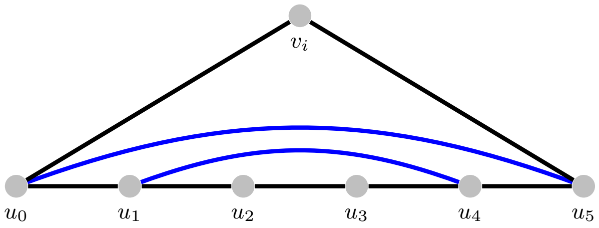

Figure 12 Illustration for the case where $\omega_2' > 2$, where $t = 4$.

Combining Lemmas 8, 9, 10, 11, 13 and Observation 7, we have the following corollary.

▶ **Corollary 14.** *Let $d \in LV_2'$.*

1. *The sequence d is outer-planaric except for $d \in EX$.*
2. *If $d \in LV_2$, then d is outer-planaric.*

Finally, we deal with sequences where $d_n = 1$.

▶ **Lemma 15.** *Every sequence $d \in LV_1$ is outer-planaric.*

Proof. Consider $d \in LV_1$. If $\sum d \leq 2n-2$, then the claim follows from Observation 1. So now assume that $\sum d > 2n-2$. Applying the MP-step of the HH method on d (see Section 2) with pivot 1 connecting to the largest degree ω_1 times yields a new sequence d', with $n' := |\mathsf{pos}(d')| = n - \omega_1$ nonzero degrees.

We claim that all the degrees in $\mathsf{pos}(d')$ are at least 2. If $d'_{n'} = 1$, then the other degrees in $\mathsf{pos}(d')$ have value 1 or 2 by the MP-step of the HH method. Therefore, $\sum \mathsf{pos}(d') \leq 2(n'-1)+1 = 2n-2\omega_1-1$, and consequently $\sum d = \sum d' + 2\omega_1 \leq 2n-1$, contradicting the assumption on $\sum d$. Furthermore, by the MP-step of the HH method, $\mathsf{pos}(d')$ is graphic, so $d'_1 \leq n'-1$. Also, $\sum \mathsf{pos}(d') = \sum d - 2\omega_1 \leq 3(n-\omega_1) - 2 = 3n'-2$. Hence, $\mathsf{pos}(d') \in LV'_2$. This and Corollary 14 imply that $\mathsf{pos}(d')$ is outer-planaric except for $\mathsf{pos}(d') \in EX$.

Notice that if $\mathsf{pos}(d')$ can be realized by an outer-planar graph G', then d is also outer-planaric, since a realizing graph G can be obtained from G' by inserting $d_i - d'_i$ new leaves to each vertex of degree d'_i. This completes the proof of the lemma for all cases except when $\mathsf{pos}(d') \in EX$, in which case it may be that d is outer-planaric yet $\mathsf{pos}(d')$ is not. For example, the sequence $d = (8, 4, 2^6, 1^2)$ is outer-planaric, as illustrated in Figure 13, but for the sub-sequence d' obtained by applying the MP-step of the HH method on d, the positive prefix $\mathsf{pos}(d') = (6, 4, 2^6)$ is not outer-planaric, by Lemma 11. So it remains to show that d is outer-planaric even if $\mathsf{pos}(d') \in EX$.

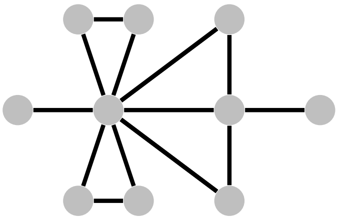

Figure 13 Outer-planar realization of the sequence $d = (8, 4, 2^6, 1^2)$.

A sequence $\mathsf{pos}(d') \in EX$ has the form $\mathsf{pos}(d') = (d'_1, d'_2, 2^{n'-2})$ where $d'_1 + d'_2 = n'+2$ and d'_1 and d'_2 are even. Since $d'_2 \geq 3$, we have $d'_2 \geq 4$.

Convert d' to $d'' = (d'_1+1, d'_2-1, 2^{n'-2})$. Note that d'' is non-increasing since $d'_2 \geq 4$. Then $d''_1 + d''_2 = d'_1 + d'_2 = n'+2$. As $d''_2 \geq 3$, we have $d''_1 \leq n'-1 = n''-1$. Also, $\sum d'' = \sum \mathsf{pos}(d') \leq 3n'-2 = 3n''-2$, so $d'' \in LV'_2$. One can check that $d'' \notin EX$, since d''_1, d''_2 are odd. By Corollary 14 (1), d'' is outer-planaric. Returning to our example of the outer-planaric $d = (8, 4, 2^6, 1^2)$ where $\mathsf{pos}(d') = (6, 4, 2^6)$ is not outer-planaric, the conversion yields $d'' = (7, 3, 2^6)$, which is outer-planaric by the construction in Lemma 10.

By the construction of d' and d'', $d_i \geq d'_i$ for $1 \leq i \leq n'$ and $d'_i \geq d''_i$ for $2 \leq i \leq n'$. As $d_1 > d'_1$, we have $d_i \geq d''_i$ for any $1 \leq i \leq n'$. Let G'' be an outer-planaric realizing graph for d''. Insert $d_i - d''_i$ leaves to the vertex with degree d''_i in G'' for any $1 \leq i \leq n'$. This yields an outer-planar graph G with degree sequence d. The lemma follows. ◀

In summary, combining Corollary 14 and Lemma 15, we get the following.

▶ **Theorem 16.** *Consider a nonincreasing n-integer graphic sequence d. If*
(1) $\omega_1 = 0$ *and* $\sum d \leq 3n-3$, *or*
(2) $\omega_1 > 0$ *and* $\sum d \leq 3n - \omega_1 - 2$,
then d is outer-planaric.

Finally, we complement the positive results of Corollary 14 and Lemma 15 by tight negative examples. Let us first consider the case of $\omega_1 = 0$. A tight example is any sequence in EX, which is not outer-planaric by Lemma 11. The volume of any sequence $d \in EX$ is

$\sum d = 3n - 2$. Next consider the case of $\omega_1 > 0$. A tight example is $d' = (3^{n-1}, 1)$ for even $n \geq 6$, which is planaric (See Figure 14) but not outer-planaric by Lemma 3. This sequence satisfies that $\sum d' = 3n - \omega_1 - 1$.

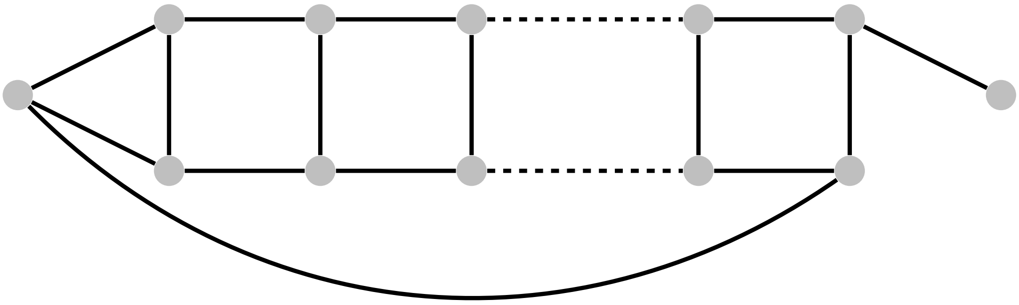

Figure 14 A non-outer-planar realization of the sequence $d = (3^{n-1}, 1)$.

Challenges of the Reachability Problem in Infinite-State Systems

Wojciech Czerwiński
University of Warsaw, Poland

Abstract

The reachability problem is a central problem for various infinite state systems like automata with pushdown, with different kinds of counters or combinations thereof. Despite its centrality and decades of research the community still lacks a lot of answers for fundamental and basic questions of that type. I briefly describe my personal viewpoint on the current state of art and emphasise interesting directions, which are worth investigating in my opinion. I also formulate several easy to formulate and understand challenges, which might be pretty hard to solve but at the same time illustrate fundamental lack of our understanding in the area.

Introduction

Since the early days of computer science the reachability problem is in its core interest. One of the first known undecidable problems was the halting problem for Turing Machines (TM), which is actually exactly the reachability problem for TM. We are given an initial configuration and final configuration and we ask whether there is a path of the TM between them. It is quite easy to come up with simpler automata models for which the reachability problem is also undecidable. The undecidability will follow from the fact that the simpler models can actually simulate TM, so are Turing powerful.

The first such a model is automaton with two pushdowns or in other words with two stacks. It has two stacks and each transition can change a state and push or pop on the top of the stacks. One can easily see that the transition of a TM can be simulated by automaton with two stacks. Let us say that the TM has one tape. One stack keeps the part of the tape of the TM to the left of the head and the other stack keeps the part of the tape to the right of the head. The top elements of both stacks are the cells of the TM, which are close to its head. To simulate a transition of a TM, say one step of the head to the left, the first stack pops the top symbol and the second stack pushes the same symbol. It is rather straightforward to see that this simulation indeed works well, which shows that automata with two stacks have undecidable reachability problem.

One can however simplify further and show that the reachability problem is undecidable already for the automaton with two counters, which can be zero-tested. Configuration of such an automaton consists of a finite state and two nonnegative integer counters. A transition can change the state and increase or decrease the counters. One can assume that increases and decreases are just by one or by some arbitrary value, it does not change the strength of the model. There are also special transitions called zero-tests. Such a transition can be fired only if a specific counter (the first or the second one) equals exactly zero. This model was shown to be undecidable by Marvin Minsky [19], so it is sometimes called a Minsky machine.

The reduction from the automaton with two stacks to the automaton with two zero-tested counters is not very complicated. A very brief sketch is the following: one stack can be simulated easily by two counters with zero-tests, one keeping value of the stack as a B-ary number (where B is the number of different stack symbols) and the other one being auxiliary. Indeed, with the help of an auxiliary counter with zero-tests one can multiply or divide the value of the first counter by B and this roughly speaking corresponds to a push or pop of a symbol from the top of the stack. Thus one can simulate automaton with two stacks by an automaton with four counters with zero-tests. Further, one can observe that the auxiliary counter can be shared, so only three counters are needed for the simulation of two stacks. Finally, one can simulate values of three counters x, y and z on two counters, one counter keeping value $2^x 3^y 5^z$ and the other one being an auxiliary counter, which helps simulating incrementing and decrementing of the three counters. The above construction can be easily made precise, and it shows that the reachability problem for automata with two zero-tested counters is indeed undecidable.

Decidable models

Automata models with undecidable reachability problem are of not much use: even the simplest fundamental problem cannot be decided for them. Therefore in order to understand the computation better, the infinite-state community searched for decidable restrictions of the above models. Of course there is plenty of ways one can restrict pushdowns or counters, but there are a few natural ones, which were considered for decades. Quite natural restrictions are in my opinion the following:

(1) disallow zero-tests and consider just nonnegative integer counters without zero-tests
(2) simplify the counters even further and allow them go to below zero
(3) consider nonnegative integer counters with just one counter being zero-tested or some other restricted version of zero-tests
(4) consider one stack with possible other counters (nonnegative integer lub just integer), but without zero-tests

Of course one can come up with other models, but it turns out that the above models were widely considered.

Below we briefly discuss all the four options and also some other interesting models. Along the way I share with you my personal feelings what seems to be interesting in my opinion. I also list several challenges, which are easy to formulate, but I think require new understanding of the models we work with. Solving them might be very hard or maybe easy, but definitely would lead to new insights in the area.

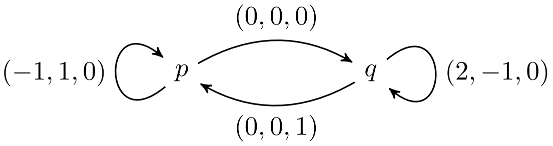
Vector addition systems

An automaton with d counters, which cannot be zero-tested on each transition just increments or decrements its counters by fixed values. It can be seen as an automaton adding vectors from $\mathbb{Z}^d$. Indeed, a configuration of such an automaton consists of a state and values of the d nonnegative integer counters, which can be seen as a vector in $\mathbb{N}^d$. A transition just adds a vector in $\mathbb{Z}^d$ to the current vector, it can be fired if the result of the addition is still a vector in $\mathbb{N}^d$. Such automata are called Vector Addition Systems with States, shortly VASS. If there is just one state they are called Vector Addition Systems, shortly VAS. It turns out that the reachability problems for VASS, for VAS and for Petri nets, a popular model of parallel computation are easily interreducible. The most robust model of out them is, in my opinion, the VASS model, so I will refer to the reachability problem in VASS. The reachability problem was shown decidable in 1981 [18], but only recently its complexity was settled to be Ackermann-complete. The upper bound was shown in 2019 [15], while the Ackermann-hardness in 2021 [6, 17]. The complexity class Ackermann is roughly speaking the class of problems, which can be solved in time around the Ackermann function. One can define easily the Ackermann function (some version of it, there are different versions, but they do not change the definition of the Ackermann complexity class as explained in [21]) using the so called hierarchy of fast growing functions F_k. We write $F_1(n) = 2n$ and $F_k(n) = \underbrace{F_{k-1} \circ \ldots \circ F_{k-1}}_{n}(1)$ for any $k \geq 2$. One can see that in particular $F_2(n) = 2^n$ and $F_3(n) = \text{Tower}(n)$. Then we define the Ackermann function $A(n) = F_n(n)$. Notice that $A(1) = 2$, $A(2) = 4$, $A(3) = 16$, while already $A(4) = \text{Tower}(\text{Tower}(\text{Tower}(\text{Tower}(1)))) = \text{Tower}(\text{Tower}(\text{Tower}(2))) = \text{Tower}(\text{Tower}(4)) = \text{Tower}(65536)$, which is an incredibly huge number. It is hard to imagine how fast the Ackermann function grows. Based on the F_k functions one can define the complexity classes $\mathcal{F}_k$, which contain roughly speaking problems solvable in time around F_k of the input size. Details can be found here [21].

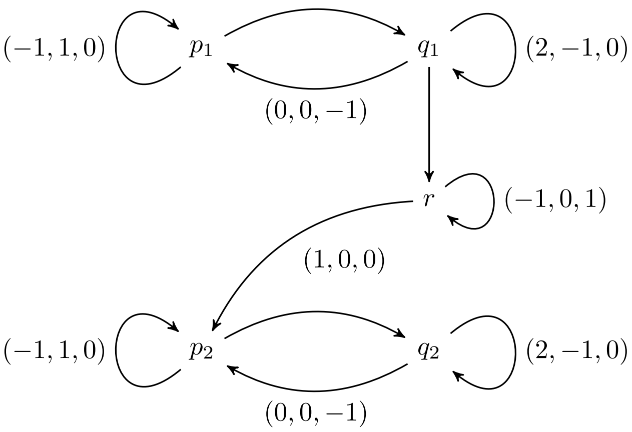
Despite the fact that the complexity of the reachability problem for VASS have been settled we still lack a lot of knowledge about the reachability properties in VASS. This can be easily seen if we look into VASS with d counters, which we also call d-dimensional VASS or shortly d-VASS. In general the complexity of the reachability problem for d-VASS is known to be in $\mathcal{F}_d$ [10]. The best currently known lower bound is $\mathcal{F}_d$-hardness in dimension $2d + 3$ [4]. The gap does not look big till we look at d-VASS for some small fixed d. Notice however, that the mentioned bounds give us Tower upper complexity bound for 3-VASS, but Tower-hardness only for 9-VASS, which is quite a big gap in understanding.

Let us summarise what is known about the reachability problem for d-VASS for small dimensions d. For small complexities it matters whether the numbers on transitions are represented in unary or in binary. Clearly binary representation is more concise, so possibly complexity of any problem for VASS with numbers represented in binary (shortly binary VASS) can be higher than the complexity for VASS with numbers represented in unary (shortly unary VASS). For dimension one it is rather easy to see that if there is a path in unary 1-VASS then there is also a path of at most cubic length, which easily implies NL algorithm and therefore also NL-completeness of the reachability problem. The complexity for binary 1-VASS is known to be NP-complete since 2009 [13]. A few years later came a big progress for 2-VASS. For binary 2-VASS it was shown in [2] that if there is a path between two configurations then there is also a path of at most exponential length. This easily implies existence of a PSpace algorithm, which just guesses this path step by step. Altogether the problem was shown in [2] to be PSpace-complete. One year later authors of [9] have proved that in unary 2-VASS if there is a path between two configurations then there is also a path of at most polynomial length, which implies algorithm in NL and thus NL-completeness.

It is a major challenge to go beyond dimension two. One particular reason for that is that reachability sets (and actually relations as well) are semilinear in 2-VASS, while it is not true for 3-VASS [14]. Recall that a set is linear of it is of a form $b + P^*$ for some vector $b \in \mathbb{N}^d$ and finite set $P \subseteq \mathbb{N}^d$ and a set is semilinear if it is a finite union of linear sets. The following example of a 3-VASS is probably the simplest way to see this and comes from the work of Hopcroft and Pansiot [14], thus we call it the HP-example. One can check that the set of configurations reachable from $p(1, 0, 0)$ in state p is of a form $\{p(x, y, z) \mid 1 \leq x + y \leq 2^z\}$, which is clearly not semilinear. Another challenge is that already in dimension three one can get VASS with finite reachability set, but of size k-fold exponential, so it is hard to obtain complexity bound below the size of the finite reachability set, so below Tower. To see that



such 3-VASS exist consider an example of a composition of a bit modified (transition from q to p now subtracts one, not adds one) two copies of the HP-example composed with itself. One can quite easily check that the reachability set from $p_1(1, 0, n)$ is doubly-exponential in n.



So see this notice that in particular any configuration of the form $p_2(x, y, 0)$ for $x + y = 2^{2^n}$ can be reached from $p_1(1, 0, n)$. Compositing k copies of the HP-example in the same fashion would result in getting $(k − 1)$-fold exponential size finite reachability set.

Unfortunately, not much upper or lower bounds are known for 3-VASS and for other d-VASS for low fixed $d \in \mathbb{N}$. I believe it is an important direction and I keep working in this area since a few years. We have some partial results with co-authors. In [5] we have shown that there exist a unary 3-VASS with two configurations such that the shortest path between them is of an exponential length. This distinguishes the situation from the unary 2-VASS, where the shortest path is always polynomial. Therefore the same way of proving membership in NL cannot work for unary 3-VASS. In fact recently together with Dmitry Chistikov, Filip Mazowiecki, Łukasz Orlikowski, Henry Sinclair-Banks and Karol Węgrzycki we have shown that the reachability problem for unary 3-VASS is NP-hard, it is a part of a paper just accepted to FOCS 2024.

On the other hand together with Ismaël Jecker, Sławomir Lasota and Łukasz Orlikowski we seem to have shown that in binary 3-VASS if there is a path between two configurations then there is one of at most doubly-exponential length. This would imply an ExpSpace membership for the reachability problem. However, the result is not yet written down, so there might be some mistake there. But, even if this result is true it might not be optimal. In every example of a 3-VASS we know, the shortest paths between two configurations are at most exponential, which would suggest PSpace algorithm. The lowest dimension in which we know that sometimes the shortest paths are of doubly-exponential length is four, in [5] we have shown an example of a 4-VASS with shortest path between some two configurations being doubly-exponential. Thus, I think that the following challenge is a very interesting one and could lead to getting a tight complexity bound for 3-VASS, which are still quite a simple and natural computation model.

▶ **Challenge 1.** *Find an example of a binary* 3*-VASS with doubly-exponential shortest path between two configurations.*

Another interesting challenge is to decide for which dimensions d reachability in d-VASS is elementary, so below Tower. The paper [4] gives us $\mathcal{F}_d$-hardness in dimension $2d + 3$, so Tower-hardness for 9-VASS. However, we have managed to show Tower-hardness already for 8-VASS in [7]. The question remains for d-VASS when $d \in \{4, 5, 6, 7\}$ (and also for $d = 3$ if our supposed ExpSpace membership for 3-VASS would turn wrong). Of course to get Tower-hardness for d-VASS we need to know examples of d-VASS with at least Tower-long shortest paths between two configurations. However, we even know no example below dimension eight with such a property. This leads to another interesting challenge.

▶ **Challenge 2.** *Find an example of a binary d-VASS with at least tower-long shortest path between two configurations for $d \leq 7$.*

Of course it might be that solving Challenges 1 and 2 is impossible, because there exist no such examples. This would however be probably hard to show, as designing faster algorithms is usually rather sophisticated. I list here challenges, which possibly might be resolved positively during one afternoon. That is why I have formulated the challenges in such a form.

Another interesting open problem for reachability in VASS is the question for fixed VASS. There is a conjecture that for every VASS V there is a constant C_V such that if there is a path from a configuration s to a configuration t then there is also one of length at most C_V times the sum of sizes of s and t [8]. Such a conjecture, if true, would imply a PSpace algorithm for the reachability problem for any fixed binary VASS V. The PSpace-hardness was already shown in [8]. I personally believe in this conjecture, but I might be wrong, so there is another hard challenge.

▶ **Challenge 3.** *Find an example of a binary VASS for which shortest paths in between its configurations are longer than linear.*

Integer VASS

Another way of relaxing infinite-state systems is to consider automata with integer counters, which cannot be zero-tested and moreover can drop below zero. Such systems are called $\mathbb{Z}$-VASS or integer VASS. Even though it is not entirely obvious, it is easy to reduce the reachability for $\mathbb{Z}$-VASS to the reachability for VASS. Every $\mathbb{Z}$-VASS counter can be simulated as a difference of two VASS counters. However, the reachability of $\mathbb{Z}$-VASS is much easier than the reachability for VASS, it is known to be NP-complete [12].

The reachability problem for automata with only $\mathbb{Z}$-counters have been well understood, as seen above. However, the power of adding $\mathbb{Z}$-counters to other systems is definitely not so fully understood. Actually, it is not clear whether an automaton with d VASS-counters and k integer-counters is closer in behaviour to a d-VASS or to $(d + k)$-VASS. One particularly interesting model is a 2-VASS with many $\mathbb{Z}$-counters. There are no known examples of these systems for which the shortest path is longer than exponential, so it is very possible that the reachability problem is in PSpace, thus PSpace-complete. On the other hand, to my best knowledge, there is no known upper complexity bound below Ackermann. Thus it is a natural challenge to investigate these systems.

▶ **Challenge 4.** *Find an example of a binary* 2*-VASS with additional $\mathbb{Z}$-counters with shortest path being longer than exponential.*

My personal conjecture is that there exists no system as mentioned above in Challenge 4, but I might be very wrong, it is always hard to imagine sophisticated examples. Notice that in the HP-example the third counter can be treated as a $\mathbb{Z}$-counter (as it never drops below zero), so reachability sets in 2-VASS with $\mathbb{Z}$-counters are not necessarily semilinear.

VASS with zero-tests

As mentioned at the beginning of this text, automata with two zero-tested counters already have undecidable reachability problem. But maybe we can allow for one zero-tested counter? If we have just an automaton with one zero-tested unary-encoded counter it is easy to show that if there is a path between two configurations then there is also a path of at most polynomial length. This means that the reachability problem is NL-complete for such automata. But, if we add more VASS-counters on top of the zero-tested counter then the situation is more sophisticated. However, in 2008 Klaus Reinhard have shown that the reachability problem for VASS with one zero-tested counter is decidable [20]. Actually, he has shown even more: decidability for VASS with hierarchical zero-tests. A d-VASS with hierarchical zero-tests (hierarchical VASS) have the following zero-tests: for each $k \leq d$ one can test whether all the first k counters are equal to zero at the same time. Interestingly, this model also has decidable reachability problem, even though it is so closed to the automaton with two zero-tested counters. Unfortunately, the proof of Reinhard was very complicated and hard to understand, so there were other tries to explain the nature of VASS with zero-tests. In 2011 Bonnet reproved the result using other techniques [3], but his work considered only VASS with one zero-test, not a hierarchical VASS. Very recently Guttenberg came up with another proof of decidability of the reachability problem for hierarchical VASS [11], this time hopefully more understandable.

Even though the decidability status of the reachability problem for hierarchical VASS is resolved its complexity is unclear. It cannot be better than Ackermann, as already the reachability problem for VASS is Ackermann-hard. However, it is interesting whether the problem is in Ackermann or maybe much higher. In particular, it would be interesting to know whether hierarchical zero-tests add anything to the power of VASS, namely whether hierarchical d-VASS are harder at some dimensions than the classical d-VASS. Interestingly, it was shown that in dimension two both models are very similar and the reachability problem for hierarchical 2-VASS is in PSpace [16]. Could this be true also in higher dimensions? It is an interesting challenge to find this out.

Pushdown VASS

Similarly as for zero-tests one can consider automata with just one stack. Reachability in a pushdown automaton is easy and can be performed in polynomial time, for example by the famous CYK algorithm. However, things become much harder if we add additional VASS-counters to this stack. An automaton with a stack and d VASS-counters is called a d-dimensional Pushdown VASS (d-PVASS). Similarly as pushdown automata are equivalent to context-free grammars the PVASS are equivalent to Grammar VAS (GVAS), which are just context-free grammars with terminals being vectors in $\mathbb{Z}^d$. A derivation of a GVAS is correct if starting in the initial vector in $\mathbb{N}^d$ and reading leaves in the prefix order one never drops below zero and finally reaches the target vector in $\mathbb{N}^d$.

Little is known about the reachability problem for PVASS. It is conjectured to be decidable, but there is no known algorithm even for 1-dimensional PVASS. An interesting result was shown by Atig and Ganty [1]. They have proved that for so called finite-index

GVAS the reachability problem is decidable. Concretely speaking they have reduced the reachability problem for finite-index d-GVAS with k nonterminals to the reachability problem for hierarchical dk-VASS, which is known to be decidable [20, 11].

Recently with Clotilde Bizière we have considered the reachability problem for 1-GVAS and we have an impression that we can show decidability by a reduction to the finite-index case. However, this result is also not confirmed and may contain a flaw. Even if it is correct the complexity of the problem for 1-GVAS remains open. We do not know any example of a 1-GVAS in which a path of length longer than exponential is needed, which would suggest low complexity. On the other hand even very simple 1-GVAS may have finite, but huge reachability sets. For example this 1-GVAS with just three nonterminals have a reachability set of Tower-size

- $X \longrightarrow 0$, $X \longrightarrow -1X2$; and
- $Y \longrightarrow 1$, $Y \longrightarrow -1YX$; and
- $Z \longrightarrow 1$; $Z \longrightarrow -1ZY$.

Indeed, with the starting nonterminal Z and starting value n we might reach up to Tower(n) values. To see this observe that nonterminal X with starting value n might output value up to $2n$. It turn the nonterminal Y with starting value n may produce up to n variables X and output value up to 2^n. Therefore nonterminal Z with starting value n may produce up to n variables Y and output value up to Tower(n). Similar grammars with d nonterminals may have finite reachability sets of size up to $F_d(n)$. So it looks interesting that we do not have any example of 1-GVAS with longer than exponential shortest path.

▶ **Challenge 5.** *Find an example of a 1-GVAS such that shortest derivations are longer than exponential.*

Other models

There are also other very interesting and natural models of infinite-state systems. One popular such system is Branching VAS (BVAS), for which the reachability problem is open in general, but was recently shown decidable in 2-dimensional BVAS. The results are not yet published, but they were referred here by Clotilde Bizière: `https://youtu.be/aKIxlgQAa2w?si=V7yWXsj8_JaoiBHv`.

Another interesting model, which illustrated how much we are in trouble with automata, which have both additive and multiplicative (or recursive) behaviour is a model about which I have heard from Anthony Lin. Consider a model, let us call it the Lin automaton, which is an automaton with one counter. A transition can increase or decrease this counter, as normally, but it can also multiply it or divide by two. Then it is unclear whether the reachability problem for such a simple automaton is decidable. Together with Moses Ganardi, Łukasz Orlikowski and Georg Zetzsche we think about this problem and we have some partial results. However, we still do not have any example of a Lin automaton, which has a path longer than exponential. Thus the following might be an interesting challenge.

▶ **Challenge 6.** *Find an example of a Lin-automaton such that shortest derivations are longer than exponential.*

To summarise, it seems that there are still many fundamental and natural challenges in the field of infinite-state systems, some of which are asking about deep properties of the computation. It might be that we are still at the beginning of our way to understand the computation even from this very high level perspective.

On Low Complexity Colorings of Grids

Jarkko Kari
Department of Mathematics and Statistics, University of Turku, Finland

Abstract

A d-dimensional configuration is a coloring of the infinite grid $\mathbb{Z}^d$ using a finite number of colors. For a finite subset $D \subseteq \mathbb{Z}^d$, the D-patterns of a configuration are the patterns of shape D that appear in the configuration. A configuration is said to be admitted by these patterns. The number of distinct D-patterns in a configuration is a natural measure of its complexity. We focus on low complexity configurations, where the number of distinct D-patterns is at most $|D|$, the size of the shape. This framework includes the notorious open Nivat's conjecture and the recently solved Periodic Tiling problem. We use algebraic tools to study the periodicity of low complexity configurations. In the two-dimensional case, if $D \subseteq \mathbb{Z}^2$ is a rectangle or any convex shape, we establish an algorithm to determine if a given collection of $|D|$ patterns admits any configuration. This is based on the fact that if the given patterns admit a configuration, then they admit a periodic configuration. We also demonstrate that a two-dimensional low complexity configuration must be periodic if it originates from the well-known Ledrappier subshift or from several other algebraically defined subshifts.

1 Overview

In the *domino problem*, one is given a finite collection of allowed $m \times n$ arrays of colors, or patterns, and must determine whether it is possible to color the infinite grid $\mathbb{Z}^2$ such that only the allowed $m \times n$ patterns appear in the coloring. A classical result by Robert Berger states that the domino problem is undecidable: no algorithm can provide the correct answer to every instance of the problem. An underlying structural property is aperiodicity, where some choices of allowed patterns force the valid colorings to be non-periodic [1].

However, the situation is different in the low complexity setting where the number of allowed patterns is at most mn, the size of the array. In this case, there are no aperiodic systems, meaning that if a valid coloring of $\mathbb{Z}^2$ exists, then a periodic coloring also exists [5]. This fact leads to an algorithm to solve the domino problem in the low complexity setting. Similar results hold if, instead of $m \times n$ rectangles, one considers patterns of any convex shape $D \subseteq \mathbb{Z}^2$.

The low complexity setting also encompasses two interesting problems: Nivat's conjecture and the Periodic Tiling problem. These specific questions are of independent interest and have driven our research on this topic in recent years. Nivat's conjecture remains open, while the Periodic Tiling problem was recently solved positively by Siddhartha Bhattacharya [2] in the two-dimensional case and negatively in sufficiently high-dimensional grids by Rachel Greenfeld and Terrence Tao [3].

To address the low complexity setting, we initiated an algebraic approach in [6]. In this approach, we represent colors as integers and colorings of $\mathbb{Z}^d$ as formal Laurent power series with d variables. If the coloring has low complexity with respect to some finite shape $D \subseteq \mathbb{Z}^d$, a simple linear algebra argument shows that the corresponding power series has a non-trivial annihilator: a d-variate Laurent polynomial whose formal product with the power series vanishes. Moreover, periodicity can be simply formulated in terms of having a difference binomial annihilator. By studying the structure of the multivariate polynomial ideal of annihilators, we prove that a two-dimensional uniformly recurrent configuration with low complexity with respect to a convex shape must be periodic [5], implying the decidability of the domino problem in such a low complexity setting. We also show that low complexity elements of certain algebraic subshifts are all periodic [4].

From TCS to Learning Theory

Kasper Green Larsen
Aarhus University, Denmark

Abstract

While machine learning theory and theoretical computer science are both based on a solid mathematical foundation, the two research communities have a smaller overlap than what the proximity of the fields warrant. In this invited abstract, I will argue that traditional theoretical computer scientists have much to offer the learning theory community and vice versa. I will make this argument by telling a personal story of how I broadened my research focus to encompass learning theory, and how my TCS background has been extremely useful in doing so. It is my hope that this personal account may inspire more TCS researchers to tackle the many elegant and important theoretical questions that learning theory has to offer.

1 A Personal Story

My goal with this invited abstract, is to inspire more theoretical computer science (TCS) researchers to engage in topics in machine learning theory. Being a TCS researcher myself, I hope that by telling my own personal story – of how I adopted the field of learning theory – may provide a unique and more compelling argument than if a core learning theorist was to attempt to convince you. Being a personal story, I will focus on some of the research results I obtained along the way, and not so much on the broader learning theory and TCS literature. The results I present have been chosen because they tell an interesting story and showcase how core TCS concepts have proven useful in learning theory. Along the way, I will tell some anecdotes on how these research projects started, and I will try to give you an idea of some of the thought processes I initially went through when trying to enter a new field. I have also tried to sprinkle in some advice for more junior researchers based on my own experiences. Finally, I will also formally define some of the learning theory questions I have studied, giving you an idea of what such questions may look like. I sincerely hope that you find this somewhat unusual abstract refreshing.

1.1 My TCS Background and Connections Between Fields

For those who do not know me, let me start by briefly giving you my background, while also trying to convince you that many fields of TCS are deeply connected, and that it pays off to have a broad interest in TCS.

I started my Ph.D. studies in 2008 under the supervision of Professor Lars Arge at Aarhus University, Denmark. My initial research was on data structures, in particular so-called *I/O-efficient* data structures [2, 5], that take the memory hierarchy of modern hardware into account. Ever since I started my studies, I have always been curious and eager to learn new areas by interacting with great colleagues in the TCS community. This openness to collaborations and sharing of ideas is one of the strongest and most rewarding traits of our community.

Initially, my interactions with other researchers were through fellow students at the department. I explicitly remember Allan Grønlund coming to my office with one of Mihai Pătraşcu's beautiful papers [33] on data structure lower bounds in the cell probe model [35], excitedly proclaiming that "*this is so cool, we need to do this too!*". At the time, I had never had a complexity course or seen a real lower bound proof, and I was immediately hooked. This led me on a long research journey trying to understand and develop the techniques for proving lower bounds on the efficiency (space, query time, update time) of data structures, see e.g. [23, 24, 29] for some highlights.

While cell probe lower bounds were my main focus for years, I always found research that bridges several fields the most exciting. The earliest such example in my own research started with a visit by Jeff M. Phillips in our research group. During his visit, Jeff introduced me to *discrepancy theory* while explaining some of his recent work. As discrepancy theory will be important later, let me give a rough definition of it here. At its core, discrepancy theory studies the following problem: Given a matrix $A \in \mathbb{R}^{m \times n}$, compute a *coloring* $x \in \{-1, 1\}^n$ minimizing the discrepancy $\|Ax\|_\infty$. Understanding the best achievable discrepancy for various types of matrices is an old and very well-studied topic in TCS [3, 34, 10, 7, 31]. In particular, I recall Jeff telling me about a result of Banaszczyk [6] showing that matrices with sparse columns always have low discrepancy colorings. While being intellectually intrigued by this result, I did not see any immediate applications of it in my own research. However, a couple of months later, Elad Verbin, a post doc in our group at the time, suggested to me that I should try to prove data structure lower bounds in the *group model.* Without going into details here, it turns out that Banaszczyk's discrepancy result could be used to directly translate decades of research on discrepancy lower bounds into group model data structure lower bounds [25]. The connection even improved some of the discrepancy upper bounds using data structure upper bounds as well.

This theme of connecting areas has proven very useful over the years. It for instance got me started on *streaming algorithms* when Jelani Nelson and Huy L. Nguyen asked whether we could use cell probe lower bound techniques to prove *time* lower bounds for streaming algorithms [27]. In later work with Jelani [26], we similarly proved optimality of the Johnson-Lindenstrauss (JL) lemma [21] in *dimensionality reduction* using an encoding-based argument. Such arguments were typically used in cell probe data structure lower bounds. As it will be important later, let us recall that the JL lemma says that any set of n points in $\mathbb{R}^d$ can be embedded into $O(\varepsilon^{-2} \log n)$ dimensions while preserving all pairwise distances to within a factor $1 \pm \varepsilon$.

Another interesting example was initiated during a visit at MIT in 2017 where Vinod Vaikuntanathan was telling me how "*data structures and crypto are a match made in heaven*". This claim got me curious, and after returning home, I read a bit on data structure in cryptography and stumbled on Oblivious RAMs (ORAMs) [17]. An ORAM is basically a primitive for obfuscating the memory access pattern of an algorithm, such that the memory accesses reveal nothing about the data stored. Checking the references of the papers I was reading, it turned out that a crypto Professor sitting just down stairs, Jesper Buus Nielsen, had made multiple contributions to ORAMs. After some brief initial discussions, we quickly realized that cell probe lower bound techniques could be tweaked to prove strong lower bounds for ORAMs [28]. This connection started a whole line of research into lower bounds for ORAMs and related primitives in crypto.

Finally, let me mention one last example outside learning theory. Back in 2017, I was attending a communication complexity workshop in Banff, where Mark Braverman was giving a talk about some work of his [11] on a conjecture in information theory/network coding [30]. The conjecture relates to communication networks, where a network is modeled by a graph with capacities on the edges, designating how many bits may be sent across. The conjecture then says that for undirected graphs (messages may be sent in both directions), if we are given k source-sink pairs that each need to send an r bit message from source to sink, then the largest number of bits r we can handle without violating capacity constraints, is equal to the multi-commodity flow rate. Intuitively, this means that the best you can do is to simply forward your messages as indivisible bits. Mark's talk was excellent, but at the time, I had no immediate applications of his result. However, while spending a semester at the Simons Institute in 2018, a coincidental conversation with MohammadTaghi Hajiaghayi led us [15] to proving conditional lower bounds for I/O-efficient algorithms using the information theory conjecture that Mark presented. Needless to say, it was quite satisfactory to come full circle and address the topic that started my Ph.D. studies. In addition to the lower bounds for I/O-efficient algorithms, the conjecture also gave a clean conditional $\Omega(n \log n)$ lower bound for constant degree boolean circuits for multiplication [1]. I find it quite fascinating how two such seemingly different problems of multiplication and communication in graphs may prove to be so intimately connected.

If there is one message to take away from my own experiences, in particular for junior researchers, it must be that many things are deeply connected and you never know when results in one branch of TCS may prove useful in another. That is one of its beauties. I would thus strongly recommend that you attend talks, seminars, and generally engage in discussions with the many brilliant TCS researchers, also in fields outside your own immediate interest. Build your expertise in one area, but always be curious and look for connections and inspiration from others.

1.2 Entering Learning Theory

Now let me get to the promised topic of entering learning theory from a TCS background, and how this background proved extremely useful. For me, this journey started around 2019. As you all know, machine learning was the big hype at the time, and probably still is. Like many others, I initially found deep neural networks and what they could do quite fascinating. This led me to consider whether I should get into machine learning and work on this extremely hot topic. However, after getting a slightly better understanding of the field, I quickly found that training a deep neural net and running some experiments on a benchmark data set, to be much more engineering and craftsmanship than deep stimulating thoughts. And with all the obligations that come with a faculty position, I just did not have the time to learn the practical skills that it takes to make efficient and competitive implementations. And probably was not that interested in it after all. I almost abandoned machine learning, had it not been for a student of mine, Alexander Mathiasen. Alexander was very independent and eager to get into machine learning. He had realized that I was more interested in theory questions and had on his own discovered the great source of open problems in learning theory that are published with the COLT proceedings. The open problem Alexander had found was related to a technique called *boosting*. Let me start by introducing the general idea in boosting and the setup for binary classification in supervised learning.

Supervised Learning and Boosting

In supervised learning, a binary classification problem is specified by an input domain $\mathcal{X}$, an unknown target function $f : \mathcal{X} \to \{-1, 1\}$ and an unknown data distribution $\mathcal{D}$ over $\mathcal{X}$. A learning algorithm receives as input a training data set of n i.i.d. samples $(x_i, f(x_i))$ with each $x_i \sim \mathcal{D}$. The goal of the learning algorithm is to output a classifier $h : \mathcal{X} \to \{-1, 1\}$ minimizing the probability of misprediction the label of a new sample from $\mathcal{D}$, i.e. where $\mathrm{er}_{\mathcal{D}}(h) := \Pr_{x \sim \mathcal{D}}[h(x) \neq f(x)]$ is as small as possible. To have an example in mind, think of $\mathcal{X}$ as the set of all images of a particular size and f as the hard-to-specify function that maps every image of a mammal to -1 and every other image to 1. The learning problem is thus to train a classifier that can detect whether an image contains a mammal or not.

Boosting is then a powerful and elegant idea that allows one to combine multiple inaccurate classifiers into a highly accurate *voting classifier*. Boosting algorithms such as AdaBoost [16] work by iteratively running a base learning algorithm on reweighed versions of the training data to produce a sequence of classifiers $h_1, \dots, h_t$. After obtaining h_i, the weighting of the training data is updated to put larger weights on samples misclassified by h_i, and smaller weights on samples classified correctly. This effectively forces the next training iteration to focus on points with which the previous classifiers struggle. After sufficiently many rounds, the classifiers $h_1, \dots, h_t$ are finally combined by taking a (weighted) majority vote among their predictions. This idea also goes under the name of *multiplicative weight updates* and has many applications in TCS.

Boosting works exceptionally well in practice and much theoretical work has gone into explaining its huge success. One important line of work in this direction is based on the notion of *margins* [8]. A voting classifier g may be written as $g(x) = \mathrm{sign}(\sum_{i=1}^{t} \alpha_i h_(x))$ with $\alpha_i \in \mathbb{R}$. If we normalize the weights so that $\sum_i |\alpha_i| = 1$, then $\sum_{i=1}^{t} \alpha_i h_i(x) \in [-1, 1]$. The margin of g on a sample $(x, y) \in \mathcal{X} \times \{-1, 1\}$ is then defined as $y \sum_{i=1}^{t} \alpha_i h_i(x)$. The margin is thus a number in $[-1, 1]$ and can be thought of as a confidence in the prediction. If the margin is 1, then all classifiers combined by g agree and are correct. If the margin is 0, then we have a (weighted) 50-50 split between the two possible predictions $-1/1$, and so on. It has then been proved that voting classifiers g with large margins on all training samples (x_i, y_i) have a small $\mathrm{er}_{\mathcal{D}}(g)$ [8].

Boosting and Discrepancy Theory

Now let me return to the open problem Alexander approached me with. Since voting classifiers with large margins have a small $\mathrm{er}_{\mathcal{D}}(g)$, it seems natural to develop boosting algorithms that obtain large margins by combining few base classifiers, i.e. with a small t. This leads to faster predictions and possibly also faster training. The question now is as follows: If the best possible margin on all training samples is $\gamma^\star$ when one is allowed to combine arbitrarily many base classifiers h_i, then how large margins can we obtain by combining t base classifiers? The best known algorithm obtained margins of $\gamma^\star - O(\sqrt{\log(n)/t})$ with n training samples, and the best known lower bound showed that this is tight whenever $t \leq n^{1/2}$. The conjecture stated that this remains tight for $t \leq n \log n$.

In my first learning theory paper [32], we observed an interesting connection between this question and discrepancy theory. In more detail, we considered the matrix A obtained by forming a row for each training sample (x_i, y_i) and a column for each h_i in a voting classifier $g(x) = \mathrm{sign}(\sum_{j=1}^{t} \alpha_j h_j(x))$. The entry corresponding to (x_i, y_i) and h_j stores the value $y_i \alpha_j h_j(x)$. Notice that the sum of the entries in the i'th row is precisely the margin of g on (x_i, y_i). Next, if we can find a coloring $x \in \{-1, 1\}^t$ such that $\|Ax\|_\infty \approx 0$, then this means that for every single row of A, the sum over the columns j where $x_j = 1$ is almost exactly the same as the sum over columns where $x_j = -1$. Thus if we replace g by a new voting classifier where we set all α_j to 0 when x_j equals the majority of $-1/1$'s in x, and to 2 when x_j is the minority, then the new g' has almost exactly the same margins as before but uses only half as many base classifiers. Recursively finding a low discrepancy coloring x using the celebrated *Spencer's six standard deviations suffice* result [34], we were able to refute the conjecture on the tradeoff between t and the achievable margin while establishing yet an interesting connection between discrepancy theory and other areas.

Support Vector Machines, Sketching and Teaching

Around the same time as our first learning theory results, I had voluntarily started teaching the Machine Learning undergraduate course at Aarhus University. Never having followed such a course myself, this was a great way of forcing myself to learn the basics. But beyond learning the basics, teaching also led to new research questions. After having completed the first project on boosting, we naturally started reading up on the references proving that large margins lead to small $\mathrm{er}_{\mathcal{D}}(g)$. Such results are referred to as *generalization bounds* and are a cornerstone of learning theory. Studying the classic proofs of generalization for large margin voting classifiers [8], there seemed to be an underlying idea of *sketching* or *compressing* the voting classifier g while exploiting that it has large margins. Intuitively, if there is a small-bit representation of g, then there are only few choices for g. A union bound over all these choices shows that it is unlikely that there is even a single g that performs great on the training data (has large margins) and poor on new data (has large $\mathrm{er}_{\mathcal{D}}(g)$).

Around the same time, I had just taught Support Vector Machines (SVMs) [14]. SVMs are another type of learning algorithm where the input domain $\mathcal{X}$ is $\mathbb{R}^d$. In the simplest setup, when given a training set of n samples $(x_i, y_i) \in \mathbb{R}^d \times \{-1, 1\}$ with $\|x_i\| \leq 1$ for all i, SVM searches for the separating hyperplane with the largest *margin* to the data. In the context of SVMs, if we assume for simplicity that a hyperplane passes through the origin and has unit length normal vector $w \in \mathbb{R}^d$, then we predict the label of a new point $x \in \mathbb{R}^d$ by returning $\mathrm{sign}(w^T x)$. The margin of the hyperplane on a labeled point (x, y) is then defined as $yx^T w$. The margin is positive if the hyperplane correctly predicts the label of (x, y) and the absolute value of the margin measures how far the point is from the hyperplane itself.

Similarly to the case for boosting, there were known generalization bounds [9] stating that if a hyperplane h has large margins, then $\mathrm{er}_{\mathcal{D}}(h)$ is small. However, these bounds were proved in a completely different way than the boosting bounds and seemed to be sub-optimal. In our work [18], we improved these generalization bounds by observing a connection to the Johnson-Lindenstrauss (JL) lemma [21] that I previously worked on [26]. Shortly after the lower bound for JL by Jelani and I, Noga Alon and Bo'az Klartag [4] presented an alternative proof that at its core gives a randomized sketch for representing a set of n unit length vectors in $\mathbb{R}^d$ using $O(\varepsilon^{-2} \log n)$ bits for each vector, while preserving their pairwise inner products up to additive ε. Our idea was then to apply this sketch to w and the training data. Since $w^T x$ changes by only additive ε, the sketched hyperplane $\tilde{w}$ remains correct (i.e. $\mathrm{sign}(\tilde{w}^T x) = \mathrm{sign}(w^T x) = y$) if the margin was larger than ε before sketching. In this way, we get a compression whose size depends on the margin. Combining this with the union bound idea mentioned earlier led to improved generalization bounds for SVMs.

Replicable Learning and Sketching

Let me give another example where the JL lemma proved useful in learning theory. In a very exciting line of work, starting with [20], core TCS researchers introduced the notion of *replicable learning* as an attempt at addressing issues with reproducibility of results in machine learning. Here the basic setup is that you want to develop learning algorithms $\mathcal{A}$, such that if $\mathcal{A}$ is run on two sets S and S' of n i.i.d. samples from the same distribution $\mathcal{D}$, then we should get the same output with high probability. The intuition is thus, if you rerun someones replicable algorithm on your own data set, you will get the same results as they did on their data set, provided that the data set is sampled from the same distribution. To help you in this seemingly difficult task, the two executions of $\mathcal{A}$ share a random seed. This may be justified in practice by publishing the seed of a pseudorandom generator along with your machine learning paper and experimental results. There is naturally a ton of problems to revisit in replicable learning and some strong connections with *differential privacy* have already been established [12].

In a recent result [22], we considered SVMs in the replicable setting. Here we are promised that there exists a hyperplane with all margins at least γ on the support of the data distribution $\mathcal{D}$, and must replicably compute a hyperplane h with small $\mathrm{er}_{\mathcal{D}}(h)$. The key idea in our work is quite simple: partition the training data into t chunks and run SVM on each to obtain hyperplanes with normal vectors $w_1, \dots, w_t$. Average these normal vectors $w = t^{-1} \sum_i w_i$ and apply the sketching technique by Alon and Klartag [4] to w. The first main observation is that computing the average w reduces variance compared to each w_i. Thus for two independent but identically distributed training data sets S and S', the resulting w and w' will be close. The key property of the sketching technique of Alon and Klartag is that such close vectors are very likely to be "rounded" to the same hyperplane/sketch if we share a carefully chosen random seed.

Multi-Distribution Learning, Discrepancy Theory and NP-Hardness

Let me conclude with one last example of TCS techniques playing a key role in learning theory results. A recent line of work in learning theory has studied learning in a setup with multiple data distributions. Formally, we have k distributions $\mathcal{D}_1, \dots, \mathcal{D}_k$ over $\mathcal{X} \times \{-1, 1\}$ and the goal is to train a classifier that performs well on all k distributions simultaneously. For this purpose, we are given a hypothesis set $\mathcal{H}$ containing hypotheses $h : \mathcal{X} \to \{-1, 1\}$. As an example, think of $\mathcal{H}$ as all hyperplanes in $\mathbb{R}^d$. If we let $\tau = \min_{h \in \mathcal{H}} \max_i \mathrm{er}_{\mathcal{D}_i}(h)$ denote the best achievable max-error of any $h \in \mathcal{H}$, then the goal is produce a classifier $f : \mathcal{X} \to \{-1, 1\}$ with $\max_i \mathrm{er}_{\mathcal{D}_i}(f) \leq \tau + \varepsilon$ using as few training samples as possible.

It is known that for a single distribution $\mathcal{D}$, this task requires $\Theta(d/\varepsilon^2)$ samples and it is straight forward to generalize the algorithm to $O(dk/\varepsilon^2)$ samples for k distributions. Very surprisingly, it turns out that this can be improved to essentially $O((d+k)/\varepsilon^2)$ samples using boosting ideas [19]. However, the upper bounds achieving this number of samples are cheating a little. Concretely, they do not output a single hypothesis f with $\max_i \mathrm{er}_{\mathcal{D}_i}(f) \leq \tau + \varepsilon$. Instead, they output a distribution $\mathcal{D}_f$ over hypotheses such that $\max_i \mathbb{E}_{f \sim \mathcal{D}_f}[\mathrm{er}_{\mathcal{D}_i}(f)] \leq \tau + \varepsilon$. Attempting to *derandomize* this does not seem to work as we only have Markov's inequality to argue that with constant probability, a random $f \sim \mathcal{D}_f$ has $\max_i \mathrm{er}_{\mathcal{D}_i}(f) = O(k(\tau + \varepsilon))$. In a current manuscript, we show that there is a good reason why this is the case. Concretely, we prove via a reduction from discrepancy minimization that it is NP-hard to compute an $f : \mathcal{X} \to \{-1, 1\}$ with $\max_i \mathrm{er}_{\mathcal{D}_i}(f) \leq \tau + \varepsilon$. Here we use a result of Charikar et al. [13] stating that it is NP-hard to distinguish whether, for a given a 0/1 matrix A, there exists an $x \in \{-1,1\}^n$ with $Ax = 0$, or whether all $x \in \{-1,1\}^n$ have $\|Ax\|_\infty = \Omega(\sqrt{n})$. In our reduction, we think of the columns as the input domain $\mathcal{X}$ and we form a distribution for each row of A. The key idea is to show that if a learning algorithm computes an $f : \mathcal{X} \to \{-1,1\}$ with $\max_i \mathrm{er}_{\mathcal{D}_i}(f) \le \tau + \varepsilon$, then the predictions made by f on the columns must give a low discrepancy coloring that can distinguish the two cases.

While showing NP-hardness is by now completely standard in TCS, let me add that my two coauthors are both from Statistics. They had heard NP-hardness mentioned before, but never used it, and found quite some joy in getting to apply it on a relevant problem. I guess the experience shows that what may be common tools in one discipline may be highly novel in another.

1.3 Conclusion and Thoughts

To summarize my research journey into learning theory, I hope that I convinced you that many techniques and tricks from TCS are extremely useful. Not only do they help in addressing learning theory questions, but they also bring an interesting new direction to the field, such as e.g. arguing computational hardness of training a classifier. Furthermore, this transfer of techniques is not isolated to learning theory, but has been a guiding principle in all my research since the early days of my Ph.D. studies. Keep your eyes open for surprising connections between seemingly disjoint topics - they are often hiding just below the surface.

To me, the questions studied in learning theory are as clean, elegant, beautiful and well-defined as any TCS topic, and are very well fit for anyone with a TCS background. What has worked well for me, has been to start in some corner (coincidentally boosting for me) and get to know the literature and related questions. Then as you have a better understanding and overview, you can start approaching neighboring questions and growing your focus. I suppose this is not much different from starting your Ph.D. studies by working on a narrow topic and broadening out as you mature. Finally, do not underestimate the value of talking to peers and attending talks for inspiration. As a newcomer, it is sometimes hard to ask the right question, and calibrating with an expert is very useful. Also, the COLT open problems have been a good source of inspiration as you at least know that some experts in the field find the question interesting.

I strongly hope that this abstract may inspire some of you to work on learning theory, or give you the courage to enter a new field that you find intriguing, knowing that your TCS skills are useful in many surprising places.

Fine-Grained Complexity of Program Analysis

Rupak Majumdar
Max Planck Institute for Software Systems (MPI-SWS), Kaiserslautern, Germany

Abstract

There is a well-known "cubic bottleneck" in program analysis and language theory: many program analysis problems can be solved in time cubic in the size of the input but, despite years of effort, there are no known sub-cubic algorithms. For example, context-free reachability (whether there is a path in a labeled graph that is labeled with a word from a context-free language), the emptiness problem for pushdown automata, and the recognition problem for two-way nondeterministic pushdown automata all belong to the cubic class. We survey the status of these problems through the lens of fine-grained complexity.

We study the related *certification* task: given an instance of any of these problems, are there small and efficiently checkable certificates for the existence and for the non-existence of a path? We show that, in both scenarios, there exist succinct certificates ($O(n^2)$ in the size of the problem) and these certificates can be checked in subcubic (matrix multiplication) time. Thus, all these problems lie in nondeterministic and co-nondeterministic *subcubic* time.

We also study a hierarchy of program analysis problems above the cubic bottleneck. A representative problem here is the recognition problem for two-way nondeterministic pushdown automata with k heads. We show fine-grained hardness results for this hierarchy.

We also discuss purely language-theoretic consequences of these results: for example, we obtain hardest languages accepted by two-way nondeterministic multihead pushdown automata, as well as separations between language classes.

(Joint work with A. R. Balasubramanian, Dmitry Chistikov, and Philipp Schepper.)

Monotonicity of the Cops and Robber Game for Bounded Depth Treewidth

Isolde Adler
University of Bamberg, Germany

Eva Fluck
RWTH Aachen University, Germany

Abstract

We study a variation of the cops and robber game characterising treewidth, where in each round at most one cop may be placed and in each play at most q rounds are played, where q is a parameter of the game. We prove that if k cops have a winning strategy in this game, then k cops have a monotone winning strategy. As a corollary we obtain a new characterisation of bounded depth treewidth, and we give a positive answer to an open question by Fluck, Seppelt and Spitzer (2024), thus showing that graph classes of bounded depth treewidth are homomorphism distinguishing closed.

Our proof of monotonicity substantially reorganises a winning strategy by first transforming it into a pre-tree decomposition, which is inspired by decompositions of matroids, and then applying an intricate breadth-first "cleaning up" procedure along the pre-tree decomposition (which may temporarily lose the property of representing a strategy), in order to achieve monotonicity while controlling the number of rounds simultaneously across all branches of the decomposition via a vertex exchange argument. We believe this can be useful in future research.

1 Introduction

Search games were introduced by Parsons and Petrov in [36, 37, 38] and since then gained much interest in many (applied and theoretical) areas of computer science and in discrete mathematics [6, 10, 9, 28, 17, 35, 25, 15, 24, 21]. In search games on graphs, a fugitive and a set of searchers move on a graph, according to given rules. The searchers' goal is to capture the fugitive, and the fugitive tries to escape. Here the interest lies in minimising the resources needed to guarantee capture. Typically this means minimising the number of searchers, but we also seek to bound the number of rounds of the game, if the searchers can only move one by one. Search games have proven very useful for providing a deep understanding of structural and algorithmic properties of width parameters of graphs, such as treewidth [8, 43], pathwidth [9], cutwidth [30], directed treewidth [26], treedepth [33], and b-branched treewidth [14, 32].

The crux in relating a given variant of a search game to a width parameter often lies in the question of whether the game is *monotone*, i. e. whether the searchers always have a winning strategy in which a previously cleared area never needs to be searched again – without needing additional resources. Furthermore, monotonicity of a search game provides a polynomial space certificate for proving that determining the winner is in NP.

In their classic paper [43], Seymour and Thomas proved monotonicity of the cops and robber game characterising treewidth. They use a very elegant inductive argument via the dual concept of *brambles*. In this paper we study a variation of this game, where k cops try

to capture a robber, but they are limited to placing at most one cop per round and playing at most q rounds, for a fixed number $q \in \mathbb{N}$. It is an open question from [13], whether this game is monotone. We give a positive answer to this question.

The notion of *treedepth* was first introduced by Nešetřil and Ossona de Mendes [33]. They exhibit a number of equivalent parameters, and a characterisation by a monotone game is implicitely given. This was subsequently made more explicit in [19]. In [18], a characterisation by a different game called *lifo game* is given for which monotonicity is proven. The game we study can be seen as generalising the monotone game implicit in [33]. However, it also captures treewidth and it is not monotone by definition.

Recently, width parameters received a renewed interest in the context of counting homomorphisms and the expressive power of logics [12, 20, 11, 41, 13]. In this context a non-monotone search game characterisation of the width parameter is useful to ensure that there are no graphs of higher width that can be added to the graph class without changing the expressive power of the logic [34, 13]. The main obstacle then is to find such a non-monotone characterisation, as the natural characterisation as a search-game of many graph parameters is inherently monotone. *Bounded depth treewidth* and the game studied in this paper were first defined in [13]. An equivalent characterisation of these graph classes by so-called k-pebble forest covers of depth q, which is bounded width treedepth, was already given in [1].

Homomorphism Counts. Homomorphism counts are an emerging tool to study equivalence relations between graphs. Many equivalence relations between graphs can be characterized as homomorphism indistinguishability relations, these include graph isomorphism [29], graph isomorphism relaxations [31, 22, 40], cospectrality (folklore) and equivalence with respect to first-order logic with counting quantifiers [12, 20, 11, 13]. In order to study the expressiveness of such equivalence relations, it is crucial to know under which circumstances distinct graph classes yield distinct equivalence relations. Towards this question one considers the closure of a graph class under homomorphism indistinguishability. Let $\mathcal{F}$ be a graph class. Two graphs G, H are *homomorphism indistinguishable over* $\mathcal{F}$, if for all $F \in \mathcal{F}$ the number of homomorphisms from F to H equals the number of homomorphisms from F to G. The graph class $\mathcal{F}$ is *homomorphism distinguishing closed*, if for every graph $F \notin \mathcal{F}$ there exists two graphs G, H, that are homomorphism indistinguishable over $\mathcal{F}$ but that do not have the same number of homomorphisms from F. It has been conjectured by Roberson [39], that all graph classes that are closed under taking minors and disjoint unions are homomorphism distinguishing closed. So far the list of graph classes for which the conjecture is confirmed is short: the class of all planar graphs [39], graph classes that are essentially finite [42], the classes of all graphs of treewidth at most $k-1$ [34] and the classes of all graphs of treedepth at most q [13]. The latter two results rely on characterisations of the graph classes in terms of non-monotone cops-and-robber games. We study *bounded depth treewidth*, which bounds both the width and the depth simultaneously. We give a game characterisation that does not rely on monotonicity, and as a consequence we obtain that the classes of all graphs of bounded depth treewidth are also homomorphism distinguishing closed.

Our Contribution. We show the following (cf. Theorem 27).

Fix integers $k, q \geq 1$. For every graph G the following are equivalent.

- *G has a tree decomposition of width at most $k-1$ and depth at most q.*
- *k cops have a monotone winning strategy in the cops and robber game on G with at most q placements.*
- *k cops have a winning strategy in the cops and robber game on G with at most q placements.*

The equivalence between the last two statements gives a positive answer to an open question from [13]. Our proof of monotonicity gives both a proof of monotonicity for the classical cops and robber game characterising treewidth as well as for the game characterising treedepth as special cases, by removing the bound on the number of rounds or respectively the number of cops. As a corollary, we obtain the following (cf. Theorem 18).

Let $k, q \geq 0$ be integers. The class of all graphs having a tree decomposition of width at most $k-1$ and depth at most q is homomorphism distinguishing closed.

Proof Techniques. In contrast to the proof of monotonicity of the classic cops and robber game [43], our proof does not use a dual concept such as brambles. Instead, we modify a (possibly non-monotone) winning strategy, turning it first into what we call a *pre-tree decomposition*, and then cleaning it up while keeping track of width and depth, thus finally transforming the pre-tree decomposition into a monotone winning strategy. Our concept of pre-tree decomposition is inspired by decompositions of matroids and it is based on ideas from [3, 7]. Our cleaning-up technique is similar to the proof of monotonicity of the game for b-branching treewidth [32]. However, the cleaning-up technique in [32] loses track of the number of cop movements, as local modifications may have non-local effects that are not controlled. We need to keep track in order to control the depth.

This poses a major challenge which we resolve in our proof by a fine grained cleaning-up technique in our pre-tree decomposition based on a careful decision of which vertices to "push up and through the tree" and which to "push down". The vertices "pushed up" may have an effect on the part of the pre-tree decomposition that was processed in previous steps, which we manage to control by a vertex exchange argument. Additionally we keep track of how the first modification at some node in the pre-tree decomposition relates back to the original strategy. We believe that our techniques will also help in future research.

Our proof provides an independent proof of monotonicity of the classic game characterising treewidth as a special case, namely when q is greater than or equal to the number of vertices of the graph. Our proof strategy is entirely different of the original proof of [43], as it does not use an equivalence via a dual object such as brambles. Instead, we provide a more direct transformation of a (possibly non-monotone) winning strategy.

Further Related Research. Search games are used to model a variety of real-world problems such as searching a lost person in a system of caves [36], clearing contaminated tunnels [28], searching environments in robotics [24], and modelling bugs in distributed environments [17], cf. [16] for a survey.

There is a fine line between games that are monotone and those that are not. For example, the marshalls and robber game played on a hypergraph is a natural generalisation of the cops and robber game, it is related to hypertreewidth, but it is not monotone [2]. However, the monotone and the non-monotone variants are strongly related [5] to each other. In a directed graph setting the games are also not monotone [27].

Structure of the Paper. In Section 2 we fix our notation and we define tree decompositions of bounded depth and width. Section 3 introduces pre-tree decomposition, relevant properties, and establishes a relation to tree decompositions. The game is introduced in Section 4, and in Section 5 we give the main construction, showing how to make a strategy tree exact while maintaining the bounds on width and depth. The insights given by our answer to the open question in the area of homomorphism counts are briefly discussed in Section 6. Due to space restrictions all proofs are deferred to the appendix.

2 Preliminaries

Sets and Partitions. Let A be a finite set. We write 2^A to denote the power-set of A and, for $k \in \mathbb{N}$, $\binom{A}{\leq k}$ to denote all subsets of A of size $\leq k$. $\mathrm{Part}(A)$ is the set of all *ordered partitions* of A, where we allow partitions to contain multiple (but finitely many) copies of the empty set. Let $\pi = \{X_1, \dots, X_d\} \in \mathrm{Part}(A)$ and $F \subseteq A$. For $i \in [d]$, the partition

$$i_{X_i \to F} \coloneqq \{X_1 \setminus F, \dots, X_{i-1} \setminus F, X_i \cup F, X_{i+1} \setminus F, \dots, X_d \setminus F\},$$

is called the *F-extension in X_i of π*. A function $w\colon \mathrm{Part}(A) \to \mathbb{N}$ is *submodular* if, for all $\pi, \pi' \in \mathrm{Part}(A)$, for all sets $X \in \pi$ and $Y \in \pi'$ with $X \cup Y \neq A$, it holds that

$$w(\pi) + w(\pi') \geq w(\pi_{X \to \overline{Y}}) + w(\pi'_{Y \to \overline{X}}).$$

Let $f\colon A \to B$ be a function and $C \subseteq A$. By $f|_C$ we denote the restriction of f to C, i. e. $f|_C\colon C \to B$ and $f|_C(c) = f(c)$, for all $c \in C$.

Graphs. A graph G is a tuple $(V(G), E(G))$, where $V(G)$ is a finite set of vertices and $E(G) \subseteq \binom{V(G)}{\leq 2}$ is the set of edges. We usually write uv or vu to denote the edge $\{u, v\} \in E(G)$. We write $\overrightarrow{E(G)}$, when we orient the edges of G, that is $\overrightarrow{E(G)} \coloneqq \{(u,v),(v,u) \mid uv \in E(G)\}$, and call $(u,v) \in \overrightarrow{E(G)}$ an arc. If G is clear from the context we write V, E instead of $V(G), E(G)$. By G° we denote the graph obtained from G by adding all self-loops that are not present in G, that is $V(G^\circ) \coloneqq V(G)$ and $E(G^\circ) \coloneqq E(G) \cup \{vv \mid v \in V(G)\}$. For $U \subseteq V$ we write $G[U]$ to denote the subgraph of G induced by U. For $v \in V$ we write $E_G(v) \coloneqq \{uv \mid uv \in E(G)\}$ for the edges incident to v and $N_G(v) \coloneqq \{u \mid uv \in E(G)\}$ for its neighbours.

A *tree* is a graph where any two vertices are connected by exactly one path. A *rooted tree* (T, r) is a tree T together with some designated vertex $r \in V(T)$, the *root* of T. At times, the following alternative definition is more convenient. We can view a rooted tree (T, r) as a pair $(V(T), \preceq)$, where $\preceq$ is a partial order on $V(T)$ and for every $v \in V(T)$ the elements of the set $\{u \in V(T) \mid u \preceq v\}$ are pairwise comparable: The minimal element of $\preceq$ is precisely the root of T, and we let $v \preceq w$ if v is on the unique path from r to w. Let $t, t' \in V(T)$, we call $t^* \in V(T)$ the *greatest common ancestor* if $t^* \preceq t, t'$ but for all $t'' \in V(T)$ with $t^* \prec t''$ either $t'' \not\preceq t$ or $t'' \not\preceq t'$. By $L(T)$ we denote the set of all *leaves* of T, that is $L(T) \coloneqq \{\ell \in V(T) \mid \text{ there is no } s \in V(T) \text{ such that } \ell \prec s\}$ is the set of all maximal elements of $\preceq$. All vertices that are not leafs are called *inner vertices.*

▶ **Definition 1.** *Let G be a graph, let (T, r) be a rooted tree and let $\beta\colon V(T) \to 2^{V(G)}$ be a function from the nodes of T to sets of vertices of G. We call (T, r, β) a* tree decomposition *of G, if*

(T1) *$\bigcup_{t \in V(T)} G[\beta(t)] = G$, and*

(T2) *for every vertex $v \in G$, the graph $T_v \coloneqq T[\{t \in V(T) \mid v \in \beta(t)\}]$ is connected.*

The sets $\beta(t)$ are called the bags *of this tree decomposition.*

The *width* of a tree decomposition (T, r, β) is $\mathrm{wd}(T, r, \beta) \coloneqq \max_{t \in V(T)} |\beta(t)| - 1$, the *depth* is $\mathrm{dp}(T, r, \beta) \coloneqq \max_{\ell \in L(T)} |\bigcup_{t \preceq \ell} \beta(t)|$. The *treewidth* of a graph G is the minimum width of any tree decomposition of G, the *treedepth* of a graph G is the minimum depth of any tree decomposition (see [13]). For $k, q \geq 1$ we define the class $\mathcal{T}_q^k$ to be all graphs that have a tree decomposition (T, r, β) with $\mathrm{wd}(T, r, \beta) \leq k - 1$ and $\mathrm{dp}(T, r, \beta) \leq q$. The following lemma is a well known consequence from (T2).

▶ **Lemma 2.** *Let G be a graph and $U \subseteq V(G)$ connected in G. Let (T, r, β) be a tree decomposition of G, then $T_U \coloneqq T[\{t \in V(T) \mid U \cap \beta(t) \neq \emptyset\}]$ is connected.*

3 Pre-Tree Decomposition, Exactness and Submodularity

Here we consider a definition of tree decompositions that is inspired by matroid tree decompositions [23]. We relax this definition into what we call a pre-tree decomposition.

▶ **Definition 3.** *Let $G = (V(G), E(G))$ be a graph. Let $X \subseteq E(G)$. We define the* boundary *of a set of edges $\delta(X) \coloneqq \{v \in V(G) \mid \exists e \in X, e' \in E(G) \setminus X, v \in e \cap e'\}$. Let π be a partition of $E(G)$. We define the* boundary *of a partition*

$$\delta(\pi) \coloneqq \bigcup_{X \in \pi} \delta(X).$$

A tuple (T, r, β, γ), where (T, r) is a (rooted) tree, $\beta \colon V(T) \to 2^{V(G)}$ and $\gamma \colon \overrightarrow{E(T)} \to 2^{E(G)}$, is a (rooted) pre-tree decomposition *if:*

(PT1) *$\beta(r) = \emptyset$ and for every connected component C of G, there is a child c of the root with $\gamma(r, c) = E(C)$.*

(PT2) *For every leaf $\ell \in L(T)$ with neighbour t, it holds that $|\gamma(t, \ell)| \leq 1$.*

(PT3) *For every $t \in V(T)$, the tuple π_t is a partition of $E(G)$ and $\delta(\pi_t) \subseteq \beta(t)$.*
For every internal node $t \in V(T) \setminus L(T)$, we define $\pi_t \coloneqq (\gamma(t, t_1), \ldots, \gamma(t, t_d))$, where $N(t) = \{t_1, \ldots, t_d\}$ is an arbitrary enumeration of the neighbours of t. For a leaf $\ell \in L(T)$ with parent p we define $\pi_\ell \coloneqq (\gamma(\ell, p), \overline{\gamma(\ell, p)})$.

(PT4) *For every edge $st \in E(T)$, it holds that $\gamma(s, t) \cap \gamma(t, s) = \emptyset$.*

We call an edge $st \in E(T)$ exact *if $\gamma(s, t) \cup \gamma(t, s) = E(G)$, we call (T, r, γ, β)* exact*, if every edge is exact and $\beta(t) = \delta(\pi_t)$, for all $t \in V(T)$. We call $\beta(t)$ the* bag *at node t and $\gamma(s, t)$ the* cone *at arc (s, t).*

The reader may note that the boundary of a set of edges is symmetric, that is for all $X \subseteq E(G)$ it holds that $\delta(X) = \delta(E(G) \setminus X)$. Furthermore it holds that $v \in \delta(X)$ if and only if $\emptyset \neq E_G(v) \cap X \neq E_G(v)$, for all $v \in V(G)$. The function γ describes a partition of the edges of the graph at every inner node, whereas the function β gives a vertex separator for this partition. This separator may contain more vertices than necessary at a certain node, which is needed to define the depth of a pre-tree decomposition, as seen below. For some edge $st \in E(T)$ with $s \prec t$, we can view $\gamma(s, t)$ as the set of edges that need to be decomposed in the subtree below and $\gamma(t, s)$ as the set of edges that is for sure decomposed somewhere else within the tree. With this point of view the axioms correspond to the following ideas:

(PT1) We start by separating the different connected components of the graph and assign one distinct subtree to decompose each component. This way we also ensure that all of the graph is decomposed in some subtree.

(PT2) We want to decompose the graph into single edges. We do allow empty leafs and even empty subtrees, to ease our cleaning up procedure in the following sections. The reader may recall that the root of a rooted tree is never a leaf, by definition.

(PT3) At every node of the tree we make sure that all edges of the original graph are accounted for and that β is indeed a separator for the given partition.

(PT4) If a parent node assigns an edge to the set that still has to be decomposed, the child node can not assign this edge to the set that is already decomposed somewhere else. But the other direction is possible, if the parent node assigns an edge to the set that is decomposed somewhere else, the child can still assign it to one of its subtrees. If the latter is also not the case the edge is exact.

Similar to the definition of width and depth for tree decompositions we define the width and depth of a pre-tree decomposition. We slightly adapt the definition of depth as (T2) does not hold in pre-tree decompositions.

▶ **Definition 4.** *The* width *of a partition π of the edges of a graph is*

$$\mathrm{wd}(\pi) := |\delta(\pi)|.$$

The width *of a pre-tree decomposition is*

$$\mathrm{wd}(T, r, \beta, \gamma) := \max_{t \in V(T)} |\beta(t)| - 1.$$

The depth *of a rooted pre-tree decomposition is*

$$\mathrm{dp}(T, r, \beta, \gamma) := \max_{t \in V(T)} \sum_{r \prec s \preceq t} |\beta(s) \setminus \beta(p_s)|,$$

where p_s is the parent of s.

The reader may note that the width of a pre-tree decomposition only gets smaller if one sets $\beta(t) := \delta(\pi_t)$, for all nodes $t \in V(T)$, but the depth can get larger. We show that the width of a partition of the edges as defined above is submodular. We need this property to show that our main construction does not enlarge the width of the pre-tree decomposition.

▶ **Lemma 5** ([7]). *For every graph G,* wd *is submodular.*

We continue this section with some lemmas, that help us to get comfortable with the definition of a pre-tree decomposition and are useful to prove that our cleaning up procedure in the following sections is correct. We start with a lemma about the cones along a path of exact edges. It is a direct consequence of exactness and the fact that the cones incident to a node form a partition of the edges.

▶ **Lemma 6.** *Let (T, r, β, γ) be a pre-tree decomposition of a graph G. Let $P = t_1, \ldots, t_\ell$ be a path in T, such that every edge $t_i t_{i+1}$, for $i \in [\ell - 1]$, is exact. Then it holds that $\gamma(t_1, t_2) \supseteq \gamma(t_2, t_3) \supseteq \ldots \supseteq \gamma(t_{\ell-1}, t_\ell)$.*

The following lemma shows, that (PT3) spreads over exact edges, that is any subtree of T that only contains exact edges induces a partition of the edges of the original graph. It is again a direct consequence of exactness and the partitions at the nodes together with the previous lemma.

▶ **Lemma 7.** *Let (T, r, β, γ) be a pre-tree decomposition of a graph G and let (T', r') be a subtree of (T, r), where r' is the minimal node of T' with respect to $\preceq$, such that all edges of T' are exact. We pick arbitrary enumerations of $N_T(V(T')) := \{t_1, \ldots, t_a\}$ and of $L(T) \cap L(T') := \{\ell_1, \ldots, \ell_b\}$. We define $U := \{t_1, \ldots, t_a, \ell_1, \ldots, \ell_b\}$ and define $s \colon U \to V(T')$ to be the natural mapping to the corresponding neighbour in $V(T')$. Then $(\gamma(s(t_1), t_1), \ldots \gamma(s(t_a), t_a), \gamma(s(\ell_1), \ell_1), \ldots, \gamma(s(\ell_1), \ell_1)))$ is an ordered partition of $E(G)$.*

The next lemma is needed to prove how one can translate exact pre-tree decompositions into tree-decompositions. Furthermore it will help us bound the depth within our cleaning up procedure in the following sections. The Lemma follows from the combination of Lemma 6 with the fact that the boundary of the partition is the union of the boundaries of the cones.

▶ **Lemma 8.** *Let (T, r, β, γ) be a pre-tree decomposition of a graph G and let (T', r') be a subtree of (T, r), where r' is the minimal node of T' with respect to $\preceq$, such that all edges of T' are exact. It holds that the induced subgraph $T'_v := T[t \in V(T') \mid v \in \delta(\pi_t)]$, for every vertex $v \in V(G)$, is connected. In particular, if $r = r'$, for every $t \in V(T')$ it holds that*

$$\sum_{\substack{s \preceq t \\ s \neq r}} |\delta(\pi_s) \setminus \delta(\pi_{p_s})| = |\bigcup_{s \preceq t} \delta(\pi_s)|,$$

where p_s is the parent of s.

We conclude this section with a lemma that shows that a pre-tree decomposition of a graph G is indeed a relaxation of a tree-decomposition of G. If every edge is exact and all bags are exactly the boundary of the partition then we can construct a tree decomposition. We need to start with a pre-tree decomposition of the graph G° with all self-loops added to ensure that every non-isolated vertex does appear in some bag and that the components corresponding to isolated vertices are covered by the pre-tree decomposition. If we drop the cones from the tuple we get a tree decomposition by Lemmas 7 and 8. On the other hand we can transform a tree-decomposition into a pre-tree decomposition, by copying the tree-decomposition of each connected component of G and adding leaves that correspond to the edges of G°.

▶ **Lemma 9.** *Let $k, q \geq 1$. Let $G = (V, E)$ be a graph. Any tree-decomposition of G of width $\leq k-1$ and depth $\leq q$ gives rise to an exact pre-tree decomposition of G° of width $\leq k-1$ and depth $\leq q$ and vice versa.*

Proof. Let (T, r, β, γ) be an exact pre-tree decomposition of G° of width $\leq k-1$ and depth $\leq q$. We define $\beta' \colon V(T) \to 2^{V(G)}$ as follows

$$\beta'(t) := \begin{cases} \{v\} & \text{if } t \in L(T) \text{ and } r \text{ is parent of } t \text{ and } \gamma(r, t) = \{vv\}, \\ \beta(t) & \text{otherwise.} \end{cases}$$

▷ Claim 10. (T, β') is a tree-decomposition of width $\leq k-1$ and depth $\leq q$.

Proof. From (PT1), (PT2) and Lemma 7 applied to the complete tree (T, r) we get that for every edge $uv \in E(G^\circ)$ there is some leaf ℓ with parent p and $\gamma(p, \ell) = \{uv\}$. Thus if $u = v$, then $\beta'(\ell) = \{v\}$ and thus $vv \in E(G[\beta'(\ell)])$. Otherwise it holds that $uu, vv \in E(G^\circ) \setminus \{uv\}$ and thus $u, v \in \beta'(\ell)$ and $uv \in E(G[\beta'(\ell)])$. All in all we get that (T1) holds.

By Lemma 8 applied to the complete tree (T, r) we know that all T_v are connected. Therefore (T2) also holds and (T, β') is a tree-decomposition.

The width and depth are obvious as $k, q \geq 1$. ◁

Now let (T, r, β) be a tree-decomposition of G of width $\leq k-1$ and depth $\leq q$. W.l.o.g. β is *tight*, that is for all $t \in V(T)$ and $v \in \beta(t)$, that (T, r, β'), where $\beta'(t) := \beta(t) \setminus \{v\}$ and $\beta'(s) = \beta(s)$, for all $s \in V(T) \setminus \{t\}$, is not a tree-decomposition of G. We construct a new tree T' with root r' and functions $\beta' \colon V(T') \to 2^{V(G)}$, $\gamma \colon \overrightarrow{E(T')} \to 2^{E(G^\circ)}$ and $f \colon V(T') \setminus (L(T') \cup \{r'\}) \to V(T)$ as follows. Let C be a connected component of G and let $V_C := \{t \in V(T) \mid V(C) \cap \beta(t) \neq \emptyset\}$. By Lemma 2 V_C is connected. If C contains only an isolated vertex v, then $V_C = \{t\}$, for some $t \in V(T)$. We add a new node t_v to T' and connect it to the root. We set $\beta'(t_v) = \emptyset$, $\gamma(r', t_v) = \{vv\}$ and $\gamma(t_v, r') = E(G^\circ) \setminus \{vv\}$. Otherwise let T_C be a copy of the subtree induced by V_C with root r_C and vertices V_C^* and $f|_{V_C^*} \colon V_C^* \to V_C$ the natural bijection between the copies and their originals. We attach r_C to the root r'. For every $v \in V(C)$, there is some $t_v \in V_C$ such that $v \in \beta(t_v)$, as C is not an isolated vertex. We add a new leaf t'_v that we attach to $f|_{V(T_C)}^{-1}(t_v)$ and set $\beta'(t'_v) = \{v\}$, $\gamma(f|_{V_C^*}^{-1}(t_v), t'_v) = \{vv\}$ and $\gamma(t'_v, f|_{V_C^*}^{-1}(t_v)) = E(G^\circ) \setminus \{vv\}$. For every $e \in E_G(C)$ there is some $t_e \in V_C$ such that $e \subseteq \beta(t_e)$. We add a new leaf t'_e that we attach to $f|_{V_C^*}^{-1}(t_e)$ and set $\beta'(t'_e) = e$, $\gamma(f|_{V_C^*}^{-1}(t_e), t'_e) = \{e\}$ and $\gamma(t'_e, f|_{V_C^*}^{-1}(t_e)) = E(G^\circ) \setminus \{e\}$. For every node $t \in V_C^*$ with parent p we add all edges $e \in E_G(C)$, where t'_e is a descendant of t, and all self-loops $vv \in E_{G^\circ}(C)$, where t'_v is a descendant of t, to $\gamma(p, t)$. Furthermore we set $\gamma(t, p) := E(G^\circ) \setminus \gamma(p, t)$ and $\beta'(t) := \delta(\pi_t) \subseteq \beta(f(t)) \cap V(C)$. By tightness of β there is some

$v \in \beta(f(\ell))$ such that $T_v = \{f(\ell)\}$, for every $\ell \in L(T_C)$, thus no leaf of T_C is a leaf in T', thus (T', r', β', γ) satisfies (PT2). (PT1), (PT3) and (PT4) hold by construction. Furthermore every edge is exact by construction. Thus we get that (T', r', β', γ) is an exact pre-tree decomposition of G°.

The width is obvious as every bag in β' is a subset of some bag in β. To see that the depth bound also holds we observe two things. For every leaf $\ell \in L(T')$ with parent p we get that $\beta'(\ell) \setminus \beta'(p) = \emptyset$. For every inner node $t \in V(T') \setminus L(T')$ with parent p we get that $\beta'(t) \setminus \beta'(p) \subseteq \beta(f(t))$ and, if $p \neq r'$, $\beta'(t) \setminus \beta'(p) \subseteq \beta(f(t)) \setminus \beta(f(p))$, by the tightness of β. ◀

4 The Game

In the cops and robber game on a graph G, the cops occupy sets X of at most k vertices of G, and the robber moves on edges of G. In order to make the rules precise, we need *edge components* of G that arise when the cops are blocking a set X.

▶ **Definition 11.** *Let $G = (V, E)$ be a graph and $X \subseteq V$. We let* the edge component graph *of G with respect to X be the graph G^X obtained as the disjoint union of the following graphs. (In order to make all graphs disjoint we introduce copies of vertices where needed.)*

- *For every $uv \in E(G[X])$, the graph $G_{uv} := (\{u, v\}, \{uv\})$, and*
- *for every connected component C of $G \setminus X$, the graph G_C, with $V(G_C) := V(C) \cup N_G(V(C))$ and $E(G_C) := E(C) \cup E(V(C), X)$, where $E(V(C), X)$ is the set of edges of G incident to both a vertex of C and a vertex in X.*

The reader may note that G^X may contain multiple copies of the vertices in X, but exactly one copy of each edge in G.

▶ **Observation 12.** *There is a natural bijection $\Psi \colon E(G^X) \to E(G)$ between the edges of G^X and the edges of G.*

▶ **Definition 13** (q-rounds k-cops-and-robber game)**.** *Let G be a graph and let $k, q \geq 1$. The* q-rounds k-cops-and-robber game $\mathrm{CR}_q^k(G)$ *is defined as follows:*

If G does not contain any edges the cop player wins immediately.

- *The cop positions are sets $X \in V(G)^{\leq k}$.*
- *The robber position is an edge $uv \in E(G)$.*
- *The initial position (X_0, u_0v_0) of the game is $X_0 = \emptyset$ and $u_0v_0 \in E(G)$, thus the game starts with no cops positioned on G and the robber on an arbitrary edge in a connected component of G of his choice.*
- *For $X \subseteq V(G)$ and $uv \in E(G)$, we write $\mathrm{esc}(X, uv) := \Psi(E(C))$ for the component C of the graph G^X, such that $uv \in E(C)$. We call this component* the robber escape space*. Thus if the cops are at positions X and robber at an edge uv we write $(X, \mathrm{esc}(X, uv))$ for the position of the game.*
- *In round i the cop player can move from the set X_{i-1} to a set X_i, if $|X_i \setminus X_{i-1}| \leq 1$, that is the cop player can add at most one new vertex to his position.*
- *In round i the robber player can move along a path with no internal vertex in $X_{i-1} \cap X_i$. Thus the robber player can move to some edge u_iv_i, such that the edge $\Psi^{-1}(u_iv_i)$ is in a connected component of G^{X_i} that is contained in $\Psi^{-1}(\mathrm{esc}(u_{i-1}v_{i-1}, X_{i-1} \cap X_i))$ via a path $p = w_1, \dots, w_\ell$ where $\{w_1, w_2\} = \{u_{i-1}, v_{i-1}\}$ and $\{w_{\ell-1}, w_\ell\} = \{u_i, v_i\}$ and $\{w_2, \dots, w_{\ell-1}\} \cap X_i \cap X_{i-1} = \emptyset$.*
- *The cop-player wins in round i, if $\{u_i, v_i\} \subseteq X_i$, and we say the cop player* captures *the robber in round i. The robber-player wins if the cop player has not won in round q.*

We call the game monotone q-round k-cops-and-robber game*, if we further restrict the movement of the cop player such that always* $\operatorname{esc}(X_{i-1}, u_{i-1}v_{i-1}) \supseteq \operatorname{esc}(X_{i-1} \cap X_i, u_{i-1}v_{i-1})$ *and write* $\text{mon-CR}_q^k(G)$*.*

This notion of monotone is also known as robber-monotone. One can also define the notion of cop-monotone, that is during a single play, the cop player may never revisit a vertex they have previously left. This is the stronger notion of monotone as a cop-monotone play is also robber-monotone. Our construction goes through unchanged with the notion of cop-monotone as the strategy that is derived from the final decomposition is cop-monotone. The game played on the graph G° corresponds to a game on G, where the robber can hide both inside a vertex or an edge. It is easy to see that this does not benefit the robber player, that is he wins the game $\text{CR}_q^k(G)$ if and only if he wins the game $\text{CR}_q^k(G^\circ)$, as the components that are reachable by the robber player are essentially the same. In [13], the authors introduce a cops-and-robber game, where the robber player can only hide in the vertices. Again this does not pose a restriction for the robber player with the same argument as above. There is a tight connection between the cops and robber game defined above and tree decompositions of graphs.

▶ **Lemma 14** ([13]). *Let G be a graph and $k, q \in \mathbb{N}$. The cop player wins* $\text{mon-CR}_q^k(G)$ *if and only if $G \in \mathcal{T}_q^k$.*

Towards strengthening the above connection to also include the non-monotone game we first introduce how to construct a pre-tree decomposition from a winning strategy of the cop player.

▶ **Definition 15** (strategy tree). *Let G be a graph without isolated vertices and let $k, q \in \mathbb{N}$. Let $\sigma \colon V(G)^{\leq k} \times E(G) \to V(G)^{\leq k}$ a cop strategy such that that for all $X \in V(G)^{\leq k}$, for all $uv \in E(G)$ and for all $u'v' \in \operatorname{esc}(X, uv)$ we have that $\sigma(X, uv) = \sigma(X, u'v')$. We write $\sigma(X, \operatorname{esc}(X, uv))$ instead of $\sigma(X, uv)$.*

The strategy tree *of σ is a pre-tree decomposition (T, r, β, γ), inductively defined as follows:*

- *$\beta(r) = \emptyset$,*
- *for every connected component C of G, there is a child c of the root r and $\gamma(r, c) = E(C)$,*
- *for every node $t \in V(T) \setminus \{r\}$ with parent $s \in V(T)$,*
  - *if the robber player is caught, we set $\beta(t) = e$, where $\gamma(s, t) = \{e\}$,*
  - *else $\beta(t) = \sigma(\beta(s), \gamma(s, t))$ and*
  - *for every connected component C of $G^{\beta(t)}$, that has a non-empty intersection with $\Psi^{-1}(\gamma(s, t))$, there is a child c of t and $\gamma(t, c) = \Psi(E(C))$,*
  - *$\gamma(t, s) := E(G) \setminus \bigcup_{c \text{ child of } t} \gamma(t, c)$, if $t \notin L(T)$, and*
  - *$\gamma(t, s) := E(G) \setminus \gamma(s, t)$, if $t \in L(T)$.*

We call $t \in V(T)$ a branching node *if the cop player placed a new cop incident to the robber escape space.*

Observe that if $t \in V(T)$ is a leaf, then the robber is captured and the depth of (T, r, β, γ) is $\leq q$ if and only if σ is a winning strategy in $\text{CR}_q^k(G)$.

Note that w.l.o.g. every child of the root is a branching node, as the cop player w.l.o.g. only plays positions that are inside the component the robber player chose in the first round. If the game is played on G°, then every branching node that does not correspond to the placement of a cop onto an isolated vertex has more than one child. We observe that the monotone moves of the cop player correspond to the exact edges in the strategy tree by construction.

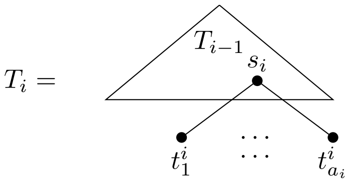

Figure 1 The subtree T_i appearing in the construction.

▶ **Lemma 16.** *For edge $st \in E(T)$, where $s \prec t$ it holds that the move $\sigma(\beta(s), \gamma(s,t))$ is monotone if and only if st is exact.*

The following lemma about the self-loops of the graph G° is key to prove the construction in the next section does not enlarge the depth of the pre-tree decomposition. To prove this one finds the node where the vertex incident to the self-loop was introduced into the bag. At this node the self-loop either was not in the robber escape space in the first place or gets removed from the robber escape space. Then as long as the cops occupy the vertex incident to the self-loop, the self-loop is not reachable by the robber.

▶ **Lemma 17.** *Considering the game on G° and some $s \in V(T) \setminus L(T)$. For all self-loops vv incident to $\beta(s)$ it holds that either $vv \in \gamma(s, p_s)$ or there is a child c of s such that $\gamma(s,c) = \{vv\}$. Furthermore s has a child c with $\gamma(s,c) = \{vv\}$, for some non-isolated vertex v if and only if s is a branching node and $v \in \beta(s) \setminus \beta(p_s)$.*

5 Making a Strategy Tree Exact

Our goal is to prove the following theorem.

▶ **Theorem 18.** *Let $G = (V(G), E(G))$ be a graph, let $k, q \geq 1$ and let (T, r, β, γ) be a strategy tree for some cop strategy $\sigma\colon V(G^\circ)^k \times E(G^\circ) \to V(G^\circ)^k$. If σ is a winning strategy in $\mathrm{CR}_q^k(G^\circ)$, then there is a tree decomposition of G with width $\leq k-1$ and depth $\leq q$.*

To prove this we construct an exact pre-tree decomposition of G° from the strategy tree, starting at the root r and traversing the tree nodes in a breadth-first-search. We then use Lemma 9 to get the desired tree decomposition. When we consider a node we change the pre-tree decomposition so that all incident edges are exact afterwards. Note that by the choice of the traversal we only need to consider outgoing edges.

The Construction. Let (T, r, β, γ) be the pre-tree decomposition of G° from a winning strategy as in Theorem 18. Let $s_1, \dots, s_{n_T}$ be an order of the nodes of T in bfs where $s_1 = r$. Let $\beta_0 := \beta$ and $\gamma_0 := \gamma$. We construct a sequence $(T, r, \beta_0, \gamma_0), \dots, (T, r, \beta_{n_T}, \gamma_{n_T})$ of pre-tree decompositions, such that $(T, r, \beta_{n_T}, \gamma_{n_T})$ is exact. We say s_i is *considered in step i*. Let

$$T_i := T[\{s_1, \dots, s_i\} \cup N_T(\{s_1, \dots, s_i\})] = T[V(T_{i-1}) \cup N_T(s_i)].$$

See Figure 1 for an illustration of T_i. (It will become clear that this is the subtree of all nodes where the pre-tree decomposition is modified in or before step i. We also point out that edges from T_i to $T \setminus T_i$ may become non-exact during our modification process.)

If s_i is a leaf, there are no outgoing edges that are not exact, and we set $\beta_i := \beta_{i-1}$ and $\gamma_i := \gamma_{i-1}$. Otherwise let $t_1^i, \dots, t_{a_i}^i \in N_T(s_i)$ be all children of s_i.

- We pick pairwise disjoint $F^i_1, \dots, F^i_{a_i} \subseteq E(G^\circ)$, with

  $$F^i_j \subseteq \overline{\gamma_{i-1}(t^i_j, s_i)} \cap \overline{\gamma_{i-1}(s_i, t^i_j)},$$

  such that the partition π^* that results from taking the F^i_j-extensions in $\gamma_{i-1}(s_i, t^i_j)$ (in arbitrary order) has the minimum size boundary. If there are multiple optimal choices for $F^i_1, \dots, F^i_{a_i}$ we select the one that minimizes the size of $\bigcup_{j\in[a_i]} F^i_j$, if there are still several options we break ties arbitrarily.
- Let $F^i \coloneqq \bigcup_{j\in[a_i]} F^i_j$ and $R^i_j \coloneqq \left(\left(\overline{\gamma_{i-1}(t^i_j, s_i)} \cap \overline{\gamma_{i-1}(s_i, t^i_j)}\right) \cup F^i\right) \setminus F^i_j$. For every vertex $p \in V(T_i)$ with child c we set

  $$\gamma_i(p,c) \coloneqq \begin{cases} \left(\gamma_{i-1}(s_i, t^i_j) \setminus F^i\right) \cup F^i_j & \text{if } (p,c) = (s_i, t^i_j), \text{ for some } j \in [a_i], \\ \gamma_{i-1}(p,c) \setminus R^i_j & \text{if } p = t^i_j, \text{ for some } j \in [a_i], \\ \gamma_{i-1}(p,c) \cup F^i & \text{if } p \prec s_i, \\ \gamma_{i-1}(p,c) \setminus F^i & \text{otherwise,} \end{cases}$$

  and

  $$\gamma_i(c,p) \coloneqq \begin{cases} \gamma_{i-1}(c,p) \cup R^i_j & \text{if } (p,c) = (s_i, t^i_j), \text{ for some } j \in [a_i], \\ \gamma_{i-1}(c,p) & \text{if } p = t^i_j, \text{ for some } j \in [a_i], \\ \gamma_{i-1}(c,p) \setminus F^i & \text{if } p \prec s_i, \\ \gamma_{i-1}(c,p) \cup F^i & \text{otherwise,} \end{cases}$$

  and all other $uv \in \overrightarrow{E(T)}$ we set $\gamma_i(u,v) \coloneqq \gamma_{i-1}(u,v)$. Furthermore we set

  $$\beta_i(t) \coloneqq \begin{cases} \delta(\pi^i_t) & \text{if } t \in V(T_i), \\ \beta_{i-1}(t) & \text{otherwise.} \end{cases}$$

Intuitively in the construction above we pick F^i_j, that is the set of edges that we add to the cone at the arc pointing towards t^i_j, from the set of edges that are not covered by the cones along the arcs in such a way that the boundary at s_i is minimized. R^i_j then corresponds to the edges that we need to remove from all cones at arcs that point away from s_i at the child t^i_j and in turn add to the cone at the arc pointing towards s_i to make the edge exact. Then we push the change at s_i through T_{i-1}, that is for all edges in T_{i-1} we add F^i to the arc that points towards s_i and remove F^i from the arcs in the other direction. This push can also be interpreted in terms of extensions.

▶ **Lemma 19.** *Let $t \in V(T_i) \setminus \{s_i\}$ and t' is next node on the path from t to s_i in T. Then*

$$\pi^i_t = \left(\pi^{i-1}_t\right)_{\gamma_{i-1}(t,t') \to \overline{\gamma_i(t',t)}}$$

and if additionally $t \in V(T_{i-1})$ also

$$\pi^i_t = \left(\pi^{i-1}_t\right)_{\gamma_{i-1}(t,t') \to F^i}.$$

Observe furthermore that if $\beta_i(s_i) = \beta_{i-1}(s_i)$, then there are no changes to the bags at other nodes than the t^i_j by minimality of $|F^i|$, and if $\beta_i(s_i) \neq \beta_{i-1}(s_i)$, we have $|\beta_i(s_i)| < |\beta_{i-1}(s_i)|$ again by the minimality of the choice. For every $i \in [n_T]$, before step i we only remove edges from the cones pointing downwards from s_i, thus we obtain the following observation.

▶ **Lemma 20.** *Let $i, j \in [n_T]$ such that s_i is the parent of s_j. Then $\gamma_\alpha(s_i, s_j) \subseteq \gamma(s_i, s_j)$, for all $\alpha < i$.*

The Proof Idea. We prove Theorem 18 in three steps. First we prove that the construction indeed yields an exact pre-tree decomposition. Next we show that the width can be bounded as desired and lastly we prove that the construction yields the desired depth.

In step i, every edge incident to s_i is made exact and for every other edge in T_i we remove from one arc exactly what we add to the other arc. We get that our construction indeed yields an exact pre-tree decomposition.

▶ **Lemma 21.** *For all $i \in [n_T]$, $(T, r, \beta_i, \gamma_i)$ is a pre-tree decomposition. Furthermore all edges in $E(T_i)$ are exact.*

Hence, for $i = n_T$, we get that $(T, r, \beta_{n_T}, \gamma_{n_T})$ is an exact pre-tree decomposition. Note that it is possible that $\gamma_{n_T}(s, t)$ is empty for an arc $(s, t) \in \overrightarrow{E(T)}$. By Lemma 9 we obtain a tree decomposition, from this pre-tree decomposition. We show below that the width and depth are as stated in the theorem.

Our construction does not change the width of the decomposition. To prove this we observe that in step i the bound in s_i is minimal. We then push the change through the subtree T_i and find that if a change would increase the width, we could push this change back to the node s_i and find an even smaller bound there, which contradicts the minimality of our choice. This argument yields the following lemma.

▶ **Lemma 22.** $\mathrm{wd}(T, r, \beta_i, \gamma_i) \leq \mathrm{wd}(T, r, \beta, \gamma)$*, for all $i \in [n_T]$.*

Proof. $\overline{\gamma_i(t', t)}$ We prove the statement for all $0 \leq i \leq n_T$ by induction. As $(T, r, \beta_0, \gamma_0) = (T, r, \beta, \gamma)$, the statement clearly holds for $i = 0$. Next we show that $\mathrm{wd}(T, r, \beta_i, \gamma_i) \leq \mathrm{wd}(T, r, \beta_{i-1}, \gamma_{i-1})$, for all $i \in [n_T]$. Obviously $|\beta_i(t)| = |\beta_{i-1}(t)|$, for all $t \notin T_i$. Furthermore by construction $|\beta_i(s_i)| \leq |\beta_{i-1}(s_i)|$. Let $j \in [a_i]$, let $X := \gamma_i(s_i, t^i_j)$ and let $Y := \gamma_{i-1}(t^i_j, s_i)$. By Lemma 19 it holds that

$$|\beta_i(t^i_j)| = \mathrm{wd}\left(\left(\pi^{i-1}_{t^i_j}\right)_{Y \to \overline{X}}\right) \leq \mathrm{wd}(\pi^{i-1}_{t^i_j}) \leq |\beta_{i-1}(t^i_j)|$$

as otherwise by submodularity for the partitions $\pi^{i-1}_{t^i_j}$ and $\pi^i_{s_i}$, we get that

$$\mathrm{wd}\left(\left(\pi^i_{s_i}\right)_{X \to \overline{Y}}\right) < \mathrm{wd}(\pi^i_{s_i}),$$

which contradicts the minimality of the bound for $F^i_1, \ldots, F^i_{a_i}$.

Lastly assume there is a node t in $V(T_i) \setminus \{s_i, t^i_1, \ldots, t^i_{a_i}\}$ such that $|\beta_i(t)| > |\beta_{i-1}(t)|$. We assume t is of minimal distance to s_i with this property. Let $x_0 = t, x_1, \ldots, x_b = s_i$ be the path from t to s_i. By minimality of the distance we know that $|\beta_i(x_1)| \leq |\beta_{i-1}(x_1)|$. Additionally we know that all edges on the path from s_i to x_1 are exact in γ_i, as well as the edge $x_1 t$ in γ_{i-1}. Now let $Y := \gamma_{i-1}(t, x_1)$, $X_\alpha := \gamma_i(x_{\alpha+1}, x_\alpha)$ and $Z_\alpha := \gamma_i(x_\alpha, x_{\alpha+1})$, for all $0 \leq \alpha < b$. From Lemma 19 we get $\left(\pi^{i-1}_t\right)_{Y \to F^i} = \left(\pi^{i-1}_t\right)_{Y \to \overline{X_0}}$. Thus assuming that $\mathrm{wd}\left(\left(\pi^{i-1}_t\right)_{Y \to F^i}\right) = |\beta_i(t)| > |\beta_{i-1}(t)| = \mathrm{wd}(\pi^{i-1}_t)$ using submodularity we get that $\mathrm{wd}(\pi^i_{x_1}) > \mathrm{wd}\left(\left(\pi^i_{x_1}\right)_{X_0 \to \overline{Y}}\right)$. As the edge $x_1 t$ was exact at step $i - 1$, we know that

$$F' := \overline{Y} \setminus X_0 = F^i \setminus Y \subseteq F^i.$$

We now push this change back to s_i along the path $x_1, \ldots, x_b$ and we again find a contradiction to the minimality of the bound of $F^i_1, \ldots, F^i_{a_i}$. For this, let us assume we have pushed the change to x_α, that is we changed $\pi^i_{x_\alpha}$ to $\pi^*_{x_\alpha} = \left(\pi^i_{x_\alpha}\right)_{X_{\alpha-1} \to F'}$ and we know that $\mathrm{wd}(\pi^*_{x_\alpha}) < \mathrm{wd}(\pi^i_{x_\alpha})$. As $x_\alpha x_{\alpha+1}$ is exact in γ_i, we get that $\left(\pi^*_{x_\alpha}\right)_{(Z_\alpha \setminus F') \to \overline{X_\alpha}} = \pi^i_{x_\alpha}$. Let

$$\pi^*_{x_{\alpha+1}} := \left(\pi^i_{x_{\alpha+1}}\right)_{X_\alpha \to \overline{(Z_\alpha \setminus F')}} = \left(\pi^i_{x_{\alpha+1}}\right)_{X_\alpha \to F'},$$

then by submodularity $\mathrm{wd}(\pi^*_{x_{\alpha+1}}) < \mathrm{wd}(\pi^i_{x_{\alpha+1}})$. When we have pushed the change to $\alpha = b$, we find the desired contradiction. ◀

To prove that our construction does not increase the depth we show that in every step i the depth up to the nodes in T_i is bounded by the depth up to these nodes in the original tree. We prove this by induction on the number of steps. We recall that $V(T_i) = V(T_{i-1}) \cup \{t_1^i, \dots, t_{a_i}^i\}$ and that $s_i \in L(T_{i-1})$. For the nodes $t \in V(T_{i-1})$ we can directly build upon the induction hypothesis. But the nodes t_j^i, with $j \in [a_i]$, are added into the subtree. Here we need to compare directly to the original bags, as we can no longer use that in step $i-1$ the depth at these nodes is bounded by the depth in the original strategy tree. We can prove for these nodes that every vertex newly placed at one of these nodes in step i is also newly placed in the original strategy. Then we can show that the difference between depth at these nodes and their parent in step i can be bounded by the difference in the original strategy tree.

▶ **Lemma 23.** *Every $j \in [a_i]$ satisfies $\beta_i(t_j^i) \setminus \beta_i(s_i) \subseteq \beta(t_j^i) \setminus \beta(s_i)$.*

Proof. Let $v \in \beta_i(t_j^i) \setminus \beta_i(s_i)$. Since $v \in \beta_i(t_j^i)$ it holds that $E_{G^\circ}(v) \not\subseteq \gamma_i(t_j^i, s_i)$. As $v \notin \beta_i(s_i)$ we get that $v \notin \delta(\gamma_i(t_j^i, s_i))$ and thus $E_{G^\circ}(v) \cap \gamma_i(t_j^i, s_i) = \emptyset$. By construction we have that $\gamma_i(t_j^i, s_i) \supseteq \gamma_{i-1}(t_j^i, s_i) = \gamma(t_j^i, s_i)$, and thus $vv \notin \gamma(t_j^i, s_i)$. As $v \in \beta_i(t_j^i) = \delta(\pi_{t_j^i})$, there are two distinct children c_1, c_2 of t_j^i such that $v \in \delta(\gamma_i(t_j^i, c_\ell))$ and thus $E_{G^\circ}(v) \cap \gamma_i(t_j^i, c_\ell) \neq \emptyset$, for $\ell = 1, 2$. By construction we have $\gamma_i(t_j^i, c_\ell) \subseteq \gamma_{i-1}(t_j^i, c_\ell) = \gamma(t_j^i, c_\ell)$, for $\ell = 1, 2$. And thus $v \in \delta(\pi_{t_j^i}) \subseteq \beta(t_j^i)$. By Lemma 17 there thus is a child c of t_j^i such that $\gamma(t_j^i, c) = \{vv\}$ and, by Lemma 17, $v \in \beta(t_j^i) \setminus \beta(s_i)$. ◀

For the nodes $t \in V(T_{i-1})$ we show that the depth is not only bounded by the depth within the original pre-tree decomposition, but within the previous step. We do this by a vertex exchange argument, that is we track all vertices added or removed from any bag within T_{i-1}. For the vertices that are added to any bag in $V(T_{i-1})$ we get the following lemma.

▶ **Lemma 24.** *Let $i \in [n_T]$ and let $t \in V(T_{i-1})$. If $v \in \beta_i(t) \setminus \beta_{i-1}(t)$, then $v \in \beta_i(t^*)$, for all t^* on the path from t to s_i.*

Proof. Let $t^* \neq t$. Let t' be the next node on the path from t to s_i. Per definition it holds that $\gamma_i(t, t') = \gamma_{i-1}(t, t') \cup F^i$. As $\gamma_i(t, t')$ is the only set incident to t where edges are added in step i, we get that $v \in \delta(\gamma_i(t, t'))$. Combined with $v \notin \delta(\gamma_{i-1}(t, t'))$ we get that $E_{G^\circ}(v) \cap \gamma_{i-1}(t, t') = \emptyset$ and thus $\emptyset \neq E_{G^\circ}(v) \cap F^i \neq E_{G^\circ}(v)$. Now suppose that $v \notin \beta_i(t^*)$, and thus also $v \notin \delta(\gamma_i(t^*, p))$, where p is the next node on the path from t^* to t. As $\emptyset \neq E_{G^\circ}(v) \cap F^i \neq E_{G^\circ}(v)$ this implies that $E_{G^\circ}(v) \cap \gamma_i(t^*, p) = E_{G^\circ}(v) \cap (\gamma_{i-1}(t^*, p) \setminus F_i) = \emptyset$. We know from Lemma 21 that all edges in T_i are exact and thus that $\gamma_i(t', t) \subseteq \gamma_i(t^*, p)$ by Lemma 6. Thus we get that $E_{G^\circ}(v) \cap \gamma_i(t', t) = \emptyset$. This is a contradiction to the assumption that $v \in \delta(\gamma_i(t, t')) = \delta(\gamma_i(t', t))$ and thus $v \in \beta_i(t^*)$. ◀

The next lemma is used to show that a vertex that disappears from a Observe that if $\beta_i(s_i) = \beta_{i-1}(s_i)$, then there are no changes to the bags at other nodes than the t_j^i by minimality of $|F^i|$, and if $\beta_i(s_i) \neq \beta_{i-1}(s_i)$, we have $|\beta_i(s_i)| < |\beta_{i-1}(s_i)|$ again by the minimality of the choice.bag in $V(T_{i-1})$ at step i also disappears from the union of bags that determine the depth at that bag, especially if a vertex disappears from the bag at s_i, then it disappears from every bag in $V(T_i)$.

▶ **Lemma 25.** *Let $i \in [n_T]$ and let $t \in V(T_{i-1})$. If $v \in \beta_{i-1}(t) \setminus \beta_i(t)$, then $v \notin \beta_i(t^*)$, for all $t^* \in V(T_{i-1})$ such that t is contained in the path from t^* to s_i.*

Proof. We have $E_{G^\circ}(v) \cap F^i \neq \emptyset$.

Let $t = s_i$. Since $v \in \beta_{i-1}(s_i) = \delta(\pi^{i-1}_{s_i})$ it holds that $E_{G^\circ}(v) \not\subseteq \gamma_{i-1}(s_i, p_{s_i})$. As $v \notin \beta_i(s_i)$ we get that $v \notin \delta(\gamma_i(s_i, p_{s_i}))$ and thus $E_{G^\circ}(v) \cap \gamma_i(s_i, p_{s_i}) = E_{G^\circ}(v) \cap \gamma_{i-1}(s_i, p_{s_i}) \cap \overline{F^i} = \emptyset$. Now let $t^* \in V(T_{i-1})$ and t' be the next node on the path from t^* to s_i. Then by Lemma 21 we get that $\gamma_i(t^*, t') \supseteq \gamma_i(p_{s_i}, s_i) \supseteq E_{G^\circ}(v)$ and thus $v \notin \beta_i(t^*)$.

Otherwise let $t \neq s_i$ Let t' be the next node on the path from t to s_i. Since $v \in \delta(\pi^{i-1}_t)$, we get that $E_{G^\circ}(v) \not\subseteq \gamma_{i-1}(t, t')$. As $v \notin \delta(\gamma_i(t, t'))$ and $E_{G^\circ}(v) \cap F^i \neq \emptyset$ it follows that $E_{G^\circ}(v) \subseteq \gamma_i(t, t') = \gamma_{i-1}(t, t') \cup F^i$ and that $E_{G^\circ}(v) \cap \gamma_{i-1}(t', t) \subseteq E_{G^\circ}(v) \cap F^i$. Assume there is some $t^* \in V(T_{i-1})$ such that $v \in \beta_i(t^*)$. We observe that due to Lemma 21 and because all edges incident to v are contained in $\gamma_i(t, t')$, we get that t is not contained in the path from t^* to s_i. ◀

This induction then yields the following lemma.

▶ **Lemma 26.** *For all $i \in [n_T]$ and all $t \in V(T_i)$, it holds that*

$$\sum_{r \prec s \preceq t} |\beta_i(s) \setminus \beta_i(p_s)| \leq \sum_{r \prec s \preceq t} |\beta(s) \setminus \beta(p_s)|.$$

Proof. Let $\ell \in [n_T]$. As by construction $\beta_\ell(t) = \delta(\pi^\ell_t)$, for all $t \in V(T_\ell)$, we get from Lemma 8 and Lemma 21 that $|\bigcup_{s \preceq t} \beta_\ell(s)| = \sum_{r \prec s \preceq t} |\beta_\ell(s) \setminus \beta_\ell(p_s)|$. Thus it suffices to show that $|\bigcup_{s \preceq t} \beta_i(s)| \leq \sum_{r \prec s \preceq t} |\beta(s) \setminus \beta(p_s)|$.

We prove the statement by induction on the steps i. Recall that $(T, r, \beta_0, \gamma_0) = (T, r, \beta, \gamma)$, thus the statement holds for $i = 0$. Now assume the statement holds for $i - 1$, thus for all $t \in V(T_{i-1})$ it holds that $|\bigcup_{s \preceq t} \beta_{i-1}(s)| \leq \sum_{r \prec s \preceq t} |\beta(s) \setminus \beta(p_s)|$. We recall that $V(T_i) = V(T_{i-1}) \cup \{t^i_1, \ldots, t^i_{a_i}\}$ and that $s_i \in L(T_{i-1})$. We consider all vertices that appear at a bag at any node in T_i due to the changes in step i.

Let $t \in V(T_{i-1})$. Let $U \coloneqq \left(\bigcup_{s \preceq t} \beta_i(s)\right) \setminus \left(\bigcup_{s \preceq t} \beta_{i-1}(s)\right)$. Let t^* be the greatest common ancestor of t and s_i. As t^* is on every path from some node $s \preceq t$ to s_i, from Lemma 24 we know that $u \in \beta_i(t^*) \setminus \beta_{i-1}(t^*)$, for all $u \in U$. Let $W \coloneqq \beta_{i-1}(t^*) \setminus \beta_i(t^*)$. As by Lemma 22 $|\beta_i(t^*)| \leq |\beta_{i-1}(t^*)|$, we know that $|U| \leq |W|$. Applying Lemma 25 we get that $W \subseteq \left(\bigcup_{s \preceq t} \beta_{i-1}(s)\right) \setminus \left(\bigcup_{s \preceq t} \beta_i(s)\right)$ and using this *vertex exchange* we conclude that $\left|\bigcup_{s \preceq t} \beta_i(s)\right| \leq \left|\bigcup_{s \preceq t} \beta_{i-1}(s)\right|$.

Otherwise it holds that $t = t^i_j$ for some $j \in [a_i]$. By construction we can conclude that $\bigcup_{s \preceq t} \beta_i(s) = \bigcup_{s \preceq s_i} \beta_i(s) \cup \beta_i(t) \setminus \beta_i(s_i)$. We know that $|\bigcup_{s \preceq s_i} \beta_i(s)| \leq \sum_{r \prec s \preceq s_i} |\beta(s) \setminus \beta(p_s)|$ and by Lemma 23 we have $\beta_i(t) \setminus \beta_i(s_i) \subseteq \beta(t) \setminus \beta(s_i)$. Thus we can bound the union $|\bigcup_{s \preceq t} \beta_i(s)| \leq \sum_{r \prec s \preceq t} |\beta(s) \setminus \beta(p_s)|$. ◀

Summarising all results we get the following equivalences.

▶ **Theorem 27.** *Let $k, q \geq 1$ and G be a graph. The following are equivalent:*

(1) *G admits a tree decomposition of width at most $k - 1$ and depth at most q.*

(2) *G° admits a tree decomposition of width at most $k - 1$ and depth at most q.*

(3) *G° admits an exact pre-tree decomposition of width at most $k - 1$ and depth at most q.*

(4) *The cop player wins* mon-$\mathrm{CR}^k_q(G^\circ)$.

(5) *The cop player wins* $\mathrm{CR}^k_q(G^\circ)$.

(6) *The cop player wins* mon-$\mathrm{CR}^k_q(G)$.

(7) *The cop player wins* $\mathrm{CR}^k_q(G)$.

6 Excursion on Counting Homomorphisms

In this section we give an overview over the field of counting homomorphisms and the equivalence relations on graphs, that can be derived from these counts. We focus ourselves to the results and open questions regarding the homomorphism counts from graphs in the class $\mathcal{T}_q^k$, for fixed $k, q \geq 0$.

We recall the definition of homomorphism distinguishing closed from the introduction. In [13] the authors have reduced the question whether the class $\mathcal{T}_q^k$ is homomorphism distinguishing closed down to the question if monotonicity is a restriction for the cop player. The following lemma is thus implied in [13].

▶ **Lemma 28** ([13])**.** *Let $k, q \geq 1$. The graph class $\mathcal{C} := \{G \mid$ cop player wins $\mathrm{CR}_q^k(G)\}$ is homomorphism distinguishing closed.*

In this paper we show that the cop player wins $\mathrm{CR}_q^k(G)$ if and only if $G \in \mathcal{T}_q^k$, thus the we get the following.

▶ **Theorem 29.** *Let $k, q \geq 0$. The class $\mathcal{T}_q^k$ is homomorphism distinguishing closed.*

7 Conclusion

We gave a new characterisation of bounded depth treewidth by the cops and robber game with both a bound on the number of cops and on the number of rounds, where the cop player is allowed to make non-monotone moves. As a corollary we gave a positive answer to an open question on homomorphism counts. The core of our contribution is a proof of monotonicity of this game. For this proof we substantially reorganise a winning strategy. First we transform it into a pre-tree decomposition. Then we apply a breadth-first "cleaning up" procedure along the pre-tree decomposition (which may temporarily lose the property of representing a strategy), in order to achieve monotonicity while controlling the number of cop rounds simultaneously across all branches of the decomposition via a vertex exchange argument. As an interesting observation we obtain that cop moves onto some vertex not incident to the robber escape space, i. e. to positions that are not part of the boundary, can be ignored and the depth of the exact pre-tree decomposition is the number of cops placed into the robber escape space. To see that consider the proof of Lemma 23 where we compute how much larger the depth at some node t_j^i at step i is than at the considered node s_i. The depth increases only if the node t_j^i is branching by Lemma 17 as t_j^i has a child where the cone contains only a self-loop and hence this is a move into the robber escape space.

▶ **Corollary 30.** $\mathrm{dp}(T, r, \beta_{n_T}, \gamma_{n_T}) \leq \max_{\ell \in L(T)} |\{t \in V(T) \mid t \preceq \ell$ *and t is branching*$\}|$.

We note that we use a slightly different notion of branching node as [32], as we use a different game characterisation. On a graph without isolated vertices our branching nodes are branching nodes in the sense of [32], but not the other way around, as in the non-deterministic cops and robber game, the cop player can chose if he whats to branch in the strategy tree, that is if he wants to know the position of the robber or not.

In the future, it would be interesting to know if it is possible to give a proof that entirely argues with game strategies (not requiring pre-tree decompositions), and we leave this open. We also leave open whether a dual object similar to brambles can be defined for bounded depth treewidth. Finally, given a winning strategy for k cops with q rounds, it would be interesting to know if it is possible to bound the number of cops necessary for winning with only $q - 1$ rounds in terms of k and q, given that the cop player still can win.

Abstract

The Polynomial-Time Hierarchy (PH) is a staple of classical complexity theory, with applications spanning randomized computation to circuit lower bounds to "quantum advantage" analyses for near-term quantum computers. Quantumly, however, despite the fact that at least *four* definitions of quantum PH exist, it has been challenging to prove analogues for these of even basic facts from PH. This work studies three quantum-verifier based generalizations of PH, two of which are from [Gharibian, Santha, Sikora, Sundaram, Yirka, 2022] and use classical strings (QCPH) and quantum mixed states (QPH) as proofs, and one of which is new to this work, utilizing quantum pure states (pureQPH) as proofs. We first resolve several open problems from [GSSSY22], including a collapse theorem and a Karp-Lipton theorem for QCPH. Then, for our new class pureQPH, we show one-sided error reduction pureQPH, as well as the first bounds relating these quantum variants of PH, namely $\mathsf{QCPH} \subseteq \mathsf{pureQPH} \subseteq \mathsf{EXP}^{\mathsf{PP}}$.

1 Introduction

Introduced by Stockmeyer in 1976 [28], the Polynomial-Time Hierarchy (PH) is one of the foundation stones of classical complexity theory. Intuitively, the levels of PH, denoted Σ_i^p (respectively, Π_i^p) for $i \geq 1$, yield progressively harder, yet natural, "steps up" from NP (respectively, coNP). Specifically, a Σ_i^p verifier is a deterministic poly-time Turing Machine M which, given input $x \in \{0,1\}^n$, takes in i proofs $y_i \in \{0,1\}^{\text{poly}(n)}$, and satisfies:

$$\text{if } x \text{ is a YES input:} \qquad \exists y_1 \forall y_2 \exists y_3 \cdots Q_i y_i \text{ s.t. } M(x, y_1, \ldots, y_i) = 1 \tag{1}$$

$$\text{if } x \text{ is a NO input:} \qquad \forall y_1 \exists y_2 \forall y_3 \cdots \overline{Q_i} y_i \text{ s.t. } M(x, y_1, \ldots, y_i) = 0. \tag{2}$$

Above, Q_i is $\forall$ ($\exists$) if i is even (odd). PH has played a prominent (and often surprising!) role in capturing the complexity of various computing setups, including the power of BPP [26, 23], low-depth classical circuits [11], counting classes [29], and even near-term quantum computers [9, 1, 8].

In contrast, the role of *quantum* analogues of PH in quantum complexity theory remains embarrassingly unknown. So, where is the bottleneck? *Defining* "quantum PH" is not the problem – indeed, Yamakami [31], Lockhart and González-Guillén [18], and Gharibian, Santha, Sikora, Sundaram and Yirka [13] all gave different definitions of quantum PH. Instead, the difficulty lies in proving even basic properties of quantum PH, which often runs up against difficult phenomena lurking about open problems such as $\exists \cdot \mathsf{BPP} \stackrel{?}{=} \mathsf{MA}$ and $\mathsf{QMA} \stackrel{?}{=} \mathsf{QMA}(2)$.

In this work, we resolve open questions regarding some fundamental properties of quantum PH. We focus on three definitions of quantum PH, chosen because they naturally generalize[1] QCMA and QMA. The first two definitions are from [13] (formal definitions in Section 2), and the third is new to this work. The definitions all use a poly-time uniformly generated quantum verifier V, and are given as follows (for brevity, here we only state the YES case definitions):

- QCPH: $\exists y_1 \forall y_2 \exists y_3 \cdots Q_i y_i$ s.t. $V(x, y_1, \ldots, y_i)$ outputs 1 with probability $\geq 2/3$.
- QPH: $\exists \rho_1 \forall \rho_2 \exists \rho_3 \cdots Q_i \rho_i$ s.t. $V(x, \rho_1, \ldots, \rho_i)$ outputs 1 with probability $\geq 2/3$.
- pureQPH: $\exists |\psi_1\rangle \forall |\psi_2\rangle \exists |\psi_3\rangle \cdots Q_i |\psi_i\rangle$ s.t. $V(x, |\psi_1\rangle, \ldots, |\psi_i\rangle)$ outputs 1 with probability $\geq 2/3$.

In words, QCPH, QPH, and pureQPH utilize poly-size quantum verifiers taking in classical, mixed quantum, and pure quantum proofs, respectively. It is immediate from the definitions that $\mathsf{QCMA} \subseteq \mathsf{QCPH}$, $\mathsf{QMA} \subseteq \mathsf{QPH}$, and $\mathsf{QMA} \subseteq \mathsf{pureQPH}$. Beyond this, not much is clear. For example, a standard use of PH is via its collapse theorem – if for any i, $\Sigma_i^p = \Pi_i^p$, then $\mathsf{PH} = \Sigma_i^p$. Do any of QCPH, QPH, or pureQPH satisfy such a collapse theorem? Does error reduction hold for QPH or pureQPH? What is the relationship between QCPH, QPH, and pureQPH? Note that standard convexity arguments (as used for e.g. QMA) cannot be used to argue $\mathsf{QPH} = \mathsf{pureQPH}$, due to the presence of alternating quantifiers (which make the verification non-convex in the proofs). Can one recover celebrated results for these hierarchies analogous to the Karp-Lipton [20] Theorem for PH?

Our results. *1. Collapse Theorem for* QCPH. We first resolve an open question of [13] by giving a collapse theorem for QCPH.

[1] QCMA and QMA are quantum generalizations of Merlin-Arthur (MA), with a classical proof and quantum verifier and a quantum proof and quantum verifier, respectively.

▶ **Theorem 1.** *If for any $k \geq 1$, $\mathsf{QC\Sigma}_k = \mathsf{QC\Pi}_k$, then $\mathsf{QCPH} = \mathsf{QC\Sigma}_k$.*

This is in contrast to QPH, for which a collapse theorem is believed difficult to show, as it would imply a subsequent collapse[2] $\mathsf{QMA}(2) \subseteq \mathsf{PSPACE}$.

2. Quantum-Classical Karp-Lipton Theorem for QCPH*.* The celebrated Karp-Lipton theorem [20] states that if SAT can be solved by polynomial-size circuits, then PH collapses to Σ_2^p. We next leverage Theorem 1 and other techniques to obtain a Karp-Lipton Theorem for QCPH:

▶ **Theorem 2** (Karp-Lipton for QCPH)**.** *If $\mathsf{QCMA} \subseteq \mathsf{BQP}_{/\mathrm{mpoly}}$, then $\mathsf{QCPH} = \mathsf{QC\Sigma}_2 = \mathsf{QC\Pi}_2$.*

Here, $\mathsf{BQP}_{/\mathrm{mpoly}}$ is BQP with poly-size classical advice (Definition 11). In words, Theorem 2 says QCMA cannot be solved by (even non-uniformly generated) poly-size quantum circuits, unless QCPH collapses to its second level. This resolves a second open question of [13].

3. Error reduction for pureQPH*.* While error reduction for QCPH follows from parallel repetition (due to its classical proofs), achieving it for pureQPH is non-trivial for the same reason it is non-trivial for QMA(2) – the tensor product structure between proofs is not necessarily preserved when postselecting on measurements across proof copies in the NO case. Here, we show *one-sided* error reduction for pureQPH (e.g. *exponentially* small soundness):

▶ **Theorem 3.** *For all $i > 0$ and $c - s \geq 1/p(n)$ for some polynomial p,*

1. *For even $i > 0$:*
   a. $\mathsf{pureQ\Sigma}_i(c, s) \subseteq \mathsf{pureQ\Sigma}_i^{\mathsf{SEP}}(1/np(n)^2, 1/e^n)$
   b. $\mathsf{pureQ\Pi}_i(c, s) \subseteq \mathsf{pureQ\Pi}_i^{\mathsf{SEP}}(1 - 1/e^n, 1 - 1/np(n)^2)$
2. *For odd $i > 0$:*
   a. $\mathsf{pureQ\Sigma}_i(c, s) \subseteq \mathsf{pureQ\Sigma}_i^{\mathsf{SEP}}(1 - 1/e^n, 1 - 1/np(n)^2)$
   b. $\mathsf{pureQ\Pi}_i(c, s) \subseteq \mathsf{pureQ\Pi}_i^{\mathsf{SEP}}(1/np(n)^2, 1/e^n)$

Above, $\mathsf{pureQ\Sigma}_i^{\mathsf{SEP}}$ and $\mathsf{pureQ\Pi}_i^{\mathsf{SEP}}$ have the promise that in the YES case, the verifier's acceptance measurement is separable (see Section 4.2). We remark the proof of this uses a new *asymmetric* version of the Harrow-Montanaro [16] Product Test, which may be of independent interest (see Lemma 13). The reason we are unable to recover exponentially small error simultaneously for both completeness and soundness is because our approach requires the final quantifier to be $\exists$.

4. Upper and lower bounds on pureQPH*.* Having introduced pureQPH in this work, we next give bounds on its power.

▶ **Theorem 4.** $\mathsf{QCPH} \subseteq \mathsf{pureQPH} \subseteq \mathsf{EXP}^{\mathsf{PP}}$*.*

While the upper bound above is not difficult to show (Theorem 17; this may be viewed as an "exponential analogue" of Toda's theorem), the lower bound is surprisingly subtle. The naive strategy of replacing each proof y_i of QCPH with pure state proof $|\psi_i\rangle$, which is then measured in the standard basis, does not work, as the measurement gives rise to mixed states. Mixed states, in turn, are difficult to handle in QPH, as the latter is not a convex optimization due to alternating quantifiers. We remark that while $\mathsf{QPH} \subseteq \mathsf{pureQPH}$ follows easily via purification of proofs, we do *not* know how to show the analogous lower bound $\mathsf{QCPH} \subseteq \mathsf{QPH}$ (our approach uses our asymmetric product test, which requires pure states).

[2] QMA(2) is QMA with two proofs in tensor product. Since its introduction in 2001 by Kobayashi, Matsumoto, and Yamakami [21, 22], its complexity remains stubbornly open. The current best bounds are $\mathsf{QMA} \subseteq \mathsf{QMA}(2) \subseteq \mathsf{Q\Sigma}_3 \subseteq \mathsf{NEXP}$, where the second and third containments are from[13].

Related Work. Yamakami [31] gave the first definition of a quantum PH, which takes quantum inputs (in contrast, we use classical inputs). The same paper [31] also discusses a variant of $\mathsf{pureQPH}$ (which they call QPH). However, their QPH is very powerful and its first level already captures QMA(2) (which is contained in the third level of $\mathsf{pureQPH}$), and error reduction is trivial for this complexity class. Gharibian and Kempe [12] defined and obtained hardness of approximation results for $\mathsf{QC\Sigma}_2$, obtaining the first hardness of approximation results for a quantum complexity class. (See [7] for a recent extension to QCMA-hardness of approximation results.) Lockhart and González-Guillén [18] defined a class QCPH' similar to QCPH, except using existential and universal *operators.* Thus, in [18] $\mathsf{QC\Sigma}_1' = \exists \cdot \mathsf{BQP}$, which is not known to equal QCMA (for the same reason $\exists \cdot \mathsf{BPP} \overset{?}{=} \mathsf{MA}$ remains open). In exchange for not capturing QCMA, however, the benefit of QCPH' is that its properties are easier to prove than QCPH. Gharibian, Santha, Sikora, Sundaram and Yirka [13] defined QCPH and QPH, and showed weaker variants of the Karp-Lipton theorem (Precise-$\mathsf{QCMA} \subseteq \mathsf{BQP}_{/\mathrm{mpoly}}$ implies $\mathsf{QC\Sigma}_2 = \mathsf{QC\Pi}_2$) and Toda's theorem [29] ($\mathsf{QCPH} \subseteq \mathsf{P}^{\mathsf{PP}^{\mathsf{PP}}}$). They also showed $\mathsf{QMA(2)} \subseteq \mathsf{Q\Sigma}_3 \subseteq \mathsf{NEXP}$, giving the first class sitting between $\mathsf{QMA(2)}$ and NEXP, and observed that $\mathsf{Q\Sigma}_2 = \mathsf{Q\Pi}_2 = \mathrm{QRG}(1) \subseteq \mathsf{PSPACE}$ (due to work of Jain and Watrous [19]). Finally, Aaronson, Ingram and Kretschmer [4] showed that relative to a random oracle, PP is not in the "QMA hierarchy", i.e. in $\mathsf{QMA}^{\mathsf{QMA}^{\cdot^{\cdot^{\cdot}}}}$. The relationship between this QMA hierarchy and any of QCPH, QPH, or $\mathsf{pureQPH}$ remains open.

The Karp-Lipton theorem has been studied in the setting of quantum advice. Prior works by Aaronson and Drucker [3], and Aaronson, Cojocaru, Gheorghiu, and Kashefi [2] studied the consequences of solving NP-complete problems using polynomial-sized quantum circuits with polynomial quantum advice. Nishimura and Yamakami [25] define the *language* class BQP with classical advice and compare it to BQP with quantum advice. In this paper, however, we study promise problems in BQP with classical advice (called $\mathsf{BQP}_{/\mathrm{mpoly}}$).

Finally, the Product Test was first introduced by Mintert, Kuŝ and Buchleitner [24], and rigorously analyzed and strikingly leveraged by Harrow and Montanaro[16] to show $\mathsf{QMA}(k) = \mathsf{QMA}(2)$ for polynomial k, as well as error reduction for $\mathsf{QMA}(2)$. (See also Soleimanifar and Wright [27].)

Concurrent Work. We mention two concurrent works on quantum variants of the polynomial hierarchy. First, our collapse theorem for QCPH (Theorem 1) was proven concurrently by Falor, Ge, and Natarajan [10]. Second, we upper bound QCPH by showing that for all k, $\mathsf{QC\Pi}_k \subseteq \mathsf{pureQ\Sigma}_k \subseteq \mathsf{pureQ\Sigma}_i \subseteq \mathsf{NEXP}^{\mathsf{NP}^{i-1}}$, implying $\mathsf{QCPH} \subseteq \mathsf{pureQPH} \subseteq \mathsf{EXP}^{\mathsf{PP}}$ (Theorem 4 and Theorem 17). Grewal and Yirka [15] show the stronger bound $\mathsf{QCPH} \subseteq \mathsf{QPH}$, at the expense of the minor caveat that their proof does not obtain level-wise containment for all k, but rather requires constant factor blowup in level. Beyond this, our papers diverge. We show a Quantum-Classical Karp-Lipton Theorem for QCPH and error reduction for $\mathsf{pureQPH}$. Grewal and Yirka [15] define a new quantum polynomial hierarchy called the *entangled quantum polynomial hierarchy* (QEPH), which allows entanglement across alternatively quantified quantum proofs. They show that QEPH collapses to its second level (even with polynomially many proofs), and is equal to $\mathsf{QRG}(1)$, the class of one round quantum-refereed games. They also define a generalization of QCPH, denoted DistributionQCPH, in which proofs are not strings but *distributions* over strings. They show QCPH=DistributionQCPH.

Techniques. We sketch our approach for each result mentioned above.

1. Collapse Theorem for QCPH*.* Collapse theorems for PH are shown via inductive argument – by fixing an arbitrary proof for the first quantifier of Σ_i^p, one obtains an instance of Π_{i-1}^p. Reference [13] noted this approach does not obviously work for QCPH, as fixing the first proof of $\mathsf{QC\Sigma}_i$ does *not* necessarily yield a valid $\mathsf{QC\Pi}_{i-1}$ instance (i.e. the latter might not satisfy the desired promise gap). We bypass this obstacle by observing that even if most choices for existentially quantified proofs are problematic, there always exists *at least one* "good" choice, for which the recursion works. Formally, we are implicitly using a *promise* version of NP which is robustly[3] defined relative to any promise oracle.

2. Quantum-Classical Karp-Lipton Theorem. The classical Karp-Lipton theorem crucially uses the search-to-decision reduction for SAT. Given a (non-uniform) circuit family that can decide a SAT instance, we can use the circuit family to find a witness for a SAT instance. However, this search-to-decision reduction does not work in the quantum-classical setting since we are working with promise problems instead of languages. As a result, we cannot replicate the classical proof in the quantum-classical setting. Instead, we first convert the QCMA problem (obtained by fixing the universally quantified proof) to a UniqueQCMA (UQCMA) problem. For this, we use the quantum-classical analogue of Valiant-Vazirani's isolation lemma [30] given by Aharonov, Ben-Or, Brandão, and Sattath [6]. We then use a single-query (quantum) search-to-decision reduction for UQCMA that was presented in a recent work by Irani, Natarajan, Nirkhe, Rao and Yuen [17].

3. Error reduction for $\mathsf{pureQPH}$*.* As with $\mathsf{QMA}(2)$, the challenge with error reduction via parallel repetition for $\mathsf{pureQPH}$ is the following: Given proof $|\psi\rangle_{A_1,B_1}\otimes|\phi\rangle_{A_2,B_2}$, postselecting on a joint measurement outcome on registers $\{A_1, B_1\}$ may entangle registers $\{A_2, B_2\}$. To overcome this, we give an asymmetric version of the Product Test [16], denoted APT. The APT takes in an n-system state $|\psi\rangle$ in register A, and (ideally) m copies of $|\psi\rangle$ in register B. It picks a random subsystem i of A, as well as a random copy j of i in B, and applies the SWAP test (Figure 1) between them. We prove (Lemma 13) that if this test passes with high probability, then $|\psi\rangle_A \approx |\psi_1\rangle\otimes\cdots\otimes|\psi_n\rangle$ for some $\{|\psi_i\rangle\}_{i=1}^n$, i.e. $|\psi\rangle_A$ was of tensor product form.

With the APT in hand, we can show error reduction for (e.g.) $\mathsf{pureQ\Pi}_i$. Here, the aim of an honest ith (existentially quantified) prover is to send many copies of proofs 1 through $i-1$. With probability 1/2, the verifier runs the APT with register A being proofs 1 to $i-1$ and register B being all their copies bundled with the ith proof, and with probability 1/2, the verifier runs parallel repetition on all copies of proofs bundled with the ith proof. This crucially leverages the fact that the ith proof is existential in the YES case, and thus can be assumed to be of this ideal form. In the NO case, however, the ith proof is universally quantified – thus, we cannot assume anything about its structure, which is why we do not get error reduction for the soundness parameter (in this case).

4. Upper and lower bounds on $\mathsf{pureQPH}$*.* We focus on the more difficult direction, $\mathsf{QCPH}\subseteq\mathsf{pureQPH}$, for which we actually show that for all even $k\geq 2$, $\mathsf{QC\Pi}_k\subseteq\mathsf{pureQPH}_k$ (Lemma 16). When simulating QCPH, the challenge is again how to deal with universally quantified proofs, denoted by index set $U\subseteq[k]$. Unlike existentially quantified proofs, which can be assumed to be set honestly to some optimal string y_i, for any index $j\in U$ the proof $|\psi_j\rangle$ can be any pure quantum state. This causes two problems: (1) Measuring $|\psi_j\rangle$ in the standard basis yields a *distribution* D_j over strings, and due to non-convexity of $\mathsf{pureQPH}$, it is not clear if

[3] Formally, let M be a deterministic machine with access to a promise oracle O. We say M is robust [14] if, regardless of how any invalid queries to O (i.e. queries violating the promise gap of O) are answered, M returns the same answer. One can define "PromiseNP" for non-deterministic M with access to O similarly: In the YES case, M has at least one robust accepting branch, and in the NO case, all branches of M are robust and rejecting. For clarity, we do not formally define and use PromiseNP in this work, but the viewpoint sketched here is equivalent to our approach for Theorem 1.

this can help a cheating prover succeed with higher probability that having sent a string. (2) Conditioned on distribution D_j, what should the next, existentially quantified, prover $j+1$ set its optimal proof/string to? We overcome these obstacles as follows. The initial setup is similar to Theorem 3 – prover k (which is existentially quantified in the YES case) send copies of all previous proofs 1 to $k-1$, and with probability $1/2$, we run the APT. However, now with probability $1/2$, we measure *all* proofs in the standard basis. The key step is to immediately *accept* if for any universally quantified proof index $i \in U$, measuring proof $|\psi_i\rangle$ does *not* match all of its copies bundled in proof k. In contrast, for existentially quantified proofs, we *reject* if a mismatch occurs. Finally, assuming no mismatches occur, we simply run the original QCPH verifier on the corresponding strings obtained via measurement. Showing correctness is subtle, and requires a careful analysis for both YES and NO cases, since recall the location of universally quantified proofs changes between cases.

Discussion and open questions. Many questions remain open for QCPH, QPH, and pureQPH. Perhaps the most frustrating for QCPH is a lack of a genuine Toda's theorem – [13] shows QCPH $\subseteq$ $\mathsf{P}^{\mathsf{PP}^{\mathsf{PP}}}$, but what one really wants is containment in P^{PP}. Is this possible? And if not, can one show an oracle separation between QCPH and P^{PP}? Moving to QPH, its role in this mess remains rather murky. Is pureQPH $\subseteq$ QPH (recall the converse direction follows via purification)? For this, our proof technique for QCPH $\subseteq$ pureQPH appears not to apply, as it requires pure states for the SWAP test. QPH *does* have one advantage over pureQPH, however – while the third level of both contains QMA(2), only $\mathsf{Q}\Sigma_3$ is known to be in NEXP [13], providing a class "between" QMA(2) and NEXP. Reference [13]'s proof breaks down for pureQPH, as its semidefinite-programming approach requires *mixed* state proofs.[4] Finally, for pureQPH, can one show two-sided error reduction? Is there a collapse theorem for pureQPH? Can one improve our bound pureQPH $\subseteq$ $\mathsf{EXP}^{\mathsf{PP}}$? As a first step, is pure$\mathsf{Q}\Sigma_3$ $\subseteq$ NEXP? If not, this would suggest the combination of "unentanglement" across proofs and alternating quantifiers yields a surprisingly powerful proof system, as it trivially holds that QMA(2) $\subseteq$ NEXP.

Organization. Section 2 begins with notation and definitions. Section 3.1 and Section 3.2 give our collapse theorem and Karp-Lipton theorem for QCPH, respectively. Section 4 shows error reduction for pureQPH. Section 5 gives upper and lower bounds for pureQPH.

2 Preliminaries

Notation. Let conv(S) denote the convex hull of set S. Then, the set of separable operators acting on $\mathbb{C}^{d_1} \otimes \cdots \otimes \mathbb{C}^{d_i}$ is

$$\operatorname{conv}\left(|\psi_1\rangle\langle\psi_1| \otimes \cdots \otimes |\psi_i\rangle\langle\psi_i| \mid \forall j \in [i],\ |\psi_j\rangle \in \mathbb{C}^{d_j} \text{ is a unit vector}\right). \tag{3}$$

Throughout this paper, we study *promise problems*. A promise problem is a pair $A = (A_{\mathrm{yes}}, A_{\mathrm{no}})$ such that $A_{\mathrm{yes}}, A_{\mathrm{no}} \subseteq \{0,1\}^*$ and $A_{\mathrm{yes}} \cap A_{\mathrm{no}} = \emptyset$, but $A_{\mathrm{yes}} \cup A_{\mathrm{no}} = \{0,1\}^*$ does not necessarily hold.

[4] Briefly, in NEXP one can guess the first existentially quantified proof of $\mathsf{Q}\Sigma_3$, leaving a $\mathsf{Q}\Pi_2$ computation. Since we are using mixed states, via duality theory one can rephrase this via an exponential-side SDP, which can be solved in exponential time. Note this "convexification" does not seem to apply for larger values of k.

2.1 Quantum-Classical Polynomial Hierarchy (QCPH)

We first recall the quantum analogue of PH that generalizes QCMA, i.e. has classical proofs [13].

▶ **Definition 5** ($\mathsf{QC}\Sigma_i$)**.** *Let $A = (A_{\text{yes}}, A_{\text{no}})$ be a promise problem. We say that A is in $\mathsf{QC}\Sigma_i(c,s)$ for poly-time computable functions $c, s : \mathbb{N} \mapsto [0,1]$ if there exists a poly-bounded function $p : \mathbb{N} \mapsto \mathbb{N}$ and a poly-time uniform family of quantum circuits $\{V_n\}_{n\in\mathbb{N}}$ such that for every n-bit input x, V_n takes in classical proofs $y_1 \in \{0,1\}^{p(n)}, \dots, y_i \in \{0,1\}^{p(n)}$ and outputs a single qubit, such that:*

- *Completeness: $x \in A_{\text{yes}} \Rightarrow \exists y_1 \forall y_2 \dots Q_i y_i$ s.t. $\text{Prob}[V_n$ accepts $(y_1, \dots, y_i)] \geq c$.*
- *Soundness: $x \in A_{\text{no}} \Rightarrow \forall y_1 \exists y_2 \dots \overline{Q}_i y_i$ s.t. $\text{Prob}[V_n$ accepts $(y_1, \dots, y_i)] \leq s$.*

Here, Q_i equals $\exists$ when m is odd and equals $\forall$ otherwise and $\overline{Q}_i$ is the complementary quantifier to Q_i. Finally, define

$$\mathsf{QC}\Sigma_i := \bigcup_{c-s\in\Omega(1/\operatorname{poly}(n))} \mathsf{QC}\Sigma_i(c,s). \tag{4}$$

Comments: Note that the first level of this hierarchy corresponds to QCMA. The complement of the i^{th} level of the hierarchy, $\mathsf{QC}\Sigma_i$, is the class $\mathsf{QC}\Pi_i$ defined next.

▶ **Definition 6** ($\mathsf{QC}\Pi_i$)**.** *Let $A = (A_{\text{yes}}, A_{\text{no}})$ be a promise problem. We say that $A \in \mathsf{QC}\Pi_i(c,s)$ for poly-time computable functions $c, s : \mathbb{N} \mapsto [0,1]$ if there exists a polynomially bounded function $p : \mathbb{N} \mapsto \mathbb{N}$ and a poly-time uniform family of quantum circuits $\{V_n\}_{n\in\mathbb{N}}$ such that for every n-bit input x, V_n takes in classical proofs $y_1 \in \{0,1\}^{p(n)}, \dots, y_i \in \{0,1\}^{p(n)}$ and outputs a single qubit, such that:*

- *Completeness: $x \in A_{\text{yes}} \Rightarrow \forall y_1 \exists y_2 \dots Q_i y_i$ s.t. $\text{Prob}[V_n$ accepts $(y_1, \dots, y_i)] \geq c$.*
- *Soundness: $x \in A_{\text{no}} \Rightarrow \exists y_1 \forall y_2 \dots \overline{Q}_i y_i$ s.t. s.t. $\text{Prob}[V_n$ accepts $(y_1, \dots, y_i)] \leq s$.*

Here, Q_i equals $\forall$ when m is odd and equals $\exists$ otherwise, and $\overline{Q}_i$ is the complementary quantifier to Q_i. Finally, define

$$\mathsf{QC}\Pi_i := \bigcup_{c-s\in\Omega(1/\operatorname{poly}(n))} \mathsf{QC}\Pi_i(c,s). \tag{5}$$

Now the corresponding quantum-classical polynomial hierarchy is defined as follows.

▶ **Definition 7** (Quantum-Classical Polynomial Hierarchy (QCPH))**.**

$$\mathsf{QCPH} = \bigcup_{m\in\mathbb{N}} \mathsf{QC}\Sigma_i = \bigcup_{m\in\mathbb{N}} \mathsf{QC}\Pi_i. \tag{6}$$

2.2 (Pure-State) Quantum Polynomial Hierarchy (pureQPH)

Next, we introduce Quantum PH with pure-state proofs (for clarity, the definition below is new to this work). Prior work [13] defined QPH using mixed-state quantum proofs. Unlike QMA or QMA(2) (where one may argue due to convexity that pure states suffice) it is not clear how to use convexity arguments in the presence of alternating quantifiers.

▶ **Definition 8** ($\mathsf{pureQ}\Sigma_i$)**.** *A promise problem $A = (A_{\text{yes}}, A_{\text{no}})$ is in $\mathsf{pureQ}\Sigma_i(c,s)$ for poly-time computable functions $c, s : \mathbb{N} \mapsto [0,1]$ if there exists a polynomially bounded function $p : \mathbb{N} \mapsto \mathbb{N}$ and a poly-time uniform family of quantum circuits $\{V_n\}_{n\in\mathbb{N}}$ such that for every n-bit input x, V_n takes $p(n)$-qubit states $|\psi_1\rangle, \dots, |\psi_i\rangle$ as quantum proofs and outputs a single qubit, then:*

- *Completeness: If $x \in A_{\text{yes}}$, then $\exists|\psi_1\rangle\forall|\psi_2\rangle \dots Q_i|\psi_i\rangle$: V_n accepts $|\psi_1\rangle \otimes |\psi_2\rangle \otimes \cdots \otimes |\psi_i\rangle$ with probability $\geq c$.*
- *Soundness: If $x \in A_{\text{no}}$, then $\forall|\psi_1\rangle\exists|\psi_2\rangle \dots \overline{Q}_i|\psi_i\rangle$: V_n accepts $|\psi_1\rangle \otimes |\psi_2\rangle \otimes \cdots \otimes |\psi_i\rangle$ with probability $\leq s$.*

Here, Q_i equals $\forall$ when m is even and equals $\exists$ otherwise, and $\overline{Q}_i$ is the complementary quantifier to Q_i. Define

$$\mathsf{pureQ\Sigma}_i = \bigcup_{c-s\in\Omega(1/\operatorname{poly}(n))} \mathsf{pureQ\Sigma}_i(c,s). \tag{7}$$

▶ **Definition 9** (pureQΠ$_i$). *A promise problem $A = (A_{\text{yes}}, A_{\text{no}})$ is in $\mathsf{pureQ\Pi}_i(c,s)$ for poly-time computable functions $c, s : \mathbb{N} \mapsto [0,1]$ if there exists a polynomially bounded function $p : \mathbb{N} \mapsto \mathbb{N}$ and a poly-time uniform family of quantum circuits $\{V_n\}_{n\in\mathbb{N}}$ such that for every n-bit input x, V_n takes $p(n)$-qubit states $|\psi_1\rangle, \dots, |\psi_i\rangle$ as quantum proofs and outputs a single qubit, then:*

- *Completeness: If $x \in A_{\text{yes}}$, then $\forall|\psi_1\rangle\exists|\psi_2\rangle \dots Q_i|\psi_i\rangle$: V_n accepts $|\psi_1\rangle \otimes |\psi_2\rangle \otimes \cdots \otimes |\psi_i\rangle$ with probability $\geq c$.*
- *Soundness: If $x \in A_{\text{no}}$, then $\exists|\psi_1\rangle\forall|\psi_2\rangle \dots \overline{Q}_i|\psi_i\rangle$: V_n accepts $|\psi_1\rangle \otimes |\psi_2\rangle \otimes \cdots \otimes |\psi_i\rangle$ with probability $\leq s$.*

Here, Q_i equals $\exists$ when m is even and equals $\forall$ otherwise, and $\overline{Q}_i$ is the complementary quantifier to Q_i. Define

$$\mathsf{pureQ\Pi}_i = \bigcup_{c-s\in\Omega(1/\operatorname{poly}(n))} \mathsf{pureQ\Pi}_i(c,s). \tag{8}$$

The Quantum Polynomial Hierarchy with pure-state proofs can now be defined as follows.

▶ **Definition 10** (Pure Quantum Poly-Hierarchy (pureQPH)).

$$\mathsf{pureQPH} = \bigcup_{m\in\mathbb{N}} \mathsf{pureQ\Sigma}_i = \bigcup_{m\in\mathbb{N}} \mathsf{pureQ\Pi}_i.$$

2.3 Other complexity classes

▶ **Definition 11** (BQP$_{/\text{mpoly}}$). *A promise problem $\Pi = (A_{\text{yes}}, A_{\text{no}})$ is in $\mathsf{BQP}_{/\text{mpoly}}$ if there exists a poly-sized family of quantum circuits $\{C_n\}_{n\in\mathbb{N}}$ and a collection of binary advice strings $\{a_n\}_{n\in\mathbb{N}}$ with $|a_n| = \operatorname{poly}(n)$, such that for all $n \in \mathbb{N}$ and all strings $x \in \{0,1\}^n$,*

$$\Pr[C_n(|x\rangle, |a_n\rangle) = 1] \geq 2/3 \text{ if } x \in A_{\text{yes}} \quad \text{and} \quad \Pr[C_n(|x\rangle, |a_n\rangle) = 1] \leq 1/3 \text{ if } x \in A_{\text{no}}.$$

3 Collapse theorems and Quantum Karp-Lipton

3.1 Collapse Theorem for QCPH

For the quantum-classical hierarchy, QCPH, we now show a quantum analogue of the standard collapse theorem for classical PH, i.e. $\mathsf{\Sigma}_2^p = \mathsf{\Pi}_2^p$ implies $\mathsf{PH} = \mathsf{\Sigma}_2^p$, resolving an open question of [13].

▶ **Lemma 12.** *If for any $k \geq 1$, $\mathsf{QC\Sigma}_k = \mathsf{QC\Pi}_k$, then for all $i \geq k$, $\mathsf{QC\Sigma}_i = \mathsf{QC\Pi}_i = \mathsf{QC\Sigma}_k$.*

Proof. We proceed by induction. For $j \geq k$, define $P(j) := \mathsf{QC\Sigma}_j = \mathsf{QC\Pi}_j = \mathsf{QC\Sigma}_k$. The base case $P(k)$ holds by the assumption of the lemma. For the inductive case, assume $P(j)$ holds for all $k \leq j \leq i-1$. We show $P(j)$ holds for $j = i$. Consider arbitrary promise problem $L = (L_{\text{yes}}, L_{\text{no}}, L_{\text{inv}}) \in \mathsf{QC\Sigma}_i$ and let $\{V_n\}$ be the verifier circuits for the promise problem. Define new promise problem $L' = (L'_{\text{yes}}, L'_{\text{no}}, L'_{\text{inv}})$:

$$L'_{\text{yes}} = \left\{ (x, y_1) \mid \forall y_2 \exists y_3 \ldots Q_i y_i \ \Pr[V(x, y_1, y_2, \ldots, y_i) = 1] \geq \frac{2}{3} \right\} \tag{9}$$

$$L'_{\text{no}} = \left\{ (x, y_1) \mid \exists y_2 \forall y_3 \ldots \overline{Q}_i y_i \ \Pr[V(x, y_1, y_2, \ldots, y_i) = 1] \leq \frac{1}{3} \right\} \tag{10}$$

$$L'_{\text{inv}} = \{0,1\}^* \setminus (L'_{\text{yes}} \cup L'_{\text{no}}). \tag{11}$$

Clearly, $L'_{\text{yes}} \cap L'_{\text{no}} = \emptyset$, and so $(L'_{\text{yes}}, L'_{\text{no}}, L'_{\text{inv}}) \in \mathsf{QC\Pi}_{i-1}$. By the induction hypothesis, there exists promise problem $L'' = (L''_{\text{yes}}, L''_{\text{no}}, L''_{\text{inv}}) \in \mathsf{QC\Sigma}_{i-1}$ such that $L'_{\text{no}} \subseteq L''_{\text{no}}$ and $L'_{\text{yes}} \subseteq L''_{\text{yes}}$. Letting $\{V''_n\}$ denote the verification circuits for L'', we have

$$\begin{aligned} (x, y_1) \in L'_{\text{yes}} \ &\Rightarrow \ (x, y_1) \in L''_{\text{yes}} \ \Rightarrow \ \exists y_2 \forall y_3 \ldots Q_i y_i \colon \ \Pr[V''(x, y_1, \ldots, y_i) = 1] \geq \tfrac{2}{3}, \\ (x, y_1) \in L'_{\text{no}} \ &\Rightarrow \ (x, y_1) \in L''_{\text{no}} \ \Rightarrow \ \forall y_2 \exists y_3 \ldots \overline{Q}_i y_i \colon \ \Pr[V''(x, y_1, \ldots, y_i) = 1] \leq \tfrac{1}{3}. \end{aligned} \tag{12}$$

Now considering again $L = (L_{yes}, L_{\text{no}}, L_{\text{inv}})$, we have

$$\begin{aligned} x \in L_{\text{yes}} \ &\Rightarrow \exists y_1 \colon (x, y_1) \in L'_{\text{yes}} \ \Rightarrow \exists y_1 \exists y_2 \forall y_3 \ldots Q_{i-1} y_i \Pr[V'(x, y_1, \ldots, y_i) = 1] \geq \tfrac{2}{3} \\ x \in L_{\text{no}} \ &\Rightarrow \forall y_1 \colon (x, y_1) \in L'_{\text{no}} \ \Rightarrow \forall y_1 \forall y_2 \exists y_3 \ldots \overline{Q}_{i-1} y_i \Pr[V'(x, y_1, \ldots, y_i) = 1] \leq \tfrac{1}{3}. \end{aligned} \tag{13}$$

We conclude $L \in \mathsf{QC\Sigma}_{i-1} = \mathsf{QC\Sigma}_i$. So $\mathsf{QC\Sigma}_j = \mathsf{QC\Sigma}_k$. Similarly, $\mathsf{QC\Pi}_i \subseteq \mathsf{QC\Pi}_{i-1} = \mathsf{QC\Sigma}_k$. Thus, $P(i)$ holds, as claimed. ◀

Theorem 1 follows from Lemma 12.

3.2 Quantum-Classical Karp-Lipton Theorem

We will show that if there exists a polynomial size circuit family $\{C_n\}_{n \in \mathbb{N}}$ that can decide a QCMA complete problem, then $\mathsf{QC\Pi}_2 \subseteq \mathsf{QC\Sigma}_2$. Using Theorem 1, it follows that if $\mathsf{QCMA} \subseteq \mathsf{BQP}_{/\text{mpoly}}$, then QCPH collapses to the second level.

▶ **Theorem 2** (Karp-Lipton for QCPH). *If* $\mathsf{QCMA} \subseteq \mathsf{BQP}_{/\text{mpoly}}$*, then* $\mathsf{QCPH} = \mathsf{QC\Sigma}_2 = \mathsf{QC\Pi}_2$.

The formal proof is presented in the full version of the paper, together with some immediate applications of the quantum-classical Karp-Lipton theorem. Here, we present an overview of the proof.

Proof-sketch. Let $L = (L_{\text{yes}}, L_{\text{no}}, L_{\text{inv}}) \in \mathsf{QC\Pi}_2$, and let V be the corresponding (quantum) verifier. Since the proofs are classical, we assume V has small error. We show that $L \in \mathsf{QC\Sigma}_2$ by using the following (quantum) verifier V': it takes as input an instance x, a quantum circuit C, a string y_1. The verifier V' runs the circuit C on input (x, y_1) and receives a string y_2. It then accepts x if V accepts (x, y_1, y_2). If $x \in L_{\text{no}}$, then there exists a y_1 such that for all y_2, $V(x, y_1, y_2)$ accepts with negligible probability. Therefore, for any circuit C, there exists a y_1 such that $V'(x, C, y_1) = V(x, y_1, C(x, y_1))$ is 1 with very low probability.

For any $x \in L_{\text{yes}}$, we have that for all y_1, the pair (x, y_1) is a YES-instance of a QCMA problem. Using the [6] isolation procedure, we obtain an instance $\phi_{(x,y_1)}$ such that with non-negligible probability $\phi_{(x,y_1)}$ has a unique witness. Next, using the assumption that $\mathsf{QCMA} \subseteq \mathsf{BQP}_{/\text{mpoly}}$, we get that there exists a circuit $\tilde{C}$ that can decide $\phi_{(x,y_1)}$. Finally, using the UQCMA search-to-decision procedure of [17], we can use C to find the unique

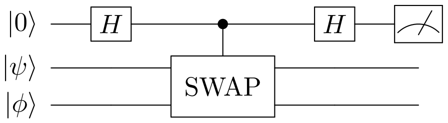

Figure 1 The SWAP test, whose output is the measurement result on the first wire.

witness for $\phi_{(x,y_1)}$. Let C be the circuit that, on input, (x, y_1), first performs the witness isolation from [6], followed by the UQCMA search-to-decision reduction from [17]. Putting these together, we get that there exists a circuit C that, for any y_1, finds a y_2 with non-negligible probability such that $V(x, y_1, y_2) = 1$. Therefore, there exists C such that for any y_1, $V'(x, C, y_1) = 1$ with non-negligible probability. ◀

4 Error reduction for pureQPH

We next study (weak) error reduction for pureQPH (pure proofs). For this, we first require an asymmetric generalization of the Product Test [24, 16], given in Section 4.1. We then give one-sided error reduction results in Section 4.2.

4.1 Asymmetric product test

We first give a generalization of the Product Test [24, 16], which we denote the Asymmetric Product Test (APT), stated as follows:

1. The input is $|\psi\rangle \in \mathbb{C}^{d_1} \otimes \cdots \otimes \mathbb{C}^{d_n}$ in register A, and $|\phi\rangle \in \mathbb{C}^{d^m}$ in register B, where for brevity $d := d_1 \cdots d_n$. We think of B as encoding m copies of A.
2. Choose $(i, j) \in [n] \times [m]$ uniformly at random.
3. Run the SWAP Test (Figure 1) between the ith register of A, and in B, the ith register of the jth copy of A.
4. Accept if the SWAP Test outputs 0, reject otherwise.

In fact, above, one can also assume that $|\phi\rangle$ in the APT is potentially entangled across two registers B and C, as we do for the main lemma of this section, given below.

▶ **Lemma 13.** *[Asymmetric Product Test (APT)] Define $d = d_1 \cdots d_n$. Consider $|\phi\rangle_{BC} \in \mathbb{C}^{d^m} \otimes \mathbb{C}^{d'}$ for some $d' > 0$. Suppose*

$$\max_{|\psi\rangle := |\psi_1\rangle \otimes \cdots \otimes |\psi_n\rangle \in \mathbb{C}^d} \langle \phi|_{BC}[(|\psi\rangle\langle\psi|^{\otimes m})_B \otimes I_C]|\phi\rangle_{BC} = 1 - \varepsilon \tag{14}$$

for $\varepsilon \geq 0$. Then, given the state $|\eta\rangle_{ABC} := |\psi\rangle_A \otimes |\phi\rangle_{BC}$, the APT accepts with probability at most $1 - \varepsilon/2mn$.

Proof. Let $\{|\alpha_{ik}\rangle\}_{k\in[d_i]}$ be an orthonormal basis of $\mathbb{C}^{d_i}$ with $|\alpha_{i1}\rangle := |\psi_i\rangle$, and define index set

$$X = \{(x_{ij})_{i\in[n],j\in[m]} \mid \forall ij : x_{ij} \in [d_i]\}. \tag{15}$$

Then, rewrite $|\phi\rangle_{BC}$ in the $\{|\alpha_{ik}\rangle\}_k$ bases to obtain:

$$|\phi\rangle = \sum_{x\in X} a_x \left(\bigotimes_{ij} |\alpha_{i,x_{ij}}\rangle \right)_B |\gamma_x\rangle_C \tag{16}$$

for some states $|\gamma_x\rangle_C$. Without loss of generality, consider the swap test between the first register of A, $\mathbb{C}^{d_1}$ (which contains $|\psi_1\rangle$), and the first copy of $\mathbb{C}^{d_1}$ in B. Just prior to the final measurement in the test, we have the state $|\eta'\rangle_{SABC}$ given by (where S encodes the control qubit for SWAP in the SWAP test)

$$\begin{aligned}&\sum_{x\in X} a_x\Big(\frac{1}{2}|0\rangle_S\big(|\psi_1\rangle|\alpha_{1,x_{11}}\rangle+|\alpha_{1,x_{11}}\rangle|\psi_1\rangle\big)+\frac{1}{2}|1\rangle_S\big(|\psi_1\rangle|\alpha_{1,x_{11}}\rangle-|\alpha_{1,x_{11}}\rangle|\psi_1\rangle\big)\Big)\\&\qquad\otimes\bigotimes_{i\neq 1\text{ or }j\neq 1}|\alpha_{i,x_{ij}}\rangle|\gamma_x\rangle\;=:\;\sum_{x\in X}a_x|\eta'_x\rangle_{SABC}.\end{aligned}\tag{17}$$

We now show that the cross terms of $\langle\eta'|\eta'\rangle$ vanish, as $\langle\eta'_x|\eta'_y\rangle=0$ with $x\neq y$, where $x,y\in X$: (1) If $x_{ij}\neq y_{ij}$ for $(i,j)\neq(1,1)$, this follows immediately from orthonormality of the basis sets $\{|\alpha_{ik}\rangle\}_{k\in[d_i]}$. (2) The only remaining case is $x_{11}\neq y_{11}$. Without loss of generality, $y_{11}\neq 1$. Then $|\alpha_{1,y_{11}}\rangle$ is orthogonal to $|\psi_1\rangle$, again by choice of our basis set. Hence, $\langle\psi_1,\alpha_{1,x_{11}}|\alpha_{1,y_{11}},\psi_1\rangle=0$. Since trivially $\langle\psi_1,\alpha_{1,x_{11}}|\psi_1,\alpha_{1,y_{11}}\rangle=0$, we again have $\langle\eta'_x|\eta'_y\rangle=0$.

As for the non-cross-terms, we first have again from our basis choice that for any $x\in X$,

$$\langle\eta'_x|(|0\rangle\langle 0|_S)|\eta'_x\rangle=\begin{cases}1, & \text{if } x_{11}=1\\ \frac{1}{2}, & \text{if } x_{11}\neq 1\end{cases}.\tag{18}$$

Recall now that the APT selects $i\in[n]$ and $j\in[m]$ uniformly at random and does a SWAP test between $|\psi_i\rangle$ (the ith register of A) and the jth copy of the i register of B. Thus, conditioned on the APT randomly choosing $(i,j)=(1,1)$, we may bound its acceptance probability as

$$\Pr[\mathrm{APT}(|\eta\rangle)=1\mid i=1,j=1]=\langle\eta'|(|0\rangle\langle 0|_S)|\eta'\rangle=\sum_{\substack{x\in X\\ \text{s.t. } x_{11}=1}}|a_x|^2+\frac{1}{2}\sum_{\substack{x\in X\\ \text{s.t. } x_{11}\neq 1}}|a_x|^2.\tag{19}$$

By symmetry, an identical argument holds for any pair (i,j), and so

$$\begin{aligned}\Pr[\mathrm{APT}(|\eta\rangle)=1]&=\frac{1}{mn}\sum_{ij}\left(\sum_{\substack{x\in X\\ \text{s.t. } x_{ij}=1}}|a_x|^2+\frac{1}{2}\sum_{\substack{x\in X\\ \text{s.t. } x_{ij}\neq 1}}|a_x|^2\right) &(20)\\ &\leq|a_{1^{mn}}|^2+\frac{2mn-1}{2mn}\sum_{x\in X\setminus\{1^{mn}\}}|a_x|^2=1-\frac{\varepsilon}{2mn}. &(21)\end{aligned}$$

◀

4.2 One-sided error reduction

With Lemma 13 (APT) in hand, we now show one-sided error reduction for $\mathsf{pureQ\Pi}_i$, which suffices to obtain statements for all desired classes subsequently in Theorem 3. For this, we define classes $\mathsf{pureQ\Sigma}_i^{\mathsf{SEP}}$ and $\mathsf{pureQ\Pi}_i^{\mathsf{SEP}}$ as identical to $\mathsf{pureQ\Sigma}$ and $\mathsf{pureQ\Pi}$, respectively, except the measurement POVM of the verifier in the YES case must additionally be a separable operator relative to the cuts between each of the i proofs $|\psi_1\rangle$ to $|\psi_i\rangle$. (This is analogous to $\mathsf{QMA}(2)$ versus $\mathsf{QMA}^{\mathsf{SEP}}(2)$ [16].)

▶ **Lemma 14.** *[One-sided* $\mathsf{pureQ\Pi}_i$ *amplification] If* i *is even, then*

$$\mathsf{pureQ\Pi}_i(c,s)\subseteq\mathsf{pureQ\Pi}_i^{\mathsf{SEP}}\left(1-\frac{1}{e^n},1-\frac{1}{np(n)^2}\right),\tag{22}$$

for all functions c *and* s *such that* $c-s\geq 1/p(n)$ *for some polynomial* p.

Proof. Let L $= (L_{yes}, L_{\text{no}}, L_{\text{inv}}) \in \mathsf{pureQ\Pi}_i(c, s)$, with verifier V taking in i proofs denoted $|\psi_1\rangle, \ldots |\psi_i\rangle$. Since i is even, the last proof, $|\psi_i\rangle$, is existentially quantified. We define a new verifier V' to decide L in $\mathsf{pureQ\Pi}_i(1 - 1/\exp, 1 - 1/\operatorname{poly})$ as follows. V' receives the following proofs from an honest prover:

$$\big(|\psi_1'\rangle \otimes \cdots \otimes |\psi_{i-1}'\rangle\big)_A = (|\psi_1\rangle \otimes \cdots \otimes |\psi_{i-1}\rangle)_A \tag{23}$$

$$|\psi_i'\rangle_{BC} = \left(\bigotimes_{j=1}^{i-1} |\psi_j\rangle\right)_B^{\otimes m} \otimes |\psi_i\rangle_C^{\otimes m} \tag{24}$$

for $m \in \Theta(n(c-s)^{-2})$, and where A, B and C are used to align with the notation of Lemma 13 (which we use shortly). In words, the last prover sends m copies of the first $i-1$ proofs in register B, and m copies of the last proof $|\psi_i\rangle$ in register C. Then, V' acts as follows:

1. With probability 1/2, apply the APT (Lemma 13) between registers A and B. Accept iff the test accepts.
2. With probability 1/2, apply verifier V m times, taking one proof $|\psi_i\rangle$ from each respective subregister of B. Accept iff at least $(c+s)/2$ measurements accept.

Correctness. *YES case.* Since the i^{th} prover is existentially quantified, it sends the state in Equation (24). Thus, the APT accepts with certainty. Similarly, for parallel repetition of V, each repetition is independent, hence the overall verifier accepts with probability at least $1 - \exp(-(c-s)^2 m/2)$, as desired.

NO case. Now the i^{th} prover is universally quantified, hence it can send us a state entangled across BC.

Suppose the APT accepts with probability $1 - \varepsilon$. By Lemma 13,

$$|\psi_i'\rangle_{BC} = \alpha \left(\bigotimes_{j=1}^{i-1} |\psi_j\rangle\right)_B^{\otimes m} |\phi\rangle_C + \beta|\gamma\rangle_{BC} =: \alpha|\eta\rangle_B|\phi\rangle_C + \beta|\gamma\rangle_{BC} \tag{25}$$

for $|\alpha|^2 \geq 1 - 2m(i-1)\varepsilon$, and arbitrary states $|\phi\rangle, |\gamma\rangle$ satisfying that $|\eta\rangle_A|\phi\rangle_B$ is orthogonal to $|\gamma\rangle_C$. We have

$$\Pr[\text{parallel repetition of } V \text{ accepts } |\eta\rangle_A|\phi\rangle_B] \leq e^{\frac{-(c-s)^2 m}{2}}. \tag{26}$$

We conclude the acceptance probability of V' is at most

$$\frac{1}{2}\Big((1-\varepsilon) + (1 - 2m(i-1)\varepsilon)e^{-(c-s)^2 m/2} + 2m(i-1)\varepsilon \tag{27}$$

$$+ 2\sqrt{2m(i-1)\varepsilon + (2m(i-1))^2\varepsilon}\Big) \leq 1 - \frac{\varepsilon}{2}, \tag{28}$$

where the maximum is attained when $\varepsilon = \Theta(1/m(i-1))$.

Finally, that the measurement operator for the YES case is separable follows via the argument of Harrow and Montanaro for $\mathsf{QMA}(2)$ amplification [16], since our use of the APT is agnostic to whether proofs are universally or existentially quantified. ◀

Lemma 14 now easily generalizes to cover all classes regarding $\mathsf{pureQPH}$ we are concerned with:

▶ **Theorem 3.** *For all $i > 0$ and $c - s \geq 1/p(n)$ for some polynomial p,*

1. *For even $i > 0$:*
   - **a.** $\mathsf{pureQ\Sigma}_i(c, s) \subseteq \mathsf{pureQ\Sigma}_i^{\mathsf{SEP}}(1/np(n)^2, 1/e^n)$
   - **b.** $\mathsf{pureQ\Pi}_i(c, s) \subseteq \mathsf{pureQ\Pi}_i^{\mathsf{SEP}}(1 - 1/e^n, 1 - 1/np(n)^2)$

2. *For odd $i > 0$:*
   a. $\mathsf{pureQ\Sigma}_i(c,s) \subseteq \mathsf{pureQ\Sigma}_i^{\mathsf{SEP}}(1-1/e^n, 1-1/np(n)^2)$
   b. $\mathsf{pureQ\Pi}_i(c,s) \subseteq \mathsf{pureQ\Pi}_i^{\mathsf{SEP}}(1/np(n)^2, 1/e^n)$

Proof. Statement $1b$ is from Lemma 14, and $1a$ follows from $1b$ since we can get a $\mathsf{pureQ\Sigma}_i$ verifier by flipping the answer of a $\mathsf{pureQ\Pi}_i$ verifier corresponding to the complement of our promise problem. The remaining cases are analogous: $2a$ follows from $1b$, and $2b$ from $1a$. ◀

5 Upper and lower bounds on pureQPH

5.1 Lower bound: QCPH versus QPH

We first give a lower bound on pureQPH, by showing that alternatingly-quantified classical proofs can be replaced by pure-state quantum proofs.

▶ **Theorem 15.** QCPH $\subseteq$ pureQPH.

This follows immediately from the following lemma.

▶ **Lemma 16.** *For all even $k \geq 2$, $\mathsf{QC\Pi}_k \subseteq \mathsf{pureQ\Pi}_k$.*

Proof. That k is even implies the kth proof is existentially quantified in the YES case, a fact we will leverage. To begin, Let V be a verifier for $\mathsf{QC\Pi}_k$, so that in the YES case $\forall_1 x_1 \ldots \exists_k x_k : \Pr[V(x_1,\ldots,x_k)=1] \geq c$ and in the NO case $\exists x_1 \ldots \forall x_k : \Pr[V(x_1,\ldots,x_k)=1] \leq s$, where we may assume without loss of generality that c and s are exponentially close to 1 and 0, respectively. We construct a pureQPH verifier V' as follows:

- V' receives k proofs, $|\psi_1\rangle \otimes \cdots \otimes |\psi_k\rangle$.
- The last proof $|\psi_k\rangle$ consists of two registers denoted A and B. We think of A as containing m copies of proofs $1,\ldots,k-1$ (as in the APT, Lemma 13), and B as containing the kth proof for V, x_k.
- V' acts as follows:
  1. With probability 1/2, run the APT (Lemma 13), and accept if and only if the APT accepts.
  2. With probability 1/2, measure proofs $|\psi_1\rangle \otimes \cdots \otimes |\psi_{k-1}\rangle$ in the standard basis to obtain strings $x_1,\ldots,x_{k-1}$, respectively, similarly measure all copies of these proofs in A, and finally measure B in the standard basis to obtain $x_{k,B}$. Let $U = \{1, 3\ldots, k-1\}$ denote the indices of universally quantified proofs (in the YES case). Then:
     a. If there exists an $i \in [k-1]$ such that the strings obtained by measuring all copies of $|\psi_i\rangle$ did *not* equal x_i, let i denote the minimal such index. Accept if $i \in U$, and reject otherwise.
     b. Otherwise, simulate $V(x_1,\ldots,x_{k-1},x_{k,B})$.

Correctness strategy. Since we are trying to simulate $\mathsf{QC\Pi}_k$, ideally we want all proofs to be strings. This can be assumed without loss of generality for existentially quantified proofs, but not for universally quantified proofs, which can be set to any pure state by definition of $\mathsf{pureQ\Pi}_k$. So, for any $i \in U$, write $|\psi_i\rangle = \sum_x \alpha_{i,x}|x\rangle$, where we view $|\alpha_{i,x}|^2$ as a distribution over strings x for proof i. Denote for any $i \in U$ by x_i^* the amplitude of highest weight, i.e. $x_i^* = \arg\max_x |\alpha_{i,x}|$ (ties broken arbitrarily). The key idea is that the existentially quantified proof at index $i+1$ will now send string y_{i+1}^*, where y_{i+1}^* is the same string that a prover for the *original* $\mathsf{QC\Pi}_k$ verifier V would have sent in response to x_i^* on proof i. (For clarity, if $i+1=k$, then y_{i+1}^* is sent in register B.)

YES case. Since the kth proof is existentially quantified, for Step 1 (APT), we may assume all copies in $|\psi_{k,A}\rangle$ (the state in register A) are correctly set, so the APT accepts with probability 1, leaving all proofs invariant. As for Step 2, for each $i \in U$, let X_i be the random variable resulting from measuring $|\psi_i\rangle$ in the standard basis, and X_{ij} the random variables for the jth copy of $|\psi_i\rangle$ in register A. The verification can now fail in one of two ways:

1. There exists an $i \in U$ such that we did not measure the "right" result, i.e. $X_i \neq x_i^*$, but that all measured copies of $|\psi_i\rangle$ returned the same string, i.e. $\forall j\ X_{ij} = X_i$. In this case, our strategy for setting the existentially quantified proof $i+1$ is not necessarily the correct response to X_i. Thus, when Step 2(b) is run, we have no guarantee for the acceptance probability of V.
2. Measuring all $i \in U$ yields the desired outcomes x_i^* (as well as $\forall j\ X_{ij} = X_i$), but V nevertheless rejects due to imperfect completeness, i.e. $c < 1$.

Combining these, via the union bound we thus have for Step 2 that

$$\begin{aligned}\Pr[\text{reject}] &\leq \Pr[\ \exists i \in U : X_i \neq x_i^* \text{ AND } \forall ij : X_i = X_{ij}\ ] + (1-c) &(29)\\ &\leq \min\{p, 1-p\}^m + 1 - c &(30)\\ &\leq 2^{-m} + 1 - c, &(31)\end{aligned}$$

where $p := \max_i |\alpha_{i,x_i}|^2$, since $\Pr[X_i \neq x_i^*] = \Pr[X_{ij} \neq x_i^*] \leq \max\{p, 1-p\}$ because $|\alpha_{i,y}|^2 \leq 1-p$ for $y \neq x_i^*$. Since we assumed the APT accepts with perfect probability, we conclude V' accepts with probability $\geq \frac{1}{2} + \frac{1}{2}(c - 2^{-m}) =: c'$. (As an aside, recall c is exponentially close to 1.)

NO case. The analysis is more subtle in this case, as the set of indices $U = \{1, 3, \ldots, k-1\}$ now refers to *existentially* quantified proofs. Thus, in Step 2(a) when V' accepts iff $i \in U$, this now means it accepts on existentially quantified proofs. This is because V' does not know whether it is in a YES or NO case. For the same reason, the actions and role of the final proof $|\psi_k\rangle$ on registers A and B remain the same, even though it is now universally quantified. Finally, the strategy of any existential prover $i \in U$ is the same as the YES case: Prover i sends the optimal response y_i^* to universally quantified proof x_{i-1}^*. (If $i = 1$, then there is no universal proof to condition on for $|\psi_1\rangle$.)

To proceed, assume for now that the APT would have succeeded in Step 1 with certainty. In Step 2, define again for all $i \in U$, X_i the random variable resulting from measuring $|\psi_i\rangle$ in the standard basis, and X_{ij} the random variables for the jth copy of $|\psi_i\rangle$ in register A. The verifier can now fail in one of two ways, the first of which differs significantly from the YES case:

1. There exists $i \in U$ such that X_i mismatched one of its copies in A, i.e. $\exists j$ such that $X_i \neq X_{ij}$. *A priori*, this seems like a problem – since $|\psi_k\rangle$ is universally quantified, most choices of $|\psi_k\rangle$ will cause a mismatch with X_i with high probability, causing V' to accept with high probability. The crucial insight is that, in order for $|\psi_1\rangle \otimes \cdots \otimes |\psi_k\rangle$ to pass the APT, it must essentially set each copy of $|\psi_i\rangle$ to string y_i^*. Thus, measuring the A register is highly unlikely to produce mismatches on existentially quantified proofs!
2. Measuring all $i \in U$ will yield the desired outcomes y_i^*, since U is existentially quantified. If in addition $\forall j\ X_{ij} = X_i$, running V may nevertheless accept due to imperfect soundness, i.e. $s > 0$.

Then, by a similar argument as for the YES case that in Step 2, in which we first assume the APT passes with certainty, $\Pr[\text{accept}] \leq 2^{-m} + s$. Now, let us assume the APT accepts with probability $\geq 1 - \varepsilon/2mn$. By Lemma 13,

$$\langle\psi_k|(|\psi_1, \ldots, \psi_{k-1}\rangle\langle\psi_1, \ldots, \psi_{k-1}|_A \otimes I_B)|\psi_k\rangle \geq 1 - \varepsilon. \qquad (32)$$

Let $\{|\beta_i\rangle\}$ be an orthonormal basis of register A with $|\beta_1\rangle = |\psi_1, \ldots, \psi_{n-1}\rangle$. Then we can write $|\psi_n\rangle = \sum_i \alpha_i |\beta_i\rangle_A |\gamma_i\rangle_B$ with $|\alpha_1|^2 \geq 1 - \varepsilon$. Hence, V' accepts with probability at most

$$\frac{1}{2}\left(1 - \frac{\varepsilon}{2mn}\right) + \frac{1}{2}\left(\varepsilon + (1-\varepsilon)s\right) \leq 1 - \frac{1}{4mn} + s =: s', \tag{33}$$

where the first inequality follows because, without loss of generality, we may assume $\varepsilon \leq 1/2$, as otherwise the prover cannot hope to succeed make V' accept with probability greater than $3/4$ (whereas $c' \approx 1$). Finally, we can choose c, s, m such that $c' - s' \geq 1/\operatorname{poly}$. ◀

5.2 Upper bound

To complement Section 5.1, we next give a simple but non-trivial upper bound on $\mathsf{pureQPH}$, which may be viewed as an "exponential analogue" of Toda's theorem. For this, let NP^k denote a tower of NP oracles of height k. (For example, $\mathsf{NP}^1 = \mathsf{NP}$ and $\mathsf{NP}^2 = \mathsf{NP}^{\mathsf{NP}}$.) Define NEXP^k analogously, by a tower of NEXP oracles. In [13], it was observed that $\mathsf{Q\Sigma}_i \subseteq \mathsf{NEXP}^i$. We show a sharper bound here.

▶ **Theorem 17.** $\mathsf{pureQPH} \subseteq \mathsf{EXP}^{\mathsf{PP}}$.

▶ **Observation 18.** $\mathsf{pureQ\Sigma}_i \subseteq \mathsf{NEXP}^{\mathsf{NP}^{i-1}}$.

Proof. Replace all proofs by by their exponential-size classical description (up to additive additive inverse exponential additive error in the entries), and simulate the verifier's action on the proofs via exponential-time matrix multiplication. The standard proof technique for showing $\Sigma_i^p \subseteq \mathsf{NP}^i$ now applies, except we only require NEXP at the base level of the oracle tower, i.e. $\mathsf{NEXP}^{\mathsf{NP}^{i-1}}$, since an exponential time base can "inflate" or pad the instance size for its oracle exponentially. ◀

For comparison, the observed bound in [13] of $\mathsf{Q\Sigma}_i \subseteq \mathsf{NEXP}^i$ is overkill, since it allows the first NEXP oracle can use *double* exponential time to process its exponential size input.

▶ **Observation 19.** $\mathsf{NEXP} \subseteq \mathsf{EXP}^{\mathsf{NP}}$.

Proof. Since using an exponential time machine we can "inflate" the instance size to exponential, an NP machine can thereafter simulate the NEXP computation on the inflated instance size. The EXP machine just returns the answer of the NP oracle. ◀

▶ **Observation 20.** $\mathsf{NEXP}^O \subseteq \mathsf{EXP}^{\mathsf{NP}^O}$ *for an oracle to any language O.*

Proof. It is easy to see that the argument in Observation 19 relativizes, since the NP oracle to the EXP machine can make the NEXP queries directly to the oracle O. ◀

▶ **Observation 21.** $\mathsf{EXP}^{\mathsf{P}^{\mathsf{PP}}} \subseteq \mathsf{EXP}^{\mathsf{PP}}$.

Proof. The EXP machine can make at most exponentially many queries to the its oracle, each of which can be of size at most exponential in the size of the input. Therefore an EXP machine can simulate the action of a P^{PP} machine (even on an exponential sized query) by making queries to a PP oracle while simulating the action of a P machine (which will only take time polynomial in size of the query). ◀

▶ **Theorem 22.** *For all $i \geq 1$, $\mathsf{Q\Sigma}_i \subseteq \mathsf{EXP}^{\mathsf{PP}}$.*

Proof. By Observation 18, Observation 20 and Toda's Theorem [29],

$$\mathsf{Q\Sigma}_i \subseteq \mathsf{NEXP}^{\mathsf{NP}^{i-1}} \subseteq \mathsf{EXP}^{\mathsf{NP}^i} \subseteq \mathsf{EXP}^{\mathsf{P}^{\mathsf{PP}}}. \tag{34}$$

The claim now follows from Observation 21. ◀

Theorem 17 now follows immediately from Theorem 22.

Abstract

Computing a shortest path between two nodes in an undirected unweighted graph is among the most basic algorithmic tasks. Breadth first search solves this problem in linear time, which is clearly also a lower bound in the worst case. However, several works have shown how to solve this problem in sublinear time in expectation when the input graph is drawn from one of several classes of random graphs. In this work, we extend these results by giving sublinear time shortest path (and short path) algorithms for expander graphs. We thus identify a natural deterministic property of a graph (that is satisfied by typical random regular graphs) which suffices for sublinear time shortest paths. The algorithms are very simple, involving only bidirectional breadth first search and short random walks. We also complement our new algorithms by near-matching lower bounds.

1 Introduction

Computing shortest paths in an undirected unweighted graph is among the most fundamental tasks in graph algorithms. In the single source case, the textbook breadth first search (BFS) algorithm computes such shortest paths in $O(m + n)$ time in a graph with n nodes and m edges. Linear time is clearly also a lower bound on the running time of any algorithm that is correct on all input graphs, even if we only consider computing a shortest s-t path for a pair of nodes s, t, and not a shortest path from s to all other nodes. Initial intuition might also suggest that linear time is necessary for computing a shortest path between two nodes s, t in a random graph drawn from any reasonable distribution, such as an Erdős-Rényi random graph or a random d-regular graph. However, this intuition is incorrect and there exists an algorithm with a sublinear expected running time for many classes of random graphs [6, 10, 18]. Moreover, the algorithm is strikingly simple! It is merely the popular practical heuristic of bidirectional BFS [19]. In bidirectional BFS, one simultaneously runs BFS from the source s and destination t, expanding the two BFS trees by one layer at a time. If the input graph is e.g. an Erdős-Rényi random graph, then it can be shown that the two BFS trees have a node in common after exploring only $O(\sqrt{n})$ nodes in expectation. If the node v is first to be explored in both trees, then the path from $s \to v \to t$ in the two BFS trees form a shortest path between s and t. The fact that only $O(\sqrt{n})$ nodes need to be explored intuitively follows from the birthday paradox and the fact that the nodes nearest

to s and t are uniform random in an Erdős-Rényi random graph (although not completely independent). Note that for sublinear time graph algorithms to be meaningful, we assume that we have random access to the nodes and their neighbors. More concretely, we assume the nodes are indexed by integers $[n] = \{1, \dots, n\}$ and that we can query for the number of nodes adjacent to a node v, as well as query for the j'th neighbor of a node v. We remark that several works have also extended the bidirectional BFS heuristic to weighted input graphs and/or setups where heuristic estimates of distances between nodes and the source or destination are known [19, 20, 12]. There are also works giving sublinear time algorithms for other natural graph problems under the assumption of a random input graph [14].

A caveat of the previous works that give provable sublinear time shortest path algorithms, is that they assume a random input graph. In this work, we identify "deterministic" properties of graphs that may be exploited to obtain sublinear time s-t shortest path algorithms. Concretely, we study shortest paths in expander graphs. An n-node d-regular (all nodes have degree d) graph G, is an (n, d, λ)-graph if the eigenvalues $\lambda_1 \geq \cdots \geq \lambda_n$ of the corresponding adjacency matrix A satisfies $\max_{i \neq 1} |\lambda_i| \leq \lambda$. Note that the eigenvalues are real since A is symmetric and real. We start by presenting a number of algorithmic results when the input graph is an expander.

Shortest s-t Path

Our first contribution demonstrates that the simple bidirectional BFS algorithm efficiently computes a shortest path between most pairs of nodes s, t in an expander:

▶ **Theorem 1.** *If G is an (n, d, λ)-graph, then for every node $s \in G$, every $0 < \delta < 1$, it holds for at least $(1 - \delta)n$ nodes t, that bidirectional BFS between s and t, finds a shortest s-t path after visiting $O((d-1)^{\lceil (1/4) \lg_{d/\lambda}(n/\delta) \rceil})$ nodes.*

While the bound in Theorem 1 on the number of nodes visited may appear unwieldy at first, we note that it simplifies significantly for natural values of d and λ. For instance, an (n, d, λ)-graph is Ramanujan if $\lambda \leq 2\sqrt{d-1}$. For Ramanujan graphs, and more generally for graphs with $\lambda = O(\sqrt{d})$, the bound in Theorem 1 simplifies to near-$\sqrt{n}$:

▶ **Corollary 2.** *If G is an $(n, d, O(\sqrt{d}))$-graph, then for every node $s \in G$, every $0 < \delta < 1$, it holds for at least $(1 - \delta)n$ nodes t, that bidirectional BFS between s and t, finds a shortest s-t path after visiting $O((n/\delta)^{1/2 + O(1/\ln d)})$ nodes.*

We also demonstrate that the bound can be tightened even further for Ramanujan graphs:

▶ **Theorem 3.** *If G is a d-regular Ramanujan graph where $d \geq 3$, then for every node $s \in G$, it holds for at least $(1 - o(1))n$ nodes t, that bidirectional BFS between s and t, finds a shortest s-t path after visiting $O(\sqrt{n} \cdot \ln^{3/2}(n))$ nodes.*

Short s-t Path

One drawback of bidirectional BFS in expanders, is that it is only guaranteed to find a shortest path efficiently for *most* pairs of nodes s, t. One can show that this is inherent. In particular, as we sketch in Section 4, for constant d and infinitely many n, there exists $(n, d, 3\sqrt{d})$-graphs with diameter at least $1.998 \lg_{d-1} n$. Picking two nodes s and t of maximum distance in such a graph and running BFS from both will only terminate after having visited $\Omega((d-1)^{(1.998/2) \lg_{d-1} n}) = \Omega(n^{0.999})$ nodes.

Motivated by this shortcoming, we also present a simple randomized algorithm for finding a short, but not necessarily shortest, s-t path. For any parameter $0 < \delta < 1$, the algorithm starts by growing a BFS tree from s until $\Theta(\sqrt{n \ln(1/\delta)})$ nodes have been explored. It then performs $O(\sqrt{n \ln(1/\delta)}/\lg_{d/\lambda}(n))$ random walks starting at t. Each of these random walks run for $O(\lg_{d/\lambda}(n))$ steps. If any of these walks discover a node in the BFS tree, it has found an s-t path of length $O(\lg_{d/\lambda}(n))$.

We show that this BFS + Random Walks algorithm has a high probability of finding an s-t path:

▶ **Theorem 4.** *If G is an (n, d, λ)-graph with $\lambda \leq d/2$, then for every pair of nodes s, t, every $0 < \delta < 1$, it holds with probability at least $1 - \delta$, that BFS + Random Walks between s and t, finds an s-t path of length $O(\lg_{d/\lambda}(n))$ while visiting $O(\sqrt{n \ln(1/\delta)})$ nodes.*

Finally, let us mention the two previous works [9, 7] that have also identified deterministic properties of graphs which suffice for provable speedups from bidirectional BFS. The deterministic properties they identify are vaguely related to expansion, but are not as standard and clean-cut as our results using the standard definition of expanders. The work [16] has also investigated short paths in expanders in the context of multicommodity flow and approximating the maximum number of disjoint paths between pairs of nodes.

Lower Bounds

While bidirectional BFS, or BFS + Random Walks, are natural algorithms for finding s-t paths efficiently, it is not a priori clear that better strategies do not exist. One could e.g. imagine sampling multiple nodes in an input graph, growing multiple small BFS trees from the sampled nodes and somehow use this to speed up the discovery of an s-t path. To rule this approach out, we complement the algorithms presented above with lower bounds. For proving lower bounds, we consider distributions over input graphs and show that any algorithm that explores few nodes fails to find an s-t path with high probability in such a random input graph. As Erdős-Rényi random graphs (with large enough edge probability) and random d-regular graphs are both expanders with good probability, we prove lower bounds for both these random graph models. The distribution of an Erdős-Rényi random graph on n nodes is defined from a parameter $0 < p < 1$. In such a random graph, each edge is present independently with probability p. A random d-regular graph on the other hand, is uniform random among all n-node graphs where every node has degree d.

Our lower bounds hold even for the problem of reporting an arbitrary path connecting a pair of nodes s, t, not just for reporting a short/shortest path. Furthermore, our lower bounds are proved in a model where we allow node-incidence queries. A node-incidence query is specified by a node index v and is returned the set of all edges incident to v. Our first lower bound holds for Erdős-Rényi random graphs:

▶ **Theorem 5.** *Any (possibly randomized) algorithm for reporting an s-t path in an Erdős-Rényi random graph, where edges are present with probability $p \geq 1.5 \ln(n)/n$, either makes $\Omega(1/(p\sqrt{n}))$ node-incidence queries or outputs a valid path with probability at most $o(1) + p$.*

Note that the lower bound assumes $p \geq 1.5 \ln(n)/n$. This is a quite natural assumption since for $p \ll \ln(n)/n$, the input graph is disconnected with good probability. The concrete constant 1.5 is mostly for simplicity of the proof. We remark that the additive p in the success probability is tight as an algorithm always reporting the direct path consisting of the single edge (s, t) is correct with probability p. Also observe that the number of edges discovered after $O(1/(p\sqrt{n}))$ node-incidence queries is about $O(pn/(p\sqrt{n})) = O(\sqrt{n})$ since each node has $p(n-1)$ incident edges in expectation.

For the case of random d-regular graphs, we show the following lower bound for constant degree d:

▶ **Theorem 6.** *Any (possibly randomized) algorithm for reporting an s-t path in a random d-regular graph with $d = O(1)$, either makes $\Omega(\sqrt{n})$ node-incidence queries or outputs a valid path with probability at most $o(1)$.*

We remark that a random d-regular graph is near-Ramanujan with probability $1 - o(1)$ as proved in [13], confirming a conjecture raised in [1]. A near-Ramanujan graph is an (n, d, λ)-expander with $\lambda \leq 2\sqrt{d-1} + o(1)$. Thus our upper bounds in Theorem 1 and Theorem 4 nearly match this lower bound.

Overview

In Section 2, we present our upper bound results and prove the claims in Theorem 1 and Theorem 4. The upper bounds are all simple algorithms and also have simple proofs using well-known facts about expanders.

In Section 3, we prove our lower bounds. These proofs are more involved and constitute the main technical contributions of this work.

2 Upper Bounds

In the following, we present and analyse simple algorithms for various s-t reachability problems in expander graphs.

2.1 Shortest Path

Let G be an (n, d, λ)-graph and consider the following bidirectional BFS algorithm for finding a shortest path between a pair of nodes s, t: grow a BFS tree $\mathcal{T}_s$ from s and a BFS tree $\mathcal{T}_t$ from t simultaneously. In each iteration, the next layer of $\mathcal{T}_s$ and $\mathcal{T}_t$ is computed and as soon as a node v appears in both trees, we have found a shortest path from s to t, namely the path $s \to v \to t$ in the two BFS trees.

We show that this algorithm is efficient for most pairs of nodes s, t as claimed in Theorem 1.

To prove Theorem 1, we show that in any (n, d, λ)-graph G, it holds for every node $s \in G$ that most other nodes have a small distance to s. Concretely, we show the following

▶ **Lemma 7.** *If G is an (n, d, λ)-graph, then for every node $s \in G$, it holds for every $0 < \delta < 1$ that there are no more than δn nodes with distance more than $(1/2)\lg_{d/\lambda}(n/\delta)$ from s.*

Theorem 1 now follows from Lemma 7 by observing that for a pair of nodes s, t of distance k in an (n, d, λ)-graph, the bidirectional searches will meet after expanding for $\lceil k/2 \rceil$ steps from s and t. Since each node explored during breadth first search has at most $d - 1$ neighbors outside the previously explored tree, it follows that the total number of nodes visited is $O((d-1)^{\lceil k/2 \rceil})$. Since it holds for every $s \in G$ that $\operatorname{dist}(s, t) \leq (1/2)\lg_{d/\lambda}(n/\delta)$ for a $1 - \delta$ fraction of all other nodes t, the conclusion follows.

Corollary 2 follows from Theorem 1 by observing that when $\lambda = O(\sqrt{d})$, we have $(1/4)\lg_{d/\lambda}(n/\delta) = (1/2)\lg_{\Omega(d)}(n/\delta)$. Noting that $\lg_{\Omega(d)}(n/\delta) = \ln(n/\delta)/(\ln(d) - O(1)) = (1 + O(1/\ln d))\lg_{d-1}(n/\delta)$, the conclusion follows.

What remains is to prove Lemma 7. While the contents of the lemma is implicit in previous works, we have not been able to find a reference explicitly stating this fact. We thus provide a simple self-contained proof building on Chung's [11] proof that the diameter of an (n, d, λ)-graph is bounded by $\lceil \lg_{d/\lambda} n \rceil$.

Proof of Lemma 7. Let A be the adjacency matrix of an (n, d, λ)-graph G. Letting $d = \lambda_1 \geq \lambda_2 \geq \cdots \geq \lambda_n$ denote the (real-valued) eigenvalues of the real symmetric matrix A, we may write A in its spectral decomposition $A = U\Sigma U^T$ with $\lambda_1, \ldots, \lambda_n$ being the diagonal entries of the diagonal matrix Σ. By definition, we have $\max\{\lambda_2, |\lambda_n|\} = \lambda$.

Notice that $(A^k)_{s,t}$ gives the number of length-k paths from node s to node t in G. Furthermore, we have $A^k = U\Sigma^k U^T$. Now let s be an arbitrary node of G and let $Z \subseteq [n]$ denote the subset of columns t such that $(A^k)_{s,t} = 0$. The eigenvalues of A^k are $\lambda_1^k, \ldots, \lambda_n^k$ and the all-1's vector $\mathbf{1}$ is an eigenvector corresponding to λ_1. Let $\mathbf{1}_Z$ denote the indicator for the set Z, i.e. the coordinates of $\mathbf{1}_Z$ corresponding to $t \in Z$ are 1 and the remaining coordinates are 0. By definition of Z, we have that $e_s^T A^k \mathbf{1}_Z = 0$. At the same time, we may write $\mathbf{1}_Z = (|Z|/n)\mathbf{1} + \beta u$ where u is a unit length vector orthogonal to $\mathbf{1}$ and $\beta = \sqrt{|Z| - |Z|^2/n}$. Hence

$$\begin{aligned} 0 &= e_s^T A^k \mathbf{1}_Z \\ &= e_s^T A^k((|Z|/n)\mathbf{1} + \beta u) \\ &= e_s^T \lambda_1^k (|Z|/n)\mathbf{1} + \beta e_s^T A^k u \\ &\geq d^k|Z|/n - \beta \cdot \|e_s\| \cdot \|A^k u\| \\ &\geq d^k|Z|/n - \beta\lambda^k. \end{aligned}$$

From this we conclude $|Z| \leq (\lambda/d)^k n\beta \leq (\lambda/d)^k n\sqrt{|Z|}$, implying $|Z| \leq (\lambda/d)^{2k} n^2$. For $k = (1/2)\lg_{d/\lambda}(n/\delta)$, this is $|Z| \leq \delta n$. ◀

For the special case of Ramanujan graphs, Theorem 3 claims an even stronger result than Theorem 1. Recall that an (n, d, λ)-graph is Ramanujan if it satisfies that $\lambda \leq 2\sqrt{d-1}$. To prove Theorem 3 we make use of the following concentration result on distances in Ramanujan graphs:

▶ **Theorem 8** ([17]). *Let G be a d-regular Ramanujan graph on n nodes, where $d \geq 3$. Then for every node $s \in G$ it holds that*

$$|\{t \in G : |\mathrm{dist}(s,t) - \lg_{d-1} n| > 3\lg_{d-1}\lg n\}| = o(n).$$

Using Theorem 8, we conclude that for every node $s \in G$, it holds for $(1 - o(1))n$ choices of t that $\mathrm{dist}(s,t) \leq \lg_{d-1} n + 3\lg_{d-1}\lg n$. The middle node v on a shortest path from s to t thus has distance at most $k = \lceil(\lg_{d-1} n + 3\lg_{d-1}\lg n)/2\rceil \leq (1/2)\lg_{d-1} n + (3/2)\lg_{d-1}\lg n + 1$ from s and t. Since the nodes in a layer ℓ of a BFS tree in a d-regular graph G has at most $d-1$ neighbors in layer $\ell + 1$, we conclude that the two BFS trees $\mathcal{T}_s$ and $\mathcal{T}_t$ contain at most $O((d-1)^k) \leq O(\sqrt{n} \cdot \ln^{3/2}(n))$ nodes each upon termination. Note that the same proof shows how to find a shortest path in time $n^{1/2+o(1)}$ between most pairs of vertices s and t in near Ramanujan graphs, as it is also proved in [17] that in such graphs, for every node s there are only $o(n)$ nodes t of distance exceeding $(1 + o(1))\lg_{d-1} n$ from s.

2.2 Connecting Path

In the following, we analyse our algorithm, BFS + Random Walks, for finding a short s-t path in an (n, d, λ)-graph. The algorithm is parameterised by an integer $k \geq \sqrt{n}$ and is as follows: First, run BFS from s until k nodes have been discovered. Call the set of discovered nodes V_s. Next, run $\tau = k/(3\lg_{d/\lambda}(n))$ random walks $\mathbf{p}_1, \ldots, \mathbf{p}_\tau$ from t, with each random walk having a length of $3\lg_{d/\lambda}(n)$. If any of the random walks intersects V_s, we have found an s-t path of length $O(\lg_{d/\lambda}(n))$ as the paths $\mathbf{p}_i$ have length $O(\lg_{d/\lambda}(n))$ and the diameter, and hence the depth of the BFS tree, in an (n, d, λ)-graph is at most $\lceil\lg_{d/\lambda}(n)\rceil$ [11].

To analyse the success probability of the algorithm, we bound the probability that all paths $\mathbf{p}_i$ avoid V_s. For this, we use the following two results

▶ **Theorem 9** ([15]). *Let G be an (n, d, λ)-graph. For any two nodes s, t in G, the probability $p^k_{s,t}$ that a random walk starting in s and of length k ends in the node t, satisfies $|1/n - p^k_{s,t}| \leq (\lambda/d)^k$.*

▶ **Theorem 10** ([3]). *Let G be an (n, d, λ)-graph and let W be a set of w vertices in G and set $\mu = w/n$. Let $P(W, k)$ be the total number of length k paths ($k+1$ nodes) that stay in W. Then*

$$P(W, k) \leq wd^k(\mu + (\lambda/d)(1-\mu))^k.$$

Now consider one of the length $3\lg_{d/\lambda}(n)$ random walks $\mathbf{p} = \mathbf{p}_i$ starting in t. To show that it is likely that the path intersects V_s, we split the random walk $\mathbf{p} = (t, \mathbf{v}_1, \dots, \mathbf{v}_{3\lg_{d/\lambda}(n)+1})$ into two parts, namely the first $2\lg_{d/\lambda}(n)$ steps $\mathbf{p}^{(1)} = (t, \mathbf{v}_1, \dots, \mathbf{v}_{2\lg_{d/\lambda}(n)+1})$ and the remaining $\lg_{d/\lambda}(n)$ steps $\mathbf{p}^{(2)} = (\mathbf{v}_{2\lg_{d/\lambda}(n)+1}, \dots, \mathbf{v}_{3\lg_{d/\lambda}(n)+1})$. Note that we let the last node $e(\mathbf{p}^{(1)}) = \mathbf{v}_{2\lg_{d/\lambda}(n)+1}$ in $\mathbf{p}^{(1)}$ equal the first node $s(\mathbf{p}^{(2)}) = \mathbf{v}_{2\lg_{d/\lambda}(n)+1}$ in $\mathbf{p}^{(2)}$. We use $\mathbf{p}^{(1)}$ to argue that $\mathbf{p}^{(2)}$ has a near-uniform random starting node. We then argue that $\mathbf{p}^{(2)}$ intersects V_s with good probability.

By Theorem 9, it holds for any node $r \in G$ that $\Pr[e(\mathbf{p}^{(1)}) = r] \leq 1/n + 1/n^2$. Next, conditioned on $e(\mathbf{p}^{(1)}) = r$, the path $\mathbf{p}^{(2)}$ is uniform random among the $d^{\lg_{d/\lambda}(n)}$ length $\lg_{d/\lambda}(n)$ paths starting in r. It follows that for any fixed path p of length $\lg_{d/\lambda}(n)$ in G, we have $\Pr[\mathbf{p}^{(2)} = p] \leq \Pr[e(\mathbf{p}^{(1)}) = s(p)]d^{-\lg_{d/\lambda}(n)} \leq (1/n + 1/n^2)d^{-\lg_{d/\lambda}(n)}$. Now by Theorem 10 with $W = V(G) \setminus V_s$ and assuming $\lambda \leq d/2$, there are at most $nd^{\lg_{d/\lambda}(n)}((1 - k/n) + (\lambda/d)(k/n))^{\lg_{d/\lambda}(n)} \leq nd^{\lg_{d/\lambda}(n)}(1-k/(2n))^{\lg_{d/\lambda}(n)} \leq nd^{\lg_{d/\lambda}(n)} \exp(-\lg_{d/\lambda}(n)k/(2n))$ paths in G that stay within $V(G) \setminus V_s$. A union bound over all of them implies that the probability that $\mathbf{p}^{(2)}$ avoids V_s is at most

$$(1/n + 1/n^2)d^{-\lg_{d/\lambda}(n)} nd^{\lg_{d/\lambda}(n)} \exp(-\lg_{d/\lambda}(n)k/(2n)) \leq \exp(-\lg_{d/\lambda}(n)k/(2n) + 1/n).$$

Since the $\tau = k/(3\lg_{d/\lambda}(n))$ random walks $\mathbf{p}_1, \dots, \mathbf{p}_\tau$ are independent, we conclude that the probability they all avoid V_s is no more than

$$\exp(-k^2/(6n) + k/(3\lg_{d/\lambda}(n)n)).$$

Letting $k = \sqrt{7n\ln(1/\delta)}$ and assuming n is at least some sufficiently large constant, we have that at least one path $\mathbf{p}_i$ intersects V_s with probability at least $1 - \delta$. This completes the proof of Theorem 4.

3 Lower Bounds

In this section, we prove lower bounds on the number of queries made by any algorithm for computing an s-t path in a random graph. Our query model allows *node-incidence queries*. Here the n nodes of a graph G are assumed to be labeled by the integers $[n]$. A node-incidence query is specified by a node index $i \in [n]$, and the query algorithm is returned the list of edges (i, j) incident to i.

We start by considering an Erdős-Rényi random graph, as it is the simplest to analyse. We then proceed to random d-regular graphs. For the lower bounds, the task is to output a path between nodes $s = 1$ and $t = n$. An algorithm for finding an s-t path works as follows: In each step, the algorithm is allowed to ask one node-incidence query. We make no assumption about how the algorithm determines which query to make in each step, other than it being computable from all edges seen so far (the responses to the node-incidence queries). For randomized algorithms, the choice of query in each step is chosen randomly from a distribution over queries computable from all edges seen so far.

3.1 Erdős-Rényi

Let $\mathbf{G}$ be an Erdős-Rényi random graph, where each edge is present independently with probability $p \geq 1.5\ln(n)/n$ and let $\mathcal{A}^\star$ be a possibly randomized algorithm for computing an s-t path in $\mathbf{G}$ when $s = 1$ and $t = n$. Let $\alpha^\star$ be the probability that $\mathcal{A}^\star$ outputs a *valid* s-t path (all edges on the reported path are in $\mathbf{G}$) and let q be the worst case number of queries made by $\mathcal{A}^\star$ (for $\mathcal{A}^\star$ making an expected q queries, we can always make it worst case $O(q)$ queries by decreasing α by a small additive constant). Here the probability is over both the random choices of $\mathcal{A}^\star$ and the random input graph $\mathbf{G}$. By linearity of expectation, we may fix the random choices of $\mathcal{A}^\star$ to obtain a deterministic algorithm $\mathcal{A}$ that outputs a valid s-t path with probability $\alpha \geq \alpha^\star$. It thus suffices to prove an upper bound on α for such deterministic $\mathcal{A}$.

For a graph G, let $\pi(G)$ denote the *trace* of running the deterministic $\mathcal{A}$ on G. If $i_1(G), \ldots, i_q(G)$ denotes the sequence of queries made by $\mathcal{A}$ on G and $\mathcal{N}_1(G), \ldots, \mathcal{N}_q(G)$ denotes the returned sets of edges, then

$$\pi(G) := (i_1(G), \mathcal{N}_1(G), i_2(G), \ldots, i_q(G), \mathcal{N}_q(G)).$$

Observe that if we condition on a particular trace $\tau = (i_1, N_1, i_2, \ldots, i_q, N_q)$, then the distribution of $\mathbf{G}$ conditioned on $\pi(\mathcal{A}, \mathbf{G}) = \tau$ is the same as if we condition on the set of edges incident to $i_1, \ldots, i_q$ being precisely $N_1, \ldots, N_q$. This is because the algorithm $\mathcal{A}$ is deterministic and the execution of $\mathcal{A}$ is the same for all graphs G with the same such sets of edges incident to $i_1, \ldots, i_q$. Furthermore, no graph G with a different set of incident edges for $i_1, \ldots, i_q$ will result in the trace τ.

For a trace $\tau = (i_1, N_1, \ldots, i_q, N_q)$, call the trace *connected* if there is a path from s to t using the *discovered* edges

$$\bigcup_{j=1}^{q} N_j.$$

Otherwise, call it *disconnected.* Intuitively, if a trace is disconnected, then it is unlikely that $\mathcal{A}$ will succeed in outputting a valid path connecting s and t as it has to guess some of the edges along such a path. Furthermore, if $\mathcal{A}$ makes too few queries, then it is unlikely that the trace is connected. Letting $\mathcal{A}(G)$ denote the output of $\mathcal{A}$ on the graph G, we have for a random graph $\mathbf{G}$ that

$$\alpha = \Pr[\mathcal{A}(\mathbf{G}) \text{ is valid}] \leq \Pr[\pi(\mathbf{G}) \text{ is connected}] + \Pr[\mathcal{A}(\mathbf{G}) \text{ is valid} \mid \pi(\mathbf{G}) \text{ is disconnected}].$$

We now bound the two quantities on the right hand side separately.

The simplest term to bound is

$$\Pr[\mathcal{A}(\mathbf{G}) \text{ is valid} \mid \pi(\mathcal{A}, \mathbf{G}) \text{ is disconnected}].$$

For this, let $\tau = (i_1, N_1, \ldots, i_q, N_q)$ be an arbitrary disconnected trace in the support of $\pi(\mathbf{G})$ when $\mathbf{G}$ is an Erdős-Rényi random graph, where each edge is present with probability $p \geq 1.5\ln(n)/n$. Observe that the output of $\mathcal{A}$ is determined from τ. Since τ is disconnected, the path reported by $\mathcal{A}$ on τ must contain at least one edge (u, v) where neither u nor v is among $\cup_j\{i_j\}$ or otherwise the output path is valid with probability 0 conditioned on τ. But conditioned on the trace τ, every edge that is not connected to $\{i_1, \dots, i_q\}$ is present independently with probability p. We thus conclude

$$\Pr[\mathcal{A}(\mathbf{G}) \text{ is valid} \mid \pi(\mathbf{G}) = \tau] \le p.$$

Since this holds for every disconnected τ, we conclude

$$\Pr[\mathcal{A}(\mathbf{G}) \text{ is valid} \mid \pi(\mathbf{G}) \text{ is disconnected}] \le p.$$

Next we bound the probability that $\pi(\mathbf{G})$ is connected. For this, define for $1 \le k \le q$

$$\pi_k(G) := (i_1(G), \mathcal{N}_1(G), i_2(G), \dots, i_k(G), \mathcal{N}_k(G))$$

as the trace of $\mathcal{A}$ on G after the first k queries. As for $\pi(G)$, we say that $\pi_k(G)$ is connected if there is a path from s to t using the discovered edges

$$E(\pi_k(G)) = \bigcup_{j=1}^{k} \mathcal{N}_j(G)$$

and that it is disconnected otherwise. We further say that $\pi_k(G)$ is *useless* if it is both disconnected and $|E(\pi_k(G))| \le 2pnk$. Since

$$\Pr[\pi_k(\mathbf{G}) \text{ is disconnected}] \ge \Pr[\pi_k(\mathbf{G}) \text{ is useless}]$$

we focus on proving that $\Pr[\pi_k(\mathbf{G})$ is useless$]$ is large. For this, we lower bound

$$\Pr[\pi_k(\mathbf{G}) \text{ is useless} \mid \pi_{k-1}(\mathbf{G}) \text{ is useless}].$$

Note that the base case $\pi_0(\mathbf{G})$ is defined to be useless as s and t are not connected when no queries have been asked and also $|E(\pi_0(G))| = 0 \le 2pn0 = 0$. Let $\tau_{k-1} = (i_1, N_1, \dots, i_{k-1}, N_{k-1})$ be any useless trace. The query $i_k = i_k(\mathbf{G})$ is uniquely determined when conditioning on $\pi_{k-1}(\mathbf{G}) = \tau_{k-1}$ and so is the edge set $E_{k-1} = E(\pi_{k-1}(\mathbf{G}))$. Furthermore, we know that $|E_{k-1}| \le 2pn(k-1)$. We now bound the probability that the query i_k discovers more than $2pn$ new edges. If i_k has already been queried, no new edges are discovered and the probability is 0. So assume $i_k \notin \{i_1, \dots, i_{k-1}\}$. Now observe that conditioned on $\pi_{k-1}(\mathbf{G}) = \tau_{k-1}$, the edges (i_k, i) where $i \notin \{i_1, \dots, i_{k-1}\}$ are independently included in $\mathbf{G}$ with probability p each. The number of new edges discovered is thus a sum of $m \le n$ independent Bernoullis $\mathbf{X}_1, \dots, \mathbf{X}_m$ with success probability p. A Chernoff bound implies $\Pr[\sum_i \mathbf{X}_i > (1+\delta)\mu] < (e^\delta/(1+\delta)^{1+\delta})^\mu$ for any $\mu \ge mp$ and any $\delta > 0$. Letting $\mu = np$ and $\delta = 1$ gives

$$\Pr[\sum_i \mathbf{X}_i > 2np] < (e/4)^{np} < e^{-np/3}.$$

Since we assume $p > 1.5\ln(n)/n$, this is at most $1/\sqrt{n}$.

We next bound the probability that the discovered edges $\mathcal{N}_k(\mathbf{G})$ makes s and t connected in $E(\pi_k(\mathbf{G}))$. For this, let V_s denote the nodes in the connected component of s in the subgraph induced by the edges E_{k-1}. Define V_t similarly. We split the analysis into three cases. First, if $i_k \in V_s$, then $\mathcal{N}_k(\mathbf{G})$ connects s and t if and only if one of the edges $\{i_k\} \times V_t$ is in $\mathbf{G}$. Conditioned on $\pi_{k-1}(\mathbf{G}) = \tau_{k-1}$, each such edge is in $\mathbf{G}$ independently either with probability 0, or with probability p (depending on whether one of the end points is in $\{i_1, \dots, i_{k-1}\}$). A union bound implies that s and t are connected in $E(\pi_k(\mathbf{G}))$ with probability at most $p|V_t|$. A symmetric argument upper bounds the probability by $p|V_s|$ in case $i_k \in V_t$. Finally, if i_k is in neither of V_s and V_t, it must have an edge to both a node in V_s and in V_t to connect s and t. By independence, this happens with probability at most $p^2|V_t||V_s|$. We thus conclude that

$$\Pr[\pi_k(\mathbf{G}) \text{ is connected} \mid \pi_{k-1}(\mathbf{G}) = \tau_{k-1}] \leq p \max\{|V_s|, |V_t|\} \leq p(|E_{k-1}| + 1) \leq 2p^2nk.$$

A union bound implies

$$\Pr[\pi_k(\mathbf{G}) \text{ is useless} \mid \pi_{k-1}(\mathbf{G}) \text{ is useless}] \geq 1 - 2p^2nk - 1/\sqrt{n}.$$

This finally implies

$$\begin{aligned}
\Pr[\pi(\mathbf{G}) \text{ is useless}] &= \prod_{k=1}^{q} \Pr[\pi_k(\mathbf{G}) \text{ is useless} \mid \pi_{k-1}(\mathbf{G}) \text{ is useless}] \\
&\geq \prod_{k=1}^{q} \left(1 - 2p^2nk - 1/\sqrt{n}\right) \\
&\geq 1 - \sum_{k=1}^{q} (2p^2nk + 1/\sqrt{n}) \\
&\geq 1 - p^2n(q+1)^2 - q/\sqrt{n}.
\end{aligned}$$

It follows that

$$\begin{aligned}
\Pr[\pi(\mathbf{G}) \text{ is connected}] &= 1 - \Pr[\pi(\mathbf{G}) \text{ is disconnected}] \\
&\leq 1 - \Pr[\pi(\mathbf{G}) \text{ is useless}] \\
&\leq p^2n(q+1)^2 + q/\sqrt{n}.
\end{aligned}$$

For $q = o(1/(p\sqrt{n}))$ and $p \geq 1.5 \ln(n)/n$, this is $o(1)$. Note that for the lower bound to be meaningful, we need $p = O(1/\sqrt{n})$ as otherwise the bound on q is less than 1. (Indeed, for $p = \Omega(1/\sqrt{n})$, s and t have a common neighbor with probability bounded away from 0 and if so 2 queries suffice). This concludes the proof of Theorem 5.

3.2 d-Regular Graphs

We now proceed to random d-regular graphs. Assume dn is even, as otherwise a d-regular graph on n nodes does not exist. Similarly to our proof for the Erdős-Rényi random graphs, we will condition on a trace of $\mathcal{A}$. Unfortunately, the resulting conditional distribution of a random d-regular graph is more cumbersome to analyse. We thus start by reducing to a slightly different problem.

Let $\mathcal{M}_{n,d}$ denote the set of all graphs on nd nodes where the edges form a perfect matching on the nodes. There are thus $nd/2$ edges in any such graph. We think of the nodes of a graph $G \in \mathcal{M}_{n,d}$ as partitioned into n groups of d nodes each, and we index the nodes by integer pairs (i, j) with $i \in [n]$ and $j \in [d]$. Here i denotes the index of the group. For a graph $G \in \mathcal{M}_{n,d}$ and a sequence of group indices $p := s, i_1, \dots, i_m, t$, we say that p is a valid s-t *meta-path* in G, if for every two consecutive indices a, b in p, there is at least one edge $((a, j_1), (b, j_2))$ in G. A meta-path is thus a valid path if and only if s and t are connected in the graph resulting from contracting the nodes in each group.

Now consider the problem of finding a valid s-t meta-path in a graph $\mathbf{G}$ drawn uniformly from $\mathcal{M}_{n,d}$ (we write $\mathbf{G} \sim \mathcal{M}_{n,d}$ to denote such a graph) while asking *group-incidence queries*. A group-incidence query is specified by a group index $i \in [n]$ and the answer to the query is the set of edges incident to the nodes $\{i\} \times \{1, \ldots, d\}$.

We start by showing that an algorithm $\mathcal{A}^\star$ for finding an s-t path in a random d-regular n-node graph, gives an algorithm $\mathcal{A}$ for finding an s-t meta-path in a random $\mathbf{G} \sim \mathcal{M}_{n,d}$ using group-incidence queries.

▶ **Lemma 11.** *If there is a (possibly randomized) algorithm $\mathcal{A}^\star$ that reports a valid s-t path with probability α in a random d-regular graph on n nodes while making q node-incidence queries, then there is a deterministic algorithm $\mathcal{A}$ that reports a valid s-t meta-path with probability at least* $\exp(-O(d^2))\alpha$ *in a random graph $\mathbf{G} \sim \mathcal{M}_{n,d}$ while making q group-incidence queries.*

Proof. Given an algorithm $\mathcal{A}^\star$ that reports a valid s-t path in a random d-regular graph on n nodes with probability α, we start by fixing its randomness to obtain a deterministic algorithm $\mathcal{A}'$ with the same number of queries that outputs a valid s-t path with probability at least α. Next, let $\mathbf{G} \sim \mathcal{M}_{n,d}$. Let $i_1 \in [n]$ be the first node that $\mathcal{A}'$ queries (which is independent of the input graph). Our claimed algorithm $\mathcal{A}$ for reporting an s-t meta-path in $\mathbf{G}$ starts by querying the group i_1. Upon being returned the set of edges $\{((i_1, 1), (j_1, k_1)), \ldots, ((i_1, d), (j_d, k_d))\}$ incident to $\{i_1\} \times \{1, \ldots, d\}$, we *contract* the groups such that each edge $((i_1, h), (j, k))$ is replaced by (i_1, j). If this creates any duplicate edges or self-edges, $\mathcal{A}$ aborts and outputs an arbitrarily chosen s-t meta-path. Otherwise, the resulting set of edges $\{(i_1, j_1), \ldots, (i_1, j_d)\}$ is passed on to $\mathcal{A}'$ as the response to the first query i_1. The next query i_2 of $\mathcal{A}'$ is then determined and we again ask it as a group-incidence query on $\mathbf{G}$ and proceed by contracting groups in the returned set of edges and passing the result to $\mathcal{A}'$ if there are no duplicate or self-edges. Finally, if we succeed in processing all q queries of $\mathcal{A}'$ without encountering duplicate or self-edges, $\mathcal{A}$ outputs the s-t path reported by $\mathcal{A}'$ as the s-t meta-path.

To see that this strategy has the claimed probability of reporting a valid s-t meta-path, let $\mathbf{G}^\star$ be the graph obtained from $\mathbf{G}$ by contracting *all* groups. Observe that if we condition on $\mathbf{G}^\star$ being a simple graph (no duplicate edges or self-edges), then the conditional distribution of $\mathbf{G}^\star$ is precisely that of a random d-regular graph on n nodes. It is well-known [5, 8, 22, 21] that the contracted graph $\mathbf{G}^\star$ is indeed simple with probability at least $\exp(-O(d^2))$ and the claim follows. ◀

In light of Lemma 11, we thus set out to prove lower bounds for deterministic algorithms that report an s-t meta-path in a random $\mathbf{G} \sim \mathcal{M}_{n,d}$ using group-incidence queries.

Let $\mathcal{A}$ be a deterministic algorithm making q group-incidence queries that reports a valid s-t meta-path with probability α in a random $\mathbf{G} \sim \mathcal{M}_{n,d}$. Similarly to our proof for Erdős-Rényi graphs, we start by defining the trace of $\mathcal{A}$ on a graph $G \in \mathcal{M}_{n,d}$. If $i_1(G), \ldots, i_q(G) \in [n]$ denotes the sequence of group-incidence queries made by $\mathcal{A}$ on G and $\mathcal{N}_1(G), \ldots, \mathcal{N}_q(G)$ denotes the returned sets of edges, then for $1 \le k \le q$, we define

$$\pi_k(G) = (i_1(G), \mathcal{N}_1(G), \ldots, i_k(G), \mathcal{N}_k(G)).$$

We also let $\pi(G) := \pi_q(G)$ denote the full trace. Call a trace $\tau_k = (i_1, N_1, \ldots, i_k, N_k)$ connected if there is a sequence of group indices $p := s, i_1, \ldots, i_m, t$ such that for every two consecutive indices a, b in p, there is an edge $((a, h), (b, k))$ in $\cup_i N_i$. Otherwise, call the trace disconnected. Letting $\mathcal{A}(G)$ denote the output of $\mathcal{A}$ on the graph G, we have

$$\alpha = \Pr[\mathcal{A}(\mathbf{G}) \text{ is valid}] \le \Pr[\pi(\mathbf{G}) \text{ is connected}] + \Pr[\mathcal{A}(\mathbf{G}) \text{ is valid} \mid \pi(\mathbf{G}) \text{ is disconnected}].$$

We bound the two terms separately, starting with the latter. So let $\tau = (i_1, N_1, \ldots, i_q, N_q)$ be a disconnected trace in the support of $\pi(\mathbf{G})$. The output meta-path $\mathcal{A}(\mathbf{G}) = p = s, i_1, \ldots, i_m, t$ of $\mathcal{A}$ is determined from τ. Since τ is disconnected, there must be a pair of consecutive indices a, b in p such that there is no edge $((a,h),(b,k)) \in \cup_i N_i$. Fix such a pair a, b. We now consider two cases. First, if either a or b is among $i_1, \ldots, i_q$, then all edges incident to that group are among $\cup_i N_i$ conditioned on $\pi(\mathbf{G}) = \tau$. It thus follows that p is a valid s-t meta-path with probability 0 conditioned on $\pi(\mathbf{G}) = \tau$. Otherwise, neither of a and b are among $i_1, \ldots, i_q$. The set of edges $\cup_i N_i$ specify at most dq edges of the matching $\mathbf{G}$. For any node whose matching edge is not specified by $\cup_i N_i$, the conditional distribution of its neighbor is uniform random among all other nodes whose matching edge is not in $\cup_i N_i$. For each of the d^2 possible edges $((a,h),(b,k))$ between the groups a and b, there is thus a probability at most $1/(nd - 1 - 2dq)$ that the edge is in $\mathbf{G}$ conditioned on $\pi(\mathbf{G}) = \tau$. A union bound over all d^2 such edges finally implies

$$\Pr[\mathcal{A}(\mathbf{G}) \text{ is valid} \mid \pi(\mathbf{G}) = \tau] \leq \frac{d^2}{nd - 1 - 2dq}.$$

Since this holds for every disconnected τ, we conclude

$$\Pr[\mathcal{A}(\mathbf{G}) \text{ is valid} \mid \pi(\mathbf{G}) \text{ is disconnected}] \leq \frac{d^2}{nd - 1 - 2dq}.$$

Next, to bound $\Pr[\pi(\mathbf{G}) \text{ is connected}]$, we show that

$$\Pr[\pi_k(\mathbf{G}) \text{ is disconnected} \mid \pi_{k-1}(\mathbf{G}) \text{ is disconnected}]$$

is large. So let $\tau_{k-1} = (i_1, N_1, \ldots, i_{k-1}, N_{k-1})$ be a disconnected trace in the support of $\pi_{k-1}(\mathbf{G})$. The next query $i_k = i_k(\mathbf{G})$ of $\mathcal{A}$ is fixed conditioned on $\pi_{k-1}(\mathbf{G}) = \tau_{k-1}$. We have a two cases. First, if $i_k \in \{i_1, \ldots, i_{k-1}\}$ then no new edges are returned by the query and we conclude

$$\Pr[\pi_k(\mathbf{G}) \text{ is disconnected} \mid \pi_{k-1}(\mathbf{G}) = \tau_{k-1}] = 1.$$

Otherwise, let V_s denote the subset of group-indices j for which there is a meta-path from s to j. Similarly, let V_t denote the subset of group-indices j for which there is a meta-path from t to j. We have $V_s \cap V_t = \emptyset$. Now if $i_k \in V_s$, we have that $\pi_k(\mathbf{G})$ is connected only if there is an edge between a node (i_k, j) with $j \in [d]$ and a node (b, k) with $b \in V_t$. Let $r \in \{0, \ldots, d\}$ denote the number of nodes (i_k, j) with $j \in [d]$ for which the corresponding matching edge is not in $\cup_i N_i$. Conditioned on $\pi_{k-1}(\mathbf{G}) = \tau_{k-1}$, the neighbor of any such node is uniform random among all other nodes for which the corresponding matching edge is not in $\cup_i N_i$. There are at least $nd - 1 - 2d(k-1)$ such nodes. A union bound over at most $rd|V_t| \leq d^2|V_t|$ pairs $((i_k, j),(b,k))$ implies that $\pi_k(\mathbf{G})$ is connected with probability at most $d^2|V_t|/(nd - 1 - 2d(k-1))$. A symmetric arguments gives an upper bound of $d^2|V_s|/(nd - 1 - 2d(k-1))$ in case $i_k \in V_t$. Finally, if i_k is in neither of V_s and V_t, then there must still be an edge $((i_k, j),(a,k))$ for a group $a \in V_s$. We thus conclude

$$\Pr[\pi_k(\mathbf{G}) \text{ is connected} \mid \pi_{k-1}(\mathbf{G}) = \tau_{k-1}] \leq \frac{d^2 \max\{|V_s|, |V_t|\}}{nd - 1 - 2d(k-1)} \leq \frac{d^3 k}{nd - 1 - 2dq}.$$

Since this holds for every disconnected trace τ_{k-1}, we finally conclude

$$\begin{aligned}\Pr[\pi(\mathbf{G}) \text{ is disconnected}] &\geq \prod_{k=1}^{q}\left(1-\frac{d^3k}{nd-1-2dq}\right)\\ &\geq 1-\sum_{k=1}^{q}\frac{d^3k}{nd-1-2dq}\\ &\geq 1-\frac{d^3q^2}{nd-1-2dq},\end{aligned}$$

and thus

$$\Pr[\pi(\mathbf{G}) \text{ is connected}] \leq \frac{d^3q^2}{nd-1-2dq}.$$

For constant degree d, if $q = o(\sqrt{n})$, this is $o(1)$. Together with Lemma 11, we have thus proved Theorem 6.

4 Large Diameter Expanders

In this section, we sketch the claim from Section 1 that there exists large diameter expanders. Concretely, using the techniques in [4] with a slightly different choice of parameters it is not difficult to show that there are (n', d, λ)-graphs with $\lambda < 3\sqrt{d}$ and diameter larger than $(2 - 0.003) \lg_{d-1} n'$ for constant d. Here is a sketch of the argument proving this fact.

Start with a Ramanujan $(n, d, 2\sqrt{d-1})$-graph, with girth $\Omega(\lg_{d-1} n)$ (for example, taking an LPS expander). Choose in it a set X of $2(d-1)^{0.999 \lg_{d-1} n}$ vertices so that the distance between any pair of them is $\Omega(\lg_{d-1} n)$. This can be done by choosing the vertices one by one, always adding a vertex far from all vertices chosen already. Omit these vertices and identify their $2d(d-1)^{0.999 \lg_{d-1} n}$ neighbors with the leaves of two d-regular trees, each of depth $0.999 \lg_{d-1} n$ and each having $d(d-1)^{0.999 \lg_{d-1} n}$ leaves. The graph obtained is d-regular and has n' vertices (the original n plus the vertices of the two trees). The distance between the roots of the two trees is clearly bigger than $(2 - 0.002) \lg_{d-1} n > (2 - 0.003) \lg_{d-1} n'$.

By the argument in [4] (see also [2], Lemma 3.2) based on the delocalization of eigenvectors of high girth graphs it is not difficult to show that the absolute value of every nontrivial eigenvalue of the graph obtained is smaller than $3\sqrt{d}$, implying the required fact. We omit the detailed computation.

Abstract

In this work we study quantum algorithms for Hopcroft's problem which is a fundamental problem in computational geometry. Given n points and n lines in the plane, the task is to determine whether there is a point-line incidence. The classical complexity of this problem is well-studied, with the best known algorithm running in $O(n^{4/3})$ time, with matching lower bounds in some restricted settings. Our results are two different quantum algorithms with time complexity $\widetilde{O}(n^{5/6})$. The first algorithm is based on partition trees and the quantum backtracking algorithm. The second algorithm uses a quantum walk together with a history-independent dynamic data structure for storing line arrangement which supports efficient point location queries. In the setting where the number of points and lines differ, the quantum walk-based algorithm is asymptotically faster. The quantum speedups for the aforementioned data structures may be useful for other geometric problems.

1 Introduction

In this work we investigate the quantum complexity of Hopcroft's problem, a classic problem in computational geometry. Given n lines and n points in the plane, it asks to determine whether some point lies on some line. In a line of research spanning roughly 40 years culminating with a recent paper by Chan and Zheng [19], the classical complexity has settled on $O(n^{4/3})$ time, with matching lower bounds in some models of computation [27]. Along with its natural setting, the problem also captures the essence of a class of other geometric problems with complexity $\widetilde{O}(n^{4/3})$ [26].

There are several reasons why we find Hopcroft's problem interesting in the quantum setting. Firstly, classical algorithms for this problem typically use data structures supporting some fundamental geometric query operations. For example, Hopcroft's problem can be reduced to the *simplex range searching*, in which the data structure stores the given points and each query asks whether a given region contains any of the points [4]. Another approach is to store the given lines instead and answer *point location queries*, that is, for a given point, determine which region of the line configuration it belongs to [40, 25]. Thus, Hopcroft's problem gives a good playground for improving and comparing the complexity

of ubiquitous geometric data structures quantumly. We are also interested in finding new *history-independent* data structures that can be used in quantum walk algorithms, following the ideas started with Ambainis' element distinctness algorithm [7] (see also [1, 15]).

Secondly, Hopcroft's problem is closely related to a large group of geometric tasks that can be solved in the same time $\widetilde{O}(n^{4/3})$. A speedup for Hopcroft's problem may automatically give an improvement for some of those. Erickson studied the class of such problems [26], some examples include detecting/counting intersections in a set of segments and detecting/counting points in a given set of regions. The problem can be also reduced to various other geometric problems, giving fine-grained lower bounds. For example, Hopcroft's problem in d dimensions (replacing lines with hyperplanes) can be reduced to halfspace range checking in $d+1$ dimensions for $d \geq 4$ (are all given points above all given hyperplanes?) and others [26].

In fact, Hopcroft's problem in d dimensions can also be equivalently formulated as follows: given two sets of vectors $\mathcal{A}, \mathcal{B} \in \mathbb{R}^{d+1}$, determine whether there are $a \in \mathcal{A}$, $b \in \mathcal{B}$ such that $\langle a, b\rangle = 0$ [46]. The famous Orthogonal Vectors problem (OV) in fine-grained complexity is a special case of Hopcroft's when $\mathcal{A}, \mathcal{B} = \{0,1\}^d$ [44, 3]. The complexities of these problems differ; if $|A| = |B| = n$, then, classically, the complexity of OV is $\Theta(n)$ in $O(1)$ dimensions [45] and $\Theta(n^{2-o(1)})$ in $\operatorname{polylog} n$ dimensions under SETH [2, 18]. In contrast, the complexity of Hopcroft's problem in d dimensions is $O(n^{2d/(d+1)})$ [19]. Quantumly, the complexity of OV was settled in [1]; for $O(1)$ dimensions, it is $\Theta(\sqrt{n})$ and for $\operatorname{polylog} n$ dimensions, $\Theta(n^{1+o(1)})$ under QSETH, the quantum analogue of SETH. In this work we also examine the quantum complexity of Hopcroft's problem in an arbitrary number of dimensions d.

In general, we are interested in investigating quantum speedups for computational geometry problems. In recent years, there have been several works researching this topic. First, Ambainis and Larka gave a nearly optimal $O(n^{1+o(1)})$ quantum algorithm for the Point-On-3-Lines (detecting whether three lines are concurrent among the n given) and similar problems [11]. This problem is closely connected to fine-grained complexity as well, as it is an instance of the 3-Sum-Hard problem class. Classically, it is conjectured that 3-Sum cannot be solved faster than $O(n^2)$; the authors also conjectured a quantum analogue that 3-Sum cannot be solved quantumly faster than $O(n)$, and Buhrman et al. used this conjecture to prove conditional quantum lower bounds on various geometrical problems [14]. Aaronson et al. studied the quantum complexity of the Closest Pair problem (finding the closest pair of points among the n given), proving an optimal $\widetilde{\Theta}(n^{2/3})$ running time in $O(1)$ dimensions using a quantum walk algorithm with a dynamic history-independent data structure for storing points that is able to detect ϵ-close pairs of points [1]. For Bipartite Closest Pair problem in d dimensions (finding the closest pair of points between two sets of size n), they gave an $O(n^{1-1/2d+\delta})$ time quantum algorithm for any $\delta > 0$. For more results in quantum algorithms for computational geometry, see [39, 38, 12, 42, 43, 31].

For Hopcroft's problem, the best classical results give complexity $O((nm)^{2/3} + m\log n + n\log m)$, where n and m are the number of lines and points, respectively. In d dimensions, these generalize to $O((nm)^{d/(d+1)} + m\log n + n\log m)$ complexity [19]. The first complexity is unconditionally optimal if the algorithm needs to list all incidences, since there exists a planar construction with $\Omega((nm)^{2/3})$ incidence pairs ([25], Section 6.5.). It is also believed to be optimal for detection as well, with matching lower bounds in some models [27]. The dependence on n and m is symmetric since Hopcroft's problem is self-dual, in the sense that there is a geometric transformation which maps lines to points and vice versa, while preserving the point-line incidences ([25], Section 14.3.).

Finally, quite often the quantum query complexity of a problem matches its time complexity, like in Unstructured Search [29, 13], Element Distinctness [9, 8, 32], Closest Pair [1], Claw Finding [41, 47], just to name a few. In other cases even the precise query complexity is not yet clear, for example, Triangle Finding [33] or Boolean Matrix Product Verification [16, 24]. In the case of Hopcroft's problem, its quantum query complexity can be easily characterized to be $\Theta((nm)^{1/3} + \sqrt{n} + \sqrt{m})$ from known results, see Theorem 5. The query-efficient algorithm does not immediately generalize to time complexity; therefore, the main focus here falls to improving the performance of the relevant classical data structures quantumly, which we find interesting.

1.1 Our results

In this work we show two quantum algorithms for Hopcroft's problem with time complexity $\widetilde{O}(n^{5/6})$. This constitutes a polynomial speedup over the classical $O(n^{4/3})$ time. We obtain our results by speeding up classical geometric data structures using different quantum techniques. We look at two underlying fundamental problems one usually encounters on the way to solve Hopcroft's problem.

1. **Simplex range searching.** In simplex range searching, the input is a set of n points in the d-dimensional space. A query then asks whether a given simplex contains any of the given points. The query may also ask to list or count the points in the simplex, among other variants [4]. Usually, there is some *preprocessing time* to precompute the data structure and some *query time* to answer each query. Classically, these complexities are well-understood; in a nutshell, a data structure of size m can be constructed in $\widetilde{O}(m)$ time and each query can then be answered in $\widetilde{O}(n/m^{1/d})$ time [35], and this is matched by lower bounds in the semigroup model [23, 22]. If the allowed memory size is linear, then preprocessing and query times become respectively $O(n \log n)$ and $O(n^{1-1/d})$ [17]. In this paper we require a variant of simplex range queries which we call *hyperplane emptiness queries*, where we have to determine whether a query hyperplane contains any of the given points. We show that quantumly we can speed up query time quadratically by using Montanaro's quantum algorithm for searching in the backtracking trees [36]:

   ▶ **Theorem 1.** *There is a bounded-error quantum algorithm that can answer hyperplane emptiness queries in $\widetilde{O}(\sqrt{n^{1-1/d}})$ time.*

   We note that this result is not really specific to the hyperplane emptiness queries, as all what we are doing is speeding up search in the *partition tree* data structure [17], thus this result can applied to other types of queries as well. However, this speedup does not extend to the counting version of simplex queries, since essentially, our procedure implements a search for a marked vertex in a tree using quantum walk. Using this result, we show a quantum speedup for Hopcroft's problem in d dimensions:

   ▶ **Theorem 2.** *There is a bounded-error quantum algorithm which solves Hopcroft's problem with n hyperplanes and $m \leq n$ points in d dimensions in time:*
   - $\widetilde{O}(n^{\frac{d}{2(d+1)}} m^{1/2})$, *if* $m \geq n^{\frac{d}{d+1}}$;
   - $\widetilde{O}(n^{1/2} m^{\frac{d-1}{2d}})$, *if* $m \leq n^{\frac{d}{d+1}}$.

   If $n = m$, then the algorithm has complexity $\widetilde{O}(n^{1-\frac{1}{2(d+1)}})$.

   In particular, the complexity is $\widetilde{O}(n^{5/6})$ in 2 dimensions for $n = m$.
2. **Planar point location.** The second approach is to use point location queries. One can use usually use classical point location data structures to determine whether a query point lies on the boundary of a planar region it belongs to. More specifically, we consider only *planar* point location data structures in the *line arrangements.* A set of n lines partitions the plane into $O(n^2)$ regions; this an old and well-researched topic, with many approaches to construct a data structure that holds the description of these regions in $O(n^2)$ time, the same amount of space and polylog n point location query time [25] (in fact, $O(n^d)$ preprocessing time and space and $O(\log n)$ query time in d dimensions [21, 20]).

In addition, there are also dynamic data structures with the same preprocessing and query times. More specifically, one can insert or remove a line in time $O(n)$ (or $O(n^{d-1})$ in d dimensions) [37]. We take an opportunity to employ such a data structure in a *quantum walk* algorithm on a Johnson graph to solve Hopcroft's problem. In particular, we develop a history-independent randomized data structure for storing an arrangement of an r-subset of n lines with ability to perform line insertion/removal in $O(r \operatorname{polylog} n)$ time and point location in $\operatorname{polylog} n$ time, requiring $O(r \operatorname{polylog} n)$ memory storage.

To do that, we store k-levels of the line arrangement in the history-independent skip lists a la Ambainis [9]. A k-level of a line arrangement is a set of segments of lines such that there are exactly k lines above each edge. Turns out that skip lists are ideal for encoding the k-levels. For example, when a new line is inserted, it splits each k-level in two parts, one of which will still belong to the k-level, but the other will belong to the $(k+1)$-level. We can then "reglue" these two tails to the correct levels of the arrangements in $\operatorname{polylog} n$ time by utilizing the properties of the skip list, all while keeping the history independence of the data structure. Using this data structure, we show the following quantum speedup for Hopcroft's problem in 2 dimensions:

▶ **Theorem 3.** *There is a bounded-error quantum algorithm that solves Hopcroft's problem with n lines and $m \leq n$ points in the plane in time:*

- $\widetilde{O}(n^{1/3}m^{1/2})$, *if* $n^{2/3} \leq m$;
- $\widetilde{O}(n^{2/5}m^{2/5})$, *if* $n^{1/4} \leq m \leq n^{2/3}$;
- $\widetilde{O}(n^{1/2})$, *if* $m \leq n^{1/4}$.

In particular, the complexity is $\widetilde{O}(n^{5/6})$ when $n = m$.

Both of Theorems 2 and 3 have their pros and cons. Theorem 2 is arguably simpler, since it is a quite direct application of the quantum speedup for backtracking. It also has a lower polylogarithmic factor hidden in the $\widetilde{O}$ notation, only $\log n$ compared to $\log^6 n$ in Theorem 3. However, Theorem 3 gives better asymptotic complexity if the number of lines n differ from the number of points m. On the other hand, Theorem 2 gives a speedup in the case of an arbitrary number of dimensions, while Theorem 3 has something to say only about the planar case; we leave a possible generalization of the quantum walk approach to larger dimensions for future research.

2 Preliminaries

We assume that the sets of points and lines are both in a general position (no two lines are parallel, no three lines intersect at the same point, no three points lie on the same line). Our algorithms work in the standard quantum circuit model augmented with Quantum Random Access Gates that allow to perform read/write operations in superposition; for details, see Appendix A. One of our building blocks is the following version of Grover's search:

▶ **Theorem 4** (Grover's search with bounded-error inputs [5, 30])**.** *Let $\mathcal{A} : [N] \to \{0,1\}$ be a bounded-error quantum procedure with running time T. Then there exists a bounded-error quantum algorithm that computes $\bigvee_{i\in[N]} \mathcal{A}(i)$ with running time $O(\sqrt{N}(T + \log N))$.*

Effectively, this result states that even if the inputs to Grover's search are faulty with constant probability, no error boosting is necessary, which would add another logarithmic factor to the complexity. We say that an algorithm is *bounded-error* if its probability of incorrect output is some constant strictly less than 1/2.

3 Query complexity

Before examining time-efficient quantum algorithms, we take a look at the quantum query complexity of Hopcroft's problem, which in this case can be fully characterized. We assume that with a single query, we can obtain the description of any given line or point. In Appendix B, we prove the following:

▶ **Theorem 5.** *The quantum query complexity of Hopcroft's problem on n lines and m points in two dimensions is $\Theta(n^{1/3}m^{1/3} + \sqrt{n} + \sqrt{m})$.*

In particular, this proves that Theorem 3 is asymptotically optimal for $m \le n^{1/4}$. The query complexity and the complexities of our algorithms are shown graphically in Figure 1.

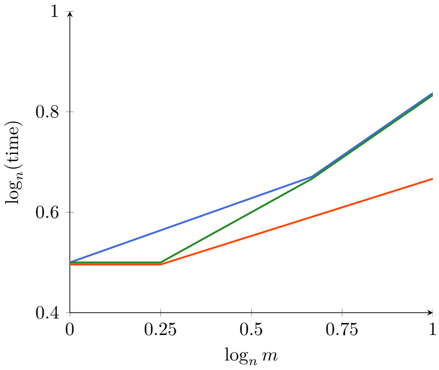

Figure 1 Quantum complexity of Hopcroft's problem in 2 dimensions on n lines and m points, assuming $m \le n$. The blue line shows the complexity of the quantum algorithm with the partition tree (Theorem 2); the green line shows the complexity of the quantum walk algorithm with the line arrangement data structure (Theorem 3); the red line shows the query complexity (Theorem 5).

The upper bound in Theorem 5 is given by the algorithm of Tani [41]. There is an obvious hurdle in implementing it in the same time complexity here. Their quantum walk would require a history-independent dynamic data structure for storing a set of lines and a set of points supporting the detection of incidence existence. Even assuming the most optimistic quantum versions of the known data structures, the sufficiently powerful speedup looks unfeasible. The next two sections describe the algorithms we have obtained by speeding up two fundamental geometrical query data structures quantumly.

4 Algorithm 1: quantum backtracking with partition trees

We begin with a brief overview of the classical partition tree data structure and its quantum speedup, and then proceed with the description of the quantum algorithm.

4.1 Partition trees

The partition tree is a classical data structure designed for the task of *simplex range searching*. In this problem, one is given n points in a d-dimensional space; the task is to answer queries where the input is a simplex and the answer is the number of points inside that simplex. The *partition tree* is a well-known data structure which can be used to solve this task [4].

This data structure can be described as a tree in the following way. The tree stores n points and each subtree stores a subset of these points. Each interior vertex v is attributed with a simplex $\Delta(v)$ such that all of the points stored in this subtree belong to the interior of $\Delta(v)$. For each interior vertex v, the subsets of the points stored in its children subtrees form a partition of the points stored in the subtree of v. Each leaf vertex stores a constant number of points in a list. For our purposes, each interior vertex is attributed only with information about its children and no information about the points stored in its subtree.

In this work, we are interested in the *hyperplane emptiness queries.* Given n points in the d-dimensional space, the task is to answer queries where the input is an arbitrary hyperplane and the answer is whether there is a point that lies on the given hyperplane. These queries can also be answered using partition trees:

▶ **Lemma 6** (Hyperplane emptiness query procedure)**.** *Let $\mathcal{T}$ be a partition tree storing a set of points. Let the* tree query cost *$c(\mathcal{T})$ be the maximum number of simplices of $\mathcal{T}$ that intersect an arbitrary hyperplane. Then the hyperplane emptiness query can be answered in $O(c(\mathcal{T}))$ time.*

Proof. The procedure for answering a query is as follows. We start at the root and traverse $\mathcal{T}$ recursively. If the current vertex is an interior vertex v and the query hyperplane is h, then we recurse only in the children of v such that $\Delta(v)$ intersects h. If the current vertex is a leaf vertex, we check whether any of its points lies on h. The running time is evidently linear in the number of simplices intersecting h. ◀

There are different ways to construct partition trees, but a long chain of works in computational geometry resulted in an optimal version of the partition tree [17]. Even though their goal is to answer simplex queries, in fact the main result gives an upper bound on $c(\mathcal{T})$ for their partition tree:

▶ **Theorem 7** (Partition tree [17])**.** *For any set of n points in d dimensions, there is a partition tree $\mathcal{T}$ such that:*

- *it can be built in $O(n \log n)$ time and requires $O(n)$ space;*
- *$c(\mathcal{T}) = O(n^{1-1/d})$; hence, a hyperplane emptiness query requires $O(n^{1-1/d})$ time;*
- *each vertex has $O(1)$ children and the depth of the tree is $O(\log n)$.*

To speed up the emptiness query time of the partition tree quantumly we use the quantum backtracking algorithm [36]. Their quantum algorithm searches for a *marked* vertex in a tree $\mathcal{S}$. The markedness is defined by a black-box function $P : V(\mathcal{T}) \to \{\textsc{true}, \textsc{false}, \textsc{indeterminate}\}$. For leaf vertices v, we have $P(v) \in \{\textsc{true}, \textsc{false}\}$. A vertex v is marked if $P(v) = \textsc{true}$, and the task is to determine whether $\mathcal{S}$ contains a marked vertex.

The root of $\mathcal{S}$ is known and the rest of the tree is given by two other black-box functions. The first, given a vertex v, returns the number of children $d(v)$ of v. The second, given v and an index $i \in [d(v)]$, returns the i-th child of v. The main result is a quantum algorithm for detecting a marked vertex in $\mathcal{S}$:

▶ **Theorem 8** (Quantum algorithm for backtracking [36, 10])**.** *Suppose you are given a tree $\mathcal{S}$ by the black boxes described above and upper bounds T and h on the size and the height of the tree. Additionally suppose that each vertex of $\mathcal{S}$ has $O(1)$ children. Then there is a bounded-error quantum algorithm that detects a marked vertex in $\mathcal{S}$ with query and time complexity $O(\sqrt{Th})$.*

When we apply it to the partition tree from Theorem 7, we get:

▶ **Theorem 1.** *There is a bounded-error quantum algorithm that can answer hyperplane emptiness queries in $\widetilde{O}(\sqrt{n^{1-1/d}})$ time.*

Proof. The procedure of Lemma 6 examines a subtree $\mathcal{S}$ of $\mathcal{T}$. We will apply Theorem 8 to $\mathcal{S}$. Suppose that h is a query hyperplane. The black box P returns INTERMEDIATE for any interior vertex v and for a leaf vertex v returns TRUE iff some point stored in v lies on h. The second black box returns the number of children of v in $\mathcal{T}$ if $\Delta(v)$ intersects h and 0 otherwise. The black box returning the i-th child simply fetches it from the partition tree that is stored in memory. All of these black boxes require only constant time to implement. Since we know that $|\mathcal{S}| = O(n^{1-1/d})$ and the height of $\mathcal{S}$ is $O(\log n)$ from Theorem 7, there is a quantum algorithm that solves the problem in $O(\sqrt{n^{1-1/d} \cdot \log n})$ time by Theorem 8. ◀

4.2 Quantum algorithm

Now we can apply the previous theorem to Hopcroft's problem.

▶ **Theorem 2.** *There is a bounded-error quantum algorithm which solves Hopcroft's problem with n hyperplanes and $m \le n$ points in d dimensions in time:*

- $\widetilde{O}(n^{\frac{d}{2(d+1)}} m^{1/2})$, *if* $m \ge n^{\frac{d}{d+1}}$;
- $\widetilde{O}(n^{1/2} m^{\frac{d-1}{2d}})$, *if* $m \le n^{\frac{d}{d+1}}$.

If $n = m$, then the algorithm has complexity $\widetilde{O}(n^{1-\frac{1}{2(d+1)}})$.

Proof. In the first case, we partition the whole set of points into m/r groups of size $r = n^{\frac{d}{d+1}}$. Using Grover's search, we search for a group that contains a point belonging to some line. To determine whether it's true for a fixed group, first we build a partition tree of Theorem 7 to store these points. Then we run Grover's search over all lines and determine whether a line contains some point from the group using the quantum query procedure from Theorem 1. Overall, the complexity of this algorithm (without logarithmic factors) is

$$O\left(\sqrt{\frac{m}{r}}\left(r + \sqrt{n} \cdot \sqrt{r^{1-1/d} \cdot \log r}\right)\right) = O\left(\sqrt{mr} + \sqrt{\frac{nm}{r^{1/d}} \log r}\right) = O\left(\sqrt{mn^{\frac{d}{d+1}} \log n}\right)$$

If we use the variation of Grover's search with bounded-error inputs (Theorem 4), then we do not incur extra logarithmic factors. If $m \le n^{\frac{d}{d+1}}$, then we simply build the partition tree on all m points, then use Grover's search over all lines and query the partition tree for each of them. The complexity in that case is

$$O\left(m \log m + \sqrt{n} \cdot \left(\sqrt{m^{1-1/d} \cdot \log m} + \log n\right)\right) = O\left(\sqrt{nm^{1-1/d}} \cdot \log n\right),$$

because the second term dominates the first (up to logarithmic factors). ◀

5 Algorithm 2: quantum walk with line arrangements

First we describe a classical history-independent data structure for storing an arrangement of a set of lines. After that, we describe the quantum walk algorithm that uses it for solving Hopcroft's problem.

5.1 Line arrangements

We begin with a few definitions (for a thorough treatment, see e.g. [25]). For a set of lines L, the *line arrangement* $\mathcal{A}(L)$ is the partition of the plane into connected regions bounded by the lines. The convex regions with no other lines crossing them are called *cells* and their sides are called the *edges* of the arrangement (note that some cells may be infinite). The intersection points of the lines are called the *vertices* of the arrangement.

For a set of lines L in a general position, the *k-level* is the set of edges of $\mathcal{A}(L)$ such that there are exactly k lines above each edge (for the special case of a vertical line, we consider points to the left of it to be "above"). By this construction each k-level forms a polygonal chain. Our data structure will store the line arrangement of a subset S of lines by keeping track of all $|S|$ levels, with each level being stored in a skip list. We will be able to support the following operations:

- Answering whether a point lies on some line in $O(\log^6 n)$ time.
- Inserting or removing a line in $O(|S| \log^4 n + \log^6 n)$ time.

5.2 Skip lists

We will need a history-independent data structure which can store a set of elements and support polylogarithmic time insertion/removal operations. For that purpose use the skip list data structure by Ambainis from the Element Distinctness algorithm [9]. Among other applications, it was also used by [1] for the Closest Pair problem, where they also gave a brief description. Here we shortly describe only the details required in our algorithm and rely on the facts already proved in these papers.

Suppose that the skip list stores some set of elements $S \subseteq [N]$, according to some order such that comparing two elements requires constant time. In a skip list, each element $i \in S$ is assigned an integer $\ell_i \in [0, \ldots, \ell_{\max}]$, where $\ell_{\max} = \lceil \log_2 N \rceil$. The skip list itself then consists of $\ell_{\max} + 1$ linked lists where the k-th list contains all $i \in S$ such that $\ell_i \geq k$. We will call the k-th linked list by the k-th layer (to not confuse them with k-levels). In other words, each element $i \in S$ is attributed with $\ell_i + 1$ pointers, where the k-th of them points to the smallest element j such that $j > i$ and $\ell_j \geq k$, or to `Null`, if there is no such j. The first element of the skip list is called the *head* and it only stores the $\ell_{\max}$ pointers, the beginnings of each layer (it is convenient to imagine this element storing value 0, which is smaller then any element of S).

The search of an element $i \in S$ is implemented in the following way. First, we traverse the $\ell_{\max}$-th layer to find the last element j such that $j \leq i$. If $j = i$, we are done; otherwise, traverse the layer below starting from j to find the last element $j' \leq i$ there. By repeating such iterations, we will find i. Insertion of $i \notin S$ is implemented similarly: first we find the last element $j_k \in S$ such that $j < i$, for all layers k. Then we update the pointers: for each layer $k \leq l_i$, we set the pointer from i to be be equal to the pointer from j_k; then we set the pointer from j_k to i. If an operation requires more than $O(\log^4 N)$ time, it is terminated.

To store the elements in memory, a specific hash table is used. Element's entry contains the description of the element together with other data attributed to it (in particular, the values of the pointers). We will not describe the details of the implementation, as it is the same as Ambainis'. The whole data structure can sometimes malfunction (e.g., the hash table buckets can overflow or the operation of the skip list can take too long), but it is shown in [9] that probability of such is small. More specifically, the probability that at least one operation malfunctions among $O(N)$ operations is only $O(1/\sqrt{N})$. Thus, as we are aiming at a sublinear algorithm, we don't need to worry about the error probability of the skip lists. We also note that the memory requirement of Ambainis' skip list is $O(r \log^3 N)$, if at most r elements need to be stored.

5.3 Data structure

Our data structure will operate mainly using the intersection points of the lines. To keep the unique description of the data for history independence, we describe each intersection point in the following way. Suppose the given lines are labeled $\ell_1, \ldots, \ell_n$. For any two lines ℓ_i and

ℓ_j, let $P_{i,j}$ be its intersection point. In an arrangement which includes both of these lines, we describe the left and right edges of ℓ_i connected to $P_{i,j}$ by $\texttt{left}(\ell_i, \ell_j)$ and $\texttt{right}(\ell_i, \ell_j)$. In that case there will be a k such that the k-level contains the edges $\texttt{left}(\ell_i, \ell_j)$ and $\texttt{right}(\ell_j, \ell_i)$, and the $(k+1)$-level contains the edges $\texttt{left}(\ell_j, \ell_i)$ and $\texttt{right}(\ell_i, \ell_j)$. We describe $P_{i,j}$ in the first case by the by the pair of integers $\nu_{i,j} = (i, j)$ and by $\nu_{j,i} = (j, i)$ in the second case, see Figure 2. We call these pairs *path points* of $P_{i,j}$. Note that we can calculate the coordinates of any path point in constant time as it description consists of the indices of the lines.

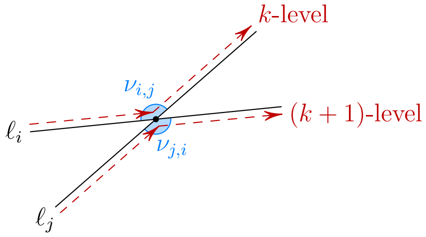

Figure 2 Path points of a line intersection.

Now we will describe the data structure, which stores an arrangement of a subset of given lines. It will operate with multiple skip lists each storing a set of path points of the arrangement. To ensure the unique representation of the data, we encode the pointers of the skip lists with the values of the path points themselves. To represent the beginning of a level from line ℓ_i, we use a "fictitious" starting path point $\nu_{i,i} = (i, i)$. The last element of skip lists we encode with a special "null" path point $\nu_{\texttt{Null}}$. We implement the following skip lists:

- The skip lists that contain the path points of the current k-levels in order from left to right. These skip lists are stored implicitly, since adding and removing lines changes the indexing of the levels and the levels themselves. For each path point ν stored in such a skip list, we additionally store an array $\texttt{Next}_\nu[0 \ldots l_{\max}]$ storing the values of next path points of its skip list for each skip list layer.
- $\texttt{Start}$ – contains the heads of all level skip lists in the current arrangement. If the first edge of a k-level belongs to ℓ_i, the head of its skip list is $\nu_{i,i}$, and we additionally store $\texttt{Next}_{\nu_{i,i}}$ to access the respective level skip list. The heads are ordered by the slope of the lines with the x-axis corresponding to the head path points.

Further we will describe the implementation of the operations.

5.3.1 Point location

To detect whether a point belongs to some line, we essentially binary search through all k-levels and check whether the given point is strictly above, below or belongs to that level. The binary search is implicitly performed by searching in the skip list $\texttt{Start}$. For a given level, we then search for its edge such that the x-coordinate of the point belongs to the projection of that edge on the x-axis. When this edge is found, we check the relative vertical position of this point in constant time.

Essentially we have two nested searches in the skip list structure, so the complexity of this step is $O(\log^8 n)$, but we can show a better estimate. Ambainis ([9], see the proof of Lemma 6) showed that in a skip list operation, at most $O(\log^2 n)$ pointer accesses are necessary. We run the search in the inner skip list only after accessing a pointer. Therefore, the outer search requires $O(\log^4 n)$ steps and the inner searches altogether require $O(\log^6 n)$ steps, so we improve our estimate to $O(\log^6 n)$.

5.3.2 Line insertion and removal

We will only describe the procedure of inserting a line in the data structure, as removing a line can be implemented by a reverse quantum circuit. Suppose the line to be inserted is ℓ_i; our task is to correctly update the pointers of the skip lists. As we will see, conveniently it suffices to update only the pointers of the new edges created by the insertion of the new line.

Our first step is to construct the edge along the given line. Figure 3 shows an example of the new edges collinear with ℓ_i being created. Suppose that P_{i,j_1} and P_{i,j_2} are two consecutive intersection points with ℓ_i (P_{i,j_1} is left of P_{i,j_2}). Some k-level will pass through an edge connecting P_{i,j_1} and P_{i,j_2}. This level will also pass through $\texttt{left}(\ell_{j_1}, \ell_i)$ and $\texttt{right}(\ell_{j_2}, \ell_i)$, as all edges of a level are directed from left to right. Therefore, the edge should connect $\nu_{j_1,i}$ with ν_{i,j_2}. There are two special cases for the first and the last edge; in the first case, the first path point is $\nu_{i,i}$ and for the second, the second path point is $\nu_{\texttt{Null}}$. According to this order, we insert all path points to the skip list starting with $\nu_{i,i}$ (and using the pointers $\texttt{Next}$). However, we don't insert $\nu_{i,i}$ into $\texttt{Start}$ yet.

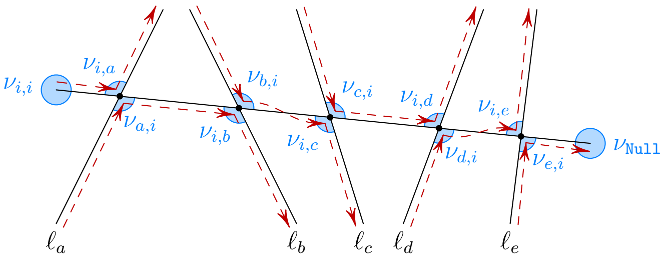

Figure 3 New edges along the inserted line.

Next we will correct all of the level skip lists according to the updated arrangement. Essentially, our algorithm performs a sweep line from right to left which swaps the tails of skip lists at the intersection points of ℓ_i with other lines. First, we create an array containing the same set of path points as the skip list of ℓ_i except $\nu_{i,i}$ and $\nu_{\texttt{Null}}$ and sort them by the x coordinate (at the end of the procedure we null the array by applying this in reverse). We then examine the intersection points of ℓ_i with the other lines from right to left.

Suppose we examine the intersection point $P_{i,j}$ of ℓ_i with ℓ_j.Then there is some edge from the old arrangement from $\nu^{(1)}$ to $\nu^{(2)}$ along ℓ_j which intersects ℓ_i at $P_{i,j}$. The respective pair of path points is $\nu_{i,j}$ and $\nu_{j,i}$. Then some k-level will pass along ℓ_i through $\nu_{i,j}$ and $\nu^{(2)}$, and some adjacent level (either $(k+1)$-level or $(k-1)$-level) will pass along ℓ_j from $\nu^{(1)}$ to $\nu_{j,i}$. Observe that the tails of these levels (from this intersection point to the right) have been correctly updated by the sweep line. Therefore, we just need to swap the tails of these two level skip lists.

To find the edge from $\nu^{(1)}$ to $\nu^{(2)}$, we use the point location operation with $P_{i,j}$. Since we know that this point will belong to some k-level, we modify the point location operation so as to return the head $\nu_{h,h}$ of this k-level. Note that although the level skip lists are partially updated, they still represent the old arrangement to the left of the previously examined intersection point, since the sweepline operates from right to left. Now we have to swap the tails of the skip list with head $\nu_{i,i}$ after $\nu_{i,j}$ and the skip list with head $\nu_{h,h}$ after $\nu^{(1)}$.

Generally, suppose that we wish to swap the tails of skip lists with heads $\nu^{(a_h)}$ and $\nu^{(b_h)}$ after elements $\nu^{(a_t)}$ and $\nu^{(b_t)}$, respectively. By searching $\nu^{(a_t)}$ in the $\nu^{(a_h)}$ skip list, we find all $l_{\max}$ path nodes $\nu^{(a_l)}$ such that $\texttt{Next}_{\nu^{(a_l)}}[l]$ points to a path node after $\nu^{(a_t)}$, for each $l \in [l_{\max}]$. Similarly we define and find $\nu^{(b_l)}$ path nodes. Then we simply swap the values of $\texttt{Next}_{\nu^{(a_l)}}[l]$ and $\texttt{Next}_{\nu^{(b_l)}}[l]$ for all $l \in [0, l_{\max}]$.

To conclude the procedure, we insert $\nu_{i,i}$ (together with $\texttt{Next}_{\nu_{i,i}}$) into $\texttt{Start}$. As we only performed $O(r)$ skip list searching and insertion operations (swapping the tails has the same complexity as an element insertion, as it's only updating $2l_{\max} + 2$ pointers) and a point location operation, the complexity of the procedure is $O(r \log^4 n + \log^6 n)$. If $r = n^p$ for some $p > 0$, this simplifies to $O(r \log^4 n)$.

5.4 Quantum algorithm

We use the MNRS framework quantum walk on the Johnson graph [9, 34]. In this framework, we search for a marked vertex in an ergodic reversible Markov chain on a state space X defined by the transition matrix $P = (p_{x,y})_{x,y \in X}$. Let the subset of marked states be $M \subseteq X$. To perform the quantum walk, the following procedures need to be implemented:

- Setup operation with complexity S. This procedure prepares the initial state of the quantum walk:

$$|0\rangle\,|0\rangle \mapsto \sum_{x \in X} \sqrt{\pi_x}\,|x\rangle\,|0\rangle\,,$$

  where π_x is the stationary distribution of P.
- Update operation with complexity U. This procedure essentially performs a step of the quantum walk by applying the transformation:

$$|x\rangle\,|0\rangle \mapsto |x\rangle \sum_{y \in X} \sqrt{p_{x,y}}\,|y\rangle\,.$$

- Checking operation with complexity C. This procedure performs the phase flip on the marked vertices:

$$|x\rangle\,|y\rangle \mapsto \begin{cases} -\,|x\rangle\,|y\rangle & \text{if } x \in M, \\ |x\rangle\,|y\rangle & \text{otherwise.} \end{cases}$$

We examine the Johnson graph on the state space X being the set of all size r subsets of $[n]$. Two vertices $x, y \in X$ are connected in this graph if the intersection of the corresponding subsets has size $r - 1$. For the Markov chain, the transition probability is $p_{x,y} = \frac{1}{r(n-r)}$ for all edges. Then we have the following theorem:

▶ **Theorem 9** (Quantum walk on the Johnson graph [9, 34])**.** *Let P be the random walk on the Johnson graph on size r subsets of $[n]$ with intersection size $r - 1$, where $r = o(n)$. Let M be either empty or the set of all size r subsets that contain a fixed element. Then there is a bounded-error quantum algorithm that determines whether M is empty, with complexity*

$$O\left(S + \frac{1}{\sqrt{r/n}}\left(\frac{1}{\sqrt{1/r}} \cdot U + C\right)\right) = O\left(S + \sqrt{n} \cdot U + \sqrt{\frac{n}{r}} \cdot C\right).$$

We can now prove our result:

▶ **Theorem 3.** *There is a bounded-error quantum algorithm that solves Hopcroft's problem with n lines and $m \leq n$ points in the plane in time:*

- $\widetilde{O}(n^{1/3} m^{1/2})$, *if* $n^{2/3} \leq m$;
- $\widetilde{O}(n^{2/5} m^{2/5})$, *if* $n^{1/4} \leq m \leq n^{2/3}$;
- $\widetilde{O}(n^{1/2})$, *if* $m \leq n^{1/4}$.

In particular, the complexity is $\widetilde{O}(n^{5/6})$ when $n = m$.

Proof. By the duality of Hopcroft's problem, we can exchange n and m; from here on, suppose that $m \geq n$. We do this, since in Theorem 2 it is important that the number of lines is larger and here it is important that the number of points is larger, but we wish to keep the meaning of n and m to avoid confusion. Our algorithm is a quantum walk on the Johnson graph of size r subsets of the given n lines. We will choose r depending on m, but r will always be m^p for some $p > 0$. A set S is marked if it contains a line such that there exists a point from the set of m given points that belongs to this line.

For the implementation, we follow the description of [1] for the quantum algorithm for closest points. For a set S, the state of the walk will be $|S, d(S)\rangle$, where $d(S)$ is our data structure for the line arrangement of S. We then implement the quantum walk procedures:

- For the Johnson graph, π is the uniform distribution. Thus, we first generate a uniform superposition over all subsets S in $O(\log \binom{n}{r}) = O(r \log n)$ time. Then we create $d(S)$ by inserting all lines of S into an initially empty data structure, requiring $O(r^2 \log^4 n)$ time.
- Suppose that S and S' are two size r subsets with $|S \cap S'| = r - 1$ so that $S' = (S \setminus \{i\}) \cup \{j\}$. We then represent a state $|S, d(S)\rangle |S', d(S')\rangle$ with $|S, d(S)\rangle |i, j\rangle$. As the Markov chain probabilities are the same for all edges, we need to implement the transition $|S, d(S)\rangle |0, 0\rangle \mapsto \sum_{i \in S} \sum_{j \notin S} |S', d(S)'\rangle |j, i\rangle$. To do that, first we create a uniform superposition of all $i \in S$ and $j \notin S$ in $O(r \log^4 n)$ time (see Appendix C), obtaining $\sum_{i \in S} \sum_{j \notin S} |S, d(S)\rangle |i, j\rangle$. Then, for fixed i and j, we remove ℓ_i from $d(S)$ and insert ℓ_j, obtaining $d(S')$; this takes $O(r \log^4 n)$ time. Finally, we swap the indices i and j in the second register in $O(\log n)$ time.
- The checking operation runs Grover's search over all m points and for each of them performs the point location operation. The complexity is $O(\sqrt{m} \log^6 n)$.

By Theorem 9 the complexity of the algorithm is

$$O\left(r^2 \log^4 n + \sqrt{n} r \log^4 n + \sqrt{\frac{n}{r}} \sqrt{m} \log^6 n\right).$$

Suppose that $m^{2/3} \leq n$ and pick $r = m^{1/3}$. Then the second term dominates the first and we can simplify the expression to

$$O\left(\sqrt{n} \log^4 n \left(r + \sqrt{\frac{m}{r}} \log^2 n\right)\right) = O(n^{1/2} m^{1/3} \log^6 n).$$

If we have $m^{1/4} \leq n \leq m^{2/3}$ we pick $r = (nm)^{1/5}$. Then we have $r \geq (n^{1+3/2})^{1/5} = \sqrt{n}$, and this time the first term in the complexity dominates the second, and the complexity is

$$O\left(r^2 \log^4 n + \sqrt{\frac{nm}{r}} \log^6 n\right) = O(n^{2/5} m^{2/5} \log^6 n).$$

Finally, for $n \leq m^{1/4}$, we don't have to use either the quantum walk or the history-independent data structure. First, we build any classical data structure for point location in a line arrangement with $O(n^2 \log n)$ build time and space and $O(\log n)$ query time (e.g. see [25], Chapter 11). Then we run Grover's search over all points and for each check whether it belongs to some line. The complexity in this case is

$$O(n^2 \log n + \sqrt{m}(\log m + \log n)) = O(\sqrt{m} \log m). \qquad \blacktriangleleft$$

A Model

We use the standard quantum circuit model together with Quantum Random Access Gates (QRAG) (see, for example, [6]). This gate implements the following mapping:

$$|i\rangle\,|b\rangle\,|x_1,\dots,x_N\rangle \mapsto |i\rangle\,|x_i\rangle\,|x_1,\dots,x_{i-1},b,x_{i+1},\dots,x_N\rangle\,.$$

Here, the last register represents the memory space of N bits. Essentially, QRAG gates allow both for reading memory in superposition as well as writing operations. We note that both our algorithms require "read-write" quantum memory, so it is not sufficient to use the weaker "read-only" QRAM gate, which is enough for some quantum algorithms.

To keep the analysis of the algorithms clean, we abstract the complexity of basic underlying operations under the "unit cost". This includes the running time of:

- basic arithmetic operations on $O(\log n)$ bits;
- the implementation of QRAG and elementary gates;
- the running time of a quantum oracle, which with a single query can return the description of any point or line.

In the end, we measure the time complexity in the total amount of unit cost operations. The unit cost can be taken as the largest running time of the operations listed above, which will add a multiplicative factor in the complexity.

Assuming that an application of a QRAG gate takes unit time is also useful for utilizing the existing classical algorithms in the RAM model. The classical algorithms that we use work in the real RAM model, where arithmetic operations and memory calls on $O(\log n)$ bits are considered to be executed in constant time. Thus, we work in the quantum analogue of the real RAM, and if there is a time T classical real RAM algorithm, then we can use it in time $O(T)$ in this model. The actual implementation of QRAG is an area of open research and debate; however, there exist theoretical proposals that realize such operations in time polylogarithmic in the size of the memory, like the bucket brigade architecture of [28].

B Query complexity

Proof of Theorem 1. For the upper bound, Hopcroft's problem can be seen as an instance of the bipartite *subset-finding* problem, in which one is given query access to two sets X and Y of sizes n and m, respectively, and needs to detect whether there is a pair $x \in X$, $y \in Y$ satisfying some predicate $R : X \times Y \to \{0, 1\}$. For this problem, Tani gave a quantum algorithm with query complexity $O(n^{1/3}m^{1/3} + \sqrt{n} + \sqrt{m})$ [41].

For the lower bound, we can reduce the bipartite element distinctness problem (also known as Claw Finding) to Hopcroft's problem. In this problem, we have two sets of variables $x_1, \ldots, x_n \in [N]$ and $y_1, \ldots, y_m \in [N]$ and we need to detect whether $x_i = y_j$ for some i, j. Zhang proved that for this problem $\Omega(n^{1/3}m^{1/3} + \sqrt{n} + \sqrt{m})$ quantum queries are needed [47]. We reduce each x_i to a line $x = x_i$ and each y_j to a point $(y_j, 0)$. Then $x_i = y_j$ only iff some point belongs to some line, so the statement follows. ◀

C Implementation details

To generate a uniform state proportional to $\sum_{i \in S} |i\rangle$ from $|S, d(S)\rangle$, we can proceed as follows. First generate the uniform superposition $\sum_{k \in [r]} |k\rangle$ in $O(\log n)$ time. Then we can find the number of the k-th line in S by iterating over the elements of the `Start` skip list as in the usual linked list until we find the k-th one; this requires $O(r \log^4 n)$ time. We then null the register $|k\rangle$ by applying a reverse procedure and decrementing k in each step. Overall, we obtain the state proportional to $\sum_{i \in S} |i\rangle$ in $O(r \log^4 n)$ time.

To generate a uniform state proportional to $\sum_{j \notin S} |j\rangle$ from $|S, d(S)\rangle$, we can apply a different procedure. First, we can generate the state $\sum_{k \in [n]} |k\rangle |0\rangle$ in $O(\log n)$ time. For a fixed k, we can check whether $k \in S$ using $d(S)$ in $O(\log^4 n)$ time and write 1 in that case in the second register. By measuring the second register, we obtain the required state with probability $1 - r/n > 1/2$. We can use $O(\log n)$ copies of such state to obtain the required state with error probability only $O(1/n)$, which doesn't impact the final constant success probability. Overall, this step requires $O(\log^5 n)$ time, which is negligible compared to $O(r \log^4 n)$.

A New Characterization of FAC^0 via Discrete Ordinary Differential Equations

Abstract

Implicit computational complexity is an active area of theoretical computer science, which aims at providing machine-independent characterizations of relevant complexity classes. One of the seminal works in this field appeared in 1965, when Cobham introduced a function algebra closed under bounded recursion on notation to capture **FP**. Later on, several complexity classes have been characterized using *limited* recursion schemas. In this context, a new approach was recently introduced, showing that ordinary differential equations (ODEs) offer a natural tool for algorithmic design and providing a characterization of **FP** by an ODE-schema. The overall goal of the present work is precisely that of generalizing this approach to parallel computation, obtaining an original ODE-characterization for the small circuit classes $\mathbf{FAC}^0$ and $\mathbf{FTC}^0$.

2012 ACM Subject Classification Theory of computation → Complexity classes; Theory of computation → Circuit complexity

1 Introduction

As computability theory investigates the limits of what is algorithmically computable, complexity theory classifies functions based on the amount of resources, typically time and space, required by a machine to compute them. Taking a different point of view, implicit computational complexity (ICC) aims at providing machine-independent characterizations, which in turn have offered remarkable insights on the corresponding classes and led to relevant meta-theorems in various domains, such as database theory and constraint satisfaction.

One of the major approaches to computability and (implicit) complexity theory is constituted by the study of recursion. A foundational work in this area is due to Cobham [15], who gave a characterization of the class of poly-time computable functions **FP**, relying on a restricted recursion mechanism, called bounded recursion on notation (BRN). This groundbreaking result has inspired several characterizations based on *limited* recursion schemas for various other classes, but also alternative implicit ways to capture **FP**, for instance, via safe recursion [5] and ramification [25, 26].

Cobham's work [15], together with other early results in recursion theory [20, 6, 29, 27], have even paved the way to recursion-theoretic characterizations for small circuit classes [11, 12, 16, 1, 14, 9]. Specifically, in [11, 12], an algebra based on the so-called *concatenation recursion on notation* schema (CRN) was introduced and shown able to capture functions computable in (**Dlogtime**-uniform) $\mathbf{AC}^0$ (i.e. computable by families of polynomial size and constant depth circuits) [11, 12]. This result was extended to $\mathbf{AC}^i$ and $\mathbf{NC}^i$ due to the notions of *k-bounded* and *weak bounded recursion on notation* [12]. A few years later, a similar function algebra to capture $\mathbf{TC}^0$ was introduced [14]. Other characterizations for subclasses of **NC** were independently presented in [16, 1, 9].

Related, but alternative, approaches to capture small circuit classes have also been provided in the framework of model- and proof-theory. In particular, it is well-known that there is an equivalence between $\mathbf{AC}^0$ and first-order logic, which naturally generalizes to extensions of the latter and larger circuit classes [23, 4, 22, 21, 28]. In [16], both a function algebra, based on so-called *upward recursion tree*, and a logical system to capture $\mathbf{NC}^1$ are presented. On the proof-theoretical side, in [1], together with the corresponding algebra, Allen defined a proof system *à la Buss* to capture **NC**. Another bounded theory to capture **NC** is introduced in [13] and then extended to several small circuit classes [14]. Theories for $\mathbf{TC}^0$ have been developed in [24] and, in the setting of second-order theories, in [18]. Alternative, proof-theoretical characterizations for $\mathbf{NC}^1$ were presented in [2], and, in the context of two-sorted theories, in [17].

A different descriptive approach to complexity, based on discrete ordinary differential equations (ODEs), was recently introduced in [10]. Informally speaking, its objective is to characterize functions computable in a given complexity class as solutions of a corresponding type of ODE. In this vein, in [10] a purely syntactic characterization of **FP** was given by linear systems of equations deriving along a logarithmically growing function. Intuitively, the latter condition controls the number of steps, while linearity controls the growth of objects generated during the computation. Recently, this approach has also been generalized to the continuous setting [7, 8].

Although small circuit classes have been characterized in multiple ways, it is an interesting and challenging question whether they can be studied through an ODE-based approach and whether this would shed some new light on these well-known classes. Interesting, because for a descriptive approach based on ODEs to make sense and be fruitful it has to be able to cope with very subtle and restricted modes of computation. Challenging, because even simple and useful mathematical functions may not be computable (e.g. multiplication is not in $\mathbf{AC}^0$), thus tools at hand and the naturalness of the approach are drastically restricted. In the present paper, we investigate these questions, and show that, in fact, natural ways to introduce ODE-oriented function algebras to capture small circuit classes can be found. Our approach relies on the introduction of ODE-schemas, still using derivation along the logarithmic function and allowing for bit shifting operations through restricted forms of linear equations. Our case study focuses on the smallest classes $\mathbf{AC}^0$ and $\mathbf{TC}^0$, but is intended as the first step towards a uniform characterization of other relevant classes in the **AC** and **NC** hierarchies.

Structure of the paper. The paper is divided into two main sections. In Section 2, we introduce notions and results at the basis of our ODE-style characterizations. In particular, in Section 2.1, we summarize salient aspects of the approach by [10], which we aim to generalize from the study of **FP** to that of small circuit classes. In Section 2.2, we briefly recap basic notions in parallel complexity and recall the function algebra approach of [11, 12, 14] to capture $\mathbf{AC}^0$ and $\mathbf{TC}^0$. In Section 3, we present our ODE-characterizations for the mentioned classes. Specifically, in Section 3.1, we introduce restricted ODE-schemas, and, using them, in Sections 3.2 and 3.3, we define ODE-function algebras capturing the analog for functions of $\mathbf{AC}^0$ and $\mathbf{TC}^0$, respectively. Then, in Section 3.4, we provide alternative and direct completeness proofs for both classes in the non-uniform setting, namely assuming that functions describing the circuits are given as basic functions. Finally, in Section 4, we briefly point at possible directions of future research.

2 Preliminaries

2.1 Capturing Complexity Classes via ODEs

We suppose the reader familiar with the basics of complexity theory [3, 30]. In order to introduce the approach to complexity delineated in [10], we start by cursorily recalling Cobham's result, capturing **FP** by the following BRN schema.

▶ **Definition 1** (Bounded Recursion on Notation, BRN). *Given $g : \mathbb{N}^p \to \mathbb{N}, k : \mathbb{N}^{p+1} \to \mathbb{N}$ and $h_i : \mathbb{N}^{p+2} \to \mathbb{N}$, with $i \in \{0,1\}$, $f : \mathbb{N}^{p+1} \to \mathbb{N}$ is defined by BRN from g, h_0, h_1 and k if*

$$f(0,\mathbf{y}) = g(\mathbf{y}) \qquad \text{and} \qquad f(\mathsf{s}_i(x),\mathbf{y}) = h_i(f(x,\mathbf{y}),x,\mathbf{y}), \text{ for } x \neq 0$$

with $f(x,\mathbf{y}) \leq k(x,\mathbf{y})$ and $\mathsf{s}_j(x) = 2x + j$ ($j \in \{0,1\}$) being the binary successor functions.

The growth of f is controlled by the function k (in **FP**), while the number of induction steps is kept under control by the application of the binary successor functions s_i. Such a schema is not fully satisfactory as it imposes an explicit bound on recursion in the form of an already known function.

As anticipated, Cobham's paper not only led to a variety of implicit characterizations for classes other that **FP**, but also inspired alternative approaches to capture this class. Among them, the proposal by [10] has the specificity of not imposing any explicit bound on the recursion schema or assigning specific role to variables. Instead, it is based on Discrete Ordinary Differential Equation (a.k.a. Difference Equations) and combines two peculiar features: derivation along specific functions, so to control the number of computation steps, and a special syntactic form of the equation itself (here linearity), allowing to control the object size. We present the basics of the method as necessary to formulate our new results.

Recall that the *discrete derivative of* $\mathbf{f}(x)$ is defined as $\Delta\mathbf{f}(x) = \mathbf{f}(x+1) + \mathbf{f}(x)$, and that ODEs are expressions of the form:

$$\frac{\partial \mathbf{f}(x,\mathbf{y})}{\partial x} = \mathbf{h}(\mathbf{f}(x,\mathbf{y}),x,\mathbf{y}),$$

where $\frac{\partial \mathbf{f}(x,\mathbf{y})}{\partial x}$ stands for the derivative of $\mathbf{f}(x,\mathbf{y})$ considered as a function of x, for a fixed value for $\mathbf{y}$. When some initial value $\mathbf{f}(0,\mathbf{y}) = \mathbf{g}(\mathbf{y})$ is added, this is called *Initial Value Problem* (IVP). Then, in order to deal with complexity, some restrictions are needed. First, the notion of derivation has to be generalized, allowing to *derive along functions.*

▶ **Notation 1.** For $x \neq 0$, let $\ell(x)$ denote the length of x written in binary, i.e. $\lceil \log_2(x+1) \rceil$, and $\ell(0) = 0$. For $u \geq 0$, $\alpha(u) = 2^u - 1$ denotes the greatest integer the binary length of which is u. Also, we use $\div 2$ to denote integer division by 2, i.e. for all $x \in \mathbb{Z}$, $x \div 2 = \left\lfloor \frac{x}{2} \right\rfloor$.

▶ **Definition 2** (λ-ODE Schema). *Let $\mathbf{f}, \lambda : \mathbb{N}^p \to \mathbb{Z}$ and $\mathbf{h} : \mathbb{N}^{p+1} \to \mathbb{Z}$ be functions. Then,*

$$\frac{\partial \mathbf{f}(x,\mathbf{y})}{\partial \lambda} = \frac{\partial \mathbf{f}(x,\mathbf{y})}{\partial \lambda(x,\mathbf{y})} = \mathbf{h}\big(\mathbf{f}(x,\mathbf{y}),x,\mathbf{y}\big) \tag{1}$$

is a formal synonym of $\mathbf{f}(x+1,\mathbf{y}) = \mathbf{f}(x,\mathbf{y}) + \big(\lambda(x+1,\mathbf{y}) - \lambda(x,\mathbf{y})\big) \times \mathbf{h}(\mathbf{f}(x,\mathbf{y}),x,\mathbf{y})$. *When $\lambda(x,\mathbf{y}) = \ell(x)$, we call* (1) *a* length-ODE.

Intuitively, one of the key properties of the λ-ODE schema is its dependence on the number of distinct values of λ, i.e., the value of $\mathbf{f}(x, \mathbf{y})$ changes only when the value of $\lambda(x, \mathbf{y})$ does.

The computation of solutions of λ-ODEs have been fully described in [10]. Here, we focus on the special case of $\lambda = \ell$, which is particularly relevant for our characterizations. First, observe that the value of $\ell(x)$ changes (i.e. increases by 1) when x goes from $2^t - 1$ to 2^t, i.e. from $\alpha(t)$ to $\alpha(t) + 1$. So, if $\mathbf{f}$ is a solution of (1) with $\lambda = \ell$ and initial value $\mathbf{f}(0, \mathbf{y}) = \mathbf{g}(\mathbf{y})$, then $\mathbf{f}(1, \mathbf{y}) = \mathbf{f}(0, \mathbf{y}) + \mathbf{h}\big(\mathbf{f}(\alpha(0), \mathbf{y}), \alpha(0), \mathbf{y}\big)$, and, more generally, for all x and $\mathbf{y}$, $\mathbf{f}(x, \mathbf{y}) = \mathbf{f}(x-1, \mathbf{y}) + \Delta(\ell(x-1)) \times \mathbf{h}\big(\mathbf{f}(x-1, \mathbf{y}), x-1, \mathbf{y}\big) = \mathbf{f}(\alpha(\ell(x)-1), \mathbf{y}) + \mathbf{h}\big(\mathbf{f}\big(\alpha\big(\ell(x)-1\big), \mathbf{y}\big), \alpha(\ell(x)-1), \mathbf{y}\big)$, where $\Delta\big(\ell(t-1)\big) = \ell(t) - \ell(t-1)$. Starting from $t = x \geq 1$ and taking successive decreasing values of t, the first difference such that $\Delta(t) \neq 0$ is given by the biggest $t-1$ such that $\ell(t-1) = \ell(x) - 1$, i.e. $t - 1 = \alpha(\ell(x) - 1)$. Hence, by induction, it is established that:

$$\mathbf{f}(x, \mathbf{y}) = \sum_{u=-1}^{\ell(x)-1} \mathbf{h}\big(\mathbf{f}(\alpha(u), \mathbf{y}), \alpha(u), \mathbf{y}\big),$$

with $\mathbf{h}(\cdot, \alpha(-1), \mathbf{y}) = \mathbf{f}(0, \mathbf{y})$ and, as seen, $\alpha(u) = 2^u - 1$.

The second crucial novelty is the introduction of a special concept of *linearity*, utilized to control the growth of functions defined by ODEs. First, we present the notion of *degree for a polynomial expression*, which is a generalized (and slightly modified) version of the corresponding definition in [10]. Here, the degree of an expression is considered in relation to a set of variables, instead of a single one.

Let $\mathsf{sg} : \mathbb{Z} \to \mathbb{Z}$ be the sign function over $\mathbb{Z}$, taking value 1 for $x > 0$ and 0 otherwise.

▶ **Definition 3.** *A* sg-polynomial expression $P(x_1, \ldots, x_h)$ *is an expression built over the signature* $\{+, -, \times\}$*, the* sg *function and a set of variables* $X = \{x_1, \ldots, x_h\}$ *plus integer constants. Given a list of variables* $\mathbf{x} = x_{i_1}, \ldots, x_{i_m}$*, for* $i_1, \ldots, i_m \in \{1, \ldots, h\}$ *the* degree of a set $\mathbf{x}$ in a sg-polynomial expression P, $\deg(\mathbf{x}, P)$*, is inductively defined as follows:*

- $\deg(\mathbf{x}, P) = 0$ *for* P *constant*
- $\deg(\mathbf{x}, x_{i_j}) = 1$*, for* $x_{i_j} \in \{x_{i_1}, \ldots x_{i_m}\}$*, and* $\deg(\mathbf{x}, x_{i_j}) = 0$*, for* $x_{i_j} \notin \{x_{i_1}, \ldots, x_{i_m}\}$
- $\deg(\mathbf{x}, P + Q) = \deg(\mathbf{x}, P - Q) = \max\{\deg(\mathbf{x}, P), \deg(\mathbf{x}, Q)\}$
- $\deg(\mathbf{x}, P \times Q) = \deg(\mathbf{x}, P) + \deg(\mathbf{x}, Q)$
- $\deg(\mathbf{x}, \mathsf{sg}(P)) = 0.$

A sg-polynomial expression P is said to be *essentially constant in a set of variables* $\mathbf{x}$ when $\deg(\mathbf{x}, P) = 0$. A sg-polynomial expression P is said to be *essentially linear in a set* $\mathbf{x}$, when $\deg(\mathbf{x}, P) = 1$.

In what follows, we consider functions $\mathbf{f} : \mathbb{N}^{p+1} \to \mathbb{Z}^d$, i.e. vectors of functions $\mathbf{f} = f_1, ..., f_d$ from $\mathbb{N}^{p+1}$ to $\mathbb{Z}$, and we introduce the linear λ-ODE schema.

▶ **Definition 4** (Linear λ-ODE)**.** *Given* $\mathbf{g} : \mathbb{N}^p \to \mathbb{N}^d$*,* $\mathbf{h} : \mathbb{N}^{p+1} \to \mathbb{Z}$ *and* $\mathbf{u} : \mathbb{Z} \times \mathbb{N}^{p+1} \to \mathbb{Z}^d$*, the function* $\mathbf{f} : \mathbb{N}^{p+1} \to \mathbb{Z}^d$ *is* linear λ-ODE *definable from* $\mathbf{g}$*,* $\mathbf{h}$ *and* $\mathbf{u}$ *if it is the solution of the IVP with initial value* $\mathbf{f}(0, \mathbf{y}) = \mathbf{g}(\mathbf{y})$ *and such that:*

$$\frac{\partial \mathbf{f}(x, \mathbf{y})}{\partial \lambda} = \mathbf{u}\big(\mathbf{f}(x, \mathbf{y}), \mathbf{h}(x, \mathbf{y}), x, \mathbf{y}\big),$$

where $\mathbf{u}$ *is* essentially linear in $\mathbf{f}(x, \mathbf{y})$*. For* $\lambda = \ell$*, such schema is called* linear length ODE.

If $\mathbf{u}$ is *essentially linear in* $\mathbf{f}(x,\mathbf{y})$, there exist matrices $\mathbf{A}$ and $\mathbf{B}$, whose coefficients are essentially constant in $\mathbf{f}(x,\mathbf{y})$ and such that:

$$\mathbf{f}(0,\mathbf{y}) = \mathbf{g}(\mathbf{y})$$
$$\frac{\partial \mathbf{f}(x,\mathbf{y})}{\partial \ell} = \mathbf{A}\big(\mathbf{f}(x,\mathbf{y}),\mathbf{h}(x,\mathbf{y}),x,\mathbf{y}\big) \times \mathbf{f}(x,\mathbf{y}) + \mathbf{B}\big(\mathbf{f}(x,\mathbf{y}),\mathbf{h}(x,\mathbf{y}),x,\mathbf{y}\big).$$

Then, for all x and $\mathbf{y}$,

$$\mathbf{f}(x,\mathbf{y}) = \sum_{u=-1}^{\ell(x)-1} \left(\prod_{t=u+1}^{\ell(x)-1} \Big(1+\mathbf{A}\big(\mathbf{f}(\alpha(t),\mathbf{y}),\mathbf{h}(\alpha(t),\mathbf{y}),\alpha(t),\mathbf{y}\big)\Big)\right) \times \mathbf{B}\big(\mathbf{f}(\alpha(u),\mathbf{y}),\mathbf{h}(\alpha(u),\mathbf{y}),\alpha(u),\mathbf{y}\big),$$

with the convention that $\prod_{x}^{x-1} \kappa(x) = 1$ and $\mathbf{B}(\cdot,\cdot,\alpha(-1),\mathbf{y}) = \mathbf{f}(0,\mathbf{y})$.

▶ **Example 5** (Function $2^{\ell(x)}$)**.** The function $x \mapsto 2^{\ell(x)}$ can be seen as the solution of the IVP with initial value $f(0) = 1$ and such that $\frac{\partial f(x)}{\partial \ell} = f(x)$, i.e. where $A = 1$, $B = 0$. Indeed, the solution of this system is of the form $f(x) = \prod_{u=0}^{\ell(x)-1} 2 = 2^{\ell(x)}$. In addition, the function $(x,y) : x,y \mapsto 2^{\ell(x)} \times y$ can be captured by the same equation, with initial value $f(0,y) = y$.

One of the main results of [10] is the implicit characterization of **FP** by the algebra made of basic functions $0, 1, \pi_i^p, \ell, +, -, \times, \mathsf{sg}$ and closed under composition ($\circ$) and ℓ-ODE:

$$\mathbb{LDL} = [0, 1, \pi_i^p, \ell, +, -, \times, \mathsf{sg}; \circ, \ell\text{-ODE}].$$

2.2 On Parallel Computation and Function Algebras for $\mathbf{FAC}^0$

Boolean circuits are vertex-labeled directed acyclic graphs whose nodes are either *input nodes* (no incoming edges), *output nodes* (no outgoing edges) or labeled with a Boolean function from the set $\{\wedge, \vee, \neg\}$. A Boolean circuit with majority gates allows in addition gates labeled by the function Maj, that outputs 1 when the majority of its inputs are 1's. A family of circuits (C_n) is **Dlogtime**-uniform if there is a Turing machine (with a random access tape) that decides in deterministic logarithmic time the *direct connection language of the circuit*, i.e. which, given 1^n, a, b and $t \in \{\wedge, \vee, \neg\}$, decides if a is of type t and b is a predecessor of a in the circuit (and analogously for input and output nodes). When dealing with circuits, the resources of interests are *size*, i.e. the number of its gates, and *depth*, i.e. the length of the longest path from the input to the output (see [30] for more details and related results).

▶ **Definition 6** (Classes $\mathbf{FAC}^i$ and $\mathbf{FTC}^i$)**.** *For $i \in \mathbb{N}$, the class $\mathbf{AC}^i$ (resp., $\mathbf{TC}^i$) is the class of languages recognized by a* **Dlogtime***-uniform family of Boolean circuits (resp. circuits including majority gates) of polynomial size and depth $O((\log n)^i)$. We denote by $\mathbf{FAC}^i$ and $\mathbf{FTC}^i$ the corresponding function classes.*

For $\mathbf{FAC}^0$, a particularly relevant recursion-theoretic characterization was provided by Clote [11, 12]. It relies on the schema of concatenation recursion on notation.

▶ **Definition 7** (Concatenation Recursion on Notation, CRN)**.** *A function f is defined by* concatenation recursion on notation *from g and h_i, with $i \in \{0,1\}$, if for all $x, \mathbf{y}$:*

$$f(0,\mathbf{y}) = g(\mathbf{y}) \quad \textit{and} \quad f(\mathsf{s}_i(x),\mathbf{y}) = \mathsf{s}_{h_i(x,\mathbf{y})}(f(x,\mathbf{y})), \textit{ for } x \neq 0.$$

Then, Clote's function algebra is defined as the class:

$$\mathcal{A}_0 = [0, \pi_i^p, \mathsf{s}_0, \mathsf{s}_1, \ell, \mathsf{BIT}, \#; \circ, \text{CRN}],$$

where $\mathsf{BIT}(x,y)$ returns the y^{th} value in the binary representation of x, and $x\#y = 2^{\ell(x)\times\ell(y)}$ is the smash function. This class was also proved able to capture $\mathbf{FAC}^0$ [11, 12].

▶ **Theorem 8** ([11, 12]). $\mathcal{A}_0 = \mathbf{FAC}^0$.

That $\mathcal{A}_0 \subseteq \mathbf{FAC}^0$ is proved by passing through the (function version of the) logarithmic time hierarchy **FLH**, which is known to be equivalent to $\mathbf{FAC}^0$. Then, $\mathcal{A}_0 \subseteq \mathbf{FLH}$ is established by showing that basic functions are computable in log-time and that **FLH** is closed under composition and CRN. That $\mathbf{FLH} \subseteq \mathcal{A}_0$ is proved by the arithmetization of log-time bounded RAM. Remarkably, in [14], these results are even generalized to $\mathbf{FTC}^0$, which is proved equivalent to the function algebra:

$$\mathcal{TC}_0 = [0, \pi_i^p, \mathsf{s}_0, \mathsf{s}_1, \ell, \mathsf{BIT}, \times, \#; \circ, \mathrm{CRN}].$$

3 Towards an ODE-Characterization of FAC^0

In this section, we provide the first implicit characterization of $\mathbf{FAC}^0$ in the ODE-setting. We start by introducing the new ODE-schemas which are at the basis of our characterizations of $\mathbf{FAC}^0$ and $\mathbf{FTC}^0$ and intuitively corresponding to left- and right-shifting (Sec. 3.1). Due to them, we introduce the function algebra $\mathbb{ACDL}$, the defining feature of which is precisely the presence of these special ODE-schemas, and prove this class able to capture $\mathbf{FAC}^0$ (Sec. 3.2). This is established passing through Clote's $\mathcal{A}_0$. As a byproduct, we obtain a similar ODE-characterization for $\mathbf{FTC}^0$ (Sec. 3.3). Finally, an alternative, direct proof of completeness is provided for both classes in a non-uniform setting (Sec. 3.4).

▶ Remark 9. Here, functions can take images in $\mathbb{Z}$. Accordingly, a convention for the binary representation of integers must be adopted, e.g. by assuming that, in any binary sequence, the first bit indicates the sign. Then, all arithmetic operations can be easily re-designed to handle encodings of possibly negative integers by circuits of the same size and depth.

3.1 Discrete ODE-Schemas for Shifting

We start by considering the ODE-schemas which are at the basis of our characterizations of $\mathbf{FAC}^0$ and $\mathbf{FTC}^0$. Observe that they will sometimes include $\times$. This is admissible since, as we shall see, the "kind of multiplication" we consider is actually limited to special cases (namely, multiplication by 2^i), which are proved to be computable in $\mathbf{FAC}^0$.

The ℓ-ODE$_1$ and ℓ-ODE$_2$ Schemas. We start with the limited ℓ-ODE$_1$ schema, intuitively corresponding to left shifting(s) and (possibly) adding a bit.

▶ **Definition 10** (ℓ-ODE$_1$ Schema). *Given $g : \mathbb{N}^p \to \mathbb{N}$ and $h : \mathbb{N}^{p+1} \to \mathbb{N}$, such that h takes values in $\{0,1\}$ only, the function $f : \mathbb{N}^{p+1} \to \mathbb{N}$ is defined by ℓ-ODE$_1$ from functions g and h when it is the solution of the IVP with initial value $f(0,\mathbf{y}) = g(\mathbf{y})$ and such that:*

$$\frac{\partial f(x,\mathbf{y})}{\partial \ell} = f(x,\mathbf{y}) + h(x,\mathbf{y}).$$

The definition of the function $2^{\ell(x)}$ (and $2^{\ell(x)} \times y$) given in Example 5 is a special case of a ℓ-ODE$_1$ (with $h(x,\mathbf{y}) = 0$).

▶ Remark 11. An equivalent, purely-syntactical formulation of Definition 10 is obtained by substituting the explicit constraint that $h(x,\mathbf{y}) \in \{0,1\}$ with the assumption that $h(x,\mathbf{y})$ is of the form $\mathsf{sg}\big(B(h_1,\ldots,h_m,x,\mathbf{y})\big)$, where B is an expression built over the signature $\{+,-,\div 2,\mathsf{sg}\}$ and calling previously defined $\mathbf{FAC}^0$ functions $h_1(x,\mathbf{y}),\ldots,h_m(x,\mathbf{y})$.

In terms of circuits, this schema intuitively allows us to iteratively left-shifting (the binary representation of) a given number, each time possibly adding 1 to its final position. This is clarified by the proof below, establishing that $\mathbf{FAC}^0$ is closed under the mentioned schema.

▶ **Proposition 12.** *If f is defined by ℓ-ODE$_1$ from g and h in $\mathbf{FAC}^0$, then f is in $\mathbf{FAC}^0$.*

Proof Sketch. By Def. 10, for all x and $\mathbf{y}$: $f(x, \mathbf{y}) = \sum_{u=-1}^{\ell(x)-1} \Big(\prod_{t=u+1}^{\ell(x)-1} 2\Big) \times h\big(\alpha(u), \mathbf{y}\big) = \sum_{u=-1}^{\ell(x)-1} 2^{\ell(x)-u-1} \times h(\alpha(u), \mathbf{y})$, with the convention that $\alpha(u) = 2^u - 1$, $\prod_x^{x-1} \kappa(x) = 1$ and $h\big(\alpha(-1), \mathbf{y}\big) = f(0, \mathbf{y})$. Clearly, the multiplication here involved is always by a power of 2 (which basically corresponds to left-shifting, so is computable in $\mathbf{FAC}^0$). Since $h(x, \mathbf{y}) \in \{0, 1\}$, the outermost sum amounts to a concatenation (which again can be computed in $\mathbf{FAC}^0$). ◀

Notice that this schema is not as weak as it may seem since, together with sg, it is enough to express bounded quantification.

▶ Remark 13. Let $R \subseteq \mathbb{N}^{p+1}$ and h_R be its characteristic function. Then, for all x and $\mathbf{y}$, it holds that $(\exists z \leq \ell(x))R(z, \mathbf{y}) = \mathsf{sg}\big(f(x, \mathbf{y})\big)$, where f is such that $f(0, \mathbf{y}) = h_R(0, \mathbf{y})$ and

$$\frac{\partial f(x, \mathbf{y})}{\partial \ell} = f(x, \mathbf{y}) + h_R\big(\ell(x+1), \mathbf{y}\big).$$

Clearly, $f(x, \mathbf{y})$ is an instance of ℓ-ODE$_1$. Intuitively, $f(x, \mathbf{y}) \neq 0$ when, for some z smaller than x, $R(z, \mathbf{y})$ is satisfied (i.e. $h_R(z, \mathbf{y}) = 1$): when such instance exists, our bounded search ends with a positive answer. Universally bounded quantification can be expressed in a similar way, considering $\mathsf{cosg}(f(x, \mathbf{y}))$, where f is defined substituting the value of h_R with its co-sign (such that, $\mathsf{cosign}(x) = 1 - \mathsf{sg}(x)$).

The more general schema ℓ-ODE$_2$ allows multiple left-shifting, such that each "basic operation" corresponds to shifting a given value of a number of digits determined by $\ell(k(\mathbf{y}))$.

▶ **Definition 14** (ℓ-ODE$_2$ Schema). *Given $g : \mathbb{N}^p \to \mathbb{N}$, $h : \mathbb{N}^{p+1} \to \mathbb{N}$ and $k : \mathbb{N}^p \to \mathbb{N}$, the function $f : \mathbb{N}^{p+1} \to \mathbb{N}$ is defined by ℓ-ODE$_2$ from g, h and k if it is the solution of the IVP with initial value $f(0, \mathbf{y}) = g(\mathbf{y})$ and such that:*

$$\frac{\partial f(x, \mathbf{y})}{\partial \ell} = \big(2^{\ell(k(\mathbf{y}))} - 1\big) \times f(x, \mathbf{y}) + h(x, \mathbf{y}),$$

where $h(x, \mathbf{y}) \in \{0, 1\}$, and if, for some x and $\mathbf{y}$, $h(x, \mathbf{y}) \neq 0$, then $k(\mathbf{y}) \neq 0$.

Since this schema is introduced to characterize $\mathbf{FAC}^0$, the constraint imposing $k(\mathbf{y}) \neq 0$, when at some point $h(x, \mathbf{y})$ takes value 1, is really essential. Indeed, as we shall see (Sec. 3.3), if we omit it, ℓ-ODE$_2$ will be too strong, as able to capture binary counting (which is not in $\mathbf{FAC}^0$).

Observe that ℓ-ODE$_1$ is a special case of ℓ-ODE$_2$, such that $\ell(k(\mathbf{y})) = 1$, and that, also for it, the following closure result holds.

▶ **Proposition 15.** *If f is defined by ℓ-ODE$_2$ from $\mathbf{FAC}^0$-functions g, k and h, then f is in $\mathbf{FAC}^0$.*

Proof Sketch. There are two cases: if $k(\mathbf{y}) \neq 0$, the proof is analogous to that of Prop. 12; if $k(\mathbf{y}) = 0$ (and $h(x, \mathbf{y}) = 0$), for all x and $\mathbf{y}$, $f(x, \mathbf{y}) = g(\mathbf{y})$, in $\mathbf{FAC}^0$ by hypothesis. ◀

The Schema ℓ-ODE$_3$. Let us now consider ℓ-ODE$_3$, intuitively corresponding to (basic) right-shifting operations.

▶ **Definition 16** (ℓ-ODE$_3$ Schema). *Given $g : \mathbb{N}^p \to \mathbb{N}$, the function $f : \mathbb{N}^{p+1} \to \mathbb{N}$ is defined by ℓ-ODE$_3$ from g if it is the solution of the IVP with initial value $f(0, \mathbf{y}) = g(\mathbf{y})$ and such that:*

$$\frac{\partial f(x, \mathbf{y})}{\partial \ell} = -\left\lceil \frac{f(x, \mathbf{y})}{2} \right\rceil$$

where $\lceil \frac{z}{2} \rceil$ is a shorthand for $z - (z \div 2)$.

▶ **Proposition 17.** *If f is defined by ℓ-ODE$_3$ from g in $\mathbf{FAC}^0$, then f is in $\mathbf{FAC}^0$ as well.*

Proof Sketch. The proof is similar to the one for Prop. 12. By Def. 16 and since $(a \div 2^b) \div 2 = a \div 2^{b+1}$, it can be shown by induction that for all x and $\mathbf{y}$: $f(x, \mathbf{y}) = g(\mathbf{y}) \div 2^{\ell(x)-1}$. This intuitively corresponds to right-shifting $g(\mathbf{y})$ a number of times equal to $\ell(x) - 1$ and can be easily shown computable by a constant-depth circuit. ◀

3.2 An ODE-Characterization of $\mathbf{FAC}^0$

We now define a new class of functions, crucially relying on the ODE-schemas just introduced:

$$\mathbb{ACDL} = [0, 1, \pi_i^p, \ell, +, -, \div 2, \mathsf{sg}; \circ, \ell\text{-ODE}_2, \ell\text{-ODE}_3].$$

Observe that all its basic functions and (restricted) schemas are natural in the context of differential equations and calculus. In $\mathbb{ACDL}$, multiplication is, of course, not allowed. Compared to $\mathbb{LDL}$, the linear-length ODE schema is substituted by the two schemas ℓ-ODE$_2$ and ℓ-ODE$_3$, characterized by a very limited form of "multiplication" and intuitively allowing to capture left and right shifting.

In order to prove that $\mathbb{ACDL}$ captures $\mathbf{FAC}^0$ we start by providing an *indirect* proof that $\mathbf{FAC}^0 \subseteq \mathbb{ACDL}$. This is established by showing that any basic function and schema defining Clote's $\mathcal{A}_0$ (so its arithmetization of log-time bounded RAM) can be simulated in our setting by functions and schemas of $\mathbb{ACDL}$. Preliminarily, observe that some important operations "come for free" by composition. For instance, the modulo 2 operation is defined as $(x \bmod 2) = x - \lfloor \frac{x}{2} \rfloor - \lfloor \frac{x}{2} \rfloor$, while binary successor functions are expressed in our setting as $\mathsf{s}_0(x) = x + x$ and $\mathsf{s}_1(x) = \mathsf{s}_0(x) + 1$ (being the constant 0 and $+$ basic functions of $\mathbb{ACDL}$).

The smash function $2^{\ell(x)\times\ell(y)}$. The smash function $x\#y : x, y \mapsto 2^{\ell(x)\times\ell(y)}$ is rewritten as the solution of the IVP defined by the initial value $f(0, y) = 1$ and such that $\frac{\partial f(x,y)}{\partial \ell} = (2^{\ell(y)} - 1) \times f(x)$. This is clearly an instance of ℓ-ODE$_2$, such that $g(\mathbf{y}) = 1$, $k(\mathbf{y}) = y$ and $h(x, \mathbf{y}) = 0$. Recall that, since $h(x, \mathbf{y}) = 0$, even the limit case of $y = 0$ is properly captured.

The BIT function. Intuitively, the function $\mathsf{BIT}(x, y)$ returns the y^{th} bit in the binary representation of x. In order to capture it, a series of auxiliary functions are needed:

- the *log most significant part function* $\mathsf{msp}(x, y) : x, y \mapsto \left\lfloor \frac{y}{2^{\ell(x)}} \right\rfloor$, which can be rewritten via ℓ-ODE$_3$,
- the *basic conditional function* $\mathsf{if}(x, y, z)$, returning y if $x = 0$ and z otherwise, can be rewritten in our setting by composition, using, in particular, the "shift function" $2^{\ell(x)} \times y$ (defined using ℓ-ODE$_1$),

- the *special bit function* $\mathsf{bit}(x, y)$, returning 1 when the $\ell(y)^{th}$ bit of x is 1, can be rewritten in $\mathbb{ACDL}$ due to msp,
- the *bounded exponentiation function* $\mathsf{bexp}(x, y)$, that, for any $y \leq \ell(x)$, returns 2^y, can be obtained relying on functions in $\mathbb{ACDL}$, including, in particular, msp, if and $2^{\ell(\cdot)}$ together with ODE-schemas.

Then, using bexp and bit, the desired BIT function can be rewritten in our setting by composition: $\mathsf{BIT}(x, y) = \mathsf{bit}(x, \mathsf{bexp}(x, y) - 1)$.

The CRN Schema. A function f defined by CRN from g, h_0 and h_1 can be simulated in $\mathbb{ACDL}$ via the ℓ-ODE$_1$ schema. Let us consider the IVP with initial value $F(0, x, \mathbf{y}) = g(\mathbf{y})$ and such that:

$$\frac{\partial F(t, x, \mathbf{y})}{\partial \ell(t)} = F(t, x, \mathbf{y}) + h(t + 1, x, \mathbf{y})$$

where $h(t, x, \mathbf{y}) \in \{0, 1\}$ is, in turn, defined as:

$$\mathsf{if}\big(\mathsf{bit}(x, 2^{\ell(x)-\ell(t)} - 1), h_0(\mathsf{msp}(2^{\ell(x)-\ell(t)}, x), \mathbf{y}), h_1(\mathsf{msp}(2^{\ell(x)-\ell(t)}, x), \mathbf{y})\big).$$

The function $F(t, x, \mathbf{y})$ is clearly an instance of ℓ-ODE$_1$, and $h(t, x, \mathbf{y})$ is defined by composition from functions proved to be in $\mathbb{ACDL}$. Then, we set $f(x, \mathbf{y}) = F(x, x, \mathbf{y})$.

We now have all the ingredients to prove our main result.

▶ **Theorem 18.** $\mathbb{ACDL} = \mathbf{FAC}^0$.

Proof. $\mathbb{ACDL} \subseteq \mathbf{FAC}^0$. All basic functions of $\mathbb{ACDL}$ are computable in $\mathbf{FAC}^0$. Moreover, the class is closed under composition and, by Prop. 15 and 17, under ℓ-ODE$_2$ and ℓ-ODE$_3$. $\mathbf{FAC}^0 \subseteq \mathbb{ACDL}$ since, as we just proved, functions and schemas constituting $\mathcal{A}_0$ have been rewritten in $\mathbb{ACDL}$. ◀

A careful analysis of the above definitions shows that ℓ-ODE$_2$ is actually used only to capture the smash # function. One obtains a class equivalent to $\mathbb{ACDL}$ by allowing # and by replacing ℓ-ODE$_2$ with the simpler ℓ-ODE$_1$ schema.

▶ **Corollary 19.** $\mathbf{FAC}^0 = [0, 1, \pi_i^p, \ell, +, -, \div 2, \mathsf{sg}, \#; \circ, \ell\text{-}ODE_1, \ell\text{-}ODE_3]$

3.3 An ODE-Characterization of $\mathbf{FTC}^0$

As a byproduct, an ODE-characterization for $\mathbf{FTC}^0$ is easily obtained, this time passing through $\mathcal{TC}_0$ [14]. We consider an extension of $\mathbb{ACDL}$ endowed with the basic function ×:

$$\mathbb{TCDL} = [0, 1, \pi_i^p, \ell, +, -, \div 2, \times, \mathsf{sg}; \circ, \ell\text{-ODE}_2, \ell\text{-ODE}_3].$$

▶ **Proposition 20.** *Let f be defined by ℓ-ODE$_2$ from functions in $\mathbf{FTC}^0$. Then, f is in $\mathbf{FTC}^0$.*

Proof Sketch. The proof is similar to that of Prop. 15. The main difference concerns the computation of level 0, i.e. that of the initial values $g(\mathbf{y})$ and $h(x, \mathbf{y})$, which are now expressions possibly including ×. This does not affect the overall structure of the circuit. ◀

▶ **Proposition 21.** *Let f be defined by ℓ-ODE$_3$ from functions in $\mathbf{FTC}^0$. Then, f is in $\mathbf{FTC}^0$.*

Proof Sketch. Straightforward generalization of Prop. 17, with the same provisos of Prop. 20. ◀

Then, the desired characterization easily follows from Propositions 20 and 21 and from [14], rewritten in our ODE-setting (see Sec. 3.2).

▶ **Theorem 22.** $\mathbb{TCDL} = \mathbf{FTC}^0$.

An alternative characterization of $\mathbf{FTC}^0$ is obtained by considering the following class:

$$\mathbb{TCDL}^* = [0, 1, \pi_i^p, \ell, +, -, \div 2, \mathsf{sg}; \circ, \ell\text{-ODE}_2^*, \ell\text{-ODE}_3].$$

where $\mathbb{TCDL}^*$ does not include $\times$ as a basic function, but allows the generalized schema ℓ-ODE$_2^*$, with no constraint over the function k:

▶ **Definition 23** (ℓ-ODE$_2^*$ Schema). *Let $g : \mathbb{N}^p \to \mathbb{N}, h : \mathbb{N}^{p+1} \to \mathbb{N}$ and $k : \mathbb{N}^p \to \mathbb{N}$, where h takes values in $\{0, 1\}$. Then, the function $f : \mathbb{N}^{p+1} \to \mathbb{N}$ is defined by ℓ-ODE$_2^*$ from g, h and k when it is the solution of the IVP with initial value $f(0, \mathbf{y}) = g(\mathbf{y})$ and such that:*

$$\frac{\partial f(x, \mathbf{y})}{\partial \ell} = \left(2^{\ell(k(\mathbf{y}))} - 1\right) \times f(x, \mathbf{y}) + h(x, \mathbf{y}).$$

▶ **Example 24** (bcount). Observe that if $k(\mathbf{y}) = 0$, then ℓ-ODE$_2^*$ is enough to express the binary counting function $\mathsf{bcount}(x)$, that outputs the sum of the bits of x. Indeed, $\mathsf{bcount}(x) = f(x, x)$ where f is the solution of the IVP with initial value $f(0, \mathbf{y}) = \mathsf{bit}(0, y)$ and such that:

$$\frac{\partial f(x, \mathbf{y})}{\partial \ell} = \mathsf{bit}(x, \mathbf{y}).$$

Since such function is not in $\mathbf{FAC}^0$ (see [19]), this also illustrates that ℓ-ODE$_2^*$ is really more expressive than ℓ-ODE$_2$.

It is easy to see that ℓ-ODE$_2^*$ is enough to capture majority (and to "simulate" multiplication, see [30]), which is the essential step to show that $\mathbb{TCDL}^* = \mathbf{FTC}^0$.

This observation, together with the fact that what really makes ℓ-ODE$_2^*$ more expressive than ℓ-ODE$_2$ is its behavior for $k(\mathbf{y}) = 0$, leads us to an alternative characterization for $\mathbf{FTC}^0$, in line with the one of Corollary 19. Let's consider the following schema.

▶ **Definition 25** (ℓ-ODE$_1^*$ Schema). *Let $g : \mathbb{N}^p \to \mathbb{N}$ and $h, k : \mathbb{N}^{p+1} \to \{0, 1\}$. Then the function $f : \mathbb{N}^{p+1} \to \mathbb{N}$ is defined by ℓ-ODE$_1^*$ from g, h and k, when it is the solution of the IVP with initial value $f(0, \mathbf{y}) = g(\mathbf{y})$ and such that:*

$$\frac{\partial f(x, \mathbf{y})}{\partial \ell} = k(x, \mathbf{y}) \times f(x, \mathbf{y}) + h(x, \mathbf{y}).$$

By straightforward inspection and Example 24, it is easily seen that $\mathbf{FTC}^0$ is again captured by adding the basic function # and by replacing ℓ-ODE$_2^*$ with the simpler schema ℓ-ODE$_1^*$.

▶ **Corollary 26.** $\mathbf{FTC}^0 = \mathbb{TCDL}^* = [0, 1, \pi_i^p, \ell, +, -, \div 2, \mathsf{sg}, \#; \circ, \ell\text{-}ODE_1^*, \ell\text{-}ODE_3]$.

3.4 Alternative Direct Proofs

In this section, we introduce alternative classes $\mathbb{ACDL}_{\mathcal{C}}$ and $\mathbb{TCDL}_{\mathcal{C}}$, (resp.) extending $\mathbb{ACDL}$ and $\mathbb{TCDL}$ with new basic functions that arithmetize the circuit families of polynomial size and constant depth $(C_n)_{n \geq 0}$ used for computation. In this non-uniform context, we prove both $\mathbf{FAC}^0 \subseteq \mathbb{ACDL}_{\mathcal{C}}$ (Sec. 3.4.1) and $\mathbf{FTC}^0 \subseteq \mathbb{TCDL}_{\mathcal{C}}$ (Sec. 3.4.2) *directly*, i.e. without any references to results in [11, 14], .

3.4.1 Direct Completeness for $\mathbb{ACDL}_{\mathcal{C}}$

Let $\mathcal{C} = (C_n)_{n \geq 0}$ be a class of circuits of polynomial size n^k, for some $k \in \mathbb{N}$, and constant depth d. We assume that each circuit C_n is in a special normal form, such that it strictly alternates between $\wedge$ and $\vee$ (and edges are only between gates of consecutive layers): input gates are all at level 0, negation gates are all at level 1, even levels are all $\wedge$ gates, odd levels (other than 1) are all $\vee$ gates, and the depth d is even (so output gates are $\wedge$ gates).

In this context we keep the basic functions of $\mathbb{ACDL}$, but add a set $\mathbf{circ}_{\mathcal{C}} = \{C, L_0^{in}, L_0^{\neg}, L_e\}$ of characteristic functions associated to the following predicates. The predicate $C \subseteq \mathbb{N} \times \mathbb{N} \times \mathbb{N}$ describes the underlying graph of the circuit: for any integers x, α, β, $(x, \alpha, \beta) \in C$ when, in $C_{\ell(x)}$, the $\alpha^{th} \leq \ell(x)^k$ gate of some level is a predecessor of the $\beta^{th} \leq \ell(x)^k$ gate of the next level (thus, in this encoding, α and β are exponentially smaller than x). The relations $L_0^{in}, L_0^{\neg}, L_e \subseteq \mathbb{N} \times \mathbb{N}$, for $e \in \{1, \dots, d\}$, describe the level of gates (and, implicitly, their type): L_0^{in} refers to input gates, $L_0^{\neg}$ to negation gates, and L_e to $\wedge$ and $\vee$ gates, depending on e being odd or even. Since we aim at defining functions over integers, we assume that input gates are numbered from $n-1$ to 0 and output gates from $m-1$ to 0, with $m \leq \ell(x)^k$. By considering the functions corresponding to the given relations, we obtain the desired ODE-style family of classes (parameterized by $\mathcal{C}$):

$$\mathbb{ACDL}_{\mathcal{C}} = [0, 1, \pi_i^p, \ell, +, -, \div 2, \mathsf{sg}, \mathbf{circ}_{\mathcal{C}}; \circ, \ell\text{-ODE}_2, \ell\text{-ODE}_3].$$

▶ Remark 27. If the family $\mathcal{C}$ is **Dlogtime**-uniform, then the functions in $\mathbf{circ}_{\mathcal{C}}$ are computable in $\mathcal{A}_0$. Consequently, in this case, it holds that $\mathbb{ACDL}_{\mathcal{C}} = \mathbb{ACDL}$.

In this non-necessarily uniform context, a completeness proof still holds.

▶ **Proposition 28.** *If a function $f : \mathbb{N} \to \mathbb{N}$ is computable by a family $\mathcal{C} = (C_n)_{n \geq 0}$ of polynomial size and constant-depth circuits, then it is in $\mathbb{ACDL}_{\mathcal{C}}$.*

To prove it we need the following lemma (which is easily established relying on Remark 13).

▶ **Lemma 29.** *Let g and h be functions computable in $\mathbb{ACDL}_{\mathcal{C}}$ and $k \in \mathbb{N}$. Then, the function $\mathsf{min}_{i \leq \ell(x_1)^k}\{g(i, \mathbf{x}) : h(i, \mathbf{x}) \rhd j\}$, for $\rhd \in \{<, \leq, >, \geq, =\}$ and $j \in \{0, 1\}$, is in $\mathbb{ACDL}_{\mathcal{C}}$.*

Proof of Prop. 28. Let $\mathsf{Eval}(t, x)$ be a function that returns the value of the t^{th} output gate of the circuit $C_{\ell(x)}$ of input x when $t \leq m-1$ (and $\mathsf{Eval}(t, x) = 0$ for $t > m-1$). Then, the following expression defines a function f such that $f(2^{\ell(x)^k}, x)$ outputs the value of the computation of C_n (for $n = \ell(x)$) on input x:

$$\frac{\partial f(y, x)}{\partial \ell(y)} = f(y, x) + \mathsf{Eval}(\ell(x) - \ell(y) - 1, x)$$

with $f(0, x) = 0$. Intuitively, the function above computes the successive suffixes of the output word, starting from the bits of bigger weights. Remarkably, this is an instance of the ℓ-ODE$_1$ schema (indeed, $\mathsf{Eval}(y, x) \in \{0, 1\}$). So, the given f can be rewritten in $\mathbb{ACDL}_{\mathcal{C}}$.

It remains to describe how the function $\mathsf{Eval}(t, x)$ is computed. Again, we assume that C_n has depth d, is in the normal form described above, and d is even. Concretely, we start by defining a special (bounded) minimum operator function such that, given $k \in \mathbb{N}$ and two functions g and h, with $h(t, \mathbf{x}) \in \{0, 1\}$ for $t \in \mathbb{N}$ and $\mathbf{x} = x_1, \dots, x_h$,

$$\mathsf{min}_{i \leq \ell(x_1)^k}\{g(i, \mathbf{x}) : h(i, \mathbf{x}) \rhd 0\},$$

with $\rhd \in \{<, \leq, >, \geq, =\}$ and $j \in \{0, 1\}$. Intuitively, given $i \in \{0, \dots, \ell(x_1)\}$, this function computes the minimum of the values of $g(i, \mathbf{x})$, for i and $\mathbf{x}$ such that $h(i, \mathbf{x}) \rhd j$.

The inductive definition of Eval relies on those of the $d+1$ functions $\mathsf{Eval}_0, \dots, \mathsf{Eval}_d$, with $\mathsf{Eval}_d = \mathsf{Eval}$:

- $\mathsf{Eval}_0(t,x)$ is equal to $\mathsf{BIT}(t,x)$ if $L_0^{in}(t,x)$ holds and to $1-\mathsf{BIT}(t,x)$ if $L_0^{\neg}(t,x)$ does. For t not corresponding to gate index, $\mathsf{Eval}_0(t,x)$ is set to an arbitrary value, say 0. Recall that, since BIT can be rewritten in $\mathbb{ACDL}$ (Sec. 3.2), Eval_0 is in $\mathbb{ACDL}_{\mathcal{C}}$ as well.
- $\mathsf{Eval}_{2e}(y,x)$ is equal to $\mathsf{min}_{i\leq\ell(x)^k}\{\mathsf{Eval}_{2e-1}(i,x) : C(x,i,t)=1\}$, for $L_{2e}(t,x)$ (i.e., if t is the index of a gate at this level). The evaluation for the i^{th} gate of the level $2e$ (a $\wedge$-gate) is the minimum of the evaluations of its predecessor gates of level $2e-1$. As seen, min is in $\mathbb{ACDL}$ (Lemma 29), so Eval_{2e} can also be rewritten in this class.
- Similarly, $\mathsf{Eval}_{2e+1}(y,x)$ is the $1-\mathsf{min}_{i\leq\ell(x)^k}\{1-\mathsf{Eval}_{2e}(i,x) : C(x,i,t)=1\}$. The evaluation for the t^{th} gate of level $2e+1$ (a $\wedge$-gate) is the maximum among evaluations of its predecessor gates of level $2e$. As for Eval_{2e}, Eval_{2e+1} can be rewritten in $\mathbb{ACDL}$. ◀

▶ Remark 30. The following converse to Proposition 28 also holds (by inspecting the proofs of Proposition 15 and 17): If a function $f:\mathbb{N}\to\mathbb{N}$ is in $\mathbb{ACDL}_{\mathcal{C}}$ for some family $\mathcal{C}$ of polynomial size and constant-depth circuits, then there exists a family $\mathcal{C}'$ of polynomial size and constant-depth circuits that computes it.

3.4.2 Direct Completeness for FTC^0

Let us now consider the similar, direct characterization for $\mathbf{FTC}^0$. Suppose that C_n strictly alternates between $\wedge,\vee$ and Maj gates, and that input gates and their negation are all at level 0, $\vee$ gates are at levels $3e+1$, $\wedge$ gates at levels $3e+2$, and Maj gates at levels $3e$. Accordingly, in this case L_e describes the level of a gate of a type not limited to $\wedge,\vee$, but including Maj. Then, the desired family of classes is defined as:

$$\mathbb{TCDL}_{\mathcal{C}} = [0, 1, \pi_i^p, \ell, +, -, \div 2, \mathsf{sg}, \mathbf{circ}_{\mathcal{C}}; \circ, \ell\text{-ODE}_2^*, \ell\text{-ODE}_3]$$

where, with a slight abuse of notation, we use $\mathbf{circ}_{\mathcal{C}}$ to denote the function corresponding to a (set of) relation(s), this time including the *extended* L_e. The proof that non-uniform $\mathbf{FTC}^0 \subseteq \mathbb{TCDL}_{\mathcal{C}}$ is similar to the one from Section 3.4.1.

▶ **Proposition 31.** *If a function $f:\mathbb{N}\to\mathbb{N}$ is computable by a family $\mathcal{C}=(C_n)_{n\geq 0}$ of polynomial-size and constant-depth circuits including* Maj *gates, then it is in $\mathbb{TCDL}_{\mathcal{C}}$.*

Proof Sketch. The functions f and Eval are globally defined as before. Modifications only affect the definition of Eval_d and, in particular, the inductive levels corresponding to Maj. Specifically, it is obtained as follows:

- for a given function h and integer k, $\mathsf{bcount}_h(t,x)=\sum_{i\leq\ell(x)^k} h(i,t,x)$. Notice that this function is in $\mathbb{TCDL}_{\mathcal{C}}$, since it can be rewritten as an instance of ℓ-ODE$_2^*$, and h is in $\mathbb{TCDL}^*$ (due to Lemma 29),
- for any i such that $L_{3e-1}(i)$ and $3e-1<d$: $v^0_{3e-1}(i,t,x)=\mathsf{sg}(C(x,i,t))$ and $v^1_{3e-1}(i,t,x)=\mathsf{if}(C(x,i,t),\mathsf{Eval}_{3e-1(i,x)},0)$. The value of $v^0_{3e-1}(i,t,x)$ is 1 when i is a predecessor of gate t, and $v^1_{3e-1}(i,t,x)$ is 1 when, in addition, the value of gate i, on input x, is 1,
- for t such that $L_{3e}(t)$, $\mathsf{Eval}_{3e}(t,x)$ is defined as $\mathsf{sg}\big(\mathsf{bcount}_{v^0_{3e-1}}(t,x)-2\times\mathsf{bcount}_{v^1_{3e-1}}(t,x)\big)$. The function outputs 1 when more than half of the inputs of gate t are 1. ◀

4 Conclusion

We have presented new characterizations for $\mathbf{FAC}^0$ and $\mathbf{FTC}^0$ through the prism of discrete differential equations. Although the use of classical arithmetical functions is intrinsically limited by the low computational power of these classes, the ODEs used are surprisingly natural restrictions of linear ODEs. More generally, this work is intended as the first step of a project aiming at characterizing other relevant classes, starting with $\mathbf{FAC}^k$ and $\mathbf{FNC}^k$. Another challenging direction of future research would be to develop logical and proof-theoretical counterparts to ODE-style algebras, e.g. by defining *natural* rule systems (oriented by the ODE design) to syntactically characterize the corresponding classes.

A Proofs from Section 3

A.1 The Schemas ℓ-ODE$_1$ and ℓ-ODE$_2$

Proof of Proposition 12. By Definition 10, for all x and $\mathbf{y}$:

$$\begin{aligned} f(x,\mathbf{y}) &= \sum_{u=-1}^{\ell(x)-1} \left(\prod_{t=u+1}^{\ell(x)-1} 2 \right) \times h\big(\alpha(u),\mathbf{y}\big) \\ &= \sum_{u=-1}^{\ell(x)-1} 2^{\ell(x)-u-1} \times h(\alpha(u),\mathbf{y}) \end{aligned}$$

with the convention that $\alpha(u) = 2^u - 1$, $\prod_x^{x-1} \kappa(x) = 1$ and $h\big(\alpha(-1),\mathbf{y}\big) = f(0,\mathbf{y})$. Notice that the given multiplication is always by a power of 2 decreasing for each increasing value of u, which basically corresponds to left-shifting (which can be computed in $\mathbf{FAC}^0$). Hence, since by Definition 10, $h(x,\mathbf{y}) \in \{0,1\}$, the outermost sum amounts to a concatenation (which again can be computed in $\mathbf{FAC}^0$).

Concretely, for any inputs x and $\mathbf{y}$, the desired polynomial-sized and constant-depth circuit to compute $f(x,\mathbf{y})$ is defined as follows:

- In parallel compute the values of $g(\mathbf{y})$ and of each $h(\alpha(u),\mathbf{y})$, for any $u \in \{0,\dots,\ell(x)-1\}$. For hypothesis, g and h are computable in $\mathbf{FAC}^0$, and, since there are $\ell(x)+1$ initial values to be computed, the whole desired computation can be done in polynomial size and constant depth.
- In one step, (left-)shift the value of $h\big(\alpha(-1),\mathbf{y})\big) = g(\mathbf{y})$ by padding $\ell(x)$ zeros on the right and, for $u \geq 0$, (left-)shift each value $h\big(\alpha(u),\mathbf{y}\big)$ by padding on the right $\ell(x)-u-1$ zeros (this corresponds to multiply by $2^{\ell(x)-u-1}$) and padding on the left $u + \ell(g(\mathbf{y}))$ zeros.
- Compute, bit-by-bit, the disjunction of all values computed above. Clearly, this is done in constant depth. ◀

Proof of Proposition 15. There are two main cases to be taken into account. If $k(\mathbf{y}) \neq 0$, the proof is similar to that of Proposition 12. Indeed, for all x and $\mathbf{y}$:

$$\begin{aligned} f(x, \mathbf{y}) &= \sum_{u=-1}^{\ell(x)-1} \left(\prod_{t=u+1}^{\ell(x)-1} 2^{\ell(k(\mathbf{y}))} \right) \times h\big(\alpha(u), \mathbf{y}\big) \\ &= \sum_{u=-1}^{\ell(x)-1} 2^{\ell(k(\mathbf{y})) \times (\ell(x)-u-1)} \times h\big(\alpha(u), \mathbf{y}\big) \end{aligned}$$

with the convention that $\alpha(u) = 2^u - 1$, $\prod_x^{x-1} \kappa(x) = 1$ and $h\big(\alpha(-1), \mathbf{y}\big) = f(0, \mathbf{y})$. Observe that here multiplication corresponds to a left-shifting where "basic shifting" corresponds to a left movement of $\ell(k(\mathbf{y}))$ digits. As for the basic case, it can be easily shown that this operation can be implemented by a constant-depth circuit. Then, analogously to Proposition 12, the outermost iterated sum amounts to concatenation (as, by construction, $h(\alpha(u), \mathbf{y}) \in \{0, 1\}$).

Concretely, we can construct a constant-depth circuit generalizing the procedure defined for the special case of ℓ-ODE$_1$:

- In parallel, compute the values of $g(\mathbf{y})$ and $h(\alpha(u), \mathbf{y})$, for each $u \in \{0, \dots, \ell(x) - 1\}$. This can be done in constant depth by hypothesis.
- In one step, shift the value of $g(\mathbf{y})$ by padding $\ell(k(\mathbf{y})) \times \ell(x)$ zeros on the right, and, for $u \geq 0$, shift all values $h(\alpha(u), \mathbf{y})$ by padding on the right $\ell(k(\mathbf{y})) \times (\ell(x) - u - 1)$ zeros (i.e. multiplying by $2^{\ell(k(\mathbf{y})) \times (\ell(x)-u-1)}$) and by padding on the left $\ell(g(\mathbf{y})) + \ell(k(\mathbf{y})) \times (u + 1) - 1$ zeros.
- Compute, bit-by-bit, the disjunction of all the values above.

In the special case of $k(\mathbf{y}) = 0$ and $h(x, \mathbf{y}) = 0$, it holds that for all x and $\mathbf{y}$, $f(x, \mathbf{y}) = g(\mathbf{y})$. This is clearly computable in $\mathbf{FAC}^0$, as corresponding to compute $g(\mathbf{y})$, which is computable in constant depth by hypothesis. ◀

A.2 The Schema ℓ-ODE$_3$

For $x > 0$, the equation characterizing Definition 16 can be re-written as:

$$f(x, \mathbf{y}) = f(x - 1, \mathbf{y}) - \Delta\ell(x - 1) \times \left\lceil \frac{f(x-1, \mathbf{y})}{2} \right\rceil,$$

where, as seen, $\Delta\ell(x - 1) = \ell(x) - \ell(x - 1)$. Observe that also in this case we are using $\times$ with a slight abuse of notation: indeed, we are dealing with "bit multiplication" and multiplying a number by 0 or 1 can be easily done in $\mathbf{FAC}^0$ (and easily rewritten in our setting using the basic conditional function if, which, in turn, can be defined in $\mathbb{ACDL}$, see Sec. 3.3). In other words,

$$\begin{aligned} f(x, \mathbf{y}) &= \begin{cases} f(x-1, \mathbf{y}) & \text{if } \ell(x) = \ell(x-1) \\ f(x-1, \mathbf{y}) - \left\lceil \frac{f(x-1, \mathbf{y})}{2} \right\rceil & \text{otherwise} \end{cases} \\ &= \begin{cases} f(x-1, \mathbf{y}) & \text{if } \ell(x) = \ell(x-1) \\ \left\lfloor \frac{f(x-1, \mathbf{y})}{2} \right\rfloor & \text{otherwise} \end{cases} \\ &= \begin{cases} f(x-1, \mathbf{y}) & \text{if } \ell(x) = \ell(x-1) \\ f(x-1, \mathbf{y}) \div 2 & \text{otherwise.} \end{cases} \end{aligned}$$

A bit more formally,

$$f(x,\mathbf{y}) = \left\lfloor \frac{f(\beta(\ell(x)-1),\mathbf{y})}{2} \right\rfloor = \left\lfloor \frac{f(2^{\ell(x)-1}-1,\mathbf{y})}{2} \right\rfloor = f\big(2^{\ell(x)-1}-1,\mathbf{y}\big) \div 2$$

where $\beta\big(\ell(z)\big) = 2^{\ell(z)}-1$ is the greatest integer the length of which is $\ell(z)$, i.e. here, $2^{\ell(x)-1}-1$ is the greatest integer the length of which is $\ell(x)-1$. Hence, starting with $x>0$, there are $\ell(x)-1$ jumps of values.

Proof of Proposition 17. By Definition 16 (as clarified by the remarks above),and, since $(a \div 2^b) \div 2 = a \div 2^{b+1}$, it is easily shown by induction that, for all x and $\mathbf{y}$:

$$\begin{aligned} f(x,\mathbf{y}) &= \left\lfloor \prod_{u=1}^{\ell(x)-1} \frac{g(\mathbf{y})}{2} \right\rfloor \\ &= \left\lfloor \frac{g(\mathbf{y})}{2^{\ell(x)-1}} \right\rfloor \\ &= g(\mathbf{y}) \div 2^{\ell(x)-1}. \end{aligned}$$

This corresponds to right-shifting $g(\mathbf{y})$ a number of times equal to $\ell(x)-1$, which can be easily implemented by a constant-depth circuit. ◀

A.3 Rewriting the Function BIT in $\mathbb{ACDL}$

First, the *log most significant part function* $\mathsf{msp}(x,y) : x,y \mapsto \left\lfloor \frac{y}{2^{\ell(x)}} \right\rfloor$ can be rewritten as the solution of the IVP:

$$\begin{aligned} f(0,y) &= y \\ \frac{\partial f(x,y)}{\partial \ell} &= -\left\lceil \frac{f(x,y)}{2} \right\rceil \end{aligned}$$

which is clearly an instance of ℓ-ODE$_3$.

Second, we introduce the basic conditional function:

$$\mathsf{if}(x,y,z) = \begin{cases} y & \text{if } x = 0 \\ z & \text{otherwise.} \end{cases}$$

Notice that this function is also crucial to rewrite the CRN schema. As seen, the "shift function" $2^{\ell(x)} \times y$ can be easily rewritten via ℓ-ODE$_1$. Thus, $\mathsf{if}(x,y,z)$ is simulated in our setting by composition from shift, addition and subtraction:

$$\mathsf{if}(x,y,z) = \big(2^{\ell(1-\mathsf{sg}(x))} \times y - y\big) + \big(2^{\ell(\mathsf{sg}(x))} \times z - z\big).$$

Indeed, as desired, if $x=0$, then $\mathsf{sg}(x)=0$ and $\ell(\mathsf{sg}(x))=0$, so that $\mathsf{if}(0,y,z) = \big(2^{\ell(1)} \times y - y\big) + \big(2^{\ell(0)\times z - z}\big) = y$; similarity, for $x \neq 0$, $\mathsf{if}(0,y,z) = \big(2^{\ell(0)} \times y - y\big) + \big(2^{\ell(1)} \times z - z\big) = z$. Generalizing this definition we can capture a more general conditional function below:

$$\mathsf{cond}(x,v,y,z) = \begin{cases} y & \text{if } x < v \\ z & \text{otherwise} \end{cases}$$

Then, we consider the special bit function $\mathsf{bit}(x,y)$ returning 1 when the $\ell(y)^{th}$ bit of x is 1. This can be rewritten in $\mathbb{ACDL}$ due to msp:

$$\mathsf{bit}(x,y) = \mathsf{msp}(y,x) - 2 \times \mathsf{msp}(2y+1,x).$$

Finally, we introduce the function $\mathsf{bexp}(x, y)$, that, for any $y \leq \ell(x)$, returns 2^i. We start by defining $f_{aux}(t, x, i)$ by the ℓ-ODE$_1$ schema below:

$$f_{aux}(0, x, i) = \mathsf{if}(i, 1, 0)$$
$$\frac{\partial f_{aux}(t, x, i)}{\partial \ell(t)} = f_{aux}(t, x, i) + h_{aux}(t, i)$$

where

$$h_{aux}(t, i) = \mathsf{if}(\ell(t) - i, 1, 0).$$

Observe that, as seen, if can be rewritten in $\mathbb{ACDL}$ (while ℓ and subtraction are basic functions). Then, for $i \leq \ell(x)$, we obtain $f_{aux}(x, x, i) = 2^{\ell(x)-i}$. The function bexp is then defined as follows:

$$\mathsf{bexp}(x, i) = \mathsf{msp}\big(f_{aux}(x, x, i) - 1, 2^{\ell(x)}\big) = \left\lfloor \frac{2^{\ell(x)}}{2^{\ell(x)-i}} \right\rfloor = 2^i,$$

as the length of $f_{aux}(x, x, i) - 1$ is $\ell(x) - i$. Clearly, the function bexp is also in $\mathbb{ACDL}$ as all the functions involved in its definitions (namely, msp, f_{aux} and $2^{\ell(\cdot)}$) are in $\mathbb{ACDL}$.

We conclude by showing that, due to bexp and bit, the desired BIT function can be rewritten in our setting by composition:

$$\mathsf{BIT}(x, y) = \mathsf{bit}(x, \mathsf{bexp}(x, y) - 1).$$

Observe that alternative proofs are possible, but the one proposed here, and based on the introduction of bexp, not only has the advantage of being straightforward, but also avoids the unnatural use of function most significant part function, MSP.

A.4 On the ODE-Characterization of FTC^0

Proof of Proposition 20. The proof is similar to that of Proposition 15. The main difference concerns $g(\mathbf{y})$ and $h(x, \mathbf{y})$, which are now expressions possibly including ×.

As seen, for all x and $\mathbf{y}$:

$$f(x, \mathbf{y}) = \sum_{u=-1}^{\ell(x)-1} \left(\prod_{t=u+1}^{\ell(x)-1} 2^{\ell(k(\mathbf{y}))} \right) \times h\big(\alpha(u), \mathbf{y}\big)$$

with the convention that $\alpha(u) = 2^u - 1$, $\prod_x^{x-1} \kappa(x) = 1$ and $h\big(\alpha(-1), \mathbf{y}\big) = f(0, \mathbf{y})$. Intuitively, the (constant-depth) circuit we are going to construct is equivalent to that of Proposition 15, but the values to be initially computed in parallel are obtained even via ×. Yet, the introduction of multiplication does not affect the overall structure of the circuit, as $h\big(\alpha(u), \mathbf{y}\big) \in \{0, 1\}$, so that the final sum again corresponds to a simple bit-concatenation (without carries).

More precisely, the desired constant-depth circuit is defined as follows:

- In parallel, compute the values of $g(\mathbf{y})$ and, for any $u = 0, \ldots, \ell(x) - 1$, of $h\big(\alpha(u), \mathbf{y}\big)$. Observe that this can be done in $\mathbf{FTC}^0$, but possibly not in $\mathbf{FAC}^0$, as now these arithmetic expressions may include ×.
- The value of $g(\mathbf{y})$ is shifted by padding $2^{\ell(k(\mathbf{y})) \times \ell(x)}$ zeros on the right and, for $u \geq 0$, all values $h\big(\alpha(u), \mathbf{y}\big)$ are shifted by padding on the right $\ell(k(\mathbf{y}))$ zeros $\ell(x) - u - 1$ times, and by padding on the left $\ell(k(\mathbf{y}))$ zeros $\ell(g(\mathbf{y})) + u$ times.
- the disjunction of the above values is computed bit by bit. ◀

Proof of Proposition 22. $\mathbb{TCDL} \subseteq \mathbf{FTC}^0$. All basic functions are computable in $\mathbf{FTC}^0$, and the class is closed under composition and, by Propositions 20 and 21, under ℓ-ODE$_2$ and ℓ-ODE$_3$.

$\mathbf{FTC}^0 \subseteq \mathbb{TCDL}$. By mimicking the arithmetization proof provided in [14] (see Sec. 2.2), as all the functions defining $\mathcal{TC}_0$ can be rewritten in $\mathbb{TCDL}$ (this time including ×, which is basic in $\mathbb{TCDL}$). ◀

Switching Classes: Characterization and Computation

Abstract

In a graph, the switching operation reverses adjacencies between a subset of vertices and the others. For a hereditary graph class $\mathcal{G}$, we are concerned with the maximum subclass and the minimum superclass of $\mathcal{G}$ that are closed under switching. We characterize the maximum subclass for many important classes $\mathcal{G}$, and prove that it is finite when $\mathcal{G}$ is minor-closed and omits at least one graph. For several graph classes, we develop polynomial-time algorithms to recognize the minimum superclass. We also show that the recognition of the superclass is NP-hard for H-free graphs when H is a sufficiently long path or cycle, and it cannot be solved in subexponential time assuming the Exponential Time Hypothesis.

1 Introduction

In a graph G, the operation of *switching* a subset A of vertices is to reverse the adjacencies between A and $V(G) \setminus A$. Two vertices $x \in A$ and $y \in V(G) \setminus A$ are adjacent in the resulting graph if and only if they are not adjacent in G. The switching operation, introduced by van Lint and Seidel [35] (see more at [29, 30, 31]), is related to many other graph operations, most notably variations of graph complementation. The *complement* of a graph G is a graph defined on the same vertex set of G, where a pair of distinct vertices are adjacent if and only if they are not adjacent in G. The *subgraph complementation* on a vertex set A is to replace the subgraph induced by A with its complement, while keeping the other part, including connections between A and the outside, unchanged [2]. Switching A is equivalent to taking the complement of the graph itself and the subgraphs induced by A and $V(G) \setminus A$. Indeed, the widely used *bipartite complementation* operation of a bipartite graph is nothing but switching one part of the bipartition. A special switching operation where A consists of a single vertex is also well studied. It is a nice exercise to show that switching A is equivalent to switching the vertices in A one by one. This is somewhat related to the local complementation operation [28].

Two graphs are *switching equivalent* if one can be obtained from the other by switching. Colbourn and Corneil [9] proved that deciding whether two graphs are switching equivalent is polynomial-time equivalent to the graph isomorphism problem. Another interesting topic is to focus on graphs from a hereditary graph class $\mathcal{G}$ – a class is *hereditary* if it is closed under taking induced subgraphs. There are two natural questions in this direction. Given a graph G,

- whether G can be switched to a graph in $\mathcal{G}$? and
- whether all switching equivalent graphs of G are in $\mathcal{G}$?

We use the *upper $\mathcal{G}$ switching class* and the *lower $\mathcal{G}$ switching class*, respectively, to denote the set of positive instances of these two problems. Since switching the empty set does not change the graph, the answer of the first question is yes for every graph in $\mathcal{G}$, while the answer of the second question can only be yes for a graph in $\mathcal{G}$. Thus, the class $\mathcal{G}$ is sandwiched in between these two switching classes. Note that the three classes collapse into one when $\mathcal{G}$ is closed under switching, e.g., complete bipartite graphs.

Both switching classes are also hereditary. For the upper switching class, if a graph G can be switched to a graph H in $\mathcal{G}$, then any induced subgraph of G can be switched to an induced subgraph of H, which is in $\mathcal{G}$ because $\mathcal{G}$ is hereditary. For the lower switching class, recall that a hereditary graph class $\mathcal{G}$ can be characterized by a (not necessarily finite) set $\mathcal{F}$ of forbidden induced subgraphs. A graph is in $\mathcal{G}$ if and only if it does not contain any forbidden induced subgraph. If G contains any induced subgraph that is switching equivalent to a graph in $\mathcal{F}$, then G cannot be in the lower $\mathcal{G}$ switching class. Thus, the forbidden induced subgraphs of the lower $\mathcal{G}$ switching class are precisely all the graphs that are switching equivalent to some graphs in $\mathcal{F}$.

Even when $\mathcal{G}$ has an infinite set of forbidden induced subgraphs, the lower $\mathcal{G}$ switching class may have very simple structures. The list of forbidden induced subgraphs obtained as above is usually not minimal. For example, Hertz [18] showed that the lower perfect switching class has only four forbidden induced subgraphs, all switching equivalent to the five-cycle. In the same spirit as Hertz [18], we characterize the lower $\mathcal{G}$ switching classes of a number of important graph classes.

▶ **Theorem 1.** *The lower $\mathcal{G}$ switching class is characterized by a finite number of forbidden induced subgraphs when $\mathcal{G}$ is one of the following graph classes: weakly chordal, comparability, co-comparability, permutation, distance-hereditary, Meyniel, bipartite, chordal bipartite, complete multipartite, complete bipartite, chordal, strongly chordal, interval, proper interval, Ptolemaic, and block.*

Indeed, since the forbidden induced subgraphs of threshold graphs are $2K_2, C_4$, and P_4 [8], by the arguments given above, the forbidden subgraphs of the lower threshold switching class are all graphs on four vertices (every graph on four vertices is switching equivalent to a graph in $\{2K_2, C_4, P_4\}$). This class, consisting of only graphs of order at most three, is finite. Also finite are lower switching classes of minor-closed graph classes that are nontrivial[1] (there exists at least one graph not in this class).

▶ **Theorem 2.** *Let $\mathcal{G}$ be a nontrivial minor-closed graph class, and let p be the smallest order of a forbidden minor of $\mathcal{G}$. Then $|V(G)| = O(p\sqrt{p})$, for graphs G in lower $\mathcal{G}$ switching class.*

[1] We thank an anonymous reviewer for the bound in Theorem 2, which improves the bound in a previous version of this manuscript.

Theorems 1 and 2 immediately imply polynomial-time and constant-time algorithms, respectively, for recognizing these lower switching classes, i.e., deciding whether a graph is in the class. We remark that there are classes $\mathcal{G}$ such that the lower $\mathcal{G}$ switching class has an infinite number of forbidden induced subgraphs.

The upper $\mathcal{G}$ switching classes turn out to be more complicated. These classes are nontrivial even for the class of H-free graphs for a fixed graph H. Although $\mathcal{G}$ has only one forbidden induced subgraph, the number of forbidden induced subgraphs of the upper $\mathcal{G}$ switching class is usually infinite. Based on our current knowledge, exceptions do exist but are rare [19]. Even so, for many graph classes $\mathcal{G}$, polynomial-time algorithms for recognizing the upper $\mathcal{G}$ switching class exist, e.g., bipartite graphs [16]. Our understanding of this problem is very limited, even for classes defined by forbidding a single graph H. For all graphs H on at most three vertices, polynomial-time algorithms are known for recognizing the upper H-free switching class [16, 17, 24]. Of a graph H on four vertices, the four-path [18] and the claw [19] have been settled. We present a polynomial-time algorithm for paw-free graphs. If two graphs H_1 and H_2 are complements to each other, then the recognition of the upper H_1-free switching class is polynomially equivalent to that of the upper H_2-free switching class. Thus, the remaining cases on four vertices are the diamond, the cycle, and the complete graph. We made attempt to them by solving the class of forbidding the four-cycle and its complement, which is known as pseudo-split graphs.

▶ **Theorem 3.** *The upper $\mathcal{G}$ switching class can be recognized in polynomial time when $\mathcal{G}$ is one of the following graph classes: paw-free graphs, pseudo-split graphs, split graphs, $\{K_{1,p}, \overline{K_{1,q}}\}$-free graphs, and bipartite chain graphs.*

In Theorem 3, we want to highlight the algorithms for pseudo-split graphs and for split graphs. We actually show a stronger result. Any input graph G has only a polynomial number of ways to be switched to a graph in these two classes, and we can enumerate them in polynomial time. Thus, the algorithms can apply to hereditary subclasses of pseudo-split graphs, provided that these subclasses themselves can be recognized in polynomial time. This is only possible when the lower switching classes of them are finite. It is unknown whether the other direction also holds true.

Jelínková and Kratochvíl [19] found graphs H such that the upper H-free switching class is hard to recognize. The smallest graph they found is on nine vertices. More specifically, they showed that, for all $k \geq 3$, there is a graph of order $3k$ with this property. The graph is obtained from a three-vertex path by substituting one degree-one vertex with an independent set of k vertices, and each of the other two vertices with a clique of k vertices. We show that the recognition of the upper H-free switching class is already hard when H is a cycle on seven vertices or a path on ten vertices. Our proofs can be adapted to longer ones.

▶ **Theorem 4.** *Deciding whether a graph is switching equivalent to a P_{10}-free graph or a C_7-free graph is NP-complete, and it cannot be solved in subexponential time (on $|V(G)|$) assuming the Exponential Time Hypothesis.*

Since the problem admits a trivial $2^{|V(G)|} \cdot |V(G)|^{O(1)}$-time algorithm, by enumerating all subsets of $V(G)$, our bound in Theorem 4 is asymptotically tight. We conjecture that it is NP-complete to decide whether a graph can be switched to an H-free graph when H is a cycle or path of length six.

Theorem 1 and 2 are proved in Section 3, Theorem 3 is proved in Section 4, and Theorem 4 is proved in Section 5. Due to space constraints, most of the proofs are left to a full version of the paper.

Other related work

Jelínková et al. [20] studied the parameterized complexity of the recognition problem of the upper switching classes. Let us remark that there is also study on the upper switching classes for non-hereditary graph classes. For example, we can decide in polynomial time whether a graph can be switching equivalent to a Hamiltonian graph [11] or to an Eulerian graph [16], but it is NP-complete to decide whether a graph can be switching equivalent to a regular graph [23]. Cameron [6] and Cheng and Wells Jr. [7] generalized the switching operation to directed graphs. Foucaud et al. [13] studied switching operations in a different setting.

Seidel [30] showed that the size of a maximum set of switching inequivalent graphs on n vertices is equivalent to the number of two-graphs of size n. This is further shown to be the same as the number Eulerian graphs on n vertices [25] and graphs on $2n$ vertices admitting certain coloring [26]. Bodlaender and Hage [4] showed that the switching operation does not change the cliquewidth of a graph too much, though it may change the treewidth significantly. The switching equivalence between graphs in certain classes can be decided in polynomial time. For example, acyclic graphs because two forests are switching equivalent if and only if they are isomorphic [14]. In a complementary study, Hage and Harju [15] characterized graphs that cannot be switched to any forest. They are either a small graph on at most nine vertices, or switching equivalent to a cycle.

From a graph G on n vertices, we can obtain n graphs by switching each vertex, called the *switching deck* of G. The *switching reconstruction conjecture* of Stanley [32] asserts that for any $n > 4$, if two graphs on n vertices have the same switching deck, they must be isomorphic. The conjecture remains widely open, and we know that it holds on triangle-free graphs [12]. A similar question in digraph is also studied [5].

2 Preliminaries

All the graphs discussed in this paper are finite and simple. The vertex set and edge set of a graph G are denoted by, respectively, $V(G)$ and $E(G)$. Let $n = |V(G)|$ and $m = |E(G)|$. For a subset $U \subseteq V(G)$, we denote by $G[U]$ the subgraph of G induced by U, and by $G - U$ the subgraph $G[V(G) \setminus U]$, which is shortened to $G - v$ when $U = \{v\}$. The *neighborhood* of a vertex v, denoted by $N_G(v)$, comprises vertices adjacent to v, i.e., $N_G(v) = \{u \mid uv \in E(G)\}$, and the *closed neighborhood* of v is $N_G[v] = N_G(v) \cup \{v\}$. The *closed neighborhood* and the *neighborhood* of a set $X \subseteq V(G)$ of vertices are defined as $N_G[X] = \bigcup_{v \in X} N_G[v]$ and $N_G(X) = N_G[X] \setminus X$, respectively. We may drop the subscript if the graph is clear from the context. We write $N(u, v)$ and $N[u, v]$ instead of $N(\{u, v\})$ and $N[\{u, v\}]$; i.e., we drop the braces when writing the neighborhood of a vertex set. Two vertex sets X and Y are *complete* (resp., *nonadjacent*) *to* each other if all (resp., no) edges between X and Y are present.

For positive ℓ, we use C_ℓ ($\ell \geq 3$), P_ℓ, and K_ℓ to denote the cycle, path, and complete graph, respectively, on ℓ vertices. When $\ell \geq 4$, an induced C_ℓ is called an *ℓ-hole.* A complete bipartite graph with p and q vertices in the two parts are denoted as $K_{p,q}$.

The *disjoint union* of two graphs G_1 and G_2 is denoted by $G_1 + G_2$. The *complement graph* $\overline{G}$ of a graph G is defined on the same vertex set $V(G)$, where a pair of distinct vertices u and v is adjacent in $\overline{G}$ if and only if $uv \notin E(G)$. By $\mathcal{G}^c$, we denote the set of graphs not in $\mathcal{G}$. The switching of a vertex subset A of a graph G is denoted by $S(G, A)$. It has the same vertex set as G and its edge set is $E(G[A]) \cup E(G - A) \cup \{uv \mid u \in A, v \in V(G) \setminus A, uv \notin E(G)\}$. The following observations are immediate from the definition. The *symmetric difference* of two sets is defined as $A \Delta B = (A \setminus B) \cup (B \setminus A)$.

▶ **Proposition 5** (folklore). *Let G be a graph, and $A, B \subseteq V(G)$.*

- $S(G, A) = S(G, (V(G) \setminus A))$.
- $S(S(G, A), A) = G$.
- $S(S(G, A), B) = S(S(G, B), A) = S(G, A \Delta B)$.
- $\overline{S(G, A)} = S(\overline{G}, A)$.

Two graphs G and G' are called *switching equivalent* if $S(G, A) = G'$ for some $A \subseteq V(G)$. By Proposition 5, switching is an equivalence relation. For example, the eleven graphs of order 4 can be partitioned into the following three sets

$$\{C_4, \overline{K_3 + K_1}, 4K_1\}, \{2K_2, K_3 + K_1, K_4\}, \{P_4, K_2 + 2K_1, \overline{K_2 + 2K_1}, P_3 + K_1, \overline{P_3 + K_1}\}.$$

Note that $\overline{K_3 + K_1}$ is the claw, $\overline{P_3 + K_1}$ is the paw, and $\overline{K_2 + 2K_1}$ is the diamond; see Figure 1 and 2a. For a graph G, we use $\mathcal{S}(G)$ to denote the set of non-isomorphic graphs that can be obtained from G by switching. Figure 2 illustrates $\mathcal{S}(C_4)$ and $\mathcal{S}(C_5)$. For a set $\mathcal{G}$ of graphs, by $\mathcal{S}(\mathcal{G})$ we denote the union of $\mathcal{S}(G)$ for $G \in \mathcal{G}$.

A graph G is a *split graph* if the vertex set of G can be partitioned in such a way that one is a clique and the other is an independent set. *Split partitions* of a split graph refer to such (clique, independent set) partitions. An *edgeless graph* is a graph without any edges.

In general, for two sets $\mathcal{G}$ and $\mathcal{H}$ of graphs, we say that $\mathcal{G}$ is $\mathcal{H}$-free if G is H-free for every $G \in \mathcal{G}$ and for every $H \in \mathcal{H}$. By $\mathcal{F}(\mathcal{H})$, we denote the class of $\mathcal{H}$-free graphs. Note that $\mathcal{F}(\mathcal{H} \cup \mathcal{H}') = \mathcal{F}(\mathcal{H}) \cap \mathcal{F}(\mathcal{H}')$.

For a graph property $\mathcal{G}$, the *lower $\mathcal{G}$ switching class*, denoted by $\mathcal{L}(\mathcal{G})$, consists of all graphs G with $\mathcal{S}(G) \subseteq \mathcal{G}$. Note that every graph in $\mathcal{L}(\mathcal{G})$ is also in $\mathcal{G}$. Thus, $\mathcal{L}(\mathcal{G})$ is the maximal subset $\mathcal{G}'$ of $\mathcal{G}$ such that $\mathcal{S}(\mathcal{G}') = \mathcal{G}'$. The *upper $\mathcal{G}$ switching class*, denoted by $\mathcal{U}(\mathcal{G})$, consists of all graphs G with $\mathcal{S}(G) \cap \mathcal{G} \neq \emptyset$. Clearly, every graph in $\mathcal{G}$ is in $\mathcal{U}(\mathcal{G})$. Therefore, $\mathcal{U}(\mathcal{G})$ is the minimal superset $\mathcal{G}'$ of $\mathcal{G}$ such that $\mathcal{S}(\mathcal{G}') = \mathcal{G}'$. We note that $\mathcal{U}(\mathcal{G}) = \mathcal{S}(\mathcal{G})$. The following proposition is immediate from the definitions and Proposition 5.

▶ **Proposition 6.** *Let $\mathcal{G}$ and $\mathcal{G}'$ be graph classes. Then the following hold true.*

1. $(\mathcal{L}(\mathcal{G}))^c = \mathcal{U}(\mathcal{G}^c)$.
2. *If $\mathcal{G}' \subseteq \mathcal{G}$, then $\mathcal{L}(\mathcal{G}') \subseteq \mathcal{L}(\mathcal{G})$ and $\mathcal{U}(\mathcal{G}') \subseteq \mathcal{U}(\mathcal{G})$.*
3. $\mathcal{L}(\mathcal{G}) \cap \mathcal{L}(\mathcal{G}') = \mathcal{L}(\mathcal{G} \cap \mathcal{G}')$.

▶ **Proposition 7.** *For a set $\mathcal{H}$ of graphs, $\mathcal{L}(\mathcal{F}(\mathcal{H})) = \mathcal{F}(\mathcal{U}(\mathcal{H}))$.*

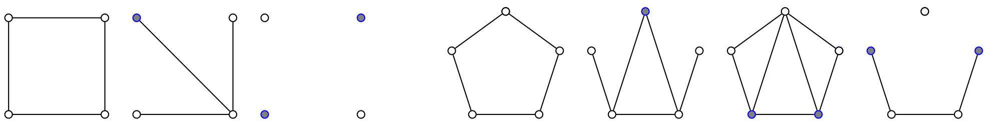
Figure 1 Small graphs.

3 Lower switching classes

Every (odd) hole of length at least seven contains an induced $P_4 + K_1$, and its complement contains an induced gem. Both $P_4 + K_1$ and the gem are in $\mathcal{S}(C_5)$; see Figure 2b. Thus, all the forbidden induced subgraphs of perfect graphs, namely, odd holes and their complements, boil down to $\mathcal{S}(C_5)$, and the lower perfect switching class is equivalent to the lower C_5-free



(a) $\mathcal{S}(C_4) = \{C_4, \text{claw}, 4K_1\}$ **(b)** $\mathcal{S}(C_5) = \{C_5, \text{bull}, \text{gem}, P_4 + K_1\}$

Figure 2 Switching equivalent graphs of C_4 and C_5. Switching the solid nodes (or the rest) results in the first graph in the list.

switching class [18]. In the same spirit, we characterized the lower $\mathcal{G}$ switching classes of a number of important graph classes listed in Figure 3. The results are listed in Table 1. Since all these lower switching classes have finite characterizations, they can be recognized in polynomial time. For the class of chordal graphs and several of its subclasses, we show a stronger structural characterization of their lower switching classes. They have to be proper interval graphs with a very special structure. The following lemma, a consequence of Proposition 6(2), is crucial for our arguments.

▶ **Lemma 8.** *Let $\mathcal{G}_1, \mathcal{G}_2$, and $\mathcal{G}_3$ be three classes of graphs such that $\mathcal{G}_1 \subseteq \mathcal{G}_2 \subseteq \mathcal{G}_3$. If $\mathcal{L}(\mathcal{G}_3) = \mathcal{L}(\mathcal{G}_1)$, then $\mathcal{L}(\mathcal{G}_2) = \mathcal{L}(\mathcal{G}_1)$. In particular, the following is true. Let $\mathcal{H}_1, \mathcal{H}_2$, and $\mathcal{H}_3$ be three sets of graphs such that $\mathcal{H}_3 \subseteq \mathcal{H}_2 \subseteq \mathcal{H}_1$. If $\mathcal{L}(\mathcal{F}(\mathcal{H}_3)) = \mathcal{L}(\mathcal{F}(\mathcal{H}_1))$, then $\mathcal{L}(\mathcal{F}(\mathcal{H}_2)) = \mathcal{L}(\mathcal{F}(\mathcal{H}_1))$.*

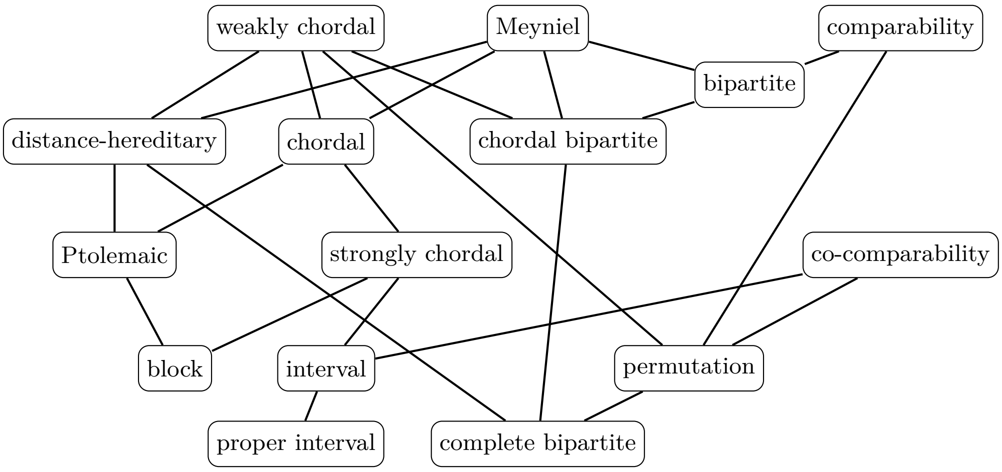


Figure 3 The Hasse diagram of graph classes studied in Section 3.

To see a simple application of Lemma 8, let $\mathcal{G}$ be the class of complete bipartite graphs and $\mathcal{G}'$ be the class of bipartite graphs. Since K_3 and $K_2 + K_1$ are switching equivalents, and bipartite graphs are K_3-free, we obtain that lower bipartite switching class is $\{K_3, K_2 + K_1\}$-free. Recall that $\{K_3, K_2 + K_1\}$-free graphs are exactly the class of complete bipartite graphs. Further, switching a complete bipartite graph results in a complete bipartite graph. Therefore, lower $\mathcal{G}''$ switching class is equivalent to the class of complete bipartite graphs, where $\mathcal{G}''$ is a subclass of bipartite graphs and a superclass of complete bipartite graphs, such as bipartite graphs, complete bipartite graphs, and chordal bipartite graphs (bipartite graphs in which every cycle longer than 4 has a chord).

▶ **Lemma 9.** *Let $\mathcal{G}$ be any subclass of bipartite graphs and any superclass of complete bipartite graphs. Then $\mathcal{L}(\mathcal{G})$ is the class of complete bipartite graphs.*

Table 1 Lower switching classes of various graph classes.

$\mathcal{G}$	$\mathcal{L}(\mathcal{G})$	By
weakly chordal, permutation	$\{C_5, C_6, \overline{C_6}\}$-free	Corollary 11
distance-hereditary	$\{\text{domino}, \text{house}, C_5, C_6\}$-free	
comparability	$\{C_5, \overline{C_6}\}$-free	
co-comparability	$\{C_5, C_6\}$-free	
Meyniel graphs	$\{C_5, \text{house}\}$-free	
complete bipartite, chordal bipartite, bipartite	complete bipartite	Lemma 9
chordal, strongly chordal, interval, proper interval, Ptolemaic	$\mathcal{C}_0$	Corollary 13
block	$(+)$, $(+, 0, +)$, $(1, 1, 1)$, and $(1, 0, 1, 0, 1)$	Lemma 14

Let $\mathcal{H}$ be the set of all graphs having an induced subgraph isomorphic to at least one graph in $\mathcal{S}(C_5)$. A *building* is obtained from a hole by adding an edge connecting two vertices of distance two; e.g., the house, see Figure 1. An *odd building* is a building with odd number of vertices.

▶ **Observation 10.** *$\mathcal{H}$ contains C_5, holes of length at least seven, complements of holes of length at least seven, and buildings of at least six vertices.*

Lemma 8 and Observation 10 lead us to Corollary 11.

▶ **Corollary 11.** *The forbidden induced subgraphs of the lower $\mathcal{G}$ switching class of $\mathcal{G}$ being weakly chordal, distance-hereditary, comparability, co-comparability, permutation, and Meyniel graphs are* $\{C_5, C_6, \overline{C_6}\}$, $\{\text{domino}, \text{house}, C_5, C_6\}$, $\{C_5, \overline{C_6}\}$, $\{C_5, C_6\}$, $\{C_5, C_6, \overline{C_6}\}$, $\{C_5, \text{house}\}$, *respectively.*

Next we deal with the class of chordal graphs and its subclasses. We start with showing that the lower $\{C_4, C_5, C_6\}$-free switching class is a subclass of proper interval graphs and has very simple structures. Let $a_1, \ldots, a_p$ be p nonnegative integers. For $1 \leq i \leq p$, we substitute the ith vertex of a path on p vertices with a clique of a_i vertices. We denote the resulting graph as $(a_1, a_2, \ldots, a_p)$. For example, the paw and the diamond are $(1, 1, 2)$ and $(1, 2, 1)$, respectively, while the complement of the diamond can be represented as $(2, 0, 1, 0, 1)$. We use "+" to denote an unspecified positive integer, and hence $(+)$ stands for all complete graphs.

The forbidden induced subgraphs of proper interval graphs are holes, sun, net, and claw. Note that a sun and a net (see Figure 1) contains an induced bull ($\in \mathcal{S}(C_5)$), while any cycle on at least seven vertices contains an induced $P_4 + K_1 \in \mathcal{S}(C_5)$. A claw is in $\mathcal{S}(C_4)$. Therefore, lower $\{C_4, C_5, C_6\}$-free switching class is a subclass of proper interval graphs. A careful analysis shows that the structure is much simpler.

▶ **Lemma 12.** *The lower $\{C_4, C_5, C_6\}$-free switching class consists of graphs* $(+)$, $(+, +, 1)$, $(+, 1, +)$, $(+, 0, +)$, $(+, +, 1, 0, +)$, $(+, 0, +, 0, 1)$, $(+, +, 1, +)$, *and* $(+, +, 1, +, +)$.

Let $\mathcal{C}_0$ denote the lower $\{C_4, C_5, C_6\}$-free switching class. Since chordal graphs are $\{C_4, C_5, C_6\}$-free, lower chordal switching class is a subclass of $\mathcal{C}_0$. By Lemma 12, $\mathcal{C}_0$ is a subclass of lower chordal switching class. Therefore, they are equivalent. This same observation applies to subclasses of chordal graphs that contain all the graphs in $\mathcal{C}_0$ and by Lemma 8 to superclasses of chordal graphs which are $\{C_4, C_5, C_6\}$-free.

▶ **Corollary 13.** *The following switching classes are all equivalent to $\mathcal{C}_0$: lower chordal switching class, lower strongly chordal switching class, lower interval switching class, lower proper interval switching class, and lower Ptolemaic switching class.*

Proof. Since chordal graphs, strongly chordal graphs, interval graphs, and proper interval graphs are all hole-free, all the lower switching classes are subclasses of $\mathcal{C}_0$ by Proposition 6. On the other hand, by Lemma 12, all the graphs in $\mathcal{C}_0$ are proper interval graphs. Thus, $\mathcal{C}_0$ is a subclass of proper interval switching graphs, hence also a subclass of the first three switching classes. Ptolemaic graphs are gem-free chordal graphs. Since gem is in $\mathcal{S}(C_5)$, the lower Ptolemaic switching class is also $\mathcal{C}_0$. Thus, they are all equal. ◀

The class of line graphs has nine forbidden induced subgraphs [3], two of which are switching equivalent to C_6, and one C_4. Although C_5 is not forbidden, we show that a graph in the lower line switching class contains an induced C_5 if and only if it is a C_5. Thus, this switching class consists of $\mathcal{S}(C_5)$ and a subclass of $\mathcal{C}_0$.

▶ **Lemma 14.** *The lower block switching class consists of graphs* $(+)$, $(+,0,+)$, $(1,1,1)$, *and* $(1,0,1,0,1)$. *The lower line switching class comprises of (+), (1,1,1), (2,1,1), (1,2,1), (2,1,2), (+,0,+), (1,1,1,0,1), (2,1,1,0,1), (1,0,1,0,1), (2,0,1,0,1), (2,0,2,0,1), (1,1,1,1), (1,2,1,1), (1,1,1,1,1), and $\mathcal{S}(C_5)$.*

A graph F is a *minor* of a graph G if F can be obtained from a subgraph of G by contracting edges (identifying the two ends of the edge and keeping one edge between the resulting vertex and each of the neighbors of the end points of the edge). For example, any cycle contains all shorter cycles as minors. A graph class $\mathcal{G}$ is *minor-closed* if every minor of a graph in $\mathcal{G}$ also belongs to $\mathcal{G}$. In other words, there is a set $\mathcal{M}$ of *forbidden minors* such that a graph belongs to $\mathcal{G}$ if and only if it does not contain as a minor any graph in $\mathcal{M}$. Since an induced subgraph of a graph G is a minor of G, a minor-closed graph class is hereditary. We say that a graph class is *nontrivial* if there is at least one graph not in the class.

Kostochka [21, 22] and Thomason [33] proved that, there exists an absolute constant $c > 0$ such that every graph G with at least $c \cdot |V(G)| \cdot p\sqrt{p}$ edges has K_p as a minor. See [34] for an overview. This helps us to prove Theorem 2:

▶ **Theorem 2.** *Let $\mathcal{G}$ be a nontrivial minor-closed graph class, and let p be the smallest order of a forbidden minor of $\mathcal{G}$. Then $|V(G)| = O(p\sqrt{p})$, for graphs G in lower $\mathcal{G}$ switching class.*

Proof. Let $G \in \mathcal{L}(\mathcal{G})$ be a graph with n vertices. It is straight-forward to verify that there exists a constant $c' > 0$ such that either G or $S(G, A)$ has $c' \cdot n^2$ edges, where A is any subset of $V(G)$ with cardinality $\lfloor n/2 \rfloor$. If $c' \cdot n^2 \geq c \cdot n \cdot p\sqrt{p}$, then G has a K_p-minor. Therefore, $n = O(p\sqrt{p})$. ◀

We have found that, for the class of outerplanar graphs, planar graphs, and series-parallel graphs, the maximum orders of graphs in the lower switching classes are five, seven, and at most 12, respectively.

Let us mention that there are classes $\mathcal{G}$ such that the lower $\mathcal{G}$ switching class has an infinite number of forbidden induced subgraphs.

▶ **Lemma 15.** *For any infinite set $I \subseteq \{9, 10, \ldots\}$, the forbidden induced subgraphs of the lower $\{C_\ell, \ell \in I\}$-free switching class are $\bigcup_{\ell \in I} \mathcal{S}(C_\ell)$.*

4 Upper switching classes: algorithms

For the recognition of the upper $\mathcal{G}$ switching class, the input is a graph G, and the solution is a vertex subset $A \subseteq V(G)$ such that $S(G,A) \in \mathcal{G}$.

We start with split graphs. If the input graph G is a split graph, then we have nothing to do. Suppose that G is in the upper split switching class. Let A be a solution, and $K \uplus I$ a split partition of $S(G,A)$. Note that if $A \in \{K, I\}$, then G is a split graph. We may assume that A intersects both K and I: if A is a proper subset of K or I, we replace A with $V(G) \setminus A$. We can guess a pair of vertices $u \in A \cap K$ and $v \in A \cap I$. The vertex set $V(G) \setminus \{u, v\}$ can be partitioned into four parts, namely, $N(u) \setminus N[v]$, $N(v) \setminus N[u]$, $N(u) \cap N(v)$, and $V(G) \setminus N[u,v]$. It is easy to see that the first is a subset of A while the second is disjoint from A. The subgraphs $G[N(u) \cap N(v)]$ and $G - N[u,v]$ must be split graphs, and each admits a special split partition with respect to A. The algorithm is described in Figure 4. We can modify the algorithm so that it enumerates all solutions.

▶ **Theorem 16.** *Let G be a graph. There are a polynomial number of subsets A of $V(G)$ such that $S(G,A)$ is a split graph, and they can be enumerated in polynomial time.*

```
1.        if $G$ is a split graph then return “yes”;
2.        for each pair of vertices $u, v \in V(G)$ do
2.1.          if $G[N(u) \cap N(v)]$ is not a split graph then continue;
2.2.          if $G - N[u,v]$ is not a split graph then continue;
2.3.          for each split partition $K_1 \uplus I_1$ of $G[N(u) \cap N(v)]$ do
2.3.1.            for each split partition $K_2 \uplus I_2$ of $G - N[u,v]$ do
2.3.1.1.              if $S(G, \{u,v\} \cup (N(u) \setminus N[v]) \cup K_1 \cup I_2)$ is a split graph
                      then return “yes”;
3.        return “no.”
```

Figure 4 The algorithm for split graphs.

A *pseudo-split graph* is either a split graph, or a graph whose vertex set can be partitioned into a clique K, an independent set I, and a set H that (1) induces a C_5; (2) is complete to K; and (3) is nonadjacent to I. We say that $K \uplus I \uplus H$ is a *pseudo-split partition* of the graph, where H may or may not be empty. If H is empty, then $K \uplus I$ is a split partition of the graph. When H is nonempty, the pseudo-split partition is unique.

For pseudo-split graphs, we start with checking whether the input graph can be switched to a split graph. We are done if the answer is “yes.” Henceforth, we are looking for a resulting graph that contains a hole C_5. Suppose that G is in the upper pseudo-split switching class. Let A be a solution, and $K \uplus I \uplus H$ is a *pseudo-split partition* of $S(G,A)$. We may assume that $|A \cap H| \geq 3$: otherwise, we replace A with $V(G) \setminus A$. The subgraph $G[H]$ must be one of Figure 2b, and $A \cap H$ are precisely the vertices represented as empty nodes. We can guess the vertex set H as well as its partition with respect to A, and then all the other vertices are fixed by the following observation:

- K is complete to $H \cap A$ and nonadjacent to $H \setminus A$, and
- I is complete to $H \setminus A$ and nonadjacent to $H \cap A$.

The algorithm is described in Figure 5. We can modify the algorithm so that it enumerates all solutions.

```
1.        if $G$ can be switched to a split graph then return “yes”;
2.        for each vertex set $H$ such that $G[H] \in \mathcal{S}(C_5)$ do
2.0.          $H_1 \leftarrow$ the empty nodes of $G[H]$ as in Figure 2b; $H_2 \leftarrow H \setminus H_1$;
2.1.          for each vertex $x$ in $V(G) \setminus H$ do
2.1.1.            if $N(x) \cap H$ is neither $H_1$ nor $H_2$ then continue;
2.2.          if $N(H_1) \setminus H$ does not induce a split graph then continue;
2.3.          if $N(H_2) \setminus H$ does not induce a split graph then continue;
2.4.          for each split partition $K_1 \uplus I_1$ of the subgraph induced by $N(H_1) \setminus H$ do
2.4.1.            for each split partition $K_2 \uplus I_2$ of the subgraph induced by $N(H_2) \setminus H$ do
2.4.1.1.              if $S(G, H_1 \cup K_1 \cup I_2)$ is a pseudo-split graph then return “yes”;
3.        return “no”.
```

Figure 5 The algorithm for pseudo-split graphs.

▶ **Theorem 17.** *Let G be a graph. There are a polynomial number of subsets A of $V(G)$ such that $S(G, A)$ is a pseudo-split graph, and they can be enumerated in polynomial time.*

As a result, we have an algorithm for any hereditary subclass $\mathcal{G}$ of pseudo-split graphs that can be recognized in polynomial time. Since a graph has 2^n subsets, and the switching of only a polynomial number of them leads to a pseudo-split graph, every graph of sufficiently large order can be switched to a graph that is not a pseudo-split graph. Thus, the lower pseudo-split switching class is finite.

Next we give an algorithm for recognizing upper paw-free switching class. Since a paw contains an induced C_3 and an induced $\overline{P_3}$, both C_3-free graphs and $\overline{P_3}$-free graphs are paw-free. Olariu [27] showed that a connected paw-free graph is C_3-free or $\overline{P_3}$-free (i.e., complete multipartite). We start with checking whether G can be switched to a C_3-free graph [17] or a $\overline{P_3}$-free graph [24]. When the answers are both “no”, we look for a set $A \subseteq V(G)$ such that $S(G, A)$ is not connected and contains a triangle. It is quite simple when $S(G, A)$ has three or more components. We can always assume that A intersects two of them. We guess one vertex from each of these intersections, and an arbitrary vertex from another component (which can be in A or not). The three vertices are sufficient to determine A. It is more challenging when $S(G, A)$ comprises precisely two components. The crucial observation here is that one of the components is C_3-free and the other $\overline{P_3}$-free. We have assumed the graph contains a triangle. If both components contain triangles, hence $\overline{P_3}$-free, then $S(G, A)$ can be switched to a complete multipartite graph, contradicting the assumption above. We guess a triple of vertices that forms a triangle in $S(G, A)$, and they can determine A. The algorithm is described in Figure 6. A *co-component* of a graph G is a component of the complement of G. Indeed, a graph is complete multipartite if and only if every co-component is an independent set. With two tailored algorithms we prove that recognizing upper $\{K_{1,p}, \overline{K_{1,q}}\}$-free switching class and upper bipartite chain switching class can be solved in polynomial-time.

We end this section with the following remark. By Proposition 6(1), we know that recognizing $\mathcal{L}(\mathcal{G})$ is polynomially equivalent to recognizing $\mathcal{U}(\mathcal{G}^c)$. This implies polynomial-time algorithms for $\mathcal{U}(\mathcal{G}^c)$ for all the classes $\mathcal{G}$ for which we proved (in Section 3) the finiteness of $\mathcal{L}(\mathcal{G})$ or finiteness of the set of forbidden induced subgraphs of $\mathcal{L}(\mathcal{G})$. In particular, this implies that we have polynomial-time algorithms for recognizing upper non-planar switching class and upper non-chordal switching class.

```
1.        if $G$ can be switched to a $\overline{P_3}$- or $C_3$-free graph then return "yes";
2.        for each pair of nonadjacent vertices $u_1, u_2$ do // three or more components.
2.1.          for each $u_3 \in V(G) \setminus N[u_1, u_2]$ do
2.1.1.            $A \leftarrow \{x \in V(G) \mid |N[x] \cap \{u_1, u_2, u_3\} \leq 1\}$;
2.1.2.            if $S(G, A)$ is paw-free then return "yes";
2.2.          for each $u_3 \in N(u_1) \cap N(u_2)$ do
2.2.1.            $A \leftarrow (V(G) \setminus N[u_1, u_2]) \cup ((N[u_1] \Delta N[u_2]) \setminus N(u_3))$;
2.2.2.            if $S(G, A)$ is paw-free then return "yes";

3.3.          for each $I \subseteq \{1, \ldots, p\}$ and $J \subseteq \{1, \ldots, q\}$ with $|I|, |J| \leq 2$ do
3.3.1.            $X \leftarrow \bigcup_{i \notin I}$ $i$th co-component of $G[N(u_1) \cap N(u_2)]$;
3.3.2.            $Y \leftarrow \bigcup_{j \in J}$ $j$th co-component of $G - N[u_1, u_2]$;
3.3.3.            if $X \neq \emptyset$ then
3.3.3.1.              $u_3 \leftarrow$ an arbitrary vertex from $X$;
3.3.3.2.              $A \leftarrow X \cup Y \cup ((N(u_1) \Delta N(u_2)) \cap N(u_3))$;
3.3.4.            else
3.3.4.1.              $u_3 \leftarrow$ an arbitrary vertex from $V(G) \setminus (N[u_1, u_2] \cup Y)$;
3.3.4.2.              $A \leftarrow X \cup Y \cup ((N(u_1) \Delta N(u_2)) \setminus N(u_3))$;
3.3.5.            if $S(G, A)$ is paw-free then return "yes";
4.        return "no."
```

Figure 6 The algorithm for paw-free graphs.

5 Upper switching classes: hardness

In this section, we prove hardness results for recognition problems for $\mathcal{U}(\mathcal{G})$, for $\mathcal{G}$ being the class of P_{10}-free graphs or the class of C_7-free graphs. For convenience, we denote the recognition problem for $\mathcal{U}(\mathcal{G})$ as Switching-to-$\mathcal{G}$. We prove that Switching-to-$\mathcal{F}(P_{10})$ and Switching-to-$\mathcal{F}(C_7)$ are NP-complete and cannot be solved in time subexponential in the number of vertices, assuming the Exponential Time Hypothesis (ETH). We refer to the book [10] for an exposition to ETH and linear reductions which can be used to transfer complexity lower bounds.

Our reductions are from Monotone NAE k-SAT. A Monotone NAE k-SAT instance is a boolean formula Φ with n variables and m clauses where each clause contains exactly k positive literals (and no negative literals). The objective is to check whether there is a truth assignment to the variables so that there is at least one TRUE literal and at least one FALSE literal in each clause in Φ. It is folklore that the problem is NP-complete and cannot be solved in subexponential-time assuming ETH.

▶ **Proposition 18** (folklore). *For every $k \geq 3$, Monotone NAE k-SAT is NP-complete. Further, the problem cannot be solved in time $2^{o(n+m)}$, assuming ETH.*

We use the following construction for a reduction from Monotone NAE 5-SAT to Switching-to-$\mathcal{F}(P_{10})$.

▶ **Construction 1.** *Let Φ be a* Monotone NAE 5-SAT *formula with n variables $X_1, X_2, \cdots, X_n$, and m clauses $C_1, C_2, \cdots, C_m$. We construct a graph G_Φ as follows:*

- *For each variable X_i in Φ, introduce a variable vertex x_i. Let L be the set of all variable vertices, which forms an independent set of size n.*
- *For each clause C_i in Φ of the form $\{\ell_{i1}, \ell_{i2}, \ell_{i3}, \ell_{i4}, \ell_{i5}\}$, introduce a set of clause vertices, also named C_i, consisting of an independent set of size 5, denoted by I_i, and 5 disjoint P_9s each of which is denoted by B_{ij}, for $1 \leq j \leq 5$. Let $B_i = \bigcup_{j=1}^{5} B_{ij}$. The adjacency among the set B_{ij} and I_i, for $1 \leq j \leq 5$, is in such a way that the set of vertices in the P_9 induced by the B_{ij}, except one of the end vertex v_{ij}, is complete to I_i. Note that $C_i = B_i \cup I_i$. The set of union of all clause vertices is denoted by C. Let the 5 vertices introduced (in the previous step) for the variables $\ell_{i1}, \ell_{i2}, \ell_{i3}, \ell_{i4}, \ell_{i5}$ be denoted by $L_i = \{x_{i1}, x_{i2}, x_{i3}, x_{i4}, x_{i5}\}$. Make the adjacency between the vertices in L_i and the sets of P_9s in B_is in such a way that, taking one vertex from each set B_{ij} along with the variable vertices in L_i induces a P_{10}, where the vertices in L_i correspond to an independent set of size 5 in P_{10}. More precisely, x_{i1} is complete to B_{i1} and x_{ij} is complete to $B_{i(j-1)} \cup B_{ij}$, for $2 \leq j \leq 5$. Further, make the adjacency among the set I_i and L_i in such a way that, if exactly one of the set L_i or I_i is in the switching set A, then the vertices in $L_i \cup I_i$ together induce a P_{10} in $S(G_\Phi, A)$.*
- *For all $i \neq j$, C_i is complete to C_j.*

This completes the construction of the graph G_Φ (see Figure 7 for an example of the construction).

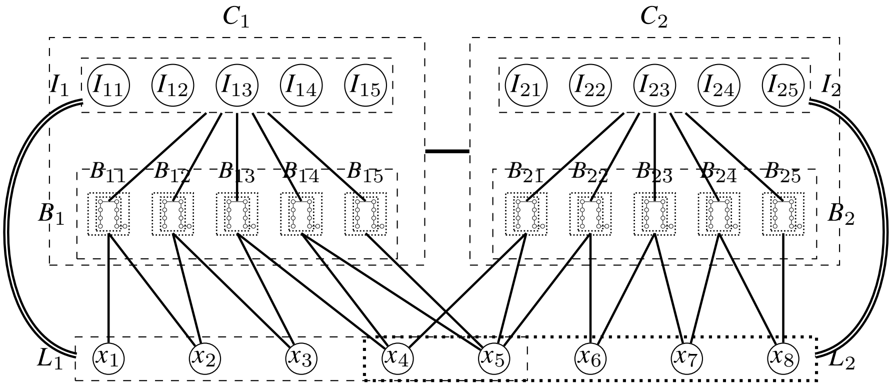

Figure 7 An example of Construction 1 with the formula $\Phi = C_1 \wedge C_2$, where $C_1 = \{x_1, x_2, x_3, x_4, x_5\}$ and $C_2 = \{x_4, x_5, x_6, x_7, x_8\}$. Single lines connecting two rectangles indicate that each vertex in one rectangle is adjacent to all vertices in the other rectangle. The double line connecting two rectangles indicates that each vertex in one rectangle is adjacent to the vertices in the other rectangle in such a way that if a switching set A contains all the vertices of one rectangle and no vertex of the other rectangle, then a P_{10} is induced by these two sets of vertices after switching.

We recall that the vertices in L_i and one vertex each from B_{ij}s ($1 \leq j \leq 5$) induce a P_{10}. If we have a truth assignment which satisfies Φ, then the vertices in L corresponding to the TRUE literals can be switched to obtain a P_{10}-free graph. The backward direction is easy and is proved in Lemma 19.

▶ **Lemma 19.** *Let Φ be an instance of* Monotone NAE 5-SAT. *If $S(G_\Phi, A)$ is P_{10}-free, for some $A \subseteq V(G_\Phi)$, then there exists a truth assignment satisfying Φ.*

Proof. We claim that assigning TRUE to the variables corresponding to the variable vertices in $A \cap L$ satisfies Φ. It is sufficient to prove that $A \cap L_i \neq \emptyset$ and $L_i \setminus A \neq \emptyset$, for every $1 \leq i \leq m$.

For a contradiction, assume that $A \cap L_i = \emptyset$, for some $1 \leq i \leq m$. Since L_i and one vertex each from B_{ij} induces a P_{10}, we obtain that $B_{ij} \subseteq A$, for some $1 \leq j \leq 5$. Then $I_i \subseteq A$ (otherwise, there is a P_{10} induced in $S(G_\Phi, A)$ by B_{ij} and a vertex in I_i not in A - recall that one end vertex v_{ij} of the P_9 formed by B_{ij} is not adjacent to I_i). Then at least one vertex from L_i is in A, otherwise there is a P_{10} induced in $S(G_\Phi, A)$ by $I_i \cup L_i$. This gives us a contradiction.

Next we show that L_i is not a subset of A. For a contradiction, assume that $L_i \setminus A = \emptyset$. Then at least one vertex $I_{i\ell} \in I_i$ (for some $1 \leq \ell \leq 5$) is in A - otherwise there is an P_{10} induced in $S(G_\Phi, A)$ by $L_i \cup I_i$. Then at least one vertex from each B_{ij} (for $1 \leq j \leq 5$) must be in A - otherwise there is a P_{10} induced in $S(G_\Phi, A)$ by $I_{i\ell}$ and B_{ij}, where $B_{ij} \cap A = \emptyset$. Then there is a P_{10} induced by L_i and one vertex, which is in A, from each B_{ij} (for $1 \leq j \leq 5$). This is a contradiction. ◀

With a similar reduction from MONOTONE NAE 3-SAT, we prove that SWITCHING-TO-$\mathcal{F}(C_7)$ is NP-complete and cannot be solved in subexponential-time.

6 Concluding remarks

There are many interesting questions one can ask about the characterization and computation of lower and upper switching classes of various graph classes. Here we list a few of them.

Since recognizing $\mathcal{U}(\mathcal{F}(P_{10}))$ and recognizing $\mathcal{U}(\mathcal{F}(C_7))$ are NP-complete, by Proposition 6(1), we obtain that recognizing $\mathcal{L}(\mathcal{G})$ is NP-complete, where $\mathcal{G}$ is the class of graphs containing an induced P_{10} or the class of graphs containing an induced C_7. Note that these classes are non-hereditary. For a hereditary graph class $\mathcal{G}$, is it true that whenever $\mathcal{G}$ is recognizable in polynomial-time, lower $\mathcal{G}$ switching class is also recognizable in polynomial-time? We know by Proposition 7 that this is true whenever $\mathcal{G}$ is characterized by a finite set of forbidden induced subgraphs.

Is it true that recognizing upper H-free switching class is polynomially equivalent to recognizing the upper H'-free switching class, where H and H' are switching equivalent? We know that the answer to the corresponding question for lower switching class is trivial, as both lower H-free and lower H'-free switching classes can be recognized in polynomial-time. In particular, can we recognize the upper H-free switching class in polynomial time when H is C_4, K_4, or diamond? For each of them, we know a switching equivalent H' such that the upper H'-free switching class can be recognized in polynomial time.

Let $\mathcal{G}$ be a graph class. Assume that, for any graph G, there are only polynomial number of ways to switch G to a graph in $\mathcal{G}$. Then every large enough graph G can be switched to a graph not in $\mathcal{G}$. Therefore, $\mathcal{L}(\mathcal{G})$ is finite. Is it true that whenever $\mathcal{L}(\mathcal{G})$ is finite, then $\mathcal{U}(\mathcal{G})$ can be recognized in polynomial-time?

What is the smallest integer ℓ such that the recognition of $\mathcal{U}(\mathcal{F}(P_\ell))$ is NP-complete? We know that $5 \leq \ell \leq 10$. Similarly, what is the smallest integer ℓ such that the recognition of $\mathcal{U}(\mathcal{F}(C_\ell))$ is NP-complete? We know that $4 \leq \ell \leq 7$.

Abstract

For any natural number d, a graph G is a (disjoint) d-interval graph if it is the intersection graph of (disjoint) d-intervals, the union of d (disjoint) intervals on the real line. Two important subclasses of d-interval graphs are unit and balanced d-interval graphs (where every interval has unit length or all the intervals associated to a same vertex have the same length, respectively). A celebrated result by Roberts gives a simple characterization of unit interval graphs being exactly claw-free interval graphs. Here, we study the generalization of this characterization for d-interval graphs. In particular, we prove that for any $d \geqslant 2$, if G is a $K_{1,2d+1}$-free interval graph, then G is a unit d-interval graph. However, somehow surprisingly, under the same assumptions, G is not always a *disjoint* unit d-interval graph. This implies that the class of disjoint unit d-interval graphs is strictly included in the class of unit d-interval graphs. Finally, we study the relationships between the classes obtained under disjoint and non-disjoint d-intervals in the balanced case and show that the classes of disjoint balanced 2-intervals and balanced 2-intervals coincide, but this is no longer true for $d > 2$.

1 Introduction

Interval graphs are the intersection graphs of intervals on the real line: every vertex represents an interval and there is an edge between two vertices if and only if their corresponding intervals intersect. The class of interval graphs is one of the most important classes of intersection graphs, mostly due to their numerous applications in scheduling or allocation problems and in bioinformatics, see for examples these monographs [11, 23, 25].

Already in the late 70s, situations arising naturally in scheduling and allocation motivated the generalization of interval graphs to *multiple interval graphs*, where every vertex is associated to the union of d intervals on the real line (called a d-interval), for some natural number d, instead of to a single interval. This allowed a more robust modeling of problems such as multi-task scheduling or allocation of multiple associated linear resources [15, 22, 29], and led to several interesting problems [10, 12, 17, 18, 19]. The applications of 2-interval graphs to bioinformatics also increased the interest on this class of graphs [20, 30].

These concrete applications of multiple interval graphs, specifically 2-interval graphs, suggested a focus on different restrictions, such as unit 2-interval graphs [2], or balanced 2-interval graphs [7]. For both interval and multiple interval graphs, we say that they are *unit* if all the intervals in the representation, i.e. the set of intervals associated to the graph, have unit length. For multiple interval graphs, we also define the subclass of *balanced* d-interval graphs, where all intervals forming the same d-interval have equal length, but intervals of different d-intervals can have different lengths. Finally, for both interval and multiple interval graphs, we say that they are *proper* if there exists an interval representation where no interval properly contains another one. The class of unit 2-interval graphs is known to be properly contained in the class of balanced 2-interval graphs [13].

Let us remark that in the literature, d-intervals have been defined both as the union of d *disjoint* intervals [2, 5, 31], as the union of d *not necessarily disjoint* intervals [29], and simply as the union of d intervals, without specifying whether they are disjoint or not [9, 27]. This ambiguity is not relevant in the general case, since both definitions lead to the same class of graphs. However, in this paper we focus on subclasses of multiple interval graphs, namely unit and balanced, for which this equivalence is not known to be true. Therefore, we will distinguish between the two possible definitions of d-intervals. The first definition is denoted as *disjoint d-intervals* while the second is simply denoted as *d-intervals* (further details are discussed in Section 2).

From an algorithmic perspective, another reason why interval graphs have been widely studied is because many problems that are NP-hard become solvable in polynomial time when restricted to this class of graphs. This is not the case for d-interval graphs [2, 5, 12]. The problem of recognizing d-interval graphs is no exception: it is NP-complete for every natural number $d \geqslant 2$ [31], even for unit 2-interval graphs [1] and balanced 2-interval graphs [13]. In sharp contrast, the recognition of interval graphs (both in the unit and unrestricted case) can be done in polynomial time [4, 16], and there exist multiple characterizations of them, including a characterization in terms of forbidden induced subgraphs [21, 24]. In particular, in 1969, Roberts proved that the class of proper interval graphs and the class of unit interval graphs coincide [24], and showed that unit interval graphs are exactly $K_{1,3}$-free interval graphs (i.e., interval graphs that do not contain the star with three leaves as an induced subgraph). To do so, he used the Scott-Suppes characterization of semiorders (see [3, 14] for short constructive proofs of this result). This is a remarkable result as it gives a simple characterization of unit interval graphs. It also implies that if $G = (V, E)$ is a unit interval graph, then there exists a semiorder $S(V, P)$ on the vertices of V such that $(u, w) \in P$ if and only if $(u,w) \notin E$, which justifies the original name of "indifference graphs" for unit interval graphs (as they can represent indifference relations by joining two elements by an edge if neither is preferred over the other one).

It is straight-forward to check that being $K_{1,3}$-free is a necessary condition for being a unit interval graph, as an interval of unit length cannot intersect three pairwise disjoint intervals of length one. The reader can observe that this necessary condition extends naturally to multiple interval graphs: a unit 2-interval graph cannot contain a $K_{1,5}$ as an induced subgraph; and more generally, a unit d-interval graph cannot contain a $K_{1,2d+1}$ as an induced subgraph. Thus the following natural question arises: can we generalize Roberts characterization of unit interval graphs to multiple interval graphs? Perhaps the most straight-forward generalization would be to characterize unit d-interval graphs as $K_{1,2d+1}$-free d-interval graphs, but this has already been proven false in [28]: there exists a graph which is 2-interval and $K_{1,5}$-free, but not unit 2-interval. But not all hope of generalizing Roberts characterization must be lost yet! What if we add some additional constraints?

Already in 2016, Durán et al. decided to focus on d-interval graphs which are also *interval* [8]. In a presentation at VII LAWCG, they claimed that if G is an interval graph, then G is a disjoint unit d-interval graph if and only if it is $K_{1,2d+1}$-free [1]. In this paper, we show that the aforementioned statement is actually false, and that, perhaps surprisingly, Roberts characterization can only be generalized depending on the chosen definition of d-interval graphs! (See Figure 1 for a summary of the main results).

We also study the subclasses obtained under the two definitions of d-intervals in the balanced case, expanding the knowledge of the relationships between the different subclasses of 2-interval graphs.

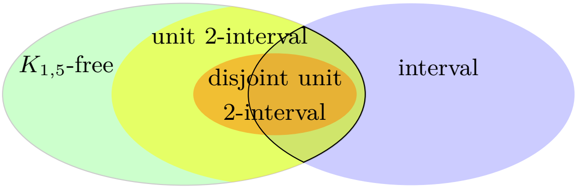

Figure 1 $K_{1,5}$-free interval graphs are not contained in the class of disjoint unit 2-interval graphs. The class of unit 2-interval graphs is a superclass of disjoint unit 2-interval graphs, and spans the whole intersection of $K_{1,5}$-free and interval graphs.

The structure of the paper is as follows: Section 2 briefly introduces the necessary definitions and discusses the definition of d-interval. In Section 3, we prove that if G is an interval graph, then it is unit d-interval if and only if it is $K_{1,2d+1}$-free. We then show that this result cannot be generalized for *disjoint* multiple intervals in Section 4, which implies that the class of disjoint unit d-interval graphs is actually properly contained in the class of unit d-interval graphs. Finally, we study the balanced case in Section 5, and show that the definition of d-interval also matters, as the classes of disjoint balanced 2-intervals and balanced 2-intervals coincide, but this is no longer true for $d > 2$. We conclude with some open questions in Section 6. Due to space constraints, some proofs, marked with a $(\star)$, are deferred to the full version of this paper.

[1] Note that they refer to disjoint unit d-intervals simply as unit d-intervals, but they are explicitly defined beforehand as the union of d disjoint intervals.

2 Preliminaries

In the following, $G = (V, E)$ will denote a simple undirected graph on the set of vertices V and with edges E, and an interval will be a set of real numbers of the form $[a, b] := \{x \in \mathbb{R} \mid a \leqslant x \leqslant b\}$.

A graph G is an *interval graph* if there exists a bijection from the vertices of G to a multiset of intervals, $f : V \to \mathcal{I}$, such that there exists an edge between two vertices if and only if their corresponding intervals intersect. The multiset $\mathcal{I}$ is called an *interval representation* of G.

For any natural number $d > 0$, a (disjoint) *d-interval* is the union of d (disjoint) intervals on the real line.

For any natural number $d > 0$, a graph G is a (disjoint) *d-interval graph* if there exists a bijection from the vertices of G to a multiset of (disjoint) d-intervals, $f : V \to \mathcal{I}$, such that there exists an edge between two vertices if and only if their corresponding d-intervals intersect. The multiset $\mathcal{I}$ of d-intervals is called a d-interval representation of G, and the family of all intervals that compose the d-intervals in $\mathcal{I}$ is called the *underlying family of intervals* of $\mathcal{I}$.

A (disjoint) d-interval graph is *unit* if there exists a (disjoint) d-interval representation where all the intervals of the underlying family have unit length, and it is *proper* if there exists a representation where no interval of the underlying family is properly contained in another one. A (disjoint) d-interval graph is *balanced* if there exists a (disjoint) d-interval representation where the d intervals of a same d-interval have the same length, but intervals of different d-intervals can differ in length.

The graph $K_{1,t}$ is the star with t leaves (also referred to as *t-claw* in the following). For any $t \geqslant 3$, if the set of vertices $\{v_0, v_1, \ldots, v_t\}$ induces a $K_{1,t}$ with center v_0, we will denote it by $[v_0; v_1, \ldots, v_t]$. We say that a graph is $K_{1,t}$-free if it does not contain any induced $K_{1,t}$'s. Furthermore, we say that an induced t-claw $K_{1,t}$ is *maximal* if it is not contained in an induced $K_{1,m}$ with $m > t$.

Discussion on the definition of d-intervals. As mentioned in the introduction, d-interval graphs have been defined in the literature both as the union of d disjoint intervals and as the union of d not necessarily disjoint intervals. This might be related to the fact that when there are no length restrictions on the intervals, both definitions lead to the same class of graphs (as one can simply stretch the intervals associated to a same vertex that intersect to make them disjoint without changing any of the other intersections).

▶ **Observation 1.** ($\star$) *The classes of disjoint d-interval and d-interval graphs are equivalent.*

However, if there are length restrictions, the previous observation does not hold. For unit intervals, one cannot replace two intersecting intervals $[a, b]$ and $[c, d]$, with $a < c < b < d$, by $[a, d]$, as the resulting interval would not be of unit length, and stretching it to make it unit might disrupt the rest of the intersections. Thus, in this case, it cannot be inferred that both definitions of multiple intervals lead to the same class of graphs. In fact, our results prove that they do not. Therefore, we study the generalization of Roberts characterization separately for both definitions of d-intervals.

3 Unit d-interval graphs

In this section, we generalize Roberts characterization of unit interval graphs for d-interval graphs. Recall that by d-interval graphs we refer to intersection graphs of d-intervals where the d intervals are not necessarily disjoint, or in other words, to the most general definition.

▶ **Theorem 2.** *Let G be an interval graph. Then, for any natural number $d \geqslant 2$, G is a unit d-interval graph if and only if G does not contain a copy of a $K_{1,2d+1}$ as an induced subgraph. Furthermore, given a $K_{1,2d+1}$-free interval graph, a unit d-interval representation can be constructed in $\mathcal{O}(n+m)$ time, where n and m are the number of vertices and edges of the graph, respectively.*

We present a polynomial-time algorithm that, given an arbitrary interval representation $\mathcal{I}$ of a $K_{1,2d+1}$-free graph, returns a d-interval representation $\mathcal{I}'$ of the graph where no interval of the underlying family of $\mathcal{I}'$ intersects three or more pairwise disjoint intervals. This ensures that the underlying family of intervals returned corresponds to an interval representation of a $K_{1,3}$-free graph, so we can use the algorithm described in [3] to turn it into a proper representation (and then to a unit one in linear time [14]). Note that if an interval representation of the graph is not given, we can always compute it in linear time [6].

Before presenting the algorithm formally, let us give the idea behind it. The algorithm constructs a family $\mathcal{I}'$ of d-intervals in the following way: for every interval $I \in \mathcal{I}$ that intersects m (and no more than m) pairwise disjoint intervals, we create a t-interval $I_1 \cup \ldots \cup I_t$, where $t = \lceil \frac{m}{2} \rceil$. Note that for every interval I that intersect only two disjoint intervals, we have $t = 1$, and the interval I_1 added to $\mathcal{I}'$ will be exactly I. We will refer to such intervals as *original intervals*, as they are equal to the ones in $\mathcal{I}$. After creating the t-intervals described above, to obtain a d-interval representation of the graph, it suffices to add $d-t$ "dummy" intervals for each vertex that is represented by $t < d$ intervals (where by "dummy" intervals we mean that they do not intersect any other interval from the representation). Each d-interval $I_1 \cup \ldots \cup I_d$ introduced will preserve the same intersections as the interval $I \in \mathcal{I}$, and each I_i will possess three key properties: it intersects at most two disjoint original intervals, it contains an original interval, and each of its endpoints coincides with an endpoint of an original interval. These properties ensure that the representation $\mathcal{I}'$ can be made unit.

Algorithm

Let the family of intervals $\mathcal{I}$ be an interval representation of G. For every interval $I \in \mathcal{I}$, let $l(I)$ and $r(I)$ stand for its left and right endpoint, respectively. Furthermore, define a partial order as follows: given two intervals $I, J \in \mathcal{I}$, let $I \prec J$ if and only if $r(I) < l(J)$ (i.e. interval J is fully to the right of interval I). Two intervals are incomparable if they intersect.

Step 1 Initialize a set of intervals $\mathcal{C}$ with all the intervals of $\mathcal{I}$, set $\mathcal{I}' := \emptyset$, and go to **Step 2**.

Step 2 Pick an interval I of $\mathcal{C}$, remove it from the set and define its neighborhood $\mathcal{N}(I) = \{J \in \mathcal{I} \colon J \cap I \neq \emptyset\}$. Let m be the maximum number of pairwise disjoint intervals that I intersects. If $m \leqslant 2$, go to **Step 3**; if $m = 3$, go to **Step 4**; and if $m > 3$, go to **Step 5**.

Step 3 If $m \leqslant 2$, add the interval $I_1 = I$ to the family $\mathcal{I}'$ and call I_1 an original interval. Then go to **Step 6**.

Step 4 If $m = 3$, define four auxiliary intervals:

$$A_1 = \operatorname*{arg\,min}_{J \in \mathcal{N}(I)} \{r(J)\} \qquad A_2 = \operatorname*{arg\,min}_{\{J \in \mathcal{N}(I) \colon A_1 \prec J\}} \{r(J)\}$$

$$A_4 = \operatorname*{arg\,max}_{J \in \mathcal{N}(I)} \{l(J)\} \qquad A_3 = \operatorname*{arg\,max}_{\{J \in \mathcal{N}(I) \colon J \prec A_4\}} \{l(J)\}$$

Then add to $\mathcal{I}'$ the 2-interval $I_1 \cup I_2$, with $I_1 = [l(I), r(A_2)]$ and $I_2 = [l(A_3), r(I)]$. Note that A_2 and A_3 necessarily intersect, as otherwise we would have $m \geqslant 4$, so $I_1 \cup I_2$ is not a disjoint 2-interval. After adding it to $\mathcal{I}'$, go to **Step 6**.

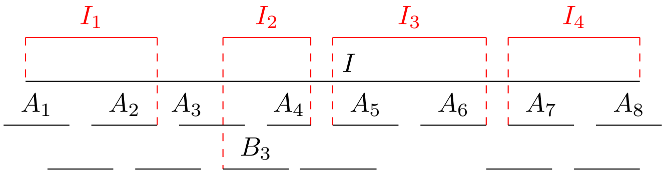

Figure 2 Interval I intersects 8 disjoint intervals. In red, the 4-interval returned by the algorithm. Note that if $l(I_2)$ were defined as $l(A_3)$ instead of $l(B_3)$, it would create a forbidden $K_{1,3}$.

Step 5 If $m > 3$, define two families of auxiliary intervals. The first family $\mathcal{A} := \{A_i \,|\, i \in \{1, \dots, m\}\}$ forms a maximum set of pairwise disjoint intervals intersecting I, and it will ensure that all the intersections are preserved. It is defined as follows:

$$A_1 = \underset{J \in \mathcal{N}(I)}{\arg\min}\{r(J)\} \qquad A_i = \underset{\{J \in \mathcal{N}(I) \colon A_{i-1} \prec J\}}{\arg\min}\{r(J)\}\ , \forall\ i \in \{2, \dots, m-2\}$$

$$A_m = \underset{J \in \mathcal{N}(I)}{\arg\max}\{l(J)\} \quad A_{m-1} = \underset{\{J \in \mathcal{N}(I) \colon J \prec A_m\}}{\arg\max}\{l(J)\}$$

The second family $\mathcal{B} := \{B_i \,|\, i \in \{1, \dots, m\}\}$ is a tool to ensure that each new interval I_i intersects only two disjoint intervals in $\mathcal{I}'$. Note that restricting each I_i to intersect only two disjoint intervals from the family $\mathcal{A}$ is not enough: for example, in Figure 2, if I_2 were defined as $[l(A_3), r(A_4)]$, then it would intersect three pairwise disjoint intervals in $\mathcal{I}'$ (as all the intervals except I are original intervals in this example), whereas if the left endpoint of I_2 were chosen as $r(A_{2i-1})$, then an original interval that was not the center of a claw in $\mathcal{I}$ might become the center of a new claw in $\mathcal{I}'$. Thus, for every $i \in \{1, \dots, m\}$, B_i is defined as follows:

$$B_i = \underset{J \in \mathcal{N}(A_i) \cup A_i}{\arg\max}\{l(J)\}$$

In other words, B_i is the interval in the closed neighborhood of A_i starting the latest. Note that if there does not exist any interval intersecting A_i which starts after A_i, then $B_i = A_i$ since we are considering the closed neighborhood. Now, add to $\mathcal{I}'$ the t-interval $I_1 \cup ... \cup I_t$, defined as follows. We distinguish two slightly different cases:

a. If m is even, i.e., $m = 2t$ for some $t > 1$, define $I_1 = [l(I), r(A_2)]$, $I_i = [l(B_{2i-1}), r(A_{2i})]$ for every $i \in \{2, \dots, t-1\}$, and $I_t = [l(A_{2t-1}, r(I)]$.

b. If m is odd, i.e., $m = 2t - 1$ for $t > 2$, define I_{t-1} and I_t differently, as $I_{t-1} = A_{2t-3}$ and $I_t = [l(A_{2t-2}, r(I)]$, and the rest of the intervals as before.

Notice that by definition, the intervals $I_1, ..., I_t$ are actually pairwise disjoint, so if $m > 3$, the t-interval added to $\mathcal{I}'$ is a disjoint d-interval. After adding the t-interval, go to **Step 6**.

Step 6 If $\mathcal{C} = \emptyset$, return $\mathcal{I}'$, else go to **Step 2**.

Figure 2 illustrates the algorithm on a concrete interval which intersects eight pairwise disjoint intervals. Before proceeding to the proof of correctness of the algorithm, we highlight the properties of the intervals constructed that will be useful to prove the next three claims. In the following, we say that an interval I of $\mathcal{I}$ has been *transformed* into a t-interval $I_1 \cup \cdots \cup I_t$ by the algorithm after it has been processed.

▶ **Observation 3.** *Let $I \in \mathcal{I}$ be an interval transformed into $I_1 \cup \cdots \cup I_t$ by the algorithm, for some $1 < t \leqslant d$. Then, for every $i \in \{1, \ldots, t\}$:*

1. *The left (resp., right) endpoint of every interval I_i coincides with the left (resp., right) endpoint of an original interval.*
2. *There is an original interval contained in I_i.*

Now, to prove the correctness of the algorithm, we need to show that for every interval $I \in \mathcal{I}$, the t-interval $I_i \cup ... \cup I_t \in \mathcal{I}'$ preserves the same intersections as I, and that no interval in the underlying family of $\mathcal{I}'$ intersects three pairwise disjoint intervals. In the next claim, we prove that intersections are preserved:

▷ Claim 4. Let I be an interval transformed into $I_1 \cup \cdots \cup I_t$ by the algorithm, for some $1 \leqslant t \leqslant d$. Then, the t-interval $I_1 \cup \ldots \cup I_t$ preserves the intersections of I.

Proof. It is clear that no new intersections are created as $I_1 \cup \ldots \cup I_t \subseteq I$. To see that no intersection is lost, suppose that there exists an interval L that intersects I in the original representation $\mathcal{I}$, and after the algorithm finishes, L is transformed into a t_0-interval $L_1 \cup \ldots \cup L_{t_0}$ (for some $1 \leqslant t_0 \leqslant d$, where if $t_0 = 1$, the interval remains as in the original representation) such that the t-interval $I_1 \cup \ldots \cup I_t$ does not intersect the t_0-interval $L_1 \cup \ldots \cup L_{t_0}$ in $\mathcal{I}'$. Since $l(I_1) = l(I)$ and $r(I_t) = r(I)$ (and the same holds for L), this means that there exists an L_j (with $1 \leqslant j \leqslant t_0$) such that $I_i \prec L_j \prec I_{i+1}$ for some $1 \leqslant i \leqslant t-1$.

For $1 \leqslant t \leqslant 2$, this cannot occur because $I \subseteq I_1 \cup \ldots \cup I_t$. For $t > 3$, since the set of intervals A_k used to defined the t-interval associated to I forms a maximal set of pairwise disjoint intervals intersecting I, we cannot have that $A_k \prec L_j \prec A_{k+1}$ for any $1 \leqslant k \leqslant 2t-1$. Indeed, this would contradict maximality, as L_j is either an original interval or it contains an original interval (by Observation 3). Thus, the only possible option is that there exists an i such that $A_{2i} \prec L_j \prec B_{2i+1}$ (where B_{2i+1} is different from A_{2i+1}). Then, since B_{2i+1} intersects A_{2i+1} and $L_j \prec B_{2i+1}$, we have that $r(L_j) < r(A_{2i+1})$. But this contradicts the choice of A_{2i+1}, which should have been L_j or the original interval contained in L_j, as $A_{2i} \prec L_j$. ◁

The next two claims are dedicated to proving that no interval in the underlying family of $\mathcal{I}'$ intersects three or more pairwise disjoint intervals. We distinguish the cases when the center of the claw is an original interval and when it is not.

▷ Claim 5. Let $I \in \mathcal{I}$ be an original interval (i.e., transformed to I_1 by the algorithm). Then, I_1 intersects at most two disjoint intervals in the underlying family of $\mathcal{I}'$.

Proof. Suppose, towards a contradiction, that there exists an original interval I_1 that intersects three pairwise disjoint intervals L_1, L_2 and L_3 in the underlying family of $\mathcal{I}'$, with $L_1 \prec L_2 \prec L_3$. By Observation 3, there exists an original interval L_1' with the same right endpoint as L_1, an original interval L_2' contained in L_2, and an original interval L_3' with the same left endpoint as L_3. Note that if any of the L_i are original, then $L_i' = L_i$. But then, $L_1' \prec L_2' \prec L_3'$ are three pairwise disjoint original intervals that intersect I_1, which contradicts the fact that it is an original interval. Indeed, this implies that the interval I intersects three pairwise disjoint intervals in $\mathcal{I}$, and so the algorithm would have transformed it into a t-interval with t strictly greater than 1. ◁

▷ Claim 6. Let $I \in \mathcal{I}$ be an interval transformed into the t-interval $I_1 \cup \cdots \cup I_t$ by the algorithm, for some $1 < t \leqslant d$. For every $1 \leqslant i \leqslant t$, I_i intersects at most two disjoint intervals of the underlying family of $\mathcal{I}'$.

Proof. We proceed by contradiction. Suppose that there exists an interval I_i, with $1 \leqslant i \leqslant t$ that intersects three pairwise disjoint intervals L_1, L_2, L_3, with $L_1 \prec L_2 \prec L_3$. By Observation 3, there exists an original interval L'_1 with the same right endpoint as L_1, an original interval L'_2 contained in L_2, and an original interval L'_3 with the same left endpoint as L_3.

Assume first that $t = 2$. Then, if $i = 1$, this contradicts the choice of the interval A_2 (resp. A_3 if $i = 2$), which should have been L'_2.

Let us now study the general case for $t > 2$. Suppose first that $1 < t < d$ and I_i is defined as $[B_{2i-1}, A_{2i}]$ with $B_{2i-1} \neq A_{2i-1}$. We distinguish two cases:

1. $r(L_1) > r(A_{2i-1})$. Then, since we are assuming that L_1 and L_2 are disjoint, $l(L_2) > r(A_{2i-1})$. Furthermore, as L_3 also intersects I_i, we need $r(L_2) < r(A_{2i})$. But this contradicts the choice of A_{2i}, which should have been L'_2.
2. $r(L_1) < r(A_{2i-1})$. If $l(L_2) > r(A_{2i-1})$, we are in the same case as before. Thus, L_2 and A_{2i-1} must intersect. However, we have $l(L_2) > l(B_{2i-1})$ (since otherwise I_i would not be able to intersect L_1 on its left extreme). This contradicts the choice of B_{2i-1} if L'_2 intersects A_{2i-1}, or the choice of A_{2i} otherwise.

On the other hand, if $B_{2i-1} = A_{2i-1}$, then by construction, since we take the two disjoint intervals that finish first, we cannot have three pairwise disjoint intervals intersecting I_i. This is also the case for I_1 and I_t (although in the latter case, we take the two disjoint intervals starting last). Finally, for odd claws, it is also clear that I_{t-1} intersects at most two disjoint intervals, as it is equal to an original interval. ◁

Combining Claims 4, 5 and 6, plus the fact that we can trivially transform a t-interval with $t < d$ into a d-interval, we obtain that the algorithm returns a d-interval representation of the input graph where no interval of the underlying family intersects more than two disjoint intervals, which as explained before can be converted into a unit representation. The last part of Theorem 2 follows because an efficient implementation of the algorithm described above requires $\mathcal{O}(1 + deg(v))$ operations for each vertex v (where $deg(v)$ denotes the degree of vertex v), as it suffices to iterate over the neighborhood of a given interval to transform it into the corresponding d-interval. Finally, the obtained representation can be converted to a unit representation in linear time, which yields the stated runtime $\mathcal{O}(n + m)$. This concludes the proof of Theorem 2.

We have proven that the algorithm constructs a unit d-interval representation, but it is not a disjoint one. Indeed, as mentioned before, in the case of maximal $K_{1,3}$'s, the constructed intervals I_1 and I_2 intersect each other. However, in the case of maximal $K_{1,m}$'s with $m > 3$, the t intervals of the t-interval created are actually pairwise disjoint. Thus, we obtain as a direct corollary that if G is a $K_{1,2d+1}$-free interval graph not containing any maximal $K_{1,3}$'s, then G is a disjoint unit d-interval graph. In fact, with a more careful analysis, we can infer an even stronger corollary, which instead of requiring the absence of maximal 3-claws altogether, only forbids a subset of them. We refer to these forbidden claws, which are exactly those maximal 3-claws contained in an induced E graph, as E-claws. Recall that an E graph (or star$_{1,2,2}$) is a graph on six vertices which has as edge set a path v_1, v_2, v_3, v_4, v_5 and an additional edge (v_3, v_6).

▶ **Corollary 7.** *Let G be a $K_{1,2d+1}$-free graph that does not contain any E-claws. Then, G is a disjoint unit d-interval graph.*

Proof. To prove the theorem, we modify **Step 4** of the previous algorithm so that it produces a disjoint 2-interval.

Step 4' Let I be an interval and let $m = 3$ be the maximum number of pairwise disjoint intervals that it intersects. By assumption, the vertex associated to I is a center of a maximal claw which is not an E-claw. We define

$$A_1 = \arg\min_{J \in \mathcal{N}(I)} \{r(J)\}$$

$$A_2 = \arg\min_{\{J \in \mathcal{N}(I) \colon A_1 \prec J\}} \{r(J)\}$$

$$A_4 = \arg\max_{J \in \mathcal{N}(I)} \{l(J)\}$$

$$A_3 = \arg\max_{\{J \in \mathcal{N}(I) \colon J \prec A_4\}} \{l(J)\}$$

Note that A_2 and A_3 necessarily intersect (or are the same interval). Now, since the vertex associated to I is a center of a claw that is not an E-claw, this means that at least one of A_1 or A_4 does not intersect an interval which is disjoint from I. Thus, we can modify the representation so that A_1 (resp. A_4) is properly contained in I without loosing any intersections, by simply stretching them. Then, if A_1 is properly contained in I, we define $I_1 = A_1$ and $I_2 = [l(A_3), r(I)]$. On the other hand, if A_4 is properly contained in I instead, we define $I_1 = [l(I), r(A_2)]$ and $I_2 = A_4$. If both of them are properly contained in I, we can define I_1 and I_2 either way.

Notice that the 2-intervals introduced in this step have the same properties as in Observation 3, so the proof of correctness of the previous algorithm can be directly adapted for this extension. ◀

4 Disjoint unit d-interval graphs

In this section, we prove that Theorem 2 cannot be generalized for disjoint unit d-interval graphs. Note that by Corollary 7, if we have a graph which does not contain any E-claws, then the generalization still holds for disjoint unit d-interval graphs, but this is not the case in general. Indeed, suppose there is an interval I that intersects exactly three pairwise disjoint intervals, A_1, A_2 and A_3, and both A_1 and A_3 intersect each an interval disjoint from I. Then, the algorithm presented in the previous section would return a 2-interval $I_1 \cup I_2$, where I_1 and I_2 are not disjoint. If we try to extend the algorithm in the most natural way, that is, stretching these two intervals until they are disjoint, we would still not succeed. This is because, since I_1 and I_2 cannot intersect, then either $r(I_1)$ will be to the left of the right endpoint returned by the algorithm, or $l(I_2)$ will be to the right of the endpoint returned by the algorithm. But then, one of I_1 or I_2 might not properly contain a complete interval from the original representation, which can cause I_1 or I_2 – the interval which does not properly contain a complete original interval – to be contained in an interval that intersects three pairwise disjoint intervals (see Figure 3).

In the following, we show that there is no way to extend the algorithm to make it work in the general case for disjoint unit d-interval graphs. In particular, we prove the following theorem.

▶ **Theorem 8.** *There exists a $K_{1,5}$-free interval graph that is not a disjoint unit 2-interval graph.*

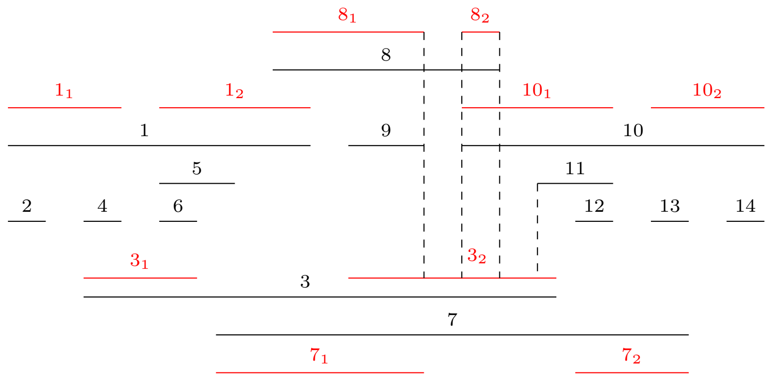

Figure 3 Interval representation of a $K_{1,5}$-free graph that cannot be turned into a disjoint unit 2-interval representation just by "cutting" intervals that intersect more than three pairwise disjoint intervals. In the figure, the intervals in red are all obtained using a natural extension of the algorithm. We can see that in this way, 3_2 intersects three disjoint intervals: $8_1, 8_2, 11$. The reader can check that no other way of stretching the intervals works if 8_1 and 8_2 are required to be disjoint.

To prove Theorem 8, we offer the graph G in Figure 4 as a certificate. The reader can check that G has no induced $K_{1,5}$, and an interval representation of G is provided in Figure 5. The proof that G is not a disjoint unit 2-interval graph is the challenging part. Indeed, checking whether a graph is disjoint unit 2-interval is a computationally expensive task, and even with the aid of computer search, a naive ILP implementation already takes too much time to consider an exhaustive search. Needless to say, checking manually by brute force leads to a very long branching process. The proof presented here is based on a careful analysis of the graph, and the technique employed (which uses the characterization of unit 2-interval graphs in [[1], Lemma 5]) may be applied to establish that other graphs are not disjoint unit 2-interval graphs. We also verify the proof computationally, using an encoding in answer set programming based on the semiorder characterization of unit interval graphs, which proves to be way more efficient than an ILP encoding. Our code and experimental setting can be found on our git repository [2]. Furthermore, there exist five other $K_{1,5}$-free interval graphs on the same number of vertices, and with a very similar structure, that are not disjoint unit 2-interval (see the full version of this paper). The proof that they are not disjoint unit 2-interval is omitted, but it is analogous to the one presented here. These six graphs are the only such graphs on 14 vertices, and there does not exist a graph satisfying the conditions of Theorem 8 with fewer vertices. These assertions were verified by computer search over all interval graphs of a given size without induced $K_{1,5}$'s [32].

Theorem 8 follows directly from the next lemma.

▶ **Lemma 9.** ($\star$) *The graph G in Figure 4 is not a disjoint unit 2-interval graph.*

We conclude this section showing that Theorem 8 can actually be generalized for disjoint unit d-interval graphs for any $d > 2$.

▶ **Corollary 10.** ($\star$) *There exists a $K_{1,2d+1}$-free interval graph that is not a disjoint unit d-interval graph.*

[2] https://github.com/AbdallahS/unit-graphs

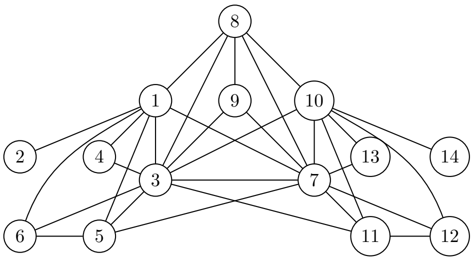

Figure 4 One of the 6 graphs with 14 vertices (the one with the fewest edges) which is an interval graph (see Figure 5) and $K_{1,5}$-free, but not disjoint unit 2-interval.

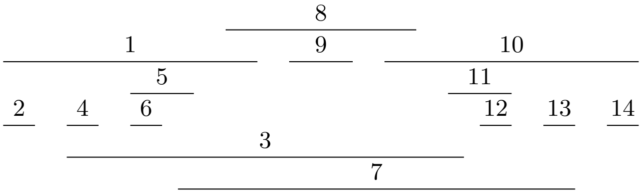

Figure 5 An interval representation of the graph in Figure 4.

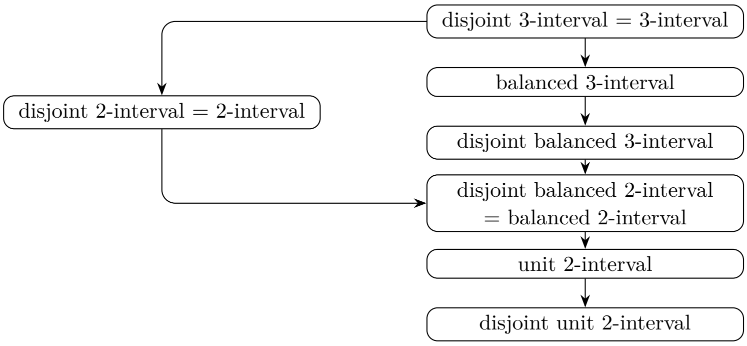
5 Inclusions between the different subclasses of d-interval graphs

In this section, we analyze the relationships between different subclasses of multiple interval graphs. We have already seen that 2-interval graphs and disjoint 2-interval graphs are equivalent. Furthermore, the results from the previous two sections imply that the class of disjoint unit 2-interval graphs is properly contained in the class of unit 2-interval graphs. In the following, we summarize the containment relationships between unit 2-interval graphs, disjoint unit 2-interval graphs, balanced 2-interval graphs and disjoint balanced 2-interval graphs (see Figure 6 for a graphical illustration).



disjoint 3-interval = 3-interval
balanced 3-interval
disjoint 2-interval = 2-interval
disjoint balanced 3-interval
disjoint balanced 2-interval = balanced 2-interval
unit 2-interval
disjoint unit 2-interval

Figure 6 Landscape of graph subclasses of 3-interval graphs. An arrow from a graph class $\mathcal{C}$ to a $\mathcal{C}'$ indicates that $\mathcal{C}' \subset \mathcal{C}$. The relationships between the class of 2-interval graphs and the classes of balanced 3-interval graphs and disjoint balanced 3-interval graphs are not known.

▶ **Theorem 11.** ($\star$)

1. *The classes of* 2-interval *and* disjoint 2-interval *graphs are* equivalent*.*
2. *The classes of* balanced 2-interval *and* disjoint balanced 2-interval *graphs are* equivalent*.*
3. *The class of* unit 2-interval graphs *is* properly contained *in the class of* disjoint balanced 2-interval *graphs.*
4. *The class of* disjoint unit 2-interval *graphs is* properly contained *in the class of* unit 2-interval *graphs.*

We finish by showing that the previous theorem cannot be completely generalized for the subclasses of d-interval graphs, as the class of balanced d-interval graphs is not equivalent to the class of disjoint balanced d-interval graphs for $d > 2$. We first construct a graph that is balanced 3-interval but not disjoint balanced 3-interval and then show how to generalize this construction for every $d > 3$.

▶ **Theorem 12.** *The class of disjoint balanced 3-interval graphs is properly contained in the class of balanced 3-interval graphs.*

Proof. We construct a graph G which is balanced 3-interval but not disjoint balanced 3-interval. The high-level idea of the construction is that for a particular vertex, one of its intervals is forced to a given length, while the other two are forced to be placed somewhere where there is not enough space for both of them, and thus they cannot be disjoint (note that the difference with the case $d = 2$ is that now, if we stretch two of the intervals so that they do not intersect, we also have to modify the length of the third interval, and as we show here, this is not always possible). To enforce these constraints, we use the complete bipartite graph $K_{11,4}$ as a gadget and exploit the fact that any 3-interval representation of this gadget must be continuous (i.e., the union of the intervals in its underlying family is an interval) [31, Lemma 2] (see also [13, Fig. 3] for the idea of its representation).

We construct G as follows: we connect in a chain five $K_{11,4}$'s, to which we add six vertices v_1, v_2, v_3, v_4, v_5, v_6 (Figure 7 shows how to link v_1, v_2, v_3, v_4 to the chain, while vertices v_5 and v_6 mimic the behavior of v_3 and v_4 with a different set of neighbors, namely, v_5 is connected to the corresponding vertices of the first two $K_{11,4}$'s, and v_6 is connected to the corresponding vertices of the second and the third $K_{11,4}$'s). More precisely, let C_i, with $i \in \{1, \ldots, 5\}$, be the five $K_{11,4}$'s forming the chain, enumerated from left to right. Moreover, for every C_i, let f_i^j with $j \in \{1, \ldots, 11\}$ be the eleven vertices of one side of the bipartition, and t_i^k, with $k \in \{1, 2, 3, 4\}$, the four vertices of the other side of the bipartition. We assume that the chain is connected such that f_i^{11} is linked to f_{i+1}^1. Then, v_1 is connected to all the vertices of C_2 and C_4, and to f_3^{11} and f_5^1, plus another independent vertex. Similarly, v_2 is connected to all the vertices of C_2 and C_4, to v_1 and to f_1^{11} and f_3^1. On the other hand, v_3 is connected to f_3^{11}, t_3^4, t_4^1 and f_4^j for $j \in \{1, \ldots, 9\}$; while v_4 is connected to f_5^1, t_4^4, t_5^1 and f_4^j for $j \in \{3, \ldots, 11\}$. Finally, v_5 is connected to f_1^{11}, t_1^3, t_2^1 and f_2^j for $j \in \{1, \ldots, 7\}$, as well as f_4^8 and f_4^9, whereas v_6 is connected to f_3^1, t_2^4, t_3^1 and f_2^j for $j \in \{5, \ldots, 11\}$, as well as f_4^8 and f_4^9. The vertices v_1 and v_2 are both connected to v_3, v_4, v_5 and v_6.

Now, as any 3-interval representation of a $K_{11,4}$ is continuous, any realization of G groups the five $K_{11,4}$'s in a block [31]. For $j \in \{1, 2, 3\}$, let I_j be the intervals associated to v_1, J_j the intervals associated to v_2, and K_j the intervals associated to v_3. First, it is clear that we need three different intervals to cover the neighbors of v_1 (and these three intervals must be disjoint). Instead, the neighbors of v_2 could be covered only with two intervals. However, we will see that the two segments of the real line that need to be covered cannot have the same length (assuming that the 3-interval associated to v_1 is balanced). We will show that we need two intersecting intervals to cover the first segment.

Suppose that only two intervals are needed to represent the adjacencies of v_2, and let J be the interval displaying the edges between C_2 and v_2, and J_3 the interval displaying the edges between C_4 and v_2. Similarly, let I_1 be the interval associated to v_1 used to represent the edges with C_2, let I_2 the interval used to represent the edges with C_4, and I_3 the interval displaying the edge with the isolated vertex. One can easily see that J_3 is properly contained in I_2 (since I_2 must also intersect an interval associated to f_3^{11} on its left and an interval associated to f_5^1 on its right), while I_1 is properly contained in J (by an analogous argument). Thus, $len(J_3) < len(I_2) = len(I_1) < len(J)$. In order for the representation to be balanced,

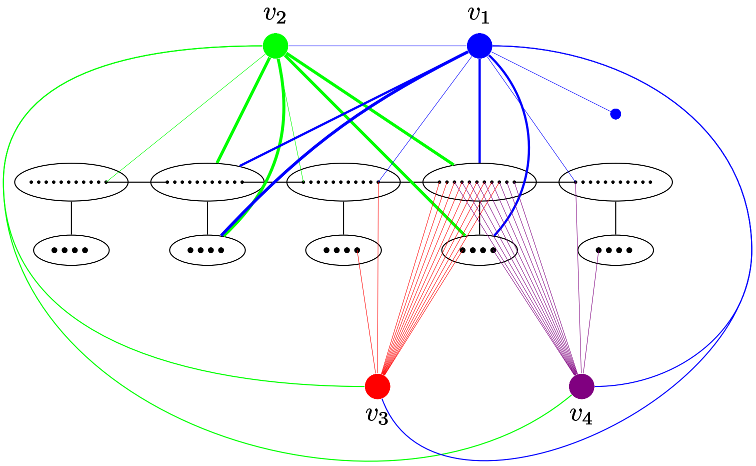


Figure 7 G is balanced 3-interval but not disjoint balanced 3-interval. $K_{11,4}$ graphs are drawn abstractly and are chained. A thick edge stopping at the border of the ellipse means that the vertex is connected to every vertex in the corresponding part of the $K_{11,4}$. Vertices v_5 and v_6 are omitted for readability purposes.

the segment of the real line covered by J needs to be covered by two different intervals, say J_1 and J_2. To prove that G is balanced 3-interval but not disjoint balanced 3-interval, we need to bound $len(J) - len(J_3)$. In particular, we need $len(J) - len(J_3) < len(J_3)$. Vertices v_3 and v_4 will allow us to find constants a and a' to bound $len(I_2) - len(J_3) \leqslant a + a'$, while vertices v_5 and v_6 will serve to find constants b and b' to bound $len(J) - len(I_1) \leqslant b + b'$. By showing that we can force the constants such that $a + a' + b + b' < len(J_3)$, we have the result. This will follow since we will have eight pairwise disjoint intervals properly contained in J_3: two of length a, two of length a', two of length b and two of length b'.

Indeed, let a and a' be the lengths of the intervals associated to v_3 and to v_4, respectively. The next claim implies that there are two disjoint intervals associated to v_3 properly contained in J_3, and another disjoint interval that properly contains the segment between $l(I_2)$ and $l(J_3)$, and so $l(J_3) - l(I_2) < a$.

▷ Claim 13. (⋆) Let G be a graph formed by the union of a $K_{11,4}$ and a vertex v which is adjacent to nine vertices in S_{11}, where S_{11} denotes the side of the bipartition with eleven vertices. Then, vertex v must be represented by three pairwise disjoint intervals, two of which are each properly contained in an interval representing a vertex of S_{11}.

Similarly, the segment between $r(I_2)$ and $r(J_3)$ is also contained in an interval associated to v_4, which has the same properties as v_3 and does not intersect any interval associated to v_3. This proves that there are two intervals of length a and two intervals of length a' (all pairwise disjoint) contained in J_3. Doing the same to bound $l(I_1) - l(J)$ and $r(J) - l(I_1)$, we get the result. Thus, to represent v_2, we need two intervals associated to v_2 to intersect. If we do not allow intersection, the length of these two intervals will be smaller than the length of the third interval associated to v_2, contradicting the fact that they are balanced. ◀

▶ **Corollary 14.** (⋆) *The class of disjoint balanced d-interval graphs is properly contained in the class of balanced d-interval graphs for every natural number* $d \geqslant 3$.

6 Concluding remarks

We have shown that the natural generalization of Roberts characterization for unit interval graphs remains valid for the most general definition of d-interval graphs that are interval graphs. However, quite surprisingly, if we require the d intervals to be disjoint, then the result does not hold anymore. It remains as an open question whether disjoint d-interval graphs that are also interval can be characterized in some other way, or simply if they can be recognized in polynomial time. Finally, we have obtained a relatively complete landscape of the containment relationships between different subclasses of 2-interval graphs, that cannot be fully generalized for $d > 2$. In particular, for $d > 2$, it is still unknown whether the class of unit d-interval graphs is contained in the class of disjoint balanced d-interval graphs.

A Direct Translation from LTL with Past to Deterministic Rabin Automata

Nir Piterman
University of Gothenburg, Sweden

Abstract

We present a translation from linear temporal logic *with past* to deterministic Rabin automata. The translation is direct in the sense that it does not rely on intermediate non-deterministic automata, and asymptotically optimal, resulting in Rabin automata of doubly exponential size. It is based on two main notions. One is that it is possible to encode the history contained in the prefix of a word, as relevant for the formula under consideration, by performing simple rewrites of the formula itself. As a consequence, a formula involving past operators can (through such rewrites, which involve alternating between weak and strong versions of past operators in the formula's syntax tree) be correctly evaluated at an arbitrary point in the future without requiring backtracking through the word. The other is that this allows us to generalize to linear temporal logic with past the result that the language of a pure-future formula can be decomposed into a Boolean combination of simpler languages, for which deterministic automata with simple acceptance conditions are easily constructed.

1 Introduction

Finite-state automata over infinite words, commonly referred to as ω-automata, have been studied as models of computation since their introduction in the 1960s. Their introduction was followed by extensive investigations into their expressive power, closure properties, and the decidability and complexity of related decision problems, such as non-emptiness and language containment. In particular, it was soon established that determinization constructions of such automata are considerably more complex than they are for their finite word counterparts, for which a simple subset construction is sufficient.

In the 1970s, Pnueli [15] proposed linear temporal logic (*LTL*) as a specification language for the analysis and verification of programs, based on the idea that a program can be viewed in the context of a stream of interactions between it and its environment. It has since become ubiquitous in both academia and the industry due to the perceived balance of its expressive power and the computational complexity of its related decision procedures. The intimate semantic connection between *LTL* and ω-automata further motivated research into the properties of both, also from a practical point of view. In addition to being of theoretical interest, the fact that multiple automata-based applications of *LTL* as a specification language – such as reactive synthesis and probabilistic model checking – require deterministic automata, has drawn additional attention to the study of efficient translation procedures from *LTL* to deterministic ω-automata.

In the classic approach to determinization, the given *LTL* formula is first translated to a non-deterministic Büchi automaton. This automaton is subsequently determinized, for example using Safra's procedure [16], or the more modern Safra/Piterman variant [13]. Such constructions are both conceptually complex and difficult to implement. Moreover, information about the structure of the given formula is lost in the initial translation to Büchi automata; in particular, because of the generality of such determinization procedures, they cannot take advantage of the fact that *LTL* is less expressive than ω-automata.

In 2020, Esparza et al. [5] presented a novel translation from *LTL* to various automata, that is asymptotically optimal in both the deterministic and non-deterministic cases. The translation is direct in the sense that it avoids the intermediate steps of the classic approach, which involve employing a variety of separate translation procedures. In particular, for deterministic automata, it forgoes Safra-based constructions. Instead, the language of the formula under consideration is decomposed into a Boolean combination of simpler languages, for which deterministic automata with simple acceptance conditions can easily be constructed using what the authors have dubbed the "after-function"; that such a decomposition exists is a fundamental result named the "Master Theorem". These simpler automata are then combined into the desired final automaton using basic product or union operations according to the structure of the decomposition.

In this paper, we consider past linear temporal logic (*pLTL*); the extension of *LTL* that includes the past operators "Yesterday" and "Since", analogous to the standard operators "Next" and "Until", respectively. We adapt the Master Theorem and generalize the derived *LTL*-to-deterministic-Rabin-automata translation to *pLTL*, while maintaining its optimal asymptotic complexity. The merits of *LTL* extended with past operators were argued by Lichtenstein et al. [9], who also showed that their addition does not result in a more expressive logic with respect to initial equivalence of formulae. At the same time, the complexity of satisfiability/validity- and model checking remains PSPACE-complete for *pLTL* [17]. When it comes to determinization, as Esparza's approach [5] applies only to (future) *LTL*, the only option is the two-step approach: translate *pLTL* to nondeterministic Büchi automata [14] and convert to deterministic parity/Rabin automata [16, 13]. Our generalization to *pLTL* is of both theoretical and practical interest, for two main reasons. First, certain properties are more naturally and elegantly expressed with the help of past operators. Secondly, there exist formulae in *pLTL* such that all (initially) equivalent *LTL* formulae are exponentially larger [11]. Both of these properties can be exemplified by considering the natural language specification *"At any point in time, p should occur if and only if q and r have occurred at least once in the past"*. Expressing this in *LTL* requires explicitly describing the possible desired orders of occurrences of p, q, and r:

$$\big((\neg p \wedge \neg q)\,\mathbf{W}\,(r \wedge ((\neg p \wedge \neg q)\,\mathbf{W}\,(p \wedge q))) \vee (\neg p \wedge \neg r)\,\mathbf{W}\,(q \wedge ((\neg p \wedge \neg r)\,\mathbf{W}\,(p \wedge r)))\big) \\ \wedge \mathbf{G}(p \Rightarrow \mathbf{XG}p).$$

The same specification is very intuitively and succinctly expressed in *pLTL* by the formula $\mathbf{G}(p \Leftrightarrow \mathbf{O}q \wedge \mathbf{O}r)$.

The main contributions of this paper are an adaptation of the Master Theorem for *pLTL* and a utilization of this in the form of an asymptotically optimal direct translation from *pLTL* to deterministic Rabin automata. The paper is structured in the following manner: In Section 2, we define the syntax and semantics of linear temporal logic with past, infinite words and ω-automata, and the notion of propositional equivalence. As the automata we aim to construct are one-way, we need a way to encode information about the input history directly into the formula being translated; the machinery required to accomplish this is introduced in Section 3. The foundation of the translation from *pLTL* to Rabin automata is the after-function of Section 4. The subsequent Sections 5 and 6 are adaptations of the corresponding sections in Esparza et al. [5]. The decomposition of the language of the formula to be translated into a Boolean combination of simpler languages requires considering the limit-behavior of the formula. This notion is made precise in Section 5, which finishes with a presentation of the Master Theorem for *pLTL*. Section 6 describes how to create deterministic automata from the simpler languages of the decomposition, and how to combine them into a deterministic Rabin automaton. Finally, we conclude with a brief discussion in Section 7.

2 Preliminaries

2.1 Infinite Words and ω-automata

An infinite word w over a non-empty finite alphabet Σ is an infinite sequence $\sigma_0, \sigma_1, \ldots$ of letters from Σ. Given an infinite word w, we denote the finite infix $\sigma_t, \sigma_{t+1}, \ldots, \sigma_{t+s-1}$ of w by w_{ts}. If $t = s$, then w_{ts} is defined as representing the empty word ϵ. Note that no ambiguity will arise as we use parentheses whenever required; for example, $w_{(st)(en)}$ rather than w_{sten} We denote the infinite suffix $\sigma_t, \sigma_{t+1}, \ldots$ of w by w_t. We will also consider finite words, using the same infix- and suffix notation.

An *ω-automaton* over an alphabet Σ is a quadruple (Q, Q_0, δ, α), where Q is a finite set of states, $Q_0 \subseteq Q$ a non-empty set of initial states, $\delta \in Q \times \Sigma \to 2^Q$ a (partial) transition function, and α a set constituting its acceptance condition. In the case where $|Q_0| = 1$ and $|\delta(q, \sigma)| \leq 1$ for all $q \in Q$ and all $\sigma \in \Sigma$, the automaton is called *deterministic*. For deterministic automata we write $\delta : Q \times \Sigma \to Q$. Given an ω-automaton $\mathcal{A} = (Q, Q_0, \delta, \alpha)$ and an infinite word $w = \sigma_0, \sigma_1, \ldots$, both over the same alphabet, a *run* of $\mathcal{A}$ on w is a sequence of states $r = r_0, r_1, \ldots$ of Q such that $r_0 \in Q_0$ and $r_{i+1} \in \delta(r_i, \sigma_i)$ for all $i \geq 0$. Given such a run r, we write $\mathit{Inf}(r)$ to denote the set of states appearing infinitely often in r.

In this paper, we consider three particular classes of ω-automata, which differ only by their acceptance condition α. *Büchi-* and *co-Büchi* automata are ω-automata with α as a set $Q' \subseteq Q$. A Büchi automaton *accepts* the infinite word w iff there exists a run r on w such that $\mathit{Inf}(r) \cap Q' \neq \varnothing$, while a co-Büchi automaton accepts w iff there exists a run r on w such that $\mathit{Inf}(r) \cap Q' = \varnothing$. We will also consider Rabin automata. A Rabin automaton has a set of subsets $R \subseteq 2^Q \times 2^Q$ as acceptance condition, and accepts w iff there exists a run r on w and a pair $(A, B) \in R$ such that $\mathit{Inf}(r) \cap A = \varnothing$ and $\mathit{Inf}(r) \cap B \neq \varnothing$. We write *DBA*, *DCA*, and *DRA* to refer to deterministic Büchi-, co-Büchi-, and Rabin automata, respectively.

We use a specialized form of cascade composition of two automata: bed automaton and runner automaton. Bed automata are automata without an acceptance condition. Runner automata read input letters and (next) states of bed automata: given a bed automaton $\mathcal{A}$ with S as set of states, a runner automaton is $\mathcal{B} = (S, Q, Q_0, \delta, \alpha)$, where Q, Q_0, and α are as before and $\delta : Q \times S \times \Sigma \to 2^Q$ is the transition function. The composition $\mathcal{A} \ltimes \mathcal{B}$ is the automaton $(Q \times S, Q_0 \times S_0, \overline{\delta}, \overline{\alpha})$, where $\overline{\delta}(q, s, \sigma) = \{(q', s') \mid q' \in \delta_B(q, s', \sigma), s' \in \delta_{\mathcal{A}}(s, \sigma)\}$ and either

$\overline{\alpha} = \alpha \times S$ if $\mathcal{B}$ is a Büchi- or co-Büchi automaton, or $\overline{\alpha} = \bigcup\{(A \times S) \times (B \times S) \mid (A, B) \in \alpha\}$ if $\mathcal{B}$ is a Rabin automaton. Note that $\mathcal{A} \ltimes \mathcal{B}$ is an ω-automaton with $\mathcal{B}$'s acceptance, e.g., if $\mathcal{A}$ is deterministic and $\mathcal{B}$ is a deterministic co-Büchi runner automaton, then $\mathcal{A} \ltimes \mathcal{B}$ is a DCA.

2.2 Linear Temporal Logic with Past

Given a non-empty finite set of propositional variables AP, the well-formed formulae φ of *pLTL* are generated by the following grammar:

$$\varphi ::= \top \mid \bot \mid p \mid \neg\varphi \mid \varphi \wedge \varphi \mid \varphi \vee \varphi \mid \mathbf{X}\varphi \mid \varphi \mathbf{U} \varphi \mid \mathbf{Y}\varphi \mid \varphi \mathbf{S} \varphi,$$

where $p \in AP$. Given a formula φ, we write $\mathit{Var}(\varphi)$ to denote the set of all atomic propositions appearing in φ. Given a formula φ, natural number t, and infinite word $w = \sigma_0, \sigma_1, \ldots$ over $2^{\mathit{Var}(\varphi)}$, we write $(w, t) \models \varphi$ to denote that w satisfies φ at index t. The meaning of this is made precise by the following inductive definition:

$$\begin{array}{ll}
(w,t) \models \top & (w,t) \not\models \bot \\
(w,t) \models p \text{ iff } p \in \sigma_t & (w,t) \models \neg\varphi \text{ iff } (w,t) \not\models \varphi \\
(w,t) \models \varphi \wedge \psi \text{ iff } (w,t) \models \varphi \text{ and } (w,t) \models \psi & (w,t) \models \varphi \vee \psi \text{ iff } (w,t) \models \varphi \text{ or } (w,t) \models \psi \\
(w,t) \models \mathbf{X}\varphi \text{ iff } (w,t+1) \models \varphi & (w,t) \models \mathbf{Y}\varphi \text{ iff } t > 0 \text{ and } (w,t-1) \models \varphi
\end{array}$$

$$(w,t) \models \varphi \mathbf{U} \psi \text{ iff } \exists r \geq t \,.\, ((w,r) \models \psi \text{ and } \forall s \in [t,r) \,.\, (w,s) \models \varphi)$$

$$(w,t) \models \varphi \mathbf{S} \psi \text{ iff } \exists r \leq t \,.\, ((w,r) \models \psi \text{ and } \forall s \in (r,t] \,.\, (w,s) \models \varphi) \,.$$

When $t = 0$ we omit the index and simply write $w \models \varphi$. Observe that $\mathbf{Y}$ is almost exactly the past analog of $\mathbf{X}$, with a similar relationship between $\mathbf{S}$ and $\mathbf{U}$. They differ in that the past is bounded; in particular, a formula $\mathbf{Y}\varphi$ is never satisfied at $t = 0$. The *language* of a formula φ, denoted $\mathcal{L}(\varphi)$, is the set of all infinite words w such that $w \models \varphi$. Two *pLTL* formulae φ and ψ are semantically equivalent, denoted $\varphi \equiv \psi$, iff $\mathcal{L}(\varphi) = \mathcal{L}(\psi)$.

In addition to the above, we will also consider the following derived operators:

$$\begin{array}{ccc}
\mathbf{F}\varphi \coloneqq \top \mathbf{U} \varphi & \mathbf{O}\varphi \coloneqq \top \mathbf{S} \varphi & \mathbf{G}\varphi \coloneqq \neg\mathbf{F}\neg\varphi \\
\mathbf{H}\varphi \coloneqq \neg\mathbf{O}\neg\varphi & \varphi \mathbf{W} \psi \coloneqq \varphi \mathbf{U} \psi \vee \mathbf{G}\varphi & \varphi \tilde{\mathbf{S}} \psi \coloneqq \varphi \mathbf{S} \psi \vee \mathbf{H}\varphi \\
\varphi \mathbf{M} \psi \coloneqq \psi \mathbf{U} (\varphi \wedge \psi) & \varphi \mathbf{B} \psi \coloneqq \psi \mathbf{S} (\varphi \wedge \psi) & \varphi \mathbf{R} \psi \coloneqq \psi \mathbf{W} (\varphi \wedge \psi) \\
\varphi \tilde{\mathbf{B}} \psi \coloneqq \psi \tilde{\mathbf{S}} (\varphi \wedge \psi) & \tilde{\mathbf{Y}}\varphi \coloneqq \mathbf{Y}\varphi \vee \neg\mathbf{Y}\top. &
\end{array}$$

The past operators above are defined in analogy with their standard future counterparts. An important exception is the *weak yesterday* operator $\tilde{\mathbf{Y}}$, which is similar to $\mathbf{Y}$. However, a formula $\tilde{\mathbf{Y}}\varphi$ is always satisfied at $t = 0$.

A *pLTL* formula that is neither atomic nor whose syntax tree is rooted with a Boolean operator is called a *temporal* formula, and a *pLTL* formula whose syntax tree is rooted with an element of $\{\mathbf{Y}, \tilde{\mathbf{Y}}, \mathbf{S}, \tilde{\mathbf{S}}, \mathbf{B}, \tilde{\mathbf{B}}\}$ a *past* formula. Finally, a *pLTL* formula that is a proposition or the negation thereof is *propositional.* We write $\mathit{sf}(\varphi)$ to denote the set of propositional and temporal subformulae of φ, and $\mathit{psf}(\varphi)$ the set of past subformulae of φ. The *size* of a *pLTL* formula φ, denoted $|\varphi|$, is defined as the number of nodes of its syntax tree that are either temporal or propositional.

A *pLTL* formula where negations only appear before atomic propositions is in *negation normal form.* Observe that with the derived operators above, an arbitrary *pLTL* formula can be rewritten in negation normal form with a linear increase in size. For the remainder of the paper, when we write “formula” we implicitly refer to *pLTL* formulae in negation normal form, with no occurrences of $\mathbf{F}, \mathbf{G}, \mathbf{O}$ or $\mathbf{H}$. Subformulae rooted with either of these four operators can be replaced by equivalent formulae of the same size: every subformula of the form $\mathbf{F}\psi$ can be replaced with $\top \mathbf{U} \psi$ and every subformula of the form $\mathbf{G}\psi$ with $\psi \mathbf{W} \bot$, and analogously for $\mathbf{O}\psi$ and $\mathbf{H}\psi$. While these four derived operators are not part of the syntax under consideration – for the purpose of keeping the presentation more concise – we will occasionally use them as convenient shorthand. When we write "word" we implicitly refer to infinite words, unless otherwise stated.

We conclude this section by defining the notion of *propositional equivalence*, which is a stronger notion of equivalence than that given by the semantics of *pLTL*. It is relatively simple to determine whether two formulae are propositionally equivalent, which makes the notion useful in defining the state spaces of automata as equivalence classes of formulae. We also state a lemma that allows us to lift functions defined on formulae to the propositional equivalence classes they belong to. Both are due to Esparza et al. [5].

▶ **Definition 1** (Propositional Semantics of *pLTL*). *Let $\mathcal{I}$ be a set of formulae and φ a formula. The propositional satisfaction relation $\mathcal{I} \models_p \varphi$ is inductively defined as*

$$\begin{array}{ll} \mathcal{I} \models_p \top & \mathcal{I} \models_p \psi \wedge \xi \text{ iff } \mathcal{I} \models_p \psi \text{ and } \mathcal{I} \models_p \xi \\ \mathcal{I} \not\models_p \bot & \mathcal{I} \models_p \psi \vee \xi \text{ iff } \mathcal{I} \models_p \psi \text{ or } \mathcal{I} \models_p \xi, \end{array}$$

with $\mathcal{I} \models_p \varphi$ iff $\varphi \in \mathcal{I}$ for all other cases. Two formulae φ and ψ are propositionally equivalent, denoted $\varphi \sim \psi$, if $\mathcal{I} \models_p \varphi \Leftrightarrow \mathcal{I} \models_p \psi$ for all sets of formulae $\mathcal{I}$. The (propositional) equivalence class of a formula φ is denoted $[\varphi]_\sim$. The (propositional) quotient set of a set of formulae Ψ is denoted $\Psi_{/\sim}$.

▶ **Lemma 2.** *Let f be a function on formulae such that $f(\top) = \top$, $f(\bot) = \bot$, and for all formulae φ and ψ, $f(\varphi \wedge \psi) = f(\varphi) \wedge f(\psi)$ and $f(\varphi \vee \psi) = f(\varphi) \vee f(\psi)$. Then, for all pairs of formulae φ and ψ, if $\varphi \sim \psi$ then $f(\varphi) \sim f(\psi)$.*

3 Encoding the Past

Informally, given a formula φ and word w, our aim is to define a function that consumes a given finite prefix of w, of arbitrary length t, and produces a new formula φ', such that the suffix w_t satisfies φ' iff w satisfies φ. This function will serve as the foundation for defining the state spaces and transition relations of the automata that we are to construct. For standard *LTL*, defining such a function is straightforward using the local semantics of *LTL*. With the introduction of past operators the situation becomes more complicated. As a prefix of w is consumed we lose the information about the past therein, and must instead encode this information in the rewritten formula. The key insight is that this can be accomplished by rewriting strong past operators of φ – the operators $\mathbf{Y}$, $\mathbf{S}$, and $\mathbf{B}$ – into their weak counterparts $\tilde{\mathbf{Y}}$, $\tilde{\mathbf{S}}$, and $\tilde{\mathbf{B}}$, respectively, and vice versa, based on the consumed input. This section makes this idea precise.

▶ **Definition 3** (Weakening and strengthening formulae). *The weakening $\varphi_\mathcal{W}$ and strengthening $\varphi_\mathcal{S}$ of a formula φ is defined by case distinction on φ as*

$$\begin{array}{lll} (\mathbf{Y}\psi)_\mathcal{W} := \tilde{\mathbf{Y}}\psi & (\psi \,\mathbf{S}\, \xi)_\mathcal{W} := \psi \,\tilde{\mathbf{S}}\, \xi & (\psi \,\mathbf{B}\, \xi)_\mathcal{W} := \psi \,\tilde{\mathbf{B}}\, \xi \\ (\tilde{\mathbf{Y}}\psi)_\mathcal{S} := \mathbf{Y}\psi & (\psi \,\tilde{\mathbf{S}}\, \xi)_\mathcal{S} := \psi \,\mathbf{S}\, \xi & (\psi \,\tilde{\mathbf{B}}\, \xi)_\mathcal{S} := \psi \,\mathbf{B}\, \xi. \end{array}$$

For all other cases we have $\varphi_\mathcal{W} := \varphi$ and $\varphi_\mathcal{S} := \varphi$.

▶ **Definition 4** (Rewriting past operators under sets). *Given a formula φ and set of past formulae C, we write $\varphi\langle C\rangle$ to denote the result of weakening or strengthening the past operators in the syntax tree of φ according to C while otherwise maintaining its structure, as per the following inductive definition:*

$$\begin{aligned} a\langle C\rangle &\coloneqq a && (a \text{ atomic})\\ (op\,\psi)\langle C\rangle &\coloneqq \begin{cases}(op\,\psi\langle C\rangle)_{\mathcal{W}} & (op\,\psi \in C)\\ (op\,\psi\langle C\rangle)_{\mathcal{S}} & (\text{otherwise})\end{cases} && (op \text{ unary})\\ (\psi\ op\,\xi)\langle C\rangle &\coloneqq \begin{cases}(\psi\langle C\rangle\ op\,\xi\langle C\rangle)_{\mathcal{W}} & (\psi\ op\,\xi \in C)\\ (\psi\langle C\rangle\ op\,\xi\langle C\rangle)_{\mathcal{S}} & (\text{otherwise}).\end{cases} && (op \text{ binary}).\end{aligned}$$

We overload this definition to sets: given a set of formulae S, we define $S\langle C\rangle \coloneqq \{s\langle C\rangle \mid s \in S\}$.

▶ **Example 5.** Consider the formula $\varphi = \mathbf{Y}(p\,\tilde{\mathbf{S}}\,q)$ and set $C = \{\varphi\}$. We then have $\varphi\langle C\rangle = \tilde{\mathbf{Y}}(p\,\mathbf{S}\,q)$. For the same formula φ and set $C = \{p\,\tilde{\mathbf{S}}\,q)$, we instead have $\varphi\langle C\rangle = \varphi$.

▶ **Definition 6** (Weakening conditions). *Given a past formula φ, we define the weakening condition function $wc(\varphi)$:*

$$\begin{aligned} &wc(\mathbf{Y}\psi) \coloneqq \psi \quad && wc(\psi\,\mathbf{S}\,\xi) \coloneqq \xi && wc(\psi\,\mathbf{B}\,\xi) \coloneqq \psi \wedge \xi\\ &wc(\tilde{\mathbf{Y}}\psi) \coloneqq \psi && wc(\psi\,\tilde{\mathbf{S}}\,\xi) \coloneqq \psi \vee \xi \quad && wc(\psi\,\tilde{\mathbf{B}}\,\xi) \coloneqq \xi.\end{aligned}$$

The weakening condition for a past formula serves as a requirement that must hold immediately in order to justify weakening the formula for the next time step. More precisely, if $w \models wc(\varphi)$ then it is enough to check that $w_1 \models \varphi_{\mathcal{W}}$ to conclude that $(w, 1) \models \varphi$.

▶ **Example 7.** Let $\varphi = \mathbf{X}(p\,\mathbf{S}\,q)$ and w be a word such that $w_{02} = \{q\}\{p\}$. By establishing that $w \models wc(p\,\mathbf{S}\,q) = q$, we can "forget" about the initial letter $\{q\}$; it is enough to check that $w_1 \models p\,\tilde{\mathbf{S}}\,q$ to conclude that $(w, 1) \models p\,\mathbf{S}\,q$, and hence that $w \models \varphi$.

This suggests that there exists a set of past subformulae of φ that precisely captures the information contained in the initial letter of w required to evaluate all past subformulae of φ at every point in time. This is the main result of this section, which we now summarize.

▶ **Definition 8** (Sets of entailed subformulae). *Let φ be a formula, w a word, and $t \in \mathbb{N}$. The set of past subformulae of φ entailed by w at t is inductively defined as*

$$C^w_{\varphi,0} \coloneqq \{\psi \in psf(\varphi) \mid \psi = \psi_{\mathcal{W}}\} \qquad C^w_{\varphi,t} \coloneqq \{\psi \in psf(\varphi\langle C^w_{\varphi,t-1}\rangle) \mid w_t \models wc(\psi)\} \quad (t > 0).$$

When the word w above is clear from the context, we simply write $C_{\varphi,t}$. Given $t \in \mathbb{N}$ we denote the sequence $C_{\varphi,0}, \ldots, C_{\varphi,t}$ of length $t+1$ by $\vec{C}_{\varphi,t}$. Given a sequence $\vec{C} = C_0, C_1, \ldots, C_t$ of sets of past formulae, there exists a set $C \subseteq psf(\varphi)$ that has the same effect in a rewrite as the sequential application of rewrites of $\vec{C}$, i.e., such that $\varphi\langle C\rangle = \varphi\langle C_0\rangle\langle C_1\rangle \ldots \langle C_t\rangle$. This is the set $\{\psi \in psf(\varphi) \mid \psi\langle C_0\rangle\langle C_1\rangle \ldots \langle C_t\rangle = (\psi\langle C_0\rangle\langle C_1\rangle \ldots \langle C_t\rangle)_{\mathcal{W}}\}$, which we denote by $\circ\,\vec{C}$. In particular, there exists a set that captures the sequence of sets of entailed subformulae, denoted $\circ\,\vec{C}_{\varphi,t}$.

▶ **Lemma 9.** *Given a formula φ, word w, and $t \in \mathbb{N}$, we have $(w, t) \models \varphi$ iff $w_t \models \varphi\langle\circ\,\vec{C}_{\varphi,t}\rangle$.*

With these definitions in place, we are ready to define the after-function for *pLTL*.

4 The after-function for *pLTL*

The after-function is the foundation for defining the states and transition relations of all automata used in our *pLTL*-to-DRA translation. We begin by defining the *local* after-function:

▶ **Definition 10** (The local after-function). *Given a formula φ, a letter $\sigma \in 2^{Var(\varphi)}$, and a set of past formulae C, we inductively define the local after-function af_ℓ mutually with the local past update-function pu_ℓ as follows:*

$$\begin{aligned}
af_\ell(\top, \sigma, C) &:= \top \\
af_\ell(\bot, \sigma, C) &:= \bot \\
af_\ell(p, \sigma, C) &:= \mathit{if}\ (p \in \sigma)\ \mathit{then}\ \top\ \mathit{else}\ \bot \\
af_\ell(\neg p, \sigma, C) &:= \mathit{if}\ (p \in \sigma)\ \mathit{then}\ \bot\ \mathit{else}\ \top \\
af_\ell(\mathbf{X}\psi, \sigma, C) &:= pu_\ell(\psi, \sigma, C) \\
af_\ell(\mathbf{Y}\psi, \sigma, C) &:= \bot \\
af_\ell(\tilde{\mathbf{Y}}\psi, \sigma, C) &:= \top \\
af_\ell(\psi\ op\ \xi, \sigma, C) &:= af_\ell(\psi, \sigma, C)\ op\ af_\ell(\xi, \sigma, C) && (op \in \{\wedge, \vee\}) \\
af_\ell(\psi\ op\ \xi, \sigma, C) &:= af_\ell(\xi, \sigma, C) \vee af_\ell(\psi, \sigma, C) \wedge pu_\ell(\psi\ op\ \xi, \sigma, C) && (op \in \{\mathbf{U}, \mathbf{W}\}) \\
af_\ell(\psi\ op\ \xi, \sigma, C) &:= af_\ell(\xi, \sigma, C) \wedge (af_\ell(\psi, \sigma, C) \vee pu_\ell(\psi\ op\ \xi, \sigma, C)) && (op \in \{\mathbf{R}, \mathbf{M}\}) \\
af_\ell(\psi\ op\ \xi, \sigma, C) &:= af_\ell(wc(\psi\ op\ \xi), \sigma, C)) && (op \in \{\mathbf{S}, \tilde{\mathbf{S}}, \mathbf{B}, \tilde{\mathbf{B}}\}),
\end{aligned}$$

where

$$pu_\ell(\varphi, \sigma, C) := \varphi\langle C\rangle \wedge \bigwedge_{\psi \in psf(\varphi) \cap C} af_\ell(wc(\psi), \sigma, C).$$

Intuitively, in the context of reading the initial letter σ of the word w, the local after-function decomposes φ into parts that can be fully evaluated using σ and immediately be replaced with $\top$ or $\bot$, and parts that can only be partially evaluated using σ. The resulting formula is then left to be further evaluated in the future; in the automaton, it corresponds to the state reached upon reading σ from the state corresponding to φ. Crucially, the past subformulae of the partially evaluated part are updated by pu_ℓ, using the information in C. Here, C is to be thought of as a guess of the past subformulae of φ whose weakening conditions hold upon reading σ. Finally, the weakening conditions that must hold to justify the guess are added conjunctively. Observe that, as these weakening conditions may contain subformulae referring to the future, it may not be possible to fully evaluate them immediately; this motivates the recursive application of af_ℓ in pu_ℓ.

▶ **Definition 11** (The extended local after-function). *Given a (possibly empty) finite word w of length n and sequence of sets of past formulae $\vec{C}$ of length $n+1$, we extend af_ℓ to w and $\vec{C}$ as follows:*

$$\begin{aligned}
af_\ell(\varphi, \epsilon, \vec{C}_{01}) &:= \varphi && (n = 0) \\
af_\ell(\varphi, w_{0n}, \vec{C}_{0(n+1)}) &:= af_\ell\left(\varphi_{n-1}, w_{(n-1)n}, \vec{C}_{n(n+1)}\right) && (n > 0),
\end{aligned}$$

where $\varphi_n = af_\ell(\varphi, w_{0n}, \vec{C}_{0(n+1)})$.

Observe that the initial set of $\vec{C}$ in the above definition is discarded; this is to match the sequence of Definition 8. For formulae where no future operators are nested inside past operators, the set of entailed subformulae is completely determined by the prefix w_{0n}. This is not the case in general, however, and so the (global) after-function is defined to consider all possible subsets of past subformulae of φ as a disjunction.

▶ **Definition 12** (The after-function). *Let φ be a formula and σ a letter. The after-function af is defined as:*

$$af(\varphi,\sigma) := \bigvee_{C \in 2^{psf(\varphi)}} af_\ell(\varphi,\sigma,C).$$

The extension of af to finite words is done in the natural way: given a formula φ and word w of length n, we define

$$\begin{aligned} af(\varphi,\epsilon) &:= \varphi && (n=0)\\ af(\varphi,w_{0n}) &:= af(af(\varphi,w_{0(n-1)}),w_{(n-1)n}) && (n>0). \end{aligned}$$

▶ **Example 13.** Let $\varphi = \mathbf{X}(p\,\mathbf{S}\,\mathbf{X}q)$. Observe that $\varphi \equiv \mathbf{X}(p \wedge q \vee \mathbf{X}q)$. Upon reading a letter σ we can guess that the "since" started holding at the current point, corresponding to the set $C = \{p\,\mathbf{S}\,\mathbf{X}q\}$ and formula $p\,\tilde{\mathbf{S}}\,\mathbf{X}q \wedge q$. Alternatively, we may guess that the "since" did *not* start holding upon reading σ, corresponding to the set $C = \varnothing$ and formula $p\,\mathbf{S}\,\mathbf{X}q$. Hence $af(\varphi,\sigma) = p\,\tilde{\mathbf{S}}\,\mathbf{X}q \wedge q \vee p\,\mathbf{S}\,\mathbf{X}q$. This is equivalent (at $t = 0$) to $p \wedge q \vee \mathbf{X}q$, which is what must be satisfied by w_1, as desired.

The correctness of af is established by the following theorem:

▶ **Theorem 14.** *For every formula φ, word w, and $t \in \mathbb{N}$ we have $w \models \varphi$ iff $w_t \models af(\varphi, w_{0t})$.*

5 Stability and the Master Theorem

We consider two fragments of *pLTL*: *μ-pLTL*, the set of formulae whose future operators are members of $\{\mathbf{X},\mathbf{U},\mathbf{M}\}$, and *$\nu$-pLTL*, the set of formulae whose future operators are members of $\{\mathbf{X},\mathbf{W},\mathbf{R}\}$. Given a formula φ, we define the set $\mu(\varphi)$ of subformulae of φ whose syntax trees are rooted with $\mathbf{U}$ or $\mathbf{M}$. Similarly, we define the set $\nu(\varphi)$ of subformulae of φ whose syntax trees are rooted with $\mathbf{W}$ or $\mathbf{R}$.

The Master Theorem for *pLTL* establishes that the language of a *pLTL* formula can be decomposed into a Boolean combination of simple languages. It is motivated by two ideas:

i) Assume that φ is a formula and w is a word such that all subformulae in $\mu(\varphi)$ that are eventually satisfied by w are infinitely often satisfied by w, and all subformulae in $\nu(\varphi)$ that are almost always satisfied by w never fail to be satisfied by w. In this case, we say that w is a *stable* word of φ, as will be properly defined shortly. Under these circumstances, a subformula of φ of the form $\psi\,\mathbf{U}\,\xi$ is satisfied by w iff both $\psi\,\mathbf{W}\,\xi$ and $\mathbf{GF}(\psi\,\mathbf{U}\,\xi)$ are. Dually, a subformula of φ of the form $\psi\,\mathbf{W}\,\xi$ is satisfied by w iff either $\psi\,\mathbf{U}\,\xi$ or $\mathbf{FG}(\psi\,\mathbf{W}\,\xi)$ are. Hence, we can partition all words over $\mathrm{Var}(\varphi)$ into partitions of the form $P_{M,N}$, where $w \in P_{M,N}$ iff M is the set of *μ-pLTL*-subformulae of φ satisfied infinitely often by w, and N the set *ν-pLTL*-subformulae of φ that are almost always satisfied by w. Given two such sets M and N, the above implies that φ can be rewritten into a formula that belongs to either the fragment *μ-pLTL* or *ν-pLTL*, as desired.

ii) Given a formula φ and word w, there exists a point in the future from which the above holds. Indeed, if we look far ahead into the future, all subformulae of φ that are satisfied by w only finitely often will have been satisfied for the last time. In particular, this is true for the μ-*pLTL*-subformulae of φ. Similarly, there exists a point in the future at which all subformulae of φ that are almost always satisfied by w will have failed to be satisfied by w for the last time. In particular, this is true for the ν-*pLTL*-subformulae of φ.

These two notions suggest that, given a formula φ and word $w \in P_{M,N}$, it is possible to transform φ using the after-function until w becomes stable, and then rewrite it according to either M or N. Since these sets are unknown, we need to consider all possible combinations of such subsets, which ultimately manifests as a number of Rabin pairs exponential in the size of the formula. For more details and further examples we refer the reader to Section 5 of Esparza et al. [5]. The exposition of this section follows the similar exposition therein. However, the Master Theorem and the lemmata that imply it require considerable "pastification".

We now make precise the idea expressed in ii). Given a formula φ, word w, and $t \in \mathbb{N}$, we define the set of subformulae in $\mu(\varphi)$ that are satisfied by w at least once at t and the set of subformulae in $\mu(\varphi)$ that are satisfied by w infinitely often at t. Similarly, we define the set of subformulae in $\nu(\varphi)$ that are always satisfied by w at t and the set of subformulae in $\nu(\varphi)$ that are almost always satisfied by w at t:

$$\mathcal{F}^{\varphi}_{w,t} \coloneqq \{\psi \in \mu(\varphi) \mid (w,t) \models \mathbf{F}\psi\} \quad \mathcal{GF}^{\varphi}_{w,t} \coloneqq \{\psi \in \mu(\varphi) \mid (w,t) \models \mathbf{GF}\psi\}$$
$$\mathcal{G}^{\varphi}_{w,t} \coloneqq \{\psi \in \nu(\varphi) \mid (w,t) \models \mathbf{G}\psi\} \quad \mathcal{FG}^{\varphi}_{w,t} \coloneqq \{\psi \in \nu(\varphi) \mid (w,t) \models \mathbf{FG}\psi\}.$$

As mentioned, we are in particular interested in the point at which the two sets in each row coincide. We express this as the word being *stable* at that point.

▶ **Definition 15** (Stable words). *A word w is μ-stable (ν-stable) with respect to a formula φ at index t if $\mathcal{F}^{\varphi}_{w,t} = \mathcal{GF}^{\varphi}_{w,t}$ ($\mathcal{G}^{\varphi}_{w,t} = \mathcal{FG}^{\varphi}_{w,t}$). If w is both μ-stable and ν-stable with respect to φ at index t, then it is stable with respect to φ at index t.*

▶ **Lemma 16.** *Let φ be a formula and w a word. Then there exists an index $r \in \mathbb{N}$ such that w is stable with respect to φ at all indices $t \geq r$.*

The following two definitions specify how to rewrite a formula according to sets M and N, as indicated in i):

▶ **Definition 17.** *Let φ be a formula and M a set of μ-pLTL-formulae. The formula $\varphi[M]_\nu$ is inductively defined as*

$$\begin{aligned}
a[M]_\nu &\coloneqq a && (a \text{ atomic})\\
(op\,\psi)[M]_\nu &\coloneqq op\,(\psi[M]_\nu) && (op \text{ unary})\\
(\psi\;op\;\xi)[M]_\nu &\coloneqq (\psi[M]_\nu)\;op\;(\xi[M]_\nu) && (op \in \{\mathbf{W},\mathbf{R},\mathbf{S},\tilde{\mathbf{S}},\mathbf{B},\tilde{\mathbf{B}}\})\\
(\psi\,\mathbf{U}\,\xi)[M]_\nu &\coloneqq \begin{cases}(\psi[M]_\nu)\,\mathbf{W}\,(\xi[M]_\nu) & (\psi\,\mathbf{U}\,\xi \in M)\\ \bot & (\text{otherwise})\end{cases}\\
(\psi\,\mathbf{M}\,\xi)[M]_\nu &\coloneqq \begin{cases}(\psi[M]_\nu)\,\mathbf{R}\,(\xi[M]_\nu) & (\psi\,\mathbf{M}\,\xi \in M)\\ \bot & (\text{otherwise}),\end{cases}
\end{aligned}$$

▶ **Definition 18.** *Let φ be a formula and N a set of ν-pLTL-formulae. The formula $\varphi[N]_\mu$ is inductively defined as*

$$\begin{aligned}
(\psi\,\mathbf{W}\,\xi)[N]_\mu &\coloneqq \begin{cases}\top & (\psi\,\mathbf{W}\,\xi \in N)\\ (\psi[N]_\mu)\,\mathbf{U}\,(\xi[N]_\mu) & (\text{otherwise})\end{cases}\\
(\psi\,\mathbf{R}\,\xi)[N]_\mu &\coloneqq \begin{cases}\top & (\psi\,\mathbf{R}\,\xi \in N)\\ (\psi[N]_\mu)\,\mathbf{M}\,(\xi[N]_\mu) & (\text{otherwise}).\end{cases}
\end{aligned}$$

The other cases are defined by recursive descent similarly to Definition 17.

Notice that once a formula has been rewritten by M, it becomes a ν-formula. Dually, once a formula has been rewritten by N, it becomes a μ-formula. In terms of the hierarchy of Manna and Pnueli [10], these are safety and guarantee formulae, respectively. It is relatively simple to construct deterministic automata for such formulae as they do not require complicated acceptance conditions.

▶ **Theorem 19** (The Master Theorem for $pLTL$). *Let φ be a formula and w a word stable with respect to φ at index r. Then $w \models \varphi$ iff there exist $M \subseteq \mu(\varphi)$ and $N \subseteq \nu(\varphi)$ such that*

1) $w_r \models af_\ell(\varphi, w_{0r}, \vec{C}_{\varphi,r})[M\langle \circ\, \vec{C}_{\varphi,r}\rangle]_\nu$.

2) $\forall \psi \in M \,.\, \forall s \,.\, \exists t \geq s \,.\, w_t \models \mathbf{F}(\psi\langle \circ\, \vec{C}_{\varphi,t}\rangle[N\langle \circ\, \vec{C}_{\varphi,t}\rangle]_\mu)$.

3) $\forall \psi \in N \,.\, \exists t \geq 0 \,.\, w_t \models \mathbf{G}(\psi\langle \circ\, \vec{C}_{\varphi,t}\rangle[M\langle \circ\, \vec{C}_{\varphi,t}\rangle]_\nu)$.

The statements of the Master Theorem in the only if-direction can be significantly strengthened. The existential quantification over t in premise 2 can be made universal. The statement $w_t \models \ldots$ in premise 3 holds for all $t' \geq r$. Given the semantics of $\mathbf{F}$ and $\mathbf{G}$, this is not a surprise. However, the ability to do the rewrites at every given moment is technically involved due to the incorporation of the past. In the next section we show how to use the Master Theorem in the construction of a DRA.

6 From $pLTL$ to DRA

We are now ready, based on the Master Theorem, to construct a DRA for the language of a formula φ. We decompose the language of φ into a Boolean combination of languages, each of which is recognized by a deterministic automaton with the relatively simple acceptance condition of Büchi or co-Büchi. For every possible pair of sets M and N of μ- and ν-subformulae we try to establish the premises of the Master Theorem. Premise 1 can be checked by trying to identify a stability point r from which the safety automaton for $af_\ell(\varphi, w_{0r}, \vec{C}_{\varphi,r})[M\langle \circ\, \vec{C}_{\varphi,t}\rangle]_\nu$ continues forever. Whenever this safety check fails, simply try again. Overall, this corresponds to a co-Büchi condition and a DCA. Premise 2 can be checked for every $\psi \in M$ by identifying infinitely many points from which the guarantee automaton for $\mathbf{F}(\psi\langle \circ\, \vec{C}_{\varphi,t}\rangle[N\langle \circ\, \vec{C}_{\varphi,t}\rangle]_\mu)$ finishes its check. Overall, this corresponds to a Büchi condition and a DBA. Premise 3 is dual to premise 2 and leads to a DCA. The three together are combined to a DRA with one pair. Overall, we get a DRA with exponentially many Rabin pairs; one for each choice of M and N. We will as shorthand make use of the operators $\mathbf{F}$ and $\mathbf{G}$ in the construction of these automata, as described in Section 2.2.

The major difficulty of incorporating the past into this part, is that the rewriting using the set M and N needs to be done with the past subformulae correctly weakened. To facilitate this, we begin by defining an auxiliary automaton in Section 6.1 that serves to track the weakening conditions that must hold in order to justify rewrites by $\cdot\langle\cdot\rangle$.

The state spaces of the automata we construct are defined in terms of the following notions. Given a formula φ we denote by $\mathbb{B}(\varphi)$ the set of formulae ψ satisfying $sf(\psi) \subseteq sf(\varphi) \cup \{\top, \bot\}$. Similarly, consider a formula that is a disjunction of formulae with the property that for each such disjunct ψ there exists a $C \in 2^{psf(\varphi)}$ such that $\psi \in \mathbb{B}(\varphi\langle C\rangle)$. We denote by $\mathbb{B}^\vee(\varphi)$ the set of all such formulae. A key observation is that the sizes of the quotient sets $\mathbb{B}(\varphi)_{/\sim}$ and $\mathbb{B}^\vee(\varphi)_{/\sim}$ are doubly exponential in the size of φ.

For the remainder of this section we consider a fixed formula φ that is to be translated into a Rabin automaton and a fixed ordering $C_1, C_2, \ldots, C_k$ of the elements of $2^{psf(\varphi)}$. For simplicity, we assume $C_1 = \{\psi \in psf(\varphi) \mid \psi = \psi_{\mathcal{W}}\} = C_{\varphi,0}$. We freely make use of af, $\cdot[\cdot]_\nu$, and $\cdot[\cdot]_\mu$ lifted to equivalence classes of formulae. This is justified by Lemma 2.

6.1 The Weakening Conditions Automaton

The weakening conditions automaton (WC automaton) is a bed automaton that tracks the development of weakening conditions under rewrites of the local after-function. Its states are k-tuples of formulae, each of which describes the requirements that remain to be verified in order to justify a sequence of rewrites. To facilitate the construction of the WC automaton, we define the following function:

▶ **Definition 20.** *Given a k-tuple of formulae $\psi^\times = \langle \psi_1, \psi_2, \ldots, \psi_k \rangle$ and a letter σ, the rewrite condition function is defined as $rc(\psi^\times, \sigma) := \langle \psi'_1, \psi'_2, \ldots, \psi'_k \rangle$, where*

$$\psi'_i = \bigvee_{j \in J_i} \Big(af_\ell(\psi_j, \sigma, C_i\langle C_j\rangle) \wedge \bigwedge_{\xi \in C_i} af_\ell(wc(\xi\langle C_j\rangle), \sigma, C_i\langle C_j\rangle) \Big),$$

and where $J_i := \big\{ j \in [1..k] \mid \forall \xi, \xi' \in psf(\varphi) \,.\, \xi\langle C_j\rangle = \xi'\langle C_j\rangle \Rightarrow \xi\langle C_i\rangle = \xi'\langle C_i\rangle \big\}$.

The definition of J_i ensures that $\psi'_i \in \mathbb{B}(\varphi\langle C_i\rangle)$. The rewrite condition function takes a k-tuple of formulae and a letter, and returns an updated k-tuple. In the resulting tuple, the i^{th} item ψ'_i is a formula that encodes the updated requirements for further applying the rewrite $\cdot\langle C_i\rangle$. We remark that, for every $t > 0$, there exist indices $i \leq k$ and $j \in J_i$ such that $C_i = \circ\vec{C}_{\varphi,t}$, $C_j = \circ\vec{C}_{\varphi,t-1}$, and $C_i\langle C_j\rangle = C_{\varphi,t}$.

We now define the WC automaton $\mathcal{H}_\varphi := (S, S_0, \delta_\mathcal{H})$ over $2^{Var(\varphi)}$. Its set of states S is $\Pi_{i=1}^k \mathbb{B}(\varphi\langle C_i\rangle)_{/\sim}$. The initial state S_0 is the k-tuple $\langle [\top]_\sim, [\bot]_\sim, \ldots, [\bot]_\sim \rangle$, which represents that the set used to rewrite φ into its initial form is known to be C_1. Finally, the transition relation δ is defined by $\delta_\mathcal{H}(\psi^\times, \sigma) = rc(\psi^\times, \sigma)$, with rc lifted to propositional equivalence classes of formulae in the natural way.

6.2 Verifying the Premises of the Master Theorem

We now describe the automata that are capable of verifying the premises of the Master Theorem. They are all runner automata with bed automaton $\mathcal{H}_\varphi := (S, S_0, \delta_\mathcal{H})$.

Given a formula $\psi \in \mu(\varphi)$ and set $N \subseteq \nu(\varphi)$ we define the runner automaton $\mathcal{B}^\psi_{2,N} := (S, Q, Q_0, \delta, \alpha)$ over $2^{Var(\varphi)}$ with set of states $Q := \mathbb{B}^\vee(\varphi[N]_\mu \wedge \mathbf{F}(\psi[N]_\mu))_{/\sim}$, initial state $Q_0 := [\mathbf{F}(\psi[N]_\mu)]_\sim$, and Büchi acceptance condition $\alpha := [\top]_\sim$. Finally, its transition relation is defined as

$$\delta(\zeta, \xi^\times, \sigma) := \begin{cases} \displaystyle\bigvee_{i \in [1..k]} \mathbf{F}(\psi\langle C_i\rangle[N\langle C_i\rangle]_\mu) \wedge \xi_i[N\langle C_i\rangle]_\mu & (\zeta \sim \top) \\ af(\zeta, \sigma) & (\text{otherwise}), \end{cases}$$

where $\xi^\times = \langle \xi_1, \xi_2, \ldots, \xi_k \rangle$. For readability, we express δ in terms of formulae, but ask the reader to note that they represent their corresponding propositional equivalence classes.

Informally, the automaton $\mathcal{B}^\psi_{2,N}$ begins by checking that the input word w satisfies the formula $\mathbf{F}(\psi[N]_\mu)$. Because this formula is in the fragment *μ-pLTL*, it is satisfied by w iff the after-function eventually rewrites it into a propositionally true formula. At this point, the automaton restarts, checking the formula again. Because the subset of $psf(\varphi)$ that puts $\psi[N]_\mu$ in the correct form at this point – with respect to its past subformulae – is unknown, all possible such sets are considered in the form of a disjunction. To each disjunct the corresponding weakening conditions, as tracked by the WC automaton, are added. It follows that $\mathcal{H}_\varphi \ltimes \mathcal{B}^\psi_{2,N}$ is able to verify premise 2) of the Master Theorem for the considered formula ψ and sets M and N.

Given a formula $\psi \in \nu(\varphi)$ and set $M \subseteq \mu(\varphi)$ we define the runner automaton $\mathcal{C}^{\psi}_{3,M} \coloneqq (S, Q, Q_0, \delta, \alpha)$ over $2^{\mathit{Var}(\varphi)}$ with set of states $Q \coloneqq \mathbb{B}^{\vee}(\varphi[M]_{\nu} \wedge \mathbf{G}(\psi[M]_{\nu}))_{/\sim}$, initial state $Q_0 \coloneqq [\mathbf{G}(\psi[M]_{\nu})]_{\sim}$, and co-Büchi acceptance condition $\alpha \coloneqq [\bot]_{\sim}$. Finally, its transition relation is defined as

$$\delta(\zeta, \xi^{\times}, \sigma) \coloneqq \begin{cases} \bigvee_{i \in [1..k]} \mathbf{G}(\psi\langle C_i\rangle[M\langle C_i\rangle]_{\nu}) \wedge \xi_i[M\langle C_i\rangle]_{\nu} & (\zeta \sim \bot) \\ \mathit{af}(\zeta, \sigma) & \text{(otherwise)}, \end{cases}$$

where $\xi^{\times} = \langle \xi_1, \xi_2, \ldots, \xi_k\rangle$. As before, the formulae of δ represent their corresponding equivalence classes. By a similar argument as before, the automaton $\mathcal{H} \ltimes \mathcal{C}^{\psi}_{3,M}$ is able to verify premise 3) of the Master Theorem for the formula ψ and sets M and N.

We now turn to constructing automata for verifying the first premise of the Master Theorem. Given a set $M \subseteq \mu(\varphi)$, we define the runner automaton $\mathcal{C}^{1}_{\varphi,M} \coloneqq (S, Q, Q_0, \delta, \alpha)$ over $2^{\mathit{Var}(\varphi)}$ with set of states $Q \coloneqq \mathbb{B}^{\vee}(\varphi)_{/\sim} \times \mathbb{B}^{\vee}(\varphi[M]_{\nu})_{/\sim}$, initial state $Q_0 \coloneqq \langle [\varphi]_{\sim}, [\varphi[M]_{\nu}]_{\sim}\rangle$, and co-Büchi acceptance condition $\alpha \coloneqq \mathbb{B}^{\vee}(\varphi)_{/\sim} \times \{[\bot]_{\sim}\}$. Its transition relation is defined as

$$\delta(\langle \psi, \zeta\rangle, \xi^{\times}, \sigma) \coloneqq \begin{cases} \Big\langle \mathit{af}(\psi, \sigma), \bigvee_{i \in [1..k]} \mathit{af}(\psi, \sigma)[M\langle C_i\rangle]_{\nu} \wedge \xi_i[M\langle C_i\rangle]_{\nu} \Big\rangle & (\zeta \sim \bot) \\ \Big\langle \mathit{af}(\psi, \sigma), \mathit{af}(\zeta, \sigma) \Big\rangle & \text{(otherwise)}, \end{cases}$$

where $\xi^{\times} = \langle \xi_1, \xi_2, \ldots, \xi_k\rangle$. Again, we remind the reader that the formulae in the above definition represent equivalence classes of formulae. The purpose of the above automaton is to "guess" an index at which w is stable with respect to φ, starting with the guess that it is initially stable. Both φ and $\varphi[M]$ are evaluated in tandem. If the current guess of point of stability is incorrect, the second component will eventually collapse into a formula propositionally equivalent to $\bot$. At this point, the automaton proceeds with a new guess by reapplying $\cdot[M]_{\nu}$ to φ as it has currently been transformed by the after-function. As with the other automata, the formulae that make up the states of the WC automaton are used to justify the rewrite by each set C_i. The automaton $\mathcal{H}_{\varphi} \ltimes \mathcal{C}^{1}_{\varphi,M}$ is able to verify premise 1) of the Master Theorem for the formula φ and the set M.

6.3 The Rabin Automaton

We now construct the final deterministic Rabin automaton. The automaton is the disjunction of up to 2^n simpler Rabin automata; one for every possible choice of $M \subseteq \mu(\varphi)$ and $N \subseteq \mu(\varphi)$. Taking the disjunction of deterministic Rabin automata is possible by running automata for all disjuncts in parallel (via a product construction) and taking the acceptance condition that checks that at least one of them is accepting. Each simpler Rabin automaton checks the three premises of the Master Theorem for its specific M and N: (a) $M \subseteq \mathcal{GF}^{\varphi}_{w,0}$, (b) $N \subseteq \mathcal{FG}^{\varphi}_{w,0}$, and (c) w satisfies a version of φ simplified by M. Each of the three is checked by a Büchi or co-Büchi automaton. In order to check all three we have to consider their conjunction. For a Rabin automaton (with one pair) it is possible to check the conjunction of Büchi and co-Büchi by running automata for all conjuncts in parallel (product construction) and using the Rabin acceptance condition (one pair) to ensure that all co-Büchi automata and all Büchi automata are accepting.

▶ **Theorem 21.** *Let φ be a formula. For each $M \subseteq \mu(\varphi)$ and $N \subseteq \nu(\varphi)$, define*

$$\mathcal{B}^2_{M,N} \coloneqq \bigcap_{\psi\in M} \mathcal{H}_\varphi \ltimes \mathcal{B}^\psi_{2,N} \qquad \mathcal{C}^3_{M,N} \coloneqq \bigcap_{\psi\in N} \mathcal{H}_\varphi \ltimes \mathcal{C}^\psi_{3,M}$$
$$\mathcal{R}_{\varphi,M,N} \coloneqq (\mathcal{H}_\varphi \ltimes \mathcal{C}^1_{\varphi,M}) \cap \mathcal{B}^2_{M,N} \cap \mathcal{C}^3_{M,N},$$

where $\mathcal{R}_{\varphi,M,N}$ has one Rabin pair. Then the following DRA over $2^{Var(\varphi)}$ recognizes φ:

$$\mathcal{A}_{DRA}(\varphi) \coloneqq \bigcup_{\substack{M\subseteq\mu(\varphi)\\ N\subseteq\nu(\varphi)}} \mathcal{R}_{\varphi,M,N}.$$

▶ **Corollary 22.** *Let φ be a formula of size $n + m$, where n is the number of future- and propositional subformulae of φ, and m is the number of past subformulae of φ. There exists a deterministic Rabin automaton recognizing φ with doubly exponentially many states in the size of the formula and at most 2^n Rabin pairs.*

7 Discussion

We presented a direct translation from *pLTL* to deterministic Rabin automata. Starting from a formula with n future subformulae and m past subformulae, we produce an automaton with an optimal $2^{2^{O(n+m)}}$ states and $2^{O(n)}$ acceptance pairs. Our translation relies on extending the classical "after"-function of *LTL* to *pLTL* by encoding memory about the past through the weakening and strengthening of embedded past operators. We extended the Master Theorem about decomposition of languages expressed for *LTL* to *pLTL*.

The only applicable approach (prior to our work) to obtain deterministic automata from *pLTL* formulae was to convert the formula to a nondeterministic automaton [14] and then determinize this automaton [16, 13]. The first can be done either directly [9, 14] or through two-way very-weak alternating automata [7]. In any case, the first translates a formula with n future operators and m past operators to an automaton with $2^{O(n+m)}$ states and the second translates an automaton with k states to a parity automaton with $O(k!^2)$ states and $O(k)$ priorities. It follows that the overall complexity of this construction is $2^{2^{O((n+m)\cdot\log(n+m))}}$ states and $2^{O(n+m)}$ priorities. Our approach improves this upper bound to $2^{2^{O(m+n)}}$. It is well known that *pLTL* does not extend the expressive power of *LTL*. However, conversion from *pLTL* to *LTL* is not viable algorithmically. The best known translation is worst-case non-elementary [6], and the conversion is provably exponential [11]. So using a conversion to *LTL* as a preliminary step to determinization could result in a triple exponential construction. We note that in the case where there are no future operators nested within past operators, it is possible to convert the past subformulae directly to deterministic automata. Then, the remaining future can be determinized independently. This approach has been advocated for usage of the past in reactive synthesis [3, 4] and implemented recently in a bespoke tool [2].

As future work, we note that the approach of Esparza et al. [5] additionally led to translations from *LTL* to nondeterministic automata, limit-deterministic automata, and deterministic automata. The same should be done for *pLTL*. Their work also led to a normal form for *LTL* formulae, which we believe could be generalized to work for *pLTL*. The latter could have interesting relations to the temporal hierarchy of Manna and Pnueli [10]. Such a normal form could also be related to more efficient translations from *pLTL* to *LTL*. Finally, this approach has led to a competitive implementation of determinization [8] and reactive synthesis [12]. Extending these implementations to handle past is of high interest.

Abstract

Fagin's seminal result characterizing NP in terms of existential second-order logic started the fruitful field of descriptive complexity theory. In recent years, there has been much interest in the investigation of quantitative (weighted) models of computations. In this paper, we start the study of descriptive complexity based on weighted Turing machines over arbitrary semirings. We provide machine-independent characterizations (over ordered structures) of the weighted complexity classes $\mathsf{NP}[\mathcal{S}], \mathsf{FP}[\mathcal{S}]$, $\mathsf{FPLOG}[\mathcal{S}]$, $\mathsf{FPSPACE}[\mathcal{S}]$, and $\mathsf{FPSPACE}_{poly}[\mathcal{S}]$ in terms of definability in suitable weighted logics for an arbitrary semiring $\mathcal{S}$. In particular, we prove weighted versions of Fagin's theorem (even for arbitrary structures, not necessarily ordered, provided that the semiring is idempotent and commutative), the Immerman–Vardi's theorem (originally for P) and the Abiteboul–Vianu–Vardi's theorem (originally for PSPACE). We also discuss a recent open problem proposed by Eiter and Kiesel.

Recently, the above mentioned weighted complexity classes have been investigated in connection to classical counting complexity classes. Furthermore, several classical counting complexity classes have been characterized in terms of particular weighted logics over the semiring $\mathbb{N}$ of natural numbers. In this work, we cover several of these classes and obtain new results for others such as NPMV, $\oplus\mathsf{P}$, or the collection of real-valued languages realized by polynomial-time real-valued nondeterministic Turing machines. Furthermore, our results apply to classes based on many other important semirings, such as the max-plus and the min-plus semirings over the natural numbers which correspond to the classical classes $\mathsf{MaxP}[O(\log n)]$ and $\mathsf{MinP}[O(\log n)]$, respectively.

1 Introduction

Descriptive complexity is a branch of computational complexity, as well as finite model theory, where the difficulty in solving a problem by a Turing machine is characterized not by the amount of resources required (such as time, space and so on) but rather in terms of the complexity of describing the problem in some logical formalism. This field was

49th International Symposium on Mathematical Foundations of Computer Science (MFCS 2024).

initially started in 1974 by Ronald Fagin with the celebrated result in [19] (coined by Neil Immerman as "Fagin's theorem") which stated that the class of NP languages coincides with the class of languages definable in existential second-order logic. Many further surprising results followed this development, particularly the Immerman–Vardi's theorem characterizing P over ordered structures using fixed-point logic [31, 48] and the Abiteboul–Vianu–Vardi characterization of PSPACE in terms of partial fixed-point logic [1, 48]. Today there are several textbooks that cover the fundamentals of the area as a line of research within finite model theory [15, 38, 25, 32]. In this paper, we propose to study quantitative versions of some of these key results in this important field in connection with weighted computation. We work over finite structures that come with a linear ordering, which is a standard restriction in descriptive complexity.

Weighted automata are nondeterministic finite automata augmented with values from a semiring as weights on the transitions [45]. These weights may model, e.g. the cost involved when executing a transition, the amount of resources or time needed for this, or the probability or reliability of its successful execution. The theory of weighted automata and weighted context-free grammars was essential for the solution of such classical automata-theoretic problems as the decidability of the equivalence of unambiguous context-free languages and regular languages [43] (in fact, the only known proofs of this involve weighted automata), the decidability of two given deterministic multitape automata [30], and the decidability of two given deterministic pushdown automata [39, 46]. This led to quick development of this field, described in the books [6, 12, 16, 36, 42, 43]. Furthermore, weighted automata and weighted context-free grammars have been used as basic concepts in natural language processing and speech recognition, as well as in algorithms for digital image compression [2]. Weighted logic [11], with weights in an arbitrary semiring, was developed originally to obtain a weighted version of the Büchi–Elgot–Trakhtenbrot theorem, showing that a certain weighted monadic second-order logic has the same expressive power on words as weighted automata. Consequently, this weighted logic over suitable semirings like fields has similar decidability properties on words as unweighted monadic second-order logic. It is worth remarking that the classical Büchi–Elgot–Trakhtenbrot theorem is usually regarded as part of the "prehistory" of descriptive complexity [25, p. 145].

Weighted Turing machines extend the concept of weighted automata as natural quantitative counterparts of classical Turing machines. They were first introduced under the name "algebraic Turing machines" in [10, 9] and they have attracted further attention in [34]. Instances of this concept include the so called "fuzzy Turing machines" [49, 4]. Recently, the articles [18, 17] have introduced a related notion of "semiring Turing machine" and explicitly asked for the development of descriptive complexity in such framework as an open problem, focusing specifically on Fagin's theorem in connection to weighted logic [18, p. 255]. We will address this problem at the end of Section 5.

Our contribution. The present paper develops a theory of weighted descriptive complexity and establishes quantitative versions of some celebrated classical theorems. The novel contributions of this work can be summarized in the following characterizations (for an arbitrary semiring $\mathcal{S}$):

- The weighted complexity class $\mathsf{NP}[\mathcal{S}]$ coincides with the queries definable by weighted existential second-order logic on ordered structures, with weights in $\mathcal{S}$, respectively for all structures if $\mathcal{S}$ is idempotent and commutative (Theorem 22).
- The weighted complexity class $\mathsf{FP}[\mathcal{S}]$ coincides with the queries definable by weighted inflationary fixed-point logic, with weights in $\mathcal{S}$ (Theorem 26).

- The weighted complexity class $\mathsf{FPSPACE}[\mathcal{S}]$ coincides with the queries definable by weighted partial fixed-point logic with the addition of second-order multiplicative and additive quantifiers, with weights in $\mathcal{S}$ (Theorem 29).
- The weighted complexity class $\mathsf{FPSPACE}_{poly}[\mathcal{S}]$ coincides with the queries definable by weighted partial fixed-point logic, with weights in $\mathcal{S}$ (Theorem 31).
- The weighted complexity class $\mathsf{FPLOG}[\mathcal{S}]$ coincides with the queries definable by weighted deterministic transitive closure logic (Theorem 33).

Related work. Despite the fact that some characterizations of counting complexity classes using Boolean logics were known [33, 44, 14], observe that the article [3] (following up on the work of [44]) already proposes the idea of using certain weighted logics (with weights in the semiring $\mathbb{N}$ of natural numbers or, in a couple of cases, $\mathbb{Z}$) to characterize well-known counting complexity classes. The authors obtain several interesting results that are also covered by our more encompassing work here (that is, they provide logical characterizations of #P, FP, FPSPACE, FPSPACE($poly$), GapP, and MaxP). There is, however, some orthogonality as they cover some classical complexity classes that we do not and, similarly, we cover some that they do not, as we do not restrict our semiring to being $\mathbb{N}$ or $\mathbb{Z}$. Moreover, the investigation in [3], by contrast to ours, concentrates on the study of classical counting classes for ordered structures, while we consider both ordered and arbitrary structures (provided, in the latter case, that the semiring is idempotent and commutative; examples include e.g. the max-plus- and min-plus-semirings). In the present article, the central aim is rather starting the study of weighted complexity classes via logic, and the corollaries characterizing classical complexity classes are obtained as interesting byproducts of the work. In this way, we are also meeting the challenge posed in [34, p.3] of developing "quantitative descriptive complexity theory based on weighted logics [...] over some fairly general class of semirings". Further work on the model theory of weighted logics includes a Feferman–Vaught result [13], but the area remains largely unexplored despite being one of the open problems suggested in [11]. Finally, an approach related to the weighted logics discussed here has been recently proposed in [26, 27] motivated by problems in database theory [23]. The idea there is that the atomic facts of a model are annotated by values from a semiring whereas in the present paper this aspect is fully classical.

2 Weighted Turing machines

In order to introduce the notion of a weighted Turing machine, first we need to define the kind of algebraic structures that will provide the weights, that is, semirings.

▶ **Definition 1** (Semirings). *A* semiring *is a tuple $\mathcal{S} = \langle S, +, \cdot, \mathbb{0}, \mathbb{1}\rangle$, with operations addition $+$ and multiplication $\cdot$ and constants $\mathbb{0}$ and $\mathbb{1}$ such that*

- *$\langle S, +, \mathbb{0}\rangle$ is a commutative monoid and $\langle S, \cdot, \mathbb{1}\rangle$ is a monoid,*
- *multiplication distributes over addition, and*
- *$s \cdot \mathbb{0} = \mathbb{0} \cdot s = \mathbb{0}$ for every $s \in S$.*

We say that $\mathcal{S}$ is commutative *if the monoid $\langle S, \cdot, \mathbb{1}\rangle$ is commutative, and we say that $\mathcal{S}$ is* idempotent *if the monoid $\langle S, +, \mathbb{0}\rangle$ is idempotent (that is, $s + s = s$ for each $s \in S$).*

Some examples of semirings, including those that we will use in this paper, are the following:

- the *Boolean semiring* $\mathbb{B} = \langle\{0, 1\}, \min, \max, 0, 1\rangle$,
- any bounded distributive lattice $\langle L, \vee, \wedge, 0, 1\rangle$,
- the semiring of natural numbers $\langle \mathbb{N}, +, \cdot, 0, 1\rangle$,

- the semiring of extended natural numbers $\langle \mathbb{N} \cup \{+\infty\}, +, \cdot, 0, 1\rangle$ where $0 \cdot (+\infty) = 0$,
- the ring of integers, $\langle \mathbb{Z}, +, \cdot, 0, 1\rangle$,
- the ring of integers modulo n, $\langle \mathbb{Z}_n, +_n, \cdot_n, \overline{0}, \overline{1}\rangle$, for each $n \in \mathbb{N}$,
- the field of rational numbers $\langle \mathbb{Q}, +, \cdot, 0, 1\rangle$,
- the *max-plus* or *arctic semiring* $\mathrm{Arct} = \langle \mathbb{R}_+ \cup \{-\infty\}, \max, +, -\infty, 0\rangle$, where $\mathbb{R}_+$ denotes the set of non-negative real numbers,
- the restriction of the arctic semiring to the natural numbers $\mathbb{N}_{\max} = \langle \mathbb{N} \cup \{-\infty\}, \max, +, -\infty, 0\rangle$,
- the *min-plus* or *tropical semiring* $\mathrm{Trop} = \langle \mathbb{R}_+ \cup \{+\infty\}, \min, +, +\infty, 0\rangle$,
- the restriction of the tropical semiring to the natural numbers $\mathbb{N}_{\min} = \langle \mathbb{N} \cup \{+\infty\}, \min, +, +\infty, 0\rangle$,
- the semiring $\mathcal{F}_* = \langle [0,1], \max, *, 0, 1\rangle$ given by a t-norm $*$ [49],
- the semiring of finite languages $2^{\Sigma^*}_{\text{fin}} = \langle 2^{\Sigma^*}_{\text{fin}}, \cup, \cdot, \emptyset, \{\varepsilon\}\rangle$, for an alphabet Σ,
- the semiring $\mathcal{S}_{\max} = \langle \{0,1\}^* \cup \{-\infty\}, \max, \cdot, -\infty, \varepsilon\rangle$ of binary words in which max is computed according to the *radix order* (for $x, y \in \{0,1\}^*$, $x \preceq y$ iff $|x| < |y|$ or $|x| = |y|$ and x is smaller than or equal to y in the lexicographic order) and $\max(x, -\infty) = \max(-\infty, x) = x$ for each x, $\cdot$ is the concatenation operation, and $x \cdot (-\infty) = (-\infty) \cdot x = -\infty$ for each x,
- the semiring $\mathcal{S}_{\min} = \langle \{0,1\}^* \cup \{+\infty\}, \min, \cdot, +\infty, \varepsilon\rangle$ analogous to the previous one.

▶ **Definition 2** (Weighted Turing Machines). *Let $\mathcal{S}$ be a semiring and Σ an alphabet. A* weighted (or algebraic) Turing machine *over $\mathcal{S}$ and input alphabet Σ is a septuple $\mathcal{M} = \langle Q, \Gamma, \Delta, \nu, q_0, F, \square\rangle$, where*

- *Q is a nonempty finite set whose elements are called* states*,*
- *$\Gamma \supseteq \Sigma$ is an alphabet (*working alphabet*),*
- *$\Delta \subseteq (Q \setminus F) \times \Gamma \times Q \times \Gamma \times \{-1, 0, 1\}$ and its elements are called* transitions*,*
- *$\nu \colon \Delta \longrightarrow S$ is called a* transition weighting function*, $q_0 \in Q$ is called the* initial state*, $F \subseteq Q$ and its elements are called* accepting states*, and $\square \in \Gamma \setminus \Sigma$ is the blank symbol.*

We call $\mathcal{M}$ a Turing machine *if $\mathcal{S}$ is the Boolean semiring $\mathbb{B}$. We call $\mathcal{M}$* deterministic *if for every pair $\langle p, a\rangle \in Q \times \Gamma$, there is at most one transition $\langle p, a, q, b, d\rangle \in \Delta$.*

A *configuration* of $\mathcal{M}$ is a unique description of the machine's state, contents of the working tape, and the position of the machine's head. If $e = \langle p, c, q, d, t\rangle \in \Delta$ is a transition and C_1, C_2 are configurations of $\mathcal{M}$, then we write $C_1 \longrightarrow_e C_2$ if C_1 is a configuration with state p and the head reading c, while C_2 is obtained from C_1 by changing state to q, rewriting the originally read symbol c to d, and moving the head as prescribed by t. We write $C_1 \longrightarrow C_2$ if $C_1 \longrightarrow_e C_2$ for some $e \in \Delta$.

A *computation* of $\mathcal{M}$ is a word $\gamma = C_1 e_1 C_2 e_2 C_3 \dots C_n e_n C_{n+1}$ such that $C_1, \dots, C_{n+1}$ are configurations of $\mathcal{M}$, $e_1, \dots, e_n \in \Delta$, $C_k \longrightarrow_{e_k} C_{k+1}$ for each $k \in \{1, \dots, n\}$, and C_1 is a configuration with state q_0 and the head at the leftmost non-blank cell (if there is some). The *weight* of γ is defined as $\nu(\gamma) := \nu(e_1)\nu(e_2)\dots\nu(e_n)$. γ is called an *accepting* computation if C_{n+1} has an accepting state. We say that γ is a computation on w in Σ^*, and write $\Sigma(\gamma) = w$ if C_1 is a configuration with w on the working tape. We denote the set of all computations of $\mathcal{M}$ by $C(\mathcal{M})$ and the set of all accepting computations by $A(\mathcal{M})$.

▶ **Convention 3.** *From now on we will assume that every Turing machine $\mathcal{M}$ is* finitely terminating*, that is, the set $C_w(\mathcal{M}) = \{\gamma \in C(\mathcal{M}) \mid \Sigma(\gamma) = w\}$ is finite for each $w \in \Sigma^*$. In particular, the set $A_w(\mathcal{M}) = \{\gamma \in A(\mathcal{M}) \mid \Sigma(\gamma) = w\}$ is finite.*

By a *series* σ we mean a mapping $\sigma\colon \Sigma^* \longrightarrow S$ where Σ is an alphabet, Σ^* the corresponding language and $\mathcal{S}$ is a semiring. Thanks to the convention, we can introduce the following notion:

▶ **Definition 4** (Behavior of a weighted Turing machine). *Let $\mathcal{M}$ be a weighted Turing machine. The* behavior *of $\mathcal{M}$ as the mapping $\|\mathcal{M}\|\colon \Sigma^* \longrightarrow S$ defined as*

$$\|\mathcal{M}\|(w) := \sum_{\gamma \in A_w(\mathcal{M})} \nu(\gamma).$$

We say that a series $\sigma\colon \Sigma^* \longrightarrow S$ is recognized *by a weighted Turing machine $\mathcal{M}$ if $\|\mathcal{M}\| = \sigma$.*

The definition of weighted Turing machine we have used here is exactly the same as that of algebraic Turing machines [10, Def. 5.1] (see also [34]). Similarly, the notion of the behavior of the machine coincides. The semiring Turing machines of [17, 18], by contrast, differ in that they impose some conditions on the allowed transitions [18, cf. Def. 12]. Given distributivity of multiplication over addition, the notion of a semiring Turing machine function in [18, Def. 13] coincides with that of the behavior we use here. Semiring Turing Machines allow semiring values on the tape in somewhat of a black-box manner. Intuitively, one can transition with the weight of the value on the tape, but cannot differentiate the values on the tape or modify them. If semiring values are not allowed in the input string then the definition of weighted and semiring Turing Machines are equivalent (in the sense that one can be transformed into the other without a significant change of execution time). All these definitions generalize the corresponding notions for weighted automata.

3 Some weighted complexity classes

Let $\mathcal{M} = \langle Q, \Gamma, \Delta, \nu, q_0, F, \square\rangle$ be a weighted Turing machine over $\mathcal{S}$ and Σ. For $w \in \Sigma^*$, we denote by $\mathsf{TIME}(\mathcal{M}, w)$ the maximal length of a computation of $\mathcal{M}$ on w, and define, for $n \in \mathbb{N}$, $\mathsf{TIME}(\mathcal{M}, n) := \max\{\mathsf{TIME}(\mathcal{M}, w) : w \in \Sigma^*, |w| \leq n\}$.

For a function $f\colon \mathbb{N} \longrightarrow \mathbb{N}$, we denote by $\mathsf{SERIES}[S, \Sigma](f)$ the set of all series σ such that $\sigma = \|\mathcal{M}\|$ for some weighted Turing machine $\mathcal{M}$ over $\mathcal{S}$ and Σ with $\mathsf{TIME}(\mathcal{M}, n) = O(f(n))$. Now we can define the complexity classes:

$\mathsf{SERIES}[\mathcal{S}](f(n)) := \bigcup\{\mathsf{SERIES}[S, \Sigma](f(n)) : \Sigma \text{ is an alphabet}\}$.

▶ **Definition 5.** *Let $\mathcal{S}$ be a semiring. We define the following weighted complexity class*

$$\mathsf{NP}[\mathcal{S}] := \bigcup\{\mathsf{SERIES}[\mathcal{S}](n^k) : k \in \mathbb{N}\}.$$

$\mathsf{NP}[\mathcal{S}]$ (cf. [34, Def. 4.1]) coincides with the definition of the class $\mathcal{S}$-#P in [10, Def. 5.2]. Furthermore, it is contained as a subclass in the similarly defined class NP[$\mathcal{R}$] from [18, Def. 14] when $\mathcal{R}$ is a commutative semiring. Below (Proposition 35), we will actually show that this containment is proper, in the sense that NP[$\mathcal{R}$] will contain some series that are not in $\mathsf{NP}[\mathcal{S}]$.

▶ **Example 6.** Following [10, Prop. 5.3] and [34, Examples 4.2–4.6], we can list some prominent instances of $\mathsf{NP}[\mathcal{S}]$:

- the usual complexity class NP, obtained when $\mathcal{S} = \mathbb{B}$ is the two-element Boolean semiring and each transition is weighted by 1 (this is the standard way of representing a classical machine model in the weighted context),
- the counting class #P [47], obtained when $\mathcal{S} = \langle \mathbb{N}, +, \cdot, 0, 1\rangle$ is the semiring of natural numbers and each transition is weighted by 1,

- the complexity class $\bigoplus$P [40], obtained when $\mathcal{S} = \langle \mathbb{Z}_2, +_2, \cdot_2, \overline{0}, \overline{1} \rangle$ is the finite field of two elements and each transition is weighted by 1,
- the class GapP, closure of #P under subtraction [20, 28], obtained when $\mathcal{S} = \langle \mathbb{Z}, +, \cdot, \overline{0}, \overline{1} \rangle$ is the ring of integers and transitions are weighted by 1 and -1,
- the class $\mathsf{MOD}_q - \mathsf{P}$ (for $q \geq 2$) [8], defined similarly to #P but with respect to counting modulo q, obtained when $\mathcal{S} = \langle \mathbb{Z}_q, +_q, \cdot_q, \overline{0}, \overline{1} \rangle$ and transitions are weighted by 1.

▶ **Example 7.** Some further instances of NP[$\mathcal{S}$], this time following [34, Examples 4.7–4.11], are:

- the class NP[F_*] of all fuzzy languages realizable by fuzzy Turing machines [49] with t-norm $*$ in polynomial time, obtained when the semiring is $\mathcal{F}_* = \langle [0,1], \max, *, 0, 1 \rangle$ and the weights correspond to degrees of membership in the fuzzy language,
- the class NPMV of all multivalued functions realized by nondeterministic polynomial-time transducer machines [7], obtained when, given alphabets Σ_1 and Σ_2, the semiring is $\langle 2^{\Sigma_2^*}_{\text{fin}}, \cup, \cdot, \emptyset, \{\varepsilon\} \rangle$ and weighted Turing machines have input alphabet Σ_1,
- the class of all multiset-valued functions computed by nondeterministic polynomial-time transducer machines with counting, obtained as in the previous example but using the free semiring $\langle \mathbb{N}\langle \Sigma_2^* \rangle, +, \cdot, 0, 1 \rangle$ instead,
- the class MaxP $\subseteq$ OptP of problems in which the objective is to compute the value of a solution to an optimization problem in NPO [35], obtained when the semiring is $\mathcal{S}_{\max}$, and the class MinP $\subseteq$ OptP, obtained when the semiring is $\mathcal{S}_{\min}$,
- the class MaxP$[[O(\log n)]] \subseteq$ OptP$[O(\log n)]$ of problems in which the objective is to compute the value of a solution to an optimization problem in NPO PB [35], obtained when the semiring is $\mathbb{N}_{\max}$, and MinP$[[O(\log n)]] \subseteq$ OptP$[O(\log n)]$, , obtained when the semiring is $\mathbb{N}_{\min}$.

A notion from universal algebra (cf. [5]) that we will make use of in defining some of the complexity classes below (e.g. FP[$\mathcal{S}$], FPSPACE[$\mathcal{S}$] and FPLOG[$\mathcal{S}$]) is the following:

▶ **Definition 8** (Term algebra). *Consider a semiring $\mathcal{S} = \langle S, +, \cdot, \mathbb{0}, \mathbb{1} \rangle$ and a subset $X \subseteq S$. The* set of terms *$T(X)$ is the collection of all well-formed strings that can be constructed using the symbols in X and $+', \cdot', \mathbb{0}, \mathbb{1}$ (in particular, $\mathbb{0}, \mathbb{1} \in T(X)$), that is, the smallest set such that: (1) $X \subseteq T(X)$ and (2) $(t_1 +' t_2) \in T(X)$ and $(t_1 \cdot' t_2) \in T(X)$ for every two terms $t_1, t_2 \in T(X)$; we abuse notation and omit parentheses whenever associativity permits. The* term algebra *$\mathcal{T}(X)$ is the structure with universe $T(X)$ and operations $+', \cdot'$ defined in the obvious way.*

Recall that classically FP is the set of function problems that can be solved by a deterministic Turing machine in polynomial time.

▶ **Definition 9.** *We define the complexity class* FP[$\mathcal{S}$] *as*

$$\mathsf{FP}[\mathcal{S}] := \bigcup_{\substack{\{0,1\} \subseteq G \subseteq_{\text{fin}} S \\ \Sigma \textit{ is a finite alphabet}}} \mathsf{FP}[G, \Sigma]$$

where FP[G, Σ] *is the set of all series $\sigma \colon \Sigma^* \longrightarrow \langle G \rangle$ (where $\langle G \rangle$ is the subsemiring of $\mathcal{S}$ generated by G) such that there is a constant $k \in \mathbb{N}$ and a deterministic polynomial-time Turing machine which outputs for every word $w \in \Sigma^*$ a word of the form $\sum_{i_1=1}^{m_1} \prod_{j_1=1}^{n_1} \cdots \sum_{i_k=1}^{m_k} \prod_{j_k=1}^{n_k} s_{i_1 j_1 \cdots i_k j_k}$ in the algebra of terms $T(G)$ in S with value $\sigma(w)$ in $\mathcal{S}$.*

In Definition 9, we employ a classical deterministic Turing machine which outputs, in each transition, symbols from $G \cup \{(,), +', \cdot', \mathbb{0}, \mathbb{1}\}$ or a blank. Thus, for our outputs we could obtain arbitrarily complex expressions. Therefore, the constant k limiting the number of alternations of sums and products is a proper restriction. Hence this definition of $\mathsf{FP}[\mathcal{S}]$ differs from the one of [34]. Later on, we will model logical formulas with alternating sum and product quantifiers using Turing machines which compute functions in $\mathsf{FP}[\mathcal{S}]$, hence $k = 1$ would be insufficient to model these alternations. For the converse, in order to model these Turing machines by formulas, the number of alternations of sums and products in each such Turing machine needs to be bounded to obtain a formula with nested quantifiers.

▶ **Example 10.** If $\mathcal{S} = \mathbb{B}$ is the two-element Boolean semiring, then $\mathsf{FP}[\mathbb{B}]$ is just P [34, Example 5.4]. Observe that the terms output by the machine in that example are already trivially of the form $\sum_{i=1}^{n} \prod_{j=1}^{m} s_{ij}$.

FP is to $\#\mathsf{P}$ what P is to NP. Thus, considering $\mathsf{NP}[\mathcal{S}]$ as a generalization of $\#\mathsf{P}$ (as it is done in [10]), the relationship between $\mathsf{FP}[\mathcal{S}]$ and $\mathsf{NP}[\mathcal{S}]$ is similar to that between P and NP.

▶ **Example 11.** If $\mathcal{S} = \mathbb{N}$ is the natural numbers semiring, then $\mathsf{FP}[\mathbb{N}]$ is just FP [34, Example 5.5]. As before, observe that the terms output by the machine in that example are already of the form $\sum_{i=1}^{n} \prod_{j=1}^{m} s_{ij}$.

▶ **Definition 12.** *The class* $\mathsf{FPLOG}[\mathcal{S}]$ *is defined as* $\mathsf{FP}[\mathcal{S}]$ *except that we allow the machine to have logarithmic space on the length of the input rather than polynomial time.*

▶ **Example 13.** If $\mathcal{S} = \mathbb{B}$, then $\mathsf{FPLOG}[\mathbb{B}]$ is just $\mathsf{DLOGSPACE}$.

▶ **Example 14.** If $\mathcal{S} = \mathbb{N}$, then $\mathsf{FPLOG}[\mathbb{N}]$ is just FPLOG, which is defined as FP but allowing the machine to use logarithmic space on the size of the input (cf. [22]).

▶ **Definition 15.** *The class* $\mathsf{FPSPACE}[\mathcal{S}]$ *is defined as* $\mathsf{FP}[\mathcal{S}]$ *except that we allow the machine to have polynomial space on the length of the input rather than polynomial time.*

▶ **Example 16.** If $\mathcal{S} = \mathbb{B}$, then $\mathsf{FPSPACE}[\mathbb{B}]$ is just PSPACE.

▶ **Example 17.** If $\mathcal{S} = \mathbb{N}$, then $\mathsf{FPSPACE}[\mathbb{N}]$ is just $\mathsf{FPSPACE}$ ([37]).

▶ **Definition 18.** *The class* $\mathsf{FPSPACE}_{poly}[\mathcal{S}]$ *is defined as* $\mathsf{FPSPACE}[\mathcal{S}]$ *except that we require the word* $\sum_{i=1}^{n} \prod_{j=1}^{m} s_{ij}$ *to have length bounded by a polynomial. Here, every semiring element is considered to have length* 1.

▶ **Example 19.** If $\mathcal{S} = \mathbb{B}$, then $\mathsf{FPSPACE}_{poly}[\mathbb{B}]$ is just PSPACE.

▶ **Example 20.** If $\mathcal{S} = \mathbb{N}$, then $\mathsf{FPSPACE}_{poly}[\mathbb{N}]$ is just $\mathsf{FPSPACE}_{poly}$ ([37]).

4 Weighted logics

A *vocabulary* (or *signature*) τ is a pair $\langle \mathrm{Rel}_\tau, \mathrm{ar}_\tau \rangle$ where Rel_τ is a set of relation symbols and $\mathrm{ar}_\tau \colon \mathrm{Rel}_\tau \longrightarrow \mathbb{N}_+$ is the arity function. A τ*-structure* $\mathfrak{A}$ is a pair $\langle A, \mathcal{I}_\mathfrak{A} \rangle$ where A is a set, called the *universe of* $\mathfrak{A}$, and $\mathcal{I}_\mathfrak{A}$ is an *interpretation*, which maps every symbol $R \in \mathrm{Rel}_\tau$ to a set $R^\mathfrak{A} \subseteq A^{\mathrm{ar}_\tau(R)}$. We assume that each structure is *finite*, that is, its universe is a finite set. A structure is called *ordered* if it is given for a vocabulary $\tau \cup \{<\}$ where $<$ is interpreted as a linear ordering with endpoints. By $\mathrm{Str}(\tau)_<$ we denote the class of all finite ordered τ-structures.

We provide a countable set $\mathcal{V}$ of first and second-order variables, where lower case letters like x and y denote first-order variables and capital letters like X and Y denote second-order variables. Each second-order variable X comes with an associated arity, denoted by $\mathrm{ar}(X)$. We define first-order formulas β over a signature τ and weighted first-order formulas φ over τ and a semiring $\mathcal{S}$, respectively, by the grammars

$$\beta ::= \texttt{false} \mid R(x_1, \dots, x_n) \mid \neg\beta \mid \beta \vee \beta \mid \exists x.\beta$$
$$\varphi ::= \beta \mid s \mid \varphi \oplus \varphi \mid \varphi \otimes \varphi \mid \bigoplus x.\varphi \mid \bigotimes x.\varphi,$$

where $R \in \mathrm{Rel}_\tau$, $n = \mathrm{ar}_\tau(R)$, $x, x_1, \dots, x_n \in \mathcal{V}$ are first-order variables, and $s \in S$. Likewise, we define second-order formulas β over τ and weighted second-order formulas φ over τ and $\mathcal{S}$ through

$$\beta ::= \texttt{false} \mid R(x_1, \dots, x_n) \mid X(x_1, \dots, x_n) \mid \neg\beta \mid \beta \vee \beta \mid \exists x.\beta \mid \exists X.\beta$$
$$\varphi ::= \beta \mid s \mid \varphi \oplus \varphi \mid \varphi \otimes \varphi \mid \bigoplus x.\varphi \mid \bigotimes x.\varphi \mid \bigoplus X.\varphi \mid \bigotimes X.\varphi,$$

with $R \in \mathrm{Rel}_\tau$, $n = \mathrm{ar}_\tau(R) = \mathrm{ar}(X)$, $x, x_1, \dots, x_n \in \mathcal{V}$ first-order variables, $X \in \mathcal{V}$ a second-order variable, and $s \in S$. We also allow the usual abbreviations $\wedge$, $\forall$, $\rightarrow$, $\leftrightarrow$, and $\texttt{true}$. By $\mathrm{FO}(\tau)$ and $\mathrm{wFO}(\tau, S)$ we denote the sets of all first-order formulas over τ and all weighted first-order formulas over τ and $\mathcal{S}$, respectively, and by $\mathrm{SO}(\tau)$ and $\mathrm{wSO}(\tau, S)$ we denote the sets of all second-order formulas over τ and all weighted second-order formulas over τ and $\mathcal{S}$, respectively.

The notion of *free variables* is defined as usual, i.e., the operators $\exists, \forall, \bigoplus$, and $\bigotimes$ bind variables. We let $\mathrm{Free}(\varphi)$ be the set of all free variables of φ. A formula φ with $\mathrm{Free}(\varphi) = \emptyset$ is called a *sentence*. For a tuple $\bar{\varphi} = \langle \varphi_1, \dots, \varphi_n \rangle \in \mathrm{wSO}(\tau, S)^n$, we define $\mathrm{Free}(\bar{\varphi}) = \bigcup_{i=1}^n \mathrm{Free}(\varphi_i)$.

We define the semantics of SO and wSO as follows. Let τ be a signature, $\mathfrak{A} = \langle A, \mathcal{I}_\mathfrak{A} \rangle$ a τ-structure, and $\mathcal{V}$ a set of first and second-order variables. A $(\mathcal{V}, \mathfrak{A})$-assignment ρ is a function $\rho\colon \mathcal{V} \longrightarrow A \cup \mathcal{P}(A)$ such that, whenever $x \in \mathcal{V}$ is a first-order variable and $\rho(x)$ is defined, we have $\rho(x) \in A$, and whenever $X \in \mathcal{V}$ is a second-order variable and $\rho(X)$ is defined, we have $\rho(X) \subseteq A^{\mathrm{ar}(X)}$. For a first-order variable, this restriction may cause the variable to become undefined. Let $\mathrm{dom}(\rho)$ be the domain of ρ. For a first-order variable $x \in \mathcal{V}$ and an element $a \in A$, the *update* $\rho[x \to a]$ is defined through $\mathrm{dom}(\rho[x \to a]) = \mathrm{dom}(\rho) \cup \{x\}$, $\rho[x \to a](\mathcal{X}) = \rho(\mathcal{X})$ for all $\mathcal{X} \in \mathcal{V} \setminus \{x\}$, and $\rho[x \to a](x) = a$. For a second-order variable $X \in \mathcal{V}$ and a set $I \subseteq A^{\mathrm{ar}(X)}$, the update $\rho[X \to I]$ is defined in a similar fashion. By $\mathfrak{A}_\mathcal{V}$ we denote the set of all $(\mathcal{V}, \mathfrak{A})$-assignments.

For $\rho \in \mathfrak{A}_\mathcal{V}$ and a formula $\beta \in \mathrm{SO}(\tau)$ the relation "$\langle \mathfrak{A}, \rho \rangle$ satisfies β", denoted by $\langle \mathfrak{A}, \rho \rangle \models \beta$, is defined as

$$\begin{aligned}
&\langle \mathfrak{A}, \rho \rangle \models \texttt{false} && && \text{never holds}\\
&\langle \mathfrak{A}, \rho \rangle \models R(x_1, \dots, x_n) && \iff && x_1, \dots, x_n \in \mathrm{dom}(\rho) \text{ and } (\rho(x_1), \dots, \rho(x_n)) \in R^\mathfrak{A}\\
&\langle \mathfrak{A}, \rho \rangle \models X(x_1, ..., x_n) && \iff && x_1, ..., x_n, X \in \mathrm{dom}(\rho) \text{ and } \langle \rho(x_1), \dots, \rho(x_n) \rangle \in \rho(X)\\
&\langle \mathfrak{A}, \rho \rangle \models \neg\beta && \iff && \langle \mathfrak{A}, \rho \rangle \models \beta \text{ does not hold}\\
&\langle \mathfrak{A}, \rho \rangle \models \beta_1 \vee \beta_2 && \iff && \langle \mathfrak{A}, \rho \rangle \models \beta_1 \text{ or } \langle \mathfrak{A}, \rho \rangle \models \beta_2\\
&\langle \mathfrak{A}, \rho \rangle \models \exists x.\beta && \iff && \langle \mathfrak{A}, \rho[x \to a] \rangle \models \beta \text{ for some } a \in A\\
&\langle \mathfrak{A}, \rho \rangle \models \exists X.\beta && \iff && \langle \mathfrak{A}, \rho[X \to I] \rangle \models \beta \text{ for some } I \subseteq A.
\end{aligned}$$

Let $\varphi \in \mathrm{wSO}(\tau, S)$ and $\mathfrak{A} \in \mathrm{Str}(\tau)_<$, $a_1, \dots, a_k$ be an enumeration of the elements of $\mathfrak{A}$ according to the ordering that serves as the interpretation of $<$, and for every integer n, let $I_1^n, \dots, I_{l_n}^n$ be an enumeration of the subsets of A^n according to the lexicographic ordering induced by the interpretation of $<$. The *(weighted) semantics* of φ is a mapping $[\![\varphi]\!](\mathfrak{A}, \cdot)\colon \mathfrak{A}_{\mathcal{V}} \longrightarrow S$ inductively defined as

$$\begin{aligned}
[\![\beta]\!](\mathfrak{A},\rho) &= \begin{cases} \mathbb{1} & \text{if } \langle \mathfrak{A},\rho\rangle \models \beta \\ \mathbb{0} & \text{otherwise} \end{cases} \\
[\![s]\!](\mathfrak{A},\rho) &= s \\
[\![\varphi_1 \oplus \varphi_2]\!](\mathfrak{A},\rho) &= [\![\varphi_1]\!](\mathfrak{A},\rho) + [\![\varphi_2]\!](\mathfrak{A},\rho) \\
[\![\varphi_1 \otimes \varphi_2]\!](\mathfrak{A},\rho) &= [\![\varphi_1]\!](\mathfrak{A},\rho) \cdot [\![\varphi_2]\!](\mathfrak{A},\rho) \\
[\![\textstyle\bigoplus x.\varphi]\!](\mathfrak{A},\rho) &= \sum_{a \in A} [\![\varphi]\!](\mathfrak{A},\rho[x \to a]) \\
[\![\textstyle\bigotimes x.\varphi]\!](\mathfrak{A},\rho) &= \prod_{1 \leq i \leq k} [\![\varphi]\!](\mathfrak{A},\rho[x \to a_i]) \\
[\![\textstyle\bigoplus X.\varphi]\!](\mathfrak{A},\rho) &= \sum_{I \subseteq A^{\mathrm{ar}(X)}} [\![\varphi]\!](\mathfrak{A},\rho[X \to I]) \\
[\![\textstyle\bigotimes X.\varphi]\!](\mathfrak{A},\rho) &= \prod_{1 \leq i \leq l_{\mathrm{ar}(X)}} [\![\varphi]\!](\mathfrak{A},\rho[X \to I_i^{\mathrm{ar}(X)}]).
\end{aligned}$$

Thanks to the lexicografic ordering our product quantifiers have a well-defined semantics. Note that if the semiring is commutative, in the clauses of universal quantifiers, the semantics is defined by using any order for the factors in the products.

We will usually identify a pair $\langle \mathfrak{A}, \emptyset \rangle$ (where $\emptyset$ is the empty mapping) with $\mathfrak{A}$. We will also refer to the following expansions of FO:

- Transitive closure logic (TC) is obtained by adding the following rule for building formulas: if $\varphi(\overline{x}, \overline{y})$ is a formula with variables $\overline{x} = x_1, \dots, x_k$ and $\overline{y} = y_1, \dots, y_k$, and $\overline{u}, \overline{v}$ are k-tuples of terms, then $[\mathbf{tc}_{\overline{x},\overline{y}}\, \varphi(\overline{x},\overline{y})](\overline{u},\overline{v})$ is also a formula, and its semantics is given as $\mathfrak{A} \models [\mathbf{tc}_{\overline{x},\overline{y}}\, \varphi(\overline{x},\overline{y})](\overline{a},\overline{b}) \iff$ there exist an $n \geq 1$ and $\overline{c_0}, \dots, \overline{c_n} \in A^k$ such that $\overline{c_0} = \overline{a}$, $\overline{c_n} = \overline{b}$, and $\mathfrak{A} \models \varphi(\overline{c_i}, \overline{c_{i+1}})$ for each $i \in \{0, \dots, n-1\}$.
- Deterministic transitive closure logic (DTC) is obtained by adding the following rule for building formulas: if $\varphi(\overline{x}, \overline{y})$ is a formula with variables $\overline{x} = x_1, \dots, x_k$ and $\overline{y} = y_1, \dots, y_k$, and $\overline{u}, \overline{v}$ are k-tuples of terms, then $[\mathbf{dtc}_{\overline{x},\overline{y}}\, \varphi(\overline{x},\overline{y})](\overline{u},\overline{v})$ is also a formula, and its semantics is defined by the equivalence $[\mathbf{dtc}_{\overline{x},\overline{y}}\, \varphi(\overline{x},\overline{y})](\overline{u},\overline{v}) \equiv [\mathbf{tc}_{\overline{x},\overline{y}}\, \varphi(\overline{x},\overline{y}) \wedge \forall z(\varphi(\overline{x},\overline{z}) \to \overline{y} = \overline{z})](\overline{u},\overline{v})$.
- Least fixed-point logic (LFP) is obtained by adding the following rules for building formulas: if $\varphi(R, \overline{x})$ is a formula of vocabulary $\tau \cup \{R\}$ with only positive occurrences of R, $\overline{x}$ is a tuple of variables, and $\overline{t}$ is a tuple of terms (both matching the arity of R), then $[\mathbf{lfp}\, R\overline{x}.\psi](\overline{t})$ and $[\mathbf{gfp}\, R\overline{x}.\psi](\overline{t})$ are also formulas. For their semantics, we need to define some auxiliary notions. The *update operator* $F_\psi\colon \mathcal{P}(A^k) \longrightarrow \mathcal{P}(A^k)$ is defined by $F_\psi(R) := \{\overline{a} \mid \langle \mathfrak{A}, R\rangle \models \psi(R, \overline{a})\}$ for any relation R, and it is monotone because R occurs only positively in ψ. A *fixed point* of F_ψ is a relation R such that $F_\psi(R) = R$. Since F_ψ is monotone, it has a least and a greatest fixed point (by Knaster–Tarski Theorem). The semantics is given by: $\mathfrak{A} \models [\mathbf{lfp}\, R\overline{x}.\psi](\overline{t})$ iff $\overline{t}^{\mathfrak{A}}$ is contained in the least fixed point of F_ψ (analogously for $[\mathbf{gfp}\, R\overline{x}.\psi](\overline{t})$ and the greatest fixed point).
- Partial fixed-point logic (PFP) is obtained by adding the following rule for building formulas: if $\varphi(R, \overline{x})$ is a formula of vocabulary $\tau \cup \{R\}$, $\overline{x}$ is a tuple of variables, and $\overline{t}$ is a tuple of terms (both matching the arity of R), then $[\mathbf{pfp}\, R\overline{x}.\psi](\overline{t})$ is also a formula. For

the semantics, we consider again the update operator (now not necessarily monotone) and the sequence of its finite stages: $R^0 := \emptyset$ and $R^{m+1} := F_\psi(R^m)$. In a finite structure $\mathfrak{A}$, the sequence either reaches a fixed point or it enters a cycle of period greater than one. We define the partial fixed point of F_ψ as the fixed point reached in the former case, or as the empty set in the latter case. Now, the semantics is given by: $\mathfrak{A} \models [\mathbf{pfp}\, R\overline{x}.\psi](\overline{t})$ iff $\overline{t}^{\mathfrak{A}}$ is contained in the partial fixed point of F_ψ.

- Inflationary fixed-point logic (IFP) is obtained by adding the following rules for building formulas: if $\varphi(R, \overline{x})$ is a formula of vocabulary $\tau \cup \{R\}$, $\overline{x}$ is a tuple of variables, and $\overline{t}$ is a tuple of terms (both matching the arity of R), then $[\mathbf{ifp}\, R\overline{x}.\psi](\overline{t})$ is also a formula. For its semantics, we need to define some auxiliary notions. An operator $G : \mathcal{P}(B) \longrightarrow \mathcal{P}(B)$ is said to be *inflationary* if $X \subseteq G(X)$ for all $X \in \mathcal{P}(B)$. With any operator $F : \mathcal{P}(B) \longrightarrow \mathcal{P}(B)$ one can associate an inflationary operator G by setting $G(X) := X \cup F(X)$. Iterating G gives a fixed point that we will called the *inflationary fixed point* of F. The semantics is given by: $\mathfrak{A} \models [\mathbf{ifp}\, R\overline{x}.\psi](\overline{t})$ iff $\overline{t}^{\mathfrak{A}}$ is contained in the inflationary fixed point of F_ψ.

The weighted version of each of these logics is defined analogously as in the case of FO and SO by expanding the logics TC, DTC, LFP, PFP, and IFP with the same weighted constructs as given for wFO and wSO. By a famous result of Gurevich and Shelah [29], on finite structures, LFP coincides with IFP and thus their weighted versions, wIFP and wLFP, as we have defined them here, will also coincide in expressive power.

5 Logical characterizations of complexity classes

We are finally ready to present and prove the main results of the paper: the quantitative versions of several logical characterizations of prominent complexity classes. We may assume that every $\mathfrak{A} \in \mathrm{Str}(\tau)_<$ is encoded by a string of 0s and 1s. For example, where $\mathfrak{A} = \langle A, R_1^{\mathfrak{A}}, \ldots, R_j^{\mathfrak{A}} \rangle$ with $|A| = n$ (and we may assume in fact that $A = \{0, \ldots, n-1\}$) we might let

$$\mathrm{enc}(\mathfrak{A}) = \mathrm{enc}(R_1^{\mathfrak{A}}) \cdot \cdots \cdot \mathrm{enc}(R_j^{\mathfrak{A}})$$

where if $R_i^{\mathfrak{A}}$ is an l-ary relation, then $\mathrm{enc}(R_i^{\mathfrak{A}})$ is a string of symbols of length n^l with a 1 in its mth position if the mth tuple of n^l is in $R_i^{\mathfrak{A}}$ and a 0 otherwise.

▶ **Definition 21.** *Consider a weighted logic* $\mathrm{L}[\mathcal{S}]$ *(with weights in a semiring* $\mathcal{S}$*) and a weighted complexity class* $\mathcal{C}$*, which is simply a collection of series. We say that* $\mathrm{L}[\mathcal{S}]$ captures $\mathcal{C}$ *over ordered structures in the vocabulary* $\tau = \{R_1, \ldots, R_j\}$ *if:*

(1) *For every* $\mathrm{L}[\mathcal{S}]$*-formula* ϕ*, there exists* $P \in \mathcal{C}$ *such that* $P(enc(\mathfrak{A})) = \|\phi\|(\mathfrak{A})$ *for every finite ordered* τ*-structure* $\mathfrak{A}$*, and*

(2) *For every* $P \in \mathcal{C}$*, there exists an* $\mathrm{L}[\mathcal{S}]$*-formula* ϕ *such that* $P(enc(\mathfrak{A})) = \|\phi\|(\mathfrak{A})$ *for every finite ordered* τ*-structure* $\mathfrak{A}$*.*

The seminal Fagin's Theorem characterizes NP for ordered structures by existential second-order logic. Our goal is to present a weighted version of this result with arbitrary semirings as weight structures. Whereas in the classical setting one obtains an equivalence between the existence of runs of a Turing machine vs. the satisfiability of an existential logical formula, in the weighted setting of general semirings we have to derive a one-to-one correspondence between the runs of a Turing machine and satisfying assignments for the formulas. Moreover, due to the absence of a natural negation function in the semiring, here, beyond the classical setting, we need conjunctions and universal quantifications. For weighted finite automata over words, in [11] weighted conjunction and universal quantification turned out to be too powerful in general and had to be restricted. Surprisingly, here we do not need these restrictions, but we can show the expressive equivalence between weighted polynomial-time Turing machines and the full weighted existential second-order logic. Moreover, we do not need commutativity of the multiplication of $\mathcal{S}$ (essential in [11]), but can develop our characterization for arbitrary, also non-commutative, semirings $\mathcal{S}$. This is due to new constructions, in this setting, for the involved weighted Turing machines. By wESO we mean the fragment of wSO where the only second-order quantifiers appear at the beginning of the formula and are additive existential.

▶ **Theorem 22** (Weighted Fagin's theorem). *Let $\mathcal{S}$ be a semiring and τ a vocabulary.*

(i) *The logic* wESO$[\mathcal{S}]$ *captures* $\mathsf{NP}[\mathcal{S}]$ *over* ordered *finite τ-structures.*

(ii) *Assume that $\mathcal{S}$ is idempotent and commutative. Then, the logic* wESO$[\mathcal{S}]$ *captures* $\mathsf{NP}[\mathcal{S}]$ *over* all *finite structures in the vocabulary τ.*

Let us indicate some ideas for the proof. For (i), first, for a given wESO-formula ϕ, we have to construct an NP Turing machine $\mathcal{M}$ with $\|\phi\| = \|\mathcal{M}\|$. For Boolean formulas β, we can follow the classical proof. Regarding weighted formulas ϕ, let us comment on the interesting cases. For weighted conjunctions and universal quantifications, we employ new constructions. Since we are dealing with Turing machines, we can execute weighted Turing machines for the components successively, by saving the word and using transitions of weight 1 in a deterministic way to restore the initial tape configuration. We can show, using the distributivity of the semiring, that the constructed nondeterministic machine $\mathcal{M}$ computes precisely the values prescribed by the semantics of the weighted conjunction or the weighted universal quantifications, respectively.

Second, given a weighted NP Turing machine $\mathcal{M}$, by the assumption on its polynomial time usage, we construct a second-order formula ψ reflecting the accepting computation paths of $\mathcal{M}$ and their employed transitions in a one-to-one correspondence; this enables us to incorporate the weights of the transitions by means of constants in the formula. The order is used for the construction of the formula such that the interpretation of weighted universal quantification reflects precisely the weights of the computation sequences of the given Turing machine.

For (ii), the order in universal quantifications now is taken care of by the commutativity of the multiplication, and the existence of an order is taken care of by an additional existential second-order quantification where idempotency of $\mathcal{S}$ implies that we obtain the same value.

From Theorem 22 and Examples 6 and 7, we immediately obtain the following corollary:

▶ **Corollary 23.** *For ordered structures in a finite vocabulary τ, we have that:*

(1) wESO$[\mathbb{B}]$ captures NP *(originally proved in [19]).*

(2) wESO$[\mathbb{N}]$ captures $\#\mathsf{P}$ *(originally proved in [3] and [44]).*

(3) wESO$[\mathbb{Z}]$ captures GapP *(originally proved in [3]).*

(4) wESO$[\mathcal{S}_{\max}]$ *(respectively,* wESO$[\mathcal{S}_{\min}]$*).* captures MaxP *(*MinP*) (originally proved in [3]).*

(5) wESO$[\mathbb{Z}_2]$ captures $\bigoplus\mathsf{P}$.

(6) wESO$[\mathbb{Z}_q]$ captures $\mathsf{MOD}_q - \mathsf{P}$.

(7) wESO$[\mathbb{N}_{\max}]$ *(respectively,* wESO$[\mathbb{N}_{\min}]$*)* captures $\mathsf{MaxP}[O(\log n)]$ *(*$\mathsf{MinP}[O(\log n)]$*).*

(8) wESO$[\mathcal{F}_*]$ captures *the class of all fuzzy languages realizable by fuzzy Turing machines with t-norm $*$ in polynomial time.*

(9) wESO$[2^{\Sigma_2^*}_{\text{fin}}]$ captures NPMV.

(10) wESO$[\mathbb{N}\langle\Sigma_2^*\rangle]$ captures *the class of all multiset-valued functions computed by non-deterministic polynomial-time transducer machines with counting.*

▶ Remark 24. It is worth observing that the proofs of (2)-(4) in [3] (Prop. 4.2, Cor. 4.8, and Thm. 4.10) are (as expected) different from ours. Our argument works in all those cases but neither of the three arguments given in [3] works for our more general setting.

Our next application of the weighted Fagin's theorem consist in providing a natural computational problem complete for the class $\mathsf{NP}[\mathcal{S}]$ for certain semirings $\mathcal{S}$. Given a semiring $\mathcal{S}$, alphabets Σ_1, Σ_2, and series $\sigma_1 : \Sigma_1^* \longrightarrow S$ and $\sigma_2 : \Sigma_2^* \longrightarrow S$, we say that σ_1 is *polynomially many-one reducible* to σ_2 ($\sigma_1 \leq_m \sigma_2$, in symbols) if there is an $f\colon \Sigma_1^* \longrightarrow \Sigma_2^*$ computable deterministically in polynomial time such that $\sigma_2(f(w)) = \sigma_1(w)$ for each $w \in \Sigma_1^*$. A series $\sigma : \Sigma^* \longrightarrow S$ is said to be $\mathsf{NP}[\mathcal{S}]$*-hard* if $\sigma' \leq_m \sigma$ for all σ' in $\mathsf{NP}[\mathcal{S}]$. If, moreover, σ belongs to $\mathsf{NP}[\mathcal{S}]$, then it is called $\mathsf{NP}[\mathcal{S}]$*-complete.*

Fix an infinite set X. The language of the weighted propositional logic over a finitely generated semiring $\mathcal{S}$ is built from X as propositional variables, elements of S as truth-constants, and logical connectives $\wedge, \vee, \neg$ (where negation is only applied to propositional variables). Let $\mathtt{Fmla}[\mathcal{S}]$ be the set of all formulas.

A *truth assignment* is a mapping $V\colon X \longrightarrow \{0,1\}$ extended to $\overline{V}$ for all formulas in the following way:

1. For each propositional variable $x \in X$, let $\overline{V}(x) := V(x)$ and $\overline{V}(\neg x) := 1$ iff $V(x) = 0$. Moreover, let $\overline{V}(a) := a$ for each $a \in S$.
2. $\overline{V}(\varphi \vee \psi) := \overline{V}(\varphi) + \overline{V}(\psi)$ and $\overline{V}(\varphi \wedge \psi) := \overline{V}(\varphi) \cdot \overline{V}(\psi)$.

For each formula $\varphi \in \mathtt{Fmla}[\mathcal{S}]$, let X_φ be the set of propositional variables that occur in φ. Clearly, $\overline{V}(\varphi)$ depends only the values of V on X_φ. The "problem" $\mathrm{SAT}[\mathcal{S}]$ is the series $\sigma\colon \mathtt{Fmla}[\mathcal{S}] \longrightarrow S$ defined as follows: $\mathrm{SAT}[\mathcal{S}](\varphi) = \sum_{V \in \{0,1\}^{X_\varphi}} \overline{V}(\varphi)$.

The following corollary of our weighted version of Fagin's theorem has also appeared as [34, Thm. 6.3] with a direct proof. Our proof generalizes the reasoning for the Boolean case in [25].

▶ **Corollary 25** (Weighted Cook–Levin's theorem). *Let $\mathcal{S}$ be a finitely generated semiring. Then,* $\mathsf{SAT}[\mathcal{S}]$ *is* $\mathsf{NP}[\mathcal{S}]$*-complete.*

Now it is natural to wonder what happens with other well-known descriptive complexity results. In the reminder of this section we will tackle a few more of these. We start with the Immerman–Vardi's theorem, a result that first appeared in the Boolean case in the papers [31, 48]. Our own approach is inspired by [3, Thm. 4.4] where a version of the result for the counting complexity class FP is provided using a weighted logic with the semiring $\mathbb{N}$. We must observe, however, that our proof is a generalization of that in [3] that works for all semirings and not only $\mathbb{N}$.

▶ **Theorem 26** (Weighted Immerman–Vardi's theorem). *The logic* $\mathrm{wLFP}[\mathcal{S}]$ *(with weights in a semiring $\mathcal{S}$)* captures $\mathsf{FP}[\mathcal{S}]$ *over ordered structures in the vocabulary τ.*

▶ **Corollary 27.** *For ordered structures in a finite vocabulary τ, we have that:*

(1) $\mathrm{wLFP}[\mathbb{B}]$ captures P *(originally proved in [31, 48]).*
(2) $\mathrm{wLFP}[\mathbb{N}]$ captures FP *(originally proved in [3]).*

▶ Remark 28. Observe that using second-order Horn logic (which is known to capture P [24]) instead of least fixed-point logic, would not work for us, as in the weighted version one can encode a #P-complete problem (namely #HORNSAT). This was already noted in [3].

In the next result, $\mathrm{wPFP}[\mathcal{S}] + \{\prod X, \sum X\}$ will denote the logic that is obtained from $\mathrm{wPFP}[\mathcal{S}]$ by the addition of the second-order quantitative quantifiers $\prod X$ and $\sum X$. Clearly, when $\mathcal{S} = \mathbb{B}$, this is the same as second-order logic with partial fixed points. The Boolean counterpart of Theorem 29, namely that second-order logic extended with partial fixed points characterizes PSPACE is folklore, but a proof can be found in [41, Thm. 4]. The classical argument also uses the result for partial fixed-point logic in [1, 48] stating that the logic characterizes PSPACE over ordered structures.

▶ **Theorem 29.** *The logic* $\mathrm{wPFP}[\mathcal{S}] + \{\prod X, \sum X\}$ *(with weights in a semiring* $\mathcal{S}$*)* captures $\mathsf{FPSPACE}[\mathcal{S}]$ *over ordered structures in the vocabulary* τ*.*

▶ **Corollary 30.** *For ordered structures in a finite vocabulary* τ*, we have that:*

(1) $\mathrm{wPFP}[\mathbb{B}] + \{\prod X, \sum X\}$ captures PSPACE *(folklore, cf. [41]).*

(2) $\mathrm{wPFP}[\mathbb{N}] + \{\prod X, \sum X\}$ captures FPSPACE *(originally proved in [3]).*

▶ **Theorem 31.** *The logic* $\mathrm{wPFP}[\mathcal{S}]$ *(with weights in a semiring* $\mathcal{S}$*)* captures $\mathsf{FPSPACE}_{poly}[\mathcal{S}]$ *over ordered structures in the vocabulary* τ*.*

▶ **Corollary 32.** *For ordered structures in a finite vocabulary* τ*, we have that:*

(1) $\mathrm{wPFP}[\mathbb{B}]$ captures PSPACE *(originally proved in [1, 48]).*

(2) $\mathrm{wPFP}[\mathbb{N}]$ captures $\mathsf{FPSPACE}_{poly}$ *(originally proved in [3]).*

▶ **Theorem 33.** *The logic* $\mathrm{wDTC}[\mathcal{S}]$ *(with weights in a semiring* $\mathcal{S}$*)* captures $\mathsf{FPLOG}[\mathcal{S}]$ *over ordered structures in the vocabulary* τ*.*

▶ **Corollary 34.** *For ordered structures in a finite vocabulary* τ*, we have that:*

(1) $\mathrm{wDTC}[\mathbb{B}]$ captures DLOGSPACE *(originally proved in [31]).*

(2) $\mathrm{wDTC}[\mathbb{N}]$ captures FPLOG.

To end the present section, we address the general and interesting open problem suggested in [18] regarding a Fagin theorem that characterizes the class $\mathrm{NP}[\mathcal{R}]$ from [18, Def. 14]. We begin by observing that for the machine model in [18, Def. 12], Fagin's theorem will fail if the logic considered is wESO. This is essentially due to the fact that semiring Turing machines allow for arbitrary semiring values on the tape and can transition with these values. However, such a large set of transitions, is only actually needed when there are infinitely many semiring values in the input words.

▶ **Proposition 35.** *Let* $\mathcal{R}$ *be a commutative semiring. There is a series* $P \in \mathrm{NP}[\mathcal{R}]$ *such that for no* $\varphi \in \mathrm{wESO}$*,* $||\varphi|| = P$*.*

Thus one might reasonably further ask what kind of logic would capture $\mathrm{NP}[\mathcal{R}]$. Observe that an obvious challenge here is that in the proof of Fagin's theorem at some point we need to encode in the logic by means of a sentence involving a long (but finite) disjunction what the legal transitions of our machine are. Consequently, in the presence of infinitely many transitions, it is not clear how to achieve a Fagin-style characterization in a finitary language as before. Furthermore, it appears that semiring Turing machines are more suitable for an analysis that involves semirings that are not finitely generated.

By contrast to the above situation, we might ask a more restricted question if what we are doing is trying to capture $\mathrm{NP}[\mathcal{R}]$ over the class of all finite ordered structures. Recall that we are considering finite structures to be given via their binary encodings and thus the relevant series in $\mathrm{NP}[\mathcal{R}]$ are those that take as input merely binary strings. These series are not computed by SRTMs that involve infinitely many transitions because the input words do not involve semiring values. So let us consider now the modification of [18, Def. 12] that only allows semiring Turing machines to come with a finite set of transitions. In this case we will easily see that their machine model coincides with ours.

▶ **Proposition 36.** *Let $\mathcal{R}$ be a commutative semiring and allow only finitely many transitions in a semiring Turing machine. Then* $\mathrm{NP}[\mathcal{R}] = \mathsf{NP}[\mathcal{R}]$*, i.e. the NP class in the sense of [18] coincides with the NP class in our sense.*

6 Conclusions and further work

In this paper, we have established a few central results in weighted descriptive complexity, providing quantitative versions of Fagin's theorem and the Immerman–Vardi's theorem, among other logical characterizations of complexity classes. We also plan to extend our weighted Fagin's theorem to the even larger class of valuation monoids containing all semirings and supporting average calculations by the theory developed in [21] for weighted finite automata over words and weighted EMSO logic.

Furthermore, in future work, we aim to characterize further weighted complexity classes. For example, in the definition of $\mathsf{NP}[\mathcal{S}]$, by changing the requirement about polynomial time to logarithmic space on the size of the input, we can obtain a weighted complexity class that generalizes the classical counting class $\#\mathsf{L}$. The latter has been characterized by means of a logic weighted on the semiring $\mathbb{N}$ in [3, Thm. 6.4]. We suspect that this work can be generalized.

Abstract

The Subset Feedback Vertex Set problem (SFVS) is to delete k vertices from a given graph such that in the remaining graph, any vertex in a subset T of vertices (called a terminal set) is not in a cycle. The famous Feedback Vertex Set problem is the special case of SFVS with T being the whole set of vertices. In this paper, we study exact algorithms for SFVS in Split Graphs (SFVS-S) and SFVS in Chordal Graphs (SFVS-C). SFVS-S generalizes the minimum vertex cover problem and the prize-collecting version of the maximum independent set problem in hypergraphs (PCMIS), and SFVS-C further generalizes SFVS-S. Both SFVS-S and SFVS-C are implicit 3-Hitting Set problems. However, it is not easy to solve them faster than 3-Hitting Set. In 2019, Philip, Rajan, Saurabh, and Tale (Algorithmica 2019) proved that SFVS-C can be solved in $\mathcal{O}^*(2^k)$ time, slightly improving the best result $\mathcal{O}^*(2.0755^k)$ for 3-Hitting Set. In this paper, we break the "2^k-barrier" for SFVS-S and SFVS-C by introducing an $\mathcal{O}^*(1.8192^k)$-time algorithm. This achievement also indicates that PCMIS can be solved in $\mathcal{O}^*(1.8192^n)$ time, marking the first exact algorithm for PCMIS that outperforms the trivial $\mathcal{O}^*(2^n)$ threshold. Our algorithm uses reduction and branching rules based on the Dulmage-Mendelsohn decomposition and a divide-and-conquer method.

1 Introduction

The Feedback Vertex Set problem (FVS), one of Karp's 21 NP-complete problems [32], is a fundamental problem in graph algorithms. Given a graph G with n vertices and a parameter k, FVS is to decide whether there is a subset of vertices of size at most k whose deletion makes the remaining graph acyclic. FVS arises in a variety of applications in various fields such as circuit testing, network communications, deadlock resolution, artificial intelligence, and computational biology [6, 11, 29]. Because of the importance of FVS, different variants and generalizations have been extensively studied in the literature. The Subset Feedback Vertex Set problem (SFVS), introduced by Even et al. [17] in 2000, is a famous case. In SFVS, we are further given a vertex subset $T \subseteq V$ called *terminal set*, and we are asked to determine whether there is a set of vertices of size at most k whose removal makes each terminal in T not contained in any cycle in the remaining graph. When the terminal set is the whole vertex set of the graph, SFVS becomes FVS. SFVS also generalizes another famous

problem, i.e., Node Multiway Cut. Whether SFVS is FPT had been once a well-known open problem [12]. Until 2013, Cygan et al. [11] proved the fixed-parameter tractability of SFVS by giving an algorithm with running time $\mathcal{O}^*(2^{\mathcal{O}(k\log k)})$. Recently, Iwata et al. [30, 31] showed the first single-exponential algorithm with running time $\mathcal{O}^*(4^k)$ for SFVS. In 2018, Hols and Kratsch showed that SFVS has a randomized polynomial kernelization with $\mathcal{O}(k^9)$ vertices [25]. Besides, FVS admits a quadratic kernel [28, 40], whereas whether there is a deterministic polynomial kernel for SFVS is still unknown.

SFVS has also been studied in several graph classes [35, 37, 2, 3, 4], such as interval graphs, permutation graphs, chordal graphs, and split graphs. SFVS remains NP-complete even in split graphs [18], while FVS in split and chordal graphs are polynomial-time solvable [44]. It turns out that both SFVS in Split Graphs (SFVS-S) and SFVS in Chordal Graphs (SFVS-C) can be regarded as implicit 3-Hitting Set. Its importance stems from the fact that 3-Hitting Set can be used to recast a wide range of problems, and now it can be solved in time $\mathcal{O}^*(2.0755^k)$ [42]. On the other hand, when we formulate SFVS-S or SFVS-C in terms of 3-Hitting Set, the structural properties of the input graph are lost. We believe these structural properties can potentially be exploited to obtain faster algorithms for the original problems. However, designing a faster algorithm for SFVS-S and SFVS-C seems challenging. Only recently did Philip et al. [37] improve the running bound to $\mathcal{O}^*(2^k)$, where they needed to consider many cases of the clique-tree structures of the chordal graphs. In some cases, they needed to branch into seven branches. Note that 2^k is another barrier frequently considered in algorithm design and analysis. Some preliminary brute force algorithms, dynamic programming, and advanced techniques, such as inclusion-exclusion, iterative compression, and subset convolution, always lead to the bound 2^k. Breaking the "2^k-barrier" becomes an interesting question for many problems.

We highlight that SFVS-S and SFVS-C are important since they generalize a natural variation of the maximum independent set problem called Prize-Collecting Maximum Independent Set in hypergraphs (PCMIS). In PCMIS, we are given a hypergraph H with n vertices. The object is to find a vertex subset S maximizing the size of S minus the number of hyperedges in H that contain at least two vertices from S. In other words, we may balance the size of the vertex subset against the number of hyperedges on which S violates the independent constraints. The prize-collecting version of many important fundamental problems has drawn certain attention recently, such as Prize-Collecting Steiner Tree [36], Prize-Collecting Network Activation [21], and Prize-Collecting Travelling Salesman Problem [5]. To the best of our knowledge, no exact algorithm for PCMIS faster than $\mathcal{O}^*(2^n)$ is known before.

Fomin et al. [19] showed that Cluster Vertex Deletion and Directed FVS in Tournaments admit subquadratic kernels with $\mathcal{O}(k^{5/3})$ vertices and $\mathcal{O}(k^{3/2})$ vertices, respectively; while the size of the best kernel for SFVS-C is still quadratic, which can be easily obtained from the kernelization for 3-Hitting Set [1]. As for parameterized algorithms, Dom et al. [14] first designed an $\mathcal{O}^*(2^k)$-time algorithm for Directed FVS in Tournaments, breaking the barrier of 3-Hitting Set, and the running time bound of which was later improved to $\mathcal{O}^*(1.6191^k)$ by Kumar and Lokshtanov [33]. For Cluster Vertex Deletion, in 2010, Hüffner et al. [27] first broke the barrier of 3-Hitting Set by obtaining an $\mathcal{O}^*(2^k)$-time algorithm. Now it can be solved in $\mathcal{O}^*(1.7549^k)$ time [41].

Contributions and Techniques

In this paper, we contribute to parameterized algorithms for SFVS-S and SFVS-C. Our main contributions are summarized as follows.

1. We firstly break the "2^k-barrier" for SFVS-S and SFVS-C by giving an $\mathcal{O}^*(1.8192^k)$-time algorithm, which significantly improves previous algorithms.
2. We show that an $\mathcal{O}^*(\alpha^k)$-time algorithm ($\alpha > 1$) for SFVS-S leads to an $\mathcal{O}^*(\alpha^n)$-algorithm for PCMIS. Thus, we can solve PCMIS in time $\mathcal{O}^*(1.8192^n)$, also breaking the "2^n-barrier" for this problem for the first time.
3. We make use of the Dulmage-Mendelsohn decomposition of bipartite graphs to catch structural properties, and then we are able to use a new measure μ to analyze the running time bound. This is the most crucial technique for us to obtain a significant improvement. Note that direct analysis based on the original measure k has encountered bottlenecks. Any tiny improvement may need complicated case-analysis.
4. The technique based on Dulmage-Mendelsohn decomposition can only solve SFVS-S. We also propose a divide-and-conquer method by dividing the instance of SFVS-C into instances of SFVS-S. We show that SFVS-C can be solved in time $\mathcal{O}^*(\alpha^k + 1.6191^k)$ if SFVS-S can be solved in time $\mathcal{O}^*(\alpha^k)$.

2 Preliminaries

2.1 Graphs

Let $G = (V, E)$ stand for an undirected graph with a set V of vertices and a set E of edges. We adopt the convention that $n = |V|$ and $m = |E|$. When a graph G' is mentioned without specifying its vertex and edge sets, we use $V(G')$ and $E(G')$ to denote these sets, respectively. For a subset $X \subseteq V$ of vertices, we define the following notations. The *neighbour set* of X, denoted by $N_G(X)$, is the set of all vertices in $V \backslash X$ that are adjacent to a vertex in X, and the *closed neighbour set* of X is expressed as $N_G[X] \coloneqq N_G(X) \cup X$. The subgraph of G induced by X is denoted by $G[X]$. We simply write $G - X \coloneqq G[V \backslash X]$ as the subgraph obtained from G removing X together with edges incident on any vertex in X. For ease of notation, we may denote a singleton set $\{ v \}$ by v.

The *degree* of v in G is defined by $\deg_G(v) \coloneqq |N_G(v)|$. An edge e is a *bridge* if it is not contained in any cycle of G. A *separator* of a graph is a vertex set such that its deletion increases the number of connected components of the graph. The shorthand $[r]$ is expressed as the set $\{ 1, 2, \ldots, r \}$ for $r \in \mathbb{N}^+$.

In an undirected graph $G = (V, E)$, a set $X \subseteq V$ is a *clique* if every pair of distinct vertices u and v in X are connected by an edge $uv \in E$; X is an *independent set* if $uv \notin E$ for every pair of vertices u and v in X; X is a *vertex cover* if for any edge $uv \in E$ at least one of u and v is in X. A subset $S \subseteq V$ is a vertex cover of G if and only if $V \backslash S$ is an independent set. A vertex v is called *simplicial* in G if $N_G[v]$ is a clique [13]. A clique in G is *simplicial* if it is maximal and contains at least one simplicial vertex. A *matching* is a set of edges without common vertices.

2.2 Chordal Graphs and Split Graphs

A *chord* of a cycle is an edge that connects two non-consecutive vertices of the cycle. A graph G is said to be *chordal* if every cycle of length at least 4 contains a chord. A chordal graph G holds the following properties that will be used in the paper: Every induced subgraph of a chordal graph G is chordal, and every minimal separator of G is a clique [13].

Consider a connected chordal graph G, and let $\mathcal{Q}_G$ denote the set of all maximal cliques in G. A *clique graph* of G is an undirected graph $(\mathcal{Q}_G, \mathcal{E}_G, \sigma)$ with the edge-weighted function $\sigma \colon \mathcal{E}_G \to \mathbb{N}$ satisfying that an edge $Q_1Q_2 \in \mathcal{E}_G$ if $Q_1 \cap Q_2$ is a minimal separator and

$\sigma(Q_1Q_2) \coloneqq |Q_1 \cap Q_2|$. A *clique tree* $\mathcal{T}_G$ of G is a maximum spanning tree of the clique graph of G, and the following facts hold [7, 23, 43]: (1) Each leaf node of a clique tree $\mathcal{T}_G$ is a simplicial clique in G; (2) For a pair of maximal cliques Q_1 and Q_2 such that $Q_1Q_2 \in \mathcal{E}_G$, $Q_1 \cap Q_2$ separates each pair of vertices $v_1 \in Q_1 \backslash Q_2$ and $v_2 \in Q_2 \backslash Q_1$.

Whether a graph is chordal can be checked in linear time $\mathcal{O}(n+m)$ [38]. The number of maximal cliques in a chordal graph G is at most n [22], and all of them can be listed in linear time $\mathcal{O}(n+m)$ [23]. These properties will be used in our algorithm.

A graph is a *split graph* if its vertex set can be partitioned into a clique K and an independent set I [39]. Such a partition (I, K) is called a *split partition.* It is worth noting that every split graph is chordal, and whether a graph is a split graph can also be checked in linear time $\mathcal{O}(n+m)$ by definition.

2.3 Subset Feedback Vertex Set in Split and Chordal Graphs

Given a terminal set $T \subseteq V$ of an undirected graph $G = (V, E)$, a cycle in G is a *T-cycle* if it contains a terminal from T, and a *T-triangle* is specifically a T-cycle of length three. A *subset feedback vertex set* of a graph G with a terminal set T is a subset of V whose removal makes G contain no T-cycle.

In this study, we focus on SFVS in split and chordal graphs. The problem takes as input a chordal graph $G = (V, E)$, a terminal set $T \subseteq V$, and an integer k. The task is to determine whether there is a subset feedback vertex set S of size at most k. Moreover, the following lemma shows that the problem can be transformed into the problem of finding a subset of vertices intersecting all T-triangles instead of all T-cycles.

▶ **Lemma 1** ([37]). *Let $G = (V, E)$ be a chordal graph and $T \subseteq V$ be the terminal set. A vertex set $S \subseteq V$ is a subset feedback vertex set of G if and only if $G - S$ contains no T-triangles.*

For the sake of presentation, this paper considers a slight generalization of SFVS-C. In this generalized version, a set of marked edges $M \subseteq E$ is further given, and we are asked to decide whether there is a subset feedback vertex set of size at most k, which also covers all marked edges, i.e., each marked edge must have at least one of its endpoints included in the set. This set is called a *solution* to the given instance. Among all solutions, a *minimum solution* is the one with the smallest size. The size of a minimum solution to an instance $\mathcal{I}$ is denoted by $s(\mathcal{I})$. Formally, the generalization of SFVS-C is defined as follows.

(Generalized) SFVS-C
Input: A chordal graph $G = (V, E)$, a terminal set $T \subseteq V$, a marked edge set $M \subseteq E$, and an integer k.
Output: Determine whether there is a subset of vertices $S \subseteq V$ of size at most k, such that neither edges in M nor T-cycles exist in $G - S$.

We have the following simple observations. Let abc be a T-triangle with a degree-2 vertex b in the graph. Any solution must contain at least one of the vertices a, b, and c. If vertex b is included in the solution, we can replace it with either a or c without affecting the solution's feasibility. Consequently, we can simplify the graph by removing b and marking edge ac. This observation motivates the consideration of the generalized version.

We will simply use SFVS-C to denote the generalized version. When the input graphs are restricted to split graphs, the problem becomes SFVS-S. An instance of our problem is denoted by $\mathcal{I} = (G, T, M, k)$. During our algorithm, it may be necessary to consider some sub-instances where the graph is a subgraph of G. We define the *instance induced by $X \subseteq V$ or $G[X]$* as $(G[X], T \cap X, M \cap E(G[X]), k)$.

In this paper, our algorithms follow a standard branch-and-reduce paradigm. An operation on the input instance, such as the reduction rule, is *safe* if the input instance is a Yes-instance if and only if the output instance is a Yes-instance. A branching operation is *safe* if the input instance is a Yes-instance if and only if at least one of the resulting sub-instances is a Yes-instance. Additionally, we use branching vectors and branching factors in our analysis. The definitions of these standard concepts can be found in [10].

3 The Dulmage-Mendelsohn Decomposition and Reduction

This section introduces the Dulmage-Mendelsohn decomposition of a bipartite graph [15, 16]. The Dulmage-Mendelsohn decomposition will play a crucial role in our algorithm for SFVS-S.

▶ **Definition 2** (Dulmage-Mendelsohn Decomposition [34, 9]). *Let F be a bipartite graph with bipartition $V(F) = A \cup B$. The Dulmage-Mendelsohn decomposition (cf. Fig. 1) of F is a partitioning of $V(F)$ into three disjoint parts C, H and R, such that*

1. *C is an independent set and $H = N_F(C)$;*
2. *$F[R]$ has a perfect matching;*
3. *H is the intersection of all minimum vertex covers of F; and*
4. *any maximum matching in F includes all vertices in $R \cup H$.*

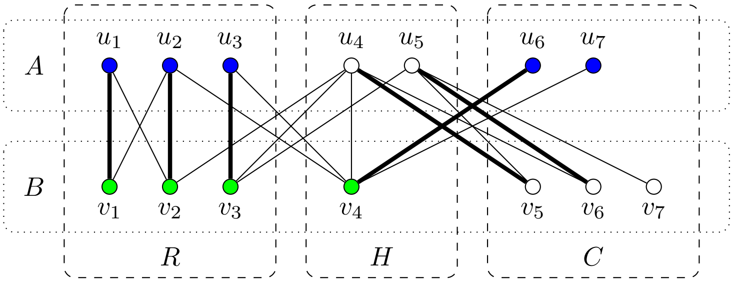

Figure 1 A bipartite graph F with bipartition $V(F) = A \cup B$, where $A = \{u_i\}_{i=1}^{7}$ and $B = \{v_i\}_{i=1}^{7}$. The thick edges form a maximum matching of F. The Dulmage-Mendelsohn decomposition of F is (C, H, R) with $C = \{u_6, u_7, v_5, v_6, v_7\}$, $H = \{u_4, u_5, v_4\}$, and $R = \{u_1, u_2, u_3, v_1, v_2, v_3\}$. If F is an auxiliary subgraph of an instance of SFVS-S, then $\hat{A} = \{u_1, u_2, u_3, u_6, u_7\}$ (denoted by blue vertices) and $\hat{B} = \{v_1, v_2, v_3, v_4\}$ (denoted by green vertices).

The Dulmage-Mendelsohn decomposition always exists and is unique [34], which can be computed in time $\mathcal{O}(m\sqrt{n})$ by finding the maximum matching of the graph F [26]. Leveraging this decomposition, we propose a crucial reduction rule for SFVS-S.

Consider an instance $\mathcal{I} = (G = (V, E), T, M, k)$ of SFVS-S. Let (I, K) be a split partition of G, where I is an independent set and K is a clique. Based on the split partition (I, K) of G, we can uniquely construct an auxiliary bipartite subgraph F with bipartition $V(F) = A \cup B$. In subgraph F, partition A is the subset of the vertices in I that are only incident to marked edges and $B = N_G(A)$. In addition, $E(F)$ is the set of all edges between A and B, i.e., $E(F) \coloneqq \{ab \in E : a \in A,\ b \in B\}$. Notice that F contains no isolated vertex, and all edges in F are marked by the definitions of A and B.

Let (R, H, C) denote the Dulmage-Mendelsohn decomposition of the auxiliary subgraph F. Define $\hat{A} \coloneqq A \cap (R \cup C)$ and $\hat{B} \coloneqq B \cap (R \cup H)$ (see Fig. 1). We have $\hat{B} = N_G(\hat{A})$, and there exists a matching saturating all vertices in $\hat{B}$. This indicates that every solution contains at least $|\hat{B}|$ vertices in $\hat{A} \cup \hat{B}$. On the other hand, $\hat{B}$ is a minimum vertex cover of the subgraph induced by $\hat{A} \cup \hat{B}$. Consequently, there exists a minimum solution to $\mathcal{I}$ containing $\hat{B}$. Next, we introduce the reduction rule, which is called the *DM Reduction*.

▶ **Reduction Rule** (DM Reduction). *Let F be the auxiliary subgraph with bipartition $V(F) = A \cup B$, and let (R, H, C) denote the Dulmage-Mendelsohn decomposition of F. If $\hat{A}$ and $\hat{B}$ are non-empty, delete $\hat{A}$ and $\hat{B}$ from the graph G and decrease k by $|\hat{B}| = |R|/2 + |H \cap B|$.*

▶ **Lemma 3.** *The DM Reduction is safe.*

Proof. Recall that $\hat{A} \coloneqq A \cap (R \cup C)$ and $\hat{B} \coloneqq B \cap (R \cup H)$. According to the definition of the Dulmage-Mendelsohn decomposition, we know that $N_F(\hat{A}) = \hat{B}$, and $\hat{B}$ is a minimum vertex cover of the subgraph induced by $\hat{A} \cup \hat{B}$. For a solution S to the input instance $\mathcal{I}$, the size of $S \cap (\hat{A} \cup \hat{B})$ is no less than $|\hat{B}|$ since S covers every edge in M. Let $S' = (S \backslash \hat{A}) \cup \hat{B}$. Observe that $|\hat{A}| > |\hat{B}|$; otherwise, A would be a minimum vertex cover of F, contradicting that H is a subset of any minimum vertex cover. Consequently, we derive that $|S'| \leqslant |S|$. In addition, we can see that S' is also a solution, leading to the safeness of the DM Reduction. ◀

▶ **Lemma 4.** *Given an instance $\mathcal{I} = (G, T, M, k)$ of SFVS-S, let F be the auxiliary subgraph of G with bipartition $V(F) = A \cup B$. If the DM Reduction cannot be applied, for any non-empty subset $A' \subseteq A$, it holds that $|A'| < |N_G(A')|$.*

Proof. If the DM Reduction cannot be applied, the Dulmage-Mendelsohn decomposition of F must be $(R, H, C) = (\varnothing, A, B)$. According to the definition of the Dulmage-Mendelsohn decomposition, A is a vertex cover, and $H = A$ is the intersection of all minimum vertex covers of F. As a result, we know that A is the unique minimum vertex cover of the auxiliary subgraph F. We assume to the contrary that there exists a subset $A' \subseteq A$ such that $|A'| \geqslant |N_G(A')|$. Then we immediately know that $(A \backslash A') \cup N_G(A')$ is a minimum vertex cover distinct from A, leading to a contradiction. ◀

▶ **Lemma 5.** *Given an instance $\mathcal{I} = (G, T, M, k)$ of SFVS-S, let F be the auxiliary subgraph of G with bipartition $V(F) = A \cup B$. If the DM Reduction cannot be applied and $k < |A|$, the instance $\mathcal{I}$ is a No-instance.*

Proof. The size of the solution to $\mathcal{I} = (G, T, M, k)$ is no less than the size of the minimum vertex cover of F since all marked edges need to be covered. If the DM Reduction cannot be applied, Lemma 4 implies that A is the minimum vertex cover of F. Consequently, the size of the minimum solution to $\mathcal{I}$ must be no less than $|A|$, which means that an instance $\mathcal{I}$ is a No-instance if $k < |A|$. ◀

4 Algorithms for SFVS in Split and Chordal Graphs

This section mainly presents an algorithm for SFVS-S. This algorithm plays a critical role in the algorithm for SFVS-C.

4.1 Good Instances

We begin by introducing a special instance of SFVS-S, which we refer to as a *good instance*. We show that solving good instances is as hard as solving normal instances of SFVS-S in some sense.

▶ **Definition 6** (Good Instances). *An instance $\mathcal{I} = (G = (V, E), T, M, k)$ of SFVS-S is called* good *if it satisfies the following properties:*

(i) *$(T, V \backslash T)$ is the split partition, where terminal set T is the independent set and $V \backslash T$ forms the clique;*

(ii) *every marked edge connects one terminal and one non-terminal; and*

(iii) *the DM reduction cannot be applied on the auxiliary subgraph determined by $(T, V \backslash T)$.*

▶ **Lemma 7.** *For any constant $\alpha > 1$, SFVS-S can be solved in time $\mathcal{O}^*(\alpha^k)$ if and only if SFVS-S on good instances can be solved in time $\mathcal{O}^*(\alpha^k)$.*

Proof. We only need to show that if there exists an algorithm `GoodAlg` solving good instances in time $\mathcal{O}^*(\alpha^k)$, there also exists an algorithm for SFVS-S running in the same time bound $\mathcal{O}^*(\alpha^k)$. The other direction is trivial.

Let $\mathcal{I} = (G = (V, E), T, M, k)$ be an instance of SFVS-S. Notice that α is a constant. We select a sufficiently large constant C such that the branching factor of the branching vector $(1, C, C)$ does not exceed the constant α. Our algorithm for SFVS-S is constructed below.

First, we find the split partition (I, K) of G in polynomial time. If $|K| \leqslant 2C$, we solve the instance directly in polynomial time by brute-force enumerating subsets of K in the solution. Otherwise, we assume that the size of K is at least $2C + 1$. We consider two cases.

Case 1. There is a terminal $t \in K$. In this case, we partition $K \setminus \{t\}$ into two parts K' and K'' such that $|K'| \geqslant C$ and $|K''| \geqslant C$. If t is not included in the solution, at most one vertex in the clique $K \setminus \{t\}$ is not contained in the solution. Consequently, either K' or K'' must be part of the solution. We can branch into three instances by either

- removing t, and decreasing k by 1;
- removing K', and decreasing k by $|K'|$; or
- removing K'', and decreasing k by $|K''|$.

This branching rule yields a branching vector $(1, |K'|, |K''|)$ (w.r.t. the measure k) with the branching factor not greater than α since $|K'| \geqslant C$ and $|K''| \geqslant C$.

Case 2. No terminal is in K. For this case, each non-terminal $v \in I$ is not contained in any T-triangle. However, we cannot directly remove v since it may be incident to marked edges. We can add an edge between v and each vertex $u \in K$ not adjacent to v without creating any new T-triangle. This operation will change v from a vertex in I to a vertex in K, preserving the graph as a split graph. After handling all non-terminal $v \in I$, we know that the terminal set and non-terminal set form a split partition. Subsequently, for each marked edge between two non-terminals v and u, we add a new degree-2 terminal t_{uv} adjacent to u and v and unmark the edge uv. We then apply the DM Reduction and obtain a good instance. Finally, we call the algorithm `GoodAlg` to solve the good instance in time $\mathcal{O}^*(\alpha^k)$.

By either branching with a branching factor not greater than α or solving the instance directly in $\mathcal{O}^*(\alpha^k)$ time, our algorithm runs in time $\mathcal{O}^*(\alpha^k)$. ◀

In the rest of this section, we only need to focus on the algorithm, denoted as `GoodAlg`, for good instances of SFVS-S.

4.2 The Measure and Its Properties

With the help of the auxiliary subgraph and DM Reduction (defined in Section 3), we use the following specific measure to analyze our algorithm.

▶ **Definition 8** (The Measure of Good Instances). *Given a good instance $\mathcal{I} = (G, T, M, k)$ of SFVS-S, let F be the auxiliary subgraph of G with bipartition $V(F) = A \cup B$. We define the measure of the instance $\mathcal{I}$ as*

$$\mu(\mathcal{I}) := k - \frac{2}{3}|A|.$$

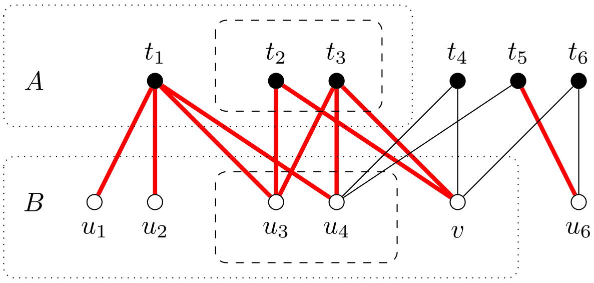

Figure 2 The graph G, where black vertices are terminals, white vertices are non-terminals, thick and red edges are marked edges, and edges between two non-terminals are not presented in the graph; the auxiliary subgraph is F with bipartition $V(F) = A \cup B$, where $A = \{t_1, t_2, t_3\}$ and $B = \{u_1, u_2, u_3, u_4, v\}$ (denoted by dotted boxes). After deleting v, the DM Reduction can be applied. When doing the DM Reduction, $\hat{A} = \{t_2, t_3\}$ and $\hat{B} = \{u_3, u_4\}$ (denoted by dashed boxes) are deleted.

In our algorithm `GoodAlg`, the DM Reduction will be applied as much as possible once the graph changes to keep the instance always good. Additionally, according to Lemma 5, an instance $\mathcal{I}$ can be solved in polynomial time when $\mu(\mathcal{I}) \leqslant 0$. Thus, we can use $\mu(\cdot)$, defined in Definition 8, as our measure to analyze the algorithm.

We may branch on a vertex by including it in the solution or excluding it from the solution in our algorithm. In the first branch, we delete the vertex from the graph and decrease the parameter k by 1. In the second branch, we execute a basic operation of *hiding* the vertex, which is defined according to whether the vertex is a terminal.

Hiding a terminal t: delete every vertex in $N_M(t)$ and decrease k by $|N_M(t)|$.

Hiding a non-terminal v: delete every terminal in $N_M(v)$ and decrease k by $|N_M(v)|$; for each T-triangle vtu containing v, mark edge tu; and last, delete v from the graph.

Here, the notation $N_M(v)$ represents the set of the vertices adjacent to v via a marked edge.

▶ **Lemma 9.** *If there exists a solution containing a vertex v, then it is safe to delete v, decrease k by 1, and do the DM Reduction. If there exists a solution not containing a vertex v, then it is safe to hide v and do the DM Reduction. Moreover, the resulting instance is good after applying either of the above two operations.*

Proof. Assuming a solution S contains v, it is trivial that $S \backslash \{v\}$ is also a solution to the instance $(G - v, T \backslash \{v\}, k - 1)$. Moreover, since the DM Reduction is safe by Lemma 3, the first operation in the lemma is safe.

Now, we assume that a solution S does not contain a vertex v. Since S must cover all edges in M, we know that S contains all neighbours of v in M. This shows that hiding v is safe if v is a terminal. Suppose that v is a non-terminal, for every T-triangle vut containing v, we have that $S \cap \{u, t\} \neq \varnothing$. Consequently, it is safe to mark the edge ut further. Moreover, since the DM Reduction is safe by Lemma 3, the second operation in the lemma is safe.

Finally, either operation only deletes some vertices and marks some edges between terminals and non-terminals. Hence, the terminal set and the non-terminal set still form an independent set and a clique, repetitively. Additionally, the DM Reduction cannot be applied on the resulting instances. Therefore, the resulting instance is good after applying either of the above two operations. ◀

▶ **Lemma 10.** *Given the good instance $\mathcal{I} = (G = (V, E), T, M, k)$, let F be the auxiliary subgraph of G with bipartition $V(F) = A \cup B$, and v be a vertex in $V \backslash A$. Let $\mathcal{I}_1$ be the instance obtained from $\mathcal{I}$ by first deleting v and then doing the DM Reduction (cf. Fig. 2). Then $\mathcal{I}_1$ is a good instance such that $\mu(\mathcal{I}) - \mu(\mathcal{I}_1) \geqslant 0$.*

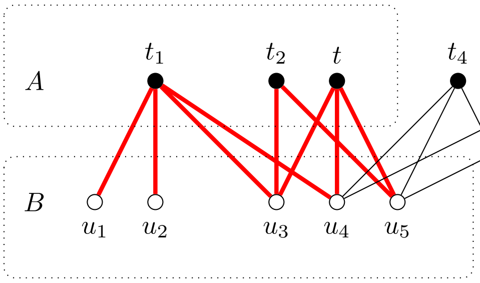

Figure 3 The graph G, where black vertices are terminals, white vertices are non-terminals, thick and red edges are marked edges, and edges between two non-terminals are not presented in the graph; the auxiliary subgraph is F with bipartition $V(F) = A \cup B$, where $A = \{ t_1, t_2, t_3 \}$ and $B = \{ u_1, u_2, u_3, u_4, u_5 \}$ (denoted by dotted boxes). After hiding t, the terminal t_2 becomes isolated, and the DM Reduction cannot be applied.

Proof. Let $\mathcal{I}_0 = (G_0, T_0, M_0, k_0)$ be the instance after deleting v from $\mathcal{I}$. Then, $\mathcal{I}_1 = (G_1, T_1, M_1, k_1)$ is the instance after doing the DM Reduction from $\mathcal{I}_0$. Let F_i with bipartition $V(F_i) = A_i \cup B_i$ be the auxiliary subgraph of G_i, where $i \in \{ 0, 1 \}$.

It is clear that $\mu(\mathcal{I}_0) = \mu(\mathcal{I})$ since no edge is newly marked and $k_0 = k$ holds. Assume that $\hat{A}_0 \subseteq A_0$ and $\hat{B}_0 \subseteq B_0$ are deleted. We note that the DM Reduction cannot be applied if and only if $\hat{A}_0 = \hat{B}_0 = \varnothing$. Observe that $A_1 = A_0 \backslash \hat{A}_0$, $B_1 = B_0 \backslash \hat{B}_0$ and $k_1 = k_0 - |\hat{B}_0|$. Thus, we have

$$\mu(\mathcal{I}) - \mu(\mathcal{I}_1) = \mu(\mathcal{I}_0) - \mu(\mathcal{I}_1) = (k_0 - 2/3 \cdot |A_0|) - (k_1 - 2/3 \cdot |A_1|) = |\hat{B}_0| - 2/3 \cdot |\hat{A}_0|.$$

If the DM Reduction cannot be applied, then $\hat{A}_0 = \hat{B}_0 = \varnothing$, which already implies that $\mu(\mathcal{I}) - \mu(\mathcal{I}_1) = 0$. Otherwise, the DM Reduction can be applied after deleting v. In this case, we have $v \in B$. Additionally, according to Lemma 4, $\mathcal{I}$ is a good instance implying that $N_G(\hat{A}_0) = \hat{B}_0 \cup \{ v \}$ and $|\hat{B}_0 \cup \{ v \}| > |\hat{A}_0|$. Therefore, we obtain that $|\hat{A}_0| = |\hat{B}_0|$. Thus we get $\mu(\mathcal{I}) - \mu(\mathcal{I}_1) \geqslant 0$. The lemma holds. ◀

▶ **Lemma 11.** *Given a good instance $\mathcal{I} = (G = (V, E), T, M, k)$, let F be the auxiliary subgraph of G with bipartition $V(F) = A \cup B$, and t be a terminal in T. Let $\mathcal{I}_1$ be the instance obtained from $\mathcal{I}$ by first hiding t and then doing the DM Reduction (cf. Fig. 3). Then $\mathcal{I}_1$ is a good instance such that*

- *If $t \in A$, it holds $\mu(\mathcal{I}) - \mu(\mathcal{I}_1) \geqslant 4/3$; and*
- *If $t \notin A$, it holds $\mu(\mathcal{I}) - \mu(\mathcal{I}_1) \geqslant 0$.*

Proof. Let instance $\mathcal{I}_0 = (G_0, T_0, M_0, k_0)$ denote the instance after hiding t from $\mathcal{I}$. Then, $\mathcal{I}_1 = (G_1, T_1, M_1, k_1)$ is the instance after doing the DM Reduction from $\mathcal{I}_0$. Let F_i with bipartition $V(F_i) = A_i \cup B_i$ be the auxiliary subgraph of G_i, where $i \in \{ 0, 1 \}$.

After hiding terminal t, a non-terminal is removed if and only if it is adjacent to t via a marked edge. Thus, $B_0 = B \backslash N_M(t)$ and $k_0 = k - |N_M(t)|$ hold. It follows that

$$\mu(\mathcal{I}) - \mu(\mathcal{I}_0) = (k - 2/3 \cdot |A|) - (k_0 - 2/3 \cdot |A_0|) = |N_M(t)| - 2/3 \cdot (|A| - |A_0|).$$

Notice that after hiding t the only deleted terminal is t. Besides, a terminal $t' \neq t$ is removed from A if and only if it becomes an isolated vertex. It follows that $N_G(t') \subseteq N_M(t)$ if $t' \in A \backslash A_0$.

Assume that $\hat{A}_0 \subseteq A_0$ and $\hat{B}_0 \subseteq B_0$ are deleted after doing the DM Reduction. We note that the DM Reduction cannot be applied if and only if $\hat{A}_0 = \hat{B}_0 = \varnothing$. Observe that $k_1 = k_0 - |\hat{B}_0|$ and $|A_1| = |A_0| - |\hat{A}_0|$. Thus, we derive that

$$\begin{aligned}\mu(\mathcal{I}) - \mu(\mathcal{I}_1) &= |N_M(t)| - 2/3 \cdot (|A| - |A_0|) + |\hat{B}_0| - 2/3 \cdot |\hat{A}_0| \\ &\geqslant |N_M(t) \cup \hat{B}_0| - 2/3 \cdot |A \backslash A_1|.\end{aligned}$$

Consider a terminal $t' \in A\backslash A_1$. If $t' \in A\backslash A_0$, we know $N_G(t') \subseteq N_M(t)$. Otherwise, we have $t' \in \hat{A}_0$, and all neighbours of t' in G are deleted, which indicates that $N_G(t') \subseteq \hat{B}_0 \cup N_M(t)$. It follows that $N_G(A\backslash A_1) \subseteq \hat{B}_0 \cup N_M(t)$. Since $\mathcal{I}$ is good, by Lemma 4, we have $A\backslash A_1 = \varnothing$ or $|N_G(A\backslash A_1)| > |A\backslash A_1|$.

If $A\backslash A_1 = \varnothing$ holds, every terminal in A is not deleted, which implies that $t \notin A$. In this case, we have

$$\mu(\mathcal{I}) - \mu(\mathcal{I}_1) \geqslant |N_M(t) \cup \hat{B}_0| \geqslant 0.$$

If $|N_G(A\backslash A_1)| > |A\backslash A_1|$ holds, we have

$$\mu(\mathcal{I}) - \mu(\mathcal{I}_1) \geqslant |N_G(A\backslash A_1)| - 2/3 \cdot |A\backslash A_1| \geqslant 4/3.$$

Therefore, we complete our proof. ◀

▶ **Lemma 12.** *Given a good instance $\mathcal{I} = (G = (V,E), T, M, k)$, let F be the auxiliary subgraph of G with bipartition $V(F) = A \cup B$, and v be a non-terminal in $V\backslash T$. Let $\mathcal{I}_1$ be the instance obtained from $\mathcal{I}$ by first hiding v and then doing the DM Reduction (cf. Fig. 4). Then $\mathcal{I}_1$ is a good instance such that $\mu(\mathcal{I}) - \mu(\mathcal{I}_1) \geqslant 0$.*

Furthermore, if every terminal (resp. non-terminal) is adjacent to at least two non-terminals (resp. terminals) and no two 2-degree terminals have identical neighbours in G, it satisfies that

- *If $v \in B$, it holds*

$$\mu(\mathcal{I}) - \mu(\mathcal{I}_1) \geqslant \min\left\{ \frac{2}{3}|N_G(v) \cap T| - \frac{1}{3}|N_M(v) \cap A|, \frac{4}{3} \right\}.$$

- *If $v \notin B$, it holds*

$$\mu(\mathcal{I}) - \mu(\mathcal{I}_1) \geqslant \min\left\{ \frac{2}{3}|N_G(v) \cap T| + \frac{1}{3}|N_M(v) \cap A|, \frac{4}{3} \right\} = \frac{4}{3}.$$

Proof. Let instance $\mathcal{I}_0 = (G_0, T_0, M_0, k_0)$ denote the instance after hiding v from $\mathcal{I}$. Then, $\mathcal{I}_1 = (G_1, T_1, M_1, k_1)$ is the instance after doing the DM Reduction from $\mathcal{I}_0$. Let F_i with bipartition $V(F_i) = A_i \cup B_i$ be the auxiliary subgraph of G_i, where $i \in \{0, 1\}$.

After hiding v, a vertex is removed if and only if it is a terminal adjacent to v via a marked edge. Thus, $k_0 = k - |N_M(v)|$ and $A\backslash A_0 = A \cap N_M(v)$. It follows that

$$\begin{aligned}\mu(\mathcal{I}) - \mu(\mathcal{I}_0) &= (k - \frac{2}{3}|A|) - (k_0 - \frac{2}{3}|A_0|) \\ &= (k - k_0) + \frac{2}{3}|A_0\backslash A| - \frac{2}{3}|A\backslash A_0| \\ &= |N_M(v)| + \frac{2}{3}|A_0\backslash A| - \frac{2}{3}|A \cap N_M(v)|.\end{aligned}$$

It is easy to see that $\mu(\mathcal{I}) - \mu(\mathcal{I}_0) \geqslant 0$ since $|A \cap N_M(v)| \leqslant |N_M(v)|$. Thus, if the DM Reduction cannot be applied, we have $\mu(\mathcal{I}_0) = \mu(\mathcal{I}_1)$, leading that $\mu(\mathcal{I}) - \mu(\mathcal{I}_1) \geqslant 0$.

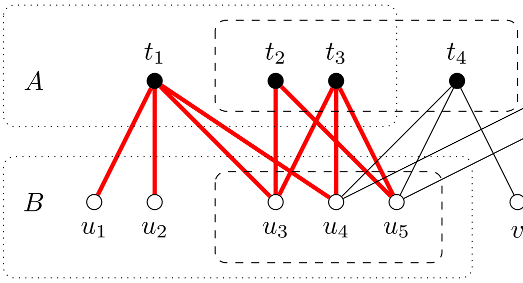

Figure 4 The graph G, where black vertices are terminals, white vertices are non-terminals, thick and red edges are marked edges, and edges between two non-terminals are not presented in the graph; the auxiliary subgraph is F with bipartition $V(F) = A \cup B$, where $A = \{ t_1, t_2, t_3 \}$ and $B = \{ u_1, u_2, u_3, u_4, u_5 \}$ (denoted by dotted boxes). After hiding v, the DM Reduction can be applied. When doing the DM Reduction, $\hat{A} = \{ t_2, t_3, t_4 \}$ and $\hat{B} = \{ u_3, u_4, u_5 \}$ (denoted by dashed boxes) are deleted.

Next, we consider what terminals belong to set $A_0 \backslash A$. On the one hand, a terminal $t \in A_0 \backslash A$ must be adjacent to v via an unmarked edge. On the other hand, t should not be an isolated vertex after hiding v, which implies that the terminal t is adjacent to at least one vertex distinct from v. Thus, if every terminal is adjacent to at least two non-terminals, we derive that $A_0 \backslash A = (N_G(v) \cap T) \backslash N_M(v)$. It follows that

$$\begin{aligned}
\mu(\mathcal{I}) - \mu(\mathcal{I}_0) &= |N_M(v)| + \frac{2}{3}|A_0 \backslash A| - \frac{2}{3}|A \cap N_M(v)| \\
&= |N_M(v)| + \frac{2}{3}|(N_G(v) \cap T) \backslash N_M(v)| - \frac{2}{3}|A \cap N_M(v)| \\
&= |N_M(v)| + \frac{2}{3}(|N_G(v) \cap T| - |N_M(v)|) - \frac{2}{3}|A \cap N_M(v)| \\
&\geqslant \frac{2}{3}|N_G(v) \cap T| - \frac{1}{3}|A \cap N_M(v)|.
\end{aligned}$$

If the DM Reduction cannot be applied on $\mathcal{I}_0$, we can derive that

$$\mu(\mathcal{I}) - \mu(\mathcal{I}_1) = \mu(\mathcal{I}) - \mu(\mathcal{I}_0) \geqslant \frac{2}{3}|N_G(v) \cap T| - \frac{1}{3}|A \cap N_M(v)|.$$

Furthermore, if $v \notin B$, then v is not adjacent to any terminal in A, leading that $|A \cap N_M(v)| = 0$. In the case that v belongs to B and it is adjacent to at least two terminals, we further have

$$\mu(\mathcal{I}) - \mu(\mathcal{I}_1) = \mu(\mathcal{I}) - \mu(\mathcal{I}_0) \geqslant \frac{2}{3}|N_G(v) \cap T| \geqslant \frac{4}{3}. \tag{1}$$

Now, we assume that the DM Reduction can be applied on $\mathcal{I}_0$. Suppose $\hat{A}_0 \subseteq A_0$ and $\hat{B}_0 \subseteq B_0$ are deleted. We know that $\hat{A}_0$ and $\hat{B}_0$ are non-empty, and $k_1 = k_0 - |\hat{B}_0| = k - |N_M(v)| - |\hat{B}_0|$ holds. Consider a terminal $t' \in A \backslash A_1$. If $t' \in A \cap N_M(v)$ it is deleted when hiding v; otherwise, it is deleted when doing the DM Reduction which means that $t' \in A \cap \hat{A}_0$. It follows that

$$\begin{aligned}
\mu(\mathcal{I}) - \mu(\mathcal{I}_1) =& (k - \frac{2}{3}|A|) - (k_1 - \frac{2}{3}|A_1|) \\
=& |N_M(v)| + |\hat{B}_0| + \frac{2}{3}|A_1 \backslash A| - \frac{2}{3}|A \backslash A_1| \\
\geqslant& |N_M(v)| + |\hat{B}_0| + \frac{2}{3}|A_1 \backslash A| - \frac{2}{3}(|A \cap \hat{A}_0| + |A \cap N_M(v)|) \\
\geqslant& \frac{1}{3}|N_M(v)| + |\hat{B}_0| + \frac{2}{3}|A_1 \backslash A| - \frac{2}{3}|A \cap \hat{A}_0|.
\end{aligned}$$

Now, we analyze the lower bound of $\mu(\mathcal{I}) - \mu(\mathcal{I}_1)$ and there are two cases.

Case 1.1. $A \cap \hat{A}_0$ is non-empty. We observe that in graph G, v is not adjacent to any terminal in $\hat{A}_0$. This is because all the terminals adjacent to v via a marked edge are deleted after hiding v and they do not appear in the graph G_0. Hence we know $\hat{B}_0 = N_G(\hat{A}_0)$. Besides, we have $B = N_G(A)$, and thus $B \cap \hat{B}_0 = N_G(A \cap \hat{A}_0)$ holds. since $\mathcal{I}$ is good and $A \cap \hat{A}_0$ is non-empty, we get $|B \cap \hat{B}_0| > |A \cap \hat{A}_0|$. Then we derive that the decrease of the measure is

$$\mu(\mathcal{I}) - \mu(\mathcal{I}_1) \geqslant |\hat{B}_0| - \frac{2}{3}|A \cap \hat{A}_0| \geqslant 1 + \frac{1}{3}|A \cap \hat{A}_0| \geqslant \frac{4}{3}.$$

Case 1.2. $A \cap \hat{A}_0$ is empty. In this case, we can directly obtain that

$$\mu(\mathcal{I}) - \mu(\mathcal{I}_1) \geqslant \frac{1}{3}|N_M(v)| + |\hat{B}_0| + \frac{2}{3}|A_1 \backslash A| \geqslant \frac{1}{3}|N_M(v)| + 1 \geqslant 1. \tag{2}$$

Thus, we have proven the measure does not increase.

Finally, we show that $\mu(\mathcal{I}) - \mu(\mathcal{I}_1) \geqslant 4/3$ always holds when the input graph satisfies the condition in the lemma. We consider two subcases.

Case 2.1. $v \in B$. For this subcase, v is adjacent to at least one terminal in A via a marked edge. Hence, set $N_M(v)$ is non-empty, and we get $\mu(\mathcal{I}) - \mu(\mathcal{I}_1) \geqslant 1/3 + 1 = 4/3$. This completes that the measure is decreased by at least 4/3 for $v \in B$.

Case 2.2. $v \notin B$. We assume to the contrary that if the DM Reduction can be applied and $\mu(\mathcal{I}) - \mu(\mathcal{I}_1) < 4/3$. According to (2), we can obtain that $|N_M(v)| = 0$, $|\hat{B}_0| = 1$ and $|A_1 \backslash A| = 0$. It means that for every terminal t adjacent to v, it satisfies that

1. $\deg_G(t) \geqslant 2$ holds according to the condition in the lemma;
2. tv is unmarked and $t \notin A$ since $N_M(v)$ is empty;
3. t is in A_0 since $\deg_G(t) \geqslant 2$ and v is the unique non-terminal deleted after hiding v;
4. t is deleted when doing the DM Reduction (i.e., $t \in \hat{A}_0$) since $A_1 \subseteq A$ but $t \notin A$; and
5. t has exactly two neighbours in G which are v and the unique vertex in $\hat{B}_0$ (i.e., $N_G(t) = \{ v \} \cup \hat{B}_0$) since $|\hat{B}_0| = 1$.

Above all, we derive that all terminals in $N_G(v)$ are 2-degree vertices and have the same neighbours. By the condition in the lemma, vertex v is adjacent to at least two terminals, contradicting the condition that no two 2-degree terminals have identical neighbours in G. Combine with (1), we conclude that for any vertex $v \notin B$, it holds

$$\mu(\mathcal{I}) - \mu(\mathcal{I}_1) \geqslant \min\left\{ \frac{2}{3}|N_G(v) \cap T|, \frac{4}{3} \right\} = \frac{4}{3}. \qquad ◀$$

4.3 An Algorithm for Good Instances

We now give the algorithm `GoodAlg` that solves the good instances. When introducing a step, we assume all previous steps cannot be applied.

▷ Step 1. If $|A| > k$ or even $\mu(\mathcal{I}) < 0$, return No and quit. If $|T| \leqslant k$, return Yes and quit.

▷ Step 2. Delete any vertex in G that is not contained in any T-triangle or marked edge, and then do the DM Reduction on the instance.

▷ Step 3. If there exists a non-terminal v such that $|N_G(v) \cap T| = 1$, hide v and then do the DM Reduction on the instance.

Note that the input instance is good, and every terminal is in some T-triangle after Step 3. Thus, every terminal (resp. non-terminal) is adjacent to at least two non-terminals (resp. terminals).

▷ Step 4. This step deals with some degree-2 terminals in $T \backslash A$, and there are two cases.

1. Let t be a degree-2 terminal in $T \backslash A$. If t is adjacent to exactly one marked edge, hide t and do the DM Reduction.
2. Let t and t' be two degree-2 terminals in $T \backslash A$. If t and t' have the same neighbours and none of them is adjacent to a marked edge, delete one of them and do the DM reduction.

After this step, one can easily find that the condition in Lemma 12 holds.

▷ Step 5. If there exists a non-terminal $v \in B$ adjacent to exactly one terminal t via a marked edge and exactly one terminal t' via an unmarked edge, we branch into two instances by either

- hiding the vertex v and doing the DM Reduction; or
- hiding the vertex t and doing the DM Reduction.

▷ Step 6. If there exists a non-terminal $v \in V \backslash T$ incident to at least one unmarked edge, we branch into two instances by either

- deleting the vertex v, decreasing k by 1, and doing the DM Reduction; or
- hiding v and doing the DM Reduction.

Based on Lemmas 9-12, we can show that Steps 1-4 are safe and they do not increase the measure. After applying any one of Steps 1-6, the resulting instance (or each resulting instance of the branching rule) is good. The complete proofs can be found in the full version.

One can easily find that every edge between a terminal and a non-terminal is marked if Step 6 cannot be applied. Thus, we have $T = A$, and Step 1 will be applied and return the answer. Therefore, we obtain the following result.

▶ **Lemma 13.** *SFVS-S can be solved in time* $\mathcal{O}^*(1.8192^k)$.

Proof. `GoodAlg` contains only two branching operations in Steps 5 and 6. By Lemmas 10, 11, and 12, their branching vectors are not worse than $(1, 4/3)$ whose branching factor is 1.81918. Thus, we conclude that `GoodAlg` solves good instances of SFVS-S in time $\mathcal{O}^*(1.81918^k)$. According to Lemma 7, SFVS-S can be solved in time $\mathcal{O}^*(1.81918^k) \leqslant \mathcal{O}^*(1.8192^k)$. ◀

4.4 SFVS in Chordal Graphs

Our result for SFVS-S (i.e., the $\mathcal{O}^*(1.8192^k)$-time parameterized algorithm) can also be effectively adapted to develop fast parameterized algorithms for SFVS-C.

Our algorithm for SFVS-C is divided into two parts. In the first part, we introduce some reduction rules and branching rules to deal with several easy cases and simplify the instance. If none of the steps in the first part can be applied, we call the instance a "thin" instance. In a thin instance, if all terminals are simplicial, we can easily reduce it to a good instance of SFVS-S and solve it by calling `GoodAlg`. However, if there are "inner" terminals (terminals not being simplicial), we employ a divide-and-conquer approach based on the clique-tree decomposition of chordal graphs in the second part. This technique involves branching on a minimal separator containing inner terminals. In each branch, we will obtain a good instance of SFVS-S for each sub-instance and call `GoodAlg` to solve it. We finally obtain Theorem 14. The details of the algorithm and analysis can be found in the full version.

▶ **Theorem 14.** *For any constant $\alpha > 1$, SFVS-C can be solved in time $\mathcal{O}^*(\alpha^k + 1.6191^k)$ if SFVS-S can be solved in time $\mathcal{O}^*(\alpha^k)$.*

▶ **Corollary 15.** *SFVS-C can be solved in time $\mathcal{O}^*(1.8192^k)$.*

5 Prize-Collecting Maximum Independent Set in Hypergraphs

Although we study the subset feedback vertex set problem in graph subclasses, SFVS-S already generalizes other interesting problems.

Several graph connectivity problems [24, 8, 20] can be modeled as natural problems in hypergraphs. In hypergraphs, an edge can connect any number of vertices, whereas in an ordinary graph, an edge connects exactly two vertices. Given a hypergraph H, the set of vertices and hyperedges are denoted by $V(H)$ and $E(H)$, respectively. The maximum independent set problem in hypergraphs aims to find a maximum vertex subset $I \subseteq V(H)$ such that every hyperedge contains at most one vertex from I. The maximum independent set problem in hypergraphs can be easily reduced to the maximum independent set problem in ordinary graphs: we only need to replace each hyperedge $e \in E(H)$ with a clique formed by the vertices in e to get an ordinary graph. In terms of exact algorithms, we may not need to distinguish this problem in hypergraphs and ordinary graphs. However, the prize-collecting version in hypergraphs becomes interesting, which allows us to violate the independent constraint with penalty. As mentioned above, the prize-collecting version of many central NP-hard problems has drawn certain attention recently.

Prize-Collecting Maximum Independent Set in hypergraphs (PCMIS)
Input: A hypergraph H and an integer p.
Output: Determine whether there is a subset of vertices $I \subseteq V(H)$ of the prize at least p, where the prize of I is the size of I minus the number of hyperedges that contain at least two vertices from I.

▶ **Lemma 16.** *PCMIS is polynomially solvable for $p \leqslant 1$, and PCMIS is NP-hard for each constant $p \geqslant 2$.*

Proof. By definition, any singleton set has a prize of 1. Therefore, PCMIS is polynomially solvable when $p \leqslant 1$.

We will prove the NP-hardness of PCMIS with $p \geqslant 2$ by reducing from the maximum independent set problem in ordinary undirected graphs. Let (G, k) be an instance of the maximum independent set problem. We construct an instance (H, p) of PCMIS, where $p \geqslant 2$ is a constant. Since p is a constant, we can assume that $k \geqslant p$.

Suppose $|V(G)| = n$ and $|E(G)| = m$. We now construct a hypergraph H with n vertices and $nm + k - p$ hyperedges. Specifically, for each vertex $v \in V(G)$, we introduce a vertex v', and thus we obtain $V(H) = \{v' : v \in V(G)\}$. Next, for each edge $uv \in E(G)$, we introduce n identical hyperedges $e_i^{uv} = \{u, v\}$ $(i \in [n])$; we also add $k - p$ identical hyperedges $e'_i = V(H)$ $(i \in [k - p])$. Hence, H contains $nm + (k - p)$ hyperedges: $E(H) = E'_1 \cup E'_2$, where $E'_1 = \{e_i^{uv} = \{u, v\} : uv \in E(G),\ i \in [n]\}$ and $E'_2 = \{e'_i = V(H) : i \in [k - p]\}$.

Finally, we show (G, k) is a Yes-instance if and only if (H, p) is a Yes-instance. On the one hand, let $I \subseteq V(G)$ be an independent set of G with the size k. Let $I' = \{v' : v \in I\}$, and we have that every hyperedge in E'_1 contains at most one vertex from I'. Additionally, each hyperedge in E'_2 contains exactly k vertices from I'. Since $k \geqslant p \geqslant 2$, we derive that the prize of I' is $k - |E'_2| = k - (k - p) = p$, which means that (H, p) is a Yes-instance.

On the other hand, let $I' \subseteq V(H)$ be a vertex subset of H with the prize p. Let X be the set of hyperedges containing at least two vertices from I'. We have that $p = |I'| - |X|$. Note that if one hyperedge $e_i^{vu} \in E_1'$ ($i \in [n]$) is in X, then all the n hyperedges identical with e_i^{vu} should be in X, which will make $p \leqslant |I'| - n \leqslant 0$, a contradiction. Therefore, we derive that $I = \{v \in V(G) : v' \in I'\}$ is an independent set in G and $X \cap E_1' = \varnothing$. Since $X \subseteq E_2'$, we have $|I| = |I'| = p + |X| \geqslant p + (k - p) \geqslant k$. We conclude that I is an independent set of G with size at least k, leading that (G, k) is a Yes-instance. ◀

Previously, no exact algorithm for PCMIS faster than $\mathcal{O}^*(2^n)$ is known. We show that PCMIS can be solved by reducing it to SFVS-S, and then we break the "2^n-barrier" for PCMIS. For an instance (H, p) of PCMIS, we construct an instance (G, T, M, k) of SFVS-S. Suppose that H contains n vertices and m hyperedges. We construct a split graph G as follows. We first introduce a clique with vertices $\{v' : v \in V(H)\}$; then for each hyperedge $e \in E(H)$, introduce a new terminal t_e' whose neighbors are exactly the vertices in the clique corresponding to the vertices in hyperedge e. The terminal set is set as $T = \{t_e' : e \in E(H)\}$, the marked edge set is set as $M = \varnothing$, and let $k = n - p$.

▶ **Lemma 17.** *For any constant $\alpha > 1$, an $\mathcal{O}^*(\alpha^k)$-time algorithm for SFVS-S leads to an $\mathcal{O}^*(\alpha^{n-p})$-algorithm for PCMIS.*

Proof. For an instance (H, p) of PCMIS, we construct an instance (G, T, M, k) of SFVS-S. Suppose that H contains n vertices and m hyperedges. We construct a split graph G as follows. We first introduce a clique with vertices $\{v' : v \in V(H)\}$; then for each hyperedge $e \in E(H)$, introduce a new terminal t_e' whose neighbors are exactly the vertices in the clique corresponding to the vertices in hyperedge e. The terminal set is set as $T = \{t_e' : e \in E(H)\}$, the marked edge set is set as $M = \varnothing$, and let $k = n - p$.

We have the key idea: every hyperedge in a hypergraph contains at most one vertex if and only if the corresponding split graph of the hypergraph contains no T-triangle. Let S be a solution to (G, T, M, k) containing m' terminals and n' non-terminals. We can see that $I = \{v : v' \in V(G) \backslash (T \cup S)\}$ is a vertex set with the prize at least $(n - n') - m' = n - k = p$ in (H, p). As for the opposite direction, suppose I is a solution to (H, p) of size n', and the prize of I is p. We can derive that there are at most $m' = n' - p$ hyperedges containing at least two vertices from I. This means that in G, we can remove m' terminals and $n - n'$ non-terminals to obtain a subgraph without any T-triangle, leading that (G, T, M, k) has a solution of size $(n - n') + m' = n - p = k$. Therefore, (G, T, M, k) is a Yes-instance if and only if (H, p) is a Yes-instance. We finish the proof of Lemma 17. ◀

Based on Lemma 13, we obtain an exact algorithm for PCMIS breaking the 2^n barrier.

▶ **Corollary 18.** *PCMIS can be solved in time $\mathcal{O}^*(1.8192^n)$.*

6 Conclusion

In this paper, we broke the "2^k-barrier" for SFVS in Chordal Graphs. As a corollary, we obtained an exact algorithm faster than $\mathcal{O}^*(2^n)$ for Prize-Collecting Maximum Independent Set in hypergraphs. To achieve this breakthrough, we introduced a new measure based on the Dulmage-Mendelsohn decomposition. This measure served as the basis for designing and analyzing an algorithm that addresses a crucial sub-case. Furthermore, we analyzed the whole algorithm using the traditional measure k, employing various techniques such as a divide-and-conquer approach and reductions based on small separators. The bottleneck of our algorithm occurs when dealing with SFVS in Split Graphs.

We think it is interesting to break the "2^k-barrier" or "2^n-barrier" for more important problems, say the Steiner Tree problem and TSP. For SFVS in general graphs, the best result is $\mathcal{O}^*(4^k)$ [30, 31]. It will also be interesting to reduce the gap between the results in general graphs and chordal graphs.

Abstract

Given an undirected graph G and a set $A \subseteq V(G)$, an A-path is a path in G that starts and ends at two distinct vertices of A with intermediate vertices in $V(G) \setminus A$. An A-path is called an (A, ℓ)-path if the length of the path is exactly ℓ. In the (A, ℓ)-Path Packing problem (ALPP), we seek to determine whether there exist k vertex-disjoint (A, ℓ)-paths in G or not.

The problem is already known to be fixed-parmeter tractable when parameterized by $k + \ell$ via color coding while it remains Para-NP-hard when parameterized by k (Hamiltonian Path) or ℓ (P_3-Partition) alone. Therefore, a logical direction to pursue this problem is to examine it in relation to structural parameters. Belmonte et al. initiated a study along these lines and proved that ALPP parameterized by $\mathsf{pw} + |A|$ is W[1]-hard where pw is the pathwidth of G. In this paper, we strengthen their result and prove that it is unlikely that ALPP is fixed-parameter tractable even with respect to a bigger parameter $(|A| + \mathsf{dtp})$ where dtp denotes the distance between G and a path graph (distance to path). We use a randomized reduction to achieve the mentioned result. Toward this, we prove a lemma similar to the influential "isolation lemma": Given a set system $(X, \mathcal{F})$ if the elements of X are assigned a weight uniformly at random from a set of values *fairly large*, then each subset in $\mathcal{F}$ will have a unique weight with *high probability*. We believe that this result will be useful beyond the scope of this paper.

ALPP being hard even for structural parameters like distance to path+$|A|$ rules out the possibility of any FPT algorithms for many well-known other structural parameters, including FVS+$|A|$ and treewidth+$|A|$. There is a straightforward FPT algorithm for ALPP parameterized by vc, the vertex cover number of the input graph. Following this, we consider the parameters CVD (cluster vertex deletion)+$|A|$ and CVD +$|\ell|$ and show the problem to be FPT with respect to these parameters. Note that CVD is incomparable to the treewidth of a graph and has been in vogue recently.

1 Introduction

Disjoint Path problems form a fundamental class within algorithmic graph theory. These well-studied problems seek the largest collection of vertex-disjoint (or edge-disjoint) paths that satisfy specific additional constraints. Notably, in the absence of such constraints, the problem reduces to the classical maximum matching problem. One of the most well-studied variants for disjoint path problems is the Disjoint s-t Path where given a graph G and two vertices s and t, the objective is to find the maximum number of internally vertex-disjoint paths between s and t. This problem is polynomial-time solvable by reducing to max-flow problem using Menger's Theorem.

Another classical version of the disjoint path problem is Mader's $\mathcal{S}$-Path. For a graph G and a set $\mathcal{S}$ of disjoint subsets of $V(G)$, an $\mathcal{S}$-Path is a path between two vertices in different members of $\mathcal{S}$. Given G and $\mathcal{S}$, the objective of Mader's $\mathcal{S}$-Path problem is to find the maximum number of vertex-disjoint $\mathcal{S}$-paths. It is solvable in polynomial time, as demonstrated by Chudnovsky, Cunningham, and Geelen [5]. One closely related and well-known variant of Mader's $\mathcal{S}$-Path problem is the A-Path Packing problem [1, 3, 6, 14, 12]. Given a graph G and a subset of vertices A, an *A-path* is a path in G that starts and ends at two distinct vertices of A, and the internal vertices of the path are from $V(G) \setminus A$. The A-Path Packing problem aims to find the maximum number of vertex disjoint A-paths in G. A-Path Packing problem can be modelled as an $\mathcal{S}$-path problem, where for every vertex v, we create a set $\{v\}$ in $\mathcal{S}$. Consequently, the A-Path Packing problem becomes polynomial-time solvable.

Recently, Golovach and Thilikos [11], have explored an interesting variant of the classical s-t path problem known as Bounded s-t Path problem by introducing additional constraints on path lengths. In this variant, given a graph G, two distinct vertices s and t, and an integer ℓ, one seeks to find the maximum number of vertex disjoint paths between s and t of length at most ℓ. Surprisingly, the problem becomes hard with this added constraint in contrast to the classical s-t path problem. In a similar line of study, Belmonte et al. [1] considered the following variant of the A-Path Packing problem.

(A, ℓ)-Path Packing (ALPP)
Input: An undirected graph $G = (V, E)$, $A \subseteq V(G)$ and integers k and ℓ.
Question: Are there k vertex-disjoint A-paths each of length ℓ in G?

This version of A-Path Packing problem is also proved to be intractable [1]. While considering this problem in the parameterized framework, the two most natural parameters for ALPP are the solution size k and the length constraint ℓ. While parameterized by the combined parameter of $k + \ell$, the problem admits an easy FPT algorithm via *color-coding*, parameterized by the individual parameters k and ℓ, the problem becomes Para-NP-hard due to reductions from Hamiltonian Path for k and P_3-Packing for ℓ.

Although it may appear that one has exhausted the possibilities for exploration of the problem within the parameterized framework, another set of parameters, known as *structural parameters*, emerges, allowing for further investigation. Belmonte et al. [1] initiated this line of study by considering the size of set A ($|A|$) as a parameter. They proved that the problem is W[1]-hard parameterized by $\mathsf{pw}(G) + |A|$, which translates to $\mathsf{tw}(G) + |A|$ as well, where $\mathsf{pw}(G)$ and $\mathsf{tw}(G)$ denote the pathwidth and treewidth of G respectively.

The intractability result for the parameter $\mathsf{tw}(G)+|A|$ refutes the possibility of getting FPT algorithms for many well-known structural parameters. Nonetheless, one of the objectives of structural parameterization is to delimit the border of the tractability of the problem, i.e., determining the smallest parameter for which the problem becomes FPT or the largest parameters that make the problem W-hard. Therefore one natural direction is to study ALPP with respect to parameters that are either larger than $\mathsf{tw}(G) + |A|$ or incomparable with $\mathsf{tw}(G) + |A|$.

Our Contribution. As our first result, we improve upon the hardness result of Belmonte et al. [1] by showing hardness for a much larger parameter, $\mathsf{dtp}(G) + |A|$. Here $\mathsf{dtp}(G)$ denotes the distance from G to a path graph (formal definitions of all the parameters can be found in Section 2). We present a randomized reduction from a known W[1]-hard problem, which establishes the hardness of (A, ℓ)-Path Packing under the assumption of randomized Exponential Time Hypothesis (rETH). The randomized reduction technique employed in our proof is highly adaptable and can be utilized to demonstrate the hardness of various analogous problems. We use the following lemma to prove our hardness result, which can be of independent interest.

▶ **Lemma 1** (Separation Lemma). *Let $(X, \mathcal{F})$ be a set system where $\mathcal{F}$ is a family of subsets of X. For an arbitrary assignment of weights $w : X \mapsto [M]$, let $w(S) = \sum_{x \in S} w(x)$ denote the weight of the subset $S \subseteq X$. For any random assignment of weights to the elements of X independently and uniformly from $[M]$, with probability at least $1 - \frac{\binom{|\mathcal{F}|}{2}}{M}$, each set $S \in \mathcal{F}$ has a unique weight.*

In addition to refining the boundaries of hardness, we have also considered the problem with respect to the parameter of $\mathsf{cvd}(G)$ denoting the cluster vertex deletion size of G in combination with the natural parameters A and ℓ. The incomparability of $\mathsf{cvd}(G)$ with tw and pw makes it an intriguing parameter to explore. We have proved that ALPP is fixed-parameter tractable with respect to the parameters $\mathsf{cvd}(G) + |A|$ as well as $\mathsf{cvd}(G) + \ell$ where $\mathsf{cvd}(G)$ denotes the cluster vertex deletion size of G (see Section 2). Below we provide brief overviews of these two algorithms.

$\mathbf{cvd(G) + |A|}$. We start by combining $|A|$ and the $\mathsf{cvd}(G)$ to form a “modulator” M. Now, each A-path comprises subpaths between certain modulator vertices. Once we guess the interaction of M with these paths, the role of the cliques in $G - M$ reduces to providing vertices for these subpaths. Next, we first employ a color-coding scheme and color the cliques. This coloring determines the role of a clique to provide required subpaths of a certain kind. And a clique within a color class is deemed *feasible* if it can provide the necessary subpaths barring the length requirements. The feasibility of a clique is identified through its color and *modulator neighborhood*. Following this, we make an important observation that the largest *feasible* cliques are the optimal choices for providing these length-constrained paths. Subsequently, we design an Integer Linear Program that checks their ability to provide subpaths with necessary length requirements.

$\mathbf{cvd(G)} + \ell$. In the context of a modulator M of size m, each clique in $G - M$ is termed “local”. A path is labeled “local” if it contains no vertices from M and lies entirely within a local component (clique). It is worth noting that there are at most m non-local paths in any optimal solution. From each clique, we designate a few vertices with a *marking scheme* that are utilized in providing these non-local paths. The remaining vertices from cliques are utilized in providing local paths and possess very specific characteristics. Exploiting this property, we can extract such local paths from unmarked vertices of cliques, effectively bounding the size of each clique. Subsequently, we identify *equivalent*/indistinguishable cliques based on their *modulator neighborhood* and only need to retain a few of the equivalent cliques (as almost all of them are used in providing local paths, and we can extract these local paths). This bounds the size of the instance as the clique size, the number of equivalent classes, and the number of equivalent cliques inside a class are bounded.

We design a cubic kernel for a larger parameter (than $\mathsf{tw}(G)$) vertex cover $\mathsf{vc}(G)$ in a manner very similar to the algorithm designed for $\mathsf{cvd}(G) + \ell$.

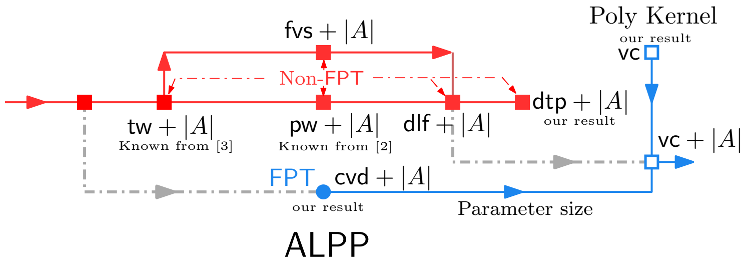

Figure 1 Structural Parameterizations of ALPP. The arrow represents the hierarchy of different structural parameters, while the dashed line represents the parameters that have yet to be explored in the context of our problems.

2 Preliminaries

Sets, Numbers and Graph Theory. We use $\mathbb{N}$ to denote the set of all natural numbers and $[r]$ to denote the set $\{1, \ldots, r\}$ for every $r \in \mathbb{N}$. Given a finite set S and $r \in \mathbb{N}$, we use $\binom{S}{r}$ and $\binom{S}{\leq r}$ to denote the collection of subsets of S with exactly r elements and at most r elements respectively. We use standard graph theoretic notations from the book by Diestel [9]. For any two vertices x, y and a path P, we denote $V[x, y]$ as the number of vertices in the subpath between x and y in P. And for a path P we denote the set of vertices in P by $V(P)$. Further, for a collection $\mathcal{P}$ of paths, $V(\mathcal{P}) = \{\bigcup_{P_i \in \mathcal{P}} V(P_i)\}$. In a graph G, let $P_i(v_1, v_2, \cdots, v_j)$ be a path and $X \subseteq V$ be a set. An *ordered intersection* of P_i with X, denoted as $X_i = (v_a, v_b, \cdots, v_p)$, is defined as $V(P_i) \cap X = X_i$, where the ordering of the vertices in X_i is the same as that in P_i. Additionally, we define $X_1, X_2, \cdots, X_x$ as an *ordered partition* of X if each X_i is an ordered set and $\bigcup_{i=1}^{x} X_i = X$. Given a path $P_i(v_1, v_2, \cdots, v_j)$, we denote $P_i(v_1, v_2, \cdots, v_{j-1})$ as $P_i \setminus (v_{j-1, v_j})$.

Structural Parameters. Given a graph class $\mathcal{H}$ and a graph G, we define the *distance* of G to $\mathcal{H}$ as the minimum number of vertices that need to be deleted to obtain a graph in class $\mathcal{H}$, denoted by $d^{\mathcal{H}}(G)$. For instance, the vertex cover size $\mathsf{vc}(G)$ represents the distance to the class of edgeless graphs or independent sets, the feedback vertex set size $\mathsf{fvs}(G)$ is the distance to the class of forests and cluster vertex deletion set size $\mathsf{cvd}(G)$ denotes the distance to the class of cluster graphs (collection of disjoint cliques). Furthermore, a graph is called a *path graph* if it has only one connected component and that connected component is an induced path. The class of all path graphs and all linear forests are denoted by Γ and $\mathcal{F}$, respectively. We denote $d^{\Gamma}(G)$ and $d^{\mathcal{F}}(G)$ by $\mathsf{dtp}(G)$ and $\mathsf{dlf}(G)$, respectively. Formal definitions of all these parameters can be found in [7].

3 (A, ℓ)-Path Packing Parameterized by $\mathsf{dtp}(G) + |A|$

This section establishes that ALPP is unlikely to be fixed-parameter tractable with respect to the combined parameter $(\mathsf{dtp}(G) + |A|)$ under standard complexity theoretic assumptions. We begin by presenting some key ideas that will be instrumental in our subsequent hardness reduction.

ALPP **Parameter:** $a + m$
Input: A graph G, two subsets $A, M \subseteq V$ of cardinality a and m respectively, and integers k and ℓ such that $G - M \in \Gamma$, where Γ denotes the family of paths.
Question: Are there k vertex-disjoint A-paths each of length exactly ℓ in G?

3.1 Essential Results

We show the hardness for ALPP under the assumption that the randomized Exponential Time Hypothesis (rETH) holds. The concept of rETH was introduced by Dell et al. [8], which states the following. There exists a constant $c > 0$, such that no randomized algorithm can solve 3-SAT in time $\mathcal{O}^*(2^{cn})$ with a (two-sided) error probability of at most $\frac{1}{3}$, where n represents the number of variables in the 3-SAT instance. The $\mathcal{O}^*$ notation hides polynomial factors in the input size.

In the realm of parameterized complexity, rETH has been widely employed to prove hardness for many well-known parameterized problems. The following theorem can be derived from Theorem 12 in [4] when $\epsilon = 1/m$ in Conjecture 5.

▶ **Theorem 2.** *Unless rETH fails, there is no randomized algorithm that decides k-Clique in time $f(k) \cdot n^{o(k)}$ correctly with probability at least $2/3$.*

We establish the intractability result for ALPP parameterized by $(|A| + \mathsf{dtp}(G))$ through a "parameter preserving reduction" from the k-Independent Set problem on a 2-interval graph, which in turn was shown to be W[1]-complete following a reduction from the k-Clique problem by Fellows et al. [10]. A 2-*interval* $\mathcal{I}_i$ is a disjoint pair of intervals $\{I_i^a, I_i^b\}$ on a real line. We say that a pair of 2-intervals, $\mathcal{I}_i$ and $\mathcal{I}_j$ *intersect* if they have at least one point in common, that is $\{I_i^a \cup I_i^b\} \cap \{I_j^a \cup I_j^b\} \neq \emptyset$. Conversely, if two 2-intervals do not intersect, they are called *disjoint*.

A 2-*interval representation* of a graph G is a set of two intervals $\mathcal{J}$ such that there is a one to one correspondence between $\mathcal{J}$ and $V(G)$ such that there exists an edge between u and v if and only if the 2-intervals corresponding to u and v intersect. A graph is a 2-*interval graph* if there is a 2-*interval representation* for G. For a graph G, a set of vertices $W \subseteq V(G)$ is said to be independent if for any pair of vertices u and v in W, $(u, v) \notin E(G)$. Given a graph G, the k-Independent Set problem asks whether there exists a k size independent set in G. Observe that given a 2-interval graph G and a 2-interval representation $\mathcal{J}$ of G a k-independent set W for G corresponds to a set of pairwise disjoint 2-intervals in $\mathcal{J}$.

Fellows et al. [10] presented a parameterized reduction from an arbitrary instance (G, k) of the k-Clique problem to an instance $(\mathcal{J}, k')$ of the k'-Independent Set problem on a 2-interval graph such that there exists a k size clique in G if and only if there exists a $k' = k + 3\binom{k}{2}$ sized independent set in $\mathcal{J}$. Thus, we have the following theorem.

▶ **Theorem 3.** *Unless rETH fails, there is no randomized algorithm that decides k-Independent Set on a 2-interval graph in $f(k) \cdot n^{o(k)}$-time correctly with probability at least $2/3$.*

Next, we present a lemma, which we will use later on. We believe that this can be of independent interest and applicable to various other problem domains. This lemma is similar to the well-known isolation lemma [13]. Recall that $[r]$ denotes the set $\{1, \ldots, r\}$ where $r \in \mathbb{N}^+$.

▶ **Lemma 1** (Separation Lemma). *Let $(X, \mathcal{F})$ be a set system where $\mathcal{F}$ is a family of subsets of X. For an arbitrary assignment of weights $w : X \mapsto [M]$, let $w(S) = \sum_{x \in S} w(x)$ denote the weight of the subset $S \subseteq X$. For any random assignment of weights to the elements of X independently and uniformly from $[M]$, with probability at least $1 - \frac{\binom{|\mathcal{F}|}{2}}{M}$, each set $S \in \mathcal{F}$ has a unique weight.*

Proof. Let w be a random assignment of weights to the elements of X independently and uniformly from $[M]$ and S_1 and S_2 be two arbitrary sets in $\mathcal{F}$. Our objective is to find the probability of the event "$w(S_1) = w(S_2)$". Observe that if $S_1 \setminus S_2 = \emptyset$ or $S_2 \setminus S_1 = \emptyset$, then $\mathbb{P}\big(w(S_1) = w(S_2)\big) = 0$. Let $S_1 \setminus S_2 = \{x_1, x_2, \cdots, x_a\}$ and $S_2 \setminus S_1 = \{y_1, y_2, \cdots y_b\}$. We define a random variable W_{12} as follows.

$$W_{12} = \{w(x_1) + \cdots + w(x_a)\} - \{w(y_2) + \cdots + w(y_b)\} = w(S_1) - w(S_2) + w(y_1)$$

From the law of total probability, we have the following.

$$\begin{aligned}
&\mathbb{P}\big(w(S_1) = w(S_2)\big) = \sum \mathbb{P}\big(w(S_1) = w(S_2) | W_{12} = z\big) \cdot \mathbb{P}(W_{12} = z) \\
&= \sum \mathbb{P}\big(w(y_1) = z\big) \cdot \mathbb{P}(W_{12} = z) \\
&= \sum_{z \in [M]} \mathbb{P}\big(w(y_1) = z\big) \cdot \mathbb{P}(W_{12} = z) \qquad \text{if } z \notin [M] \text{ then } \mathbb{P}\big(w(y_1) = z\big) = 0 \\
&= \sum_{z \in [M]} \frac{1}{M} \mathbb{P}(W_{12} = z) = \frac{1}{M} \sum_{z \in [M]} \mathbb{P}(W_{12} = z) \leq \frac{1}{M}
\end{aligned}$$

Using Boole's inequality, we can prove that none of the two sets in $\mathcal{F}$ are of equal weight with probability at least $1 - \frac{\binom{|\mathcal{F}|}{2}}{M}$. Thus, the claim holds. ◀

3.2 Hardness Proof

We are ready to present a randomized reduction from the k-Independent Set problem in 2-interval graphs to the ALPP problem. Throughout this section, we denote the family of path graphs by Γ. Let $(G_{\mathcal{J}}, k)$ be an instance of k-Independent Set problem in 2-interval graph where the set of 2-intervals representing $G_{\mathcal{J}}$ be $\mathcal{J}$.

Now, we present a randomized construction of an ALPP problem instance (G, A, M, ℓ, k) from $(G_{\mathcal{J}}, k)$ where $H = G \setminus M$ is in Γ and $|M| = 4k$. We assume that we are given $\mathcal{J}$. The construction of G is done in two phases. In the first phase, we generate a set of points P on the real line $\mathbb{R}$. In the second phase, we construct the graph G. Observe that the points in P naturally induce a path graph H which is defined as follows. Corresponding to each point in P, we define a vertex in $V(H)$, and there is an edge between two vertices if the points corresponding to them are adjacent in $\mathbb{R}$. We additionally add $4k$ vertices. Before detailing our construction, let us establish a few notations and assumptions that can be accommodated without changing the combinatorial structure of the problem. Let $\mathcal{J} = \{\mathcal{I}_1, \mathcal{I}_2, \cdots, \mathcal{I}_n\}$ where each 2-interval $\mathcal{I}_j$ is a collection of two intervals I_j^a and I_j^b. We presume that all the intervals in $\mathcal{J}$ are inside the interval $[0, 1]$ in the real line. Furthermore, we assume that all the endpoints of the intervals are distinct, and the distance between any two consecutive endpoints is at least 2ϵ, where ϵ is an arbitrarily small constant. We use $L(I)$ and $R(I)$ to denote the left and right endpoints of an interval I, respectively.

Construction Phase 1. We place a set of points P on $\mathbb{R}$ as follows. For each interval I_j^c, where $c \in \{a, b\}$ and $j \in [n]$, we generate two random numbers $n_r(L(I_j^c))$ and $n_r(R(I_j^c))$ between 1 and N. We will decide on the value of N at a later stage.

Let $P(L(I_j^c))$ be the set of $n_r(L(I_j^c))$ equally spaced points in the interval $[L(I_j^c), L(I_j^c)+\epsilon]$. The first point of $P(L(I_j^c))$ coincides with $L(I_j^c)$, and the last point coincides with $L(I_j^c) + \epsilon$. Let $P_L = \bigcup_{c\in\{a,b\},j\in[n]} P(L(I_j^c))$. Similarly, let $P(R(I_j^c))$ be the set of $n_r(R(I_j^c))$ equally spaced points in the interval $[R(I_j^c) - \epsilon, R(I_j^c)]$. The first point of $P(R(I_j^c))$ coincides with $R(I_j^c) - \epsilon$ and the last point coincides with $R(I_j^c)$. Let $P_R = \bigcup_{c\in\{a,b\},j\in[n]} P(R(I_j^c))$. An illustration of this process can be seen in Figure 2. Observe that the cardinality of $P_L \cup P_R$ is at most $4nN$.

Consider $\mathcal{I}_j = (I_j^a, I_j^b)$ be a 2-interval, and n_j be the total number of points from $P_L \cup P_R$ that are inside $\mathcal{I}_j$. Let $\overline{n_j} = 8nN - n_j$ for all $j \in [n]$. Define C_j as the collection of $\overline{n_j}$ points evenly distributed within the interval $[2j, 2j + 1]$ and let $P_C = \cup_{j\in[n]} C_j$. To ease the notations, we denote $L_j = 2j$, $R_j = 2j + 1$ and I_j as the interval (L_j, R_j). Observe that the total number of points inside I_j^a, I_j^b and I_j is $8nN$.

We add a large number of points (exactly $8nN + 4$ many) between R_j and L_{j+1} for $j \in [n]$ and denote all these points by P_X. Let $P = P_L \cup P_R \cup P_C \cup P_X$.

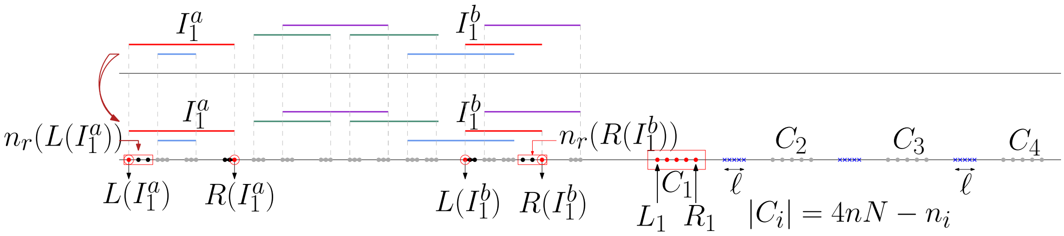

Figure 2 Illustration of Construction Phase 1. Note that $|C_i| = \overline{n_i} = 8nN - n_i$.

Construction Phase 2. Consider the set of points P in $\mathbb{R}$. Observe that there is a natural ordering among the points in P. We define adjacency based on this ordering. Consider the path graph G_P induced by P. Specifically, we introduce a vertex for each point in P and add an edge between two vertices if and only if the points corresponding to them are adjacent. With slight abuse of notation, we denote the vertex corresponding to a point p by p. For any interval I, let $V(I)$ denote the number of points/vertices within the interval I. For two points a and b in P, $\lambda[a, b]$ denotes the path from a to b in G_P.

We construct G, by setting $V(G) = V(G_P) \cup V_M$ where $V_M = \{a_i, b_i, c_i, d_i | \ i \in [k]\}$. And, $E(G) = E(G_P) \cup E_a \cup E_b \cup E_c \cup E_d$, where $E_a = \{(a_i, L(I_j^a)) \mid j \in [n] \text{ and } i \in [k]\}$, $E_b = \{(b_i, R(I_j^a)), (b_i, L_j) \mid j \in [n] \text{ and } i \in [k]\}$, $E_c = \{(c_i, L(I_j^b)), (c_i, R_j) \mid j \in [n] \text{ and } i \in [k]\}$, $E_d = \{(d_i, R(I_j^b)) \mid j \in [n] \text{ and } i \in [k]\}$.
Informally, the edges are defined as follows. Each $a_i \in V_M$ is adjacent to $L(I_j^a)$ for all $j \in [n]$ (see Figure 3). Similarly each $b_i \in V_M$ is adjacent to $R(I_j^a)$ for all $j \in [n]$. Additionally, each b_i is adjacent to every other L_j for all $j \in [n]$. Each c_i is adjacent to $L(I_j^b)$ and R_j, and each d_i is adjacent to $R(I_j^b)$.
We denote $A = \{a_i, d_i | \ i \in [k]\}$ and set $\ell = 8nN + 4$.

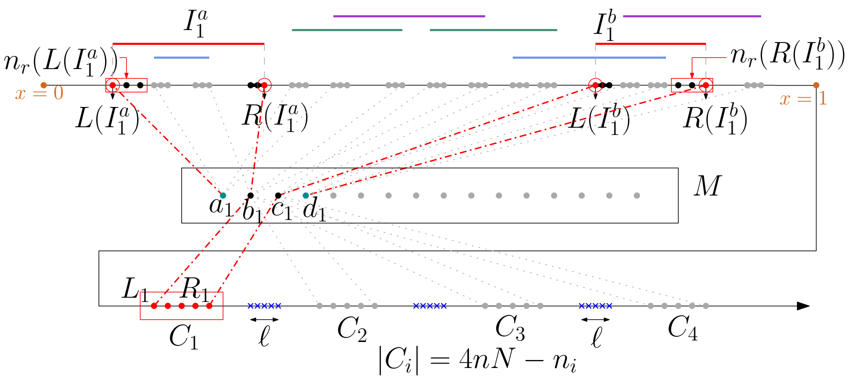

Figure 3 Illustration of construction of (A, ℓ)-Path Packing. Note that $|C_i| = \overline{n_i} = 8nN - n_i$.

Next, we demonstrate that if there exists a k-size independent set in $G_{\mathcal{J}}$, then with probability 1 there exist k many vertex-disjoint (A, ℓ)-paths in G where $\ell = 8nN + 4$ (Lemma 4). Following this, we show that if there exist k many vertex-disjoint (A, ℓ)-paths in G where $\ell = 8nN + 4$, then with *high* probability there is a k-size independent set in $G_{\mathcal{J}}$.

▶ **Lemma 4.** *If there are k disjoint 2-intervals in $\mathcal{J}$, then there are k vertex-disjoint (A, ℓ)-paths in G.*

Proof. Without loss of generality, let us assume that the k disjoint 2-intervals are $\mathcal{I}_1, \mathcal{I}_2, \ldots, \mathcal{I}_k$. Recall that for two vertices a and b in the path graph G_P, $\lambda[a, b]$ denotes the path from a to b in G_P. Consider the following set of paths, defined for $1 \le i \le k$,

$$\lambda_i = a_i \cdot \lambda[L(I_i^a), R(I_i^a)] \cdot b_i \cdot \lambda[L_i, R_i] \cdot c_i \cdot \lambda[L(I_i^b), R(I_i^b)] \cdot d_i$$

Observe that the paths in $\{\lambda_i | 1 \le j \le k\}$ are pairwise vertex-disjoint, each having ℓ vertices, with two endpoints at two different vertices in A (See Figure 4 for an illustration). By construction, they contain $\ell = 8nN + 4$ many vertices. Thus, the claim holds. ◀

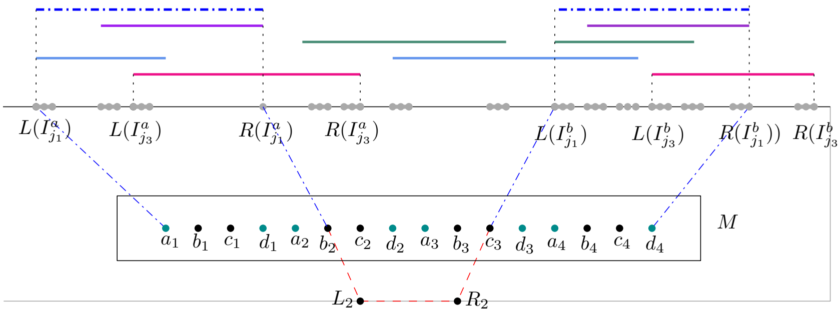

Figure 4 Construction of the paths λ_i in the proof of Lemma 4.

Next, we show that if there exist k many vertex-disjoint (A, ℓ)-paths in G where $\ell = 8nN + 4$, then with *high* probability there is a k size independent set in $G_{\mathcal{J}}$.

Recall that the set of intervals $\{I_j | j \in [n]\}$ where $I_j = [L_j, R_j]$. Let $V_j = V(I_j)$. And, the path corresponding to I_j is $\lambda[L_j, R_j]$. Let us define $\mathcal{C} = \{C_i | 1 \le i \le n\}$. Next, we have the following observation.

▶ **Observation 5.** *For any A-path L of length exactly $\ell = 8nN + 4$ in G, there exists an integer $y \in [n]$ such that $V_y \subset V(L)$ and for any $i \neq y$, $V_i \cap V(L) = \emptyset$. Further L contains the subpath $b_x \cdot \lambda[L_y, R_y] \cdot c_z$ for some $x, z \in [k]$.*

Proof. As the total number of points/vertices in $[0, 1]$ is at most $4nN < \ell$, note that every (A, ℓ)-path should contain all points/vertices from at least one set of points from $\mathcal{C}$. Observe that any path with a length of exactly ℓ contains exactly one set of points $C_i \in \mathcal{C}$ as between two consecutive set of points in $\mathcal{C}$ there are more than ℓ points. As only neighbors of C_i which is not in H is b_x and c_z, where $x, z \in [k]$, therefore, the path must include a subpath of the form $b_x \cdot \lambda[L_y, R_y] \cdot c_z$ for some $y \in [n]$ and $x, z \in [k]$. ◀

Let $\mathcal{P} = \{P_1, \dots, P_k\}$ be a set of k vertex-disjoint A-paths of length exactly ℓ in G. We show that with *high* probability, there is a k size independent set in $G_{\mathcal{J}}$.

▶ **Observation 6.** *Each path $P_i \in \mathcal{P}$ is of the form $p \cdot \lambda[r, s] \cdot b_x \cdot \lambda[L_y, R_y] \cdot c_z \cdot \lambda[t, u] \cdot q$ where $p, q \in A$, $r, s, t, u \in M$, $y \in [n]$ and $x, z \in [k]$.*

Proof. Since the total number of points in A is $2k$, each path must contain exactly two points from A. It follows from Observation 5 that any such path contains a subpath of the form $b_x \cdot \lambda[L_y, R_y] \cdot c_z$. By construction, for any path P, that connects p with b_x, $P \setminus \{p, b_x\}$ induces a continuous set of points on the path graph with endpoints in M (see Figure 4). A similar argument can be made for c_z and q as well. Thus, the claim holds. ◀

Observation 6 indicates that from the disjoint paths in $\mathcal{P}$, it is possible to construct a disjoint set of 3-intervals $\mathcal{J} = \{((x_i, y_i), (z_i, w_i), I_j) | 1 \leq i \leq k\}$ where $x_i, y_i, z_i, w_i \in M$ and $I_j = (L_j, R_j)$. Next we prove that with *high* probability the interval $(x_i, y_i) = I^a_{y_i}$ and the interval $(z_i, w_i) = I^b_{y_i}$, which will give us the desired set of k disjoint 2-intervals.

Let a, b, c, d be any four points in M. Without loss of generality, assume that $a < b < c < d$. Consider the 2-interval $((a, b), (c, d))$ defined by a, b, c, d. Let $\mathcal{J}_{\mathcal{F}}$ be the set of all such intervals, formally defined as $\mathcal{J}_{\mathcal{F}} = \{((a, b), (c, d)) | a, b, c, d \in \text{ and } a < b < c < d\}$. Note that $|\mathcal{J}_{\mathcal{F}}| < n^4$. From Lemma 1, we know that each 2-interval in $\mathcal{J}_{\mathcal{F}}$ contains a unique number of points with probability at least $1 - \frac{\binom{n^4}{2}}{N}$. If we set $N = 3\binom{n^4}{2}$, with probability at least $\frac{2}{3}$ every 2-interval in $\mathcal{J}_{\mathcal{F}}$ contains a unique number of points. Thus with probability at least $\frac{1}{3}$, for every $1 \leq j \leq n$, no other 2-interval except (I^a_j, I^b_j) contains $\ell - V(I_j) - 4$ many points where $V(I)$ denotes the number of points in the interval I. Therefore with probability at least $\frac{2}{3}$, for every 3-interval $((x_i, y_i), (z_i, w_i), I_{y_i})$ in $\mathcal{J}$, $(x_i, y_i) = I^a_{y_i}$ and $(z_i, w_i) = I^b_{y_i}$. Hence we have the following lemma.

▶ **Lemma 7.** *If there are k vertex-disjoint (A, ℓ)-paths in G, then there are k disjoint 2-intervals in $\mathcal{J}$.*

The following conclusive theorem arises from the combination of Theorem 3, Lemma 4, and Lemma 7.

▶ **Theorem 8.** *Unless rETH fails, there is no randomized algorithm for (A, ℓ)-Path Packing which runs in $f(\mathsf{dtp}(G) + |A|) \cdot n^{o(\mathsf{dtp}(G)+|A|)}$-time correctly with probability at least $2/3$.*

4 (A, ℓ)-Path Packing Parameterized by $\mathsf{cvd}(G)+|A|$

In this section, we design an FPT algorithm for the (A, ℓ)-Path Packing problem parameterized by combining the two following parameters: the size of a cluster vertex deletion set and $|A|$. Our algorithm operates under the assumption that we are provided with a minimum size set M as input, satisfying the conditions $A \subseteq M$ and $G - M$ forms a cluster graph. This assumption is justified by the fact that one can efficiently find the smallest size cluster vertex deletion set of $G - A$ in time $1.9102^k \cdot n^{\mathcal{O}(1)}$ [2]. We restate the problem definition and illustrate a brief sketch of our algorithm.

ALPP **Parameter:** $m = |M|$
Input: A graph G, two subsets $A, M \subseteq V$ of cardinality a and m respectively, and integers k and ℓ such that $A \subseteq M$ and $G - M$ is a cluster graph.
Question: Does there exist k vertex-disjoint paths of length exactly ℓ that have endpoints in A?

Overview of the Algorithm. Our algorithm starts by making an educated guess regarding the precisely ordered intersection of each path within an optimal solution ($\mathcal{P}$) with the modulator set M. This involves exploring a limited number of possibilities, specifically on the order of $f(|M|) \cdot n^{\mathcal{O}(1)}$ choices. Once we fix a choice, the problem reduces to finding subpaths (of any given path in $\mathcal{P}$) between modulator vertices satisfying certain length constraints. To provide a formal description, let $P \in \mathcal{P}$ be a path of the form $m_1 P_{1,2} m_2 m_3 m_4 P_{4,5} m_5$ (our guess for $P \in \mathcal{P}$) where each $m_i \in M$ and each $P_{i,i+1}$ is contained in $G - M$. Subsequently, our algorithm proceeds to search for the subpaths $P_{1,2}$ and $P_{4,5}$ each contained in cliques of $G - M$ with endpoints adjacent to vertices m_1, m_2 and m_4, m_5 respectively. A collection of constraints within our final *integer linear program (ILP)* guarantees that the combined length of the paths $P_{1,2}$ and $P_{4,5}$ precisely matches $\ell - 5$, satisfying the prescribed length requirement. Before presenting the ILP formulation, we make informed decisions about the cliques that are well-suited and most appropriate for providing these subpaths. Towards that, we partition the at most $|M|$ many subpaths (originating from all the paths in $\mathcal{P}$), with each partition containing subpaths exclusively from a single clique of $G - M$. Moreover, no two subpaths in separate partitions come from the same clique. Once such a choice is fixed, we apply a color coding scheme on the cliques in $G - M$ where we color the cliques with the same number of colors as the number of sets in the mentioned partition of subpaths into sets. With a *high* probability, each clique involved in the formation of $\mathcal{P}$ is assigned a distinct color. These assigned colors play a crucial role in determining the roles of the cliques in providing subpaths and, consequently, in constructing the final solution $\mathcal{P}$. We show that among all the cliques colored with a single color, a largest size *feasible* clique is an optimal choice for providing the necessary subpaths of $\mathcal{P}$. A *feasible* clique is a clique that is able to provide the necessary subpaths determined by its assigned color, barring the length requirements, and, is identified by its adjacency relation with M. Therefore, we keep precisely one feasible clique of the maximum size for each color and eliminate the others. Thus the number of cliques in the reduced instance is bounded by a function $f(m)$. Following these steps, our problem reduces to finding required subpaths (with length constraints) for which we design a set of ILP equations where the number of variables is a function of m. Below, we give a detailed description of our algorithm.

Algorithm.

Phase 1: The Guessing Phase

1. Find a cluster vertex deletion set S of the minimum size in $G - A$. Then, set $M = A \cup S$.
2. Generate all $M' \subseteq M$. For a fixed M', generate all its *ordered partitions* such that only the first and last vertices of every set of the partitions are from A. Let $\mathcal{M} = \{M'_1, \ldots, M'_{|\mathcal{M}|}\}$ be a fixed such partition of M'.

3. Without loss of generality, let $M'_i = (m_{g(i)}, m_{g(i)+1}, \dots, m_{l(i)})$. For any two consecutive vertices m_j and m_{j+1} where $j \in [g(i), l(i) - 1]$, we introduce a variable $P_{j,j+1}$. These variables serve as placeholders representing subpaths within the optimal solution that we are aiming to find. We use $\mathbb{P}$ to denote the collection of $P_{j,j+1}$.
4. We enumerate all partitions of $\mathbb{P}$. Let $\mathcal{X}_{\mathbb{P}} = \{\mathcal{P}_1, \mathcal{P}_2, \dots, \mathcal{P}_x\}$ be a partition of $\mathbb{P}$ with $x = |\mathcal{X}_{\mathbb{P}}|$.
5. Additionally, we generate all *valid* functions $h : \mathbb{P} \to \{0, 1, > 1\}$, i.e., we guess whether the length of each subpath is exactly 0, 1, or more than 1. The function h is *valid* if $h(P_{j,j+1}) = 0$, implies m_j and m_{j+1} are adjacent. The validity of h concerning the other two values (1 and > 1) is inherently assured by the presence of a feasible clique.
6. We create a function $T : \mathcal{X}_{\mathbb{P}} \to 2^{2^M}$ as follows. For each part $\mathcal{P}_i \in \mathcal{X}_{\mathbb{P}}$, create the set $T(\mathcal{P}_i) = \{\{m_j, m_{j+1}\} : P_{j,j+1} \in \mathcal{P}_i \text{ and } h(P_{j,j+1}) = 1\} \cup \{\{m_j\} \cup \{m_{j+1}\} : P_{j,j+1} \in \mathcal{P}_i \text{ and } h(P_{j,j+1}) > 1\}$.

At the conclusion of Step 6, we have generated all the tuples denoted as $\tau = (M', \mathcal{M}, \mathbb{P}, \mathcal{X}_{\mathbb{P}}, h, T)$. For each specific τ, we proceed to Phase 2 in order to bound the number of cliques and subsequently generate a set of ILPs.

Phase 2: Bounding the number of Cliques Phase

1. We color all the cliques in $G - M$ with x many colors uniformly at random. From a set of cliques colored with color i, we choose a largest *feasible* clique Q_i. A clique with color i is *feasible* if and only if it has $|T(\mathcal{P}_i)|$ distinct vertices, each being a neighbor to a different set in $T(\mathcal{P}_i)$. Also, we denote the above coloring function by $\mathcal{C}_\tau$.
2. Following the Algorithm, we construct the following set of ILPs.

$$
\begin{aligned}
ILP(\tau, \mathcal{C}_\tau) : \quad & \sum_{j=g(i)}^{l(i)-1} x_{j,j+1} = \ell - |M'_i|, && \forall M'_i \in \mathcal{M} \\
& \sum_{P_{j,j+1} \in \mathcal{P}_i} x_{j,j+1} \leq |Q_i|, && \forall \mathcal{P}_i \in \mathcal{X}_{\mathbb{P}} \\
& x_{j,j+1} = 1, && \text{iff} \;\; h(P_{j,j+1}) = 1
\end{aligned}
$$

Correctness of The Guessing Phase (Steps 1 to 6). Let $\mathcal{P} = \{P_1, \dots, P_p\}$ be an optimal solution of size p where any ℓ-path in $\mathcal{P}$ by definition has both its endpoints in A. In the above ILP, note that the variable $x_{j,j+1}$ represents the path $P_{j,j+1}$. The M' generated in the Step 2 is $V(\mathcal{P}) \cap M$. Each M'_i is the *ordered intersection* of a path P_i with M' , i.e., the sequence of vertices of $V(P_i) \cap M$ appearing in the path is given by M'_i (Step 2). In Step 3, we create the variables (corresponding to the subpaths of $\mathcal{P}$) for each pair of consecutive vertices from M'_i for every $M'_i \in \mathcal{M}$ (Step 3). Any such subpath with a non-zero length is contained in exactly one of the cliques in $G - M$. The subpaths of $\mathcal{P}$ that come from single cliques together are denoted by the partition $\mathcal{X}_{\mathbb{P}}$, i.e., the subpaths (in $\mathcal{P}$) in a part of the partition are exactly the subpaths that are contained in a single clique of $G - M$ (Step 4). We further divide these subpaths into three groups ($h^{-1}(0)$, $h^{-1}(1)$, $h^{-1}(> 1)$) based on whether their lengths are exactly 0, 1, or more than 1 (Step 5). If $h(P_{j,j+1}) = 0$, then the corresponding subpath has length *zero* implying m_j and m_{j+1} are adjacent in $\mathcal{P}$. If $h(P_{j,j+1}) = 1$, then the corresponding subpath has length exactly one and the lone vertex in the subpath is adjacent to both m_j and m_{j+1} in $\mathcal{P}$. When $h(P_{j,j+1}) > 1$, the correcponding subpath has length *more than one* and has two vertices, one is adjacent to m_j while another is adjacent to m_{j+1}. The set $T(\mathcal{P}_i)$ basically stores the adjacency relations (required) between the endpoints of non-zero length subpaths of $\mathcal{P}$ and M. The correctness of the first 6 steps follows directly because of the fact that we exhaust all possible choices at each step.

Correctness of Phase 2. We apply the *color-coding* scheme in the first step of second phase of our algorithm. Each clique $Q_i \in \{Q_1, \ldots, Q_x\}$ that contains vertices from $\mathcal{P}$ gets a different color with *high* probability. Moreover, each Q_i colored with color i exactly contains the subpaths denoted by $\mathcal{P}_i$. We compute this exact probability later in the runtime analysis of our algorithm. Notice the role of the cliques in $G - M$ is to provide subpaths of certain lengths between the vertices from M. And, a *feasible* clique of color i is able to provide all the subpaths in $\mathcal{P}_i$ between the vertices of M, barring the length requirements. Thus, given a feasible clique Q'_i of maximum size, we can reconstruct an equivalent optimal solution $\mathcal{P}'$ in which all its paths within $\mathcal{P}_i$ are entirely contained within Q'_i, all the while sticking to the specified length requirements. This reconstruction can be systematically applied to guarantee the existence of an optimal solution where all its subpaths are derived from a collection of feasible cliques with the largest size available from each color class. Let τ be a correctly guessed tuple, $\mathcal{C}_\tau$ be a correct coloring scheme (coloring each of the x cliques involved in the solution distinctly), and Q'_i be a feasible clique of the largest possible size colored with color i respecting the guessed tuple for each color i. Then, there exists an optimal solution that is entirely contained in the subgraph $G[\bigcup_{i=1}^{x} Q'_i \cup M]$. To obtain the desired solution for a YES instance, we narrow our attention to the subgraph and formulate the specified ILP denoted as ILP$(\tau, \mathcal{C}_\tau)$. The primary objective of the ILP equations is to guarantee that every path we are seeking has an exact length of ℓ. The first set of constraints enforces the specified length requirements for the subpaths, ensuring that each subpath adheres to its designated length. And the second set of constraints ensures that the combined total of all vertices to be utilized from a clique (across all subpaths) in a solution to the ILP does not surpass the total number of vertices within the largest feasible clique.

Runtime Analysis. The total number of ordered partitions generated in Step 2 is $\mathcal{O}(2^m \cdot m^m)$. In Step 3, $|M'_i|$ can be of $\mathcal{O}(m)$. Hence for a fixed $\mathcal{M}$, the number of permutations enumerated is of $\mathcal{O}(m!) \cdot m$. Notice the number of $P_{j,j+1}$ ($|\mathbb{P}|$) is bounded by m. Therefore in the next step, $\mathcal{X}_{\mathbb{P}}$ can be partitioned in m^m ways. In Step 5, each $P_{j,j+1} \in \mathbb{P}$ takes one of the three values. Thus there can be at most 3^m assignments for a fixed $\mathbb{P}$. Hence total number of tuples generated at the end of Step 6 is bounded by $\mathcal{O}(2^m \cdot m^m \cdot m! \cdot m \cdot m^m \cdot 3^m) \equiv 2^{\mathcal{O}(m \log m)}$. Since $x \leq m$, the probability that we get a coloring that colors all the x cliques properly and distinctly is at least $\frac{1}{m!}$. Once we have a good coloring instance, we formulate the ILP$(\tau, \mathcal{C}_\tau)$ to solve the problem. Since both $|\mathcal{M}|$ and $|\mathcal{X}_{\mathbb{P}}|$ are bounded by $\mathcal{O}(m)$, the ILP can be solved in time $m^{\mathcal{O}(m)}$. This immediately implies a randomized FPT algorithm running in time $2^{\mathcal{O}(m \log m)}$. Notice the randomization step (Phase 2) can be derandomized using (m, x)-universal family [7]. And we have the following theorem.

▶ **Theorem 9.** *(A, ℓ)-Path Packing is FPT parameterized by* cvd(G)+$|A|$.

5 (A, ℓ)-Path Packing Parameterized by cvd$(G) + \ell$

In this section, we design an FPT algorithm for the instance (G, S, A, k, ℓ) of ALPP parameterized by the combined parameter cvd$(G) + \ell$.

(A, ℓ)-Path Packing Problem **Parameter:** $|M| (= m) + \ell$
Input: A graph G, two subsets $A, M \subseteq V$ of cardinality a and m respectively, and integers k and ℓ such that $G - M$ is a cluster graph.
Question: Does there exist k vertex-disjoint paths of length exactly ℓ that have endpoints in A?

We denote the set of cliques in $G - M$ by $\mathcal{Q}$ and the vertices in the cliques by $V_{\mathcal{Q}} = \cup_{Q \in \mathcal{Q}} V(Q)$. Let $\mathcal{I} = (G, M, A, k, \ell)$ be a YES instance of ALPP and let $\mathcal{P}$ be any arbitrary solution for $\mathcal{I}$. We denote the set paths in $\mathcal{P}$ that contain at least one vertex from M by $\mathcal{P}^{\mathrm{M}}$ and the set of paths in $\mathcal{P}$ that are completely inside a clique by $\mathcal{P}^{\mathrm{Q}}$. Note that $\mathcal{P}^{\mathrm{M}} \cap \mathcal{P}^{\mathrm{Q}} = \emptyset$ and $\mathcal{P} = \mathcal{P}^{\mathrm{M}} \cup \mathcal{P}^{\mathrm{Q}}$.

▶ **Observation 10.** *The total number of vertices present in the paths $\mathcal{P}^{M}$ is at most $\ell \cdot m$, i.e. $|\cup_{P \in \mathcal{P}^M} V(P)| \leq \ell \cdot m$.*

Next, we present a marking procedure followed by a few reduction rules to bound the size of each clique.

Marking Procedure.

1. For each vertex $u \in M$, mark $\ell m + 1$ many of its neighbors from both $A \cap V(Q)$ and $V(Q) \setminus A$ for each clique $Q \in \mathcal{Q}$. If any clique does not contain that many neighbors of u, we mark all the neighbors of u in that clique.
2. For each pair of vertices u, v in M, mark $\ell m + 1$ many common neighbors of u and v outside A, in every clique of $\mathcal{Q}$.
3. Additionally, mark $\ell m + 1$ many vertices from both $A \cap V(Q)$ and $V(Q) \setminus A$ for each clique $Q \in \mathcal{Q}$.

In the marking procedure the upper bound on the number of marked vertices for each clique Q from A (in $A \cap V(Q)$) is $f_1(\ell, m) = (m+1)(\ell m + 1)$ and the number of marked vertices outside A (in $V(Q) \setminus A$) is $f_2(\ell, m) = (m^2 + m + 1)(\ell m + 1)$.

Exchange Operation. Consider any two arbitrary paths $P_1, P_2 \in \mathcal{P}$ and $< a_1, a_2, a_3 >$ and $< b_1, b_2, b_3 >$ be any two subsequences of vertices in P_1 and P_2 respectively. Let a_2 be a neighbour of b_1 and b_3 and b_2 be a neighbour of a_1 and a_3. We define the operation *exchange* with respect to P_1, P_2, a_2, and b_2 as follows. We create the path P_1' by replacing the vertex a_2 with b_2, and we create the path P_2' by replacing the vertex b_2 with a_2. Observe that $\mathcal{P} \setminus \{P_1, P_2\} \cup \{P_1', P_2'\}$ also forms a solution.

▶ **Lemma 11.** *There exists a solution $\mathcal{P}$ for (G, M, A, k, ℓ) such that all the vertices in $\mathcal{P}^{M}$ are either from M or are marked.*

Proof. Suppose there is a path P in $\mathcal{P}^{\mathrm{M}}$ that contains an unmarked vertex w. There are at most two neighbors of w in P. We assume here that there are exactly two neighbors of w. The case when w has only one neighbor in P can be argued similarly. Let the neighbors of w in P be w_1 and w_2. We have the following three exhaustive cases.

$\boldsymbol{w_1, w_2 \in V(Q)}$**:** Recall that we have marked an additional $\ell m + 1$ many vertices from outside A in each clique (vertices that w may be replaced with) and from Observation 10, we know at most $m\ell$ many of them are contained in $\mathcal{P}^{\mathrm{M}}$. Thus, there is at least one marked vertex, say, w' in $V(Q)$, that is not contained in any path of $\mathcal{P}^{\mathrm{M}}$. If w' is also not contained in any path of $\mathcal{P}^{\mathrm{Q}}$, we simply replace w by w' in P. If it is in a path $P' \in \mathcal{P}^{\mathrm{Q}}$, we do an *exchange* operation with respect to P, P', w and w' and reconstruct a new solution.

$\boldsymbol{w_1 \in V(Q)}$ **and** $\boldsymbol{w_2 \in M}$**:** Recall that we have marked $\ell m + 1$ many vertices from $N(w_2) \cap V(Q) \setminus A$. From Observation 10, at most $m\ell$ many of them are contained in $\mathcal{P}^{\mathrm{M}}$. Hence, there is at least one marked vertex in $V(Q) \setminus A$ that is not contained in any path from $\mathcal{P}^{\mathrm{M}}$. Similar to the arguments outlined in the previous case, we replace the vertex w by

w' when w' is not contained in any path of $\mathcal{P}^{\mathrm{Q}}$, or perform an *exchange* operation with respect to P, P', w and w' and reconstruct a new solution when w' is contained in some $P' \in \mathcal{P}^{\mathrm{Q}}$.

$\boldsymbol{w_1, w_2 \in M}$**:** Using arguments similar to the previous case, we can again replace an unmarked vertex in $\mathcal{P}^{\mathrm{M}}$ with a marked vertex and reconstruct a new solution for this case as well.

After exhaustively replacing unmarked vertices of $\mathcal{P}^{\mathrm{M}}$ (that are not in M), we derive a solution $\mathcal{P}$ in which paths from $\mathcal{P}^{\mathrm{M}}$ do not include unmarked vertices from the cliques. ◀

Henceforth, we seek for a solution $\mathcal{P}$ for (G, M, A, k, ℓ) such that all the vertices in any path of $\mathcal{P}^{\mathrm{M}}$ are either from M or marked. Next, we have the following reduction rule.

▶ **Reduction Rule 1.** *If there exists a clique Q containing a pair of unmarked vertices $u, v \in A$ and a set X of $(\ell - 2)$ unmarked vertices outside A, then delete u, v along with X and return the reduced instance $(G - \{X \cup \{u, v\}\}, M, A \setminus \{u, v\}, k - 1, \ell)$.*

We prove the safeness of the reduction rule below.

▶ **Lemma 12.** *(G, M, A, k, ℓ) is a* YES *instance if and only if $(G - \{X \cup \{u, v\}\}, M, A \setminus \{u, v\}, k - 1, \ell)$ is a* YES *instance.*

Proof. If $(G - \{X \cup \{u, v\}\}, M, A \setminus \{u, v\}, k - 1, \ell)$ is a YES instance with a solution $\mathcal{P}^R$, then (G, M, A, k, ℓ) is also a YES instance as $\mathcal{P}^R$ along with the path formed by $X \cup \{u, v\}$ forms a solution to the instance.

Conversely, let (G, M, A, k, ℓ) be a YES instance with a solution $\mathcal{P}$. Now, we will obtain a solution $\mathcal{P}'$ for $G - \{X \cup \{u, v\}\}$ of size at least $k - 1$. We denote the paths in $\mathcal{P}$ that intersect with $X \cup \{u, v\}$ by $\mathcal{P}_X$ (with slight abuse of notation). If $|\mathcal{P}_X| \leq 1$ then $\mathcal{P}' = \mathcal{P} \setminus \mathcal{P}_X$ is the desired solution. From now on, we assume that $|\mathcal{P}_X| > 1$. Observe that as the vertices in $X \cup \{u, v\}$ are unmarked, $\mathcal{P}_X \cap \mathcal{P}^{\mathrm{M}} = \emptyset$ (from Lemma 11). We can reconstruct a new solution $\mathcal{P}_1$ from $\mathcal{P}$ where exactly one path P in $\mathcal{P}_1$ intersects $X \cup \{u, v\}$, and the rest of the paths in $\mathcal{P}_1$ do not intersect with $X \cup \{u, v\}$, by repeatedly utilizing the *exchange* operation among the paths in $\mathcal{P}_X$. Observe that $\mathcal{P}' = \mathcal{P}_1 \setminus \{P\}$ is the desired solution. Thus, the claim holds. ◀

Note that the upperbound on the number of marked vertices from $A \cap V(Q)$ is $f_1(\ell, m) = (m+1)(\ell m+1)$ and the number of marked vertices $V(Q) \setminus A$ is $f_2(\ell, m) = (m^2+m+1)(\ell m+1)$. And, after exhaustive application of Reduction Rule 1, in any clique Q, either there are at most $\ell - 3$ unmarked vertices in $V(Q) \setminus A$ or at most one unmarked vertex in $A \cap V(Q)$.

Case (i): There is at most one unmarked vertex in $A \cap V(Q)$.
Case (ii): There are at most $\ell - 3$ unmarked vertices in $V(Q) \setminus A$.

Based on the aforementioned cases, we introduce two reduction rules – one for each case – that help us limit the overall number of unmarked vertices in Q, thereby bounding the size of each clique in $G - M$. First we consider the Case (i) when the number of unmarked vertices form $A \cap V(Q)$ is bounded by one and bound the number of the unmarked vertices in $V(Q) \setminus A$ with the following reduction rule.

▶ **Reduction Rule 2.** *If there exists a clique Q containing at most one unmarked vertex from A and at least $(f_1(\ell, m) + 1) \cdot \frac{\ell}{2} + 1$ unmarked vertices outside A, then delete one unmarked vertex $u \in V(Q) \setminus A$ and return the reduced instance $(G - \{u\}, M, A, k, \ell)$.*

Let $G' = G - \{u\}$ be the new graph following an application of Reduction Rule 2. We prove the safeness of the reduction rule in the following lemma.

▶ **Lemma 13.** *(G, M, A, k, ℓ) is a* YES *instance if and only if (G', M, A, k, ℓ) is a* YES *instance.*

Proof. If (G', M, A, k, ℓ) is a YES instance, then (G, M, A, k, ℓ) is a YES instance since G' is a subgraph of G. Conversely, suppose (G, M, A, k, ℓ) is a YES instance, and $\mathcal{P}$ is a solution. If u does not belong to any path in $\mathcal{P}$, then $\mathcal{P}$ is a solution to (G', M, A, k, ℓ) as well. Otherwise, let $P \in \mathcal{P}^{\mathrm{Q}}$ contain u. This is true since any unmarked vertex can only be used in a path in $\mathcal{P}^{\mathrm{Q}}$. But any such path uses exactly 2 vertices from $V(Q) \cap A$. Hence we can upper bound the number of unmarked vertices outside A that are contained in $\mathcal{P}^{\mathrm{Q}}$ and hence $\mathcal{P}$ by $(f_1(\ell, m) + 1) \cdot \frac{\ell}{2}$. Hence, there is at least one unmarked vertex $u' \neq u$ in $V(Q) \setminus A$ which is not used by any path in $\mathcal{P}$. We replace u with u' in P to get a desired solution to (G', M, A, k, ℓ). ◀

For the Case (ii) when the number of unmarked vertices form $V(Q) \setminus A$ is bounded by $l - 3$ and we bound the number of the unmarked vertices in $V(Q) \cap A$ with the following reduction rule.

▶ **Reduction Rule 3.** *If there exists a clique Q containing at most $\ell-3$ unmarked vertices from $V(Q) \setminus A$ and at least $(f_2(\ell, m) + (\ell - 3)) \cdot \frac{1}{\ell-2} + 1$ many unmarked vertices in A, then delete an unmarked vertex $u \in A \cap Q$ and return the reduced instance $(G - \{u\}, M, A \setminus \{u\}, k, \ell)$.*

Proof. If $(G - \{u\}, M, A \setminus \{u\}, k, \ell)$ is a YES instance, then (G, M, A, k, ℓ) is trivially a YES instance since G' is a subgraph of G. Conversely, suppose (G, M, A, k, ℓ) is a YES instance, and $\mathcal{P}$ is a solution. If u does not belong to any path in $\mathcal{P}$, then $\mathcal{P}$ is a solution to (G', M, A, k, ℓ) as well. Otherwise, let $P \in \mathcal{P}^{\mathrm{Q}}$ contain u. This is true since any unmarked vertex can only be used in a path in $\mathcal{P}^{\mathrm{Q}}$. But any such path uses exactly $\ell - 2$ vertices from $V(Q) \cap A$. Hence we can upper bound the number of unmarked vertices from A that are contained in $\mathcal{P}^{\mathrm{Q}}$ and hence $\mathcal{P}$ by $(f_2(\ell, m) + (\ell - 3)) \cdot \frac{1}{\ell-2}$. Hence, there is at least one unmarked vertex $u' \neq u$ in $V(Q) \cap A$ which is not used by any path in $\mathcal{P}$. We replace u with u' in P to get a desired solution to (G', M, A, k, ℓ). ◀

After exhaustive application of Reduction Rules 2 and 3, the upper bound on the number of vertices of different types in each clique is as follows:

- Marked vertices in A: $f_1(\ell, m) = (m + 1)(\ell m + 1)$
- Marked vertices in $V(Q) \setminus A$: $f_2(\ell, m) = (m^2 + m + 1)(\ell m + 1)$
- Unmarked vertices in A: $(f_2(\ell, m) + (\ell - 3)) \cdot \frac{1}{\ell-2} + 2$
- Unmarked vertices in $V(Q) \setminus A$: $(f_1(\ell, m) \cdot \ell + 1$

Hence the total number of vertices in each clique is bounded by $\mathcal{O}(\ell^2 m^2 + \ell m^3)$.

Equivalent cliques. Now we aim to bound the number of cliques by introducing the concept of *equivalent* cliques. Two cliques Q_i and Q_j, are equivalent (belong to the same *equivalent class*) if and only if the number of vertices from the cliques that are in A, and that are outside A with an exact neighborhood of $M' \subseteq M$ is same for each $M' \in 2^M$. Two cliques Q_i, Q_j in an equivalence class are essentially *indistinguishable* from each other, i.e., there is a bijective mapping $g_{ij} : V(Q_i) \mapsto V(Q_j)$, so that $N(u) \cap M = N(g(u)) \cap M$, for all $u \in V(Q_i)$. This fact is crucial in the construction of our next reduction rule. Observe that the number of equivalence classes is at most $\mathcal{O}(\ell^2 m^2 + \ell m^3)^{2^m}$=$f(\ell, m)$. The following reduction rule bounds the number of cliques in each equivalent class.

▶ **Reduction Rule 4.** *If there exists an equivalent class $\mathcal{C}$ with at least $\ell m + 1$ cliques, then delete one of the cliques $Q_i \in \mathcal{C}$ and return the reduced instance $(G - Q_i, M, A \setminus (A \cap V(Q_i)), k - x_i, \ell)$ where, $x_i = \min\left\{\frac{|A \cap V(Q_i)|}{2}, \frac{|V(Q_i) \setminus A|}{\ell - 2}\right\}$.*

▶ **Lemma 14.** *(G, M, A, k, ℓ) is a* YES *instance if and only if $(G - Q_i, M, A \setminus (A \cap V(Q_i)), k - x_i, \ell)$ is a* YES *instance.*

Proof. In the forward direction, let (G, M, A, k, ℓ) be a YES instance. Recall that the number of the vertices contained in paths of $\mathcal{P}_M$ for any optimal solution $\mathcal{P}$ is bounded by ℓs. Thus, there are at most ℓm many cliques in total and also from any equivalence class that has vertices in paths from $\mathcal{P}_M$. Let Q_j be one such clique in the equivalence class $\mathcal{C}$ that does not contain any vertex in the paths from $\mathcal{P}_M$. From the definition of an equivalence class, it is evident that the two cliques Q_i, Q_j in the equivalence class $\mathcal{C}$ are *indistinguishable* from each other, i.e., there is a bijective mapping $g_{ij} : V(Q_i) \mapsto V(Q_j)$, so that $N(u) \cap M = N(g(u)) \cap M$, for all $u \in V(Q_i)$. Let $X_i = V(\mathcal{P}) \cap V(Q_i)$ and $X_j = V(\mathcal{P}) \cap V(Q_j)$, i.e, the set of vertices from Q_i and Q_j that are used in paths from $\mathcal{P}$, respectively. We construct an alternate solution, $\mathcal{P}'$, where we replace X_i with $g_{ij}(X_i)$ and X_j with $g_{ij}^{-1}(X_j)$ in $\mathcal{P}$. Since $X_j \cap M = \emptyset$, we have $g_{ij}^{-1}(X_j) \cap M = \emptyset$. Therefore in $\mathcal{P}'$, there is no path that contain vertices from both M and $V(Q_i)$. In other words, vertices in Q_i can only be contained in paths from $\mathcal{P}' \setminus \mathcal{P}'_M$ (paths that are completely contained inside the clique). And, the number of such paths is bounded by $x_i = \min\left\{\frac{|A \cap V(Q_i)|}{2}, \frac{|V(Q_i) \setminus A|}{\ell - 2}\right\}$. Hence $(G - Q_i, M, A \setminus (A \cap V(Q_i)), k - x_i, \ell)$ is a YES instance.

In the reverse direction, let $(G - Q_i, M, A \setminus (A \cap V(Q_i)), k - x_i, \ell)$ be a YES instance with a solution $\mathcal{P}$. But there are x_i many paths (say $\mathcal{P}_i$) that are completely contained in Q_i.Hence, $\mathcal{P} \cup \mathcal{P}_i$ is a set of k vertex-disjoint (A, ℓ)-paths contained in G, making (G, M, A, k, ℓ) a YES instance. ◀

After exhaustively applying all the aforementioned reduction rules, the following bounds hold.

- The number of vertices in each clique is bounded by $\mathcal{O}(\ell^2 m^2 + \ell m^3)$.
- The number of equivalence classes is at most $\mathcal{O}(\ell^2 m^2 + \ell m^3)^{2^m}$.
- The number of cliques in each equivalence class is at most $\ell m + 1$.

Consequently, the size of the reduced instance is upper-bounded by a computable function of ℓ and m, thus directly implying the following theorem.

▶ **Theorem 15.** ALPP *parameterized by* $\mathsf{cvd}(G) + \ell$ *admits an algorithm running in FPT time.*

6 (A, ℓ)-Path Packing parameterized by vc(G)

In this section, we design a polynomial kernel for (A, ℓ)-Path Packing parameterized by the size of a vertex cover of the graph.

ALPP **Parameter:** $m = |M|$
Input: An undirected graph $G = (V, E)$, $A, M \subseteq V(G)$ such that M is a vertex cover of G and integers k and ℓ.
Question: Are there k vertex-disjoint A-paths each of length ℓ in G?

For a YES instance (G, M, A, k), a solution $\mathcal{P}$ contains at most $3m$ vertices. This limitation arises because there are no consecutive vertices from $I = V(G) - M$ in any path within $\mathcal{P}$.

▶ **Observation 16.** *Any solution $\mathcal{P}$ to a* YES *instance of (G, M, A, k, ℓ), has at most $3m$ vertices.*

Our kernelization approach comprises the following marking process followed by a reduction rule that bounds the instance size by a polynomial function of m.

Marking Procedure.

1. For each vertex $u \in M$, mark $3m + 1$ many of its neighbors in $I \cap A$. If any vertex $u \in M$ has less than $3m + 1$ neighbors, we mark all of them.
2. For each pair of vertices $u, v \in M$, mark $3m + 1$ many common neighbors in $I \setminus A$ for each clique. If any pair $u, v \in M$ has less than $3m + 1$ common neighbors, we mark all of them.

Now we apply the following reduction rule to eliminate unmarked vertices in I.

▶ **Reduction Rule 5.** *We delete any unmarked vertex $u \in I$ from G, and return the reduced instance $(G - \{u\}, M, A, k, \ell)$.*

Let $G' = G - \{u\}$ be the new graph obtained after an application of Reduction Rule 5. The safeness of the reduction rule is not very difficult to see and will be provided in the full version.

Following the exhaustive application of the Reduction Rule 5, there are $3m + 1$ vertices marked in I for each pair of vertices as well as each individual vertex in M. Consequently, in the reduced instance, $|I|$ is bounded by $\mathcal{O}(m^3)$. As a result, we have the following theorem.

▶ **Theorem 17.** ALPP *parameterized by* vc(G) *admits a kernel with $\mathcal{O}(m^3)$ vertices.*

7 Conclusion

Our results have extended the works of Belmonte et al. [1] by addressing the parameterized complexity status of (A, ℓ)-Path Packing (ALPP) across numerous structural parameters. It was known from Belmonte et al. [1] that ALPP is W[1]-complete when parameterized by pw $+ |A|$. We prove an intractability result for a much larger parameter of dtp$(G) + |A|$. Also, the parameterized complexity of ALPP when parameterized by the combined parameter of cliquewidth and ℓ was an open question [1]. While that problem still remains open, we have been successful in making slight progress by obtaining an FPT algorithm for the problem when parameterized by the combined parameter of cvd(G) and ℓ. Another direction to explore would be to determine the fixed-parameter tractability status of the problem when parameterized by cvd(G) only. It would be interesting to explore if this FPT result can be generalized to the combined parameter of cograph vertex deletion set size and ℓ since cographs are graphs of cliquewidth at most two. We believe that the positive results presented in this paper are not optimal and some of those results can be improved with more involved structural analysis. Therefore, improving the efficiency of our positive results are exciting research direction for future works.

Abstract

Vertex deletion problems for graphs are studied intensely in classical and parameterized complexity theory. They ask whether we can delete at most k vertices from an input graph such that the resulting graph has a certain property. Regarding k as the parameter, a dichotomy was recently shown based on the number of quantifier alternations of first-order formulas that describe the property. In this paper, we refine this classification by moving from quantifier alternations to individual quantifier patterns and from a dichotomy to a trichotomy, resulting in a complete classification of the complexity of vertex deletion problems based on their quantifier pattern. The more fine-grained approach uncovers new tractable fragments, which we show to not only lie in FPT, but even in parameterized constant-depth circuit complexity classes. On the other hand, we show that vertex deletion becomes intractable already for just one quantifier per alternation, that is, there is a formula of the form $\forall x \exists y \forall z(\psi)$, with ψ quantifier-free, for which the vertex deletion problem is W[1]-hard. The fine-grained analysis also allows us to uncover differences in the complexity landscape when we consider different kinds of graphs and more general structures: While basic graphs (undirected graphs without self-loops), undirected graphs, and directed graphs each have a different frontier of tractability, the frontier for arbitrary logical structures coincides with that of directed graphs.

1 Introduction

A recent research topic in parametrized complexity are *distance to triviality problems.* We are asked how many modification steps (the "distance") we need to apply to a logical structure in order to transform it into a "trivial" one – which can mean anything from "no edges at all" to "no cycles" or even more exotic properties like "no cycles of odd length." Such problems have been found highly useful in modern algorithm design [1, 2, 11, 21] and are now an important test bed for new algorithmic ideas and data reduction procedures [14, 15, 22, 23].

Many problems that have been studied thoroughly in the literature turn out to be vertex deletion problems. The simplest example arises from *vertex covers,* which measure the "distance in terms of vertex deletions" of a graph from being edge-free: A graph has a vertex cover of size k iff it can be made edge-free by deleting at most k vertices. For a slightly more complex example, the *cluster deletion problem* asks whether we can delete at most k vertices from a graph so that it becomes a cluster graph, meaning that every connected component is a clique or, equivalently, is P_3-free (meaning, there is no induced path on three vertices). The *feedback vertex set problem* asks if we can delete at most k vertices, such that the resulting graph has no cycles. The *odd cycle transversal problem* asks if there is a set of vertices of size at most k, such that removing it destroys every odd cycle. Equivalently, the problem asks if we can delete at most k vertices, such that the resulting graph is bipartite.

To investigate the complexity of vertex deletion problems in a systematic way, it makes sense to limit the graph properties to have some structure. An early result in this direction [25] is the NP-completeness of vertex deletion to hereditary graph properties that can be tested in polynomial time. Intuitively, vertex deletion problems should be easier to solve for graph properties that are simpler to express. Phrased in terms of descriptive complexity theory, if we can describe a graph property using, say, a simple first-order formula, the corresponding vertex deletion problem should also be simple. The intuition was proven to be correct in 2020, when Fomin et al. [17] established a dichotomy based on the number of quantifier alternations that characterizes the classes of first-order logic formulas for which the vertex deletion problem is fixed-parameter tractable.

The results of Fomin et al. directly apply to some of the above examples: Consider the problem p-VERTEX-COVER, whose "triviality" property is described by the formula $\phi_{\text{vc}} = \forall x \forall y (x \not\sim y)$, or the problem p-CLUSTER-DELETION, whose triviality property is described by $\phi_{\text{cd}} = \forall x \forall y \forall z \big((x \sim y \land y \sim z) \to x \sim z\big)$. Both first-order formulas use *no quantifier alternations,* which by [17] already implies that the problems lie in para-P = FPT. Naturally, not all problems can be characterized so easily: Properties like acyclicity (which underlies the feedback vertex set problem) cannot be expressed in first-order logic and, thus, the results of Fomin et al. do not apply to them. Fomin et al. also show that if there are enough quantifier alternations (three, to be precise) in the first-order formulas describing the property, then the resulting vertex deletion problem can be W[1]-hard. Nevertheless, the descriptive approach allows us to identify large fragments of logical formulas and hence large classes of vertex deletion problems that are (at least fixed-parameter) tractable.

A first central question addressed in the present paper is whether the number of quantifier *alternations* (the property studied in [17]) overshadows all other aspects in making problems hard, or whether the individual quantifier pattern of the formula plays a significant role as well. This question appears to be of particular importance given that formulas describing natural problems (like ϕ_{vc} and ϕ_{cd} above) tend to have short and simple quantifier patterns: We might hope that even though we describe a particular triviality property using, say, four alternations, the fact that we use only, say, two existential quantifiers in total still assures us that the resulting vertex deletion problem is easy.

A second central question is whether the *kind* of graphs that we allow as inputs has an influence on the complexity of the problem. Intuitively, allowing only, say, *basic graphs* (simple undirected graphs without self-loops) should result in simpler problems than allowing directed graphs or even arbitrary logical structures as input. This intuition is known to be correct in the closely related question of deciding graph properties described in existential second-order logic. As we will see, in the context of vertex deletion problems it makes a difference whether we consider basic graphs, undirected graphs, or directed graphs, but not whether we consider directed graphs or arbitrary logical structures.

Our Contributions. We completely classify the parameterized complexity of vertex deletion problems in dependence of the quantifier pattern of the formulas that are used to express the triviality property and also in dependence of the kind of graphs that we allow as inputs (basic, undirected, directed, or arbitrary logical structures). An overview of the results is given in Table 1, where the following notations are used (detailed definitions are given later): For a first-order formula ϕ over the vocabulary $\tau = \{\sim^2\}$ of (directed, simple) graphs, the parameterized problem p_k-VERTEX-DELETION$_{\text{dir}}(\phi)$ (abbreviated p-VD$_{\text{dir}}(\phi)$) asks us to tell on input of a directed graph G and a parameter $k \in \mathbb{N}$ whether we can delete at most k vertices from G, so that for the resulting graph G' we have $G' \models \phi$. The problems p-VD$_{\text{undir}}(\phi)$ and p-VD$_{\text{basic}}(\phi)$ are the restrictions where the input graphs are undirected or basic graphs (undirected graphs without self-loops), respectively. For instance, p-VERTEX-COVER = p-VD$_{\text{basic}}(\phi_{\text{vc}})$ = p-VD$_{\text{basic}}\big(\forall x \forall y (x \not\sim y)\big)$. In the other direction, let p-VD$_{\text{arb}}(\phi)$ denote the generalization where we allow an arbitrary logical vocabulary τ and arbitrary (finite) logical structures $\mathcal{A}$ instead of just graphs G (and where "vertex deletion" should better be called "element deletion," but we stick with the established name). For a *(first-order) quantifier pattern p*, which is just a string of a's and e's standing for the universal and existential quantifiers at the beginning of a formula ϕ, we write p-VD$_{\text{basic}}(p)$ for the class of all problems p-VD$_{\text{basic}}(\phi)$ where ϕ has all its quantifiers at the beginning and they form the pattern p. For instance, p-VERTEX-COVER $\in$ p-VD$_{\text{basic}}(aa)$ as ϕ_{vc} has two universal quantifiers. The same notation is used for undirected graphs, directed graphs, and arbitrary structures.

Table 1 Complete complexity classification of vertex deletion problems for first-order formulas in dependence of the quantifier pattern $p \in \{a, e\}^*$ (where $p \preceq q$ means that p is a subsequence of q). The four different considered restrictions on the allowed input structures lead to three distinct complexity landscapes. Note that para-AC$^0 \subsetneq$ para-AC$^{0\uparrow} \subseteq$ para-P = FPT holds and that it is a standard assumption that FPT $\cap$ W[2]-hard $= \emptyset$ also holds.

p-VD$_{\text{basic}}(p)$	$\subseteq$ para-AC^0, when	$p \preceq e^*a^*$ or eae.
	$\not\subseteq$ para-AC^0 but $\subseteq$ para-AC$^{0\uparrow}$, when	$eeae$, aae or $aee \preceq p \preceq e^*a^*e^*$.
	$\cap$ W[2]-hard $\neq \emptyset$, when	$aea \preceq p$.
p-VD$_{\text{undir}}(p)$	$\subseteq$ para-AC^0, when	$p \preceq ae$ or e^*a^*.
	$\not\subseteq$ para-AC^0 but $\subseteq$ para-AC$^{0\uparrow}$, when	eae, aae or $aee \preceq p \preceq e^*a^*e^*$.
	$\cap$ W[2]-hard $\neq \emptyset$, when	$aea \preceq p$.
p-VD$_{\text{dir}}(p)$ and p-VD$_{\text{arb}}(p)$	$\subseteq$ para-AC^0, when	$p \preceq e^*a^*$.
	$\not\subseteq$ para-AC^0 but $\subseteq$ para-AC$^{0\uparrow}$, when	$ae \preceq p \preceq e^*a^*e^*$.
	$\cap$ W[2]-hard $\neq \emptyset$, when	$aea \preceq p$.

The results in Table 1 give an answer to the first central question formulated earlier, which asked whether it is the *number of alternations* of quantifiers in patterns (and not so much the actual number of quantifiers) that are responsible for the switch from tractable to intractable observed by Fomin et al. [17], or whether the frontier is formed by short patterns that "just happen" to have a certain number of alternations. As can be seen, the latter is true: All intractability results hold already for very short and simple patterns. Thus, while it was previously known that there is a formula in Π_3 (meaning it has a pattern of the form $\forall^*\exists^*\forall^*$ or $a^*e^*a^*$ in our notation) defining an intractable problem, we show that already one quantifier per alternation (the pattern aea) suffices. On the positive side, Table 1 shows that all vertex deletion problems that are (fixed-parameter) tractable at all already lie in the classes para-AC^0 or at least para-AC$^{0\uparrow}$. From an algorithmic point of view this means that all of the vertex deletion problems that we classify as fixed-parameter tractable admit efficient *parallel* fixed-parameter algorithms.

Concerning the second central question, which asked whether it makes a difference which kind of graphs or logical structures we consider, Table 1 also provides a comprehensive answer: First, the *frontier of tractability* (the patterns where we switch from membership in FPT to hardness for W[1]) *is the same for all kinds of inputs* (namely from "does not contain aea as a subsequence" to "contains aea as a subsequence"). Second, if we classify the tractable fragments further, a more complex complexity landscape arises: While p-$\mathrm{VD}_{\mathrm{dir}}(p)$ and p-$\mathrm{VD}_{\mathrm{arb}}(p)$ have the same classification for all p, the classes p-$\mathrm{VD}_{\mathrm{basic}}(p)$ and p-$\mathrm{VD}_{\mathrm{undir}}(p)$ each exhibit a different behavior. In other words: For simple patterns p, it makes a difference whether the inputs are basic, undirected, or directed graphs.

The just-discussed structural results are different from classifications in dependence of quantifier patterns p established in previous works: Starting with Eiter et al. [13] and subsequently Gottlob et al. [20], Tantau [27] and most recently Bannach et al. [3], different authors have classified the complexity of *weighted definability problems* by the quantifier patterns used to describe them. In these problems, formulas have a free set variable and we ask whether there is an assignment to the set variable with at most k elements such that the formula is true. Since it is easy to see that the vertex deletion problems we study are special cases of this question, upper bounds from earlier research also apply in our setting. However, our results show that (as one would hope) for vertex deletion problems for many patterns p we get better upper bounds than in the more general setting. Furthermore, there is an interesting structural insight related to our second central question: While the results in [3] for weighted definability show that, there, the complexities for undirected graphs, directed graphs, and arbitrary logical structures all coincide (but differ for basic graphs), for the vertex deletion setting, we get three different complexity characterizations for basic, undirected, and directed graphs – but the latter coincide with arbitrary structures once more.

Related Work. The complexity-theoretic investigation of vertex deletion problems has a long and fruitful history. Starting in classical complexity theory, results on vertex deletion problems were established as early as in the late 1970s [24, 25, 28]. The focus was mostly on deletion to commonly known graph properties, such as planarity, acyclicity or bipartiteness.

Since it is very natural to regard the number of allowed modifications as the parameter of the problem, the investigation of vertex deletion problems quickly gained traction in parameterized complexity, with continued research to this day [7, 19, 26]. Specifically for graphs, similar problems like the deletion or modification of edges [8] or alternative distance measures such as elimination distance [18] are also considered. Regarding first-order definable properties, a dichotomy is shown in [17].

The quantifier patterns we employ in this paper have also received a lot of attention, especially in the context of descriptive complexity. Early uses go as far back as the classification of decidable fragments of first-order logic [6]. They were then considered in the context of classical complexity [13, 20, 27] and later also in the context of parameterized complexity [3].

Organization of this Paper. Following a review of basic concepts and terminology in Section 2, we present the complexity-theoretic classification of the vertex deletion problems for basic, undirected and directed graphs in Sections 3, 4 and 5, respectively. For theorems and lemmas marked "▼ [4]", the proofs can be found in the full version [4].

2 Background in Descriptive and Parameterized Complexity

Terminology from Finite Model Theory. In this paper, we will use standard terminology from finite model theory, for a thorough introduction, see, for example [12]. A *relational vocabulary* τ (also known as a *signature*) is a set of *relation symbols* to each of which we assign a positive *arity,* denoted using a superscript. For example, $\tau = \{P^1, E^2\}$ is a relational vocabulary with a monadic relation symbol P and a dyadic relation symbol E. A τ*-structure* $\mathcal{A}$ consists of a *universe* A and for each relation symbol $R \in \tau$ of some arity r of a relation $R^{\mathcal{A}} \subseteq A^r$. We denote the set of *finite* τ*-structures* as $\textsc{struc}[\tau]$. For a first-order τ-sentence ϕ, we write $\textsc{models}(\phi)$ for the class of finite models of ϕ. A *decision problem* P is a subset of $\textsc{struc}[\tau]$ which is closed under isomorphisms. A formula ϕ *describes* P if $\textsc{models}(\phi) = P$.

For τ-structures $\mathcal{A}$ and $\mathcal{B}$ with universes A and B, respectively, we say that $\mathcal{A}$ is an *induced substructure* of $\mathcal{B}$ if $A \subseteq B$ and for all r-ary $R \in \tau$, we have $R^{\mathcal{A}} = R^{\mathcal{B}} \cap A^r$. For a set $S \subseteq B$, we denote by $\mathcal{B} \setminus S$ the substructure induced on $B \setminus S$.

We regard *directed* graphs $G = (V, E)$ (which are pairs of a nonempty vertex set V and an edge relation $E \subseteq V \times V$) as logical structures $\mathcal{G}$ over the vocabulary $\tau_{\text{digraph}} = \{\sim^2\}$ where V is the universe and $\sim^{\mathcal{G}} = E$. An *undirected* graph is a directed graph that additionally satisfies $\phi_{\text{undirected}} := \forall x \forall y (x \sim y \to y \sim x)$, while a *basic* graph satisfies $\phi_{\text{basic}} := \forall x \forall y \bigl(x \sim y \to (y \sim x \land x \neq y)\bigr)$.

For a first-order logic formula in prenex normal form (meaning all quantifiers are at the front), we can associate a *quantifier prefix pattern* (or *pattern* for short), which are words over the alphabet $\{e, a\}$.[1] For example, the formula ϕ_{basic} has the pattern aa, while the formula $\phi_{\text{degree-}\geq 2} := \forall x \exists y_1 \exists y_2 \bigl((x \sim y_1) \land (x \sim y_2) \land (y_1 \neq y_2)\bigr)$ has the pattern aee. As another example, the formulas in the class Π_2 (which start with a universal quantifier and have one alternation) are exactly the formulas with a pattern $p \in \{a\}^* \circ \{e\}^*$, which we write briefly as $p \in a^* e^*$. We write $p \preceq q$ if p is a subsequence of q.

Terminology from Parameterized Complexity. We use standard definitions from parameterized complexity, see for instance [9, 10, 16]. A *parameterized problem* is a set $Q \subseteq \Sigma^* \times \mathbb{N}$ for an alphabet Σ. In an *instance* $(x, k) \in \Sigma^* \times \mathbb{N}$ we call x the *input* and k the *parameter.* The central problem we consider in this paper is the following:

▶ **Problem 2.1** ($\text{p-}\textsc{vd}_{\text{arb}}(\phi)$, where ϕ is a first-order τ-formula).

Instance: *(An encoding of) a logical τ-structure $\mathcal{A}$ and an integer $k \in \mathbb{N}$.*
Parameter: *k.*
Question: *Is there a set $S \subseteq A$ with $|S| \leq k$ such that $\mathcal{A} \setminus S \models \phi$?*

As mentioned earlier, we also consider the problems $\text{p-}\textsc{vd}_{\text{basic}}(\phi)$, where the input structures are basic graphs (formally, $\text{p-}\textsc{vd}_{\text{basic}}(\phi) = \text{p-}\textsc{vd}_{\text{arb}}(\phi) \cap \bigl(\textsc{models}(\phi_{\text{basic}}) \times \mathbb{N}\bigr)$), the problems $\text{p-}\textsc{vd}_{\text{undir}}(\phi)$, where the input structures are undirected graphs, and $\text{p-}\textsc{vd}_{\text{dir}}(\phi)$, where the input structures are directed graphs. For a pattern $p \in \{a, e\}^*$, the class $\text{p-VD}_{\text{arb}}(p)$ contains all problems $\text{p-}\textsc{vd}_{\text{arb}}(\phi)$ such that ϕ has pattern p. The classes with the subscripts “basic”, “undir”, and “dir” are defined similarly.

[1] One uses “a” and “e” in patterns rather than “$\forall$” and “$\exists$” since in the context of second-order logic one needs a way to differentiate between first-order and second-order quantifiers and, there, “E” refers to a “second-order $\exists$” while “e” refers to a “first-order $\exists$”. In our paper, we only use first-order quantifiers so only lowercase letters are needed.

We will consider some parameterized circuit complexity classes. We define para-AC^0 as the class of parameterized problems that can be decided by a family of unbounded fan-in circuits $(C_{n,k})_{n,k\in\mathbb{N}}$ of constant depth and size $f(k)\cdot n^{O(1)}$ for some computable function f. Similarly, para-FAC^0 is the class of functions that can be computed by a family of unbounded fan-in circuits $(C_{n,k})_{n,k\in\mathbb{N}}$ of constant depth and size $f(k)\cdot n^{O(1)}$ for some computable function f. For para-AC$^{0\uparrow}$, we allow the circuit to have depth $f(k)$. Questions of uniformity will not be important in the present paper. For these classes, we have the following inclusions: para-AC^0 $\subsetneq$ para-AC$^{0\uparrow}$ $\subseteq$ para-P = FPT.

A parameterized problem $Q\subseteq\Sigma^*\times\mathbb{N}$ is para-AC^0-many-one-reducible to a problem $Q'\subseteq\Gamma^*\times\mathbb{N}$, written $Q\leq_{\text{m}}^{\text{para-AC}^0} Q'$, if there is a function $f\colon\Sigma^*\times\mathbb{N}\to\Gamma^*\times\mathbb{N}$, such that (1) for all $(x,k)\in\Sigma^*\times\mathbb{N}$ we have $(x,k)\in Q$ iff $f(x,k)\in Q'$, (2) there is a computable function $g\colon\mathbb{N}\to\mathbb{N}$ such that for all $(x,k)\in\Sigma^*\times\mathbb{N}$, we have $k'\leq g(k)$, where $f(x,k)=(x',k')$, and (3) $f\in$ para-FAC^0. The more general para-AC^0 disjunctive truth table reduction, written $Q\leq_{\text{dtt}}^{\text{para-AC}^0} Q'$, is defined similarly, only f maps (x,k) to a sequence $(x_1,k_1),\dots,(x_\ell,k_\ell)$ of instances such that (1$'$) $(x,k)\in Q$ iff there is an $i\in\{1,\dots,\ell\}$ with $(x_i,k_i)\in Q'$ and (2$'$) $k_i\leq g(k)$ holds for all $i\in\{1,\dots,\ell\}$. Both para-AC^0 and para-AC$^{0\uparrow}$ are closed under $\leq_{\text{m}}^{\text{para-AC}^0}$- and $\leq_{\text{dtt}}^{\text{para-AC}^0}$-reductions.

3 Basic Graphs

Basic graphs, that is, undirected graphs without self-loops, are one of the simplest non-trivial logical structures one can imagine. Despite that, many NP-hard problems on graphs, like vertex cover, clique or dominating set, are NP-hard even for basic graphs. This also transfers in some sense to our setting: The "tractability frontier", the dividing line between the fragments which are tractable and those where we can express intractable problems, is the same for all graph classes we consider. However, when we shift our attention to the complexity landscape inside the tractable fragments, we also see that the complexity of the logical structure has an impact on the complexity of the problems we can define: Basic, undirected, and directed graphs all have provably distinct complexity characterizations.

We begin by stating the main theorem of the section, the complexity classification for basic graphs. In the rest of the section, we show the upper and lower bounds that lead to this classification.

▶ **Theorem 3.1** (Complexity Trichotomy for p-VD$_{\text{basic}}(p)$). *Let $p\in\{a,e\}^*$ be a pattern.*

1. p-VD$_{\text{basic}}(p)$ $\subseteq$ para-AC^0, *if $p\preceq eae$ or $p\preceq e^*a^*$.*
2. p-VD$_{\text{basic}}(p)$ $\subseteq$ para-AC$^{0\uparrow}$ *but* p-VD$_{\text{basic}}(p)$ $\not\subseteq$ para-AC^0, *if $eeae\preceq p$, $aae\preceq p$ or $aee\preceq p$ holds, but also still $p\preceq e^*a^*e^*$.*
3. p-VD$_{\text{basic}}(p)$ *contains a* W[2]*-hard problem, if $aea\preceq p$.*

The theorem covers all possible patterns. It follows from the following lemma, where we state the individual complexity characterizations we will prove:

▶ **Lemma 3.2** (Detailed Bounds for p-VD$_{\text{basic}}(p)$).

1. p-VD$_{\text{basic}}(eae)$ $\subseteq$ para-AC^0.
2. p-VD$_{\text{basic}}(e^*a^*)$ $\subseteq$ p-VD$_{\text{arb}}(e^*a^*)$ $\subseteq$ para-AC^0.
3. p-VD$_{\text{basic}}(e^*a^*e^*)$ $\subseteq$ p-VD$_{\text{arb}}(e^*a^*e^*)$ $\subseteq$ para-AC$^{0\uparrow}$.
4. p-VD$_{\text{basic}}(eeae)$ *contains a problem not in* para-AC^0.
5. p-VD$_{\text{basic}}(aae)$ *contains a problem not in* para-AC^0.
6. p-VD$_{\text{basic}}(aee)$ *contains a problem not in* para-AC^0.
7. p-VD$_{\text{basic}}(aea)$ *contains a* W[2]*-hard problem.*

Notice that in particular, we know unconditionally that $\mathrm{W}[2] \not\subseteq \text{para-AC}^0$, and, hence, a W[2]-hard problem cannot lie in para-AC^0. It is furthermore widely conjectured that $\mathrm{W}[2] \not\subseteq \text{para-AC}^{0\uparrow}$, as $\text{para-AC}^{0\uparrow} \subseteq \text{FPT}$. We devote the rest of this section to proving the individual items of the lemma.

Upper Bounds. Previous work by Bannach et al. [3] showed that in the weighted definability setting, formulas with the pattern ae already suffice to describe W[2]-hard problems. We now show that the situation is more favorable in the vertex deletion setting, which is a special case of weighted definability: All problems in $\text{p-VD}_{\text{basic}}(e^*a^*e^*)$ are tractable and the problems in $\text{p-VD}_{\text{basic}}(e^*a^*)$ and in $\text{p-VD}_{\text{basic}}(eae)$ are even in para-AC^0, the smallest class commonly considered in parameterized complexity. We start with the last claim:

▶ **Lemma 3.3** (▼ [4]). $\text{p-VD}_{\text{basic}}(eae) \subseteq \text{para-AC}^0$.

Proof idea. To check whether we can delete at most k vertices to satisfy a formula with prefix pattern eae, we first branch over the possible assignments to the first existentially quantified variable. Now, the neighborhood of this variable induces a 2-coloring on the rest of the graph. For the rest of the prefix, ae, we prove that a vertex has to be deleted if and only if there is no special set of constant size, called *stable set*. This can all be checked in para-AC^0. ◀

Since the algorithms used to prove the next two upper bounds do not make use of the fact that the input structure is a basic graph, we prove them for arbitrary input structures.

▶ **Lemma 3.4.** $\text{p-VD}_{\text{arb}}(e^*a^*) \subseteq \text{para-AC}^0$.

Proof. For a given formula ϕ of the form $\exists x_1 \cdots \exists x_f \forall y_1 \cdots \forall y_g(\psi)$ for a quantifier-free formula ψ, we show that $\text{p-VD}_{\text{arb}}(\phi) \leq_{\text{dtt}}^{\text{para-AC}^0}$ p-g-HITTING-SET, where the hitting set problem is defined as shown below. Since p-g-HITTING-SET is known [5] to lie in para-AC^0, we get the claim.

▶ **Problem 3.5** (p-d-HITTING-SET for fixed $d \in \mathbb{N}$).

Instance: *A universe U and a set E of subsets $e \subseteq U$ (called* hyperedges*) with $|e| \leq d$ for all $e \in E$, and a number k.*

Parameter: k.

Question: *Is there a* hitting set *$X \subseteq V$, meaning that $X \cap e \neq \emptyset$ holds for all $e \in E$, with $|X| \leq k$?*

For an arbitrary input structure $\mathcal{A}$ with universe A, we proceed as follows: For the existentially bound variables x_1 to x_f we consider all possible assignments to them in parallel. For each of these, we prepare a query to the hitting set problem, resulting in n^f queries in total. For a given assignment, which fixes each x_i to some constant c_i, replace each occurrence of x_i in ϕ by c_i. Build a hitting set instance H as follows: The universe is $A \setminus \{c_1, \dots, c_f\}$. For each assignment $(d_1, \dots, d_g)$ of to the g universally quantified variables, check if the formula ψ is true, that is, whether $\mathcal{A} \models \psi(c_1, \dots, c_f, d_1, \dots, d_g)$. If this is not the case, add the hyperedge $\{d_1, \dots, d_g\} \setminus \{c_1, \dots, c_f\}$ to make sure that at least one element is deleted from the universe of $\mathcal{A}$ that cause this particular violation. If $\{d_1, \dots, d_g\} \setminus \{c_1, \dots, c_f\}$ is empty, an empty hyperedge is generated and the hitting set solver correctly rejects the input.

We claim that $\mathcal{A} \in \text{p-VD}_{\text{arb}}(\phi)$ iff for at least one of the constructed H we have $(H, k) \in$ p-g-HITTING-SET: For the first direction, let S with $|S| \leq k$ be the elements of $\mathcal{A}$'s universe that we can delete, that is, for which $\mathcal{A} \setminus S \models \phi$. Then there are constants $(c_1, \dots, c_f)$ that we can assign to the existentially bound variables such that $\mathcal{A} \setminus S \models \forall y_1 \cdots \forall y_g \big(\psi(c_1, \dots, c_f, y_1, \dots, y_g)\big)$. But, then, S is a hitting set of the instance corresponding to these constants: If there were an edge $e \subseteq A$ with $e \cap S = \emptyset$ in the hitting set instance, there would be an assignment to the y_i to elements in $A \setminus S$ that makes ψ false, violating the assumption.

For the other direction, let X with $|X| \leq k$ be the solution of one of the produced hitting set instances with $(H, k) \in$ p-g-HITTING-SET (at least one must exist). Then $\mathcal{A} \setminus X \models \phi$, since we can assign the existentially bound variables to the values that correspond to H (which will not be in X by construction) and there can be no assignment to the universally quantified variables that makes ψ false as any assignment where this would be case is hit by X by construction and, thus, at least one element of the tuple that causes the violation gets removed in $\mathcal{A} \setminus X$. ◀

▶ **Lemma 3.6.** p-$\mathrm{VD}_{\mathrm{arb}}(e^*a^*e^*) \subseteq$ para-$\mathrm{AC}^{0\uparrow}$.

Proof. Let ϕ be fixed and of the form $\exists x_1 \cdots \exists x_f \forall y_1 \cdots \forall y_g \exists z_1 \cdots \exists z_h(\psi)$ for a quantifier-free formula ψ. We describe a para-$\mathrm{AC}^{0\uparrow}$-algorithm that, given an arbitrary input structure $\mathcal{A}$ with universe A, decides whether there is a set S with $|S| \leq k$ such that $\mathcal{A} \setminus S \models \phi$.

Now, we have for each assignment to the universally quantified variables a witness which is bound by the block of h existential quantifiers. The problem compared to the e^*a^*-fragment is that by the deletion of elements, we could potentially destroy witnesses needed to satisfy other assignments. Because of this, we use a direct search tree algorithm to resolve violations of the universal quantifiers.

In detail, we once more consider all possible assignments $(c_1, \dots, c_f)$ to the x_i in parallel. Then we use k layers to find and resolve violations: At the start of each layer, we will already have fixed a set D of vertices that we wish to delete, starting in the first layer with $D = \emptyset$. Then in the layer, we find the (for example, lexicographically) first assignment of the y_i to elements $(d_1, \dots, d_f)$ that all lie in $A \setminus D$ for which we cannot find an assignment of the z_i to elements $(e_1, \dots, e_h)$ in $A \setminus D$ such that $\mathcal{A} \setminus D \models \psi(c_1, \dots, c_f, d_1, \dots, d_g, e_1, \dots, e_h)$. When we cannot find such an assignment, we can accept since we have found a D for which $\mathcal{A} \setminus D \models \phi$ holds. Otherwise, we *have to* delete one of the elements in $\{d_1, \dots, d_g\} \setminus \{c_1, \dots, c_f\}$ to make the formula true, so we branch over these at most g possibilities, entering g copies of the next layers, where the ith copy starts with $D \cup \{d_i\}$.

Since the block of universal quantifiers has constant length, the number of branches in each level of the search tree is constant, so the total size of the search tree is at most g^k. The depth of the search tree is bounded by the number of vertices we can delete, which is our parameter. In total, we get a para-$\mathrm{AC}^{0\uparrow}$ circuit. ◀

Lower Bounds. We now go on to show the lower bounds claimed in Lemma 3.2. The next lemmas all follow the same rough strategy: To show that some problems that can be expressed in the given fragments are (unconditionally) not in para-AC^0, we reduce from a variant of the reachability problem. In contrast, the last lower bound is obtained via a reduction from p-SET-COVER, and improves a result from Fomin et al. [17]. They establish that there is a formula $\phi \in \Pi_3$, such that p-$\mathrm{VD}_{\mathrm{basic}}(\phi)$ is W[2]-hard. In terms of patterns, the formula they construct has the pattern $a^5e^{26}a$. We show that there is a formula with pattern aea for which this holds.

The reachability problem that will be central for the following lower bounds is:

▶ **Problem 3.7** (p-MATCHED-REACH).

Instance: *A directed layered graph G with vertex set $\{1, \dots, n\} \times \{1, \dots, k\}$, where the ith layer is $V_i := \{1, \dots, n\} \times \{i\}$, such that for each $i \in \{1, \dots, k-1\}$ the edges point to the next layer and they form a perfect matching between V_i and V_{i+1}; and two designated vertices $s \in V_1$ and $t \in V_k$.*
Parameter: *k.*
Question: *Is t reachable from s in G?*

(We require that in the encoding of G the vertex "addresses" (i, l) are given explicitly as, say, pairs of binary numbers, so that even a AC^0 circuit will have no trouble determining which vertices belong to a layer V_i or what the number k of layers is.)

Observe that the input instance can be alternatively described as a collection of n directed paths, each of length k. We call the paths in this graph *original paths* with *original vertices and edges*. We call the vertices in the layers V_1 and V_k the *outer vertices* and the vertices in the layers V_i for $i \in \{2, \dots, k-1\}$ the *inner vertices*. The reductions add vertices and edges to the graphs, which will be referred to as the *new vertices and edges* (and will be indicated in yellow in figures).

▶ **Fact 3.8** ([3]). *p-MATCHED-REACH $\notin$ para-AC^0 and, thus, for any problem Q with p-MATCHED-REACH $\leq_{\mathrm{m}}^{\text{para-AC}^0}$ Q we have $Q \notin$ para-AC^0.*

The proof of every lemma using a reduction from the matched reachability problem will consist of four parts:

1. The construction of a formula ϕ with the quantifier pattern p given in the lemma.
2. The construction of the instance for the vertex deletion problem (G', k') from the input instance of the matched reachability problem (G, s, t) (typically by adding new vertices and edges).
3. Showing $(G, s, t) \in$ p-MATCHED-REACH implies $(G', k') \in \text{p-VD}_{\text{basic}}(\phi)$, called the *forward direction.*
4. Showing $(G', k') \in \text{p-VD}_{\text{basic}}(\phi)$ implies $(G, s, t) \in$ p-MATCHED-REACH, called the *backward direction.*

We present the application of the above steps in detail in the following lemma. In subsequent lemmas, which follow the same line of arguments, but with appropriate variations in the constructions and correctness proofs, we only highlight the differences.

▶ **Lemma 3.9.** $\text{p-VD}_{\text{basic}}(eeae) \not\subseteq \text{para-AC}^0$.

Proof. We want there to be a deletion strategy for (G', k') iff in the instance (G, s, t), the vertices s and t lie on the same original path. We take $k' = k$, the number of layers in G, and construct a graph G' from G by adding two special vertices c_1 and c_2, and regard the adjacency of every vertex on the original paths to the vertices c_1 and c_2 as a 3-coloring with colors $i \in \{0, 1, 2\}$. We then add appropriate gadgets at the start and the end of each original path, with special gadgets being added at s and at t (although, in this proof, their "special gadgets" are just the empty gadget).

The formula. Consider the following formulas, where ϕ_a specifies that every vertex that is neither c_1 nor c_2 should be connected in a certain way to them, and ϕ_b asks that every vertex of color i should have a neighbor of color $(i-1) \pmod 3$. We encode the color 0 with $(x \sim c_1 \land x \not\sim c_2)$, the color 1 with $(x \not\sim c_1 \land x \sim c_2)$, and the color 2 with $(x \sim c_1 \land x \sim c_2)$.

$$
\begin{aligned}
\phi_a(c_1,c_2,x) &= (c_1 \neq c_2) \wedge (c_1 \sim x \vee c_2 \sim x)\\
\phi_b(c_1,c_2,x,y) &= x \sim y \wedge \big((x \sim c_1 \wedge x \sim c_2) \to (y \not\sim c_1 \wedge y \sim c_2)\big)\\
&\qquad \wedge \big((x \not\sim c_1 \wedge x \sim c_2) \to (y \sim c_1 \wedge y \not\sim c_2)\big)\\
&\qquad \wedge \big((x \sim c_1 \wedge x \not\sim c_2) \to (y \sim c_1 \wedge y \sim c_2)\big)\\
\phi_{3.9} &= \exists c_1 \exists c_2 \forall x \exists y \Big(\big((x \neq c_1) \wedge (x \neq c_2)\big) \to\\
&\qquad\qquad \big((y \neq c_1) \wedge (y \neq c_2) \wedge\\
&\qquad\qquad\; \phi_a(c_1,c_2,x) \wedge \phi_b(c_1,c_2,x,y)\big)\Big)
\end{aligned}
$$

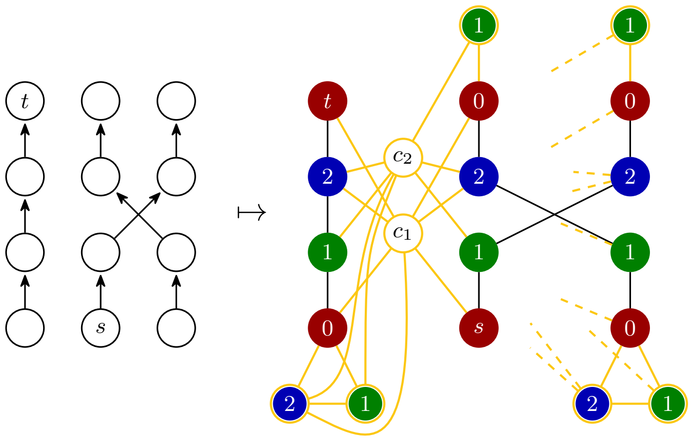

Figure 1 Example for the reduction from Lemma 3.9. The input graph on the left is a directed layered graph with perfect matchings between consecutive layers. The reduction maps it to the undirected graph shown right by forgetting about the direction of edges, by adding gadgets at the beginnings and ends of the paths (with special empty gadgets at s and t), and by adding two special vertices c_1 and c_2 that are connected in three different ways to the other vertices, corresponding to three different colors. Newly added vertices and edges are indicated in yellow. Note that the indicated colors, numbers, and labels are not part of the output, they are only for explaining how the formula interprets the connection of the vertices to c_1 and c_2.

The reduction. On input (G, s, t) the reduction first checks that the graph is, indeed, a layered graph with perfect matchings between consecutive levels (this can easily be done by an AC^0 circuit due to the way we encode G). Then, we let k' be the number k of layers in $G = (V, \sim)$ and construct $G' = (V', \sim')$ by first forgetting about the direction of the edges (making the graph undirected). We then add the following gadgets:

1. At each end $v \in V_k$ of a path, *except for* $v = t$, we add a vertex v' to V' and connect v to v', so $v \sim' v'$. Let V_{k+1} be the set of all new vertices added in this way. The gadget for $t \in V_k$ is empty: We do not add anything.
2. At each beginning $v \in V_1$ of a path, *except for* $v = s$, add two vertices v' and v'' to V' and connect the three vertices to a triangle, so $v \sim' v' \sim' v'' \sim' v$. Let V_0 contain all vertices v' added in this way and let V_{-1} contain all vertices v'' added in this way. Once more, the special gadget for $s \in V_1$ is just the empty gadget.
3. Finally, we add two further vertices c_1 and c_2 and connect them to the other vertices as follows: For $v \in V_i$ with $i \in \{-1, 0, 1, 2, \ldots, k + 1\}$:

- If $i \equiv 0 \mod 3$, let $c_1 \sim' v$.
- If $i \equiv 1 \mod 3$, let $c_2 \sim' v$.
- If $i \equiv 2 \mod 3$, let $c_1 \sim' v$ and $c_2 \sim' v$.

An example for the reduction is depicted in Figure 1. We claim that through this construction, the instance (G', k') is in p-VD$_{\text{basic}}(\phi_{3.9})$ iff the input graph with vertices s and t is in p-MATCHED-REACH:

Forward direction. Suppose that $(G, s, t) \in$ p-MATCHED-REACH. We show that $(G', k') \in$ p-VD$_{\text{basic}}(\phi_{3.9})$: In input G', just delete every vertex in the original s-t-path. Then every vertex $v \in V_i$ for $i \in \{2, \dots, k\}$ has its predecessor in the original path as a neighbor, and the predecessor has the previous color regarding the ordering. Furthermore, every vertex $v \in V_1$ is part of a triangle where the three vertices each have a different color, so every one of these three vertices has a neighbor of the previous color.

Backward direction. Suppose that $(G', k') \in$ p-VD$_{\text{basic}}(\phi_{3.9})$. We show that $(G, s, t) \in$ p-MATCHED-REACH. By assumption, there is a set D of size $|D| \leq k = k'$ such that $G' \setminus D$ is a model of $\phi_{3.9}$. Observe that $c_1 \notin D$ and $c_2 \notin D$ must hold since they are the only vertices satisfying the formula part ϕ_a, which requires that there are two different vertices that are connect to everyone else. On the other hand, we *have to* delete s, since by construction, it has no neighbor with the previous color (s has color 0, the successor of s has color 1). But, now, the successor of s has no neighbor of the previous color, so we have to delete it as well. We have to continue for the whole original path of s, so D has to contain at least the vertices on the original path starting at s, which encompasses k vertices. If the last vertex $v \in V_k$ on the original path starting at s is not t (that is, if t is not reachable from s), then there is another vertex $v' \in V_{k+1}$ with $v \sim' v'$ and we also have to delete v', contradicting the assumption that we only have to delete k vertices. Thus, t must be reachable from s. ◀

▶ **Lemma 3.12** (▼ [4]). p-VD$_{\text{basic}}(aea)$ *contains a* W[2]*-hard problem.*

4 Undirected Graphs

Whether allowing self-loops has an impact on the complexity of the problems is hard to predict: While in the setting of Fomin et al. [17], the same dichotomy arises for basic and undirected graphs, in the setting of weighted definability considered by Bannach et al. [3], one class of problems jumps from being contained in para-AC^0 to containing para-NP-hard problems just by allowing self-loops. In our setting, we get an *intermediate* blow-up of the complexities by allowing self-loops: While the tractability frontier stays the same, the frontier of fragments that are solvable in para-AC^0 shifts.

Let us now classify the complexity of vertex deletion problems on undirected graphs. We can use some of the upper and lower bounds established in the section before, and only consider the differences.

▶ **Theorem 4.1** (Complexity Trichotomy for p-VD$_{\text{undir}}(p)$). *Let $p \in \{a, e\}^*$ be a pattern.*

1. p-VD$_{\text{undir}}(p) \subseteq$ para-AC^0*, if $p \preceq ae$ or $p \preceq e^*a^*$.*
2. p-VD$_{\text{undir}}(p) \subseteq$ para-AC$^{0\uparrow}$ *but* p-VD$_{\text{undir}}(p) \not\subseteq$ para-AC^0*, if one of $eae \preceq p$, $aae \preceq p$ or $aee \preceq p$ holds, but still $p \preceq e^*a^*e^*$ holds.*
3. p-VD$_{\text{undir}}(p)$ *contains a* W[2]*-hard problem, if $aea \preceq p$.*

▶ **Lemma 4.2.**

1. $\text{p-VD}_{\text{undir}}(ae) \subseteq \text{para-AC}^0$.
2. $\text{p-VD}_{\text{undir}}(e^*a^*) \subseteq \text{para-AC}^0$.
3. $\text{p-VD}_{\text{undir}}(e^*a^*e^*) \subseteq \text{para-AC}^{0\uparrow}$.
4. $\text{p-VD}_{\text{undir}}(eae)$ *contains a problem not in* para-AC^0.
5. $\text{p-VD}_{\text{undir}}(aae)$ *contains a problem not in* para-AC^0.
6. $\text{p-VD}_{\text{undir}}(aee)$ *contains a problem not in* para-AC^0.
7. $\text{p-VD}_{\text{undir}}(aea)$ *contains a* $\text{W}[2]$*-hard problem.*

Proof. Item 1 is proven below in Lemma 4.3. Items 2 and 3 follow directly from Lemmas 3.4 and 3.6. Item 4 is proven below in Lemma 4.4, Item 5 follows from Lemma 3.10, Item 6 from Lemma 3.11 and Item 7 from Lemma 3.12. ◀

▶ **Lemma 4.4** (▼ [4]). $\text{p-VD}_{\text{undir}}(eae) \nsubseteq \text{para-AC}^0$.

5 Directed Graphs and Arbitrary Structures

The final class of logical structures we investigate in this paper are directed graphs. Interestingly, from the viewpoint of quantifier patterns, this class of structures is as complex as arbitrary logical structures.

▶ **Theorem 5.1** (Complexity Trichotomy for $\text{p-VD}_{\text{dir}}(p)$). *Let $p \in \{a, e\}^*$ be a pattern.*

1. $\text{p-VD}_{\text{dir}}(p) \subseteq \text{para-AC}^0$, *if* $p \preceq e^*a^*$.
2. $\text{p-VD}_{\text{dir}}(p) \subseteq \text{para-AC}^{0\uparrow}$ *but* $\text{p-VD}_{\text{dir}}(p) \nsubseteq \text{para-AC}^0$, *if* $ae \preceq p \preceq e^*a^*e^*$.
3. $\text{p-VD}_{\text{dir}}(p)$ *contains a* $\text{W}[2]$*-hard problem, if* $aea \preceq p$.

▶ **Lemma 5.2.**

1. $\text{p-VD}_{\text{dir}}(e^*a^*) \subseteq \text{para-AC}^0$.
2. $\text{p-VD}_{\text{dir}}(e^*a^*e^*) \subseteq \text{para-AC}^{0\uparrow}$.
3. $\text{p-VD}_{\text{dir}}(ae)$ *contains a problem not in* para-AC^0.
4. $\text{p-VD}_{\text{dir}}(aea)$ *contains a* $\text{W}[2]$*-hard problem.*

Proof. Items 1 and 2 follow directly from Lemmas 3.4 and 3.6. Item 3 is shown in Lemma 5.3, and Item 4 follows from Lemma 3.12. ◀

▶ **Lemma 5.3** (▼ [4]). $\text{p-VD}_{\text{dir}}(ae) \nsubseteq \text{para-AC}^0$.

6 Conclusion

In this paper, we fully classified the parameterized complexity of vertex deletion problems where the target property is expressible by first-order formulas and where the inputs are basic graphs, undirected graphs, directed graphs, or arbitrary logical structures. The classification is based on the quantifier patterns of the formulas, and sheds additional light on the complexity properties that emerge from these patterns: We have seen that while the tractability barrier is the same for all logical structures, $\text{p-VD}_{\text{basic}}(e^*a^*e^*)$, $\text{p-VD}_{\text{undir}}(e^*a^*e^*)$, $\text{p-VD}_{\text{dir}}(e^*a^*e^*)$ and $\text{p-VD}_{\text{arb}}(e^*a^*e^*)$ all being tractable and $\text{p-VD}_{\text{basic}}(aea)$, $\text{p-VD}_{\text{undir}}(aea)$, $\text{p-VD}_{\text{dir}}(aea)$ as well as $\text{p-VD}_{\text{arb}}(aea)$ all containing intractable problems, in the tractable cases, basic, undirected and directed graphs have provably different complexities, the latter coinciding with arbitrary structures.

The granularity we gained with the viewpoint of quantifier patterns could be useful to examine the complexity of vertex deletions problems where the property is given by a formula of a more expressive logic: For both *monadic second-order logic* (MSO) and *existential second-order logic* (ESO), even the model checking problem becomes NP-hard. This would allow us to express many more natural problems such as feedback vertex set, that have no obvious formalization as a vertex deletion problem to plain FO-properties. Similarly, we could allow extensions such as transitive closure or fixed point operators.

Compared to previous work on weighted definability, where the objective is to instantiate a free set variable with *at most, exactly,* or *at least* k elements such that a formula holds, we only considered deleting *at most* k elements. How does the complexity of vertex deletion problems change, if we *have to* delete exactly k elements – or, for that matter, *at least* k elements?

Abstract

A sequence $d = (d_1, d_2, \ldots, d_n)$ of positive integers is *graphic* if it is the degree sequence of some simple graph G, and *planaric* if it is the degree sequence of some simple planar graph G. It is known that if $\sum d \leq 2n - 2$, then d has a realization by a forest, hence it is trivially planaric. In this paper, we seek bounds on $\sum d$ that guarantee that if d is graphic then it is also planaric. We show that this holds true when $\sum d \leq 4n - 4 - 2\omega_1$, where ω_1 is the number of 1's in d. Conversely, we show that there are graphic sequences with $\sum d = 4n - 2\omega_1$ that are non-planaric. For the case $\omega_1 = 0$, we show that d is planaric when $\sum d \leq 4n - 4$. Conversely, we show that there is a graphic sequence with $\sum d = 4n - 2$ that is non-planaric. In fact, when $\sum d \leq 4n - 6 - 2\omega_1$, d can be realized by a graph with a 2-page book embedding.

1 Introduction

Background. In a graph G with n vertices, the degree of a vertex is the number of edges incident to it. Let $\deg(G)$ denote the sequence of length n of vertex degrees of G. The Degree Realization problem concerns deciding, given a sequence d of n positive integers, whether d has a *realizing graph*, namely, a graph G with n vertices such that $\deg(G) = d$, and finding such a graph if exists. A *graphic* sequence is one admitting a realizing graph. A full characterization of graphic degree sequences was given by Erdös and Gallai [7]. Havel and Hakimi [11, 12] described an algorithm that, given a sequence d, generates a realization, or verifies that d is not graphic.

The realizability characterization of [7] for general graphs takes into account all the elements of the sequence d. In contrast, the realizability of degree sequences by some special graph classes can be characterized more economically. An extreme example is realizability by a *forest* (cycle-free graph). Here, a single parameter suffices, namely, the *volume* $\sum d = \sum_{i=1}^{n} d_i$ of d. Concretely, if $\sum d \leq 2n - 2$, then d can be realized by a forest, and if $\sum d \geq 2n$ then it cannot [10]. A slightly more involved and less economical characterization applies for realizations by *cacti* graphs. A cactus graph is a connected graph in which every edge occurs on at most one cycle, namely, different cycles do not share edges (but may share one vertex).

The paper [16] gives a full characterization for sequences that can be realized by a cactus graph based only on the volume of the sequence, the number of 2's in the sequence, and the number of odd degrees in the sequence.

In this paper, we are interested in realizability by planar graphs, which turns out to be a challenging task that is still an open problem after more than half a century. A sequence $d = (d_1, d_2, \ldots, d_n)$ of positive integers is *planaric* if it is the degree sequence of some planar graph G. Planaric sequences were studied in, e.g., [13, 1, 18, 8, 9, 17] and more. At the moment, however, a complete characterization for planaric sequences is not yet available.

Contributions. Let d be a sequence with n positive integers and let ω_i be the *multiplicity* of i in d. This paper investigates the impact of the volume $\sum d$ and the multiplicity parameters ω_1 and ω_2 of the sequence d on its realizability by a planar graph. One direction follows from [18] which implies that if $\sum d > 6n - 12 - 2\omega_2 - 4\omega_1$ then d is not planaric. (This is tight in the sense that there are planaric sequences with $\sum d \leq 6n - 12 - 2\omega_2 - 4\omega_1$.) In this paper, we focus on the converse direction, i.e., we seek bounds on these parameters that guarantee that if d is graphic then it is also planaric. A simple bound is obtained by recalling the above-mentioned known fact that if $\sum d \leq 2n - 2$, then d has a a realization by a forest with $(2n - \sum d)/2$ components, hence it is planaric [10]. Here, we give stronger bounds for this problem, depending on $\sum d$ and ω_1. It turns out that most of the technical effort involves handling the *leaf-free* case (the case in which d does not contain 1s). We establish the following.

▶ **Theorem 1.** *Every graphic sequence d with $\omega_1 = 0$ and $\sum d \leq 4n - 4$ is planaric.*

This in turn enables us to prove our more general main result.

▶ **Theorem 2.** *Every graphic sequence d with $\sum d \leq 4n - 4 - 2\omega_1$ is planaric.*

In fact, when $\sum d \leq 4n - 6 - 2\omega_1$, our constructed realizing graphs are not only planar but also enjoy a 2-page book embedding, yielding the following corollary.

▶ **Corollary 3.** *Every graphic sequence d with $\sum d \leq 4n - 6 - 2\omega_1$ can be realized by a graph with a 2-page book embedding.*

This corollary can be interpreted as saying that the family $\mathcal{D}$ of all graphic sequences d such that $\sum d \leq 4n - 6 - 2\omega_1$ enjoy a 2-page book embedding realization. In comparison, the main result of [2] gives a partition of $\mathcal{D}$ into *non-outerplanaric* sequences and sequences enjoying a 2-book embedding realization. Moreover, by [2] if d is outerplanaric and $\sum d \geq 2n$, then $\sum d \leq 4n - 6 - 2\omega_1$. Therefore, this corollary can be seen as an alternative way to obtain the main result of [2].

Conversely, we show that there are graphic sequences with $\sum d \leq 4n - 2\omega_1$ that are non-planaric. For the case of $\omega_1 = 0$, there is a known graphic but non-planaric sequence with $\sum d = 4n - 2$. The gap between the bounds for $\omega_1 > 0$ is left for future study.

Note that the parameters $\sum d$, ω_1 and ω_2 are insufficient for charting the borderline between planaric and non-planaric sequences, and leave a "grey area" in between our upper and lower bounds, in which some sequences are planaric and some are not. This hints that a full characterization may require using additional parameters, and perhaps involve all the degrees, as is the case with realizability by general graphs.

Related work. Planaric sequences for regular planar graphs were classified in [13], and planaric bipartite biregular degree sequences were studied in [1]. In [18], Schmeichel and Hakimi determined which graphic sequences with $d_1 - d_n = 1$ are planaric, and presented similar results for $d_1 - d_n = 2$ with a small number of unsolved cases. Some of the sequences left unsolved in [18] were later resolved in [8, 9]. Some additional studies on special cases of the planaric degree realization problem are discussed in Rao's survey [17].

An economical characterization is given in [5] for the class of 2-trees, which is a subfamily of planar graphs, that is based on $\sum d$, ω_2, and ω_{odd}. For the Outerplanar Degree Realization problem, a full characterization of *forcibly* outerplanar graphic sequences (namely, sequences each of whose realizations is outerplanar) was given in [6]. A characterization of the degree sequence of maximal outerplanar graphs having exactly two 2-degree nodes was provided in [5]. A characterization of the degree sequences of maximal outerplanar graphs with at most four vertices of degree 2 was given in [15]. In [3] it is shown that a nonincreasing n-element graphic sequence d is outer-planaric if either $\omega_1 = 0$ and $\sum d \leq 3n - 3$, or $\omega_1 > 0$ and $\sum d \leq 3n - \omega_1 - 2$. Conversely, there are graphic sequences that are not outer-planaric with $\omega_1 = 0$ and $\sum d = 3n - 2$, as well as ones with $\omega_1 > 0$ and $\sum d = 3n - \omega_1 - 1$

2 Preliminaries

Given a sequence $d = (d_1, \dots, d_n)$ of n integers, we assume that it is non-increasing, namely that $d_{i+1} \leq d_i$, for every $i \in \{1, \dots, n-1\}$. Given two sequences d and d', denote by $d \ominus d' = (d_1 - d'_1, \dots, d_n - d'_n)$ their componentwise difference. For a nonincreasing sequence d of n nonnegative integers, let $\mathsf{pos}(d)$ denote the prefix consisting of the positive integers of d. We use the shorthand a^k to denote a subsequence of k consecutive a's. For any graph G, let $E(G)$ be the edge set of G.

Euler's theorem implies that if d is planaric, where $n \geq 3$, then $\sum d \leq 6n - 12$. Call d a *maximal* Euler sequence if $\sum d = 6n - 12$.

Known planaric sequences. A sequence d is called a *k-sequence* if $d_1 - d_n = k$. Schmeichel and Hakimi [18] divided the analysis for 2-sequences into maximal and non-maximal 2-sequences. They left a few open cases, some of which were resolved by Fanelli [8, 9].

▶ **Lemma 4** ([9, 18]). *Every graphic non-maximal Euler 2-sequence is planaric except for* $(4^5, 2)$, $(5^5, 3^3)$, $(5^{11}, 3)$, $(5^{13}, 3)$, $(6^{n-7}, 4^7)$ *for* $n > 7$, $(7, 5^{15})$, $(7, 5^{17})$, *and possibly* $(7^3, 5^{17})$, *whose status is unresolved.*

The following lemma describess another (relatively small[1]) class of degree sequences known to be planaric.

▶ **Lemma 5** ([18],Theorem 5(a)). *For $n \geq 3$, if d such that $d_1 \geq d_2 \geq \cdots \geq d_n$ is graphic, $\sum d \leq 6n - 12$ and $d_3 \leq 3$, then d is planaric.*

▶ **Observation 6.** *If G is a planar graph, then adding a parallel edge to $E(G)$ maintains the planarity of the resulting graph.*

Minimum pivot Havel-Hakimi algorithm. The *minimum pivot* version of the Havel-Hakimi algorithm [12, 11] for realizing a degree sequence $d = (d_1, \dots, d_n)$ associated with the vertices $v_1, \dots, v_n$, presented explicitly in [19] is based on repeatedly performing the following operation, hereafter referred to as the *MP-step*, until all the vertices reach their required degrees. Suppose that the current sequence of residual degrees is $\delta = (\delta_1, \cdots, \delta_h)$.

[1] The condition $d_3 \leq 3$ implies that the number of sequences in the class is upper bounded by n^4.

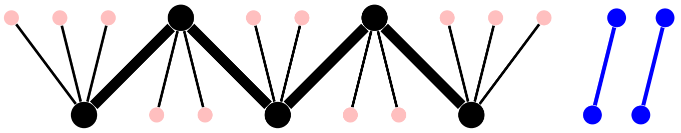

Figure 1 Realization of the forestic sequence $(4^5, 1^{16})$ by an alternating caterpillar and a matching. The spine is depicted by bold black vertices and edges.

The MP-step.

- Pick as a pivot one of the vertices with the minimum non-zero residual degree v_i whose degree is δ_i (break ties arbitrarily).
- Set v_i's neighbors to be the δ_i vertices with the highest residual degrees $v_{i_1}, v_{i_2}, \ldots, v_{i_{\delta_i}}$ (break ties arbitrarily).
- Set $\delta_i \leftarrow 0$ and reduce by 1 the residual degrees of its selected neighbors. That is, set $\delta_{i_j} \leftarrow \delta_{i_j} - 1$ for $j \in \{1, \ldots, \delta_i\}$.

The Minimum pivot Havel-Hakimi algorithm terminates when all the n residual degrees are zero, that is, when $\delta_j = 0$ for $j \in \{1, \ldots, n\}$. The key observation is that, whenever the MP-step transforms the residual degree sequence δ into δ', the following holds: δ is graphic if and only if δ' is graphic.

Caterpillar-based realizations. It is known that if $\sum d \leq 2n - 2$, then d can be realized by a cycle-free graph (forest). In this case, d is called a *forestic* sequence. If $\sum d = 2n - 2$, then d can be realized by a tree and the sequence is called a *treeic* sequence. The following lemma concerns the realization of forestic sequences. We make use of a special type of realizations of forestic and treeic sequences by *caterpillar trees.* In a caterpillar tree $G = (V, E)$, all the non-leaves vertices are arranged on a path, called the *spine.*

▶ **Lemma 7.** *A forestic sequence $d = (d_1, d_2, \ldots, d_n)$ of positive integers can be realized by a union of a caterpillar tree and a matching. Moreover, the order of the vertices on the spine may be chosen arbitrarily.*

For the sake of our later constructions, let us outline the way the realization of Lemma 7 is obtained. Run the *minimum pivot* version of the Havel-Hakimi algorithm while applying the MP-step until all the degrees in the residual sequence are at most 2. Then realize the residual sequence with a path (of arbitrary order) and a matching. The interior of the path is the spine of the caterpillar while the pivots and the two end vertices of the path are the leaves of the caterpillar. Our later constructions make critical use of the "arbitrary ordering" property. It is convenient to illustrate a caterpillar tree with its spine drawn horizontally (in a zigzagged fashion), and its groups of leaves drawn alternately above and below the spine. We refer to this representation as an *alternating caterpillar.* (See Figure 1.)

Outer-planar graphs. An *outer-planar* graph is a graph that has a planar embedding in which all the vertices occur on the outer face. A *maximal outer-planar* (MOP) graph is an outer-planar graph such that adding any new edge to it results in a non-outer-planar graph. Given a planar embedding in which all the vertices occur on the outer face, an *external* edge is an edge residing on the outer face. If $d = (d_1, \ldots, d_n)$ is an outer-planaric degree sequence where $n \geq 2$, then $\sum d \leq 4n - 6$, with equality if and only if d is maximal outer-planaric [20].

A (directed) *circuit* in G is an *ordered set* of vertices $C = \{v_0, v_1, \ldots, v_{k-1}\}$ such that $v_i \neq v_{(i+1) \bmod k}$ and $(v_i, v_{(i+1) \bmod k}) \in E$ for every $i = 0, \ldots, k-1$. In a directed circuit, vertices may appear more than once while each edge may appear at most once. Note that

$e = (u, w)$ is an external edge if u and w are neighbors on a circuit which is part of the outer face. All other edges of G are *internal*. An *internal triangle* in G is a triangle all of whose edges are internal. Jao and West [14] show that the number of internal triangles in a maximal outer-planar graph (MOP) is related to ω_2.

▶ **Lemma 8** ([14]). *Let G be a MOP on n vertices, let $d = \deg(G)$, and let t be the number of internal triangles. If $n \geq 4$, then $t = \omega_2 - 2$.*

Given a graph $G = (V, E)$, let $E = E_1 \cup \ldots \cup E_p$ be a partition of its edges such that each subgraph $G_i = (V, E_i)$ is outerplanar. For a book embedding of G, think of a book in which the pages (half-planes) are filled by outerplanar embeddings of the G_i's such that the vertices are embedded on the spine of the book and in the same location on each page. This constraint is equivalent to requiring that the vertices appear in the same order along the cyclic order of each of the outerplanar embeddings of the G_i's. The *book thickness* or *pagenumber* [4] is the minimal number of pages for which a graph has a valid book embedding. Note that a graph is outerplanar if and only if it has pagenumber 1, and it is known that the pagenumber of planar graphs is at most 4 [21].

▶ **Lemma 9** ([4]). *A graph G has a 2-book embedding if and only if G is a subgraph of a Hamiltonian planar graph.*

3 Tools and sufficient conditions for OP and MOP realizations

3.1 Leaf-free sequences with $\sum d \leq 4n - 6$ and $\omega_2 = 2$ are outer-planaric

We start with a special class of sequences for which we present a basic construction of an *outerplanar* realization. A number of our later constructions of planar realizations start from this basic construction (typically applied to a sub-sequence) and modify it in various ways in order to derive the required planar realization. In many of these cases, the modification requires adding a few more edges. For each additional edge, this requires finding a pair of vertices u, w such that

(i) the edge (u, w) does not appear in the construction, and

(ii) adding it preserves planarity.

We make use of the following lemma, established in [2].

▶ **Lemma 10** ([2]). *Let d be a graphic sequence such that $d_1 \geq d_2 \geq \cdots \geq d_n$ with $\omega_1 = 0$, $\omega_2 = 2$, and $\sum d \leq 4n - 6$. Then d is outer-planaric.*

We outline the construction of the realizing graph, since it will be instrumental in what follows. Let $d' = \mathsf{pos}(d \ominus (2^n))$. Then $n' = n - 2$ and $\sum d' \leq 2n' - 2$ because

$$\sum d' = \sum d - 2n \leq 2n - 6 = 2(n' + 2) - 6 = 2n' - 2 \ .$$

By Lemma 7, d' can be realized by a graph $G' = (V', E')$ composed of a union of an alternating caterpillar T' and a matching M'. Next, construct an outer-planar realization G for d based on G' as follows.

Let $S = (x_1, \ldots, x_s)$ be the vertices on the spine of T', and let $X_i = \{\ell_{i,1}, \ldots, \ell_{i,k_i}\} \subseteq V'$ be the leaves adjacent to the spine vertex x_i, for $i \in \{1, \ldots, s\}$. Note that in T', $deg(x_i) = k_i + 1$ for $i \in \{1, s\}$ and $deg(x_i) = k_i + 2$ otherwise. Assume that the matching is $M' = \{(y_1, z_1), (y_2, z_2), \ldots, (y_t, z_t)\}$. To construct an outer-planar realization of d, add to

G' a set of edges that form a Hamiltonian cycle (including two additional new vertices of degree 2). The construction consists of two steps. We describe it for $s = 0$ and for an odd s; an analogous construction applies for a positive even s.

(1) Construct two paths
$P_1 = (x_1, \ell_{2,1}, \dots, \ell_{2,k_2}, x_3, \ell_{4,1}, \dots, \ell_{4,k_4}, \dots, x_{s-2}, \ell_{s-1,1}, \dots, \ell_{s-1,k_{s-1}}, x_s, y_1, y_2, \dots, y_t)$,
$P_2 = (z_t, \dots, z_2, z_1, \ell_{s,k_s}, \dots, \ell_{s,1}, x_{s-1}, \dots, \ell_{3,k_3}, \dots, \ell_{3,1}, x_2, \ell_{1,k_1}, \dots, \ell_{1,1})$,
connecting the spine vertices in odd and even positions, respectively. If $s = 0$, then $P_1 = (y_1, \dots, y_t)$ and $P_2 = (z_t, \dots, z_1)$.

(2) Add two new vertices x_0 and x_{s+1}. If $s > 0$ and $t > 0$, then connect x_0 with x_1 and $\ell_{1,1}$ and connect x_{s+1} with y_t and z_t. If $s = 0$ and $t > 0$, then connect x_0 with y_1 and z_1 and connect x_{s+1} with y_t and z_t. If $t = 0$ and $s > 0$, then connect x_0 with x_1 and $\ell_{1,1}$ and connect x_{s+1} with x_s and ℓ_{s,k_s}. These two vertices form a cycle C together with P_1 and P_2. The new edges added to G' to construct G are the edges of the cycle C ($E(C)$) which are the edges from the two paths P_1 ($E(P_1)$) and P_2 ($E(P_2)$) and the four edges that connect x_0 and x_{s+1} to these paths.

Observe that after adding the cycle to G', the degree of each one of the n' vertices is increased by 2. Together, with the two new vertices of degree 2 the modified graph G is an outer-planar realization of the original sequence d. For an illustration of the resulting outer-planar graph G for $s = 5$ and $t = 2$, see Figure 2.

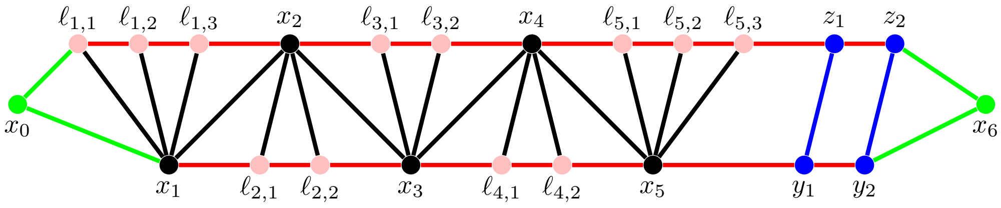

Figure 2 Illustration for the outer-planar construction described in Lemma 10.

3.2 Leaf-free sequences with $\sum d = 4n - 6$ and $\omega_2 = 3$ are outer-planaric

The following lemma is used in our analysis for sequences in which $\sum d = 4n - 4$, $w_1 = 0$ and $w_2 = 3$.

▶ **Lemma 11.** *Let d, such that $d_1 \geq d_2 \geq \dots \geq d_n$, be a degree sequence such that*
(i) $\sum d = 4n - 6$,
(ii) $d_1 \geq 5$,
(iii) $d_3 \geq 4$,
(iv) $d_n = 2$, *and*
(v) $\omega_2 = 3$.
Then
(a) *d can be realized by a maximal outer-planaric graph G,*
(b) *A vertex $v \in V$ cannot be adjacent to three vertices of degree 2 in G.*

Proof. Let d be as in the lemma. By (iii) and (v), $n \geq 6$. Moreover, if $n = 6$ then $d_4 = 2$ by (iv) and (v), and combining it with (i) we get $\sum d = 18 = d_1 + d_2 + d_3 + 6$, so $d_1 + d_2 + d_3 = 12$, which contradicts (ii) and (iii). Therefore, $n \geq 7$. Also note that if $d_4 = 2$ then $n \leq 6$ by (iv)

and (v), leading to the same contradiction. Hence, $d_4 \geq 3$. Due to Lemma 8, if d has a MOP realization G, then G has exactly one internal triangle because $\omega_2 - 2 = 1$. To prove the lemma, we construct a MOP realization of d in which the internal triangle is formed by the vertices whose degrees are d_1, d_2, and d_3. We divide the sequences satisfying the conditions of the lemma into three (possibly overlapping) families, named $\mathcal{A}$, $\mathcal{B}$ and $\mathcal{C}$, a nd show the realizations of sequences that belong to each class separately.

Family $\mathcal{A}$. This family contains all the sequences that satisfy the requirements of the lemma with the additional requirement that $d_1 + d_2 < 10$. Since $d_1 \geq 5$ and $d_3 \geq 4$, it follows that in these sequences $d_1 = 5$ and $d_2 = d_3 = 4$. Therefore, $\mathcal{A}$ contains all the sequences of the type $(5, 4^{\omega_4}, 3^{\omega_3}, 2^3)$ for $\omega_4 \geq 2$. To satisfy the $\sum d = 4n - 6$ requirement of the lemma, it must be the case that $\omega_3 = 1$ as shown below.

$$\begin{aligned} \sum d &= 5 + 4\omega_4 + 3\omega_3 + 6 = 4\omega_4 + 3\omega_3 + 11 \\ 4n - 6 &= 4(\omega_4 + \omega_3 + 4) - 6 = 4\omega_4 + 4\omega_3 + 10 \end{aligned}$$

This implies that $\omega_3 = 1$. To summarize, $\mathcal{A}$ contains all the sequences of the type

$$a(\omega_4) = (5, 4^{\omega_4}, 3, 2^3)$$

of length $n = \omega_4 + 5$ for $\omega_4 \geq 2$.

The following describes how to construct a MOP graph with one inner triangle, denoted by $G(\omega_4)$, realizing the sequence $a(\omega_4)$ for $\omega_4 \geq 3$. Let the $n = \omega_4 + 5$ vertices of $G(\omega_4)$ be

$$(u_1, u_2, u_3, t_0, t_1, \ldots, t_{\omega_4-3}, t_{\omega_4-2}, t_{\omega_4-1}, r_1, r_2)$$

and associate them respectively with the degrees $(5, 4, 4, \overbrace{4, \ldots, 4}^{\omega_4-2}, 3, 2, 2, 2)$. Note that the ω_4 vertices of degree 4 are $u_2, u_3, t_0, t_1, \ldots, t_{\omega_4-3}$ while the degrees of t_{ω_4-2} and t_{ω_4-1} are 3 and 2 respectively. Let the $2\omega_4 + 7$ $(= \sum d/2)$ edges of $G(\omega_4)$ be the three edges of the triangle (u_1, u_2, u_3), the six edges (u_1, t_0), (u_1, r_1), (u_2, r_1), (u_2, r_2), (u_3, r_2), and (u_3, t_0), the $\omega_4 - 1$ edges forming the path $(t_0, t_1, \ldots, t_{\omega_4-2}, t_{\omega_4-1})$, and the $\omega_4 - 1$ edges forming the two paths $(t_0, t_2, t_4 \ldots)$ and $(u_1, t_1, t_3, \ldots)$ of length $\lfloor(\omega_4 - 1)/2\rfloor$ and $\lceil(\omega_4 - 1)/2\rceil$ respectively. For an odd ω_4 the first path is $(t_0, t_2, t_4 \ldots, t_{\omega_4-3}, t_{\omega_4-1})$ and the second path is $(u_1, t_1, t_3, \ldots, t_{\omega_4-4}, t_{\omega_4-2})$ while for an even ω_4 the first path is $(t_0, t_2, t_4 \ldots, t_{\omega_4-4}, t_{\omega_4-2})$ and the second path is $(u_1, t_1, t_3, \ldots, t_{\omega_4-3}, t_{\omega_4-1})$.

Figure 3 illustrates the outer-planar layout of $G(5)$. Observe that for an odd ω_4 the outer Hamiltonian cycle of $G(\omega_4)$ that contains all of its vertices is

$$(u_1, r_1, u_2, r_2, u_3, t_0, t_2, \ldots, t_{\omega_4-3}, t_{\omega_4-1}, t_{\omega_4-2}, t_{\omega_4-4}, \ldots, t_3, t_1, u_1)$$

and for an even ω_4 it is

$$(u_1, r_1, u_2, r_2, u_3, t_0, t_2, \ldots, t_{\omega_4-4}, t_{\omega_4-2}, t_{\omega_4-1}, t_{\omega_4-3}, \ldots, t_3, t_1, u_1)$$

In both cases, (u_1, u_2, u_3) is the only inner triangle.

Family $\mathcal{B}$. This family contains all the sequences that satisfy the requirements of the lemma with an additional requirement that $d_4 = 3$. Hence, $d_1 = 4 + j$ for $j \geq 1$ because $d_1 \geq 5$, $d_2 = 4 + i$ and $d_3 = 4 + h$ for $i, h \geq 0$ because $d_2 \geq d_3 \geq 4$, and $j \geq i \geq h$ because d is a non-increasing sequence. Therefore, $\mathcal{B}$ contains all the sequences of the type

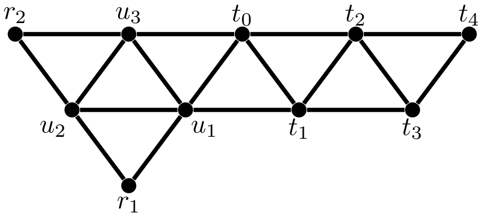

Figure 3 The MOP realization $G(5)$ of the sequence $(5, 4^5, 3, 2^3)$.

$b(j,i,h) = ((4+j),(4+i),(4+h),3^{\omega_3},2^3)$ for $j \geq i \geq h \geq 0$ and $j \geq 1$. To satisfy the $\sum d = 4n-6$ requirement of the lemma, it must be the case that $\omega_3 = (j+i+h)$ as shown below.

$$\begin{aligned}\sum d &= (4+j)+(4+i)+(4+h)+3\omega_3+6 = (j+i+h)+3\omega_3+18\\ 4n-6 &= 4(\omega_3+6)-6 = 4\omega_3+18\end{aligned}$$

This implies $\omega_3 = (j+i+h)$. To summarize, $\mathcal{B}$ contains all the sequences of the type

$$b(j,i,h) = ((4+j),(4+i),(4+h),3^{j+i+h},2^3)$$

of length $n = j+i+h+6$ for $j \geq i \geq h \geq 0$ and $j \geq 1$.

The following describes how to construct a MOP graph with one inner triangle, denoted by $G(j,i,h)$, realizing the sequence $b(j,i,h)$ for $j \geq i \geq h \geq 0$ and $j \geq 1$. Let the $n = j+i+h+6$ vertices of $G(j,i,h)$ be

$$(u_1, u_2, u_3, p_0, \ldots, p_{j-1}, q_0, \ldots, q_{i-1}, r_0, \ldots, r_{h-1}, p_j, q_i, r_h)$$

and associate them respectively with the degrees

$$((4+j),(4+i),(4+h),\overbrace{3,\ldots,3}^{j},\overbrace{3,\ldots,3}^{i},\overbrace{3,\ldots,3}^{h},2,2,2)$$

Let the $2(j+i+h)+9$ $(=\sum d/2)$ edges of $G(j,i,h)$ be the three edges of the triangle (u_1,u_2,u_3), the three edges (u_1,q_0), (u_2,r_0), and (u_3,p_0), the $j+1$ edges (u_1,p_ℓ) for $0 \leq \ell \leq j$, the $i+1$ edges (u_2,q_ℓ) for $0 \leq \ell \leq i$, the $h+1$ edges (u_3,r_ℓ) for $0 \leq \ell \leq h$, the j edges forming the path $(p_0,p_1,\ldots,p_j)$, the i edges forming the path $(q_0,q_1,\ldots,q_i)$, and the h edges forming the path $(r_0,r_1,\ldots,r_h)$,

Figure 4 illustrates the outer-planar layout of $G(4,3,2)$. Observe that the outer Hamiltonian cycle of $G(j,i,h)$ that contains all of its vertices is

$$(u_1, p_j, p_{j-1}, \ldots, p_0, u_3, r_h, r_{h-1}, \ldots, r_0, u_2, q_i, q_{i-1}, \cdots, q_0, u_1)$$

and that (u_1,u_2,u_3) is the only inner triangle.

Family $\mathcal{C}$. This family contains all the sequences that satisfy the requirements of the lemma but do not belong to $\mathcal{A} \cup \mathcal{B}$. That is, the requirement *(iii)* is modified and a new requirement *(vi)* is added as follows,

(iii) $d_4 \geq 4$

(iv) $d_1 + d_2 \geq 10$

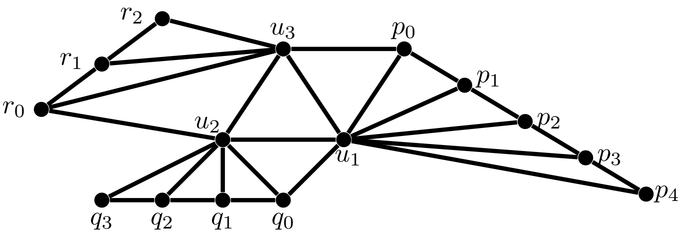

Figure 4 The MOP realization $G(4,3,2)$ of the sequence $(8,7,6,3^9,2^3)$.

The outline of the construction of the MOP realization of d that satisfies the new set of six requirements is as follows. The construction is done in two phases. In the first phase, d is modified to a shorter sequence d' of length $n' = n-3$ by contracting the three largest degrees in d into one degree and eliminating one appearance of 2 in the sequence d. We will show that the new sequence d' satisfies all the requirements of Lemma 10. As a result, this lemma will provide an outer-planar realization G' of d'. In the second phase, the construction of the realization G of the sequence d of length n will be completed by replacing the highest degree vertex in G' with a triangle of vertices and adding another vertex of degree 2 while making sure that all the $n = n' + 3$ vertices in G has the required degrees from the sequence d.

Formally, generate the sequence d' such that $d'_1 \geq d'_2 \geq \cdots \geq d'_n$ of length $n' = n-3$ by removing d_n and merging d_1, d_2 and d_3 as follows.

$$d'_i = \begin{cases} d_1 + d_2 + d_3 - 10, & \text{for } i = 1, \\ d_{i+2}, & \text{for } i = 2, \ldots, n-3. \end{cases}$$

Note that since $d_1 + d_2 \geq 10$, it follows that $d_1 + d_2 + d_3 - 10 \geq d_3 \geq d_4 = d'_2$ and therefore since d is non-increasing it follows that d' is also non-increasing.

Note that $\sum d = 4n - 6$ by the assumptions of the lemma and that $\omega'_2 = 2$ and $d'_{n'} = 2$ by the definition of d'. Consequently,

$$\sum d' = \sum d - 10 - 2 = 4n - 18 = 4(n'+3) - 18 = 4n' - 6 \ .$$

By Lemma 10, d' is outer-planaric.

By the proof of Lemma 10, $d'' = \mathsf{pos}(d' \ominus (2^{n'}))$ can be realized by a caterpillar T and there exists an outer-planar realization G' of d' that is based on a caterpillar T with vertices $S = (x_1, \ldots, x_s)$ forming its spine and a cycle C composed of two paths P_1 and P_2 and two new vertices x_0 and x_{s+1}. (An illustration of this outer-planar graph can be found in Figure 5.) Recall that in T, $X_i = \{\ell_{i,1}, \ldots, \ell_{i,k_i}\} \subseteq V'$ is the set of leaves adjacent to the spine vertex x_i, for $i \in \{1, \ldots, s\}$. This realization G' does not have an internal triangle. We continue referring to these vertices as the spine vertices and leaves although G' is not a caterpillar.

Transforming G' into a realization G of d involves two steps. In the first step, x_1 whose degree is d'_1 will be replaced by three vertices u_1, u_2, and u_3. Note that by Lemma 7, the order of the vertices on the spine can be chosen arbitrarily. As a result, it can be assumed that the degree of x_1 is d'_1. In the second step, the outer cycle of G' will be modified to cover the new vertices with the addition of a new vertex of degree 2.

By the construction of G' from the caterpillar T and since $d'_2 = d_4 \geq 4$ by the new requirement *(iv)*, it follows that the spine of T has at lease two vertices x_1 and x_2 and x_1 is connected in G' to the two vertices x_0 (one of the two vertices of degree 2 in G') and x_2. In

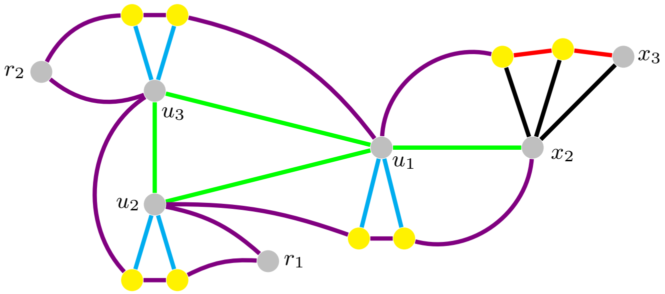

Figure 5 Realization of the sequence $d = (7, 6^2, 5, 3^8, 2^3)$. (Red and black edges are part of the original construction.)

addition, x_1 is connected in G' to the k_1 leaves $\{\ell_{1,1}, \ldots, \ell_{1,k_1}\}$ from the set X_1, as well as to $\ell_{2,1}$ (or to x_3 in case x_2 does not have leaves). Therefore,

$$k_1 = d'_1 - 3 = d_1 + d_2 + d_3 - 13 \; . \tag{1}$$

The expansion of x_1 into a triangle of vertices is done as follows. Remove x_0, x_1, and the leaves of X_1 from G'. Add the three vertices u_1, u_2, and u_3, add a triangle of edges connecting them, namely, the edges (u_1, u_2), (u_1, u_3) and (u_2, u_3), and add the edge (u_1, x_2). (See the green edges in Figure 5.)

Next, split the k_1 leaves in X_1 between the vertices u_1, u_2, and u_3 toward satisfying their degrees d_1, d_2, and d_3, respectively. Specifically, add a set U_1 of $d_1 - 5$ new leaves adjacent to u_1, and a set U_i of $d_i - 4$ new leaves adjacent to u_i, for $i = 2, 3$. (See the blue edges in Figure 5.) The split is perfect since $\sum_{i=1}^{3} |U_i| = k_1$ by Equation 1. In summary,

- u_1 is adjacent to u_2, u_3, x_2, and the $d_1 - 5$ vertices in U_1;
- u_2 is adjacent to u_1, u_3, and the $d_2 - 4$ vertices in U_2; and
- u_3 is adjacent to u_1, u_2, and the $d_3 - 4$ vertices in U_3 .

Therefore, at this point $\deg(u_i) = d_i - 2$, for $i = 1, 2, 3$.

Finally, add two more degree-2 vertices r_1 and r_2 to complete the outer cycle. One of them replaces x_0 while the other is an additional degree 2 vertex, as d_n was removed in the definition of d'. For $i = 1, 2, 3$, connect the leaves in U_i to form a path whose starting and ending vertices (of degree 1) are u_i^s and u_i^e respectively. Next, add the edges (x_2, u_1^s) and (u_1^e, u_2) if $|U_1| > 0$, otherwise add the edge (x_2, u_2). Analogously, add the edges (u_2, r_1), (r_1, u_2^s), (u_2^e, u_3) if $|U_2| > 0$, otherwise add edges (u_2, r_1) and (r_1, u_3). Add edges (u_3, r_2), (r_2, u_3^s), and (u_3^e, u_1) if $|U_3| > 0$, otherwise add edges (u_3, r_2) and (r_2, u_1). Finally, add the edge $(u_1, \ell_{2,1})$, or (u_1, x_3) in case x_2 does not have leaves. (See the violet edges in Figure 5.) At this stage the degrees of u_1, u_2, u_3 are d_1, d_2, and d_3 respectively and the degrees of r_1 and r_2 are 2.

See Figure 5 for an illustration of the realization G of d. One can verify that the construction is a realization of d. ◀

3.3 Degree-Two Removal (Procedure Deg_2_Remove)

As it turns out, sequences with a small number of 2 degrees are easier to realize directly. Consequently, when dealing with a sequence d with many 2's, a convenient approach is to first transform it into a "similar" sequence d' with only a few 2's, construct a graph G' realizing d', and then transform G' into a graph G realizing the original d. We next present a procedure called *Degree-Two Removal (*Deg_2_Remove*)* that will be used to that end in some of our constructions. The input to this procedure is a graphic sequence for which $d_3 \geq 4$,

$\omega_2 \geq 3$ and $\omega_1 = 0$. The procedure applies repeatedly the MP-step of the Havel-Hakimi algorithm until in the residual sequence either $\omega_2 < 3$ or the second maximum degree is less than 4. As a result, throughout its execution it is always the case that the residual sequence is graphic. For any degree sequence $d = (d_1, d_2, \ldots, d_n)$, let $d(\ell)$ be the ℓ'th largest degree in d, for $1 \leq \ell \leq n$. (Note that possibly $d(\ell) = d(\ell+1)$ for some ℓ values.)

Procedure 1 Deg_2_Remove.

```
Set $\bar{d} \leftarrow d$
Set $\bar{\omega}_2 \leftarrow |\{i \mid d_i = 2\}|$
while $\bar{d}(2) \geq 4$ and $\bar{\omega}_2 \geq 3$ do
    Let $j$ be such that $\bar{d}_j = \bar{d}(1)$ and let $j'$ be such that $\bar{d}_{j'} = \bar{d}(2)$
    $\bar{d}_j \leftarrow \bar{d}_j - 1$
    $\bar{d}_{j'} \leftarrow \bar{d}_{j'} - 1$
    Change one degree-2 in $\bar{d}$ to 0
    set $\bar{\omega}_2 \leftarrow \bar{\omega}_2 - 1$
Set $\bar{d}^s \leftarrow$ sort($\bar{d}$)          /* The final $\bar{d}$ sorted in non-increasing order */
```

Assume that Procedure Deg_2_Remove executes k iterations of its while-loop. Observe that during the run of the Deg_2_Remove procedure, no new degree 2 vertices appear because $\bar{d}(2) \geq 4$ is one of the conditions of the while-loop. As a result, $\bar{\omega}_2$, which is initially the number of degree-2 vertices in d, decreases by 1 after each iteration. Let $\bar{\omega}_2^i$ be the value of $\bar{\omega}_2$ after the i'th iteration, for $0 \leq i \leq k$. For $0 \leq i \leq k$, let $\bar{d}^i$ be the sequence $\bar{d}$ after the i'th iteration (note that $\bar{d}^s$ is the sorted version of $\bar{d}^k$), and let $\bar{n}^i$ be the length of $\mathsf{pos}(\bar{d}^i)$. We make use of the set A indices of high degrees that were reduced by Procedure Deg_2_Remove and the set B of indices of 2 degrees that were eliminated by the procedure. Formally,

$$A = \{i \mid d_i > \bar{d}_i,\ d_i \geq 4\}, \qquad B = \{i \mid d_i = 2,\ \bar{d}_i = 0\}. \tag{2}$$

▶ **Observation 12.**
(i) $\bar{n}^{i+1} = \bar{n}^i - 1$,
(ii) $\bar{\omega}_2^{i+1} = \bar{\omega}_2^i - 1$,
(iii) $\sum \bar{d}^{i+1} = \sum \bar{d}^i - 4$,
(iv) $|B| = k$,
(v) $\sum_{i \in A}(d_i - \bar{d}_i^k) = 2k$,
(vi) $\sum \bar{d}^k - 4\bar{n}^k = \sum d - 4n$,
(vii) $\bar{n}^k = n - k$,
(viii) $\bar{d}^i$ *is graphic for* $1 \leq i \leq k$.

▶ **Observation 13.** *When Procedure* Deg_2_Remove *terminates, the following properties hold.*
(i) *Either* $\bar{d}^k(2) \geq 3$ *and* $\bar{\omega}_2 = 2$*, or* $\bar{d}^k(2) = 3$ *and* $\bar{\omega}_2 \geq 3$.
(ii) *If* $\bar{d}_2^s \geq 5$*, then* $\bar{d}_i^k \geq 4$ *for every* $i \in A$.

The following lemma (whose proof is omitted) demonstrates the usefulness of Procedure 1 in reducing the number of degree 2 vertices to generate an outer-planar sequence. Later, it will be shown how to add back the removed degree 2 vertices to get a planar realization for the original sequence.

▶ **Lemma 14.** *Applying Procedure* Deg_2_Remove *(Procedure 1) on a graphic sequence* d *with* $\sum d \leq 4n - 6$*,* $\omega_1 = 0$ *and* $\omega_2 \geq 3$*, the output sequence* $\bar{d}^k$ *satisfies that* $\mathsf{pos}(\bar{d}^k)$ *is outer-planaric.*

4 Main Result

This section presents our main result (Theorem 2). Specifically, Subsection 4.1 shows that this theorem is implied directly by Theorem 1. The following two subsections establish Theorem 1, where Subsection 4.2 handles the easy case of sequences with few 2 degrees ($\omega_2 \leq 2$) and Subsection 4.3 handles the more elaborate case of sequences with many 2 degrees ($\omega_2 \geq 3$). Finally, Subsection 4.4 provides examples showing that our bounds are almost tight.

4.1 The planarity of low-volume sequences with $\omega_1 > 0$

We first rely on Theorem 1 to prove our main result.

Proof of Theorem 2. If $\sum d \leq 2n-2$, then d can be realized by a forest, hence it is planaric [10]. For the case where $\sum d \geq 2n$, we prove the claim by induction on ω_1. In the base case, $\omega_1 = 0$, the claim follows by Theorem 1. Now assume that the claim holds for $\omega_1 \leq i$ and consider $\omega_1 = i+1$. Construct d' by setting $d'_1 = d_1 - 1$, $d'_n = 0$ and $d'_i = d_i$ for $i \in \{2, \ldots, n-1\}$. Since $\sum d \geq 2n$ and $\omega_1 > 0$, we have that $d_1 \geq 3$ and hence $d'_1 \geq 2$. Let $d'' = \mathsf{pos}(d')$ and denote the number of 1-degrees in d'' by ω''_1. Then $\omega''_1 = \omega_1 - 1$ and $n'' = n-1$, implying that $\sum d'' \leq 4n'' - 4 - 2\omega''_1$. Also note that when applying the MP-step of the Havel-Hakimi method on d here, using d_n as pivot, we get d'', and hence d'' is graphic. Therefore, d'' satisfies the conditions of induction hypothesis and hence can be realized by a planar graph G''. To complete the construction, add one leaf to the vertex with degree d'_1 in G''. This yields a planar graph G realizing d. The theorem follows. ◀

The following two subsections are dedicated to the leaf-free case ($\omega_1 = 0$), and prove Theorem 1.

4.2 The planarity of leaf-free sequences with $\sum d \leq 4n-4$ and $\omega_2 \leq 2$

The case of "few degrees 2" is relatively easier, and is covered by the following lemma.

▶ **Lemma 15.** *Every graphic sequence d such that $d_1 \geq d_2 \geq \cdots \geq d_n$ with $\omega_1 = 0$, $\omega_2 \leq 2$, and $\sum d \leq 4n-4$ is planaric.*

Proof. If $d_3 < 4$, then d is planaric by Lemma 5. From now on assume in addition that $d_3 \geq 4$. We consider three cases depending on ω_2.

Case 1: $\omega_2 = 0$.
In this case, $d_n = 3$ since $d_n \geq 4$ would imply $\sum d \geq 4n$. Let $d' = d \ominus (2^n)$. Then $n' = n$ and $\sum d' = \sum d - 2n \leq 2n' - 4$. Therefore, d' is a forestic sequence. By Lemma 7, d' can be realized by a graph $G' = (V', E')$ composed of a union of an alternating caterpillar T' and a matching M'. This matching contains at least one edge because when $\sum d' \leq 2n' - 4$, any realization forest must contain at least two connected components.

Define the spine S, the leaf sets X_i in T' and the matching M' analogously to the proof of Lemma 10. Observe that since $d_3 \geq 4$ and the spine contains all the vertices whose degree in G' is at least 2, it follows that the spine S contains at least three vertices.

To construct a planar realization of d, add to G' a set of edges that form two disjoint cycles. The construction consists of two steps. We describe it for odd s; an analogous construction applies for even s.

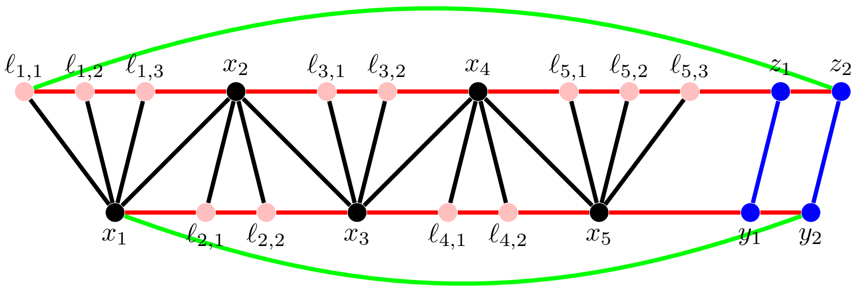

Figure 6 Illustration for a planar construction when $\omega_2 = 0$. This is essentially the outer-planar graph of Figure 2 after omitting the vertices x_0 and x_6 with the addition of the green edges (x_1, y_2) and $(z_2, \ell_{1,1})$.

(1) Construct two paths P_1 and P_2 as in the proof of Lemma 10.

(2) Connect x_1 with y_t and $\ell_{1,1}$ with z_t, thereby transforming the paths P_1 and P_2 into a cycle.

For an illustration of the resulting outer-planar graph G for $s = 5$ and $t = 2$, see Figure 6.

Case 2: $\omega_2 = 1$.
In this case, $d_n = 2$ and $d_{n-1} = 3$, since again $d_{n-1} \geq 4$ would contradict the assumption $\sum d \leq 4n - 4$. If $d_1 \leq 4$, then $d = (4^{\omega_4}, 3^{\omega_3}, 2)$ with even $\omega_3 \geq 2$ is planaric by Lemma 4. Hereafter, we assume that $d_1 \geq 5$.

Define d' by setting $d'_1 = d_1 - 1$, $d'_{n-1} = 2$ (replacing $d_{n-1} = 3$) and $d'_i = d_i$ for all other $i \in \{2, \ldots, n-2, n\}$. Then $\sum d' \leq 4n' - 6$ and $n' = n$. Let $d'' = \mathsf{pos}(d' \ominus (2^n))$. We have $n'' = n' - 2$ and $\sum d'' = \sum d' - 2n \leq 2n' - 6 = 2(n'' + 2) - 6 = 2n'' - 6$. By Lemma 7, d'' can be realized by a graph $G'' = (V'', E'')$ composed of a union of an alternating caterpillar T'' and a matching M''. Notice that $d''_1 \geq 2$ since $d_1 \geq 5$. Therefore, the vertex with degree d''_1 occurs on the spine of T'' and can be identified as x_1 since by Lemma 7 the spine-vertices may appear in any order.

Define the spine S, the leaf sets X_i in T'' and the matching M'' analogously to the proof of Lemma 10. Since $d_3 \geq 4$, by the construction of d' and d'', there are at least two vertices on the spine S and $s \geq 2$. To construct a planar realization of d, we add a set of edges to G'' as done in the proof of Lemma 10 and one extra edge. The construction consists of two steps. Again, we describe it only for odd s.

(1) Construct two paths P_1, P_2 and $E(C)$ as in the proof of Lemma 10

(2) Connect x_{s+1} and x_1 by an edge.

An illustration of the above steps is presented in Figure 7. Note that steps (1) and (2) build an outer-planar graph $G' = (V, E')$ with $E(G') = E(G'') \cup E(C)$ realizing d'. Notice that $(x_{s+1}, x_1) \notin E(G')$ since $s \geq 2$. Therefore, step (3) yields a simple planar graph $G = (V, E)$ with $E(G) = E(G'') \cup E(C) \cup \{(x_{s+1}, x_1)\}$ realizing d.

Case 3: $\omega_2 = 2$ (i.e., $d_n = d_{n-1} = 2$ and $d_{n-2} \geq 3$).
In this case, for $\sum d \leq 4n - 6$, the result follows directly from Lemma 10.

Next consider $\sum d = 4n - 4$. This case is divided into three sub-cases.

Case 3.1: $d_1 = 4$.
In this case, d is a 2-sequence, i.e., it satisfies $d_1 - d_n = 2$, and such d is known to be planaric, see Lemma 4.

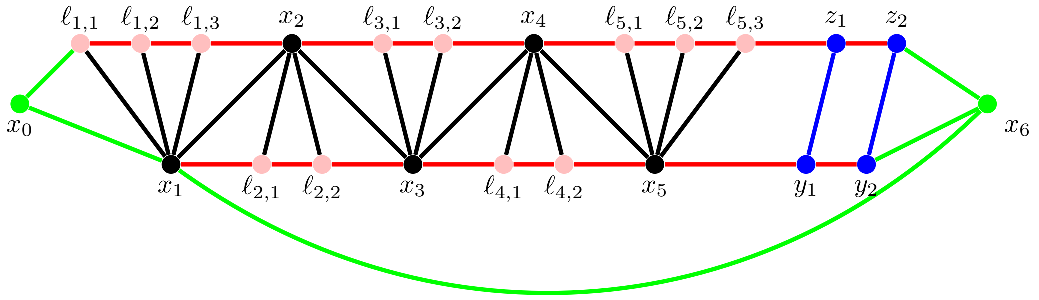

Figure 7 Illustration for planar construction when $\omega_2 = 1$. This is essentially the outer-planar graph of Figure 2 with the addition of the green edge (x_1, x_6).

Case 3.2: $d_1 = 5$ and $d_2 = 4$.
In this case, $\sum d = 4n - 4$ dictates that $d = (5, 4^{\omega_4}, 3, 2^2)$ for $\omega_4 \geq 2$ since $d_3 \geq 4$. The following describes how to construct a planar graph, denoted by $G(\omega_4)$, realizing the sequence d for $\omega_4 \geq 2$. Let the $n = \omega_4 + 4$ vertices of $G(\omega_4)$ be $(u, x_1, x_2, \ldots, x_{\omega_4}, r_1, r_2, r_3)$, and associate them respectively with the degrees $(5, \overbrace{4, \ldots, 4}^{\omega_4}, 3, 2, 2)$. Let the $2\omega_4 + 6$ $(= \sum d/2)$ edges of $G(\omega_4)$ be the five edges (u, r_1), (u, r_2), (u, r_3), (u, x_1), (u, x_2), the four edges $(r_1, x_{\omega_4 - 1})$, (r_1, x_{ω_4}), (r_2, x_{ω_4}), and (r_3, x_1), the $\omega_4 - 1$ edges forming the path $(x_1, x_2, \ldots, x_{\omega_4 - 1}, x_{\omega_4})$, and the $\omega_4 - 2$ edges forming the two paths $(x_1, x_3, \ldots)$ and $(x_2, x_4, \ldots)$ of length $\lceil(\omega_4 - 2)/2\rceil$ and $\lfloor(\omega_4 - 2)/2\rfloor$ respectively. For an even ω_4 the first path is $(x_1, x_3, \ldots, x_{\omega_4 - 1})$ and the second path is $(x_2, x_4, \ldots, x_{\omega_4})$ while for an odd ω_4 the first path is $(x_1, x_3, \ldots, x_{\omega_4})$ and the second path is $(x_2, x_4, \ldots, x_{\omega_4 - 1})$. Figure 8 illustrates the planar layout of $G(6)$.

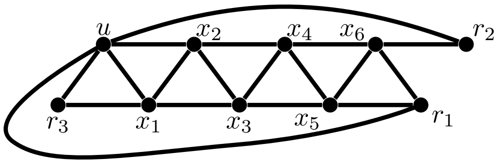

Figure 8 The planar realization of the sequence $G(6) = (5, 4^6, 3, 2^2)$.

Case 3.3: $d_1 \geq 6$ or $d_2 \geq 5$.
If $d_{n-2} \geq 4$, then $\sum d \geq 4n - 2$, which contradicts with $\sum d = 4n - 4$. Therefore, $d_{n-2} = 3$. Construct d' from d by letting $d'_1 = d_1 - 1$, $d'_{n-2} = 2$ and $d'_i = d_i$ for all other $i \in \{2, \ldots, n-3, n-1, n\}$. Then $\mathsf{pos}(d') = d'$, $n' = n$, $\sum d' = 4n' - 6$ and $\omega'_2 = 3$.

Combining $d_3 \geq 4$ and the condition of this case, the maximum degree in d' is at least 5 and the third maximum degree is at least 4. Hence, d' satisfies the conditions of Lemma 11, and therefore it can be realized by an outer-planar graph G'. In the construction of G', there exists a vertex u of degree 2 not adjacent to the vertex v of degree d'_1 by (b) of Lemma 11. Construct the planar graph G realizing d by adding the edge (u, v) to G'.

Summarizing the above three cases, d is planaric. ◀

4.3 The planarity of leaf-free sequences with $\sum d \leq 4n - 4$ and $\omega_2 \geq 3$

This subsection handles the more complex case of "many degrees 2". The analysis is separated into two main parts. First (Lemma 16), we consider sequences of volume $\sum d \leq 4n - 6$. Later (Lemma 17) we analyze the extremal case where $\sum d = 4n - 4$.

▶ **Lemma 16.** *Every graphic sequence d, such that $d_1 \geq d_2 \geq \cdots \geq d_n$, with $\omega_1 = 0$, $\omega_2 \geq 3$, and $\sum d \leq 4n - 6$ is planaric.*

For lack of space, we present an overview of the construction, deferring the complete proof to the full version. The construction of this lemma involves four phases. Phase (1) transforms d into a sequence $\bar{d}^k$ with just two degrees 2 (or, $\bar{d}^k(2) = 3$). This is done by using Procedure `Deg_2_Remove`. Phase (2) constructs an outer-planar graph G_k realizing $\bar{d}^k$, which is illustrated in Figure 9(a). Phase (3) adds a multi-graph $\bar{G}$ with edges connecting the vertices corresponding to indices in the set A defined in Eq. (2). It is illustrated in Figure 9(b). For Phase (4) we need to use the *vertex insertion* operation, defined as follows. For any multi-graph $\hat{G}$, let $I(\hat{G})$ denote the graph obtained from $\hat{G}$ by inserting one new vertex $z_{u,v}$ into every edge $e = (u, v)$ in $E(\hat{G})$, namely, replacing e by the 2-edge path $(u, z_{u,v}, v)$. Note that this operation cancels all parallel edges, so the resulting graph is simple. Observe that if we transform $\bar{G}$ into $I(\bar{G})$, then $I(\bar{G})$ realizes $\mathsf{pos}(d \ominus \bar{d}^k)$ and the combined graph $I(\bar{G}) \cup G_k$ realizes d. Moreover, as G_k is outer-planar, if there are no cross edges between vertices of $\bar{G}$, then $G_k \cup I(\bar{G})$ is a *planar* realization for d, as shown in Figure 9(c). However, the multi-graph $\bar{G}$ might contain crossing edges, as shown in Figure 9(b). In this case, some preliminary processing is needed. At the beginning of Phase (4), apply procedure `Edge_Swap` and replace $\bar{G}$ by a *modified* multi-graph G^M with no edge crossings. Only then, invoke the vertex insertion operation to insert k new vertices into the edges of G^M and get $I(G^M)$. Since the inserted new vertices in $I(G^M)$ do not exist in G_k, the graph $G_k \cup I(G^M)$ is simple. Consequently, $G_k \cup I(G^M)$ can be shown to be a simple planar graph realizing d, as shown in Figure 9(d).

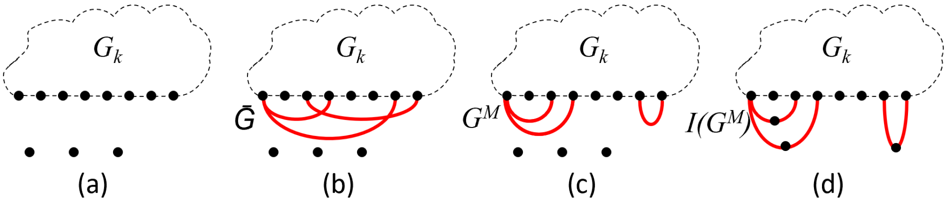

Figure 9 A schematic description of the realization process in Case 4. The preliminary step involves separating the sequence d into a sequence $\bar{d}^k$ with reduced high degrees and only two degrees 2 (depicted by the higher row of vertices in the figures, forming the spine of G_k), and k degrees 2 kept separately (the lower row in the figures).

Careful inspection of the proofs of Lemmas 5, 9 and 16 reveals that when $\sum d \leq 4n - 6 - 2\omega_1$, the constructed realizing graphs are not only planar but also enjoy a 2-page book embedding, yielding Corollary 3.

The next lemma shows the case for $\sum d = 4n - 4$ and $\omega_1 = 0$, $\omega_2 \geq 3$. A schematic description of the construction process in this case is as follows. First apply Procedure `Deg_2_Remove` (Procedure 1 in Section 2) to create a modified degree sequence $\bar{d}^k$ and sets A and B. Next construct a simple graph G_k realizing $\bar{d}^k$, as a combination of an outer-planar graph G' and an edge (u, v), using the method described in the proof of Lemmas 10 and 11. Then, apply procedure `Deg_2_Recover` on G' and output a simple planar graph G. As a final step, construct a graph G'' with $E(G'') = E(G) \cup \{(u, v)\}$. Note that by Procedure `Deg_2_Recover`, $G'' = G_k \cup I(G^M)$. Since $I(G^M)$ realizes $\mathsf{pos}(d \ominus \bar{d}^k)$, G'' realizes d. Since (u, v) does not exist in G, G'' is a simple graph. Combining it with the fact that G is an "almost outer-planaric" graph, if one can show that there are no cross edges between (u, v) and any edges in $E(G^M)$, then G'' is a simple planar graph. The formal proof involves a rather complex case analysis, and is omitted for lack of space.

▶ **Lemma 17.** *Every graphic sequence d with $\omega_1 = 0$, $\omega_2 \geq 3$, and $\sum d = 4n - 4$ is planaric.*

Combining Lemmas 15, 16 and 17 yields the proof for our main Theorem 1.

4.4 Almost tight negative examples

We complement the positive result of Theorem 2 by almost tight negative examples. Consider first the case of $\omega_1 = 0$, for which we present a tight example.

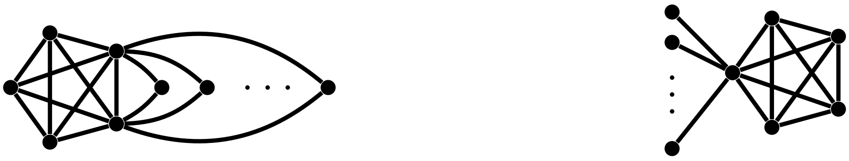
▶ **Lemma 18.** *There exists a graphic sequence of volume $4n - 2$ and $\omega_1 = 0$, which is non-planaric.*

Proof. The sequence $d = (4^5, 2)$ is non-planaric by Lemma 4, and satisfies $\sum d = 4n - 2$. ◀

However, we do not know non-planaric sequences for which $\omega_1 = 0$ and $\sum d = 4n - 2$ for $n > 6$. Instead, the next lemma shows that for any $n \geq 5$ there exists a non-planaric sequence with $\omega_1 = 0$ and $\sum d = 4n$.

▶ **Lemma 19.** *For any non-negative integer k, the sequence $d[k] = ((4 + k)^2, 4^3, 2^k)$, for which $\sum d[k] = 4n$, is graphic but not planaric.*

Proof. See Figure 10a for the unique realization of the sequence $d[k] = ((4 + k)^2, 4^3, 2^k)$. This realization is non-planaric because it has a a K_5 subgraph consisting of the two vertices of degree $4 + k$ and the three vertices of degree 4. This is a unique realization becaus the two degree $4 + k$ vertices each must be connected to all other $n - 1 = 4 + k$ vertices. ◀



(a) The unique realization of $((4 + k)^2, 4^3, 2^k)$.

(b) The unique realization of $(4 + k, 4^4, 1^k)$.

Figure 10 Two non-planaric families of sequences.

Turning to sequences with $\omega_1 > 0$, there is again a small gap. The next lemma shows that for any $n \geq 6$ there exists a non-planaric sequence with $\omega_1 > 0$ and $\sum d = 4n - 2\omega_1$.

▶ **Lemma 20.** *For any non-negative integer k, the sequence $d'[k] = (4 + k, 4^4, 1^k)$, for which $\sum d'[k] = 4n - 2\omega_1$, is graphic but not planaric.*

Proof. See Figure 10b for the unique realization of the sequence $d'[k] = ((4 + k, 4^4, 1^k)$. This realization is non-planaric because it has a K_5 subgraph consisting of the vertex of degree $4 + k$ and the four vertices of degree 4. This is a unique realization becaus the degree $4 + k$ vertex must be connected to all other $n - 1 = 4 + k$ vertices. ◀

Recall that Theorem 2 states that every graphic sequence d such that $\sum_d \leq 4n - 4 - 2\omega_1$ is planaric. In light of Lemma 19 and Lemma 20 it follows that the remaining gap for the case $\omega_1 = 0$ involves sequences d with $\sum d = 4n - 2$ while the remaining gap for the case $\omega_1 > 0$ involves sequences d with $\sum d = 4n - 2 - 2\omega_1$.

Abstract

We study the k-Canadian Traveller Problem, where a weighted graph $G = (V, E, \omega)$ with a source $s \in V$ and a target $t \in V$ are given. This problem also has a hidden input $E_* \subsetneq E$ of cardinality at most k representing blocked edges. The objective is to travel from s to t with the minimum distance. At the beginning of the walk, the blockages E_* are unknown: the traveller discovers that an edge is blocked when visiting one of its endpoints. Online algorithms, also called strategies, have been proposed for this problem and assessed with the competitive ratio, *i.e.*, the ratio between the distance actually traversed by the traveller divided by the distance he would have traversed knowing the blockages in advance.

Even though the optimal competitive ratio is $2k + 1$ even on unit-weighted planar graphs of treewidth 2, we design a polynomial-time strategy achieving competitive ratio 9 on unit-weighted outerplanar graphs. This value 9 also stands as a lower bound for this family of graphs as we prove that, for any $\varepsilon > 0$, no strategy can achieve a competitive ratio $9 - \varepsilon$. Finally, we show that it is not possible to achieve a constant competitive ratio (independent of G and k) on weighted outerplanar graphs.

1 Introduction

The k-*Canadian Traveller Problem* (k-CTP) was introduced by Papadimitriou and Yannakakis [24]. It models the travel through a graph where some obstacles may appear. Given an undirected weighted graph $G = (V, E, \omega)$, with $\omega : E \to \mathbb{Q}^+$, and two of its vertices $s, t \in V$, a traveller walks from s to t on G despite the existence of blocked edges $E_* \subsetneq E$ (also called *blockages*), trying to contain the length of his walk. The traveller does not know which edges are blocked when he begins his journey. He discovers that an edge $e = uv$ is blocked, *i.e.*, belongs to E_*, when he visits one of its endpoints u or v. The parameter k is an upper bound on the number of blocked edges: $|E_*| \leq k$. Several variants have also been studied: where edges are blocked with a certain probability [1, 5, 13, 19], with multiple travellers [11, 25], where we can pay to sense remote edges [19], or where we seek the shortest tour [20, 22]. This problem has applications in robot routing for various kinds of logistics [1, 2, 8, 18, 23].

For a given walk on the graph, its *cost* (also called distance) is the sum of the weights of the traversed edges. The objective is to minimize the cost of the walk used by the traveller to go from s to t. A pair (G, E_*) is called a *road map*. All the road maps considered are feasible: there exists an (s, t)-path in $G \setminus E_*$, the graph G deprived of E_*. In other words, there is always a way to reach target t from source s despite the blockages.

A solution to the k-CTP is an online algorithm, called a *strategy*, which guides the traveller through his walk on the graph : given the input graph, the history of visited nodes, and the information collected so far (here, the set of discovered blocked edges), it tells which neighbor of the current vertex the traveller should visit next. The quality of the strategy can be assessed with competitive analysis [14]. Roughly speaking, the *competitive ratio* is the quotient between the distance actually traversed by the traveller and the distance he would have traversed knowing which edges are blocked in advance. The k-CTP is PSPACE-complete [5, 24] in its decision version that asks, given a positive number r and the input weighted graph, whether there exists a strategy with competitive ratio at most r. Westphal [26] proved that no deterministic strategy achieves a competitive ratio less than $2k + 1$ on all road maps satisfying $|E_*| \leq k$. Said differently, for any deterministic strategy A, there is at least one k-CTP road map for which the competitive ratio of A is at least $2k + 1$. Randomized strategies have also been studied, see *e.g.* [10, 16].

Our goal is to distinguish between graph classes on which the k-CTP has competitive ratio $2k + 1$ (the optimal ratio for general graphs) and the ones for which this bound can be improved. This direction of research has already been explored in [12]: there is a polynomial-time deterministic strategy which achieves ratio $\sqrt{2}k + O(1)$ on graphs with bounded-size maximum (s, t)-cuts. We pursue this study by focusing on a well-known family of graphs: outerplanar graphs, which are graphs admitting a planar embedding (without edge-crossing) where all the vertices lie on the outer face. In [12], an outcome dedicated to a superclass of weighted outerplanar graphs implies that there is a strategy with ratio $2\frac{3}{4}k + O(1)$ on them. Interestingly, however, even very simple unit-weighted planar graphs of treewidth 2, consisting only of disjoint (s, t)-paths, admit the general ratio $2k + 1$ as optimal [15, 26].

Our results and outline. After some preliminaries (Section 2), we describe in Section 3 a polynomial-time strategy achieving a competitive ratio 9 on instances where the input graph is a unit-weighted outerplanar graph:

▶ **Theorem 1.1.** *There is a strategy with competitive ratio 9 for unit-weighted outerplanar graphs.*

In the input outerplanar graph, vertices s and t lie on the outer face. The latter can be seen (provided 2-connectedness) as a cycle embedded in the plane, allowing to explore two sides when we travel from s to t (the two sides are the two internally disjoint (s, t)-paths forming the cycle). The core of the strategy consists in an exploration of both sides via a so-called *exponential balancing*. Then, the most technical part consists in the handling of the chords linking both sides. We maintain a competitiveness invariant of the strategy which produces a final ratio of 9.

Note that Theorem 1.1 can be extended as a corollary to outerplanar graphs where the *stretch*, defined as the ratio between the maximum and minimum weight, is bounded by some fixed S. In this case, the strategy has ratio $9S$.

Surprisingly, the k-CTP on unit-weighted outerplanar graphs has connections with another online problem called the *linear search* problem [3, 7, 9] or the *cow-path* problem [21]. In this problem, a traveller walks on an infinite line, starting at some arbitrary point, and its goal is to reach some target fixed by the adversary. It was shown that applying an exponential balancing on this problem is the optimal way, from the worst case point of view, to reach the target [3]. We explain in Section 3.3 why, on unit-weighted outerplanar graphs, the competitive ratio stated in Theorem 1.1 is optimal and how it can be deduced from the literature on the linear search problem.

▶ **Theorem 1.2.** *For any $\varepsilon > 0$, no deterministic strategy achieves competitive ratio $9 - \varepsilon$ on all road maps (G, E_*), where G is a unit-weighted outerplanar graph.*

Finally, in Section 4, we show that no constant competitive ratio can be achieved on outerplanar graphs where weights can be selected arbitrarily.

▶ **Theorem 1.3.** *There is no constant C, independent from G and k, such that a deterministic strategy achieves competitive ratio C on all road maps (G, E_*) where G is a weighted outerplanar graph.*

We summarize in Table 1 the state-of-the-art of the competitive analysis of deterministic strategies for the k-CTP, giving for each family an upper bound of competitiveness (*i.e.*, a strategy with such ratio exists) and a lower bound (*i.e.*, no strategy can achieve a smaller ratio). Our contributions are framed.

Due to space limitation, the proofs of results marked with **(*)** are omitted here and available in the full version [6].

2 Definitions and first observations

2.1 Graph preliminaries

We work on undirected connected weighted graphs $G = (V, E, \omega)$, where $\omega : E \to \mathbb{Q}^+$. A graph is *equal-weighted* (resp. *unit-weighted*) if the value of $\omega(e)$ is the same (resp. 1) for every edge $e \in E$. This article follows standard graph notations from [17]. We denote by $G[U]$ the subgraph of G induced by $U \subseteq V$: $G[U] = (U, E[U], \omega_{|E[U]})$; and by $G \setminus U$ the graph deprived of vertices in U: $G \setminus U = G[V \setminus U]$. A *simple* (u, v)*-path* is a sequence of

Table 1 Deterministic strategies performances for the k-CTP.

Family of graphs	upper bound	lower bound
unit-weighted planar of treewidth 2	$2k + 1$ [26]	$2k + 1$ [15, 26]
bounded maximum edge (s, t)-cuts	$\sqrt{2}k + O(1)$ [12]	?
outerplanar	$2^{\frac{3}{4}}k + O(1)$ [12]	$\boxed{\text{not constant}}$
unit-weighted outerplanar	$\boxed{9}$	$\boxed{9}$

pairwise different vertices between u and v, while, in a (u, v)-*walk*, vertices can be repeated. The *cost* (or *traversed distance*) of a walk or a path is the sum of the weights of the edges it traverses. A vertex v is an *articulation point* if $G \setminus \{v\}$ is not connected.

An (s, t)-*separator* $X \subsetneq V \setminus \{s, t\}$ in graph G is a set of vertices such that s and t are disconnected in graph $G \setminus X$. We denote by $R_G(s, X)$ (resp. $R_G(t, X)$) the *source* (resp. *target*) *component* of separator X, which is a set made up of the vertices of X together with all vertices reachable from s (resp. t) in $G \setminus X$.

A graph is *outerplanar* if it can be embedded in the plane in such a way that all vertices are on the outer face. An outerplanar graph is 2-connected if and only if the outer face forms a cycle. Given an embedding of a 2-connected outerplanar graph $G = (V, E)$ and two vertices s and t, let $s \cdot p_1 \cdot p_2 \cdots p_h \cdot t \cdot q_1 \cdot q_2 \cdots q_\ell \cdot s$ be the cycle along the outer face of G and let $S_1 = \{p_1, p_2, \ldots, p_h\}$ and $S_2 = \{q_1, q_2, \ldots, q_\ell\}$ with $V = \{s, t\} \cup S_1 \cup S_2$. We can slightly deform the embedding so that s and t are aligned along the horizontal axis; since the outer face forms a cycle, we will refer to S_1 (resp. S_2) as the *upper* (resp. *lower*) *side* of G. A chord xy of the cycle formed by the outer face is said to be (s, t)-*vertical* (resp. (s, t)-*horizontal*) if x and y belong to different sides (resp. to the same side), see Figure 1. When $x = s$ or $y = t$, the chord is considered as (s, t)-horizontal and not (s, t)-vertical. Any (s, t)-vertical chord (simply *vertical chord* when the context is clear) is an (s, t)-separator. Considering a set of vertical chords, we say that the *rightmost* one has the minimal inclusion-wise target component. Due to planarity, the rightmost vertical chord is unique for any such set.

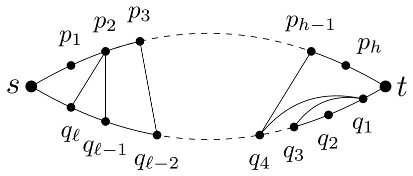

Figure 1 Example of an outerplanar graph: p_2q_ℓ, $p_2q_{\ell-1}$, $p_3q_{\ell-2}$, and $p_{h-1}q_4$ are vertical chords and q_1q_3, q_1q_4 are horizontal chords.

2.2 Problem definition and competitive analysis

Let $G = (V, E, \omega)$ be a graph and E_* represent a set of blocked edges. A pair (G, E_*) is a *road map* if s and t are connected in $G \setminus E_*$.

▶ **Definition 2.1** (k-CTP).

Input: *A graph $G = (V, E, \omega)$, two vertices $s, t \in V$, and a set E_* of blocked edges which are unknown such that $|E_*| \leq k$ and (G, E_*) is a road map.*

Objective: *Traverse graph G from s to t with minimum cost.*

A solution to the k-CTP is an (s,t)-walk. The set of blocked edges E_* is a hidden input at the beginning of the walk. We say an edge is *revealed* when one of its endpoints has already been visited. A *discovered blocked edge* is a revealed edge which is blocked. At any moment of the walk, we usually denote by $E'_* \subseteq E_*$ the set of discovered blocked edges, in other words the set of blocked edges for which we visited at least one endpoint. During the walk, we are in fact working on $G \setminus E'_*$ as discovered blocked edges can be removed from G.

We call a path *blocked* if one of its edges was discovered blocked; *apparently open* if no blocked edge has been discovered on it for now (it may contain a blocked edge which has not been discovered yet); *open* if we are sure that it does not contain any blocked edge (either all of its edges were revealed open, or it is apparently open and $|E'_*| = k$, or by connectivity considerations since s and t must stay connected in road maps).

For any $F \subseteq E_*$ and two vertices x, y of G, let $d_F\left(G, x, y\right)$ be the cost of the shortest (x,y)-path in graph $G \setminus F$. If the context is clear, we will use $d_F\left(x, y\right)$.

We denote by P_{opt} some *optimal offline path* of road map (G, E_*): it is one of the shortest (s,t)-paths in the graph $G \setminus E_*$. Its cost, the *optimal offline cost*, given by $d_{\text{opt}} = d_{E_*}\left(s, t\right)$, is the distance the traveller would have traversed if he had known the blockages in advance. Given a strategy A for the k-CTP, the *competitive ratio* [14] $c_A(G, E_*)$ over road map (G, E_*) is defined as the ratio between the cost $d_A^{\text{Tr}}\left(G, E_*\right)$ of the traversed walk and d_{opt}. Formally:

$$c_A(G, E_*) = \frac{d_A^{\text{Tr}}\left(G, E_*\right)}{d_{\text{opt}}}.$$

Given a monotone family of graphs $\mathcal{F}$ (i.e. closed under taking subgraph), we say that a strategy A admits a competitive ratio $c(k)$ for the family $\mathcal{F}$ if it is an upper bound for all values $c_A\left(G, E_*\right)$ over all k-CTP road maps (G, E_*) such that $G \in \mathcal{F}$. Conversely, we say that some ratio $c(k)$ cannot be achieved for family $\mathcal{F}$ if, for every strategy A, there is a road map (G, E_*) with $G \in \mathcal{F}$ such that $c_A(G, E_*) > c(k)$.

Westphal [26] identified, for any integer k, a relatively trivial family of graphs for which any deterministic strategy achieves ratio at least $2k + 1$. These graphs are made up of only $k + 1$ identical disjoint (s,t)-paths: they are planar and have treewidth 2. As those paths are indistinguishable, the traveller might have to traverse k of them before finding the open one. This outcome still works if we restrict ourselves to unit weights [15]. Conversely, there are two strategies in the literature achieving competitive ratio $2k + 1$ on general graphs: REPOSITION [26] and COMPARISON [27].

Note that articulation points allow a preliminary decomposition and simplification of any input graph, before even exploring:

▶ **Lemma 2.2.** *Let $\mathcal{F}$ be a monotone family of graphs, and assume that we have a strategy A achieving competitive ratio C on graphs of $\mathcal{F}$ that do not contain any articulation point. Then, there exists a strategy A' achieving the same competitive ratio C on all graphs of $\mathcal{F}$.*

Proof. The strategy A' goes as follows: let (G, E_*) be a road map with $G \in \mathcal{F}$. If G does not contain any articulation point, apply strategy A. Otherwise, let z be an articulation point of G. If $\{z\}$ is not an (s,t)-separator, then, recursively apply strategy A' on $R_G(s, \{z\})$, which is both the source and the target component, to reach t from s. Otherwise (so $\{z\}$ is an (s,t)-separator), recursively apply strategy A' on the source component $R_G(s, \{z\})$ to reach z from s, then recursively apply strategy A' on the target component $R_G(t, \{z\})$ to reach t from z. The procedure is illustrated in Figure 2.

We prove by induction on the number p of articulation points that A' terminates and achieves competitive ratio C. The base case $p = 0$ holds by property of A. For the inductive step, we distinguish two cases. If $\{z\}$ is not an (s,t)-separator, the walk we obtain is of

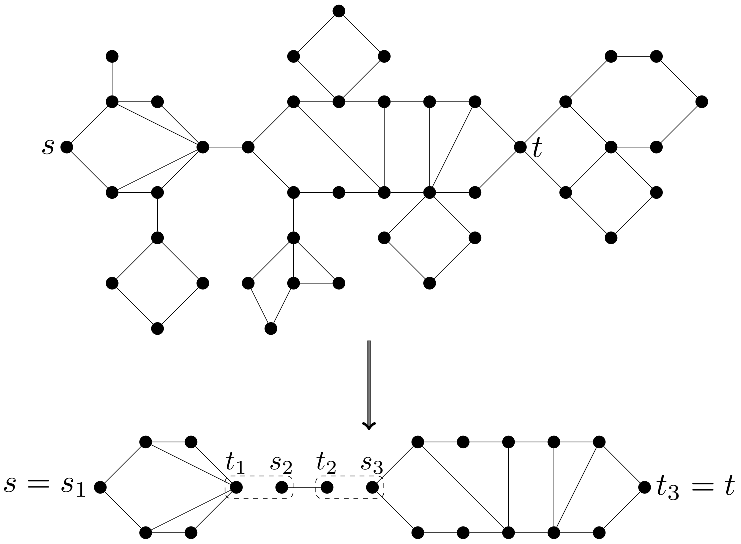

Figure 2 Decomposing the graph into components with no articulation points and removing the useless components (the vertices in a dashed rectangle are the same in the original graph).

length at most Cd_{opt}, which gives competitive ratio C. Otherwise, the length of the whole walk at most $Cd_{E_*}(s,z) + Cd_{E_*}(z,t)$. Since z is an (s,t)-separator, $z \in P_{\text{opt}}$ and we have $d_{\text{opt}} = d_{E_*}(s,z) + d_{E_*}(z,t)$, which concludes the proof. ◀

3 Optimal competitive ratio 9 for unit-weighted outerplanar graphs

We propose a polynomial-time strategy called ExpBalancing dedicated to unit-weighted outerplanar graphs. We show that it achieves competitive ratio 9 for this family of graphs, which we will later prove is optimal (see Theorem 1.2).

3.1 Presentation of the strategy

First, note that Lemma 2.2 allows us to work on outerplanar graphs without articulation points. The input is a unit-weighted 2-connected outerplanar graph G and two vertices s and t. We provide a detailed description of the strategy ExpBalancing that we follow to explore the graph G.

1. **Reaching t.** If, at any point in our exploration, we reach t, then we exit the algorithm and return the processed walk.
2. **Horizontal chords treatment.** If, at any point in our exploration, we visit a vertex $u \in S_i$, $i \in \{1,2\}$, incident with an open horizontal chord uv revealed for the first time, then we can remove all the vertices on side S_i that lie between u and v on the outer face. Said differently, we get rid of the vertices which are surrounded by the chord uv. If several horizontal chords incident with u are open, then it suffices to apply this rule to the chord which surrounds all others. This procedure comes from the observation that, due to both unit weights and planarity, the open horizontal chord uv with the rightmost v is necessarily the shortest way to go from u to t on side S_i, and thus visiting the vertices surrounded by it will occur an extra, useless cost.

3. **Exponential balancing.** The core *exponential balancing* principle of the strategy consists in alternately exploring sides within a given budget that doubles each time we switch sides. The budget is initially set to 1. Hence, we walk first on side S_1 with budget 1, second on side S_2 with budget 2, then on side S_1 with budget 4, and so on. We say each budget corresponds to an *attempt*. During each attempt, we traverse a path starting from the source s and stay exclusively on some side S_i, $i \in \{1, 2\}$. As evoked in the previous step, at each newly visited vertex, we use an open horizontal chord from our position which brings us as close as possible to t on our side. Either a horizontal chord is open and we use the one which surrounds all other open chords, or if no such chord is open, we pursue our walk on the outer face.

   This balancing process can be described on an automaton depicted in Figure 3 which will be particularly useful in the analysis of this strategy. Here, we assume that we neither are completely blocked on one side nor reveal an open vertical chord. We will handle these cases in Steps 4-6.

   We start our walk on s (state $\mathbf{E_1}$), make an attempt on an arbitrary side (say S_1) with budget 1 (state $\mathbf{E_2}$), and decide to come back to s if t was not reached. During our first attempt on side S_2 with budget 2, we cross a first edge and reach state **A**. Then, we cross a second edge if we are not blocked, but this part of the journey corresponds to the transition between states **A** and **B**. The automaton works as follows:

   - In state **A**, we have explored D vertices on each side (in the description above, $D = 1$ when we first arrive in state **A**). Call x and y the last explored vertices on each side, assume we are on x. The current budget is $2D$ and we pursue our attempt on the side of x.
   - We then explore at most D more vertices on the side of x. We reach state **B**.
   - We then go back to y through s, reaching state **C**.
   - We explore at most D more vertices on the side of y. We go back to state **A** with an updated value of D that is doubled, update x and y, and the sides are switched.

4. **Bypassing a blocked side.** If, during some attempt on side S_i, we are completely blocked (there is no open (s, t)-path on $G[S_i] \setminus E'_*$) before reaching the budget, hence exploring αD ($\alpha < 1$) instead of D (see Figures 4a and 4b), then we backtrack to s and pursue the balancing on the other side S_j ($j \in \{1, 2\}, j \neq i$). However, we forget any budget consideration: we travel until we either reach t or visit the endpoint u of some open vertical chord uv. In case there are several open vertical chords incident with u revealed at the same time, we consider the rightmost one. At this moment, we update the current graph $G \setminus E'_*$ by keeping only the target component of separator $\{u, v\}$ and considering u as a new source. Concretely, we concatenate the current walk computed before arriving at u with a recursive call of ExpBalancing on input $(G[R_G(t, \{u, v\})], u, t)$.

5. **Handling open vertical chords between states A and B.** If, during some attempt on side S_i, especially in the transition between states **A** and **B**, we reveal an open vertical chord uv, $u \in S_i$, after having explored distance αD (parameter α is rational, $0 < \alpha \leq 1$, but αD is an integer), then we go to the other side S_j, $j \neq i$, through uv and explore side S_j from v towards s until we:

   - either "see" a vertex y already visited after distance βD (we fix $\beta D \leq \alpha D - 1$, so $0 \leq \beta < \alpha$),
   - or explore distance $\alpha D - 1$ and do not see any already visited vertex,
   - or are completely blocked on S_j before we reach distance $\alpha D - 1$.

   By "see", we mean that we can reach - or not - a neighbor of y which reveals the status of the edge between them: in this way, we actually know the distance to reach y from v even if we did not visit v. Figure 4c describes this rule with an example.

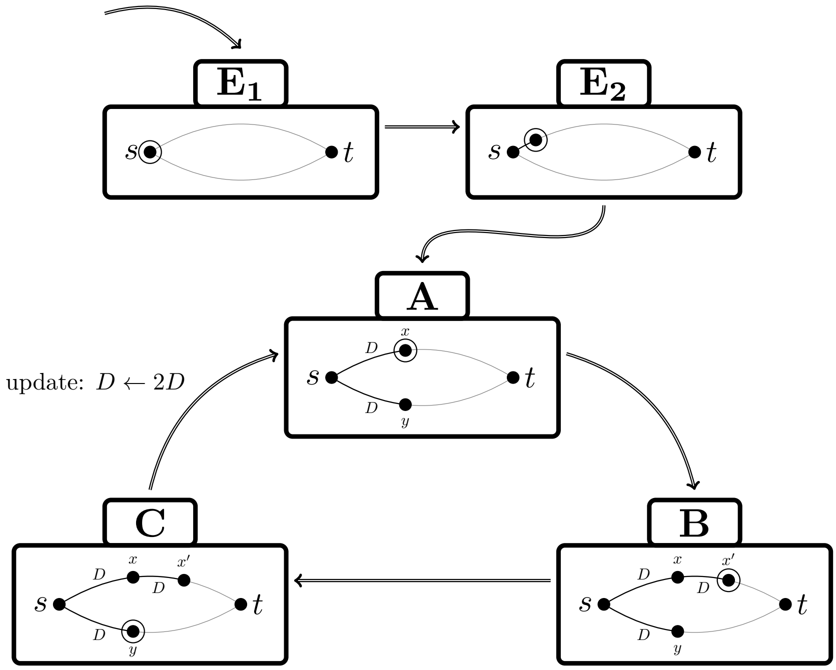

Figure 3 Representation of the exponential balancing divided into three different states. The circled vertex is the one we are currently exploring.

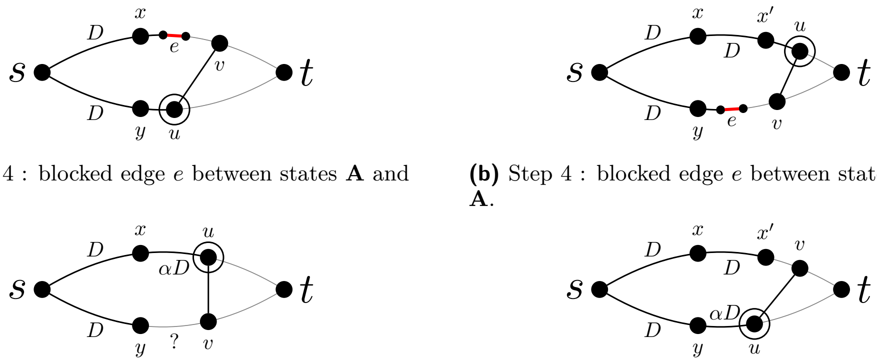
The role of this procedure is to know which endpoint of the chord is the closest to s. If we see, after distance $\beta D = \alpha D - 1$, an already visited vertex (denoted by y in Figure 4c) at distance αD from v, then, we continue the exponential balancing: we go back to v and thus to state **A** in the automaton, update the budget value D which becomes $D + \alpha D$.

Otherwise, we update G by keeping only the target component of separator $\{u, v\}$. The current graph becomes $G' = G[R(t, \{u, v\})]$. If we saw an already visited vertex $y \in S_j$ by exploring distance $\beta D < \alpha D - 1$, then the new source becomes $s' = v$. Otherwise, the new source is $s' = u$. We concatenate the current walk with the walk returned by applying ExpBalancing on input (G', s', t).

6. **Handling open vertical chords between states C and A.** If, during the transition between states **C** and **A** (when some attempt is launched on the side of y and the traversed distance on the other side is larger, see Figure 3), an open vertical chord uv is revealed (see Figure 4d), then we keep only the target component of $\{u, v\}$ and set u as the new source. More formally, we concatenate the current walk with the walk returned by applying ExpBalancing on input (G', u, t), where $G' = G[R_G(t, \{u, v\})]$.

Steps 4–6 can be summarized in this way: when we reveal an open vertical chord uv such that $d_{E_*}(s, v) = d_{E_*}(s, u) + 1$, we launch a recursive call on the target component of separator $\{u, v\}$ with source u and target t. Indeed, any optimal offline path must pass through separator $\{u, v\}$ and, as $d_{E_*}(s, v) = d_{E_*}(s, u) + 1$, we can say there is one optimal offline path P_{opt} such that $u \in P_{\text{opt}}$. Hence, it makes sense to select u as a new source, there is no interest in visiting vertices different from $\{u, v\}$ belonging to their source component.



(a) Step 4 : blocked edge e between states **A** and **B**.

(b) Step 4 : blocked edge e between states **C** and **A**.

(c) Step 5 : open vertical chord uv between states **A** and **B**.

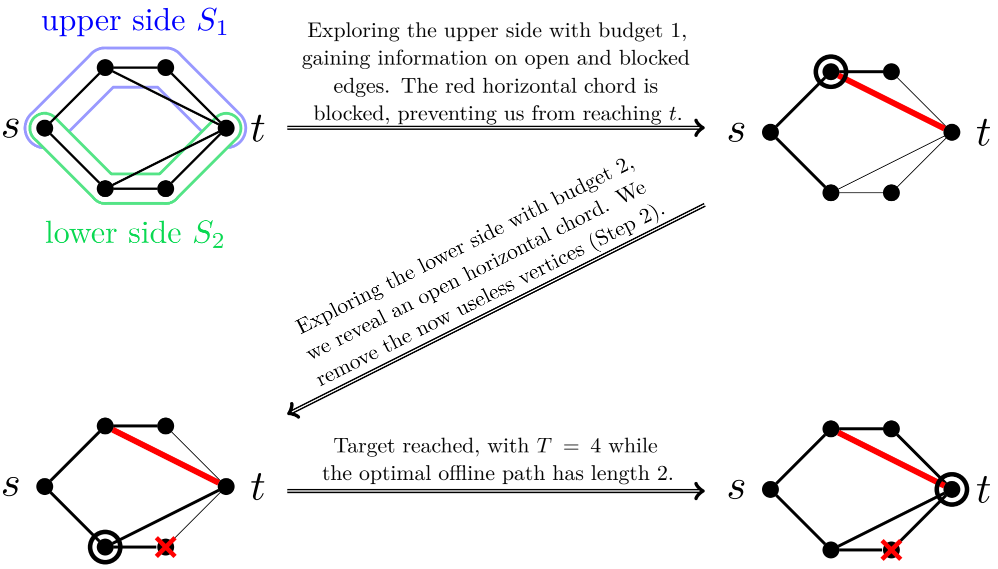
(d) Step 6 : open vertical chord uv between states **C** and **A**.

Figure 4 Four situations potentially met with ExpBalancing on some unit-weighted outerplanar graph.

3.2 Competitive analysis

We now show that the strategy ExpBalancing presented above has competitive ratio 9 on unit-weighted outerplanar graphs. We prove this statement by minimal counterexample. In this subsection, let G denote the smallest (by number of vertices, then number of edges) unit-weighted outerplanar graph on which ExpBalancing does not achieve competitive ratio 9. We will see that the existence of such a graph G necessarily implies a contradiction.

Examples of executions of ExpBalancing are given in Figures 5 and 6.



Exploring the upper side with budget 1, gaining information on open and blocked edges. The red horizontal chord is blocked, preventing us from reaching t.

Exploring the lower side with budget 2, we reveal an open horizontal chord. We remove the now useless vertices (Step 2).

Target reached, with $T = 4$ while the optimal offline path has length 2.

Figure 5 Application of ExpBalancing on the first graph of the decomposition of Figure 2. At each step, the circled vertex is the one we are currently exploring, and we know the status of the bold edges: black is open, red is blocked.

The two following technical lemmas prove that a recursive call has to happen when ExpBalancing is applied on G (Lemma 3.1) and that such a recursive call implies certain properties (Lemma 3.2).

▶ **Lemma 3.1.** *During the execution of* ExpBalancing, *let T be the distance travelled at a given point before the first recursive call (if any). Then, $T \leq 9d_{\text{opt}}$. Moreover, if we are in state* **A**, *let x and y be the last two vertices explored on each side during the exponential balancing. Then: (i) $d_{E_*}(s,x) = D$, (ii) $d_{E_*}(s,y) = D$ and (iii) $T \leq 5D$.*

Proof. Assume that we have applied ExpBalancing on G until a certain point and that no recursive call was launched so far. We first focus on the second part of the invariant we want to show:

$$\text{In state } \mathbf{A},\ (i)\ d_{E_*}(s,x) = D,\ (ii)\ d_{E_*}(s,y) = D \text{ and } (iii)\ T \leq 5D.$$

Items (i) and (ii) are true, since no shortcut between s and either x or y can exist: any open horizontal chord is used, and an open vertical chord opening up a shortcut leads to a recursive call (Steps 5 and 6).

Item (iii) is trivially true when we kick-start the exponential balancing: when entering **A** from $\mathbf{E_2}$, we have $T = 3$ and $d_{E_*}(s,x) = d_{E_*}(s,y) = 1$. Assume that it is true for a given $D \geq 1$, and let T_0 be the value of T at this point. When we reach state **B**, we have $T = T_0 + D \leq 6D$. When we reach state **C**, we have $T = T_0 + D + 3D \leq 9D$. In brief, from state **A** to **C**, we have $d_{\text{opt}} \geq D$ as distance D was explored on both sides without reaching t. The largest ratio of T by D on these phases is 9 at state **C**, where we have $T \leq 9d_{\text{opt}}$.

During the transition from **C** to **A**, if $D + \alpha D$ denotes the traversed distance on current side at any moment (see Figure 3), then $d_{\text{opt}} \geq D + \alpha D$ and $T = 9D + \alpha D$. The ratio $\frac{T}{d_{\text{opt}}}$ admits a decreasing upper bound, from 9 in state **C** to 5 in **A**. Indeed, when we are back to state **A**, we have $T = T_0 + D + 3D + D$, but the value of D is updated. Let $D' = 2D$. We have $T = T_0 + 5D \leq 5D + 5D = 5D'$, and so item (iii) remains true during the core loop.

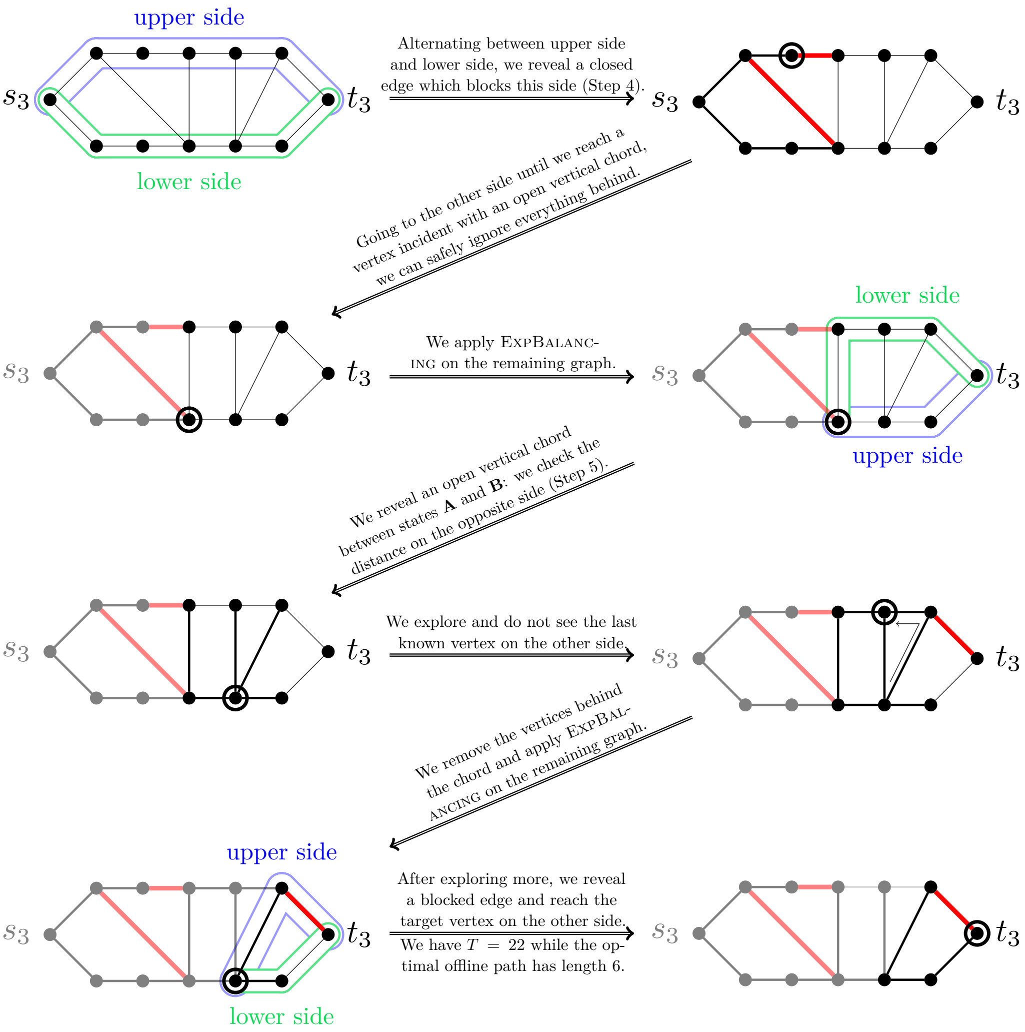
We also have to check that it is true when we met an open vertical chord uv between states **A** and **B** which satisfies $d_{E_*}(s,v) = d_{E_*}(s,u)$ (case $\beta D = \alpha D - 1$ in Step 5). In this case, the new value of D is $D' = D + \alpha D$ and we have $T \leq 5D + \alpha D + 1 + 2\alpha D \leq 5(D + \alpha D) = 5D'$ (since $\alpha D \geq 1$), so item (iii) remains true.

Thus, conditions (i)-(iii) hold in state **A**, and we always (during all states and transitions between them) have $T \leq 9d_{\text{opt}}$, hence the statement holds. ◀

▶ **Lemma 3.2.** *Assume that we are currently executing* ExpBalancing *on G and that a recursive call is launched after revealing the vertical chord uv with new source u. Let T be the distance traversed before the recursive call. Then, either $T > 9d_{E_*}(s,u)$ or $d_{E_*}(s,v) < d_{E_*}(s,u) + 1$.*

Proof. If $d_{E_*}(s,v) \geq d_{E_*}(s,u) + 1$, following the rules established in Steps 4-6, we will launch a recursive call on the target component of $\{u,v\}$ with new source u. Hence, we will have $d^{\text{Tr}}_{\text{EXP}}(G, E_*) = T + T'$, where $T' \leq 9d_{E_*}(u,t)$ by minimality of G and EXP abbreviates ExpBalancing. By way of contradiction, suppose that $T \leq 9d_{E_*}(s,u)$. The optimal offline path P_{opt} necessarily goes through the separator $\{u,v\}$ in graph G and, since $d_{E_*}(s,v) = d_{E_*}(s,u) + 1$, u belongs to some optimal offline path. Consequently, $T + T' \leq 9(d_{E_*}(s,u) + d_{E_*}(u,t)) = 9d_{E_*}(s,t)$. ◀

We are now ready to prove the major contribution of this article.



upper side

▶ **Theorem 1.1.** *There is a strategy with competitive ratio 9 for unit-weighted outerplanar graphs.*

Proof. A direct consequence of Lemma 3.1 is that, during some attempt, ExpBalancing will launch a recursive call on G (otherwise, it has competitive ratio 9, a contradiction). Let T be the distance traversed before the recursive call. Lemma 3.2 has an important consequence: if we launch a recursive call on the open vertical chord uv with new source u and can guarantee that both $d_{E_*}(s, v) = d_{E_*}(s, u) + 1$ and $T \leq 9d_{E_*}(s, u)$, then, we have a contradiction. According to the description of ExpBalancing, a recursive call is launched when we are sure that $d_{E_*}(s, v) = d_{E_*}(s, u) + 1$: this concerns Step 4, Step 5 when $\beta D < \alpha D - 1$ and Step 6.

Assume first that we are blocked on one side between states **A** and **B** in Step 4 (see Figure 4a). We know that $d_{E_*}(s,v) = d_{E_*}(s,u) + 1$ because u is an articulation point of $G \setminus E'_*$. Also, $d_{E_*}(s,u) = D + d_{E_*}(y,u)$. Using Lemma 3.1:

$$\begin{aligned} T &\leq (5D+\alpha D) + (\alpha D + 2D) + d_{E_*}(y,u) \\ &\leq (7+2\alpha)D + d_{E_*}(y,u) \\ &\leq 9(D + d_{E_*}(y,u)) && (\alpha \leq 1) \\ &\leq 9d_{E_*}(s,u) \end{aligned}$$

which, by Lemma 3.2, leads to a contradiction.

Assume now that we are blocked on one side between states **C** and **A** in Step 4 (see Figure 4b). Let x' be the last vertex reached at the end of state **A**, we know that $d_{E_*}(s,v) = d_{E_*}(s,u) + 1$ because u is an articulation point of $G \backslash E'_*$ and $d_{E_*}(s,u) = 2D + d_{E_*}(x',u)$. Using Lemma 3.1:

$$\begin{aligned} T &\leq (9D+\alpha D) + (\alpha D + 3D) + d_{E_*}(x',u) \\ &\leq (12+2\alpha)D + d_{E_*}(x',u) \\ &\leq 9(2D + d_{E_*}(x',u)) \leq 9d_{E_*}(s,u) && (\alpha \leq 1) \end{aligned}$$

which, by Lemma 3.2, leads to a contradiction.

Assume now that we reveal an open vertical chord uv between states **A** and **B** in Step 5 (see Figure 4c). Recall that $d_{E_*}(s,u) \leq D + \alpha D$, and we explore up to distance $\alpha D - 1$ towards y. There are two possibilities: either we see y by exploring distance βD (with $\beta D < \alpha D - 1$), or we do not see y even if we explore distance $\alpha D - 1$.

If we see y, then, we know that $d_{E_*}(s,u) = d_{E_*}(s,v) + 1$ since going to u through x will yield distance $D + \alpha D$ while going through y and v will yield distance at most $D + \beta D + 2$, and we know that $\beta D < \alpha D - 1$ and $\beta D \geq 0$. So, $d_{E_*}(s,v) = D + \beta D + 1$. Using Lemma 3.1:

$$\begin{aligned} T &\leq (5D+\alpha D) + (1 + 2(\beta D + 1)) \\ &\leq (5+\alpha+2\beta)D + 3 \\ &\leq 9(D + \beta D + 1) \leq 9d_{E_*}(s,v) && (\beta < \alpha \leq 1) \end{aligned}$$

which, by Lemma 3.2 leads to a contradiction (the roles of u and v are reversed here, since v is the new source).

If we do not reach y, either by blocked edges or because we have explored distance $\alpha D - 1$ without reaching it, then, we know that $d_{E_*}(s,v) = d_{E_*}(s,u) + 1$. Using Lemma 3.1:

$$\begin{aligned} T &\leq (5D+\alpha D) + (1 + 2(\alpha D - 1) + 1) \\ &\leq (5+3\alpha)D \\ &\leq 9(D + \alpha D) \leq 9d_{E_*}(s,u) && (\alpha \leq 1) \end{aligned}$$

which, by Lemma 3.2, leads to a contradiction.

Finally, assume that we reveal an open vertical chord uv between states **C** and **A** after having explored αD vertices in Step 6 (see Figure 4d). Since uv was not revealed before, this implies that the shortest path from s to v goes through u, and so $d_{E_*}(s,v) = d_{E_*}(s,u) + 1$. Using Lemma 3.1:

$$\begin{aligned} T &\leq 9D + \alpha D \\ &\leq 9(D + \alpha D) \leq 9d_{E_*}(s,u) && (\alpha \leq 1) \end{aligned}$$

which, by Lemma 3.2, leads to a contradiction.

All the possible cases lead to contradictions, and so such a G cannot exist. ExpBalancing thus achieves competitive ratio 9 on unit-weighted outerplanar graphs. ◀

3.3 Lower bound 9 for unit-weighted outerplanar graphs

In this subsection we prove that the competitive ratio achieved with the ExpBalancing strategy is optimal on unit-weighted outerplanar graphs.

▶ **Theorem 1.2.** *For any $\varepsilon > 0$, no deterministic strategy achieves competitive ratio $9 - \varepsilon$ on all road maps (G, E_*), where G is a unit-weighted outerplanar graph.*

This result can be obtained by a natural reduction from the linear search problem [9] (or, equivalently, the cow-path problem on two rays [21]). The *linear search problem* is defined as follows: an immobile hider is located on the real line. A searcher starts from the origin and wishes to discover the hider in minimal time. The searcher cannot see the hider until he actually reaches the point at which the hider is located and the time elapsed until this moment is the duration of the game.

This problem reduces to the k-CTP on specific road maps that we call *shell road maps*. The *shell graph* on $2n$ vertices, denoted by Sh_n (see Figure 7), is the graph obtained from a cycle on $2n$ vertices $\{v_0, v_1, \ldots, v_{2n-1}\}$ with all possible chords incident with vertex v_n, except v_0v_n. It is clearly outerplanar, and all edge weights are set to 1. In our setting, we shall consider v_0 as the source s and v_n as the target t. We call *shell road maps* the specific road maps (Sh_n, E_*) where E_* is made up only of edges incident with t. Said differently, the traveller cannot be blocked on the outer face on some edge v_iv_{i+1}.

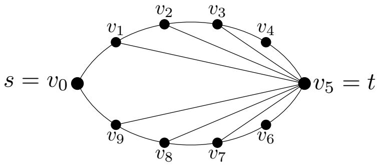

Figure 7 The shell graph on 10 vertices Sh_5.

The shell graph is 2-connected, so it contains an upper side S_1 and a lower side S_2 which can simulate the positive and the negative sides of the real line. The position of the hider will then intuitively correspond to the first encountered open chord to t : if the hider is at position $x > 0$ (resp. $x < 0$), then E_* will contain all $v_it \in E$ except $v_{\lceil x \rceil}t$ (resp. $v_{\lfloor 2n+x \rfloor}t$). In such a way, any strategy for the k-CTP with some competitive ratio r, will give a strategy for the linear search problem with asymptotic competitive ratio $r + \varepsilon$ for any $\varepsilon > 0$. However, it is known that the linear search problem has an optimal ratio of 9 [3] which gives the lower bound we want on the k-CTP. Note however that, in the sketched reduction, small details need to be cared of, for example the distance of the traveller has a unit additive term compared to the searcher on the line (cost of crossing the discovered chord to t). In order to remove any doubt related to these details, we provide in the full version [6] a complete proof of Theorem 1.2 (without reducing to the linear search, but sharing some features with the proof of [3]).

4 The case of arbitrarily weighted outerplanar graphs

Given our results on the unit-weighted case (which give as an easy corollary ratio $9S$ for fixed stretch S), a natural question is whether we can design a deterministic strategy achieving a constant competitive ratio for the more general family of arbitrarily weighted outerplanar graphs. In this section, we prove that this is impossible since, for any constant $C \geq 1$, there exists a weighted outerplanar graph on which the competitive ratio obtained is necessarily greater than C. Let us introduce a sub-family of outerplanar graphs that will be useful here.

▶ **Definition 4.1.** *An outerplanar graph G containing s and t is said to be* (s,t)-unbalanced *if either it is a single st edge or one of its sides contains all vertices V of the graph.*

In other words, an (s,t)-unbalanced outerplanar graph is such that s and t are neighbors on the outer face. While one side (say w.l.o.g. the lower side) contains all vertices, the upper one only contains s and t and simply consists of a single edge st. Thus, such a graph does not have any vertical chord. We show in the remainder that constant competitive ratio cannot be obtained even on weighted (s,t)-balanced outerplanar graphs.

We begin with the definition of a graph transformation $\mathcal{T}$ which takes as input a weighted (s,t)-unbalanced outerplanar graph $H = (V, E, \omega)$, three positive rational values α, C, and η, and an integer N. The construction of the output graph $\mathcal{T}(H, \alpha, C, \eta, N)$ works as follows:

- Create two vertices s and t with an edge st of weight C. This edge will stand as the upper side of the graph.
- Add N copies of the graph αH, where $\alpha H = (V_\alpha, E_\alpha, \omega_\alpha)$ is a graph such that $V_\alpha = V$, $E_\alpha = E$ and $\omega_\alpha(e) = \alpha\omega(e)$ for every edge $e \in E$. These copies are denoted by $\alpha H^{(1)}, \dots, \alpha H^{(N)}$ and the source/target pair of each $\alpha H^{(j)}$ is denoted by (s_j, t_j).
- Connect in series all copies $\alpha H^{(1)}, \dots, \alpha H^{(N)}$ from s to t in order to form the lower side of the graph, using their source/target as input/output vertices. In brief, merge s with s_1, t_i with s_{i+1} for $i \in \{1, \dots, N-1\}$, and t_N with t.
- Add all edges $t_j t$ for $1 \le j \le N-1$ with weight η.

Figure 8 illustrates the graph $\mathcal{T}(H, \alpha, C, \eta, N)$ obtained. Observe that it is an (s,t)-unbalanced outerplanar graph because the lower side of each αH contains all its own vertices. Therefore, all vertices of $\mathcal{T}(H, \alpha, C, \eta, N)$ lie on its lower side. We also set $t_0 = s$.

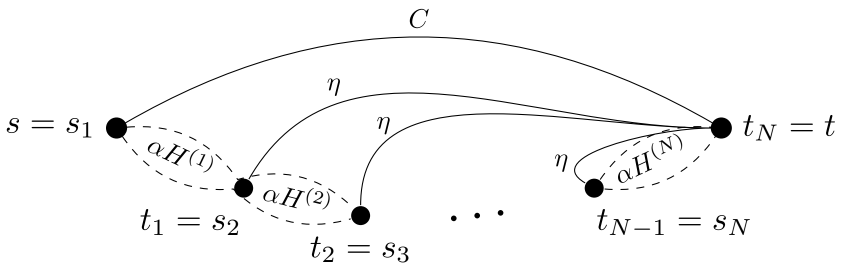

Figure 8 The graph $\mathcal{T}(H, \alpha, C, \eta, N)$ with its outerplanar embedding.

For the remainder, we define a trivial arithmetic sequence generating all positive half-integers: for any integer $i \ge 0$, let $C_i = \frac{1}{2} + i$. For any value C_i, we are able to construct a collection of road maps for which ratio C_i cannot be achieved by any deterministic strategy.

▶ **Proposition 4.2 (*).** *For any nonnegative integer i, there exists a family $\mathcal{R}_i$ of road maps which satisfies the following properties:*

- *all the road maps of $\mathcal{R}_i$ are defined on the same weighted (s,t)-unbalanced outerplanar graph,*
- *no deterministic strategy can achieve ratio C_i on family $\mathcal{R}_i$.*

Sketch of the proof. By induction, we assume that the property holds for some $i \ge 1$. We focus on some graph $H_{i+1} = \mathcal{T}(H_i, \alpha, C_i, \eta, N)$. The reasoning consists in a trade-off on the optimal distance between s and the last visited t_j vertex on the lower side, denoted by t_q. If $d_{E_*}(s, t_q)$ is at least C_i, then it appears that the st edge is the optimal offline path and we realize that exploring the lower side was too costly. We deduce that the obtained competitive ratio is necessarily greater than $C_i + 1$ using the induction hypothesis. Otherwise, if $d_{E_*}(s, t_q) < C_i$, then it means that we did not explore far enough on the lower side, hence the optimal offline path passes through it. We obtain the same conclusion that the ratio is greater than $C_i + 1$. See full version [6] for the proof.

Hence, no deterministic strategy can achieve constant competitive ratio on weighted outerplanar graphs since integer i can take arbitrarily large values:

▶ **Theorem 1.3.** *There is no constant C, independent from G and k, such that a deterministic strategy achieves competitive ratio C on all road maps (G, E_*) where G is a weighted outerplanar graph.*

Proof. By contradiction, for any $C \geq 1$, apply Proposition 4.2 on $i = \lceil C \rceil$. ◀

5 Perspectives

We highlighted a non-trivial unit-weighted family of graphs (outerplanar) for which there exists a deterministic strategy with constant competitive ratio 9, which is optimal. However, we proved that no constant competitive ratio can be achieved for arbitrarily weighted outerplanar graphs. Several questions arise.

Since some sub-families of outerplanar graphs have constant competitive ratio in the weighted case (trees and cycles, which imply cacti from Lemma 2.2) while a very close super-family admits the general bound $2k + 1$ in the unit-weighted case (planar of treewidth 2), a natural question is to investigate where the competitive gaps lie in both cases. For the unit-weighted case, future research could focus on the natural extension of p-outerplanar graphs [4], with p successive outer faces, in order to generalize constant competitiveness.

To achieve constant competitive ratio on arbitrarily weighted graphs, a good candidate could be graphs with bounded-sized minimal edge (s, t)-cuts, for which ratio $\sqrt{2}k + O(1)$ is known [12]. Observe that our construction $\mathcal{T}$ which disproves constant ratio increases the size of edge (s, t)-cuts. We conjecture that there exists a polynomial-time deterministic strategy achieving constant competitive ratio on graphs with edge (s, t)-cuts of bounded size.

Richard D. P. East
Haiqu

Abstract

The ZX calculus and ZH calculus use diagrams to denote and compute properties of quantum operations, using "rewrite rules" to transform between diagrams which denote the same operator through a functorial *semantic map*. Different semantic maps give rise to different rewrite systems, which may prove more convenient for different purposes. Using discrete measures, we describe semantic maps for ZX and ZH diagrams, well-suited to analyse unitary circuits and measurements on qudits of any fixed dimension $D > 1$ as a single "ZXH-calculus". We demonstrate rewrite rules for the "stabiliser fragment" of the ZX calculus and a "multicharacter fragment" of the ZH calculus.

1 Introduction

The ZX calculus [10, 2, 28, 42] and ZH calculus [3, 40] are systems using annotated graphs ("ZX diagrams" and "ZH diagrams"), to denote tensor networks for quantum computation, and other problems involving tensors over $\mathbb{C}^2$ [16, 19, 39, 18, 17, 26]. They include rewrite rules, to perform computations on diagrams without recourse to exponentially large matrices. Complicated procedures may involve diagrams of mounting complexity to analyse, but the ZX- and ZH-calculi often simplify the analysis of many-qubit procedures. It is also increasingly common to consider versions of the ZX- and ZH-calculi for qudits [20, 44, 48, 6, 41, 27, 33, 32], which promise similar benefits for the analysis of procedures on qudits.

Most treatments of these calculi [2, 3, 4, 5, 6, 11, 14, 21, 22, 23, 24, 25, 28, 29, 30, 33, 37, 38, 40, 42, 43, 45, 46, 47, 48, 49] are "scalar exact": equational theories, that do not introduce changes by scalar factors. Changes by scalar factors do not matter for some applications (e.g., testing equivalence of unitary transformations), but *are* important for probabilistic processes (e.g., postselection) or to compute specific numerical values [26]. But "scalar exact" treatments may involve frequent accumulation or deletion of *scalar gadgets*: disconnected sub-diagrams which obliquely denote normalisation factors. Presentations of these calculi which avoid such book-keeping, are simpler for instruction and practical use, and may also admit a unified rewrite system (a "ZXH calculus") incorporating the rules of each [14, 19, 18].

In previous work [14], one of us addressed this issue of bookkeeping of scalars for ZX- and ZH-diagrams on qubits through a carefully constructed semantic map. The result, described as "well-tempered" versions of these calculi, are scalar exact while avoiding the modifications of scalar gadgets for the most often-used rewrites. However, while the rewrite rules of this "well-tempered" notation are simple, the notational convention itself (i.e., the semantics of the generators of the calculi) is slightly unwieldly. Furthermore, it left open how to address similar issues with scalars for versions of these calculi on qudits of dimension $D > 2$.

In this work, we consider how different normalisations of the ZX- and ZH-calculus may be expressed in a more uniform way, by representing operators on qudits (of any fixed dimension $D > 1$) through the use of integrals with respect to a discrete measure.

For a finite set S, let $\#S$ denote its cardinality. Consider a measure $\mu(S) = \#S \cdot \nu^2$ on subsets $S \subseteq \mathbb{Z}$, for $\nu > 0$ to be fixed later. This is a "measure" on sets S (see Section 2.1) which allows us to define a formal notion of integration of functions $f : \mathbb{Z} \to \mathbb{C}$,

$$\int\limits_{x \in S} f(x) \;:=\; \int\limits_{x \in S} f(x)\, \mathrm{d}\mu(x) \;:=\; \sum_{x \in S} f(x)\, \nu^2 \,. \tag{1}$$

(For the sake of brevity, we often use the standard convention of suppressing the differential $\mathrm{d}\mu$, as on left-hand expression below, when the measure of integration is understood.) Such integrals allow us to express sums with certain normalising factors more uniformly, by absorbing the factors into the measure μ by an appropriate choice of $\nu > 0$. For a finite-dimensional Hilbert space $\mathcal{H}$ with standard basis $|x\rangle := \mathbf{e}_x$ for some index set $x \in \mathbf{D}$, we may define the (not-necessarily normalised) *point-mass distributions* $|x\rangle\!\rangle = \nu^{-1} |x\rangle \in \mathcal{H}$, and their adjoints $\langle\!\langle x| = |x\rangle\!\rangle^\dagger$. Then, if we have some "state-function" $|f\rangle\!\rangle := \int_{x \in \mathbf{D}} f(x)\, |x\rangle\!\rangle$ for an arbitrary function $f : \mathbb{Z} \to \mathbb{C}$, it is easy to show that

$$\langle\!\langle z|f\rangle\!\rangle \;:=\; \int\limits_{x \in \mathbf{D}} \langle\!\langle z|x\rangle\!\rangle\, f(x) \;=\; f(z), \tag{2}$$

similar to how Dirac measures are used with integration over $\mathbb{R}$. While a similar result $\langle z|f\rangle = f(z)$ holds if we simply define $|f\rangle = \sum_{x \in D} f(x)\, |x\rangle$, couching this sort of analysis in terms of discrete integrals and point-mass functions $|x\rangle\!\rangle$ allows us to accommodate scalar factors which may arise when manipulating expressions involving operators such as $\sum_{x \in \mathbf{D}} |x\rangle^{\otimes n} \langle x|^{\otimes m}$ for $m, n > 1$. This is an example of the sort of operator, for which book-keeping of scalar factors frequently arises in most versions of the ZX- or ZH-calculi.

By introducing the additional layer of abstraction, provided by discrete integrals and their accompanying point-mass functions $|x\rangle\!\rangle$, we describe semantics for ZX- and ZH-diagrams which are simple, and which admits a system of rewrites which largely dispenses with the need for modifications to scalar gadgets in the diagrams. This approach to notation, and the rewrites which we demonstrate, are applicable for generators representing operators on qudits of *any* finite dimension, and enables the two calculi to be used interoperably as a single "ZXH-calculus". We present this approach in the hopes that it facilitates the development of practically useful extensions of these calculi beyond qubits.

Structure of this article. Section 2 sets out number-theoretic preliminaries, some background in string diagrams, and common approaches to defining ZX and ZH calculi. Section 3 introduces discrete measures and integrals on $\mathbf{D}$, including what little measure theory we require, and considers the constraints that follow from a particular treatment of discrete Fourier transforms. Section 4 demonstrates how using such discrete integrals as the basis for a semantic map for ZX and ZH diagrams, leads to convenient representations of particular unitary operators and convenient rewrites for both the ZX and ZH calculi. We frequently refer to the Appendices of the full version [15] of this work, where we provide complete proofs, more details about our constructions, and connections to related subjects.

Related work. As we note above, there is recent and ongoing work [20, 44, 48, 6, 41, 27, 33, 32, 34] on ZX, ZH, and related calculi on qudits of dimension $D > 2$ (though often restricted to the case of D an odd prime). Our work is influenced in particular by Booth and Carette [6], and Roy [33], and we are aware of parallel work by collaborations involving these authors [34, 31]. Our work is distinguished in presenting convenient semantics for both ZX and ZH diagrams for arbitrary $D > 1$, notably including the case where D is composite or even.

2 Preliminaries

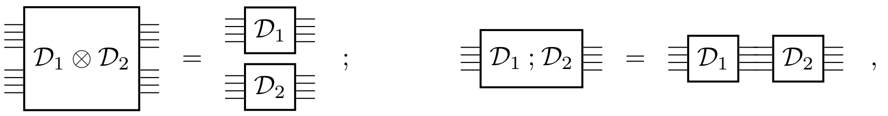
2.1 Number-theoretic preliminaries

Let $D > 1$ be a fixed integer, and $\omega = \mathrm{e}^{2\pi i/D}$. We assume basic familiarity with number theory, in particular with $\mathbb{Z}_D$, the integers modulo D. While it is common to associate $\mathbb{Z}_D$ with the set $\{0, 1, \ldots, D-1\}$ of non-negative "residues" of integers modulo D, one may associate them $\mathbb{Z}_D$ with any contiguous set of residues $\mathbf{D} = \{L, L+1, \ldots, U-1, U\}$ where $U - L + 1 = D$.[1] We may then occasionally substitute $\mathbb{Z}_D$ for $\mathbf{D}$ when this is unlikely to cause confusion: this will most often occur in the context of expressions such as ω^{xy}, which is well-defined modulo D in each of the variables x and y (i.e., adding any multiple of D to either x or y does not change the value of the expression). In such an expression, while we may intend for one of x or y or both may be an element of $\mathbb{Z}_D$ in principle, they would in practise be interpreted as a representative integer $x, y \in \mathbf{D} \subseteq \mathbb{Z}$.

2.2 String diagrams

ZX- and ZH-diagrams are examples of *string diagrams*, which can be described as diagrams composed of dots (or boxes) and wires, where the wires denote objects and the dots/boxes denote maps on those objects.

In the string diagrams which we consider in this article, diagrams are composed of dots or boxes, and wires. These diagrams can be described as being a composition of "generators", which typically consist of one (or zero) dots/boxes with some amount of meta-data, and any number (zero or more) directed wires, where the direction is usually represented by an orientation in the diagram. (In this article, wires are oriented left-to-right, though they are also allowed to bend upwards or downwards.) For any two diagrams $\mathcal{D}_1$ and $\mathcal{D}_2$, we may define composite diagrams $\mathcal{D}_1 \otimes \mathcal{D}_2$ and $\mathcal{D}_1 \,;\, \mathcal{D}_2$, represented schematically by



$\mathcal{D}_1 \otimes \mathcal{D}_2$
=
$\mathcal{D}_1$
$\mathcal{D}_2$
;
$\mathcal{D}_1 \,;\, \mathcal{D}_2$
=
$\mathcal{D}_1$
$\mathcal{D}_2$
,

(3)

which we call the "parallel" and "serial" composition of $\mathcal{D}_1$ and $\mathcal{D}_2$. In the latter case we require that the number of output wires of $\mathcal{D}_1$ (on the right of $\mathcal{D}_1$) equal the number of input wires of $\mathcal{D}_2$ (on the left of $\mathcal{D}_2$), for the composition to be well-defined.

String diagrams may be used to denote maps in a monoidal category $\mathbf{C}$ (in which objects can be aggregated to form composite objects through a parallel product, which we denote by "$\otimes$"). This is done through a *semantic map* $\llbracket \cdot \rrbracket$ which maps each generator to a map in $\mathbf{C}$. This semantic map is defined to be consistent with respect to composition, in the sense that

$$\Big\llbracket \mathcal{D}_1 \otimes \mathcal{D}_2 \Big\rrbracket = \llbracket \mathcal{D}_1 \rrbracket \otimes \llbracket \mathcal{D}_2 \rrbracket, \qquad \Big\llbracket \mathcal{D}_1 \,;\, \mathcal{D}_2 \Big\rrbracket = \llbracket \mathcal{D}_2 \rrbracket \circ \llbracket \mathcal{D}_1 \rrbracket. \tag{4}$$

[1] The reader may wonder why we do not simply adopt the conventional choice of $\mathbf{D} = \{0, 1, \ldots, D-1\}$. There are multiple reasons, the simplest of which being that allowing for the index to include negative integers may be useful for representing certain "quantum numbers" in application to physics.

Note the reversal of the order for sequential composition, which is just an artefact of the difference in orientation of diagrams (left-to-right), and the conventional right-to-left application order of functions that is common e.g. in quantum information theory.

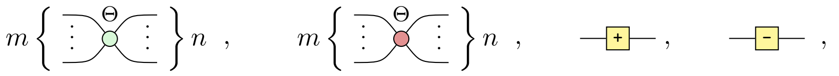
2.3 Preliminary remarks on ZX and ZH diagrams

ZX and ZH diagrams are string diagrams which denote multi-linear operators on some finite-dimensional vector space $\mathcal{H} \cong \mathbb{C}^{\mathbf{D}}$, equipped with a standard basis $|x\rangle$ for $x \in \mathbf{D}$ and functionals $\langle x| = |x\rangle^\dagger$. (For $\mathbf{D}$ a set of D consecutive integers, we may use arithmetic expressions, such as $|x+y\rangle$, to index basis vectors; specifically in the labels of "kets" and "bras", such expressions can be understood to be evaluated mod D.) The parallel product in this case is the usual tensor product $\otimes$, and the sequential product is composition of operators. For a generator $\mathcal{D}$ with m input wires and n output wires, one assigns an operator $[\![\mathcal{D}]\!] : \mathcal{H}^{\otimes m} \to \mathcal{H}^{\otimes n}$. To represent string diagrams to represent maps in which some of the "parallel" operands are being permuted or unaffected, we also consider generators consisting only of wires. We consider four such generators, to which we assign semantics as follows:

 $= \sum_{x\in\mathbf{D}} |x\rangle\langle x|\,,$  $= \sum_{x,y\in\mathbf{D}} |y,x\rangle\langle x,y|\,,$  $= \sum_{x\in\mathbf{D}} |x,x\rangle\,,$  $= \sum_{x\in\mathbf{D}} \langle x,x|\,.$ (5)

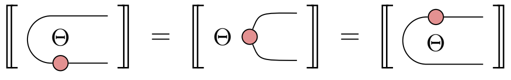
ZX and ZH diagrams are designed with different priorities, but have common features. ZX diagrams are effective for representing operations generated by single-qubit rotations and controlled-NOT gates; in most cases (excepting, e.g., Refs. [46, 6]) it rests on the unitary equivalence of two conjugate bases. ZH diagrams were developed to facilitate reasoning about quantum circuits over the Hadamard-Toffoli gate set [36, 1]. Both were originally defined so that the semantics is preserved by a change in the presentation of the underlying graph, which preserves the connectivity of the diagram [10, 12].

ZX Diagrams. We define the following ZX generators on qudits with state-space $\mathcal{H}$,



(6)

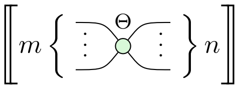
where $m, n \in \mathbb{N}$, and for any function $\Theta : \mathbb{Z} \to \mathbb{C}$. (Our approach of using functions mildly extends the approach of Wang [48], who prefers to parameterise the generators with vectors indexed from 1. For the constant function $\Theta(x) = 1$, we may omit the label Θ entirely.) We call these generators "green dots", "red dots", "Hadamard plus boxes", and "Hadamard minus boxes". The usual approach to assigning semantics to ZX generators is by considering the green and red dots to represent similar operations, subject to different (conjugate) choices of orthonormal basis, and a unitary "Hadamard" gate relating the two bases. One defines a semantic map $[\![\,\cdot\,]\!]$ in which the (lighter-coloured) "green" dots are mapped to an action on the basis $|x\rangle$, and the (darker-coloured) "red" are mapped to an action on the basis $|\omega^x\rangle$, where $|\omega^k\rangle = \frac{1}{\sqrt{D}} \sum_x \omega^{-kx} |x\rangle$ for $k \in \mathbf{D}$ (and where again $\omega = \mathrm{e}^{2\pi i/D}$).[2]The conventional choice would be, for a green dot, to assign an interpretation such as $\sum_{x\in\mathbf{D}} \Theta(x)\,|x\rangle^{\otimes n}\langle x|^{\otimes m}$; and for a red dot, to assign the interpretation $\sum_{x\in\mathbf{D}} \Theta(x)\,|\omega^x\rangle^{\otimes n}\langle\omega^x|^{\otimes m}$. Unfortunately, for $D > 2$, such a conventional interpretation does not yield a "flexsymmetric" [7] calculus, in effect because $\langle\omega^a|^{\mathsf{T}} = |\omega^a\rangle^* = |\omega^{-a}\rangle$. In particular, the conventional approach described just above would mean that the equality



(7)

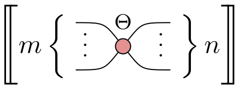
[2] In the notation of Ref. [6], we have $|\omega^k\rangle = |k{:}X\rangle$, up to a relabeling of the basis elements of $\mathcal{H}$.

would not hold: the first diagram would denote $\sum_x \Theta(x)\,|\omega^{-x},\omega^{x}\rangle$, the second would denote $\sum_x \Theta(x)\,|\omega^{x},\omega^{x}\rangle$, and the third would denote $\sum_x \Theta(x)\,|\omega^{x},\omega^{-x}\rangle$. This represents a way in which such a calculus would fail to have the useful syntactic property that "only the connectivity matters" [10, 12]; and other inconveniences would also arise, which would make these diagrams more difficult to work with. To avoid this problem, we endorse the convention adopted by Refs. [6, 41] of involving a generator which is related to the green dot by *different* unitary transformations on the inputs and outputs, but which differ only by a permutation. We then interpret the generators of Eqn. (6) as operators using a model $[\![\,\cdot\,]\!]$ which satisfies



$$\propto \sum_{x\in\mathbf{D}} \Theta(x)\;|x\rangle^{\otimes n}\langle x|^{\otimes m}\;,$$

$$\propto \sum_{x,k\in\mathbf{D}}\sum \omega^{kx}\,|x\rangle\langle k| \qquad (8)$$

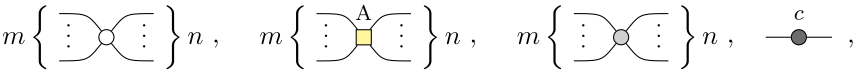


$$\propto \sum_{k\in\mathbf{D}} \Theta(k)\;|\omega^{-k}\rangle^{\otimes n}\langle \omega^{k}|^{\otimes m}\;,$$

$$\propto \sum_{x,k\in\mathbf{D}}\sum \omega^{-kx}\,|x\rangle\langle k|$$

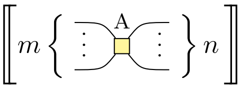
so that the "Hadamard" plus and minus boxes are proportional to the quantum Fourier transform $|\omega^{k}\rangle \mapsto |k\rangle$ (i.e., the inverse discrete Fourier transform), and its adjoint.

ZH Diagrams. We define the following ZH generators on qudits with Hilbert space $\mathcal{H}$,



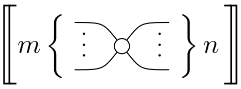
$$(9)$$

where $m,n\in\mathbb{N}$, $c\in\mathbb{Z}$, and for any function $\mathrm{A}:\mathbb{Z}\to\mathbb{C}$. (If $\mathrm{A}(t)=\alpha^{t}$ for some $\alpha\in\mathbb{C}^{\times}$, we may write the scalar α in place of A, consistent with the notation for ZH generators in Refs. [3, 14]. Following Roy [33], we later define a further short-hand notation for $\mathrm{A}(t)=\chi_c(t)=\exp(2\pi i c t/D)$ with $c\in\mathbb{Z}$.) We call these generators "white dots", "H-boxes", "gray dots", and "generalised-not dots".[3] We interpret the generators of Eqn. (9) as operators using a model $[\![\,\cdot\,]\!]$ which satisfies the following:

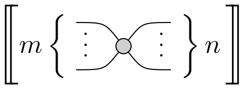


$$\propto \sum_{x\in\mathbf{D}^m,\,y\in\mathbf{D}^n}\sum \mathrm{A}(x_1\cdots x_m y_1\cdots y_n)\;|y\rangle\!\langle x|$$

$$\propto \sum_{x\in\mathbf{D}} |{-c}{-x}\rangle\langle x| \qquad (10)$$



$$\propto \sum_{x\in\mathbf{D}} |x\rangle^{\otimes n}\langle x|^{\otimes m}$$



$$\propto \sum_{\substack{x\in\mathbf{D}^m,\,y\in\mathbf{D}^n\\ \sum_h x_h+\sum_k y_k\equiv 0}}\sum |y\rangle\!\langle x|\,,$$

where for the gray dots, we constrain the indices $x\in\mathbf{D}^m$ and $y\in\mathbf{D}^n$, so that the sum of their entries is 0 mod D; and for the not-dots we interpret the index of the vector $|-c-x\rangle$ modulo D. By contrast, note that for the H-boxes, we consider the products of the input and output labels $x_1,\ldots,x_m,y_1,\ldots,y_m$ as *integers*,[4] i.e., elements of $\mathbb{Z}$, whose product is the argument of A in the the expression $\mathrm{A}(x_1\cdots y_m)$. In particular, we fix the semantics so that

$$= \sum_{\text{(singleton)}} \alpha^{\text{(empty product)}}\cdot 1 \;=\; \alpha^{1} \;=\; \alpha, \qquad (11)$$

again using the short-hand that $\alpha\in\mathbb{C}^{\times}$ stands for the function $\mathrm{A}(t)=\alpha^{t}$.

[3] We follow Ref. [14] in considering the gray and not dots to be (primitive) generators, rather than gadgets or "derived generators", e.g., as in Refs. [3, 33].

[4] Note that our use of the index-set $x\in\mathbf{D}=\{L,L+1,\ldots,U-1,U\}$ means that the exponential function $t\mapsto\alpha^{t}$ for $\alpha=0$ is not well-defined if $L<0$. We may instead consider a function $\mathbf{X}_{\{0\}}:\mathbb{Z}\to\mathbb{C}$ given by $\mathbf{X}_{\{0\}}(t)=1$ for $t=0$, with $\mathbf{X}_{\{0\}}(t)=0$ otherwise: this is substitution is adequate, e.g., for applications to counting complexity [16, 26].

Remarks on semantics, and rewriting systems. Eqns. (8) and (10) describe not one semantic map $[\![\,\cdot\,]\!]$ for ZX diagrams or ZH diagrams, but rather the conventional approach (with minor elaborations) to choosing such semantic maps. A specific semantic map determines which pairs of diagrams have the same semantics, and therefore which *diagrammatic rewrites* are *sound* (i.e., which local transformations one may perform to a diagram without changing its semantics). We suggest that rewrite systems, in which the most commonly used diagrammatic rewrites can be expressed simply, are to be preferred over others. However, this depends on obtaining a semantic map $[\![\,\cdot\,]\!]$ for which such a rewrite system is sound.

- Some authors (e.g., [10, 12]) prefer to define semantics only up to proportionality, in which case Eqns. (8) and (10) suffice to determine when two diagrams are equivalent up to an neglected scalar factor. This has the virtue of simplicity, but does not provide the precision needed for all applications one might wish to consider for these calculi.
- Most "scalar exact" treatments of ZX and ZH fix a map $[\![\,\cdot\,]\!]$ by replacing the proportionalities in Eqns. (8) and (10) with equalities – except for the "Hadamard" boxes of Eqn. (8), where a factor of $1/\sqrt{D}$ is used to yield unitary operators. However, the rewrites in those systems often involve book-keeping of auxiliary sub-diagrams ("scalar gadgets").
- In the case $D = 2$, Ref. [14] presents a different, unified semantic map $[\![\,\cdot\,]\!]_\nu$ for both ZX and ZH diagrams, in order to support rewrites involving fewer scalar gadgets. However, the scalar factors involved in those semantics could be considered non-obvious, and does not provide insights into how one would achieve the same goal for arbitrary $D \geqslant 2$.

The aim of this work is to extend the results of Ref. [14], providing a simple approach to fixing a semantic map $[\![\,\cdot\,]\!]$ for both ZX and ZH diagrams for arbitrary $D \geqslant 2$, which supports a set of diagrammatic rewrites without much use of scalar gadgets.

3 Discrete integrals

Our main theoretical contribution is to demonstrate how discrete integrals provide a way to fix a semantic map for ZX and ZH diagrams, with favourable properties. In this section, we introduce discrete measures and discrete integrals independently of string diagrams, and consider the constraints on discrete measures obtained through a particular representation of discrete Fourier transforms.

3.1 Introducing discrete measures and discrete integrals

We begin by introducing more fully the concepts first described on page 2. For a set $\mathbf{X}$, let $\wp(\mathbf{X})$ be the power-set of $\mathbf{X}$. We may define a *σ-algebra on* $\mathbf{X}$ to be a set $\Sigma \subseteq \wp(\mathbf{X})$ which contains $\mathbf{X}$, which is closed under set complements ($S \in \Sigma \iff \mathbf{X} \setminus S \in \Sigma$), and which is closed under countable unions (if $S_1, S_2, \ldots \in \Sigma$, then $S_1 \cup S_2 \cup \cdots \in \Sigma$). – The purpose of defining Σ is to allow the notion of a *measure* $\mu : \Sigma \to \mathbb{R} \cup \{+\infty\}$ to be defined, where the sets $S \in \Sigma$ are the ones which have a well-defined measure. Such a function μ is a measure, if and only if $\mu(\varnothing) = 0$, $\mu(S) \geqslant 0$ for all $S \in \Sigma$, and if

$$\mu\bigl(S_1 \cup S_2 \cup \cdots\bigr) = \mu(S_1) + \mu(S_2) + \cdots \tag{12}$$

for any sequence of disjoint sets $S_j \in \Sigma$. An example is the σ-algebra Σ consisting of all countable unions of intervals over $\mathbb{R}$, with μ defined by assigning $\mu(J) = b - a$ to any interval $J = (a,b)$, $J = (a,b]$, $J = [a,b)$, or $J = [a,b]$ for $a \leqslant b$. A somewhat more exotic measure is the Dirac distribution μ_δ on $\mathbb{R}$, for which $\mu_\delta(S) = 1$ if $0 \in S$, and $\mu_\delta(S) = 0$ otherwise. (We remark on the Dirac distribution and related concepts in Appendix [15, Appendix D].) However, we are mainly interested in measures μ defined on subsets $S \subseteq \mathbf{D}$, for which $\mu(S) \propto \#S$.

For the set $\mathbf{D} = \{L, L+1, \ldots, U-1, U\}$, consider the σ-algebra $\mathcal{B} = \wp(\mathbf{D})$ consisting of all subsets of $\mathbf{D}$. Define the measure $\mu : \mathcal{B} \to \mathbb{R}$ on this σ-algebra given by $\mu(S) \;=\; \#S \cdot \nu^2$, where $\nu > 0$ can in principle be chosen freely. This presents $\mathbf{D}$ as a measure space, the purpose of which is to allow us to define (multi-)linear operators on $\mathcal{H}$ as arising from integrals with respect to that measure. For a function $f : \mathbb{Z} \to \mathbb{C}$, we may define a notion of integration of f over a subset $S \subseteq \mathbf{D}$:

$$\int\limits_{x \in S} f(x)\, \mathrm{d}\mu(x) \;=\; \sum_{x \in S} f(x)\, \mu(\{x\}) \;=\; \sum_{x \in S} f(x)\, \nu^2 \,. \tag{13}$$

We may apply this notion of integration to operator-valued functions, as is typical for wave-functions in quantum mechanics. For instance, one may define

$$\int\limits_{x \in S} f(x)\; |x\rangle\; \mathrm{d}\mu(x) \;=\; \nu^2 \sum_{x \in S} f(x)\; |x\rangle \,. \tag{14}$$

In the usual approach to describing wave-functions over $\mathbb{R}$, one takes $|x\rangle$ to represent a point-mass distribution (i.e., not a vector $\boldsymbol{v} \in \mathbb{C}^{\mathbb{R}}$ for which $v_x = 1$), so that the equality

$$\langle z| \left[\; \int\limits_{x \in \mathbb{R}} f(x)\; |x\rangle\; \mathrm{d}x \right] = \int\limits_{x \in \mathbb{R}} f(x)\, \delta_z(x)\, \mathrm{d}x \;=\; f(z), \tag{15}$$

holds. Here $\delta_z(x)$ is a shifted Dirac distribution (see Ref. [15, Appendix D.1] for more details).[5] To avoid notational confusion, we prefer to reserve the symbol "$|x\rangle$" to represent a unit-norm standard basis vector in $\mathcal{H}$ (i.e., a vector $\boldsymbol{v} \in \mathcal{H}$ such that $v_x = 1$), and introduce a symbol "$|x\rangle\!\rangle$" which denotes the vector $|x\rangle\!\rangle \;=\; \frac{1}{\nu}\, |x\rangle$, specifically so that

$$\langle\!\langle z| \left[\; \int\limits_{x \in \mathbf{D}} f(x)\; |x\rangle\!\rangle\; \mathrm{d}\mu(x) \right] = \int\limits_{x \in \mathbf{D}} f(x)\; \langle\!\langle z|x\rangle\!\rangle\; \mathrm{d}\mu(x) \;=\; \nu^2 \sum_{x \in \mathbf{D}} f(x) \frac{\langle z|x\rangle}{\nu^2} \;=\; f(z)\,, \tag{16}$$

and also

$$\int\limits_{x \in \mathbf{D}} |x\rangle\!\rangle\langle\!\langle x|\; \mathrm{d}\mu(x) \;=\; \nu^2 \sum_{x \in \mathbf{D}} \frac{|x\rangle\,\langle x|}{\nu^2} \;=\; \sum_{x \in \mathbf{D}} |x\rangle\,\langle x| \;=\; \mathbf{1}\,. \tag{17}$$

The notation "$|x\rangle\!\rangle$" provides us the flexibility to consider which measures $\mu : \mathcal{B} \to \mathbb{R}$ are best suited for defining convenient semantics for ZX and ZH generators, while retaining the features provided by Dirac distributions over $\mathbb{R}$, and without constraining ν.

For maps U and V described in this way, one may analyse compositions UV in the same way that one would do if U and V were given by sums of operators: by using the expressions for U and V in terms of discrete integrals, manipulating expressions within the integrals, and well-judged use of algebraic identities such as Eqns. (16) and (17). For instance, if we have

$$U \;=\; \iint\limits_{x,y \in \mathbf{D}} u_{x,y}\; |x\rangle\!\rangle\langle\!\langle y| \qquad\qquad V \;=\; \iint\limits_{w,z \in \mathbf{D}} v_{w,z}\; |w\rangle\!\rangle\langle\!\langle z| \tag{18}$$

then we may express the composite operation UV by

[5] While it is not necessary to understand our results, readers who are interested in connections between the integrals and measures presented here with integration over compact groups, may be interested in remarks which we make in Ref. [15, Appendix D.3].

$$\begin{aligned} UV \;&=\; \left[\;\iint\limits_{x,y\in\mathbf{D}} u_{x,y}\;|x\rangle\!\rangle\langle\!\langle y|\right]\left[\;\iint\limits_{w,z\in\mathbf{D}} v_{w,z}\;|w\rangle\!\rangle\langle\!\langle z|\right] \\ &=\; \iiiint\limits_{w,x,y,z\in\mathbf{D}} u_{x,y}v_{w,z}\;|x\rangle\!\rangle\langle\!\langle y|w\rangle\!\rangle\langle\!\langle z| \;=\; \iint\limits_{x,z\in\mathbf{D}}\left(\;\iint\limits_{w,y\in\mathbf{D}} u_{x,y}v_{w,z}\;\langle\!\langle y|w\rangle\!\rangle\right)|x\rangle\!\rangle\langle\!\langle z| \\ &\qquad\qquad\qquad\qquad\qquad\qquad\;=\; \iint\limits_{x,z\in\mathbf{D}}\left(\;\int\limits_{y\in\mathbf{D}} u_{x,y}v_{y,z}\right)|x\rangle\!\rangle\langle\!\langle z|\;. \end{aligned} \tag{19}$$

Composition of such integrals generalises straightforwardly for tensors of any signature: examples can be seen in Appendix A.1 of Ref. [15] (and Appendix A.3 makes heavy use of such analysis of compositions to prove the soundness of various diagrammatic rewrites of ZX and ZH diagrams.) The only distinction between this approach and one expressed directly in terms of summation, are the scalar factors which are subsumed in the integral notation and operators such as $|x\rangle\!\rangle\langle\!\langle z|$, both of which are governed by the choice of measure μ.

3.2 Constraints on normalisation motivated by the Fourier transform

Having defined the discrete measure (and discrete integrals) over $\mathbf{D}$, and the corresponding point-mass distributions $|x\rangle\!\rangle$ to satisfy Eqn. (2), we may consider how this might influence our approach to analysis of complex-valued functions over $\mathbf{D}$ (or $\mathbb{Z}_D$, using a similar measure).

In analogy to a common representation[6] of the Fourier transform of functions on $\mathbb{R}$, we may describe the (discrete) Fourier transform of a function $f : \mathbb{Z}_D \to \mathbb{C}$ by

$$\hat{f}(k) \;=\; \int\limits_{x\in\mathbb{Z}_D} \mathrm{e}^{-2\pi i k x/D}\, f(x)\;\mathrm{d}\mu(x). \tag{20}$$

In principle, the domain $\mathbb{Z}_D$ of $\hat{f}$ indexes a character $\chi_k(x) = \mathrm{e}^{-2\pi ikx/D}$ in the dual group $\widehat{\mathbb{Z}_D}$. The dual group $\widehat{\mathbb{Z}_D}$ can itself be assigned a measure $\tilde{\mu}$ which is in principle *independent* of μ. As $\mathbb{Z}_D$ is a finite abelian group, we use the fact that there is an isomorphism $\varepsilon : \widehat{\mathbb{Z}_D} \to \mathbb{Z}_D$ to describe $\hat{f}$ as a function $\mathbb{Z}_D \to \mathbb{C}$. The isomorphism ε induces a measure $\mu' = \tilde{\mu} \circ \varepsilon^{-1}$ on $\mathbb{Z}_D$, which may differ from μ and which would be relevant to any integrals involving the argument of $\hat{f}$.[7] – Note that there are different conventions for normalising the Fourier transform (over $\mathbb{R}$ or $\mathbb{Z}_D$): one might consider modifying Eqn. (20) to include a non-trivial scalar factor on the right-hand side. This is related to the questions of whether we take the Fourier transform $f \mapsto \hat{f}$ to preserve the ℓ_2-norm $\|f\|_2 = \Bigl(\int_x |f(x)|^2\,\mathrm{d}\mu(x)\Bigr)^{1/2}$, and whether we take μ' to differ from μ. We simply adopt the convention of defining the Fourier transform of $f : \mathbb{Z}_D \to \mathbb{C}$ as in Eqn. (20), and consider the constraints that this imposes on these other considerations.

[6] We emulate the presentation of the Fourier transform in terms of an oscillation frequency k (including the minus sign in the exponent, which for historical reasons is absent in the definition of the quantum Fourier transform). The main difference between Eqn. (20) and the usual Fourier transform over $\mathbb{R}$ is the factor of $1/D$ in the exponent: this can be shown to arise from a representation of functions $f : \mathbb{Z}_D \to \mathbb{C}$ in terms of discrete distributions on $\mathbb{R}$ (see Ref. [15, Appendix D.3.4]).

[7] The precise relationship between μ and μ', corresponds to the question in physics of the choice of units for x and k as continuous variables ranging over $\mathbb{R}$.

In analogy to standard practise in physics, we may use f to describe a "wave-function",[8]

$$|f\rangle\!\rangle \;:=\; \int\limits_{x\in\mathbb{Z}_D} f(x)\,|x\rangle\!\rangle\;\mathrm{d}\mu(x)\,. \tag{21}$$

A similar "wave function" for $\hat{f}$ would involve the measure μ', the measure on the argument of $\hat{f}$, which may in principle differ from μ:

$$|\hat{f}\,\rangle\!\rangle \;=\; \int\limits_{k\in\mathbb{Z}_D} \hat{f}(k)\,|k\rangle\!\rangle\;\mathrm{d}\mu'(k)\,, \tag{22}$$

integrating with respect to that different measure. Taking $\mu' \neq \mu$ would imply that the functions $f : (\mathbb{Z}_D, \mu) \to \mathbb{C}$, defined on $\mathbb{Z}_D$ considered as a space with measure μ, are strictly speaking not of the same type as their Fourier transforms $\hat{f} : (\mathbb{Z}_D, \mu') \to \mathbb{C}$ which are defined over a space with a different measure. String diagrams representing the transformations of such functions would then require wires of more than one type. While this is admissible in principle, we prefer to consider f and $\hat{f}$ to have the same measure space $(\mathbb{Z}_D, \mu)$ for their domains, so that we may treat them using string diagrams with wires of a single type, as we do in the ZX and ZH calculi. Identifying $\mu' = \mu$, we obtain

$$|\hat{f}\,\rangle\!\rangle \;=\; \int\limits_{k\in\mathbb{Z}_D} \hat{f}(k)\,|k\rangle\!\rangle\;\mathrm{d}\mu(k) \;=\; \iint\limits_{k,x\in\mathbb{Z}_D} \mathrm{e}^{-2\pi i k x/D} f(x)\;|k\rangle\!\rangle\;\mathrm{d}\mu(x)\;\mathrm{d}\mu(k)\,. \tag{23}$$

This motivates the definition of the discrete Fourier transform operator F over $\mathbb{Z}_D$, as

$$F \;=\; \iint\limits_{k,x\in\mathbb{Z}_D} \mathrm{e}^{-2\pi i k x/D}\;|k\rangle\!\rangle\langle\!\langle x|\;\mathrm{d}\mu(x)\;\mathrm{d}\mu(k)\;, \tag{24}$$

so that $|\hat{f}\rangle\!\rangle = F|f\rangle\!\rangle$; this is the interpretation given to the "Hadamard minus box" in Eqn. (28). We adopt the convention that F is unitary, to allow it to directly represent a possible transformation of state-vectors over $\mathcal{H}$. This has the benefit that the inverse Fourier transform can be expressed similarly (now suppressing the differentials $\mathrm{d}\mu$, for brevity):

$$f(x) \;=\; \langle\!\langle x|F^\dagger|\hat{f}\rangle\!\rangle \;=\; \iiint\limits_{x,h,k\in\mathbb{Z}_D} \mathrm{e}^{2\pi i k x/D}\;|x\rangle\!\rangle\langle\!\langle k|\Bigl(\hat{f}(h)\,|h\rangle\!\rangle\Bigr) \;=\; \int\limits_{k\in\mathbb{Z}_D} \mathrm{e}^{2\pi i k x/D}\;\hat{f}(x)\;. \tag{25}$$

The definition of F in Eqn. (24) and the constraint that it should be unitary, imposes a constraint on the measure μ on $\mathbb{Z}_D$. We first prove a routine Lemma (which is used often in the Appendices of Ref. [15] in simplifying iterated integrals):

▶ **Lemma 1.** *Let $\omega = \mathrm{e}^{2\pi i/D}$ and $E \in \mathbf{D}$. Then* $\displaystyle\int\limits_{k\in\mathbb{Z}_D} \omega^{Ek}\;\mathrm{d}\mu(k) \;=\; \langle\!\langle E|0\rangle\!\rangle\,D\nu^4$.

Proof. This holds by reduction to the usual exponential sum:

$$\begin{aligned}\int\limits_{k\in\mathbf{D}} \mathrm{e}^{2\pi i E k/D}\;\mathrm{d}\mu(k) \;&=\; \nu^2 \sum_{k\in\mathbf{D}} \bigl(\omega^E\bigr)^k \;=\; \left\{\begin{array}{r} \nu^2\cdot\omega^{EL_D}\cdot\dfrac{(\omega^E)^D-1}{\omega-1}\,,\;\;\text{if } \omega^E\neq 1 \\ \nu^2\cdot D,\;\;\text{if } \omega^E = 1\end{array}\right\} \\ &=\; \delta_{E,0}\;D\nu^2 \;=\; \langle E|0\rangle\;D\nu^2 \;=\; \langle\!\langle E|0\rangle\!\rangle\;D\nu^4\;.\end{aligned}$$ ◀

[8] Note that $|f\rangle\!\rangle$ may not be a unit vector; whether this is the case depends on the values taken by f.

We may apply this in the case of the Fourier transform as follows. If F as expressed in Eqn. (24) is unitary, we have

$$\begin{aligned}
\mathbf{1} \;=\; F^\dagger F \;&=\; \Biggl[\;\iint\limits_{y,h\in\mathbf{D}} \mathrm{e}^{2\pi i h y/D}\; |y\rangle\!\rangle\langle\!\langle h|\;\mathrm{d}\mu(y)\;\mathrm{d}\mu(h)\Biggr]\Biggl[\;\iint\limits_{k,x\in\mathbf{D}} \mathrm{e}^{-2\pi i k x/D}\; |k\rangle\!\rangle\langle\!\langle x|\;\mathrm{d}\mu(k)\;\mathrm{d}\mu(x)\Biggr]\\
&=\; \iiiint\limits_{y,h,k,x\in\mathbf{D}} \mathrm{e}^{2\pi i(hy-kx)/D}\; |y\rangle\!\rangle\langle\!\langle h|k\rangle\!\rangle\langle\!\langle x|\;\mathrm{d}\mu(y)\;\mathrm{d}\mu(h)\;\mathrm{d}\mu(k)\;\mathrm{d}\mu(x)\\
&=\; \iiint\limits_{y,k,x\in\mathbf{D}} \mathrm{e}^{2\pi i k(y-x)/D}\; |y\rangle\!\rangle\langle\!\langle x|\;\mathrm{d}\mu(y)\;\mathrm{d}\mu(k)\;\mathrm{d}\mu(x)\\
&=\; \iint\limits_{y,x\in\mathbf{D}} \Biggl[\;\int\limits_{k\in\mathbf{D}} \mathrm{e}^{2\pi i k(y-x)/D}\;\mathrm{d}\mu(k)\Biggr]\; |y\rangle\!\rangle\langle\!\langle x|\;\mathrm{d}\mu(y)\;\mathrm{d}\mu(x)\\
&=\; \iint\limits_{y,x\in\mathbf{D}} \Bigl[D\nu^4\cdot\langle\!\langle y|x\rangle\!\rangle\Bigr]\; |y\rangle\!\rangle\langle\!\langle x|\;\mathrm{d}\mu(y)\;\mathrm{d}\mu(x)\\
&=\; D\nu^4\int\limits_{x\in\mathbf{D}} |x\rangle\!\rangle\langle\!\langle x|\;\mathrm{d}\mu(x) \;=\; D\nu^4\cdot\mathbf{1}\,.
\end{aligned}\tag{26}$$

This implies that $\nu = D^{-1/4}$ (or equivalently, $N = \mu(\mathbb{Z}_D) = D\nu^2 = \sqrt{D}$).

As there are multiple conventions for representing the discrete Fourier transform, one might wish to consider how adopting a different convention to Eqn. (20) affects constraints on the measure μ; we consider this question in Ref. [15, Appendix B.5].

4 Semantics for ZX- and ZH-diagrams using discrete interals

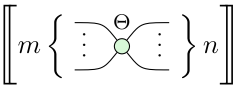
We present an approach to simply and systematically define semantic maps for ZX and ZH generators, which **(a)** yields simple diagrams for unitary transformations of interest, **(b)** admits scalar-exact diagrammatic rewrites involving few scalar gadgets, and **(c)** allows the two notational systems to be used seamlessly together.

Our approach is to subsume all considerations of normalising factors into the measure of a discrete integral, and its accompanying point-mass functions, as indicated on page 2. Our use of integrals and discrete measures in this way is standard, if somewhat uncommon in quantum information theory: see Ref. [35, 27] for comparable examples. Our intent is explicitly to draw attention to the freedom involved in the choice of measure, as a way forward to defining a semantic map $[\![\,\cdot\,]\!]$ for ZX and ZH diagrams that has desirable features.

Defining a discrete integral on $\mathbf{D}$ with $\mu(\mathbf{D}) = \sqrt{D}$, as we do in the preceding Section, allows us to easily define semantic maps for ZX and ZH diagrams with a number of convenient properties. Let

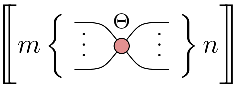
$$|\omega^k\rangle\!\rangle \;=\; F|k\rangle\!\rangle \;=\; \int\limits_{x\in\mathbf{D}} \omega^{-kx}\,|x\rangle\!\rangle \tag{27}$$

be the non-normalised point-mass distributions analogous to the Fourier basis states $|\omega^k\rangle$ introduced on page 4 (so that $|\omega^k\rangle\!\rangle$ is an ω^k-eigenvector of the cyclic shift operator X given by $X\,|a\rangle = |a{+}1\rangle$). We then define a semantic map $[\![\,\cdot\,]\!]$ on the ZX generators of Eqns. (6),



$$= \int_{x\in\mathbf{D}} \Theta(x)\; |x\rangle\!\rangle^{\otimes n} \langle\!\langle x|^{\otimes m}$$

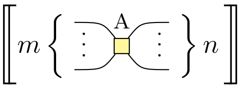
$$= F^\dagger = \iint_{x,k\in\mathbf{D}} \mathrm{e}^{2\pi i k x/D} |k\rangle\!\rangle\langle\!\langle x| \tag{28}$$



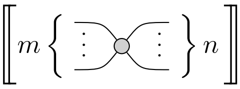
$$= \int_{k\in\mathbf{D}} \Theta(k)\; |\omega^{-k}\rangle\!\rangle^{\otimes n} \langle\!\langle\, \omega^{k}\, |^{\otimes m}$$

$$= F = \iint_{x,k\in\mathbf{D}} \mathrm{e}^{-2\pi i k x/D} |k\rangle\!\rangle\langle\!\langle x|$$

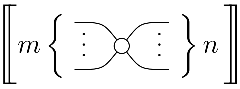
and the ZH generators of Eqn. (9):



$$= \iint_{\substack{x\in\mathbf{D}^m\\ y\in\mathbf{D}^n}} \mathrm{A}(x_1\cdots x_m y_1\cdots y_n)\; |y\rangle\!\rangle\langle\!\langle x|\,,$$



$$= \iint_{\substack{x\in\mathbf{D}^m\\ y\in\mathbf{D}^n}} \Big\langle\!\!\Big\langle\, \sum_h x_h + \sum_k y_k \,\Big|\, 0 \,\Big\rangle\!\!\Big\rangle\;\; |y\rangle\!\rangle\langle\!\langle x|\,, \tag{29}$$



$$= \int_{x\in\mathbf{D}} |x\rangle\!\rangle^{\otimes n} \langle\!\langle x|^{\otimes m}\,,$$

$$= \int_{x\in\mathbf{D}} |{-c}{-x}\rangle\!\rangle\langle\!\langle x|\,,$$

These semantics are consistent with those set out in Eqns. (8) and (10), replacing the sums and the vectors $|x\rangle$ with discrete integrals and the corresponding point-mass distributions $|x\rangle\!\rangle$, and substitute proportionality relations with equalities. The discrete integrals (and point-mass functions) serve to specify specific scalar factors for the proportionalities.

These definitions are ones that we could choose to make, regardless of the measure μ that we consider for $\mathbf{D}$. Regardless of the choice made for ν, the above interpretations are certainly similar in their simplicity to the standard interpretations. By taking $\nu = D^{-1/4}$ as suggested in the preceding section, we not only obtain rewrite systems involving very few scalar gadgets – see Figs. 1 and 2 – but also, the most commonly considered states and unitary operations of qudit circuits admit simple presentations using these semantics. We may demonstrate this as follows.

4.1 The stabiliser sub-theory of ZX for arbitrary $D > 1$

We describe below a *stabiliser subtheory* of the ZX calculus, concerning ZX diagrams which suffice to represent stabiliser states [13] on systems of arbitrary dimension $D > 1$. These are characterised by ZX diagrams whose phase parameters are governed by restricted functions, for which arithmetic modulo D plays a central role.

We begin by describing the stabiliser sub-theory of quantum circuits. Following Ref. [13], define the complex unit $\tau = \mathrm{e}^{\pi i(D^2+1)/D}$, which is relevant to the analysis of stabiliser circuits on qudits of dimension D. The scalar τ is defined in such a way that $\tau^2 = \omega$, but also so that $\tau X^\dagger Z^\dagger$ is an operator of order D, where X and Z given by

$$X\,|t\rangle \;=\; |t+1\rangle\,, \qquad\qquad Z\,|t\rangle \;=\; \omega^t\,|t\rangle\,, \tag{30}$$

are the D-dimensional generalised Pauli operators. (As always, arithmetic performed in the kets are evaluated modulo D.) Choosing τ in this way makes it possible [13] to define a simple and uniform theory of unitary stabiliser circuits on qudits of dimension D, generated

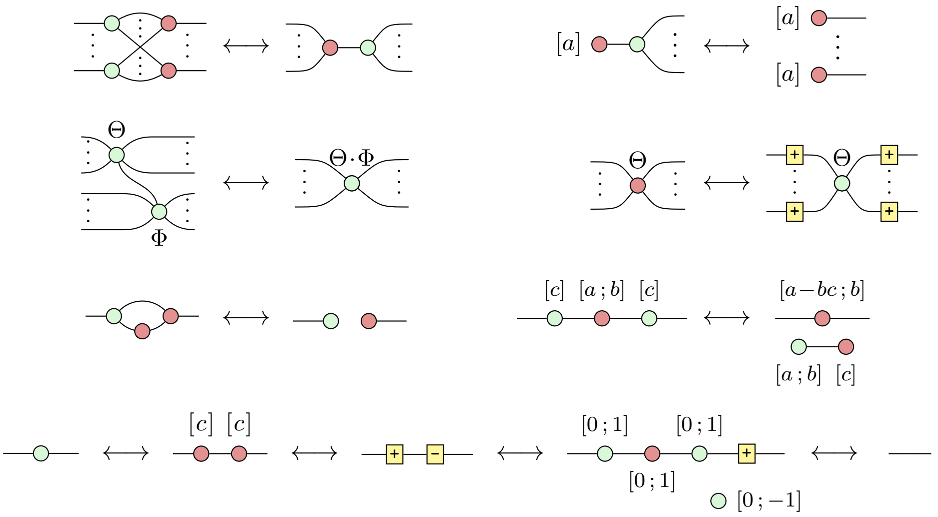


Figure 1 A sample of the (scalar-exact) rewrites which are sound for ZX diagrams with semantics as in Eqn. (28), when $\nu = D^{-1/4}$. Throughout, we have $\Theta, \Phi : \mathbb{Z} \to \mathbb{C}$, and $a, b, c \in \mathbb{Z}$. Node labels of the form $[a]$ or $[a\,;b]$ stand respectively for the amplitude functions $x \mapsto \tau^{2ax}$ and $x \mapsto \tau^{2ax+bx^2}$, where $\tau = \exp(\pi i(D^2{+}1)/D)$. A more complete list of rewrites, and proofs of their soundness, may be found in Ref. [15, Appendix A.3.3].

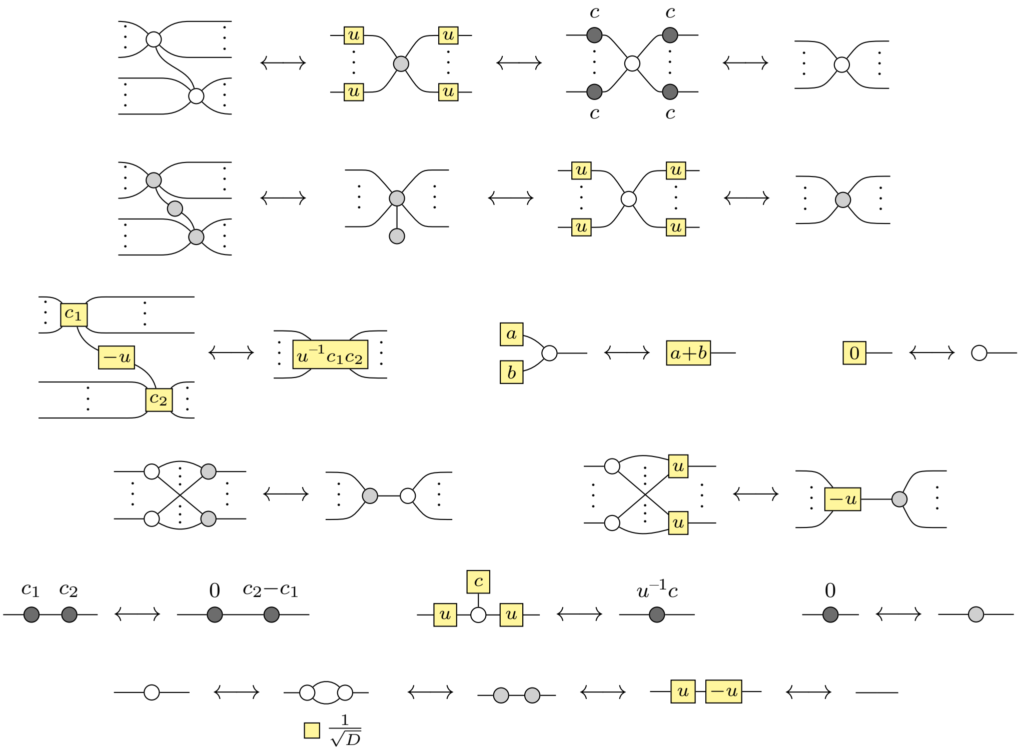

Figure 2 A sample of the (scalar-exact) rewrites which are sound for ZH diagrams with semantics as in Eqn. (29) when $\nu = D^{-1/4}$. H-boxes which are labeled inside with an integer parameter such as $c \in \mathbb{Z}$, indicate an amplitude of $\omega^c = \mathrm{e}^{2\pi i c/D}$; H-boxes labelled with "+" or "−" indicate $c = \pm 1$. Throughout, we have$a, b, c, c_1, c_2, u, v \in \mathbb{Z}$ (which may be evaluated modulo D), where in particular u and v are coprime to D. A more complete list of rewrites, and proofs of their soundness, may be found in Ref. [15, Appendix A.3.1].

by the single-qudit operators [9]

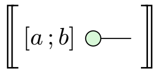
$$S \;=\; \int\limits_{x\in\mathbf{D}} \tau^{\,x^2}\;|x\rangle\!\rangle\langle\!\langle x|\;; \qquad F \;=\; \iint\limits_{k,x\in\mathbf{D}} \tau^{-2kx}\;|k\rangle\!\rangle\langle\!\langle x|\;; \qquad M_u \;=\; \int\limits_{x\in\mathbf{D}} |ux\rangle\!\rangle\langle\!\langle x|\;, \tag{31}$$

where in the case of M_u we restrict to $u \in \mathbb{Z}$ which is relatively prime to D; and either one of the two-qudit operators

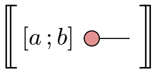
$$\mathrm{CX} \;=\; \iint\limits_{x,y\in\mathbf{D}} |x\rangle\!\rangle\langle\!\langle x| \otimes |x{+}y\rangle\!\rangle\langle\!\langle y|\;; \qquad\qquad \mathrm{CZ} \;=\; \iint\limits_{x,y\in\mathbf{D}} \tau^{2xy}\;|x,y\rangle\!\rangle\langle\!\langle x,y|\;. \tag{32}$$

Finally, the full range of stabiliser circuits also admit measurements in the standard basis (and bases which may be related to the standard basis by the above unitaries).

Booth and Carette [6] describe a version of the ZX calculus which is complete for this subtheory, for the special case of D an odd prime. Following them, we may describe how the semantics of Eqn. (28) allows a simplification of these rewrites, extending them in most cases to arbitrary $D > 1$. To this end, it will be helpful to use a slightly different notational convention to Booth and Carette [6], we may easily denote these with ZX diagrams using the semantics of Eqn. (28). For $a, b \in \mathbb{Z}$, when parameterising a green or red dot, let $[a\,;b]$ stand for the amplitude function $\Theta(x) = \tau^{2ax+bx^2}$, so that

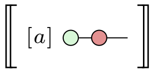


$$=\; \int\limits_{x\in\mathbf{D}} \tau^{\,2ax\,+\,bx^2}\;|x\rangle\!\rangle\;;$$

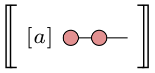


$$=\; \int\limits_{k\in\mathbf{D}} \tau^{\,2ak\,+\,bk^2}\;|\omega^{-k}\rangle\!\rangle\;; \tag{33}$$

generalising these to dots with multiple edges (or with none) similarly to Ref. [6]. When $b = 0$, we may abbreviate this function simply by $[a]$, so that we may represent the states $|a\rangle\!\rangle$ and $|\omega^a\rangle\!\rangle$ straightforwardly (albeit with the use of auxiliary red dots to represent an antipode operator, mapping $|\omega^a\rangle\!\rangle \mapsto |\omega^{-a}\rangle\!\rangle$ and $|a\rangle\!\rangle \mapsto |{-a}\rangle\!\rangle$ for $a \in \mathbb{Z}_D$):

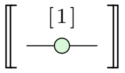


$$=\; \iint\limits_{k,x\in\mathbf{D}} \tau^{2ax}\,|\omega^{-k}\rangle\!\rangle\langle\!\langle \omega^k\,|x\rangle\!\rangle \;=\; |\omega^a\rangle\!\rangle\,; \tag{34a}$$

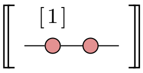


$$=\; \iint\limits_{h,k\in\mathbf{D}} \tau^{2ah}\,|\omega^{-k}\rangle\!\rangle\langle\!\langle \omega^k\,|\omega^{-h}\rangle\!\rangle \;=\; |a\rangle\!\rangle\,. \tag{34b}$$

We may also easily represent the operators Z, and X as $1 \to 1$ dots:

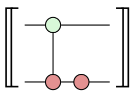


$$=\; \int\limits_{x\in\mathbf{D}} \tau^{2x}\,|x\rangle\!\rangle\langle\!\langle x| \;=\; Z\,;$$

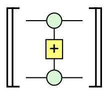


$$=\; \int\limits_{h\in\mathbf{D}} \tau^{2h}\,|\omega^h\rangle\!\rangle\langle\!\langle \omega^h| \;=\; X\,. \tag{35}$$

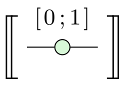
Regarding the unitary stabiliser operators on qudits, we may express them without any phases, using multi-edges between green and red dots, or using Hadamard boxes:



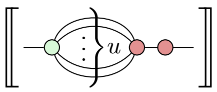
$= \mathrm{CX},$



$= \mathrm{CZ},$



$= S,$

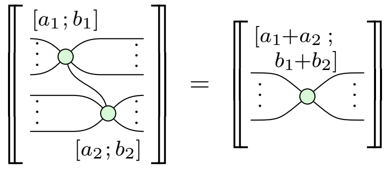


$= M_u\,.$ (36)

(The diagram shown for M_u also generalises to operators $M_u = \int_x |ux\rangle\!\rangle\langle\!\langle x|$ for u not a multiplicative unit modulo D, though in that case the operator will not be invertible.)

[9] Despite the different convention we adopt for the labeling of the standard basis, the definitions below are equivalent to those of Ref. [13]: the relative phases τ^{2ax+bx^2} remain well-defined on substitution of values $x < 0$ with $D + x$, as $\tau^{2a(D+x)+b(D+x)^2} = \tau^{2aD+2ax+bD^2+2bD+bx^2} = \tau^{2ax+bx^2}$ (using the fact that $\tau^{D^2} = \tau^{2D} = 1$ for both even and odd D).

The stabiliser subtheory of ZX may produce green or red dots *of degree zero* with phase parameter $[a\ ;\, b]$ for some $a, b \in \mathbb{Z}$. These may occur when evaluating the probability of measurement outcomes (e.g., in the standard basis) arising from a stabiliser qudit circuit. As we show in Ref. [15, Appendix A.3.3] (as a simple corollary of a more general fusion rule), we have



(37)

where each instance of "$\vdots$" denotes some number (zero or more) of incident wires. In the case where there are *no* other dots connected to two green dots as above, the right-hand side would be an isolated dot denoting a scalar, for which we define the notation $\Gamma(a, b, D)$:

$$\left[\!\!\left[\ [a\,;b]\,\bigcirc\ \right]\!\!\right] \;=\; \int\limits_{x\in\mathbf{D}} \tau^{2ax+bx^2} \;=:\; \Gamma(a,b,D)\ . \tag{38}$$

Evaluating such a discrete integral is connected with the subject of quadratic Gaussian sums, which is addressed in some detail in Ref. [15, Appendix C]. As a result of the normalisation convention for our discrete integrals, it is possible to show (see Ref. [15, Appendix C, Eqn. (103)]) that

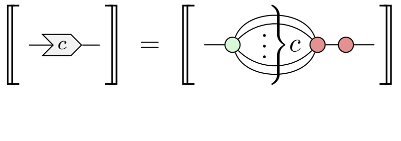
$$\Gamma(a,b,D) \;:=\; \int\limits_{x\in\mathbf{D}} \tau^{2ax+bx^2} \;=\; \begin{cases} \sqrt{t}\cdot \mathrm{e}^{i\gamma}, & \text{if } t = \gcd(b,D) \text{ and } a \text{ is divisible by } t; \\ \quad 0, & \text{otherwise,} \end{cases} \tag{39}$$

where γ is a phase parameter described in more detail in Ref. [15, Appendix C, Eqn. (103)]. In particular, if b is a multiplicative unit modulo D, this represents a global phase factor. (If we also have $a = 0$, then $\Gamma(a, b, D)$ is in fact a power of $\mathrm{e}^{\pi i/4}$.) More generally, $\Gamma(a, b, D)$ will either be 0, or have magnitude $\sqrt{t}$, where $t = \gcd(b, D)$.

In this way, we obtain a diagrammatic language which is capable of expressing the rewrites similar to those described by Ref. [6], while involving fewer scalar factors (see Ref. [15, Appendix A.3.3, Fig. 6] for a more complete list of sound rewrites).

4.2 Multipliers and multicharacters in qudit ZH

It would be cumbersome to reason about stabiliser multiplication operators M_u or iterated CX or CZ gates using parallel edges between dots. Booth and Carette [6] describe how these may be denoted using gadgets called "multipliers", denoted  for $c \in \mathbb{N}$, which represent a limited form of scalable ZX notation [9, 8]. Using discrete integrals and the semantics described in Eqn. (28), we would simply write



$$= \int\limits_{x\in\mathbf{D}} |cx\rangle\!\rangle\langle\!\langle x|\ . \tag{40}$$

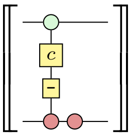
Using these multipliers, Booth and Carette [6, p. 24] then define "Fourier boxes" $-\boxed{c}-$:= $-\succ c\rangle-\boxed{+}-$ (using our notation for Hadamard boxes), whose interpretation coincides with the ones we assign using Eqn. (29) to an H-box with an amplitude parameter ω^c. Using this as a primitive, and composing this with the inverse $-\boxed{-}-$ of the positive Hadamard box $-\boxed{+}-$, we may directly describe multipliers instead as a ZH gadget, loosely following Roy [33]:

$$-\boxed{c}-\boxed{-}- \quad =: \quad -\succ c\rangle- \;. \tag{41}$$

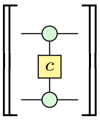
On the left, we employ a short-hand for H-boxes with an amplitude parameter ω^c. This is short-hand for a character function $\chi_c : \mathbb{Z} \to \mathbb{C}$ given by $\chi_c(x) = \omega^{cx}$, which is well-defined modulo D, and which we may then regard as a character on $\mathbb{Z}_D$. The function $\mathbb{Z} \times \mathbb{Z} \to \mathbb{C}$ given by $(x, y) \mapsto \chi_c(xy)$ is a *bicharacter*, which is also well-defined modulo D on each of its arguments; and more generally we may consider *multicharacters*, which are functions $\mathbb{Z}_D \times \cdots \times \mathbb{Z}_D \to \mathbb{C}$ given by $(x_1, \ldots, x_n) \mapsto \omega^{cx_1 \cdots x_n}$. We may call H-boxes with any number of edges, and with amplitude parameter ω^c for some $c \in \mathbb{Z}_D$, a ($\mathbb{Z}_D$-)*multicharacter box*.

We may use these ideas to define a *multicharacter subtheory* of ZH, consisting of the subtheory in which the H-boxes are indexed by paramters $c \in \mathbb{Z}_D$ in this way. Roy [33] has substantially investigated this fragment of ZH, in odd prime dimension. Our choice of semantic map allows us [15, Appendix A.3.1, Fig. 4] to reproduce many of the rewrites considered by Roy, while making minor simplifications and extending them to arbitrary dimensions $D > 1$.

We may use multiplier gadgets and multicharacter boxes to usefully describe unitary transformations, such as exponentiations of the qudit controlled-X and controlled-Z gates:

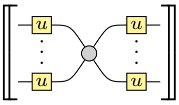


$$= \mathrm{CX}^c = \iint\limits_{x,y\in\mathbf{D}} |x, y{+}cx\rangle\!\rangle\langle\!\langle x, y| \;,$$

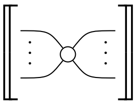


$$= \mathrm{CZ}^c = \iint\limits_{x,y\in\mathbf{D}} \omega^{cxy}\, |x, y\rangle\!\rangle\langle\!\langle x, y| \;. \tag{42}$$

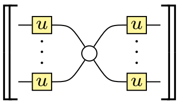
These degree-2 multicharacter boxes are effectively a Fourier transform over an isomorphic presentation of $\mathbb{Z}_D$ in some cases. This occurs in particular when $c = u \in \mathbb{Z}_D^\times$ is a multiplicative unit modulo D. We can witness this by rewrites which are valid for H-boxes parameterised by units $u \in \mathbb{Z}_D^\times$, such as ones which relate the white dots and the gray dots among the ZH generators (similar remarks apply for the green and red ZX generators):



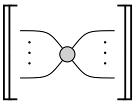
$=$



and



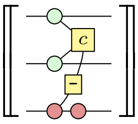
$=$



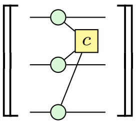
(43)

While there cannot be any perfect symmetry between the white and gray dots in general in the ZH calculus (as it involves the standard basis as a preferred basis), in this case a symmetry is recovered which one does not normally expect of presentations of the ZH calculusx.

We may also easily describe multi-qudit analogues of the qudit controlled-X and controlled-Z gates, using the fact that the H-boxes denote multi-characters. For example:



$$= \mathrm{CCX}^c = \iiint\limits_{x,y,z\in\mathbf{D}} |x, y, z{+}cxy\rangle\!\rangle\langle\!\langle x, y, z| \;, \tag{44a}$$



$$= \mathrm{CCZ}^c = \iiint\limits_{x,y,z\in\mathbf{D}} \omega^{cxyz}\, |x, y, z\rangle\!\rangle\langle\!\langle x, y, z| \;. \tag{44b}$$

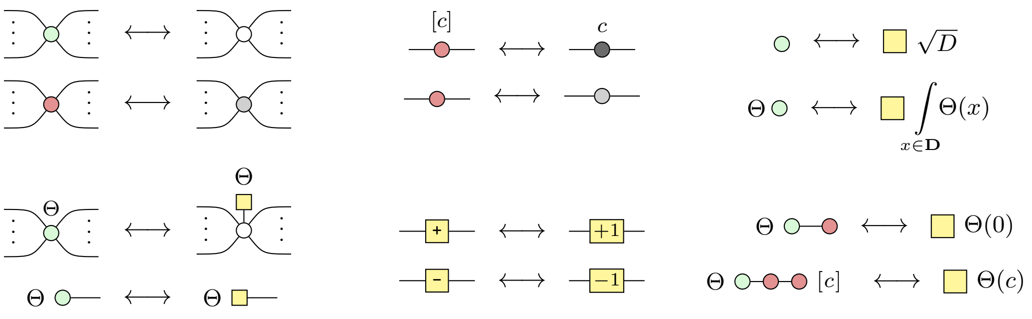


Figure 3 Sound rewrites between the ZX generators and the ZH generators, subject to the semantics of Eqns. (28) and (29) in the case $\nu = D^{-1/4}$. The proofs of the soundness of these rewrites are shown in Ref. [15, Appendix A.3.2].

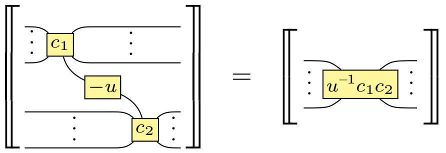
While it would quickly become cumberson to represent each of the integrals in such an operation – this being a motivation for diagrammatic calculi in general – this demonstrates the genericity of the representation for these unitary transformations, and the relative lack of minor details to attend to in using them. Finally, we note the quasi-spider property that H-boxes are known for in the qubit case and in (and also shown in a more complicated form for odd prime D by Roy [33]), which can also be shown for a pair of multicharacter boxes connected to a common H-box with parameter $u \in \mathbb{Z}_D^\times$:



(45)

We do not claim to have a complete multicharacter subtheory for ZH over arbitrary qudits, but many of the rewrites which one may show in this case [15, Appendix A.3.1, Fig. 4] can be specialised in a useful way to the multicharacter case.

4.3 Compatibility and universality

In addition to the semantics of Eqns. (28) and (29) yielding ZX and ZH calculi which are each convenient in their own right, it also assigns the same semantics to certain ZX generators and certain ZH generators. This is illustrated in Fig. 3. This allows us to relate the two calculi to each other, to describe a “ZXH calculus” which has the features of both.

It is not necessary to consider such a united calculus to be able to denote arbitrary operators: see Ref. [15, Appendix A.2] for a sketch of a proof of universality of the ZH diagrams, in terms of a “normal form”-like diagram which mirrors the construction of Ref. [3]. However, while using both sets of generators may be redundant in principle, it should be expected to facilitate analysis, as the rewrite rules of each system effectively represents at least an important Lemma or Theorem of the other system.

We do not demonstrate any completeness results for these calculi; more rewrites may be necessary to prove completeness for arbitrary $D > 1$, for each of these two calculi, even in the stabiliser and multicharacter fragments described above.

5 Discussion

As well as providing an approach to define ZX and ZH calculi with simple rewrite systems on qudits, this approach is a simpler, and apparently independent, way to reproduce[10] the "well-tempered" semantic map $[\![\,\cdot\,]\!]_\nu$ described in Ref. [14] for $D = 2$. In this way, Eqns. (28) and (29) provide a more intuitive definition of those semantics, and extend them to arbitrary $D > 1$. It is possible to show that this is essentially down to the constraints imposed on the representation of the discrete Fourier transform in Section 3.2. Ref. [15, Appendix B] describes **(a)** the way that Eqns. (28) and (29) fail to constrain a generic "Ockhamic" interpretation of ZH diagrams while fixing a specific "Ockhamic" interpretations of ZX diagrams; and **(b)** to what extent this approach to fixing semantics actually differs from the approach of Ref. [14].

As well as discrete integrals, and amplitude functions $\Theta, \mathrm{A} : \mathbb{Z} \to \mathbb{C}$ in place of (vectors of) phases or amplitudes, we consider an index set for $\mathcal{H}$ which is not simply $\{0, 1, \ldots, D{-}1\}$, but instead $\{L, L+1, \ldots, U-1, U\}$ for some integers such that $U - L + 1 = D$. One conventional choice is $L = 0$ and $U = D - 1$, but most of out results (in particular: all those to do with the stabiliser / multicharacter fragments of ZX or ZH) hold equally well with any such set of labels for the standard basis. This less committal choice of index set demonstrates the flexibility of this system, which may prove useful for future applications (e.g., problems in physics where it may prove useful to consider negative index values).

We conclude with a highly speculative thought regarding discrete measures. One constraint which we imposed on the measure μ on $\mathbf{D}$ – interpreted as a measure on $\mathbb{Z}_D$ – was that the Fourier transform should be interpretable as an involution $\mathbb{C}^{(\mathbb{Z}_D,\mu)} \to \mathbb{C}^{(\mathbb{Z}_D,\mu)}$ on functions on the measure space $(\mathbb{Z}_D, \mu)$, rather than a bijection $\mathbb{C}^{(\mathbb{Z}_D,\mu)} \to \mathbb{C}^{(\mathbb{Z}_D,\mu')}$ between functions on distinct measure spaces $(\mathbb{Z}_D, \mu)$ and $(\mathbb{Z}_D, \mu')$. This may seem like a technical but necessary step; for a conventional presentation of ZX diagrams, it *is* necessary, if all of the wires are to have the same type. However, many quantum algorithms have a structure in which some classical operation with a distinguished control register, where that control operates on a state which is conceived as being in the Fourier basis. This structure is consistent with the control register having different "datatypes" at different stages of the algorithm. Could it be more appropriate to make a distinction on logical qudits of each dimension D, between a "standard" type and a "Fourier" type (possibly among others), than to have just a single "type" for each D? It would be interesting to consider what insights into the structure of quantum algorithms might arise by investigating along these lines; it is conceivable that this could give rise to new insights into structured quantum programming.

[10] Strictly speaking, the calculi of Ref. [14] involve red and green dots with parameters $\theta \in \mathbb{R}$, H-boxes with parameters $\alpha \in \mathbb{C}$, only one type of Hadamard box instead of two, and a "nu box" which is missing from the calculus presented here. We may bridge these differences using the short-hand described for phases / amplitudes to parameterise these nodes, identifying both Hadamard plus and minus boxes with the single Hadamard box of Ref. [14], and replacing the nu-boxes with some suitable scalar gadgets (such as H-boxes parameterised by powers of $\nu = D^{-1/4}$).

On Complexity of Confluence and Church-Rosser Proofs

Arnold Beckmann
Department of Computer Science, Swansea University, UK

Georg Moser
Department of Computer Science, University of Innsbruck, Austria

Abstract

In this paper, we investigate *confluence* and the *Church-Rosser property* – two well-studied properties of rewriting and the λ-calculus – from the viewpoint of proof complexity. With respect to confluence, and focusing on orthogonal term rewrite systems, our main contribution is that the size, measured in number of symbols, of the smallest rewrite proof is polynomial in the size of the peak. For the Church-Rosser property we obtain exponential lower bounds for the size of the join in the size of the equality proof. Finally, we study the complexity of proving confluence in the context of the λ-calculus. Here, we establish an exponential (worst-case) lower bound of the size of the join in the size of the peak.

1 Introduction

Confluence and the Church-Rosser property are two (very) well-known properties of rewriting that have been studied for several decades. *Confluence* expresses that if we have terms s, t, t', where s can be successively rewritten to t, as well as to t', then t and t' have a common descendent in the rewriting relation, cf. Figure 1 i). In short, if there is a *peak*: $t\ {}^*\!\!\leftarrow s \rightarrow^* t'$, we conclude the existence of a *rewrite proof*: $t \rightarrow^* \cdot\ {}^*\!\!\leftarrow t'$. The *Church-Rosser property* – illustrated in Figure 1 ii) – expresses that from the equality between t and t' ($t \leftrightarrow^* t'$), we conclude the existence of a rewrite proof: $t \rightarrow^* \cdot\ {}^*\!\!\leftarrow t'$. It is a folklore result that both properties are equivalent. And, as indicative in the name, their intensive study goes back to work by Church and Rosser [8].

Despite the large body of work on confluence and the Church-Rosser property, it seems that the, to us, natural question about the inherent proof complexities has only received scarce attention. A noteworthy exception is work by Ketema and Grue Simonsen [11]. Focusing on orthogonal term rewrite systems and employing the number of reductions as measure of proof complexity, they obtain in the context of confluence optimal exponential upper bounds on the size of the rewrite proof in relation to the size of the peak. With respect to the Church-Rosser property only a non-elementary upper bound can be shown. Related results have been obtained for the λ-calculus, where again non-elementary bounds are obtained for both properties, cf. [10].

If, however, proof complexity is measured more in the tradition of computational complexity, that is, as the number of symbols occurring in a proof, then more tractable results are possible. For example for orthogonal term rewrite systems, we prove that for confluence the size of the least rewrite proof is always polynomially bounded in the size of the peak.

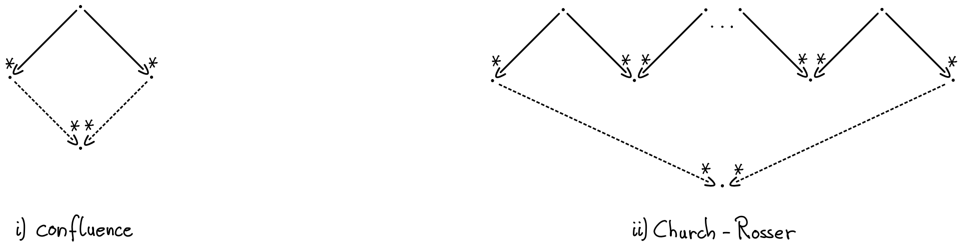

Figure 1 Confluence and Church-Rosser property.

Motivation. These results may open the way for the application of rewriting techniques in complexity theoretic studies, in particular in the context of Bounded Arithmetic [6]. A major open problem in Bounded Arithmetic is the separation of its fragments, which has deep connections to similar questions about the separation of computational complexity classes like the Polynomial Time Hierarchy, including the P vs. NP problem. Consider equational theories, restricted to term equations that define functions symbols exclusively by recursion. As established in [5] by the first author, consistency of such equational theories can be proved in the fragment of Bounded Arithmetic S^1_2. This is remarkable, as it disproves the general impression in Bounded Arithmetic, that consistency statements cannot be used for separation arguments - consistency of equational theories with a richer set of axioms are usually unprovable in Bounded Arithmetic [7].

In the proof in [5], the given equational proof is reconstructed in S^1_2 using a technically involved process of "approximation" and "calculation". An alternative, much more elegant, proof could employ the Church-Rosser property of the induced term rewrite system. To our best knowledge it is, however, unclear whether this property (or confluence) is formalisable in S^1_2. The results of this paper are conceivable as a first step towards this direction.

Contributions. In summary, we make the following contributions, where we are only concerned with *orthogonal* term rewrite systems.

1) Our main result, Theorem 17, shows that the size – measured in the number of symbols – of the smallest possible rewrite proofs is in the worst-case polynomially bounded in the size of the peak, cf. Figure 1. This shows that confluence properties are polynomial time computable, hence are formalisable in Bounded Arithmetic.
The polynomial (in fact biquadratic) upper bound stems from a quadratic bound on the number of reductions in the rewrite proof in the size of the peak, and a quadratic bound on the size of each term in the rewrite proof.

2) For the Church-Rosser property we give an exponential worst-case lower bound to the size of the join in the size of the equality proof, cf. Theorem 19. This shows that it is not possible to formalise Church-Rosser properties directly in Bounded Arithmetic. The (worst-case) bound is precise.

3) We give matching (worst-case) upper and lower bounds based on different complexity measures. For confluence, we show that the size of the join is linear in the size of the product of the end terms in the peak, cf. Corollary 15 and Proposition 10. For the Church-Rosser property, we show that the size of the join is polynomial in the product of the sizes of the intermediary terms in the equational proof, cf. Theorem 22 and Proposition 21.

4) Finally, we study the complexity of proving confluence in the context of the λ-calculus. We obtain that the size of the join is at least exponential in the size of the peak. Hence, confluence is also not formalisable directly in Bounded Arithmetic.

Outline

The next section introduces basic notions and results. In Section 3 we establish the mentioned lower bound results for rewriting. Section 4 introduces technical notions that underly the methodology of our main results, to be presented in Section 5. In Section 6 we study lower and upper bounds on the complexity of Church-Rosser proofs. The lower bound of confluence proofs is established in Section 7. Section 8 discusses related works. Finally, in Section 9, we conclude and present future work.

2 Preliminaries

We assume (at least nodding) acquaintance with term rewriting [2, 12], however recall basic definitions and notations for ease of readability.

General. Let R be a binary relation. We write R^n for the n-fold iteration of R and R^* for the reflexive and transitive closure of R. Let $\mathcal{V}$ denote a countable infinite set of variables, and $\mathcal{F}$ a countable infinite set of function symbols (also called signature). The set of terms over $\mathcal{F}$ and $\mathcal{V}$ is denoted by $\mathcal{T}(\mathcal{F}, \mathcal{V})$.

Let t be a term (over $\mathcal{F}$ and $\mathcal{V}$). A *position* p is a finite sequence of positive integers. Via positions, we uniquely identifying subterms of t, denoted as $t|_p$. We write $p \| q$ to indicate parallel positions, generalising the notions suitably to sets of positions. We write $\mathsf{Var}(t)$ to denote the set of variables occurring in t, ie. $\mathsf{Var}\, t = \{x \mid t|_p \text{ is a variable for some position } p\}$ and we write $\mathsf{rt}(t)$ to denote its root symbol. For example, for $\{x, y\} \subseteq \mathcal{V}$, $\mathsf{Var}(x + y) = \{x, y\}$ and $\mathsf{rt}(x + y) = +$. The *size* $|t|$ of term t is defined as the number of symbol occurrences in t, for example, $|x + y|= 3$. A term t is *linear* if every variable in t occurs only once.

Term Rewriting. A *rewrite rule* is a pair $l \to r$ of terms, such that (i) the left-hand side l is not a variable and (ii) $\mathsf{Var}(l) \supseteq \mathsf{Var}(r)$. A *term rewrite system* (TRS) over $\mathcal{F}$ is a finite set of rewrite rules $\mathcal{R}$; it will be denoted by the pair $(\mathcal{F}, \mathcal{R})$. If the signature $\mathcal{F}$ is clear from context, we simply denote a TRS by its set of rules $\mathcal{R}$. If $l \to r$ is a rewrite rule and σ a renaming, then the rule $l\sigma \to r\sigma$ is called a *variant* of $l \to r$. A TRS is said to be *variant-free*, if it does not contain rewrite rules that are variants. In the following we assume that TRSs are variant-free.

The rewrite relation based on $\mathcal{R}$ is denoted as $\to_{\mathcal{R}}$ and its transitve and reflexive closure as $\to_{\mathcal{R}}^*$. If the TRS is clear from context, we will simply write $\to$ and $\to^*$ respectively. Let s be a redex in term t. Here a *redex* is an occurrence of a term s that is an instance of the left-hand side l of a rule $l \to r \in \mathcal{R}$. We write $t \xrightarrow{s}_{\mathcal{R}} t'$ to indicate that redex s is contracted in the rewrite step. A term t over $\mathcal{T}(\mathcal{F}, \mathcal{V})$ is in *normal form* with respect to a TRS $\mathcal{R}$, if t does not contain any redex. We call a substitution σ *normalised* (with respect to $\mathcal{R}$), if all terms in the range of σ are in normal form. The *innermost rewrite relation* $\xrightarrow{\mathrm{i}}_{\mathcal{R}}$ of a TRS $\mathcal{R}$ is defined as follows: $s \xrightarrow{\mathrm{i}}_{\mathcal{R}} t$ if there exists a rewrite rule $l \to r \in \mathcal{R}$, a context C, and a substitution σ such that $s = C[l\sigma]$, $t = C[r\sigma]$, and all proper subterms of $l\sigma$ are normal forms of $\mathcal{R}$.

An *overlap* for $\mathcal{R}$ is a triple $\langle l \to r, p, l' \to r' \rangle$, such that (i) $l \to r$, $l' \to r'$ are rules in $\mathcal{R}$, whose variables are disjoint, (ii) p is not a variable position in l', (iii) l and $l'|_p$ are unifiable, (iv) if $p = \varepsilon$, then $l \to r$, $l' \to r'$ are not variants. A TRS is *left-linear* if the left-hand sides of all rules are linear. A TRS $\mathcal{R}$ without overlap is called *non-ambiguous*; a left-linear, non-ambiguous TRS is called *orthogonal*.

Let s and t be terms. Then an *(innermost) derivation* $D\colon s \to_{\mathcal{R}}^* t$ with respect to a TRS $\mathcal{R}$ is a finite sequence of (innermost) rewrite steps. Given an equational system $\mathcal{E}$, we can define, as usual, a TRS $\mathcal{R}$ such that

$$s =_{\mathcal{E}} t \quad \text{iff} \quad s \leftrightarrow_{\mathcal{R}}^* t \;.$$

(See [2, 12] for the straightforward construction.) A finite sequence of equational steps: $t_1 \leftrightarrow_{\mathcal{R}} t_2 \cdots \leftrightarrow_{\mathcal{R}} t_n$ is called an *equational proof.*

A term $s \in \mathcal{T}(\mathcal{F}, \mathcal{V})$ is *confluent*, if for all $t, t' \in \mathcal{T}(\mathcal{F}, \mathcal{V})$ with $t \;{}^*\!\!\leftarrow s \to^* t'$, there exists a common reduct v, that is, $t \to^* v \;{}^*\!\!\leftarrow t'$. A TRS $(\mathcal{F}, \mathcal{R})$ is *confluent* if all terms in $\mathcal{T}(\mathcal{F}, \mathcal{V})$ are confluent. We call the equational proof $t \;{}^*\!\!\leftarrow s \to^* t'$ a *peak*, the term v the *join* and the derivations $t \to^* v \;{}^*\!\!\leftarrow t'$ a *rewrite proof.* A peak is *local*, if it consists of one step each: $t \leftarrow s \to t'$. Confluence is equivalent to the *Church-Rosser property*, which states that for any equational proof $t \leftrightarrow^* t'$ there is a rewrite proof $t \to^* v \;{}^*\!\!\leftarrow t'$. A rewrite relation $\to$ has the *diamond property*, if any local peak over $\to$ can be joined immediately, that is, if $\leftarrow \cdot \to \subseteq \to \cdot \leftarrow$ holds.

Descendants and Residuals. Let $(\mathcal{F}, \mathcal{R})$ be a TRS and let L be a set of labels. The *labelled TRS* $(\mathcal{F}^L, \mathcal{R}^L)$ is defined by setting (i) $\mathcal{F}^L := \mathcal{F} \cup \{f^\ell \mid f \in \mathcal{F} \text{ and } \ell \in L\}$, (ii) the projection $\langle t \rangle$ of a term $t \in \mathcal{T}(\mathcal{F}^L, \mathcal{V})$ removes all labels, and (iii) $\mathcal{R}^L := \{l \to r \mid \langle l \rangle \to r \in \mathcal{R}\}$. The next proposition is from Terese [12, Proposition 4.2.3].

▶ **Proposition 1.** *Consider a left-linear TRS $(\mathcal{F}, \mathcal{R})$ and a set of labels L. Let $s \in \mathcal{T}(\mathcal{F}, \mathcal{V})$ and let s' be a labelled term such that $\langle s' \rangle = s$. Then each reduction step $s \to t$ can be lifted to a reduction step $s' \to t'$ in the labelled TRS $(\mathcal{F}^L, \mathcal{R}^L)$ such that $\langle t' \rangle = t$.*

In the following, we write $\mathcal{R}^L$ in short for the labelled TRS $(\mathcal{F}^L, \mathcal{R}^L)$, if the (labelled) signature is clear from context.

▶ **Definition 2.** *Let t be a term in a TRS $\mathcal{R}$, let s be a redex and let f be a function symbol occurring at position p in t, ie. $\mathsf{f} = \mathsf{rt}(t|_p)$. Let t_f denote the term that results from t by labelling this occurrence of f with label $\ell \in L$. Then the reduction step $t \xrightarrow{s} t'$ (contracting redex s) is lifted to a reduction step $t_\mathsf{f} \to t''$ in $\mathcal{R}^L$.*

The occurrences of f in t' that have label ℓ in t'' are the descendants *of the original symbol occurence of f in t. Conversely, the original f is called the* ancestor *of its descendants.*

The descendant/ancestor relation is extended to subterm occurrences via their root symbols. The descendant of a redex is called a *residual.* For a set of redexes S, we call the set of residuals of redexes in S simply the set of residuals of S. The descendant/ancestor relation naturally generalises to sequence of rewrite steps, that is, derivations. Note that the ancestor relation is unique, that is, for any derivation $D\colon s \to^* t$ the ancestor of a subterm u in t is given as a unique occurrence of a subterm u' in s, if it exists, cf. [12, Chapter 4].

Orthogonality. It is well-known that every orthogonal TRS is confluent, which can for example be verified by repeated applications of the Parallel Moves Lemma, cf. [12, Lemma 4.3.3].

▶ **Lemma 3** (Parallel Moves Lemma). *In an orthogonal TRS, let $t \to^* t_2$ be given. Let $t \xrightarrow{s} t_1$ be a one-step reduction by contraction of redex s. Then a common reduct t_3 of t_1 and t_2 can be found by contracting in t_2 of all residuals of redex s. Observe that all residuals will be pairwise disjoint.*

In order to prove the Parallel Moves Lemma, one makes use of the parallel rewriting relation, formalising the notion of contraction of pairwise disjoint redexes.

▶ **Definition 4.** *Let $\mathcal{R}$ be a TRS. We define the* parallel rewriting *relation $\Rightarrow_{\mathcal{R}}$ as follows*

1. *$x \Rightarrow_{\mathcal{R}} x$ for any variable x,*
2. *$f(\vec{s}) \Rightarrow_{\mathcal{R}} f(\vec{t})$ for any function symbol f, if for all i $s_i \Rightarrow_{\mathcal{R}} t_i$, and*
3. *$l\sigma \Rightarrow_{\mathcal{R}} r\sigma$, if $l \to r \in \mathcal{R}$ and σ a substitution.*

We often omit $\mathcal{R}$ and simply write $s \Rightarrow t$, if the TRS is clear from context.

Note that $\to_{\mathcal{R}} \subseteq \Rightarrow_{\mathcal{R}} \subseteq \to^*_{\mathcal{R}}$, in particular we have that $\to^*_{\mathcal{R}} = \Rightarrow_{\mathcal{R}}{}^*$. Making use of parallel rewriting, we can state the Parallel Moves Lemma succinctly as follows. A strengthening of the lemma has been stated and proven in [11].

▶ **Lemma 5.** *Parallel rewriting has the diamond property for every orthogonal TRS $\mathcal{R}$, that is, if $t \Leftarrow_{\mathcal{R}} s \Rightarrow_{\mathcal{R}} t'$, then there exists a join t'' such that $t' \Rightarrow_{\mathcal{R}} t'' \Leftarrow_{\mathcal{R}} t$.*

Let TRS $\mathcal{R}$ be fixed and let $s \Rightarrow t$ denote a paralel rewriting step with respect to $\mathcal{R}$. Suppose the (occurrences of) disjoint redexes contracted are collected in set S. Then we succinctly write $s \overset{S}{\Longrightarrow} t$. Due to the Parallel Moves Lemma, we obtain the following proposition, cf. [12, Proposition 4.5.6].

▶ **Proposition 6.** *Let $\mathcal{R}$ be an orthogonal TRS, and let $t \in \mathcal{T}(\mathcal{F}, \mathcal{V})$. Let S, T be sets of pairwise disjoint redexes in t and let $t \overset{S}{\Longrightarrow} t'$. Then the set of residuals of T in t' is unique, that is, independent of the order in which redexes in S are contracted.*

Proof. This is a direct consequence of the diamond property of $\Rightarrow$. Actually a stronger results holds. The single parallel rewriting step employed, is generalisable to a complete development step, without affecting the validity of the proposition, cf. [12, Proposition 4.5.6]. ◀

Based on Proposition 6 we denote with T/S the (unique) set of residuals of T in t' that are obtained by the parallel rewriting step $t \overset{S}{\Longrightarrow} t'$. With Lemma 3 we observe that T/S consists of pairwise disjoint redexes in t'.

Following the definition of the functions $\mathsf{cvs}_{\mathcal{R}}$ and $\mathsf{vs}_{\mathcal{R}}$ in [11], we define functions that compute the worst case of joining derivations based on peaks, resp. equation proofs, of a given size in the most effective way. Let $\|D\|$ denote the number of symbol occurrences in D.

▶ **Definition 7.** *Let $\mathcal{R}$ be an orthogonal term rewrite system. With $\mathsf{j}_{\mathcal{R}}(t, t')$ we denote the minimal size of a joining derivation of terms t and t', if it exist:*

$$\mathsf{j}_{\mathcal{R}}(t,t') = \begin{cases} \min\{\|D'\| \colon D' : t \to^*_{\mathcal{R}} \cdot {}^*\!\!\leftarrow_{\mathcal{R}} t'\} & \text{if } t \text{ and } t' \text{ have a joining derivation} \\ \infty & \text{otherwise} \end{cases}$$

The worst case join complexities *for confluence* Conf *and Church-Rosser* CR *are defined as*

$$\begin{aligned} \mathsf{Conf}(n) &= \max\{\mathsf{j}_{\mathcal{R}}(t,t') \colon \exists D; \|D\| = n,\ D : t \,{}^*_{\mathcal{R}}\!\!\leftarrow \cdot \to^*_{\mathcal{R}} t',\ \mathcal{R} \text{ orthogonal TRS}\} \\ \mathsf{CR}(n) &= \max\{\mathsf{j}_{\mathcal{R}}(t,t') \colon \exists D; \|D\| = n,\ D : t \leftrightarrow^*_{\mathcal{R}} t',\ \mathcal{R} \text{ orthogonal TRS}\}\ . \end{aligned}$$

In the following we will give some (worst-case) upper and (worst-case) lower bounds to those functions. Our main result will be a polynomial upper bound to Conf in Corollary 18. We also provide an exponential lower bound to CR in Corollary 20.

For the remainder of the paper, we restrict to *orthogonal* TRSs.

3 Lower Bounds for Confluence

For our lower bound considerations we use the following big-O facts, which follow easily from definitions.

▶ **Lemma 8.**
1. *If* $e_1(n) = \mathsf{O}(e(n))$ *and* $e_2(n) = \Omega(e(n))$ *then* $e_2(n) = \Omega(e_1(n))$.
2. *If* $e_1(n) = e(n)^{\mathsf{O}(1)}$ *and* $e_2(n) = e(n)^{\Omega(1)}$, *then* $e_2(n) = e_1(n)^{\Omega(1)}$.

We first give a linear lower bound to the number of steps for joining a peak in the size of the splitting sequence. We will provide a corresponding upper bound in Corollary 16.

▶ **Proposition 9.** *There is an orthogonal TRS $\mathcal{R}$ satisfying the following: Let $D_1\colon a \to^* b$ and $D_2\colon a \to^* c$ be derivations over $\mathcal{R}$, such that $b \to^k d$, and $c \to^l d$ holds for numbers k, l, and term d. Then $k + l = \Omega(\|D_1\| + \|D_2\|)$, that is, $k + l$ is at least linear in the number of symbols in D_1 and D_2 together.*

Proof. Consider the TRS $\mathcal{R}_1$ given by

$$\mathsf{f}(x) \to \mathsf{g}(x, x) \qquad \mathsf{a}(x) \to \mathsf{b}(x, x)\ . \tag{1}$$

We define meta term symbols via $A(T) := \mathsf{a}(T)$, $B(T) := \mathsf{b}(T, T)$, $F(T) := \mathsf{f}(T)$, $G(T) := \mathsf{g}(T, T)$. For a meta term symbol T let $T^{(n)}$ denote its n-fold iteration.

We define

$$S_n = F^{(n)}(A^{(n)}(0)) \qquad U_n = F^{(n)}(B^{(n)}(0))$$
$$V_n = G^{(n)}(A^{(n)}(0)) \qquad W_n = G^{(n)}(B^{(n)}(0))\ ,$$

and compute

$$|S_n| = \mathsf{O}(n) \qquad |U_n| = \mathsf{O}(2^n) \qquad |V_n| = \mathsf{O}(n2^n)\ .$$

Consider the following peak in $\mathcal{R}_1$, rewriting innermost redexes first.

$$D_1 :\quad S_n \xrightarrow{\mathsf{a}} F^{(n)}(A^{(n-1)}(B(0))) \xrightarrow{\mathsf{a}} F^{(n)}(A^{(n-2)}(B^{(2)}(0))) \xrightarrow{\mathsf{a}} \cdots \xrightarrow{\mathsf{a}} U_n$$
$$D_2 :\quad S_n \xrightarrow{\mathsf{f}} F^{(n-1)}(G(A^{(n)}(0))) \xrightarrow{\mathsf{f}} F^{(n-2)}(G^{(2)}(A^{(n)}(0))) \xrightarrow{\mathsf{f}} \cdots \xrightarrow{\mathsf{f}} V_n\ .$$

To discern ambiguity, we have identified the root symbol of the redex above the rewrite relation.

The size of each term in the first derivation is $\mathsf{O}(2^n)$, hence the overall size of D_1 is $\mathsf{O}(n2^n)$. The size of the k-th term in the second derivation is $\mathsf{O}(n2^k)$, so adding them up for $k \leqslant n$ gives a bound of $\mathsf{O}(n2^n)$ for the overall derivation length of D_2 as well. Hence $(\|D_1\| + \|D_2\|) = \mathsf{O}(n2^n)$.

The 'fastest' join of U_n and V_n is given by rewriting innermost redexes first:

$$U_n \xrightarrow{\mathsf{f}}^1 F^{(n-1)}(G(B^{(n)}(0))) \xrightarrow{\mathsf{f}}^1 F^{(n-2)}(G^{(2)}(B^{(n)}(0))) \xrightarrow{\mathsf{f}}^1 \cdots \xrightarrow{\mathsf{f}}^1 W_n$$
$$V_n \xrightarrow{\mathsf{a}}^{2^n} G^{(n)}(A^{(n-1)}(B(0))) \xrightarrow{\mathsf{a}}^{2^n} G^{(n)}(A^{(n-2)}(B^{(2)}(0))) \xrightarrow{\mathsf{a}}^{2^n} \cdots \xrightarrow{\mathsf{a}}^{2^n} W_n\ .$$

The length of the first derivation is n, and of the second $n2^n$, respectively.

Thus, a lower bound to the number of steps S_{join} of any derivations that join U_n and V_n is $n2^n$: $S_{\text{join}} = \Omega(n2^n)$. Together with $(\|D_1\| + \|D_2\|) = \mathsf{O}(n2^n)$ and Lemma 8.(1), we obtain $S_{\text{join}} = \Omega(\|D_1\| + \|D_2\|)$. Hence, S_{join} must be at least linear in the size of the derivations D_1 and D_2 constituting the peak. ◀

We also give a linear lower bound to the size of the join of the diamond in the product of the sizes of meet-able terms in a peak. The corresponding upper bound will be given in Corollary 15.

▶ **Proposition 10.** *There is an orthogonal TRS $\mathcal{R}$ satisfying the following: Let $b \ {}^*\!\!\leftarrow a \rightarrow^* c$ be a peak over $\mathcal{R}$ with consequent join d such that $b \rightarrow^* d$ and $c \rightarrow^* d$. Then $|d|= \Omega(|b|\cdot|c|)$, that is, the size $|d|$ of d is at least linear in $|b|\cdot|c|$.*

Proof. Fix n. We will basically follow the example from the proof of Proposition 9, with a slight modification to obtain optimal bounds.

With the notation from the proof of Proposition 9, expand TRS $\mathcal{R}_1$, cf. (1), with the rule $\mathsf{h} \rightarrow A^{(n)}(\mathsf{0})$. Let the resulting TRS be denoted as $\mathcal{R}_2$. We define

$$S'_n = F^{(n)}(\mathsf{h}) \qquad U_n = F^{(n)}(B^{(n)}(\mathsf{0}))$$
$$V'_n = G^{(n)}(\mathsf{h}) \qquad W_n = G^{(n)}(B^{(n)}(\mathsf{0})) ,$$

and compute

$$|U_n|= \mathsf{O}(2^n) \qquad |V'_n|= \mathsf{O}(2^n) \qquad |W_n|= \Omega(2^{2n}) .$$

Consider the following peak:

$$S'_n \xrightarrow{\mathsf{h}} F^{(n)}(A^{(n)}(\mathsf{0})) \xrightarrow{\mathsf{a}}{}^* U_n$$
$$S'_n \xrightarrow{\mathsf{f}} F^{(n-1)}(G(\mathsf{h})) \xrightarrow{\mathsf{f}} F^{(n-2)}(G^{(2)}(\mathsf{h})) \xrightarrow{\mathsf{f}}{}^* V'_n .$$

The 'smallest' join of U_n and V_n is given by rewriting only residuals:

$$U_n \xrightarrow{\mathsf{f}}{}^* W_n$$
$$V'_n \xrightarrow{\mathsf{h}}{}^* G^{(n)}(A^{(n)}(\mathsf{0})) \xrightarrow{\mathsf{a}}{}^* W_n .$$

We compute $|U_n|\cdot|V'_n|= \mathsf{O}(2^{2n})$. Together with $|W_n|= \Omega(2^{2n})$ and (1) we obtain $|W_n|= \Omega(|U_n|\cdot|V'_n|)$. Hence, the size of any join must be at least linear in the product of the sizes of U_n and V'_n. ◀

4 Injectivity

For the sequel, we fix an orthogonal TRS $\mathcal{R}$. Let $t' \ {}^*\!\!\leftarrow s \rightarrow^* t$ denote a peak over $\mathcal{R}$.

Consider the tiling diagramme in Figure 2 obtained by repeated applications of Lemma 5. We assume that $H_{0,\nu}$ denotes a singleton set of one redex in $s_{0,\nu}$, for $\nu = 0\dots,i{-}1$, and that $V_{\mu,0}$ denotes a singleton set of one redex in $s_{\mu,0}$, for $\mu = 0\dots,j{-}1$. Note that this implies $|H_{0,\nu}|= 1$ and $|V_{\mu,0}|= 1$. Further, we obtain

$$V_{\mu,\nu+1} = V_{\mu,\nu}/H_{\mu,\nu} \qquad H_{\mu+1,\nu} = H_{\mu,\nu}/V_{\mu,\nu} ,$$

as sets of residuals using Proposition 6. Moreover, using Proposition 6, we have that $H_{\mu,\nu}$ and $V_{\mu,\nu}$ are sets of pairwise disjoint redexes in $s_{\mu,\nu}$, for all $\mu = 0\dots,j{-}1$, $\nu = 0\dots,i{-}1$. Recall that a *redex* is an occurrence of a term t that is an instance of the left-hand side l of a rule $l \rightarrow r \in \mathcal{R}$.

\end{tikzcd}$$

Figure 2 The tiling situation.

Generalised Ancestors

Given a sequence of rewrite steps

$$t \to_{s'} t' \to_{s''} t'' \to \ldots \to_{s^{(n-1)}} t^{(n-1)} \to_{s^{(n)}} t^{(n)}$$

we generalise the notion of ancestor to trace any subterm in the sequence back to t – we denote this *generalised ancestor*, or short *g.-ancestor*.

Ancestors are also g.-ancestors. Consider a subterm u_j in $t^{(j)}$, and its ancestors u_{j-1} in $t^{(j-1)}$, etc., until u_i in $t^{(i)}$ cannot be extended any further. Let f denote the root symbol of u_i in $t^{(i)}$. As f does not have an ancestor in $t^{(i-1)}$, we must be in the following situation: There exist a context $C[*]$, substitution σ, and rule $l \to r$ in $\mathcal{R}$, such that $t^{(i-1)} = C[l\sigma]$, $t^{(i)} \equiv C[r\sigma]$, and f occurs in r. We now define the *generalised ancestor* of f in $t^{(i)}$ as the root symbol of l in $C[l\sigma] = t^{(i-1)}$. Continue until t is reached.

▶ **Proposition 11.** *In the tiling diagramme in Figure 2, the generalised ancestors of any symbol occurrence are unique, that is, independent of the path chosen to compute them.*

Proof. Arguing inductively, it suffices to prove the statement for a single square:

$$\begin{tikzcd}
s_{\mu,\nu} \arrow[r, Rightarrow, "H_{\mu,\nu}"] \arrow[d, Rightarrow, "V_{\mu,\nu}"] & s_{\mu,\nu+1} \arrow[d, Rightarrow, "V_{\mu,\nu+1}"] \\
s_{\mu+1,\nu} \arrow[r, Rightarrow, "H_{\mu+1,\nu}"] & s_{\mu+1,\nu+1} .
\end{tikzcd}$$

Recall that using Proposition 6, we have that $H_{\mu,\nu}$ and $V_{\mu,\nu}$ are sets of disjoint redexes in $s_{\mu,\nu}$, for all $\mu = 0 \ldots, j-1$, $\nu = 0 \ldots, i-1$. Thus, in proof of the claim, we can assume without loss of generality that $|H_{\mu,\nu}| = |V_{\mu,\nu}| = 1$.

Let u be a subterm of $s_{\mu+1,\nu+1}$. First, suppose u has an *ancestor* in $s_{\mu,\nu}$. Then, this ancestor is unique, as mentioned above.

Second, suppose u has only *generalised ancestors* in $s_{\mu,\nu}$. Then, we distinguish cases on the relative positioning of redexes in $H_{\mu,\nu}$ and $V_{\mu,\nu}$, respectively. Recall, that by assumption the redexes in $H_{\mu,\nu}$ and $V_{\mu,\nu}$ are pairwise disjoint.

Case. Suppose $H_{\mu,\nu} \| V_{\mu,\nu}$, that is, the redexes in $H_{\mu,\nu} \cup V_{\mu,\nu}$ are all pairwise disjoint. Then the claim is obvious.

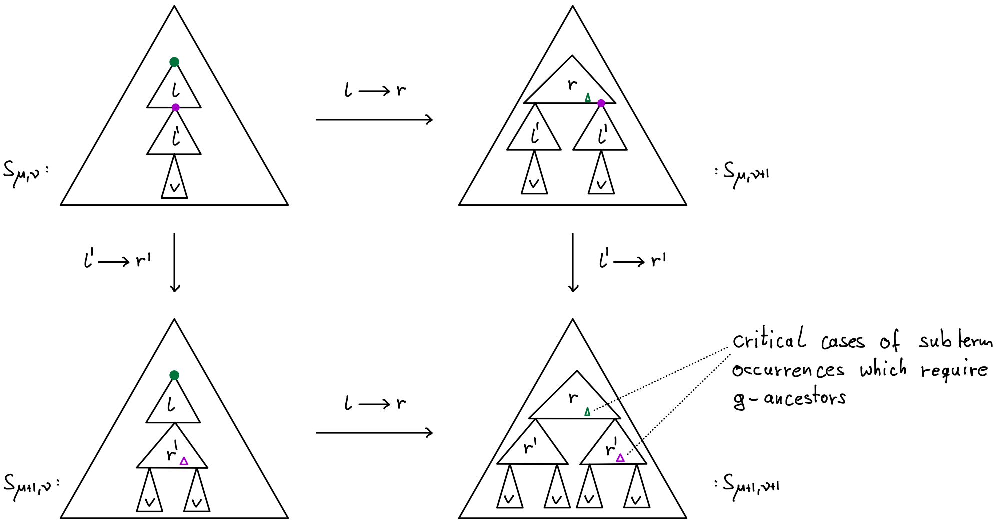

Figure 3 Critical cases where generalised ancestors occur.

Case. Suppose there exists rules $l \to r, l' \to r' \in \mathcal{R}$, and substitutions σ, σ' such that $l\sigma \in H_{\mu,\nu}$ and $l'\sigma' \in V_{\mu,\nu}$. Further $l'\sigma' \lhd l\sigma$. (The case $l\sigma = l'\sigma$ is trivial, because we must have $(l \to r) = (l' \to r')$ due to orthogonality of $\mathcal{R}$.) As u does not have an ancestor in $s_{\mu,\nu}$, $\mathsf{rt}(u)$ either occurs in r or in r'. The situation of this case is depicted in Figure 3.

Wlog. $\mathsf{rt}(u)$ occurs in r' and thus u occurs in any of the occurrences of $r'\sigma'$ in $s_{\mu+1,\nu+1}$. By assumption on $l\sigma$ and $l'\sigma'$, u has an ancestor in $s_{\mu+1,\nu}$ and a generalised ancestor in $s_{\mu,\nu+1}$, which are both unique and consequently their join in $s_{\mu,\nu}$ is unique, too. ◀

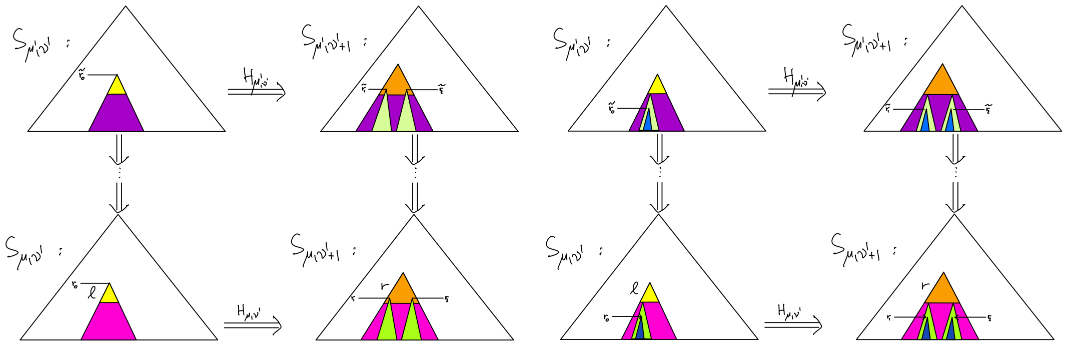
▶ **Definition 12.** *Let the tiling diagramme in Figure 2 be given, and let $\mu < j$, $\nu < i$. Let f be a function symbol occurrence in $s_{\mu,\nu}$, and let $\mu' \leqslant \mu$, $\nu' \leqslant \nu$. We define $\mathrm{ga}^{\mu,\nu}_{\mu',\nu'}(\mathsf{f})$ as the g.-ancestor of f in $s_{\mu',\nu'}$.*

We now formulate the main result of this section.

▶ **Lemma 13.** *Let the tiling diagramme in Figure 2 be given, and let $\mu < j$, $\nu < i$, and $\mu' \leqslant \mu$, $\nu' \leqslant \nu$. The mapping of function symbol occurrences f in $s_{\mu,\nu}$ to the pair $(\mathrm{ga}^{\mu,\nu}_{\mu,\nu'}(\mathsf{f}), \mathrm{ga}^{\mu,\nu}_{\mu',\nu}(\mathsf{f}))$ is an injection.*

Proof. This claim can be proven by induction on $\nu - \nu'$. The case for $\nu = \nu'$ is obvious, because $\mathrm{ga}^{\mu,\nu}_{\mu,\nu}$ is the identity, which is injective.

For the induction step from $\nu' + 1$ to ν' we can assume by induction hypothesis that the claim is true for $(\mu', \nu' + 1)$. We then show the claim for (μ', ν'), depicted as follows.



(a) Case A. **(b)** Case B.

Figure 4 Cases A and B in proof of Lemma 13.

$$\begin{tikzcd}
s_{\mu',\nu'} \arrow[r, Rightarrow] \arrow[d, Rightarrow, "\vdots"] & s_{\mu',\nu'+1} \arrow[r, Rightarrow] \arrow[d, Rightarrow, "\vdots"] & \cdots \arrow[r, Rightarrow] & s_{\mu',\nu} \arrow[d, Rightarrow, "\vdots"] \arrow[r, phantom, "\ni"] & \mathrm{ga}^{\mu,\nu}_{\mu',\nu}(\mathsf{f}) & \mathrm{ga}^{\mu,\nu}_{\mu',\nu}(\mathsf{g}) \\
s_{\mu,\nu'} \arrow[r, Rightarrow] \arrow[d, phantom, sloped, "\ni"] & s_{\mu,\nu'+1} \arrow[r, Rightarrow] \arrow[d, phantom, sloped, "\ni"] & \cdots \arrow[r, Rightarrow] & s_{\mu,\nu} \arrow[dr, phantom, "\ni"] & & \\
\mathrm{ga}^{\mu,\nu}_{\mu,\nu'}(\mathsf{f}) & \mathrm{ga}^{\mu,\nu}_{\mu,\nu'+1}(\mathsf{f}) \arrow[l, mapsto] & & & \mathsf{f} \arrow[lll, mapsto] \arrow[uu, mapsto] & \\
\mathrm{ga}^{\mu,\nu}_{\mu,\nu'}(\mathsf{g}) & \mathrm{ga}^{\mu,\nu}_{\mu,\nu'+1}(\mathsf{g}) \arrow[l, mapsto] & & & & \mathsf{g} \arrow[llll, mapsto] \arrow[uuu, mapsto]
\end{tikzcd}$$

For sake of contradiction assume the claim is wrong for (μ',ν'). That is, there are f,g occurring in $s_{\mu,\nu}$ with f,g different symbol occurrences, such that $\mathrm{ga}^{\mu,\nu}_{\mu',\nu}(\mathsf{f}) = \mathrm{ga}^{\mu,\nu}_{\mu',\nu}(\mathsf{g})$ and $\mathrm{ga}^{\mu,\nu}_{\mu,\nu'}(\mathsf{f}) = \mathrm{ga}^{\mu,\nu}_{\mu,\nu'}(\mathsf{g})$. By i.h. we must have $\mathrm{ga}^{\mu,\nu}_{\mu,\nu'+1}(\mathsf{f}) \neq \mathrm{ga}^{\mu,\nu}_{\mu,\nu'+1}(\mathsf{g})$. Let $r_1 = \mathrm{ga}^{\mu,\nu}_{\mu,\nu'+1}(\mathsf{f})$, $r_2 = \mathrm{ga}^{\mu,\nu}_{\mu,\nu'+1}(\mathsf{g})$, and $r_0 = \mathrm{ga}^{\mu,\nu}_{\mu,\nu'}(\mathsf{f}) = \mathrm{ga}^{\mu,\nu}_{\mu,\nu'}(\mathsf{g})$. This situation is depicted below.

$$\begin{tikzcd}
s_{\mu',\nu'} \arrow[r, Rightarrow, "H_{\mu',\nu'}"] \arrow[d, Rightarrow, "\vdots"] & s_{\mu',\nu'+1} \arrow[r, Rightarrow] \arrow[d, Rightarrow, "\vdots"] & \cdots \arrow[r, Rightarrow] & s_{\mu',\nu} \arrow[d, Rightarrow, "\vdots"] \arrow[r, phantom, "\ni"] & \hat{r} \\
s_{\mu,\nu'} \arrow[r, Rightarrow, "H_{\mu,\nu'}"] \arrow[dd, phantom, sloped, "\ni"] & s_{\mu,\nu'+1} \arrow[r, Rightarrow] \arrow[d, phantom, sloped, "\ni"] & \cdots \arrow[r, Rightarrow] & s_{\mu,\nu} \arrow[dr, phantom, "\ni"] & \\
 & r_1 \arrow[dl, mapsto] & & & \mathsf{f} \arrow[lll, mapsto] \arrow[uu, mapsto] \\
r_0 & & & & \\
 & r_2 \arrow[ul, mapsto] & & & \mathsf{g} \arrow[lll, mapsto] \arrow[uuuu, mapsto]
\end{tikzcd}$$

We must be in the following situation: There are rule $l \to r$ in $\mathcal{R}$, substitution ρ, terms $u_1,\ldots,u_k$, context $C[*_1,\ldots,*_k]$, such that $H_{\mu,\nu'} = \{u_1,\ldots,u_k\}$, $u_1 = l\rho$, $s_{\mu,\nu'} = C[u_1,\ldots,u_k]$, and r_1 and r_2 occur in $r\rho$ in $s_{\mu,\nu'+1} = C[r\rho,\ldots]$, and either

- the roots of r_1 and r_2 occur already in r in $C[r\rho,\ldots]$, hence their joint g.-ancestor r_0 is the root of l in $C[l\rho,u_2,\ldots,u_k]$, see Figure 4a;
- or we have a variable x occuring in l which occurs multiple times in r, e.g. as $C_r[*_1,*_2]$ with $r = C[x,x]$ – hence $r\rho = C_r\rho[x\rho,x\rho]$ – and r_1 occurs in the first $x\rho$, r_2 occurs in the second $x\rho$, and their joint ancestor r_0 occurs in $x\rho$ in $l\rho$ in $s_{\mu,\nu'}$, see Figure 4b.

Let $\hat{r} = \mathrm{ga}^{\mu,\nu}_{\mu',\nu}(\mathsf{f}) = \mathrm{ga}^{\mu,\nu}_{\mu',\nu}(\mathsf{g})$ be the g.-ancestor of f and g in $s_{\mu',\nu}$. $H_{\mu,\nu'}$ are residuals of $H_{\mu',\nu'}$, hence the ancestors $\tilde{r}_0$ of r_0 in $s_{\mu',\nu'}$ and $\tilde{r}_1,\tilde{r}_2$ of r_1,r_2 in $s_{\mu',\nu'+1}$ will occur in $l\rho'$ and $r\rho'$ for some ρ'. In particular in A), the roots of $\tilde{r}_1$ and $\tilde{r}_2$ are in r, and $\tilde{r}_0$ is at the root of l. In case B) we have that $r\rho' = C_r\rho'[x\rho',x\rho']$ with $\tilde{r}_1$ occuring in 1st and $\tilde{r}_2$ in 2nd of $x\rho'$.

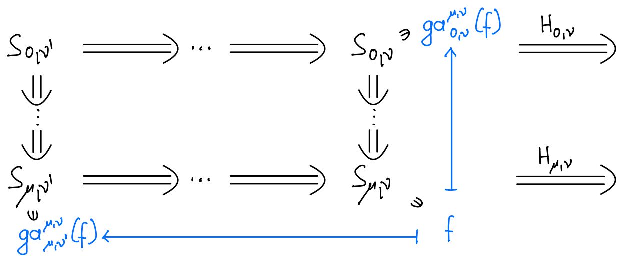
In both cases we have that $\tilde{r}_1$ and $\tilde{r}_2$ are two distinct g.-ancestors of f and g in $s_{\mu',\nu'+1}$, resp., by following from $s_{\mu,\nu}$ the derivation first to $s_{\mu,\nu'+1}$ and then to $s_{\mu',\nu'+1}$. However, by following from $s_{\mu,\nu}$ the derivation to $s_{\mu',\nu}$, f and g have a joint ancestor $\hat{r}$, hence can only have one joint ancestor in $s_{\mu',\nu'+1}$ when following the derivation from $s_{\mu',\nu}$ to $s_{\mu',\nu'+1}$ to the left. This contradicts Proposition 11 that g.-ancestors are unique. ◀

▶ **Lemma 14.** *Let the tiling diagramme in Figure 2 be given, and let $\mu < j$, $\nu < i$.*

Assuming $|H_{0,\nu}|= 1$, the mapping of each redex in $H_{\mu,\nu}$ to their generalised ancestors in $s_{\mu,\nu'}$ for $\nu' < \nu$ is an injection.

Similar for $V_{\mu,\nu}$: Assuming $|V_{\mu,0}|= 1$, the mapping of each redex in $V_{\mu,\nu}$ to their generalised ancestors in $s_{\mu',\nu}$ for $\mu' < \mu$ is an injection.

Proof. We only consider the first assertion, the second is dual. Ie., we are in the following situation.



Let s be a term, H a set of redexes in s, and f a function symbol occurrence in s. We succinctly write $\mathsf{f} \in H$ to indicate that f is the occurrence of the root symbol of some redex in H.

By Lemma 13 we have that the mapping

$$\mathsf{f} \in H_{\mu,\nu} \mapsto (\mathrm{ga}^{\mu,\nu}_{\mu,\nu'}(\mathsf{f}), \mathrm{ga}^{\mu,\nu}_{0,\nu}(\mathsf{f}))$$

is an injection. By assumption we have that $|H_{0,\nu}|= 1$, hence $H_{0,\nu} = \{\hat{r}\}$ for some $\hat{r}$. This implies that $\mathrm{ga}^{\mu,\nu}_{0,\nu}(\mathsf{f}) = \hat{r}$ for all $\mathsf{f} \in H_{\mu,\nu}$. Hence

$$\mathsf{f} \in H_{\mu,\nu} \mapsto \mathrm{ga}^{\mu,\nu}_{\mu,\nu'}(\mathsf{f})$$

must be injective. ◀

5 Upper Bounds on Confluence

In this short section, we state and prove our main result that the size, that is, the number of symbols, of a rewrite proof is polynomial in the size of the peak, cf. Figure 1. First, we draw two easy corollaries from Lemma 13 and Lemma 14, respectively.

▶ **Corollary 15.** *Consider the tiling diagramme in Figure 2. The size of the join t'' is bounded by the product of the sizes of t and t':*

$$|t''| \quad \leqslant \quad |t|{\cdot}|t'| \ .$$

Proof. This is a direct consequence of Lemma 13. ◀

▶ **Corollary 16.** *Consider the tiling diagramme in Figure 2, assuming $|H_{0,\nu}|= 1$ and $|V_{\mu,0}|= 1$. In this situation, the number of (sequential) reduction steps needed to join t and t' via t'', is bounded by the square of the size of the initial sequence. More precisely:*

$$\sum_{\nu=0}^{i-1}|H_{j,\nu}| \quad + \quad \sum_{\mu=0}^{j-1}|V_{\mu,i}| \;\leqslant\; i\cdot|t'|+j\cdot|t| \;\leqslant\; \Big(\sum_{\mu=0}^{j}|s_{\mu,0}|+\sum_{\nu=1}^{i}|s_{0,\nu}|\Big)^2 .$$

Proof. For the first inequality, observe that by Lemma 14, we have that $|H_{j,\nu}|\leq |s_{j,0}|$ for $\nu < i$ and $|V_{\mu,i}|\leq |s_{0,i}|$ for $\mu < j$. Thus, $|H_{j,\nu}|\leq |t'|$ and $|V_{\mu,i}|\leq |t|$ by definition. Then, the second inequality follows by elementary calculations. Finally, observe that if the set of redex S is disjoint then $\overset{S}{\Longrightarrow} \subseteq \to^S$, from which the claim follows. ◀

Now, our main result follows with ease.

▶ **Theorem 17.** *Let $\mathcal{R}$ be an orthogonal TRS and assume the existence of a peak $D\colon t' \;{}^*\!\!\leftarrow s \to^* t$. Then there exists a rewriting proof $D'\colon t' \to^* t'' \;{}^*\!\!\leftarrow t$ whose size is polynomially bounded in the size of D. In fact, the size of D' is biquadratic in the size of D.*

Proof. This is a consequence of Corollaries 15 and 16. Let D' be the joining derivation given by the tiling diagram in Figure 2, where $s_{0,0} = s$, $s_{0,\nu}$ is the ν-th term in $s \to^i t$, and $s_{\mu,0}$ the μ-th term in $s \to^j t'$. Employing the notation of that figure, we obtain

$$\|D\| \;=\; \sum_{\mu=0}^{j}|s_{\mu,0}|+\sum_{\nu=1}^{i}|s_{0,\nu}| .$$

Recall that $\|D\|$ denotes the number of symbol occurrences in D. Due to Corollary 15, we have, for each μ, ν ($0 \leqslant \mu \leqslant j$, $0 \leqslant \nu \leqslant i$), that

$$|s_{\mu,\nu}| \;\leqslant\; |s_{\mu,0}|\cdot|s_{0,\nu}| \;\leqslant\; \|D\|^2 . \tag{2}$$

Moreover, due to Corollary 16, the number of joining steps in D' is bounded by $\|D\|^2$:

$$\text{number of joining steps} \quad\leqslant\quad \sum_{\nu=0}^{i-1}|H_{j,\nu}| + \sum_{\mu=0}^{j-1}|V_{\mu,i}| \quad\leq\quad \|D\|^2 . \tag{3}$$

Combining (2) and (3), we conclude that $\|D'\| \leqslant \|D\|^4$. ◀

▶ **Corollary 18.** Conf *is biquadratically bounded, i.e.* $\mathsf{Conf}(n) = \mathsf{O}(n^4)$.

A closer inspection of the example in the proof of Proposition 10 establishes a cubic lower bound, i.e. $\mathsf{Conf}(n) = \Omega(n^3)$.

6 Lower and Upper Bounds for the Church-Rosser Property

In the case of the Church-Rosser property, we first give an exponential lower bound to the size of the join, which in particular gives an exponential lower bound to the join complexity CR.

▶ **Theorem 19.** *There is an orthogonal TRS $\mathcal{R}$ satisfying the following: Let D be a derivation of $a \leftrightarrow^* b$ over $\mathcal{R}$, such that $a \to^* c$ and $b \to^* c$ holds, then $|c|$ is exponential in $\|D\|$ in general, i.e. $|c|= 2^{\|D\|^{\Omega(1)}}$.*

Proof. Consider the TRS $\mathcal{R}_3$ given by

$$\mathsf{f}_i(x) \to \mathsf{a}_i(x,x) \quad \mathsf{g}_i(x) \to \mathsf{a}_i(x,x) \qquad (i = 1,\dots,k)\ . \tag{4}$$

We define meta term symbols via $A_i(T) := \mathsf{a}_i(T,T)$, define

$$S_i^k = \mathsf{g}_1(\dots \mathsf{g}_{i-1}(\mathsf{g}_i(\mathsf{f}_{i+1}(\dots \mathsf{f}_k(\mathsf{0})\dots)))\dots) \qquad U^k = A_1(\dots A_k(\mathsf{0})\dots)$$
$$T_i^k = \mathsf{g}_1(\dots \mathsf{g}_{i-1}(A_i(\mathsf{f}_{i+1}(\dots \mathsf{f}_k(\mathsf{0})\dots)))\dots)\ ,$$

and compute

$$|S_i^k| = \mathsf{O}(k) \qquad |T_i^k| = \mathsf{O}(k) \qquad S_i^k \xrightarrow{g_i} T_i^k \qquad S_i^k \xrightarrow{f_{i+1}} T_{i+1}^k\ .$$

Consider the following derivation:

$$D \quad := \quad T_1^k \leftarrow S_1^k \to T_2^k \leftarrow S_2^k \to T_3^k \ \dots\ T_{k-1}^k \leftarrow S_{k-1}^k \to T_k^k$$

The unique Church-Rosser join is given by $T_i^k \to^* U$ for all $i = 1,\dots,k$. From now on we drop the superscript k.

Let $S_D = \|D\|$ and $S_U = |U|$. We compute $S_D = \mathsf{O}(n^2)$ and $S_U = \Omega(2^n)$. Thus $S_D \leqslant ck^2$ for some $c > 0$, hence $k \geqslant \sqrt{\frac{1}{c}S_D} \geqslant {S_D}^{\epsilon}$ for small $\epsilon > 0$. Thus $S_U \geqslant 2^k \geqslant 2^{{S_D}^{\epsilon}}$. ◀

▶ **Corollary 20.** $\mathsf{CR}(n)$ *is exponential in* n*, i.e.* $\mathsf{CR}(n) = 2^{n^{\Omega(1)}}$.

Inspecting our upper bounds, Corollaries 15 and 16, establishes that this bound is optimal up to the degree, i.e. $\mathsf{CR}(n) = 2^{n^{\mathsf{O}(1)}}$.

We now show that the size of the join in the case of Church-Rosser is polynomially related to the product of the sizes of the terms in the starting derivation. We first state the lower bound.

▶ **Proposition 21.** *There is an orthogonal TRS* $\mathcal{R}$ *satisfying the following: Let* $a_1 \leftrightarrow a_2 \leftrightarrow \dots \leftrightarrow a_k$ *be a derivation over* $\mathcal{R}$ *such that* $a_1 \to^* b$ *and* $a_k \to^* b$ *for some* b*. Then* $|b|$ *is polynomial in* $|a_1|{\cdot}|a_2|{\cdot}\dots{\cdot}|a_k|$ *in general, i.e.* $|b|= (|a_1|{\cdot}|a_2|{\cdot}\dots{\cdot}|a_k|)^{\Omega(1)}$.

Proof. We modify the TRS from the previous proof so that the starting terms are of constant size: Expand the TRS from the proof of Theorem 19 by

$$\bar{\mathsf{f}}_i^k \to \mathsf{f}_i(\bar{\mathsf{f}}_{i+1}^k) \quad \bar{\mathsf{g}}_i^k(x) \to \bar{\mathsf{g}}_{i-1}^k(\mathsf{g}_i(x)) \qquad (i = 1,\dots,k) \tag{5}$$

where $\bar{\mathsf{f}}_{k+1}^k$ represents 0. We define

$$\bar{S}_i^k = \bar{\mathsf{g}}_i^k(\bar{\mathsf{f}}_{i+1}^k) \qquad \bar{T}_i^k = \bar{\mathsf{g}}_{i-1}^k(A_i(\bar{\mathsf{f}}_{i+1}^k))\ ,$$

and compute

$$|\bar{S}_i^k| = \mathsf{O}(1) \qquad \bar{S}_i^k = \bar{\mathsf{g}}_i^k(\bar{\mathsf{f}}_{i+1}^k) \xrightarrow{\bar{\mathsf{g}}_i^k} \bar{\mathsf{g}}_{i-1}^k(\mathsf{g}_i(\bar{\mathsf{f}}_{i+1}^k)) \xrightarrow{\mathsf{g}_i} \bar{\mathsf{g}}_{i-1}^k(A_i(\bar{\mathsf{f}}_{i+1}^k)) \ = \ \bar{T}_i^k$$
$$|\bar{T}_i^k| = \mathsf{O}(1) \qquad \bar{S}_i^k = \bar{\mathsf{g}}_i^k(\bar{\mathsf{f}}_{i+1}^k) \xrightarrow{\bar{\mathsf{f}}_{i+1}^k} \bar{\mathsf{g}}_i^k(\mathsf{f}_{i+1}(\bar{\mathsf{f}}_{i+2}^k)) \xrightarrow{\mathsf{f}_{i+1}} \bar{\mathsf{g}}_i^k(A_{i+1}(\bar{\mathsf{f}}_{i+2}^k)) \ = \ \bar{T}_{i+1}^k\ .$$

From now on we will drop the superscript k. Consider the following derivation:

$$\bar{D} \quad := \quad \bar{T}_1 \leftarrow^2 \bar{S}_1 \to^2 \bar{T}_2 \leftarrow^2 \bar{S}_2 \to^2 \bar{T}_3 \ \dots\ \bar{T}_{k-1} \leftarrow^2 \bar{S}_{k-1} \to^2 \bar{T}_k\ .$$

The unique Church-Rosser join is again given by $\bar{T}_i \to^* r$ for all $i = 1,\dots,k$.

Let $\bar{S} = \Pi_{t\in\bar{D}}|t|$ and $S_r = |r|$. We compute $\bar{S} = c^{2k}$ for some $c = \mathsf{O}(1)$ which is an upper bound on the size of terms occurring in $\bar{D}$. Hence $\bar{S} = (2^k)^{\mathsf{O}(1)}$. We also have $S_r = (2^k)^{\Omega(1)}$. Hence $S_r = \bar{S}^{\Omega(1)}$ using Lemma 8(2). ◀

We also have a corresponding upper bound.

▶ **Theorem 22.** *Let $\mathcal{R}$ be an orthogonal TRS. Given a derivation $a_1 \leftrightarrow a_2 \leftrightarrow \cdots \leftrightarrow a_k$ over $\mathcal{R}$, there is a join $a_1 \to^* b \;{}^*\!\!\leftarrow a_k$ for some b, such that $|b|$ is bounded by $|a_1|{\cdot}|a_2|{\cdot}\cdots{\cdot}|a_k|$.*

Proof. The upper bound is obtained by induction on k using the related upper bound for confluence, Corollary 15: Assume $a_1 \leftrightarrow \cdots \leftrightarrow a_k \leftrightarrow a_{k+1}$. By induction hypothesis there are some b, $a_1 \to^* b$ and $a_k \to^* b$ such that $|b|$ is bounded by $|a_1|{\cdot}|a_2|{\cdot}\cdots{\cdot}|a_k|$. If $a_{k+1} \to a_k$ then b is also the join for a_1 and a_{k+1} and we are already done. Otherwise, $a_k \to a_{k+1}$. Using that $a_k \to^* b$, we can join this peak with some c of size $\leqslant |b|{\cdot}|a_{k+1}|$ using Corollary 15. Thus $|c| \leqslant |b|{\cdot}|a_{k+1}| \leqslant |a_1|{\cdot}|a_2|{\cdot}\cdots{\cdot}|a_k|{\cdot}|a_{k+1}|$. ◀

7 A Lower Bound for the Lambda Calculus

For this section, we assume(at least nodding) acquaintance with the (untyped) λ-calculus [3, 4]. While we refrain from re-stating (hopefully) well-known notions, the result should be easy to understand.

We show that for confluence in λ-calculus, the size of the join is exponential in the product of the sizes of the starting terms in general.

▶ **Proposition 23.** *Given a peak $D\colon b \leftarrow_\lambda^* a \to_\lambda^* c$, and a joining derivation $b \to_\lambda^* d \leftarrow_\lambda^* c$. Then $|d|$ is exponential in $\|D\|$ as well as in $|b|{\cdot}|c|$ in general: $|d| = 2^{\|D\|^{\Omega(1)}}$ and $|d| = 2^{(|b|\cdot|c|)^{\Omega(1)}}$.*

Proof. Let f, g, h, x, y be variables. Let $A := \lambda x.((\lambda y.hyy)(gx))$ and $B := \lambda x.(h(gx)(gx))$. We have $A \xrightarrow{\lambda y}_\lambda B$, $|A|= \Theta(1)$, $|B|= \Theta(1)$.

Define terms T^k, U^k, V^k, W^k as follows: Let $T^0 = U^0 = V^0 = W^0 = f$, and inductively

$$T^{k+1} = (A\,T^k), \quad U^{k+1} = (B\,U^k), \quad V^{k+1} = (\lambda y.hyy)(gV^k), \quad W^{k+1} = h(gW^k)(gW^k) \ .$$

Then $|T^k|= \mathsf{O}(k)$, $|U^k|= \mathsf{O}(k)$, $|V^k|= \mathsf{O}(k)$, and $|W^k|= \Omega(2^k)$. We have

$$T^k \xrightarrow{\lambda y}{}_\lambda^k U^k \qquad T^k \xrightarrow{\lambda x}{}_\lambda^k V^k \qquad U^k \xrightarrow{\lambda x}{}_\lambda^k W^k \qquad V^k \xrightarrow{\lambda y}{}_\lambda^k W^k$$

by induction on k. Let D be $U^k \leftarrow_\lambda^* T^k \to_\lambda^* V^k$. Then $\|D\| = \mathsf{O}(k^2)$, hence $k \geqslant (\|D\|)^\epsilon$ for some $\epsilon > 0$, hence $|W^k| = \Omega(2^k) = \Omega(2^{(\|D\|)^\epsilon})$. As $|b|{\cdot}|d|= \mathsf{O}(k^2)$ as well, the same calculation applies in this case as well. ◀

8 Related Works

Ketema and Grue Simonsen have studied similar properties in [11]. For a given TRS $\mathcal{R}$, they define functions $\mathsf{cvs}_\mathcal{R}$ and $\mathsf{vs}_\mathcal{R}$, estimating the least number of reduction steps necessary in a rewrite proof, assuming an equational proof or a peak, respectively. More precisely, $\mathsf{cvs}_\mathcal{R}(m, n)$ denotes the least number of reduction steps required to complete a rewrite proof, given an equational proof involving at most n steps between two terms t, t' of size at most m. Likewise, $\mathsf{vs}_\mathcal{R}(m, n)$ denotes the least number of reduction steps in a rewrite proof, given a peak $t \;{}^*\!\!\leftarrow s \to^* t'$, where the size of s is at most m and the reduction lengths are at most of size n. For orthogonal TRSs $\mathcal{R}$ they obtain optimal exponential upper bound on $\mathsf{vs}_\mathcal{R}$ and an upper bound on $\mathsf{cvs}_\mathcal{R}$ that belongs to the 4^{th}-level of the Grzegorczyk hierarchy. I.e. the upper bound on $\mathsf{cvs}_\mathcal{R}$ is at least non-elementary. Wrt. the λ-calculus, confluence already requires an non-elementary upper bound. In subsequent work, Fujita proved that for the λ-calculus $\mathsf{cvs}_\mathcal{R}$ is upper bounded in the 4^{th}-level of the Grzegorczyk hierarchy, cf. [10]. Only optimality of the bound on $\mathsf{vs}_\mathcal{R}$ for orthogonal rewrite systems has been established.

We emphasise that these results are orthogonal to our contributions, as we make use of a different notion of proof complexity: the number of symbols, rather than the number of reduction steps. While this measure is natural in the context of rewriting (or even the λ-calculus), it is less so in the context of computational complexity, from our point of view. In short, for orthogonal TRSs, this change allows us to provide (optimal) polynomial upper bounds on confluence proofs and (optimal) exponential upper bounds on Church-Rosser proofs, while we establish an exponential lower bound on confluence proofs for the λ-calculus. Note that our changed notion of size not only allows tractable upper bounds, but also differentiates precisely between the expressivity of (first-order) term rewrite systems and (higher-order) λ-calculus, a difference that got somewhat blurred in related works.

To the best of our knowledge, confluence or Church-Rosser properties in term-rewriting have not been studied in general in Bounded Arithmetic (though they have been used as tools in the analysis of related artefacts, as in work by Das [9]). The closest we are aware of are the results by the first author [5] that formalises a restricted and very involved property the resembles elements of Church-Rosser, and which are used to prove the consistency of any equational theory that exclusively is based on recursive defining equations, in a weak theory of bounded arithmetic. These results were improved by Yamagata [13] by also allowing rules for substituting terms into equations in the equational reasoning while proving consistency in a weak theory of bounded arithmetic. However, Yamagata formalised ideas from programming semantics with no connection to rewriting.

9 Conclusion

In this paper, we have investigated two well-studied properties of rewriting and the λ-calculus, namely confluence and the Church-Rosser property, through the lens of proof complexity. In particular, for orthogonal TRSs, we have shown that the shortest rewrite proof obtained in a confluence argument is polynomially related to the size of the peak.

This is in contrast to earlier results on upper bounds on the size of confluence and Church-Rosser proofs that used the number of steps as size measure. While this measure is natural in the context of rewriting (or even the λ-calculus), it is less so in the context of computational complexity, from our point of view. We emphasise that our changed notion of size not only allows tractable upper bounds, but also differentiates precisely between the expressivity of (first-order) term rewrite systems and (higher-order) λ-calculus, a difference, that got somewhat blurred in related works.

We have established preliminary steps towards our motivation to study consistency proofs in weak theories of arithmetic through the lens of rewriting technologies. In future work we want to expand this direction. It seems natural to us to employ techniques from graph rewriting [12, Chapter 13] (see also [1]) to overcome the exponential lower bound on the size of the join that we have established for the Church-Rosser property. Due to the succinct encoding of multiple occurrences in graph rewriting it could be possible to allow an alternative encoding of the join and of the rewrite proof, altogether. The latter could potentially give rise to a polynomial encoding. These investigations are left to future work.

Abstract

The last in-tree recognition problem asks whether a given spanning tree can be derived by connecting each vertex with its rightmost left neighbor of some search ordering. In this study, we demonstrate that the last-in-tree recognition problem for Generic Search is NP-complete. We utilize this finding to strengthen a complexity result from order theory. Given a partial order π and a set of triples, the NP-complete intermezzo problem asks for a linear extension of π where each first element of a triple is not between the other two. We show that this problem remains NP-complete even when the Hasse diagram of the partial order forms a tree of bounded height. In contrast, we give an XP-algorithm for the problem when parameterized by the width of the partial order. Furthermore, we show that – under the assumption of the Exponential Time Hypothesis – the running time of this algorithm is asymptotically optimal.

1 Introduction

In the realm of computational combinatorics, one of the primary challenges is to determine a feasible configuration based on incomplete information. This paper aims to elucidate the relationships between two notable instances of this problem category: recognition of search trees of graph searches and total ordering with constraints. Specifically, our focus will be on exploring the last-in-tree recognition in the context of generic search and the intermezzo problem.

Graph Searches. Graph searches like *Breadth First Search* (BFS) or *Depth First Search* (DFS) are among the most basic algorithms in computer science. Their simplicity belies their significance as they form the backbone of more complex algorithms used to compute key properties of graphs. For instance, DFS can be employed to test for planarity as demonstrated by Hopcraft and Tarjan [17] and *Lexicographic Breadth First Search* (LBFS) aids in the recognition and minimum coloring of chordal graphs through a perfect elimination ordering [22]. Notably, all the above mentioned algorithms operate in linear time, underscoring their efficiency.

In this context, *Generic Search* (GS) represents the most general form of a graph search, with connectivity being its sole constraint: To elaborate, starting from a root vertex r, every subsequently visited vertex merely needs to be adjacent to a previously visited vertex. Consequently, GS can yield any total order of the vertices, provided each prefix is connected. A search methodology that bears a close resemblance to GS is the *Maximum Neighborhood Search* (MNS) [8], which can be perceived as a lexicographic variant of GS. Similarly, BFS and DFS can be implemented by using a queue and a stack, respectively, to store vertices that have not yet been visited.

Recognizing the significance of basic graph search algorithms such as BFS or DFS, recent efforts have been directed towards a deeper understanding of these algorithms. The primary focus of these studies revolves around two structures: end vertices and search trees (for a summary of known results see [26, Tables 1 and 2]). Given a graph G and a specific search rule (e.g., BFS or DFS), the *End Vertex Problem* aims to identify potential final vertices of the search. For GS, solving the end vertex problem is relatively straightforward. As long as a vertex v is not an articulation point, i.e., $G - v$ remains connected, v can serve as an end vertex of GS [5]. However, the end vertex problem is NP-complete for all other common search rules on general graphs [1, 5, 9, 31]. By restricting to special graph classes, linear-time algorithms have been developed to solve this problem, e.g., for BFS on split graphs [5], for DFS on interval graphs [1], and for MNS on chordal graphs [1].

Given a graph G and a spanning tree T, the *Tree Recognition Problem* seeks to determine whether T can be derived as a search tree. In essence, it questions the feasibility of reconstructing a linear order of vertices from the tree. This problem is typically studied in two variants: first-in-trees and last-in-trees [2]. In first-in-trees, each vertex is connected to its neighbor that appears first in the search order. Conversely, in last-in-trees (or $\mathcal{L}$-trees), each vertex v is a child of its neighbor that appears last before v in the search order. Normally, first-in-trees are used for BFS and last-in-trees for DFS, with existing linear-time algorithms capable of recognizing the corresponding trees in both cases [15, 16, 18, 20]. Interestingly, the problem becomes NP-complete when the search-tree paradigms are swapped between these searches, i.e., using last-in-trees for BFS and first-in-trees for DFS [24]. Furthermore, Scheffler [26] shows that the first-in-tree recognition problem of GS can be solved in linear time.

Total Ordering. A well-known theorem in order theory states that any partial order can be extended to a linear order. This holds true even for infinite sets, as demonstrated by Szpilrajn (Marczewski) through the use of the axiom of choice [28].[1] The process simplifies considerably for finite sets, where topological sorting algorithms can determine such an extension in linear time [7].

While partial orders are typically defined by a binary relation, total order problems offer a more general perspective. Here, one is given a set A, a family $\mathcal{B}$ of subsets $A_i \subseteq A$, and for each $A_i \in \mathcal{B}$ one or more valid orderings of the elements within A_i. The objective is to ascertain a total order of the elements in A that adheres to all these constraints.

Among the problems, the *Betweenness Problem* and the *Cyclic Ordering Problem* are particularly noteworthy. These two problems have already been discussed in the seminal textbook by Garey and Johnson [13]. In the betweenness problem, we are presented with

[1] He also references unpublished proofs by Banach, Kuratowski, and Tarski.

triples (a, b, c), and the only valid configurations are $a < b < c$ or $c < b < a$. In simpler terms, b must be positioned between a and c. The cyclic ordering problem involves given triples (a, b, c) for which there are three feasible orderings: $a < b < c$, $b < c < a$, or $c < a < b$. As the appearance in Garey and Johnson's book already suggests, both of these problems are indeed NP-complete.

In [14], Guttmann and Maucher systematically categorized total ordering problems based on pairs and triples. They also introduced the term *Intermezzo* to describe a specific variant: given pairs (b, c) where $b < c$, and triples (a, b, c) where either $a < b < c$ or $b < c < a$, implying that a is not placed between b and c. Note that a partial order is defined by both pairs and triples through the relation $b < c$. This problem has been proven to be NP-complete.

Interconnections. In this context, the problems of identifying end vertices and search trees are interconnected with the total ordering problem, given the underlying vertex order. The end vertex problem asks if a vertex can be the maximal element within this order. On the other hand, the correct search order offers a certificate for the search tree problem that can be checked in linear time. However, the constraints, which include all valid search orders and could potentially be exponential in number, are not explicitly given. Instead, they are implicitly defined by the underlying search paradigm.

Recently, Scheffler [23] introduced the more general problem of linearizing partial orders where the resultant total order must serve as a search order of a specified graph G. He presents polynomial-time algorithms for this problem for several searches and graph classes. In particular, he shows that the problem can be solved for GS on general graphs using a simple greedy algorithm. These results generalize the polynomial-time algorithms for the end vertex problem, given that the partial order can be selected to determine the end vertex.

Our Contribution. After providing the necessary notation, we prove NP-completeness of the $\mathcal{L}$-tree problem for Generic Search (GS) in Section 3. It is worth noting that two aspects of this result may appear surprising: Firstly, for GS all other problems considered so far can be solved in polynomial time with straightforward methods. Secondly, until now, for any given combination of a search rule (such as BFS, DFS, etc.) and a graph class (like chordal, interval, split, etc.), both tree recognition problems have not been harder than the end vertex problem. Thus, GS on general graphs represents the first known instance where the end vertex problem is simpler than a tree-recognition problem. We use the NP-completeness of the $\mathcal{L}$-tree problem of GS in Section 4 to show that the Intermezzo Problem is also NP-complete even if the partial order π is a cs-tree or the height of π is bounded. In contrast, we give an XP-algorithm for the problem when parameterized by the width of π. Under the assumption of the Exponential Time Hypothesis, we show that the running time of this algorithm is asymptotically optimal. Proofs omitted due to space constraints can be found in the full version [3].

2 Preliminaries

All the graphs that we consider are simple, finite, non-empty and undirected. Given a graph G, we denote by $V(G)$ the set of *vertices* and by $E(G)$ the set of *edges*.

A path P of G is a non-empty subgraph of G with $V(P) = \{v_1, \ldots, v_k\}$ and $E(P) = \{v_1v_2, \ldots, v_{k-1}v_k\}$, where $v_1, \ldots, v_k$ are all distinct. We will sometimes denote such a path by $v_1 - v_2 - \ldots - v_{k-1} - v_k$. A graph G is called a *tree* if it is connected and does not contain a cycle. A *spanning tree* T is a subgraph of a graph G which is a tree with $V(T) = V(G)$. A tree together with a distinguished *root vertex* r is said to be *rooted.* In such a rooted tree a vertex v is an *ancestor* of vertex w if v is an element of the unique path from w to the root r. In particular, if v is adjacent to w, it is called the *parent* of w. Furthermore, a vertex w is called the *descendant (child)* of v if v is the ancestor (parent) of w. We define the *height of a rooted tree* as the maximum number of edges of a path from the root r to any other vertex. A graph is a *split graph* if its vertex set can be partitioned into a clique and an independent set.

Given a set X, a *(binary) relation* $\mathcal{R}$ on X is a subset of the set $X^2 = \{(x, y) \mid x, y \in X\}$. The set X is called the *ground set of* $\mathcal{R}$. The *reflexive and transitive closure* of a relation $\mathcal{R}$ is the smallest relation $\mathcal{R}'$ such that $\mathcal{R} \subseteq \mathcal{R}'$ and $\mathcal{R}'$ is reflexive and transitive. A *partial order* π on a set X is a reflexive, antisymmetric and transitive relation on X. The tuple (X, π) is then called a *partially ordered set.* We also denote $(x, y) \in \pi$ by $x \prec_\pi y$ if $x \neq y$. A *minimal element* of a partial order π on X is an element $x \in X$ for which there is no element $y \in X$ with $y \prec_\pi x$. A *chain* of a partial order π on a set X is a set of elements $\{x_1, \ldots, x_k\} \subseteq X$ such that $x_1 \prec_\pi x_2 \prec_\pi \ldots \prec_\pi x_k$. The *height* of π is the number of elements of the largest chain of π. An *antichain* of π is a set of elements $\{x_1, \ldots, x_k\} \subseteq X$ such that $x_i \not\prec_\pi x_j$ for any $i, j \in \{1, \ldots, k\}$. The *width* of π is the number of elements of the largest antichain of π.

A *linear ordering* of a finite set X is a bijection $\sigma : X \rightarrow \{1, 2, \ldots, |X|\}$. We will often refer to linear orderings simply as orderings. Furthermore, we will denote an ordering by a tuple $(x_1, \ldots, x_n)$ which means that $\sigma(x_i) = i$. Given two elements x and y in X, we say that x is *to the left* (resp. *to the right*) of y if $\sigma(x) < \sigma(y)$ (resp. $\sigma(x) > \sigma(y)$) and we denote this by $x \prec_\sigma y$ (resp. $x \succ_\sigma y$).

A *vertex ordering* of a graph G is a linear ordering of the vertex set $V(G)$. A vertex ordering $\sigma = (v_1, \ldots, v_n)$ is called *connected* if for any $i \in \{1, \ldots, n\}$ the graph $G[v_1, \ldots, v_i]$ is connected. In this paper, a *graph search* is an algorithm that, given a graph G as input, outputs a connected vertex ordering of G. The graph search that is able to compute any such ordering is called *Generic Search (GS).*

3 Complexity of the $\mathcal{L}$-tree Recognition Problem

The definition of the term *search tree* varies between different paradigms. However, typically, it consists of the vertices of the graph and, given the search ordering $(v_1, \ldots, v_n)$, for each vertex v_i exactly one edge to a $v_j \in N(v_i)$ with $j < i$. By specifying to which of the previously visited neighbors a new vertex is adjacent in the tree, we can define different types of graph search trees. For example, in DFS trees a vertex v is adjacent to the rightmost neighbor to the left of v. This motivates the following definition.

▶ **Definition 3.1.** *Given a search ordering $\sigma := (v_1, \ldots, v_n)$ of a graph search on a connected graph G, we define the* last-in tree *(or $\mathcal{L}$-tree) to be the tree consisting of the vertex set $V(G)$ and an edge from each vertex v_i to its rightmost neighbor v_j in σ with $j < i$.*

As explained above, for a classical DFS the tree T is an $\mathcal{L}$-tree with respect to σ. Given this definition, we can state the following decision problem.

▶ **Problem 1** ($\mathcal{L}$-Tree Recognition Problem of graph search $\mathcal{A}$).
Instance: *A connected graph G and a spanning tree T of G.*
Question: *Is there a graph search ordering of $\mathcal{A}$ such that T is its $\mathcal{L}$-tree of G?*

Note that we have defined the $\mathcal{L}$-tree recognition problem without a given start vertex for the search. It is also possible to define this problem with a fixed start vertex and we call this the *rooted $\mathcal{L}$-tree recognition problem.* Obviously, a polynomial-time algorithm for the rooted tree recognition problem yields a polynomial-time algorithm for the general problem by simply repeating the procedure for all vertices. The other direction, however, is not necessarily true.

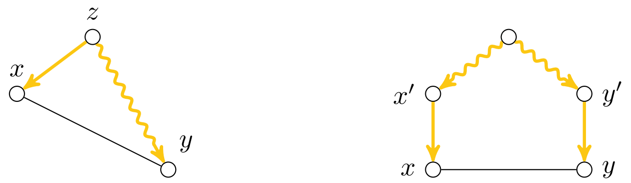

Figure 1 On the left is an example of a *hook configuration*. On the right is an example of a *U-bend*. The yellow edges symbolize edges of the spanning tree, the black edges are non-tree edges of the graph and the wavy line represents a directed path in the spanning tree.

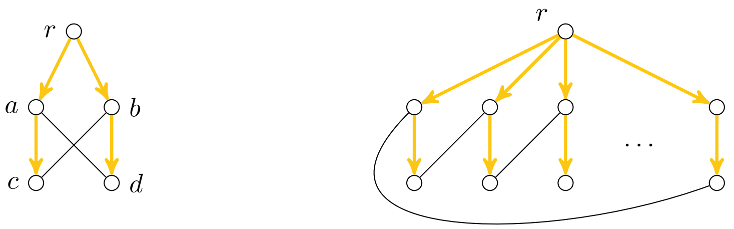

Figure 2 Family of graphs where the rooted spanning trees (yellow edges) are not $\mathcal{L}$-trees of GS.

The $\mathcal{L}$-tree recognition problem of GS raised in [24] and [27] is an open problem and in the following we will show that it is in fact NP-complete. This result will also answer another open question, as Scheffler showed in [24] that the $\mathcal{L}$-tree recognition problem of BFS for split graphs is at least as hard as that of GS.

An important property of $\mathcal{L}$-trees of GS can be derived from the non-tree edges that connect vertices of different branches of the tree.

▶ **Lemma 3.2.** *Let T be a spanning tree of a graph G rooted in r. Let xy be an edge in $E(G) \setminus E(T)$ and let x' and y' be the parents of x and y in T, respectively. If T is an $\mathcal{L}$-tree of a GS ordering σ starting with r, then it either holds that $x' \prec_\sigma x \prec_\sigma y' \prec_\sigma y$ or $y' \prec_\sigma y \prec_\sigma x' \prec_\sigma x$.*

The configuration described in Lemma 3.2 will be called a *U-bend configuration* (see Figure 1 on the right).

Before we begin with our main results, we should analyze examples of some rooted spanning trees that cannot be $\mathcal{L}$-trees of GS. One of the smallest examples can be found to the left in Figure 2. The example on the right is a generalization with arbitrary many branches of the spanning tree. These examples can be easily described using a concept called *hook configuration*. This is a special case of a U-bend where the parent of one vertex is an ancestor of the others.

▶ **Definition 3.3.** *Let T be a spanning tree of a graph G rooted in $r \in V(G)$. We say that a triple of vertices x, y, and z forms a* hook configuration *or a* hook *if z is the parent of x in T, $xy \in E(G) \setminus E(T)$ and y is a descendant of z but y is not a descendant of x (see Figure 1 on the left). We call x the* point *and y the* eye *of the hook.*

These hook configurations have a strong a priori effect on the sequence of any search ordering corresponding to that tree.

▶ **Lemma 3.4.** *Let x and y be part of a hook configuration of T rooted in $r \in V(G)$ with point x and eye y. Then for any GS ordering σ starting in r with $\mathcal{L}$-tree T it holds that $x \prec_\sigma y$.*

For the examples shown in Figure 2, it is possible to see that the hook configurations create something like a cycle in the ordering using Lemma 3.4: We see that $a \prec d$ and $b \prec c$ and these contradict each other because of the tree edges.

In the special case that the graph together with its spanning tree does not contain any hooks, it is trivial to decide the $\mathcal{L}$-Tree Recognition Problem.

▶ **Theorem 3.5.** *Let T be a spanning tree of a graph G rooted in $r \in V(G)$. If there is no hook configuration, then any DFS ordering of T starting in r is a GS ordering of G with $\mathcal{L}$-tree T. Therefore, any such tree together with G is a* Yes*-instance for the $\mathcal{L}$-Tree Recognition Problem of Generic Search.*

Proof. Let σ be a DFS ordering of T starting in r. This ordering σ fulfills the following property also called *four point condition* (see for example [8]): If $a \prec_\sigma b \prec_\sigma c$ and $ac \in E$ and $ab \notin E$, then there exists a vertex d with $a \prec_\sigma d \prec_\sigma b$ such that $db \in E$.

Suppose that σ does not induce the $\mathcal{L}$-tree T for G. Let w be the leftmost vertex in σ such that there exist u and v with $u \prec_\sigma v \prec_\sigma w$ with $uw \in E(T)$ and $vw \in E(G) \setminus E(T)$. If uv is an edge in the tree T, then u, v and w form a hook configuration; a contradiction to the assumption. Therefore, we can assume that $uv \notin E(T)$. Now we can apply the four point condition to vertices u, v and w (note that the DFS was executed on T). A result of the four point condition, is the fact that there must exist a u-v-path $u = d_1 - \cdots - d_k = v$ with $u \prec_\sigma d_2 \prec_\sigma \cdots \prec_\sigma d_{k-1} \prec_\sigma v$ (Corollary 2.6 in [8]). In particular, we see that v is a descendant of u. Together with the fact that $uw \in T$ and $vw \in E(G) \setminus E(T)$, we see that u, v and w form a hook configuration; a contradiction to the assumptions of the theorem. This implies that each vertex in the search is connected to its correct parent in T, proving that T is an $\mathcal{L}$-tree of GS in G. ◀

This theorem could lead to the assumption that deciding whether a given spanning tree is an $\mathcal{L}$-tree of GS only amounts to an analysis of all the hook configurations. In fact, it is easy to see that we can find all hook configurations in polynomial time. However, it is not always so simple. In fact, we show in the following that in general the $\mathcal{L}$-Tree Recognition Problem of GS is NP-complete. We describe a reduction from 3-SAT, i.e., we are given an instance $\mathcal{I}$ of 3-SAT and derive an instance $(G(\mathcal{I}), T(\mathcal{I}))$ for the $\mathcal{L}$-Tree Recognition Problem of GS.

Let $\mathcal{I}$ be an instance of 3-SAT with variable set $\{X_1, \ldots, X_n\}$ and clause set $\{C^1, \ldots, C^m\}$. For ease of notation, we define the positive literal X_j as $X_j(1)$ and the negative literal $\neg X_j$ as $X_j(0)$. First we define the spanning tree $T(\mathcal{I})$ and then we add the edges missing to give the full graph $G(\mathcal{I})$. For each variable X_j of $\mathcal{I}$ we add two vertices $x_j(0)$ and $x_j(1)$ (representing the two literals of X_j) to $V(G(\mathcal{I}))$. These vertices are all adjacent to a common root vertex r. Furthermore, r is adjacent to the clause-hub-vertex C. Now we add a vertex c^i for each clause C^i and connect it to C (see Figure 3 for a depiction of this setup.). Furthermore, for each occurrence of a literal associated with vertex $x_j(p)$ in a clause C^i we add a vertex x^i_j. As we may assume that only one of the literals appears in a clause, we do not have to use an index to mark whether the vertex belongs to a negated variable or not. This sums up the basic setup concerning the variables and clauses. However, for technical reasons we need several more vertices (see Figure 4):

- For each c^i we add the vertices $a^i_0, a^i_1, a^i_2, b^i_0, b^i_1, b^i_2$ in $T(\mathcal{I})$. These are called the *technical vertices of c^i*.
- These vertices form the paths $c^i - a^i_0 - b^i_0$, $c^i - a^i_1 - b^i_1$ and $c^i - a^i_2 - b^i_2$ in $T(\mathcal{I})$.
- For each x^i_j we add vertices d^i_j, e^i_j, f^i_j. These are called the *technical vertices of x^i_j*.
- These vertices form the path $x^i_j - d^i_j - e^i_j - f^i_j$ in $T(\mathcal{I})$.

This concludes the definition of the tree $T(\mathcal{I})$, to which we will now add the remaining edges for $G(\mathcal{I})$ (see Figure 3 and Figure 4):

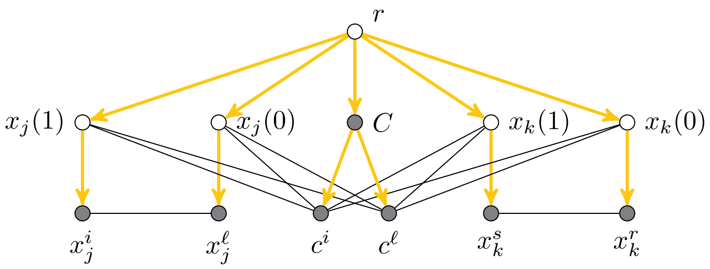

Figure 3 This figure illustrates the variable gadget. The yellow edges are the tree edges, and the vertices marked in gray appear again in the clause gadget. The literal X_j appears in clause C^k, the literal $\neg X_j$ appears in clause C^ℓ. Note that for the x_j^i vertices we do not need to denote whether they belong to X_j or its negation, as each clause only contains either X_j or $\neg X_j$.

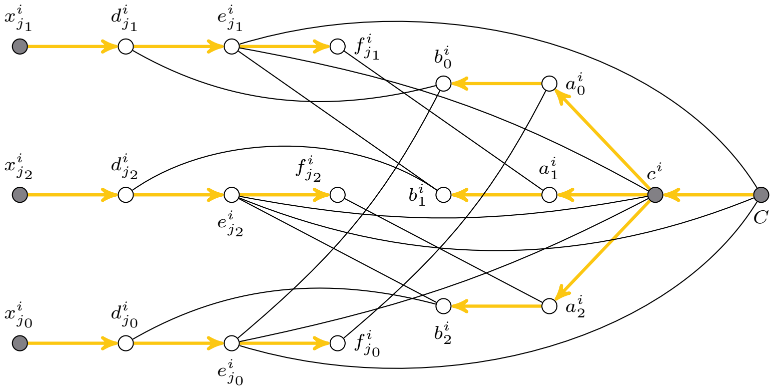

Figure 4 This figure illustrates the clause gadget. The tree edges are colored yellow and the gray vertices mark the vertices that can be found in the variable gadget. Note that we have drawn this figure horizontally to make the embedding cleaner. The directions of the tree edges denote the direction from the root of the tree.

- For each X_j we add edges $x_j(0)c^i$ and $x_j(1)c^i$ for $i \in \{1, \dots, m\}$.
- For each x_j^i adjacent to x_j we add an edge $x_j^i x_j^k$ if both X_j occurs in clause C^i and $\neg X_j$ occurs in literal C^k.
- For any clause $C^i = \{X_{j_0}(p_0), X_{j_1}(p_1), X_{j_2}(p_2)\}$ we add the edges:
  - $Ce^i_{j_p}$ for $p \in \{0, 1, 2\}$.
  - $c^i e^i_{j_p}$ for $p \in \{0, 1, 2\}$.
  - $a^i_p f^i_{j_p}$ for $p \in \{0, 1, 2\}$.
  - $b^i_p e^i_{j_p}$ for $p \in \{0, 1, 2\}$.
  - $b^i_p d^i_{j_{(p+1) \bmod 3}}$ for $p \in \{0, 1, 2\}$.

The modulo operation applied to the indices to define the edges in the clause gadget illustrates the circularity inherent in that gadget. Visiting one of the branches below c^i effectively unlocks one of the branches below an x^i_j. Conversely, visiting an x^i_j before c^i blocks a corresponding branch of c^i. This effect is what leads to the property that we will show in Lemma 3.7.

The first step in our reduction is to check whether we can use a search ordering that achieves $T(\mathcal{I})$ to construct an assignment of the 3-SAT instance $\mathcal{I}$. For each variable we will choose the assignment that corresponds to the literal vertex chosen *second*, i.e., if $x_j(1)$ is chosen first we assign X_j the value 0 and if $x_j(0)$ is chosen first we assign X_j the value 1. The following lemma shows that the children of the literal vertex that is chosen first are visited before the clause vertices.

▶ **Lemma 3.6.** *If $T(\mathcal{I})$ is an $\mathcal{L}$-tree of some GS ordering σ of $G(\mathcal{I})$ starting in r, then it holds for every variable x_j that all the children of $x_j(1)$ or all the children of $x_j(0)$ are to the left of vertex C in σ. In particular, if $x_j(p) \prec_\sigma x_j(q)$, then the children of $x_j(p)$ are all to the left of $x_j(q)$.*

Proof. The sets of vertices $\{x_j(1), c^i, r\}$ and $\{x_j(0), c^i, r\}$ form hook configurations with eye c^i and point $x_j(1)$ or $x_j(0)$, respectively. By Lemma 3.4, it holds that $x_j(1) \prec_\sigma c^i$ and $x_j(0) \prec_\sigma c^i$. Furthermore, with Lemma 3.2 we see that $x_j(1) \prec_\sigma C$ and $x_j(0) \prec_\sigma C$, as for example $r, x_j(1), c^i$ and C form a U-bend. W.l.o.g., we may assume that $x_j(1) \prec_\sigma x_j(0)$. Let u be an arbitrary child of $x_j(1)$ and let v be an arbitrary child of $x_j(0)$. By construction of $G(\mathcal{I})$ and $T(\mathcal{I})$, we know that $uv \in E(G(\mathcal{I})) \setminus E(T(\mathcal{I}))$. Then, due to Lemma 3.2 and our assumption, we see that $u \prec_\sigma x_j(0) \prec_\sigma c_i$. Therefore, the children of $x_j(1)$ are to the left of $x_j(0)$ and thus also to the left of the clause hub vertex C, proving the statement of the lemma. ◀

The next lemma motivates how the choice of the variable assignment is used to check whether a given clause is fulfilled.

▶ **Lemma 3.7.** *If $T(\mathcal{I})$ is an $\mathcal{L}$-tree of $G(\mathcal{I})$ for the search ordering σ, then for each clause $C^i = \{X_{j_0}(p_0), X_{j_1}(p_1), X_{j_2}(p_2)\}$ it holds that $c^i \prec_\sigma x^i_{j_q}$ for some $q \in \{0, 1, 2\}$.*

Proof. Assume for contradiction that c^i is to the right of $x^i_{j_q}$ for all $q \in \{0, 1, 2\}$. Using the hook and U-bend rules from Lemmas 3.2 and 3.4, we can show that $T(\mathcal{I})$ is not an $\mathcal{L}$-tree for σ. For all $q \in \{0, 1, 2\}$, the set $\{C, e^i_{j_q}, r\}$ forms a hook with point C and eye $e^i_{j_q}$ and, thus, $C \prec_\sigma e^i_{j_q}$. Now the U-bend induced by the edge $e^i_{j_q} c^i$ implies that $c^i \prec_\sigma e^i_{j_q}$. For any $q \in \{0, 1, 2\}$, the vertex $d^i_{j_q}$ is adjacent to some vertex $b^i_{q'}$ and the corresponding edge induces a U-bend. Since all three vertices $x^i_{j_q}$ are to the left of all three vertices $a^i_{q'}$, these U-bends imply that at least one vertex $d^i_{j_q}$ is to the left of all $a^i_{q'}$. Fix that vertex $d^i_{j_q}$. Now the edge $b^i_q e^i_{j_q}$ implies that $e^i_{j_q} \prec_\sigma a^i_q$. Summarizing, $c^i \prec_\sigma e^i_{j_q} \prec_\sigma a^i_q$. However, this contradicts Lemma 3.2 as the edge $f^i_{j_q} a^i_q$ induces a U-bend where both parents (c^i and $e^i_{j_q}$) are to the left of both children (a^i_q and $f^i_{j_q}$). This concludes the proof. ◀

This lemma shows that for each clause there is one literal for which the corresponding child belonging to that clause has to be chosen after the clause vertex. This will be the literal that satisfies the clause in a fulfilling assignment. On the other hand, if there is a literal whose child is chosen after the clause vertex, then the corresponding clause gadget can be correctly traversed. Combining these results proves the main result of this section.

▶ **Theorem 3.8.** *The rooted $\mathcal{L}$-tree recognition problem of Generic Search is* NP*-complete for rooted spanning trees of height* 5*.*

Proof. Let σ be a GS ordering with $\mathcal{L}$-tree $T(\mathcal{I})$. We define an assignment $\mathcal{A}$ by setting any variable to false if and only if the positive literal appears before its negative literal in σ. We claim that this is a fulfilling assignment. Clearly we only need to show that for each clause at least one literal was chosen to be true. In particular, by Lemma 3.7 we see that for each $C^i = \{X_{j_0}(p_0), X_{j_1}(p_1), X_{j_2}(p_2)\}$ at least one vertex $x^i_{j_q}$ is to the right of c^i and, thus, to the right of the vertex C. Due to Lemma 3.6, the parent of $x^i_{j_q}$ is to the right of the vertex of variable. This implies that at least one literal contained in C^i is fulfilled in $\mathcal{A}$.

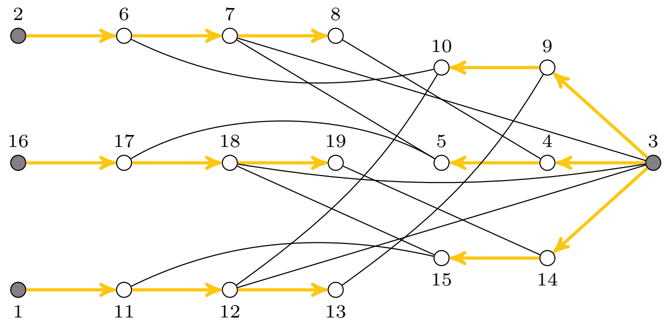

Figure 5 Example of an ordering of the technical vertices for a clause where two literals (1 and 2) were chosen to be false. Compare with Figure 4.

Let $\mathcal{A}$ be a fulfilling assignment of $\mathcal{I}$. We now show that in this case we can construct a GS ordering of $G(\mathcal{I})$ which has the $\mathcal{L}$-tree $T(\mathcal{I})$. The broad idea is to choose the literals that are false for $\mathcal{A}$ first followed by their children. Then we choose the literals that are true, followed by the clause hub vertex C and then the clause vertices. Finally, we need to visit the technical vertices in the correct order, followed by the descendants of the true literals. In the following, we define several suborders that need to be combined into the final linear ordering σ.

As explained above, we begin the search ordering σ by visiting the root r and then all literals that are set to false by $\mathcal{A}$ in arbitrary order. Next we visit all children of these vertices. In the next phase, we visit all remaining literal vertices in an arbitrary order. At this point, we can visit the clause hub vertex C (see Lemma 3.6) followed by the clause vertices in arbitrary order. Let $C^i = \{X_{j_0}(p_0), X_{j_1}(p_1), X_{j_2}(p_2)\}$ be some clause. If all literals of C^i were chosen to be true (i.e., all the vertices $x^i_{j_0}$, $x^i_{j_1}$, and $x^i_{j_2}$ are to the right of c^i), then we can visit the technical vertices of c^i in the order $a^i_0, a^i_1, a^i_2, b^i_0, b^i_1, b^i_2$ (or any other order that conforms with GS) followed by the literal vertices and their technical vertices following the order that is implied by the tree edges. If exactly one of the literals, say w.l.o.g. $X_{j_0}(p_0)$, is chosen to be false by $\mathcal{A}$, then we use the order $x^i_{j_0}, c^i, a^i_0, b^i_0, d^i_{j_0}, e^i_{j_0}, f^i_{j_0}$. Then we visit the remaining technical vertices of c^i followed by $x^i_{j_1}, x^i_{j_2}$ and their technical vertices.

If exactly two of the literals, say w.l.o.g. $X_{j_0}(p_0)$ and $X_{j_1}(p_1)$, are chosen to be false by $\mathcal{A}$, then we use the order $x^i_{j_0}, x^i_{j_1}, c^i, a^i_1, b^i_1, d^i_1, e^i_1, f^i_1, a^i_0, b^i_0, d^i_0, e^i_0, f^i_0$. Then we visit the remaining technical vertices of c^i followed by $x^i_{j_2}$ and its technical vertices (see Figure 5 for an illustration).

Because $\mathcal{A}$ is a fulfilling assignment, we know that each clause has at most two literals that are set to false. Therefore, we can combine all of these orderings to a comprehensive GS ordering σ and confirm that $T(\mathcal{I})$ is in fact an $\mathcal{L}$-tree of σ. ◀

Using [24, Theorems 21 and 23], we can strengthen Theorem 3.8 to the case of split graphs and give a similar result for Breadth First Search.

▶ **Corollary 3.9.** *The rooted $\mathcal{L}$-tree recognition problems of Generic Search and Breadth First Search are* NP*-complete even if the input is restricted to split graphs and to rooted spanning trees of height* 12.

Note that these results are all for the *rooted* $\mathcal{L}$-tree recognition problem. Using a small gadget, we can also extend the hardness of the GS $\mathcal{L}$-tree recognition to the unrooted problem.

▶ **Corollary 3.10.** *The $\mathcal{L}$-tree recognition problem of Generic Search is* NP*-complete.*

Proof. Let G be some graph and T be a spanning tree of G with root r. We add three vertices a, b, c to G in the following way to form a new graph G': Let $V(G') = V(G) \cup \{a, b, c\}$. Furthermore, $E(G') = E(G) \cup \{ab, ac, bc, ar\}$. Finally, we define a spanning tree T' of G' with $V(T') = V(G')$ and $E(T') = E(T) \cup \{ar, ab, ac\}$.

Due to the conflicting hooks among a, b, c, either b or c must be visited before a, if T' is to be an $\mathcal{L}$-tree of G'. This makes r the de facto root of $T' - \{a, b, c\}$, showing that the rooted $\mathcal{L}$-tree recognition problem for G and T is equivalent to the unrooted one for G' and T'. ◀

4 The Intermezzo Problem

Given a rooted spanning tree T, the basic property that has to be fulfilled by a vertex ordering σ for it to have T as an $\mathcal{L}$-tree is the following: If there is a vertex z with parent y and z has a non-tree edge to vertex x, then x is not allowed to be between y and z in the vertex ordering. These constraints are similar to those used in the following problem introduced by Guttmann and Maucher [14].

▶ **Problem 2** (General Intermezzo Problem).
Instance: *Finite set A, set C of triples of distinct elements of A*
Question: *Is there an ordering of A such that for all $(x, y, z) \in C$ it holds that $x \prec_\sigma y \prec_\sigma z$ or $y \prec_\sigma z \prec_\sigma x$?*

We call an ordering that fulfills the constraints of C an *intermezzo ordering*. Note that Guttmann and Maucher do not give a name for the general problem as they introduce it as one case of a large family of constrained ordering problems. We derived the name from the more restricted *Intermezzo problem*. This problem additionally forces the triples in C to be pairwise disjoint.

▶ **Problem 3** (Intermezzo Problem [14]).
Instance: *Finite set A, set B of pairs of A, set C of pairwise disjoint triples of distinct elements of A.*
Question: *Is there an ordering of A such that for all $(x, y) \in B$ it holds that $x \prec_\sigma y$ and for all $(x, y, z) \in C$ it holds that $x \prec_\sigma y \prec_\sigma z$ or $y \prec_\sigma z \prec_\sigma x$?*

Besides the tuples in B, in both problems the second and the third entry of the triples in C imply simple order constraints on the elements of A. Therefore, we can define the relations $\pi(B, C)$ and $\pi(C)$, respectively, as the reflexive and transitive closure of the relation $R \subseteq A \times A$ where $(y, z) \in R$ if and only if $(y, z) \in B$ or there is some tuple $(x, y, z) \in C$. If (A, C) is a positive instance of the General Intermezzo problem, then $\pi(C)$ must form a partial order and every intermezzo ordering of (A, C) forms a linear extension of $\pi(C)$. The same properties hold for positive instances (A, B, C) of the Intermezzo problem and the partial order $\pi(B, C)$. Thus, we also can interpret the (General) Intermezzo problem as a special kind of linear extension problems with additional non-betweenness constraints. This motivates the consideration of restricted problems where the partial order has to fulfill certain properties.

4.1 The Intermezzo Problem for CS-trees

Following the terminology of Trotter [29], we call a partial order a *cs-tree* (short for *computer science tree*) if its Hasse diagram forms a tree rooted in the unique minimal element. Using the terminology in [25], we call a leaf of a rooted tree a *branch leaf* if it is not equal to the root of the tree. Recall that the height of a cs-tree and the height of the tree that is formed by its Hasse diagram differ by one.

▶ **Lemma 4.1.**

1. *The rooted $\mathcal{L}$-tree recognition problem of Generic Search for rooted spanning trees of fixed height $h \geq 2$ is polynomial-time reducible to the General Intermezzo problem for instances (A, C) where $\pi(C)$ is a cs-tree of height $h+1$.*
2. *The General Intermezzo problem for instances (A, C) where $\pi(C)$ is a cs-tree of fixed height $h \geq 2$ is polynomial-time reducible to the rooted $\mathcal{L}$-tree recognition problem of Generic Search for rooted spanning trees of height $2h-1$.*
3. *The rooted $\mathcal{L}$-tree recognition problem of Generic Search for rooted spanning trees having k branch leaves is polynomial-time equivalent to the General Intermezzo problem for instances (A, C) where $\pi(C)$ is a cs-tree of width k.*

Proof. First, we reduce the $\mathcal{L}$-tree recognition problem of GS to the General Intermezzo Problem. Let G be a graph and T be a spanning tree of G rooted in r of height $h \geq 2$. Let $A = V(G) \cup \{s\}$ where $s \notin V(G)$. Let C be the set containing the following triples:

(C1) (r, t, s), for some child t of r in T,

(C2) (s, u, v), for any vertex $v \in V(G) \setminus \{r\}$ and its parent u in T,

(C3) (w, u, v), for any vertex $v \in V(G) \setminus \{r\}$, its parent u in T and any vertex w with $vw \in E(G) \setminus E(T)$.

It is easy to see that $\pi(C)$ is a cs-tree of height $h+1$. We claim that there is an intermezzo ordering of A fulfilling the constraints given by C if and only if T is a rooted GS $\mathcal{L}$-tree of G.

First assume that there is an intermezzo ordering σ fulfilling the constraints of C. We delete s from σ and call the resulting ordering σ'. The following claim is implied by the constraints given in (C2).

▷ Claim 1. If u is the parent of v in T, then $u \prec_{\sigma'} v$.

This claim implies directly that σ' is a GS ordering of G starting in r. Now assume for contradiction that the $\mathcal{L}$-tree T' of σ' is not equal to T. Then there is a vertex v whose parent u' in T' is different from its parent u in T. By Claim 1, it holds that $u \prec_{\sigma'} v$. Therefore, it must hold that $u \prec_{\sigma'} u' \prec_{\sigma'} v$. This implies that u' is not a child of v in T, due to Claim 1. Hence, the edge $u'v$ is not part of T but part of G. Then, the set C contains the triple (u', u, v) (see (C3)). This is a contradiction because σ' and, thus, σ does not fulfill the constraint given by that triple.

Now assume that T is the $\mathcal{L}$-tree of the GS ordering σ starting with r. Then let σ' be the ordering constructed by appending s to the end of σ. The ordering fulfills the constraint (r, t, s) given in (C1). Furthermore, as parents are to the left of their children in σ, the ordering σ' also fulfills the constraints given by (C2). Assume for contradiction that some triple (w, u, v) of (C3) is not fulfilled in σ', i.e., $u \prec_{\sigma'} w \prec_{\sigma'} v$. Then u is not the parent of v in the $\mathcal{L}$-tree of σ since w is a neighbor of v and w lies between u and v in σ'; a contradiction.

This proves the first statement of the lemma. To prove the same direction for the third statement, we slightly change the set C. Instead of the triple (r, t, s) given in (C1), we add the triple (t, s, r). It is easy to see that then the width of $\pi(C)$ is equal to the number of branch leaves of T. The rest of the proof works analogously with the only difference that we append s to the beginning and not to the end of the GS ordering of G.

Now we reduce the General Intermezzo problem where $\pi(C)$ is a cs-tree to the rooted $\mathcal{L}$-tree recognition problem of GS. Let (A, C) be an instance where $\pi(C)$ is a cs-tree of height h and width k. We define the vertex set to be $V(G) := \{v^1, v^2 \mid v \in A\}$. Let H be the Hasse diagram of $\pi(C)$. The set of edges of T is defined as $E(T) := \{v^1 v^2 \mid v \in A\} \cup \{u^2 v^1 \mid uv \in E(H) \wedge (u, v) \in \pi(C)\}$. Let $(x, y, z) \in C$ and let $y = w_0, w_1, \ldots, w_\ell = z$ be the elements of the path between y and z in the Hasse diagram of $\pi(C)$. We add a non-tree edge to G from x^2 to any vertex w_i^1 and w_i^2 with $i \geq 1$. It is obvious that the constructed tree T has height $2h - 1$ and k branch leaves if it is rooted in the minimal element of $\pi(C)$.

First assume that there is an intermezzo ordering σ for (A, C). Then let σ' be the ordering that is constructed by replacing every element $v \in A$ in σ by the ordering (v^1, v^2). Then we claim that σ' is a GS ordering of G having $\mathcal{L}$-tree T. Let T' be the $\mathcal{L}$-tree of σ'. Obviously, it holds for σ' that any vertex is to the right of its parent in T since σ' is constructed from a linear extension of $\pi(C)$. Therefore, σ' is a GS ordering of G. Furthermore, any vertex v^2 has parent v^1 both in T and T' since these two vertices are consecutive in σ'. Assume for contradiction that there is a vertex v^1 whose parent in T is u^2 but the parent of v^1 in T' is t^p with $u^2 \neq t^p$. By construction it holds that $t^p = t^2$ since v^1 has no neighbor with index 1. It holds that $u^2 \prec_{\sigma'} t^2 \prec_{\sigma'} v^1$ and t^2v^1 is an edge in $E(G) \setminus E(T)$. This non-tree edge has been added to $E(G)$ because of some triple $(t, a, b) \in C$ where a is an ancestor of v and b is a descendant of v in the Hasse diagram of $\pi(C)$ (or $b = v$). However, by construction of σ', it holds that $a^2 \prec_{\sigma'} u^2 \prec_{\sigma'} t^2 \prec_{\sigma'} v^1 \prec_{\sigma'} b^2$. Hence $a \prec_\sigma t \prec_\sigma b$; a contradiction to the fact that σ is an intermezzo ordering of C.

Now assume that there is a GS ordering σ of G having T as its $\mathcal{L}$-tree. We construct the ordering σ' of A as follows. Consider the subordering of σ containing only the vertices v^2 for any $v \in A$ and replace v^2 by v. We claim that σ' is an intermezzo ordering of (A, C). Let (x, y, z) be a triple in C. It holds that $y \prec_\sigma z$ since y^2 is an ancestor of z^2 in T. Assume for contradiction that $y \prec_{\sigma'} x \prec_{\sigma'} z$. Consider the $w_0, \ldots, w_\ell$ as defined above. Note that these vertices appear by ascending index in σ'. Let w_i be the leftmost of these vertices in σ' that is to the right of x. Then it holds that $y \preceq_{\sigma'} w_{i-1} \prec_{\sigma'} x \prec_{\sigma'} w_i \preceq_{\sigma'} z$. This implies that $w_{i-1}^2 \prec_\sigma x^2 \prec_\sigma w_i^2$. Now we consider two cases. If $w_i^1 \prec_\sigma x^2$, then it must hold that $w_{i-1}^2 \prec_\sigma w_i^1 \prec_\sigma x^2 \prec_\sigma w_i^2$ as w_{i-1}^2 is the parent of w_i^1 in T. However, by construction x^2 is adjacent to w_i^2 and, hence, w_i^1 cannot be the parent of w_i^2 in the $\mathcal{L}$-tree of σ. If $x_2 \prec_\sigma w_i^1$, then it must hold that $w_{i-1}^2 \prec_\sigma x^2 \prec_\sigma w_i^1 \prec_\sigma w_i^2$ as w_i^1 is the parent of w_i^2 in T. However, by construction x^2 is adjacent to w_i^1 and, hence, w_{i-1}^2 cannot be the parent of w_i^1 in the $\mathcal{L}$-tree of σ. This contradicts the choice of σ. ◀

Combining the first statement of the lemma with Theorem 3.8 yields the following result.

▶ **Theorem 4.2.** *The General Intermezzo problem is* NP*-complete even if the input is restricted to instances (A, C) where $\pi(C)$ is a cs-tree of height* 6.

We can extend this result to the Intermezzo problem as follows.

▶ **Lemma 4.3.** *The General Intermezzo Problem for instances (A, C) where $\pi(C)$ is a cs-tree of width k is polynomial-time reducible to the Intermezzo Problem for instances (A', B', C') where $\pi(B', C')$ is a cs-tree of width k.*

This lemma implies the following complexity result.

▶ **Theorem 4.4.** *The Intermezzo problem is* NP*-complete even if the input is restricted to instances (A, B, C) where $\pi(B, C)$ is a cs-tree.*

As was shown by Wolk [30], cs-trees have dimension 2. Combining this with Theorems 4.2 and 4.4, we get the following result.

▶ **Corollary 4.5.** *The (General) Intermezzo problem is* NP*-complete even if $\pi(B, C)$ or $\pi(C)$, respectively, has dimension at most 2.*

Note that – in difference to Theorem 4.2 – we were not able to bound the height of the partial order in Theorem 4.4 since in the proof of Lemma 4.3 the height of the constructed partial order depends on the number of elements in A. We can adapt the proof of that lemma such that the height of the partial order increases only by a constant factor. However, in this case, we then loose the property that the partial order is a cs-tree.

▶ **Corollary 4.6.** *The Intermezzo problem is* NP*-complete even if the input is restricted to instances (A, B, C) where $\pi(B, C)$ has height* 36*.*

The complexity of the Intermezzo problem for cs-trees of bounded height remains open.

4.2 The Intermezzo Problem for Partial Orders of Bounded Width

As we have seen in the section above, the (General) Intermezzo problem is NP-complete even if the height or the dimension of the partial order is bounded. One may ask whether this also holds for another notable parameter of partial orders, the width. Adapting an idea of Colbourn and Pulleyblank [6] (explained in more detail in [4]), we can show that – unless P = NP – this is not the case as we can give an XP-algorithm for the General Intermezzo problem parameterized by the width of $\pi(C)$.

▶ **Theorem 4.7.** *The General Intermezzo problem can be solved in time $\mathcal{O}(k \cdot n^{k+2})$ on any instance (A, C) where $n = |A|$ and k is the width of $\pi(C)$.*

Proof. We only sketch the idea of the algorithm; for a comprehensive description and analysis of a similar algorithm see [4]. Using Dilworth's Chain Covering Theorem [11], we can partition the set A into k disjoint chains of $\pi(C)$. Now the set of elements of any prefix σ^{pre} of a linear extension of $\pi(C)$ can be represented by a tuple $(a_1, \dots, a_k) \in \{0, \dots, |A|\}^k$ where a_i represents the number of elements of chain i that are part of σ^{pre}. Since all elements of a chain are strictly ordered, the number of used elements of the chain directly implies the elements of the chain that are part of the prefix set.

Now the algorithm uses dynamic programming to compute whether a given prefix set can be reached in such a way that it fulfills all conditions of C. To this end, we have a table M with 0-1-entries for every tuple representing a prefix. We fill the entries of this table inductively, starting with those tuples whose entries sum up to 1. Such a tuple gets a 1-entry in M if and only if the minimal element of the respective chain is a minimal element of the partial order. For tuples $\gamma = (a_1, \dots, a_k)$ with larger entry sums we check for any tuple γ' that is constructed by decrementing exactly one non-zero entry of γ, say a_i, the following:

1. Is the M-entry of tuple γ' equal to 1?
2. Is the a_i-th element x of the i-th chain minimal in $\pi(C)$ restricted to those elements that are not part of the prefix set encoded by γ'?
3. Is there no triple (x, y, z) with y is an element of the prefix set encoded by γ' and z is not such an element?

If the answer to all three question is yes, then we set the M-entry of γ to 1. It is easy to check that M has $\mathcal{O}(n^k)$ entries and for any entry we can answer the three questions above for all triples γ' in time $\mathcal{O}(kn^2)$. This leads to the claimed running time. ◀

Lemma 4.1 implies an XP-algorithm for the rooted $\mathcal{L}$-tree recognition of GS parameterized by the number of branch leaves of the given spanning tree.

▶ **Corollary 4.8.** *The rooted $\mathcal{L}$-tree recognition problem of Generic Search can be solved in time $\mathcal{O}(k \cdot n^{k+2})$ on a graph G and a rooted spanning tree T of G where $n = |V(G)|$ and k is the number of branch leaves of T.*

One may ask whether this rather poor running time bound given in Theorem 4.7 can be improved significantly and whether there is an FPT algorithm for the (General) Intermezzo problem parameterized by the width of the partial order. We will show that – under certain assumptions – this is not the case.

▶ **Theorem 4.9.** *The (General) Intermezzo problem is* W[1]*-hard if it is parameterized by the width k of $\pi(C)$ or $\pi(B, C)$, respectively, even if that partial order is a cs-tree. Furthermore – under the assumption of the Exponential Time Hypothesis – there is no algorithm that solves the problem in time $f(k) \cdot n^{o(k)}$ for any computable function f where $n = |A|$.*

We prove this result by an FPT-reduction from the following problem, applying a technique also used in [4].

▶ **Problem 4** (Multicolored Clique Problem (MCP)).
Instance: *A graph G with a proper coloring of k colors.*
Question: *Is there a clique in G that contains exactly one vertex of each color?*

The MCP was shown to be W[1]-hard by Pietrzak [21] and independently by Fellows et al. [12]. In fact, in [10, 19] the authors show the following result.

▶ **Theorem 4.10** (Cygan et al. [10], Lokshtanov et al. [19]). *Under the assumption of the Exponential Time Hypothesis, there is no $f(k)n^{o(k)}$ time algorithm for the Multicolored Clique Problem for any computable function f where n is the number of vertices of the given graph.*

We give an FPT-reduction from the MCP to the General Intermezzo problem parameterized by the width of $\pi(C)$. Lemma 4.3 implies such a reduction also for the Intermezzo problem.

Let G be an instance of the MCP with k colors. W.l.o.g. we may assume that every color class has exactly q elements, i.e., we assume that $V(G) = \{v_p^i \mid 1 \leq i \leq k, 1 \leq p \leq q\}$. In the following, we construct an equivalent instance (A, C) for the General Intermezzo problem.

First we describe the set A. For every $i \in \{1, \dots, k\}$ and every $p \in \{1, \dots, q\}$, we define the set $U_p^i := \{u_{p,j}^i \mid 0 \leq j \leq k\}$. The set U^i is defined as $U^i := \bigcup_{1 \leq p \leq q} U_p^i$. Now set A is defined as follows.

$$A := \{s^i \mid 1 \leq i \leq k+1\} \cup \{c^{i,j} \mid 1 \leq i \leq j \leq k\} \cup \bigcup_{1 \leq i \leq k} U^i.$$

In the remainder of the section, we construct the set C by adding subsets of triples with specific properties. We start with some simple order constraints. For the sake of convenience, we only give a set B of tuples encoding these constraints. Note that these tuples can also be encoded using triples by introducing a new element that is not allowed to be between any of the elements of those tuples.

$$\begin{aligned}
B := &\{(s^i, u_{p,j}^i) && \mid 1 \leq i \leq k,\ 0 \leq j \leq k,\ 1 \leq p \leq q\} \cup \\
&\{(u_{p,j}^i, u_{r,\ell}^i) && \mid 1 \leq i \leq k,\ p < r \text{ or } p = r \text{ and } j < \ell\} \cup \\
&\{(u_{1,0}^i, s^{i+1}) && \mid 1 \leq i \leq k\} \cup \\
&\{(c^{i,j}, c^{\ell,m}) && \mid i < \ell \text{ or } i = \ell \text{ and } j < m\} \cup \\
&\{(c^{i,k}, c^{i+1,i+1}) && \mid i < k\} \cup \\
&\{(s^{k+1}, c^{1,1})\}
\end{aligned}$$

▶ **Lemma 4.11.** *The reflexive and transitive closure of B forms a cs-tree of width $k+1$.*

In the following, we will present the rest of the triples of the set C. First note that the last two elements of these triples will also be contained as a tuple in the reflexive and transitive closure of B. Thus, they do not contribute any new tuples to $\pi(C)$ and, hence, Lemma 4.11 implies that $\pi(C)$ is a cs-tree of width $k+1$.

We will present the new triples not all at once. Instead we present specific subsets of them. Then we will give properties that are fulfilled by any intermezzo ordering of A that fulfills the constraints of B and all triples presented up to that point. In any of these properties, the ordering σ will be the respective intermezzo ordering of A. We divide this ordering into a *selection phase* where we choose one vertex of every color to be part of the candidate clique. In the *verification phase*, we check whether the chosen vertices indeed form a clique in G. We start with the triples for the selection phase.

$$\begin{aligned}
C^1_{\text{sel}} &:= \{(s^{i+1}, u^i_{p,j}, u^i_{p+1,0}) \mid 1 \le i \le k, 1 \le p < q, 1 \le j \le k\}\\
C^2_{\text{sel}} &:= \{(u^i_{q,j}, s^i, s^{i+1}) \quad\quad \mid 1 \le i \le k, 1 \le j \le k\}\\
C^3_{\text{sel}} &:= \{(u^i_{p,j}, s^{i+1}, c^{1,1}) \quad \mid 1 \le i \le k, 1 \le p \le q, 0 \le j \le k\}
\end{aligned}$$

▶ **Property 1.** *There exist indices $p_1, \dots, p_k \in \{1, \dots, q\}$ such that the prefix σ' of σ ending in $c^{1,1}$ fulfills the following conditions:*

1. *σ' starts with s^1 and does not contain any vertices $c^{i,j}$ with $i \neq 1$ or $j \neq 1$.*
2. *for all $i \in \{1, \dots, k\}$ it holds:*
   a. *vertex s^i and $\bigcup_{r=1}^{p_i-1} U^i_r$ are part of σ',*
   b. *$U^i_{p_i} \cap \sigma' = \{u^i_{p_i,0}\}$,*
   c. *none of the vertices of U^i_r with $r > p_i$ are part of σ'.*

We now present the first triples for the verification phase. They ensure that between certain c-elements only some elements are allowed to be taken. By Property 1 we assume in the following that $p_1, \dots, p_k$ are fixed.

$$\begin{aligned}
C^1_{\text{ver}} &:= \{(x, c^{i,k}, c^{i+1,i+1}) \quad \mid 1 \le i < k,\ x \in A \setminus \{c^{i,k}, c^{i+1,i+1}\}\}\\
C^2_{\text{ver}} &:= \{(u^i_{p,j}, c^{\ell,m}, c^{\ell,m+1}) \mid i \neq \ell \text{ and } i \neq m+1 \text{ or } i = m+1 \text{ and } j \neq \ell \text{ or}\\
&\qquad\qquad\qquad\qquad\qquad\quad i = \ell \text{ and } j \neq m\}
\end{aligned}$$

▶ **Property 2.** *There are at most two elements in σ between $c^{\ell,m}$ and $c^{\ell,m+1}$, namely $u^\ell_{p_\ell,m}$ and $u^{m+1}_{p_{m+1},\ell}$.*

In the next step we want to ensure that $u^\ell_{p_\ell,m}$ and $u^{m+1}_{p_{m+1},\ell}$ have to be taken between $c^{\ell,m}$ and $c^{\ell,m+1}$.

$$\begin{aligned}
C^3_{\text{ver}} := &\{(c^{\ell,m+1}, u^\ell_{p,m-1}, u^\ell_{p,m}) \mid 1 \le \ell \le m < k, 1 \le p \le q\} \cup\\
&\{(c^{\ell,m+1}, u^{m+1}_{p,\ell-1}, u^{m+1}_{p,\ell}) \mid 1 \le \ell \le m < k, 1 \le p \le q\}
\end{aligned}$$

▶ **Property 3.** *The elements $u^\ell_{p_\ell,m}$ and $u^{m+1}_{p_{m+1},\ell}$ have to be between $c^{\ell,m}$ and $c^{\ell,m+1}$ in σ.*

Finally, we have to ensure that $u^\ell_{p_\ell,m}$ and $u^{m+1}_{p_{m+1},\ell}$ can only be taken if $v^\ell_p v^{m+1}_{p_{m+1}} \in E(G)$. This is ensured by the following triples.

$$\begin{aligned}
C^4_{\text{ver}} := &\{(u^{m+1}_{r,\ell}, u^\ell_{p,m}, u^\ell_{p,m+1}) \mid 1 \le \ell \le m < k, 1 \le p \le q, 1 \le r \le q, v^\ell_p v^{m+1}_r \notin E(G)\} \cup\\
&\{(u^\ell_{p,m}, u^{m+1}_{r,\ell}, u^{m+1}_{r,\ell+1}) \ \mid 1 \le \ell \le m < k, 1 \le p \le q, 1 \le r \le q, v^\ell_p v^{m+1}_r \notin E(G)\}
\end{aligned}$$

▶ **Property 4.** *The elements $u^\ell_{p_\ell,m}$ and $u^{m+1}_{p_{m+1},\ell}$ can be between $c^{\ell,m}$ and $c^{\ell,m+1}$ in σ only if $v^\ell_{p_\ell} v^{m+1}_{p_{m+1}} \in E(G)$.*

Using Properties 1–4, we can prove that the described instance of the General Intermezzo problem is a feasible reduction from the MCP.

▶ **Lemma 4.12.** *There is an intermezzo ordering σ for (A, C) if and only if G has a multicolored clique of size k.*

Proof. First assume that there is an intermezzo ordering σ. Let the p_i be chosen as in Property 1. Then, we define the set $K \subseteq V(G)$ as follows: $K := \{v^i_{p_i} \mid 1 \leq i \leq k\}$. Properties 3 and 4 imply that the set K forms a clique in G.

For the other direction, assume that there is a multicolored clique $K = \{v^1_{p_1}, \dots, v^k_{p_k}\}$ in G. We start our intermezzo ordering in s^1. Now we take all the elements of U^1 following their ordering implied by B up to $u^1_{p_1,0}$ and then we take s^2. We repeat this process for all $i \in \{2, \dots, k\}$. Now we take the c-elements following the ordering implied by B. Between $c^{\ell,m}$ and $c^{\ell,m+1}$, we take $u^\ell_{p_\ell,m}$ and $u^{m+1}_{p_{m+1},\ell}$ which is possible due to Property 4 since K forms a clique. Eventually, we take $c^{k,k}$. Now we first take the remaining elements of U^1 in their order in B, followed by the remaining elements of U^2 and so on. It is easy to check that this ordering is an intermezzo ordering. ◀

Theorem 4.9 follows directly from Lemmas 4.3, 4.11, and 4.12, Theorem 4.10 as well as the W[1]-hardness of the Multicolored Clique Problem [12, 21]. Furthermore, Theorem 4.9 and Lemma 4.1 imply the following.

▶ **Theorem 4.13.** *The $\mathcal{L}$-tree recognition problem of Generic Search is* W[1]*-hard if it is parameterized by the number k of leaves of the spanning tree. Furthermore, assuming the Exponential Time Hypothesis, there is no algorithm that solves the problem in time $f(k) \cdot n^{o(k)}$ for any computable function f where n is the number of vertices of the given graph.*

5 Conclusion

We have investigated two problems that extend a partial order to a total order while maintaining certain additional constraints. In the first problem, a spanning tree of a graph G is given, which is supposed to be the $\mathcal{L}$-tree of Generic Search on G. Surprisingly, deciding this problem turned out to be NP-complete, although numerous problems involving Generic Search, such as the associated end vertex problem, are straightforward to solve in polynomial time. This complexity result could be used in the investigation of the second problem. Here we have shown that the General Intermezzo problem cannot be solved in polynomial time even when the Hasse diagram of the given partial order forms a tree. With respect to the width, we were able to specify an XP-algorithm and at the same time show W[1]-hardness.

Several questions remain unanswered. For the GS $\mathcal{L}$-tree problem it is not clear whether the bounds for the tree height in the NP-completeness results are best possible. We conjecture that the problem is easy for height 2 and maybe even 3. Furthermore, we suspect that the NP-completeness also holds for the class of bipartite graphs. While the problem is hard for split graphs, it might be solved efficiently on the subclass of threshold graphs.

Similar questions arise for the (General) Intermezzo problem: We have not shown that the height-bounds for the partial order are best possible. In particular, the bound of 36 in Corollary 4.6 seems very high. Restricting these partial orders in other ways, e.g. lattices or interval orders, could also be used to find tractable instances of the problem. Furthermore, the complexity status of the Intermezzo problem for cs-trees of bounded height remains open.

Abstract

Weighted automata (WA) are an extension of finite automata that define functions from words to values in a given semiring. An alternative deterministic model, called Cost Register Automata (CRA), was introduced by Alur et al. It enriches deterministic finite automata with a finite number of registers, which store values, updated at each transition using the operations of the semiring. It is known that CRA with register updates defined by linear maps have the same expressiveness as WA. Previous works have studied the register minimization problem: given a function computable by a WA and an integer k, is it possible to realize it using a CRA with at most k registers?

In this paper, we solve this problem for CRA over a field with linear register updates, using the notion of linear hull, an algebraic invariant of WA introduced recently by Bell and Smertnig. We then generalise the approach to solve a more challenging problem, that consists in minimizing simultaneously the number of states and that of registers. In addition, we also lift our results to the setting of CRA with affine updates. Last, while the linear hull was recently shown to be computable by Bell and Smertnig, no complexity bounds were given. To fill this gap, we provide two new algorithms to compute invariants of WA. This allows us to show that the register (resp. state-register) minimization problem can be solved in 2-ExpTime (resp. in NExpTime).

1 Introduction

Weighted automata (WA). WA are a quantitative extension of finite state automata and have been studied since the sixties [17]. These automata define functions from words to a given semiring: each transition has a weight in the semiring and the weight of an execution is the product of the weights of the transitions therein; the non-determinism of the model is handled using the sum of the semiring: the weight associated with a word is the sum of the weights of the different executions over this word. Functions realized by weighted automata are called rational series. This fundamental model has been widely studied during the last decades [14]. While some expressiveness results can be obtained in a general framework (such as the equivalence with rational expressions), the decidability status of important problems heavily depends on the considered semiring. Amongst the classical problems of interest, one can mention *equivalence*, *sequentiality* (resp. *unambiguity*), which aims at determining whether there exists an equivalent deterministic (resp. unambiguous) WA, and *minimization*, which aims at minimizing the number of states.

Weighted automata over a field (e.g. the field of rationals $\mathbb{Q}$) enjoy many nice properties: the equivalence of weighted automata is decidable and they can be minimized, and both can be done efficiently (see e.g. [16, Theorem 4.10 and Corollary 4.17 (Chapter III)]). The

sequentiality and unambiguity are also decidable, as shown recently in [3, 4], with no complexity bounds however. The most studied semirings which are not fields are the tropical semirings and the semiring of languages, and in both cases equivalence is undecidable (see [9, Section 3] and [6, Theorem 8.4]) and no minimization algorithm is known. Regarding sequentiality, partial decidability results have been obtained for these semirings using the notion of twinning property [7, 15].

Cost register automata (CRA). CRA have been introduced more recently by Alur et al. [1]. A cost register automaton is a deterministic finite state automaton endowed with a finite number of registers storing values from the semiring. The registers are initialized by some values, then at each transition the values are updated using the operations and constants of the semiring. Several fragments of CRA can be considered by restricting the operations allowed. For instance, an easy observation is that WA are exactly CRA with one state (however, one can observe that adding states does not extend expressiveness) and linear updates, *i.e.* updates of the form $X \coloneqq \sum_{i=1}^{k} X_i * c_i$ (intuitively, the new values of the registers only depend linearly on the previous ones). Thus, the model of linear CRA is an alternative to WA which allows to trade non-determinism for registers.

The register minimization problem. As CRA are finite state automata extended with registers storing elements from the semiring, it is natural to aim at minimizing the number of registers used. For a given class $\mathcal{C}$ of CRA, this problem asks, given a WA and a number k, whether there exists an equivalent CRA in $\mathcal{C}$ with at most k registers. From a practical point of view, reducing the number of registers allows to reduce the memory usage, since a register can require unbounded memory. From a theoretical point of view, this problem can be understood as a refinement of the classical problem of minimization of WA. Indeed, a WA can be translated into a linear CRA with a single state, and as many registers as the number of states of the WA. This problem has been studied in [2, 11, 10] for three different models of CRA but in all these works, the additive law of the semiring is not allowed (*i.e.* updates of the form $X \coloneqq Y + Z$ are forbidden). It is worth noticing that [11] encompasses the case of CRA over a field, with only updates of the form $X \coloneqq Y * c$, with c an element of the field.

While the minimal number of registers needed to realise a WA (also known as the *register complexity*) is upper bounded by the number of states of a minimal WA, it may be possible to build an equivalent CRA with fewer registers, but more states. Hence there is a *tradeoff* between the number of states and the number of registers. This leads to the following *state-register minimization problem for* CRA which asks, for a class $\mathcal{C}$ of CRA, given a WA and integers n, k whether an equivalent CRA in $\mathcal{C}$ with n states and k registers can be constructed. In this framework, the classical minimization of WA corresponds to minimizing the number of registers while using only one state, for the class of linear CRA.

The linear hull. As mentioned before, the case of fields is well-behaved to obtain decidability results. In their recent work [3], Bell and Smertnig introduced the notion of *linear hull* of a WA. This notion is inspired by the algebraic theory needed to study polynomial automata but cast into a linear setting. A linear algebraic set (aka linear Zariski closed set) is a finite union of vector subspaces: we later call them *Z-linear sets.* Given a Z-linear set $S = \bigcup_{i=1}^{p} V_i$, the dimension of S is the maximum of the dimensions of the V_is. In this work, the size of the union, p, is called the length of S. Observe that such Z-linear sets were also used in [8] for a category-theoretic approach to minimization of weighted automata over a field. We say such a set is an invariant if it contains the initial vector and is stable under the updates of the automaton. Then the linear hull of a weighted automaton is the strongest Z-linear invariant. In [3], Bell & Smertnig show that computing the linear hull of a minimal automaton allows to decide sequentiality and unambiguity. In addition, in [4], they show that the linear hull can effectively be computed, without providing complexity bounds however.

Contributions. In this work, we deepen the analysis of the linear hull of a WA in order to solve the register and state-register minimization problems for linear CRA. In addition, we also provide new algorithms to compute the linear hull which come with complexity upper bounds, which can be used to derive complexity results for minimization problems as well as for sequentiality and unambiguity of WA. More precisely, our contributions are as follows:

- Firstly, we show that *the register minimization problem* for the class of linear CRA over a field can be solved in 2-ExpTime. To this end, given a rational series f, we show that the minimal number of registers needed to realize f using a linear CRA is exactly the dimension of the linear hull of a minimal WA of f. We then show that the linear hull of a WA can be computed in 2-ExpTime. We show that this complexity drops down to ExpTime for the particular case of commuting transition matrices (which includes the case of a single letter alphabet), with a matching lower bound.
- As a consequence of the computation of the linear hull of a WA and of results proved in [3], we obtain a 2-ExpTime upper bound for the problems of *sequentiality and unambiguity of weighted automata* over a field, closing a question raised in [4].
- Secondly, we prove that the *state-register minimization problem* for linear CRA can be solved in NExpTime. More precisely, given a minimal WA A, we show a correspondence between Z-linear invariants of A and linear CRA equivalent to A. This correspondence maps the length (resp. dimension) of the invariant to the number of states (resp. registers) of the equivalent linear CRA. We then provide a (constructive) NExpTime algorithm that, given a minimal WA and two integers n, k, guesses a well-behaved invariant allowing to exhibit a satisfying equivalent CRA.
- Last, we actually present these results in a more general setting, by considering *affine* CRA, which are a slight extension of linear CRA allowing to use affine maps in the updates of the registers.

Outline of the paper. We present the models of weighted automata and cost register automata in Section 2. We then formally define the two problems we consider, *i.e.* register and state-register minimization problems, and state our main results in Section 3. In Section 4, we introduce the necessary topological notions to define Z-linear/Z-affine set and invariants of weighted automata, and detail our characterizations of the register and state-register complexities of a rational series. Finally in Section 5, we present our algorithms, as well as their consequences in terms of decidability and complexity for the two problems we consider. Omitted proofs and more details for Sections 4 and 5 can be found in the appendix of the full version of this paper [5].

2 Weighted Automata and Cost Register Automata

Basic concepts and notations. An alphabet Σ is a finite set of letters. The set of finite words over Σ will be denoted by Σ^*, the empty word by ϵ and, for two words u and v, uv will denote their concatenation. For two sets X and Y, we denote by $X \times Y$ their cartesian product and by $\pi_X : X \times Y \to X$ and $\pi_Y : X \times Y \to Y$ we denote the canonical projection on X and Y respectively. The set nonnegative integers will be denoted by $\mathbb{N}$. For two integers i, j, we will denote by $[\![i, j]\!]$ the interval of integers between i and j (both included).

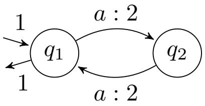

Figure 1 The WA of Example 2.

A *semigroup* $(S, *)$ is a set S together with an associative binary operation $*$. If $(S, *)$ has an identity element e, $(S, *, e)$ is called a *monoid* and if, moreover, every element has an inverse, $(S, *, e)$ is called a *group*. If there is no ambiguity, we will identify algebraic structures with the set that they are defined on. A semigroup (or a monoid/group) is said to be *commutative* if its law is. A sub-semigroup (or submonoid/subgroup) of S is a subset of S that is a semigroup (or a monoid/group). Given $E \subseteq S$, the monoid *generated* by E, denoted $\langle E \rangle$, is the smallest sub-monoid of S containing E.

A *field* $(\mathbb{K}, +, \cdot)$ is a structure where $(\mathbb{K}, +, 0)$ and $(\mathbb{K} \setminus \{0\}, \cdot, 1)$ are commutative groups and multiplication distributes over addition. In this work, we will consider $\mathbb{K}$ as the field of rational numbers $\mathbb{Q}$, or any finite field extension of $\mathbb{Q}$, to perform basic operations in polynomial time. For all $n \in \mathbb{N}$, $\mathbb{K}^n$ is an n-dimensional *vector space* over the field $\mathbb{K}$. We will work with row vectors and apply matrices on the right, and we will identify linear maps (resp. linear forms) with their corresponding matrices (resp. column vectors). The set of n by m matrices over $\mathbb{K}$ will be denoted by $\mathbb{K}^{n\times m}$, and $\mathbb{K}^{1\times n}$ (or simply $\mathbb{K}^n$ when there is no ambiguity) will denote the set of n-dimensional vectors. For any matrix M (resp. vector v), and indices i and j, $M_{i,j}$ (resp. v_i) will denote the value of the entry in the i-th row and the j-th column of M (resp. the i-th entry of v). Matrix transposition will be denoted by M^t. A *vector subspace* of $\mathbb{K}^n$ is a subset of $\mathbb{K}^n$ stable by linear combinations and for all subsets E of $\mathbb{K}^n$, $\mathsf{span}\,(E)$ will denote the smallest vector subspace of $\mathbb{K}^n$ containing E (if E contains a single vector $(x_1, \ldots, x_n)$, $\mathsf{span}\,(E)$ will be denoted by $\mathsf{span}\,(x_1, \ldots, x_n)$).

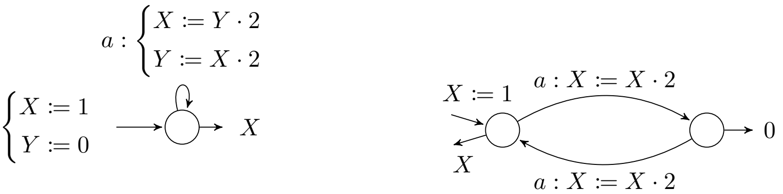
$\mathbb{K}^n$ can also be seen as an n-dimensional *affine space*. Affine maps $f \colon \mathbb{K}^n \to \mathbb{K}^m$ are maps of the form $f(u) = uf^{(l)} + f^{(a)}$ where $f^{(l)} \in \mathbb{K}^{n\times m}$ and $f^{(a)} \in \mathbb{K}^{1\times m}$. An *affine subspace* A of $\mathbb{K}^n$ is a subset of $\mathbb{K}^n$ of the form $A = p + V$ with $p \in A$ and V a vector subspace of $\mathbb{K}^n$. They are stable by affine combinations (linear combinations with coefficients adding up to 1). For all $E \subseteq \mathbb{K}^n$, $\mathsf{aff}\,(E)$ will denote the smallest affine subspace of $\mathbb{K}^n$ containing E.

Weighted Automata. Let Σ be a finite alphabet and $(\mathbb{K}, +, \cdot)$ be a field.

▶ **Definition 1** (Weighted Automaton). *A* Weighted Automaton *(*WA *for short) of dimension d, on Σ over $\mathbb{K}$, is a triple $\mathcal{R} = (u, \mu, v)$, where $u \in \mathbb{K}^{1\times d}$, $v \in \mathbb{K}^{d\times 1}$ and $\mu \colon \Sigma^* \to \mathbb{K}^{d\times d}$ is a monoid morphism. We will call u and v the* initial *and* terminal *vectors respectively and $\mu(a)$, for $a \in \Sigma$, will be called a* transition matrix. *A* WA *realizes a* formal power series *over Σ^* with coefficients in $\mathbb{K}$ (a function from Σ^* to $\mathbb{K}$) defined, for all $w \in \Sigma^*$, by $[\![\mathcal{R}]\!](w) = u\mu(w)v$. Any series that can be realized by a* WA *will be called* rational.

WA also have a representation in terms of finite-state automata, in which transitions are equipped with weights. We then say that a WA is sequential (resp. unambiguous) when its underlying automaton is. Formally, we say that a WA $\mathcal{R} = (u, \mu, v)$ is *sequential* when u has a single non-zero entry and, for each letter a, and each index i, there is at most one index j such that $\mu(a)_{i,j} \neq 0$.

▶ **Example 2.** We consider the WA, on the alphabet $\{a\}$ and over the field of real numbers, $\mathcal{R} = (u, \mu, v)$ with $u = (1, 0)$, $v = (1, 0)^t$, and $\mu(a) = \begin{pmatrix} 0 & 2 \\ 2 & 0 \end{pmatrix}$. One can verify that the function realized by this WA maps the word a^n to 2^n if n is even, and to 0 otherwise. It can be represented graphically by the automaton depicted on Figure 1.



$a : \begin{cases} X := Y \cdot 2 \\ Y := X \cdot 2 \end{cases}$
$\begin{cases} X := 1 \\ Y := 0 \end{cases}$
X
$X := 1$
$a : X := X \cdot 2$
X
$a : X := X \cdot 2$
0

Figure 2 Two CRA detailed in Example 5. Registers are denoted by letters X, Y.

A WA realizing a rational series f is said to be *minimal* if its dimension is minimal among all the WA realizing f. We also have the following characterization of minimal WA (see [16, Proposition 4.8 (Chapter III)]):

▶ **Proposition 3.** *Let $\mathcal{R} = (u, \mu, v)$ be a d-dimensional* WA *and let $\mathsf{LR}(\mathcal{R}) = u\mu(\Sigma^*) = \{u\mu(w) \mid w \in \Sigma^*\}$ be its (left)* reachability set *and $\mathsf{RR}(\mathcal{R}) = \mu(\Sigma^*)v$ be its right reachability set.*

$\mathcal{R}$ is a minimal WA *if and only if $\mathsf{span}(\mathsf{LR}(\mathcal{R})) = \mathbb{K}^{1\times d}$ and $\mathsf{span}(\mathsf{RR}(\mathcal{R})) = \mathbb{K}^{d\times 1}$.*

Expressions, substitutions and Cost Register Automata. For a field $(\mathbb{K}, +, \cdot)$ and a finite set of variables $\mathcal{X}$ disjoint from $\mathbb{K}$, let $\mathsf{Exp}(\mathcal{X})$ denote the set of expressions generated by the grammar $e ::= k \mid X \mid e + e \mid e \cdot e$, where $k \in \mathbb{K}$ and $X \in \mathcal{X}$. A *substitution* over $\mathcal{X}$ is a map $s\colon \mathcal{X} \to \mathsf{Exp}(\mathcal{X})$. It can be extended to a map $\mathsf{Exp}(\mathcal{X}) \to \mathsf{Exp}(\mathcal{X})$ by substituting each variable X in the expression given as an input by $s(X)$. By identifying s with its extension, we can compose substitutions. We call *valuations* the substitutions of the form $v\colon \mathcal{X} \to \mathbb{K}$. The set of substitutions over $\mathcal{X}$ will be denoted by $\mathsf{Sub}(\mathcal{X})$ and the set of valuations $\mathsf{Val}(\mathcal{X})$.

▶ **Definition 4** (Cost Register Automaton). *A* cost register automaton *(*CRA *for short), on the alphabet Σ over the field $\mathbb{K}$, is a tuple $\mathcal{A} = (Q, q_0, \mathcal{X}, v_0, o, \delta)$ where Q is a finite set of* states, *$q_0 \in Q$ is the initial state, $\mathcal{X}$ is a finite set of registers (variables), $v_0 \in \mathsf{Val}(\mathcal{X})$ is the registers' initial valuation, $o\colon Q \to \mathsf{Exp}(\mathcal{X})$ is the output function, and $\delta\colon Q \times \Sigma \to Q \times \mathsf{Sub}(\mathcal{X})$ is the transition function. We will denote by $\delta_Q := \pi_Q \circ \delta$ the transition function of the underlying automaton of the* CRA *and $\delta_{\mathcal{X}} := \pi_{\mathsf{Sub}(\mathcal{X})} \circ \delta$ its register update function.*

$\mathcal{A}$ computes a function $[\![\mathcal{A}]\!]\colon \Sigma^* \to \mathbb{K}$ defined as follows: the configurations of $\mathcal{A}$ are pairs $(q, v) \in Q \times \mathsf{Val}(\mathcal{X})$. The run of $\mathcal{A}$ on a word $w = a_1 \ldots a_n \in \Sigma^*$ is the sequence of configurations $(q_i, v_i)_{i\in[\![0,n]\!]}$ where, q_0 is the initial state, v_0 is the initial valuation and, for all $i \in [\![1, n]\!]$, $q_i = \delta_Q(q_{i-1}, a_i)$ and $v_i = v_{i-1} \circ \delta_{\mathcal{X}}(q_{i-1}, a_i)$. We then define $[\![\mathcal{A}]\!](w) = v_n(o(q_n))$.

δ can be extended to words by setting, for all $q \in Q$, $\delta(q, \epsilon) = (q, id_{\mathcal{X}})$, where $id_{\mathcal{X}}$ is the substitution such that $id_{\mathcal{X}}(X) = X$ for all $X \in \mathcal{X}$, and, for all $a \in \Sigma$ and $w \in \Sigma^*$, $\delta_Q(q, aw) = \delta_Q(\delta_Q(q, a), w)$ and $\delta_{\mathcal{X}}(q, aw) = \delta_{\mathcal{X}}(q, a) \circ \delta_{\mathcal{X}}(\delta_Q(q, a), w)$. We then have

$$[\![\mathcal{A}]\!](w) = v_0 \circ \delta_{\mathcal{X}}(q_0, w)(o(\delta_Q(q_0, w)))$$

▶ **Example 5** (Example 2 continued). Two CRA are depicted on Figure 2. They are both on the alphabet $\{a\}$ and over the field of real numbers, and both realize the same function as the WA considered in Example 2.

An expression is called *linear* if it has the form $\sum_{i=1}^{k} \alpha_i X_i$, for some family of $\alpha_i \in \mathbb{K}$ and $X_i \in \mathcal{X}$, and if it has the form $\sum_{i=1}^{k} \alpha_i X_i + \beta$, for some $\beta \in \mathbb{K}$, it is called *affine.* We will denote by $\mathsf{Exp}_\ell(\mathcal{X})$ (resp. $\mathsf{Exp}_a(\mathcal{X})$) the set of linear (resp. affine) expressions.

▶ **Definition 6** (Linear/Affine CRA). *A* CRA $\mathcal{A} = (Q, q_0, \mathcal{X}, v_0, o, \delta)$ *is called* linear *if,* $\delta_{\mathcal{X}}(q, a)(X) \in \mathsf{Exp}_\ell(\mathcal{X})$ *and* $o(q) \in \mathsf{Exp}_\ell(\mathcal{X})$*, for all* $q \in Q, a \in \Sigma$ *and* $X \in \mathcal{X}$*, and if* $\delta_{\mathcal{X}}(q, a)(X) \in \mathsf{Exp}_a(\mathcal{X})$ *and* $o(q) \in \mathsf{Exp}_a(\mathcal{X})$*, the* CRA *is called* affine.

Linear CRA are a particular case of affine CRA and, given an affine CRA it is always possible to define an equivalent linear CRA using one more register with a constant value of 1 to realize affine register updates in a linear way, thus :

▶ Remark 7. Linear and affine CRA have the same expressiveness.

The added cost of a register will however become relevant when we will consider minimization problems in the next sections.

Observe that we can assume that $\mathcal{X} = \{X_1, \dots, X_k\}$ is ordered, and identify any linear expression $e = \sum_{i=1}^{k} \alpha_i X_i$ (with the α_i not present in the expression assumed to be 0) with the linear form $\underline{e}\colon \mathbb{K}^k \to \mathbb{K}$ defined by the column vector $(\alpha_1, \dots, \alpha_k)^t$. We can then identify any linear substitution $s\colon \mathcal{X} \to \mathsf{Exp}_\ell(\mathcal{X})$ with the linear map $\underline{s}\colon \mathbb{K}^k \to \mathbb{K}^k$ defined by the block matrix $(\underline{s(X_1)}|\cdots|\underline{s(X_k)})$, and we can identify any valuation $v\colon \mathcal{X} \to \mathbb{K}$ with the vector $\underline{v} = (v(X_1), \cdots, v(X_k))$ of the vector space $\mathbb{K}^k$.

In the following, we will drop the underline notation and make the identifications implicitly.

Thanks to these observations, the registers of a linear CRA and their updates can be characterized by the values of the vector associated with v_0, and the linear maps associated with the $\delta_{\mathcal{X}}(q, a)$ and $o(q)$, for all $q \in Q$ and $a \in \Sigma$, and we can check that

$$[\![\mathcal{A}]\!](w) = v_0 \ \delta_{\mathcal{X}}(q_0, w) \ o(\delta_Q(q_0, w))$$

We can also identify affine expressions with affine forms and affine substitutions with affine maps to simplify dealing with affine CRA. We define and use these identifications in Appendix A.2 of the full version of this paper [5].

▶ **Proposition 8** ([1]). *There is a bijection between* WA *and linear* CRA *with a single state.*

Given a WA, one can build an equivalent CRA with as many registers as states of the WA: for each letter a, the transition matrix $\mu(a)$ can be interpreted as a (linear) substitution, associated with the self-loop of label a. The converse easily follows from the previous observations when the CRA has a single state.

▶ **Example 9** (Example 2 continued). The CRA depicted on the left of Figure 2 is obtained by the translation of the WA of Figure 1 into CRA with a single state.

▶ Remark 10. Sequential WA are exactly linear CRA with a single register.

Indeed, both sequential WA and linear CRA with only one register are deterministic finite automata that can also store a single value updated at each transition using only products. They can then be identified.

3 Problems and Main Results

▶ **Definition 11** (Register minimization problem). *Given a class* $\mathcal{C}$ *of* CRA*, we ask:*

- ***Input:*** *a rational series* f *realized by a given* WA*, and an integer* $k \in \mathbb{N}$
- ***Question:*** *Does there exist a* CRA *realizing* f *in the class* $\mathcal{C}$ *with at most* k *registers?*

We will show this problem is decidable for the classes of linear and affine CRA:

▶ **Theorem 12.** *The register minimization problem is decidable for the classes of linear and affine* CRA *in 2-*ExpTime*. Furthermore, the algorithm exhibits a solution when it exists.*

For a rational series f, the minimal number of registers needed to realize f using CRA in some class $\mathcal{C}$ is called its *register complexity with respect to class $\mathcal{C}$*. Dually, if one wants to minimize the number of states, then we know we can always build a linear (hence affine) CRA with a single state (Proposition 8). A more ambitious goal is to try to reduce simultaneously the number of states and of registers, in some given class $\mathcal{C}$ of CRA. Observe that, in general, there is no CRA with minimal numbers of both states and registers (see Example 5). Given a rational series f, we say that a pair (n, k) is *optimal* if f can be realized by a CRA in class $\mathcal{C}$ with n states and k registers and no CRA of $\mathcal{C}$ realizing f with at most n states can have strictly less than k registers and vice-versa.

Formally, we call the *state-register complexity with respect to class $\mathcal{C}$* of a rational series f, the set of optimal pairs of integers (n, k).

This leads to the definition of a second minimization problem:

▶ **Definition 13** (State-Register minimization problem)**.** *Given a class $\mathcal{C}$ of* CRA*, we ask:*

- ***Input:*** *a rational series f realized by a given* WA*, and two integers $n, k \in \mathbb{N}$*
- ***Question:*** *Does there exist a* CRA *realizing f in the class $\mathcal{C}$ with at most n states and at most k registers?*

In the sequel, we solve this problem for linear and affine CRA:

▶ **Theorem 14.** *The state-register minimization problem is decidable for the classes of linear and affine* CRA *in NExpTime. Furthermore, the algorithm exhibits a solution when it exists.*

▶ Remark 15. The complexities we give are valid for fields where it is possible to perform elementary operations efficiently (e.g. $\mathbb{Q}$). See Remark 40 for a more detailed discussion on the matter.

4 Characterizing the state-register complexity using invariants of WA

4.1 Zariski topologies and invariants of WA

Let $\mathbb{K}$ be a field and $n \in \mathbb{N}$. The *Zariski topology* on $\mathbb{K}^n$ is defined as the topology whose closed sets are the sets of common roots of a finite collection of polynomials of $\mathbb{K}[X_1, \ldots, X_n]$. A linear version of this topology, called the *linear Zariski topology*, was introduced by Bell and Smertnig in [3]. Its closed sets, which we will call *Z-linear sets*, are finite unions of vector subspaces of $\mathbb{K}^n$.

A set $S \subseteq \mathbb{K}^n$ is called *irreducible* if, for all closed sets C_1 and C_2, such that $S \subseteq C_1 \cup C_2$, we have either $S \subseteq C_1$ or $S \subseteq C_2$. The Zariski topologies defined above are Noetherian topologies in which every closed set can be written as a finite union of irreducible components. We then define the *dimension* of a Z-linear set as the maximum dimension of its irreducible components and their number will be called its *length.*

For a set $S \subseteq \mathbb{K}^n$, $\overline{S}^{\ell}$ will denote its closure in the linear Zariski topology. In this topology, closed irreducible sets are vector subspaces of $\mathbb{K}^n$ and linear maps are continuous and closed maps (mapping closed sets to closed sets). In particular, for all $S \subseteq \mathbb{K}^n$ and linear map $f : \mathbb{K}^n \to \mathbb{K}^n$,$\overline{f(S)}^{\ell} = f(\overline{S}^{\ell})$. Moreover, if $S \subseteq \mathbb{K}^n$ is irreducible and $f : \mathbb{K}^n \to \mathbb{K}^n$ is continuous, then $f(S)$ is irreducible. These properties will be used implicitly in the following (see [3, Lemma 3.5] for more details and references).

We will also define an affine version of this topology that enjoy the same properties in Subsection 4.4.

▶ **Definition 16.** *Let Σ be a finite alphabet and let $\mathcal{R} = (u, \mu, v)$ be a d-dimensional* WA *on Σ over $\mathbb{K}$. A subset $I \subseteq \mathbb{K}^d$ is called an* invariant *of $\mathcal{R}$ if $u \in I$ and, for all $w \in I$ and $a \in \Sigma$, $w\mu(a) \in I$. For two invariants I_1 and I_2, we say that I_1 is* stronger *than I_2 if $I_1 \subseteq I_2$. In particular, the strongest invariant of $\mathcal{R}$ is its* reachability set $\mathsf{LR}(\mathcal{R}) = u\mu(\Sigma^*)$.

An invariant that is also a Z-linear set will be called a Z-linear *invariant. The strongest Z-linear invariant of $\mathcal{R}$ is the closure of* $\mathsf{LR}(\mathcal{R})$ *in the linear Zariski topology (which is well-defined since the topology is Noetherian).*

▶ **Example 17** (Example 2 continued)**.** The reachability set of the WA considered in Example 2 is $\mathsf{LR}(\mathcal{R}) = \{(2^{2n}, 0) \mid n \in \mathbb{N}\} \cup \{(0, 2^{2n+1}) \mid n \in \mathbb{N}\}$. Its strongest Z-linear invariant is then the union of the two coordinate axes of the plane $\overline{\mathsf{LR}(\mathcal{R})}^{\ell} = \mathsf{span}(1,0) \cup \mathsf{span}(0,1)$.

Indeed, the inclusion $\subseteq$ comes from the fact that $u = (1,0) \in \mathsf{span}(1,0)$ and $\mathsf{span}(1,0) \cup \mathsf{span}(0,1)$ is stable by multiplication by $\mu(a)$ and the inclusion $\supseteq$ comes from the fact that, for the linear Zariski topology, $\{(1,0)\}$ is dense in $\mathsf{span}(1,0)$ and $\{(0,2)\}$ is dense in $\mathsf{span}(0,1)$.

▶ Remark 18. In the previous example, the strongest Z-linear invariant is actually the strongest algebraic invariant (*i.e.* closed in the Zariski topology). Of course, this is not always the case.

The Z-linear invariants of two WA realizing the same function do not necessarily coincide but, since $\mathbb{K}$ is a field, it is well-known that for every rational series f, there exists a (computable) minimal WA realizing f that is unique up to similarity in the following sense (see [16, Proposition 4.10 (Chapter III)]):

▶ **Definition 19.** *Let $\mathcal{R} = (u, \mu, v)$ and $\mathcal{R}' = (u', \mu', v')$ be two d-dimensional* WA *over $\mathbb{K}$.*

$\mathcal{R}$ and $\mathcal{R}'$ are said to be similar *if there exists an invertible (change of basis) matrix $P \in \mathbb{K}^{d \times d}$ such that $u' = uP$, $\mu'(a) = P^{-1}\mu(a)P$ for all $a \in \Sigma$ and $v' = P^{-1}v$.*

▶ Remark 20. The Z-linear invariants of two similar WA $\mathcal{R}$ and $\mathcal{R}'$ only differ by a change of basis. i.e. there is a bijection between the Z-linear invariants of $\mathcal{R}$ and those of $\mathcal{R}'$ that, in particular, preserves the length and dimension.

4.2 Strongest invariants and characterization

The notion of strongest Z-linear invariant was introduced by Bell and Smertnig in [3], under the name "linear hull". They showed, in [4], that it is computable and can be used to decide whether a WA is equivalent to a deterministic (or an unambiguous) one.

▶ **Theorem 21** ([3, Theorem 1.3])**.** *A rational series f can be realized by a sequential* WA *iff the strongest Z-linear invariant of a minimal* WA *realizing f has dimension at most 1.*

The following result generalizes this theorem by linking linear CRA to Z-linear invariants. It constitutes the key characterization that will allow us to solve the minimization problems.

▶ **Theorem 22** (Characterization)**.** *Let f be a rational series. Then f can be realized by a linear* CRA *with n states and k registers iff there exists a minimal* WA *realizing f that has a Z-linear invariant of length at most n and dimension at most k.*

As we will see in Subsection 4.4, this theorem can also be extended to affine CRA.

Observe that, thanks to Remark 20, the property of the above characterization is actually valid for *every* minimal WA realizing f. Moreover, since the dimension of the strongest Z-linear invariant is minimal, finding this dimension allows to solve the register minimization problem for linear CRA. This is formalized in the following result, which generalizes Theorem 21 thanks to Remark 10.

▶ **Corollary 23.** *The register complexity of a rational series f w.r.t. the class of linear* CRA *is the dimension of the strongest Z-linear invariant of any minimal* WA *realizing f.*

An immediate consequence of this result is that computing the strongest invariant allows to decide the register minimization problem.

▶ **Example 24** (Example 2 continued)**.** As we have seen in Example 17, $\overline{\mathsf{LR}(\mathcal{R})}^{\ell}$ is 1-dimensional and has two irreducible components, thus $[\![\mathcal{R}]\!]$ can be realized by a CRA with two states and one register (depicted on the right of Figure 2).

4.3 Invariants of minimal WA and correspondence with CRA

▶ **Proposition 25.** *Let $\mathcal{R}$ be a* WA *realizing a rational series f. If $\mathcal{R}$ has a Z-linear invariant of length n and dimension k, then every minimal* WA *realizing f has a Z-linear invariant of length $\leq n$ and dimension $\leq k$.*

Thanks to Remark 20, it suffices to show the existence of one minimal WA verifying the proposition, since they are all similar. It is known (see Proposition 3) that a minimal WA can be obtained from a WA by alternating between two constructions which reduce the dimension to make it match the one of the span of the left (resp. right) reachability set. The result then follows from the next lemma, which states that both constructions decrease the length and dimension of the invariants. We prove it by considering an adequate change of basis, and verifying that it preserves invariants.

▶ **Lemma 26.** *Let $\mathcal{R}$ be a* WA *realizing a rational series f, let $S_{\mathcal{R}}$ be a Z-linear invariant of $\mathcal{R}$ of length n and dimension k and let $r = \dim(\mathsf{span}\,(\mathsf{LR}\,(\mathcal{R})))$. We can construct an r-dimensional* WA *$\mathcal{R}'$ realizing f, with a Z-linear invariant $S_{\mathcal{R}'}$ of length $\leq n$ and dimension $\leq k$. The same holds with $r = \dim(\mathsf{span}\,(\mathsf{RR}\,(\mathcal{R})))$.*

The next proposition allows to go from Z-linear invariants of WA to CRA. This construction builds on the one of [3, Lemma 3.13], in which they build an equivalent WA from the strongest Z-linear invariant of a WA. We show that an analogous construction is valid for any Z-linear invariant, and that we can use states of CRA to represent the different irreducible components of the invariant, thus reducing the number of registers used to the dimension of the invariant.

▶ **Proposition 27.** *Let $\mathcal{R}$ be a* WA*. If $\mathcal{R}$ has a Z-linear invariant of length n and dimension k, then there exists a linear* CRA *$\mathcal{A}$, with n states and k registers, such that $[\![\mathcal{A}]\!] = [\![\mathcal{R}]\!]$.*

The next proposition shows the converse direction, from CRA to invariants of WA. The construction is the classical one from CRA to WA. The existence of the adequate invariant follows from the determinism of the CRA which ensures that in any reachable configuration, only coordinates associated with the reachable state of the CRA can be non-zero.

▶ **Proposition 28.** *Let $\mathcal{A}$ be a linear* CRA*. If $\mathcal{A}$ has n states and k registers, then there exists a* WA *$\mathcal{R}$, with a Z-linear invariant of length n and dimension k, such that $[\![\mathcal{A}]\!] = [\![\mathcal{R}]\!]$.*

Using the three previous propositions, we can finally prove the main characterization:

Proof of Theorem 22. Given a linear CRA with n states and k registers, we can construct, thanks to Proposition 28, an equivalent WA with a Z-linear invariant of length n and dimension k. Then the desired minimal WA exists thanks to Proposition 25.

Reciprocally, applying the construction of Proposition 27 to any minimal WA gives the desired linear CRA. ◀

As we will discuss in the next subsection below, the three propositions we used for this proof can also be adapted to yield the same result for affine CRA.

4.4 Z-affine invariants and affine CRA

All the results of Section 4 can actually be extended to affine CRA using the *affine Zariski topology* instead of the linear one. It is a slight generalization of the linear Zariski topology where closed sets, called *Z-affine* sets, are finite unions of affine spaces instead of vector spaces, with lengths and dimensions defined like in the linear case. It is still a Noetherian topology coarser than the Zariski topology, affine maps are continuous and closed maps in this topology and, more broadly, it enjoys the same properties as the linear Zariski topology we considered throughout this section. For a set $S \subseteq \mathbb{K}^n$, we will denote by $\overline{S}^a$ it closure in the affine Zariski topology and, similarly to the linear case, for a WA $\mathcal{R} = (u, \mu, v)$, we will call any invariant of $\mathcal{R}$ that is a Z-affine set a *Z-affine invariant* of $\mathcal{R}$. Of course, the strongest Z-affine invariant of $\mathcal{R}$ is still the closure of its reachability set i.e. its "affine hull" $\overline{\mathsf{LR}(\mathcal{R})}^a$ and Remark 20 is still true for Z-affine invariants.

We obtain the same characterization of Theorem 22 in the affine setting :

▶ **Theorem 29** (Characterization). *Let f be a rational series. Then f can be realized by an affine* CRA *with n states and k registers iff there exists a minimal* WA *realizing f that has a Z-affine invariant of length at most n and dimension at most k.*

We can show that Propositions 25, 27 and 28 are also true if we replace Z-linear invariants by Z-affine ones and linear CRA by affine ones. So, the proof of Theorem 29 remains the same as Theorem 22. All the details can be found in Appendix A.2 of the full version of this paper [5].

Of course, this theorem has the same consequences of its linear counterpart and we obtain an affine version of Corollary 23

▶ **Corollary 30.** *The register complexity of a rational series f w.r.t. the class of affine* CRA *is the dimension of the strongest Z-affine invariant of any minimal* WA *realizing f.*

Working in the affine Zariski topology instead of the linear one can decrease the dimension of the strongest invariant by one, as shown in the following example.

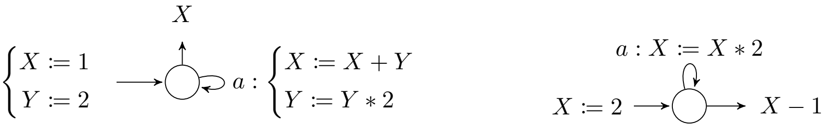
▶ **Example 31.** On the alphabet $\Sigma = \{a\}$, let $\mathcal{R} = (u, \mu, v)$, where $u = (1, 2)$, $\mu(a) = \begin{pmatrix} 1 & 0 \\ 1 & 2 \end{pmatrix}$ and $v = (1, 0)^t$, be a WA (over $\mathbb{R}$) realizing the rational series f defined by $f(a^n) = \sum_{i=0}^{n} 2^i = 2^{n+1} - 1$.

The reachability set of $\mathcal{R}$ is $\mathsf{LR}(\mathcal{R}) = \left\{ \left(\sum_{i=0}^{n} 2^i, 2^{n+1}\right) \,\middle|\, n \in \mathbb{N} \right\}$.

For the linear Zariski topology, $\mathsf{LR}(\mathcal{R})$ is dense in $\mathbb{R}^2$. So the strongest Z-linear invariant $\overline{\mathsf{LR}(\mathcal{R})}^\ell = \mathbb{R}^2$ is two-dimensional. However, note that, for all $(x, y) \in \mathsf{LR}(\mathcal{R})$, $y = x + 1$. So, by an argument of density in the affine Zariski topology, the strongest Z-affine invariant $\overline{\mathsf{LR}(\mathcal{R})}^a$ is the affine line $y = x + 1$, which is one-dimensional.

Thus, in the case where the dimensions of the affine and linear hulls doesn't match, using affine CRA instead of linear CRA can allow to save one register :

▶ **Example 32** (Example 31 continued). The two CRA depicted on Figure 3 both realize the function of Example 31. On the left we have a linear CRA with two registers and, on the right, an affine CRA with only one register. The characterization theorems show that both have the minimal number of registers for their respective classes of CRA.



$\begin{cases} X := 1 \\ Y := 2 \end{cases}$
X
$a : \begin{cases} X := X + Y \\ Y := Y * 2 \end{cases}$
$a : X := X * 2$
$X := 2$
$X - 1$

Figure 3 Two CRA detailed in Example 32.

5 Algorithms and complexity for the minimization problems

We present two original algorithms to solve the minimization problems we consider. It is worth observing the difference between the two characterizations we have obtained: while the register complexity can be computed from a canonical object (the strongest Z-linear invariant of the WA), the state-register complexity is based on the existence of a particular Z-linear invariant. This explains why we derive a non-deterministic procedure for the latter, and a deterministic for the former.

5.1 Algorithm for the state-register minimization problem

We provide here a NExpTime algorithm for the state-register minimization problem, hence proving Theorem 14. The algorithm runs in NPTime in n, k, and the size of the automaton. The fact that n is given in binary explains the exponential discrepancy.

Small representations of Z-affine sets. Let $\mathcal{R} = (u, \mu, v)$ be a WA of dimension d over an alphabet Σ. Let $L = A_1 \cup \cdots \cup A_n$ be a Z-affine set of length n of $\mathbb{K}^d$.

An $\mathcal{R}$-representation R of L is a set of n finite sets of words $S_1, \ldots, S_n$ such that $\mathsf{aff}\left(\{u\mu(w) | \; w \in S_i\}\right) = A_i$ for all $i \in \{1, \cdots, n\}$. The *size* of R is the sum of the lengths of all words appearing in R. The following key lemma shows that all Z-affine invariants of $\mathcal{R}$ have small $\mathcal{R}$-representations, up to considering stronger invariants.

▶ **Lemma 33.** *Let $\mathcal{R}$ be a* WA*. Let I be a Z-affine invariant of $\mathcal{R}$ of length n and dimension k. There exists an $\mathcal{R}$-representation R of size $\leq n^2k^2$ of a Z-affine invariant $J \subseteq I$, of dimension $\leq k$ and length $\leq n$.*

This property allows to derive the non-deterministic algorithm. First, minimization of a WA over a field can be performed in polynomial time (see e.g. [16, Corollary 4.17]). Then, let $\mathcal{R}$ be a minimal WA and let k, n be positive integers. From Lemma 33, we know that a Z-affine invariant of dimension k and length n can be represented in size $O(k^2n^2)$ (up to finding a stronger invariant with smaller dimension and length). The algorithm works thusly: first step is to guess an $\mathcal{R}$-representation R of a Z-affine set. The second step is to check that R represents an invariant, which can be done easily using basic linear algebra. From this one can compute an affine CRA with k registers and n states. Moreover, if we require that R is Z-linear, we obtain a linear CRA. If R is not an invariant, the computation rejects. Note that different accepting computations may give rise to different invariants and thus different CRAs.

5.2 Algorithm for the computation of Z-affine invariants

We describe a deterministic procedure which, given a WA $\mathcal{R}$ and an integer c, returns a Z-affine invariant J which is stronger that any Z-affine invariant I of $\mathcal{R}$ of length at most c. When c is chosen large enough, this procedure returns the strongest Z-affine invariant of $\mathcal{R}$. A similar procedure works as well for the computation of Z-linear invariants.

Algorithm 1 Computing a Z-affine invariant.

```
Require: A WA $\mathcal{R} = (u, \mu, v)$ of dimension $d$, an integer $c$
Ensure: A Z-affine invariant $J$ of $\mathcal{R}$ stronger than $I_c(\mathcal{R})$
1: $J \coloneqq \{u\}$
2: while $J$ is not an invariant of $\mathcal{R}$ do
3:     Pick some component $A$ of $J$, and some matrix $M$ of $\mathcal{R}$ s.t. $A \cdot M \not\subseteq J$
4:     $J \coloneqq J \cup A \cdot M$
5:     if length$(J) > c^d$ then
6:         $J \coloneqq$ REDUCE$(J)$
7:     end if
8: end while
9: return $J$
```

Intuitively, this procedure will build a Z-affine set J as follows: it starts with a set containing only the initial vector of $\mathcal{R}$, and incrementally extends it until it forms an invariant. During this process, it should ensure that J is included in every Z-affine invariant I of $\mathcal{R}$ of length at most c. This relies on the following easy observation: if such an invariant I contains at least $c + 1$ points on the same affine line (*i.e.* a 1-dimensional affine space, denoted D), then I must have a component that contains D. Indeed, as I has length at most c, one of its components contains two such points. As this component is irreducible, it is an affine subspace, hence contains D. This reasoning can be lifted to higher dimensions as follows.

Given a WA $\mathcal{R}$, and $c \in \mathbb{N}$, we denote by $I_c(\mathcal{R}) = \bigcap_{\mathrm{length}(I) \leq c} I$ the intersection of all Z-affine invariants of $\mathcal{R}$ with at most c components.

▶ **Lemma 34.** *Let $\mathcal{R}$ be a* WA *and let $c, k \in \mathbb{N}$. Let $A_1, \ldots, A_{c^k+1} \subseteq I_c(\mathcal{R})$ be affine spaces such that: for any $P \subseteq [\![1, c^k + 1]\!]$ with $|P| \geq c^{k-1} + 1$,* $\mathsf{aff}\left(\cup_{i \in P} A_i\right)$ *has dimension k. Then* $\mathsf{aff}\left(\cup_{i \in [\![1,c^k+1]\!]} A_i\right) \subseteq I_c(\mathcal{R})$*.*

Using this lemma, we derive an effective procedure to simplify a Z-affine set $J = A_1 \cup \cdots \cup A_{c^d+1}$ by "merging" two components. We denote by REDUCE(J) the resulting set.

▷ Claim 35. Let $\mathcal{R} = (u, \mu, v)$ be a WA of dimension d, let $c \in \mathbb{N}$. Let $A_1, \ldots, A_{c^d+1} \subseteq I_c(\mathcal{R})$ be affine spaces. One can find $1 \leq i < j \leq c^d + 1$ such that $\mathsf{aff}\left(A_i \cup A_j\right) \subseteq I_c(\mathcal{R})$, in time $O(c^{p(d)})$, for some fixed polynomial p.

▶ **Theorem 36.** *Algorithm 1 is correct and terminates in time $O(c^{p(d)})$.*

Proof. Let us first discuss termination. Because of line 5-7, the length of J is at most $c^d + 1$. Moreover J is an increasing Z-affine set, thus its value can be modified at most $(d+1) \cdot (c^d + 1)$ times, thus from Claim 35 the algorithm terminates in time $O(c^{p(d)})$.

We now discuss correctness. We need to show that J is stronger than $I_c(\mathcal{R})$. Initially, this holds. Moreover, if $A \subseteq I_c(\mathcal{R})$ is an affine set, then for any $M \in \mu(\Sigma), A \cdot M \subseteq I_c(\mathcal{R})$, since $I_c(\mathcal{R})$ is invariant. Thus, line 4 preserves the property that J is stronger than $I_c(\mathcal{R})$. Using Claim 35, the REDUCE subroutine also preserves this property, since it only merges components whose affine span is contained in $I_c(\mathcal{R})$. ◀

5.3 Complexity of the register minimization problem

In order to compute the strongest Z-linear and Z-affine invariants of a WA using Algorithms 1, it is sufficient to be able to bound their lengths. The following result gives such bounds.

▶ **Theorem 37.** *Let $\mathcal{R} = (u, \mu, v)$ be a d-dimensional* WA *on a finite alphabet Σ. We have the following upper bounds :*

- *The lengths of $\overline{\mathsf{LR}(\mathcal{R})}^{\ell}$ and $\overline{\mathsf{LR}(\mathcal{R})}^{a}$ are at most doubly-exponential in d.*
- *If $\langle\mu(\Sigma)\rangle$ is commutative (*e.g.* Σ is unary), then the length of $\overline{\mathsf{LR}(\mathcal{R})}^{\ell}$ is at most exponential in d.*

We also have the following lower bound (which also hold for WA *over a unary alphabet):*

- *For all $d > 0$, there exist a d-dimensional* WA *having strongest Z-linear and Z-affine invariants with lengths exponential in d.*

Proof sketch. The first item is shown in [4], where the authors sketch a proof of a double-exponential upper bound on the length of the strongest Z-linear invariant of a WA, using tools from algebraic geometry, which holds for $\mathbb{Q}$ in particular and for any field $\mathbb{K}$ where there is a double-exponential bound on the maximal order of finite groups of invertible matrices (see [4, Proposition 48 and Remark 41]). Their proof can be adapted to $\overline{\mathsf{LR}(\mathcal{R})}^{a}$. The proof of the second item relies on basic linear algebra and on results and ideas from [4] for invertible matrices (see [4, Lemma 13 and Theorem 10]). Last, the lower bound is shown using a family of WA $(\mathcal{R}_i)_{i\in\mathbb{N}}$ whose dimension is polynomial in i and strongest Z-linear invariant has a length that is exponential in i. It is defined, using permutation matrices of dimension p, for some prime number p, which generate cyclic groups. The family is obtained by using block matrices composed of such permutation matrices. All the details are given in Appendix B.4 of the full version of this paper [5]. ◀

Thanks to this theorem, using Algorithm 1 with a large enough c (at most doubly-exponential in the dimension of the given WA), and thanks to Theorem 36, we can prove the following result:

▶ **Theorem 38.** *The strongest Z-linear/affine invariant of a* WA *is computable in 2-*EXPTIME*.*

This allows us to prove Theorem 12. Indeed, given a WA $\mathcal{R}$, we first compute an equivalent minimal WA, which can be done in polynomial time (see e.g. [16, Corollary 4.17]). Then, using Algorithm 1, we compute the strongest Z-linear (resp. Z-affine) invariant of $\mathcal{R}$. Corollary 23 (resp. Corollary 30) ensures that its dimension is the register complexity of f w.r.t. the class of linear (resp. affine) CRA, and the effectiveness follows from Proposition 27 (resp. its affine version).

Moreover, thanks to Theorem 38 and the results of [3], we also have:

▶ **Theorem 39.** *The sequentiality and unambiguity of a rational series are in 2-*EXPTIME*.*

Note that the complexities of the last two theorems drop down to EXPTIME when we have a simply exponential bound on the length of the strongest invariant. This is the case when one considers unary alphabets or WA with commuting transition matrices in the linear setting, as stated in Theorem 37. In these cases, the bound is sharp. It is still not clear however whether it is possible to close the gap between the bounds in the general case.

▶ Remark 40. It is also worth noting that, while the characterizations that we obtained are valid for any field, the complexities of the algorithms are given in terms of number of elementary operations over the considered field. Which means that they hold for fields where we can perform basic operations in polynomial time (such as $\mathbb{Q}$ or its finite extensions). Moreover, the general upper bounds on the lengths given by Theorem 37 were proven only for fields verifying a specific property (which is verified by $\mathbb{Q}$). See the proof for more details.

5.4 State/register tradeoff

Reducing the number of registers may increase the number of states and vice-versa. The following theorem summarizes what we know on this tradeoff.

▶ **Theorem 41.** *Let f be a rational series realized by some d-dimensional* WA $\mathcal{R}$*. Consider some pair of integers (n, k) optimal for f w.r.t. the class of linear* CRA*. The inequalities* $1 \leq n \leq \mathrm{length}(\overline{\mathsf{LR}\,(\mathcal{R})}^{\ell}) = O(2^{2^d})$ *and* $\dim(\overline{\mathsf{LR}\,(\mathcal{R})}^{\ell}) \leq k \leq d$ *hold true.*

(They are valid in the affine setting as well)

▶ Remark 42. Building the CRA from the strongest invariant is not always optimal. There are some cases where it is possible to reduce the number of states of a CRA exponentially, while keeping the minimal number of registers, by choosing an invariant that is weaker than the strongest Z-linear/Z-affine invariant but shorter.

6 Conclusion

We have shown how to decide variants of CRA minimization problems, and have given complexity for the respective algorithms. There are several ways in which these algorithms could be improved. First, it would be worth reducing the gap between the lower and the upper bounds on the length of the strongest Z-linear invariant. Second, identifying a canonical invariant associated with the state-register minimization problem would allow to derive a deterministic algorithm for this problem. Third, one could hope for better complexity if one only considers the existence of equivalent CRA. For instance, in [13] the authors give a PSpace algorithm for the determinization problem (i.e. 1-register minimization problem) in the case of a polynomially ambiguous automaton, via a quite different approach.

Another line of research consists in trying to use the techniques we developed to solve the register minimization problem for other classes of CRA, for instance copyless CRA (which correspond to multi-sequential WA). Another ambitious goal is to consider register minimization in the context of different semirings, but there all the linear algebra tools which are crucial to solving these problems completely break down. Similarly, it seems that register minimization for polynomial automata would be very difficult: it was shown recently in [12] that the strongest algebraic invariant of a polynomial automaton is not computable. One possibility may be to bound the “degree” of the invariants, where Z-affine sets would correspond to algebraic sets of degree one.

Abstract

We study Dominated Cluster Deletion. Therein, we are given an undirected graph $G = (V, E)$ and integers k and d and the task is to find a set of at most k vertices such that removing these vertices results in a graph in which each connected component has a dominating set of size at most d. We also consider the special case where d is a constant. We show an almost complete tetrachotomy in terms of para-NP-hardness, containment in XP, containment in FPT, and admitting a polynomial kernel with respect to parameterizations that are a combination of k, d, c, and Δ, where c and Δ are the degeneracy and the maximum degree of the input graph, respectively. As a main contribution, we show that the problem can be solved in $f(k, d) \cdot n^{O(d)}$ time, that is, the problem is FPT when parameterized by k when d is a constant. This answers an open problem asked in a recent Dagstuhl seminar (23331). For the special case $d = 1$, we provide an algorithm with running time $2^{\mathcal{O}(k \log k)}nm$. Furthermore, we show that even for $d = 1$, the problem does not admit a polynomial kernel with respect to $k + c$.

1 Introduction

Cluster Vertex Deletion is an important problem in theoretical computer science [3, 22]. Therein, one is given a graph and the task is to delete as few vertices as possible such that the resulting graph is a *cluster graph*, that is, a graph in which each connected component is a clique. However in many real-world applications, it is often too restrictive to require that each connected component is a clique. For this reason, many generalizations (but also special cases) of Cluster Vertex Deletion have been studied. Examples include variants where each connected component in the resulting graph is an s-club (a graph of diameter at most s) [12, 19] or an s-plex (a graph in which each vertex has degree at least $n - s$) [15, 23]. The special case, where each clique in the solution graph has to be of size one is Vertex Cover, one of the most studied problems in the entire field of theoretical computer science [1, 16].

Different problems of this clustering type were explored in the recent Dagstuhl seminar on "Recent Trends in Graph Decomposition" [2]. Starting from the observation that each connected component of the resulting graph in Cluster Vertex Deletion contains a dominating set of size 1, the participants introduced a problem that explores a generalization in which the resulting connected components (clusters) satisfy other "simple integrity requirements" (see Ajwani et al. [2]). The notion they came up with was the following.

Dominated Cluster Deletion

Input: A graph G and positive integers k and d.

Question: Is there a set S of at most k vertices such that the domination number of each connected component of $G - S$ is at most d?

In this work, we consider both Dominated Cluster Deletion as well as the special case where d is a constant. We refer to the latter problem as d-Dominated Cluster Deletion. A natural question to ask is whether Dominated Cluster Deletion is fixed parameter tracatble (FPT) when parameterized by $k+d$? That is, can the problem be solved in $f(k,d) \cdot n^{\mathcal{O}(1)}$, where f is a function that depends only on k and d. Unfortunately, even for $k = 0$, the problem corresponds to the Dominating Set, and hence it is unlikely to be FPT, as Dominating Set is W[2]-complete parameterized by solution size [10]. This led the participants of the Dagstuhl seminar to ask for a parameterized tractability result, where d is allowed to play an XP-role in the exponent of the polynomial. In particular, they ask the following question, which we answer in the affirmative.

Can Dominated Cluster Deletion be solved in $f(k,d) \cdot n^{\mathcal{O}(d)}$ time?

Our Results. We study Dominated Cluster Deletion and d-Dominated Cluster Deletion and show an almost complete tetrachotomy in terms of para-NP-hardness, containment in XP, containment in FPT, and admitting a polynomial kernel with respect to parameterizations that are a combination of k, d, c, and Δ, where c and Δ are the degeneracy and the maximum degree of the input graph, respectively. As a main contribution and using the framework of *recursive understanding*, we show that the problem can be solved in $f(k,d) \cdot n^{O(d)}$ time, that is, the problem is FPT when parameterized by k when d is a constant. For the special case $d = 1$, we provide an algorithm with running time $2^{\mathcal{O}(k \log k)}nm$. Furthermore, we show that even for $d = 1$, the problem does not admit a polynomial kernel with respect to $k + c$ using OR-cross-compositions. Our results are summarized in Figure 1.

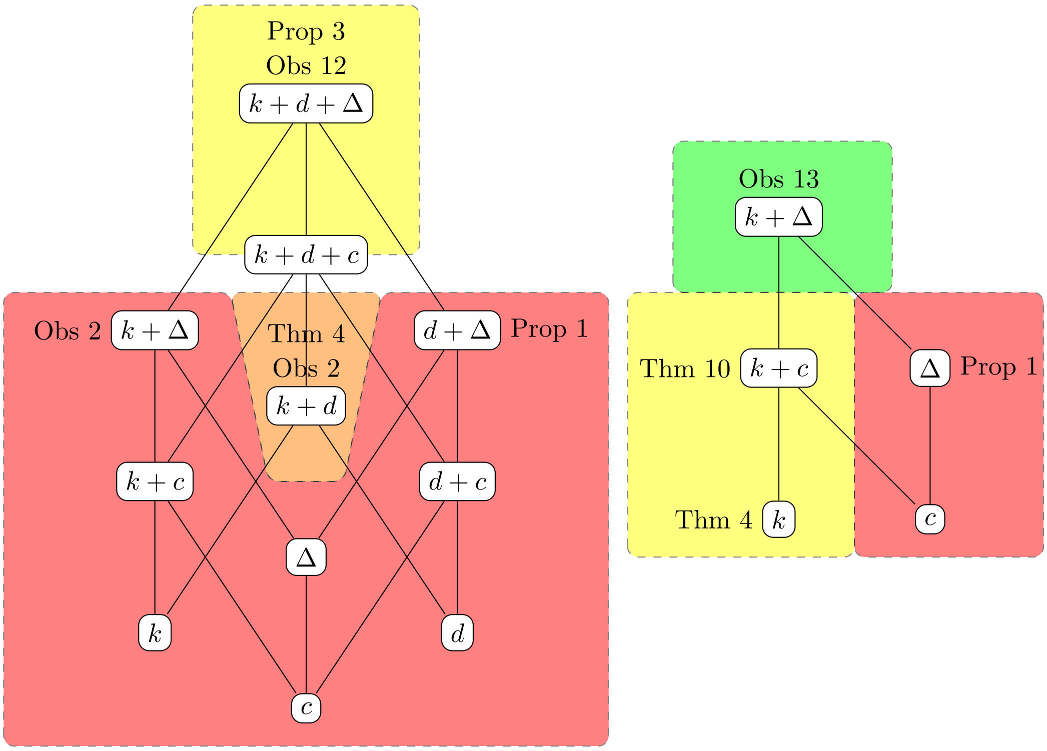

Figure 1 Overview over our results. Results for Dominated Cluster Deletion are shown on the left and results for d-Dominated Cluster Deletion are shown on the right. Therein, k and d are the input values and c and Δ are the degeneracy and the maximum degree of the input graph, respectively. An edge between two parameters α and β where β is above α indicates that the value of β in any instance will always be larger than the value of α in that instance. Any hardness result for β immediately implies the same hardness result for α and any positive result for α immediately implies the same positive result for β. The red boxes indicate parameters that lead to para-NP-hardness (NP-hardness for constant parameter values), an orange box indicates that the problem is in XP and W[1]-hard, a yellow box indicates that the parameterized problem is fixed-parameter tractable, but does not admit a polynomial kernel, and a green box indicated that the problem admits a polynomial kernel. We remark that all negative results apply even if the input graph is connected with the exception of $k+d+\Delta$, which does not admit a polynomial kernel in general but does so when the input graph is connected. We do not know whether Dominated Cluster Deletion parameterized by $k+d+c$ is fixed-parameter tractable or W[1]-hard.

2 Preliminaries and Basic Observations

We consider only undirected simple graphs and use the standard graph-theoretic terminology (see, e.g., [9]). Throughout the paper, we use n and m to denote the number of vertices and edges of G, respectively. For a set of vertices $X \subseteq V(G)$, $G[X]$ denotes the subgraph of G induced by the vertices in X. We define $G - X = G[V(G) \setminus X]$ and we write $G - v$ instead of $G - \{v\}$ for a single vertex. For a vertex v, $N_G(v)$ denotes the *open neighborhood* of v, that is, the set of vertices adjacent to v, and $N_G[v] = \{v\} \cup N_G(v)$ is the *closed neighborhood*. For $X \subseteq V(G)$, we define $N_G(X) = \left(\bigcup_{v\in X} N_G(v)\right) \setminus X$ and $N_G[X] = \bigcup_{v\in X} N_G[v]$. For a vertex v, $d_G(v) = |N_G(v)|$ denotes the *degree* of v. We write $P = v_0v_1 \ldots v_\ell$ to denote the path P with vertices $v_0, v_1, \ldots, v_\ell$ and edges $\{v_{i-1}, v_i\}$ for $i \in \{1, \ldots, \ell\}$. The vertices v_0 and v_ℓ are the *end-vertices* of P. The *length* of P is the number of edges of P. For a path P

with end-vertices u and v, we say that P is a (u, v)*-path.* A (u, v)-path of minimum length is a *shortest* (u, v)-path. We also say that P is a shortest path if P is a shortest (u, v)-path for the end-vertices u and v of P. A graph G is *connected* if for every two vertices u and v, G contains a path whose end-vertices are u and v. A *connected component* (or simply a *component*) is an inclusion maximal induced connected subgraph of G. The *diameter* of a connected graph G is the maximum length of a shortest (u, v)-path where the maximum is taken over all pairs of vertices u and v. A vertex u *dominates* $v \in V(G)$ if $v \in N_G[u]$. A set of vertices $D \subseteq V(G)$ is a *dominating set* if every vertex $v \in V(G)$ is dominated by some vertex of D, that is, $N_G[D] = V(G)$. The minimum size of a dominating set is called the *domination number* of G and is denoted by $\gamma(G)$. For two distinct vertices u and v of a graph G, a set $S \subseteq V(G)$ is a (u, v)*-separator* if $G - S$ has no (u, v)-path. A pair (A, B), where $A, B \subseteq V(G)$ and $A \cup B = V(G)$, is called a *separation* of G if there is no edge $\{u, v\}$ with $u \in A \setminus B$ and $v \in B \setminus A$. In other words, $A \cap B$ is a (u, v)-separator for every $u \in A \setminus B$ and $v \in B \setminus A$. We consider only separations with $A \setminus B \neq \emptyset$ and $B \setminus A \neq \emptyset$. The *order* of (A, B) is $|A \cap B|$.

We refer to the books of Downey and Fellows [11] and Cygan et al. [7] for a detailed introduction to parameterized complexity theory. Formally, a *parameterized problem* is a language $L \subseteq \Sigma^* \times \mathbb{N}$, where Σ^* is a set of strings over a finite alphabet Σ. This means that an input of a parameterized problem is a pair (x, k), where x is a string over Σ and $k \in \mathbb{N}$ is a *parameter.* A parameterized problem is *fixed-parameter tractable* (or FPT) if it can be solved in $f(k) \cdot |x|^{\mathcal{O}(1)}$ time for some computable function f. We also say that a parameterized problem belongs to the class XP if it can be solved in $|x|^{f(k)}$ time for some computable function f. The complexity class FPT contains all fixed-parameter tractable parameterized problems.

A *kernelization algorithm* (or *kernel*) for a parameterized problem is a polynomial-time algorithm that maps each instance (x, k) of a parameterized problem L to an instance (x', k') of the same problem such that (i) $(x, k) \in L$ if and only if $(x', k') \in L$, and (ii) $|x'| + k' \leq f(k)$ for some computable function f. A kernel is *polynomial* if f is polynomial. While it can be shown that every decidable parameterized problem is FPT if and only if it admits a kernel, it is unlikely that every problem in FPT has a polynomial kernel. In particular, the standard *cross-composition* technique [4] can be used to show that a parameterized problem has no polynomial kernel unless NP $\subseteq$ coNP /poly.

In the conclusion of the section, we show a couple of simple observations. We start by showing that Dominated Cluster Deletion is NP-complete. Notice that the property that each connected component of a graph has a dominating set of size at most d is not hereditary and we cannot use the general result of Lewis and Yannakakis [18] about deletion problems.

▶ **Proposition 1.** *For any constant $d \geq 1$, d-Dominated Cluster Deletion is* NP*-complete in graphs of maximum degree* 4.

Proof. We reduce from Vertex Cover in graphs of maximum degree 3, which is known to be NP-hard [14]. We remind that a set S of vertices in a graph G is a *vertex cover* if for each edge $\{u, v\}$ in G, $u \in S$ or $v \in S$. Then, the task of Vertex Cover is the following. Given a graph G and a positive integer k, decide whether G has a vertex cover of size at most k.

Let (G, k) be an instance of Vertex Cover where the maximum degree in G is 3. We construct the graph G' as follows:

- construct a copy of G,
- for each vertex $v \in V(G)$, construct a path P_v on $3d$ vertices and identify one end-vertex of P_v with v.

Note that the maximum degree in G' is four. We claim that G has a vertex cover of size at most k if and only if (G', k) is a yes-instance of d-Dominated Cluster Deletion.

If G has a vertex cover S of size at most k, then each connected component of $G - S$ is either P_v or $P_v - v$ for $v \in V(G)$. Observe that $\gamma(P_v) = \gamma(P_v - v) = d$. Thus, S is a solution to the instance (G', k) of d-Dominated Cluster Deletion, that is, (G', k) is a yes-instance.

For the opposite direction, assume that (G', k) is a yes-instance of Dominated Cluster Deletion, that is, there is a set $S' \subseteq V(G')$ of at most k vertices such that for each connected component C of $G' - S'$, $\gamma(C) \leq d$. We construct the set $S \subseteq V(G)$ from S' by replacing each vertex $u \in S' \setminus V(G)$ by the nearest vertex in G. This means that if u is a vertex of $P_v - v$ for some $v \in V(G)$ then u is replaced by v. Clearly, $|S| \leq |S'| \leq k$. We claim that S is a vertex cover of G. The proof is by contradiction. Assume that there is an edge $\{u, v\}$ of G such that $u \notin S$ and $v \notin S$. By the construction of S, we have that $V(P_u) \cap S' = \emptyset$ and $V(P_v) \cap S = \emptyset$. This means that the vertices of P_u and P_v are in the same component C of $G' - S'$. However, any set D_u dominating the vertices of $P_u - u$ has size at least d. Symmetrically, we need at least d vertices to dominate the vertices of $P_v - v$. This implies that $\gamma(C) \geq 2d > d$; a contradiction. We obtain that S is a vertex cover of G of size at most k. This concludes the proof. ◀

We next observe that Dominated Cluster Deletion with $k = 0$ is equivalent to Dominating Set on connected input graphs. In Dominating Set, we ask whether a graph G has a dominating set of size at most d. It is well-known that Dominating Set is W[2]-complete when parameterized by the solution size and hence, an algorithm with running time $f(d) \cdot n^{\mathcal{O}(1)}$ would contradict the basic assumptions of parameterized complexity that FPT $\neq$ W[2] [11]. Furthermore, the existence of an algorithm running in $f(k) \cdot n^{o(d)}$ time would contradict the Exponential Time Hypothesis (ETH) of Impagliazzo, Paturi, and Zane [17] (we refer to the textbook by Cygan et al. [7] for an introduction to computational lower bounds based on the ETH). Finally, Dominating Set is NP-hard on graphs of maximum degree 3 [5].

▶ **Observation 2.** *Dominated Cluster Deletion with $k = 0$ is NP-hard on subcubic graphs,* W[2]*-hard on general graphs, and any $f(k) \cdot n^{o(d)}$-time algorithm for it would contradict the ETH.*

Finally, we show that Dominated Cluster Deletion is fixed-parameter tractable when parameterized by $k + d + \Delta$.

▶ **Proposition 3.** *Dominated Cluster Deletion can be solved in $\mathcal{O}((d(\Delta + 1) + 1)^k \cdot 3^{d(\Delta+1)} \cdot (n + m))$ time.*

Proof. We construct a simple branching algorithm as follows. First, we find any connected subgraph with $d(\Delta + 1) + 1$ vertices. Note that any connected component in the graph obtained after removing a solution S can contain at most $d(\Delta + 1)$ vertices as it has a dominating set of size d and the maximum degree is Δ. Hence, each of the d vertices in the dominating set can dominate at most $(\Delta + 1)$ vertices each. Thus, at least one vertex of the chosen connected subgraph is contained in the solution S and we branch on that vertex and reduce k by one. After reaching depth k in the search tree, we discard the current branch if we can still find a connected subgraph with $d(\Delta + 1) + 1$ vertices. Each remaining branch represents a graph in which each connected component contains at most $d(\Delta + 1)$ vertices. For each such component, we can compute an optimal solution in $\mathcal{O}(3^{d(\Delta+1)}(n + m))$ time by trying all possible choices of assigning vertices in the subgraph to the solution S, the dominating set, or the rest of the graph. We can then check in linear time whether the current assignment is a valid solution and remember the solution that assigns a minimum number of vertices to S. Finally, we sum up all the optimal values for k in each of the connected components to check whether the current branch in the search tree leads to a solution. If any branch leads to a solution, then we return yes and otherwise we return no. The correctness follows from the fact that we exhaustively search for all possible solutions and the running time is in $\mathcal{O}((d(\Delta+1)+1)^k \cdot 3^{d(\Delta+1)} \cdot (n+m))$. This concludes the proof. ◀

3 An FPT algorithm for d-Dominated Cluster Deletion

In this section, we show d-Dominated Cluster Deletion parameterized by k is fixed-parameter tractable. This also shows that Dominated Cluster Deletion is contained in XP.

▶ **Theorem 4.** *For every positive integer d, d-Dominated Cluster Deletion can be solved in $f(k,d) \cdot n^{\mathcal{O}(d)}$ time.*

We remark that the exponential dependency on d of the polynomial part of the running time seems unavoidable by Observation 2. We prove Theorem 4 by applying the *recursive understanding* technique introduced by Chitnis et al. [6] and using the meta theorem of Lokshtanov et al. [20]. The meta theorem considerably simplifies the arguments. However, the proof becomes nonconstructive and we can only claim a nonuniform FPT algorithm. Still, a uniform FPT algorithm may be given using the techniques of Chitnis et al. [6] or the dynamic programming approach of Cygan et al. [8].

The meta theorem of Lokshtanov et al. [20] allows to reduce solving a graph problem on general graphs to highly connected graphs. Let p, q be positive integers. A graph G is said to be (p,q)-*unbreakable* if for every separation (A,B) of G of order at most q, either $|A \setminus B| \leq p$ or $|B \setminus A| \leq p$, that is, G has no separator of size at most q that partitions the graph into two parts of size at least $p+1$ each.

We remind that in *monadic second-order logic* (MSO) on graphs, we have logical connectives $\vee$, $\wedge$, $\neg$, and variables for vertices, edges, and sets of vertices and edges. We can apply the quantifiers $\forall$ and $\exists$ to these variables and use the predicates (i) $x \in X$ where x is a vertex (respectively, edge) variable and X is a vertex (respectively, edge) set variable, (ii) $inc(u,e)$ where u is a vertex variable and e is an edge variable that denotes that u is incident to e, (iii) $adj(u,v)$ where u and v are vertex variables denoting the adjacency of u and v, and (iv) the equality predicate for variables of the same type. The *counting monadic second-order logic* (CMSO) extends MSO by allowing testing whether the cardinality of a set is equal to p modulo q for integers $0 \leq p < q$ with $q \geq 2$. Given a CMSO sentence φ, the task of the model-checking problem for φ (denoted by CMSO[φ]) is to decide whether $G \models \varphi$ for a graph G. Lokshtanov et al. [20] proved the following result.

▶ **Proposition 5** ([20]). *Let φ be a CMSO sentence. For all positive integers q, there exists a positive integer p such that if there exists an algorithm that solves CMSO[φ] on (p,q)-unbreakable graphs in $\mathcal{O}(n^c)$ time for some $c > 4$ then there exists an algorithm that solves CMSO[φ] on general graphs in $\mathcal{O}(n^c)$ time.*

To apply Proposition 5, we observe that Dominated Cluster Deletion can be expressed in MSO.

▶ **Observation 6.** *For given $d \geq 1$ and $k \geq 0$, there is a MSO sentence φ (depending on d and k) such that $G \models \varphi$ if and only if (G,k) is a yes-instance of Dominated Cluster Deletion.*

Proof. For $k = 0$, (G, k) is a yes-instance of Dominated Cluster Deletion if and only if every connected component C of G has a dominating set of size at most d, that is, it holds that $\exists v_1 \in V(C)\colon \dots \exists v_d \in V(C)\colon \forall w \in V(C)\colon (w = v_1) \vee \dots \vee (w = v_d) \vee adj(w, v_1) \vee \dots \vee adj(w, v_d)$. Further, we have that $C = G[X]$ for $X \subseteq V(G)$ is a connected component of G if and only if $G[X]$ is connected and for any proper superset Y of X, $G[Y]$ is not connected. It is standard to express the connectivity of $G[X]$ as follows: $\forall Z \subset X\colon\ \exists u \in Z\colon\ \exists v \in X \setminus Z\colon adj(u, v)$. This proves that the property that $(G, 0)$ is a yes-instance of Dominated Cluster Deletion can be expressed in MSO.

For $k \geq 1$, (G, k) is a yes-instance of Dominated Cluster Deletion if and only if $(G, 0)$ is a yes-instance or $\exists v_1 \in V(G) \dots \exists v_k \in V(G)$ such that every connected component C of $G - \{v_1, \dots, v_k\}$ has a dominating set of size at most d. It is straightforward to modify the formula for $k = 0$ to get an MSO sentence for the case $k \geq 1$. ◀

We next show that d-Dominated Cluster Deletion is fixed-parameter tractable for unbreakable graphs. More precisely, we prove the following lemma.

▶ **Lemma 7.** *Let p and k be positive integers. Then, d-Dominated Cluster Deletion can be solved in $(p + k)^{\mathcal{O}(k+d)} \cdot n^{\mathcal{O}(d)}$ time on (p, k)-unbreakable graphs.*

Proof. Let (G, k) be an instance of d-Dominated Cluster Deletion where G is (p, k)-unbreakable.

Suppose that (G, k) is a yes-instance, that is, there is a set $S \subseteq V(G)$ of at most k vertices such that for each connected component C of $G - S$, $\gamma(C) \leq d$. Because G is a (p, k)-unbreakable graph, $G - S$ has a connected component C with at least $n - |S| - p \geq n - k - p$ vertices and the total number of vertices in the other connected components of $G - S$ is at most p. We call the component C *big*. Denote by $C_1, \dots, C_\ell$ the connected components of $G - S$ that are distinct from C and let D be a dominating set of C of size at most d. Observe that $V(C) \subseteq N_G[D] \subseteq V(C) \cup S$ and $V(C_i) \subseteq V(G) \setminus N_G[D]$ for all $i \in \{1, \dots, \ell\}$. Furthermore, if $S' = S \setminus N_G[D]$ then $S = S' \cup N_G(\bigcup_{i=1}^{\ell} V(G_i))$. These observations lead to the following algorithm.

We guess a dominating set D of the (potential) big connected component by trying all possible choices of at most d vertices of G. Let $R = V(G) \setminus N_G[D]$. We immediately discard the choice of D if $|R| > p + k$ because such sets D cannot be dominating sets of the big component. From now on, we assume that D is fixed and $|R| \leq p + k$.

Next, we guess the set of at most k vertices $S' = R \cap S$ for a potential solution S to (G, k) by trying all possible choices of such a set. For each choice of S', we consider $H = G[R \setminus S']$ and find the connected components $C_1, \dots, C_\ell$ of H. For each $i \in \{1, \dots, \ell\}$, we verify whether C_i has a dominating set of size at most d and immediately discard the current choice of S' if this does not hold. Further, we construct $S = S' \cup N_G(\bigcup_{i=1}^{\ell} V(C_i))$ and check whether $|S| \leq k$. If this holds then we conclude that S is a solution, return it, and stop. Otherwise, we discard the current choice of S'.

If we do not find a solution for all choices of S' for the given D, we discard the choice of D. If all sets D are discarded, then we conclude that (G, k) is a no-instance.

Our structural observations about yes-instances immediately imply the correctness of the algorithm. To evaluate the running time, observe that we have at most n^d choices of D that can be generated in $n^{\mathcal{O}(d)}$ time. For each choice of D with $|R| \leq p + k$, we have at most $(p + k)^k$ possibilities to choose S'. We can find connected components of H in $\mathcal{O}(p + k)$ time, and we can check in time $(p + k)^{\mathcal{O}(d)}$ whether each connected component can be dominated by at most d vertices. Thus, the total running time is $(p + k)^{\mathcal{O}(k+d)} \cdot n^{\mathcal{O}(d)}$. This concludes the proof. ◀

Combining Observation 6 and Lemma 7, we obtain Theorem 4 as a direct corollary of Proposition 5.

4 An FPT algorithm for 1-Dominated Cluster Deletion

In this section, we demonstrate a uniform algorithm for Dominated Cluster Deletion for the special case $d = 1$, that is, for 1-Dominated Cluster Deletion. The crucial property that makes the problem significantly easier for $d = 1$ is that each cluster is of diameter at most two. We use a simple branching algorithm to reduce the input graph to a connected graph of diameter at most two. Then we can exploit the following structural property of a solution.

▶ **Lemma 8.** *Let G be a graph of diameter at most two and let (A, B) be a separation of G with $X = A \cap B$. Suppose that for $S \subseteq V(G)$, each connected component of $G - S$ is dominated by a single vertex and it holds that (i) $(A \setminus B) \setminus S \neq \emptyset$, (ii) $(B \setminus A) \setminus S \neq \emptyset$, and (iii) $X \cap S = \emptyset$. Then for every connected component C of $G - S$, any vertex $v \in V(C)$ dominating C is in X. Furthermore, the vertices of each connected component of $G[X]$ are in the same connected component of $G - S$ and the vertices of distinct connected component of $G[X]$ are in separate components of $G - S$.*

Proof. Let C be a connected component of $G - S$. Assume for the sake of a contradiction that there is a vertex $v \in V(C)$ that dominates C such that $v \in A \setminus B$. By (ii), there is a vertex $u \in (B \setminus A) \setminus S$. Since the diameter of G is at most two, there is a (u, v)-path P of length at most two. Since u and v are separated by X, $P = uxv$ for some $x \in X$. Note that (iii) implies that $x \notin S$. Then, $u \in V(C)$. However, u is not dominated by v; a contradiction. This proves the first claim.

For the second claim, it is straightforward to see that the vertices of each connected component of $G[X]$ are in the same connected component of $G - S$ because of (iii). Let C_1 and C_2 be distinct connected components of $G[X]$. Notice that any vertex of G adjacent to some vertices in both connected components is either in $A \setminus B$ or $B \setminus A$. According to the first claim of the lemma, such vertices cannot be dominating vertices for the cluster. This proves that the vertices of distinct connected components of $G[X]$ are in separate components of $G - S$ and this concludes the proof. ◀

We are now in a position to prove the main theorem of this section.

▶ **Theorem 9.** *1-Dominated Cluster Deletion can be solved in $\mathcal{O}((k + 3)^{k+5/2} \cdot nm)$ time.*

Proof. We use the method of bounded search trees to solve the problem. Our recursive branching algorithm, called Cluster (Algorithm 1), takes as input a graph G and an integer k, and returns either Yes or No depending on whether (G, k) is a yes- or a no-instance. For simplicity, we solve the decision problem, but the algorithm can easily be modified to output a solution if it exists.

We analyze the algorithm to show its correctness. Trivially, if $k < 0$ then (G, k) is a no-instance. Hence, we correctly return No and quit in Line 2. Also, if the set of vertices becomes empty then we should return Yes as is done in Line 3.

If G has a connected component C that can be dominated by one vertex, then this component is already a required cluster and we can exclude it from the consideration. This is done in Lines 4–5.

In Lines 7–14, we deal with disconnected graphs. In this case, we solve the problem for each connected component separately, and for each component C_i, we find the minimum k_i such that (C_i, k_i) is a yes-instance. Notice that because of the previous step, each connected component is not dominated by a single vertex. Thus, we consider only k_i satisfying $1 \leq k_i \leq k - 1$. Then, we verify whether the solutions for components can be combined. From now on, we assume that G is connected.

Algorithm 1 Cluster(G, k).

```
Input: A graph $G$ and an integer $k$.
Result: Yes or No.
begin
    if $k < 0$ then return No and quit;
    if $V(G) = \emptyset$ then return No and quit;
    if $G$ has a connected component $C$ with $\gamma(G) = 1$ then
        call Cluster$(G - V(C), k)$, return the result, and quit
    end
    if $G$ is disconnected then
        find connected components $C_1, \dots, C_\ell$ of $G$;
        foreach $i \in \{1, \dots, \ell\}$ do
            find minimum $1 \leq k_i \leq k - 1$ s.t. Cluster$(C_i, k_i)$ returns Yes and
            set $k_i := k$ if Cluster$(C_i, k - 1)$ returns No
        end
        return Yes if $k_1 + \dots + k_\ell \leq k$ and return No, otherwise, and quit
    end
    if there is a shortest path $v_1v_2v_3v_4$ then
        foreach $i \in \{1, 2, 3, 4\}$ do
            call Cluster$(G - v_i, k - 1)$;
            return Yes and quit if the algorithm returns Yes
        end
        return No and quit
    end
    if there is $v \in V(G)$ s.t. $|V(G) \setminus N_G[v]| \leq k$ then
        return Yes and quit
    end
    find a separation $(A, B)$ of $G$ with the separator $X = A \cap B$ of size at most $k$
    and return No and quit if such a separation does not exist;
    foreach $v \in X$ do
        call Cluster$(G - v, k - 1)$;
        return Yes and quit if the algorithm returns Yes
    end
    call Cluster$(G - (A \setminus B)|, k - |A \setminus B|)$ and
    return Yes and quit if the algorithm returns Yes;
    call Cluster$(G - (B \setminus A)|, k - |B \setminus A|)$ and
    return Yes and quit if the algorithm returns Yes;
    if there is $v \in V(G) \setminus X$ s.t. $v$ has neighbors in distinct components of $G[X]$ then
        call Cluster$(G - v, k - 1)$;
        return Yes and quit if the algorithm returns Yes
    end
    return No
end
```

In Lines 15–21, we analyze the case when G has a shortest path on four vertices. If $v_1v_2v_3v_4$ is a shortest (v_1, v_4)-path then the vertices v_1, v_2, v_3, v_4 cannot belong to the same cluster because they cannot be dominated by the same vertex. This implies that at least one vertex of such a path should be included in any solution. We branch on four possible options and return Yes if we have a yes-instance for one of the branches. Otherwise, we return No and stop. From this moment, we assume that G has no shortest paths of length three, that is, the diameter of G is at most two.

Further, in Lines 22–24, we check whether the instance admits a trivial solution with one cluster. This holds if there is $v \in V(G)$ such that $|V(G) \setminus N_G[v]| \leq k$ – we simply delete all the vertices that are not dominated by v. Now, we can assume that for each solution S, $G - S$ has at least two components.

In Lines 25–26, we find a separation (A, B) of G with the separator $X = A \cap B$ of size at most k (we remind that we only consider separations (A, B) where both $A \setminus B$ and $B \setminus A$ are nonempty). If such a separation does not exist, then for each $S \subseteq V(G)$ of size at most k, $G - X$ is connected. Hence, (G, k) may have only a solution with one cluster. However, this case was already excluded. Thus, we correctly return No and stop in Line 26. From now on, we assume that a separation (A, B) of order at most k exists.

In Lines 27–30, we branch on the possibility that X contains a vertex of a solution. We return Yes and stop if we find such a solution. Next, in Lines 31–34, we check whether there is a solution that includes either every vertex of $A \setminus B$ or every vertex of $B \setminus A$.

Finally, we conclude that any solution to (G, k) excludes the vertices of X and, furthermore, each solution contains at least one vertex of $A \setminus B$ and at least one vertex of $B \setminus A$. Then by Lemma 8, for any solution S to (G, S), it holds that for each connected component C of $G - S$, any vertex $v \in V(C)$ dominating C is in X and, furthermore, the vertices of each connected component of $G[X]$ are in the same connected component of $G - S$ and the vertices of distinct connected component of $G[X]$ are in separate components of $G - S$. Recall that we excluded the case when (G, k) has a solution with one cluster. Hence, if (G, k) is a yes-instance then $G[X]$ should have at least two connected components. Let C_1 and C_2 be two distinct connected components of $G[X]$. Because the diameter of G is at most two, we have that for every $u \in V(C_1)$ and every $v \in V(C_2)$, there is a vertex $x \in V(G) \setminus X$ such that uxv is a path in G. Because u and v are in distinct connected components of $G - S$, it holds that $x \in S$. We conclude that if (G, k) is a yes-instance then there is at least one vertex $v \in V(G) \setminus X$ which has neighbors in two distinct connected components of $G[X]$ and all such vertices are included in any solution S. We use this in Lines 35-39. We either find v and obtain that that $(G - v, k - 1)$ is a yes-instance or conclude that (G, k) is a no-instance. This concludes the correctness proof.

To evaluate the running time, notice that in Lines 15–21, we have four recursive calls. If we go to Lines 27-38, then we have at most $|X| + 3 \leq k + 3$ branches. For each branch, we reduce the parameter by at least one. Thus, the total number of leaves of the search tree is at most $(k+3)^k$. We can find connected components in $\mathcal{O}(n+m)$ time using standard techniques and we can check in $\mathcal{O}(n)$ time whether a connected graph has a dominating vertex. A shortest path on four vertices can be found in $\mathcal{O}(nm)$ time by performing a breadth-first search from each vertex. The existence of a vertex v such that $|V(G) \setminus N_G[v]| \leq k$ can be checked in $\mathcal{O}(m)$ time. To verify whether G has a separation of order k, we can use the algorithm of Gabow [13] with running time $\mathcal{O}((n + \min(k^{5/2}, kn^{3/4}))m)$. In fact, for undirected graphs, m can be replaced by kn, but we use the bound in the weaker form $\mathcal{O}(k^{5/2}nm)$. Finally, note that in Lines 9–11, for each $i \in \{1, \ldots, \ell\}$, we compute the minimum k_i such that (C_i, k_i) is a yes-instance. For this, we can use binary search, which adds an additional $\log k$-factor to

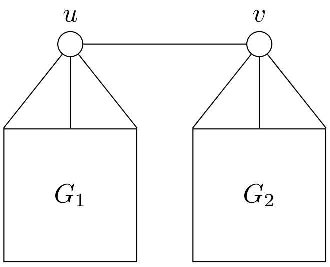

Figure 2 An illustration of the construction in the proof of Theorem 10.

the running time. However, $k_i \leq k-1$ and this means that the steps in Lines 9–11 can be executed in time $\mathcal{O}((k+3)^{k+5/2} \cdot nm)$. Summarizing, we obtain that the total running time is in $\mathcal{O}((k+3)^{k+5/2} \cdot nm)$. This concludes the proof. ◀

5 (No) Polynomial Kernels

In this section, we show some results related to the existence of polynomial kernels. Our main result here is that Dominated Cluster Deletion does not admit a polynomial kernel with respect to $k+c$ even if $d=1$. We mention that the construction is identical to a reduction by Figiel et al. [12] that shows that 2-Club Cluster Vertex Deletion does not have a polynomial kernel with respect to the solution size k. The two problems are loosely related as a graph with a universal vertex (a dominating set of size one) is a 2-Club. However, the other direction is not true, that is, not every 2-club has a dominating set of size one. The two results therefore do not directly follow from one another.

▶ **Theorem 10.** *1-Dominated Cluster Deletion does not admit a polynomial kernel with respect to $k+c$ unless $\mathrm{NP} \subseteq \mathrm{coNP}/\mathrm{poly}$ even if the input graph is connected.*

Proof. We show this result by providing a OR-cross-composition (see [4]) for 1-Dominated Cluster Deletion from itself. Recall that 1-Dominated Cluster Deletion is NP-complete by Proposition 1. Without loss of generality, we start with $T = 2^t$ instances of 1-Dominated Cluster Deletion, where each instance has the same number n of vertices, the same value of $k < n-1$, and where each of the input graphs is connected.

The main ingredient for our proof is a construction to merge two instances $I_1 = (G_1, k)$ and $I_2 = (G_2, k)$ into one instance $I^* = (G^*, k^*)$. We first prove that I^* is a yes-instance if and only if at least one of I_1 and I_2 is a yes-instance. Afterwards, we will show how to use this construction to get a cross-composition for all t instances.

The construction is depicted in Figure 2 and works as follows. We take the disjoint union of the two graphs G_1 and G_2 and add two vertices u and v. We make u adjacent to all vertices in G_1 and v adjacent to all vertices in G_2. Moreover, we add the edge $\{u, v\}$. Finally, we set the parameter $k^* = k+1$.

It remains to show that I^* is a yes-instance if and only if at least one of I_1 and I_2 is a yes-instance. First assume, that one of I_1 and I_2 is a yes-instance. Since both cases are completely analogous, we assume without loss of generality that I_1 is a yes instance. A solution for I^* consists of an optimal solution for I_1 and the vertex u. Note that adding u to the solution disconnects the graphs G_1 and G_2. Moreover, the connected component including G_2 also contains v and therefore has a domination number of one.

For the other direction, assume that the constructed instance contains a solution S of size at most $k+1$. Note that since we assume $k < n-1$, we need to include either u or v in S as otherwise we would need to include all $n > k^*$ vertices in either G_1 or G_2 into S as one vertex of each instance together with u and v induces a P_4 and no vertex is adjacent to both a vertex in G_1 and a vertex in G_2. We assume without loss of generality that u is included in S. Note that this leaves the graph G_1 as one connected component and since we already know that $u \in S$, it holds that S contains at most k vertices from G_1 which results in each connected component of G_1 being dominated by a single vertex. Thus I_1 is a yes-instance.

To complete the reduction, we iteratively half the number of instances by partitioning all instances into arbitrary pairs and merge the two instances in a pair into one instance. Note that in each iteration, all of our assumption still hold as all instances have $d = 1$, the number of vertices in I^* is $2n + 2 > k^* + 1$, and G^* is connected. After $\log(T)$ iterations, we are left with a single instance which is a yes-instance if and only if at least one of the T original instances is a yes-instance. The time required to compute the cross composition is in $O(\sum_{i\in[T]} |G_i| \cdot \log(T))$ which is polynomial in $\sum_{i\in[T]} |G_i|$ as each graph G_i contains at least one vertex. Moreover, the parameter k in the constructed instance is $k + \log(T)$ and the degeneracy of the instance is at most $n + \log(T)$ as we can put all the vertices in the T original instances first into the degeneracy ordering and afterwards add the newly added vertices in increasing order of their degree. Note that each vertex in an original instance has at most $n + \log(T)$ neighbors and each of the newly added vertices has at most $\log(T)$ neighbors "above themself". Thus, all requirements of a cross-composition are met and the proof is completed. ◀

We mention in passing that it is simple to generalize Theorem 10 to any constant $d > 0$. In each step, we simply add the following graph to each of the two newly added vertices u and v. We show the construction only for v. We start with a path $(w_1, w_2, \ldots, w_{3d-2})$ with $3d - 2$ vertices and make w_1 adjacent to v. Next, we iteratively replace each vertex w_i by a clique of size $k + \log(T) + 1$ vertices, where each vertex has the same neighborhood as w_i had. Note that we cannot fully remove any of the cliques and hence whenever we remove neither u nor v, then we are left with a connected graph which requires at least $2d > d$ vertices to dominate. Whenever we remove one of the two vertices, say u, then we can dominate the connected component of v by selecting v and one copy of each vertex in the clique corresponding to the vertices $w_3, w_6, \ldots, w_{3(d-1)}$. The rest of the proof is completely analogous to the proof of Theorem 10.

We next show that d-Dominated Cluster Deletion parameterized by $k + \Delta$ admits a polynomial kernel.

▶ **Proposition 11.** *d-Dominated Cluster Deletion parameterized by $k + \Delta$ admits a polynomial kernel of size $\mathcal{O}(k^2\Delta^3)$.*

Proof. First, we check for each connected component of the input graph whether it contains a dominating set of size d in $\mathcal{O}(n^{d+2})$ time. Note that since we assume d to be a constant, this is a polynomial running time. Moreover, each such connected component can be removed from the input graph to create a smaller equivalent instance. If afterwards, the number of connected components in the graph is larger than k, then we return a trivial no-instance as we need to include at least one vertex from each connected component into the solution S, meaning that any solution has size at least $k+1$. Finally, we bound the size of each connected component as follows. If the number of vertices in one connected component is larger than $k + (k(\Delta - 1) + 1)d(\Delta + 1) \in \mathcal{O}(k\Delta^2)$, then we again return a trivial no-instance as removing any solution S of size at most k leaves at most $k(\Delta - 1) + 1$ connected components and hence by the pigeonhole principle, at least one connected component has size larger than $d(\Delta + 1)$. Note that this connected component cannot contain a dominating set of size at most d and hence the entire instance is a no-instance.

The number remaining vertices is now at most $k\cdot(k+(k(\Delta-1)+1)d(\Delta+1)) \in \mathcal{O}(k^2\Delta^2)$ and since the maximum degree is Δ, the number of vertices and edges is in $\mathcal{O}(k^2\Delta^3)$. This concludes the proof. ◀

Next, we show that the previous result cannot be generalized to Dominated Cluster Deletion even if we include the parameter d to the kernel and restrict k to be 0.

▶ **Observation 12.** *Dominated Cluster Deletion does not admit a polynomial kernel with respect to $d+\Delta$ even if $k=0$ unless $\mathrm{NP} \subseteq \mathrm{coNP}/\mathrm{poly}$.*

Proof. We show a simple AND-composition from Dominating Set on connected input graphs. Given t instances of Dominating Set where all instances are connected and all instances ask for a dominating set of the same size d, we simply take the disjoint union of all of these graphs and set $k=0$. If all t instances are yes-instances, then each connected component of the constructed graph has a dominating set of size at most d, that is, the constructed instance is a yes-instance. If the constructed instance is a yes-instance, then also each connected component of the constructed graph has a dominating set of size at most d as $k=0$. Thus, all t original instances are yes-instances. Note that $k=0$, the value of d is the same as in each input instance, and the maximum degree is at most the number of vertices in one of the t input instances. Thus, we have provided an AND-cross-composition and this concludes the proof. ◀

Note that the previous reduction produces a disconnected graph. We show that this is necessary as Dominated Cluster Deletion admits a polynomial kernel when parameterized by $k+d+\Delta$ if the input graph is connected.

▶ **Observation 13.** *Dominated Cluster Deletion admits a kernel of size $\mathcal{O}(kd\Delta^3)$ when parameterized by $k+d+\Delta$ if the input graph is connected.*

Proof. If the number of vertices in the input graph is at most $kd\Delta^2+k+d(\Delta+1)-kd$, then we return the input graph as a trivial kernel of size $\mathcal{O}(kd\Delta^3)$. Otherwise we return a trivial no-instance as a kernel. We next show that this is justified. Assume towards a contradiction that the input instance has more vertices but is a yes-instance. Then, it contains a set S of at most k vertices such that removing S from the graph results in connected components which can each be dominated by at most d vertices. Note that removing a set of k vertices of degree at most Δ from a connected graph can result in a graph with at most $k(\Delta-1)+1$ connected components. Moreover, the dominating set of size d in each of these can dominate at most $d(\Delta)+1$ vertices. Thus, the entire graph contains at most $k+(k(\Delta-1)+1)d(\Delta+1) = kd\Delta^2+k+d(\Delta+1)-kd$ vertices, a contradiction. ◀

6 Conclusion

In this work, we initiated the study of Dominated Cluster Deletion and showed an almost complete tetrachotomy regarding its parameterized complexity when parameterized by combinations of k, d, c, and Δ. We remark that we leave two questions unanswered. First, is Dominated Cluster Deletion fixed-parameter tractable or W[1]-hard when parameterized by $k+d+c$? We conjecture that it is fixed-parameter tractable and the algorithm may be obtained by combining the recursive understanding technique [6, 20] and the results of Telle and Villanger [21]. Second, does d-Dominated Cluster Deletion parameterized by k admit a polynomial kernel when d and c are constants?

Abstract

In the Multiway Cut problem, we are given an undirected graph with nonnegative edge weights and a subset of k terminals, and the goal is to determine a set of edges of minimum total weight whose removal disconnects each terminal from the rest. The problem is APX-hard for $k \geq 3$, and an extensive line of research has concentrated on closing the gap between the best upper and lower bounds for approximability and inapproximability, respectively.

In this paper, we study several generalizations of Multiway Cut where the terminals can be chosen as *representatives* from sets of *candidates* $T_1, \ldots, T_q$. In this setting, one is allowed to choose these representatives so that the minimum-weight cut separating these sets *via their representatives* is as small as possible. We distinguish different cases depending on (A) whether the representative of a candidate set has to be separated from the other candidate sets completely or only from the representatives, and (B) whether there is a single representative for each candidate set or the choice of representative is independent for each pair of candidate sets.

For fixed q, we give approximation algorithms for each of these problems that match the best known approximation guarantee for Multiway Cut. Our technical contribution is a new extension of the CKR relaxation that preserves approximation guarantees. For general q, we show $o(\log q)$-inapproximability for all cases where the choice of representatives may depend on the pair of candidate sets, as well as for the case where the goal is to separate a fixed node from a single representative from each candidate set. As a positive result, we give a 2-approximation algorithm for the case where we need to choose a single representative from each candidate set. This is a generalization of the $(2 - 2/k)$-approximation for k-Cut, and we can solve it by relating the tree case to optimization over a gammoid.

1 Introduction

For an undirected graph $G = (V, E)$ with weight function $w : E \to \mathbb{R}_+$, the Multiway Cut problem asks for a minimum-weight cut $C \subseteq E$ separating any pair of terminals in a given terminal set $S = \{s_1, \ldots s_k\}$. As cuts can be identified with partitions of the nodes, this is equivalent to finding a node coloring of G with k colors such that terminal s_i is colored with color i for $i \in [k]$, and we seek to minimize the total weight of dichromatic edges.

1.1 Previous work

Dahlhaus et al. [5] showed that Multiway Cut is NP-hard even for $k = 3$, and provided a very simple combinatorial $(2 - 2/k)$-approximation that works as follows. For each s_i, determine a minimum-weight cut $C_i \subseteq E$ that separates s_i from all other s_j for $j \neq i$ – such a cut is called an *isolating* cut of s_i – and then take the union of the $k - 1$ smallest ones among the k cuts thus obtained. In an optimal multiway cut, the boundary of the component containing s_i is a cut isolating s_i, hence its weight is at least as large as that of C_i. Summing up these inequalities for all but the largest isolating cuts, since this counts each edge at most twice except for the boundary of the largest one, leads to a $(2 - 2/k)$-approximation.

Since the pioneering work of Dahlhaus et al., Multiway Cut has been a central problem in combinatorial optimization. The best known approximability as well as inapproximability bounds are based on a geometric relaxation called the *CKR relaxation*, introduced by Călinescu, Karloff and Rabani [4]. The current best approximation algorithm is due to Sharma and Vondrák [18] with an approximation factor of 1.2965, while the best known lower bound (assuming the Unique Games Conjecture) is slightly above 1.2 [2].

Various generalizations of Multiway Cut have been introduced. In the Multicut problem, we are given an undirected graph with non-negative edge weights, together with a demand graph consisting of edges $(s_1, t_1), \ldots, (s_k, t_k)$, and the goal is to determine a minimum-weight cut whose removal disconnects each s_i from its pair t_i. Multicut is NP-hard to approximate within any constant factor assuming the Unique Games Conjecture [3], and there is a polynomial-time $O(\log k)$-approximation algorithm [7]. The Uniform Metric Labeling problem takes as input a list of possible colors for each node in an edge-weighted graph, and asks for a coloring that respects these lists with the minimum total weight of dichromatic edges; Multiway Cut arises as a special case when the terminals have distinct lists of length 1 and all other nodes can be colored arbitrarily. Kleinberg and Tardos [12] gave a 2-approximation to Uniform Metric Labeling with a tight integrality gap using a geometric relaxation, similar to that of CKR. In the k-Cut problem, we are given only an edge-weighted graph G and a positive integer k, and the goal is to find a minimum-weight cut whose deletion breaks the graph into k components. One can think of this problem as a version of Multiway Cut where the terminals can be chosen freely. The k-Cut problem admits a 2-approximation [16] that is tight [13]. The Steiner Multicut [11] problem takes as input an undirected graph G and subsets $X_1, X_2, \ldots, X_q$ of nodes, and asks for a minimum cut such that each X_i is separated into at least 2 components. A generalization of Steiner Multicut is the Requirement Cut problem [9], where requirements r_i are given for each set X_i, and the goal is to find the minimum cut that cuts each X_i into at least r_i components. The current best algorithms for Requirement Cut are those given in [9, 17], of which we will use the $O(\log k \log q)$ approximation, where $k = |\bigcup_{i=1}^{q} X_i| \leq n$.

1.2 Our results

We introduce generalizations of Multiway Cut, where we are allowed to choose *representatives* from some terminal candidate sets $T_1, \dots, T_q \subseteq V$, and the goal is to find the minimum-weight cut separating these sets *via their representatives.* The variants are distinguished by (A) whether the representative has to be separated from all candidates of the other candidate sets or only from their representatives, and (B) whether there is a single representative for each candidate set or whether the choice of representative is independent for each pair of candidate sets. In order to make it easier to distinguish these problems, we use the following naming rules.

- When the goal is to separate *all* candidates, we use All; for example, the All-to-All problem requires all nodes of T_i to be separated from all nodes of T_j, for each $i \neq j$.
- When the goal is to choose a *single* representative for each candidate set, we use Single, and we denote the chosen representative of T_i by t_i. For example, the Single-to-Single problem requires choosing a representative $t_i \in T_i$ for every $i \in [q]$, and finding a cut that separates t_i from t_j for all $i \neq j$. On the other hand, Single-to-All requires the chosen representative $t_i \in T_i$ to be separated from every node of T_j, for all $i \neq j$.
- When only *some* representative of T_i ought to be separated from some part of T_j for each i, j pair, we use Some, and denote the representative chosen from T_i to be separated from T_j by t_i^j. For example, the Some-to-Some problem asks for a minimum-weight subset of edges such that after deleting these edges, for any pair $i \neq j$, there are nodes $t_i^j \in T_i$ and $t_j^i \in T_j$ that are in different components.
- When there is a *fixed* node that needs to be separated from the candidate sets, we use Fixed, and denote the fixed node by s. In the Fixed-to-Single problem, we are given a fixed node s, and we want a minimum-weight subset of edges such that after deleting these edges, s is separated from at least one element $t_j \in T_j$ for every $j \in [q]$.

These problems are natural generalizations of Multiway Cut that provide various ways to interpolate between problems with fixed terminals like Multiway Cut and problems with freely chosen terminals like k-Cut. Although, as we will discuss later, some of our problems are equivalent or closely related to problems that have already been considered in the literature, a systematic study of this type of generalization has not yet been done, and some of our results (Theorem 3, Theorem 9) require new observations and techniques.

In each problem, we want to minimize over all possible choices of representatives, as well as over all possible subsets of edges. The problem where we need to separate each candidate set from every other, All-to-All, is equivalent to Multiway Cut by contracting each candidate set to a single node. The other problems are not directly reducible to Multiway Cut. We denote by $\alpha \approx 1.2965$ the current best approximation factor for Multiway Cut [18]. The different problems, as well as our results, are summarized in Table 1. The main results that require new techniques are indicated in bold in the table, and are discussed in the next subsection.

1.3 Techniques

Approximation when q is part of the input. We give 2-approximations for Single-to-All and Single-to-Single. For the latter, we first give an exact algorithm on trees, by showing that the feasible solutions have a gammoid structure. This then leads to a 2-approximation for general graphs using the Gomory-Hu tree, which is best possible, since Single-to-Single generalizes the k-Cut problem. Also, we show that the Some-to-Some problem is equivalent to Steiner Multicut, leading to an $O(\log q \cdot \log n)$ approximation in this case.

Table 1 A summary of our results, where $\alpha \approx 1.2965$ [18] is the current best approximation factor for Multiway Cut. The tightness of 2-approximation assumes SSEH, while the other inapproximability results hold assuming P $\neq$ NP. The main results are highlighted in bold.

Problem	Demands	Fixed q	Unbounded q
All-to-All	$T_i - T_j$	α-approx	α-approx
Single-to-All	$t_i - T_j$	**α-approx**	2-approx
Single-to-Single	$t_i - t_j$	α-approx	**Tight 2-approx**
Fixed-to-Single	$s - t_j$	In P	No $o(\log q)$ approx
Some-to-Single	$t_i^j - t_j$	α-approx	No $o(\log q)$ approx
Some-to-Some	$t_i^j - t_j^i$	α-approx	$O(\log q \cdot \log n)$ approx [9]
Some-to-All	$t_i^j - T_j$	**α-approx**	No $o(\log q)$ approx

Approximation for fixed q. Some of the problems with fixed q are directly reducible to solving a polynomial number of Multiway Cut instances. However, this is not the case for Single-to-All and Some-to-All. Our α-approximation algorithms for these are obtained by extending the CKR relaxation to a more general problem that we call Lifted Cut (see Section 3) in such a way that the rounding methods used in [18] still give an α-approximation. Lifted Cut may have independent interest as a class of metric labeling problems that is broader than Multiway Cut but can still be approximated to the same ratio. We then show that for fixed q, problems Single-to-All and Some-to-All are reducible to solving polynomially many instances of Lifted Cut.

Hardness of approximation. We prove hardness of Fixed-to-Single by reducing from Hitting Set. We then reduce Some-to-All, Some-to-Single, and Some-to-Some from Fixed-to-Single to give hardness results for those problems as well.

1.4 Structure of the paper

In Section 2, we present the main tools used in our algorithms and proofs. Section 3 introduces the Lifted Cut problem and describes how to extend the α-approximation of [18] to Lifted Cut. The remaining sections present the results for the problems listed in Table 1.

2 Background

Throughout the paper, we denote the set of non-negative reals by $\mathbb{R}_+$, and use $[k] = \{1, \ldots, k\}$. We use e^i to denote ith elementary vector, and Δ_k denotes the convex hull of $\{e^1, \ldots, e^k\}$, that is, $\Delta_k = \{x \in \mathbb{R}^k : x \geq 0,\ \sum_{i=1}^k x_i = 1\}$.

Given an undirected graph $G = (V, E)$, the edge going between nodes $u, v \in V$ is denoted by (u, v). For a weight function $w : E \to \mathbb{R}_+$ and $C \subseteq E$, we use $w(C) = \sum_{e \in C} w(e)$. The graph obtained by deleting the edges in C is denoted by $G - C$. We denote the set of components of G by $\mathcal{K}(G)$. The boundary of a given subset of nodes $S \subseteq V$ is $\delta(S) = \{(u, v) \in E : u \in S, v \in V \setminus S\}$.

We briefly summarize the background results that we build upon in our proofs.

2.1 The CKR Relaxation and Rounding Methods

For a graph $G = (V, E)$ with edge weights $w : E \to \mathbb{R}_+$ and terminals $S = \{s_1, \ldots, s_k\}$, the CKR relaxation [4] is the following linear program (CKR-LP) which assigns to each node $u \in V$ a geometric location x^u in the k-dimensional simplex.

$$\begin{aligned} \text{minimize} \quad & \sum_{(u,v)\in E} w_{u,v} \|x^u - x^v\|_1 \\ \text{subject to} \quad & x^u \in \Delta_k \quad u \in V, \\ & x^{s_i} = e^i \qquad i \in [k]. \end{aligned} \tag{CKR-LP}$$

The original paper of Călinescu, Karloff and Rabani [4] gives a $(3/2 - 1/k)$-approximation algorithm that works as follows. First take a threshold $\rho_i \in (0, 1)$ uniformly at random for each dimension $i \in [k]$. Then take one of the two permutations $\sigma = (1, \ldots, k - 1, k)$ and $(k - 1, k - 2, \ldots, 1, k)$ of the terminals at random (that is, with probability 1/2), assign nodes within a distance $\rho_{\sigma(i)}$ of $x^{s_{\sigma(i)}}$ to the component of $s_{\sigma(i)}$ for $i \in [k - 1]$, and assign the remaining nodes to s_k. We call an algorithm that chooses a permutation of the terminals and then assigns the nodes within some threshold to the terminals in that order a *threshold algorithm*. The analyses of the above linear programming formulation revealed several useful properties of the CKR relaxation. One of these observations is that the edges of the graph may be assumed to be *axis-aligned*. An edge u, v is said to be (i, j)-axis-aligned if x^u and x^v differ only in coordinates i and j. Roughly speaking, any edge that is not axis-aligned can be subdivided into several edges that are axis-aligned, forming a piecewise linear path between x^u and x^v. This observation significantly simplifies the analysis of threshold algorithms, as there are at most two thresholds that can cut any axis-aligned edge. Another useful property is *symmetry*. For any threshold algorithm, there is one that achieves the same guarantees by choosing a uniformly random permutation. See [10, Section 2] for a more detailed discussion of these properties.

Another way of rounding the CKR relaxation is provided by the *exponential clocks* algorithm of Buchbinder, Naor and Schwartz [1]. Their approach can be thought of as choosing a uniformly random point in the simplex, and splitting the simplex by axis parallel hyperplanes that meet at this given point. The algorithm gives the same guarantees as the algorithm of Kleinberg and Tardos [12] for Uniform Metric Labeling. This latter problem takes as input a list of possible colors $\ell(v)$ for each node v in a given graph, and asks for a coloring that respects these lists with the minimum total weight of dichromatic edges. Their relaxation (UML-LP) is similar to the CKR relaxation when there are a total of q colors, but it does not require there to be nodes at every vertex of the simplex.

$$\begin{aligned} \text{minimize} \quad & \sum_{(u,v)\in E} w_{u,v} \|x^u - x^v\|_1 \\ \text{subject to} \quad & x^u \in \Delta_q \quad u \in V, \\ & x^v_i = 0 \qquad i \notin \ell(v). \end{aligned} \tag{UML-LP}$$

It is shown in [1, Section 6] that Algorithm 1 gives the same guarantees as the exponential clocks algorithm.

The approximation algorithm of Sharma and Vondrák [18] for Multiway Cut randomly chooses between four different algorithms of the above two types with some careful analysis to achieve an α-approximation, where $\alpha \approx 1.2965$.

Algorithm 1 The Kleinberg-Tardos Algorithm for Uniform Metric Labeling.

```
Input: A graph $G = (V, E)$, weights $w : E \to \mathbb{R}_+$, labels $\ell : V \to \mathcal{P}([q])$, and an LP solution $x^u$ for each $u \in V$.
Output: A solution to Uniform Metric Labeling.
while $\exists u \in V$ s.t. $u$ is unassigned do
    Pick a label $i \in [q]$ uniformly at random, and a threshold $\rho \sim unif[0, 1]$.
    Assign label $i$ to any unassigned $u \in V$ with $x^u_i \geq \rho$.
end while
```

2.2 Other Relevant Tools

Our hardness of approximation results are based on two different complexity assumptions. The $o(\log q)$ inapproximability results hold assuming $\mathrm{P} \neq \mathrm{NP}$, based on the hardness of approximating Hitting Set proved by Dinur and Steurer [6]. The other complexity assumption that we use is the *Small Set Expansion Hypothesis* (SSEH), a core hypothesis for proving hardness of approximation for problems that do not have straightforward proofs assuming the Unique Games Conjecture (UGC). It implies the UGC, and we will use it as evidence against a $(2 - \varepsilon)$-approximation, for any $\varepsilon > 0$, for k-Cut [13]. For completeness, we include the relevant theorems here.

▶ **Theorem 1** ([6, 14]). *For any fixed $0 < \alpha < 1$, Hitting Set cannot be approximated in polynomial time within a factor of $(1 - \alpha) \ln N$ on inputs of size N, unless $\mathrm{P} = \mathrm{NP}$.*

▶ **Theorem 2** ([13]). *Assuming the Small Set Expansion Hypothesis, it is NP-hard to approximate k-Cut to within $(2 - \varepsilon)$ factor of the optimum, for any constant $\varepsilon > 0$.*

From matroid theory, we use the notion of gammoids. A *gammoid* $M = (D, S, T)$ is a matroid defined by a digraph $D = (V, E)$, a set of source nodes $S \subseteq V$, and a set of target nodes $T \subseteq V \setminus S$. A set $X \subseteq T$ is independent in M if there exist $|X|$ node-disjoint paths from elements of S into X. Optimizing over a gammoid, as with any other matroid, can be done efficiently using the greedy algorithm.

Finally, Gomory-Hu (GH) tree [8] is a standard tool in graph cut algorithms. The *GH tree* of a graph $G = (V, E)$ with weight function $w : E \to \mathbb{R}_+$ is a tree $T = (V, F)$ together with weight function $w_T : F \to \mathbb{R}_+$ that encodes the minimum-weight $s - t$ cuts for each pair s, t of nodes in the following sense: the minimum w_T-weight of an edge on the $s - t$ path in T is equal to the minimum w-weight of a cut in G separating s and t. Furthermore, the two components of the tree obtained by removing the edge of minimum w_T-weight on the path give the two sides of a minimum w-weight $s - t$ cut in G.

3 Lifted Cuts

The goal of this section is to show that the following restriction of the Uniform Metric Labeling relaxation to a one-dimensional lifting of the CKR relaxation admits an α-approximation to its integer optimum. We define the lifted cut problem Lifted Cut, which takes as input a graph $G = (V, E)$ with edge-weights $w : E \to \mathbb{R}_+$, *fixed* terminals $S = \{s_1, s_2, \ldots, s_q\} \subseteq V$, and a list of possible colors for each node $\ell : V \to \mathcal{P}[q + 1]$, the power set of $[q + 1]$, satisfying the following two conditions:

(A) $\ell(s_i) = \{i\}$ for $i = 1 \ldots q$,

(B) $q + 1 \in \ell(v)$ for all $v \in V \setminus S$.

The goal is then to assign a color to each node from its list such that the total weight of dichromatic edges is minimized. We call the following linear programming relaxation of the Lifted Cut problem LIFT-LP:

$$\begin{aligned} \text{minimize} \quad & \sum_{(u,v)\in E} w_{u,v}\|x^u - x^v\|_1 \\ \text{subject to} \quad & x^u \in \Delta_{q+1}, \quad u \in V \\ & x_i^u = 0 \qquad\quad i \notin \ell(u). \end{aligned}$$

Condition A ensures that the set S indeed defines terminals that vertices of the simplex are assigned to, as in Multiway Cut, but Condition B offers a relaxation, allowing a vertex of the simplex to not be assigned to any terminal. This condition gives an additional dimension to the simplex (see Figure 1), while still preserving the approximation guarantees given by the rounding algorithms for CKR.

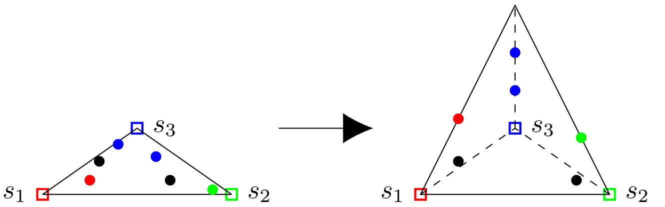

Figure 1 An example of the original CKR relaxation in relation to our extended LIFT-LP on the case for $t_i - T_j$. The point colors represent the different candidate sets.

▶ **Theorem 3.** *The rounding scheme of [18], when applied to LIFT-LP using Algorithm 1 in place of the exponential clocks algorithm, and with the modification that only the first q coordinates are permuted in the threshold algorithms while coordinate $q+1$ is always left last, gives an α-approximation to Lifted Cut.*

Proof. First, we have to argue that the threshold algorithms give feasible solutions to Lifted Cut (for Algorithm 1, this follows since Lifted Cut is a metric labeling problem). In all algorithms, s_i is assigned to the ith component, since x^{s_i} is the ith vertex of the simplex. For other nodes $v \in V \setminus S$, $x_i^v = 0$ guarantees that v is not assigned to the ith component if $i \notin \ell(v)$. Here, we use the fact that the $(q+1)$st component is the only one for which there is no threshold. Although it is possible that $x_{q+1}^v = 0$ and v is still assigned to the $(q+1)$st component, this is not a problem, because $q+1 \in \ell(v)$ by definition.

To prove that we have an α-approximation, we need to show that the relevant bounds that are used in the analysis of the four algorithms mentioned in Sharma-Vondrák [18] carry through to this modified LIFT-LP. We give a sketch here, but the details are written out more carefully in Appendix B. We consider the two types of algorithms (i.e. threshold and exponential clocks) separately.

It was observed in [1] that the exponential clocks algorithm can be replaced by the 2-approximation for the Uniform Metric Labeling problem of Kleinberg-Tardos [12]. Since LIFT-LP corresponds to a Uniform Metric Labeling problem, the bound in [1, Lemma 3] remains valid in our case. Since this is the relevant bound for the exponential clocks algorithm used in the analysis, we can conclude that Algorithm 1 for LIFT-LP gives the same guarantees.

The other algorithms we need to consider are the threshold algorithms. These assume that there is a node at every vertex of the simplex, which is not necessarily true for the LIFT-LP as no variable needs to be at e^{q+1}. We can however use that there is only *one* such vertex, and change the order of the terminals so that this vertex is cut last. We can then use the analysis in [18] and [1] of the CKR relaxation for $k = q + 1$, as sketched below.

The threshold algorithms first choose a random permutation of the nodes to achieve some symmetry, which is necessary for *only* the first $k - 1$ terminals. The last terminal, which is just assigned the remaining nodes, *does not have its own threshold.* In each of the Single Threshold, Descending Threshold and Independent Threshold algorithms of [18], thry prove results for the first two indices, and then argue that these hold for any pair of indices by symmetry. This is only directly clear for pairs in the first $k - 1$. However, when we consider an (i, k)-axis-aligned edge for some $i \in [k - 1]$, the probability of cutting this edge can only be smaller as there is one less threshold to cut it; see [1, Remark 2] for a discussion. This reasoning holds even when there is no terminal at the kth vertex of the simplex.

Thus, the rounding scheme of [18], with the modifications of using Algorithm 1 rather than exponential clocks and only permuting the first q coordinates, gives an α-approximation for Lifted Cut. For completeness, we include the relevant algorithms and lemmas from [18], with the appropriate modifications, in Appendix B. ◀

4 Single-to-All Problem

In this problem, we are looking for a *single* representative from each candidate set that will be separated from *every* candidate in other candidate sets. This includes the other representatives, making the problem very similar to Multiway Cut once the representatives are chosen. A key difference is that the optimal partition may have $q + 1$ components.

We first look at the case where q is constant.

▶ **Theorem 4.** *There is an α-approximation algorithm for Single-to-All when q is fixed.*

Proof. First, guess the representative t_i for each $i \in [q]$. As there are only $\prod_{i=1}^{q} |T_i| \leq n^q$ possible choices, this is polynomial in n for fixed q. If a representative t_i is in T_j for some $j \neq i$, then there is obviously no solution. Otherwise, for a fixed choice of representatives, Single-to-All is an instance of Lifted Cut. To see this, observe that the problem is equivalent to the Uniform Metric Labeling problem obtained by fixing the labels $\ell(v)$ for $v \in V$ as follows:

1. If $v = t_i$ for some i, then set $\ell(v) := \{i\}$.
2. Otherwise, if $v \in T_i \setminus \{t_i\}$ for a unique i, then set $\ell(v) := \{i, q + 1\}$.
3. If $v \in T_i \cap T_j \setminus \{t_i, t_j\}$ for $i \neq j$, then set $\ell(v) := \{q + 1\}$.
4. Finally, if $v \in V \setminus \bigcup_{i\in[q]} T_i$, then set $\ell(v) := [q + 1]$.

This is an instance of Lifted Cut: Condition A is a clear consequence of the first rule, and since any node that is not a representative has $q + 1$ as one of its labels, Condition B follows as well. Therefore, Theorem 3 leads to an α-approximation. ◀

Following the idea of the classical 2-approximation for Multiway Cut discussed in the introduction, there is a simple 2-approximation when q is arbitrary.

▶ **Theorem 5.** *There is a 2-approximation algorithm for Single-to-All.*

Proof. For each candidate set T_i, let $t_i \in T_i$ be a node for which the minimum-weight cut separating t_i from $\cup_{j\neq i} T_j$ is as small as possible, and let C be the union of these isolating cuts. To see that the solution is within a factor 2 of the optimum, consider an optimal solution to

Algorithm 2 Greedy algorithm for Single-to-Single on trees.

```
Input: A tree $G = (V, E)$, weights $w : E \to \mathbb{R}_+$, candidates $T_1, \dots, T_q \subseteq V$.
Output: A minimum-weight good cut $C \subseteq E$.
Set $C \leftarrow \emptyset$.
while $|C| < q - 1$ do
    $e \leftarrow \arg\min\{w(e) : e \notin C, C + e \text{ is } good\}$
    $C = C + e$
end while
```

Single-to-All and let $V_1, V_2, \dots, V_q, V_{q+1}$ denote the components after its deletion, where V_{q+1} may be empty and the components are ordered by the index of the representative they contain. The boundary of each V_i is an isolating cut of some candidate in T_i, which the algorithm minimized. Summing up the weights of the boundaries, we count each edge twice, and the theorem follows. ◀

5 Single-to-Single Problem

In this problem, we are looking for a *single* representative from each candidate set together with a minimum multiway cut separating them. Note that when $T_1 = T_2 = \ldots = T_q = V$, Single-to-Single generalizes k-Cut where we seek the minimum-weight cut that partitions the graph into k parts. It is known that k-Cut is hard to approximate within a factor of $2 - \varepsilon$ for any $\varepsilon > 0$, assuming SSEH [13].

▶ **Theorem 6.** *There is an α-approximation for Single-to-Single when q is fixed.*

Proof. When q is fixed, one can iterate through all the $O(n^q)$ possible choices of representatives, approximate the corresponding Multiway Cut instance, and choose the best one. ◀

For general q, it is helpful to first look at the case where G is a tree. We show that in this special case, the problem reduces to finding the minimum cost basis of a gammoid. We call a cut $C \subseteq E$ *good* if $G - C$ has a valid set of representatives, that is, if we can choose $|C| + 1$ representatives that form a partial transversal of the candidate sets, and each component of $G - C$ contains a single representative from this partial transversal. The algorithm is presented as Algorithm 2.

▶ **Theorem 7.** *Algorithm 2 computes an optimal solution to Single-to-Single on trees.*

Proof. We prove the statement by showing that the problem is equivalent to optimizing over a gammoid. We construct a directed graph as follows. Let $r \in V$ be an arbitrary root node, and orient the edges of the tree towards r. For a non-root node v, we denote the unique arc leaving v by $e(v)$ and define the cost of v to be $w(e(v))$. Furthermore, for each set T_i, we add a node s_i together with arcs from s_i to the candidates in T_i.

Let D denote the digraph thus obtained, $S \coloneqq \{s_1, \dots, s_q\}$, and $T \coloneqq V$, and consider the gammoid $M = (D, S, T)$. The key observation is the following.

▷ Claim 8. For a set $Z \subseteq V \setminus \{r\}$, $C = \{e(v) : v \in Z\}$ is a good cut if and only if $Z \cup \{r\}$ is independent in M.

Proof. For the forward direction, assume that $C = \{e(v) : v \in Z\}$ forms a good cut. Let $Z = \{v_1, \dots, v_p\}$. Without loss of generality, we may assume that the candidate sets having a valid set of representatives in $G - C$ are $T_1, \dots, T_p, T_{p+1}$, where v_i is in the component of the representative t_i of T_i and r is in the same component as the representative t_{p+1} of T_{p+1}.

Algorithm 3 Approximation algorithm for Single-to-Single on graphs.

```
Input: A graph $G = (V, E)$, weights $w : E \to \mathbb{R}_+$, candidates $T_1, \dots, T_q \subseteq V$.
Output: A feasible cut $C \subseteq E$.
Compute the Gomory-Hu tree $H$ of $G$.
Run Algorithm 2 on $H$.
Return the union of the cuts corresponding to edges found in Step 2.
```

For $i \in [p]$, the edge (s_i, t_i) and the path t_i-v_i in the tree form an s_i-v_i path; similarly, the edge (s_{p+1}, t_{p+1}) and the path t_{p+1}-r in the tree form an s_{p+1}-r path. Furthermore, these paths are pairwise node-disjoint, since they use different connected components of $G - C$.

For the other direction, assume that $Z \cup \{r\}$ is independent in M, and let $Z = \{v_1, \dots, v_p\}$. Without loss of generality, we may assume that there are pairwise node-disjoint paths from s_i to v_i for $i \in [p]$ together with a path from s_{p+1} to r. Let $t_i \in T_i$ be the first node on the path starting from s_i for $i \in [p + 1]$. Then $\{t_1, \dots, t_{p+1}\}$ form a valid system of distinct representatives for the cut C as each of these nodes are in a separate component of $G - C$. ◁

By Claim 8, a minimum-weight good cut can be determined using the greedy algorithm for matroids, which is exactly what Algorithm 2 is doing. ◀

Algorithm 2 solves the special case when G is a tree. The classical $(2-2/k)$ approximation for Multiway Cut [5] uses 2-way cuts coming from the Gomory-Hu tree, and so does the $(2 - 2/k)$ approximation for k-Cut [16]. We follow a similar approach in Algorithm 3. The algorithm can be interpreted as taking the minimum edges in the GH tree as long as they allow a valid system of representatives. The algorithm is presented as Algorithm 3.

▶ **Theorem 9.** *Algorithm 3 computes a $(2 - 2/q)$ approximation to Single-to-Single on arbitrary graphs.*

Proof. Let OPT be the optimal solution with representatives $t_1^*, \dots, t_q^*$, and components $V_1^*, \dots, V_q^*$, where V_q^* has the maximum weight boundary $\delta(V_q^*)$. Let also H be the GH tree of G.

We transform OPT into a solution OPT_{GH} on H, losing at most a factor of $(2 - 2/q)$. We do this by repeatedly removing the minimum weight edge in $E(H)$ that separates a pair among the representatives $t_1^*, \dots, t_q^*$ that are in the same component of H. More precisely, we start with $H_0 = H$, and take the minimum-weight edge $e_1 \in E(H_0)$ separating some pair of representatives t_i^*, t_j^* in OPT that are in the same component of H_0. Define the edge $f_1 = (t_i^*, t_j^*)$. Then we construct $H_1 = H_0 - e_1$, and repeat this process to get a sequence of edges $e_1, e_2, \dots, e_{q-1}$ and a tree of representative pairs $F = (\{t_1^*, \dots, t_q^*\}, \{f_1, \dots, f_{q-1}\})$.

Direct the edges of F away from t_q^*, and reorder the edges such that f^1 is the edge going into t_1^*, f^2 into t_2^*, and so on. Let e^i be the edge of the GH tree corresponding to f^i, i.e., the minimum weight edge of the path between the two endpoints of f^i, and let $U(e^i)$ be the cut corresponding to e^i for each i. Then the boundary of each component satisfies $w(\delta(V_i^*)) \geq w(U(e^i))$, as $\delta(V_i^*)$ separates the two representatives in f^i as well, and $U(e^i)$ is the minimum-weight cut between these.

Let the solution OPT_{GH} be $\bigcup_{i \in [q-1]} U(e_i)$, ALG the cut found by the algorithm, ALG_{GH} the corresponding edges in the GH tree H, and w_H the weight function on H. Then

$$w(ALG) \leq w_H(ALG_{GH}) \leq w_H(OPT_{GH}) = \sum_{i=1}^{q-1} w(U(e^i)) \leq \sum_{i=1}^{q-1} w(\delta(V_i^*))$$

$$\leq (1 - 1/q) \sum_{i=1}^{q} w(\delta(V_i^*)) \leq (2 - 2/q) w(OPT).$$ ◀

6 Fixed-to-Single, Some-to-Single, Some-to-Some, and Some-to-All Problems

In this section, we combine the study of four problems, as the techniques are similar.

6.1 Hardness of approximation

All four have similar proofs of hardness of approximation, which we state here but leave the proofs to appendix A for brevity.

▶ **Theorem 10.** *For general q, Fixed-to-Single, Some-to-Single and Some-to-All are at least as hard to approximate as Hitting Set.*

We omit the Some-to-Some problem from Theorem 10 because it follows as a corollary to Theorem 11, which states that it is equivalent to the known Steiner Multicut problem. The conditional $o(\log n)$ inapproximability was already proved for Steiner Multicut in [15], using similar instances as those in our proof of Theorem 10. The Some-to-Some problem asks to find a cut such that each pair of candidate sets have at least one element in separate components, where this choice can depend on the pair.

▶ **Theorem 11.** *The Some-to-Some problem is equivalent to Steiner Multicut.*

Proof. To reduce from Steiner Multicut, we are given q subsets $X_0, X_1, \ldots, X_{q-1}$ of nodes of a graph G, each of which needs to be cut into at least two components. We construct a Some-to-Some instance on the same graph with $2q$ candidate sets $T_0, T_1, \ldots, T_{2q-1}$, where $T_i = X_{\lfloor i/2 \rfloor}$ for $0 \le i \le 2q-1$. Then, for each $j = 0 \ldots q-1$, the condition that T_{2j} must be separated from T_{2j+1} ensures that there are two nodes $t_{2j}^{2j+1}, t_{2j+1}^{2j} \in X_j$ that are in different components. In other words, the solution is a minimal cut that, once removed, divides each set into at least two components. If the conditions of Some-to-Some hold for T_{2j} and T_{2j+1} for any j, then they hold automatically for any other pair of candidate sets too, because once a set has elements in two components, at least one of them will be in a different component than some element of any given candidate set.

For the other direction, we are given q subsets $T_1, \ldots, T_q$ of nodes of a graph G as a Some-to-Some instance. We then make a Steiner Multicut instance with $\binom{q}{2}$ vertex sets indexed by pairs $i, j \in [q]^2$ with $i \neq j$. The set $X_{i,j}$ will then be $T_i \cup T_j$, which means any valid Steiner Multicut solution C will split each of these sets into at least two components. We claim C is a valid Some-to-Some solution as well. Let $v_{i,j}, u_{i,j} \in X_{i,j}$ be in different components of $G \setminus C$. Then one of the following cases must hold:

1. $v_{i,j} \in T_i$ and $u_{i,j} \in T_j$. In this case, let $t_j^i := u_{i,j}$ and $t_i^j := v_{i,j}$.
2. $u_{i,j} \in T_i$ and $v_{i,j} \in T_j$. In this case, let $t_j^i := v_{i,j}$ and $t_i^j := u_{i,j}$.
3. $u_{i,j}, v_{i,j} \in T_i$. Then either
   (i) all of T_j is in the same component of $G \setminus C$ as $u_{i,j}$, in which case let $t_i^j := v_{i,j}$, and set t_j^i to an arbitrary element of T_j, or
   (ii) some vertex $w \in T_j$ is in a different component of $G \setminus C$ than $u_{i,j}$, in which case let $t_j^i := w$, and $t_i^j := u_{i,j}$.
4. Similarly, if $u_{i,j}, v_{i,j} \in T_j$, then either
   (i) all of T_i is in the same component of $G \setminus C$ as $u_{i,j}$, in which case let $t_j^i := v_{i,j}$, and set t_i^j to an arbitrary element of T_i, or
   (ii) some vertex $w \in T_i$ is in a different component of $G \setminus C$ than $u_{i,j}$, in which case let $t_i^j := w$, and $t_j^i := u_{i,j}$.

In all cases above, t_j^i is in a different component than t_i^j on $G \setminus C$, so C is a valid Some-to-Some solution. Any Some-to-Some solution is clearly also a solution for this Steiner Multicut instance, so the optimal cut is the same for both. ◀

6.2 Fixed q

The techniques when q is fixed differ, suggesting that the problems themselves are quite different, despite the apparent similarities.

Fixed Terminal

The Fixed-to-Single problem is slightly different from the others, as the goal here is to choose representatives that need to be separated only from a *fixed* node s. In this case, the problem can be solved efficiently.

▶ **Proposition 12.** *For fixed q, Fixed-to-Single can be solved in polynomial time.*

Proof. In this case, one can iterate through all possible choices of representatives, of which we have at most n^q, calculate a minimum two-way $s - \{t_i : i \in [q]\}$ cut for each, and then take the best of all solutions. ◀

Some to single/some

The Some-to-Single and Some-to-Some problems both become Multicut instances with a constant number of terminals in this case, which gives the following theorem:

▶ **Theorem 13.** *For fixed q, there is an α-approximation to Some-to-Single and Some-to-Some.*

Proof. We will use the α-approximation to Multiway Cut on a polynomial number of instances with fixed terminals. We begin with the Some-to-Single problem. In this problem, the goal is to choose a single representative t_j for each $j \in [q]$ together with some candidate $t_i^j \in T_i$ for each pair $i \neq j$ that are then separated by the cut.

When q is fixed, one can guess the representatives t_i^j and t_j to get a set of terminals S together with some separation demands on them. The number of such terminals can be bounded as $|S| \leq q^2$. A slightly more careful analysis shows that the number of different t_i^j nodes for a candidate set T_i can be bounded by two. Thus, we only have to guess three representatives from each T_i, implying $|S| \leq 3q$. Either way, the number of guesses for S is polynomial in n. Each guess of S defines a minimum multicut problem since we know which pairs of representatives have to be separated. We can compute an α-approximation to each of these Multicut problems by enumerating all possible partitions of S (of which there are exponentially many in q) that satisfy the multicut demands, collapsing the partitions into fixed terminals, and calculating an α-approximating multiway cut for each.

For the Some-to-Some problem, again guess the representatives t_i^j for each $i, j \in [q], i \neq j$ to get a set of terminals S together with some separation demands on them. Since any candidate set with terminals in different components already has at least one element in a separate component for any other candidate set, the number of such terminals can be bounded by $|S| \leq 2q$. For each fixed S, we can find an α-approximation the same way as above. ◀

Combining this approximation for Some-to-Some with Theorem 11 gives the current best approximation for Steiner Multicut in the regime where the number of candidates depends on n, and the number of sets is constant.

Some to all

Finally, we consider the Some-to-All problem, which asks to find representatives $t_i^j \in T_i$ for each pair $i, j \in [q]$ and a minimum-weight cut $C \subseteq E$ such that t_i^j is separated from *all* of T_j in $G - C$. The case for constant q uses the tool from Section 3.

▶ **Theorem 14.** *There is an α-approximation for Some-to-All when q is fixed.*

Proof. We guess all representatives t_i^j; there are at most n^{q^2} possible choices, which is polynomial if q is fixed. Note that we may assume that $t_i^j \neq t_j^\ell$ if $i \neq j$, otherwise there is obviously no solution. We also guess a valid partition $V_1, \ldots, V_{q_1}$ of these representatives into q_1 components, where $2 \leq q_1 \leq q^2$ (validity means that t_i^j and t_j^ℓ are in different classes of the partition if $i \neq j$). The number of such partitions is exponential in q, but we can still enumerate them when q is fixed (note that this is not a partition of V, but a partition of the set of all chosen representatives, which is a vertex set of size at most q^2). For such a partition, the problem becomes an instance of $(q_1 + 1)$-dimensional Lifted Cut with the following labels.

a) If $v \in V_k$ for some $k \in [q_1]$, then set $\ell(v) := \{k\}$.

b) Otherwise, if $v \in T_j$, then we must ensure that the label cannot be any partition containing some t_i^j. In other words, set $\ell(v) := \{1, 2, \ldots, q_1 + 1\} \setminus \{k : v \in T_j \text{ and } t_i^j \in V_k \text{ for some } i, j\}$.

c) Finally, if $v \in V \setminus \bigcup_{i \in [q]} T_i$, then set $\ell(v) := [q_1 + 1]$.

Conditions A and B of Lifted Cut are not difficult to verify. The solution to this problem is a solution to Some-to-All. Indeed, consider the partition given by a solution to Lifted Cut, which is an extension of the partition $V_1, \ldots, V_{q_1}$ by condition a, with an additional class for label $q_1 + 1$. Condition b then ensures, for a given t_i^j, that the component of t_i^j cannot contain any element of T_j. Thus, Theorem 3 gives an α-approximation for Some-to-All as well. ◀

A Hardness Proofs for Fixed-to-Single, Some-to-Single, and Some-to-All

Here we prove Theorem 10. In the Hitting Set problem, the input is a family $S_1, \dots, S_m$ of sets, and the goal is to find a smallest set of elements that intersects each of them.

▶ **Proposition 15.** *For general q, Fixed-to-Single is at least as hard to approximate as Hitting Set.*

Proof. To reduce Hitting Set to Fixed-to-Single, we create a graph G by adding a node s together with edges of weight 1 from s to the elements of the ground set. Thus we get a star with center s, and choose the candidate sets to be the sets $S_1, \dots, S_m$. Then, minimizing the number of edges needed to separate at least one node of each S_i from s is equivalent to finding a minimum hitting set; see Figure 2 for an illustration. Note that the reduction is approximation factor preserving. Since there is no $o(\log m)$ approximation for Hitting Set assuming $\mathrm{P} \neq \mathrm{NP}$ [6,14], the hardness of Fixed-to-Single follows. ◀

▶ **Proposition 16.** *For general q, Some-to-Single is at least as hard to approximate as Fixed-to-Single.*

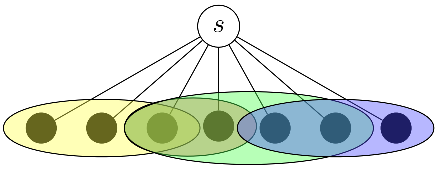

Figure 2 A picture of the reduction for Fixed-to-Single from Hitting Set.

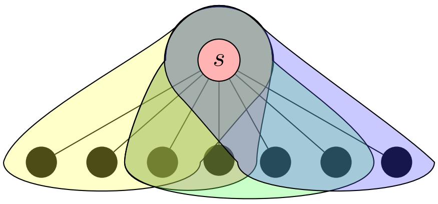

Figure 3 A picture of the reduction from Fixed-to-Single to Some-to-Single.

Proof. Given an instance $s, T_1, \ldots, T_q$ of Fixed-to-Single, we create an instance of Some-to-Single with $T'_i \coloneqq T_i \cup \{s\}$ for $i \in [q]$, and $T'_{q+1} \coloneqq \{s\}$; see Figure 3 for an example.

Given a solution to the Fixed-to-Single instance, we can obtain a solution of the same weight to the Some-to-Single instance by keeping the representatives t_i for $i \in [q]$, setting $t_{q+1} = t^i_{q+1} \coloneqq s$ for $i \in [q]$, $t^{q+1}_i \coloneqq t_i$ for $i \in [q]$, and $t^j_i \coloneqq s$ for $i, j \in [q], i \neq j$.

For the other direction, we observe that each t_j $(j \in [q])$ must be separated from s in a solution of the Some-to-Single instance. Thus, we obtain a solution with the same weight for the Fixed-to-Single if we keep the same representatives t_j $(j \in [q])$. ◀

▶ **Proposition 17.** *For general q, Some-to-All is at least as hard to approximate as Fixed-to-Single.*

Proof. Given an instance of Fixed-to-Single with sets $T_1, \ldots, T_q$ on a graph $G = (V, E)$ where $q \geq 2$, we construct a Some-to-All instance as follows. We add additional nodes $V_0 = \{s_1, s_2, \ldots, s_q\}$, $G' = (V \cup V_0, E)$, $T'_i = T_i \cup \{s_i\}$ for $i = 1 \ldots q$, and $T'_{q+1} = \{s, s_1, s_2, \ldots, s_q\}$; see Figure 4 for an example.

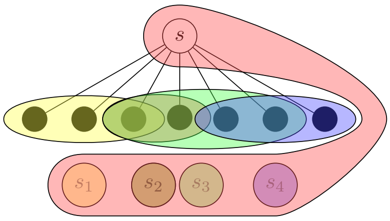

Figure 4 A picture of the reduction from Fixed-to-Single. The candidate set T_1 is in yellow, T_2 in brown, T_3 in green, T_4 in blue, and T_5 in red.

Given a Fixed-to-Single solution with representatives $t^*_1, \ldots, t^*_q$, we get a solution to this instance as follows: $t^j_{q+1} = s_{(j+1) \bmod q}$ for $j \in [q+1]$; if $i \in [q]$, then $t^{q+1}_i = t^*_i$, and $t^j_i = s_i$ for $j \in [q]$. Then the same cut will separate each t^j_i from all of T'_j, and have the same weight.

Given an optimal solution to the Some-to-All instance, we can assume without loss of generality that $t^j_i = s_{(j+1) \bmod q}$ when $i = q+1$, and $t^j_i = s_i$ when $i \neq q+1, j \neq q+1$, as these are separated from the corresponding T'_j in G'. Then we can get a Fixed-to-Single solution by setting $t_j = t^{q+1}_j$ for all $j \in [q]$ and removing the same edges. This reduction preserves approximation, as the solutions have the same weight. ◀

B Details of the Threshold Algorithms

For completeness, we include a detailed description of the α-approximation algorithm for lifted cut. This is just a collection of the results of Sharma and Vondrák [18], but understanding this is necessary for the proof of Theorem 3. The content of this section can be found in more detail in [18], the only modifications we make are to perform the rounding in $k+1$ dimensions and make more clear the role of the $(k+1)$st vertex.

First we describe the three threshold rounding schemes: Single Threshold, Descending Thresholds, and Independent Thresholds. These are described in Algorithms 4, 5, and 6, respectively. Each scheme is given a solution to LIFT-LP, and rounds it to an integer solution by assigning vertices to terminals. The Single Threshold Scheme takes as input some distribution with probability density ϕ, Descending Thresholds some distribution with density ψ, and Independent Thresholds with density ξ. Finally, these schemes are combined with appropriate parameters along with Algorithm 1 according to Algorithm 7, which takes additionally parameters $b, p_1, p_2, p_3, p_4 \in [0,1]$, along with some probability density ϕ.

Algorithm 4 The Single Threshold Rounding Scheme.

```
Choose threshold $\theta \in [0,1)$ with probability density $\phi(\theta)$.
Choose a random permutation $\sigma$ of $[k]$.
for all $i \in [k]$ do
    For any unassigned $u \in V$ with $x^u_{\sigma(i)} \geq \theta$, assign $u$ to terminal $\sigma(i)$.
end for
Assign all remaining unassigned vertices to terminal $k+1$
```

Algorithm 5 Descending Thresholds Rounding Scheme.

```
For each $i \in [k]$, choose threshold $\theta_i \in [0,1)$ with probability density $\psi(\theta)$.
Choose a random permutation $\sigma$ of $[k]$ such that $\theta_{\sigma(1)} \geq \theta_{\sigma(2)} \geq \ldots \geq \theta_{\sigma(k)}$.
for all $i \in [k]$ do
    For any unassigned $u \in V$ with $x^u_{\sigma(i)} \geq \theta_{\sigma_i}$, assign $u$ to terminal $\sigma(i)$.
end for
Assign all remaining unassigned vertices to terminal $k+1$
```

Algorithm 6 Independent Threshold Rounding Scheme.

```
For each $i \in [k]$, choose independently threshold $\theta_i \in [0,1)$ with probability density $\xi(\theta)$.
Choose a uniformly random permutation $\sigma$ of $[k]$.
for all $i \in [k]$ do
    For any unassigned $u \in V$ with $x^u_{\sigma(i)} \geq \theta_{\sigma(i)}$, assign $u$ to terminal $\sigma(i)$.
end for
Assign all remaining unassigned vertices to terminal $k+1$
```

The following three Lemmas are key to the analysis of Algorithm 7. The cut density for an edge of type (i,j) located at $(u_1, u_2, \ldots, u_{k+1}) \in \Delta_{k+1}$ is the limit of the probability that the given threshold scheme assigns $(u_1, u_2, \ldots, u_{k+1})$ and $(u_1+\varepsilon, u_2-\varepsilon, \ldots, u_{k+1})$ to different terminals, normalized by ε as $\epsilon \to 0$.

Algorithm 7 The Sharma-Vondrák Rounding Scheme.

```
With probability $p_1$, choose the Kleinberg-Tardos Rounding Scheme (Algorithm 1).
With probability $p_2$, choose the Single Threshold Rounding Scheme (Algorithm 4) with probability density $\phi$.
With probability $p_3$, choose the Descending Threshold Rounding Scheme (Algorithm 5), where the thresholds are chosen uniformly in $[0, b]$.
With probability $p_4$, choose the Independent Threshold Rounding Scheme (Algorithm 6), where the thresholds are chosen uniformly in $[0, b]$.
```

▶ **Lemma 18** (Lemma 5.1 in [18]). *Given a point $(u_1, u_2, \dots, u_{k+1}) \in \Delta_{k+1}$ and the parameter b of Algorithm 7, let $a = \frac{1-u_i-u_j}{b}$. If $a > 0$, the cut density for an edge of type (i, j), where $i \neq j$ are indices in $[k+1]$ located at $(u_1, u_2, \dots, u_{k+1})$ under the Independent Thresholds Rounding Scheme with parameter b is at most*

- $\frac{2(1-e^{-a})}{ab} - \frac{(u_i+u_j)(1-(1+a)e^{-1})}{a^2b^2}$, *if all the coordinates $u_1, u_2, \dots, u_{k+1}$ are in $[0, b]$.*
- $\frac{(a+e^{-a}-1)}{a^2b}$, *if $u_i \in [0, b], u_j \in (b, 1]$ and $u_\ell \in [0, b]$ for all other $\ell \in [k] \setminus \{i, j\}$.*
- $\frac{1}{b} - \frac{(u_i+u_j)}{6b^2}$, *if $u_i, u_j \in [0, b]$ and $u_\ell \in (b, 1]$ for some other $\ell \in [k] \setminus \{i, j\}$.*
- $\frac{1}{3b}$, *if $u_i \in [0, b], u_j \in (b, 1]$ and $u_\ell \in [0, b]$ for some other $\ell \in [k] \setminus \{i, j\}$.*
- 0, *if $u_i, u_j \in (b, 1]$.*

For $a = 0$, the cut density is given by the limit of the expressions above as $a \to 0$.

▶ **Lemma 19** (Lemma 5.2 in [18]). *For an edge of type (i, j) located at $(u_1, u_2, \dots, u_{k+1})$, where $i \neq j$ are indices in $[k+1]$, the cut density under the Single Threshold Rounding Scheme is at most*

- $\frac{1}{2}\phi(u_i) + \phi(u_j)$, *if $u_\ell \leq u_i \leq u_j$ for all other $\ell \in [k] \setminus \{i, j\}$.*
- $\frac{1}{3}\phi(u_i) + \phi(u_j)$, *if $u_i < u_\ell \leq u_j$ for some other $\ell \in [k] \setminus \{i, j\}$.*
- $\frac{1}{2}\phi(u_i) + \phi(u_j)$, *if $u_i \leq u_j < u_\ell$ for some other $\ell \in [k] \setminus \{i, j\}$.*

▶ **Lemma 20** (Lemma 5.3 in [18]). *For an edge of type (i, j) located at $(u_1, u_2, \dots, u_{k+1})$, where $i \neq j$ are indices in $[k+1]$, the cut density under the Descending Thresholds Rounding Scheme is at most*

- $(1 - \int_{u_i}^{u_j} \psi(u)du)\psi(u_i) + \psi(u_j)$, *if $u_\ell \leq u_i \leq u_j$ for all other $\ell \in [k] \setminus \{i, j\}$.*
- $(1 - \int_{u_i}^{u_j} \psi(u)du)((1 - \int_{u_i}^{u_\ell} \psi(u)du))\psi(u_i) + \psi(u_j)$, *if $u_i < u_\ell \leq u_j$ for some other $\ell \in [k] \setminus \{i, j\}$.*
- $(1 - \int_{u_i}^{u_j} \psi(u)du)(1 - \int_{u_i}^{u_\ell} \psi(u)du)\psi(u_i) + (1 - \int_{u_j}^{u_\ell} \psi(u)du)\psi(u_j)$, *if $u_i \leq u_j < u_\ell$ for some other $\ell \in [k] \setminus \{i, j\}$.*

The proof for each of these Lemmas is exactly as in [18], save for one additional trivial observation: the cut density of an edge of type $(i, k+1)$ is at most that of an edge of type (i, j) for any $j \neq i, j \neq k+1$. This is because the $(k+1)$st terminal is considered last, and has no threshold of its own, and therefore cannot increase the separation probability. With these Lemmas in hand, Theorem 5.6 of [18] shows, with a specific choice of parameters, that Algorithm 7 is a 1.2965-approximation to Lifted Cut as well.

Capturing the Shape of a Point Set with a Line Segment

Abstract

Detecting location-correlated groups in point sets is an important task in a wide variety of applications areas. In addition to merely detecting such groups, the group's shape carries meaning as well. In this paper, we represent a group's shape using a simple geometric object, a line segment. Specifically, given a radius r, we say a line segment is *representative* of a point set P of n points if it is within distance r of each point $p \in P$. We aim to find the shortest such line segment. This problem is equivalent to stabbing a set of circles of radius r using the shortest line segment. We describe an algorithm to find the shortest representative segment in $O(n \log h + h \log^3 h)$ time, where h is the size of the convex hull of P. Additionally, we show how to maintain a stable approximation of the shortest representative segment when the points in P move.

1 Introduction

Studying location-correlated groups or clusters in point sets is of interest in a wide range of research areas. There are many algorithms and approaches to find such groups; examples include the well-known *k-means clustering* [23] or *DBSCAN* [18]. In addition to the mere existence of such groups, the group's characteristics can carry important information as well. In wildlife ecology, for example, the perceived shape of herds of prey animals contains information about the behavioral state of animals within the herd [30]. Since shape is an abstract concept that can get arbitrarily complex, it is often useful to have a simplified representation of group shape that can efficiently be computed. The simplest shape (besides a point) that may represent a group is a line segment, suggesting that the group is stretched in a single direction.

When the points move in the plane, as is the case for animals, the representing line segment may change orientation and length. Also, it may disappear if the shape of the points is no longer captured well by a line segment. Conversely, it can also appear when the points form a segment-like shape again.

Let us concentrate on the static version of the problem first. There are a few simple ways to define a line segment for a set of points. We can use the width of the point set to define a narrowest strip, put tight semi-circular caps on it, and use the centers of these semi-circles as the endpoints of the line segment. We can also use the focal points of the smallest enclosing ellipse, and use them as the endpoints. We can also use a maximum allowed distance from the points to the line segment, and use the shortest line segment possible. The first and third option are based on a hippodrome shape (the Minkowski sum of a line segment and a disk). We note that the second and third option still need a threshold distance to rule out that points are arbitrarily far from the defining line segment. In particular, the case that a line segment is *not* a suitable representation should exist in the model, and also the case where the line segment can become a single point. There are multiple other options besides the three given, for example, by using the first eigenvector of the points, or the diameter.

In this paper we study the model given by the third option: given a set P of n points in general position, we want to find the shortest line segment q_1q_2 such that all points are within distance r. This model has several advantages: (i) It is a simple model. (ii) It naturally includes the case that no line segment represents the points, or a single point already represents the points. (iii) It guarantees that all points are close to the approximating line segment. (iv) It has desirable properties when the points move: in the first two options, there are cases where the points intuitively remain equally stretched in the direction of the line segment, but points moving orthogonally away from it yields a shorter(!) line segment. This issue does not occur in the chosen model. Moreover, it was studied before in computational geometry, and we can build on existing algorithmic methods and properties.

The first algorithm published that solves the optimization version of the static problem (in fact, the first option) uses $O(n^4 \log n)$ time, for a set of n points [24]. This was improved by Agarwal et al. [1] to $O(n^2\alpha(n)\log^3 n)$, where $\alpha(n)$ is the extremely slowly growing functional inverse of Ackermann's function. The first subquadratic bound was given by Efrat and Sharir [17], who presented an $O(n^{1+\varepsilon})$ time algorithm, for any constant $\varepsilon > 0$. They use the fixed-radius version as a subroutine and then apply parametric search. Their fixed-radius algorithm already has the bound of $O(n^{1+\varepsilon})$, as it uses vertical decompositions of a parameter space in combination with epsilon-nets. They remark that their methods can solve the shortest stabber problem for unit disks within the same time, which is our problem.

In this paper we present an improved static result and new kinetic results. We solve the static version in $O(n \log^3 n)$ time by exploiting the geometry of the situation better, which allows us to avoid the use of parametric search and epsilon-nets. Our new algorithm uses a rotating calipers approach where we predict and handle events using relatively simple data structures. We still use a key combinatorial result from [17] in our efficiency analysis. For the kinetic problem, we are interested in developing a strategy to maintain a "stable" line segment that does not frequently appear and disappear, and whose endpoints move with bounded speed. To accomplish this, we must relax (approximate) the radius around the line segment in which points can be. We show that with constant speeds and a constant factor approximation in radius, the endpoints of the line segment move at a speed bounded by a linear function in r, while also avoiding frequent (dis)appearances of the line segment. These results complement recent results on stability.

Related work. A number of shape descriptors have been proposed over the years. A few popular ones are the *alpha shape* of a point set [15] and the *characteristic shape* [12], both of which generate representative polygons. Another way to generate the shape of a point set is to fit a function to the point set [6, 22, 32]. Bounding boxes and strips are much closer related

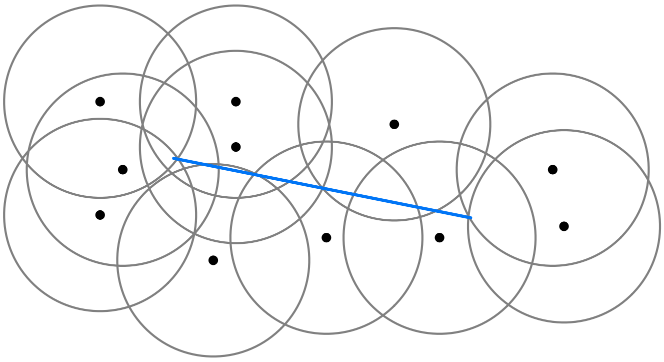

Figure 1 The line segment (blue) must hit every circle of radius r, centered at the points in P.

to the line segment we propose. In the orientation of the first eigenvector, bounding boxes (and strips) have been shown to not capture the dimensions of a point set well [11]. Optimal bounding boxes and strips, of minimum area and width, respectively, align with a convex hull edge and can be computed in linear time given the convex hull [19, 31]. Problems of finding one or more geometric objects that intersect a different set of geometric objects are known as *stabbing* problems [16], and several variants have been studied [5, 10, 29]. As mentioned, stabbing a set of unit circles with the shortest line segment was studied in [17]. The inverse variant, line segments stabbed by one or more circles, has also been studied [7, 25].

Recently, considerable attention has been given to stability of structures under the movement of a set of points or motion of other objects. Stability is a natural concern in, for example, (geo)visualization and automated cartography: In air traffic control planes may be visualized as labeled points on a map, and the labels are expected to smoothly follow the locations of the moving points [8]. Similarly, for interactive maps that allow, for example zooming and panning, labels should not flicker in and out of view [2, 20, 21, 28]. In computational geometry, only the stability of k-center problems was studied [3, 9, 13, 14], until Meulemans et al. introduced a framework for stability analysis [26]. Applying the framework to shape descriptors, they proved that an $O(1)$-approximation of an optimal oriented bounding box or strip moves only a constant-factor faster than the input points [27].

2 Computing the Shortest Representative Segment

Given a set P of n points and a distance bound r, we show how to construct the shortest segment q_1q_2 with maximum distance r to P. See Figure 1 for an example. Omitted proofs can be found in the full version.

Our algorithm uses the rotating calipers approach [31]. We start by finding the shortest representative segment for fixed orientation α, after which we rotate by π while maintaining the line segment, and return the shortest one we encounter. Note that, even though a representative segment does not exist for every orientation, we can easily find an initial orientation α for which it does exist using rotating calipers; these are the orientations at which the rotating calipers have width $\leq 2r$. Although our input point set P can be of any shape, the following lemma shows that it suffices to consider only its convex hull $\mathsf{CH}(P)$.

▶ **Lemma 1.** *If a line segment q_1q_2 intersects all circles defined by the points in the convex hull $\mathsf{CH}(P)$, then q_1q_2 also intersects all circles defined by the points in P.*

We can compute $\mathsf{CH}(P)$ in $O(n \log h)$ time, where h is the size of the convex hull [4].

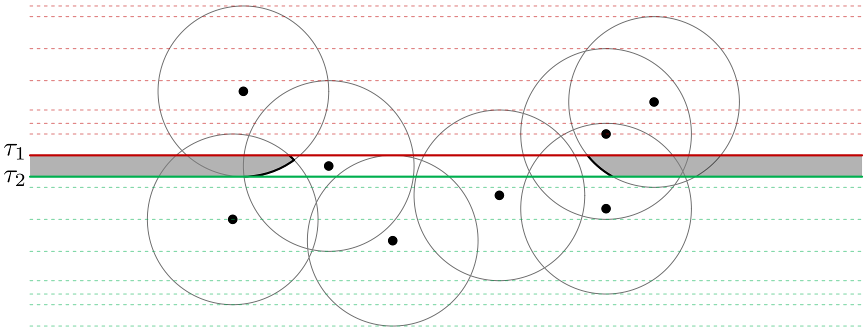

Figure 2 Two extremal tangents τ_1 and τ_2 for horizontal orientation α. The shortest line segment of orientation α that intersects all circles, ends at the boundary of the gray regions.

2.1 Fixed orientation

We describe how to find the shortest representative segment with fixed orientation α. Using rotating calipers [31], we can find all orientations in which a representative segment exists, and pick α such that a solution exists. For ease of exposition and without loss of generality, we assume α to be horizontal. Let the *left* and *right half-circle* of a circle C be the half-circle between $\pi/2$ and $3\pi/2$ and between $3\pi/2$ and $5\pi/2$, respectively. Lemma 1 permits us to consider only points of P on the convex hull, thus for the remainder of this paper we use $\mathcal{C}_P$ to indicate the set of circles of radius r centered at the points of P in $\mathsf{CH}(P)$.

Observe that every horizontal line that lies below the bottom-most top horizontal tangent τ_1 and above the top-most bottom horizontal tangent τ_2 of all circles crosses all circles (see Figure 2). If τ_1 lies below τ_2, then there exists no horizontal line that crosses all circles.

To place q_1q_2 in the strip between τ_1 and τ_2, we can define regions R_1, R_2 in which endpoints q_1 and q_2 must be placed such that q_1q_2 intersects all circles (see Figure 2).

The region R_1 is defined as the set of points below or on τ_1 and above or on τ_2 and right or on the right-most envelope of all left half-circles. The region R_2 is defined analogously using the left envelope of right half-circles. We use S_1 and S_2 to denote the envelope boundary of R_1 and R_2 respectively. Note that S_1 and S_2 are convex and consist of circular arcs from the left and right half-circles respectively. If R_1 and R_2 intersect, then we can place a single point in their intersection at distance at most r from all points in P. Otherwise, note that q_1 and q_2 must be on the convex sequences S_1 and S_2, respectively; otherwise, we can move the endpoint onto the convex sequence, shortening q_1q_2 and still intersecting all circles.

We will show that we can compute S_1 and S_2 in $O(h)$ time. First, we show that the half-circles on a convex sequence appear in order of the convex hull.

▶ **Lemma 2.** *The order of the circular arcs in S_1 or S_2 matches the order of their corresponding centers in* $\mathsf{CH}(P)$.

Now we can compute the convex sequences in linear time, given the tangents τ_1 and τ_2, which can easily be found in linear time.

▶ **Lemma 3.** *Given tangents τ_1 and τ_2, and* $\mathsf{CH}(P)$, *we can construct S_1 and S_2 in $O(h)$.*

Proof. We assume that a solution exists, which can easily be checked in $O(h)$ time. We describe only the construction of S_1, as S_2 can be constructed symmetrically. Without loss of generality, assume that τ_1 denotes the start of S_1 in clockwise order. We can find the first arc on S_1 by checking all intersections between τ_1 and the relevant half-circles, and

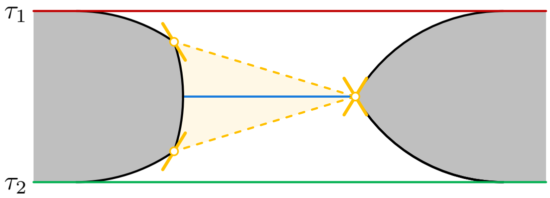

Figure 3 Two convex sequences between τ_1 and τ_2. There are multiple points on the left convex sequence that have the same tangent as the right yellow vertex. Still, there is only one line segment in horizontal orientation for which the tangents of its endpoints are equal (blue).

identifying the most extremal intersection in $O(h)$ time (see Figure 2) We add the part of the circle that lies between τ_1 and τ_2 to S_1. We then process each point p_i along the convex hull in clockwise order from the point defining our initial arc.

Next, let $\frown{c}_1, \ldots, \frown{c}_k$ denote the circular arc pieces for S_1 constructed so far. Let p_i be the next point on the convex hull that we process. Let c_i denote the left half-circle centered at p_i and let c_k be the support left half-circle of $\frown{c}_k$. We find the intersection between c_i and c_k. If there is no intersection, then c_i must lie entirely to the left of c_k and it cannot contribute to S_1. If the intersection point is below τ_2 then between τ_1 and τ_2 we have that c_i lies left of c_k and it cannot contribute to S_1. If the intersection point lies within $\frown{c}_k$ then we update S_1 to switch at the intersection point from c_k to c_i as then c_i must lie right of c_k below the intersection point. If the intersection point lies above $\frown{c}_k$ then the entirety of $\frown{c}_k$ lies to the left of c_i, therefore $\frown{c}_k$ cannot contribute to S_1 and we can discard $\frown{c}_k$. We then continue by comparing c_i to c_{k-1}.

Whenever a half-circle is possibly added it is compared to at most $O(|S_1|)$ arcs. However, when the half-circle is compared to i arcs, then $i-1$ arcs would be removed from S_1. Thus, by an amortization argument, this happens $O(h)$ times. ◀

Next, we must place q_1 and q_2 on S_1 and S_2, respectively, such that q_1q_2 is shortest. We show that q_1q_2 is the shortest line segment of orientation α when the tangents of S_1 at q_1 and S_2 at q_2 are equal. Vertices on S_1 and S_2 have a range of tangents (see Figure 3).

▶ **Lemma 4.** *Let S_1 and S_2 be two convex sequences of circular arcs, and let q_1 and q_2 be points on S_1 and S_2, respectively, such that line segment q_1q_2 has orientation α. If the tangent on S_1 at q_1 is equal to the tangent on S_2 at q_2, then q_1q_2 is minimal.*

Observe that the length of q_1q_2 is unimodal between τ_1 and τ_2. We can hence binary search in $O(\log h)$ time for the optimal placement of q_1 and q_2. By Lemmata 3 and 4 we can compute the shortest representative segment of fixed orientation α in $O(h)$ time.

2.2 Rotation

After finding the shortest line segment for a fixed orientation α, as described in the previous section, we sweep through all orientations α while maintaining τ_1, τ_2, S_1, S_2, and the shortest representative segment q_1q_2 of orientation α. We allow all of these maintained structures to change continuously as the orientation changes, and store the shortest representative segment found. Any time a discontinuous change would happen, we trigger an *event* to reflect these changes. We pre-compute and maintain a number of *certificates* in an event queue, which indicate at which orientation the next event occurs. This way we can perform the continuous motion until the first certificate is violated, recompute the maintained structures, repair the event queue, and continue rotation.

We distinguish five types of events:

1. q_1 or q_2 moves onto/off a vertex of S_1 or S_2;
2. τ_1 or τ_2 is a bi-tangent with the next circle on the convex hull;
3. τ_1 and τ_2 are the same line;
4. τ_1 or τ_2 is tangent to S_1 or S_2 and rotates over a (prospective) vertex of S_1 or S_2;
5. τ_1 or τ_2 is not tangent to S_1 or S_2 and rotates over a (prospective) vertex of S_1 or S_2.

Since the shortest line segment q_1q_2 in orientation α is completely determined by τ_1, τ_2, S_1, and S_2, the above list forms a complete description of all possible events. Thus, we maintain at most two certificates for events of type 1 (one for each convex sequence) and 2 (one for each tangent), and a single type-3 certificate. Additionally, there must be exactly one type-4 or type-5 certificate for each endpoint of S_1 and S_2, so four in total. These are stored in a constant-size event queue Q, ordered by appearance orientation. Insert, remove, and search operations on Q can hence be performed in $O(1)$ time.

We will describe below how all events over a full rotational sweep can be handled in $O(h \log^3 h)$ time in total. Combined with the computation of the convex hull of P this yields the following theorem. Note that in the worst case P is in convex position, and $n = h$.

▶ **Theorem 5.** *Given a point set P consisting of n points and a radius r, we can find the shortest representative segment in $O(n \log h + h \log^3 h)$ time, where $|\mathsf{CH}(P)| = h$.*

Event handling. In the following descriptions, we assume that an event happens at orientation α, and that ε is chosen such that no other events occur between $\alpha - \varepsilon$ and $\alpha + \varepsilon$. We also assume that no two events happen simultaneously, which is a general position assumption. We describe, for each event type, the time complexity of computing a new certificate of that type, the time complexity of resolving the event, and the number of occurrences.

(1) q_1/q_2 moves onto/off of a vertex of S_1/S_2. We describe, without loss of generality, how to handle the event involving q_1 and S_1; the case for q_2 and S_2 is analogous. See Figure 4 for an example of this event. First, observe that we can compute certificates of this type in $O(1)$ time, simply by walking over S_1 to find the next vertex/arc q_1 should move onto.

▶ **Observation 6.** *We can construct a new certificate of type 1 in $O(1)$ time.*

Observe that, since vertices of S_1 cover a range of tangents, there are intervals of orientations at which q_1 remains at a vertex of S_1. As such, we describe two different cases for this event: q_1 moves *onto* or *off* a vertex of S_1.

If q_1 was moving over an arc of S_1 at $\alpha - \varepsilon$ and encounters a vertex at α, then the movement path of q_1 is updated to remain on the encountered vertex. Additionally, we place a new type-1 certificate into the event queue that is violated when q_1 should move off the vertex, when the final orientation covered by the vertex is reached.

If q_1 is at a vertex at $\alpha - \varepsilon$ and orientation α is the final orientation covered by that vertex, then the movement path of q_1 must be updated to follow the next arc on S_1. Additionally, we place a new type-1 certificate into the event queue that is violated when q_1 encounters the next vertex, at the orientation at which this arc of S_1 ends.

▶ **Lemma 7.** *Throughout the full π rotation, type-1 events happen at most $O(h)$ times, and we can resolve each occurrence of such an event in $O(1)$ time.*

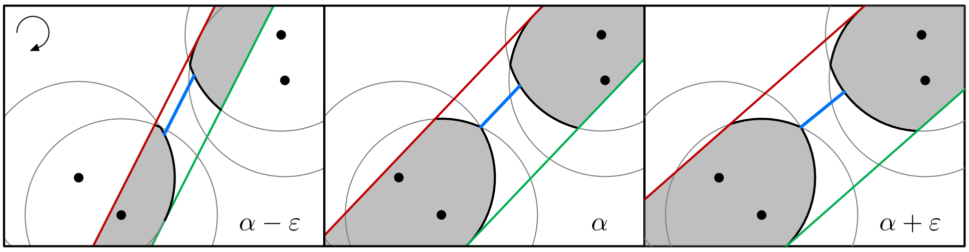

Figure 4 When q_1/q_2 is at a vertex of S_1/S_2, it stops moving.

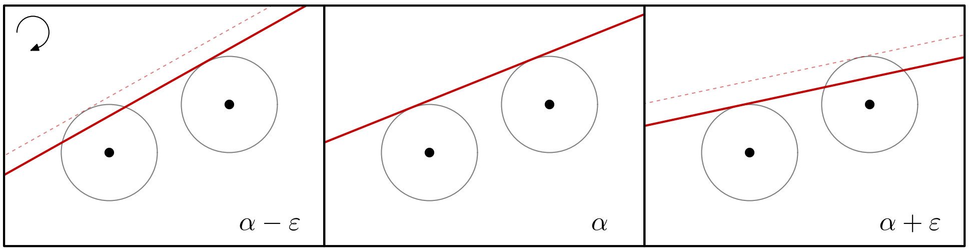

Figure 5 When the defining circle of τ_1/τ_2 changes, τ_1/τ_2 is parallel to a convex hull edge.

(2) τ_1 or τ_2 is bi-tangent with the next circle on the convex hull. We describe, without loss of generality, how to handle the event involving τ_1; handling τ_2 is analogous. See Figure 5 for an illustration. First, observe that we can compute certificates of this type in $O(1)$ time, since these certificates depend only on the orientation of the next convex hull edge.

▶ **Observation 8.** *We can construct a new certificate of type 2 in $O(1)$ time.*

When τ_1 is a bi-tangent of two circles defined by their centers $u, v \in P$ then, by definition of τ_1, u and v must both be the extremal points in the direction θ perpendicular to α. Therefore, (u, v) must be an edge on the convex hull. Suppose that, without loss of generality, u was the previous extremal vertex in direction $\theta - \varepsilon$, then v is extremal in direction $\theta + \varepsilon$. As such, τ_1 belongs to u at $\alpha - \varepsilon$, and to v at $\alpha + \varepsilon$. When this happens, we insert a new type-2 certificate into the event queue that is violated at the orientation of the next convex hull edge. Additionally, we must recompute the certificates of type 3, 4 and 5 that are currently in the event queue, since these are dependent on τ_1.

▶ **Lemma 9.** *Throughout the full π rotation, type-2 events happen at most $O(h)$ times, and we can resolve each occurrence of such an event in $O(\log^2 h)$ time.*

(3) τ_1 and τ_2 are the same line. When this event takes place, τ_1 and τ_2 are the inner bi-tangents of their two respective defining circles. See Figure 6 for an example. First, observe that we can compute certificates of this type in $O(1)$ time by simply finding the inner bi-tangent of the circles corresponding to τ_1 and τ_2.

▶ **Observation 10.** *We can construct a new certificate of type 3 in $O(1)$ time.*

We distinguish two different cases for this event: either there is a solution at $\alpha - \varepsilon$ and no solution at $\alpha + \varepsilon$, or vice versa.

If there was a solution at $\alpha - \varepsilon$ and there is none at $\alpha + \varepsilon$, we simply stop maintaining q_1q_2, S_1 and S_2 until there exists a solution again. As such, we remove all type-1, type-5 and type-4 certificates from the event queue and place a new type-3 certificate into the event queue that is violated at the next orientation where τ_1 and τ_2 are the same line.

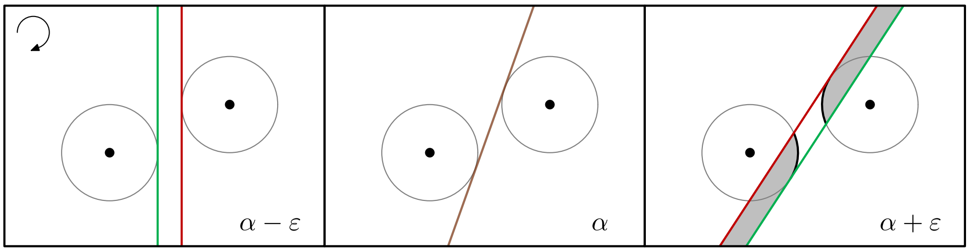

Figure 6 When τ_1 and τ_2 are the same line, they are an inner bi-tangent of their two defining circles.

If there was no solution at $\alpha - \varepsilon$ and there is a solution at $\alpha + \varepsilon$, we must recompute S_1, S_2, and $q_1 q_2$ at orientation α. At orientation α, S_1 and S_2 are single vertices where τ_1 and τ_2 intersect the extremal half-circles of the arrangement. Then, $q_1 q_2$ is the line segment between these single vertices of S_1 and S_2. We place new type-1, type-4 and type-5 certificates into the event queue reflecting the newly found S_1, S_2, q_1 and q_2. Additionally, we insert a new type-3 certificate that is violated at the next orientation where τ_1 and τ_2 are the same line.

▶ **Lemma 11.** *Throughout the full π rotation, type-3 events happen at most $O(h)$ times, and we can resolve each occurrence of such an event in $O(\log^2 h)$ time.*

(4) τ_1 or τ_2 is tangent to S_1 or S_2 and rotates over a (prospective) vertex of S_1 or S_2. We describe, without loss of generality, how to handle the event involving τ_1 and S_1; the case for τ_2 and S_2 is analogous. See Figure 7 for an example of this event. First, observe that we can compute certificates of this type in $O(1)$ time: Let C_i be the circle to which τ_1 is tangent. Then, to construct a certificate, we find the orientation at which τ_1 hits the intersection point of C_i and S_1. Note that this intersection is part of S_1 or will appear at τ_1.

▶ **Observation 12.** *We can construct a new certificate of type 4 in $O(1)$ time.*

Let vertex v be the vertex of the convex chain S_1 that is intersected by τ_1 at orientation α. Then either vertex v is a vertex of S_1 at orientation $\alpha - \varepsilon$ but not at $\alpha + \varepsilon$, or vice versa.

In the prior case, at orientation α the arc to which τ_1 is a tangent is completely removed from S_1. Vertex v becomes the endpoint of S_1 and starts moving along the next arc of S_1. If the affected arc or vertex appeared in a type-1 certificate in the event queue, it is updated to reflect the removal of the arc and the new movement of the vertex. Additionally, we place a new type-5 certificate into the event queue.

In the latter case, at orientation α an arc of the incident circle to τ_1 needs to be added to S_1. If the arc that was previously the outer arc of S_1 appeared in a type-1 certificate in the event queue, it may need to be updated to reflect the addition of the new arc. Additionally, we place a new type-4 certificate into the event queue.

▶ **Lemma 13.** *Throughout the full π rotation, type-4 events happen at most $O(h)$ times, and we can resolve each occurrence of such an event in $O(\log^2 h)$ time.*

(5) τ_1 or τ_2 is not tangent to S_1 or S_2 and rotates over a (prospective) vertex of S_1 or S_2. We describe, without loss of generality, how to handle the event involving τ_1 and S_1; the case for τ_2 and S_2 is analogous. See Figure 8 for an example of this event. The time complexity of constructing a certificate of this type is stated in the following lemma.

▶ **Lemma 14.** *We can construct a new certificate of type 5 in $O(\log^2 h)$ time.*

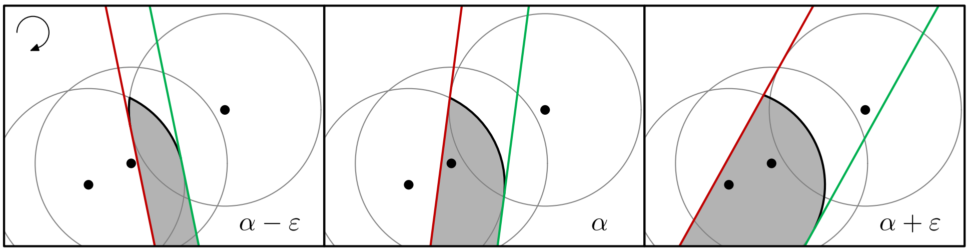

Figure 7 When τ_1/τ_2 hits an intersection of its defining circle that is also on S_1/S_2, an arc is removed from S_1/S_2.

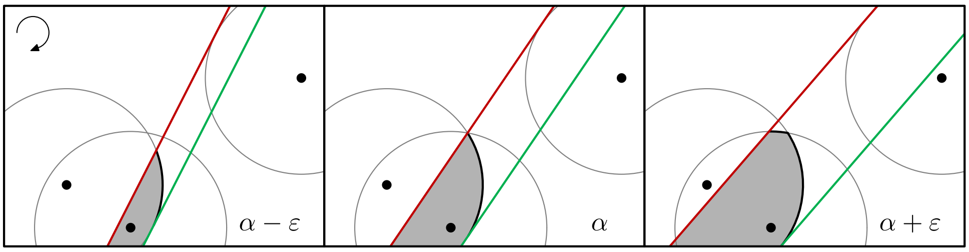

Figure 8 When τ_1/τ_2 hits an intersection of two circles, an arc needs to be added to S_1/S_2.

Additionally, we get the following bounds on handling type-5 events.

▶ **Lemma 15.** *Throughout the full π rotation, τ_1 or τ_2 hits a vertex of S_1 or S_2 at most $O(h \log h)$ times, and we handle each occurrence of this event in $O(\log^2 h)$ time.*

We prove Lemmata 14 and 15 using an additional data structure in the following section.

2.3 Finding and maintaining the convex sequence

In this section, we describe an additional data structure necessary to maintain the convex sequences S_1 and S_2 efficiently. We can use this data structure to construct and handle violations of type-5 certificates efficiently, as well as to find new starting positions of S_1 and S_2 after a type-3 event.

Let $p_1, \ldots, p_h$ be the vertices of the convex hull in clockwise order. At a given orientation α, let p_i be the point corresponding to the circle C_i to which τ_1 is tangent. We use v_τ to denote the intersection point between τ_1 and S_1, if it exists, which is simultaneously an endpoint of S_1. Let p_j be the point corresponding to the circle C_j on which v_τ is located. This implies that the arc on S_1 intersected by τ_1 belongs to circle C_j. Then, during our rotational sweep, v_τ is moving over C_j. A type-5 event takes place when v_τ hits the intersection of C_j with another circle C_k corresponding to point p_k.

If, before a type-5 event, the arc of C_j on S_1 was shrinking due to the movement of v_τ, then C_j is fully removed from S_1 at the event, and v_τ continues moving over S_1. Constructing the certificate in this case is very easy, since all we need to do is walk over S_1 from v_τ to find the next vertex. As such, for the remainder of this section, we consider only the more complicated type-5 event, where the arc of C_j on S_1 is growing due to the movement of v_τ.

In that case, when the type-5 event happens, an arc of C_k is added to S_1, and v_τ starts moving over C_k instead of C_j. As such, to construct a type-5 certificate, we must find the intersection between C_j and another circle C_k belonging to a point $p_k \in P$, such that the intersection between C_j and C_k is the first intersection hit by v_τ. To do this, we will first state some characteristics of C_k and p_k.

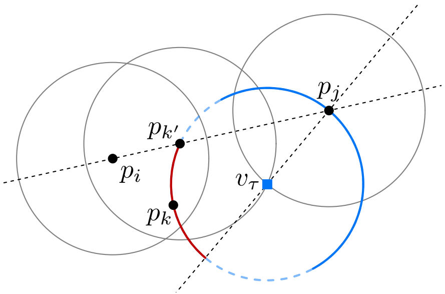

Figure 9 Point p_k is placed on the red arc, which is a subset of the (blue dashed) convex semi-circle centered at v_τ, and disjoint from the (blue solid) concave semi-circle centered at v_τ.

First, observe that finding the first intersecting circle C_k of C_j is not necessarily enough. We are only interested in the semi-circles of all circles in $\mathcal{C}_P$ that have the same "opening direction" as the convex chain S_1 for a given orientation α. As such, let the *convex semi-circle* of a given circle C be the semi-circle of C that is convex with respect to S_1. Conversely, let the *concave semi-circle* of C be the opposite semi-circle of C. Then, circle C_k appears on S_1 after a hit by v_τ at orientation α if v_τ is on the convex semi-circle of C_k at orientation α. If this is not the case, C_k should be skipped. We show that, for this reason, we never have to consider points p_l such that $l < i$ or $j < l$ when constructing a type-5 certificate.

▶ **Lemma 16.** *Let C_i be the circle defining τ_1, and let C_j be the circle on which v_τ is located, for $i \neq j$. Let C_k be the first circle hit by v_τ during rotation at orientation α. If $k < i$ or $j < k$, then at orientation α, v_τ lies on the concave semi-circle of C_k with orientation α.*

Proof. Without loss of generality assume p_i is positioned left of p_j, then assuming that $k < i$ or $j < k$, p_k must lie below the line through p_i and p_j (since $i < j$ and the points are ordered in clockwise order). See Figure 9 for the following construction.

Consider point $p_{k'}$ placed on the line through p_i and p_j, such that v_τ could be the bottom intersection of C_j and a radius-r circle centered at $p_{k'}$. Let p_k be a point placed on the circle of radius r centered at v_τ. If p_k is placed on the other side of the line through v_τ and p_j, compared to $p_{k'}$, then v_τ would enter C_k at orientation α, which does not induce an event. As such, p_k must be on the same side of the line through v_τ and p_j as $p_{k'}$. Additionally, since $k < i$ or $j < k$, p_k must be below the line through p_i and p_j.

It is easy to see that all points on the convex semi-circle of v_τ will have v_τ on their concave semi-circle. Since the arc on which p_k is placed is a strict subset of the concave semi-circle of v_τ, any placement of p_k must have v_τ on its concave semi-circle. ◀

Lemma 16 implies that, while constructing a type-5 certificate, we need to consider only candidate points p_k such that $i < k < j$. Note that, if $i = j$, we get a type-4 event. Then, all that is left is to find the first circle C_k with $i < k < j$ that is intersected by v_τ as it moves over C_j. To this end, we describe a data structure that allows us to perform a circular ray shooting query along C_j from the orientation at which the certificate must be constructed.

Data structure. Our data structure is essentially a balanced binary tree $\mathcal{T}$ on the vertices of the convex hull in clockwise order, where each node stores an associated structure (see Figure 10). For any i, let D_i be the disk bounded by circle C_i. Suppose a node in $\mathcal{T}$ is the root of a subtree with $p_i, \ldots, p_j$ in the leaves. Then its associated structure stores the boundary of $\bigcap_{i \le l \le j} D_l$ as a sorted sequence of circular arcs. Given a range (i, j) we can

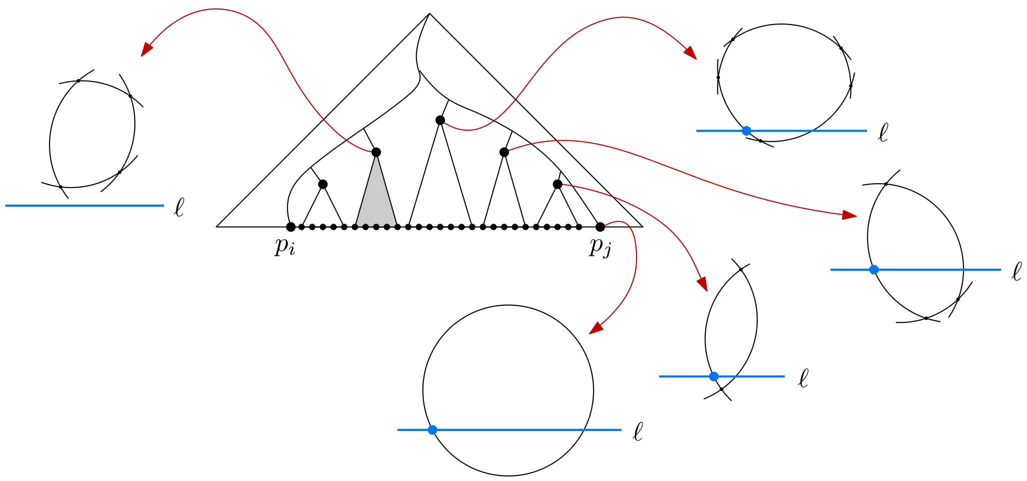

Figure 10 A schematic representation of the data structure $\mathcal{T}$ and a query with ray ℓ.

query this data structure with a (circular) ray in $O(\log^2 h)$ time to find the first intersection of the ray with the boundary of $\bigcap_{i \leq l \leq j} D_l$. A more detailed description of the data structure can be found in the full version of this paper, along with the query algorithms needed to handle certain events and find new certificates.

Event handling. Whenever a certificate of type 5 is violated at orientation α, it means some circle C_k is hit by v_τ at orientation α. It is still possible, however, that this hit happens on the concave semi-circle of C_k. In that case, C_k should not be added to S_1, and v_τ should simply continue moving over its original trajectory. We call these events, where a type-5 certificate is violated but S_1 is not updated, *internal events.* To handle an internal event, we merely need to construct another new type-5 certificate and continue our rotational sweep. In this case, however, we do not have to search the entire range $p_i, \ldots, p_j$ when constructing a new certificate, as shown in the following lemma.

▶ **Lemma 17.** *Let p_i be the point corresponding to τ_1, and let v_τ be at the intersection of circles C_j and C_k, where C_j is the circle that defines the current trajectory of v_τ and where v_τ is on the concave semi-circle of C_k. Then if the next circle hit by v_τ is C_l for $i < l < k$, this circle is hit on its concave semi-circle.*

Proof. Let C_l be the next circle hit by v_τ for $i < l < k$, and see Figure 11 for the following construction. Since v_τ is on the concave semi-circle of p_k, p_k must be on the convex semi-circle of v_τ. Furthermore, as C_k was hit by v_τ, p_k must lie on the same side of the line through p_j and v_τ as p_i. Let the endpoint of the concave semi-circle of v_τ that lies clockwise from p_k be denoted v_c, and observe that $d(p_k, p_j) > d(v_c, p_j)$, where $d(a, b)$ denotes the Euclidean distance between a and b. Additionally, since we consider only points on the convex hull, point p_l must lie above line $p_i p_k$ but below line $p_k p_j$, resulting in a cone with its apex at p_k.

Every point in this cone is further away from p_j than p_k: Since v_τ is part of S_1, placing q_1 at v_τ must yield a valid solution for $q_1 q_2$. This means that all points must be in the Minkowski sum of a radius r disc and the ray with orientation α originating from v_τ, and hence p_k lies below the line $v_c p_i$ (see Figure 12). Finally, p_j lies on the concave semi-circle around v_τ, and p_k lies on the convex semi-circle around v_τ, which shows that the cone lies on the far side of p_k with respect to p_j. This implies that $d(p_l, p_j) > d(p_k, p_j)$.

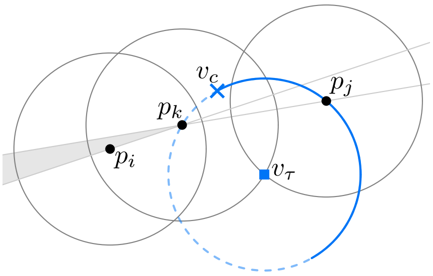

Figure 11 p_l must be located in the gray cone.

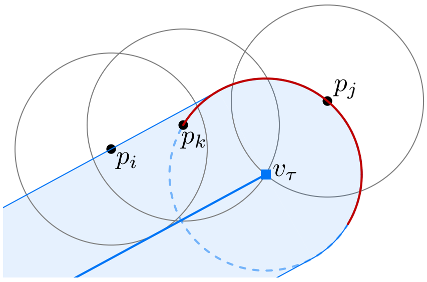

Figure 12 All points in $\mathsf{CH}(P)$ must be in the blue shaded area. When an internal event happens, the red semi-circle is a witness that (p_k, p_j) is conjugate.

During our monotone rotational sweep, v_c must continuously move closer to p_j as we continue our sweep. Therefore, when v_τ intersects C_l, we must have $d(p_l, p_j) > d(v_c, p_j)$: This directly implies that v_c must lie clockwise from p_l on the radius r circle centered at v_τ. Thus, v_τ lies on the concave semi-circle of C_l. ◀

Lemma 17 implies that, after an internal event with circle C_l, it is sufficient to consider only points p_k with $l < k < j$ when constructing a new type-5 certificate.

When a type-5 certificate is violated and v_τ is on the convex semi-circle of C_k, however, we do need to update S_1 to reflect v_τ moving over the intersection between C_k and C_j. Additionally, we must construct new certificates: We possibly need to compute a new type-1 certificate, as well as either a type-4 certificate or a new type-5 certificate using C_k as the new trajectory of v_τ and searching for the next hit with C_l for $i < l < k$. We are now ready to prove Lemmata 14 and 15.

▶ **Lemma 14.** *We can construct a new certificate of type 5 in $O(\log^2 h)$ time.*

Proof. Let p_i be the point corresponding to τ_1, C_j be the circle over which v_τ is currently moving, and α be the current orientation. To construct a type-5 certificate, we find the first circle C_k with $i \leq l < k < j$ that is intersected by v_τ. Here, if this certificate is constructed during an internal event, l is the index of the circle C_l intersected by v_τ during that event. Otherwise, $l = i$. Since v_τ moves over C_j, we can use the data structure described in the full version of this paper to perform a circular ray shooting query on the sequence $C_l, \ldots, C_{j-1}$ with starting point v_τ to find C_k in $O(\log^2 h)$. This gives us the point p_k to include in the certificate, and we can find the orientation at which p_k is hit by drawing the tangent of C_i through the intersection point between C_j and C_k. ◀

▶ **Lemma 15.** *Throughout the full π rotation, τ_1 or τ_2 hits a vertex of S_1 or S_2 at most $O(h \log h)$ times, and we handle each occurrence of this event in $O(\log^2 h)$ time.*

Proof. To show that this event happens $O(h \log h)$ times during a π rotation, we need the following definition. Let an ordered pair (p_g, p_h) of vertices of $\mathsf{CH}(P)$ be *conjugate* if we can place a semi-circle of radius r so that it hits p_g and p_h, p_h lies clockwise from p_g on this semi-circle, and the semi-circle does not intersect the interior of $\mathsf{CH}(P)$. Efrat and Sharir prove that any convex polygon with n vertices has at most $O(n \log n)$ conjugate pairs if the vertices are placed in general position [17]. We charge each occurrence of a type-5 event to a conjugate pair, and prove that each pair is charged only a constant number of times. This immediately yields the bound of $O(h \log h)$ on the number of type-5 events.

Consider an internal type-5 event. We charge these events to the pair (p_k, p_j). To this end, we show that this pair of points must be conjugate. Consider orientation α at which this event takes place. At that point, we can draw a circle of radius r, centered at v_τ, through p_k and p_j. Since, by definition of an internal event, v_τ is on the concave semi-circle of p_k, p_k must be on the convex semi-circle centered around v_τ.

Now again observe that, since v_τ is part of S_1, placing q_1 at v_τ must yield a valid solution for q_1q_2. This means that all points must be in the Minkowski sum of a radius r disc and the ray with orientation α originating from v_τ. See Figure 12. Therefore, the concave semi-circle of radius r centered at v_τ does not intersect $\mathsf{CH}(P)$. If we rotate this semi-circle counter-clockwise until one of its endpoints coincides with p_k, we obtain a semi-circle through p_k and p_j that does not intersect $\mathsf{CH}(P)$. This means it is a witness that (p_k, p_j) is conjugate.

Next, consider a type-5 event that is not internal. The same argument as above holds, except p_k is already on the concave semi-circle of radius r centered at v_τ. Since this semi-circle does not intersect $\mathsf{CH}(P)$, that semi-circle is a direct witness that (p_k, p_j) is conjugate.

Every conjugate pair only induces at most one type-5 event. In order for conjugate pair (p_k, p_j) to induce a second type-5 event, v_τ must again hit the intersection between p_k and p_j while it is moving in the same angular movement direction. This can only happen if we perform a full 2π rotational sweep, or if v_τ first moves over this intersection in the opposite direction. The prior is not possible in a π rotational sweep. The latter is only possible if p_k is first involved in a type-4 event. But then, $k = i$, and by construction p_k can never be involved in another type-5 certificate.

Handling a type-5 event consists of updating S_1 and the movement trajectory of v_τ, which can be done in $O(1)$ time. Additionally, we construct new type-1 certificate and either a type-4 or type-5 certificate, which can be done in $O(1)$ and $O(\log^2 h)$ time by Observations 6 and 12 and Lemma 14. ◀

After analyzing all events that occur during the rotational sweep, we can prove Theorem 5.

▶ **Theorem 5.** *Given a point set P consisting of n points and a radius r, we can find the shortest representative segment in $O(n \log h + h \log^3 h)$ time, where $|\mathsf{CH}(P)| = h$.*

Proof. We initialize the algorithm by computing the convex hull $\mathsf{CH}(P)$. By Lemma 1, it is sufficient to consider only points in $\mathsf{CH}(P)$ to find a representative segment of P. We use rotating calipers to check that the shortest representative segment is not a point, and find an orientation α in which a solution exists. For this fixed α we find τ_1 and τ_2, compute S_1 and S_2, as well as the shortest line segment q_1q_2 in orientation α. Computing the convex hull can be done in $O(n \log h)$ [4]. By Lemma 3, S_1 and S_2 can be initialized in $O(h)$, and we can initialize q_1q_2 in $O(\log h)$ time. As such, initialization of the algorithm can be done in $O(n \log h)$ time in total.

Next, we rotate orientation α over π in total, maintaining τ_1, τ_2, S_1, and S_2, as well as q_1q_2. Note that a rotation of π is sufficient, since we consider orientations, which identify opposite directions of a 2π rotation. Throughout the rotation we maintain the shortest

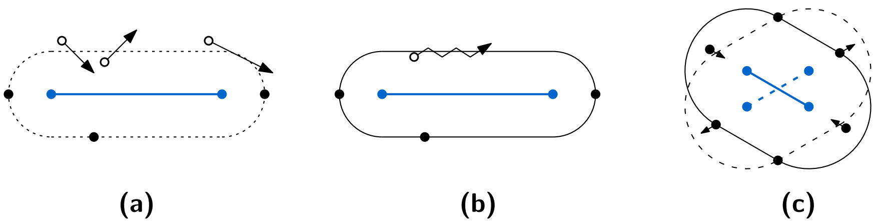

Figure 13 Examples of representative segments (blue) for moving points. These show that a representative segment may appear and disappear frequently **(a)** due to the motion of two points (top left) or one point (top right) or **(b)** due to minor oscillations in a movement path. **(c)** Small movements can trigger a discrete change of the representative segment.

representative segment, and return the shortest such line segment found over all orientations. Over the full rotation, we encounter five different types of events. By Lemmata 7–15, these events can be handled in $O(h \log^3 h)$ time in total.

As we mentioned in Section 2.1, the shortest representative segment is defined by only τ_1, τ_2, S_1, and S_2. Each tangent is defined by a circle. Hence, τ_1 and τ_2 can only change when they are defined by a new circle. Thus, by Lemma 9, we correctly maintain τ_1 and τ_2 throughout the full π rotation. Furthermore, S_1 and S_2 can only exist when τ_1 and τ_2 appear in the correct order. By Lemma 11 we correctly maintain when S_1 and S_2 exist. Finally, S_1 and S_2 can only make a discrete change as the tangents τ_1 and τ_2 hit intersections between circles in $\mathcal{C}_P$. If the tangents do not touch a vertex, then S_1 and S_2 must change continuously along the arcs that τ_1 and τ_2 cross. By Lemmata 13 and 15, we correctly maintain S_1 and S_2 when they exist. In conclusion, we correctly maintain τ_1, τ_2, S_1, and S_2 throughout the full π rotation. Since we maintain the shortest line segment between S_1, and S_2 in any orientation using Lemma 7, we also maintain the shortest representative segment for any orientation. ◀

3 Stable Representative Segments for Moving Points

In this section, we consider maintaining representative segment q_1q_2 while the points in P move. We first show what can happen if we would maintain the optimal solution explicitly under continuous motion of the points.

There are examples where a representative segment exists for a value of r for an arbitrarily short duration. This can happen because one point moves towards a hippodrome shape and another point moves out of it, giving a brief moment with a valid hippodrome. The same effect can be caused by a single linearly moving point that grazes the hippodrome at a join point. These examples are illustrated in Figure 13(a). It can also happen that a minor oscillating movement of a point causes a quick sequence of changes between a valid and no valid segment, see Figure 13(b).

Now, consider the point set P in which the points form a regular k-gon (see Figure 13(c)). When r is equal to half the width of the k-gon, then we can force a discrete change in the placement of q_1 and q_2, with very slow movement of points in P. In this case there is always a valid representative segment, but its endpoints make a jump.

We see that continuously maintaining the optimal solution has two artifacts that are undesirable to a human observer: (1) the segment can appear and disappear frequently within an arbitrarily short time frame, and (2) a segment may jump to a new location, leading to infinitely high speeds of the endpoints even if the points themselves move slowly.

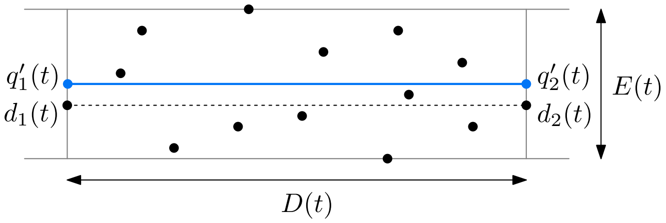

Figure 14 The prospective segment $q'_1q'_2$ in relation to D, E, and diametrical line d_1d_2 at time t.

Our goal is therefore to ensure that the segment movement is *stable* over time: We want q_1 and q_2 to move continuously and with bounded speed, preventing discrete or (near) instantaneous changes. We accomplish this as follows. First, we will sample the positions of the moving points only at integer moments, and then decide immediately to show or not show a solution in the next time unit. This implies that existence and non-existence of a solution lasts at least one time unit, and we avoid the solution (dis)appearing frequently. Second, we make the assumption that the maximum speed of the points is unit. We have to make some bounded speed assumption otherwise we cannot hope to get a bounded speed of the endpoints either. Third, we allow more flexibility in when we have a solution. We do this using a less strict regime on r, and by assuming that $r \geq 1$. Whenever the real solution exists (with the actual r), then we guarantee that we also have a solution. Whenever there is no solution even for a radius of $2\sqrt{2} \cdot r + 4$, then we never give a solution. When the radius is in between these bounds, we may have a solution or not. Our algorithm can then ensure that the speeds of the endpoints are bounded, and the length of our chosen segment always approximates the true optimum (when it exists), at any moment in time, also between the integer sampling moments.

So we assume that a point $p \in P$ is described by a trajectory that is sampled at integer timestamps. That is, each point in P is described by $p(i) \to \mathbb{R}^2$ where $i \in \mathbb{Z}$ is the timestamp. We also assign each endpoint of the representative segment a position as a function of $t \in \mathbb{R}$, which means that the representative segment at time t is now defined by $q_1(t)q_2(t)$. Furthermore, we use $D(t)$ and $W(t)$ as the *diameter* and *width* of the point set, which are respectively the maximum pairwise distance of points in P and the width of the thinnest strip containing P. Let $d_1(t), d_2(t) \in P$ be a pair of points defining the diameter. Lastly, we also use the *extent* $E(t)$ of P in the direction orthogonal to the line segment $d_1(t)d_2(t)$. For all of the above definitions, we omit the dependence on t when it is clear from the context.

In the following, we describe how to specify $q_1(t)$ and $q_2(t)$ such that they move with bounded speed, and such that the length of the segment $q_1(t)q_2(t)$ as well as the proximity of the segment to P can be bounded at any time t. In particular, we define such a segment $q_1(t)q_2(t)$ as an *approximating* segment, and prove that the length of an optimal representative segment is approximated by an additive term l, and at the same time the maximum distance from any point in P to the segment $q_1(t)q_2(t)$ is at most $h \cdot r$, for some constant h.

Algorithm. Our algorithm $A(t)$ is *state-aware*. This means that the output of $A(t)$ is dependent only on the input at or before time t, but it has no knowledge of the input after time t. At every integer timestamp $i \in \mathbb{Z}$, we compute a *canonical solution* $q'_1(i)q'_2(i)$. The endpoints $q'_1(i)$ and $q'_2(i)$ of this canonical solution are placed on the lines orthogonal to the diametric line through $d_1(i)$ and $d_2(i)$, respectively, such that $q'_1(i)q'_2(i)$ lies in the middle of the narrowest strip containing P in the diametric orientation, see Figure 14.

Our algorithm is now a special kind of state-aware algorithm called a *chasing algorithm* [27]: At at every integer time step $i \in \mathbb{Z}$, the algorithm computes the canonical solution $q'_1(i)q'_2(i)$ and then linearly interpolates from $q'_1(i-1)q'_2(i-1)$ to $q'_1(i)q'_2(i)$, arriving there at time $i+1$. At that point, $q'_1(i+1)q'_2(i+1)$ can be computed, and we continue in a similar manner.

However, if the maximum distance from P to the canonical solution becomes too large, we no longer want the algorithm to output any solution. In this case, no (optimal) representative solution exists, and we do not produce an approximating segment either.

Formally, for any timestamp $t \in (i, i+1)$, we linearly interpolate q_1 and q_2 between their previous canonical placements as follows. We define $\alpha = (t-i)$ and set $q_j(t) = \alpha \cdot q'_j(i-1) + (1-\alpha) \cdot q'_j(i)$, for $j \in \{1,2\}$. Then, the output of our algorithm is $A(t) = q_1(t)q_2(t)$ if $E(\lfloor t \rfloor) \leq 2r\sqrt{2}+2$ and $\varnothing$ otherwise.

The above algorithm yields the bounds stated in the following theorem. Detailed proofs for these bounds can be found in the full version of this paper.

▶ **Theorem 18.** *Given a set P of points moving with at most unit speed, algorithm A yields a stable approximating segment with $l = 2r + 4$ and $h = 2\sqrt{2} + 4$, for which speed of the endpoints is bounded by $(2r+1)\sqrt{2} + 2$.*

4 Conclusion

In this paper, we presented an $O(n \log h + h \log^3 h)$ time algorithm to find the shortest representative segment of a point set, improving the previous $O(n^{1+\varepsilon})$ time solution. Additionally, we showed how to maintain an approximation of the shortest representative segment in a stable manner, such that its endpoints move with a speed bounded by a linear function in r.

There may be possibilities for improving the running time of our static solution to $O(n \log h + h \log^2 h)$, or even $O(n \log h)$. The $O(h \log^3 h)$ term comes from having to handle $O(h \log h)$ type-5 events in $O(\log^2 h)$ time each. However, it may be possible to show that there are at most $O(h)$ type-5 events, since the conjugate pairs used to bound the number of internal events each have a unique starting point. Additionally, it may be possible to improve the query time of the data structure described in the full version of this paper to $O(\log h)$ time using ideas like fractional cascading, but there is no straightforward way to make this work for the circular query.

Abstract

We initiate an in-depth proof-complexity analysis of polynomial calculus ($\mathcal{Q}$-PC) for Quantified Boolean Formulas (QBF). In the course of this we establish a tight proof-size characterisation of $\mathcal{Q}$-PC in terms of a suitable circuit model (polynomial decision lists). Using this correspondence we show a size-degree relation for $\mathcal{Q}$-PC, similar in spirit, yet different from the classic size-degree formula for propositional PC by Impagliazzo, Pudlák and Sgall (1999).

We use the circuit characterisation together with the size-degree relation to obtain various new lower bounds on proof size in $\mathcal{Q}$-PC. This leads to incomparability results for $\mathcal{Q}$-PC systems over different fields.

1 Introduction

Proof complexity studies the problem to understand the minimal size of proofs of specific formulas in various formal proof systems. The field bears deep connections to computational complexity [28,40], logic – mainly through the correspondence to bounded arithmetic [8,27,40] – and has practical significance due to intricate relations to SAT solving [23]. In fact, proof complexity is the main theoretical framework to assess the strength and limitations of solvers.

While traditionally proof complexity concentrated on propositional logic, there has been intense work in the past two decades on proof complexity for further logics, most notably for *Quantified Boolean Formulas* (QBF) [9], but also for other non-classical logics such as modal and intuitionistic logics [19,36,46]. For QBF, one of the main drivers for the field has been significant advances in QBF solving [18,44]. As in the propositional case, QBF proof complexity provides the theoretical tools to model, assess and guide QBF solving [12,21,38].

In propositional proof complexity, various proof systems have been studied intensively, including resolution, Frege systems, algebraic and geometric systems [40]. While resolution has arguably received most attention – and underpins modern SAT solving in the form of CDCL [2,5,42] – algebraic proof complexity has enjoyed a boost of interest in the past decade with many strong results shown for Nullstellensatz, polynomial calculus (PC), sum of squares (SOS), and very strong systems such as the ideal proof system (cf. e.g. [26,29,31,32,34,35,43]).

Algebraic proof systems typically work with polynomials and the central system of polynomial calculus [25] is a refutational proof system demonstrating that a given set of polynomial equations does not admit a common solution.

Similarly, in QBF proof complexity there are many results on various QBF resolution systems [4,9,11,14]. Yet, in stark contrast to the propositional case, information on algebraic proof systems for QBF is rather scarce. A version of polynomial calculus for QBF – called $\mathcal{Q}$-PC here – is straightforward to define [13] as there is a general framework how to lift a line-based propositional proof system P – fulfilling some modest closure properties – to a quantified system $\mathcal{Q}$-P by adding just one rule of universal reduction that allows to substitute a universal variable u from a formula F (under the condition that u is quantified rightmost in F) [13]. This system $\mathcal{Q}$-PC naturally works with polynomials as lines and provides a succinct way to prove the falsity of QBFs. Hence we view this algebraic system as a refutational system for QBFs. The existential and universal variables are therefore propositional and take $0/1$ values in accordance with the QBF semantics, while intermediate values computed by the polynomials can be arbitrary field elements, making proofs more succinct.

So far, the only information on proof size in $\mathcal{Q}$-PC stems from the general semantic technique of cost through the size-cost-capacity theorem from [10] which allows to obtain lower bounds for QBF proof systems of bounded capacity (which applies to $\mathcal{Q}$-PC as well as to most QBF resolution systems). With the cost technique, QBFs become hard to prove whenever the universal player needs large winning strategies (measured as the number of different answers of the universal player in the game interpretation of QBFs) and these lower bounds simultaneously hold in all QBF systems to which this technique is applicable. Hence this method does not allow to separate QBF resolution from $\mathcal{Q}$-PC, for example.

One key motivation to study algebraic proof systems in the propositional case is their recently emerging connection to algebraic circuit complexity [31, 35, 43]. In general, a correspondence between progress for lower bounds for circuit and proof size has often been postulated (e.g. [6]), but formal connections for propositional proofs could not yet be established outside the algebraic domain. In fact, it could be argued that this correspondence perfectly works in the QBF setting: for QBF resolution – tightly corresponding to a version of decision lists [11] – and for QBF Frege systems where proof size is characterised by circuit size in Boolean circuits [13]. This is quite fruitful as it allows a direct transfer of known circuit lower bounds to proof complexity, e.g. from $\mathsf{AC}^0[p]$ to the corresponding system of $\mathcal{Q}$-$\mathsf{AC}^0[p]$-Frege [13,47]. A similar transfer in the propositional case remains wide open.

Curiously, an analogous relation between algebraic circuits and algebraic QBF systems is missing, whereas exactly in this algebraic case, some connections are known propositionally [31,35,43], as mentioned above.

Our aim in this paper is to initiate a comprehensive analysis of the algebraic system $\mathcal{Q}$-PC. In the course of this investigation we achieve a circuit characterisation for $\mathcal{Q}$-PC. This leads to new lower bound techniques for proof size in $\mathcal{Q}$-PC, which we apply to show a number of new proof size lower bounds for this system.

Our contributions

A. Circuit characterisation for $\mathcal{Q}$-PC. Our first result is a tight circuit characterisation of $\mathcal{Q}$-PC proof size by circuit size in an appropriate circuit model. The circuit model in question is a generalisation of decision lists [45], which are lists of simple statements of the form: If *(condition on existential variables)* Then *(assignment to universal variables).*

The decision lists – termed PDLs here for *p*olynomial *d*ecision *l*ists – have polynomial equations in existential variables as conditions and compute a complete assignment to the universal variables. Semantically, a PDL for a quantified set of polynomial equations Φ computes a countermodel for Φ in the two-player game semantics of QBFs.

We show that the minimal proof size for Φ (of bounded quantifier complexity) in $\mathcal{Q}$-PC is polynomially equivalent to the minimal size of a PDL for Φ. In fact, we show a more general result that applies to a whole class of QBF proof systems with bounded capacity [10] (and fulfilling some closure properties). The result is parameterised by the lines of the proof system, which in turn correspond to the conditions in the decision lists. This generalises a result for Q-Resolution [11] and lifts it to $\mathcal{Q}$-PC.

B. Size-degree relation for $\mathcal{Q}$-PC. Having the PDL characterisation in place, we can obtain a size-degree result, relating minimal proof size in $\mathcal{Q}$-PC to the minimal degree of polynomials in the refutation. This is similar in spirit to the size-degree method known for propositional PC [37], albeit the actual relation is different and includes the quantifier depth of the QBF. Technically, the result is shown via the degree-preserving transfer from $\mathcal{Q}$-PC to PDLs and back explained above, together with an additional size-degree relation that we show for PDLs. The technique is similar to a prior size-width result for Q-Resolution [11].

C. New lower bounds for $\mathcal{Q}$-PC. Having both the PDL characterisation and size-degree relation at hand opens the door to new lower bounds for degree and size in $\mathcal{Q}$-PC.

Specifically, we show that the parity and more generally the modulo k functions mod_n^k on n variables as well as the majority function maj_n all require high-degree PDLs over all subfields of $\mathbb{C}$. Using a general construction from [13, 14] we can turn any Boolean function f into a QBF $\mathcal{Q}$-f that has f as its only countermodel. Together with our results above this implies that the $\mathcal{Q}$-mod_n^k and $\mathcal{Q}$-maj_n QBFs require both linear degree and exponential monomial size in $\mathcal{Q}$-PC.

In addition to using the size-degree method to prove lower bounds for PDLs and hence for $\mathcal{Q}$-PC proofs, we show that for finite fields of characteristic p, PDLs can be efficiently transformed into $\mathsf{AC}^0[p]$ circuits. This allows to directly transfer circuit lower bounds of [47] into $\mathcal{Q}$-PC proof lower bounds. As a result, either if F and G are both finite fields of different characteristics, or if F is finite and G is a subfield of $\mathbb{C}$, then the systems $\mathcal{Q}$-PC over F and G are incomparable.

In fact, all our lower bounds are very strong as they apply to a succinct model of QBF proof systems were propositional sub-derivations – for PC comprised of additions and multiplications of polynomials – can be abbreviated as semantic entailment steps that are checked with an NP oracle [17]. This implies that all our lower bounds and incomparability results also hold in the traditional proof model with “unfolded” computations, but remain even valid in the mentioned stronger NP oracle model.

Due to space constraints, some proofs are omitted.

2 Preliminaries

We assume familiarity with basic notions from computational complexity, cf. [1], as well as from logic, cf. [39], and algebra, cf. [41], but define all specific concepts needed in this paper.

We consider propositional formulas φ built from constants $0, 1$, connectors $\neg, \wedge, \vee, \rightarrow, \leftrightarrow$, and propositional variables. A literal is a variable v or its negation $\overline{v}$. A clause is a disjunction of literals, and a formula is in Conjunctive Normal Form (CNF) if it is a conjunction of clauses. When V is a set of variables, a (partial) assignment to V is a (partial) function $\alpha : V \to \{0,1\}$. We write $\langle V \rangle$ for the set of all complete assignments to V, and $\mathrm{vars}(\varphi)$ or $\mathrm{vars}(\alpha)$ for the set of all variables occurring in φ or α. For $V' \subseteq V$, we denote by $\alpha|_{V'}$ the restriction of α to the variables in V'. We denote by $\varphi[\alpha]$ the formula φ where each variable $v \in \mathrm{vars}(\alpha)$ has been substituted by $\alpha(v)$, and by $\phi[v_1/\theta_1, \ldots, v_k/\theta_k]$ the formula φ where variables v_i have been substituted by formulas θ_i.

Circuit classes. We recall the definitions of standard circuit classes used in this paper. The class AC^0 contains all languages computable by polynomial-size circuits with gates $\neg$, $\vee$, $\wedge$ with bounded depth and unbounded fan-in. The class $\mathsf{AC}^0[p]$ additionally uses MOD_p gates determining whether the sum of the inputs is 0 modulo p. $\mathsf{P/poly}$ uses circuits of polynomial size but arbitrary depth. For an in-depth account on circuit complexity we refer to [48].

Proof systems. We refer to [28] for a formal definition of proof systems and only illuminate certain restrictions. We only consider *line-based proof systems* where proofs consist of a sequence of lines (in our case polynomials) that are derived with certain rules. A propositional *base system* is a line-based proof system with certain very natural restrictions, formally defined in [10]. All propositional proof systems discussed in this paper are base systems.

Polynomial Calculus. Polynomial Calculus (PC) [25] is an algebraic proof system showing that a set of polynomials does not have common roots. For variables $V = \{v_1, \ldots, v_n\}$ over a field F, its lines are polynomial equations $0 = \sum_{i=1}^{m} c_i \prod_{v \in V_i} v$ with $m \in \mathbb{N}, c_i \in F, V_i \subseteq V$. A PC *refutation* starts with a set of polynomials, derives linear combinations of previous polynomials, and ends with the contradiction $0 = 1$. The size of a polynomial is its number of monomials, and the size of a PC refutation is the sum of the sizes of its polynomials.

Here, we view PC as a propositional proof system, and allow only the values 0 and 1 for each variable. This is ensured by including the Boolean axioms $v^2 - v = 0$ for each $v \in V$. In order to represent literals and clauses compactly, we introduce *complementary variables* $\overline{v}$ that are required to have the value $1 - v$, and introduce axioms $v + \overline{v} - 1 = 0$.

Perhaps counterintuitively, a variable that is 0 in a polynomial corresponds to a propositional variable that is true, and 1 corresponds to false. We recall that a polynomial equation is true if its polynomial equals 0. This way, a monomial corresponds to a clause containing the same literals, and a CNF can be efficiently encoded as a set of monomial equations.

When p is a polynomial, v a variable, and $c \in \{0,1\}$, we denote by $p[v/c]$ the polynomial p where v has been replaced by c and $\overline{v}$ by $1 - c$.

Quantified Boolean Formulas. A (closed prenex) *Quantified Boolean Formula* (QBF) is a formula $Q\,\phi$ where ϕ is a propositional formula and Q is the quantifier prefix that quantifies all variables v in ϕ either existentially as $\exists v$ or universally as $\forall v$. We typically use x_i for existentially quantified variables and u_i for universally quantified variables. When a system includes complementary variables $\overline{v}$ as in PC, those do not occur in the quantifier prefix. Their values are determined by the corresponding variables v instead.

Whether a QBF is true or not can be defined recursively. The formula $\forall u\, Q\, \varphi$ is true if both $Q\,\varphi[u = 0]$ and $Q\,\varphi[u = 1]$ are true. The formula $\exists x\, Q\, \varphi$ is true if at least one of $Q\,\varphi[x = 0]$ and $Q\,\varphi[x = 1]$ is true. When a QBF proof system is derived from an algebraic system such as PC, it nonetheless has these Boolean semantics.

In a fully quantified prenex QBF, the quantifier prefix determines a total order of the variables. Given a variable v, we will sometimes refer to the variables preceding v in the prefix as variables *left* of v; analogously we speak of the variables *right* of v.

A QBF $Q_1x_1 \cdots Q_kx_k\,\phi$ can be seen as a game between two players: *universal* ($\forall$) and *existential* ($\exists$). In the i-th step of the game, the player Q_i assigns a value to the variable x_i. The existential player wins if ϕ evaluates to 1 under the assignment constructed in the game. The universal player wins if ϕ evaluates to 0. Given a universal variable u with index i, a *strategy for u* is a function from all variables of index $< i$ to $\{0, 1\}$. A QBF is false if and only if there exists a *winning strategy* for the universal player, that is if the universal player has a strategy for all universal variables that wins any possible game [1, 33].

3 A general characterisation of $\mathcal{Q}$-P proof size by decision lists

We start by characterising proof size in $\mathcal{Q}$-PC by a suitable circuit model. In fact, we will show a more general result that applies to a class of QBF proof systems which are lifted from a propositional base system P to the QBF system $\mathcal{Q}$-P. This lifting is done by adding the $\forall$red rule to the rules of P. The $\forall$red rule allows to derive $l[\mu]$ from a line l and a propositional assignment μ to universal variables, as long as $\mathrm{vars}(\mu)$ occur after all existential variables in l in the quantifier prefix [13].

However, lower bounds for the resulting $P + \forall$red system are trivial to obtain from lower bounds for P by existentially quantifying all variables. We are not too interested in such bounds, but in "genuine" QBF lower bounds that arise from quantifier alternation (cf. [17, 24] for a longer discussion and details). In other words, we want to filter out any propositional hardness in a QBF by ignoring purely propositional sub-derivations. For this, we introduce the Sem rule for semantic steps. It can derive a line l from a line r if $r \models l$. In general this inference step cannot be checked efficiently, but needs an NP oracle call [17]. Using Sem steps also removes the need for any other propositional inference rules as these can be carried out by Sem. We call the resulting system $\mathcal{Q}$-P.

▶ **Definition 1** ($\mathcal{Q}$-P). *Let P be a propositional base system. The system $\mathcal{Q}$-P is a refutational proof system for QBF that has the same lines as P, and rules $\forall$red and Sem.*

The system we are most interested in is $\mathcal{Q}$-PC where the lines are polynomials. We briefly review the semantics of this system. As specified in Definition 1, its only rules are $\forall$red and Sem. Its lines are polynomial equations with coefficients from a field F. The $\forall$red rule can be applied to a polynomial p to obtain $p[u/0]$ (which is p with variable u set to 0 and $\overline{u}$ set to 1) or $p[u/1]$ (which is p with variable u set to 1 and $\overline{u}$ set to 0) as long as u is quantified universally right of all existential variables in p. This also means that u cannot be a complementary variable $\overline{v}$. The Sem rule allows to derive polynomial equations that semantically follow from previous equations, the Boolean axioms, and the $v + \overline{v} = 1$ axioms. Semantically, the variables can only take the values 0 or 1, and $\overline{v}$ must always take the value $1 - v$. The propositional rules of PC can be added, but are not strictly needed and do not shorten proofs in the presence of Sem.

We now define the circuit model that we will use for the characterisation of $\mathcal{Q}$-P proof size. The model is a variant of decision lists [10, 45].

▶ **Definition 2** (P-UDL). *Let P be a base system and X, U sets of variables. A P-UDL of length k is a sequence $L = (p_1, \mu_1), (p_2, \mu_2), \ldots, (p_k, \mu_k)$ where $(\overline{p_i})$ is a line of P, $\mathrm{vars}(p_i) \subseteq X$, $\mu_i \in \langle U \rangle$ for each $i \in [k]$ and $p_k = \top$. It computes a function $f_L : \langle X \rangle \to \langle U \rangle$ with $f_L(\alpha) = \mu_j$ for the smallest j such that $\alpha \models p_j$.*

Intuitively, a P-UDL checks conditions p_j, which are negations of lines of P using only existential variables and outputs a full assignment μ_j to the universal variables.

Again the main instantiation of this definition for us is to choose P as PC. To ease notation we abbreviate PC-UDL by PDL for *p*olynomial *d*ecision *l*ists. The lines of PDLs are then polynomials. As lines in PC are polynomials p with the implicit meaning of $p = 0$, conditions in a PDL check that the polynomial is *not* zero. Hence a line p in a PDL becomes active, if the p does not evaluate to 0 under the assignment.

We use P-UDLs to compute countermodels for QBFs. More formally, we say that a P-UDL L is *correct* for a QBF $\mathcal{Q}.\varphi$ if it has all of the following properties:

- All variables in X are existential variables of $\mathcal{Q}$.
- All universal variables of $\mathcal{Q}$ are in U.
- Let $\alpha, \beta \in \langle X \rangle, u \in U$. If $f_L(\alpha)$ and $f_L(\beta)$ disagree on u, then α and β disagree on a variable $x \in X$ that occurs before u in $\mathcal{Q}$.
- For every $\alpha \in \langle X \rangle$, $\alpha \wedge f_L(\alpha)$ falsifies φ.

For P-UDL $L = (p_1, \mu_1), \ldots, (p_k \mu_k)$, we define the *size* of L, $|L| = \sum_{i=1}^{k} size_P(\overline{p_i})$, where $size_P$ corresponds to the respective size measure in the base system P. Additionally, the length of L is defined as $\text{len}(L) = k$.

Our goal is to use P-UDLs to characterise the hardness of $\mathcal{Q}$-P proofs on QBFs of constant alternation depth, i.e. to show that there exists a short P-UDL for a QBF Φ if and only if there exists a short $\mathcal{Q}$-P proof of Φ.

From the definition of P-UDL, it is apparent that the size of P-UDL for a QBF Φ is always at least as big as the size of the smallest countermodel of Φ, since each line always assigns all universal variables. As such, P-UDL cannot possibly characterise proof size in $\mathcal{Q}$-P for all base systems P. In fact, we need three restrictions on $\mathcal{Q}$-P for the characterisation to work. Firstly, the negations of the lines of P must allow to succinctly represent assignments to variables. Secondly, the base system P must be *closed under disjunction*, i.e. for two arbitrary lines l and p of P, the disjunction $l \vee p$ is also a valid line in P with size $\mathcal{O}(|l| \cdot |p|)$.

Thirdly, we require $\mathcal{Q}$-P to have limited *capacity.* Capacity is a measure introduced in [10], which counts how many different answers the universal player needs at most to respond to one line in a $\mathcal{Q}$-P proof π. In particular, we require that the capacity of $\mathcal{Q}$-P is at most polynomial in the size of π for all proofs π. For the formal definition of capacity, we refer to [10]. We remark that $\mathcal{Q}$-PC and $\mathcal{Q}$-Res (as well as the QBF cutting planes system $\mathcal{Q}$-CP) all have bounded capacity [10].

We are now ready to characterise proof size in $\mathcal{Q}$-P by the size of P-UDLs.

▶ **Theorem 3.** *Let P be a line-based, propositional proof system, where the lines are closed under disjunction, such that $\mathcal{Q}$-P has at most polynomial capacity. Then for QBFs Φ with bounded quantifier alternation depth, we can efficiently transform a P-*UDL *for Φ into a $\mathcal{Q}$-P refutation for Φ and vice versa. In particular, the minimal size of a P-*UDL *for Φ is polynomially equivalent to the size of the minimal $\mathcal{Q}$-P refutation for Φ.*

Proof sketch. The proof outline follows [11]. *From $\mathcal{Q}$-P to P-*UDL. Let a QBF Φ of alternation depth d and a $\mathcal{Q}$-P refutation π of Φ be given. Using bounded capacity, we can show that w.l.o.g. π always uses universal reductions on entire blocks of universal variables. Employing the paradigm of strategy extraction [3, 11, 30], we can extract a set of P-decision lists computing a countermodel of Φ from π. Each of these decision lists computes the universal strategy for one of the universal blocks and has size at most $|\pi|$. We combine these decision lists to a single decision list, whose size is at most the product of the sizes of the original lists, using the *direct product* construction from [11]. The resulting decision list computes the correct function and is a P-UDL. Since there are d decision lists of size $|\pi|$, the computed P-UDL has size $\mathcal{O}(|\pi|^d)$.

From P-UDL to $\mathcal{Q}$-P. Let a QBF Φ of alternation depth d and a P-UDL L computing a countermodel of Φ be given. We define the *entailment sequence* $\mathcal{E}$ of L recursively in d.

- if $d = 1$, $\mathcal{E}(L) := \overline{\varepsilon_1} \vee \overline{\mu_1}, \dots, \overline{\varepsilon_s} \vee \overline{\mu_s}$
- if $d \geq 2$, for each $i \in [s]$ define L_i as the list obtained from L by replacing the first $i - 1$ existential terms by their X_1 components and setting all U_1 components to $\mu_i|_{U_1}$. $\mathcal{E}(L)$ is the sequence $\pi_1, \dots, \pi_s$, where $\pi_i := (\overline{\varepsilon_i}|_{X_1} \vee \overline{\mu_i}|_{U_1}) \otimes \mathcal{E}(L_i[\alpha])$ and α is some arbitrary but fixed assignment on $X_1 \cup U_1$ satisfying $\varepsilon_i|_{X_1} \wedge \mu_i|_{U_1}$.

Here, the $\otimes$-operator between a line of P and the entailment sequence defines an elementwise disjunction between the line and each element in the entailment sequence, i.e. $\ell \otimes (c_1, c_2, \dots, c_r) = (\ell \vee c_1, \ell \vee c_2, \dots, \ell \vee c_r)$. For a line ℓ, we call $\mathrm{red}(\ell)$ the line obtained by using universal reduction on ℓ by some specific universal assignment. Since negations of lines of P can succinctly represent assignments, $\overline{\mu_i}$ can be represented in P. If $\mathcal{E}(L) = (c_1, \dots, c_r)$, then $(c_1, \mathrm{red}(c_1), c_2, \mathrm{red}(c_2), \dots, c_r, \mathrm{red}(c_r))$ is a $\mathcal{Q}$-P refutation of Φ. ◀

This reproves a characterisation of QBF resolution by decision lists from [11]. The main application for us is polynomial calculus (PC) for which this result is new. PC has a capacity of $\sqrt{n}$, where n is the size of the proof [10]. Additionally, PC is closed under disjunctions as the disjunction of two lines can be expressed as the product of the respective polynomials. The size of the disjunction is the product of the sizes of the original lines.

▶ **Corollary 4.** *For QBFs of bounded quantifier depth, the minimal size of $\mathcal{Q}$-PC proofs and the minimal PDL sizes are polynomially equivalent.*

4 Size-degree bounds for polynomial calculus in QBF

Using the connection between $\mathcal{Q}$-PC and PDLs from Corollary 4, we now aim to show lower bounds for $\mathcal{Q}$-PC by proving lower bounds for PDLs. The latter task will be simplified by a relation between PDL size and PDL degree, which is measured as the maximal degree of the polynomial conditions in the PDL. As these polynomials are just defined in existential variables, it makes sense to define the *existential degree* for PDLs and $\mathcal{Q}$-PC refutations. This is in line with an analogous definition of existential width for Q-Resolution [11, 15].

▶ **Definition 5** (Existential degree of a $\mathcal{Q}$-PC refutation). *Let $f = \exists X_1 \forall U_1 \cdots \exists X_{d+1}.\varphi$, $\pi = (\pi_1, \dots, \pi_s)$ be a $\mathcal{Q}$-PC refutation of f and $X = \bigcup_{i=1}^{d} X_i$. The* existential degree $\deg_\exists$ *of f is defined as $\deg_\exists(\pi) = \max_{i \in [s]} \deg(\pi_i|_X)$.*

Analogously, the degree of a PDL L is defined as the maximal degree of all queries in L. We can show a size-degree relation for PDLs.

▶ **Theorem 6.** *Let f be a multi-output Boolean function with n input variables. If f is computed by a PDL of size s, it is also computed by a PDL of degree $O(\sqrt{n \log s})$.*

In essence, the proof of this theorem is the same as the original size-degree result for propositional polynomial calculus by Impagliazzo, Pudlák and Sgall [37] (cf. also [7, 22] for similar arguments). Equivalently, a function f that can only be computed by PDLs of degree at least k needs PDLs of size $\exp(\Omega(\frac{k^2}{n}))$.

We can use this size-degree relation for PDLs to obtain a size-degree relation on $\mathcal{Q}$-PC.

▶ **Theorem 7.** *Let f be a QBF with n variables of alternation depth d such that every $\mathcal{Q}$-PC proof has existential degree at least k. Then every $\mathcal{Q}$-PC proof has size at least $\exp(\Omega(\frac{k^2}{d^3 n}))$.*

Proof. Let $f = \exists X_1 \forall U_1 \cdots \exists X_{d+1}.\varphi$, $X = \bigcup_{i=1}^{d} X_i$ the set of existential variables except the last block and $|X| = v$. Additionally, let π be a shortest $\mathcal{Q}$-PC refutation of f. Using Corollary 4, π can be transformed into a PDL L of size at most $|\pi|^d$. With Theorem 6, L can then be transformed into a PDL M with degree at most $\mathcal{O}(\sqrt{dv\log|\pi|})$. Transforming M back into a $\mathcal{Q}$-PC proof with Corollary 4 results in a proof π' with degree at most $k = \mathcal{O}(d\sqrt{dv\log|\pi|})$. Solving this equation for $|\pi|$ yields the result. ◀

The proof is similar to Theorem 6.2 in [11]. In contrast to the size-degree relation from [37], Theorem 7 includes the quantifier depth of the QBF, but not the initial degree of the QBF.

In the rest of this section, we will explore specific lower bounds for the degree of PDLs. We will first show degree lower bounds for PDLs computing specific functions and then turn this into $\mathcal{Q}$-PC size lower bounds for related QBFs.

4.1 Parity and mod functions require PDLs of high degree

Let $\mathrm{par}_n(x_1, \ldots, x_n) = \bigoplus_{i=1}^{n} x_n$ be the parity function. Lower bounds for this function only hold for PDLs over certain fields; in fact, par_n is just the sum of input variables in fields of characteristic 2, and is therefore trivial for PDLs over those fields. However, it seems to be hard in fields of characteristic 0. We prove a lower bound for $\mathbb{C}$ and its subfields.

▶ **Proposition 8.** *A PDL with polynomials over a subfield of* $\mathbb{C}$ *computing* par_n *has degree at least* $\frac{n}{2}$.

Proof. We consider the first line of the PDL and assume without loss of generality that it has output 1.[1]

Let p be the first line's polynomial and d its degree. Let $X = \{x_1, \ldots, x_n\}$. We can assume that there is a $w \in \langle X \rangle$ with $p(w) \neq 0$ or we could omit the first line. However, to avoid giving any wrong answers, for every $a \in \langle X \rangle$ with $\mathrm{par}_n(a) = 0$, it must hold that $p(a) = 0$.

We compute the complex conjugate p^* by conjugating every coefficient. Because we only evaluate the polynomials on real numbers (specifically 0 and 1), we know that $p^*(a) = (p(a))^*$ for every $a \in \langle X \rangle$. We define $q := p \cdot p^*$ and note that $\deg(q) \leq 2d$ and for all $a \in \langle X \rangle$, $q(a) = p(a) \cdot p(a)^* \in \mathbb{R}^{\geq 0}$.

For a polynomial r, define the function

$$s(r) := \sum_{\substack{a \in \langle X \rangle \\ \mathrm{par}(a)=1}} r(a) - \sum_{\substack{a \in \langle X \rangle \\ \mathrm{par}(a)=0}} r(a)$$

which is linear with respect to r. If r is a monomial that does not contain the variable x,

$$\begin{aligned} s(r) &= \sum_{\substack{a \in \langle X \setminus \{x\} \rangle \\ b \in \langle \{x\} \rangle \\ \mathrm{par}(a,b)=1}} r(a,b) - \sum_{\substack{a \in \langle X \setminus \{x\} \rangle \\ b \in \langle \{x\} \rangle \\ \mathrm{par}(a,b)=0}} r(a,b) = \sum_{\substack{a \in \langle X \setminus \{x\} \rangle \\ b \in \langle \{x\} \rangle \\ \mathrm{par}(a,b)=1}} r(a) - \sum_{\substack{a \in \langle X \setminus \{x\} \rangle \\ b \in \langle \{x\} \rangle \\ \mathrm{par}(a,b)=0}} r(a) \\ &= \left(\sum_{\substack{a \in \langle X \setminus \{x\} \rangle \\ \mathrm{par}(a)=1}} r(a) + \sum_{\substack{a \in \langle X \setminus \{x\} \rangle \\ \mathrm{par}(a)=0}} r(a) \right) - \left(\sum_{\substack{a \in \langle X \setminus \{x\} \rangle \\ \mathrm{par}(a)=0}} r(a) + \sum_{\substack{a \in \langle X \setminus \{x\} \rangle \\ \mathrm{par}(a)=1}} r(a) \right) \\ &= 0. \end{aligned}$$

[1] If it has output 0, we can invert all outputs in the PDL and replace every occurence of x_1 with $1 - x_1$. This does not change its degree, and the resulting PDL computes $\neg\mathrm{par}_n(\overline{x_1}, x_2, \ldots, x_n) = \mathrm{par}_n(x_1, \ldots, x_n)$.

Because s is linear, $s(r) = 0$ also holds for any polynomial r of degree $< n$.

To obtain a value of $s(q)$, we use that

$$\sum_{\substack{a\in\langle X\rangle\\ \mathrm{par}(a)=1}} q(a) > 0 \quad \text{and} \quad \sum_{\substack{a\in\langle X\rangle\\ \mathrm{par}(a)=0}} q(a) = 0$$

(in the left equation, none of the summands are negative; one of them is $q(w) = |p(w)|^2 > 0$). Consequently, $s(q) > 0$ and $\deg(q) \geq n$, so using $\deg(q) \leq 2d$ we conclude that $d \geq \frac{n}{2}$. ◀

To turn this lower bound into a $\mathcal{Q}$-PC bound we need QBFs based on the parity function. For this we describe a general transformation originating from [13, 14] to construct QBFs that are false, but force the universal player to use a unique strategy by computing a particular function f. We define the QBF $\mathcal{Q}$-f:

▶ **Definition 9** ($\mathcal{Q}$-f). *Let $f : \langle X\rangle \to \langle U\rangle$ be a function that is computed by a* P/poly *circuit C. Then $\mathcal{Q}$-$f := \exists X\forall U\exists T\,\varphi$ where φ is the Tseitin transformation of the circuit $U \neq C(X)$, and T is the corresponding set of auxiliary Tseitin variables.*

In our case above, f is par_n and C is a simple P/poly circuit for par_n. The existential player wins if and only if the circuit $U \neq C(X)$ yields true, after the assignments to X and U were chosen by the respective players. The universal player therefore has the unique winning strategy of playing $U = f(X)$.

From Proposition 8 together with the size-degree relation for PDLs (Theorem 6) and the efficient transformation into $\mathcal{Q}$-PC (Theorem 3) we obtain:

▶ **Corollary 10.** *$\mathcal{Q}$-PC refutations over a subfield of $\mathbb{C}$ of $\mathcal{Q}$-par_n require size $\exp(\Omega(n))$.*

We can generalise this to the modulo k functions. Let $\mathrm{mod}_n^k(x_1, \ldots, x_n) = 1$ if and only if $\sum_{i=1}^n x_i \equiv 0 \mod k$ (otherwise it is 0). With a similar, but somewhat more technical proof than for Proposition 8 we can show:

▶ **Proposition 11.** *A PDL with polynomials over a subfield of $\mathbb{C}$ computing mod_n^k has degree at least $\frac{1}{2}\left\lfloor \frac{n}{(k-1)} \right\rfloor$.*

Consequently, the $\mathcal{Q}$-mod_n^k QBFs are hard for $\mathcal{Q}$-PC over $\mathbb{C}$.

▶ **Corollary 12.** *$\mathcal{Q}$-PC refutations over a subfield of $\mathbb{C}$ of $\mathcal{Q}$-mod_n^k have size $\exp(\Omega(\frac{n}{k}))$.*

4.2 Majority PDLs have high degree

Next we want to show degree lower bounds for PDLs that compute the majority functions $\mathrm{maj}_n(x_1, \ldots, x_n)$, which evaluate to one, if and only if $\sum_{i=1}^n x_i \geq \frac{n}{2}$. In contrast to the par_n and mod_n^k functions, this lower bound does not depend on the underlying field. We start by proving a useful lemma about PDLs:

▶ **Lemma 13.** *Let $X = \{x_1, \ldots, x_n\}$, $\alpha \in \langle X\rangle$ a complete assignment and p a polynomial with variables in X that is not the constant 0. There is an assignment $\beta \in \langle X\rangle$ such that α and β only differ in at most $\deg(p)$ variables, and $p(\beta) \neq 0$.*

Proof. We start by taking p and constructing an equivalent polynomial q that contains no variables according to their polarity in α: when $\alpha(x) = 0$, we replace $\overline{x}$ by $1 - x$, and when $\alpha(x) = 1$, we replace x by $1 - \overline{x}$. Let m be one of the lowest-degree monomials in q, and β the assignment that satisfies every literal in m, and assigns every other variable according to α. Note that α and β only differ in at most $\deg(m) \leq \deg(q) = \deg(p)$ variables. Because m has minimal degree, every other monomial in q contains a variable $v \notin \mathrm{vars}(m)$, so $\beta(v) = \alpha(v)$. Because v only occurs in the polarity opposite of $\alpha(v)$, β does not satisfy that other monomial. Therefore, $0 \neq m(\beta) = q(\beta) = p(\beta)$. ◀

With this, we can show the lower bound fairly easily:

▶ **Proposition 14.** *A PDL computing* $\mathrm{maj}_n(x_1, \dots, x_n)$ *has degree at least* $\frac{n}{2}$.

Proof. Let L be such a PDL, d its degree, and p its first polynomial. We also define $X := \{x_1, \dots, x_n\}$. If the first line of L has output 1, let α be the assignment that assigns all $x_i = 0$, and apply Lemma 13. Because $p(\beta) \neq 0$ and L is correct, we obtain $\mathrm{maj}_n(\beta) = 1$. So β has to assign 1 to at least $\frac{n}{2}$ variables and thus differs from α in at least $\frac{n}{2}$ variables. Therefore, $\frac{n}{2} \leq \deg(p) \leq d$. If the first line has output 0 instead, let α be the assignment that assigns all $x_i = 1$. Lemma 13 yields an assignment β with $p(\beta) \neq 0$, so $\mathrm{maj}_n(\beta) = 0$ and β has to assign 0 to at least $\frac{n}{2}$ variables. Therefore, $\frac{n}{2} \leq \deg(p) \leq d$. ◀

▶ **Corollary 15.** *Q-PC refutations of* $\mathcal{Q}$-maj_n *have size* $\exp(\Omega(n))$.

4.3 Limits of the size-degree method

While the size-degree technique is useful for showing several lower bounds as demonstrated above, it does not capture all nuances of PDL size. We will illustrate this by constructing two functions, each having n^2 variables and requiring PDLs of degree n. For these values, Theorem 6 does not yield any useful lower bound. Indeed, one of the functions requires PDLs of size $\exp(\Omega(n))$, while for the other one, size $O(n)$ is sufficient.

▶ **Theorem 16.** *Given a function f, the minimal size of its PDLs is not solely determined by its number of variables and minimal PDL degree. In particular, there are families of functions f_n and g_n, each with n^2 input variables and minimal PDL degree n, such that f_n has PDLs of size $O(n)$ and g_n requires PDLs of size* $\exp(\Omega(n))$.

In order to prove this, we introduce examples for those functions g and f. We define the square-majority function as $\mathrm{sqm}_n(x_1, \dots, x_{n^2}) = 1$ if and only if $\sum_{i=1}^{n^2} x_i \geq n$, otherwise 0.

▶ **Lemma 17.** *The* sqm_n *function can be computed by PDLs of degree n, but not by PDLs of smaller degree. It requires PDLs of size* $\exp(\Omega(n))$.

The lower bound on the size of PDLs for sqm already cannot be shown by Theorem 6. This raises the question of whether our size-degree relation is simply too weak, and whether we could obtain a stronger one that can capture the complexity of the sqm function. It turns out that this is not the case: there are functions with the same degree and number of variables, but smaller decision lists. The complexity of the sqm function cannot be derived from its degree and number of variables alone.

To obtain such a function, let $X = \{x_i^j \mid i, j \in \{1, \dots, n\}\}$ and $f_n(X) := \bigvee_{i=1}^{n} \bigwedge_{j=1}^{n} x_i^j$.

▶ **Lemma 18.** *The function f_n defined above can be computed by PDLs of degree n and size $O(n)$, but not by PDLs of smaller degree.*

Proof of Theorem 16. Let f_n be the function defined above, and $g_n = \mathrm{sqm}_n$. The statement follows directly from Lemmas 17 and 18. ◀

5 Converting PDLs into Boolean circuits

We now establish a different lower bound method for $\mathcal{Q}$-PC that directly imports circuit lower bounds. For this we show a connection between PDLs over finite fields and $AC^0[p]$ circuits. First we convert PDLs over a finite field to PDLs over a prime-order finite field.

▶ **Lemma 19.** *Let p be a prime, $k, l, m \in \mathbb{N}^{\geq 1}$ and L a PDL of length l and size m over the finite field $\mathbb{F}_{p^k}$. Then L can be converted into a PDL of length $k \cdot l$ and size $k \cdot m$ over the finite field $\mathbb{F}_p$ that computes the same function.*

This lemma is based on the fact that $\mathbb{F}_{p^k}$ has the structure of a k-dimensional $\mathbb{F}_p$ vector space with respect to addition. An equation in $\mathbb{F}_{p^k}$ that does not use multiplication can therefore be split up into k equations in $\mathbb{F}_p$. The only multiplication that occurs in the polynomials of a PDL is between coefficients and the corresponding unit monomials, and those unit monomials can only be 1 or 0. We can use this to convert each line of a PDL over $\mathbb{F}_{p^k}$ into k lines over $\mathbb{F}_p$.

We will now efficiently convert PDLs over $\mathbb{F}_p$ for primes p into $AC^0[p]$ circuits.

▶ **Proposition 20.** *Let $f : \{0,1\}^n \to \{0,1\}^s$ be a function that is computed by a PDL of size m over a finite field $\mathbb{F}_p$. Then f can be computed by an $\mathsf{AC}^0[p]$ circuit of depth 6 with only $O(pm + s)$ AND or OR gates.*

Proof. We construct the circuit iteratively starting at the inputs and ending at the output. At each layer, we describe the semantics of the newly-added circuit gates.

- Start with v input gates for the variables.
- Add v NOT gates, each negating one of the variables. All literals are now represented in the circuit.
- Consider each monomial $c \cdot \prod_i t_i$ where $c \in \mathbb{F}_p$ and the t_i are literals. Add c identical AND gates with all the t_i as inputs. The sum of the outputs of these gates will be equivalent to the value of the monomial. Because each $c < p$, the total number of these gates is smaller than pm.
- For each line, add a MOD_p gate over all the AND gates of its monomials. The sum of its inputs will be equivalent to the sum of the values of its monomials, so its output indicates whether the polynomial equation holds in $\mathbb{F}_p$.
- For each line, add a NOT gate negating the MOD_p gate.
- For each line, add an AND gate that checks if all polynomial equations of previous lines hold, but the equation of the current line does not. Its output indicates whether this line's output value is active.
- Finally, for each output variable z add an OR gate connecting the AND gates of those lines whose output sets $z = 1$. Its output indicates whether the PDL sets $z = 1$, it is the output of the circuit for variable z.

This circuit has depth 6 and at most $O(pm + s)$ AND or OR gates. ◀

Using Lemma 19 we can extend this result to fields $\mathbb{F}_{p^k}$:

▶ **Corollary 21.** *Let $f : \{0,1\}^n \to \{0,1\}^s$ be a function that is computed by a PDL of size m over a finite field $\mathbb{F}_{p^k}$. Then f can be computed by an $\mathsf{AC}^0[p]$ circuit of depth 6 with only $O(pmk + s)$ AND or OR gates.*

This corollary allows us to lift lower bounds for $\mathsf{AC}^0[p]$ circuits to PDLs over finite fields. We cite such a circuit lower bound by Smolensky [47]. Let p be a prime and r not a power of p. An $\mathsf{AC}^0[p]$ circuit of depth k that computes mod_n^r requires $\exp(\Omega(n^{\frac{1}{2k}}))$ AND or OR gates. Using Corollary 21 we can apply this result to PDLs:

▶ **Corollary 22.** *Let p, r be distinct primes. A PDL over the finite field $\mathbb{F}_{p^k}$ that computes* mod_n^r *needs size* $\exp(\Omega(\sqrt[12]{n} - \log(pk)))$*.*

We also want to apply these results to another class of functions that we call balance. $\mathrm{balance}_{2n}(x_1, x_2, \ldots, x_{2n}) = 1$ if and only if $\sum x_i = n$, else it is zero.

We now show that PDLs for the balance function can be transformed into $AC^0[p]$ circuits for the function mod_n^q with arbitrary q.

▶ **Proposition 23.** *If there is a PDL of size m over $\mathbb{F}_p$ that computes* $\mathrm{balance}_{2n}$*, then* mod_n^q *can be computed by an* $\mathsf{AC}^0[p]$ *circuit of depth 8 that uses only $O(pnm)$* AND *or* OR *gates.*

Proof. Let $R = \{q \cdot i \mid i \in \mathbb{Z}, 0 \le q \cdot i \le n\} = q\mathbb{Z} \cap [0; n]$, and note that $|R| = \left\lceil \frac{n+1}{q} \right\rceil$. When exactly k of the variables $x_1, \ldots, x_n$ are true, then $\mathrm{mod}_n^q(x_1 \ldots, x_n) = 1$ if and only if $k \in R$.

Using Proposition 20 we can obtain a circuit that computes $\mathrm{balance}_{2n}$ with $pm + l$ AND gates and one OR gate. We instantiate this circuit once for each $k \in R$, replacing the $2n$ inputs with n actual inputs $x_1, \ldots, x_n$, as well as k constants 0 and $n - k$ constants 1. The output of such an instance is 1 if and only if k of the actual inputs are 1. We use a single OR gate over all these outputs to obtain $\mathrm{mod}_n^q(x_1 \ldots, x_n)$. The total number of AND or OR gates is $|R|(pm + l) + 1 = \left\lceil \frac{n+1}{q} \right\rceil (pm + l) + 1 \le (n + 1)(p + 1)m + 1$. ◀

▶ **Corollary 24.** *The balance formulas require exponential-sized PDLs over finite fields.*

We can now show that many of the systems $\mathcal{Q}$-PC over different fields are incomparable.

▶ **Theorem 25.** *Let F be a finite field, and G either a finite field with different characteristic, or a subfield of $\mathbb{C}$. Then the $\mathcal{Q}$-PC systems over F and G are incomparable.*

Proof. Because PC systems and PDLs are polynomially equivalent, we can use exponential separations between the respective PDLs to obtain the result. Let p and q be the characteristics of F and G, respectively. The function mod_n^p is trivial for PDLs over F and requires only linear size. However, it requires exponential-sized PDLs over G, either due to Corollary 12 (if G is a finite field) or due to Corollary 22 (if G is a subfield of $\mathbb{C}$).

If G is a finite field, the function mod_n^q requires exponential-size PDLs over F and only linear-size PDLs over G. If G is a subfield of $\mathbb{C}$, the $\mathrm{balance}_n$ functions can be computed in linear size by PDLs over G, but require exponential-size PDLs over F by Corollary 24. ◀

6 Conclusion

While we concentrated on $\mathcal{Q}$-PC in this paper, it is interesting to explore the wider consequences of our P-UDL characterisation in Theorem 3 for further proof systems $\mathcal{Q}$-P. Besides PC and Res, the most studied base systems are arguably *Cutting Planes* (CP) and the various $\mathcal{C}$-Frege systems, where $\mathcal{C}$ is some circuit class, e.g. $\mathsf{AC}^0, \mathsf{NC}^1$ or P/poly.

While $\mathcal{Q}$-CP has polynomial capacity (the capacity is 1) [10], the lines are not closed under disjunction. Hence we cannot use Theorem 3 to obtain a CP-UDL characterisation. We leave open, whether the result itself does not hold or if it only requires a different proof.

For $\mathcal{Q}$-$\mathcal{C}$-Frege, we cannot use Theorem 3 either. Here the lines are closed under disjunction, but the capacity is exponential. However, it is known that the circuit class $\mathcal{C}$ itself, which is a strictly stronger model than $\mathcal{C}$-UDL, tightly characterises $\mathcal{Q}$-$\mathcal{C}$-Frege [20]. As such, the equivalence between $\mathcal{C}$-UDLs and $\mathcal{Q}$-$\mathcal{C}$-Frege fails.

Interestingly, if we consider treelike $\mathcal{Q}$-$\mathcal{C}$-Frege systems, the $\mathcal{C}$-UDL characterisation does hold, even though the capacity is still superpolynomial. Intuitively, this could be explained by the fact that limited capacity is only required for blockwise reductions, and such reductions can (possibly) be obtained by combining reductions along a path in the proof-tree. We prove the result even without using Theorem 3, as a direct proof is straightforward to obtain using a previous characterisation of treelike $\mathcal{Q}$-$\mathfrak{C}$-Frege from [16]. We just state the result.

▶ **Theorem 26.** *For a circuit class* $\mathfrak{C}$ *and a QBF family, the minimal sizes of* $\mathcal{Q}$-$\mathfrak{C}$-$\mathsf{Frege}_{\text{tree}}$ *proofs and the minimal* $\mathfrak{C}$-UDL *sizes are polynomially bounded by each other.*

Interestingly, this result even holds for QBFs with unbounded quantifier alternation. We leave open whether similar characterisations can be obtained for daglike systems $\mathcal{Q}$-P on formulas with unbounded alternation depth.

Generalized Completion Problems with Forbidden Tournaments

Zeno Bitter

Antoine Mottet
Hamburg University of Technology, Research Group for Theoretical Computer Science, Germany

Abstract

A recent result by Bodirsky and Guzmán-Pro gives a complexity dichotomy for the following class of computational problems, parametrized by a finite family $\mathcal{F}$ of finite tournaments: given an undirected graph, does there exist an orientation of the graph that avoids every tournament in $\mathcal{F}$? One can see the edges of the input graphs as constraints imposing to find an orientation. In this paper, we consider a more general version of this problem where the constraints in the input are not necessarily about pairs of variables and impose local constraints on the global oriented graph to be found. Our main result is a complexity dichotomy for such problems, as well as a classification of such problems where the yes-instances have bounded treewidth duality. As a consequence, we obtain a streamlined proof of the result by Bodirsky and Guzmán-Pro using the theory of smooth approximations due to Mottet and Pinsker.

1 Introduction

1.1 Completion Problems

For every fixed finite family $\mathcal{F}$ of tournaments, the $\mathcal{F}$-free orientation problem consists in deciding whether an undirected graph G admits an orientation G^* such that no tournament from $\mathcal{F}$ is contained in G^*. The complexity of such problems was systematically studied recently in [5], where it is shown that every such problem is solvable in polynomial time or NP-complete.

We extend this result by considering the following variation of the problem. Fix an $r \geq 2$ and let R be a set of tournaments on r vertices, labelled with the numbers $1, \ldots, r$. An input in our problem is a set V of vertices where some r-tuples are marked. The yes-instances to this problem are those where there exists an $\mathcal{F}$-free digraph on V such that whenever $(x_1, \ldots, x_r)$ is marked, then the labelled subdigraph induced on $\{x_1, \ldots, x_r\}$ is isomorphic to an element of R.

This is an extension of the $\mathcal{F}$-free orientation problem, as can be seen by taking $r = 2$ and R consisting of the two possible tournaments on 2 (labelled) vertices. We call this the $(\mathcal{F}, R)$-orientation problem, see Figure 1 for an example. One can view $\mathcal{F}$ as imposing *global* constraints (find a directed graph on V that globally avoids every tournament in $\mathcal{F}$), and R as imposing *local* constraints (find a directed graph on V that satisfies the local restrictions on the marked tuples). Our more general result is a P versus NP-complete complexity dichotomy for such problems.

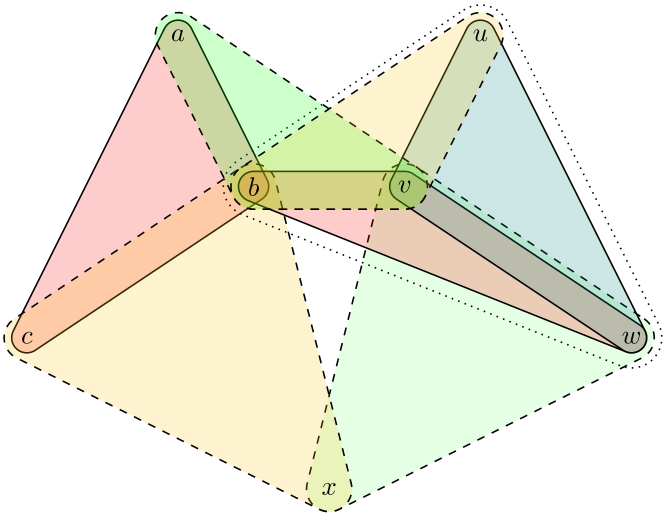

Figure 1 Example of an instance of $(\mathcal{F}, R)$-orientation where $\mathcal{F}$ consists of the transitive tournament on 4 vertices, and R contains the oriented graphs on 3 vertices inducing a transitive tournament. The markings are given by hyperedges. Note that due to the symmetry of R we do not need to specify the order of the vertices in the hyperedges. To solve such an instance, one needs to determine whether there exists an oriented graph on the given vertices, not inducing a transitive tournament on any four vertices, while all marked triples of vertices induce a transitive tournament.

▶ **Theorem 1.** *Let $\mathcal{F}$ be a finite set of finite tournaments and let R be a set of labelled r-vertex tournaments. Then the $(\mathcal{F}, R)$-orientation problem is solvable in polynomial time or NP-complete.*

1.2 Constraint Satisfaction Problems

Given a finite family $\mathcal{F}$ of tournaments, Fraïssé's theorem asserts that there exists a countably infinite digraph $D_{\mathcal{F}}$ whose finite subgraphs are exactly the oriented graphs avoiding every tournament in $\mathcal{F}$. Moreover, $D_{\mathcal{F}}$ satisfies a certain model-theoretic condition called *homogeneity*, which defines $D_{\mathcal{F}}$ uniquely up to isomorphism (see Section 2 for the detailed definitions). The following observation by Bodirsky and Guzmán-Pro in [5] is crucial for their complexity result. Consider the symmetric closure of $D_{\mathcal{F}}$, i.e., the undirected graph $H_{\mathcal{F}}$ obtained by forgetting about the directions of arcs in $D_{\mathcal{F}}$. Then it can be observed that given an undirected graph G, one has a homomorphism $G \to H_{\mathcal{F}}$ if, and only if, G admits an $\mathcal{F}$-free orientation. Thus, the $\mathcal{F}$-free orientation problem coincides with the *constraint satisfaction problem* for the graph $H_{\mathcal{F}}$, denoted by $\mathrm{CSP}(H_{\mathcal{F}})$. The complexity of this CSP can then be investigated using standard methods.

In order to obtain a generalization of [5] for the $(\mathcal{F}, R)$-orientation problem, we start with a similar observation. In $D_{\mathcal{F}}$, consider the subset $R' \subseteq V^r$ containing all tuples $(v_1, \ldots, v_r)$ inducing in $D_{\mathcal{F}}$ a tournament from R. The structure $\mathbb{A} = (V; R')$ is a so-called *first-order reduct* of $D_{\mathcal{F}}$. Note that if R consists of the two labelled tournaments on 2 vertices, then $\mathbb{A}$ thus defined coincides with $H_{\mathcal{F}}$. An input to the $(\mathcal{F}, R)$-orientation problem can then be seen as a structure in the same signature as $\mathbb{A}$. One obtains that an input to the $(\mathcal{F}, R)$-orientation problem admits a solution if, and only if, it admits a homomorphism to the structure $\mathbb{A}$. The structure $\mathbb{A}$ obtained in this way moreover satisfies two important properties:

- Provided R contains more than one tournament, the symmetric closure U of the edge relation of $D_{\mathcal{F}}$ is invariant under the higher-order symmetries of $\mathbb{A}$, called *polymorphisms*. In particular, the group of automorphisms of $\mathbb{A}$ is a subgroup of $\mathrm{Aut}(H_{\mathcal{F}})$.
- $\mathbb{A}$ has a particular type of binary injective polymorphism that we call an *injective projection*.

Theorem 1 then follows from the following technical result. The notion that "$\mathbb{A}$ pp-constructs every finite structure" appearing in the statement is defined in Section 2; for now, the reader can view this as a natural condition allowing to reduce the boolean satisfiability problem to the constraint satisfaction problem of $\mathbb{A}$, which is then NP-hard.

▶ **Theorem 2.** *Let $\mathcal{F}$ be a finite set of tournaments, and let $\mathbb{A}$ be a first-order reduct of $D_{\mathcal{F}}$ that admits injective projections and such that U is invariant under* $\mathrm{Pol}(\mathbb{A})$. *One of the following holds:*

- $\mathbb{A}$ *pp-constructs every finite structure and* $\mathrm{CSP}(\mathbb{A})$ *is NP-complete, or*
- $\mathrm{CSP}(\mathbb{A})$ *is solvable in polynomial time.*

The proof follows the *smooth approximations* approach introduced in [25] and uses the refinements thereof from [22, 26]. This provides a streamlined proof and an extension of the dichotomy result from [5].

Another consequence of our proof is the following. Say that the class of $\mathcal{F}$-free orientable graphs has *bounded treewidth duality* if there exists a set $\mathcal{G}$ of undirected graphs of bounded treewidth such that for every finite graph G, there exists an $\mathcal{F}$-free orientation of G if, and only if, no graph from $\mathcal{G}$ admits a homomorphism to G. This notion can be extended to structures with an $(\mathcal{F}, R)$-orientation by generalizing the notion of treewidth for relational structures in general, we refer the interested reader to [15] for precise definitions. Any class of structures corresponding to a CSP and having bounded treewidth duality can be recognized in polynomial time by a Datalog program, giving a particularly simple algorithm recognizing the class.

As a by-product of our proof, we obtain a characterization of the sets $\mathcal{F}, R$ for which the class of structures with an $(\mathcal{F}, R)$-orientation has bounded treewidth duality. As above, this characterization is phrased in terms of the algebraic properties of a first-order reduct of $D_{\mathcal{F}}$. Using the recent results from [22], this also allows us to obtain a bounded on the treewidth in a possible duality depending on the size of the tournaments in $\mathcal{F}$ and R.

▶ **Theorem 3.** *Let $\mathcal{F}$ be a finite set of tournaments, and let $\mathbb{A}$ be a first-order reduct of $D_{\mathcal{F}}$ that admits injective projections and such that U is invariant under* $\mathrm{Pol}(\mathbb{A})$. *Let r be the maximal arity of a relation of $\mathbb{A}$ and ℓ be the maximal size of a tournament in $\mathcal{F}$. Then, the following are equivalent:*

1. $\mathrm{Pol}(\mathbb{A})$ *contains an* $\mathrm{Aut}(D_{\mathcal{F}})$*-canonical pseudo-majority polymorphism modulo* $\overline{\mathrm{Aut}(D_{\mathcal{F}})}$*,*
2. *The class of finite structures admitting a homomorphism to $\mathbb{A}$ has a duality of treewidth at most* $\max(6, r, \ell)$.

In particular, when the class of $\mathcal{F}$-free orientable graphs has a bounded treewidth duality, then Theorem 3 implies that the duality $\mathcal{G}$ can be chosen to consist of graphs of treewidth at most $\max(6, \ell)$.

1.3 Related Work

The approach we follow here shows an equivalence between $(\mathcal{F}, R)$-completion problems and a subclass of constraint satisfaction problems (CSPs). A P/NP-complete complexity dichotomy is known for CSPs with a finite template [14, 29], while for CSPs with infinite templates in general it is known that the complexity varies greatly [4, 17, 18]. For a subclass of infinite structures, so-called *first-order reducts of finitely bounded homogeneous structures*, Bodirsky and Pinsker have conjectured that a dichotomy similar to that of finite-domain CSPs exists. The templates $D_{\mathcal{F}}$ studied here are in the scope of that conjecture. The conjecture has been proved for a variety of finitely bounded homogeneous structures (e.g., all homogeneous undirected graphs [8], certain homogeneous hypergraphs [26], the universal homogeneous tournament [25], $(\mathbb{Q}; <)$ [7], and the universal homogeneous poset [20]). There exist natural subclasses of the Bodirsky-Pinsker class for which the conjecture is still open; this is the case for example for first-order reducts of finitely bounded homogeneous directed graphs, or for first-order reducts of *homomorphically bounded* homogeneous structures. It can be shown that if D is a homogeneous homomorphically bounded homogeneous directed graph, then $D = D_{\mathcal{F}}$ for some finite family $\mathcal{F}$ of finite tournaments. Thus, our result can be seen as making progress on the Bodirsky-Pinsker conjecture for both mentioned subclasses.

1.4 Organization of the paper

We recall some elementary notions from graph theory and the universal-algebraic approach to the complexity of infinite-domain CSPs in Section 2. In Section 3, we prove some elementary properties of the templates $\mathbb{A}$ arising from $(\mathcal{F}, R)$-completion problems. Due to space restrictions, we only describe a high-level proof strategy for Theorems 2 and 3 in Section 4, focusing on making the presentation accessible to a non-expert.

2 Definitions and Notations

2.1 Elementary model-theoretic notions

For the purposes of this paper, a *structure* is a tuple $\mathbb{A} = (A; R_1^{\mathbb{A}}, \dots, R_k^{\mathbb{A}})$ consisting of a set A (the *domain*) together with finitely many relations $R_i^{\mathbb{A}} \subseteq A^{r_i}$ on A. The *signature* of $\mathbb{A}$ is the list $(r_1, \dots, r_k)$ containing the arities of the relations of $\mathbb{A}$. We assume the reader is familiar with the standard notions of homomorphisms, embeddings, and isomorphisms between structures. As is standard in model theory, all substructures and subgraphs in this paper are *induced* substructures and subgraphs.

An oriented graph is a directed graph $G = (V, E)$ where at most one of $(u, v) \in E$ or $(v, u) \in E$ holds for all $u, v \in V$, and where $(u, u) \notin E$ for all $u \in V$. A tournament is an oriented graph such that the symmetric closure of its edge relation induces a complete graph. For a (finite) set $\mathcal{F}$ of finite tournaments we say that an oriented graph is $\mathcal{F}$-free if it contains no $F \in \mathcal{F}$ as an induced subgraph.

Let $\mathcal{F}$ be a finite set of finite tournaments. Let $\mathcal{C}_{\mathcal{F}}$ be the class of all $\mathcal{F}$-free oriented graphs. It can be seen that this class has the so-called *amalgamation property*: given two $\mathcal{F}$-free oriented graphs, their union is also $\mathcal{F}$-free due to $\mathcal{F}$ consisting of tournaments only. By the classical result of Fraïssé [16], there exists an oriented graph $D_{\mathcal{F}} = (V, E)$ on a countable set whose finite subgraphs are exactly the graphs isomorphic to a graph in $\mathcal{C}_{\mathcal{F}}$. Moreover, this graph is *homogeneous*, in the sense that for every finite subset $S \subseteq V$ and every partial isomorphism $f \colon S \to V$, there exists an automorphism α of $D_{\mathcal{F}}$ such that $f|_S = \alpha|_S$. These two properties describe $D_{\mathcal{F}}$ uniquely up to isomorphism. We write $H_{\mathcal{F}} = (V, U)$ for the undirected graph whose edge set is the symmetric closure of E. We note that $H_{\mathcal{F}}$ is in general not homogeneous, and in fact we will focus in this paper on the case where $H_{\mathcal{F}}$ is *not* homogeneous for reasons that are made clear below.

A *first-order reduct* of $\mathbb{A}$ is a structure $\mathbb{B}$ with the same domain as $\mathbb{A}$ and whose relations all have a first-order definition in $\mathbb{A}$. For example, $H_{\mathcal{F}}$ is a first-order reduct of $D_{\mathcal{F}}$, because the symmetric closure U of E is definable by $(v, w) \in E \vee (w, v) \in E$, which is a first-order definition of U in $D_{\mathcal{F}}$. An *expansion* of $\mathbb{A}$ is a structure $\mathbb{B}$ obtained from $\mathbb{A}$ by adding new relations.

An example of a natural expansion of $D_{\mathcal{F}}$ is obtained as follows. Consider the class $\mathcal{C}_{\mathcal{F}}^{<}$ of all structures $(V', E', \prec)$ where $(V', E') \in \mathcal{C}_{\mathcal{F}}$ and where $\prec$ is an arbitrary linear order on V'. This class also has the amalgamation property as described above, and its Fraïssé limit can be taken to be $(V, E, <)$, an expansion of $D_{\mathcal{F}}$ by a linear order.

Let $\mathscr{G}$ be a group of permutations on a set A. Let $\equiv_k$ be the equivalence relation on A^k containing the pairs (a, b) of tuples such that there exists $\alpha \in \mathscr{G}$ such that $\alpha(a_i) = b_i$ for all $i \in \{1, \ldots, k\}$. We call the equivalence classes of $\equiv_k$ the *orbits* of $\mathscr{G}$. The orbit of a pair $(a, b) \in V^2$ under $\mathrm{Aut}(D_{\mathcal{F}})$ is given, by the homogeneity of $D_{\mathcal{F}}$, by the isomorphism type of the labelled graph induced by $\{a, b\}$. There are therefore 4 orbits, corresponding to whether $a = b$, whether $a \neq b$ are connected by an edge, and if they are whether $(a, b) \in E$ or $(b, a) \in E$. We denote the orbit containing the pairs (a, b) such that $a \neq b$ and $(a, b) \notin U$ by N, the orbit of all $(a, b) \in E$ by $\rightarrow$, and the orbit of all (a, b) such that $(b, a) \in E$ by $\leftarrow$.

Let $\mathbb{A}, \mathbb{B}$ be structures with $B = A^n$. We say $\mathbb{B}$ is a *pp-power* of A if every relation in $\mathbb{B}$ is definable by a primitive positive formula over $\mathbb{A}$, that is a formula only using $\exists$ and $\wedge$. For arbitrary structures $\mathbb{A}, \mathbb{B}$ we say $\mathbb{A}$ *pp-constructs* $\mathbb{B}$ if there is a pp-power $\mathbb{C}$ of $\mathbb{A}$ such that $\mathbb{B}$ and $\mathbb{C}$ are homomorphically equivalent.

2.2 Clones, naked and affine sets

A relation $R \subseteq A^m$ is said to be *invariant* under a function $f\colon A^n \to A$ if for every $a^1, \ldots, a^n \in R$, then $f(a^1, \ldots, a^n)$, the tuple obtained by applying f componentwise to the tuples $a^1, \ldots, a^n$, is also in R. A function $f\colon A^n \to A$ is a *polymorphism* of a structure $\mathbb{A}$ if all the relations of $\mathbb{A}$ are invariant under f. In particular, every automorphism and endomorphism of $\mathbb{A}$ is a polymorphism of $\mathbb{A}$. The set $\mathrm{Pol}(\mathbb{A})$ of all polymorphisms of $\mathbb{A}$ forms a *clone*: it contains all the projections $p_i^k\colon (a_1, \ldots, a_k) \mapsto a_i$ for $1 \leq i \leq k$ and it is closed under composition. We write $\mathscr{P}$ for the clone consisting of only the projections on the set $\{0, 1\}$. This clone is relevant in the theory of constraint satisfaction because it is exactly the clone of polymorphisms of a structure $\mathbb{S}$ with domain $\{0, 1\}$ and having all ternary relations on $\{0, 1\}$ as its relations, whose CSP corresponds to the problem CNF-3SAT.

If $S \subseteq A^k$ is invariant under a clone $\mathscr{C}$, and θ is an equivalence relation on S that is also invariant under $\mathscr{C}$, then the operations in $\mathscr{C}$ naturally induce a clone of functions on the set S/θ, where $f \in \mathscr{C}$ of arity n induces the function $([s_1], \ldots, [s_n]) \mapsto [f(s_1, \ldots, s_n)]$. We use the notation $\mathscr{C} \curvearrowright S/\theta$ to denote this clone and if θ has at least two equivalence classes we call (S, θ) a *subfactor* of $\mathscr{C}$. A subfactor is *minimal* if for all $a, b \in S$ that are not θ-equivalent, the smallest $\mathscr{C}$-invariant set containing a, b is equal to S.

A subfactor (S, θ) of $\mathscr{C}$ is called a *naked set* if $\mathscr{C} \curvearrowright S/\theta$ only consists of projections. Similarly, if S/θ is finite and can be endowed with a structure of a module over a ring R, in a way that $\mathscr{C} \curvearrowright S/\theta$ consists of *affine* functions, of the form $(x_1, \ldots, x_n) \mapsto \sum \lambda_i \cdot x_i$ for $\lambda_1, \ldots, \lambda_n \in R$ such that $\sum \lambda_i = 1$, then we call (S, θ) an *affine set* for $\mathscr{C}$. Note that every naked set is a particular example of an affine set: if (S, θ) is a naked set of $\mathscr{C}$, then the maps induced by $\mathscr{C}$ on S/θ have exactly one non-zero λ_i, which is equal to 1.

For a clone $\mathscr{C}$ on a 2-element set (in this paper, the 2-element set is $\{\leftarrow, \rightarrow\}$), the notions of having a naked set or an affine set can be rephrased using Post's classification of such clones [28]:

- $\mathscr{C}$ has a naked set if, and only if, every operation in $\mathscr{C}$ is essentially unary, of the form $(x_1, \dots, x_n) \mapsto e(x_i)$ for some permutation e of $\{\leftarrow, \rightarrow\}$ and $i \in \{1, \dots, n\}$. If $\mathscr{C}$ does not have a naked set, then it contains an operation f satisfying the equation

  $$f(x, y, z) = f(y, z, x)$$

  for all $x, y, z \in \{\leftarrow, \rightarrow\}$. Such an f is called a *ternary cyclic operation.*
- $\mathscr{C}$ has an affine set if, and only if, every operation in $\mathscr{C}$ is of the form

  $$(x_1, \dots, x_n) \mapsto \sum \lambda_i \cdot x_i + \mu$$

  where $\lambda_1, \dots, \lambda_n, \mu \in \{0, 1\}$ are such that $\sum \lambda_i = 1$, addition and multiplication are understood modulo 2, and after choosing an arbitrary bijection between $\{\leftarrow, \rightarrow\}$ and $\{0, 1\}$. If $\mathscr{C}$ does not have an affine set, then it contains an operation m satisfying the identities

  $$m(x, x, y) = m(x, y, x) = m(y, x, x) = x$$

  for all $x, y \in \{\leftarrow, \rightarrow\}$ or a binary operation s that is associative, commutative, and satisfies $s(x, x) = x$ for all $x \in \{\leftarrow, \rightarrow\}$. Such an m is called a *majority* operation, while s is called a *semilattice.*

For an ω-categorical structure $\mathbb{A}$ it is known that the complexity of CSP($\mathbb{A}$) is captured by the polymorphisms of $\mathbb{A}$. For our purposes, we need the following two special cases:

▶ **Theorem 4** ([21]). *Let $\mathbb{A}$ be an ω-categorical structure. The following hold:*

- *If* Pol($\mathbb{A}$) *has a naked set, then $\mathbb{A}$ pp-constructs every finite structure and* CSP($\mathbb{A}$) *is NP-hard.*
- *If* Pol($\mathbb{A}$) *has an affine set, then the class of structures admitting a homomorphism to $\mathbb{A}$ does not have bounded treewidth duality.*

2.3 Canonical Functions

Let $S \subseteq A^k$ be invariant under a function $f\colon A^n \to A$. We say that $f\colon A^n \to A$ is *canonical on S with respect to a permutation group $\mathscr{G}$* if whenever $a^1 \equiv_k b^1, \dots, a^n \equiv_k b^n$ for $a^1, b^1, \dots, a^n, b^n \in S$, then $f(a^1, \dots, a^n) \equiv_k f(b^1, \dots, b^n)$. In other words, f is canonical on S if the restriction of $\equiv_k$ to S is invariant under f; in particular, the set of functions f that are canonical on S with respect to $\mathscr{G}$ forms a clone $\mathscr{C}$, and this clone has an action $\mathscr{C} \curvearrowright S/{\equiv_k}$. If $f(a^1, \dots, a^n) \equiv_k f(\alpha a^1, \dots, \alpha a^n)$ holds for all $\alpha \in \mathrm{Aut}(\mathbb{A})$ and all $a^1, \dots, a^n$, we call f *diagonally* canonical. In order to simplify notation and to make the dependence on the group clearer, we write $S/\mathscr{G}$ for the set of orbits of S induced by $\mathscr{G}$.

Let $k \geq 1$. We write $I_k \subseteq V^k$ for the set of tuples with pairwise distinct entries, and $K \subseteq I_k$ for the set of tuples whose components induce a clique in $H_{\mathcal{F}}$. We will be considering the following clones:

- $\mathscr{C}^K_{(D_{\mathcal{F}},<)}$ is the clone of polymorphisms of $\mathbb{A}$ that are canonical on K with respect to $\mathrm{Aut}(D_{\mathcal{F}}, <)$.
- $\mathscr{C}^K_{D_{\mathcal{F}}}$ the clone of polymorphisms of $\mathbb{A}$ that are canonical on K with respect to $\mathrm{Aut}(D_{\mathcal{F}})$,
- $\mathscr{C}^I_{\mathbb{A}}$ the clone of polymorphisms of $\mathbb{A}$ that are, for all $k \geq 1$, canonical on I_k with respect to $\mathrm{Aut}(\mathbb{A})$.

Note that since canonicity is considered with respect to different groups, the clones above are not necessarily comparable with respect to inclusion.

2.4 Smooth approximations

Central to our proof of Theorem 2 is the theory of smooth approximations, further developed in [23]. It relies on comparing two clones $\mathscr{C} \subseteq \mathscr{D}$ and whether a naked set (resp. affine set) for $\mathscr{C}$ can be lifted to a naked set (resp. affine set) for $\mathscr{D}$. The lifting is formalized by smooth approximations.

▶ **Definition 5** (Smooth Approximations). *Let A be a set, $k \geq 1$, and $\sim$ be an equivalence relation on $S \subseteq A^k$. An equivalence relation η on some set S' with $S \subseteq S' \subseteq A^k$ approximates $\sim$ if the restriction of η to S is a possible (non-proper) refinement of $\sim$; in that case, η is an* approximation *of $\sim$.*

Suppose that the $\sim$-equivalence classes as well as η are invariant under a group $\mathscr{G}$ of permutations on A. We say that the approximation is

- presmooth *with respect to a group $\mathscr{G}$ if each equivalence class C of $\sim$ intersects some equivalence class C' of η such that $C \cap C'$ contains two disjoint tuples in the same $\mathscr{G}$-orbit;*
- very smooth *with respect to a group $\mathscr{G}$ if $\equiv_k$ is a (possibly non-proper) refinement of η; in other words, if any two k-tuples in the same orbit must be η-equivalent.*

The equivalence relations $\sim$ for which we want to find approximations come from subfactors of $\mathscr{C}$. If $\mathscr{D}$ contains $\mathscr{C}$, it might not act at all on $S/{\sim}$ (if S or $\sim$ is not invariant under $\mathscr{D}$), and even in the case that it does, its action might contain operations that are not from $\mathscr{C} \curvearrowright S/{\sim}$. However, the theory of smooth approximations gives us that we can (under certain conditions) find a $\mathscr{D}$-invariant set $S' \supseteq S$ and an equivalence relation η on S' that approximates $\sim$, and such that $\mathscr{D} \curvearrowright S'/\eta$ is not "richer" than $\mathscr{C} \curvearrowright S/{\sim}$.

One of the central results from [25] is the so-called *loop lemma of smooth approximations*. We do not give the general formulation of the loop lemma here and rather phrase it directly the way we apply it in our proof.

▶ **Theorem 6** (Consequence of Theorem 11 and Lemma 14 in [25]). *Let $k \geq 1$, and suppose that $\mathscr{C}^I_{\mathbb{A}} \curvearrowright I_k/\mathrm{Aut}(\mathbb{A})$ has a naked (resp. affine) set. Then there exists a naked (resp. affine) set $(S, \sim)$ of $\mathscr{C}^I_{\mathbb{A}}$ with $S \subseteq I_k$ and $\mathrm{Aut}(\mathbb{A})$-invariant $\sim$-classes such that one of the following holds:*

1. *$\sim$ is approximated by a $\mathrm{Pol}(\mathbb{A})$-invariant equivalence relation that is presmooth with respect to $\mathrm{Aut}(D_{\mathcal{F}})$;*
2. *there exists $f \in \mathrm{Pol}(\mathbb{A})$ such that $f(a,b) \sim f(b,a)$ holds for all disjoint injective tuples $a, b \in V^k$ such that $f(a,b), f(b,a) \in S$.*

▶ **Lemma 7.** *Let $f\colon V^n \to V$ be an arbitrary operation defined on V. There exists $g\colon V^n \to V$ that is canonical with respect to $\mathrm{Aut}(D_{\mathcal{F}}, <)$ and that is* locally interpolated *by f, i.e., for every finite $S \subseteq V$ there exist $\alpha_1, \ldots, \alpha_n, \beta \in \mathrm{Aut}(D_{\mathcal{F}}, <)$ such that $g(a_1, \ldots, a_n) = \beta f(\alpha_1 a_1, \ldots, \alpha_n a_n)$ holds for all $a_1, \ldots, a_n \in S$.*

Proof. By the theorem of Nešetřil and Rödl [27], the class of all $\mathcal{F}$-free oriented graphs endowed with a linear order is a so-called *Ramsey class*. The conclusion is then obtained by applying [13, Lemma 14], see also [12, Theorem 5] for an alternative presentation. ◀

In particular, if $\mathbb{A}$ is a first-order reduct of $D_{\mathcal{F}}$, then for every $f \in \mathrm{Pol}(\mathbb{A})$ there exists $g \in \mathscr{C}^K_{(D_{\mathcal{F}},<)}$ that is locally interpolated by f. Similarly, for every $f\colon V^n \to V$, there exists $g\colon V^n \to V$ that is diagonally canonical with respect to $\mathrm{Aut}(D_{\mathcal{F}}, <)$ and that is *diagonally interpolated* by f, that is, for every finite $S \subseteq V$ there exist $\alpha, \beta \in \mathrm{Aut}(D_{\mathcal{F}}, <)$ such that $g(a_1, \ldots, a_n) = \beta f(\alpha a_1, \ldots, \alpha a_n)$ holds for all $a_1, \ldots, a_n \in S$.

3 Injective Projections and Preliminary Results

We define here the notion of injective projections appearing in Theorem 2.

▶ **Definition 8** (Injective projections). *An* injective projection *is a function $q_i^n \colon V^n \to V$ such that for all $a_1, \ldots, a_n \in V^2$, at least one of which is not a constant pair, the following hold:*

- *$q_i^n(a_1, \ldots, a_n) \in \mathrm{N}$ if $a_j \notin U$ for some $j \in \{1, \ldots, n\}$,*
- *$q_i^n(a_1, \ldots, a_n)$ and a_i are in the same orbit under $\mathrm{Aut}(D_{\mathcal{F}})$ otherwise.*

If $\mathbb{A}$ is a reduct of $D_{\mathcal{F}}$ and $q_i^n \in \mathscr{C}_{\mathbb{A}}^I$ for all $1 \leq i \leq n$ then we say $\mathbb{A}$ has injective projections.

Note that injective projections are canonical with respect to $D_{\mathcal{F}}$. Indeed, suppose that $a_1, b_1, \ldots, a_n, b_n$ are tuples of the same length m such that a_j and b_j induce the same graph in $D_{\mathcal{F}}$, for all $j \in \{1, \ldots, n\}$. Then by definition, $q_i^n(a_1, \ldots, a_n)$ and $q_i^n(b_1, \ldots, b_n)$ induce the same directed graph in $D_{\mathcal{F}}$, and thus they are in the same orbit under $\mathrm{Aut}(D_{\mathcal{F}})$ by homogeneity of $D_{\mathcal{F}}$.

▶ **Proposition 9.** *Let $\mathcal{F}$ be a finite set of finite tournaments, and let $\mathbb{A}$ be a first-order reduct of $D_{\mathcal{F}}$ whose relations only contain tuples inducing tournaments in $D_{\mathcal{F}}$. Then $q_i^n \in \mathrm{Pol}(\mathbb{A})$ for all $1 \leq i \leq n$. If one of the relations of $\mathbb{A}$ contains tuples inducing different tournaments, then U is invariant under $\mathrm{Pol}(\mathbb{A})$.*

Proof. Let R be a relation of $\mathbb{A}$ that contains two tuples inducing different tournaments in $D_{\mathcal{F}}$. In particular the arity n of R must be at least 2. Since R contains tuples a, b inducing different tournaments, there exist distinct $i, j \in \{1, \ldots, n\}$ such that (a_i, a_j) and (b_i, b_j) induce different tournaments, i.e., they form edges in opposite directions. Thus, the projection of R onto the coordinates i, j is equal to U, and it follows that U is invariant under $\mathrm{Pol}(\mathbb{A})$.

Let $1 \leq i \leq n$. We define a directed graph $D = (V^n, E')$ by $(x, y) \in E'$ if, and only if, $(x_j, y_j) \in U$ for all $j \in \{1, \ldots, n\}$ and $(x_i, y_i) \in E$.

We prove that D is $\mathcal{F}$-free. Assume for contradiction otherwise. Then there is a finite $V' \subseteq V^n$ inducing a tournament from $\mathcal{F}$ in D. By definition, the projection

$$\{v \in V \mid \exists x_1, \ldots, x_{i-1}, x_{i+1}, \ldots, x_n \in V : (x_1, \ldots, x_{i-1}, v, x_{i+1}, \ldots, x_n) \in V'\}$$

of V' onto its ith coordinate induces the same tournament in $D_{\mathcal{F}}$. But this contradicts the fact that $D_{\mathcal{F}}$ is $\mathcal{F}$-free. Thus, since $D_{\mathcal{F}}$ is universal for the class of $\mathcal{F}$-free digraphs, there exists an embedding $q_i^n \colon D \hookrightarrow D_{\mathcal{F}}$.

We can then view q_i^n as an n-ary function on V. We prove that it is a polymorphism of $\mathbb{A}$. Let R be a relation of $\mathbb{A}$, and let $r_1, \ldots, r_n \in R$. By assumption on R, all $r_1, \ldots, r_n$ induce tournaments in $D_{\mathcal{F}}$. Thus, $q_i^n(r_1, \ldots, r_n)$ induce the same tournament as r_i, and therefore $q_i^n(r_1, \ldots, r_n) \in R$. ◀

As a consequence of Proposition 9, we obtain that all templates $\mathbb{A}$ arising from a $(\mathcal{F}, R)$-completion problem in the way outlined in the introduction satisfy the assumptions of Theorem 2.

We now prove that the injective projections are canonical with respect to $\mathrm{Aut}(\mathbb{A})$, for any first-order reduct $\mathbb{A}$ of $D_{\mathcal{F}}$ such that $\mathrm{Aut}(\mathbb{A}) \subseteq \mathrm{Aut}(H_{\mathcal{F}})$. The proof of this fact is the only place where the classification of first-order reducts of $D_{\mathcal{F}}$ due to Agarwal and Kompatscher [1] is needed.

▶ **Lemma 10.** *Let $\mathbb{A}$ be a first-order reduct of $D_{\mathcal{F}}$ with $\mathrm{Aut}(\mathbb{A}) \subseteq \mathrm{Aut}(H_{\mathcal{F}})$. The injective projections are canonical with respect to $\mathrm{Aut}(\mathbb{A})$ and are therefore elements of $\mathscr{C}_{\mathbb{A}}^I$.*

Proof. Let $1 \leq k \leq n$ and let $a^1, b^1, \ldots, a^n, b^n$ be such that a^i and b^i are injective tuples that are in the same orbit under $\mathrm{Aut}(\mathbb{A})$, for all $i \in \{1, \ldots, n\}$. We need to show that $q_k^n(a^1, \ldots, a^n)$ and $q_k^n(b^1, \ldots, b^n)$ are in the same orbit under $\mathrm{Aut}(\mathbb{A})$.

The $\mathrm{Aut}(D_{\mathcal{F}})$-orbit of $q_k^n(a^1, \ldots, a^n)$ is the orbit of n-tuples c such that for all $i \neq j$, either $(c_i, c_j) \in \mathrm{N}$ whenever for some ℓ, $(a_i^\ell, a_j^\ell) \in \mathrm{N}$, and otherwise (c_i, c_j) is in the same $\mathrm{Aut}(D_{\mathcal{F}})$-orbit as (a_i^k, a_j^k). Since a^ℓ and b^ℓ are in the same orbit under $\mathrm{Aut}(\mathbb{A})$ for all $\ell \in \{1, \ldots, n\}$, for all $i \neq j$ we have $(a_i^\ell, a_j^\ell) \in \mathrm{N}$ if, and only if, $(b_i^\ell, b_j^\ell) \in \mathrm{N}$. Therefore, the indices i, j where the restrictions of the tuples $q_k^n(a^1, \ldots, a^n)$ and $q_k^n(b^1, \ldots, b^n)$ are in N coincide.

By the classification of all first-order reducts $\mathbb{A}$ of $D_{\mathcal{F}}$ such that $\mathrm{Aut}(D_{\mathcal{F}}) \leq \mathrm{Aut}(\mathbb{A}) \leq \mathrm{Aut}(H_{\mathcal{F}})$ due to Agarwal and Kompatscher [1], the tuple b^k can be obtained from a^k by a sequence of *switching* steps and *reversing* steps defined as follows. Given a directed graph, a switching step consists in choosing a vertex of the graph and reversing the direction of every edge incident to that vertex; a reversing step consists in reversing the direction of all edges. Note that if the directed graph induced by b can be obtained by finitely many such operations starting from the directed graph induced by a, then the same is true if one removes in a and b edges at the same position. It follows that $q_k^n(a^1, \ldots, a^k)$ and $q_k^n(b^1, \ldots, b^k)$ are in the same orbit under $\mathrm{Aut}(\mathbb{A})$. ◀

4 Description of the proof strategy

We describe here the strategy for the proof of Theorem 2 on a relatively high level.

4.1 Preprocessing of the Reducts of $D_{\mathcal{F}}$

A structure $\mathbb{A}$ is a *model-complete core* if for every finite $S \subseteq A$ and every endomorphism $f\colon \mathbb{A} \to \mathbb{A}$, there exists an automorphism $\alpha \in \mathrm{Aut}(\mathbb{A})$ such that $f|_S = \alpha|_S$. It is often very convenient for studying the complexity of $\mathrm{CSP}(\mathbb{A})$ and the polymorphisms of $\mathbb{A}$ to work with a structure that is a model-complete core; as an example of an important application for us, if $\mathbb{A}$ is a model-complete core, then for all $n \geq 1$ and $a \in A^n$, the orbit of a under $\mathrm{Aut}(\mathbb{A})$ is invariant under all the polymorphisms of $\mathbb{A}$.

While not every structure is a core, it is known that every ω-categorical structure, and in particular every first-order reduct $\mathbb{A}$ of $D_{\mathcal{F}}$, is homomorphically equivalent to a structure $\mathbb{B}$ that is a model-complete core, i.e., such that there exist homomorphisms $\mathbb{A} \to \mathbb{B}$ and $\mathbb{B} \to \mathbb{A}$ [3, 2]. Moreover, this structure is unique up to isomorphism and is called the *model-complete core of* $\mathbb{A}$.

If $\mathbb{A}$ is a first-order reduct of $D_{\mathcal{F}}$, it is *a priori* not guaranteed that the model-complete core of $\mathbb{A}$ is a first-order reduct of $D_{\mathcal{F}}$. The following statement that we prove first establishes this property and relies on a recent result by Mottet and Pinsker [24].

▶ **Lemma 11.** *Let $\mathbb{A}$ be a first-order reduct of $D_{\mathcal{F}}$, and let $\mathbb{A}'$ be the model-complete core of $\mathbb{A}$. Then $\mathbb{A}'$ is either isomorphic to $\mathbb{A}$, or a 1-element structure, or a first-order reduct of a homogeneous undirected graph or the universal homogeneous tournament.*

In the following statement, a function $g\colon A \to A$ with respect to a group $\mathscr{G}$ of permutations on A is *range-rigid* if for every $\alpha \in \mathscr{G}$ and every finite $S \subseteq A$, there exists $\beta \in \mathscr{G}$ such that $g|_S = \beta \circ g \circ \alpha \circ g|_S$. In words, this means that g essentially behaves like a retraction (modulo elements of $\mathscr{G}$) on every orbit of $\mathscr{G}$ that intersects the range of g.

While the first outcome in Theorem 6 only yields a presmooth approximation, it is a very smooth approximation that is needed in Proposition 21. As in [25], the step from presmooth to very smooth is achieved by leveraging a certain primitivity property of the automorphism group of the base structure under consideration, in this case $D_{\mathcal{F}}$.

For $n \geq 1$, we call a permutation group $\mathscr{G}$ acting on a set A *n-primitive* if for every orbit $O \subseteq A^n$ of $\mathscr{G}$, every $\mathscr{G}$-invariant equivalence relation on O containing a pair (a, b) where a, b are disjoint is full. We say an ω-categorical structure $\mathbb{A}$ has *no algebraicity* if none of its elements are first-order definable using other elements as parameters.

▶ **Lemma 12.** *For all $n \geq 1$,* $\mathrm{Aut}(D_{\mathcal{F}})$ *is n-primitive and has no algebraicity.*

Proof. Let $n \geq 1$ and O an orbit of n-tuples under $\mathrm{Aut}(D_{\mathcal{F}})$ and $a \sim b$ for some equivalence relation $\sim$ on O with a, b disjoint, and c, d arbitrary tuples in O. We define a digraph $\mathbb{X}$ on $5n$ vertices, partitioned into five n-tuples $x, y, z, u, v \in V^n$ such that the entries of x, u and v, z induce the same graph as the entries of a, b in $D_{\mathcal{F}}$. Similar let u, y and y, v induce b, a. Finally let x, z induce c, d. Then $\mathbb{X}$ is $\mathcal{F}$-free as all induced tournaments in $\mathbb{X}$ contain only vertices belonging to at most two tuples which are neighbors in the cycle x, u, y, v, z, x. By definition these two tuples induce a graph isomorphic to the graph induced by a, b or c, d in $D_{\mathcal{F}}$ respectively, so $\mathbb{X}$ is $\mathcal{F}$-free. Then there is an embedding $f \colon \mathbb{X} \to D_{\mathcal{F}}$ with $f(x) = c$ and $f(z) = d$ by homogeneity. Also by transitivity of $\sim$ we have $c = f(x) \sim f(z) = d$.

The class $\mathcal{C}$ of $\mathcal{F}$-free oriented graphs has the *free amalgamation property*, i.e., given any two such oriented graphs $D = (W, F), D' = (W', F')$ inducing the same directed graph on $W \cap W'$, then the union $(W \cup W', F \cup F')$ is an $\mathcal{F}$-free oriented graph. This implies (see, e.g., [19]) that the Fraïssé limit of $\mathcal{C}$, which is exactly $D_{\mathcal{F}}$, has no algebraicity. ◀

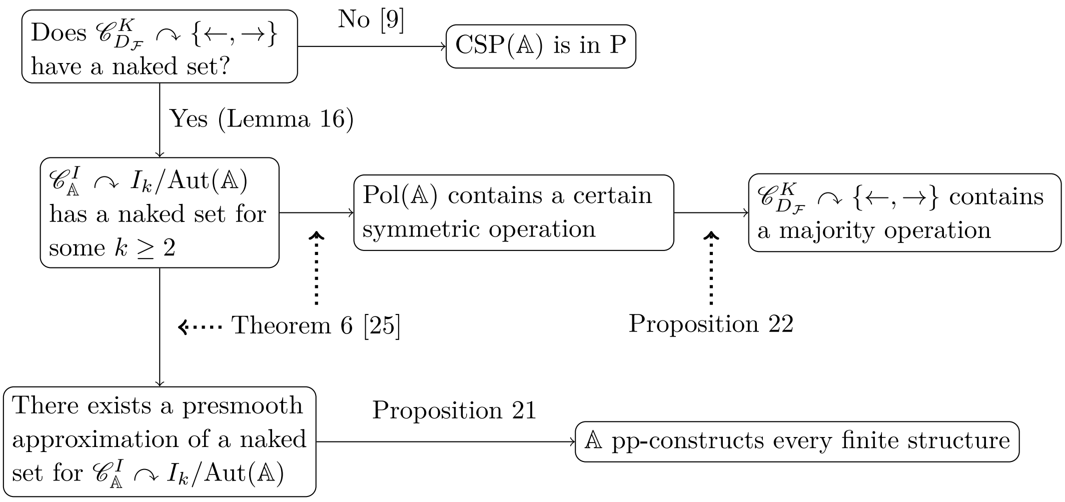
▶ **Lemma 13.** *Let $\mathbb{A}$ be a first-order reduct of $D_{\mathcal{F}}$ that is a model-complete core and such that* $\mathrm{Aut}(\mathbb{A}) \subseteq \mathrm{Aut}(H_{\mathcal{F}})$*. Then $\neq$ and* N *are invariant under* $\mathrm{Pol}(\mathbb{A})$*.*

Proof. Since $\mathrm{Aut}(\mathbb{A}) \subseteq \mathrm{Aut}(H_{\mathcal{F}})$, N is a single orbit under $\mathrm{Aut}(\mathbb{A})$ and is therefore invariant under $\mathrm{Pol}(\mathbb{A})$ since $\mathbb{A}$ is a model-complete core. Now, let O be another orbit of injective pairs. Then every pair (a, b) with $a \neq b$ satisfied the formula $\varphi(x, y) := \exists z((x, z) \in O \wedge (y, z) \in \mathrm{N})$. This is a primitive positive formula, and since both O and N are invariant under $\mathrm{Pol}(\mathbb{A})$, then so is the relation defined by φ. ◀

Let us call a first-order reduct $\mathbb{A}$ of $D_{\mathcal{F}}$ a *proper reduct* if the following conditions are satisfied:

- $\mathbb{A}$ is a model-complete core, i.e., if every homomorphism $\mathbb{A} \to \mathbb{A}$ locally resembles an automorphism an automorphism of $\mathbb{A}$ (the precise definition is given in Section 4.1),
- $\mathrm{Aut}(\mathbb{A}) \subseteq \mathrm{Aut}(H_{\mathcal{F}})$,
- if $\mathrm{Aut}(\mathbb{A}) = \mathrm{Aut}(H_{\mathcal{F}})$, then $H_{\mathcal{F}}$ is not homogeneous.

Our next step is to show that $\mathbb{A}$ can without loss of generality be assumed to be proper. Indeed, if $\mathbb{A}$ is not a model-complete core, then by Lemma 11 the model-complete core of $\mathbb{A}$ is a 1-element structure, or is a first-order reduct of a homogeneous graph, or is a first-order reduct of the universal homogeneous tournament; Theorem 2 is known to hold for all such structures [8, 25]. Since replacing $\mathbb{A}$ by its model-complete core does not change the outcome of Theorem 2, we are immediately done if $\mathbb{A}$ is not a model-complete core. If $\mathrm{Aut}(\mathbb{A}) \not\subseteq \mathrm{Aut}(H_{\mathcal{F}})$, then by Theorem 2.2(i) of [1] we have $\mathrm{Aut}(H_{\mathcal{F}}) \subsetneq \mathrm{Aut}(\mathbb{A})$, in which case either $H_{\mathcal{F}}$ is a homogeneous undirected graph, or $H_{\mathcal{F}}$ is not homogeneous and then



Does $\mathscr{C}^K_{D_\mathcal{F}} \curvearrowright \{\leftarrow,\rightarrow\}$ have a naked set?
No [9]
CSP($\mathbb{A}$) is in P
Yes (Lemma 16)
$\mathscr{C}^I_\mathbb{A} \curvearrowright I_k/\mathrm{Aut}(\mathbb{A})$ has a naked set for some $k \geq 2$
Pol($\mathbb{A}$) contains a certain symmetric operation
$\mathscr{C}^K_{D_\mathcal{F}} \curvearrowright \{\leftarrow,\rightarrow\}$ contains a majority operation
Theorem 6 [25]
Proposition 22
There exists a presmooth approximation of a naked set for $\mathscr{C}^I_\mathbb{A} \curvearrowright I_k/\mathrm{Aut}(\mathbb{A})$
Proposition 21
$\mathbb{A}$ pp-constructs every finite structure

Figure 2 A simplified overview of the proof strategy of Theorem 2 after the preprocessing step.

$\mathrm{Aut}(\mathbb{A})$ is the full symmetric group by Theorem 2.2(iii) of [1]. Both of these cases can be handled by [25].[1] Finally, if $\mathrm{Aut}(\mathbb{A}) = \mathrm{Aut}(H_\mathcal{F})$ and $H_\mathcal{F}$ is homogeneous, then we are again done by [25].

4.2 An Algebraic Dichotomy for Proper Reducts

After this "preprocessing" step, the main technical result is the following.

▶ **Theorem 14.** *Let $\mathcal{F}$ be a finite set of finite tournaments. Let $\mathbb{A}$ be a proper reduct of $D_\mathcal{F}$ that admits injective projections and such that U is invariant under* Pol($\mathbb{A}$)*. Then exactly one of the following holds:*

1. Pol($\mathbb{A}$) *has a naked set,*
2. Pol($\mathbb{A}$) *contains a ternary operation f that is canonical with respect to* $\mathrm{Aut}(D_\mathcal{F})$ *and $u, v \in \overline{\mathrm{Aut}(D_\mathcal{F})}$ such that $u \circ f(x,y,z) = v \circ f(y,z,x)$ holds for all $x,y,z \in V$.*

Note that Theorem 14 is indeed a refined version of Theorem 2: the first item of Theorem 14 implies the first item of Theorem 2 by [11], and the second item of Theorem 14 implies the second item of Theorem 2 by [9].

The proof strategy is represented in Figure 2 and is based on distinguish upon whether $\mathscr{C}^K_{D_\mathcal{F}} \curvearrowright \{\leftarrow,\rightarrow\}$, which is a clone of functions on the two-element set $\{\leftarrow,\rightarrow\}$, has a naked set. If $\mathscr{C}^K_{D_\mathcal{F}} \curvearrowright \{\leftarrow,\rightarrow\}$ does not have a naked set, then we show that Pol($\mathbb{A}$) contains an operation f as in the second item of Theorem 14.

▶ **Proposition 15.** *Let $\mathbb{A}$ be a proper reduct of $D_\mathcal{F}$ that admits injective projections. The following hold:*

1. *If $\mathscr{C}^K_{D_\mathcal{F}} \curvearrowright \{\leftarrow,\rightarrow\}$ does not have a naked set, then there exists $f \in$* Pol($\mathbb{A}$) *and $u, v \in \overline{\mathrm{Aut}(D_\mathcal{F})}$, canonical with respect to* $\mathrm{Aut}(D_\mathcal{F})$*, and such that the identity*

$$u \circ f(x,y,z) = v \circ f(y,z,x)$$

holds for all $x,y,z \in V$;

[1] The first proof in the first case was given in [8], while the first proof in the case of the full symmetric group is due to [6].

2. *If* $\mathscr{C}^K_{D_\mathcal{F}} \curvearrowright \{\leftarrow, \rightarrow\}$ *does not have an affine set, then there exists* $f \in \mathrm{Pol}(\mathbb{A})$ *such that for all* $n \geq 1$ *and* $a, b \in V^n$*, the tuples* $a, f(a,a,b), f(a,b,a), f(b,a,a)$ *are all in the same orbit under* $\mathrm{Aut}(D_\mathcal{F})$*.*

Proof. If $\mathscr{C}^K_{D_\mathcal{F}} \curvearrowright \{\leftarrow, \rightarrow\}$ does not have a naked set, then it contains a ternary function f' that acts as a cyclic operation on $\{\leftarrow, \rightarrow\}$. Then $f(x,y,z) := f'(q^3_1(x,y,z), q^3_1(y,z,x), q^3_1(z,x,y))$ is a canonical polymorphism of $\mathbb{A}$ which is pseudo-cyclic modulo $\overline{\mathrm{Aut}(D_\mathcal{F})}$. If $\mathscr{C}^K_{D_\mathcal{F}} \curvearrowright \{\leftarrow, \rightarrow\}$ does not have an affine set, then it contains a ternary function m that induces a majority operation on $\{\leftarrow, \rightarrow\}$ (note that any binary operation $f \in \mathscr{C}^K_{D_\mathcal{F}}$ induces on $\{\leftarrow, \rightarrow\}$ a function such that $f(\rightarrow, \leftarrow) \neq f(\leftarrow, \rightarrow)$, so that $\mathscr{C}^K_{D_\mathcal{F}} \curvearrowright \{\leftarrow, \rightarrow\}$ cannot contain a semilattice operation). Then $f(x,y,z) := m(q^3_1(x,y,z), q^3_1(y,z,x), q^3_1(z,x,y))$ is a canonical polymorphism of $\mathbb{A}$ that satisfies the statement. ◀

Then CSP($\mathbb{A}$) can be solved in polynomial time by reducing it to a tractable finite-domain CSP [10]. Otherwise, $\mathscr{C}^K_{D_\mathcal{F}} \curvearrowright \{\leftarrow, \rightarrow\}$ has a naked set and one can prove in this case that $\mathscr{C}^I_\mathbb{A} \curvearrowright I_k/\mathrm{Aut}(\mathbb{A})$ also has a naked set for some $k \geq 1$.

▶ **Lemma 16.** *Let* $\mathbb{A}$ *be a proper reduct of* $D_\mathcal{F}$ *that admits injective projections and such that* U *is invariant under* $\mathrm{Pol}(\mathbb{A})$*. Assume* $\mathscr{C}^K_{D_\mathcal{F}} \curvearrowright \{\leftarrow, \rightarrow\}$ *has a naked (resp. affine) set. Then* $\mathscr{C}^I_\mathbb{A} \curvearrowright I_k/\mathrm{Aut}(\mathbb{A})$ *has a naked (resp. affine) set for some* $k \geq 2$*.*

In other words, there exist $S \subseteq I_k$ invariant under $\mathscr{C}^I_\mathbb{A}$ and a $\mathscr{C}^I_\mathbb{A}$-invariant equivalence relation $\sim$ on S with $\mathrm{Aut}(\mathbb{A})$-invariant equivalence classes such that $\mathscr{C}^I_\mathbb{A} \curvearrowright S/{\sim}$ only contains projections. The loop lemma of smooth approximations applies (Theorem 6), giving us two possible outcomes.

4.2.1 First Case: Presmooth Approximation

In the first case, there exists a presmooth approximation for a naked set of $\mathscr{C}^I_\mathbb{A} \curvearrowright I/\mathrm{Aut}(\mathbb{A})$. We first show how to "upgrade" this approximation into a very smooth approximation, applying general principles from the theory of smooth approximations.

▶ **Proposition 17.** *Let* $\mathbb{A}$ *be a first-order reduct of* $D_\mathcal{F}$ *that is a model-complete core and such that* $\mathrm{Aut}(\mathbb{A}) \subseteq \mathrm{Aut}(H_\mathcal{F})$*. If* $(S, \sim)$ *is a minimal subfactor of* $\mathscr{C}^I_\mathbb{A}$ *such that* $\sim$ *has* $\mathrm{Aut}(\mathbb{A})$*-invariant classes, and* η *is a presmooth approximation of* $\sim$ *with respect to* $\mathrm{Aut}(\mathbb{A})$*, then* η *is very smooth with respect to* $\mathrm{Aut}(D_\mathcal{F})$*.*

Proof. We show that η is presmooth with respect to $\mathrm{Aut}(D_\mathcal{F})$. Let C be an equivalence class of $\sim$. By assumption, there exists an equivalence class C' of η and $a, b \in C \cap C'$ that are disjoint. By Lemma 12, $\mathrm{Aut}(D_\mathcal{F})$ has no algebraicity. Thus, there exists an automorphism $\alpha \in \mathrm{Aut}(D_\mathcal{F}, a)$ such that $\alpha(b)$ and b are disjoint. Note that b and $\alpha(b)$ are $\sim$-equivalent, since the equivalence classes of $\sim$ are $\mathrm{Aut}(\mathbb{A})$-invariant. Moreover, b and $\alpha(b)$ are η-equivalent, since $(a,b) \in \eta$ and η is $\mathrm{Aut}(\mathbb{A})$-invariant. Thus, we have disjoint elements $b, \alpha(b)$ in $C' \cap C$ and in the same orbit under $\mathrm{Aut}(D_\mathcal{F})$, i.e., η is presmooth with respect to $\mathrm{Aut}(D_\mathcal{F})$.

By Lemma 13, $\neq$ is invariant under $\mathrm{Pol}(\mathbb{A})$, and by Lemma 12, $\mathrm{Aut}(D_\mathcal{F})$ is n-primitive for all n. By [25, Lemma 8], we obtain that η is very smooth with respect to $\mathrm{Aut}(D_\mathcal{F})$. ◀

We show that this can be used to obtain a naked set for $\mathrm{Pol}(\mathbb{A})$, which implies by Theorem 4 that $\mathbb{A}$ pp-constructs every finite structure. We are in the situation where the original theorem from [25, Theorem 13] used to extend a naked set (or affine set) does not apply. Indeed, this result would require that $\mathscr{C}^I_\mathbb{A}$ be locally interpolated by $\mathrm{Pol}(\mathbb{A})$, which we do not have.

However, we do have that $\mathscr{C}^K_{D_\mathcal{F}}$ *is* locally interpolated by $\mathrm{Pol}(\mathbb{A})$. Indeed, we already know that any $f \in \mathrm{Pol}(\mathbb{A})$ locally interpolates an operation g that is canonical with respect to $\mathrm{Aut}(D_\mathcal{F}, <)$. If g is not an element of $\mathscr{C}^K_{D_\mathcal{F}}$, we show that $\mathscr{C}^K_{D_\mathcal{F}} \curvearrowright \{\leftarrow, \rightarrow\}$ must contain a majority operation, a contradiction to our assumption that $\mathscr{C}^K_{D_\mathcal{F}} \curvearrowright \{\leftarrow, \rightarrow\}$ has a naked set. The proof of the following lemma is similar to the proof of Lemma 34 in [25].

▶ **Lemma 18.** *Let $\mathbb{A}$ be a proper reduct of $D_\mathcal{F}$ such that U is invariant under* $\mathrm{Pol}(\mathbb{A})$*. Suppose that:*

- $\mathrm{Pol}(\mathbb{A})$ *contains a binary injection acting like a projection on $\{\leftarrow, \rightarrow\}$,*
- *there is a function in $\mathscr{C}^K_{(D_\mathcal{F},<)}$ that is not in $\mathscr{C}^K_{D_\mathcal{F}}$.*

Then $\mathscr{C}^K_{D_\mathcal{F}} \curvearrowright \{\leftarrow, \rightarrow\}$ contains a majority operation and in particular does not have an affine set.

We can then proceed as in [26] and use Lemma 18 and the injective projections to circumvent the original limitation from [25, Theorem 13]. In the following, the "lifting" operation, which gives us that $\mathrm{Pol}(\mathbb{A})$ has a naked set, is performed by exhibiting a *uniformly continuous clone homomorphism* from $\mathrm{Pol}(\mathbb{A})$ to $\mathscr{C}^I_\mathbb{A} \curvearrowright S/{\sim}$, i.e., an arity-preserving map ξ such that $\xi(f \circ (g_1, \ldots, g_k)) = \xi(f) \circ (\xi(g_1), \ldots, \xi(g_k))$ for all $f, g_1, \ldots, g_k \in \mathrm{Pol}(\mathbb{A})$ of appropriate arities, and where the value of $\xi(f)$ for an n-ary $f \in \mathrm{Pol}(\mathbb{A})$ is only determined by the restriction $f|_S$ of f onto a finite subset S of A that does not depend on f. The existence of such a map shows that $\mathrm{Pol}(\mathbb{A})$ is not "richer" than $\mathscr{C}^I_\mathbb{A} \curvearrowright S/{\sim}$; in particular, if $\mathscr{C}^I_\mathbb{A} \curvearrowright S/{\sim}$ has a naked (resp. affine) set, then so does $\mathrm{Pol}(\mathbb{A})$. We refer the reader to [11] and in particular to Theorem 1 therein for more details.

▶ **Corollary 19.** *Let $\mathbb{A}$ be a proper reduct of $D_\mathcal{F}$ that admits injective projections and such that U is invariant under* $\mathrm{Pol}(\mathbb{A})$*. If $\mathscr{C}^K_{D_\mathcal{F}} \curvearrowright \{\leftarrow, \rightarrow\}$ has an affine set, we have $\mathscr{C}^K_{(D_\mathcal{F},<)} \subseteq \mathscr{C}^K_{D_\mathcal{F}}$. In particular, every $f \in$* $\mathrm{Pol}(\mathbb{A})$ *locally interpolates a function in $\mathscr{C}^K_{D_\mathcal{F}}$.*

Proof. Lemma 18 applies since $\mathbb{A}$ admits injective projections and U is invariant under $\mathrm{Pol}(\mathbb{A})$. For the second part, we know by Lemma 7 that every $f \in \mathrm{Pol}(\mathbb{A})$ locally interpolates an operation that is canonical with respect to $(D_\mathcal{F}, <)$. Such operations are in particular in $\mathscr{C}^K_{(D_\mathcal{F},<)}$. Since $\mathscr{C}^K_{(D_\mathcal{F},<)} \subseteq \mathscr{C}^K_{D_\mathcal{F}}$, we are done. ◀

▶ **Lemma 20.** *Let $\mathbb{A}$ be a proper reduct of $D_\mathcal{F}$ such that U is invariant under $\mathscr{C}^I_\mathbb{A}$. Let $(S, \sim)$ be an affine set of $\mathscr{C}^I_\mathbb{A}$ such that $S \subseteq I_k$ and where the $\sim$-equivalence classes are* $\mathrm{Aut}(\mathbb{A})$*-invariant. Then for all $a, b \in S$, a and b induce the same undirected graph in $H_\mathcal{F}$.*

Proof. Suppose first that there exist $a, b \in S$ with $a \not\sim b$ and such that a, b induce the same undirected graph in $H_\mathcal{F}$. Since both N and U are invariant under $\mathscr{C}^I_\mathbb{A}$, the set generated by $\{a, b\}$ under $\mathscr{C}^I_\mathbb{A}$ only consists of tuples all inducing the same undirected graph as a and b in $H_\mathcal{F}$. By minimality of $(S, \sim)$, such a set must be equal to S itself, so we are done.

Otherwise, whenever $a \not\sim b$, then a, b induce different undirected graphs. In other words, any tuples in S inducing the same undirected graph are in the same $\sim$-equivalence class. By assumption, $(S, \sim)$ is an affine set for $\mathscr{C}^I_\mathbb{A}$, and therefore there exists a ring R and a finite R-module M on $S/{\sim}$ such that all operations in $\mathscr{C}^I_\mathbb{A} \curvearrowright S/{\sim}$ are of the form $(x_1, \ldots, x_n) \mapsto \sum \lambda_i \cdot x_i$, where $\lambda_1, \ldots, \lambda_n \in R$ are such that $\sum \lambda_i = 1$. Let $a \in S$ be a tuple whose $\sim$-equivalence class is an arbitrary non-zero element of the module M, and let $b \in S$ be a tuple whose $\sim$-equivalence class is the zero element of M. Since M is finite, a (more precisely, its $\sim$-equivalence class $[a]$), has a finite order $n \geq 2$, that is, $n[a] = [b]$. Note that the tuples $q^n_1(a, b, \ldots, b), q^n_1(b, a, b, \ldots, b), \ldots, q^n_1(b, \ldots, b, a)$ all induce the same undirected graph, and they are all in S since $q^n_1 \in \mathscr{C}^I_\mathbb{A}$ by Lemma 10. By our assumption, all these tuples are in the same $\sim$-equivalence class. Since $\mathscr{C}^I_{\mathbb{A}} \curvearrowright S/{\sim}$ is affine, the action of q^n_1 on $S/{\sim}$ is an affine function of the form $(x_1, \ldots, x_n) \mapsto \sum \lambda_i \cdot x_i$, where $\lambda_1, \ldots, \lambda_n$ are elements of R and such that $\sum \lambda_i = 1$. If a is in the ith position, then $q^n_1(b, \ldots, b, a, b, \ldots, b)$ is $\sim$-equivalent to $\lambda_i \cdot [a]$. Thus, we get that $\lambda_i \cdot [a] = \lambda_j \cdot [a]$ for all $i, j \in \{1, \ldots, n\}$. We call this element $\lambda \cdot [a]$. Thus, the equivalence class of $q^n_1(a, \ldots, a)$ is $\sum_{i=1}^n \lambda \cdot [a] = n(\lambda \cdot [a]) = \lambda \cdot (n \cdot [a]) = \lambda \cdot [b] = [b]$. However, q^n_1 being affine, we also know that $q^n_1(a, \ldots, a)$ is $\sim$-equivalent to a, contradicting our assumption that $a \not\sim b$. ◀

▶ **Proposition 21.** *Let $\mathbb{A}$ be a proper reduct of $D_{\mathcal{F}}$ that admits injective projections and such that U is invariant under* $\mathrm{Pol}(\mathbb{A})$*. Assume that $\mathscr{C}^K_{D_{\mathcal{F}}} \curvearrowright \{\leftarrow, \rightarrow\}$ has an affine set. Suppose that there exists an affine set $(S, \sim)$ of $\mathscr{C}^I_{\mathbb{A}}$ with $S \subseteq I_k$ and $\sim$ having* $\mathrm{Aut}(\mathbb{A})$*-invariant classes. Suppose further that $\sim$ admits a* $\mathrm{Pol}(\mathbb{A})$*-invariant very smooth approximation with respect to* $\mathrm{Aut}(D_{\mathcal{F}})$*. Then* $\mathrm{Pol}(\mathbb{A})$ *admits a uniformly continuous clone homomorphism to $\mathscr{C}^I_{\mathbb{A}} \curvearrowright S/{\sim}$.*

Proof. Without loss of generality, we can assume that S is minimal with the property of intersecting two equivalence classes of $\sim$. Let η be a presmooth approximation of $\sim$ with respect to $\mathrm{Aut}(D_{\mathcal{F}})$. By [25, Lemma 8] and Lemmas 12 and 13, every $\mathrm{Pol}(\mathbb{A})$-invariant presmooth approximation of this naked set must be very smooth with respect to $\mathrm{Aut}(D_{\mathcal{F}})$.

Let $f \in \mathrm{Pol}(\mathbb{A})$ an n-ary function. Let $f' \in \mathscr{C}^K_{D_{\mathcal{F}}}$ be locally interpolated by f; such an operation exists by Corollary 19. Let q^n_i be the i-th injective projection. By Lemma 10, $q^n_i \in \mathscr{C}^I_{\mathbb{A}}$. We define $f''(x_1, \ldots, x_n) = f'(q^n_1(x_1, \ldots, x_n), \ldots, q^n_n(x_1, \ldots, x_n))$ and show that $f'' \in \mathscr{C}^I_{\mathbb{A}}$. For this let $a_1, a'_1, \ldots, a_n, a'_n$ be injective tuples of an arbitrary length such that a_i, a'_i are in the same $\mathrm{Aut}(\mathbb{A})$-orbit for all $1 \leq i \leq n$. Since $\mathrm{Aut}(\mathbb{A}) \subseteq \mathrm{Aut}(H_{\mathcal{F}})$, every pair a_i, a'_i induce the same undirected graph in $H_{\mathcal{F}}$. As $q^n_i \in \mathscr{C}^I_{\mathbb{A}}$ we know that $b_i := q^n_i(a_1, \ldots, a_n)$ and $b'_i := q^n_i(a'_1, \ldots, a'_n)$ are in the same $\mathrm{Aut}(\mathbb{A})$-orbit, too, and for the same reason as above, each pair b_i, b'_i induce the same undirected graph in $H_{\mathcal{F}}$. Moreover, the pairs of coordinates where the projection of b_i is in N are exactly the pair of coordinates where the projection of b'_i is in N. Now let $c := f''(a_1, \ldots, a_n) = f'(b_1, \ldots, b_n)$ and $c' := f''(a'_1, \ldots, a'_n) = f'(b'_1, \ldots, b'_n)$. Since $f' \in \mathscr{C}^K_{D_{\mathcal{F}}}$, since $\mathrm{Pol}(\mathbb{A})$ preserves N, and since the operation induced by f' on $\{\leftarrow, \rightarrow\}$ is an affine map, we know that c and c' are in the same orbit under $\mathrm{Aut}(\mathbb{A})$. Thus, $f'' \in \mathscr{C}^I_{\mathbb{A}}$ and therefore it acts on $I_k/\mathrm{Aut}(\mathbb{A})$.

We define $\xi(f)$ as the action of f'' on $S/{\sim}$. As in [25, Theorem 13], for all $a_1, \ldots, a_n \in S$, and any f' that is locally interpolated by f, we have $f(a_1, \ldots, a_n)(\eta \circ \sim)f'(a_1, \ldots, a_n)$. It follows that

$$f(q^n_1(a_1, \ldots, a_n), \ldots, q^n_n(a_1, \ldots, a_n))(\eta \circ \sim)f''(a_1, \ldots, a_n)$$

holds for all $a_1, \ldots, a_n \in S$. In particular, the definition of $\xi(f)$ does not depend on the choice of f' in the construction. Moreover, if $a_1, \ldots, a_n$ induce the same undirected graph in $H_{\mathcal{F}}$, then $q^n_i(a_1, \ldots, a_n)$ and a_i are in the same orbit under $\mathrm{Aut}(D_{\mathcal{F}})$, for all $i \in \{1, \ldots, n\}$. It follows that $f''(a_1, \ldots, a_n)$ and $f'(a_1, \ldots, a_n)$ are in the same orbit with respect to $\mathrm{Aut}(D_{\mathcal{F}})$, as f' is canonical with respect to $\mathrm{Aut}(D_{\mathcal{F}})$. Since $\mathrm{Aut}(D_{\mathcal{F}}) \subseteq \mathrm{Aut}(\mathbb{A})$, they are in the same orbit with respect to $\mathrm{Aut}(\mathbb{A})$, and therefore there are $\sim$-equivalent. Finally, this implies that $f(a_1, \ldots, a_n)(\eta \circ \sim)f''(a_1, \ldots, a_n)$ holds, whenever all $a_1, \ldots, a_n$ induce the same undirected graph in $H_{\mathcal{F}}$, which is the case for all $a_1, \ldots, a_n \in S$ by Lemma 20.

Now we show that ξ is a uniformly continuous clone homomorphism. It clearly preserves arities so we need to show it also preserves compositions. Let $f \in \mathrm{Pol}(\mathbb{A})$ be n-ary, $g_1, \ldots, g_n \in \mathrm{Pol}(\mathbb{A})$ be m-ary. Let $u_1, \ldots, u_m \in S$. Since $g_i(u_1, \ldots, u_m)(\eta \circ \sim)g''_i(u_1, \ldots, u_m)$ for all i, there exists $v_i \in S$ such that $g_i(u_1, \ldots, u_m)\ \eta\ v_i$. Then

$$\begin{aligned} f(g_1(u_1,\ldots,u_m),\ldots,g_n(u_1,\ldots,u_m)) \;\eta\; & f(v_1,\ldots,v_n) \\ & (\eta\circ\sim) f''(v_1,\ldots,v_n) \\ & (\eta\circ\sim) f''(g_1(u_1,\ldots,u_m),\ldots,g_n(u_1,\ldots,u_m)). \end{aligned}$$

from which we conclude that

$$\xi(f(g_1,\ldots,g_n))(u_1,\ldots,u_m) = \xi(f)(\xi(g_1)(u_1,\ldots,u_m),\ldots,\xi(g_n)(u_1,\ldots,u_m)).$$

To prove that ξ is uniformly continuous fix $n \in \mathbb{N}$ and let $a \not\sim b$ be any two k-ary tuples in S and define $F = \bigcup_{0\leq i\leq k}\{a_i,b_i\}^n$. Observe that if f,g agree on all $x \in \{a_i,b_i\}^n$ for each $i \leq k$, then they also agree on all $y \in \{a,b\}^n$ as $f(y)_i$ and $g(y)_i$ are fully determined by the values of f,g on a certain subset of $\{a_i,b_i\}^n$. Therefore they induce the same action on $S/{\sim}$ as in that case $f(x) \sim g(x)$ for all $x \in \{a,b\}^n$. Then it is clear that if f,g agree on F we also have $\xi(f) = \xi(g)$. This completes the proof. ◀

4.2.2 Second Case: Weakly Commutative Polymorphism

In the second case of Theorem 6, $\mathrm{Pol}(\mathbb{A})$ contains a well-behaved binary operation, which implies that $\mathscr{C}^K_{D_\mathcal{F}} \curvearrowright \{\leftarrow,\rightarrow\}$ contains a majority operation; this contradicts our assumption that $\mathscr{C}^K_{D_\mathcal{F}} \curvearrowright \{\leftarrow,\rightarrow\}$ has a naked set. The proof of Proposition 22 below is similar to that of Lemma 39 in [25] and is omitted due to space restrictions.

▶ **Proposition 22.** *Let $\mathbb{A}$ be a proper reduct of $D_\mathcal{F}$ with injective projections and such that U is invariant under* $\mathrm{Pol}(\mathbb{A})$. *Let $(S,\sim)$ be a minimal affine set of $\mathscr{C}^I_\mathbb{A}$ with $S \subseteq I_k$ and where $\sim$ has* $\mathrm{Aut}(\mathbb{A})$*-invariant equivalence classes. Suppose that there exists a binary $f \in$* $\mathrm{Pol}(\mathbb{A})$ *such that $f(a,b) \sim f(b,a)$ holds for all disjoint injective tuples $a,b \in V^k$ with $f(a,b), f(b,a) \in S$. Then $\mathscr{C}^K_{D_\mathcal{F}} \curvearrowright \{\leftarrow,\rightarrow\}$ contains a majority operation.*

4.2.3 Classifying Problems with Bounded Treewidth Dualities

Finally, we briefly describe the proof strategy for Theorem 3. It is very similar to the one outlined above and shares all the intermediate steps. Only the starting distinction changes, where we distinguish between whether $\mathscr{C}^K_{D_\mathcal{F}} \curvearrowright \{\leftarrow,\rightarrow\}$ has an affine set or not.

If $\mathscr{C}^K_{D_\mathcal{F}} \curvearrowright \{\leftarrow,\rightarrow\}$ does not have an affine set, then the second item in Proposition 15 states that $\mathrm{Pol}(\mathbb{A})$ contains a so-called *canonical pseudo-majority operation*, and $\mathbb{A}$ has bounded relational width by [9]. Moreover, since $D_\mathcal{F}$ is homogeneous in a binary language, [22, Theorem 2] entails that $\mathbb{A}$ has relational width at most $(4, \max(6,\ell))$, where ℓ is the maximal size of a tournament in $\mathcal{F}$. It follows from general principles [15] that there exists a duality for the class of structures admitting a homomorphism to $\mathbb{A}$ that has treewidth bounded by $\max(6,\ell,r)$, where r is the maximal arity of a relation of $\mathbb{A}$.

If $\mathscr{C}^I_\mathbb{A} \curvearrowright I_k/\mathrm{Aut}(\mathbb{A})$ has an affine set for some $k \geq 1$ (by Lemma 16), either we get an affine set for $\mathrm{Pol}(\mathbb{A})$ (by Proposition 21) or $\mathscr{C}^K_{D_\mathcal{F}} \curvearrowright \{\leftarrow,\rightarrow\}$ contains a majority operation (by Proposition 22), again a contradiction since a majority operation cannot be represented as an affine map over any module.

Abstract

In the Equitable Connected Partition (ECP for short) problem, we are given a graph $G = (V, E)$ together with an integer $p \in \mathbb{N}$, and our goal is to find a partition of V into p parts such that each part induces a connected sub-graph of G and the size of each two parts differs by at most 1. On the one hand, the problem is known to be NP-hard in general and W[1]-hard with respect to the path-width, the feedback-vertex set, and the number of parts p combined. On the other hand, fixed-parameter algorithms are known for parameters the vertex-integrity and the max leaf number.

In this work, we systematically study ECP with respect to various structural restrictions of the underlying graph and provide a clear dichotomy of its parameterised complexity. Specifically, we show that the problem is in FPT when parameterized by the modular-width and the distance to clique. Next, we prove W[1]-hardness with respect to the distance to cluster, the 4-path vertex cover number, the distance to disjoint paths, and the feedback-edge set, and NP-hardness for constant shrub-depth graphs. Our hardness results are complemented by matching algorithmic upper-bounds: we give an XP algorithm for parameterisation by the tree-width and the distance to cluster. We also give an improved FPT algorithm for parameterisation by the vertex integrity and the first explicit FPT algorithm for the 3-path vertex cover number. The main ingredient of these algorithms is a formulation of ECP as N-fold IP, which clearly indicates that such formulations may, in certain scenarios, significantly outperform existing algorithms based on the famous algorithm of Lenstra.

1 Introduction

A partition of a set V into $p \in \mathbb{N}$ parts is a set $\pi = \{V_1, \dots, V_p\}$ of subsets of V such that for every $i, j \in [p]$: $V_i \cap V_j = \emptyset$ and $\bigcup_{i=1}^{p} V_i = V$. In the Equitable Connected Partition problem, we are given an undirected graph $G = (V, E)$ together with an integer p, and our goal is to partition the vertex set V into p *parts* such that the sizes of each two parts differ by at most 1 and each class induces a connected sub-graph. Formally, our problem is defined as follows.

Equitable Connected Partition (ECP)

Input: A simple undirected and connected n-vertex graph $G = (V, E)$ and a positive integer $p \in \mathbb{N}$.

Question: Is there a partition $\pi = \{V_1, \dots, V_p\}$ of V such that every part $G[V_i]$ is connected, and $||V_i| - |V_j|| \leq 1$ for every pair $i, j \in [p]$?

The Equitable Connected Partition problem naturally arises in many fields such as redistricting theory [2, 50, 55], which is a subfield of computational social choice theory, VLSI circuit design [7], parallel computing [5], or image processing [52], to name a few.

One of the most prominent problems in the graph partitioning direction is the Bisection problem, where our goal is to split the vertex set into two parts A and B, each part of size at most $\lceil \frac{n}{2} \rceil$, such that the number of edges between A and B is at most some given $k \in \mathbb{N}$. Bisection is NP-hard [36] even if we restrict the input to unit disc graphs [24] and is heavily studied from the parameterised complexity perspective; see, e.g., [6, 13, 19, 30, 54]. The natural generalisation of the Bisection problem is called Balanced Partitioning where we partition the vertices into $p \in \mathbb{N}$ parts, each of size at most $\lceil \frac{n}{p} \rceil$. Balanced Partitioning is NP-hard already on trees [27] and a disjoint union of cliques [4]. The parameterised study of this problem is due to Ganian and Obdržálek [35] and van Bevern et al. [6]. In all the aforementioned problems, we are given only the upper-bound on the size of each part; hence, the parts are not necessarily equitable. Moreover, there is no connectivity requirement for the parts. For a survey of graph partitioning problems, we refer the reader to the monograph of Buluç et al. [14].

On the equitability side, the most notable direction of research is the Equitable k-Colouring problem (EC for short). Here, we are given an undirected graph G and the goal is to decide whether there is a proper colouring of the vertices of G using k colours such that the sizes of each two colour classes differ by at most one. Note that the graph induced by each colour class is necessarily an independent set, and hence is disconnected. As the k-Colouring problem can be easily reduced to the Equitable k-Colouring, it follows that EC is NP-hard. Polynomial-time algorithms are known for many simple graph classes, such as graphs of bounded tree-width [9, 16], split graphs [15], and many others [31]. The parameterised study was, to the best of our knowledge, initiated by Fellows et al. [28] and continued in multiple subsequent works [26, 29, 40]. For a detailed survey of the results on EC, we refer the reader to the monograph by Lih [51].

The Equitable Connected Partition problem then naturally brings the concepts of equitability and connectivity of the vertex set together. It is known that ECP is NP-complete [2]. Moreover, the problem remains NP-complete even if G is a planar graph or for every fixed p at least 2 [23, 36]. Enciso et al. [26] were the first who studied ECP from the viewpoint of parameterised complexity. They showed that ECP is fixed-parameter tractable with respect to the vertex cover number and the maximum leaf number of G. On the negative side, they showed that it is W[1]-hard to decide the problem for the combined parameter the

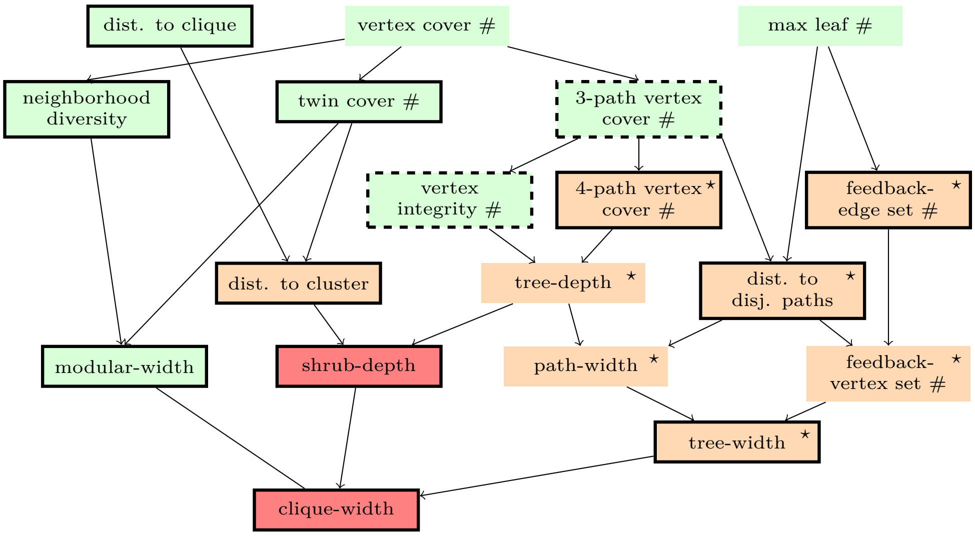

Figure 1 An overview of our results. The parameters for which the problem is in FPT are coloured green, the parameters for which ECP is W[1]-hard and in XP have an orange background, and para-NP-hard combinations are highlighted in red. Arrows indicate generalisations; e.g., modular width generalises both neighbourhood diversity and twin-cover number. The solid thick border represents completely new results, and the dashed border represents an improvement of previously known algorithms. All our W[1]-hardness results hold even when the problem is additionally parameterized by the number of parts p. Additionally, we show that the results marked with $\star$ becomes fixed-parameter tractable if the size of a larger part $\lceil n/p \rceil$ is an additional parameter.

path-width, the feedback-vertex set, and the number of parts p. Moreover, they gave an XP algorithm for ECP parameterised by tree-width. Later, Gima et al. [38] showed that the problem is fixed-parameter tractable when parameterised by the vertex-integrity of G. Very recently, Gima and Otachi [39] proved that ECP is W[1]-hard when parameterised by the tree-depth of G.

A more general variant of Equitable Connected Partition with parametric lower- and upper-bounds on the sizes of parts was studied by Ito et al. [43], and Blažej et al. [8] very recently introduced the requirement on the maximum diameter of each part.

It is worth pointing out that Equitable Connected Partition is also significant from a theoretical point of view. Specifically, this problem is a very common starting point for many W[1]-hardness reductions; see, e.,g., [6, 8, 20, 53]. Surprisingly, the graph in multiple of the before-mentioned reductions remains the same as in original instance, and therefore our study directly strengthens the results obtained in these works. Since the complexity picture with respect to structural parameters is rather incomplete, many natural questions arise. For example, what is the parameterised complexity of ECP when parameterised by the 4-path vertex cover number? Or, is ECP in FPT when parameterised by the feedback-edge set? Last but not least, is the problem easier to decide on graphs that are dense, such as cliques?

1.1 Our Contribution

In our work, we continue the line of study of the Equitable Connected Partition problem initiated by Enciso et al. [26] almost 15 years ago. For an overview of our results, we refer the reader to Figure 1; however, we believe that our contribution is much broader. We try to summarise it in the following four points.

First, directly following pioneering work on structural parameterisation of ECP, we provide a complete dichotomy between tractable and intractable cases for structural parameters that are bounded for sparse graphs. Namely, we provide W[1]-hardness proofs for ECP with respect to the 4-path vertex cover number and the feedback-edge set number, which encloses a gap between structural parameters that were known to be tractable – the vertex-cover number and the max-leaf number – and those that were known to be W[1]-hard– the path-width and the feedback-vertex set. It should also be mentioned that our constructions not only give much stronger intractability results but, at the same time, are much simpler compared to the original construction of Enciso et al. [26].

Second, we also turn our attention to dense graphs, which have, so far, been completely overlooked in the relevant literature. On our way to fixed-parameter tractable algorithms for various structural parameters, we prove polynomial-time solvability of some specific graph classes. Again, we provide a clear boundary between tractable and intractable cases. However, it turns out that for dense graphs, the problem is much easier.

Third, we clearly show where the limits of the parameterized complexity framework in the study of structural parameterisation of Equitable Connected Partition are. In particular, we show that the problem is NP-hard already on graphs of shrub-depth equal to 3, clique-width equal to 3, and twin-width equal to 2. Moreover, in some cases, our complexity results are tight. For example, we give a polynomial-time algorithm for graphs of clique-width 2.

Last but not least, in order to provide all the algorithms, we use multiple different techniques. Naturally, some algorithms are based on standard techniques such as dynamic-programming over decomposition or kernelisation; however, many of them still require deep insights into the structure of the solution and the instances. However, some of them use very careful branching together with formulation of the problem using N-fold integer linear programming, which is, informally speaking, an integer linear program with specific shape of the constraints. We are convinced that the technique of N-fold integer linear programming in the design and analysis of fixed-parameter tractable algorithms deserves more attention from the parameterised complexity community, as it in many scenarios significantly outperforms the classical FPT algorithms based on the famous Lenstra's algorithm; see, e.g., [3, 12, 45, 46, 47].

2 Preliminaries

We assume the reader to be familiar with the basic graph-theoretical notation as given by Diestel [21] and with the basics of parameterised complexity [18].

Structural Parameters. In this sub-section, we provide definitions of less widespread structural parameters we study in this work. Definitions of all the remaining parameters are provided in the full version.

▶ **Definition 1** (d-path vertex cover). *Let $G = (V, E)$ be an undirected graph and $d \in \mathbb{N}$ be an integer. A* d-path vertex cover *is a set $C \subseteq V$ such that the graph $G \setminus C$ contains no path with d vertices as a sub-graph. The* d-path vertex cover number $d\text{-pvcn}(G)$ *is the size of a minimum d-path vertex cover in G.*

Note that the 2-path vertex cover number is, in fact, the standard *vertex cover number* of a graph.

▶ **Definition 2** (Vertex integrity). *Let $G = (V, E)$ be an undirected graph.* Vertex integrity*, denoted* $\mathrm{vi}(G)$*, is the minimum $k \in \mathbb{N}$ such that there is a set $X \subseteq V$ of size at most k and every connected component C of $G \setminus X$ contains at most k vertices.*

▶ **Definition 3** (Distance to $\mathcal{G}$). *Let G be a graph, and $\mathcal{G}$ be a graph family. A set $M \subseteq V(G)$ is a* modulator *to $\mathcal{G}$, if $G \setminus M \in \mathcal{G}$. The* distance *to $\mathcal{G}$, denoted* $\mathrm{dist}_{\mathcal{G}}(G)$*, is the size of a minimum modulator to $\mathcal{G}$.*

In our paper, we will focus on the *distance to clique*, denoted by $\mathrm{dc}(G)$, the distance to disjoint union of cliques, which is usually referred to as the *distance to cluster graph* or the *cluster vertex deletion* [22] and denoted $\mathrm{dcg}(G)$, and the *distance to disjoint paths*, denoted by $\mathrm{ddp}(G)$.

▶ **Definition 4** (Neighbourhood-diversity [48]). *Let $G = (V, E)$ be a graph. We say that two vertices $u, v \in V$ have the same type iff $N(u) \setminus \{v\} = N(v) \setminus \{u\}$. The* neighbourhood diversity *of G is at most d, if there exists a partition of V into at most d sets such that all vertices in each set have the same type.*

Let $T_1, \ldots, T_d$ be a partition of V such that for each $u, v \in T_i$, $i \in [d]$, it holds that u and v are of the same type according to Definition 4. Observe that each type is either independent set or a clique. We define *type graph* to be an undirected graph with vertices being the types $T_1, \ldots, T_d$ and two vertices corresponding to some types T_i and T_j are connected by an edge iff there exists an edge $\{u, v\} \in E(G)$ such that $u \in T_i$ and $v \in T_j$.

▶ **Definition 5** (Modular-width [32]). *Consider graphs that can be obtained from an algebraic expression that uses only the following operations:*

1. *create an isolated vertex,*
2. *the disjoint union of two disjoint graphs G_1 and G_2 which is a graph $(V(G_1) \cup V(G_2), E(G_1) \cup E(G_2))$,*
3. *the complete join of two disjoint graphs G_1 and G_2 which produces a graph $(V(G_1) \cup V(G_2), E(G_1) \cup E(G_2) \cup \{\{u, v\} \mid u \in V(G_1) \text{ and } v \in V(G_2)\})$.*
4. *the substitution with respect to some pattern graph P – for a graph P with vertices $p_1, \ldots, p_\ell$ and disjoint graphs $G_1, \ldots, G_\ell$, the substitution of the vertices of P by the graphs $G_1, \ldots, G_\ell$ is the graph with vertex set $\bigcup_{i=1}^{\ell} V(G_i)$ and edge set $\bigcup_{i=1}^{\ell} E(G_i) \cup \{\{u, v\} \mid u \in V(G_i),\ v \in V(G_j),\ \text{and } \{p_i, p_j\} \in E(P)\}$.*

The width of such an algebraic expression is the maximum number of operands used by any occurrence of the substitution operation. The modular-width *of a graph G, denoted* $\mathrm{mw}(G)$*, is the least integer m such that G can be obtained from such algebraic expression of width m.*

N-fold Integer Programming. In recent years, integer linear programming (ILP) has become a very useful tool in the design and analysis of fixed-parameter tractable algorithms [37]. One of the best known results in this line of research is probably Lenstra's algorithm, roughly showing that ILP with bounded number of variables is solvable in FPT time [49].

In this work, we use the so-called *N-fold integer programming* formulation. Here, the problem is to minimise a linear objective over a set of linear constraints with a very restricted structure. In particular, the constraints are as follows. We use $x^{(i)}$ to denote a set of t_i variables (a so-called *brick*).

$$D_1 x^{(1)} + D_2 x^{(2)} + \cdots + D_N x^{(N)} = \mathbf{b}_0 \tag{1}$$

$$A_i x^{(i)} = \mathbf{b}_i \qquad \forall i \in [N] \tag{2}$$

$$\mathbf{0} \le x^{(i)} \le \mathbf{u}_i \qquad \forall i \in [N] \tag{3}$$

Where we have $D_i \in \mathbb{Z}^{r \times t_i}$ and $A_i \in \mathbb{Z}^{s_i \times t_i}$; let us denote $s = \max_{i \in [N]} s_i$, $t = \max_{i \in [N]} t_i$, and let the dimension be d, i.e., $d = \sum_{i \in [N]} t_i \le Nt$. Constraints (1) are the so-called *linking constraints* and the rest are the *local constraints*. In the analysis of our algorithms, we use the following result of Eisenbrand et al. [25].

▶ **Proposition 6** ([25, Corollary 91]). *N-fold IP can be solved in $a^{r^2 s + rs^2} \cdot d \cdot \log(d) \cdot L$ time, where*

- *L is the maximum feasible value of the objective and*
- *$a = r \cdot s \cdot \max_{i \in [N]} (\max(\|D_i\|_\infty, \|A_i\|_\infty))$.*

3 Algorithmic Results

In this section, we provide our algorithmic results. The first algorithm is for ECP parameterised by the vertex-integrity and combines careful branching with N-fold integer programming. Specifically, Gima et al. [38] showed that ECP is in FPT with respect to this parameter by giving an algorithm running in $k^{k^{k^{\mathcal{O}(k)}}} \cdot n^{\mathcal{O}(1)}$ time, where $k = \mathrm{vi}(G)$. We show that using an N-fold IP formulation, we can give a simpler algorithm with a doubly exponential improvement in the running time.

▶ **Theorem 7.** *The* Equitable Connected Partition *problem is fixed-parameter tractable parameterised by the vertex-integrity* vi *and can be solved in $k^{\mathcal{O}(k^4)} \cdot n \log n$ time, where $k = \mathrm{vi}(G)$.*

Proof. First, if it holds that $p > k$, we use the algorithm of Gima et al. [38] which, in this special case, runs in time $k^{\mathcal{O}(k^2)} \cdot n$. Therefore, the bottleneck of their approach is clearly the case when $p \le k$. In what follows, we introduce our own procedure for this case, which is based on the N-fold integer programming. Note that the algorithm of Gima et al. [38] for the case $p \le k$ is based on the algorithm of Lenstra [49].

First, we guess (by guessing we mean exhaustively trying all possibilities) a partition of the modulator vertices X in the solution. Let this solution partition be $X_1, \ldots, X_p$. Furthermore, we guess which (missing) connections between the vertices in the modulator will be realised through the components of $G - X$. Let $E(X)$ be the set of these guessed connections.

Now, we check the validity of our guess using the (configuration) N-fold ILP. Each component of $G - X$ (call them *pieces*) has at most k vertices; therefore, it can be split in at most k chunks (not necessarily connected) that will be attached to some modulator vertices already assigned to the parts of the solution. Let $\mathcal{P}(G, X)$ be the set of all pieces of $G - X$. Now, we want to verify if there exists a selection of chunks for every piece so that when we collect these together the solution is indeed connected and contains the right number of vertices. Thus, there are altogether at most k^k configurations of chunks in a piece. Let $\mathcal{C}(Z)$ be the set of all configurations of a piece Z. Let $s^Z_{C,i}$ be the number of vertices in the chunk attached to the i-th part from a piece Z in the configuration C.Let Z be a piece and $C \in \mathcal{C}(Z)$, we set $e^Z_C(u, v) = 1$ if the chunk assigned by C to the part containing both $u, v \in X$ connects u and v.

Now, we have to ensure (local constraint) that each piece is in exactly one configuration

$$\sum_{C \in \mathcal{C}(Z)} x^Z_C = 1 \qquad \forall Z \in \mathcal{P}(G, X)\,. \tag{4}$$

Observe that these constraints have no variables in common for two distinct elements of $\mathcal{P}(G, X)$. The rest of the necessary computation uses global constraints. We ensure that the total contribution of chunks assigned to the parts is the correct number (x_i is a binary slack such that $\sum_i x_i = n \bmod p$):

$$x_i + \sum_{Z \in \mathcal{P}(G,X)} \sum_{C \in \mathcal{C}(Z)} s^Z_{C,i} \cdot x^Z_C = \lceil n/p \rceil - |X_i| \qquad \forall i \in [p] \tag{5}$$

Next, we have to verify the connectivity of parts in X

$$\sum_{Z \in \mathcal{P}(G,X)} \sum_{C \in \mathcal{C}(Z)} e^Z_C(u,v) \cdot x^Z_C \geq 1 \qquad \forall \{u,v\} \in E(X) \tag{6}$$

It is not hard to verify, that the parameters of N-fold IP are as follows:

- the number s of local constraints in a brick is exactly 1 as there is a single local constraint (4) for each piece,
- the number r of global constraints is in $\mathcal{O}\left(k^2\right)$: there are $p \leq k$ constraints (5) and $\binom{k}{2}$ constraints (6),
- the number t of variables in a brick is $|\mathcal{C}(Z)|$ which is $k^{\mathcal{O}(k)}$, and
- $a \in \mathcal{O}\left(k^3\right)$, since all coefficients in the constraints are bounded by k in absolute value.

Thus, using Proposition 6, the Equitable Connected Partition problem can be solved in $k^{\mathcal{O}\left(k^4\right)} \cdot n \log n$ time. ◀

Using techniques from the proof of Theorem 7, we may give a specialised algorithm for Equitable Connected Partition parameterised by the 3-path vertex cover. The core idea is essentially the same, but the components that remain after removing the modulator are much simpler: they are either isolated vertices or isolated edges. This fact allows us to additionally speed the algorithm up.

▶ **Theorem 8.** *The Equitable Connected Partition problem is fixed-parameter tractable parameterised by the 3-path vertex cover number and can be solved in $k^{\mathcal{O}\left(k^2\right)} \cdot n \log n$ time, where $k = 3$-pvcn(G).*

The next result is an XP algorithm with respect to the tree-width of G. It should be noted that a similar result was reported already by Enciso et al. [26]; however, their proof was never published[1] and the only clue for the algorithm the authors give in [26] is that this algorithm “can be proved using standard techniques for problems on graphs of bounded treewidth”. Therefore, to fill this gap in the literature, we give our own algorithm.

▶ **Theorem 9.** *The Equitable Connected Partition problem is in XP when parameterized by the tree-width tw of G.*

Proof sketch. The algorithm is, as is usual, a leaf-to-root dynamic programming algorithm along a nice tree decomposition. The crucial observation we need for the algorithm is that at every moment of the computation, there are at most $\mathcal{O}(\text{tw})$ opened parts. This holds because each bag forms a separator in G and therefore no edge can “circumvent” currently processed bag.

The algorithm then proceeds as follows. In each node x of the tree-decomposition, we remember all possible partitions of vertices into open parts and the sizes of each open cluster including already forgotten vertices. We require that each open part is connected. Once a new vertex v is introduced, we have three possibilities: create a new part consisting of only

[1] In particular, in their conference version, Enciso et al. [26] promised to include the proof in an extended version, which, however, has never been published. There is also a version containing the appendix of the conference paper available from `https://www.researchgate.net/publication/220992885_What_Makes_Equitable_Connected_Partition_Easy`; however, even in this version, the proof is not provided.

v, put v into an existing opened part, or merge (via v) multiple already existing parts into a new one. When a vertex v is forgotten we need to check whether v is the last vertex of its part and, if yes, whether the part v is member of is of size $\lfloor n/p \rfloor$ or $\lceil n/p \rceil$. In join nodes, we just merge two records from child nodes with the same partition of bag vertices, or we merge different partitions whose connectivity is secured by the past vertices.

Once the dynamic table is correctly filled, we ask whether the dynamic table for the root of the tree-decomposition stores `true` in its single cell. The size of each dynamic programming table is $\mathrm{tw}^{\mathcal{O}(\mathrm{tw})} \cdot n^{\mathcal{O}(\mathrm{tw})} = n^{\mathcal{O}(\mathrm{tw})}$, and each table can be computed in the same time. Therefore, the algorithm runs in $\mathcal{O}\left(n \cdot \mathrm{tw}\right) \cdot n^{\mathcal{O}(\mathrm{tw})}$ time, which is in XP. ◀

Observe that if the size of every part is bounded by a parameter ς, the size of each dynamic programming table is $\mathrm{tw}^{\mathcal{O}(\mathrm{tw})} \cdot \varsigma^{\mathcal{O}(\mathrm{tw})}$ and we need the same time to compute each cell. Therefore, the algorithm also shows the following tractability result.

▶ **Corollary 10.** *The* EQUITABLE CONNECTED PARTITION *problem is fixed-parameter tractable parameterised by the tree-width* tw *and the size of a large part* $\varsigma = \lceil n/p \rceil$ *combined.*

In other words, the EQUITABLE CONNECTED PARTITION problem becomes tractable if the tree-width is bounded and the number of parts is large.

So far, we investigated the complexity of the problem mostly with respect to structural parameters that are bounded for sparse graphs. Now, we turn our attention to parameters that our bounded for dense graphs. Note that such parameters are indeed interesting for the problem, as the problem becomes polynomial-time solvable on cliques. We were not able to find this result in the literature, and, therefore, we present it in its entirety.

▶ **Observation 11.** *The* EQUITABLE CONNECTED PARTITION *problem can be solved in linear time if the graph G is a clique.*

Proof. First, we determine the number of parts of size $\lceil n/p \rceil$ as $\ell = (n \bmod p)$, and the number of smaller parts of size $\lfloor n/p \rfloor$ as $s = p - \ell$. Now, we arbitrarily assign vertices to p parts such that the first ℓ parts contain $\lceil n/p \rceil$ vertices and the remaining s parts contain exactly $\lfloor n/p \rfloor$ vertices. This, in fact, creates an equitable partition. Moreover, every partition is connected, since each pair of vertices is connected by an edge in G. ◀

Following the usual approach of distance from triviality [1, 41], we study the problem of our interest with respect to the distance to clique. We obtain the following tractability result.

▶ **Theorem 12.** *The* EQUITABLE CONNECTED PARTITION *problem is fixed-parameter tractable when parameterised by the distance to clique k.*

Next, we prove polynomial-time solvability for a more general class of graphs than cliques. Namely, we provide a tractable algorithm for co-graphs.

▶ **Theorem 13.** *The* EQUITABLE CONNECTED PARTITION *problem can be solved in polynomial time if the graph G is a co-graph.*

Next structural parameter we study is the neighbourhood diversity, which is generalisation of the famous vertex cover number that, in contrast, allows for large cliques to be present in G. Later on, we will also provide a fixed-parameter tractable algorithm for a more general parameter called modular-width; however, the algorithm for neighbourhood diversity will serve as a building block for the later algorithm, and therefore we find it useful to present the algorithm in its entirety.

▶ **Theorem 14.** *The* Equitable Connected Partition *problem is fixed-parameter tractable parameterised by the neighbourhood diversity* $\operatorname{nd}(G)$*.*

Proof. We first observe that each connected sub-graph of G "induces" a connected graph of the type-graph of G. More precisely, each connected sub-graph of G is composed of vertices that belong to types of G that induce a connected sub-graph of the type-graph. Therefore, the solution is composed of various realisations of connected sub-graphs of the type-graph of G. Note that there are at most $2^{\operatorname{nd}(G)}$ connected sub-graphs of the type-graph of G. We will resolve this task using an ILP using integral variables x_H^t for a type t and a connected sub-graph H of the type-graph of G. Furthermore, we have additional variables x_H. That is, the total number of variables is (upper-bounded by) $\operatorname{nd}(G) \cdot 2^{\operatorname{nd}(G)} + 2^{\operatorname{nd}(G)}$. The meaning of a variable x_H^t is "how many vertices of type t we use in a realisation of H". The meaning of a variable x_H is "how many realisations of H there are in the solution we find". We write $t \in H$ for a type that belongs to H (a connected sub-graph of the type-graph). Let σ denote the lower-bound on the size of parts of a solution, that is, $\sigma = \lfloor n/k \rfloor$. In order for this to hold we add the following set of constraints (here, $\xi_G = 0$ if $n = k \cdot \sigma$ and $\xi_G = 1$, otherwise):

$$\sigma x_H \le \sum_{t \in H} x_H^t \le (\sigma + \xi_G) x_H \qquad \forall H \tag{7}$$

$$x_H \le x_H^t \qquad \forall H\, \forall t \in H \tag{8}$$

$$\sum_H x_H^t = n_t \qquad \forall t \in T(G) \tag{9}$$

$$0 \le x_H^t \le n_t,\ x_H^t \in \mathbb{Z} \qquad \forall H\, \forall t \in H \tag{10}$$

$$0 \le x_H,\ x_H^t \in \mathbb{Z} \qquad \forall H \tag{11}$$

That is, (9) ensures that we place each vertex to some sub-graph H. The set of conditions (7) ensures that the total number of vertices assigned to the pattern H is divisible into parts of sizes σ or $\sigma + 1$. The set of conditions (8) ensures that each type that participates in a realisation of H contains at least x_H vertices, that is, we can assume that each realisation contains at least one vertex of each of its types. It is not difficult to verify that any solution to the Equitable Connected Partition problem fulfils (7)–(11).

In the opposite direction, suppose that we have an integral solution x satisfying (7)–(11). Let $\mathcal{H}$ be the collection of graphs H with multiplicities corresponding to x, that is, a graph H belongs to $\mathcal{H}$ exactly x_H-times. First, we observe that $|\mathcal{H}| = k$. To see this note that

$$|G| = \sum_{t \in H} n_t = \sum_{t \in H} \sum_{H \in \mathcal{H}} x_H^t = \sum_{H \in \mathcal{H}} \sum_{t \in H} x_H^t \ge \sum_{H \in \mathcal{H}} \sigma \cdot 1 \ge \sigma \sum_{H} x_H = \sigma |\mathcal{H}| \,.$$

Similarly, we have $|G| \le (\sigma + \xi_G)|\mathcal{H}|$ and the claim follows. Now, we find a realisation for every $H \in \mathcal{H}$. We know that there are $x_H^t \ge \sigma x_H$ vertices allocated to H. We assign them to the copies of H in $\mathcal{H}$ as follows. First, from each type $t \in H$ we assign one vertex to each copy of H (note that this is possible due to (8)). We assign the rest of the vertices greedily, so that there are σ vertices assigned to each copy of H; then, we assign the leftover vertices (note that there are at most x_H of them in total) to the different copies of H. In this way, we have assigned all vertices and gave a realisation of $\mathcal{H}$.

As was stated before, the integer linear program has only parameter-many variables. Hence, we can use the algorithm of Lenstra [49] to solve it in FPT time. ◀

With the algorithm from the proof of Theorem 14 in hand, we are ready to derive the result also for the modular-width.

▶ **Theorem 15.** *The* Equitable Connected Partition *problem is fixed-parameter tractable parameterised by the modular-width* $\mathrm{mw}(G)$*.*

Proof sketch. Clearly, the leaf-nodes of the modular decomposition of G have bounded neighbourhood diversity. For the graph of a leaf-node, we employ the following ILP:

$$\sigma x_H \le \sum_{t \in H} x_H^t \le (\sigma + \xi_G) x_H \qquad \forall H \tag{12}$$

$$x_H \le x_H^t \qquad \forall H\, \forall t \in H \tag{13}$$

$$\sum_{H} x_H^t \le n_t \qquad \forall t \in T(G) \tag{14}$$

$$0 \le x_H^t \le n_t,\; x_H^t \in \mathbb{Z} \qquad \forall H\, \forall t \in H \tag{15}$$

$$0 \le x_H,\; x_H^t \in \mathbb{Z} \qquad \forall H \tag{16}$$

Note the difference between (14) and (9); that is, this time we do not insist on assigning all vertices and can have some leftover vertices. We add an objective function

$$\max \sum_{H} \sum_{t \in H} x_H^t\,,$$

that is, we want to cover as many vertices as possible already in the corresponding leaf-node. Next, we observe that based on the solution of the above ILP, we can replace the leaf-node with a graph of neighbourhood diversity 2. In order to do so, we claim that if we replace the graph represented by the leaf-node by a disjoint union of a clique of size $\sum_H \sum_{t\in H} x_H^t$ and an independent set of size $\sum_H (n_t - \sum_{t\in H} x_H^t)$, then we do not change the answer to the Equitable Connected Partition problem. That is, the answer to the original graph was *yes* if and only if the answer is *yes* after we alter the leaf-node. The algorithm for modular-width then follows by a repeated application of the above ILP. ◀

As the last result of this section, we give an XP algorithm for another structural parameter called distance to cluster graph. The algorithm, in its core, is based on the same ideas as our FPT algorithm for distance to clique. Nevertheless, the number of types of vertices is no longer bounded only by a function of a parameter, and to partition the vertices that are not in the neighbourhood of the modulator vertices, we need to employ dynamic programming.

▶ **Theorem 16.** *The* Equitable Connected Partition *problem is* XP *parameterised by the distance to cluster graph* $\mathrm{dcg}(G)$*.*

4 Hardness Results

In this section, we complement our algorithmic upper-bounds from the previous section with matching hardness lower-bounds. The results from this section clearly show that no XP algorithm introduced in this paper can be improved to a fixed-parameter tractable one, or pushed to a more general parameter.

First, we observe that ECP is W[1]-hard with respect to the feedback-edge set number fes of G. This negatively resolves the question from the introduction of our paper. In fact, the actual statement shows an even stronger intractability result.

▶ **Theorem 17.** *The* Equitable Connected Partition *problem is* W[1]*-hard with respect to the path-width* $\mathrm{pw}(G)$*, the feedback-edge set number* $\mathrm{fes}(G)$*, and the number of parts* p *combined.*

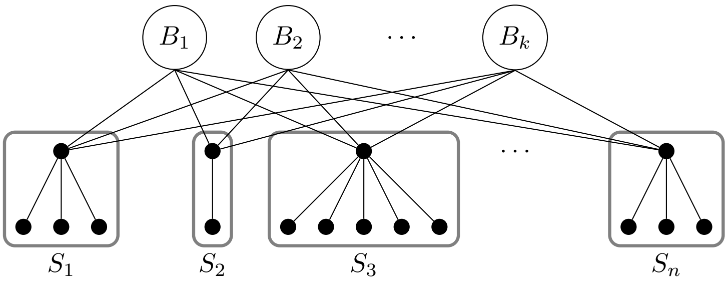

Figure 2 An illustration of the construction used to prove Theorem 19.

Note that the result from Theorem 17 can be, following the same arguments as used by [26], strengthened to show the same result for planar graphs.

▶ **Corollary 18.** *The* Equitable Connected Partition *problem is* W[1]*-hard when parameterised by the path-width, the feedback-edge set, and the number of parts combined, even if G is a planar graph.*

Next, we show that the d-pvcn parameter from Theorem 8 cannot be relaxed any more while the problem is kept tractable. Our reduction[2] is even more general and comes from the Unary Bin Packing problem, which is defined as follows.

Unary Bin Packing

Input: A number of bins k, a capacity of a single bin b, and a multi-set of integers $A = \{a_1, \ldots, a_n\}$ such that $\sum_{a\in A} a = bk$.

Question: Is there a surjective mapping $\alpha\colon A \to [k]$ such that for every $i \in [k]$ we have $\sum_{a\in\alpha^{-1}(i)} a = b$?

The Unary Bin Packing problem is well-known to be W[1]-hard when parameterised by the number of bins k and not solvable in $f(k) \cdot n^{o(k/\log k)}$ time for any computable function f, even if all numbers are given in unary [44].

▶ **Theorem 19.** *For every graph family $\mathcal{G}$ such that it contains at least one connected graph G with s vertices for every $s \in \mathbb{N}$, the* Equitable Connected Partition *problem is* W[1]*-hard parameterised by the distance to $\mathcal{G}$ referred to as $\mathrm{dist}_{\mathcal{G}}(G)$ and the number of parts p combined and, unless ETH fails, there is no algorithm running in $f(\ell) \cdot n^{o(\ell/\log \ell)}$ time for any computable function f, where $\ell = p + \mathrm{dist}_{\mathcal{G}}(G)$.*

Proof sketch. Let $\mathcal{I} = (A, k, b)$ be an instance of the Unary Bin Packing problem. We construct an equivalent instance $\mathcal{J} = (G, p)$ of the Equitable Connected Partition problem as follows (see Figure 2 for an overview of the construction). For the sake of exposition, we assume that $\mathcal{G}$ is a family containing all disjoint unions of stars; later we show how to tweak the construction to work with any $\mathcal{G}$ satisfying the conditions from the theorem statement.

For every number $a_i \in A$, we create a single *item-gadget* S_i which is a star with a_i vertices. Every S_i will be connected with the rest of the graph G only via the star centre c_i; we call this special vertex a *hub*. Next, we create k *bin-gadgets* $B_1, \ldots, B_k$. Each of these gadgets

[2] We would like to mention here that the construction used in the proof of Theorem 19 starts with the same problem and share similarities with the independent hardness construction of Gima and Otachi [39]; however, our construction is arguably easier and prove much more general hardness results.

consists of a single vertex. Slightly abusing the notation, we call this vertex also B_i, $i \in [k]$. As the last step of the construction, we add an edge connecting every bin-gadget with every item-gadget and set $p = k$. ◀

It is not hard to see that every graph G which is a disjoint union of stars has constant 4-path vertex cover number – 0, to be precise. Therefore, by Theorem 19 we obtain the desired hardness result.

▶ **Corollary 20.** *The* Equitable Connected Partition *problem is* W[1]*-hard parameterised by the* 4*-path vertex cover number 4-*pvcn *and the number of parts p combined.*

Now, a previous blind spot of our understanding of the Equitable Connected Partition problem's complexity with respect to the structural parameters that are bounded mostly for sparse graphs is the distance to disjoint paths. We again obtain hardness as a direct corollary of Theorem 19.

▶ **Corollary 21.** *The* Equitable Connected Partition *problem is* W[1]*-hard parameterised by the distance to disjoint paths* $\mathrm{ddp}(G)$ *and the number of parts p combined.*

Enciso et al. [26] stated (and we formalized in Theorem 9) that there is an XP algorithm for the Equitable Connected Partition problem parameterised by the tree-width of G. A natural question is then whether this algorithm can be improved to solve the problem in the same running-time also with respect to the more general parameter called clique-width. We give a strong evidence that such an algorithm is unlikely in the following theorem.

▶ **Theorem 22.** *The* Equitable Connected Partition *problem is* NP*-hard even if the graph G has clique-width* 3*, and is solvable in polynomial-time on graphs of clique-width at most* 2*.*

Proof. To show the hardness, we reuse the reduction used to prove Theorem 19. Recall that the construction can be done in polynomial time, thus, the reduction is also a polynomial reduction. What we need to show is that the clique-width of the constructed graph G is constant. We show this by providing an algebraic expression that uses 3 labels. First, we create a graph G_1 containing all bin-gadgets. This can be done by introducing a single vertex and by repeating disjoint union operation. We additionally assume that all vertices in G_1 have label 3. Next, we create a graph G_2 containing all item-gadgets. Every item-gadget is a star which can be constructed using two labels 1 and 2. Without loss of generality, we assume that all item-gadgets' centres have label 1 and all leaves have label 2. To complete the construction, we create disjoint union of G_1 and G_2 and, then, we perform a full join of vertices labelled 1 and 3. It is easy to see that the expression indeed leads to a desired graph. Polynomial-time solvability follows from Theorem 13 and the fact that co-graphs are exactly the graphs with clique-width at most 2 [17]. ◀

Using similar arguments, we can show para-NP-hardness also for a more restrictive parameter called shrub-depth [32, 34, 33].

▶ **Theorem 23.** *The* Equitable Connected Partition *problem is* NP*-hard even if the graph G has shrub-depth* 3*.*

As the last piece of the complexity picture of the Equitable Connected Partition problem, we show that ECP is W[1]-hard with respect to the distance to disjoint cliques. Recall that we give an XP algorithm for this parameter in Theorem 16.

▶ **Corollary 24.** *The* Equitable Connected Partition *problem is* W[1]*-hard with respect to the distance to cluster graph* $\mathrm{dcg}(G)$ *and the number of parts p combined.*

5 Conclusions

We revisit the complexity picture of the Equitable Connected Partition problem with respect to various structural restrictions of the graph. We complement the existing results with algorithmic upper-bounds and corresponding complexity lower-bounds that clearly show that no existing parameterised algorithm can be significantly improved.

Despite that the provided complexity study gives us a clear dichotomy between tractable and intractable cases, there still remain a few blind spots. One of the most interesting is the complexity classification of the Equitable Connected Partition problem with respect to the band-width parameter, which lies between the maximum leaf number and the path-width; however, is incomparable with the feedback-edge set number.

An interesting line of research can target the tightness of our results. For example, we show a clear dichotomy between the tractable and intractable cases of ECP when parameterised by the clique-width. Using similar arguments, we can show the following result for the recently introduced parameter twin-width [11].

▶ **Theorem 25.** *The Equitable Connected Partition problem is* NP*-hard even if the graph G has twin-width 2, and is solvable in polynomial-time on graphs of twin-width 0.*

We conjecture that the problem is polynomial-time solvable also on graphs of twin-width 1, which, unlike the twin-width 2 graphs, are additionally known to be recognisable efficiently [10]. Similarly, we can ask whether the provided FPT algorithms are optimal under some standard theoretical assumptions, such as the well-known Exponential-Time Hypothesis [42].

Last but not least, the parameterised complexity framework not only gives us formal tools for finer-grained complexity analysis of algorithms for NP-hard problems, but, at the same time, equips us also with the necessary formalism for analysis of effective preprocessing, which is widely known as *kernelisation*. A natural follow-up question is then whether the Equitable Connected Partition problem admits a polynomial kernel with respect to any of the studied structural parameters. We conjecture that there is a polynomial kernel with respect to the distance to clique and 3-path vertex cover number.

When Lawvere Meets Peirce: An Equational Presentation of Boolean Hyperdoctrines

Davide Trotta
University of Padova, Italy

Abstract

Fo-bicategories are a categorification of Peirce's calculus of relations. Notably, their laws provide a proof system for first-order logic that is both purely equational and complete. This paper illustrates a correspondence between fo-bicategories and Lawvere's hyperdoctrines. To streamline our proof, we introduce peircean bicategories, which offer a more succinct characterization of fo-bicategories.

1 Introduction

The first appearances of the characteristic features of first-order logic can be traced back to the works of Peirce [54] and Frege [21]. Frege was mainly motivated by the pursuit of a rigorous foundation for mathematics: his work was inspired by real analysis, bringing the concept of functions and variables into the logical realm [18]. On the other hand Peirce, inspired by the work of De Morgan [16] on relational reasoning, introduced a calculus in which operations allow the combination of relations and adhere to a set of algebraic laws. Like Boole's algebra of classes [9], Peirce's calculus of relations does not feature variables nor quantifiers and its sole deduction rule is substituting equals by equals.

Despite several negative results [51, 28, 63, 22, 2, 60] regarding axiomatizations for the calculus, its lack of binder-related complexities, coupled with purely equational proofs, has rendered the calculus of relations highly influential in computer science, e.g., in the context of database theory [13], programming languages [61, 27, 38, 1, 37] and proof assistants [58, 59, 36]. In logic, the calculus played a secondary role for many years, likely because it is strictly less expressive than first-order logic [43]. This was until Tarski in [67] recognized its algebraic flavour and initiated a program of algebraizing first-order logic, including works such as [17, 26, 62]. Quoting Quine [62]:

> "Logic in his adolescent phase was algebraic. There was Boole's algebra of classes and Peirce's algebra of relations. But in 1879 logic come of age, with Frege's quantification theory. Here the bound variables, so characteristic of analysis rather than of algebra, became central to logic."

Such a perspective, which regarded algebraic aspects and those concerning quantifiers as separate entities, changed with the work of Lawvere.

Thanks to the recent development of a new branch of mathematics, namely category theory, Lawvere introduced in [40, 41, 42] *hyperdoctrines* which enabled the study of logic from a pure algebraic perspective. The crucial insights of Lawvere was to show that quantifiers, as well as many logical constructs, can be algebraically captured through the crucial notion of adjointness. Hyperdoctrines, along with many categorical structures related to logics, such as regular, Heyting, and boolean categories [32, 33], align with Frege's functional perspective: arrows represent functions (terms), and relations are derived through specific constructions.

In the last decade, the paradigm shift towards treating data as a physical resource has motivated many computer scientists to move from traditional term-based (cartesian) syntax toward a string diagrammatic (monoidal) syntax [34, 65] (see e.g., [66, 4, 6, 8, 14, 19, 20, 24, 52, 56]). This shift in syntax enables an extension of Peirce's calculus of relations that is as expressive as first-order logic, accompanied by an axiomatization that is purely equational and complete. The axioms are those of *first-order bicategories* [3]: see Figures 1, 3 and 4. In essence, a first-order bicategory, or fo-bicategory, encompasses a cartesian and a cocartesian bicategory [11], interacting as a linear bicategory [12], while additionally satisfying linear versions of Frobenius equations and adjointness conditions.

In this paper, we reconcile Lawvere's understanding of logic with Peirce's calculus of relations by illustrating a formal correspondence between boolean hyperdoctrines and first-order bicategories.

To reach such a correspondence, we found convenient to introduce *peircean bicategories*: these are cartesian bicategories with each homset carrying a boolean algebra where the negation behaves appropriately with *maps* – special arrows that intuitively generalize functions. Our first result (Theorem 27) states that peircean and fo-bicategories are equivalent.

While the definition of peircean bicategories is not purely equational, as in the case of fo-bicategories, it is notably more concise. Moreover, it allows us to reuse from [7] an adjunction between cartesian bicategories and *elementary and existential doctrines* [46, 45, 47], which are a generalisation of hyperdoctrines, corresponding to the $(\exists, =, \top, \wedge)$-fragment of first-order logic. Our main result (Theorem 32) reveals an adjunction between the category of first-order bicategories and the category of boolean hyperdoctrines.

It is essential to note that our theorem establishes an adjunction rather than an equivalence. The discrepancy can be intuitively explained by noting that, akin to first-order logic, terms and formulas are distinct entities in hyperdoctrines. Thus for two terms t_1 and t_2, the hyperdoctrine where the formula $t_1 = t_2$ is true differs from the hyperdoctrine where t_1 and t_2 are equated as terms, a distinction not present in fo-bicategories. These issues, related to the extensionality of equality, are thoroughly analyzed in the literature (see e.g. [45, 31]).

Leveraging another result from [7], we demonstrate (Theorem 37) that the adjunction in Theorem 32 becomes an equivalence when restricted to well-behaved hyperdoctrines (i.e., those whose equality is extensional and satisfying the rule of unique choice [44]).

Synopsis. In § 2, we provide a review of (co)cartesian, linear and fo-bicategories. § 3 covers a recap of elementary and existential doctrines and boolean hyperdoctrines. The key adjunction from [7] is recalled in §4. Our original contributions commence in § 5, where we introduce peircean bicategories and establish their equivalence with fo-bicategories. This result is used in § 6 to show the adjunction and in § 7 to establish the equivalence. Missing proofs can be found in [5].

Terminology and Notation. All bicategories considered in this paper are just poset-enriched symmetric monoidal categories. For a bicategory $\mathbf{C}$, we will write $\mathbf{C}^{\mathrm{op}}$ for the bicategory having the same objects as $\mathbf{C}$ but homsets $\mathbf{C}^{\mathrm{op}}[X,Y] \stackrel{\mathrm{def}}{=} \mathbf{C}[Y,X]$. Similarly, we will write $\mathbf{C}^{\mathrm{co}}$ to denote the bicategory having the same objects and arrows of $\mathbf{C}$ but equipped with the reversed ordering $\geq$. The cartesian bicategories in this paper are called in [11] cartesian bicategories of relations. We refer the reader to [3, Rem. 2] for a comparison with the presentation of linear bicategories in [12]. In a category with finite products, we write $\langle f, g\rangle$ for the pairing of f and g and Δ_X for $\langle id^{\circ}_X, id^{\circ}_X\rangle$.

2 From (Co)Cartesian to First-Order Bicategories

In this section we recall the notion of *first-order bicategory* from [3]. To provide a preliminary intuition, it is convenient to consider $\mathbf{Rel}$, the first-order bicategory of sets and relations.

It is well known that sets and relations form a symmetric monoidal category, hereafter denoted as $\mathbf{Rel}^{\circ}$, with composition, identities, monoidal product and symmetries defined as

$$\begin{aligned}
a \overset{\circ}{,} b &\stackrel{\mathrm{def}}{=} \{(x,z) \mid \exists y \in Y \,.\, (x,y) \in a \wedge (y,z) \in b\} \subseteq X \times Z \qquad id^{\circ}_X \stackrel{\mathrm{def}}{=} \{(x,y) \mid x = y\} \subseteq X \times X \\
a \otimes c &\stackrel{\mathrm{def}}{=} \{(\,(x,z),(y,v)\,) \mid (x,y) \in a \wedge (z,v) \in c\} \subseteq (X \times Z) \times (Y \times V) \\
\sigma^{\circ}_{X,Y} &\stackrel{\mathrm{def}}{=} \{(\,(x,y),(y',x')\,) \mid x = x' \wedge y = y'\} \subseteq (X \times Y) \times (Y \times X)
\end{aligned} \tag{1}$$

for all sets X, Y, Z, V and relations $a \subseteq X \times Y$, $b \subseteq Y \times Z$ and $c \subseteq Z \times V$. As originally observed by Peirce in [55], beyond $\overset{\circ}{,}$ there exists another form of relational composition that enjoys noteworthy algebraic properties. This different composition gives rise to another symmetric monoidal category of sets and relations, hereafter denoted by $\mathbf{Rel}^{\bullet}$ and defined as follows.

$$\begin{aligned}
a \overset{\bullet}{,} b &\stackrel{\mathrm{def}}{=} \{(x,z) \mid \forall y \in Y \,.\, (x,y) \in a \vee (y,z) \in b\} \subseteq X \times Z \qquad id^{\bullet}_X \stackrel{\mathrm{def}}{=} \{(x,y) \mid x \neq y\} \subseteq X \times X \\
a \boldsymbol{\otimes} c &\stackrel{\mathrm{def}}{=} \{(\,(x,z),(y,v)\,) \mid (x,y) \in a \vee (z,v) \in c\} \subseteq (X \times Z) \times (Y \times V) \\
\sigma^{\bullet}_{X,Y} &\stackrel{\mathrm{def}}{=} \{(\,(x,y),(y',x')\,) \mid x \neq x' \vee y \neq y'\} \subseteq (X \times Y) \times (Y \times X)
\end{aligned} \tag{2}$$

Note that $\otimes$ and $\boldsymbol{\otimes}$ are both defined on objects as the cartesian product of sets and have as unit the singleton set $I \stackrel{\mathrm{def}}{=} \{\star\}$. Both $\mathbf{Rel}^{\circ}$ and $\mathbf{Rel}^{\bullet}$ are poset-enriched symmetric monoidal categories when taking as ordering the inclusion $\subseteq$ and the complement $\neg\colon (\mathbf{Rel}^{\circ})^{\mathrm{co}} \to \mathbf{Rel}^{\bullet}$ is an isomorphism. As we will explain in § 2.1, the relations defined for all sets X as

$$\begin{aligned}
\blacktriangleleft^{\circ}_X &\stackrel{\mathrm{def}}{=} \{(x,\ (y,z)) \mid x = y \wedge x = z\} \subseteq X \times (X \times X) &\quad \blacktriangleleft^{\bullet}_X &\stackrel{\mathrm{def}}{=} \{(x,\ (y,z)) \mid x \neq y \vee x \neq z\} \subseteq X \times (X \times X) \\
\blacktriangleright^{\circ}_X &\stackrel{\mathrm{def}}{=} \{((y,z),\ x) \mid x = y \wedge x = z\} \subseteq (X \times X) \times X &\quad \blacktriangleright^{\bullet}_X &\stackrel{\mathrm{def}}{=} \{((y,z),\ x) \mid x \neq y \vee x \neq z\} \subseteq (X \times X) \times X \\
!^{\circ}_X &\stackrel{\mathrm{def}}{=} \{(x,\star) \mid x \in X\} \subseteq X \times I &\quad !^{\bullet}_X &\stackrel{\mathrm{def}}{=} \varnothing \subseteq X \times I \\
¡^{\circ}_X &\stackrel{\mathrm{def}}{=} \{(\star,x) \mid x \in X\} \subseteq I \times X &\quad ¡^{\bullet}_X &\stackrel{\mathrm{def}}{=} \varnothing \subseteq I \times X
\end{aligned} \tag{3}$$

make $\mathbf{Rel}^{\circ}$ a cartesian bicategory, while $\mathbf{Rel}^{\bullet}$ a cocartesian one.

Intuitively, a first-order bicategory $\mathbf{C}$ consists of a cartesian bicategory $\mathbf{C}^{\circ}$, called the "white structure", and a cocartesian bicategory $\mathbf{C}^{\bullet}$, called the "black structure", that interact by obeying the same laws of $\mathbf{Rel}^{\circ}$ and $\mathbf{Rel}^{\bullet}$. The name "first-order" is due to the fact that such laws provide a complete system of axioms for first-order logic.

The axioms can be conveniently given by means of a graphical representation inspired by string diagrams [34, 65]: composition is depicted as horizontal composition while the monoidal product by vertically "stacking" diagrams. However, since there are two compositions $\overset{\circ}{,}$ and

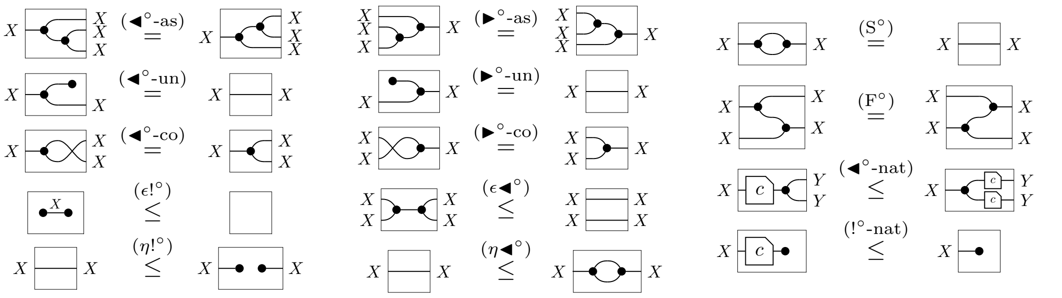

Figure 1 Axioms of cartesian bicategories.

$⨾$ and two monoidal products $\otimes$ and $\boldsymbol{\otimes}$, to distinguish them we use different colors. All white constants have white background, mutatis mutandis for the black ones: for instance $\blacktriangleleft^{\circ}_{X}$ and $\blacktriangleright^{\bullet}_{X}$ are drawn  and  , while for some arrows a, b, c, d of the appropriate type, $(a \otimes c) ⨾ (b \boldsymbol{\otimes} d)$ is drawn as on the right of (ν°_{l}) in Figure 3.

2.1 (Co)Cartesian Bicategories

We commence with the notion of cartesian bicategories by Carboni and Walters [11].

▶ **Definition 1.** *A* cartesian bicategory $(\mathbf{C}, \otimes, I, \blacktriangleleft^{\circ}, !^{\circ}, \blacktriangleright^{\circ}, ¡^{\circ})$, *shorthand* $(\mathbf{C}, \blacktriangleleft^{\circ}, \blacktriangleright^{\circ})$, *is a poset-enriched symmetric monoidal category* $(\mathbf{C}, \otimes, I)$ *and, for every object* X *in* $\mathbf{C}$, *arrows* $\blacktriangleleft^{\circ}_{X} : X \to X \otimes X$, $!^{\circ}_{X} : X \to I$, $\blacktriangleright^{\circ}_{X} : X \otimes X \to X$, $¡^{\circ}_{X} : I \to X$ *such that*

1. $(\blacktriangleleft^{\circ}_{X}, !^{\circ}_{X})$ *is a comonoid and* $(\blacktriangleright^{\circ}_{X}, ¡^{\circ}_{X})$ *a monoid, i.e., the equalities* (◀°-as), (◀°-un), (◀°-co) *and* (▶°-as), (▶°-un), (▶°-co) *in Figure 1 hold;*
2. *every arrow* $c \colon X \to Y$ *is a lax comonoid homomorphism, i.e.,* (◀°-nat) *and* (!°-nat) *hold;*
3. *comonoids are left adjoints to the monoids, i.e.,* $(\eta \blacktriangleleft^{\circ})$, $(\epsilon \blacktriangleleft^{\circ})$, $(\eta !^{\circ})$ *and* $(\epsilon !^{\circ})$ *hold;*
4. *monoids and comonoids form special Frobenius bimonoids, i.e.,* (F°) *and* (S°) *hold;*
5. *monoids and comonoids satisfy the expected coherence conditions (see e.g. [7]).*

$\mathbf{C}$ *is a* cocartesian bicategory *if* $\mathbf{C}^{\mathrm{co}}$ *is a cartesian bicategory. A* morphism of (co)cartesian bicategories *is a poset-enriched strong symmetric monoidal functor preserving monoids and comonoids. We denote by* $\mathbb{CB}$ *the category of cartesian bicategories and their morphisms.*

As already mentioned, $\mathbf{Rel}^{\circ}$ with $\blacktriangleleft^{\circ}_{X}$, $!^{\circ}_{X}$, $\blacktriangleright^{\circ}_{X}$ and $¡^{\circ}_{X}$ defined in (3) form a cartesian bicategory: the reader can easily check, using the definitions in (1) and (3), that all the laws in Figure 1 are satisfied. Similarly, one can observe that the opposite inequality of (◀°-nat) holds iff the relation $c \subseteq X \times Y$ is single-valued (i.e., deterministic), while the opposite of (!°-nat) iff c is total. In other words, c is a function iff both (◀°-nat) and (!°-nat) hold as equalities.

▶ **Definition 2.** *Let* $c \colon X \to Y$ *be an arrow of a cartesian bicategory* $\mathbf{C}$. *It is a* map *if*

(4)

Maps form a monoidal subcategory of $\mathbf{C}$, denoted by $\mathsf{Map}(\mathbf{C})$, that has finite products [11].

In a cartesian bicategory $\mathbf{C}$, each homset $\mathbf{C}[X, Y]$ carries the structure of inf-semilattice, defined for all $c, d \colon X \to Y$ as in (5) below. Furthermore, the equation (6) defines an identity-on-objects isomorphism of cartesian bicategories $(\cdot)^{\dagger} \colon \mathbf{C} \to \mathbf{C}^{\mathrm{op}}$.

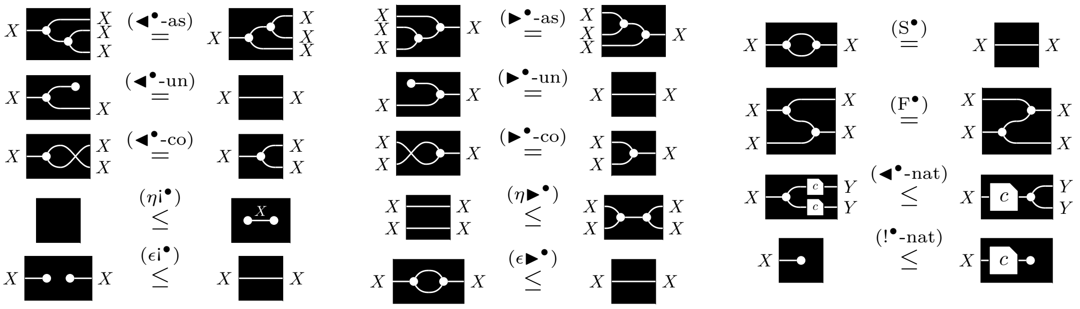

Figure 2 Axioms of cocartesian bicategories.

$c \wedge d \overset{\text{def}}{=}$  $\top \overset{\text{def}}{=}$  (5) $c^\dagger \overset{\text{def}}{=}$  (6)

The reader can check, using (1) and (3) that in $\mathbf{Rel}^\circ$, $c^\dagger\colon Y \to X$ is the opposite of the relation c, namely $\{(y,x) \mid (x,y) \in c\}$. It is well known that a relation c is a function iff it is left adjoint to $c^\dagger$. More generally in a cartesian bicategory c is a map iff it is left adjoint to $c^\dagger$. Summarising:

▶ **Proposition 3.** *Let* $\mathbf{C}$ *be a cartesian bicategory and* $c\colon X \to Y$ *an arrow of* $\mathbf{C}$. *The following hold:*

1. *every homset carries the inf-semilattice structure, defined as in* (5)*;*
2. *there is an isomorphism of cartesian bicategories* $(\cdot)^\dagger\colon \mathbf{C} \to \mathbf{C}^{\mathrm{op}}$*, defined as in* (6)*;*
3. c *is a map iff* c *is left adjoint to* $c^\dagger$*;*
4. $\mathsf{Map}(\mathbf{C})$ *is a category with finite products; moreover, a morphism of cartesian bicategories* $F\colon \mathbf{C} \to \mathbf{D}$ *restricts to a functor* $\tilde{F}\colon \mathsf{Map}(\mathbf{C}) \to \mathsf{Map}(\mathbf{D})$ *preserving finite products.*

Hereafter, we draw  for ( $)^\dagger$ and  for a map $c\colon X \to Y$.

We mentioned that $\mathbf{Rel}^\bullet$ with $\blacktriangleleft^\bullet_X$, $!^\bullet_X$, $\blacktriangleright^\bullet_X$ and $¡^\bullet_X$ defined in (3) forms a cocartesian bicategory. To prove this, it is enough to observe that the complement $\neg$ is a poset-enriched symmetric monoidal isomorphism $\neg\colon (\mathbf{Rel}^\circ)^{\mathrm{co}} \to \mathbf{Rel}^\bullet$ preserving (co)monoids.

2.2 Linear Bicategories

We have seen that $\mathbf{Rel}^\circ$ forms a cartesian bicategory, and $\mathbf{Rel}^\bullet$ a cocartesian bicategory. The next step consists of merging them into one entity and studying their algebraic interactions. However, the coexistence of two different compositions $\mathbin{⨾}$ and $\mathbin{\bullet\!\!⨾}$ on the same class of objects and arrows brings us out of the realm of ordinary categories. The appropriate setting is provided by *linear bicategories* [12] by Cockett, Koslowski and Seely.

▶ **Definition 4.** *A* linear bicategory $(\mathbf{C}, ⨾, id^\circ, \bullet⨾, id^\bullet)$ *consists of two poset-enriched categories* $(\mathbf{C}, ⨾, id^\circ)$ *and* $(\mathbf{C}, \bullet⨾, id^\bullet)$ *with the same class of objects, arrows and orderings (but possibly different identities and compositions) such that* $⨾$ *linearly distributes over* $\bullet⨾$*, i.e.,* (δ_l) *and* (δ_r) *in Figure 3 hold.*

A symmetric monoidal linear bicategory $(\mathbf{C}, ⨾, id^\circ, \bullet⨾, id^\bullet, \otimes, \sigma^\circ, \blacksquare\!\!\!\otimes, \sigma^\bullet, I)$*, shortly* $(\mathbf{C}, \otimes, \blacksquare\!\!\!\otimes, I)$*, consists of a linear bicategory* $(\mathbf{C}, ⨾, id^\bullet, \bullet⨾, id^\bullet)$ *and two poset-enriched symmetric monoidal categories* $(\mathbf{C}, \otimes, I)$ *and* $(\mathbf{C}, \blacksquare\!\!\!\otimes, I)$ *s.t.* $\otimes$ *and* $\blacksquare\!\!\!\otimes$ *agree on objects, i.e.,* $X \otimes Y = X \blacksquare\!\!\!\otimes Y$*, share the same unit* I *and*

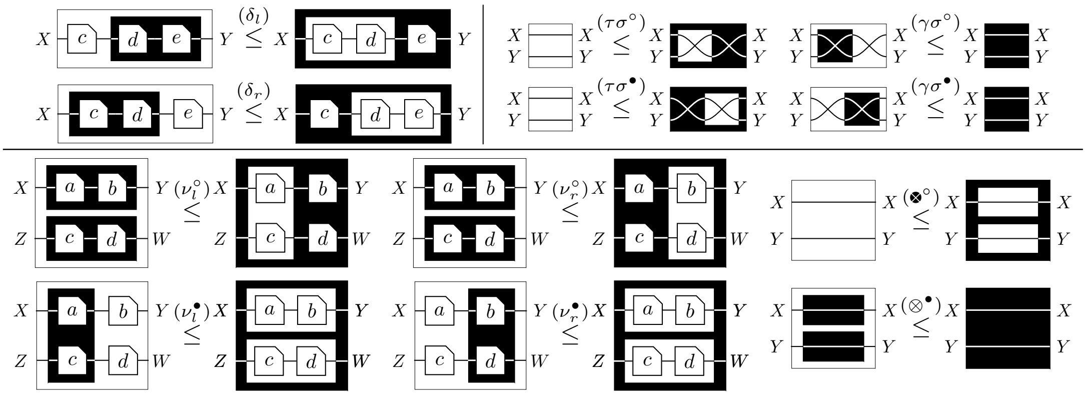

Figure 3 Axioms of closed symmetric monoidal linear bicategories.

2. *there are linear strengths for $(\otimes, \boldsymbol{\otimes})$, i.e., the inequalities (ν_l°), (ν_r°), $(\nu_l^{\bullet})$ and $(\nu_r^{\bullet})$ hold;*
3. *$\boldsymbol{\otimes}$ preserves id° colaxly and $\otimes$ preserves $id^{\bullet}$ laxly, i.e., $(\otimes^{\bullet})$ and $(\boldsymbol{\otimes}^{\circ})$ hold.*

A morphism of symmetric monoidal linear bicategories *$F\colon (\mathbf{C_1}, \otimes, \boldsymbol{\otimes}, I) \to (\mathbf{C_2}, \otimes, \boldsymbol{\otimes}, I)$ consists of two poset-enriched symmetric monoidal functors $F^{\circ}\colon (\mathbf{C_1}, \otimes, I) \to (\mathbf{C_2}, \otimes, I)$ and $F^{\bullet}\colon (\mathbf{C_1}, \boldsymbol{\otimes}, I) \to (\mathbf{C_2}, \boldsymbol{\otimes}, I)$ that agree on objects and arrows: $F^{\circ}(X) = F^{\bullet}(X)$ and $F^{\circ}(c) = F^{\bullet}(c)$.*

We omit the adjective *symmetric monoidal*, since all linear bicategories in this paper are such. In linear bicategories one can define *linear* adjoints: for $a\colon X \to Y$ and $b\colon Y \to X$, a is *left linear adjoint* to b, or b is *right linear adjoint* to a, written $b \Vdash a$, if $id_X^{\circ} \leq a \mathbin{;^{\bullet}} b$ and $b \mathbin{;^{\circ}} a \leq id_Y^{\bullet}$.

▶ **Definition 5.** *A linear bicategory $(\mathbf{C}, \otimes, \boldsymbol{\otimes}, I)$ is said to be* closed *if every $a\colon X \to Y$ has both a left and a right linear adjoint and, in particular, the white symmetry σ° is both left and right linear adjoint to the black symmetry $\sigma^{\bullet}$ ($\sigma^{\bullet} \Vdash \sigma^{\circ} \Vdash \sigma^{\bullet}$), i.e. $(\tau\sigma^{\circ})$, $(\gamma\sigma^{\circ})$, $(\tau\sigma^{\bullet})$ and $(\gamma\sigma^{\bullet})$ in Figure 3 hold.*

Our main example is the closed linear bicategory **Rel** of sets and relations. The white structure is the symmetric monoidal category $\mathbf{Rel}^{\circ}$ and the black structure is $\mathbf{Rel}^{\bullet}$. Observe that the two have the same objects, arrows and ordering. The white and black monoidal products $\otimes$ and $\boldsymbol{\otimes}$ agree on objects (they are the cartesian product of sets) and have common unit object (the singleton set I). By (1) and (2), one can easily check all the inequalities in Figure 3. Both left and right linear adjoints of a relation $c \subseteq X \times Y$ are given by $\neg c^{\dagger}$.

2.3 First-Order Bicategories

After (co)cartesian and linear bicategories, we can recall first-order bicategories from [3].

▶ **Definition 6.** *A* first-order bicategory $\mathbf{C}$ *consists of a closed linear bicategory $(\mathbf{C}, \otimes, \boldsymbol{\otimes}, I)$, a cartesian bicategory $(\mathbf{C}, \blacktriangleleft^{\circ}, \blacktriangleright^{\circ})$ and a cocartesian bicategory $(\mathbf{C}, \blacktriangleleft^{\bullet}, \blacktriangleright^{\bullet})$, such that*

1. *the white comonoid $(\blacktriangleleft^{\circ}, !^{\circ})$ is left and right linear adjoint to black monoid $(\blacktriangleright^{\bullet}, ¡^{\bullet})$ and $(\blacktriangleright^{\circ}, ¡^{\circ})$ is left and right linear adjoint to $(\blacktriangleleft^{\bullet}, !^{\bullet})$ i.e., the 16 inequalities in the top of Figure 4 hold;*
2. *white and black (co)monoids satisfy the linear Frobenius laws, i.e. $(\mathrm{F}^{\bullet}_{\circ})$, $(\mathrm{F}^{\circ}_{\bullet})$, $(\mathrm{F}_{\bullet}^{\circ})$, $(\mathrm{F}_{\circ}^{\bullet})$ hold.*

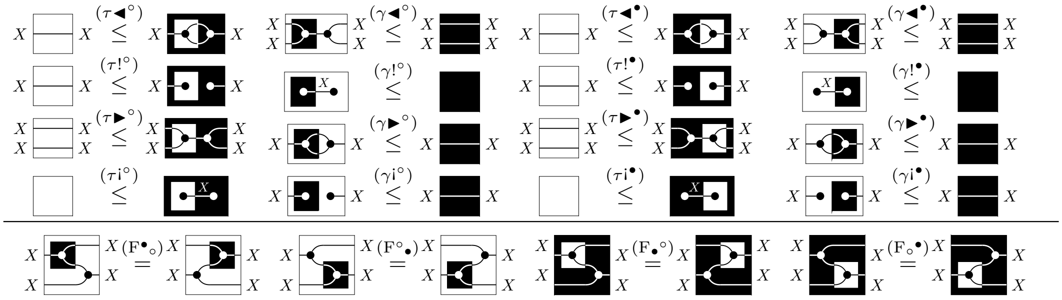

Figure 4 Additional axioms for fo-bicategories.

A morphism of fo-bicategories *is a morphism of linear bicategories* and *of (co)cartesian bicategories. We denote by* $\mathbb{FOB}$ *the category of fo-bicategories and their morphisms.*

We have seen that **Rel** is a closed linear bicategory, $\mathbf{Rel}^\circ$ a cartesian bicategory and $\mathbf{Rel}^\bullet$ a cocartesian bicategory. Given (3), it is easy to check the inequalities in Figure 4.

If $\mathbf{C}$ is a fo-bicategory, then $\mathbf{C}^{\text{co}}$ is a fo-bicategory when swapping white and black structures. Similarly, $\mathbf{C}^{\text{op}}$ is a fo-bicategory when swapping monoids and comonoids.

In a fo-bicategory $\mathbf{C}$, left and right linear adjoints of an arrow c coincide and are denoted by $c^\perp$. The assignment $c \mapsto c^\perp$ gives rise to an identity-on-objects isomorphism of fo-bicategories $(\cdot)^\perp \colon \mathbf{C} \to (\mathbf{C}^{\text{co}})^{\text{op}}$. Similarly, $(\cdot)^\dagger \colon \mathbf{C} \to \mathbf{C}^{\text{op}}$ in (6) is also an isomorphism of fo-bicategories.

Since the following diagram commutes, one can define the complement as the diagonal of the square, namely $\neg(\cdot) \stackrel{\text{def}}{=} ((\cdot)^\perp)^\dagger$.

$$\begin{tikzcd}
\mathbf{C} \arrow[r, "(\cdot)^\dagger"] \arrow[d, "(\cdot)^\perp"'] & \mathbf{C}^{\text{op}} \arrow[d, "(\cdot)^\perp"] \\
(\mathbf{C}^{\text{co}})^{\text{op}} \arrow[r, "(\cdot)^\dagger"] & \mathbf{C}^{\text{co}}
\end{tikzcd}$$

Clearly $\neg \colon \mathbf{C} \to \mathbf{C}^{\text{co}}$ is an isomorphism of fo-bicategories. Moreover, it induces a boolean algebra on each homset of $\mathbf{C}$.

▶ **Proposition 7.** *Let* $\mathbf{C}$ *be a fo-bicategory. Then, every homset of* $\mathbf{C}$ *is a boolean algebra.*

▶ **Proposition 8.** *Let* $F \colon \mathbf{C} \to \mathbf{D}$ *be a morphism of fo-bicategories. For all arrows* c*,* $\neg F(c) = F(\neg c)$*.*

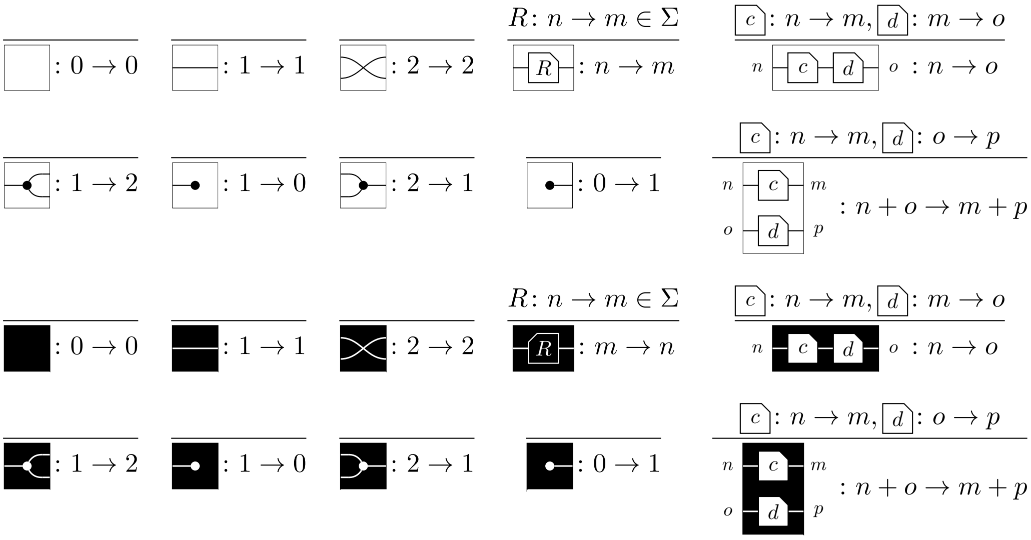
The next property of maps (Definition 2) plays a key role in our work.

▶ **Proposition 9.** *For all maps* $f \colon X \to Y$ *and arrows* $c \colon Y \to Z$*, it holds that* $f \mathbin{;} \neg c = \neg(f \mathbin{;} c)$*.*

2.4 Freely Generated First-Order Bicategories

We conclude this section by giving to the reader a taste of how fo-bicategories relate to first-order theories. First, we recall from [3] the freely generated fo-bicategory $\mathbf{FOB}_\Sigma$.

Given a monoidal signature Σ, namely a set of symbols $R \colon n \to m$ with arity n and coarity m, $\mathbf{FOB}_\Sigma$ is the fo-bicategory whose objects are natural numbers and arrows $c \colon n \to m$ are string diagrams generated by the following rules:

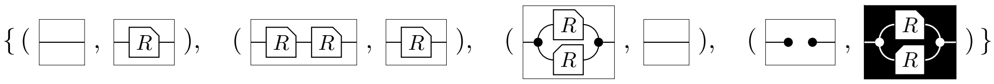


More precisely, arrows are equivalence classes of string diagrams w.r.t $\lesssim \cap \gtrsim$, where $\lesssim$ is the precongruence (w.r.t. $;$, $\otimes$, $\blacktriangledown$ and $\circledast$) generated by the axioms in Figures 1,2,3,4 (with X, Y, Z, W replaced by natural numbers, and a, b, c, d by diagrams of the appropriate type) and the axioms forcing  and  to be linear adjoints:

To give semantics to these diagrams we need *interpretations*, i.e. pairs $\mathcal{I} = (X, \rho)$, where X is a set and ρ is a function assigning to each $R\colon n \to m \in \Sigma$ a relation $\rho(R)\colon X^n \to X^m$. Since $\mathbf{FOB}_\Sigma$ is the free fo-bicategory, for any interpretation $\mathcal{I}$ there exists a unique morphism of fo-bicategories $\mathcal{I}^\sharp\colon \mathbf{FOB}_\Sigma \to \mathbf{Rel}$ such that $\mathcal{I}^\sharp(1) = X$ and $\mathcal{I}^\sharp($  $) = \rho(R) \subseteq X^n \times X^m$. Intuitively, $\mathcal{I}^\sharp$ is defined inductively by (1), (2) and (3) with the free cases provided by $\mathcal{I}$.

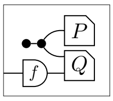
A *diagrammatic first-order theory* is a pair $\mathbb{T} = (\Sigma, \mathbb{I})$ where Σ is a monoidal signature and $\mathbb{I}$ is a set of *axioms*: pairs (c, d) for $c, d\colon n \to m$ in $\mathbf{FOB}_\Sigma$, standing for $c \leq d$. An interpretation $\mathcal{I}$ is a *model* of $\mathbb{T}$ if and only if, for all $(c, d) \in \mathbb{I}$, $\mathcal{I}^\sharp(c) \subseteq \mathcal{I}^\sharp(d)$. As illustrated in [3], one can generate the fo-bicategory $\mathbf{FOB}_\mathbb{T}$ and, in the spirit of Lawvere's functorial semantics [39], models of $\mathbb{T}$ are in one-to-one correspondence with morphisms $F\colon \mathbf{FOB}_\mathbb{T} \to \mathbf{Rel}$.

▶ **Example 10.** Consider the theory $\mathbb{T} = (\Sigma, \mathbb{I})$, where $\Sigma = \{R\colon 1 \to 1\}$ and $\mathbb{I}$ be as follows:



An interpretation is a set X and a relation $R \subseteq X \times X$. It is a model iff R is an order, i.e., reflexive ($id^\circ_X \subseteq R$), transitive ($R ; R \subseteq R$), antisymmetric ($R \cap R^\dagger \subseteq id^\circ$) and total ($\top \subseteq R \cup R^\dagger$).

▶ Remark 11. A direct encoding of traditional first-order theories into diagrammatic ones is illustrated in [3]. Shortly, a predicate symbol P of arity n becomes a symbol $P\colon n \to 0 \in \Sigma$, drawn as , and a n-ary function symbol f becomes $f\colon n \to 1 \in \Sigma$, drawn as . For instance, the formula $\exists x.P(x) \wedge Q(x, f(y))$ is rendered as follows



where  plays the role of $\exists$ and  that of $\wedge$. Note that both predicate and function symbols of traditional first-order theories are regarded as symbols of the monoidal signature Σ. Function symbols are constrained to represent functions by adding to $\mathbb{I}$ the axioms of maps, i.e., the inequalities in (4).

3 From Elementary-Existential Doctrines to Boolean Hyperdoctrines

The notion of hyperdoctrine was introduced by Lawvere in a series of seminal papers [40, 42]. Over the years, various generalizations and specializations of this concept have been formulated and applied across multiple domains in the fields of logic and computer science. In this work, we employ a generalization of the notion of hyperdoctrine introduced by Maietti and Rosolini in [46, 45, 47], namely that of an *elementary and existential doctrine.*

▶ **Definition 12.** *An* elementary and existential doctrine *is a functor* $P\colon \mathbf{C}^{\mathrm{op}} \longrightarrow \mathsf{InfSl}$ *from the opposite of a category* $\mathbf{C}$ *with finite products to the category of inf-semilattices such that:*

- *for every* Y *in* $\mathbf{C}$ *there exists an element* δ_Y *in* $P(Y \times Y)$*, called* equality predicate*, such that for a morphism* $id^\circ_X \times \Delta_Y\colon X \times Y \to X \times Y \times Y$ *in* $\mathbf{C}$ *and every element* α *in* $P(X \times Y)$*, the assignment*

$$\exists_{id^\circ_X \times \Delta_Y}(\alpha) \overset{def}{=} P_{\langle \pi_1, \pi_2 \rangle}(\alpha) \wedge P_{\langle \pi_2, \pi_3 \rangle}(\delta_Y)$$

  determines a left adjoint to the functor $P_{id^\circ_X \times \Delta_Y}\colon P(X \times Y \times Y) \to P(X \times Y)$*;*
- *for any projection* $\pi_X\colon X \times Y \to X$*, the functor* $P_{\pi_X}\colon P(X) \to P(X \times Y)$ *has a left adjoint* $\exists_{\pi_X}$*, and these satisfy the* Beck-Chevalley condition *and* Frobenius reciprocity*, see [46, Sec. 2].*

▶ Remark 13. In an elementary and existential doctrine, for every $f\colon X \to Y$ of $\mathbf{C}$ the functor P_f has a left adjoint $\exists_f$ that can be computed as $\exists_{\pi_Y}(P_{f \times id^\circ_{X\,Y}}(\delta_Y) \wedge P_{\pi_X}(\alpha))$ for α in $P(X)$, where π_X and π_Y are the projections from $X \times Y$. These left ajoints satisfy the Frobenius reciprocity but not necessarily the Beck-Chevalley condition. See [48, Rem. 6.4].

▶ **Definition 14.** *Let* $P\colon \mathbf{C}^{\mathrm{op}} \longrightarrow \mathsf{InfSl}$ *and* $R\colon \mathbf{D}^{\mathrm{op}} \longrightarrow \mathsf{InfSl}$ *be two elementary and existential doctrines. A* morphism of elementary and existential doctrines *is given by a pair* $(F, \mathfrak{b})$ *where*

- $F\colon \mathbf{C} \to \mathbf{D}$ *is a finite product preserving functor;*
- $\mathfrak{b}\colon P \to F^{\mathrm{op}} \mathbin{;} R$ *is a natural transformation;*

satisfying the following conditions:

$$\begin{tikzcd}
\mathbf{C}^{\mathrm{op}} \arrow[d, "F^{\mathrm{op}}"'] \arrow[rd, "P"] \arrow[d, phantom, shift left=12, "\mathfrak{b}\downarrow"] & \\
\mathbf{D}^{\mathrm{op}} \arrow[r, "R"'] & \mathsf{InfSl}
\end{tikzcd}$$

1. *for every object* X *of* $\mathbf{C}$*,* $\mathfrak{b}_{X \times X}(\delta_X) = \delta_{FX \times FX}$*;*
2. *for every* $\pi_X\colon X \times Y \to X$ *of* $\mathbf{C}$ *and for every* α *in* $P(X \times Y)$*,* $\exists_{F(\pi_X)} \mathfrak{b}_{X \times Y}(\alpha) = \mathfrak{b}_X(\exists_{\pi_X}(\alpha))$*.*

We write $\mathbb{EED}$ for the category of elementary and existential doctrines and morphisms.

▶ **Example 15.** The powerset functor $\mathcal{P}\colon \mathsf{Set}^{\mathrm{op}} \longrightarrow \mathsf{InfSl}$ is the archetypal example of an elementary and existential doctrine. More generally, for any regular category $\mathbf{C}$, the subobjects functor $\mathsf{Sub}_{\mathbf{C}}\colon \mathbf{C}^{\mathrm{op}} \longrightarrow \mathsf{InfSl}$ is an elementary and existential doctrine, see [45, 46]. This assignment extends to an inclusion of the category $\mathbb{REG}$ of regular categories into $\mathbb{EED}$.

▶ **Example 16.** For a cartesian bicategory $\mathbf{C}$, the functor $\mathbf{C}[-, I]\colon \mathsf{Map}(\mathbf{C})^{\mathrm{op}} \longrightarrow \mathsf{InfSl}$ is an elementary and existential doctrine, where the actions of left adjoints is given $\exists_g(f) := f \mathbin{;} g^\dagger$ [7, Thm. 20]. As we will see in §4, this assignment extends to an inclusion of $\mathbb{CB}$ into $\mathbb{EED}$.

Similarly to cartesian bicategories, elementary and existential doctrines have enough structure to deal with the notion of *functional* (or single-valued) and *entire* (total) predicates.

▶ **Definition 17** (From [44]). *Let $P\colon \mathbf{C}^{\mathrm{op}} \longrightarrow \mathsf{InfSl}$ be an elementary and existential doctrine. An element $\alpha \in P(X \times Y)$ is said to be* functional from X *to* Y *if* $P_{\langle\pi_1,\pi_2\rangle}(\alpha) \wedge P_{\langle\pi_1,\pi_3\rangle}(\alpha) \leq P_{\langle\pi_2,\pi_3\rangle}(\delta_Y)$ *in* $P(X \times Y \times Y)$. *Also, α is said to be* entire from X to Y *if* $\top_X \leq \exists_{\pi_X}(\alpha)$ *in* $P(X)$.

▶ Remark 18. By definition, a morphism of elementary and existential doctrines preserves both $\exists_{\pi_X}$ and δ_Y. Therefore it preserves functional and entire elements.

▶ **Example 19.** In $\mathcal{P}\colon \mathsf{Set}^{\mathrm{op}} \longrightarrow \mathsf{InfSl}$ from Example 15, an $\alpha \in \mathcal{P}(X \times Y)$ is functional iff it defines a partial function from X to Y, while it is entire iff it is a total relation from X to Y.

▶ **Example 20.** In the doctrine $\mathbf{C}[-,I]\colon \mathsf{Map}(\mathbf{C})^{\mathrm{op}} \longrightarrow \mathsf{InfSl}$ from Example 16, functional and entire elements are precisely maps of $\mathbf{C}$. A detailed proof is in [5, Appendix E].

We can now recall the definition of *boolean hyperdoctrine.*

▶ **Definition 21** (boolean hyperdoctrine). *Let $\mathbf{C}$ be a category with finite products. A functor $P\colon \mathbf{C}^{\mathrm{op}} \longrightarrow \mathsf{Bool}$ is a* boolean hyperdoctrine *if it is an elementary and existential doctrine.*

A morphism $(F, \mathfrak{b}) : P \to R$ of boolean hyperdoctrines is a morphism of elementary and existential doctrines such that $\mathfrak{b}_X$ is a morphism of boolean algebras for all objects X of $\mathbf{C}$. We denote by $\mathbb{BHD}$ the category of boolean hyperdoctrines and their morphisms.

It is well-known that in first-order logic the universal quantifier can be derived by the existential quantifier and the negation. The same happens in boolean hyperdoctrines: for all arrows $f\colon X \to Y$, the functor $\forall_f(-) \overset{\mathrm{def}}{=} \neg\exists_f\neg(-)$ is a right adjoint to P_f (see [5, Appendix B.1]).

▶ **Example 22.** The powerset functor $\mathcal{P}\colon \mathsf{Set}^{\mathrm{op}} \longrightarrow \mathsf{Bool}$ provides an example of a boolean hyperdoctrine. This can be generalized to an arbitrary *boolean category* $\mathbf{B}$, namely a coherent category such that every subobject has a complement, see [33, Sec. A1.4, p. 38]. The subobjects functor on $\mathbf{B}$ is a boolean hyperdoctrine $\mathsf{Sub}_{\mathbf{B}}\colon \mathbf{B}^{\mathrm{op}} \longrightarrow \mathsf{Bool}$.

▶ **Example 23.** Given a standard first-order theory Th in a first-order language $\mathcal{L}$ (for simplicity single sorted), one can consider the functor $\mathcal{L}^{\mathrm{Th}}\colon \mathcal{V}^{\mathrm{op}} \longrightarrow \mathsf{Bool}$. The base category $\mathcal{V}$ is the *syntactic* category of $\mathcal{L}$, i.e. the category where objects are natural numbers and morphisms are lists of terms, while the predicates of $\mathcal{L}^{\mathrm{Th}}(n)$ are given by equivalence classes (with respect to provable reciprocal consequence $\dashv\vdash$) of well-formed formulae with free variables in $\{x_1, \dots, x_n\}$, and the partial order is given by the provable consequences, according to the fixed theory Th. In this case, the left adjoint to the weakening functor $\mathcal{L}^{\mathrm{Th}}_{\pi}$ is computed by existentially quantifying the variables that are not involved in the substitution induced by the projection π. Dually, the right adjoint is computed by quantifying universally. The equality predicate is give by the formula $x_1 = x_2$.

▶ **Example 24.** Let A be a boolean algebra. The representable functor $\mathsf{A}^{(-)}\colon \mathsf{Set}^{\mathrm{op}} \longrightarrow \mathsf{Bool}$ assigning to a set X the poset A^X of functions from X to A with the point-wise order is a boolean hyperdoctrine.

We conclude this section with a result that, intuitively, is the analogous of Proposition 9.

▶ **Lemma 25.** *Let $P\colon \mathbf{C}^{\mathrm{op}} \longrightarrow \mathsf{Bool}$ be a boolean hyperdoctrine and $\phi \in P(X \times Y)$ a functional and entire element from X toY. For all $\psi \in P(Y \times Z)$, it holds that*

$$\exists_{\pi_{X\times Z}}(P_{\pi_{X\times Y}}(\phi) \wedge P_{\pi_{Y\times Z}}(\neg\psi)) = \neg(\,\exists_{\pi_{X\times Z}}(P_{\pi_{X\times Y}}(\phi) \wedge P_{\pi_{Y\times Z}}(\psi))\,).$$

4 An Adjunction and an Equivalence

In [7], cartesian bicategories and elementary existential doctrines are compared. The main results of [7, Thm. 28] states that there exists the following adjunction.

$$\begin{tikzcd}
\mathbb{CB} \arrow[r, hook, bend right, "\mathsf{Hml}"'] \arrow[r, phantom, "\perp"] & \mathbb{EED} \arrow[l, bend right, "\mathsf{Rel}"']
\end{tikzcd} \tag{7}$$

The embedding $\mathsf{Hml}\colon \mathbb{CB} \to \mathbb{EED}$ maps a cartesian bicategory $\mathbf{C}$ into the hom-functor $\mathbf{C}[-,I]\colon \mathsf{Map}(\mathbf{C})^{\mathrm{op}} \longrightarrow \mathsf{InfSl}$ that, as explained in Example 16, is an elementary existential doctrine. The functor $\mathsf{Rel}\colon \mathbb{EED} \to \mathbb{CB}$ is a generalisation to elementary and existential doctrines of the construction of bicategory relations associated with a regular category (see [11, Ex. 1.4]). For $P\colon \mathbf{C}^{\mathrm{op}} \longrightarrow \mathsf{InfSl}$, the cartesian bicategory $\mathsf{Rel}(P)$ is defined as follows:

- objects are those of $\mathbf{C}$; for objects X, Y, the homsets $\mathsf{Rel}(P)[X,Y]$ are the posets $P(X \times Y)$;
- the identity for an object X is the equality predicate δ_X in $P(X \times X)$;
- composition of $\phi\colon X \to Y$ and $\psi\colon Y \to Z$ is given by $\exists_{\pi_{X \times Z}}(P_{\pi_{X\times Y}}(\phi) \wedge P_{\pi_{Y \times Z}}(\psi))$.

The reader is referred to [7] or to [5, Appendix C] for further details on the adjunction in (7).

Another result in [7, Thm. 35] shows that the adjunction in (7) restricts to an equivalence

$$\mathbb{CB} \equiv \overline{\mathbb{EED}} \tag{8}$$

where $\overline{\mathbb{EED}}$ is a full subcategory of $\mathbb{EED}$ whose objects are particularly well-behaved doctrines. For the sake of readability, we will make clear in §7 what these doctrines are.

5 Peircean Bicategories

We now introduce *peircean bicategories*, an alternative presentation of fo-bicategories. The name peircean is due to the fact that, like in Peirce's algebra of relations [55], and differently from fo-bicategories, the structure of boolean algebra is taken as a primitive.

▶ **Definition 26.** *A* peircean bicategory *consists of a cartesian bicategory* $(\mathbf{C}, \blacktriangleleft^{\circ}, \blacktriangleright^{\circ})$ *such that*

1. *every homset* $\mathbf{C}[X,Y]$ *carries a Boolean algebra* $(\mathbf{C}[X,Y], \vee, \bot, \wedge, \top, \neg)$*;*
2. *for all maps* $f\colon X \to Y$ *and arrows* $c\colon Y \to Z$*,*

$$f \fatsemi \neg c = \neg(f \fatsemi c). \tag{$\neg\mathcal{M}$}$$

A morphism of peircean bicategories *is a morphism of cartesian bicategories* $F\colon \mathbf{C} \to \mathbf{D}$ *such that* $F(\neg c) = \neg F(c)$*. We write* $\mathbb{PB}$ *for the category of peircean bicategories and their morphisms.*

By Propositions 7 and 9 every fo-bicategory is a peircean bicategory. By Proposition 8 every morphism of fo-bicategories is a morphism of peircean bicategories.

Vice versa, every peircean bicategory $(\mathbf{C}, \blacktriangleleft^{\circ}, \blacktriangleright^{\circ})$ gives rise to a fo-bicategory. The black structure $(\mathbf{C}, \blacktriangleleft^{\bullet}, \blacktriangleright^{\bullet})$ is defined as expected from the white one and $\neg$. Namely:

$$\begin{array}{cccc}
c \mathbin{\overset{\bullet}{;}} d \overset{\text{def}}{=} \neg(\neg c \fatsemi \neg d) & id^{\bullet}_X \overset{\text{def}}{=} \neg id^{\circ}_X & c \mathbin{\boldsymbol{\otimes}} d \overset{\text{def}}{=} \neg(\neg c \otimes \neg d) & \sigma^{\bullet}_{X,Y} \overset{\text{def}}{=} \neg\sigma^{\circ}_{X,Y} \\
\blacktriangleleft^{\bullet}_X \overset{\text{def}}{=} \neg\blacktriangleleft^{\circ}_X & !^{\bullet}_X \overset{\text{def}}{=} \neg !^{\circ}_X & \blacktriangleright^{\bullet}_X \overset{\text{def}}{=} \neg\blacktriangleright^{\circ}_X & ¡^{\bullet}_X \overset{\text{def}}{=} \neg ¡^{\circ}_X
\end{array} \tag{9}$$

With this definition, it is immediate to see that $\neg\colon (\mathbf{C}^{\mathrm{co}}, \blacktriangleleft^{\circ}, \blacktriangleright^{\circ}) \to (\mathbf{C}, \blacktriangleleft^{\bullet}, \blacktriangleright^{\bullet})$ is an isomorphism and thus to conclude that $(\mathbf{C}, \blacktriangleleft^{\bullet}, \blacktriangleright^{\bullet})$ is a cocartesian bicategory. Proving that $(\mathbf{C}, \blacktriangleleft^{\circ}, \blacktriangleright^{\circ})$ and $(\mathbf{C}, \blacktriangleleft^{\bullet}, \blacktriangleright^{\bullet})$ give rise to a fo-bicategory is the main technical effort of this paper.

▶ **Theorem 27.** *There is an isomorphism of categories* $\mathbb{FOB} \cong \mathbb{PB}$.

Proof (sketch). As mentioned above, most of the proof is devoted to showing that every peircean bicategory is a fo-bicategory.

This is achieved by proving first that the relational operations on the homsets, like $(\cdot)^\dagger$ defined in (6), are preserved by negation, e.g. $\neg(c^\dagger) = (\neg c)^\dagger$. This is also where the property on maps ($\neg\mathcal{M}$) mostly comes into play.

Then, to prove that the axioms of fo-bicategories are satisfied, one crucially exploits the laws of boolean algebras.

Finally, to show that every morphism F of peircean bicategories is a morphism of fo-bicategories, it suffices to observe that F preserves the strucure in (9), as it preserves negation by definition.

The full diagrammatic proof can be found in [5, Appendix D]. ◀

Note that, differently from Definition 6, Definition 26 is not purely axiomatic, since ($\neg\mathcal{M}$) requires f to be a map. However, the notion of a peircean bicategory is notably more succinct than that of a fo-bicategory, making it more convenient for our purposes.

6 An Equational Presentation of Boolean Hyperdoctrines

The main purpose of this section is to establish a formal link between fo-bicategories and boolean hyperdoctrines. In particular, we are going to show that the adjunction presented in (7) restricts to an adjunction between $\mathbb{FOB}$ and $\mathbb{BHD}$. Theorem 27 allows us to conveniently work with peircean bicategories. We commence with the following result.

▶ **Proposition 28.** *Let* $\mathbf{C}$ *be a peircean bicategory. Then* $\mathsf{HmI}(\mathbf{C})$ *is a boolean hyperdoctrine.*

Proof. By (7), $\mathbf{C}[-, I] \colon \mathsf{Map}(\mathbf{C})^{\mathrm{op}} \longrightarrow \mathsf{InfSl}$ is an elementary and existential doctrine and, by definition of peircean bicategories, $\mathbf{C}[X, I]$ is a boolean algebra for all objects X. To conclude that $\mathbf{C}[-, I] \colon \mathsf{Map}(\mathbf{C})^{\mathrm{op}} \longrightarrow \mathsf{Bool}$, one has only to show that, for all maps $f \colon X \to Y$, $\mathbf{C}[f, I] \colon \mathbf{C}[Y, I] \to \mathbf{C}[X, I]$ is a morphism of boolean algebras. Since, by (7), $\mathbf{C}[f, I]$ is a morphism of inf-semilattices, it is enough to show that it preserves negation: for all $c \in \mathbf{C}[Y, I]$

$$\begin{aligned}
\mathbf{C}[f, I](\neg c) &= f \mathbin{;} \neg c && \text{(Definition of } \mathbf{C}[-, I]) \\
&= \neg(f \mathbin{;} c) && (\neg\mathcal{M}) \\
&= \neg\mathbf{C}[f, I](c) && \text{(Definition of } \mathbf{C}[-, I])
\end{aligned}$$

◀

The above proposition allows us to characterize peircean bicategories as follows:

▶ **Corollary 29.** *Let* $\mathbf{C}$ *be a cartesian bicategory. Then it is a peircean bicategory if and only if* $\mathsf{HmI}(\mathbf{C})$ *is a boolean hyperdoctrine.*

To prove that, for any boolean hyperdoctrine P, $\mathsf{Rel}(P)$ is a peircean bicategory, we need to establish a formal correspondence between Definition 2 and Definition 17.

▶ **Proposition 30.** *Let* $P \colon \mathbf{C}^{\mathrm{op}} \longrightarrow \mathsf{InfSl}$ *be an elementary and existential doctrine. Then the maps of* $\mathsf{Rel}(P)$ *are precisely the functional and entire elements of* P.

▶ **Proposition 31.** *Let* P *be a boolean hyperdoctrine. Then* $\mathsf{Rel}(P)$ *is a peircean bicategory.*

Proof. By (7), $\mathsf{Rel}(P)$ is a cartesian bicategory. Since $P(X)$ is a boolean algebra for all objects X, then each hom-set $\mathsf{Rel}(P)[X,Y]$ – by definition $P(X \times Y)$ – is a boolean algebra. To conclude that $\mathsf{Rel}(P)$ is a peircean bicategory, it is enough to show that $(\neg\mathcal{M})$ holds, that is

$$\phi \fatsemi \neg\psi = \neg(\phi \fatsemi \psi)$$

for all maps $\phi \in \mathsf{Rel}(P)[X,Y]$ and arrows $\psi \in \mathsf{Rel}(P)[Y,Z]$. By Proposition 30, ϕ is a functional and entire element of P. Thus, one can rely on Lemma 25 to conclude that

$$\begin{aligned} \phi \fatsemi \neg\psi &= \exists_{\pi_{X\times Z}}(P_{\pi_{X\times Y}}(\phi) \wedge P_{\pi_{Y\times Z}}(\neg\psi)) && \text{(Defintion of } \mathsf{Rel}(P)) \\ &= \neg(\, \exists_{\pi_{X\times Z}}(P_{\pi_{X\times Y}}(\phi) \wedge P_{\pi_{Y\times Z}}(\psi))\,) && \text{(Lemma 25)} \\ &= \neg(\phi \fatsemi \psi) && \text{(Defintion of } \mathsf{Rel}(P)) \end{aligned}$$

◀

By Propositions 28 and 31 proving the following result amounts to a few routine checks.

▶ **Theorem 32.** *The adjunction in* (7)*, restricts to the adjunction below on the left.*

$$\begin{tikzcd} \mathbb{PB} \arrow[r, bend right, "\mathsf{Hml}"'] \arrow[r, phantom, "\perp"] & \mathbb{BHD} \arrow[l, bend right, "\mathsf{Rel}"'] \end{tikzcd}$$

Thus, by Theorem 27, there is an adjunction $\begin{tikzcd} \mathbb{FOB} \arrow[r, bend right] \arrow[r, phantom, "\perp"] & \mathbb{BHD} \arrow[l, bend right] \end{tikzcd}$ *.*

Proof. First, we want to prove that the inclusion $\mathsf{Hml}\colon \mathbb{CB} \hookrightarrow \mathbb{EED}$ in (7) restricts to an inclusion of categories $\mathbb{PB} \hookrightarrow \mathbb{BHD}$. By Proposition 28, one only needs to check for morphisms in $\mathbb{PB}$. Given a morphism of peircean bicategories $F\colon \mathbf{C} \to \mathbf{D}$, $\mathsf{Hml}(F)$ is the morphism of elementary and existential doctrines $(\tilde{F}, \mathfrak{b}^F)$ defined in Section 4. In order to conclude that it is a morphism of boolean doctrines, it is enough to show that $\mathfrak{b}^F_X$ is a morphism of boolean algebras for all objects X. Since $(\tilde{F}, \mathfrak{b}^F)$ is a morphism of doctrines, $\mathfrak{b}^F_X$ is a morphism of inf-semilattices. Thus it is enough to show that $\mathfrak{b}^F_X$ preserve negation. But this is trivial since, for all $c \in \mathbf{C}[X, I]$,

$$\begin{aligned} \mathfrak{b}^F_X(\neg c) &= F(\neg c) && \text{(Def. } \mathfrak{b}^F) \\ &= \neg F(c) && \text{(morphism of Peircean, Definition 26)} \\ &= \neg \mathfrak{b}^F_X(c) && \text{(Def. } \mathfrak{b}^F) \end{aligned}$$

Now, to prove that Rel restrict to a functor $\mathsf{Rel}\colon \mathbb{BHD} \to \mathbb{PB}$, by Proposition 31, one only needs to check that for all morphisms of boolean hyperdoctrines $(F, \mathfrak{b})\colon P \to Q$, $\mathsf{Rel}(F, \mathfrak{b})\colon \mathsf{Rel}(P) \to \mathsf{Rel}(Q)$ is a morphism of peicean bicategories. Since by (7), $\mathsf{Rel}(F, \mathfrak{b})$ is a morphism of cartesian bicategories, one only needs to check that it preserves the negation. But this is obvious since for all arrows $\phi \in \mathsf{Rel}(P)[X,Y]$, $\mathsf{Rel}(F, \mathfrak{b})(\phi)$ is – by definition – $\mathfrak{b}_{X\times Y}(\phi)$ and $\mathfrak{b}_{X\times Y}$ is a morphism of boolean algebras.

To conclude, one only needs to check the unit and the counit of the adjunction in (7). The counit is an isomorphism of cartesian bicategories (see Equation (9) in [7]), and then it provides an isomorphism of peircean bicategories $\mathbf{C} \cong \mathsf{Rel}(\mathbf{C}[-, I])$ whenever $\mathbf{C}$ is a peircean bicategory. The unit of the adjunction $\eta_P\colon P \to \mathsf{Rel}(P)[-, I]$ is the morphism of elementary and existential doctrines (Γ_P, ρ) illustrated in [7, Section 7] or [5, Appendix C]. To conclude that η_P is a morphism of boolean hyperdoctrine whenever P is a boolean hyperdoctrine, one has only to prove that ρ is a morphism of boolean algebras, but this is trivial since ρ is always an isomorphism of inf-semilattices. ◀

7 Boolean Hyperdoctrines Representing First-Order Bicategories

As anticipated in §4, the adjunction in (7) becomes an equivalence for certain well-behaved doctrines. Definitions 33 and 34 state the conditions that such doctrines must satisfy.

▶ **Definition 33.** *An elementary and existential doctrine $P\colon \mathbf{C}^{\text{op}} \longrightarrow \mathsf{InfSl}$ has* comprehensive diagonals *if for the equality predicate $\delta_X \in P(X)$ it holds that $P_{\Delta_X}(\delta_X) = \top_X$ and every arrow $f\colon Y \to X \times X$ such that $P_f(\delta_X) = \top_Y$ factors (uniquely) through Δ_X .*

Intuitively, a doctrine has comprehensive diagonals if its equality is *extensional*, namely if a formula $t_1 = t_2$ is true, then the terms t_1 and t_2 are syntactically equal. In the language of cartesian bicategories, for two maps t_1, t_2, this can be stated by means of diagrams as

(10)

While it is sometimes meaningful to consider syntactic doctrines (e.g. Example 23) in which the equality is not extensional, in several semantical doctrines this condition is satisfied.

▶ **Definition 34.** *Let $P\colon \mathbf{C}^{\text{op}} \longrightarrow \mathsf{InfSl}$ be an elementary existential doctrine. We say that P satisfies the* Rule of Unique Choice *(RUC) if for every entire functional element ϕ in $P(X \times Y)$ there exists an arrow $f\colon X \to Y$ such that $\top_X \leq P_{\langle id_X^\circ, f\rangle}(\phi)$.*

The reader can think that a doctrine has (RUC) if for every element (intuitively formula) that is entire and functional, there exists an arrow in $\mathbf{C}$ (intuitively a term) that represents it.

▶ **Example 35.** The doctrine $\mathcal{P}\colon \mathsf{Set}^{\text{op}} \longrightarrow \mathsf{InfSl}$ has comprehensive diagonals, and it satisfies the (RUC) (since every functional and total relation can be represented by a function). More generally, every subobject doctrine $\mathsf{Sub}_{\mathbf{C}}\colon \mathbf{C}^{\text{op}} \longrightarrow \mathsf{InfSl}$ on a regular category, as presented in Example 15 satisfies the (RUC) and it has comprehensive diagonals, as observed in [44].

▶ **Example 36.** The doctrine $\mathbf{C}[-, I]\colon \mathsf{Map}(\mathbf{C})^{\text{op}} \longrightarrow \mathsf{InfSl}$ presented in Example 16 satisfies the (RUC) and it has comprehensive diagonals, as proved in [7]. The reader can find a diagrammatic proof of (10) in [5, Appendix A].

Hereafter – and in the equivalence in (8) – $\overline{\mathbb{EED}}$ is the full subcategory of $\mathbb{EED}$ whose objects are doctrines satisfying (RUC) and with comprehensive diagonals. Similarly $\overline{\mathbb{BHD}}$ is the full subcategory of $\mathbb{BHD}$ whose objects are boolean hyperdoctrines satisfying (RUC) and with comprehensive diagonals.

By means of Theorem 32, it is easy to prove that the equivalence in (8) restricts as follows.

▶ **Theorem 37.** $\mathbb{PB} \equiv \overline{\mathbb{BHD}}$ *and thus, by Theorem 27,* $\mathbb{FOB} \equiv \overline{\mathbb{BHD}}$*.*

Proof. By Equation (8) we have that the Hml and Rel functors provide an equivalence between the categories $\mathbb{CB}$ and $\overline{\mathbb{EED}}$. Now, since every peircean category is in particular a cartesian bicategory, we have that every boolean hyperdoctrine arising from a peircean bicategory satisfies (RUC) and it has comprehensive diagonals. Then, we have that the functor $\mathsf{Hml}\colon \mathbb{PB} \hookrightarrow \mathbb{BHD}$ factors through the canonical inclusion $\overline{\mathbb{BHD}} \hookrightarrow \mathbb{BHD}$:

$$\begin{tikzcd}
\mathbb{PB} \arrow[rr, hook, "\mathsf{Hml}"] \arrow[dr, hook, "\mathsf{Hml}"'] & & \mathbb{BHD} \\
& \overline{\mathbb{BHD}} \arrow[ur, hook] &
\end{tikzcd}$$

By Theorem 32, we have that $\mathsf{Hml}\colon \mathbb{PB} \hookrightarrow \mathbb{BHD}$ is fully and faithful (since the counit of the adjunction is an iso), so it remains to prove that it is essentially surjective (with respect to the objects of $\overline{\mathbb{BHD}}$). By the equivalence presented in Equation (8), we know that every boolean hyperdoctrine (that is in particular an elementary and existential doctrine) satisfying (RUC) and having comprehensive diagonals, is isomorphic to an elementary and existential doctrine $\mathbf{C}[-, I]\colon \mathsf{Map}(\mathbf{C})^{\mathrm{op}} \longrightarrow \mathsf{InfSl}$ for some cartesian bicategory $\mathbf{C}$. Thus, we can conclude that $\mathbf{C}[-, I]\colon \mathsf{Map}(\mathbf{C})^{\mathrm{op}} \longrightarrow \mathsf{InfSl}$ is a boolean hyperdoctrine and, by Corollary 29, that $\mathbf{C}$ is a peircean bicategory. This concludes the proof that $\mathbb{PB} \equiv \overline{\mathbb{BHD}}$. ◀

8 Related Work

There exists many structures that are closely related to fo-bicategories, as discussed in [3]. The introduction of peircean bicategory in § 5 provide clearer correspondences with such structures. Here we discuss some of them.

Boolean hyperdoctrines are used in [10] as a categorical treatment of another work of Peirce: *existential graphs* [64]. While the latter share some similarities with the graphical language of fo-bicategories there is one notable difference: negation is a primitive operator rather than a derived one, as it happens for instance also in [25] and Definition 26. In [3] and in §5, it is emphasised how this choice makes the resulting calculus less algebraic in flavour, having to deal with convoluted rules such as the one for (de)iteration or properties which are not purely equational, such as $(\neg\mathcal{M})$.

Inspired by [10], another graphical language [50] akin to Peirce's graphs is based on a decomposition of a hyperdoctrine into a bifibration. In this work, the categorical treatment revolves around the notion of monoidal *chiralities* [49], which are much more closer in spirit to fo-bicategories. We believe that our results might set an initial step towards a connection between fo-bicategories and chiralities.

A recent work [15] proposes a relational understanding of doctrines. However, these corresponds to the regular fragment of first-order logic, and thus it might by intriguing to understand the role of the additional black structure of first-order bicategories in this setting. Another route, suggested by the equivalence in Theorem 37, might be to understand the role of $(\neg\mathcal{M})$ in relational doctrines with boolean fibres.

Finally, it is also worth remarking that peircean bicategories, as well as fo-bicategories, are poset-enriched categories. Such categorical treatements of first-order logic are also found in works such as [30, 23], along with the references therein. Their primary focus, though, is on the categorical approach to classical proof theory instead of semantics.

9 Conclusions and Future Work

Theorems 32 and 37 provide a solid bridge between functional and relational approaches to classical logic. The former rely on categorical structures that are usually defined by means of exactness properties; the latter on fo-bicategories which enjoy a purely equational presentation, much in the spirit of Boole's algebra and Peirce's calulus.

To achieve our result, we found it extremely convenient to introduce the notion of peircean bicategories that, by Theorem 27, provide a far handier characterisation of fo-bicategories.

Theorem 27 might also be useful to establish a correspondence with *allegories* [22]: since cartesian bicategories are equivalent to unitary pretabular allegories [35], we expect that such allegories where, additionally, homsets carry boolean algebras satisfying $(\neg\mathcal{M})$ are equivalent to fo-bicategories. Despite searching the literature, we did not find analogous structures. Interestingly, the property $(\neg\mathcal{M})$ can be proven in any Peirce allegories, as shown in Proposition 4.6.1 in [53].

Finally, as future work we aim to investigate how our characterizations can be extended to higher-order classical logic, which is categorically represented through the notion of *tripos* [29, 57]. Indeed, we believe that the constructions and results presented in this work, together with the notion of tripos, can serve as a guide for defining a variant of fo-bicategories – hopefully, purely equational – capable of representing higher-order classical logic.

Abstract

The notion of Lyndon word and Lyndon factorization has shown to have unexpected applications in theory as well as in developing novel algorithms on words. A counterpart to these notions are those of inverse Lyndon word and inverse Lyndon factorization. Differently from the Lyndon words, the inverse Lyndon words may be bordered. The relationship between the two factorizations is related to the inverse lexicographic ordering, and has only been recently explored. More precisely, a main open question is how to get an inverse Lyndon factorization from a classical Lyndon factorization under the inverse lexicographic ordering, named CFL_{in}. In this paper we reveal a strong connection between these two factorizations where the border plays a relevant role. More precisely, we show two main results. We say that a factorization has the border property if a nonempty border of a factor cannot be a prefix of the next factor. First we show that there exists a unique inverse Lyndon factorization having the border property. Then we show that this unique factorization with the border property is the so-called canonical inverse Lyndon factorization, named ICFL. By showing that ICFL is obtained by compacting factors of the Lyndon factorization over the inverse lexicographic ordering, we provide a linear time algorithm for computing ICFL from CFL_{in}.

1 Introduction

The theoretical investigation of combinatorial properties of well-known word factorizations is a research topic that recently have witnessed special interest especially for improving the efficiency of algorithms [5]. Among these, the *Lyndon Factorization* introduced by Chen, Fox, Lyndon in [12], named CFL, undoubtedly stands. Any word w admits a unique factorization CFL(w), that is a lexicographically non-increasing sequence of factors which are *Lyndon words*. A Lyndon word w is strictly lexicographically smaller than each of its proper cyclic shifts, or, equivalently, than each of its nonempty proper suffixes [24]. Interesting applications of the use of the Lyndon factorization and Lyndon words are the development of the bijective Burrows-Wheeler Transforms [2, 6, 21] and a novel algorithm for sorting suffixes [5]. In particular, the notion of a Lyndon word has been re-discovered various times as a theoretical tool to locate short motifs [15] and relevant k-mers in bioinformatics applications [26]. In this line of research, Lyndon-based word factorizations have been explored to define a novel feature representation for biological sequences based on theoretical combinatorial properties proved to capture sequence similarities [7].

The notion of a *Lyndon word* has a counterpart that is the notion of an *inverse Lyndon word*, i.e., a word lexicographically greater than its suffixes. Inverting the relation between a word and its suffixes, as between Lyndon words and inverse Lyndon words, leads to different properties. Indeed, although a word could admit more than one *inverse Lyndon factorization*, that is a factorization into a nonincreasing product of *inverse Lyndon words*, in [8] the *Canonical Inverse Lyndon Factorization*, named ICFL, was introduced. ICFL maintains the main properties of CFL: it is unique and can be computed in linear time. In addition, it maintains a similar *Compatibility Property*, used for obtaining the sorting of the suffixes of w ("global suffixes") by using the sorting of the suffixes of each factor of CFL(w) ("local suffixes") [25]. Most notably, ICFL(w) has another interesting property [8, 9, 10]: we can provide an upper bound on the length of the longest common prefix of two substrings of a word w starting from different positions.

A relationship between ICFL(w) and CFL(w) has been proved by using the notion of *grouping* [8]. First, let $\mathrm{CFL}_{in}(w)$ be the Lyndon factorization of w with respect to the inverse lexicographic order, it is proved that ICFL(w) is obtained by concatenating the factors of a non-increasing maximal chain with respect to the prefix order, denoted by $\mathcal{PMC}_w$, in $\mathrm{CFL}_{in}(w)$ (see Section 6). Despite this result, the connection between $\mathrm{CFL}_{in}(w)$ and the inverse Lyndon factorization still remained obscure, mainly by the fact that a word may have multiple inverse Lyndon factorizations.

In this paper, we explore this connection between CFL_{in} and the inverse Lyndon factorizations. Our first main contribution consists in showing that there is a unique inverse Lyndon factorization of a word that has *border property*. The border property states that any nonempty border of a factor cannot be a prefix of the next factor. We further highlight the aforementioned connection by proving that the inverse Lyndon factorization with the border property is a *compact* factorization (Definition 6.7), i.e., each inverse Lyndon factor is the concatenation of *compact factors*. In turn, a compact factor is the concatenation of the longest sequence of identical words in a $\mathcal{PMC}$. We then show the second contribution of this paper: this unique factorization is ICFL itself and then provide a simpler linear time algorithm for computing ICFL. Our algorithm is based on a new property that characterizes ICFL(w): the last factor in ICFL(w) is the longest suffix of w that is an inverse Lyndon word. Recall that the Lyndon factorization of w has a similar property: the last factor is the longest suffix of w that is a Lyndon word.

2 Words

Throughout this paper we follow [4, 13, 22, 23, 27] for the notations. We denote by Σ^* the *free monoid* generated by a finite alphabet Σ and we set $\Sigma^+ = \Sigma^* \setminus \{1\}$, where 1 is the empty word. For a word $w \in \Sigma^*$, we denote by $|w|$ its *length*. A word $x \in \Sigma^*$ is a *factor* of $w \in \Sigma^*$ if there are $u_1, u_2 \in \Sigma^*$ such that $w = u_1 x u_2$. If $u_1 = 1$ (resp. $u_2 = 1$), then x is a *prefix* (resp. *suffix*) of w. A factor (resp. prefix, suffix) x of w is *proper* if $x \neq w$. Two words x, y are *incomparable* for the prefix order, denoted as $x \bowtie y$, if neither x is a prefix of y nor y is a prefix of x. Otherwise, x, y are *comparable* for the prefix order. We write $x \leq_p y$ if x is a prefix of y and $x \geq_p y$ if y is a prefix of x. The notion of a pair of words comparable (or incomparable) for the suffix order is defined symmetrically.

We recall that, given a nonempty word w, a *border* of w is a word which is both a proper prefix and a suffix of w [14]. The longest proper prefix of w which is a suffix of w is also called *the border* of w [14, 23]. A word $w \in \Sigma^+$ is *bordered* if it has a nonempty border. Otherwise, w is *unbordered*. A nonempty word w is *primitive* if $w = x^k$ implies $k = 1$. An unbordered word is primitive. A *sesquipower* of a word x is a word $w = x^n p$ where p is a proper prefix of x and $n \geq 1$. Two words x, y are called *conjugate* if there exist words u, v such that $x = uv, y = vu$. The conjugacy relation is an equivalence relation. A conjugacy class is a class of this equivalence relation.

▶ **Definition 2.1.** *Let $(\Sigma, <)$ be a totally ordered alphabet. The lexicographic (or alphabetic order) $\prec$ on $(\Sigma^*, <)$ is defined by setting $x \prec y$ if*

- *x is a proper prefix of y, or*
- *$x = ras$, $y = rbt$, $a < b$, for $a, b \in \Sigma$ and $r, s, t \in \Sigma^*$.*

In the next part of the paper we will implicitly refer to totally ordered alphabets. For two nonempty words x, y, we write $x \ll y$ if $x \prec y$ and x is not a proper prefix of y [3]. We also write $y \succ x$ if $x \prec y$. Basic properties of the lexicographic order are recalled below.

▶ **Lemma 2.2.** *For $x, y \in \Sigma^+$, the following properties hold.*

(1) *$x \prec y$ if and only if $zx \prec zy$, for every word z.*
(2) *If $x \ll y$, then $xu \ll yv$ for all words u, v.*
(3) *If $x \prec y \prec xz$ for a word z, then $y = xy'$ for some word y' such that $y' \prec z$.*
(4) *If $x \ll y$ and $y \ll z$, then $x \ll z$.*

Let t, j, r_j be positive integers, with $1 \leq j \leq t$. Let $\mathcal{S}_1, \ldots, \mathcal{S}_t$ be sequences, with $\mathcal{S}_j = (s_{j,1}, \ldots, s_{j,r_j})$. We let $(\mathcal{S}_1, \ldots, \mathcal{S}_t)$ stand for the sequence $(s_{1,1}, \ldots, s_{1,r_1}, \ldots, s_{t,1}, \ldots, s_{t,r_t})$.

3 Lyndon words

▶ **Definition 3.1.** *A Lyndon word $w \in \Sigma^+$ is a word which is primitive and the smallest one in its conjugacy class for the lexicographic order.*

▶ **Example 3.2.** Let $\Sigma = \{a, b\}$ with $a < b$. The words a, b, $aaab$, $abbb$, $aabab$ and $aababaabb$ are Lyndon words. On the contrary, $abab$, aba and $abaab$ are not Lyndon words.

▶ **Proposition 3.3.** *Each Lyndon word w is unbordered.*

A class of conjugacy is also called a *necklace* and often identified with the minimal word for the lexicographic order in it. We will adopt this terminology. Then a word is a necklace if and only if it is a power of a Lyndon word. A *prenecklace* is a prefix of a necklace. Then clearly any nonempty prenecklace w has the form $w = (uv)^k u$, where uv is a Lyndon word, $u \in \Sigma^*$, $v \in \Sigma^+$, $k \geq 1$, that is, w is a sesquipower of a Lyndon word uv. The following result has been proved in [16]. It shows that the nonempty prefixes of Lyndon words are exactly the nonempty prefixes of the powers of Lyndon words with the exclusion of c^k, where c is the maximal letter and $k \geq 2$.

▶ **Proposition 3.4.** *A word is a nonempty prefix of a Lyndon word if and only if it is a sesquipower of a Lyndon word distinct of c^k, where c is the maximal letter and $k \geq 2$.*

In the following $L = L_{(\Sigma^*,<)}$ will be the set of Lyndon words, totally ordered by the relation $\prec$ on $(\Sigma^*,<)$.

▶ **Theorem 3.5.** *Any word $w \in \Sigma^+$ can be written in a unique way as a nonincreasing product $w = \ell_1 \ell_2 \cdots \ell_h$ of Lyndon words, i.e., in the form*

$$w \quad = \quad \ell_1 \ell_2 \cdots \ell_h, \ \text{with } \ell_j \in L \text{ and } \ell_1 \succeq \ell_2 \succeq \ldots \succeq \ell_h \tag{3.1}$$

The sequence $\mathrm{CFL}(w) = (\ell_1, \ldots, \ell_h)$ in Eq. (3.1) is called the *Lyndon decomposition* (or *Lyndon factorization*) of w. It is denoted by $\mathrm{CFL}(w)$ because Theorem 3.5 is usually credited to Chen, Fox and Lyndon [12]. The following result, proved in [16], is necessary for our aims.

▶ **Corollary 3.6.** *Let $w \in \Sigma^+$, let ℓ_1 be its longest prefix which is a Lyndon word and let w' be such that $w = \ell_1 w'$. If $w' \neq 1$, then $\mathrm{CFL}(w) = (\ell_1, \mathrm{CFL}(w'))$.*

Sometimes we need to emphasize consecutive equal factors in CFL. We write $\mathrm{CFL}(w) = (\ell_1^{n_1}, \ldots, \ell_r^{n_r})$ to denote a tuple of $n_1 + \ldots + n_r$ Lyndon words, where $r > 0$, $n_1, \ldots, n_r \geq 1$. Precisely $\ell_1 \succ \ldots \succ \ell_r$ are Lyndon words, also named *Lyndon factors* of w. There is a linear time algorithm to compute the pair (ℓ_1, n_1) and thus, by iteration, the Lyndon factorization of w [17, 23]. Linear time algorithms may also be found in [16] and in the more recent paper [19].

4 Inverse Lyndon words

For the material in this section see [8, 9, 10]. Inverse Lyndon words are related to the inverse alphabetic order. Their definition is recalled below.

▶ **Definition 4.1.** *Let $(\Sigma, <)$ be a totally ordered alphabet. The* inverse $<_{in}$ *of $<$ is defined by*

$$\forall a, b \in \Sigma \quad b <_{in} a \Leftrightarrow a < b$$

The inverse lexicographic *or* inverse alphabetic order *on $(\Sigma^*, <)$, denoted $\prec_{in}$, is the lexicographic order on $(\Sigma^*, <_{in})$.*

▶ **Example 4.2.** Let $\Sigma = \{a, b, c, d\}$ with $a < b < c < d$. Then $dab \prec dabd$ and $dabda \prec dac$. We have $d <_{in} c <_{in} b <_{in} a$. Therefore $dab \prec_{in} dabd$ and $dac \prec_{in} dabda$.

Of course for all $x, y \in \Sigma^*$ such that $x \bowtie y$,

$$y \prec_{in} x \Leftrightarrow x \prec y.$$

Moreover, in this case $x \ll y$. This justifies the adopted terminology.

From now on, $L_{in} = L_{(\Sigma^*,<_{in})}$ denotes the set of the Lyndon words on Σ^* with respect to the inverse lexicographic order. Following [18], a word $w \in L_{in}$ will be named an *anti-Lyndon word*. Correspondingly, an *anti-prenecklace* will be a prefix of an *anti-necklace*, which in turn will be a necklace with respect to the inverse lexicographic order.

In the following, we denote by $\mathrm{CFL}_{in}(w)$ the Lyndon factorization of w with respect to the inverse order $<_{in}$.

▶ **Definition 4.3.** *A word $w \in \Sigma^+$ is an inverse Lyndon word if $s \prec w$, for each nonempty proper suffix s of w.*

▶ **Example 4.4.** The words a, b, $aaaaa$, $bbba$, $baaab$, $bbaba$ and $bbababbaa$ are inverse Lyndon words on $\{a, b\}$, with $a < b$. On the contrary, $aaba$ is not an inverse Lyndon word since $aaba \prec ba$. Analogously, $aabba \prec ba$ and thus $aabba$ is not an inverse Lyndon word.

The following result, proved in [8, 10], and also in [11], summarizes some properties of the inverse Lyndon words.

▶ **Proposition 4.5.** *Let $w \in \Sigma^+$. Then we have*

1. *The word w is an anti-Lyndon word if and only if it is an unbordered inverse Lyndon word.*
2. *The word w is an inverse Lyndon word if and only if w is a nonempty anti-prenecklace.*
3. *If w is an inverse Lyndon word, then any nonempty prefix of w is an inverse Lyndon word.*

▶ **Definition 4.6.** *An inverse Lyndon factorization of a word $w \in \Sigma^+$ is a sequence $(m_1, \ldots, m_k)$ of inverse Lyndon words such that $m_1 \cdots m_k = w$ and $m_i \ll m_{i+1}$, $1 \leq i \leq k-1$.*

As the following example in [8] shows, a word may have different inverse Lyndon factorizations.

▶ **Example 4.7.** Let $\Sigma = \{a, b, c, d\}$ with $a < b < c < d$, $z = dabdadacddbdc$. It is easy to see that $(dab, dadacd, db, dc)$, $(dabda, dac, ddbdc)$, $(dab, dadac, ddbdc)$ are all inverse Lyndon factorizations of z.

5 The border property

In this section we prove the main result of this paper, namely, for any nonempty word w, there exists a unique inverse Lyndon factorization of w which has a special property, named the border property.

▶ **Definition 5.1** (Border property)**.** *Let $w \in \Sigma^+$. A factorization $(m_1, \ldots, m_k)$ of w* has the border property *if each nonempty border z of m_i is not a prefix of m_{i+1}, $1 \leq i \leq k-1$.*

We first prove a fundamental property of the inverse Lyndon factorizations of w which have the border property.

▶ **Lemma 5.2.** *Let $w \in \Sigma^+$, let $(m_1, \ldots, m_k)$ be an inverse Lyndon factorization of w having the border property. If α is a nonempty border of m_j, $1 \leq j \leq k-1$, then there exists a nonempty prefix β of m_{j+1} such that $|\beta| \leq |\alpha|$ and $\alpha \ll \beta$.*

Proof. Let $w \in \Sigma^+$, let $(m_1, \ldots, m_k)$ be an inverse Lyndon factorization of w having the border property, let α be a nonempty border of m_j, $1 \leq j \leq k-1$. We distinguish two cases: either $|m_{j+1}| < |\alpha|$ or $|m_{j+1}| \geq |\alpha|$.

Assume $|m_{j+1}| < |\alpha|$. By hypothesis $(m_1, \ldots, m_k)$ is an inverse Lyndon factorization, hence $m_j \ll m_{j+1}$, that is, there are $r, s, t \in \Sigma^*$, $a, b \in \Sigma$, such that $a < b$ and $m_j = ras$, $m_{j+1} = rbt$. Obviously $|ra| \leq |m_{j+1}| < |\alpha|$, thus there is $s' \in \Sigma^*$ such that $\alpha = ras'$. Consequently, $\alpha = ras' \ll rbt = m_{j+1}$ and our claim holds with $\beta = m_{j+1}$.

Assume $|m_{j+1}| \geq |\alpha|$. Let β be the nonempty prefix of m_{j+1} such that $|\beta| = |\alpha|$. Clearly $\beta \neq \alpha$ because $(m_1, \ldots, m_k)$ has the border property. Since α and β are two different nonempty words of the same length, either $\beta \ll \alpha$ or $\alpha \ll \beta$. The first case leads to a contradiction because if $\beta \ll \alpha$, then $m_{j+1} \ll m_j$ by Lemma 2.2 and this contradicts the fact that $(m_1, \ldots, m_k)$ is an inverse Lyndon factorization. Thus, $\alpha \ll \beta$ and the proof is complete. ◀

▶ **Proposition 5.3.** *For each $w \in \Sigma^+$, there exists a unique inverse Lyndon factorization of w having the border property.*

Proof. The proof is by induction on $|w|$. If $|w| = 1$, then the statement clearly holds. Thus assume $|w| > 1$. Let $F_1(w) = (f_1, \ldots, f_k)$ and $F_2(w) = (f'_1, \ldots, f'_v)$ be two inverse Lyndon factorizations of w having the border property. Thus

$$f_1 \cdots f_k = f'_1 \cdots f'_v = w \tag{5.1}$$

If $|f_k| = |f'_v|$ and $v = 1$ or $k = 1$, clearly $f_k = f'_v$ and $F_1(w) = F_2(w)$. Analogously, if $|f_k| = |f'_v|$, $v > 1$ and $k > 1$, then $f_k = f'_v$ and $F'_1(w') = (f_1, \ldots, f_{k-1})$, $F'_2(w') = (f'_1, \ldots, f'_{v-1})$ would be two inverse Lyndon factorizations of w' having the border property, where w' is such that $w = w' f_k$. Of course, $|w'| < |w|$. By induction hypothesis, $F'_1(w') = F'_2(w')$, hence $F_1(w) = F_2(w)$.

By contradiction, let $|f_k| \neq |f'_v|$. Assume $|f_k| < |f'_v|$ (similar arguments apply if $|f_k| > |f'_v|$). The word f_k is a proper suffix of f'_v. Clearly $k > 1$. Let g be the smallest integer such that $f_{g+1} \cdots f_k$ is a proper suffix of f'_v, $1 \leq g \leq k-1$, that is,

$$f'_v = \alpha f_{g+1} \cdots f_k \tag{5.2}$$

where $\alpha \in \Sigma^+$ is a suffix of f_g.

Notice that

$$\alpha \not\ll f_{g+1}. \tag{5.3}$$

Indeed, if $\alpha \ll f_{g+1}$, then, by Eq. (5.2), we would have $f'_v = \alpha f_{g+1} \cdots f_k \ll f_{g+1} \cdots f_k$, which is impossible because f'_v is an inverse Lyndon word.

The word α is a nonempty proper suffix of f_g since otherwise we would have $\alpha = f_g \ll f_{g+1}$, contrary to Eq. (5.3). Since f_g is an inverse Lyndon word and α is a nonempty proper suffix of f_g, either $\alpha \leq_p f_g$ or $\alpha \ll f_g$.

If $\alpha \leq_p f_g$, then α is a nonempty border of f_g, then, by Lemma 5.2, there exists a nonempty prefix β of f_{g+1} such that $|\beta| \leq |\alpha|$ and $\alpha \ll \beta$. Thus, $\alpha \ll f_{g+1}$ which contradicts Eq. (5.3). Assume $\alpha \ll f_g$. Since $f_g \ll f_{g+1}$, by Lemma 2.2 we have $\alpha \ll f_{g+1}$ which contradicts once again Eq. (5.3). This finishes the proof. ◀

▶ **Example 5.4.** Let $\Sigma = \{a, b, c, d\}$ with $a < b < c < d$, let $z = dabdadacddbdc$. Notice that only the last one of the inverse Lyndon factorizations of z from Example 4.7 fulfils the border property, and the others do not.

6 Groupings and compact factorizations

In this section we prove a structural property of an inverse Lyndon factorization having the border property, namely it is a *compact factorization*. This result is crucial to characterize the relationship between $\mathrm{CFL}_{in}(w)$ and the factorization into inverse Lyndon words of w. First we report the notion of *grouping* given in [8]. We refer to [8, 10] for a detailed and complete discussion on this topic.

Let $\mathrm{CFL}_{in}(w) = (\ell_1, \ldots, \ell_h)$, where $\ell_1 \succeq_{in} \ell_2 \succeq_{in} \ldots \succeq_{in} \ell_h$. Consider the partial order $\geq_p$, where $x \geq_p y$ if y is a prefix of x. Recall that a *chain* is a set of a pairwise comparable elements. We say that a chain is maximal if it is not strictly contained in any other chain. A non-increasing *(maximal) chain* in $\mathrm{CFL}_{in}(w)$ is the sequence corresponding to a (maximal) chain in the multiset $\{\ell_1, \dots, \ell_h\}$ with respect to $\geq_p$. We denote by $\mathcal{PMC}_w$, or simply $\mathcal{PMC}$ when it is understood, a non-increasing maximal chain in $\mathrm{CFL}_{in}(w)$. Looking at the definition of the (inverse) lexicographic order, it is easy to see that a $\mathcal{PMC}$ is a sequence of consecutive factors in $\mathrm{CFL}_{in}(w)$. Moreover $\mathrm{CFL}_{in}(w)$ is the concatenation of its $\mathcal{PMC}$. The formal definitions are given below.

▶ **Definition 6.1.** *Let $w \in \Sigma^+$, let $\mathrm{CFL}_{in}(w) = (\ell_1, \dots, \ell_h)$ and let $1 \leq r < s \leq h$. We say that $\ell_r, \ell_{r+1}, \dots, \ell_s$ is a non-increasing* maximal chain for the prefix order *in $\mathrm{CFL}_{in}(w)$, abbreviated $\mathcal{PMC}$, if $\ell_r \geq_p \ell_{r+1} \geq_p \dots \geq_p \ell_s$. Moreover, if $r > 1$, then $\ell_{r-1} \not\geq_p \ell_r$, if $s < h$, then $\ell_s \not\geq_p \ell_{s+1}$. Two $\mathcal{PMC}$ $\mathcal{C}_1 = \ell_r, \ell_{r+1}, \dots, \ell_s$, $\mathcal{C}_2 = \ell_{r'}, \ell_{r'+1}, \dots, \ell_{s'}$ are* consecutive *if $r' = s + 1$ (or $r = s' + 1$).*

▶ **Definition 6.2.** *Let $w \in \Sigma^+$, let $\mathrm{CFL}_{in}(w) = (\ell_1, \dots, \ell_h)$. We say that $(\mathcal{C}_1, \mathcal{C}_2, \dots, \mathcal{C}_s)$ is* the decomposition *of $\mathrm{CFL}_{in}(w)$ into its non-increasing maximal chains for the prefix order if the following holds*

(1) *Each $\mathcal{C}_j$ is a non-increasing maximal chain in $\mathrm{CFL}_{in}(w)$.*

(2) *$\mathcal{C}_j$ and $\mathcal{C}_{j+1}$ are consecutive, $1 \leq j \leq s - 1$.*

(3) *$\mathrm{CFL}_{in}(w)$ is the concatenation of the sequences $\mathcal{C}_1, \mathcal{C}_2, \dots, \mathcal{C}_s$.*

▶ **Definition 6.3.** *Let $w \in \Sigma^+$. We say that $(m_1, \dots, m_k)$ is a* grouping *of $\mathrm{CFL}_{in}(w)$ if the following holds*

(1) *$(m_1, \dots, m_k)$ is an inverse Lyndon factorization of w*

(2) *Each factor m_j, is the product of consecutive factors in a $\mathcal{PMC}$ in $\mathrm{CFL}_{in}(w)$.*

▶ **Example 6.4.** Let $\Sigma = \{a, b, c, d\}$, $a < b < c < d$, and $w = dabadabdabdadac$. We have $\mathrm{CFL}_{in}(w) = (daba, dab, dab, dadac)$. The decomposition of $\mathrm{CFL}_{in}(w)$ into its $\mathcal{PMC}$ is $((daba, dab, dab), (dadac))$. Moreover, $(daba, dabdab, dadac)$ is a grouping of $\mathrm{CFL}_{in}(w)$ but for the inverse Lyndon factorization $(dabadab, dabda, dac)$ this is no longer true.

Next, let $y = dabadabdabdabdadac$. We have $\mathrm{CFL}_{in}(y) = (daba, dab, dab, dab, dadac)$. The decomposition of $\mathrm{CFL}_{in}(w)$ into its $\mathcal{PMC}$ is $((daba, dab, dab, dab), (dadac))$. Moreover, $(daba, (dab)^3, dadac)$ and $(dabadab, (dab)^2, dadac)$ are two groupings of $\mathrm{CFL}_{in}(y)$.

For our aims, we need to consider the words that are concatenations of equal factors in CFL_{in}. This approach leads to a refinement of the partition of CFL_{in} into non-increasing maximal chains for the prefix order, as defined below.

▶ **Definition 6.5** (Compact sequences). *Let $\mathcal{C} = (\ell_1, \dots, \ell_h)$ be a non-increasing maximal chain for the prefix order in $\mathrm{CFL}_{in}(w)$. The decomposition of $\mathcal{C}$ into* maximal compact sequences *is the sequence $(\mathcal{G}_1, \dots, \mathcal{G}_n)$ such that*

(1) *$\mathcal{C} = (\mathcal{G}_1, \dots, \mathcal{G}_n)$*

(2) *For every i, $1 \leq i \leq n$, $\mathcal{G}_i$ consists of the longest sequence of consecutive identical elements in $\mathcal{C}$*

Let $(\mathcal{C}_1, \mathcal{C}_2, \dots, \mathcal{C}_s)$ be the decomposition of $\mathrm{CFL}_{in}(w)$ into its non-increasing maximal chains for the prefix order. The decomposition of $\mathrm{CFL}_{in}(w)$ into its maximal compact sequences is obtained by replacing each $\mathcal{C}_j$ in $(\mathcal{C}_1, \mathcal{C}_2, \dots, \mathcal{C}_s)$ with its decomposition into maximal compact sequences.

▶ **Definition 6.6** (Compact factor). *Let $(\mathcal{G}_1, \dots, \mathcal{G}_n)$ be the decomposition of $\mathrm{CFL}_{in}(w)$ into its maximal compact sequences. For every i, $1 \leq i \leq n$, the concatenation g_i of the elements in $\mathcal{G}_i$ is a* compact factor *in $\mathrm{CFL}_{in}(w)$.*

▶ **Definition 6.7** (Compact factorization). *Let $w \in \Sigma^+$. We say that $(m_1, \ldots, m_k)$ is a* compact factorization *of w if $(m_1, \ldots, m_k)$ is an inverse Lyndon factorization of w and each m_j, $1 \leq j \leq k$, is a concatenation of compact factors in $\mathrm{CFL}_{in}(w)$.*

▶ **Example 6.8.** Consider again $y = dabadabdabdabdadac$ over $\Sigma = \{a, b, c, d\}$, $a < b < c < d$, as in Example 6.4. The decomposition of $\mathrm{CFL}_{in}(y) = (daba, dab, dab, dab, dadac)$ into its maximal compact sequences is $((daba), (dab, dab, dab), (dadac))$. The compact factors in $\mathrm{CFL}_{in}(w)$ are $daba, (dab)^3, dadac$. Moreover, $(daba, (dab)^3, dadac)$ is a compact factorization whereas $(dabadab, (dab)^2, dadac)$ is a grouping of $\mathrm{CFL}_{in}(y)$ which is not a compact factorization.

▶ **Proposition 6.9.** *Let $w \in \Sigma^+$. If $(m_1, \ldots, m_k)$ is an inverse Lyndon factorization of w having the border property, then $(m_1, \ldots, m_k)$ is a compact factorization of w.*

Proof. Let $w \in \Sigma^+$, let $(m_1, \ldots, m_k)$ be an inverse Lyndon factorization of w having the border property. Let $\mathrm{CFL}_{in}(w) = (\ell_1, \ldots, \ell_h)$, where $\ell_1 \succeq_{in} \ell_2 \succeq_{in} \ldots \succeq_{in} \ell_h$ and $\ell_1, \ldots, \ell_h$ are anti-Lyndon words. First we prove that $(m_1, \ldots, m_k)$ is a grouping of $\mathrm{CFL}_{in}(w)$ by induction on $|w|$. If $|w| = 1$ the statement clearly holds, thus assume $|w| > 1$.

The words m_1 and ℓ_1 are comparable for the prefix order, hence either m_1 is a proper prefix of ℓ_1 or ℓ_1 is a prefix of m_1. Suppose that m_1 is a proper prefix of ℓ_1. Thus, there are j, $1 < j \leq k$, and $x, y \in \Sigma^*$, $x \neq 1$, such that $m_j = xy$ and $\ell_1 = m_1 \cdots m_{j-1}x$. Necessarily it turns out $j = 2$ because otherwise $m_1 \ll m_{j-1}$, hence, by Lemma 2.2, $\ell_1 \ll m_{j-1}x$ and this contradicts the fact that ℓ_1 is an anti-Lyndon word. In conclusion $\ell_1 = m_1x$ and $m_2 = xy$. We know that $m_1 \ll m_2$, that is, there are $r, s, t \in \Sigma^*$, $a, b \in \Sigma$, such that $a < b$ and $m_1 = ras$, $m_2 = rbt = xy$. If $|x| \leq |r|$, then x is a nonempty border of ℓ_1 and if $|x| > |r|$, then there is a word t' such that $x = rbt'$ which implies $\ell_1 \ll x$. Both cases again contradict the fact that ℓ_1 is an anti-Lyndon word.

Therefore, ℓ_1 is a prefix of m_1. If $m_1 = \ell_1 \cdots \ell_h = w$, then $k = 1$ and the statement is proved. Otherwise, let i be the largest integer such that $m_1 = \ell_1 \cdots \ell_{i-1}x$, $x, y \in \Sigma^*$, $\ell_i = xy$, $1 < i \leq h$, $y \neq 1$. Let $(\mathcal{C}_1, \mathcal{C}_2, \ldots, \mathcal{C}_s)$ be the decomposition of $\mathrm{CFL}_{in}(w)$ into its non-increasing maximal chains for the prefix order. We claim that $\ell_1 \cdots \ell_{i-1}$ is a prefix of the concatenation of the elements of $\mathcal{C}_1$, thus $(\ell_1, \ldots, \ell_{i-1})$ is a chain for the prefix order. If $i = 1$ we are done. Let $i > 1$. By contradiction, assume that there is j, $1 < j < i$, such that $\ell_j \notin \mathcal{C}_1$. Therefore, $\ell_1 \ll \ell_j$ which implies $m_1 \ll \ell_j \cdots \ell_{i-1}x$ and this contradicts the fact that m_1 is an inverse Lyndon word.

We now prove that $x = 1$. Assume $x \neq 1$. As a preliminary step, we prove that there is no nonempty prefix β of m_2 such that $|\beta| \leq |x|$ and $x \ll \beta$. In fact, if such a prefix existed, there would be $r, s, t \in \Sigma^*$, $a, b \in \Sigma$, such that $a < b$ and $x = ras$, $\beta = rbt$. Notice that y is a nonempty prefix of $m_2 \cdots m_k$, thus y and $\beta = rbt$ are comparable for the prefix order. If $|\ell_i| = |xy| \leq |xr|$, then $0 < |y| \leq |r|$ and y would be a nonempty prefix of r. Thus y would be a nonempty border of ℓ_i. If $|\ell_i| = |xy| > |xr|$, then there would be a word t' such that $\ell_i = rasrbt'$ which would imply $\ell_i \ll rbt'$. Both cases contradict the fact that ℓ_i is an anti-Lyndon word.

Now either ℓ_i is a prefix of ℓ_1 or $\ell_1 \ll \ell_i$. If ℓ_i were a prefix of ℓ_1, then x would be a nonempty border of m_1. By Lemma 5.2 there would exist a nonempty prefix β of m_2 such that $|\beta| \leq |x|$ and $x \ll \beta$ which contradicts our preliminary step.

If it were true that $\ell_1 \ll \ell_i$ then there would be $r, s, t \in \Sigma^*$, $a, b \in \Sigma$, such that $a < b$ and $\ell_1 = ras$, $\ell_i = rbt = xy$. If $|x| > |r|$, then there would be a word t' such that $x = rbt'$ which would imply $m_1 \ll x$ and this contradicts the fact that m_1 is an inverse Lyndon word. If $|x| \leq |r|$, then x would be a prefix of r and x would be a nonempty border of m_1. By Lemma 5.2 again, there would exist a nonempty prefix β of m_2 such that $|\beta| \leq |x|$ and $x \ll \beta$ which contradicts again our preliminary step.

Let $w' \in \Sigma^*$ be such that $w = m_1 w'$. We know that $w' \neq 1$ and clearly $|w'| < |w|$. Of course $(m_2, \ldots, m_k)$ is an inverse Lyndon factorization of w having the border property. Moreover, by Corollary 3.6, $\mathrm{CFL}_{in}(w') = (\ell_i, \ldots, \ell_h)$ and $(\mathcal{C}'_1, \mathcal{C}_2, \ldots, \mathcal{C}_s)$ is the decomposition of $\mathrm{CFL}_{in}(w')$ into its non-increasing maximal chains for the prefix order, where $\mathcal{C}'_1$ is defined by $\mathcal{C}_1 = (\ell_1, \ldots, \ell_{i-1}, \mathcal{C}'_1)$. By induction hypothesis, $(m_2, \ldots, m_k)$ is a grouping of $\mathrm{CFL}_{in}(w')$ and consequently $(m_1, \ldots, m_k)$ is a grouping of $\mathrm{CFL}_{in}(w)$.

Finally, to obtain a contradiction, suppose that $(m_1, \ldots, m_k)$ is a grouping of $\mathrm{CFL}_{in}(w)$ having the border property such that $(m_1, \ldots, m_k)$ is not a compact factorization of w. To adapt the notation to the proof, set $\mathrm{CFL}_{in}(w) = (\ell_1^{n_1}, \ldots, \ell_r^{n_r})$, where $r > 0$, $n_1, \ldots, n_r \geq 1$ and $\ell_1, \ldots, \ell_r$ are anti-Lyndon words. By Definitions 6.3 and 6.7, there exist integers j, h, p_h, q_h, $1 \leq j \leq k-1$, $1 \leq h \leq r$, $p_h \geq 1$, $q_h \geq 1$, $p_h + q_h \leq n_h$, such that m_j ends with $\ell_h^{p_h}$ and m_{j+1} starts with $\ell_h^{q_h}$. Thus, by Definition 6.3, ℓ_h is a prefix of m_j. Moreover, ℓ_h is a proper prefix of m_j. Indeed otherwise $\ell_h = m_j \leq_p m_{j+1}$ which is impossible because $m_j \ll m_{j+1}$ ($(m_1, \ldots, m_k)$ is an inverse Lyndon factorization). Thus ℓ_h is a nonempty border of m_j. The word ℓ_h is also a prefix of m_{j+1} and this contradicts the fact that $(m_1, \ldots, m_k)$ has the border property. ◀

7 The canonical inverse Lyndon factorization: The algorithm

In this section we state another relevant result of the paper related to the main one stated in Section 5. We have shown that a nonempty word w can have more than one inverse Lyndon factorization but w has a unique inverse Lyndon factorization with the border property (Example 4.7, Proposition 5.3). Below we highlight that this unique factorization is the canonical one defined in [8, 10].

This special inverse Lyndon factorization is denoted by ICFL because it is the counterpart of the Lyndon factorization CFL of w, when we use (I)inverse words as factors. Indeed, in [8] it has been proved that $\mathrm{ICFL}(w)$ can be computed in linear time and it is uniquely determined for a word w.

In Proposition 7.7 we show another interesting property of ICFL: the last factor of the factorization is the longest suffix that is an inverse Lyndon word. Based on this result we provide a new simpler linear algorithm for computing ICFL.

We begin by recalling previously proved results on ICFL, namely Proposition 7.7 in [8] and Proposition 9.5 in [10]. They are merged into Proposition 7.1.

▶ **Proposition 7.1.** *For any $w \in \Sigma^+$, $\mathrm{ICFL}(w)$ is a grouping of $\mathrm{CFL}_{in}(w)$. Moreover, $\mathrm{ICFL}(w)$ has the border property.*

Corollary 7.2 is a direct consequence of Propositions 5.3, 6.9 and 7.1.

▶ **Corollary 7.2.** *For each $w \in \Sigma^+$, $\mathrm{ICFL}(w)$ is a compact factorization and it is is the unique inverse Lyndon factorization of w having the border property.*

Since $\mathrm{ICFL}(w)$ is the unique inverse Lyndon factorization with the border property, from now on these two notions will be synonymous. Proposition 7.3 has been proved in [11].

▶ **Proposition 7.3.** *Let $w \in \Sigma^+$, let $\mathrm{CFL}_{in}(w) = (\ell_1, \ldots, \ell_h)$ and let $(\mathcal{C}_1, \mathcal{C}_2, \ldots, \mathcal{C}_s)$ be the decomposition of $\mathrm{CFL}_{in}(w)$ into its non-increasing maximal chains for the prefix order. Let $w_1, \ldots, w_s$ be words such that $\mathrm{CFL}_{in}(w_j) = \mathcal{C}_j$, $1 \leq j \leq s$. Then $\mathrm{ICFL}(w)$ is the concatenation of the sequences $\mathrm{ICFL}(w_1), \ldots, \mathrm{ICFL}(w_s)$, that is,*

$$\mathrm{ICFL}(w) = (\mathrm{ICFL}(w_1), \ldots, \mathrm{ICFL}(w_s)) \tag{7.1}$$

We can now state some results useful to prove the correctness of our algorithm. First we observe that, thanks to Corollary 7.2 and Proposition 7.3, to compute ICFL we can limit ourselves to the case in which CFL_{in} is a chain with respect to the prefix order.

▶ **Lemma 7.4.** *Let $\ell_1, \ldots, \ell_h$ be anti-Lyndon words over Σ that form a non-increasing chain for the prefix order, that is, $\ell_1 \geq_p \ell_2 \geq_p \ldots \geq_p \ell_h$. If $\ell_1 \neq \ell_2$, then $\ell_1 \not\leq_p \ell_2 \cdots \ell_h$.*

Proof. By contradiction, assume that ℓ_1 is a prefix of $\ell_2 \cdots \ell_h$. Then, $\ell_1 = \ell_2 \cdots \ell_t z$ where either $z = 1$ and $2 < t \leq h$ or z is a nonempty prefix of ℓ_{t+1}, $2 \leq t < h$. Thus either ℓ_t or z is a nonempty border of ℓ_1, a contradiction in both cases. ◀

▶ Remark 7.5. [10] Let x, y be two different borders of $w \in \Sigma^+$. If x is shorter than y, then x is a border of y.

▶ **Proposition 7.6.** *Let $w \in \Sigma^+$ and assume that $\mathrm{CFL}_{in}(w)$ form a non-increasing chain for the prefix order. If $(m_1, \ldots, m_k)$ is a factorization of w such that each m_j, $1 \leq j \leq k$, is a concatenation of compact factors in $\mathrm{CFL}_{in}(w)$, then $(m_1, \ldots, m_k)$ has the border property.*

Proof. Let $w \in \Sigma^+$ and assume that $\mathrm{CFL}_{in}(w)$ form a non-increasing chain for the prefix order. Let $(m_1, \ldots, m_k)$ be a factorization of w such that each m_j, $1 \leq j \leq k$, is a concatenation of compact factors in $\mathrm{CFL}_{in}(w)$. The proof is by induction on k. If $k = 1$, then the conclusion follows immediately. Assume $k > 1$.

Let $w' \in \Sigma^+$ be such that $w = m_1 w'$. It is clear that $(m_2, \ldots, m_k)$ is a factorization of w' such that each m_j, $2 \leq j \leq k$, is a concatenation of compact factors in $\mathrm{CFL}_{in}(w')$. Thus, by the induction hypothesis, $(m_2, \ldots, m_k)$ has the border property. It remains to prove that each nonempty border of m_1 is not a prefix of m_2. The proof is straightforward if m_1 is unbordered, thus assume that m_1 is bordered.

Let $\mathrm{CFL}_{in}(w) = (\ell_1^{n_1}, \ldots, \ell_r^{n_r})$, where $\ell_1^{n_1}, \ldots, \ell_r^{n_r}$ are the compact factors in $\mathrm{CFL}_{in}(w)$, that is, $\ell_1, \ldots, \ell_r$ are anti-Lyndon words such that $\ell_1 \geq_p \ldots \geq_p \ell_r$. Since m_1 is a concatenation of compact factors in $\mathrm{CFL}_{in}(w)$, there is h, $1 \leq h < r$ such that

$$m_1 = \ell_1^{n_1} \cdots \ell_h^{n_h}.$$

Notice that ℓ_h is a nonempty border of m_1. Furthermore, since ℓ_h is unbordered, ℓ_h is the shortest nonempty border of m_1.

If there were a word z which is a nonempty border of m_1 and also a prefix of m_2, by Remark 7.5, ℓ_h would be a prefix of m_2. Therefore, ℓ_h would be a prefix of the word $\ell_{h+1}^{n_{h+1}} \cdots \ell_r^{n_r}$ which contradicts Lemma 7.4. ◀

▶ **Proposition 7.7.** *Let $w \in \Sigma^+$ and let $\mathrm{ICFL}(w) = (m_1, \ldots, m_k)$ be the unique inverse Lyndon factorization of w having the border property. Then m_k is the longest suffix of w which is an inverse Lyndon word.*

Proof. Let $w \in \Sigma^+$ and let $(m_1, \ldots, m_k)$ be the unique inverse Lyndon factorization of w having the border property. If $k = 1$ we are done. Thus suppose $k > 1$. By contradiction, suppose that m_k is not the longest suffix of w that is an inverse Lyndon word. Let s be such longest suffix. Thus, there exist a nonempty suffix x of m_j, $1 \leq j < k$ such that $s = x m_{j+1} \cdots m_k$. Furthermore x must be a proper suffix of m_j or we would have $s = m_j \cdots m_k \ll m_{j+1} \cdots m_k$ contradicting the hypothesis that s is inverse Lyndon.

We claim that $x \ll m_{j+1}$. Indeed, since m_j is an inverse Lyndon word, it holds $x \preceq m_j$. Thus, if $x \ll m_j$ or $x = m_j$, it immediately follows that $x \ll m_{j+1}$. Otherwise, $x \leq_p m_j$ and x is a nonempty border of m_j. By Lemma 5.2 applied to $(m_1, \ldots, m_k)$, with $x = \alpha$, there must exist a prefix β of m_{j+1} such that $x \ll \beta$, hence $x \ll m_{j+1}$.

Since $x \ll m_{j+1}$, we have $s = xm_{j+1} \cdots m_k \ll m_{j+1} \cdots m_k$, contradicting the hypothesis that s is an inverse Lyndon word. ◀

▶ Remark 7.8. Let $w \in \Sigma^+$ and let $\mathrm{ICFL}(w) = (m_1, \ldots, m_k)$ with $k > 1$. Let w' be such that $w = w'm_k$. Then, by Propositions 5.3 and 7.7, we obtain $\mathrm{ICFL}(w) = (\mathrm{ICFL}(w'), m_k)$.

Proposition 7.9 allows us to determine the longest suffix m' of a word w such that m' is an inverse Lyndon word.

▶ **Proposition 7.9.** *Let $w \in \Sigma^+$ be an inverse Lyndon word, and let $\ell \in \Sigma^+$ be an anti-Lyndon word. Then:*

1. *If $\ell \ll w$, then for every $k \geq 1$, $\ell^k w$ is not an inverse Lyndon word.*
2. *If ℓw is not an inverse Lyndon word, then $\ell \ll w$. Furthermore, for every $k \geq 1$, w is the longest suffix of $\ell^k w$ that is an inverse Lyndon word.*

Proof. By Lemma 2.2, the proof of 1. is immediate. Suppose ℓw is not inverse Lyndon. Then, there exists a proper suffix s of ℓw such that $\ell w \preceq s$, hence $\ell w \ll s$. Since ℓ is anti-Lyndon, for every proper suffix x of ℓ it follows $x \ll \ell$ and consequently $xw \ll \ell w$. Thus, s must be a suffix of w. Since w is an inverse Lyndon word, one of the following three cases holds: (1) $w = s$; (2) $s <_p w$; (3) $s \ll w$. By $\ell w \ll s$, in each of the three cases it is evident that $\ell w \ll w$. Thus there are $r, t, t' \in \Sigma^*$ and $a, b \in \Sigma$ with $a < b$ such that $\ell w = rat$, $w = rbt'$. If $|\ell| \geq |ra|$, then clearly $\ell \ll w$. Otherwise, $|\ell| \leq |r|$ and there is $r' \in \Sigma^*$ such that $r = \ell r'$. Consequently, by $\ell w = rat = \ell r'at$, we obtain $w = r'at$. Hence $w = rbt' = \ell r'bt' = r'at$ which contradicts the fact that w is an inverse Lyndon word.

For every $k \geq 1$, w is a suffix of $\ell^k w$ that is an inverse Lyndon word. Let x be a proper nonempty suffix of ℓ. Of course $x \ll \ell$. The word xw is not an inverse Lyndon word, otherwise we would have $\ell \ll w \preceq xw \ll \ell w$, a contradiction. Moreover, by Lemma 2.2, for any j, $1 \leq j < k$, we have $x\ell^j w \ll \ell^j w$ and $x\ell^j w$ is not an inverse Lyndon word. Finally, by 1., $\ell^k w$ is not an inverse Lyndon word. ◀

Algorithm 1 Compute ICFL(w), the unique compact factorization of w having the border property.

```
1:  function FACTORIZE($w$)
2:      $(\ell_1^{e_1}, \ldots, \ell_n^{e_n}) \leftarrow$ COMPACTFACTORS($w$)        ▷ Compute compact factors of $w$
3:      $\mathcal{F} \leftarrow \varnothing$
4:      $m' \leftarrow \ell_n^{e_n}$
5:      for $t = n - 1$ downto 1 do                       ▷ Work one compact factor at a time
6:          if $\ell_t \ll m'$ then                                    ▷ Proposition 7.9
7:              $\mathcal{F} \leftarrow (m', \mathcal{F})$
8:              $m' \leftarrow \ell_t^{e_t}$
9:          else
10:             $m' \leftarrow \ell_t^{e_t} \cdot m'$
11:     $\mathcal{F} \leftarrow (m', \mathcal{F})$
12:     return $\mathcal{F}$
```

We now describe Algorithm 1. Function FACTORIZE(w) will compute the unique compact factorization of w having the border property. First, at line 2, the decomposition of w into its compact factors is computed. Then, the factorization of w is carried out from right to left. Specifically, in accordance with Proposition 7.7, the for-loop at lines 5–10 will search for the longest suffix m' of w that is an inverse Lyndon word. The update of m' is managed by iteratively applying Proposition 7.9 at line 6. Once such longest suffix is found (that is, when the condition at line 6 is true) it is added to the growing factorization $\mathcal{F}$ and a new search for the longest suffix for the remaining portion of the string is initiated. Otherwise, line 10, the suffix is extended. In the end, the complete factorization is returned.

▶ **Example 7.10.** Let $\Sigma = \{a, b, c, d\}$, $a < b < c < d$, and let us run $\textsc{Factorize}(w)$ on $w = dabadabdabdadac$. First, at line 2, we get the sequence $(\ell_1, \ell_2^2, \ell_3) = (daba, (dab)^2, dadac)$. Then, at lines 3–4 we set $\mathcal{F} = \emptyset$ and $m' = \ell_3 = dadac$. We begin the for-loop at lines 5–10 in which i is set to 2 and 1, in turn. With $i = 2$ the test of line 6 succeeds, since $\ell_2 = dab \ll dadac = m'$, and so we set $\mathcal{F} = (dadac)$ and $m' = \ell_2^2 = (dab)^2$. At the second iteration, with $i = 1$, the test of line 6 again succeeds, since $\ell_1 = daba \ll (dab)^2 = m'$, thus we set $\mathcal{F} = ((dab)^2, dadac)$ and $m' = \ell_1 = daba$. We now fall out of the loop to line 11 where we set $\mathcal{F} = (daba, (dab)^2, dadac) = \mathrm{ICFL}(w)$.

7.1 Correctness and complexity

We now prove that Algorithm 1 is correct, that is that it will compute the unique inverse Lyndon factorization of w having the border property, namely $\mathrm{ICFL}(w)$. Formally:

▶ **Lemma 7.11.** *Let $w \in \Sigma^+$, and let $\mathcal{F}$ be the result of $\textsc{Factorize}(w)$. Then, $\mathcal{F} = \mathrm{ICFL}(w)$.*

Proof. Let $(\ell_1^{e_1}, \ldots, \ell_n^{e_n})$ be the decomposition of w into its compact factors, and let $L_t = \ell_t^{e_t} \cdots \ell_n^{e_n}$. We will denote by m'_t (resp. $\mathcal{F}_t$) the value of m' (resp. $\mathcal{F}$) at the end of iteration t. We will prove the following loop invariant: at the end of iteration t, sequence $(m'_t, \mathcal{F}_t)$ is a compact factorization of L_t having the border property. The claimed result will follow by Corollary 7.2.

Initialization. Prior to entering the loop, $(m'_n, \mathcal{F}_n) = (\ell_n^{e_n})$, where the last equality follows from Proposition 7.7.

Maintenance. Let $t \leq n - 1$. By the induction hypothesis, $\mathrm{ICFL}(L_{t+1}) = (m'_{t+1}, \mathcal{F}_{t+1})$. Suppose $\ell_t \ll m'_{t+1}$. Then, by 1. of Proposition 7.9, $\ell_t \cdot m'_{t+1}$ is not inverse Lyndon and m'_{t+1} is the longest suffix of $\ell_t^{e_t} \cdot m'_{t+1}$ that is an inverse Lyndon word. Thus, by Proposition 7.7 m'_{t+1} is the last factor of any compact factorization of $\ell_t^{e_t} \cdot m'_{t+1}$. Hence, $(m'_t, \mathcal{F}_t) = (\ell_t^{e_t}, m'_{t+1}, \mathcal{F}_{t+1})$ is a compact factorization of L_t having the border property. Now, consider the case where $\ell_t \not\ll m'_{t+1}$. Then, by the contrapositive of 2. of Proposition 7.9, $\ell_t \cdot m'_{t+1}$ is inverse Lyndon and thus, again by 2. of Proposition 7.9, $\ell_t^{e_t} \cdot m'_{t+1}$ is inverse Lyndon. Therefore, $(m'_t, \mathcal{F}_t) = (\ell_t^{e_t} \cdot m'_{t+1}, \mathcal{F}_{t+1})$ is a compact factorization having the border property.

Termination. After iteration $t = 1$, sequence $(m'_1, \mathcal{F}_1) = \mathrm{ICFL}(L_1) = \mathrm{ICFL}(w)$.

Finally, line 11 sets $\mathcal{F} = (m'_1, \mathcal{F}_1) = \mathrm{ICFL}(w)$. ◀

Function $\textsc{Factorize}(w)$ has time complexity that is linear in the length of w. Indeed, the sequence of compact factors obtained at line 2 can be computed in linear time in the length of w by a simple modification of Duval's algorithm (see [23]). After that, each iteration t of loop 5–10 can be implemented to run in time $\mathcal{O}(|\ell_t|)$. Indeed, condition $\ell_t \ll m'$ can be checked by naively comparing ℓ_t against m'. Furthermore, the update of m' and $\mathcal{F}$ can be done in constant time: in fact, ℓ_t, $\ell_t^{e_t}$, m' and $\mathcal{F}$ can all be implemented as pairs of indexes (in case of the former three) or as a list of indexes (in case of the latter) of w.

8 Conclusions

We discover the special connection between the Lyndon factorization under the inverse lexicographic ordering, named CFL_{in} and the canonical inverse Lyndon factorization, named ICFL: there exists a unique inverse Lyndon factorization having the border property and this unique factorization is ICFL. Moreover each inverse factor of ICFL is obtained by concatenating compact factors of CFL_{in}. These properties give a constrained structure to ICFL that deserve to be further explored to characterize properties of words. In particular, we believe the characterization of ICFL as a compact factorization, proved in the paper, could highlight novel properties related the compression of a word, as investigated in [20]. In particular, the number of compact factors seems to be a measure of repetitiveness of the word to be also used in speeding up suffix sorting of a word.

Finally, we believe that the characterization of ICFL in terms of CFL_{in} may be used to extend to ICFL the *conservation property* proved in [10] for CFL. This property shows that the Lyndon factorization of a word w preserves common factors with the factorization of a superstring of w. This extends the conservation of Lyndon factors explored for the product $u \cdot v$ of two words u and v [1, 20].

Abstract

We introduce a dense counterpart of graph degeneracy, which extends the recently-proposed invariant symmetric difference. We say that a graph has *sd-degeneracy* (for symmetric-difference degeneracy) at most d if it admits an elimination order of its vertices where a vertex u can be removed whenever it has a d-twin, i.e., another vertex v such that at most d vertices outside $\{u, v\}$ are neighbors of exactly one of u, v. The family of graph classes of bounded sd-degeneracy is a superset of that of graph classes of bounded degeneracy or of bounded flip-width, and more generally, of bounded symmetric difference. Unlike most graph parameters, sd-degeneracy is not hereditary: it may be strictly smaller on a graph than on some of its induced subgraphs. In particular, every n-vertex graph is an induced subgraph of some $O(n^2)$-vertex graph of sd-degeneracy 1. In spite of this and the breadth of classes of bounded sd-degeneracy, we devise $\tilde{O}(\sqrt{n})$-bit adjacency labeling schemes for them, which are optimal up to the hidden polylogarithmic factor. This is attained on some even more general classes, consisting of graphs G whose vertices bijectively map to the leaves of a tree T, where transversal edges and anti-edges added to T define the edge set of G. We call such graph representations *signed tree models* as they extend the so-called tree models (or twin-decompositions) developed in the context of twin-width, by adding transversal anti-edges.

While computing the degeneracy of a graph takes linear time, we show that determining its symmetric difference is para-co-NP-complete. This may seem surprising as symmetric difference can serve as a short-sighted first approximation of twin-width, whose computation is para-NP-complete. Indeed, we show that deciding if the symmetric difference of an input graph is at most 8 is co-NP-complete. We also show that deciding if the sd-degeneracy is at most 6 is NP-complete, contrasting with the symmetric difference.

1 Introduction

There are two theories of sparse graphs: the so-called Sparsity Theory pioneered by Nešetřil and Ossona de Mendez [18], and the theory behind the equivalent notions of bounded degeneracy, maximum average degree, subgraph density, and arboricity. One of the many merits of the former theory is to capture efficient first-order model checking within subgraph-closed classes, with the so-called *nowhere dense* classes [12]. *Monadic stability* constitutes a dense analogue of nowhere denseness with similar algorithmic properties [10]. The second

theory has, as we will see, simple but useful connections with the chromatic number and adjacency labeling schemes. One of our two main motivations is to introduce and explore dense analogues of it.

The degeneracy of a graph G is the minimum integer d such that every induced subgraph of G has a vertex of degree at most d. As removing vertices may only decrease the degree of the remaining ones, checking that the degeneracy is at most d can be done greedily. This prompts the following equivalent definition, equal to the *coloring number*[1] minus one [11, 9]. A graph has degeneracy at most d if there is a total order, called *degeneracy ordering*, on its vertices such that every vertex v has at most d neighbors following v in the order. The degeneracy is then the least integer d such that an ordering witnessing degeneracy at most d exists. Given such an ordering, a graph can be properly $(d+1)$-colored by a greedy strategy: use the smallest available color looping through vertices in the given order. Another advantage of the definition via degeneracy ordering is that it yields a polynomial-time algorithm to compute the degeneracy. While the graph is nonempty, find a vertex of minimum degree, append it to the order, and remove it from the graph. Degeneracy is frequently used to bound the chromatic number from above. For instance, until recently [19] the Kostochka–Thomason degeneracy bound of graphs without K_t minor [15, 20] was the best way we knew of coloring these graphs.

Another application of bounding the degeneracy is to obtain implicit representations. Indeed graphs of bounded degeneracy admit $f(n)$-bit *adjacency labeling schemes* with $f(n) = O(\log n)$.[2] In other words, given a class of graphs of degeneracy at most d, there exists an algorithm, called *decoder*, such that the vertices of any n-vertex graph G from the class can be assigned *labels* (which are binary strings) of length $f(n)$ in such a way that the decoder can infer the adjacency of any two vertices u, v in G from their mere labels. An $O(\log n)$-bit labeling scheme is easy to design for any class $\mathcal{C}$ of bounded degeneracy. From an ordering of $G \in \mathcal{C}$ witnessing degeneracy d, the label of each vertex stores its own index in the ordering and the indices of its at most d neighbors that follow it in the order. Then the decoder just checks whether the index of one of u, v is among the indices of the neighbors of the other vertex. Note that each label has size at most $(d+1)\lceil \log n \rceil$. For example, this was recently used to show that every subgraph-closed class with single-exponential speed of growth admits such a labeling scheme [3].

Adjacency labeling schemes of size $O(\log n)$ are at the heart of the recently-refuted Implicit Graph Conjecture (IGC) [14, 17]. The IGC speculated that the information-theoretic necessary condition for a hereditary graph class to have an $O(\log n)$-bit labeling scheme is also sufficient. This necessary condition comes from the observation that a string of length $O(n \log n)$ obtained by concatenating all vertex labels is an encoding of the graph. Therefore a class of graphs that admits an adjacency labeling scheme of size $O(\log n)$ contains at most $2^{O(n \log n)}$ (un)labeled n-vertex graphs. Graph classes with such a bound on the number of (un)labeled n-vertex graphs are called *factorial*. In this terminology, the IGC can be stated as follows: any hereditary factorial graph class admits an $O(\log n)$-bit adjacency labeling scheme.

The IGC has been refuted by a wide margin; in a breakthrough work, Hatami and Hatami [13] showed that there are factorial hereditary graph classes for which any adjacency labeling scheme requires labels of length $\Omega(\sqrt{n})$. However, the refutation is based on a counting argument and does not pinpoint an explicit counterexample. There are a number

[1] not to be confused with the *chromatic* number

[2] Throughout the paper, log denotes the logarithm function in base 2.

of explicit factorial graph classes that could refute the IGC, but the conjecture is still open for these classes. Let us call EIGC (for Explicit Implicit Graph Conjecture) this very challenge. For instance, whether the IGC holds within intersection graphs of segments, unit disks, or disks in the plane, and more generally semi-algebraic graph classes, is unsettled. Despite the workable definitions of these classes, the geometric representations alone cannot lead to $O(\log n)$-bit labeling schemes [16]. If such labeling schemes exist, they are likely to utilize some non-trivial structural properties of these graphs.

The graph parameter *symmetric difference* was introduced to design a candidate to explicitly refute the IGC [2]. A graph G has symmetric difference at most d if in every induced subgraph of G there is a pair of vertices u, v such that there are at most d vertices different from u and v that are adjacent to exactly one of u, v. In other words, u and v are *d-twins*, i.e., they become twins after removing at most d vertices from the graph. One can construe symmetric difference as a dense analogue of the first definition of degeneracy given above. Symmetric difference is a hereditary graph parameter: it can only decrease when taking induced subgraphs. Like classes of bounded degeneracy, classes of bounded symmetric difference are factorial [2]. Symmetric difference generalizes degeneracy in the sense that any class of graphs of bounded degeneracy has bounded symmetric difference. Indeed, if a graph has degeneracy at most d, then it has symmetric difference as most $2d$: for any graph with an ordering witnessing degeneracy d, the first two vertices in the order are $2d$-twins. Notice that, on the other hand, complete graphs have unbounded degeneracy, but their symmetric difference is 0. Classes of bounded symmetric difference contains classes of bounded twin-width, and this containment is strict as twin-width is unbounded on degenerate graphs [5]. The existence of an $O(\log n)$-bit adjacency labeling scheme for graphs of bounded symmetric difference remains open.

Our contribution. We introduce another dense analogue of degeneracy based on the second given definition. The *sd-degeneracy* (for *symmetric-difference degeneracy*) of a graph G is the least integer d for which there is an ordering of the vertices of G such that every vertex v but the last one admits a d-twin in the subgraph of G induced by v and all the vertices following it in the order. It follows from the definitions that graphs with sd-degeneracy at most d form a superset of graphs with symmetric difference at most d. Contrary to what happens in the sparse setting with degeneracy, this superset is strict. In fact, there are classes with sd-degeneracy 1 and unbounded symmetric difference.

▶ **Proposition 1** ($\star$). *For any n-vertex graph G, there exists a graph of sd-degeneracy 1 with less than n^2 vertices containing G as an induced subgraph.*

By an aforementioned counting argument, the class of all graphs requires labeling schemes of size $\Theta(n)$. Therefore, by Proposition 1, the (non-hereditary) class of graphs with sd-degeneracy at most 1 requires adjacency labels of size $\Omega(\sqrt{n})$. Surprisingly, we match this lower bound with a labeling scheme, tight up to a polylogarithmic factor, for any class of bounded sd-degeneracy.

▶ **Theorem 2.** *The class of all graphs with sd-degeneracy at most d admits an $O(\sqrt{dn}\log^3 n)$-bit adjacency labeling scheme.*

The tool behind the proof of Theorem 2 is the second motivation of the paper. We wish to unify and extend twin-decompositions of low width (also called tree models) [4, 8] developed in the context of twin-width, and spanning paths (or Welzl orders) of low crossing number (or low alternation number) [22], which are useful orders in answering geometric range queries; also see [10] which utilizes these orders as part of efficient first-order model checking algorithms. We thus introduce *signed tree models*. A signed tree model of a graph G is a tree whose leaves are in one-to-one correspondence with the vertices of G, together with extra transversal edges and anti-edges, which fully determine (see the exact rules in Section 3) the edges of G. The novelty compared to the existing tree models is the presence of transversal anti-edges. We show that graphs with signed tree models of degeneracy at most d admit a labeling scheme as in Theorem 2. The latter theorem is then obtained by building such a signed tree model for any graph of sd-degeneracy d.

When given the vertex ordering witnessing sd-degeneracy d, the labeling scheme can be effectively computed. However, we show that computing the sd-degeneracy of a graph (hence, in particular a witnessing order) is NP-complete, even when the sd-degeneracy is guaranteed to be below a fixed constant. In the language of parameterized complexity, sd-degeneracy is para-NP-complete.

▶ **Theorem 3.** *Deciding if a graph has sd-degeneracy at most 1 is NP-complete.*

We show that, surprisingly, the other dense analogue of degeneracy, symmetric difference, is co-NP-complete. Again, the associate parameterized problem is para-co-NP-complete.

▶ **Theorem 4.** *Deciding if a graph has symmetric difference at most 8 is co-NP-complete.*

This is curious because sd-degeneracy and symmetric difference similarly extend to the dense world two equivalent definitions of degeneracy. Nevertheless, one can explain the apparent tension between Theorems 3 and 4: a vertex ordering witnesses an upper bound in the sd-degeneracy, whereas an induced subgraph witnesses a lower bound in the symmetric difference. We leave as an open question whether classes of bounded symmetric difference have labeling schemes of (poly)logarithmic size. This is excluded for bounded sd-degeneracy, for which we now know essentially optimal labeling schemes. While not an absolute barrier, the likely absence of polynomial certificates tightly upper bounding the symmetric difference complicates matters in settling this open question.

Organization. Section 2 gives definitions and notation. In Section 3 we introduce signed tree models, and prove that graphs of bounded sd-degeneracy admit signed tree models of bounded width. In Section 4 we show how to balance these signed tree models, and complete the proof of Theorem 2. In Section 5 we prove Theorem 4, and we prove Theorem 3 in the long version [23]. The proofs marked with a ⋆ have been moved to the appendix.

2 Preliminaries

We denote by $[i, j]$ the set of integers that are at least i and at most j, and $[i]$ is a shorthand for $[1, i]$. We follow standard asymptotic notation throughout, and additionally by $f(n) = \tilde{O}(g(n))$ we mean that there exists constants $c, n_0 > 0$ such that for any $n \geqslant n_0$ we have $f(n) \leqslant g(n) \log^c n$.

We denote by $V(G)$ and $E(G)$ the vertex set and edge set of a graph G, respectively. Given a vertex u of a graph G, we denote by $N_G(u)$ the set of neighbors of u in G (*open neighborhood*) and by $N_G[u]$ the set $N_G(u) \cup \{u\}$ (*closed neighborhood*). When H, G are two graphs, we may denote by $H \subseteq_i G$ (resp. $H \subseteq G$) the fact that H is an induced subgraph (resp. subgraph) of G, i.e., can be obtained by removing vertices of G (resp. by removing vertices and edges of G). We denote by $G[S]$ the subgraph of G induced by S, formed by removing every vertex of $V(G) \setminus S$. We use $G - S$ as a shorthand for $G[V(G) \setminus S]$, and $G - v$, for $G - \{v\}$.

Given two sets A and B, we denote by $A \triangle B$ their symmetric difference, that is, $(A \setminus B) \cup (B \setminus A)$. Given a graph G, and two distinct vertices $u, v \in V(G)$, we set

$$\mathrm{sd}_G(u,v) := |(N_G(u) \setminus \{v\}) \triangle (N_G(v) \setminus \{u\})|.$$

The *symmetric difference* of G, $\mathrm{sd}(G)$, is defined as $\max_{H \subseteq_i G} \min_{u \neq v \in V(H)} \mathrm{sd}_H(u,v)$. Symmetric difference was implicitly introduced in [2] and later explicitly defined in [1]. For example, if G is a planar graph, one can find in any induced subgraph H of G two vertices of degree less than 6. Hence planar graphs have symmetric difference bounded by 12. We call *sd-degeneracy* of G, denoted by $\mathrm{sdd}(G)$, the smallest non-negative integer d such that $|V(G)| = 1$ or there is a pair $u \neq v \in V(G)$ satisfying $\mathrm{sd}_G(u,v) \leqslant d$ and $G - v$ has sd-degeneracy at most d. We say that an ordering $v_1, v_2, \ldots, v_n$ of the vertices of G witnesses that the *sd-degeneracy* of G is at most d if for every $i \in [n-1]$, there is a $j > i$ such that $\mathrm{sd}_{G - \{v_k \;:\; k \in [i-1]\}}(v_i, v_j) \leqslant d$. It thus holds that for any graph G, $\mathrm{sdd}(G) \leqslant \mathrm{sd}(G)$, since for every $i \in [n]$, $G - \{v_k \;:\; k \in [i-1]\}$ is an induced subgraph of G. But, as shown by Proposition 1, there are some graphs with sd-degeneracy 1 and unbounded symmetric difference.

Two vertices u, v are said to be *d-twins* in a graph G if they are distinct and $|(N_G(u) \setminus N_G[v]) \cup (N_G(u) \setminus N_G[v])| \leqslant d$. The *$a \times b$ rook graph* has vertex set $\{(i,j) \;:\; i \in [a], j \in [b]\}$ and edge set $\{(i,j)(k,\ell) \;:\; (i,j) \neq (k,\ell),\ i = k \text{ or } j = \ell\}$. Equivalently it is the line graph of the bipartite complete graph $K_{a,b}$. For every $a, b \geqslant 3$, the symmetric difference of the $a \times b$ *rook graph* is $2(\min(a,b) - 1)$.

We will extensively use *tree orders*, i.e., partial orders defined by ancestor–descendant relationships in a rooted tree. We denote by $\prec_T$ the corresponding relation in rooted tree T. That is, $u \prec_T u'$ means that u is a *strict ancestor* of u' in T, and $u \preceq_T u'$ means that u is an *ancestor* of u', i.e., $u = u'$ or $u \prec_T u'$. We extend this partial order to elements of $\binom{V(T)}{2}$. An unordered pair uv is an *ancestor* of $u'v'$ in T, denoted by $uv \preceq_T u'v'$, whenever either $u \preceq_T u'$ and $v \preceq_T v'$, or $v \preceq_T u'$ and $u \preceq_T v'$ holds. We write $uv \prec_T u'v'$ when $uv \preceq_T u'v'$ and $\{u,v\} \neq \{u',v'\}$. A rooted binary tree is *full* if all its *internal nodes*, i.e., non-leaf nodes, have exactly two children. A rooted binary tree is *complete* if all its levels are completely filled, except possibly the last one, wherein leaves are left-aligned. The *depth* of a rooted tree is the maximum number of nodes in a root-to-leaf path. We denote by $L(T)$ the set of leafs of T.

3 Signed tree models

An unordered pair of vertices in T that is not in an ancestor–descendant relationship is called a *transversal pair of* T. Two transversal pairs $uv, u'v'$ of T *cross* if u, v have the same common ancestor as u', v' do, and neither uv is an ancestor of $u'v'$, nor $u'v'$ is an ancestor of uv. A *signed tree model* $\mathcal{T}$ is a triple $(T, A(T), B(T))$, where T is a full binary tree, $A(T)$ (for Android green, or Anti) is a set of transversal pairs of T, called *transversal anti-edges*, and $B(T)$ (for Blue, or Biclique) is a set of transversal pairs of T, called *transversal edges*, such that $A(T) \cap B(T) \neq \emptyset$ and no $uv, u'v' \in A(T) \cup B(T)$ cross. We may refer to the transversal anti-edges as *green edges*, and to the transversal edges as *blue edges*.

The *width* of the signed tree model $(T, A(T), B(T))$ is the degeneracy of the graph $(V(T), A(T) \cup B(T))$. Note that if $(V(T), A(T) \cup B(T))$ is d-degenerate, then $(V(T), A(T) \cup B(T) \cup E(T))$ is $(d+3)$-degenerate. The signed tree model is d-sparse if $|A(T) \cup B(T)| \leqslant d|V(T)|$. We observe that a signed tree model of width d is d-sparse, but an $O(1)$-sparse signed tree model can have width $\Omega(\sqrt{|V(T)|})$ (think of the disjoint union of a clique on $\sqrt{n}$ vertices with a set $n - \sqrt{n}$ independent vertices).

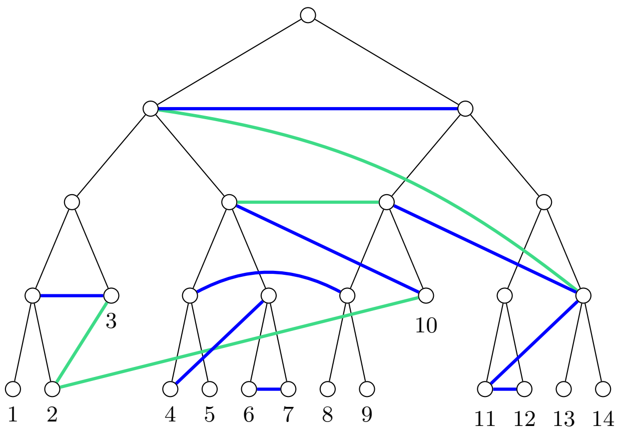

Figure 1 A signed tree model of a 14-vertex graph.

The signed tree model $\mathcal{T} := (T, A(T), B(T))$ defines a graph $G := G_{\mathcal{T}}$ with vertex set $L(T)$. Two leaves $u, v \in L(T)$ are adjacent in G if there is $u'v' \in B(T)$ such that $u' \preceq_T u$ and $v' \preceq_T v$, and there is no $u''v'' \in A(T)$ with $u'v' \prec_T u''v'' \preceq_T uv$. For example, in the representation of Figure 1, vertices 4 and 8 are adjacent in G because of the blue edge between their parents (below the green edge between their grandparents), but vertices 7 and 8 are non-adjacent because of the green edge between their grandparents (below the blue edge between their great-grand-parents). We may say that a graph G admits (or has) a signed tree model of width d if there is a signed tree model of this width that defines G. Every graph G admits a signed tree model as one can simply set $A(T) := \emptyset$, $B(T) := E(G)$ on an arbitrary full binary tree T with $L(T) = V(G)$. However this representation may have large width, while a more subtle one (linking nodes higher up in the tree) may have a lower width.

A signed tree model is said to be *clean* if every pair of siblings are linked by a green or blue edge. It is easy to turn a signed tree model into a clean one representing the same graph: simply add green edges between every pair of siblings that were previously not linked (by a blue or green edge). This operation may only increase the width of the signed tree model by 1. The advantage of working with a clean signed tree model is that for every pair of leaves u, v with least common ancestor w, there is at least one transversal edge or anti-edge connecting the paths (in T) between w and u and between w and v. Clean tree models will be useful in Section 4 when we balance the trees associated with the tree models.

Given a clean signed tree model $(T, A(T), B(T))$ and $u, v \in L(T)$, we denote by $e_T(u, v)$ the unique green or blue edge $u'v'$ such that $u'v' \preceq_T uv$ and no green or blue edge $u''v''$ satisfies $u'v' \prec_T u''v'' \preceq_T uv$. The edge $e_T(u, v)$ exists because the signed tree model is clean, and is unique because no green or blue edges may cross (or be equal). Then, u, v are adjacent in G if and only if $e_T(u, v) \in B(T)$, i.e., $e_T(u, v)$ is a blue edge. We first show that graphs of bounded sd-degeneracy (and in particular, of bounded symmetric difference) admit clean signed tree models of bounded width.

▶ **Lemma 5.** *Any graph of sd-degeneracy d admits a clean signed tree model of width $d + 1$.*

Proof. Let $v_1, \ldots, v_n$ be a vertex ordering that witnesses sd-degeneracy d for an n-vertex graph G. For $i \in [n]$, let $G_i := G - \{v_j \ : \ 1 \leqslant j \leqslant i - 1\}$. In particular, $G_1 = G$. Let u_i be a d-twin of v_i in G_i. Initially we consider a forest of n distinct 1-vertex rooted trees, each root labeled by a distinct vertex of G. We will build T (and in parallel, the transversal anti-edges and edges) by iteratively giving a common parent to two roots of this forest of n singletons. Note that different nodes of T may have the same label, as the labels will range in $V(G)$ whereas T has $2n-1$ nodes.

For i ranging from 1 to $n-1$:

- add a blue (resp. green) edge between v_i and u_i if $u_iv_i \in E(G)$ (resp. $u_iv_i \notin E(G)$),
- add a blue edge between v_i and the roots labeled by w for $w \in N_{G_i}(v_i) \setminus N_{G_i}[u_i]$,
- add a green edge between v_i and the roots labeled by w for $w \in N_{G_i}(u_i) \setminus N_{G_i}[v_i]$, and
- create a common parent, labeled by u_i, for the roots labeled u_i (left child) and v_i (right child).

This defines a full binary tree T such that $L(T) = V(G)$. In $(V(T), A(T) \cup B(T))$, the leaves labeled by v_1 and u_1 have degree at most $d+1$ and 1, respectively. Hence an immediate induction on $(T, A(T), B(T))$ (after removing these two leaves, and following the order $v_2, \dots, v_n$) shows that $(V(T), A(T) \cup B(T))$ is $(d+1)$-degenerate. As we only add transversal anti-edges and edges between pairs of roots, no pair in $A(T) \cup B(T)$ can cross. Indeed if x, y are two nodes of T that are both roots in some G_i, then it cannot happen that x', y' are also both roots of some $G_{i'}$ with $x \prec_T x'$ and $y' \prec_T y$. The first item further ensures that the signed tree model $(T, A(T), B(T))$ of width $d+1$ is clean.

Let us finally check that for every $u, v \in L(T)$, $e_T(u, v)$ is a blue edge if and only if $uv \in E(G)$. This is a consequence of the following property.

▷ Claim 6. Let x, y be two nodes of T labeled by u, v respectively. Let x' be a child of x, labeled by u', such that $x'y$ is neither a blue nor a green edge. Further assume that y was a root when the parent of x' (i.e., x) was created. Then, $uv \in E(G)$ if and only if $u'v \in E(G)$.

Proof. If x' is the left child of x, the conclusion holds since $u = u'$. We can thus assume that x' is the right child of x, and not the sibling of y since it would contradict that $x'y$ is neither a blue nor a green edge. Node x' was not linked to y by a blue or a green edge, so v cannot be a neighbor of exactly one of u, u'. ◁

Consider the moment $e_T(u, v)$ was added to the signed tree model, say between the then-roots x and y, labeled by u' and v', respectively. By the way blue and green edges are introduced, xy is a blue edge if $u'v' \in E(G)$, and xy is green if $u'v' \notin E(G)$. Thus we conclude by iteratively applying Claim 6. ◀

4 Balancing Signed Tree Models

For any signed tree model of width d of an n-vertex graph, we get an adjacency labeling scheme with labels of size $O(dh \log n)$, where h is the depth of T. Indeed, one can label a leaf v of T (i.e., vertex of G) by the identifiers (each of $\log(2n)$ bits) of all the nodes of the path from v to the root of T, followed by the identifiers of the outneighbors of these at most h nodes in a fixed orientation of $(V(T), A(T) \cup B(T))$ with maximum outdegree at most $d+1$, allocating an extra bit for the color of each corresponding edge. One can then decode the adjacency of any pair $u, v \in V(G)$ by looking at the color of $e_T(u, v)$. The latter is easy to single out, based on the labels of u and v.

▶ **Proposition 7.** *Let G be an n-vertex graph with a signed tree model of width d and depth h. Then, G admits an $O(dh \log n)$-bit adjacency labeling scheme.*

Unfortunately, the depth of the tree T of a signed tree model of low width obtained for an n-vertex graph of low sd-degeneracy could be as large as n. This makes a direct use of Proposition 7 inadequate. Instead, we first decrease the depth of the signed tree model, while controlling its sparsity. We rely on the following simple lemma.

▶ **Lemma 8.** *Let T be a full, complete tree, whose leaves read $1, \ldots, n \geqslant 2$ from left to right. Any interval $[i,j]$ with $i,j \in [n]$ is the disjoint union of the leaves of at most $2 \log n$ rooted subtrees of T.*

Proof. Let $X \subseteq V(T)$ be such that the leaves of the subtrees rooted at a node of X partition $[i,j]$, and X is of minimum cardinality among node subsets with this property. Let k be the first level of T intersected by X (with the root being at level 1). At most two nodes x, y of X are at level k (and exactly one node when $k = 2$), with $x = y$ or x to the left of y. Observe that if $x \neq y$, then x, y have to be consecutive along the left-to-right ordering of level k, but cannot be siblings (otherwise they can be substituted by their parent). At level $k+1$, at most two nodes can be part of X: the node just to the left of the leftmost child of x, and the node just to the right of the rightmost child of y. This property propagates to the last level. Thus $|X| \leqslant \max(2(\lceil \log n \rceil - 1), \lceil \log n \rceil) \leqslant 2 \log n$. Note indeed that there are $\lceil \log n \rceil + 1$ levels. ◀

From the previous proof it can also be seen that there is a unique minimum-cardinality set X representing $[i,j]$. In what follows, let us denote it by $X_{i,j}$. We also denote by $I_T(x)$ the set of leaves of the subtree of T rooted at $x \in V(T)$.

▶ **Observation 9.** *For every rooted tree T, and every $x, y \in V(T)$, if $I_T(x)$ and $I_T(y)$ intersect, then one is included in the other.*

We are now ready to prove the main lemma of this section.

▶ **Lemma 10.** *Let $(T, A(T), B(T))$ be a clean d-sparse signed tree model of an n-vertex graph G. Then, G admits a $4d \log^2 n$-sparse signed tree model $(T', A(T'), B(T'))$ of depth $\lceil \log n \rceil + 1$.*

Proof. Consider the left-to-right order on $L(T)$. To ease the notation, say that the leaves are labeled $1, 2, \ldots, n$ in this order. We choose for T' the full, complete binary tree whose leaves are also labeled by $1, 2, \ldots, n$ when read from left to right. For every transversal anti-edge (resp. edge) $xy \in A(T)$ (resp. $xy \in B(T)$), note that $I_T(x)$ and $I_T(y)$ are discrete intervals. Let $[i,j] := I_T(x)$ and $[i',j'] := I_T(y)$. We add to $A(T')$ (resp. $B(T')$) all the unordered pairs $x'y'$ with $x' \in X_{i,j}$ and $y' \in X_{i',j'}$. It may happen that some $x'y'$ is added both to $A(T')$ and $B(T')$. In which case, $x'y'$ originates from both $x_0y_0 \in A(T)$ and $x_1y_1 \in B(T)$ such that $x_0y_0 \prec_T x_1y_1$ or $x_1y_1 \prec_T x_0y_0$. In the former case, we remove $x'y'$ from $B(T')$ (and only keep it in $A(T')$), and in the latter, we remove $x'y'$ from $A(T')$ (and only keep it in $B(T')$). This finishes the construction of $\mathcal{T}' := (T', A(T'), B(T'))$.

Let us first argue that no pairs of green or blue edges cross in T'. Assume for the sake of contradiction that $a'b', c'd' \in A(T') \cup B(T')$ satisfy $a' \prec_{T'} c'$ and $d' \prec_{T'} b'$. Let $ab, cd \in A(T) \cup B(T)$ be the green or blue edges that created $a'b', c'd'$, respectively. As $I_T(a) \supseteq I_{T'}(a')$, $I_T(c) \supseteq I_{T'}(c')$, and $a' \prec_{T'} c'$, $I_T(a)$ and $I_T(c)$ intersect. Thus by Observation 9, $I_T(a) \subseteq I_T(c)$ or $I_T(c) \subseteq I_T(a)$. By minimality of the sets $X_{i,j}$, $I_T(c)$ cannot include $I_{T'}(a')$. Thus $I_T(c) \subset I_T(a)$, so $a \prec_T c$. Analogously $d \prec_T b$, which implies that ab and cd cross in T. Therefore $\mathcal{T}'$ is a signed tree model.

By design, the depth of T' is $\lceil \log n \rceil + 1$. As $\mathcal{T} := (T, A(T), B(T))$ is d-sparse, it has at most $(2n-1)d$ transversal (anti-)edges. Each blue or green edge of $\mathcal{T}$ gives rise to at most $(2 \log n)^2$ blue or green edges of $\mathcal{T}'$, by Lemma 8. Hence $\mathcal{T}'$ is $4d \log^2 n$-sparse.

Let us finally check that $\mathcal{T}'$ still represents G. Fix $u, v \in V(G)$ and $xy := e_T(u,v)$. Let $x'y'$ be the green or blue edge of $\mathcal{T}'$ originating from xy such that $u \in I_{T'}(x'), v \in I_{T'}(y')$. We claim that $x'y'$ cannot have been removed (see the technicality at the end of the construction of $\mathcal{T}'$), nor can $x''y'' \in A(T') \cup B(T')$ hold with $x'y' \prec_T x''y''$. Indeed, by the arguments of the second paragraph, the green or blue edge e of $\mathcal{T}$ giving rise to $x''y''$ would be such that $xy \prec_T e \preceq_T uv$, contradicting the definition of $e_T(u,v)$. ◀

We finally need this folklore observation.

▶ **Observation 11.** *Every m-edge graph has degeneracy at most $\lceil \sqrt{2m} \rceil - 1$.*

Proof. It is enough to show that any m-edge graph G has a vertex of degree at most $\lceil \sqrt{2m} \rceil - 1$. If all the vertices of G have degree at least $\lceil \sqrt{2m} \rceil$, then $m \geqslant \frac{1}{2} n \lceil \sqrt{2m} \rceil$. But also $n \geqslant \lceil \sqrt{2m} \rceil + 1$ for a vertex to possibly have $\lceil \sqrt{2m} \rceil$ neighbors. Thus $m \geqslant \frac{1}{2} \sqrt{2m}(\sqrt{2m}+1) > m$, a contradiction. ◀

Combining Lemmas 5 and 10, Observation 11, , and Proposition 7 yields Theorem 2.

Proof of Theorem 2. Let G be an n-vertex graph of sd-degeneracy d. By Lemma 5, G admits a clean signed tree model of width at most $d+1$, hence $(d+1)$-sparse. Thus by Lemma 10, G has a $4(d+1)\log^2 n$-sparse signed tree model $\mathcal{T}$ of depth $\lceil \log n \rceil + 1$. By Observation 11, $\mathcal{T}$ has width at most

$$\sqrt{16(d+1)n \log^2 n} = 4\sqrt{(d+1)n} \log n.$$

Therefore, by Proposition 7, G has a $O(\sqrt{dn} \log^3 n)$-bit labeling scheme. ◀

5 Symmetric Difference is para-co-NP-complete

For any fixed even integer $d \geqslant 8$, we show that the following problem is NP-complete: Does the input graph G have an induced subgraph with at least two vertices and no pair of d-twins? We call such an induced subgraph a $(d+1)$-*diverse graph*. The membership of this problem to NP is straightforward, as a $(d+1)$-diverse induced subgraph H of G is a polynomial-sized witness. One can indeed check in polynomial-time that H has at least two vertices, and that for every pair u, v of vertices of H, at least $d+1$ other vertices of H are neighbors of exactly one of u, v.

The *d-twin graph* $T_d(G)$ of a graph G is a graph with vertex set $V(G)$ and edges between every pair of d-twins.

▶ **Observation 12.** *The vertices of a $(d+1)$-diverse induced subgraph of G form an independent set of $T_d(G)$.*

Given any 3-SAT formula φ with at most three occurrences of each variable, clauses of size two or three, and at least three clauses, we build a graph $G := G(\varphi)$ such that G has a $(d+1)$-diverse induced subgraph if and only if φ is satisfiable. Such a restriction of 3-SAT is known to be NP-complete [21].

5.1 Bubble gadget

A *bubble gadget* B (or *bubble* for short) is a $w \times w$ rook graph, with $w := \frac{d}{2} + 2$, deprived of the two rightmost vertices of its top row. We say that B is *properly attached* to the rest of the graph if each vertex of the top row (of width $\frac{d}{2}$) and of the rightmost column (of height $\frac{d}{2} + 1$) has one or two neighbors outside the gadget, whereas the other vertices of B have no neighbors outside $V(B)$. Let S be the set of neighbors of the bubble outside of B.

We say that B is *neatly attached to* S if it is properly attached to S, and further, vertices of the top row and rightmost column have *exactly* one outside neighbor, and at most one vertex of S has neighbors in both the top row and rightmost column. The *neat* attachments that we will use, in this section and the next, satisfy $2 \leqslant |S| \leqslant 5$. Hence they can be described by a tuple of size between 2 and 5, listing the number of neighbors of vertices in S among $V(B)$, starting with the top row and ending with the rightmost column. For instance, Figure 2 depicts a neat $(2,2,2,7)$-attachment. A bubble properly attached to S is in a delicate state. It may entirely survive in a $(d+1)$-diverse induced subgraph of G.

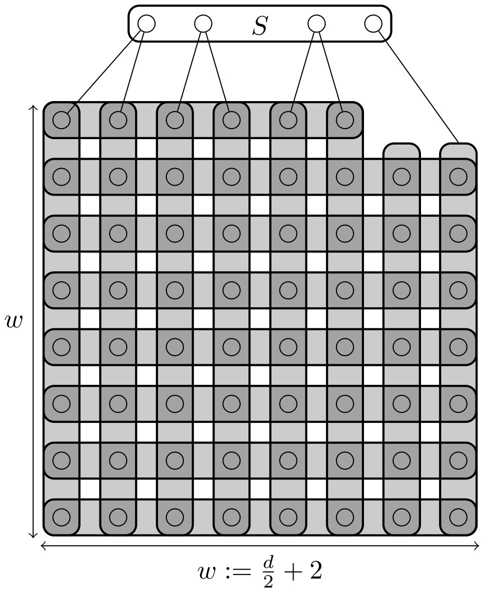

Figure 2 A neatly $(2, 2, 2, 7)$-attached bubble gadget, with $d = 12$.

▶ **Observation 13.** *Let B be a bubble gadget properly attached to S in G. No pair of vertices of B are d-twins in $G[V(B) \cup S]$.*

Proof. In B the only pairs with symmetric difference at most d, in fact exactly d, consist of a vertex in the top row and another vertex in its column, or two vertices of the same row in the two rightmost columns. In both cases, these pairs have symmetric difference at least $d+1$ in $G[V(B) \cup S]$ since vertices of the top row or rightmost column have at least one neighbor in S, while all other vertices of B have no neighbor in S. ◀

However, deletions that cause one vertex of the top row or two vertices of the rightmost column to no longer have outside neighbors cause the bubble to completely collapse.

▶ **Lemma 14** (⋆). *Let B be a bubble gadget properly attached to S in G. Let H be any $(d+1)$-diverse induced subgraph of G, such that at least one vertex of the top row or at least two vertices of the rightmost column has no neighbor in $V(H) \setminus V(B)$. Then, H contains at most one vertex of B.*

In the current section, for the hardness of symmetric difference, all the bubble gadgets will be neatly attached. Furthermore, every vertex a bubble is attached to will have at least one neighbor on the top row, or at least two neighbors in the rightmost column. Thus the deletion of *any* vertex a bubble B is attached to will result, by Lemma 14, in deleting all the vertices of B but at most one.

5.2 Variable and clause gadgets

The *variable gadget* of variable x used in φ is simply two vertices $x, \neg x$ adjacent to a set N_x of $t := \frac{d}{2} + 1$ shared neighbors. Since each literal appears positively and negatively in φ (otherwise the valuation of the literal is clear), vertices x and $\neg x$ have one or two other neighbors in G corresponding to the clause they belong to, as we will soon see. The vertices of N_x will have other neighbors split into at most four bubble gadgets. This too will be

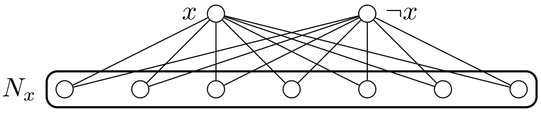

Figure 3 The variable gadget of x with $d = 12$.

described shortly. The *clause gadget* of clause c consists of a pair of adjacent vertices v_c, d_c. We make v_c (but not d_c) adjacent to the two or three vertices corresponding to the literals of c.

5.3 Construction of $G(\varphi)$

Unsurprisingly, we add one variable gadget per variable, and one clause gadget per clause of φ. Let $x_1, \dots, x_n$ be a numbering of the variables, and $c_1, \dots, c_m$, of the clauses. We neatly attach a bubble gadget to S_j made of the five vertices $z_j, v_{c_j}, d_{c_j}, v_{c_{j+1}}, d_{c_{j+1}}$ for every $j \in [m-1]$, with (in this order) a $(1, \lfloor d/4 \rfloor, \lfloor d/4 \rfloor, \lceil d/4 \rceil, \lceil d/4 \rceil)$-attachment, where z_j is a vertex of some N_x. The choice of z_j is irrelevant, but we take all the vertices z_j pairwise distinct. This is possible since there are at most $3n/2$ clauses, and more than $dn/2$ vertices contained in the union of the sets N_x. For every $j \in [m-1]$, we make $\{v_{c_j}, d_{c_j}\}$ fully adjacent to $\{v_{c_{j+1}}, d_{c_{j+1}}\}$. The construction of G is almost complete; see Figure 4 for an illustration.

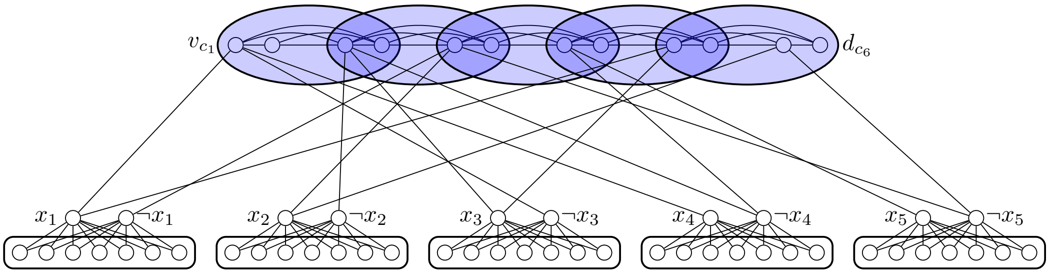

Figure 4 The essential part of G built so far, for a 3-CNF formula φ whose first two clauses are $x_1 \vee \neg x_3 \vee x_4$ and $\neg x_2 \vee x_3 \vee \neg x_4$. The blue ellipses represent the bubbles attached to the four enclosed vertices (recall that the bubble is attached to a fifth vertex among the sets N_x).

At this point, all the vertices v_{c_j}, d_{c_j} such that $j \in [2, m-1]$ have exactly $\lfloor d/4 \rfloor + \lceil d/4 \rceil = d/2$ neighbors in (two) bubble gadgets. Let $y_1, \dots, y_{nt}$ be the ordering of the vertices in $\bigcup_x N_x$ from left to right in how they appear in Figure 4. We neatly attach a bubble gadget to (v_{c_1}, d_{c_1}, y_1) by a $(\lceil d/4 \rceil, \lceil d/4 \rceil, d + 1 - 2\lceil d/4 \rceil)$-attachment. Similarly, we neatly attach a bubble gadget to $(v_{c_m}, d_{c_m}, y_{nt})$ by a $(\lceil d/4 \rceil, \lceil d/4 \rceil, d + 1 - 2\lceil d/4 \rceil)$-attachment. Finally for every $i \in [nt-2]$, we neatly attach a bubble gadget to S'_i made of the three vertices y_i, y_{i+1}, y_{i+2} with a $(1, d/2, d/2)$-attachment. This finishes the construction.

We make some observations. As all the bubble gadgets are neatly attached, no two vertices outside a bubble gadget B can share a neighbor in B.

▶ **Observation 15.** *For every $j \in [m]$, v_{c_j}, d_{c_j} each have exactly $d/2$ neighbors in bubble gadgets (all of which are non-adjacent to any other vertex outside their respective bubble).*

Vertices in $\bigcup_x N_x$ have more neighbors in bubbles.

▶ **Observation 16.** *Every $v \in \bigcup_x N_x$ has at least $d/2 + 1$ neighbors in bubble gadgets (all of which are non-adjacent to any other vertex outside their respective bubble).*

5.4 Correctness

We can now show the following strengthening of Theorem 4.

▶ **Theorem 17.** *For every fixed even integer $d \geqslant 8$, deciding if an input graph has symmetric difference at most d is co-NP-complete.*

As the graph $G := G(\varphi)$ presented in Section 5.3 can be constructed in polynomial time, we shall simply check the equivalence between the satisfiability of φ and the existence of a $(d+1)$-diverse induced subgraph of $G(\varphi)$. We recall that, by definition, G has *not* symmetric difference at most d if and only if it has a $(d+1)$-diverse induced subgraph.

▶ **Lemma 18.** *If φ is satisfiable, then G admits a $(d+1)$-diverse induced subgraph.*

Proof. Let $\mathcal{A}$ be a satisfying assignment of φ. For each variable x of φ, we delete vertex $\neg x$ if $\mathcal{A}$ sets x to true, and we delete vertex x otherwise (if $\mathcal{A}$ sets x to false). Let us call H the obtained induced subgraph of G (with at least two vertices). We claim that H has no pair of d-twins, and successively rule out such pairs

(i) within the same bubble,
(ii) between a vertex in a bubble B and a vertex outside B (but possibly in another bubble),
(iii) between two vertices both outside every bubble gadget.

(i) As H contains all the vertices of G on which bubble gadgets are attached, by Observation 13, no two distinct vertices in the same bubble are d-twins.

(ii) Let us fix a bubble gadget B attached to S, and two vertices $u \in V(B)$ and $v \in V(H) \setminus V(B)$. First observe that u has at least $d/2+1$ neighbors in $V(B)$ (hence in H) that are not neighbors of v. All the vertices $v \in V(H) \setminus (V(B) \cup S)$ have at least $d/2$ neighbors in H that are not neighbors of u. For these vertices v, $\text{sd}_H(u,v) > d$. We thus focus on the case when $v \in S$. We can assume that v is some v_{c_j} or d_{c_j}, as any other vertices have at least $d/2$ neighbors outside B. We can further assume that u is in the top row or rightmost column of B, otherwise it has d neighbors that are not neighbors of u (and u has at least one private neighbor). Now we observe that

$$\text{sd}_H(u,v) \geqslant |N_H(u) \setminus N_H[v]| + |N_H(v) \setminus N_H[u]| \geqslant d/2+1+d/2-1-\lceil d/4 \rceil + \lfloor d/4 \rfloor + 2 \geqslant d+1,$$

where $d/2+1$ lower bounds the number of neighbors of u whose neighborhood is included in $V(B)$, $d/2-1-\lceil d/4 \rceil$ lower bounds the number of neighbors of u in the top row or rightmost column of B that are not adjacent to v, $\lfloor d/4 \rfloor$ lower bounds the number of neighbors of v in another bubble than B, and 2 accounts for the at least two neighbors $v_{c_{j-1}}, d_{c_{j-1}}$ or $v_{c_{j+1}}, d_{c_{j+1}}$ of v, whichever exist. (Here we need that there are at least two clauses.)

(iii) Let u, v be two distinct vertices outside every bubble gadget. Vertex u (resp. v) has at least $d/2$ neighbors that are not neighbors of v (resp. u). This holds by Observations 15 and 16, and the fact that every vertex x_i or $\neg x_i$ is adjacent to N_{x_i}, while no other vertex outside the bubble gadgets is adjacent to any vertex in N_{x_i}. Furthermore, as $|N_{x_i}| = d/2+1$ and vertices in $\bigcup_x N_x$ have at least $d/2+1$ neighbors in bubble gadgets, the only pairs that could be d-twins in H are made of two vertices in clause gadgets. As there are at least three clauses in φ, two vertices u, v from distinct clause gadgets have at least two additional private neighbors. Thus we can assume that $u = v_{c_j}$ and $v = d_{c_j}$ for some $j \in [m]$. As $\mathcal{A}$ is a satisfying assignment, at least one vertex x or $\neg x$ adjacent to v_{c_j} has survived in H. Hence $\text{sd}_H(u,v) \geqslant d/2 + d/2 + 1 = d+1$. ◀

▶ **Lemma 19** ($\star$)**.** *If φ is not satisfiable, then G has no $(d+1)$-diverse induced subgraph.*

6 Discussion and open problems

Degeneracy can be defined either by degeneracy ordering for vertices, or by the existence of vertices of small degree in all the induced subgraphs. And despite sd-degeneracy and symmetric difference arising as dense counterparts to these two equivalent definitions, they are not equivalent: classes of bounded symmetric difference are strictly contained in classes of bounded sd-degeneracy. Using signed tree models, we achieve an adjacency labeling scheme for classes of bounded sd-degeneracy that is tight up to logarithmic factors. The necessity of these additional logarithmic factors remains questionable. Moreover, an optimal adjacency labeling scheme for classes of bounded symmetric difference is yet to be found.

▶ **Question 1.** *Is there an $O(\sqrt{n})$-adjacency labeling scheme for classes of bounded sd-degeneracy? Is there an $O(\log n)$-adjacency labeling scheme for classes of bounded symmetric difference?*

On the other hand, we prove a surprising phenomenon: not only both symmetric difference and sd-degeneracy lead to classes that are hard to recognize, but they respectively lead to para-NP-complete and para-co-NP complete problems. However, the existence of a polynomial-time approximation for remains open.

▶ **Question 2.** *Is there a polynomial-time algorithm to compute an approximation of symmetric difference (and sd-degeneracy)?*

A Proof of Proposition 1

Take any n-vertex graph G, and fix an arbitrary ordering $v_1, v_2, \dots, v_n$ of its vertices. There is a graph G' with at most $(n-1)(n-3)$ vertices that both contains G as an induced subgraph, and has sd-degeneracy at most 1. The graph G' can be built by adding to G, for every $i \in [n-1]$, up to $n-3$ vertices $v_{i,1}, \dots, v_{i,h_i}$ gradually "interpolating" between the neighborhood of v_i and that of v_{i+1} (in G). For instance, $v_{i,1}, \dots, v_{i,h'_i}$ remove one-by-one the neighbors of v_i that are not neighbors of v_{i+1}, and $v_{i,h'_i+1}, \dots, v_{i,h_i}$ add one-by-one the neighbors of v_{i+1} that are not neighbors of v_i. (We put no edge between a pair of added vertices $v_{i,p}, v_{i',p'}$.) Then an ordering witnessing sd-degeneracy at most 1 is $v_1, v_{1,1}, v_{1,2}, \dots, v_{1,h_1}, v_2, v_{2,1}, v_{2,2}, \dots, v_{2,h_2}, \dots, v_{n-1}, v_{n-1,1}, v_{n-1,2}, \dots, v_{n-1,h_{n-1}}, v_n$, for which the 1-twin of a vertex is its successor.

B More context on signed tree models

A wide range of structural graph invariants, called width parameters, can be expressed via so-called *tree layouts* (or at least parameters functionally equivalent to them can). A *tree layout* of an n-vertex graph G is a full binary tree T such that the leaves of T, that we may denote by $L(T)$, are in one-to-one correspondence with $V(G)$. Width parameters are typically defined through evaluating a particular function on bipartitions of $V(G)$ made by the two connected components of T when removing one edge of T. The width is then the minimum over tree layouts of the maximum over all such evaluations. In the definition of signed tree models, we depart from this viewpoint, and instead augment T with a sparse structure encoding the graph G.

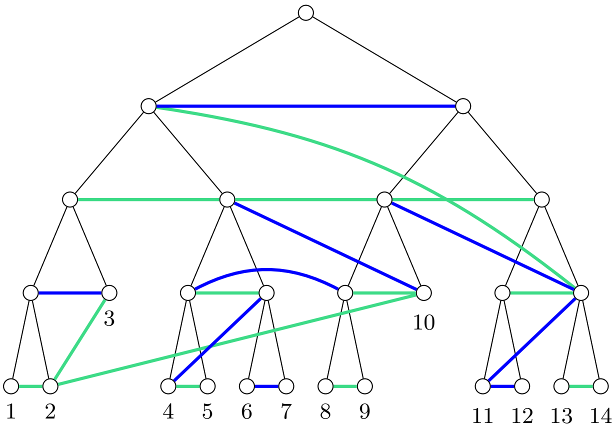

Figure 5 The signed tree model of Figure 1 made clean.

Every graph of twin-width d admits a signed tree model with $A(T) = \emptyset$ and width at most $d + 1$. *Tree models* or *twin-decompositions* are signed tree models with $A(T) = \emptyset$, and further technical requirements. We observe that similar objects to signed tree models were utilized in [6] to attain a fast matrix multiplication on matrices of low twin-width. We will not need a definition of twin-width, and refer the interested reader to [7]. In Section 1 we also mentioned Welzl orders with low alternation number [22], let us now elaborate on that.

A *Welzl order* of *alternation number* d for a graph G is a total order $<$ on $V(G)$ such that the neighborhood of every vertex is the union of at most d intervals along $<$. We claim that bipartite graphs $G = (X \uplus Y, E(G))$ with a Welzl order $<$ of alternation number d admit a signed tree model of width $2d$. Note that we can assume that for every $x \in X$ and $y \in Y$, $x < y$. We build a signed tree model $(T, A(T), B(T))$ of G as follows. Let us call *binary comb* a full binary tree whose internal nodes induce a path, rooted at an endpoint of this path. We make the root of T adjacent to the roots of two binary combs with $|X|$ and $|Y|$ leaves, respectively. The leaves are labeled from left to right with the vertices of G in the order $<$. To simplify the notations, assume that these labels describe $[n]$ in the natural order. To represent that vertex $i \in X$ has $[j, k] \subseteq Y$ in the partition of its open neighborhood into maximal intervals, we add a blue edge between leaf i and the parent of k, and a green edge between i and the parent of $j - 1$ (to stop the interval). Finally observe that $(V(T), A(T) \cup B(T))$ has maximum degree at most $2d$. (The subtree whose leaves are the vertices of X need not be a binary comb.)

A similar construction would work for graphs G of chromatic number q, and would yield a signed tree model of width $2(q - 1)d$. A more permissive definition of signed tree models, allowing leaf-to-ancestor transversal edges, would give models of width $2d$ for any graph with a Welzl order of alternation number d. However, with this alternative definition, the consequences of Section 4 would not follow. Hence we stick to the given definition of signed tree models.

C Proof of Lemma 14

We first deal with the case when a vertex v of the top row (in the entire B) has no neighbor in $V(H) \setminus V(B)$. By symmetry, assume that v is the topmost vertex of the first column. Vertex v is thus d-twin with all the other vertices of the first column. Hence by Observation 12, either v is not in H, or none of the $d/2+1$ vertices below v are in H.

If the latter holds, then any two vertices in the same column, outside the top row and rightmost column, are now d-twins. By Observation 12 within these vertices, H can only contain at most one vertex per column. In turn, the kept vertices are d-twins, so at most one can be kept overall. We conclude since the vertices of $N_H(S) \cap V(B)$ have at most two neighbors in S.

We now suppose that v is not in H. Then, in each row but the topmost, the vertices in the first and penultimate columns are d-twins. Thus, within each pair, at most one vertex can be in H. This implies that any two vertices in the same column, outside the top row and rightmost column, are now d-twins. Thus we conclude as in the previous paragraph.

We now deal with the case when two vertices x, y of the right most column have no neighbor in $V(H) \setminus V(B)$. By symmetry, we can assume that x is in the second row, and y is in the third row. Then x (resp. y) is d-twin with the vertex just to its left. After one vertex is removed in each pair, in each column but the last two, the vertices in the second and third rows have become d-twins. Therefore, H can only contain at most one vertex from all these pairs. We reach again the state that any two vertices in the same column, outside the top row and rightmost column, are d-twins, and conclude as previously.

D Proof of Lemma 19

For each variable x, the vertices $x, \neg x$ are 3-twins, thus at least one of them has to be removed in a $(d+1)$-diverse induced subgraph. The kept literals (if any) define a (partial) truth assignment. By assumption, this assignment does not satisfy at least one clause c_j. This implies that v_{c_j}, d_{c_j} are d-twins in the corresponding induced subgraph. Indeed, they each have exactly $d/2$ private neighbors in bubble gadgets, and no other private neighbor.

By Lemma 14, the bubble attached to S_j is reduced to at most one vertex, say w_j (if any). In turn, this makes the pairs $v_{c_{j-1}}, d_{c_{j-1}}$ and $v_{c_{j+1}}, d_{c_{j+1}}$ d-twins (when they exist). Indeed their symmetric difference is at most $3 + \lceil d/4 \rceil + 1 \leqslant d$, where 3 accounts for the three literals of the clause, and 1 for vertex w_j. This iteratively collapses every bubble attached to some $S_{j'}$ to a single vertex, as well as the two bubble gadgets attached to $\{v_{c_1}, d_{c_1}, y_1\}$ and $\{v_{c_m}, d_{c_m}, y_{nt}\}$, in say, w_0 and w_m. Now all the vertices w_j (for $j \in [0,m]$) are 6-twins, so at most one can be kept. We recall that at most one vertex per clause gadget could be kept. For j going from 1 to $m-1$, the vertex kept (if any) from the clause gadget of c_j is an 8-twin of the vertex kept in the next surviving clause gadget. This implies that from all the clause gadgets and all the bubble gadgets attached to them, one can only keep at most one vertex overall, say z. This vertex has degree at most 3 in the resulting induced subgraph.

Vertices y_1, y_2 are now d-twins, so the bubble gadget attached to S'_1 collapses to at most one vertex. Vertices y_1 and z are now 5-twins, so at most one can survive, which we keep calling z. Even if y_2 is kept, it is now a d-twin of y_3, thus at most one of y_2, y_3 can be kept. This implies the collapse of the bubble gadget attached to S'_2 to at most one vertex, absorbed by z. In turn, y_2 and z collapse to a single vertex. This process progressively eats up all the vertices y_j, and all the bubble gadgets attached to them. As soon as a vertex x or $\neg x$ has three remaining neighbors, it becomes a 6-twin of z, and is absorbed by it. We end up with the single vertex z.

First-Fit Coloring of Forests in Random Arrival Model

Abstract

We consider a graph coloring algorithm that processes vertices in order taken uniformly at random and assigns colors to them using First-Fit strategy. We show that this algorithm uses, in expectation, at most $(1 + o(1)) \cdot \ln n \,/\, \ln \ln n$ different colors to color any forest with n vertices. We also construct a family of forests that shows that this bound is best possible.

1 Introduction

A *proper k-coloring* of a graph $G = (V, E)$ is a function $c : V \mapsto \{1, 2, \ldots, k\}$ that assigns a color $c(v)$ to each vertex $v \in V$ so that any adjacent vertices are colored differently, i.e., for each edge $\{u, w\} \in E$, $c(u) \neq c(w)$ is satisfied. For a given graph G, the smallest number k for which G admits a proper k-coloring is the *chromatic number* of G and is denoted by $\chi(G)$. Graph coloring is one of the most prominent disciplines within graph theory, with plenty of variants, applications, and deep connections to theoretical computer science. Coloring problems arise naturally in various job scheduling and resource allocation optimization scenarios.

The graph coloring problem is also very popular and well motivated in the online setting, with applications in job scheduling, dynamic storage allocation and resource management [9, 11, 12]. In the *online graph coloring* problem, an online algorithm receives as input a graph $G = (V, E)$ presented in an online fashion. The vertices of V are revealed one after one, in a *presentation order* $v_1 \ll v_2 \ll \ldots \ll v_n$. When a new vertex v_t is revealed in the t-th round, for $1 \leqslant t \leqslant n$, all the edges connecting v_t with vertices in $V_{t-1} = \{v_1, \ldots, v_{t-1}\}$ are also revealed. An online algorithm $\mathcal{A}$ has to immediately assign a feasible color to v_t, that is,

a color that is different from those assigned to the neighbors of v_t in V_{t-1}. The goal is to minimize the total number of colors used.

The performance of an online graph coloring algorithm $\mathcal{A}$ is often measured by its *competitive ratio*. If we denote by $\chi_{\mathcal{A}}(G, \lll)$ the number of colors used by $\mathcal{A}$ when coloring a graph G in a presentation order $\lll$, then the competitive ratio of $\mathcal{A}$ is the maximum ratio $\chi_{\mathcal{A}}(G, \lll) \,/\, \chi(G)$ over all graphs G and all orders $\lll$. This means, that for a single graph, the analysis focuses on the worst case scenario, and the presentation order is often considered to be selected by an adversary. If $\mathcal{A}$ is a randomized algorithm, then it is usual to measure the competitive ratio with respect to the expected number of colors used when coloring G in order $\lll$ over all the random choices of $\mathcal{A}$.

Contrary to the offline setting, even coloring 2-colorable graphs is not easy for online algorithms. It is impossible to construct an online algorithm that would use any constant number of colors to color all 2-colorable graphs. Thus, the research focuses on restricted graph classes, and competitive ratio is often expressed as a function of the number of vertices in a graph. In fact, even for inputs restricted to online forests with n vertices, the best competitive ratio that can be achieved by either randomized or deterministic online coloring algorithm is $\Theta(\log n)$ colors [3, 6, 1]. The optimal number of colors used by any deterministic online algorithm to color 2-colorable graphs with n vertices is known to be somewhere between $2\log_2 n - 10$ (by a result of Gutowski et al. [5]) and $2\log_2 n$ (see a paper by Lovász, Saks, and Trotter [10]).

An algorithm known as First-Fit is arguably the simplest and the most understood of all online deterministic coloring algorithms. When a vertex v_t is revealed in the t-th round, First-Fit picks the least positive integer i which does not occur as a color of any of the previously colored neighbors of v_t and assigns i as a color of v_t. First-Fit performs well on online trees, achieving the competitive ratio of $\Theta(\log n)$ within this class. To be more precise, Bean [3] and, independently, Gyárfás and Lehel [6] proved that First-Fit uses at most $\log_2 n + 1$ colors on forests with n vertices. Irani [8] generalized this result, showing that First-Fit uses $O(d \log n)$ colors on d-degenerate graphs with n vertices. Later, Balogh et. al. [2] with corrections of Chang and Hsu [4] improved the above result to at most $(\log_{\frac{d+1}{d}} n + 2)$ colors. For bipartite graphs, there is an easy construction by Lovász, Saks, and Trotter [10] that shows that First-Fit uses as many as $\frac{n}{2}$ colors to color a 2-colorable graph with n vertices.

In this paper, we are interested in the *random arrival model* for online algorithms, that tries to focus on the average case, rather than the worst case scenario. In this model, the presentation order of a graph is not determined by an adversary, but instead it is selected uniformly at random from all possible permutations of the vertex set. The *performance ratio* of a deterministic online algorithm $\mathcal{A}$ on a graph G is measured by the expectation $\mathbb{E}_{\lll}\left[\frac{\chi_{\mathcal{A}}(G,\lll)}{\chi(G)}\right]$ over the random choice of $\lll$. The performance ratio of $\mathcal{A}$ on a class of graphs $\mathcal{G}$ is the the maximum performance ratio taken over all graphs in $\mathcal{G}$.

In particular, our intention is to start the systematic study of the performance ratio of First-Fit coloring algorithm in random arrival model. For a class of graphs $\mathcal{G}$, let $\mathrm{RFF}_{\mathcal{G}}(n)$ denote the maximum performance ratio of First-Fit taken over all graphs in $\mathcal{G}$ with n vertices, i.e.,

$$\mathrm{RFF}_{\mathcal{G}}(n) = \max_{G \in \mathcal{G}, |G|=n} \mathbb{E}_{\lll}\left[\frac{\chi_{\mathrm{FF}}(G, \lll)}{\chi(G)}\right].$$

For an easy comparison to the adversarial model, we define:

$$\mathrm{FF}_{\mathcal{G}}(n) = \max_{G\in\mathcal{G},|G|=n} \max_{\ll} \left[\frac{\chi_{\mathrm{FF}}(G,\ll)}{\chi(G)}\right].$$

In this paper, we prove the following result, which establishes the performance of First-Fit on the class of forests.

▶ **Theorem 1.** *For the class $\mathcal{F}$ of forests, we have* $\mathrm{RFF}_{\mathcal{F}}(n) = ({}^1\!/\!{}_2 \pm o(1)) \cdot \ln n \,/\, \ln\ln n$.

As mentioned above, we have $\mathrm{FF}_{\mathcal{F}}(n) = \Theta(\log n)$. Theorem 1 shows that the randomization of the presentation order gives a noticeable, yet rather moderate increase in performance compared to the adversarial model.

One can also consider the following natural off-line graph coloring algorithm. Given a graph G, it selects an order $\ll$ of vertices of G uniformly at random. Then it uses First-Fit strategy to color vertices of G in order $\ll$. Theorem 1 shows that this algorithm uses $O(\log n \,/\, \log\log n)$ colors in expectation to color any forest. This algorithm does not compete with easy 2-coloring algorithms based on graph traversal. Our objective, however, is to establish the groundwork for a systematic analysis of First-Fit, and other simple online algorithms, in the random arrival model for other graph classes, such as d-degenerate graphs, bipartite graphs, and subsequently, k-colorable graphs. It should be noted that for 3-colorable graphs, the most effective known randomized online algorithm utilizes expected $O\big(n^{1/2}\big)$ colors, as proved by Halldórsson [7]. Considering that the best lower bound for 3-colorable graphs is in the order of $\Omega\big(\log^2 n\big)$, as demonstrated by Vishwanathan [13], it appears that the direction we are pursuing holds promise for intriguing outcomes.

Another rationale for this line of inquiry is that First-Fit in random arrival model serves as an illustration for the following distributed coloring algorithm that works in the synchronous model. Each vertex of the graph represents a computation node, and edges represent communication links. To divide nodes into independent subsets, each node performs a sleep for a random number of units of time, and then assigns to itself the first possible number not assigned to any of the neighbors. This algorithm uses a small number of messages and is quite fast. Although we refrain from further delving into this setting, we underscore the versatility afforded by our analysis.

The paper is organized as follows. In Section 2 we show that First-Fit uses at most $(1 + o(1)) \cdot \ln n \,/\, \ln\ln n$ different colors in expectation on any forest with n vertices. In Section 3 we construct a family of trees for which First-Fit uses $(1 - o(1)) \cdot \ln n \,/\, \ln\ln n$ different colors in expectation. The final section contains brief comments and some open problems regarding the analyzed problem.

2 Upper bound

In this section we show that First-Fit uses at most $O(\log n \,/\, \log\log n)$ different colors in expectation on any forest with n vertices. For this purpose let us first make a basic observation. For any fixed graph $G = (V, E)$ and any order $\ll$ of V, we denote by $G^{\ll}$ the acyclic directed graph obtained from G by orienting every edge $\{u, v\} \in E$ so that it is oriented from u to v if and only if $u \ll v$.

▶ **Observation 2.** *For any graph $G = (V, E)$, a presentation order $\ll$ of V, a positive integer i, and a vertex $v \in V$, if First-Fit assigns color i to v when coloring G in order $\ll$ then there is a directed path in $G^{\ll}$ with i vertices and v as the last vertex.*

Proof. We prove the observation by induction with respect to i. The statement is trivial for $i = 1$, so let us assume $i \geqslant 1$ and that the thesis holds for all values up to i. Suppose that First-Fit assigns color $i + 1$ to vertex v in some round of the algorithm. At this point, v has a neighbor u with $u \ll v$ that was assigned with color i in some earlier round. By induction hypothesis, there is a directed path P in $G^{\ll}$ with i vertices and u as the last vertex. Since $u \ll v$, and $G^{\ll}$ is acyclic we know that v does not belong to P. Thus, we get the desired path by extending P with directed edge (u, v). ◀

We call a simple path P in a directed graph to be *bidirected* if it is either a directed path, or P can be split into two directed paths, each starting at one of the end points of P, and both sharing the same last vertex.

▶ **Corollary 3.** *For any forest $T = (V, E)$, a presentation order $\ll$ of V, and a positive integer $i \geqslant 2$, if First-Fit uses color i when coloring T in order $\ll$ then there is a bidirected path in $T^{\ll}$ with $2i - 2$ vertices.*

Proof. For $i = 2$, by Observation 2 we get a directed path with 2 vertices. Suppose $i \geqslant 3$, and that First-Fit assigns color i to some vertex v of T. At this point, v has a neighbor u that is colored $i - 1$, and a different neighbor w that is colored $i - 2$. By Observation 2 there is a directed path with $i - 1$ vertices and u as the last vertex, and a directed path with $i - 2$ vertices and w as the last vertex. As T is a forest, these paths are vertex disjoint. Since $u \ll v$, and $w \ll v$, we get the desired bidirected path in $T^{\ll}$ by extending both paths with directed edges (u, v) and (w, v). ◀

▶ **Lemma 4.** *For the class $\mathcal{F}$ of forests, every $n \geqslant 3$, and an $\alpha_n = \frac{\ln\ln\ln n+1}{\ln\ln n-\ln\ln\ln n-1}$, we have:*

$$\mathrm{RFF}_{\mathcal{F}}(n) \leqslant \frac{(1+\alpha_n)\ln n}{2\ln\ln n} + \frac{3}{2}.$$

Proof. It is straightforward to verify that $\mathrm{RFF}_{\mathcal{F}}(3) = 1$ and $\mathrm{RFF}_{\mathcal{F}}(4) < 2$, hence the lemma holds for $n = 3, 4$. Let us assume that $n \geqslant 5$. Then, since the function $\ln\ln x - \ln\ln\ln x - 1 > 0$ for every $x > e$ except $x = e^e$, then $\ln\ln n - \ln\ln\ln n - 1 > 0$, and hence $\alpha_n > 0$. Consider any forest T with n vertices. Let $k = \left\lceil \frac{(1+\alpha_n)\ln n}{\ln\ln n} \right\rceil$, and observe that our goal is to prove that First-Fit uses at most $k + 2$ colors in expectation when coloring T in a random order. Indeed, we can assume that $\chi(T) = 2$, as otherwise T is an independent set, and First-Fit uses only one color when coloring T in any order. Note that $(1 + \alpha_n)\ln n/\ln\ln n > \ln n/\ln\ln n > 1$. Hence, $k \geqslant 2$. By Corollary 3, for every order $\ll$ of the vertices of T and a positive integer $i \geqslant 2$, if $\chi_{FF}(T, \ll) = i$, then there is a bidirected path with $2i - 2$ vertices in $T^{\ll}$. Consider any two vertices x, y of T. There is at most one simple path in T with end points x and y. If this path exists, and is a path with exactly $2i - 2$ vertices, then the probability that this path is bidirected in $T^{\ll}$ for a random order $\ll$ is exactly $2^{2i-3} / (2i - 2)!$. Otherwise, the probability that there is such a path with end points x and y equals 0.

Thus, by the union bound, the probability that there is at least one bidirected path with $2i - 2$ vertices in $T^{\ll}$ is upper bounded by $\left(n^2 / 2\right) \cdot \left(2^{2i-3} / (2i - 2)!\right)$. Hence, the expected number of colors used by First-Fit in a random order satisfies:

$$\mathbb{E}_{\ll}\left[\chi_{FF}(T, \ll)\right] = \sum_{i=1}^{\infty} i \cdot \mathbb{P}(\chi_{FF}(T, \ll) = i) \leqslant k + 1 + \sum_{i=k+2}^{\infty} \frac{i \cdot n^2 \cdot 2^{2i-4}}{(2i-2)!} \leqslant$$

$$= k + 1 + \frac{n^2 \cdot 4^{k-1}}{(2k)!} \cdot \sum_{i=k+2}^{\infty} \frac{i \cdot 2^{2(i-(k+1))}}{(2k+1)\cdot(2k+2)\cdot\ldots\cdot(2i-3)\cdot(2i-2)} \leqslant$$

$$\begin{aligned}
&\leqslant k+1+\frac{n^2\cdot 4^{k-1}}{(2k)!}\cdot\sum_{i=k+2}^{\infty}\frac{2^{2(i-(k+1))}}{1\cdot(2k+2)\cdot\ldots\cdot(2i-3)\cdot 2}\leqslant\\
&\leqslant k+1+\frac{n^2\cdot 4^{k-1}}{(2k)!}\cdot\sum_{i=1}^{\infty}\frac{2^{2i-1}}{(2i-1)!}=\\
&=k+1+\frac{n^2\cdot 4^{k-1}}{(2k)!}\cdot\sinh 2\leqslant\\
&\leqslant k+1+\frac{n^2\cdot 4^{k}}{(2k)!}. \qquad (1)
\end{aligned}$$

For $k=\left\lceil\frac{(1+\alpha_n)\ln n}{\ln\ln n}\right\rceil$, as $x\ln x - x$ is an increasing function for $x\geqslant 1$, and $\alpha_n>0$, $k\geqslant 2$, we have that

$$\begin{aligned}
\ln\left(\frac{(2k)!}{4^k}\right)&\geqslant 2k\ln(2k)-2k-k\ln 4=2k\ln k-2k\geqslant\\
&\geqslant 2\cdot\frac{(1+\alpha_n)\ln n}{\ln\ln n}\cdot\ln\left(\frac{(1+\alpha_n)\ln n}{\ln\ln n}\right)-2\cdot\frac{(1+\alpha_n)\ln n}{\ln\ln n}\geqslant\\
&\geqslant 2\cdot\frac{(1+\alpha_n)\ln n}{\ln\ln n}\cdot\left(\ln\left(\frac{\ln n}{\ln\ln n}\right)-1\right)=\\
&=2\cdot\frac{\ln\ln n}{\ln\ln n-\ln\ln\ln n-1}\cdot\frac{\ln n}{\ln\ln n}\cdot(\ln\ln n-\ln\ln\ln n-1)=\\
&=\ln(n^2),
\end{aligned}$$

and as a consequence, $\frac{(2k)!}{4^k}\geqslant n^2$, hence by (1),

$$\mathbb{E}_{\ll}\left[\chi_{FF}(T,\ll)\right]\leqslant k+2.$$

As this holds for any forest T with n vertices, we conclude that

$$\mathrm{RFF}_{\mathcal{F}}(n)\leqslant\frac{(1+\alpha_n)\ln n}{2\ln\ln n}+\frac{3}{2},$$

which ends the proof. ◀

As $\alpha_n=O(\log\log\log n\,/\,\log\log n)$ in Lemma 4, we immediately get the following corollary.

▶ **Corollary 5.**

$$\mathrm{RFF}_{\mathcal{F}}(n)\leqslant(1/2+o(1))\cdot\ln n\,/\,\ln\ln n\,.$$

3 Lower bound

In this section, for any given $0<\gamma<1$, and a positive integer k we construct a tree T, such that First-Fit uses k colors to color T in a random presentation order with probability at least $1-\gamma$. Thus, $\mathbb{E}_{\ll}[\chi_{FF}(T,\ll)]\geqslant k(1-\gamma)$. The number of vertices in the constructed tree is of the order k^{dk} where d is a constant depending on γ. This implies that $\mathrm{RFF}_{\mathcal{F}}(n)=\Omega(\log n\,/\,\log\log n)$.

For the purpose of analysis, we use a slightly modified, yet equivalent random model. Namely, rather than choosing a permutation in a straightforward manner, we utilize a natural two-stage process. We first associate with every vertex v of a graph G an independent random variable $X_v \sim U[0,1]$ uniformly distributed over $[0,1]$ interval. We call X_v to be the *position* of a vertex v. Then, we order the vertices according to their positions, i.e., so that $u \ll v$ if and only if $X_u \leqslant X_v$. Note that such an order is uniquely determined with probability 1. Moreover, by the symmetry of the process, each resulting vertex permutation is equiprobable.

▶ **Lemma 6.** *For the class $\mathcal{F}$ of forests, we have:*

$$\mathrm{RFF}_{\mathcal{F}}(n) \geqslant (1/2 - o(1)) \cdot \ln n \,/\, \ln\ln n\,.$$

Proof. Fix any $0 < \gamma < 1$, and any integer $k \geqslant 3$. Let $c = 10/\gamma^2$ and $r = \lceil ck \ln k \rceil$. Set $\varepsilon_i = i\gamma/k$ for $i = 1, 2, \ldots, k$. We recursively define rooted trees $T^r_1, T^r_2, \ldots, T^r_k$ as follows. The tree T^r_1 is a single vertex, and for $i = 1, 2, \ldots, k-1$, the tree T^r_{i+1} is constructed of r copies of each of the trees T^r_j with $j = 1, 2 \ldots, i$ by joining their roots to a single additional vertex – the root of T^r_{i+1} (hence the root of T^r_{i+1} has degree ri). See Figure 1.

Consider First-Fit coloring of T^r_i in a random presentation order, for any fixed $i \in \{1, 2, \ldots, k\}$. We assume that the presentation order is given by the positions $X_v \in [0,1]$ drawn uniformly at random for every vertex v of T^r_i. By the construction of T^r_i, the longest simple path ending at the root of T^r_i includes at most i vertices. From Observation 2 we immediately obtain the following claim.

▷ Claim 7. The color assigned by First-Fit to the root of T^r_i when coloring T^r_i in any order, does not exceed i.

We define B_i to be the random event that First-Fit assigns color smaller then i to the root vertex of T^r_i when coloring T^r_i in a random presentation order.

▷ Claim 8. For every $i = 1, 2, \ldots, k$ we have

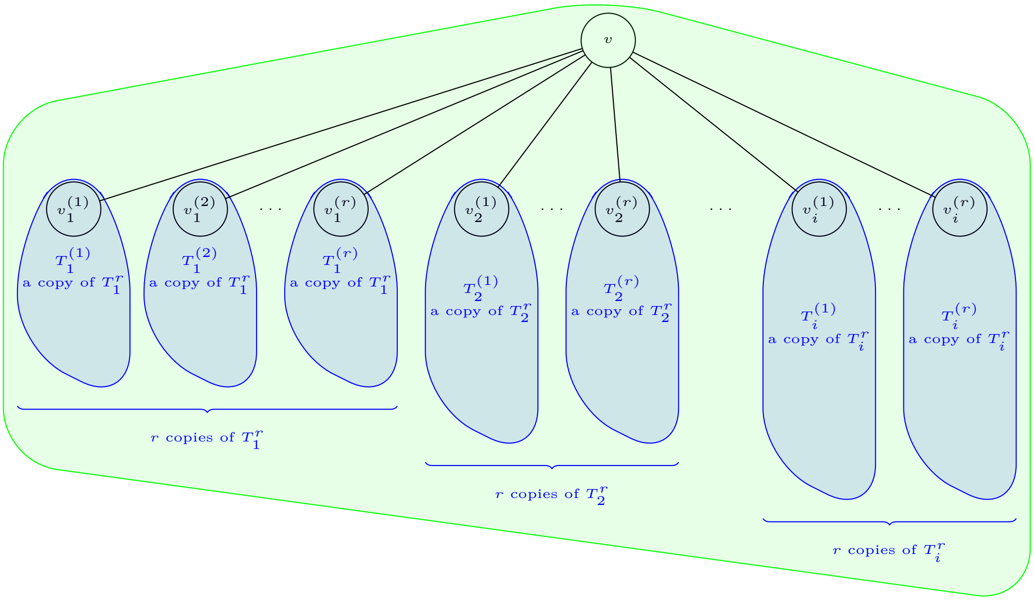
$$\mathbb{P}(B_i) \leqslant \varepsilon_i = \frac{i\gamma}{k}.$$

Proof. We prove the claim by induction on i. For $i = 1$, First-Fit assigns color 1 to the only vertex of T^r_1 and hence $\mathbb{P}(B_1) = 0$. Now, for the induction step, we fix any $1 \leqslant i \leqslant k-1$, and assume that

$$\mathbb{P}(B_j) \leqslant \varepsilon_j \tag{2}$$

holds for every $j = 1, 2, \ldots, i$. We shall prove that $\mathbb{P}(B_{i+1}) \leqslant \varepsilon_{i+1}$. For that we focus on the coloring of $T = T^r_{i+1}$. Denote the root of T by v and let $v^{(q)}_j$ with $j = 1, \ldots, i$, $q = 1, \ldots, r$ be the neighbors of v in T where each $v^{(q)}_j$ is the root of one of the r copies of T^r_j attached to v – we denote this copy as $T^{(q)}_j$. See Figure 1. We denote the (random) color First-Fit assigns to any vertex w by $c(w)$.

Suppose the position of v is fixed and equals x. Note that if for some $1 \leqslant j \leqslant i$ there is some q such that $c(v^{(q)}_j) \geqslant j$ and the position of $v^{(q)}_j$ is smaller than x, then $c(v) \neq j$. Indeed, due to Observation 2 and the fact that $v^{(q)}_j$ is positioned before v we have that $c(v^{(q)}_j) \leqslant j$ and it is assigned with color j by the assumption $c(v^{(q)}_j) \geqslant j$. Therefore, if there is such a q



v

Figure 1 Recursive construction of the tree T_{i+1}^r.

for every $1 \leqslant j \leqslant i$, then we get $c(v) \geqslant i+1$. This allows for the following inequality,

$$\begin{aligned}\mathbb{P}\left(\overline{B_{i+1}} \mid X_v = x\right) &\geqslant \mathbb{P}\left(\forall j \leqslant i\ \exists q \leqslant r : c(v_j^{(q)}) \geqslant j \wedge X_{v_j^{(q)}} < x \mid X_v = x\right) = \\ &= \prod_{j=1}^{i} \mathbb{P}\left(\exists q \leqslant r : c(v_j^{(q)}) \geqslant j \wedge X_{v_j^{(q)}} < x \mid X_v = x\right) = \\ &= \prod_{j=1}^{i}\left(1 - \prod_{q=1}^{r} \mathbb{P}\left(c(v_j^{(q)}) < j \vee X_{v_j^{(q)}} > x \mid X_v = x\right)\right)\end{aligned} \tag{3}$$

where the two last equalities above follow by the independence of the corresponding events for a fixed value of x. Obviously $\mathbb{P}(X_{v_j^{(q)}} > x \mid X_v = x) = 1 - x$, as positions of the vertices are independent. Further, for any assignment X of positions to all vertices of T, one can consider First-Fit coloring of $T_j^{(q)}$ in order given by the restriction of X to the vertices of $T_j^{(q)}$. Color assigned to the root of $T_j^{(q)}$ in this restricted coloring is not greater then the color assigned to this vertex in the coloring of T. Thus, $\mathbb{P}(c(v_j^{(q)}) < j \mid X_v = x) \leqslant \mathbb{P}(B_j)$, and by (2), for every $j \leqslant i$, we have:

$$\mathbb{P}\left(c(v_j^{(q)}) < j \vee X_{v_j^{(q)}} > x \mid X_v = x\right) \leqslant \min\left\{1, 1 - x + \varepsilon_j\right\}. \tag{4}$$

By (3) and (4), we thus obtain that

$$\begin{aligned}\mathbb{P}\left(B_{i+1}\right) = 1 - \mathbb{P}\left(\overline{B_{i+1}}\right) = 1 - \int_0^1 \mathbb{P}\left(\overline{B_{i+1}} \mid X_v = x\right) dx &\leqslant \\ \leqslant 1 - \int_0^1 \prod_{j=1}^{i} \max\left\{0, 1 - (1 - x + \varepsilon_j)^r\right\} dx &\leqslant \\ \leqslant 1 - \int_{\varepsilon_i}^1 (1 - (1 - x + \varepsilon_i)^r)^i dx, &\end{aligned} \tag{5}$$

where the last inequality follows by the fact that $\varepsilon_j \leqslant \varepsilon_i$ for $j \leqslant i$. Substituting $y = 1 - x + \varepsilon_i$ in (5) we further obtain:

$$\mathbb{P}(B_{i+1}) \leqslant 1 - \int_{\varepsilon_i}^{1} (1 - y^r)^i dy. \tag{6}$$

Let $f(y) = (1 - y^r)^i$. Observe that $f(0) = 1$, $f(1) = 0$, and f is strictly decreasing in $[0, 1]$. Thus, we obtain that $\int_0^{\varepsilon_i} f(y)dy \leqslant \varepsilon_i$, and by (6),

$$\begin{aligned} P(B_{i+1}) &\leqslant \varepsilon_i + 1 - \int_0^1 f(y)dy \leqslant \varepsilon_i + 1 - \left(1 - \frac{\gamma}{2k}\right) \cdot f\left(1 - \frac{\gamma}{2k}\right) \leqslant \\ &\leqslant \varepsilon_i + \frac{\gamma}{2k} + 1 - f\left(1 - \frac{\gamma}{2k}\right). \end{aligned} \tag{7}$$

In order to prove that $P(B_{i+1}) \leqslant \varepsilon_{i+1} = \varepsilon_i + \frac{\gamma}{k}$ it thus remains to show that $f(1 - \frac{\gamma}{2k}) \geqslant 1 - \frac{\gamma}{2k}$. Note that

$$f\left(1 - \frac{\gamma}{2k}\right) = \left(1 - \left(1 - \frac{\gamma}{2k}\right)^r\right)^i \geqslant \left(1 - \left(1 - \frac{\gamma}{2k}\right)^{ck\ln k}\right)^k = \left(1 - \left(1 - \frac{\gamma}{2k}\right)^{\frac{2k}{\gamma}\frac{\gamma}{2}c\ln k}\right)^k.$$

Now, for $\alpha = \frac{2k}{\gamma} \geqslant 1$ we have that $(1 - \frac{1}{\alpha})^\alpha < \frac{1}{e}$. Thus,

$$f\left(1 - \frac{\gamma}{2k}\right) \geqslant \left(1 - \frac{1}{e^{\frac{\gamma c \ln k}{2}}}\right)^k = \left(1 - \frac{1}{k^{\frac{\gamma c}{2}}}\right)^k.$$

As for $0 < \beta = \frac{1}{k^{\frac{\gamma c}{2}}} < 1$ we have that $1 - \beta > e^{-\frac{\beta}{1-\beta}}$, we thus further obtain that

$$f\left(1 - \frac{\gamma}{2k}\right) \geqslant e^{-\frac{\beta k}{1-\beta}} = e^{-\frac{k}{k^{\frac{\gamma c}{2}}-1}} \geqslant 1 - \frac{k}{k^{\frac{\gamma c}{2}} - 1}.$$

Now, for $c = \frac{10}{\gamma^2}$, and using $k \geqslant 3$ we get

$$f\left(1 - \frac{\gamma}{2k}\right) \geqslant 1 - \frac{k}{k^{\frac{5}{\gamma}} - 1} \geqslant 1 - \frac{1}{k^{\frac{3}{\gamma}}}.$$

Observe that $k^{\frac{3}{\gamma}} > \frac{2k}{\gamma}$ for $\gamma \in [0, 1]$, and $k \geqslant 3$. This finally gives that $f(1 - \frac{\gamma}{2k}) \geqslant 1 - \frac{\gamma}{2k}$, and consequently, by (7), $P(B_{i+1}) \leqslant \varepsilon_{i+1}$, which ends the proof of Claim 8. ◁

By Claims 7 and 8, First-Fit assigns color k to the root of T_k^r with probability at least $1 - \varepsilon_k$. Using Claim 7 (or Observation 2), one can thus easily deduce the following claim.

▷ Claim 9. $\mathbb{P}(\chi_{FF}(T_k^r, \ll) = k) \geqslant 1 - \gamma$.

▷ Claim 10. T_k^r has exactly $(r + 1)^{k-1}$ vertices.

Proof. We prove the claim by induction on k. For $k = 1$ the claim trivially holds. Let us assume that $k \geqslant 1$ and that the claim holds for all the trees $T_1^r, \ldots, T_k^r$. By the construction of T_{k+1}^r,

$$|T_{k+1}^r| = 1 + r \cdot \sum_{i=1}^{k} |T_i^r| = 1 + r \cdot \sum_{i=1}^{k} (r + 1)^{i-1} = 1 + r \cdot \frac{1 - (r + 1)^k}{1 - (r + 1)} = (r + 1)^k. \qquad ◁$$

For any value of k, we set $\gamma = \frac{1}{\ln k}$, and for this choice of γ we get $c = 10\ln^2 k$ and $r = \lceil 10k\ln^3 k \rceil$. Let us denote by n_k the number of vertices in T_k^r. Then the following hold for k large enough. Firstly, by Claim 10, we have $\ln n_k \geqslant k$. Consequently, again by Claim 10,

$$\begin{aligned}\ln n_k &\leqslant (k-1)\ln\left(2+10k\ln^3 k\right) \leqslant k\left(\ln k + 4\ln\ln k\right)\\ &\leqslant k\left(\ln\ln n_k + 4\ln\ln\ln n_k\right). \qquad (8)\end{aligned}$$

By Claim 9 and (8), we thus finally obtain that

$$\begin{aligned}\mathbb{E}_{\ll}\left[\chi_{FF}(T_k^r, \ll)\right] &\geqslant k\cdot\left(1-\frac{1}{\ln k}\right) \qquad (9)\\ &\geqslant \frac{\ln n}{\ln\ln n + 4\ln\ln\ln n}\cdot\left(1-\frac{1}{\ln\ln n - 2\ln\ln\ln n}\right) = g(n). \qquad (10)\end{aligned}$$

Note that $g(n)$ is an increasing function for large enough n. Note also that n_k is also an increasing function of k. Consider any (large enough) n such that $n_k \leqslant n \leqslant n_{k+1}$ for some k. Then, since $\mathrm{RFF}_{\mathcal{F}}(n)$ is a nondecreasing function of n, by (9) and (10),

$$\begin{aligned}\mathrm{RFF}_{\mathcal{F}}(n) &\geqslant \mathrm{RFF}_{\mathcal{F}}(n_1) \geqslant \frac{1}{2}\cdot\mathbb{E}_{\ll}\left[\chi_{FF}(T_k^r, \ll)\right] \geqslant \frac{1}{2}\cdot k\cdot\left(1-\frac{1}{\ln k}\right)\\ &\geqslant \frac{1}{2}\cdot\left((k+1)\cdot\left(1-\frac{1}{\ln(k+1)}\right)-1\right) \geqslant \frac{1}{2}\cdot\left(g(n_{k+1})-1\right)\\ &\geqslant \frac{1}{2}\cdot\left(g(n)-1\right) = \left(\frac{1}{2}-o(1)\right)\frac{\ln n}{\ln\ln n},\end{aligned}$$

which finishes the proof of Lemma 6. ◀

4 Final comments

Finally, Theorem 1 is obtained by combining the matching bounds of Corollary 5 and Lemma 6. This concludes our investigation of the efficiency of First-Fit in the random arrival model on the class of forests. First-Fit is efficient on this class even in the adversarial model. Still, the randomization of the presentation order allows for some increase in performance. This raises the hope that First-Fit is more effective in the average case than it is in the worst case also on some other graph classes.

The systematic analysis of First-Fit in the random arrival model on other graph classes should continue for the class $\mathcal{B}$ of bipartite graphs. There, First-Fit is known to be extremely inefficient in the adversarial model with $\mathrm{FF}_{\mathcal{B}} = \Theta(n)$. However, there is another simple algorithm [10], a clever modification of First-Fit, that uses $O(\log n)$ colors to color any bipartite graph with n vertices. A natural extension of our research would be to assess the First-Fit algorithm in the random arrival model on bipartite graphs. We anticipate that the outcome will not deviate significantly from the results obtained for forests.

▶ **Conjecture 11.** *First-Fit in the random arrival model uses* $\mathrm{poly}(\log n)$ *colors in expectation when coloring any bipartite graph with* n *vertices.*

Addressing the aforementioned conjecture represents a significant cognitive pursuit. However, a truly remarkable feat would be to establish some nontrivial bounds for 3-colorable graphs. We want to thank Anna Zych-Pawlewicz for inspiring the work on this project.

Abstract

The number of quantifiers needed to express first-order (FO) properties is captured by two-player combinatorial games called *multi-structural* games. We analyze these games on binary strings with an ordering relation, using a technique we call *parallel play*, which significantly reduces the number of quantifiers needed in many cases. Ordered structures such as strings have historically been notoriously difficult to analyze in the context of these and similar games. Nevertheless, in this paper, we provide essentially tight bounds on the number of quantifiers needed to characterize different-sized subsets of strings. The results immediately give bounds on the number of quantifiers necessary to define several different classes of Boolean functions. One of our results is analogous to Lupanov's upper bounds on circuit size and formula size in propositional logic: we show that every Boolean function on n-bit inputs can be defined by a FO sentence having $(1+\varepsilon)\frac{n}{\log(n)} + O(1)$ quantifiers, and that this is essentially tight. We reduce this number to $(1+\varepsilon)\log(n) + O(1)$ when the Boolean function in question is sparse.

1 Introduction

In 1981, Immerman [11] introduced *quantifier number* (QN) as a measure of the complexity of first-order (FO) sentences. For a function $g\colon \mathbb{N} \to \mathbb{N}$, he defined $\mathrm{QN}[g(n)]$ as the class of properties on n-element structures describable by a uniform sequence of FO sentences with $O(g(n))$ quantifiers. He then showed that on *ordered* structures, for $f(n) \geq \log n$, one has:

$$\mathrm{NSPACE}[f(n)] \subseteq \mathrm{QN}[(f(n))^2/\log n] \subseteq \mathrm{DSPACE}[(f(n))^2], \tag{1}$$

thereby establishing an important connection between QN and space complexity and so directly linking a logical object to classical complexity classes.

The same paper [11] described a two-player combinatorial game (which Immerman called the *separability game*), that captures quantifier number in the same way that the more well-known Ehrenfeucht-Fraïssé (EF) game [3, 7] captures quantifier rank (QR). The paper additionally showed that any property whatsoever of n-element *ordered* structures can be described with a sentence having a QR of $\log n + 3$. Since a QR of $\log n + 1$ is required just to distinguish a linear order of size n from smaller linear orders [17], QR has limited power to distinguish properties over ordered structures. QN is potentially a more fine-grained and powerful measure for this purpose. However, owing to the inherent difficulties of the analysis of Immerman's separability game, the study of the game and of QN in general lay dormant for forty years, until the game was rediscovered and renamed the *multi-structural* (MS) game in [4]. In that paper the authors made initial inroads into understanding how to analyze the game, leading to several follow-up works [1, 5, 18]. Other related games to study the number of quantifiers were recently introduced in [9], and close cousins of MS games were used to study formula size in [8, 10]. In [10] the authors study a related problem to ours – they examine the (existential) sentences of minimum size needed to express a particular set of string properties. However, even without the existential restriction, the connection between the minimum size of a sentence and its minimum number of quantifiers is not obvious. It is possible for a property to be expressible only by a much longer sentence with fewer quantifiers than one with more quantifiers.

The MS game is played by two players, Spoiler (**S**, he/him) and Duplicator (**D**, she/her), on two *sets* $\mathcal{A}, \mathcal{B}$ of structures. Essentially, **S** tries to break all partial isomorphisms between all pairs of structures (one from $\mathcal{A}$ and the other from $\mathcal{B}$) over a prescribed number of rounds, whereas **D** tries to maintain a partial isomorphism between *some* pair of structures. Unlike in EF games, **D** has more power in MS games, since she can make arbitrarily many copies of structures before her moves, enabling her to play all possible responses to **S**'s moves. The fundamental theorem for MS games [4, 11] (see Theorem 1) states that **S** has a winning strategy for the r-round MS game on $(\mathcal{A}, \mathcal{B})$ if and only if there is a FO sentence φ with at most r quantifiers that is true for every structure in $\mathcal{A}$ but false for every structure in $\mathcal{B}$. We call such a φ a *separating sentence* for $(\mathcal{A}, \mathcal{B})$. In general, our eventual objective will be to separate a set $\mathcal{A}$ of n-bit strings from all other n-bit strings (i.e., from its complement $\mathcal{A}^{\mathrm{C}}$). This is a particularly interesting question because of its intimate connection to the complexity of *Boolean functions.*

Boolean Functions. Any Boolean function on n-bit strings is specified by two complementary sets, $\mathcal{A}, \mathcal{A}^{\mathrm{C}} \subseteq \{0,1\}^n$, representing the input strings that get mapped to 1 and 0 respectively. For such a function $f\colon \{0,1\}^n \to \{0,1\}$, we say that a FO sentence φ in the vocabulary of strings *defines* the function f if φ is a separating sentence for $(f^{-1}(1), f^{-1}(0))$. Hence, the key results of this paper can be thought of as giving sharp bounds on the number of quantifiers needed to define Boolean functions. Our main results about the definability of Boolean functions are Theorems A and B below.

▶ **Theorem A.** *Given an arbitrary $\varepsilon > 0$, every Boolean function on n-bit strings can be defined by a FO sentence having $(1+\varepsilon)\frac{n}{\log(n)} + O_\varepsilon(1)$ quantifiers, where the $O_\varepsilon(1)$ additive term depends only on ε and not n. Moreover, there are Boolean functions on n-bit strings that require $\frac{n}{\log(n)} + O(1)$ quantifiers to define.*

Say that a family, $\mathscr{F} = \{f_n\}_{n=1}^{\infty}$, of Boolean functions on n-bit strings, is *sparse* if the cardinality of the set of strings mapping to 1 under each f_n is polynomial in n. For example, if $\mathcal{L}$ is a sparse language, then the family of Boolean functions, defined for each n, by the characteristic function of $\mathcal{L}$ restricted to n-bit inputs, is sparse [6,15].

▶ **Theorem B.** *Given an arbitrary $\varepsilon > 0$, and a sparse family, $\mathscr{F} = \{f_n\}_{n=1}^{\infty}$, of Boolean functions on n-bit strings, each function $f_n \in \mathscr{F}$ can be defined by a FO sentence having $(1+\varepsilon)\log(n) + O_\varepsilon(1)$ quantifiers, where the $O_\varepsilon(1)$ additive term depends only on ε and not n. Moreover, there are sparse families of Boolean functions on n-bit strings, the functions of which require $\log(n)$ quantifiers to define.*

Theorem A follows from Theorems 18 and 19 (in Section 5), whereas Theorem B follows from Theorem 16 and Proposition 14 (in Section 5). Theorem 18 can be viewed as a first-order logic analog of the upper bounds obtained by Lupanov for minimum circuit size [13] and minimum propositional formula size [14] to capture an arbitrary Boolean function. Note that *any* property whatsoever of n-bit strings can be captured trivially by a sentence with n existential quantifiers. Similar to Lupanov's bounds, our result shows that we can shave off a factor of $\log(n)$ from this trivial upper bound. Furthermore, Theorem 19 establishes via a counting argument that there are functions with a QN lower bound that essentially matches our worst-case upper bound – a result that can be viewed as a first-order logic analog of the Riordan-Shannon lower bound [16] for propositional formula size.

Parallel Play. A key technical contribution we make in this paper is the Spoiler strategy of *parallel play*, which widens the scope of winning strategies for **S** compared to previous work. The essential idea is for **S** to partition the sets $\mathcal{A}$ and $\mathcal{B}$ into subsets $\mathcal{A}_1 \sqcup \ldots \sqcup \mathcal{A}_k$ and $\mathcal{B}_1 \sqcup \ldots \sqcup \mathcal{B}_k$, and then play k MS "sub-games" in parallel on $(\mathcal{A}_i, \mathcal{B}_i)$. In certain circumstances, **S** can then combine his strategies for each of those sub-games into a strategy for the entire game, and thereby save many superfluous moves. Applying the fundamental theorem, this results in a very small number of quantifiers in the corresponding separating sentence.

Outline of the Paper. This paper is organized as follows. In Section 2, we set up some preliminaries. In Section 3, we precisely formulate what we call the *Parallel Play Lemma* (Lemma 5) and the *Generalized Parallel Play Lemma* (Lemma 6). In Section 4, we develop results on linear orders that are similar to but more nuanced than those in [4,5], with the extra nuance being critical for our subsequent string separation results. In Section 5, we present our results on separating disjoint sets of strings. In Section 6, we wrap up with some conclusions and open problems.

Owing to space constraints, in some places we provide proof sketches, and refer the reader to the full proofs in the appendix of the full version of the paper [2].

2 Preliminaries

Fix a vocabulary τ with finitely many relation and constant symbols. We typically designate structures in boldface ($\mathbf{A}$), their universes in capital letters (A), and sets of structures in calligraphic typeface ($\mathcal{A}$). This last convention includes sets of pebbled structures (see below).

We always use $\log(\cdot)$ to designate the base-2 logarithm. Furthermore, in several results in Section 5, we have an $O(1)$ additive term. This term will always be independent of n. Any additional dependence will be stated in the form of a subscript on the O, e.g., $O_t(1)$ would denote a term independent of n, but dependent on the choice of some parameter t.

Pebbled Structures and Matching Pairs. Consider a palette $\mathcal{C} = \{\mathrm{r}, \mathrm{b}, \mathrm{g}, \ldots\}$ of *pebble colors*, with infinitely many pebbles of each color available. A τ-structure $\mathbf{A}$ is *pebbled* if some of its elements $a_1, a_2, \ldots \in A$ have pebbles on them. There can be at most one pebble of each color on a pebbled structure. There can be multiple pebbles (of different colors) on the same element $a_i \in A$. Occasionally, when the context is clear, we will use the term *board* synonymously with "pebbled structure".

If $\mathbf{A}$ is a τ-structure, and the first few pebbles are placed on elements $a_1, a_2, a_3 \ldots \in A$, we designate the resulting pebbled τ-structure as $\langle \mathbf{A} \mid a_1, a_2, a_3, \ldots \rangle$. Note that $\mathbf{A}$ can be viewed as a pebbled structure $\langle \mathbf{A} \mid \rangle$ with the empty set of pebbles.

By convention, we use r, b, and g for the first three pebbles we play (in that order), as a visual aid in our proofs. Hence, the pebbled structure $\langle \mathbf{A} \mid a_1, a_2, a_3 \rangle$ has pebbles r on $a_1 \in A$, b on $a_2 \in A$, and g on $a_3 \in A$. Note that a_1, a_2, and a_3 need not be distinct.

We say that the pebbled structures $\langle \mathbf{A} \mid a_1, \ldots, a_k \rangle$ and $\langle \mathbf{B} \mid b_1, \ldots, b_k \rangle$ are a *matching pair* if the map $f \colon A \to B$ defined by:

- $f(a_i) = b_i$ for all $1 \leq i \leq k$
- $f(c^{\mathbf{A}}) = c^{\mathbf{B}}$ for all constants c in τ

is an isomorphism on the induced substructures. Note that $\langle \mathbf{A} \mid a_1, \ldots, a_k \rangle$ and $\langle \mathbf{B} \mid b_1, \ldots, b_k \rangle$ can form a matching pair even when $\mathbf{A} \ncong \mathbf{B}$.

Multi-Structural Games. Assume $r \in \mathbb{N}$, and let $\mathcal{A}$ and $\mathcal{B}$ be two sets of pebbled structures, each pebbled with the *same* set $\{x_1, \ldots, x_k\} \subseteq \mathcal{C}$ of pebble colors. The *r-round multi-structural (MS) game on* $(\mathcal{A}, \mathcal{B})$ is defined as the following two-player game, played by two players, **Spoiler** (**S**, he/him) and **Duplicator** (**D**, she/her). In each round i for $1 \leq i \leq r$, **S** chooses either $\mathcal{A}$ or $\mathcal{B}$, and an **unused** color $y_i \in \mathcal{C}$; he then places ("plays") a pebble of color y_i on an element of *every* board in the chosen set ("side"). In response, **D** makes as many copies as she wants of each board on the other side, and plays a pebble of color y_i on an element of each of those boards. **D** wins the game if at the end of round r, there is a board in $\mathcal{A}$ and a board in $\mathcal{B}$ forming a matching pair. Otherwise, **S** wins. For readability, we always call the two sets $\mathcal{A}$ and $\mathcal{B}$, even though the structures change over the course of a game in two ways:

- $\mathcal{A}$ or $\mathcal{B}$ can increase in size over the r rounds, as **D** can make copies of the boards.
- The number of pebbles on each of the boards in $\mathcal{A}$ and $\mathcal{B}$ increases by 1 in each round.

We usually refer to $\mathcal{A}$ as the *left* side, and $\mathcal{B}$ as the *right* side.

Let $\mathcal{A}$ and $\mathcal{B}$ be two sets of pebbled structures, with each pebbled structure containing pebbles colored with $\{x_1, \ldots, x_k\} \subseteq \mathcal{C}$. Let $\varphi(x_1, \ldots, x_k)$ be a FO formula with free variables $\{x_1, \ldots, x_k\}$. We say φ is a *separating formula* for $(\mathcal{A}, \mathcal{B})$ (or φ *separates* $\mathcal{A}$ and $\mathcal{B}$) if:

- for every $\langle \mathbf{A} \mid a_1, \ldots, a_k \rangle \in \mathcal{A}$ we have $\mathbf{A}[a_1/x_1, \ldots, a_k/x_k] \models \varphi$,
- for every $\langle \mathbf{B} \mid b_1, \ldots, b_k \rangle \in \mathcal{B}$ we have $\mathbf{B}[b_1/x_1, \ldots, b_k/x_k] \models \neg\varphi$.

The following key theorem [4,11], stated here without proof, relates the logical characterization of a separating formula with the combinatorial property of a game strategy.

▶ **Theorem 1** (Fundamental Theorem of MS Games, [4, 11]). **S** *has a winning strategy in the r-round MS game on $(\mathcal{A}, \mathcal{B})$ iff there is a formula with $\leq r$ quantifiers separating $\mathcal{A}$ and $\mathcal{B}$.*

In the theorem above, if $\mathcal{A}$ and $\mathcal{B}$ are sets of *unpebbled* structures, and φ is a sentence, we call φ a *separating sentence* for $(\mathcal{A}, \mathcal{B})$.

We note that $\mathbf{D}$ has a clear optimal strategy in the MS game, called the *oblivious* strategy: for each of $\mathbf{S}$'s moves, $\mathbf{D}$ can make enough copies of each pebbled structure on the other side to play all possible responses at the same time. If $\mathbf{D}$ has a winning strategy, then the oblivious strategy is winning. For this reason, the MS game is essentially a single-player game, where $\mathbf{S}$ can simulate $\mathbf{D}$'s responses himself.

We make an easy observation here without proof, that will help us *discard* some boards during gameplay; we can remove them without affecting the result of the game. This will help us in the analysis of several results in the paper.

▶ **Observation 2.** *During gameplay in any instance of the MS game, consider a board $\langle \mathbf{A} \mid a_1, \ldots, a_k \rangle$ such that there is no board on the other side forming a matching pair with it. Then, $\langle \mathbf{A} \mid a_1, \ldots, a_k \rangle$ can be removed from the game without affecting the result.*

Linear Orders. Let $\tau_{\mathsf{ord}} = \langle <;\ \mathsf{min}, \mathsf{max} \rangle$ be the vocabulary of orders, where $<$ is a binary predicate, and min and max are constant symbols. For every $\ell \geq 1$, we shall use L_ℓ to refer to a structure of type τ_{ord}, which interprets $<$ as a total linear order on $\ell + 1$ elements, and min and max as the first and last elements in that total order respectively. Note that there is only one linear order for any fixed value of ℓ. When unambiguous, we may suppress the subscript and refer to the linear order as simply L.

We define the *length* of a linear order L as the size of its universe minus one (equivalently, as the number of edges if the linear order were represented as a path graph). Hence, the length of L_ℓ is ℓ. Since we only consider $\ell \geq 1$, the length is always positive, and min and max are necessarily distinct. Our convention is different from [4] and [5], where the length of a linear order was the number of elements, and the vocabulary had no built-in constants. Note that having min and max is purely for convenience; each can be defined and reused at the cost of two quantifiers.

Let L be a linear order with elements $a < b$. The linear order $L[a, b]$ is the induced linear order on all elements from a to b, both inclusive. If the variables x and y have been interpreted by L so that $x^L = a$ and $y^L = b$, then we shall use $L[x, y]$ and $L[a, b]$ interchangeably; we adopt a similar convention for constants. If pebbles r and b have been placed on L on a and b respectively, we use $L[\mathrm{r}, \mathrm{b}]$ to mean $L[a, b]$.

We will frequently need to consider sets of linear orders. For $\ell \geq 1$, we will use the notation $L_{\leq \ell}$ to denote the set of linear orders of length at most ℓ, and $L_{> \ell}$ to denote the set of linear orders of length greater than ℓ.

Strings. Let $\tau_{\mathsf{string}} = \langle <,\ S\ ;\ \mathsf{min}, \mathsf{max} \rangle$ be the vocabulary of binary strings, where $<$ is a binary predicate, S is a unary predicate, and min and max are constant symbols. We encode a string $w = (w_1, \ldots, w_n) \in \{0, 1\}^n$ by the τ_{string}-structure $\mathbf{B}_w$ having universe $B_w = \{1, \ldots, n\}$, relation $<$ interpreted by the linear order on $\{1, \ldots, n\}$, relation $S = \{i \mid w_i = 1\}$, and min and max interpreted as 1 and n respectively.

For an n-bit string w, and i, j such that $1 \leq i \leq j \leq n$, denote by $w[i, j]$ the substring $w_i \ldots w_j$ of w. Note that $w[i, j]$ corresponds to the induced substructure of $\mathbf{B}_w$ on $\{i, \ldots, j\}$. We will often interchangeably talk about the string w and the τ_{string}-structure $\mathbf{B}_w$, when the context is clear. As in τ_{ord}, having min and max in the vocabulary is purely for convenience.

3 Parallel Play

In this section, we prove our key lemma, that shows how, in certain cases, **S** can combine his winning strategies in two sub-games, playing them in parallel in a single game that requires no more rounds than the longer of the two sub-games.

To understand why this is helpful, note that in general, if a formula φ is of the form $\varphi_1 \wedge \varphi_2$ or $\varphi_1 \vee \varphi_2$, the number of quantifiers in φ is the sum of the number of quantifiers in φ_1 and φ_2, even if the two subformulas have the same quantifier structure. We will see that playing parallel sub-games roughly corresponds to taking a φ of the form $\varphi_1 \wedge \varphi_2$ or $\varphi_1 \vee \varphi_2$ where the subformulas have the same quantifier prefix, and writing φ with the same quantifier prefix as φ_1 or φ_2, saving half the quantifiers we normally require.

Suppose **S** has a winning strategy for an instance $(\mathcal{A}, \mathcal{B})$ of the r-round MS game. In principle, the choice of which side **S** plays on could depend on **D**'s previous responses. However, note that any strategy $\mathcal{S}$ used by **S** that wins against the oblivious strategy also wins against any other strategy that **D** plays. Therefore, we may WLOG restrict ourselves to strategies used by **S** against **D**'s oblivious strategy. It follows that the choice of which side to play on in every round is completely determined by the instance $(\mathcal{A}, \mathcal{B})$, and independent of any of **D**'s responses. Let $\mathcal{S}$ be such a winning strategy for **S**. We now define the *pattern* of $\mathcal{S}$, which specifies which side **S** plays on in each round, when following $\mathcal{S}$.

▶ **Definition 3.** *Suppose $\mathcal{A}$ and $\mathcal{B}$ are sets of pebbled structures, and assume that* **S** *has a winning strategy $\mathcal{S}$ for the r-round* MS *game on $(\mathcal{A}, \mathcal{B})$. The* pattern *of $\mathcal{S}$, denoted* $\mathsf{pat}(\mathcal{S})$, *is an r-tuple $(Q_1, \dots, Q_r) \in \{\exists, \forall\}^r$, where:*

$$Q_i = \begin{cases} \exists & \textit{if } \mathbf{S} \textit{ plays in } \mathcal{A} \textit{ in round } i, \\ \forall & \textit{if } \mathbf{S} \textit{ plays in } \mathcal{B} \textit{ in round } i. \end{cases}$$

We say that **S** wins the game with pattern $(Q_1, \dots, Q_r)$ *if* **S** *has a winning strategy $\mathcal{S}$ for the game in which* $\mathsf{pat}(\mathcal{S}) = (Q_1, \dots, Q_r)$.

The following lemma is implicit in the proof of Theorem 1.

▶ **Lemma 4.** *For any two sets $\mathcal{A}$ and $\mathcal{B}$ of pebbled τ-structures, the following are equivalent:*

1. **S** *wins the r-round* MS *game on $(\mathcal{A}, \mathcal{B})$ with pattern $(Q_1, \dots, Q_r)$.*
2. *$(\mathcal{A}, \mathcal{B})$ has a separating formula with r quantifiers and quantifier prefix $(Q_1, \dots, Q_r)$.*

Note that Lemma 4 implies that, as long as there is a separating formula φ for $(\mathcal{A}, \mathcal{B})$ with r quantifiers, **S** has a winning strategy for the r-round MS game on $(\mathcal{A}, \mathcal{B})$ that "follows" φ; namely, if $\varphi = Q_1 \dots Q_r \psi$, then in round i, **S** plays in $\mathcal{A}$ if $Q_i = \exists$, and in $\mathcal{B}$ if $Q_i = \forall$. Hence, for the rest of the paper, we will refer to **S** moves in $\mathcal{A}$ and $\mathcal{B}$ as *existential* and *universal* moves respectively. We are now ready to state our main lemma from this section.

▶ **Lemma 5** (Parallel Play Lemma). *Let $\mathcal{A}$ and $\mathcal{B}$ be two sets of pebbled structures, and let $r \in \mathbb{N}$. Suppose that $\mathcal{A}$ and $\mathcal{B}$ can be partitioned as $\mathcal{A} = \mathcal{A}_1 \sqcup \mathcal{A}_2$ and $\mathcal{B} = \mathcal{B}_1 \sqcup \mathcal{B}_2$ respectively, such that for $1 \leq i \leq 2$,* **S** *has a winning strategy $\mathcal{S}_i$ for the r-round MS game on $(\mathcal{A}_i, \mathcal{B}_i)$, satisfying the following conditions:*

1. *Both $\mathcal{S}_i$'s have the same pattern $P = \mathsf{pat}(\mathcal{S}_1) = \mathsf{pat}(\mathcal{S}_2)$.*
2. *At the end of the sub-games, both of the following are true:*
   - *There does not exist a board in $\mathcal{A}_1$ and a board in $\mathcal{B}_2$ forming a matching pair.*
   - *There does not exist a board in $\mathcal{A}_2$ and a board in $\mathcal{B}_1$ forming a matching pair.*

Then **S** *wins the r-round MS game on $(\mathcal{A}, \mathcal{B})$ with pattern P.*

Proof. **S** plays the r-round MS game on $(\mathcal{A}, \mathcal{B})$ by playing his winning strategy $\mathcal{S}_1$ on $(\mathcal{A}_1, \mathcal{B}_1)$, and his winning strategy $\mathcal{S}_2$ on $(\mathcal{A}_2, \mathcal{B}_2)$, *simultaneously* in parallel. This is a well-defined strategy, since every $\mathcal{S}_i$ has the same pattern P. At the end of the game:

- for $i = j$, no board from $\mathcal{A}_i$ forms a matching pair with a board from $\mathcal{B}_j$, since **S** wins the sub-game $(\mathcal{A}_i, \mathcal{B}_i)$.
- for $i \neq j$, no board from $\mathcal{A}_i$ forms a matching pair with a board from $\mathcal{B}_j$, by assumption.

Therefore, no matching pair remains after round r, and so, **S** wins the game. The pattern for this strategy is P by construction. ◀

We observe that Lemma 5 can be generalized in two ways. Firstly, we could split into k sub-games instead of two. Secondly, we can weaken assumption 1 in the statement of the lemma, so that each of the patterns is a subsequence of some r-tuple $P = \{\exists, \forall\}^r$. This is because **S** can simply extend the strategy $\mathcal{S}_i$ with pattern P_i to a strategy $\mathcal{S}'_i$ with pattern P, where for every "missing" entry in the tuple P, **S** makes a dummy move on the corresponding side. We state a generalized version below without a proof.

▶ **Lemma 6** (Generalized Parallel Play Lemma). *Let $\mathcal{A}$ and $\mathcal{B}$ be two sets of pebbled structures, and let $r \in \mathbb{N}$. Let $P \in \{\exists, \forall\}^r$ be a sequence of quantifiers of length r. Suppose that $\mathcal{A}$ and $\mathcal{B}$ can be partitioned as $\mathcal{A} = \mathcal{A}_1 \sqcup \ldots \sqcup \mathcal{A}_k$ and $\mathcal{B} = \mathcal{B}_1 \sqcup \ldots \sqcup \mathcal{B}_k$ respectively, such that for all $1 \leq i \leq k$, **S** has a winning strategy $\mathcal{S}_i$ for the r_i-round MS game on $(\mathcal{A}_i, \mathcal{B}_i)$ (where $r_i \leq r$), satisfying the following conditions:*

1. *For all i, $\mathsf{pat}(\mathcal{S}_i)$ is a subsequence of P.*
2. *At the end of the sub-games, for $i \neq j$, there does not exist a board in $\mathcal{A}_i$ and a board in $\mathcal{B}_j$ forming a matching pair.*

*Then **S** wins the r-round MS game on $(\mathcal{A}, \mathcal{B})$ with pattern P.*

Note that Lemmas 5 and 6 can be applied in conjunction with Observation 2 as long as there is at least one structure remaining on either side, since a winning strategy (and therefore its corresponding pattern) is unaffected if some of the pebbled structures in the instance are deleted. Furthermore, in many cases, we can provide a strategy for **S** where condition 2 in Lemmas 5 and Lemma 6 will be automatically met after the first move, and therefore will continue to be satisfied at the end of the game. We shall use these two facts implicitly in the proofs that follow.

4 Linear Orders

As noted in Section 1, the results in this section are similar to those in [4,5], but somewhat more nuanced, leading ultimately to the *quantifier alternation theorems* (Theorems 12 and 13). Instead of the unwieldy function $g(\cdot)$ studied in those papers, we study the simpler function $q(\cdot)$, which, given an integer ℓ, returns the minimum number of quantifiers needed to separate $L_{\leq \ell}$ from $L_{>\ell}$. A key result, not appreciated in [4,5], is that the number of quantifiers needed to separate two linear orders of different sizes never exceeds the quantifier rank needed by more than one (Theorem 11).

Let $r(\ell)$ (resp. $q(\ell)$) be the minimum QR (resp. QN) needed to separate $L_{\leq \ell}$ and $L_{>\ell}$. Let $q_\forall(\ell)$ (resp. $q_\exists(\ell)$) be the minimum number of quantifiers needed to separate $L_{\leq \ell}$ and $L_{>\ell}$ with a sentence whose prenex normal form starts with $\forall$ (resp. $\exists$). Note that $q(\ell) = \min(q_\forall(\ell), q_\exists(\ell))$. The values of $r(\ell)$ are well understood [17]:

▶ **Theorem 7** (Quantifier Rank, [17]). *For $\ell \geq 1$, we have $r(\ell) = 1 + \lfloor \log(\ell) \rfloor$.*

Since QR lower bounds QN, we have $r(\ell) \leq q(\ell)$ for all ℓ. On the other hand, for each $\ell > 0$, we will show that **S** can always separate $L_{\leq \ell}$ from $L_{>\ell}$ in a multi-structural game of at most $r(\ell) + 1$ rounds, which shows that $q(\ell) \leq r(\ell) + 1$.

For notational convenience, we denote by $\mathrm{MSL}_{\exists,r}(\ell)$ an r-round MS game on $(L_{\leq \ell}, L_{>\ell})$, in which **S** *must* play an existential first round move. We use $\mathrm{MSL}_{\forall,r}(\ell)$ analogously, where the first round move *must* be universal. Observe that, *a priori*, any such game may be winnable by either **S** or **D**. Since we are primarily interested in upper bounds, we restrict our attention only to **S**-winnable games. We call such games simply *winnable*.

4.1 The Closest-to-Midpoint with Alternation Strategy

In this section, we describe a divide-and-conquer recursive strategy for **S** to play winnable game instances $\mathrm{MSL}_{Q,r}(\ell)$. This strategy will give us upper bounds on $q_\exists(\ell)$ and $q_\forall(\ell)$, which we will then relate to $r(\ell)$.

We define the *closest-to-midpoint* of a linear order $L[x, y]$ as the element halfway between the elements corresponding to x and y if $L[x, y]$ has even length, or the element just left of center if $L[x, y]$ has odd length.

The **S**-winning strategy is called *Closest-to-Midpoint with Alternation* (CMA). The pattern for this strategy will alternate between $\exists$ and $\forall$, splitting each game recursively into two smaller sub-games that can be played in parallel using Lemma 5. In these sub-games, placed pebbles will take on the roles of min and max. **S** continues in this way until the sub-games are on linear orders of length 2 or less, at which point he can win them easily.

The idea is for **S** to obey the following two rules throughout, except possibly the last three rounds:

- **S** starts on his designated side (determined by Q), and then alternates in every round;
- on every board, **S** plays on the closest-to-midpoint of a linear order $L[x, y]$, chosen carefully to ensure he essentially "halves" the length of the instance every round.

Note that one consequence of the second point above is that **S** will *never* play on max.

Before getting to a formal description of the strategy, let us illustrate the main idea through a worked example. Consider the (winnable) game $\mathrm{MSL}_{\exists,4}(5)$. In round 1, **S** plays on the closest-to-midpoint of all boards in $L_{\leq 5}$ (by the two conditions in the CMA strategy). Before **D**'s response, we reach the position shown in Figure 1.

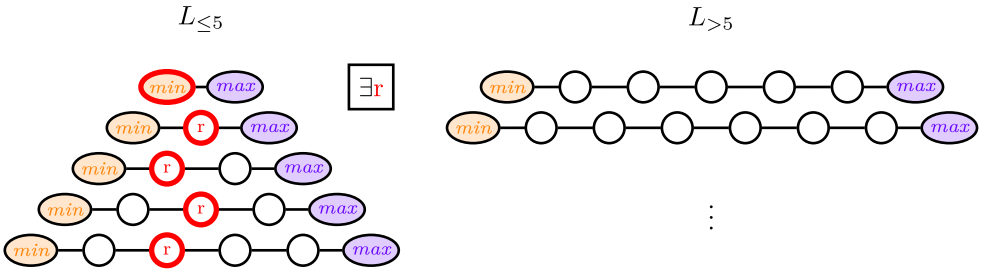

Figure 1 The position after **S**'s round 1 move in the game $\mathrm{MSL}_{\exists,4}(5)$. The pebble r is on the closest-to-midpoint of every board on the left.

Now assume **D** responds obliviously. We can first use Observation 2 to discard all boards on the right with r on max. By virtue of **S**'s first move, every board $\langle L \mid a_1 \rangle$ on the left satisfies *both* $L[\mathsf{min}, \mathrm{r}] \leq 2$, and $L[\mathrm{r}, \mathsf{max}] \leq 3$. Now consider any board $\langle L' \mid a'_1 \rangle$ on the right. Note that either $L'[\mathsf{min}, \mathrm{r}] > 2$, or $L'[\mathrm{r}, \mathsf{max}] > 3$. Partition the right side as $\mathcal{B}_1 \sqcup \mathcal{B}_2$, where every $\langle L' \mid a'_1 \rangle \in \mathcal{B}_1$ satisfies $L'[\mathsf{min}, \mathrm{r}] > 2$, and every $\langle L' \mid a'_1 \rangle \in \mathcal{B}_2$ satisfies $L'[\mathrm{r}, \mathsf{max}] > 3$.

In round 2, **S** makes a universal move (by the first condition in the CMA strategy). In all boards in $\mathcal{B}_1$, he plays pebble b on the closest-to-midpoint of $L'[\mathsf{min}, \mathrm{r}]$; similarly, in all boards in $\mathcal{B}_2$, he plays pebble b on the closest-to-midpoint of $L'[\mathrm{r}, \mathsf{max}]$. Note that in either case, **S** plays b on an element which is not on r, min, or max.

After **D** responds obliviously, we can use Observation 2 to discard all boards on the left where b is on min, max, or r. Since in particular this discards all boards on the left with r on min, we can again use Observation 2 to discard all boards from the right which have r on min. Every remaining board in $\mathcal{B}_1$ (resp. $\mathcal{B}_2$) corresponds to the isomorphism class $\mathsf{min} < \mathrm{b} < \mathrm{r} < \mathsf{max}$ (resp. $\mathsf{min} < \mathrm{r} < \mathrm{b} < \mathsf{max}$). The remaining boards on the left also correspond to exactly one of those classes. Partition the left side as $\mathcal{A}_1 \sqcup \mathcal{A}_2$ accordingly.

Now, because of this difference in isomorphism classes, we will never obtain a matching pair from $\mathcal{A}_1$ and $\mathcal{B}_2$ (or from $\mathcal{A}_2$ and $\mathcal{B}_1$). Furthermore, for the rest of the game, **S** will *only* play inside $L[\mathsf{min}, \mathrm{r}]$ on all boards in $\mathcal{A}_1$ and $\mathcal{B}_1$, and inside $L[\mathrm{r}, \mathsf{max}]$ on all boards in $\mathcal{A}_2$ and $\mathcal{B}_2$. Suppose, in response to such a move on $\mathcal{A}_1$, **D** plays outside the range $L[\mathsf{min}, \mathrm{r}]$ on a board from $\mathcal{B}_1$; the resulting board cannot form a partial match with any board from $\mathcal{A}_1$ (since there is a discrepancy with r), or with any board from $\mathcal{A}_2$ (as observed already). Therefore, this board from $\mathcal{B}_1$ can be discarded using Observation 2. A similar argument applies if **D** ever responds outside the corresponding range in $\mathcal{B}_2$, $\mathcal{A}_1$, or $\mathcal{A}_2$.

It follows that the sub-game $(\mathcal{A}_1, \mathcal{B}_1)$ (resp. $(\mathcal{A}_2, \mathcal{B}_2)$) corresponds *exactly* to the game $\mathrm{MSL}_{\forall,3}(2)$ (resp. $\mathrm{MSL}_{\forall,3}(3)$) where **S** has already made his first move using the CMA strategy by playing a universal move on the closest-to-midpoints of the (relevant) linear orders. Since **S** will alternate sides throughout, the patterns for both sub-game strategies will be the same.

We can now apply Lemma 5. Observe that the lengths of the instances in the sub-games have been roughly halved, at the cost of a single move. The game then proceeds as shown in Figure 2. The leaves of the tree correspond to base cases (analyzed in Section 4.2). The pattern of the strategy is preserved along all branches.

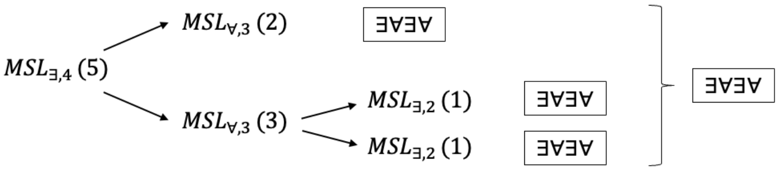

Figure 2 The $\mathrm{MSL}_{\exists,4}(5)$ game tree. Each leaf is decorated with the associated quantifier prefix. All paths can be played in parallel using Lemma 6 using the pattern $(\exists, \forall, \exists, \forall)$.

4.2 Formalizing the Strategy

The first step in formalizing the CMA strategy for **S** is to define four base cases, which we shall call *irreducible* games. We assert the following (see Appendix A in [2]).

1. $\mathrm{MSL}_{\forall,1}(1)$ is winnable with the pattern $(\forall)$.
2. $\mathrm{MSL}_{\exists,2}(1)$ is winnable with the pattern $(\exists, \forall)$.
3. $\mathrm{MSL}_{\forall,2}(2)$ is winnable with the pattern $(\forall, \forall)$.
4. $\mathrm{MSL}_{\forall,3}(2)$ is winnable with the pattern $(\forall, \exists, \forall)$.

The game $\mathrm{MSL}_{\exists,1}(1)$ is not winnable and hence not considered.

We now give a formalization of the inductive step. For a given quantifier $Q \in \{\exists, \forall\}$ and its complementary quantifier $\bar{Q}$, consider the game $\mathrm{MSL}_{Q,k}(\ell)$. Note that if **S** employs the CMA strategy the game splits into the two sub-games $\mathrm{MSL}_{\bar{Q},k-1}(\ell')$ and $\mathrm{MSL}_{\bar{Q},k-1}(\ell'')$. We designate this split as:

$$\mathrm{MSL}_{Q,k}(\ell) \to \mathrm{MSL}_{\bar{Q},k-1}(\ell') \oplus \mathrm{MSL}_{\bar{Q},k-1}(\ell'').$$

We will show in the proof of Lemma 9 that these sub-games can be played recursively, in parallel. When **S** reaches an irreducible sub-game, he plays the winning patterns asserted above. We claim the following about the rules for splitting. The proof is in [2].

▷ Claim 8 (Splitting Rules). For $k \geq 3$, we have:

$$\begin{aligned}
&\text{(i) } \mathrm{MSL}_{\exists,k}(2\ell) \to \mathrm{MSL}_{\forall,k-1}(\ell) \oplus \mathrm{MSL}_{\forall,k-1}(\ell), && \ell \geq 1\\
&\text{(ii) } \mathrm{MSL}_{\exists,k}(2\ell+1) \to \mathrm{MSL}_{\forall,k-1}(\ell) \oplus \mathrm{MSL}_{\forall,k-1}(\ell+1), && \ell \geq 1\\
&\text{(iii) } \mathrm{MSL}_{\forall,k}(2\ell) \to \mathrm{MSL}_{\exists,k-1}(\ell) \oplus \mathrm{MSL}_{\exists,k-1}(\ell-1), && \ell \geq 2\\
&\text{(iv) } \mathrm{MSL}_{\forall,k}(2\ell+1) \to \mathrm{MSL}_{\exists,k-1}(\ell) \oplus \mathrm{MSL}_{\exists,k-1}(\ell), && \ell \geq 1
\end{aligned} \tag{2}$$

Of course, the CMA strategy starts out seemingly promisingly, splitting with both initial sub-games starting on the same side; we must ensure that the strategy continues to be *well-defined*, i.e., this continues throughout the recursion stack, especially since the sub-games can have different lengths. We show this in Lemma 9, whose proof is in [2].

▶ **Lemma 9.** *The* CMA *strategy is well-specified. Moreover, for $k \geq 3$, if $MSL_{Q,k}(\ell) \to MSL_{\bar{Q},k-1}(\ell_1) \oplus MSL_{\bar{Q},k-1}(\ell_2)$ with $\ell_1 \geq \ell_2$, then the pattern of* **S***'s winning strategy for $MSL_{Q,k}(\ell)$ is Q concatenated with the pattern for the winning strategy for $MSL_{\bar{Q},k-1}(\ell_1)$.*

4.3 Bounding and Characterizing the Pattern

Define $q^*_\exists(\ell)$ (resp. $q^*_\forall(\ell)$) as the minimum $r \in \mathbb{N}$ such that **S** wins the game $\mathrm{MSL}_{\exists,r}(\ell)$ (resp. $\mathrm{MSL}_{\forall,r}(\ell)$) using the CMA strategy. Of course, we must have $q_\exists(\ell) \leq q^*_\exists(\ell)$ and $q_\forall(\ell) \leq q^*_\forall(\ell)$. Let $q^*(\ell) = \min(q^*_\exists(\ell), q^*_\forall(\ell))$. The following lemma (whose proof is omitted) follows from the complete description of the strategy from Section 4.2.

▶ **Lemma 10.** *We have $q^*_\forall(1) = 1$, $q^*_\exists(1) = 2$, and $q^*_\forall(2) = 2$. Also:*

$$\begin{aligned}
&q^*_\exists(2\ell) = q^*_\forall(\ell) + 1 \quad \textit{for } \ell \geq 1, && q^*_\exists(2\ell+1) = q^*_\forall(\ell+1) + 1 \quad \textit{for } \ell \geq 1,\\
&q^*_\forall(2\ell) = q^*_\exists(\ell) + 1 \quad \textit{for } \ell \geq 2, && q^*_\forall(2\ell+1) = q^*_\exists(\ell) + 1 \quad \textit{for } \ell \geq 1.
\end{aligned}$$

From Lemma 10 it is possible to recursively compute $q^*_\forall(\ell)$ and $q^*_\exists(\ell)$, and therefore $q^*(\ell)$ for all values of $\ell \geq 1$. These values are provided for $\ell \leq 127$ in Table 1.

We now state and prove the main result of this section.

▶ **Theorem 11.** *For all $\ell \geq 1$, we have:*

$$r(\ell) \leq q(\ell) \leq r(\ell) + 1.$$

Proof. The first inequality, $r(\ell) \leq q(\ell)$, is obvious. For the second, we will show that $q^*_\exists(\ell)$ and $q^*_\forall(\ell)$ are both bounded above by $r(\ell) + 1$ (and since $q(\ell) \leq q^*(\ell) = \min(q^*_\exists(\ell), q^*_\forall(\ell))$, so too for $q(\ell)$). Lemma 10 shows that the assertion is true for $\ell \leq 2$. Now, it can be shown recursively (see, e.g., Appendix A in [2]) that $q^*_\forall(2^k) = q^*_\exists(2^k) = k+1$ for $k \geq 1$. By Theorem 7, we also know that $r(2^k) = k+1$ for $k \geq 1$. So the three functions, $r(\cdot)$, $q^*_\forall(\cdot)$, and $q^*_\exists(\cdot)$, all equal each other at successive powers of two, and increase by one between these successive powers. Since all three functions are monotonic, they differ from one another by at most one. Therefore, we have $q^*_\exists(\ell) \leq r(\ell) + 1$ and $q^*_\forall(\ell) \leq r(\ell) + 1$. ◀

Table 1 Values of $q^*_\forall(\ell), q^*_\exists(\ell), q^*(\ell)$ and $r(\ell)$ for $1 \leq \ell \leq 127$.

We wrap up this section with two results that will be useful in Section 5. For their proofs, we refer the reader to the full version [2].

▶ **Theorem 12** (Alternation Theorem, Smaller vs. Larger). *For every $\ell \geq 1$, there is a separating sentence σ_ℓ for $(L_{\leq \ell}, L_{>\ell})$ with $q^*(\ell)$ quantifiers (and so at most $\log(\ell) + 2$ quantifiers), such that the quantifier prefix of σ_ℓ strictly alternates and ends with a $\forall$.*

▶ **Theorem 13** (Alternation Theorem, One vs. All). *For every $\ell \geq 1$, there is a sentence φ_ℓ separating L_ℓ from all other linear orders having an alternating quantifier prefix (ending with a $\forall$) and consisting of $q^*(\ell) + 2$ quantifiers (and so at most $\log(\ell) + 4$ quantifiers).*

5 Strings

In this section, we pursue our main objective: string separation results, in order to characterize the complexity of Boolean functions. We would like to bound the number of quantifiers required for these separations as a function of both the length n of the strings, as well as the sizes of the sets.

In general, we would like to separate a set of n-bit strings from the set of all other n-bit strings; recall from Section 1 that we can think of this as separating the 1 instances from the 0 instances for a Boolean function on n-bit inputs. To do so, we first need to develop a basic technique for *distinguishing* one string from another.

▶ **Proposition 14** (One vs. One). ***Upper Bound:*** *For every pair w, w' of n-bit strings such that $w \neq w'$, there is a sentence $\varphi_{w,w'}$ with $\log(n) + 6$ quantifiers separating $(\{w\}, \{w'\})$. This sentence $\varphi_{w,w'}$ (in prenex form) has an alternating quantifier prefix ending with $\forall$.*
Lower Bound: *For all sufficiently large n, there exist two n-bit strings w, w', such that separating them requires $\lfloor \log(n) \rfloor$ quantifiers.*

Proof.

Upper Bound. Let $w, w' \in \{0,1\}^n$ be any two distinct n-bit strings. There is an index $i \in [n]$ such that $w_i \neq w'_i$. Let $\mathcal{A} = \{w\}$ and $\mathcal{B} = \{w'\}$. We will show that **S** wins the MS game on $(\mathcal{A}, \mathcal{B})$ in $\log(n) + 6$ rounds.

In round 1, **S** plays pebble r on the $\mathcal{A}$ side, on the element w_i in w, creating the pebbled string $\langle w \mid w_i \rangle$. Assume **D** responds obliviously on the $\mathcal{B}$ side. We can now immediately use Observation 2 to discard the resulting pebbled string $\langle w' \mid w'_i \rangle \in \mathcal{B}$, where the pebble r is on the element w'_i. Every remaining board in $\mathcal{B}$ is of the form $\langle w' \mid w'_j \rangle$, for $j \neq i$. Note that the substring $w'[1, j]$ has length j, which is different from i, the length of the substring $w[1, i]$ of $w \in \mathcal{A}$. So now, **S** can simply play the strategy from Theorem 13 to separate a linear order of length i from all other linear orders, which he wins in $\log(n) + 4$ rounds with an alternating pattern. This gives us the desired result, after at most one more dummy move to preserve alternation.

Lower Bound. Let $\ell = 2^k + 2$ for $k > 1$, and let $w = 0^{2^{k-1}}10 0^{2^{k-1}}$ and $w' = 0^{2^{k-1}}010^{2^{k-1}}$. If **S** plays entirely on one side of the respective 1s then he is effectively playing the MS game on $(L_{2^{k-1}}, L_{2^{k-1}-1})$. By Theorem 7, we have $r(2^{k-1}) = k = \lfloor \log(\ell) \rfloor$. Since QR lower bounds QN, the MS game played in this fashion requires at least $\lfloor \log(\ell) \rfloor$ rounds to win.

Now suppose that instead of playing entirely on the same side of the respective 1s, **S** plays on both sides of a 1 and/or on the 1 during these $\lfloor \log(\ell) \rfloor$ rounds. In this case, **D** can play obliviously to the left of the 1 when **S** plays to the left of the 1, obliviously to the right of the 1 when **S** plays to the right of the 1, and on the 1 whenever **S** plays on the 1, thereby keeping matching pairs simultaneously on both sides. The lower bound follows. ◀

We also need another helpful lemma, whose proof is in Appendix B of [2].

▶ **Lemma 15.** *Let $f \colon \mathbb{N} \to \mathbb{N}$ be a function satisfying $\lim_{n\to\infty} f(n) = \infty$, and let $t \geq 2$ be any integer. Then, for some number $N(t)$ depending on t, for all $n \geq N(t)$, we have $\lceil \log_t(f(n)) \rceil! \geq f(n)$.*

We now start with our string separation problems. The first problem we will consider will be when there is a single n-bit string in $\mathcal{A}$, and the $2^n - 1$ remaining n-bit strings in $\mathcal{B}$. Note that this corresponds to our Boolean function of interest being an indicator function.

▶ **Theorem 16** (One vs. All). *For all n, and for every $\varepsilon > 0$, it is possible to separate each n-bit string from all other n-bit strings by a sentence with $(1+\varepsilon)\log(n) + O_\varepsilon(1)$ quantifiers. This sentence (in prenex form) starts with a $\forall$, then has at most $\varepsilon \log(n) + 1$ occurrences of $\exists$, and then ends with an alternating quantifier prefix of length at most $\log(n) + O_\varepsilon(1)$.*

Proof Sketch (see [2] for full proof). Fix any $\varepsilon > 0$, and fix any integer $t \geq 2^{1/\varepsilon}$. By Lemma 15, we know there is some integer $N(t)$, such that for all $n \geq N(t)$, $\lceil \log_t(n) \rceil! \geq n$. For any such n, fix an arbitrary $w \in \{0,1\}^n$, and let $\mathcal{A} = \{w\}$, and $\mathcal{B} = \{0,1\}^n - \{w\}$.

Consider the MS game on $(\mathcal{A}, \mathcal{B})$. Every $w' \in \mathcal{B}$ differs from w in at least one bit. In round 1, **S** plays a universal move, placing a pebble on each $w' \in \mathcal{B}$ on an index that disagrees with w at that index. Assume **D** responds obliviously, so that there are n resulting pebbled strings in $\mathcal{A}$. For the next $\lceil \log_t(n) \rceil$ rounds, **S** plays only existential moves, placing the $\lceil \log_t(n) \rceil$ pebbles in distinct permutations on the n strings in $\mathcal{A}$, creating n distinct isomorphism classes[2] by Lemma 15. Once we discard structures from the two sides using Observation 2,

[2] An *isomorphism class* is a maximal set of partially isomorphic pebbled structures.

we are now left with n isomorphism classes, each of them defining a **one-vs-all** sub-game; in each of these sub-games, the round 1 pebble is placed at a different index in the single string on the left from any string on the right. Therefore, **S** can view this as a game simply about lengths, and can employ any **one-vs-all** linear order strategy. The entire game therefore reduces to n parallel instances of **one-vs-all** sub-games on linear orders.

By Lemma 6 and Theorem 13, **S** can now win these parallel games in $\log(n) + 4$ further moves. Together with the initial universal move and the preprocessing moves, the total number of rounds is:

$$\lceil \log_t(n) \rceil + \log(n) + 5 \leq \frac{\log(n)}{\log(t)} + \log(n) + 6 = \log(n)\left(1 + \frac{1}{\log(t)}\right) + 6 \leq (1+\varepsilon)\log(n) + 6.$$

Note that $N(t)$ depends only on t, which in turn depends only on ε. So when $n < N(t)$, the number of quantifiers can be absorbed directly into the $O_\varepsilon(1)$ additive term. ◀

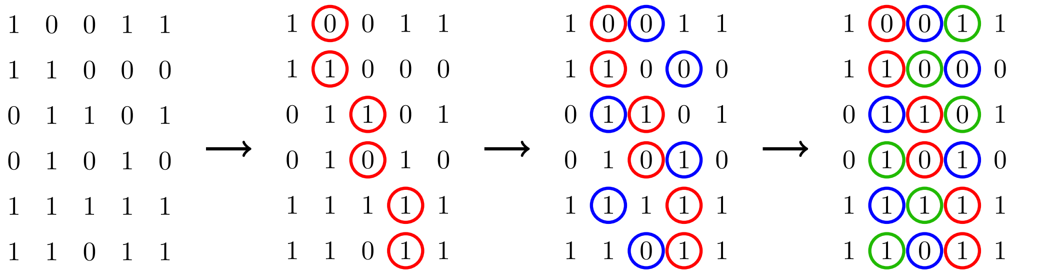

Figure 3 Illustration of the technique used by **S** to partition a set of structures into isomorphism classes. Here **S** plays three pebble moves to break the set of six strings into distinct isomorphism classes: r < b < g, r < g < b, and so on. Note that three pebbling moves suffice to give each string its own isomorphism class since $3! = 6$.

The next problem we will consider has polynomially many n-bit strings in $\mathcal{A}$, and the remaining n-bit strings in $\mathcal{B}$. This will correspond to our Boolean function of interest being a *sparse* function. Note that this immediately implies Theorem B in Section 1.

▶ **Theorem 17** (Polynomially Many vs. All). *Let $f\colon \mathbb{N} \to \mathbb{N}$ be a function that satisfies $\lim_{n\to\infty} f(n) = \infty$ and $f(n) = O(n^k)$ for some constant k. Then, for all n, and for every $\varepsilon > 0$, it is possible to separate each set of $f(n)$ n-bit strings from all other n-bit strings by a sentence with $(1+\varepsilon)\log(n) + O_{k,\varepsilon}(1)$ quantifiers.*

Proof Sketch (see [2] for full proof). Assume $n > 2$, and pick a sufficiently large constant k such that $f(n) \leq n^k$ for all n. Next, pick $\varepsilon > 0$. Let $t \geq 4$ be a large enough integer so that $t \geq 2^{2k/\varepsilon}$. By Lemma 15, we know there is some integer $N(t)$, such that for all $n \geq N(t)$, we have $\lceil \log_t(f(n)) \rceil! \geq f(n)$. **S** once again plays $\lceil \log_t(f(n)) \rceil$ existential moves, separating the $f(n)$ strings in $\mathcal{A}$ into distinct isomorphism classes by using different permutations. Now, as in the proof of Theorem 16, **S** has reduced the games to $f(n)$ parallel **one-vs-all** string separation instances. So now, using Theorem 16, he can win these instances in parallel, using $(1 + \varepsilon/2)\log(n) + 6$ quantifiers for all $n \geq \max(N(t), N'(\varepsilon))$, for some $N'(\varepsilon)$ depending only on ε. The total number of rounds used by **S** is:

$$\begin{aligned}\lceil \log_t(f(n)) \rceil + (1+\varepsilon/2)\log(n) + 6 &\leq (1+\varepsilon/2)\log(n) + k\log_t(n) + 7\\ &= (1+\varepsilon/2)\log(n) + \frac{k\log(n)}{2k/\varepsilon} + 7\\ &\leq (1+\varepsilon)\log(n) + 7.\end{aligned}$$

Again, $N(t)$ depends only on t, which depends only on k and ε, whereas $N'(\varepsilon)$ depends only on ε. So when $n < \max(N(t), N'(\varepsilon))$, the number of quantifiers can be absorbed into an additive term that depends only on k and ε, giving us the $O_{k,\varepsilon}(1)$ term. ◀

Our final results concern separating arbitrary sets of n-bit strings from their complements. As discussed in Section 1, this corresponds exactly to defining arbitrary Boolean functions. Note that this will immediately imply Theorem A in Section 1.

▶ **Theorem 18** (Arbitrary vs. Arbitrary – *Upper Bound*). *For all n, and for every $\varepsilon > 0$, any two disjoint sets of n-bit strings are separable by a sentence with $(1+\varepsilon)\frac{n}{\log(n)} + O_\varepsilon(1)$ quantifiers.*

Proof Sketch (see [2] for full proof). We first observe that for any real number $r > 2$, **S** can play $m := \lceil n/\log_r(n)\rceil$ preprocessing existential moves, putting different permutations of these m pebbles on the strings in $\mathcal{A}$ (i.e., the left side). A Stirling's approximation argument similar to Lemma 15 shows that there is some $N(r)$ such that for all $n \geq N(r)$, this number m of preprocessing moves suffices to give each string in $\mathcal{A}$ its own isomorphism class. Note that once this is done, **S** has partitioned the original instance into $|\mathcal{A}|$ disjoint instances of **one-vs-all** games.

Now, given $\varepsilon > 0$, we first choose $r > 2$ small enough that $\log(r) < 1 + \varepsilon/2$. **S** now plays the preprocessing existential moves as described above to obtain $|\mathcal{A}|$ parallel **one-vs-all** instances. Now, by Theorem 16, he can win these instances in parallel using Lemma 6, using $(1+\varepsilon/2)\log(n) + 6$ rounds for all $n \geq \max(N(r), N'(\varepsilon))$, for some $N'(\varepsilon)$ depending only on ε. The total number of rounds needed, therefore, is:

$$\begin{aligned} m + (1+\varepsilon/2)\log(n) + 6 &\leq \frac{n}{\log(n)} \cdot \log(r) + \left(1 + \frac{\varepsilon}{2}\right)\log(n) + 7 \\ &\leq \left(1 + \frac{\varepsilon}{2}\right)\left(\frac{n}{\log(n)} + \log(n)\right) + 7 \\ &< (1+\varepsilon)\frac{n}{\log(n)} + 7 \end{aligned}$$

for all $n \geq \max(N(r), N'(\varepsilon), N''(\varepsilon))$, where for all $n \geq N''(\varepsilon)$, we have $(1+\varepsilon/2)\log(n) < (\varepsilon/2)\frac{n}{\log(n)}$. Since each of $N(r)$, $N'(\varepsilon)$, and $N''(\varepsilon)$ depends only on ε, the number of quantifiers for smaller n is absorbed into the $O_\varepsilon(1)$ term. ◀

Remarkably, we cannot improve the upper bound in Theorem 18 by any significant amount. The following proposition establishes this by means of a counting argument, also showing that Theorem A is tight.

▶ **Theorem 19** (Arbitrary vs. Arbitrary – *Lower Bound*). *For all sufficiently large n, there is a nonempty set of n-bit strings, $\mathcal{A} \subsetneq \{0,1\}^n$, such that every separating sentence φ for $(\mathcal{A}, \{0,1\}^n - \mathcal{A})$ must have at least $n/\log(n)$ quantifiers.*

Proof Sketch (see [2] for full proof). If we require k quantifiers to separate any instance on n-bit strings (for sufficiently large n), we can start by counting the number of pairwise inequivalent sentences that can be written with k quantifiers. Such a sentence has a quantifier prefix of length at most k ($\leq 2^{k+1}$ possibilities), followed by a quantifier-free part, which is a disjunction of types (2^{k^k} possibilities). This puts the total number of possible such formulas to be at most $2^k \cdot 2^{2^{k\log(k)}}$. We need this number to be at least $2^{2^n} - 2$, to account for all nonempty instances of the form $(\mathcal{A}, \{0,1\}^n - \mathcal{A})$, which require pairwise inequivalent sentences to separate. Solving this shows that we need $k \geq n/\log(n)$. ◀

6 Conclusions & Open Problems

We obtained nontrivial quantifier upper bounds with matching lower bounds (up to $(1+\varepsilon)$ factors) for a variety of string separation problems. All our upper bounds arise as a result of using the technique of parallel play.

Throughout this work, with very few exceptions, we used MS games to obtain *upper* bounds. It might seem unnecessary to exhibit upper bounds using game arguments, when it ordinarily suffices to exhibit separating sentences. However, the sentences implicitly arising from our game techniques are highly nontrivial to construct. In the case of QR, since taking disjunctions and conjunctions do not increase the quantifier rank, one can build up complex sentences out of simpler ones without paying any cost; we lose this convenience with QN, and therefore need more nuanced techniques, such as parallel play.

Natural directions to extend this work include the following:

1. It would be illuminating to understand the QN required to express particular string and graph properties. While our lower bound for the **one-vs-one** problem (Proposition 14) gave a pair of strings requiring $\log(n)$ quantifiers to separate, the counting argument in Proposition 19 does not exhibit a *specific* instance on n-bit strings that provably requires $n/\log(n)$ quantifiers to separate. Note that by (1), if we can find any property that requires $\omega(\log(n))$ quantifiers to capture, then that property lies outside of NL.
2. Is it possible to use our upper bound in Theorem 18 to obtain Lupanov's upper bound of $(1+\varepsilon)2^n/\log(n)$ on the minimum formula size needed separate two sets in propositional logic (or vice versa)?
3. It is known for ordered structures that with $O(\log n)$ quantifiers, one can express the BIT predicate, or equivalently, all standard arithmetic operations on elements of the universe [12]. In particular, with BIT, some properties that would otherwise require $\log(n)$ quantifiers can be expressed using $O(\log(n)/\log\log(n))$ quantifiers. Understanding the use of BIT and other numeric relations would be valuable.

The Complexity of Simplifying ω-Automata Through the Alternating Cycle Decomposition

Antonio Casares
University of Warsaw, Poland

Corto Mascle
LaBRI, Université de Bordeaux, France

Abstract

In 2021, Casares, Colcombet and Fijalkow introduced the Alternating Cycle Decomposition (ACD), a structure used to define optimal transformations of Muller into parity automata and to obtain theoretical results about the possibility of relabelling automata with different acceptance conditions. In this work, we study the complexity of computing the ACD and its DAG-version, proving that this can be done in polynomial time for suitable representations of the acceptance condition of the Muller automaton. As corollaries, we obtain that we can decide typeness of Muller automata in polynomial time, as well as the parity index of the languages they recognise.

Furthermore, we show that we can minimise in polynomial time the number of colours (resp. Rabin pairs) defining a Muller (resp. Rabin) acceptance condition, but that these problems become NP-complete when taking into account the structure of an automaton using such a condition.

1 Introduction

1.1 Context

Automata for the synthesis problem. Since the 60s, automata over infinite words have provided a fundamental tool to study problems related to the decidability of different logics [5, 38]. Recent focus has centered on the study of synthesis of controllers for reactive systems with the specification given in Linear Temporal Logic (LTL). The original automata-theoretic approach by Pnueli and Rosner [37] remains at the heart of the state-of-the-art LTL-synthesis tools [19, 29, 33, 35]. Their method consists in translating the LTL formula into a deterministic ω-automaton which is then used to build an infinite duration game; a winning strategy in this game provides a correct controller for the system.

Different acceptance conditions. There are different ways of specifying which runs of an automaton over infinite words are accepting. Generally, we label the transitions of the automaton with some output colours, and we then indicate which colours should be seen (or not) infinitely often. This can be expressed in a variety of ways, obtaining different acceptance conditions, such as parity, Rabin or Muller. The complexity of such acceptance

conditions is crucial in the performance of algorithms dealing with automata and games over infinite words. For instance, parity games can be solved in quasi-polynomial time [6] and parity games solvers are extremely performing in practice [24], while solving Rabin and Muller games is, respectively, NP-complete [18] and PSPACE-complete [22]. Moreover, many existing algorithms for solving these games are polynomial on the size of the game graph, and are exponential only on parameters from the acceptance condition: Muller games can be solved in time $\mathcal{O}(k^{5k}n^5)$ [6, Theorem 3.4], where n is the size of the game and k is the number of colours used by the acceptance condition, and Rabin games can be solved in time $\mathcal{O}(n^{r+3}rr!)$ [36, Theorem 7], where r is the number of Rabin pairs of the acceptance condition. Also, the emptiness check of Muller automata with the condition represented by a Boolean formula ϕ (Emerson-Lei condition) can be done in time $\mathcal{O}(2^k kn^2|\phi|)$ [2, Theorem 1].

Some important objectives are therefore: (1) transform an automaton $\mathcal{A}$ using a complex acceptance conditions into an automaton $\mathcal{B}$ using a simpler one, and (2) simplify as much as possible the acceptance condition used by an automaton $\mathcal{A}$ (without adding further states).

The Zielonka tree and Zielonka DAG. The Zielonka tree is an informative representation of Muller conditions, introduced for the study of strategy complexity in Muller games [42, 17]. Zielonka showed that we can use this structure to tell whether a Muller language can be expressed as a Rabin or a parity language [42, Section 5]. Moreover, it has been recently proved that the Zielonka tree provides minimal deterministic parity automata recognising a Muller condition [10, 31], and can thus be used to transform Muller automata using this condition into equivalent parity automata.

A natural alternative is to consider the more succinct DAG-version of this structure: the Zielonka DAG. Hunter and Dawar studied the complexity of building the Zielonka DAG from an explicit representation of a Muller condition, and the complexity of solving Muller games for these different representations [23]. Recently, Hugenroth showed that many decision problems concerning Muller automata become tractable when using the Zielonka DAG to represent the acceptance condition [21].

The ACD: Theoretical applications. In 2021, Casares, Colcombet and Fijalkow [9] proposed the Alternating Cycle Decomposition (ACD) as a generalisation of the Zielonka tree. The main motivation for the introduction of the ACD was to define optimal transformations of automata: given a Muller automaton $\mathcal{A}$, we can build using the ACD an equivalent parity automaton that is minimal amongst all parity automata obtained by duplicating states of $\mathcal{A}$ [10, Theorem 5.32]. Moreover, the ACD can be used to tell whether a Muller automaton can be relabelled with an acceptance condition of a simpler type [10, Section 6.1].

However, the works introducing the ACD [9, 10] are of theoretical nature, and no study of the cost of constructing it and performing the related transformations is presented.

The ACD: Practice. The transformations based on the ACD have been implemented in the tools Spot 2.10 [16] and Owl 21.0 [27], and are used in the LTL-synthesis tools `ltlsynt` [33] and `STRIX` [29, 32] (top-ranked in the SYNTCOMP competitions [24]). In the tool paper [12], these transformation are compared with the state-of-the-art methods to transform Emerson-Lei automata into parity ones. Surprisingly, the transformation based on the ACD does not only produce the smallest parity automata, but also outperforms all other existing paritizing methods in computation time.

In [12, Section 4], an algorithm computing the ACD is proposed. However, the focus is made in the handling of Boolean formulas to enhance the algorithm's performance in practice, but no theoretical analysis of its complexity is provided.

Simplification of acceptance conditions. As already mentioned, the complexity of the acceptance conditions play a crucial role in algorithms. One can simplify the acceptance condition of a Muller automaton by adding further states (and the optimal way of doing this is determined by the ACD [10]). However, in some cases this leads to an exponential blow-up in the number of states [28]. A natural question is therefore to try to simplify the acceptance condition while avoiding adding so many states. We consider two versions of this problem:

Typeness problem. Can we relabel the acceptance condition of a Muller automaton with one of a simpler type, such as Rabin, Streett or parity?

Minimisation of colours and Rabin pairs. Can we minimise the number of colours used by the acceptance condition (or, in the case of Rabin automata, the number of Rabin pairs)?

The ACD has proven fruitful for studying the typeness problem: just by inspecting the ACD of $\mathcal{A}$, we can tell whether we can relabel it with an equivalent Rabin, parity or Streett acceptance condition [10]. Also, it is a classical result that we can minimise in polynomial time the number of colours used by a parity automaton [7]. However, it was still unclear whether the ACD could help to minimise the number of colours of Muller conditions or the number of Rabin pairs of Rabin acceptance conditions, question that we tackle in this work.

The minimisation of colours in Muller automata has recently been studied by Schwarzová, Strejček and Major [39]. In their approach, they use heuristics to reduce the number of colours by applying QBF-solvers. The final acceptance condition is however not guaranteed to have a minimal number of colours. There have also been attempts to minimise the number of Rabin pairs of Rabin automata coming from the determinisation of Büchi automata [40]. Also, in their work about minimal history-deterministic Rabin automata, Casares, Colcombet and Lehtinen left open the question of the minimisation of Rabin pairs [11].

1.2 Contributions

1. **Computation of the ACD and the ACD-DAG.** We show that we can compute the ACD of a Muller automaton in polynomial time, provided that the Zielonka tree of its acceptance condition is given as input (Theorem 13). This shows that the computation of the ACD is not harder than that of the Zielonka tree, (partially) explaining the strikingly favourable experimental results from [12]. We also show that we can compute the DAG-version of the ACD in polynomial time if the acceptance condition of $\mathcal{A}$ is given colour-explicitly or by a Zielonka DAG (Theorem 15). The main technical challenge is to prove that the ACD has polynomial size in the size of the Zielonka tree.
2. **Deciding typeness in polynomial time.** Combining the previous contributions with the results from [10], we directly obtain that we can decide in polynomial time whether a Muller automaton can be relabelled with an equivalent parity, Rabin or Streett acceptance condition (Corollary 16). Moreover, we recover a result from Wilke and Yoo [41]: we can compute in polynomial time the parity index of the language of a Muller automaton.
3. **Minimisation of colours and Rabin pairs of acceptance conditions.** For a given Muller (resp. Rabin) language L, we show that we can minimise the number of colours (resp. Rabin pairs) needed to define L in polynomial time (Theorems 20 and 21). We also relate the minimisation of Rabin pairs to a subclass of interest of Boolean formulas, called generalised Horn formulas.
4. **Minimisation of colours and Rabin pairs over an automaton structure.** Given an automaton $\mathcal{A}$ using a Muller (resp. Rabin) acceptance condition, we show that the problem of minimising the number of colours (resp. Rabin pairs) to relabel $\mathcal{A}$ with an equivalent acceptance condition over its structure is NP-complete, and it remains NP-hard even

if the ACD is given as input (Theorems 26 and 27). This came as a surprise to us, as our first intuition was that the ACD would allow to lift the previous polynomial-time minimisation algorithms to ones which take into account the structure of the automaton.

We provide proof ideas for all the results, technical proofs can be found in the full version [13]. The full version also contains further contributions and discussions about the size of different representations of Muller conditions (summarised in Figure 3).

2 Preliminaries

2.1 Automata over infinite words and their acceptance conditions

Given a set Γ, we write 2^Γ_+ for the set of its non-empty subsets. For a word $w \in \Gamma^\omega$, we let $\mathsf{Inf}(w)$ be the set of letters appearing infinitely often in w.

Automata. A *(non-deterministic) automaton* is a tuple $\mathcal{A} = (Q, q_{\mathsf{init}}, \Sigma, \Delta, \Gamma, \mathsf{col}, W)$, where Q is a finite set of states, $q_{\mathsf{init}} \in Q$ is an initial state, Σ is an *input alphabet*, $\Delta \subseteq Q \times \Sigma \times Q$ is a set of transitions, Γ is a finite set of *output colours*, $\mathsf{col}\colon \Delta \to \Gamma$ is a *colouring* of the transitions, and $W \subseteq \Gamma^\omega$ is a language over Γ. We call the tuple (col, W) the *acceptance condition* of $\mathcal{A}$. We write $q \xrightarrow{a} q'$ to denote a transition $e = (q, a, q') \in \Delta$, and $q \xrightarrow{a:c} q'$ to further indicate that $\mathsf{col}(e) = c$. We write $q \overset{w:u}{\rightsquigarrow} q'$ to represent the existence of a path from q to q' labelled with the input letters $w \in \Sigma^*$ and output colours $u \in \Gamma^*$.

Given an automaton $\mathcal{A}$ and a word $w \in \Sigma^\omega$, a *run over* w in $\mathcal{A}$ is a path $q_{\mathsf{init}} \xrightarrow{w_0:c_0} q_1 \xrightarrow{w_1:c_1} q_2 \xrightarrow{w_2:c_2} q_3 \xrightarrow{w_3:c_3} \cdots \in \Delta^\omega$. Such a run is *accepting* if $c_0c_1c_2 \cdots \in W$, and *rejecting* otherwise. A word $w \in \Sigma^\omega$ is *accepted* by $\mathcal{A}$ if it admits an accepting run. The *language recognised* by an automaton $\mathcal{A}$ is the set $\mathcal{L}(\mathcal{A}) = \{w \in \Sigma^\omega \mid w \text{ is accepted by } \mathcal{A}\}$. Two automata over the same alphabet are *equivalent* if they recognise the same language. An automaton is *deterministic* (resp. *complete*) if for every $q \in Q$ and $a \in \Sigma$, there is at most (resp. at least) one transition $q \xrightarrow{a} q'$.

We underline that the colours of the acceptance of runs appear *over transitions*. For a discussion on the differences between transition and state-based automata, and arguments in favour of the former, we refer to [8, Chap. VI].

It is sometimes useful to let transitions carry multiple colours – for instance, this is the standard model in the HOA format [1]. For many results of this paper (those from Section 3), allowing or not multiple colours per edge does not make a difference; we could always take 2^Γ or Δ as new set of colours. This will however be relevant in Section 4.2. Also, the HOA format allows for multiple transitions between the same two states with the same input letter. These transitions can always be replaced by one carrying multiple colours (we refer to [11, Prop. 18] for details).

We let the *size of* $\mathcal{A}$ be $|\mathcal{A}| = |Q| + |\Sigma| + |\Delta| + |\Gamma|$. We note that this does not take into account the size of the representation of its acceptance condition, which can admit different forms (see page 7). When necessary, we will indicate the size of the representation of the acceptance condition separately.

Acceptance conditions. We now define the main classes of languages used by automata over infinite words as acceptance conditions. We let Γ stand for a finite set of colours.

Muller. We define the *Muller language* of a family $\mathcal{F} \subseteq 2^\Gamma_+$ of non-empty subsets of Γ as:

$$\mathsf{Muller}_\Gamma(\mathcal{F}) = \{w \in \Gamma^\omega \mid \mathsf{Inf}(w) \in \mathcal{F}\}.$$

We will often refer to sets in $\mathcal{F}$ as *accepting sets* and sets not in $\mathcal{F}$ as *rejecting sets*.

Rabin. A Rabin condition is represented by a family $\mathcal{R} = \{(\mathfrak{g}_1, \mathfrak{r}_1), \dots, (\mathfrak{g}_r, \mathfrak{r}_r)\}$ of *Rabin pairs*, where $\mathfrak{g}_j, \mathfrak{r}_j \subseteq \Gamma$. We define the *Rabin language* of a single Rabin pair $(\mathfrak{g}, \mathfrak{r})$ as

$$\mathsf{Rabin}_\Gamma((\mathfrak{g}, \mathfrak{r})) = \{w \in \Gamma^\omega \mid \mathsf{Inf}(w) \cap \mathfrak{g} \neq \emptyset \wedge \mathsf{Inf}(w) \cap \mathfrak{r} = \emptyset\},$$

and the Rabin language of a family of Rabin pairs $\mathcal{R}$ as: $\mathsf{Rabin}_\Gamma(\mathcal{R}) = \bigcup_{j=1}^{r} \mathsf{Rabin}_\Gamma((\mathfrak{g}_j, \mathfrak{r}_j))$.

Streett. The *Streett language* of a family $\mathcal{R} = \{(\mathfrak{g}_1, \mathfrak{r}_1), \dots, (\mathfrak{g}_r, \mathfrak{r}_r)\}$ of Rabin pairs is defined as the complement of its Rabin language:

$$\mathsf{Streett}_\Gamma(\mathcal{R}) = \Gamma^\omega \setminus \mathsf{Rabin}_\Gamma(\mathcal{R}).$$

Parity. We define the *parity language* over a finite alphabet $\Pi \subseteq \mathbb{N}$ as:

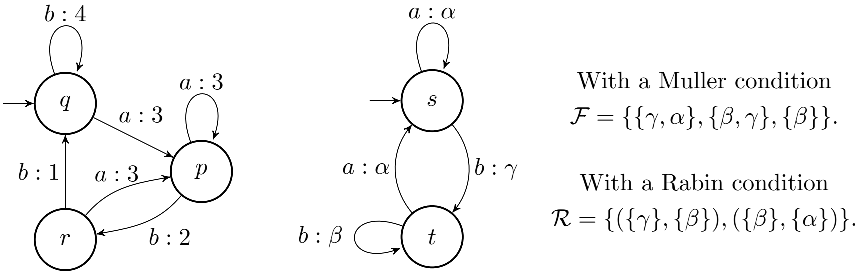
$$\mathsf{parity}_\Pi = \{w \in \Pi^\omega \mid \min \mathsf{Inf}(w) \text{ is even}\}.$$

We say that an automaton is a $\mathcal{C}$ *automaton*, for $\mathcal{C}$ one of the classes of languages above, if its acceptance condition uses a $\mathcal{C}$ language. We refer to the survey [3] for a more detailed account on different types of acceptance conditions.

▶ Remark 1. Muller languages are exactly the languages characterised by the set of letters seen infinitely often. They are also the languages recognised by deterministic Muller automata with one state.

We observe that parity languages are special cases of Rabin and Streett languages which are in turn special cases of Muller languages.

▶ **Example 2.** In Figure 1 we show different types of automata over the alphabet $\Sigma = \{a, b\}$ recognising the language of words that contain infinitely many bs and eventually do not encounter the factor abb.



With a Muller condition
$\mathcal{F} = \{\{\gamma, \alpha\}, \{\beta, \gamma\}, \{\beta\}\}$.

With a Rabin condition
$\mathcal{R} = \{(\{\gamma\}, \{\beta\}), (\{\beta\}, \{\alpha\})\}$.

Parity automaton $\mathcal{A}_1$.

Automaton $\mathcal{A}_2$ with equivalent Muller and Rabin conditions over it.

Figure 1 Different types of automata recognising the language $L = \Sigma^* b^\omega + \Sigma^*(a^+ b)^\omega$. (Note that the set of outputs that occur infinitely often in a run of $\mathcal{A}_2$ cannot be $\{\beta, \gamma\}$.)

The 8 classes of automata obtained by combining the 4 types of acceptance conditions above with deterministic and non-deterministic models are equally expressive [30, 34]. We call the class of languages that can be recognised by these automata *ω-regular languages*. The *parity index* of L is the minimal number k such that L can be recognised by a deterministic parity automaton using k output colours (which coincides with the minimal number of colours used by a Muller automaton recognising L [10, Proposition 6.14]).

Typeness. Let $\mathcal{A}_1 = (Q, q_{\mathsf{init}}, \Sigma, \Delta, \Gamma_1, \mathsf{col}_1, W_1)$ be a deterministic automaton, and let $\mathcal{C}$ be a class of languages (potentially containing languages over different alphabets). We say that $\mathcal{A}_1$ can be *relabelled* with a $\mathcal{C}$-acceptance condition, or that $\mathcal{A}$ is $\mathcal{C}$*-type*, if there is $W_2 \subseteq \Gamma_2^\omega$, $W_2 \in \mathcal{C}$, and a colouring function $\mathsf{col}_2 \colon \Delta \to \Gamma_2$ such that $\mathcal{A}_1$ is equivalent to $\mathcal{A}_2 = (Q, q_{\mathsf{init}}, \Sigma, \Delta, \Gamma_2, \mathsf{col}_2, W_2)$. In this case, we say that (col_1, W_1) and (col_2, W_2) are *equivalent acceptance conditions over* $\mathcal{A}$.

Given a Muller automaton $\mathcal{A}$, we use the expression *deciding the typeness* of $\mathcal{A}$ for the problem of answering if $\mathcal{A}$ is Rabin type, Streett type, parity type, or none of those.[1]

▶ Remark 3. In this work, we only consider typeness for deterministic automata for simplicity. For non-deterministic models, typeness admits two non-equivalent definitions [26]: (1) the acceptance status of each individual infinite path coincide for both acceptance conditions, or (2) both automata recognise the same language.

▶ **Example 4.** The automaton $\mathcal{A}_2$ from Figure 1 is Rabin type, as we have labelled it with a Rabin acceptance condition that is equivalent over $\mathcal{A}$ to the Muller condition given by $\mathcal{F}$ (in this case, both conditions use the same set of colours $\Gamma = \{\alpha, \beta, \gamma\}$). However, we note that $\mathsf{Rabin}_\Gamma(\mathcal{R}) \neq \mathsf{Muller}_\Gamma(\mathcal{F})$, as $\gamma^\omega \in \mathsf{Rabin}_\Gamma(\mathcal{R})$, while $\gamma^\omega \notin \mathsf{Muller}_\Gamma(\mathcal{F})$. This is possible, as no infinite path in $\mathcal{A}_2$ is labelled by a word that differentiates both languages (such as γ^ω).

2.2 The Zielonka tree and the Zielonka DAG

We represent *trees* and *directed acyclic graphs* (DAGs) as pairs $T = (N, \preceq)$ with N a non-empty finite set of nodes and $\preceq$ the *ancestor relation* ($n \preceq n'$ meaning that n is above n'). An A*-labelled tree* (resp. A*-labelled DAG*) is a tree (resp. DAG) together with a labelling function $\nu \colon N \to A$. We write $|T|$ to denote the number of nodes of a tree T.

▶ **Definition 5** ([42]). *Let $\mathcal{F} \subseteq 2_+^\Gamma$ be a family of non-empty subsets of a finite set Γ. The* Zielonka tree *for $\mathcal{F}$ (over Γ),*[2] *denoted $\mathcal{Z}_\mathcal{F} = (N, \preceq, \nu : N \to 2_+^\Gamma)$ is a 2_+^Γ-labelled tree with nodes partitioned into* round nodes *and* square nodes*, $N = N_\bigcirc \sqcup N_\square$, such that:*

- *The root is labelled Γ.*
- *If a node is labelled $X \subseteq \Gamma$, with $X \in \mathcal{F}$, then it is a round node, and it has a child for each maximal non-empty subset $Y \subseteq X$ such that $Y \notin \mathcal{F}$, which is labelled Y.*
- *If a node is labelled $X \subseteq \Gamma$, with $X \notin \mathcal{F}$, then it is a square node, and it has a child for each maximal non-empty subset $Y \subseteq X$ such that $Y \in \mathcal{F}$, which is labelled Y.*

▶ **Example 6.** Let $\mathcal{F} = \{\{\gamma, \alpha\}, \{\gamma, \beta\}, \{\beta\}\}$ be the Muller condition of the automaton from Example 2, over the alphabet $\{\alpha, \beta, \gamma\}$. In Figure 2 we show the Zielonka tree of $\mathcal{F}$.

The *Zielonka DAG* of a family $\mathcal{F} \subseteq 2_+^\Gamma$ is the labelled directed acyclic graph $\mathcal{Z}\text{-}\mathsf{DAG}_\mathcal{F}$ obtained by merging the nodes of $\mathcal{Z}_\mathcal{F}$ with a common label. It inherits the partition into round and square nodes, with children of round nodes being square and vice-versa.

▶ **Lemma 7** (Implied by [21, Lemma 1]). *Given a 2_+^Γ-labelled tree T with a partition into round and square nodes, we can decide in polynomial time whether there is a family $\mathcal{F} \subseteq 2_+^\Gamma$ such that $T = \mathcal{Z}_\mathcal{F}$. In the affirmative case, this family is uniquely determined.*

[1] We could consider further classes of acceptance conditions such as Büchi, coBüchi, generalised Büchi, weak, etc... We refer to [10, Appendix A] for more details on these acceptance types.

[2] The definition of $\mathcal{Z}_\mathcal{F}$, as well as most subsequent definitions, do not only depend on $\mathcal{F}$ but also on the alphabet Γ. Although this dependence is important, we do not explicitly include it in the notations in order to lighten them, as most of the times the alphabet will be clear from the context.

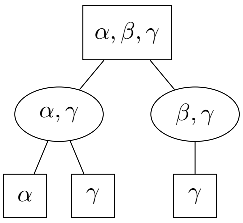


Figure 2 Zielonka tree $\mathcal{Z}_\mathcal{F}$ for $\mathcal{F} = \{\{\gamma, \alpha\}, \{\gamma, \beta\}, \{\beta\}\}$.

Representation of acceptance conditions. There is a wide variety of ways to represent a Muller language, including as its Zielonka tree, its Zielonka DAG, or *colour-explicitly*, that is, as a list of the subsets appearing in $\mathcal{F}$. In Figure 3 we summarise the relationship between these representations. We highlight that the Zielonka DAG can be built in polynomial time from both the Zielonka tree and from a colour-explicit representation of a Muller condition [23, Theorem 3.17]. The exponential-size separation between the Zielonka tree and colour-explicit representations, as well as explicit examples showing the gap between Zielonka trees and DAGs are original contributions.

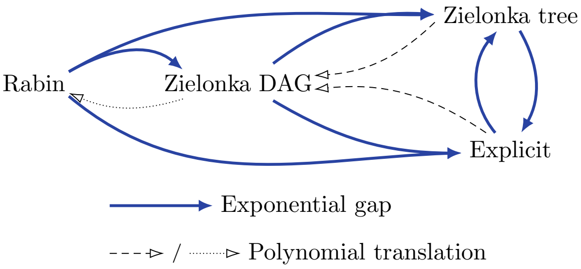

Figure 3 Comparison between the different representations of Muller conditions. A blue bold arrow from X to Y means that converting an X-representation into the form Y requires exponential time. A dashed arrow from X to Y means that a conversion can be computed in polynomial time. The dotted arrow indicates that the polynomial translation can only be applied on a fragment of X, as it is more expressive than Y.

2.3 The Alternating Cycle Decomposition

We now present the Alternating Cycle Decomposition and its DAG-version, following [10].

Let $\mathcal{A}$ be an automaton with Q and Δ as set of states and transitions, respectively. A *cycle* of $\mathcal{A}$ is a subset $\ell \subseteq \Delta$ such that there is a (not necessarily simple) path with the same starting and ending state such that the set of edges it visits is ℓ. The set of cycles of an automaton $\mathcal{A}$ is written $\mathcal{C}ycles(\mathcal{A})$. We will consider the set of cycles ordered by inclusion. If we see $\mathcal{A}$ as a graph, its cycles are the strongly connected subgraphs of that graph, and the maximal cycles are its strongly connected components (SCCs). Let $\mathcal{A}$ be a Muller automaton with acceptance condition $(\mathsf{col}, \mathsf{Muller}_\Gamma(\mathcal{F}))$. Given a cycle $\ell \in \mathcal{C}ycles(\mathcal{A})$, we say that ℓ is *accepting* (resp. *rejecting*) if $\mathsf{col}(\ell) \in \mathcal{F}$ (resp. $\mathsf{col}(\ell) \notin \mathcal{F}$).

▶ **Definition 8.** *Let $\ell_0 \in \mathcal{C}ycles(\mathcal{A})$ be a cycle. We define the* tree of alternating subcycles *of ℓ_0, denoted $\mathsf{AltTree}(\ell_0)$, as a $\mathcal{C}ycles(\mathcal{A})$-labelled tree with nodes partitioned into* round nodes *and* square nodes*, $N = N_\bigcirc \sqcup N_\square$, such that:*

- *The root is labelled* ℓ_0.
- *If a node is labelled* $\ell \in \mathcal{Cycles}(\mathcal{A})$*, and* ℓ *is an accepting cycle* ($\mathsf{col}(\ell) \in \mathcal{F}$)*, then it is a round node, and its children are labelled exactly with the maximal subcycles* $\ell' \subseteq \ell$ *such that* ℓ' *is rejecting* ($\mathsf{col}(\ell') \notin \mathcal{F}$).
- *If a node is labelled* $\ell \in \mathcal{Cycles}(\mathcal{A})$*, and* ℓ *is a rejecting cycle* ($\mathsf{col}(\ell) \notin \mathcal{F}$)*, then it is a square node, and its children are labelled exactly with the maximal subcycles* $\ell' \subseteq \ell$ *such that* ℓ' *is accepting* ($\mathsf{col}(\ell') \in \mathcal{F}$).

▶ **Definition 9** (Alternating cycle decomposition)**.** *Let* $\mathcal{A}$ *be a Muller automaton, and let* $\ell_1, \ell_2, \dots, \ell_k$ *be an enumeration of its maximal cycles. We define the* alternating cycle decomposition *of* $\mathcal{A}$ *to be the forest* $\mathcal{ACD}(\mathcal{A}) = \{\mathsf{AltTree}(\ell_1), \dots, \mathsf{AltTree}(\ell_k)\}$.

▶ Remark 10. The Zielonka tree can be seen as the special case of the alternating cycle decomposition for an automata with a single state.

As mentioned in the introduction, the ACD was introduced in order to build small parity automata from Muller ones: given the ACD of a Muller automaton $\mathcal{A}$, we can build in polynomial time an equivalent parity automaton $\mathcal{P}_{\mathcal{A}}^{\mathsf{ACD}}$ (called the *ACD-parity transform* of $\mathcal{A}$) of minimal size amongst all automata obtained from $\mathcal{A}$ by "duplication of states". See [10, Section 5.2] for a formal statement and further results.

▶ **Example 11.** Figure 4 contains the alternating cycle decomposition of the automata $\mathcal{A}_1$ and $\mathcal{A}_2$ from Figure 1. We represent their transitions as pairs $(q, a) \in Q \times \Sigma$. Since both automata are strongly connected, each ACD consists in a single tree, whose root is the whole set of transitions.

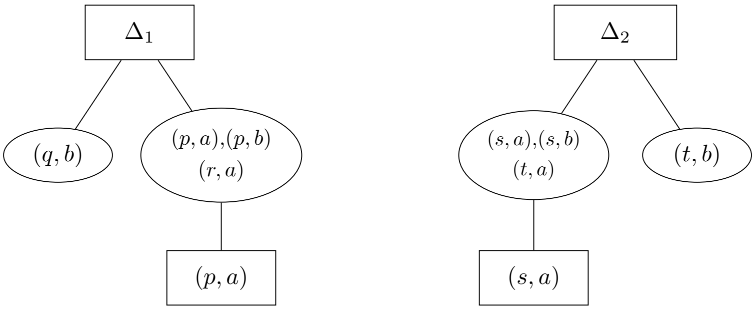

Figure 4 Alternating cycle decomposition of $\mathcal{A}_1$ (on the left) and $\mathcal{A}_2$ (on the right), from Figure 1.

The *ACD-DAG* of a Muller automaton $\mathcal{A}$, written $\mathcal{ACD}$-$\mathsf{DAG}(\mathcal{A})$, is the family of labelled DAGs obtained by merging nodes with the same label in the trees of $\mathcal{ACD}(\mathcal{A})$. It is useful for deciding the typeness and the parity index of $\mathcal{L}(\mathcal{A})$, as stated next.

▶ **Proposition 12** ([10, Section 6.1])**.** *Given a deterministic Muller automaton* $\mathcal{A}$ *and its ACD-DAG, we can decide the typeness of* $\mathcal{A}$ *and compute the parity index of* $\mathcal{L}(\mathcal{A})$ *in polynomial time.*

3 Computation of the Alternating Cycle Decomposition

We present in this section our central contribution: a polynomial-time algorithm to compute the alternating cycle decomposition of a Muller automaton with the acceptance condition given by a Zielonka tree (Theorem 13). This shows that the computation of the ACD is not harder than that of the Zielonka tree, (partially) explaining the strikingly performing experimental results from [12]. We also show that if the acceptance condition is represented as a Zielonka DAG, we can compute $\mathcal{ACD}$-DAG($\mathcal{A}$) in polynomial time (Theorem 15), from which we can derive decidability in polynomial time of typeness of Muller automata (Corollary 16).

3.1 Statements of the results

▶ **Theorem 13** (Computation of the ACD). *Given a Muller automaton $\mathcal{A}$ with acceptance condition represented by a Zielonka tree $\mathcal{Z}_{\mathcal{F}}$,*[3] *we can compute $\mathcal{ACD}(\mathcal{A})$ in polynomial time in $|\mathcal{A}| + |\mathcal{Z}_{\mathcal{F}}|$.*

As stated in the previous section, given the ACD of a Muller automaton $\mathcal{A}$, we can transform $\mathcal{A}$ in polynomial time into its ACD-parity-transform: a parity automaton equivalent to $\mathcal{A}$ that is minimal amongst parity automata obtained as a transformation of $\mathcal{A}$. The previous theorem implies that this can be done even if only the Zielonka tree of the acceptance condition of $\mathcal{A}$ is given as input, together with the automaton structure.[4]

▶ **Corollary 14.** *We can compute the ACD-parity-transform of a Muller automaton in polynomial time, if its acceptance condition is given by a Zielonka tree.*

▶ **Theorem 15** (Computation of the ACD-DAG). *Given a Muller automaton $\mathcal{A}$ with acceptance condition represented by a Zielonka DAG $\mathcal{Z}$-DAG$_{\mathcal{F}}$ (resp. colour-explicitly), we can compute $\mathcal{ACD}$-DAG($\mathcal{A}$) in polynomial time in $|\mathcal{A}| + |\mathcal{Z}\text{-DAG}_{\mathcal{F}}|$ (resp. $|\mathcal{A}| + |\mathcal{F}|$).*

Combining Theorem 15 with Propositions 12, we directly obtain that we can decide typeness of Muller automata and the parity index of their languages in polynomial time.

▶ **Corollary 16** (Polynomial-time decidability of typeness and parity index). *Given a deterministic Muller automaton $\mathcal{A}$ with its acceptance condition represented colour-explicitly, as a Zielonka tree, or as a Zielonka DAG, we can decide the typeness of $\mathcal{A}$, and determine the parity index of $\mathcal{L}(\mathcal{A})$, in polynomial time.*

The decidability of the parity index in polynomial time had already been obtained by Wilke and Yoo [41]. This result contrasts with the fact that deciding the parity index of a language represented by a deterministic Rabin or Streett automaton is NP-complete [25].

3.2 Main algorithm and complexity

Description of the algorithm. We describe an algorithm computing $\mathcal{ACD}$-DAG($\mathcal{A}$) from a Muller automaton $\mathcal{A}$. To obtain $\mathcal{ACD}(\mathcal{A})$, it suffices then to unfold this DAG. This algorithm builds the ACD-DAG in a top-down fashion: first, it computes the strongly connected components of $\mathcal{A}$ and initialises the root of each of the DAGs in $\mathcal{ACD}$-DAG($\mathcal{A}$). Then, it iteratively computes the children of the already found nodes as follows: Given a node n labelled ℓ (assume that ℓ is an accepting cycle), the algorithm goes through all square nodes m in the Zielonka DAG and for each of them computes the maximal sub-cycles of ℓ whose set of colours is included in the label of m, but not in those of any of its children. The algorithm then selects maximal cycles among those found, add them to $\mathcal{ACD}$-DAG($\mathcal{A}$) (if they do not already appear there) and sets them as children of n.

[3] Lemma 7 lets us check in polynomial time if a tree indeed is the Zielonka tree of a Muller condition.

[4] Also, we note that given $\mathcal{A}$ and its ACD, it is immediate to compute a Zielonka tree over the set of colours $\Gamma = \Delta$ defining an equivalent acceptance condition over $\mathcal{A}$.

Complexity analysis. We explain now how we obtain a polynomial upper bound on the complexity of the algorithms presented in the previous paragraph.

We first remark that we need to make at $|\mathcal{ACD}\text{-}\mathsf{DAG}(\mathcal{A})|$ computations of the children of a node, as each node of the ACD-DAG is considered at most once by the algorithm. Therefore, to obtain Theorem 15 (computation of the ACD-DAG) we need to show that:

1. We can compute the children of a node in polynomial time in $|Q| + |\mathcal{Z}\text{-}\mathsf{DAG}_{\mathcal{F}}|$, and
2. $|\mathcal{ACD}\text{-}\mathsf{DAG}(\mathcal{A})|$ is polynomial in $|Q| + |\mathcal{Z}\text{-}\mathsf{DAG}_{\mathcal{F}}|$.

To establish Theorem 13 (computation of the ACD), we remark that we can compute $\mathcal{ACD}(\mathcal{A})$ from $\mathcal{A}$ and $\mathcal{Z}_{\mathcal{F}}$ by simply folding $\mathcal{Z}_{\mathcal{F}}$ to obtain $\mathcal{Z}\text{-}\mathsf{DAG}_{\mathcal{F}}$, apply Theorem 15 to get $\mathcal{ACD}\text{-}\mathsf{DAG}(\mathcal{A})$, and then unfold the latter to obtain $\mathcal{ACD}(\mathcal{A})$. The first two steps require a time polynomial in $|\mathcal{Z}\text{-}\mathsf{DAG}_{\mathcal{F}}| + |Q| \leq |\mathcal{Z}_{\mathcal{F}}| + |Q|$, while the third step takes a time polynomial in $|\mathcal{ACD}(\mathcal{A})|$. Thus, to obtain the theorem, it suffices to establish

3. $|\mathcal{ACD}(\mathcal{A})|$ is polynomial in $|Q| + |\mathcal{Z}_{\mathcal{F}}|$.

The most technical part lies in the proofs of items 2 and 3, stated below.

▶ **Proposition 17.** *Let $\mathcal{A}$ be a Muller automaton and $\mathcal{F}$ the family defining its acceptance condition. Then,*

a) $|\mathcal{ACD}(\mathcal{A})| \leq |Q| \cdot |\mathcal{Z}_{\mathcal{F}}|$.
b) $|\mathcal{ACD}\text{-}\mathsf{DAG}(\mathcal{A})| \leq |Q| \cdot |\mathcal{Z}\text{-}\mathsf{DAG}_{\mathcal{F}}|$.

We describe now the main ideas of the proof of Proposition 17. We use the notion of *local subtree at a state* of the ACD. If q is a state of $\mathcal{A}$ appearing in the SCC ℓ_i, we define the *local subtree at* q, noted $\mathcal{T}_q$, as the subtree of $\mathsf{AltTree}(\ell_i)$ containing the nodes $N_q = \{n \in \mathsf{AltTree}(\ell_i) \mid q \text{ is a state in the label of } n\}$. We define analogously the *local subDAG of $\mathcal{ACD}$-$\mathsf{DAG}(\mathcal{A})$ at q*, noted $\mathcal{D}_q$.

We remark that $|\mathcal{ACD}(\mathcal{A})| \leq \sum_{q\in Q} |\mathcal{T}_q|$ (resp. $|\mathcal{ACD}\text{-}\mathsf{DAG}(\mathcal{A})| \leq \sum_{q\in Q} |\mathcal{D}_q|$), as each node of the ACD appears in some local subtree. Therefore, it suffices to bound the size of the local subtrees (resp. local subDAGs) to obtain a polynomial bound on the size of $\mathcal{ACD}(\mathcal{A})$ (resp. $\mathcal{ACD}\text{-}\mathsf{DAG}(\mathcal{A})$) to deduce Proposition 17. Quite surprisingly, the arguments to bound these objects are slightly different in each case.

▶ **Lemma 18.** *For every state q, the tree $\mathcal{T}_q$ has size at most $|\mathcal{Z}_{\mathcal{F}}|$.*

Proof sketch. We define in a top-down fashion an injective function $f \colon \mathcal{T}_q \to \mathcal{Z}_{\mathcal{F}}$. For the base case, we send the root of $\mathcal{T}_q$ to the root of $\mathcal{Z}_{\mathcal{F}}$. Let n be a node in $\mathcal{T}_q$ such that $f(n)$ has been defined, and let $n_1, \dots, n_k$ be its children. The key technical result is to show that there are k descendants of $f(n)$, containing the sets of labels of $n_1, \dots, n_k$, respectively, that are incomparable for the ancestor relation. Then, the subtrees rooted at these nodes are pairwise disjoint, which allows to define $f(n_i)$ for all i and carry out the induction. ◀

We conclude that the size of $\mathcal{ACD}(\mathcal{A})$ is polynomial in $|Q| + |\mathcal{Z}_{\mathcal{F}}|$, deriving the first item of Proposition 17:

$$|\mathcal{ACD}(\mathcal{A})| \leq \sum_{q\in Q} |\mathcal{T}_q| \leq |Q| \cdot |\mathcal{Z}_{\mathcal{F}}|.$$

▶ **Lemma 19.** *For every state q, the DAG $\mathcal{D}_q$ has size at most $|\mathcal{Z}\text{-}\mathsf{DAG}_{\mathcal{F}}|$.*

Proof sketch. As before, we define an injective function $f \colon \mathcal{D}_q \to \mathcal{Z}\text{-}\mathsf{DAG}_{\mathcal{F}}$. However, now we cannot use the fact that the subDAGs rooted at k incomparable elements are disjoint.

To circumvent this difficulty, for each node n in $\mathcal{D}_q$ different from the root, we fix an arbitrary immediate ancestor of n, noted $\mathsf{pred}(n)$ (that is, n is a child of $\mathsf{pred}(n)$). For a node n in $\mathcal{D}_q$, we let C_n be the set of colours appearing in the label of n. We define f recursively:

For the root n_0 of $\mathcal{D}_q$, we let $f(n_0)$ be a maximal (deepest) node in $\mathcal{Z}$-$\mathsf{DAG}_{\mathcal{F}}$ containing C_{n_0} in its label. For n a node such that we have define f for all its ancestors, we let $f(n)$ be a maximal node in the subDAG rooted at $f(\mathsf{pred}(n))$ containing C_n in its label (we note that $f(n)$ is a round node if and only if n is a round node). The most technical part of the proof is to show injectivity of the obtained function. ◀

4 Minimisation of colours and Rabin pairs

We consider the problem of minimising the representation of the acceptance condition of automata. That is, given a deterministic automaton $\mathcal{A}$ using a Muller (resp. Rabin) acceptance condition, what is the minimal number of colours (resp. Rabin pairs) needed to define an equivalent acceptance condition over $\mathcal{A}$?

We first study the minimisation of colours for Muller languages, without taking into account the structure of the automaton. We show that given the Zielonka DAG of the condition (resp. set of Rabin pairs), we can minimise its number of colours (resp. number of Rabin pairs) in polynomial time (Theorems 20 and 21). We provide an alternative point of view over the minimisation of Rabin pairs, using so-called generalised Horn formulas (see Remark 23). Then, we tackle the same question taking into account the structure of the automaton. Surprisingly, we show that in this case both problems are NP-complete, even if the ACD is given as input (Theorems 26 and 27).

4.1 Minimisation of the representation of Muller languages in PTIME and generalised Horn formulas

Minimisation of colours for Muller languages. We say that a Muller language $\mathsf{Muller}_\Sigma(\mathcal{F})$ is *k-colour type* if there is a set of k colours Γ, a family of sets $\mathcal{F}' \subseteq 2^\Gamma_+$ and a mapping $\phi\colon \Sigma \to \Gamma$ such that for all $S \in 2^\Sigma_+$, $S \in \mathcal{F} \iff \phi(S) \in \mathcal{F}'$.

Note that this is equivalent to asking if all automata using $\mathsf{Muller}_\Sigma(\mathcal{F})$ as acceptance condition can be relabelled with an equivalent Muller condition using at most k colours. (However, it is *not* the same as having a Muller automaton recognising $\mathsf{Muller}_\Sigma(\mathcal{F})$ using at most k colours.)

Colour-Minimisation-ML is the problem of deciding whether a given Muller language (represented by its Zielonka DAG) is k-colour type. We chose to specify the input as a Zielonka DAG, as it is more succinct than the other representations we consider (c.f. Figure 3). We now prove that this problem can be solved in polynomial time, which implies that it can be equally solved in polynomial time if the Muller language is represented colour-explicitly, or as a Zielonka tree.

▶ **Theorem 20** (Tractability of minimisation of colours for Muller languages). *The problem* Colour-Minimisation-ML *can be solved in polynomial time.*

Proof sketch. We define two colours $a, b \in \Sigma$ as equivalent if for every node n of $\mathcal{Z}$-$\mathsf{DAG}_{\mathcal{F}}$, $a \in \nu(n) \iff b \in \nu(n)$. It is not difficult to see that we can merge equivalent colours, that is, we can define $\mathsf{Muller}(\mathcal{F})$ using as many colours as the number of classes for this equivalence relation. We prove that this is optimal: If $\mathsf{Muller}(\mathcal{F})$ can be defined using a mapping $\phi\colon \Sigma \to \Gamma$, then, for all $\alpha \in \Gamma$, the colours in $\phi^{-1}(\alpha)$ are equivalent. Therefore, it suffices to inspect $\mathcal{Z}$-$\mathsf{DAG}_{\mathcal{F}}$ to determine the number of equivalence classes. ◀

Minimisation of Rabin pairs for Rabin languages. In this section we tackle the minimisation of the number of Rabin pairs to represent Rabin languages. We provide a polynomial-time algorithm which turns a family of Rabin pairs into an equivalent one with a minimal number of pairs. The algorithm comes down to partially computing the Zielonka tree of the input Rabin language from top to bottom, and stopping when we can infer from the partial view of the tree a set of Rabin pairs equivalent to the input. We present the algorithm differently to clarify the proofs, in particular the proof that the resulting number of pairs is minimal.

We say that a Rabin language $L \subseteq \Sigma^\omega$ is *k-Rabin-pair type* if there is a family of k Rabin pairs $\mathcal{R}$ over some set of colours Γ and a mapping $\phi\colon \Sigma \to \Gamma$ such that for all $w \in \Sigma^\omega$, $w \in L \iff \phi(w) \in \mathsf{Rabin}_\Gamma(\mathcal{R})$.

Rabin-Pair-Minimisation-ML is the problem of deciding whether a language $\mathsf{Rabin}_\Sigma(\mathcal{R})$ (represented by the Rabin pairs R) is k-Rabin-pair type.

▶ **Theorem 21** (Tractability of minimisation of Rabin pairs for Rabin languages)**.** *The problem* Rabin-Pair-Minimisation-ML *can be solved in polynomial time.*

We obtain the minimal set of Rabin pairs iteratively. We start with an empty set of pairs. While our set of pairs is not equivalent to the input one, we compute a maximal set of colours S accepted by the input set of pairs and not by our current set of pairs. We then compute the maximal subset T of S that is rejected by the input set of pairs. We infer from them a new Rabin pair, which accepts the sets of colours contained in S but not in T. We add this pair to our set of pairs.

We prove that the resulting set is optimal by showing that at all times, we can define an injective function from our current set of pairs to any set of pairs equivalent to the input.

The minimisation of pairs for Streett conditions in polynomial time follows by symmetry.

Generalised Horn formulas. We discuss an alternative point of view on the minimisation of Rabin pairs, via a generalisation of Horn formulas.

Horn formulas are a popular fragment of propositional logic, as they enjoy some convenient complexity properties. It is well-known that the satisfiability problem for those formulas can be solved in linear time [15].

We consider a succinct representation of Horn formulas, called generalised Horn formula. They allow one to merge several Horn clauses with the same premises, e.g. $(x_1 \wedge x_2 \implies y_1)$ and $(x_1 \wedge x_2 \implies y_2)$, into a single clause $(x_1 \wedge x_2 \implies y_1 \wedge y_2)$. We can apply the classical linear-time algorithm for satisfiability on this generalised form, however, note that it is not linear in the size of the generalised formula, but in the size of the implicit Horn formula represented.

▶ **Definition 22.** *A* generalised Horn clause *(or GH clause) is a Boolean formula of the form either $(x_1 \wedge \cdots \wedge x_n) \implies (y_1 \wedge \cdots \wedge y_m)$ or $(x_1 \wedge \cdots \wedge x_n) \implies \bot$ (in the latter case, the clause is called* negative*). A* generalised Horn formula *(or GH formula) is a conjunction of GH clauses. It is* simple *if none of its GH clauses are negative.*

▶ Remark 23 (Correspondence simple GH formulas ↔ Streett conditions). We observe that there is a correspondence between simple GH formulas and Streett conditions. Define the function α that turns a GH clause $(x_1 \wedge \cdots \wedge x_n) \implies (y_1 \wedge \cdots \wedge y_m)$ into the Rabin pair $(\{y_1, \ldots, y_m\}, \{x_1, \ldots, x_n\})$. We extend it into a function turning simple GH formulas into families of Rabin pairs by defining $\alpha(\bigwedge_{i=1}^k \mathrm{GH}_i) = (\alpha(\mathrm{GH}_i))_{i=1}^k$. We can then observe that α is a bijection (we consider Boolean formulas up to commutation of the terms, for instance we consider that $\varphi \vee \psi$ and $\psi \vee \varphi$ are the same formula). We also note that the number of clauses of a simple GH formula is the number of pairs of its image by α.

Note that for all simple GH formula φ, the set of sets accepted by the Streett condition $\alpha(\varphi)$ is $\{\nu^{-1}(\bot) \mid \nu : \mathrm{Var} \to \{\top, \bot\}$ is a valuation satisfying $\varphi\}$. As a result, two simple GH formula are equivalent if and only if their images by α define the same Streett language.

As a consequence of this correspondence and Theorem 21, we obtain that we can minimise the number of clauses in a GH formula in polynomial-time. This result contrasts nicely with the NP-completeness of minimising the number of clauses in a Horn formula [4] (see also [14]). On the other hand, minimising the number of literals in a GH formula remains NP-complete, just like in the case of Horn formulas [20]. This can be showed by a slight adaptation of the reduction from [14] to GH formulas.

▶ **Proposition 24.** *There is a polynomial-time algorithm to minimise the number of clauses of a GH formula.*

Proof sketch. The polynomial-time minimisation of simple GH formulas follows from Theorem 21 and Remark 23. The extension to all Generalised Horn formulas is essentially a technicality, due to the fact that negative clauses cannot be directly translated into Rabin pairs as in the previously. We circumvent this problem by replacing them with some non-negative clauses and proving that minimising the initial formula comes down to minimising the resulting simple one. ◀

On the other hand, generalised Horn formulas are likely not a suitable representation for acceptance conditions on automata, as they yield an NP-complete emptiness problem (Proposition 25). This is an interesting example of a family of acceptance conditions whose satisfiability problem is in PTIME but which yields an NP-complete emptiness problem on automata.

▶ **Proposition 25.** *Checking emptiness of an automaton with an acceptance condition represented by a GH formula is* NP*-complete.*

Proof sketch. The NP upper bound follows from the one on Emerson-Lei conditions. For the hardness, we reduce from the Hamiltonian cycle problem. ◀

4.2 Minimisation of acceptance conditions on top of an automaton

We now consider the problem of minimising the number of colours or Rabin pairs used by a Muller or Rabin condition over a fixed automaton. We could expect that it is possible to generalise the previous polynomial time algorithms by using the ACD, instead of the Zielonka DAG. Quite surprisingly, we show that these problems become NP-complete when taking into account the structure of the automata.

Minimisation of colours on top of a Muller automaton. We say that a deterministic Muller automaton $\mathcal{A}$ is *k-colour type* if we can relabel it with a Muller condition using at most k output colours that is equivalent over $\mathcal{A}$ (and uses a single colour per edge). We also consider automata with multiple colours per edge (in this section, multiple labels may be relevant). We will nevertheless show that allowing them does not change the theoretical complexity of the problem. We say that $\mathcal{A}$ is *k-multi-colour type* if we can relabel it with an equivalent Muller condition using at most k colours, with possibly several colours per edge.

Colour-Minimisation-Aut (resp. Multi-Colour-Minimisation-Aut) is the problem of deciding whether a deterministic Muller automaton is k-colour type (resp. k-multi-colour type). These problems admit different variants according to the representation of the Muller condition. We will show that for the three representations we are concerned with (colour-explicit, Zielonka tree and Zielonka DAG), both problems are NP-complete. This implies that they are NP-hard even if the ACD is provided as input, by Theorem 13. Hugenroth showed[5] that, *for state-based automata*, the problem Colour-Minimisation-Aut is NP-hard when the acceptance condition of $\mathcal{A}$ is represented colour-explicitly or as a Zielonka tree [21]. However, it is not straightforward to generalise it to *transition-based automata*, since the classic translation between state-based and transition-based automata does not preserve minimality.

▶ **Theorem 26** (NP-completeness of minimisation of colours for Muller automata)**.** *The problems* Colour-Minimisation-Aut *and* Multi-Colour-Minimisation-Aut *are* NP*-complete, if the acceptance condition* $\mathsf{Muller}_\Gamma(\mathcal{F})$ *of* $\mathcal{A}$ *is represented colour-explicitly, as a Zielonka tree, Zielonka DAG or as the ACD of* $\mathcal{A}$*.*

To obtain the NP-hardness, we reduce from the chromatic number problem for graphs. We note that the fact that these problems lie in NP is not obvious: we could be tempted to guess an acceptance condition on the same automaton structure and check equivalence of the two automata. However, reducing the number of colours might blow up the size of the representation of the acceptance condition.

NP-upper bound: Proof sketch. We guess a colouring $\mathsf{col}' : \Delta \to [k]$ and check in polynomial time that there exists a family $\mathcal{F}'$ over $[k]$ defining an equivalent condition over $\mathcal{A}$. To do so, we remark that such $\mathcal{F}'$ exists if and only if there is no pair of words $w_+ \in \mathcal{L}(A)$ and $w_- \notin \mathcal{L}(\mathcal{A})$ such that the sets of colours produced infinitely often under col' by their runs are equal. The existence of such words reduces to emptiness of adequate Streett automata. ◀

Minimisation of Rabin pairs on top of a Rabin automaton. We say that a deterministic Muller automaton $\mathcal{A}$ is *k-Rabin-pair type* if we can relabel it with an equivalent Rabin condition using at most k Rabin pairs.

Rabin-Pair-Minimisation-Aut is the problem of deciding whether a given deterministic Rabin automaton is k-Rabin-pair type. As before, we can consider different representations of the acceptance condition of the automaton: using Rabin pairs, colour-explicitly, the Zielonka tree, the Zielonka DAG or by providing the ACD.

▶ **Theorem 27** (NP-completeness of minimisation of Rabin pairs for Rabin automata)**.** *The problem* Rabin-Pair-Minimisation-Aut *is* NP*-complete for all the previous representations of the acceptance condition.*

5 Conclusion

In this work we obtained several positive results concerning the complexity of simplifying the acceptance condition of an ω-automaton. Our first technical result is that the computation of the ACD (resp. ACD-DAG) of a Muller automaton is not harder than the computation of the Zielonka tree (resp. Zielonka DAG) of its acceptance condition (Theorems 13 and 15). This provides support for the assertion that the optimal transformation into parity automata based on the ACD is applicable in practical scenarios, backing the experimental evidence provided by the implementations of the ACD-transform [12].

Furthermore, this result has several implications for our simplification purpose: We can decide the typeness of Muller automata and compute the parity index of their languages in polynomial time (Corollary 16). In addition, we showed that we can minimise in polynomial

[5] As of today, the proof is not currently publicly available online, we got access to it by a personal communication. The theorem only expresses the NP-hardness for the colour-explicit representation, but a look into the reduction works unchanged if the condition is given as a Zielonka tree.

time the colours and Rabin pairs necessary to represent a Muller language. However, these problems become NP-hard when taking into account the structure of a particular automaton using this acceptance condition, even if the ACD of the automaton is provided as input. Nevertheless, we believe that the methods for the minimisation of colours in the case of Muller languages could be combined with the structure of the ACD to obtain heuristics reducing the number of colours used by Muller automata, which might lead to substantial (although not optimal) reductions.

In sum, our results clarify the potential of the ACD and complete our understanding of the complexity of simplifying the acceptance conditions of ω-automata.

Distance to Transitivity: New Parameters for Taming Reachability in Temporal Graphs

Abstract

A temporal graph is a graph whose edges only appear at certain points in time. Reachability in these graphs is defined in terms of paths that traverse the edges in chronological order (temporal paths). This form of reachability is neither symmetric nor transitive, the latter having important consequences on the computational complexity of even basic questions, such as computing temporal connected components. In this paper, we introduce several parameters that capture how far a temporal graph $\mathcal{G}$ is from being transitive, namely, *vertex-deletion distance to transitivity* and *arc-modification distance to transitivity*, both being applied to the reachability graph of $\mathcal{G}$. We illustrate the impact of these parameters on the temporal connected component problem, obtaining several tractability results in terms of fixed-parameter tractability and polynomial kernels. Significantly, these results are obtained without restrictions of the underlying graph, the snapshots, or the lifetime of the input graph. As such, our results isolate the impact of non-transitivity and confirm the key role that it plays in the hardness of temporal graph problems.

1 Introduction

Temporal graphs have gained attention lately as appropriate tools to capture time-dependent phenomena in fields as various as transportation, social networks analysis, biology, robotics, scheduling, and distributed computing. On the theoretical side, these graphs generate interest mostly for their intriguing features. Indeed, many basic questions are still open, with a general feeling that existing techniques from graph theory typically fail on temporal graphs. In fact, most of the natural questions considered in static graphs turn out to be intractable when formulated in a temporal version, and likewise, most of the temporal analogs of classical structural properties are false.

One of the earliest examples is that the natural analog of Menger's theorem does not hold in temporal graphs [21]. Another early result is that deciding if a temporal connected component (set of vertices that can reach each other through temporal paths) of a certain size exists is NP-complete [6]. A more recent and striking result is that there exist temporally connected graphs on $\Theta(n^2)$ edges in which every edge is critical for connectivity; in other words, no temporal analog of sparse spanners exist unconditionally [5] (though they do,

probabilistically [11]). Moreover, minimizing the size of such spanners is APX-hard [2, 5]. Further hardness results for problems whose static versions are generally tractable include separators [19], connectivity mitigation [16], exploration [4, 17], flows [1], Eulerian paths [7], and even spanning trees [9].

Faced by these difficulties, the algorithmic community has focused on special cases, and tools from parameterized complexity were employed with moderate success. A natural approach here is to apply the range of classical graph parameters to restrict either the underlying graph of the temporal graph (i.e. which edges can exist at all) or its snapshots (i.e. which edges may exist simultaneously). For example, finding temporal paths with bounded waiting time at each node (which is NP-hard in general) turns out to be FPT when parameterized by treedepth or vertex cover number of the underlying graph. But the problem is already W[1]-hard for pathwidth (let alone treewidth) [10]. In fact, as observed in [18], most temporal graphs problems remain hard even when the underlying graph has bounded treewidth (sometimes, even a tree or a star [3, 4, 16]).

A possible explanation for these results is that temporal graph problems are *very* hard. Another one is that parameters based on static graph properties are not adequate. Some parameters whose definition is based on that of a temporal graph include timed feedback vertex sets (counting the cumulative distance to trees over all snapshots) [10] and the $p(\mathcal{G})$ parameter from [4], that measures in a certain way how dynamic the temporal graph is and enables polynomial kernels for the exploration problem. While these parameters represent some progress towards finer-grained restrictions, they remain somewhat structural in the sense that their definition is stable under re-shuffling of the snapshots.

A key aspect of temporal graphs is that the *ordering of events* matters. Arguably, a truly temporal parameter should be sensitive to that. An interesting step in this direction was recently made by Bumpus and Meeks [7], introducing interval-membership-width, a parameter that quantifies the extent to which the set of intervals defined by the first and last appearance of an edge at each vertex can overlap (with application to Eulerian paths). In a sense, this parameter measures how complex the interleaving of events could be. Another, perhaps even more fundamental feature of temporal graphs is that the reachability relation based on temporal paths is not guaranteed to be symmetric or transitive. While the former is a well-known limitation of directed graphs, the latter is specific to temporal graphs (directed or not), and it has been suspected to be one of the main sources of intractability since the onset of the theory. (Note that a temporal graph of bounded interval-membership-width may still be arbitrarily non-transitive.) In the present work, we explore new parameters that control how transitive a temporal graph is, thereby isolating, and confirming, the role that this aspect plays in the tractability of temporal reachability problems.

Our Contributions. We introduce and investigate two parameters that measure how far a temporal graph is from having transitive reachability. For a temporal graph $\mathcal{G}$, our parameters directly address the reachability features of $\mathcal{G}$, and as such, they are formulated in terms of its reachability graph $G_R = (V, \{(u, v) : u \rightsquigarrow v\})$, a directed graph whose arcs represent the existence of temporal paths in $\mathcal{G}$, whether $\mathcal{G}$ itself is directed or undirected. Indeed, the reachability of $\mathcal{G}$ is transitive if and only if the arc relation of G_R is transitive. Two natural ways of measuring this distance are in terms of *vertex deletion* and *arc modification*, namely:

- *Vertex-deletion distance to transitivity* (δ_{vd}) is the minimum number of vertices whose deletion from G_R makes the resulting graph transitive.
- *Arc-modification distance to transitivity* (δ_{am}) is the minimum number of arcs whose addition or deletion from G_R makes the resulting graph transitive.

As for the arc-modification distance, we may occasionally consider its restriction to arc-addition only (δ_{aa}).

Among the many problems that were shown intractable in temporal graphs, one of the first, and perhaps most iconic one, is the computation of temporal connected components [6] (see also [13, 23]). In order to benchmark our new parameters, we investigate their impact on the computational complexity of this problem. Informally, given a temporal graph $\mathcal{G}$ (defined later) on a set of vertices V, a temporal connected component is a subset $V' \subseteq V$ such that for all u and v in V', u can reach v by a temporal path. Interestingly, the non-transitive nature of reachability here makes it possible for such vertices to reach each other through temporal paths that travel outside the component, without absorbing the intermediate vertices into the component. This gives rise to two distinct notions of components: *open* temporal connected components (Open-TCC) and *closed* temporal connected components (Closed-TCC), the latter requiring that only internal vertices are used in the temporal paths, and both being NP-hard to compute.

The statement of our results requires a few more facts. Both algorithmic and structural results in temporal graphs are highly sensitive to subtle definitional variations, called *settings*. In the *non-strict* setting, the labels along a temporal path are only required to be non-decreasing, whereas in the *strict* setting, they must be increasing. It turns out that both settings are sometimes incomparable in difficulty, and the techniques developed for each may be different. Some temporal graphs, called *proper*, have the property that no two adjacent edges share a common time label, making it possible to ignore the distinction between strict and non-strict temporal paths. Whenever possible, hardness results should preferably be obtained for proper temporal graphs, so that they apply in both settings at once. Finally, with a few exceptions, our results hold for both directed and undirected temporal graphs.

Bearing these notions in mind, our results are the following. For Open-TCC, we obtain an FPT algorithm with parameter δ_{vd}, running in time $3^{\delta_{\text{vd}}} \cdot n^{\mathcal{O}(1)}$ (in all the settings). Unfortunately, δ_{vd} turns out to be too small for obtaining a kernel of polynomial size. In fact, we show that under reasonable computational complexity assumptions, no polynomial kernel in $\delta_{\text{vd}} + \text{vc} + k$ exists (except possibly for the non-strict undirected setting), where k denotes the size of the sought tcc and where vc denotes the vertex cover number of the underlying graph. Next, we obtain an FPT algorithm running in time $4^{\delta_{\text{am}}} \cdot n^{\mathcal{O}(1)}$ for the mostly larger parameter δ_{am}, and show that Open-TCC admits a polynomial kernel of size $|M|^3$, where M is a given arc set for which $(V, A(G_R)\Delta M)$ is transitive. It also admits a polynomial kernel of size δ_{aa}^2 when restricting modification to addition-only (again, all these results hold in all the settings). Closed-TCC, in comparison, seems to be a harder problem, at least with respect to our parameters. In particular, we show that it remains NP-hard even if $\delta_{\text{am}} = \delta_{\text{vd}} = 1$ in all the settings (through proper graphs). It is also W[1]-hard when parameterized by $\delta_{\text{vd}} + \delta_{\text{am}} + k$ in all the settings, except possibly in the non-strict undirected setting. In fact, these two results hold even for temporal graphs whose reachability graph misses a single arc towards being a bidirectional clique.

Put together, these results establish clearly that non-transitivity is a genuine source of hardness for Open-TCC. The case of Closed-TCC is less clear. On the one hand, the parameters do not suffice to make this particular version of the problem tractable. This is not so surprising, as the reachability graph itself does not encode which paths are responsible for reachability, in particular, whether these paths are internal or external in a component. On the other hand, this gives us a separation between both versions of the problem and provides some support for the fact that Closed-TCC may be harder than Open-TCC, which was not known before. Finally, the negative results for Closed-TCC can serve as a landmark result for guiding future efforts in defining transitivity parameters that exploit more sophisticated structures than the reachability graph.

Organization of the Work. The main definitions are given in Section 2. Then, we investigate each parameter in a dedicated section (δ_{vd} in Section 3 and δ_{am} in Section 4). The limitations of these parameters in the case of Closed-TCC are presented in Section 5. Finally, Section 6 concludes the paper with some remarks and open questions. Due to space limitations, the proofs of statements marked with ($\star$) are deferred to a full version.

2 Preliminaries

For concepts of parameterized complexity, like FPT, W[1]-hardness, and polynomial kernels, we refer to the standard monographs [14, 15]. A reduction g between two parameterized problems is called a *polynomial parameter transformation*, if the reduction can be computed in polynomial time and, if for every input instance (I, k), we have that $(I', k') = g(I, k)$ with $k' \in k^{\mathcal{O}(1)}$. We call a polynomial time reduction from a problem L to L itself a *self-reduction*.

Notation. Let j be a positive integer, we denote with $[j]$ the set $\{1, 2, \ldots, j\}$. Moreover, for $1 \leq i \leq j$, we define $[i, j] := [j] \setminus [i-1]$. For a decision problem L, we say that two instances I_1, I_2 of L are *equivalent* if I_1 is a yes-instance of L if and only if I_2 is a yes-instance of L. For two sets A and B, we denote with $A \Delta B$ the symmetric difference of A and B.

Graphs. We consider a graph $G = (V, E)$ to be a static graph. If not indicated otherwise, we assume G to be undirected. Given a (directed) graph G, we denote by $V(G)$ the set of vertices of G, by $E(G)$ (respectively, $A(G)$) the set of edges (arcs) of G. Let $G = (V, E)$ be a graph and let $X \subseteq V(G)$ be a set of vertices. We denote by $E_G(X) = \{\{u, v\} \in E \mid u \in X, v \in X\}$ the edges in G between the vertices of S. Moreover, we define the following operations on G: $G[X] = (X, E_G[X])$, $G - X = G[V \setminus X]$. We call a sequence $\rho = v_0, v_1, \ldots, v_r$ of vertices a *path* in graph G if $v_0, \ldots, v_r \in V(G)$ and for each $i \in [r]$, $\{v_{i-1}, v_i\} \in E(G)$. We denote with $N_G[v]$ the closed neighborhood of the vertex $v \in V(G)$. A vertex set $S \subseteq V$ is a *clique* in an undirected graph, if each pair of vertices in S is adjacent in G. For a directed graph $G = (V, A)$, we call a set $S \subseteq V$ a *bidirectional clique*, if for every pair of distinct vertices u, v in S, we have $(u, v) \in A$ and $(v, u) \in A$. Let $G = (V, A)$ be a directed graph. A *strongly connected component (scc)* in G is an inclusion maximal vertex set $S \subseteq V$ under the property that there is a directed path in G between any two vertices of S. For each directed graph G, there is a unique partition of the vertex set of G into sccs. Moreover, this partition can be computed in linear time [24].

Temporal graphs. A *temporal graph* $\mathcal{G}$ over a set of vertices V is a sequence $\mathcal{G} = (G_1, G_2, \ldots, G_L)$ of graphs such that for all $t \in [L], V(G_t) = V$. We call L the *lifetime* of $\mathcal{G}$ and for $t \in [L]$, we call $G_t = (V, E_t)$ the *snapshot graph* of $\mathcal{G}$ at *time step* t. We call $G = (V, E)$ with $E = \bigcup_{t \in [L]} E_t$ the *underlying graph* of $\mathcal{G}$. We denote by $V(\mathcal{G})$ the set of vertices of $\mathcal{G}$. We write V if the temporal graph is clear from context. We call an undirected temporal graph $\mathcal{G} = (G_1, G_2, \ldots, G_L)$ *proper*, if for each vertex $v \in V(\mathcal{G})$ the degree of v in G_t is one, for each $t \leq L$. We call a directed temporal graph $\mathcal{G} = (G_1, G_2, \ldots, G_L)$ *proper*, if for each vertex $v \in V(\mathcal{G})$ the out-degree or the in-degree of v in G_t is zero, for each $t \leq L$. We further call a (directed) temporal graph $\mathcal{G}$ *simple*, if each edge (arc) exists in exactly one snapshot. We call a sequence $v_0, v_1, \ldots, v_r$ of vertices that form a path in the underlying graph G of $\mathcal{G}$ a *strict (non-strict) temporal path* in $\mathcal{G}$ if for each $i \in [r]$, there exists an $j_i \in [L]$ such that $\{v_{i-1}, v_i\} \in E(G_{j_i})$ and the sequence of indices j_i is increasing (non-decreasing).

For a temporal graph $\mathcal{G}$, we say that a vertex $u \in V$ *strictly (non-strictly) reaches* a vertex $v \in V$ if there is a strict (non-strict) temporal path from u to v, i.e., with $v_0 = u$ and $v_r = v$. We define the *strict (non-strict) reachability relation* $R \subseteq V \times V$ as: for all $u, v \in V$, $(u, v) \in R$ if and only if u strictly (non-strictly) reaches v. We call the directed graph $G_R = (V, R)$ the *strict (non-strict) reachability graph* of $\mathcal{G}$. We say that G_R is transitive, if and only if R is transitive. More generally, we say that a directed graph G is *transitive*, if its set of arcs forms a transitive relation. For a directed graph $G = (V, A)$ we call a set of vertices $S \subseteq V$ a *transitivity modulator* if $G - S$ is transitive.

▶ **Observation 1.** *Let G be a transitive directed graph. Then, for each vertex $v \in V(G)$, $G[V \setminus \{v\}]$ is also transitive.*

Next we define our main problems of interest in this work: Finding open and closed temporal connected components.

> Open Temporal Connected Component (Open-TCC)
> **Input:** Temporal graph $\mathcal{G} = (G_1, G_2, \ldots, G_L)$ and integer k.
> **Question:** Does there exists an open temporal connected component of size at least k, i.e., a subset $C \subseteq V(\mathcal{G})$ with $|C| \geq k$, such that for each $u, v \in C$, u reaches v, and vice versa.

We differentiate between the strict vs. non-strict and directed vs. undirected version of Open-TCC depending on whether we consider strict vs. non-strict reachability and directed vs. undirected temporal graphs. We define the problem Closed Temporal Connected Component (Closed-TCC) similarly with the additional restriction that at least one temporal path over which u reaches v is fully contained in C. We abbreviate a temporal connected component as tcc.

Distance to transitivity. We introduce two parameters that measure how far the reachability graph $G_R = (V, A)$ of a temporal graph is from being transitive. The first parameter, *vertex-deletion distance to transitivity*, δ_{vd}, counts how many vertices need to be deleted from G_R in order to obtain a transitive reachability graph, i.e., the size of a minimum transitivity modulator. This parameter is especially suited for temporal graphs for which the reachability graph consists of cliques with small overlaps. The second parameter, *arc-modification distance to transitivity*, δ_{am}, counts how many arcs need to be added to or removed from G_R in order to obtain a transitive reachability graph and is especially suited for directed temporal graphs or temporal graphs for which the reachability graph consists of cliques with large overlaps. Formally, we define the parameters as follows.

$$\delta_{\text{vd}} = \min_{S \subseteq V}(|S|) \text{ for which } G'_R = G_R - S \text{ is transitive.}$$

$$\delta_{\text{am}} = \min_{M \subseteq V \times V}(|M|) \text{ for which } G'_R = (V, A \Delta M) \text{ is transitive.}$$

For δ_{am}, we call the set M an *arc-modification set*. Note that $\delta_{\text{vd}} \leq 2 \cdot \delta_{\text{am}}$, since the endpoints of an arc-modification set form a transitivity modulator.

2.1 Basic Observations

Next, we present basic observations that motivate the study of the considered parameters.

▶ **Lemma 2** ([6]). *Let $\mathcal{G}$ be a temporal graph with reachability graph G_R. Then a set $S \subseteq V(\mathcal{G})$ is a tcc in $\mathcal{G}$ if and only if S is a bidirectional clique in G_R.*

▶ **Lemma 3** (⋆). *Let G be a transitive directed graph. Then every vertex set $S \subseteq V(G)$ is a bidirectional clique in G if and only if each pair of vertices of S can reach each other.*

Note that this implies the following.

▶ **Corollary 4.** *Let G be a transitive directed graph. Then every scc in G is also a maximal bidirectional clique and vice versa.*

The previous observations thereby imply that both Open-TCC and Closed-TCC can be solved in polynomial time on temporal graphs with transitive reachability graphs.

3 Vertex-Deletion Distance to Transitivity

We first focus on the parameter δ_{vd}. Note that computing this parameter is NP-hard: In a strict temporal graph $\mathcal{G}$ with lifetime 1, the reachability graph G_R of $\mathcal{G}$ is exactly the directed graph obtained from orienting each edge of the underlying graph in both directions. Hence, on such a temporal graph, computing δ_{vd} is exactly the cluster vertex deletion number of the underlying graph, that is, the minimum size of any vertex set to remove, such that no induced path of length 2 remains. Since computing the latter parameter is NP-hard [22], this hardness also translates to computing the parameter δ_{vd}.

Moreover, note that computing this parameter can be done similarly to computing the cluster vertex deletion number of a graph: If a directed graph $G = (V, A)$ is not transitive, then there are vertices u, v, and w in V, such that (u, v) and (v, w) are arcs of A and (u, w) is not an arc of A. Hence, each transitivity modulator for G has to contain at least one of the vertices u, v, or w. This implies, that a standard branching algorithm that considers each of these three vertices to be removed from the graph to obtain a transitive graph, finds a minimum size transitivity modulator in $3^{\delta_{\text{vd}}} \cdot n^{\mathcal{O}(1)}$ time.

▶ **Proposition 5.** *Let $\mathcal{G}$ be a temporal graph with reachability graph G_R. Then, we can compute in time $3^{\delta_{\text{vd}}} \cdot n^{\mathcal{O}(1)}$ a minimal-size transitivity modulator of G_R.*

Based on this result, we now present an FPT-algorithm for Open-TCC when parameterized by δ_{vd}.

▶ **Lemma 6.** *Let $I := (\mathcal{G}, k)$ be an instance of Open-TCC with reachability graph G_R. Let S be a given transitivity modulator of G_R. Then, we can solve I in time $2^{|S|} \cdot n^{\mathcal{O}(1)}$.*

Proof. By Lemma 4, every scc in $G_R[V \setminus S]$ is a bidirectional clique, since S is a transitivity modulator for G_R. Lemma 2 then implies that each tcc C in $\mathcal{G}$ with $C \cap S = \emptyset$ is an scc in $G_R[V \setminus S]$ and vice versa.

The FPT-algorithm then works as follows: We iterate over all subsets S' of S with the idea to find a tcc that extends S'. If S' is not a bidirectional clique in G_R, we discard the current set and continue with the next subset of S, as no superset of S' is a bidirectional clique and thus also not a tcc. Hence, assume that S' is a bidirectional clique. If S' has size at least k, I is a trivial yes-instance of Open-TCC. Otherwise, we do the following: Let V' be the vertices of $V \setminus S$ that are bidirectional connected to every vertex in S'. As $G_R[V \setminus S]$ is transitive, Observation 1 implies that $G_R[V']$ is also transitive. Hence, the sccs in $G_R[V']$ correspond to tccs in $\mathcal{G}$ by Corollary 4 and Lemma 2. Since every vertex in S' is bidirectional connected to every other vertex in $S' \cup V'$ in G_R, for each bidirectional clique $C \subseteq V'$ in $G_R[V']$, $C \cup S'$ is a tcc in $\mathcal{G}$. Hence, it remains to check, whether any scc in $G_R[V']$ has size at least $k - |S'|$. Figure 1 illustrates the sets S, S', and V'.

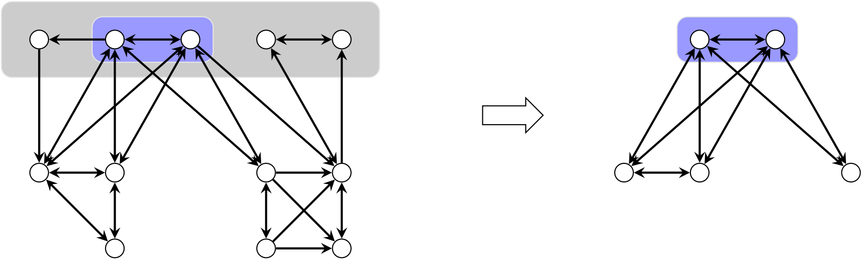

Figure 1 Illustration of the algorithm in Lemma 6. On the left: reachability graph G_R with transitivity modulator S in gray and the chosen subset $S' \subseteq S$ to extend in blue. On the right: The subset S' together with the vertices V' that are bidirectionally connected to all vertices in S'.

Finding the strongly connected components of a graph and identifying whether a set of vertices forms a bidirectional clique can be done in polynomial time. Hence, our algorithm runs in time $2^{\delta_{\mathrm{vd}}} \cdot n^{\mathcal{O}(1)}$, since we iterate over each subset S' of S. ◀

Based on Proposition 5 and Lemma 6, we thus derive our FPT-algorithm for Open-TCC when parameterized by δ_{vd}.

▶ **Theorem 7.** *Open-TCC can be solved in $3^{\delta_{\mathrm{vd}}} \cdot n^{\mathcal{O}(1)}$ time.*

Kernelization Lower Bounds

In this section, we show that a polynomial kernel for Open-TCC when parameterized by $\delta_{\mathrm{vd}} + \mathrm{vc} + k$ is unlikely, where vc is the vertex cover number of the underlying graph. Note that δ_{vd} and vc are incomparable: On the one hand, consider a temporal graph $\mathcal{G}$ where the underlying graph G is a star with leaf set $X \cup Y$ and center c, such that the edges from X to c exist in snapshots G_1 and G_3 and the edges from Y to c exist in snapshot G_2. Then, each vertex of X can reach each other vertex, but in the strict setting, no vertex of Y can reach any other vertex of Y. Hence, each minimum transitivity modulator has to contain all vertices of X or all but one vertex of Y, which implies that for $|X| = |Y|$, $\delta_{\mathrm{vd}} \in \Theta(|V(\mathcal{G})|)$, whereas the vertex cover number of G is only 1. On the other hand, consider a temporal graph $\mathcal{G}$ with only one snapshot G_1, such that G_1 is a clique. Then, the underlying graph of $\mathcal{G}$ is exactly G_1 and has a vertex cover number of $|V(\mathcal{G})| - 1$, but the strict reachability graph of $\mathcal{G}$ is a bidirectional clique, which is a transitive graph. Hence, $\delta_{\mathrm{vd}}(\mathcal{G}) = 0$.

We now present our kernelization lower bound for the strict undirected version of Open-TCC.

▶ **Theorem 8.** *The strict undirected version of Open-TCC does not admit a polynomial kernel when parameterized by $\mathrm{vc} + \delta_{\mathrm{vd}} + k$, unless NP ⊆ coNP/poly, where vc denotes the vertex cover number of the underlying graph.*

Proof. This result immediately follows from the known [21] reduction from Clique which, in fact, is as a polynomial parameter transformation.

Clique
Input: An undirected graph $G = (V, E)$ and integer k.
Question: Is there a clique of size k in G?

For the sake of completeness, we recall the reduction. Let $I := (G = (V, E), k)$ be an instance of Clique and let $\mathcal{G}$ be the temporal graph with lifetime 1, where G is the unique snapshot of $\mathcal{G}$.

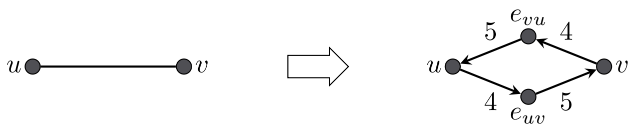

Figure 2 For two adjacent vertices u and v of S the vertices and arcs added to the temporal graph $\widetilde{\mathcal{G}}$ in the proof of Theorem 9.

Then, for each vertex set $X \subseteq V$, X is a clique in G if and only if X is a strict tcc in $\mathcal{G}$. Hence, I is a yes-instance of Clique if and only if $(\mathcal{G}, k)$ is a yes-instance of the strict undirected version of Open-TCC. It is known that Clique does not admit a polynomial kernel when parameterized by k plus the vertex cover number of G, unless $\mathsf{NP} \subseteq \mathsf{coNP/poly}$ [12]. Let S be a minimum size vertex cover of G and let G_R be the strict reachability graph of $\mathcal{G}$. Note that G_R contains an arc (u, v) with $u \neq v$ if and only if $\{u, v\}$ is an edge of G. Hence, $V \setminus S$ is an independent set in G_R, which implies that S is a transitivity modulator of G_R. Consequently, $\delta_{\text{vd}} \leq |S|$. Recall that Clique does not admit a polynomial kernel when parameterized by $k + |S|$, unless $\mathsf{NP} \subseteq \mathsf{coNP/poly}$ [12]. This implies that the strict undirected version of Open-TCC does not admit a polynomial kernels when parameterized by $\text{vc} + \delta_{\text{vd}} + k$, unless $\mathsf{NP} \subseteq \mathsf{coNP/poly}$. ◀

Next, we present the same lower bound for both directed versions of Open-TCC.

▶ **Theorem 9.** *The directed version of Open-TCC does not admit a polynomial kernel when parameterized by* $\text{vc} + \delta_{\text{vd}} + k$*, unless* $\mathsf{NP} \subseteq \mathsf{coNP/poly}$*, where* vc *denotes the vertex cover number of the underlying graph. This holds both for the strict and the non-strict version of the problem.*

Proof. Again, we present a polynomial parameter transformation from Clique.

Recall that Clique does not admit a polynomial kernel when parameterized by the size of a give minimum size vertex cover S of G plus k, unless $\mathsf{NP} \subseteq \mathsf{coNP/poly}$ [12]. This holds even if $G[S]$ is $(k-1)$-partite [20], which implies that each clique of size k in G contains exactly $k-1$ vertices of S and exactly one vertex of $V \setminus S$, since $V \setminus S$ is an independent set.

Construction. Let $I := (G := (V, E), k)$ be an instance of Clique and let S be a given minimum size vertex cover S of G, such that $G[S]$ is $(k-1)$-partite. Assume that $k > 6$.

We obtain an equivalent instance of Open-TCC in two steps: First, we perform an adaptation of a known reduction [6] from the instance $(G[S], k-1)$ of Clique to an instance $(\widetilde{\mathcal{G}}, k-1)$ of the directed version of Open-TCC where each sufficiently large (of size at least 5) vertex set X of $\widetilde{\mathcal{G}}$ is a tcc in $\widetilde{\mathcal{G}}$ if and only if X is a clique in $G[S]$. Second, we extend $\widetilde{\mathcal{G}}$ by the vertices of $V \setminus S$ and some additional connectivity-gadgets, to ensure that the resulting temporal graph has a tcc of size k if and only if there is a vertex from $V \setminus S$ for which the neighborhood in G contains a clique of size $k-1$.

Let $(\widetilde{\mathcal{G}}, k-1)$ be the instance of Open-TCC constructed as follows: We initialize $\widetilde{\mathcal{G}}$ as an edgeless temporal graph of lifetime 5 with vertex set $S \cup \{e_{uv}, e_{vu} \mid \{u, v\} \in E_G(S)\}$. Next, for each edge $\{u, v\} \in E$, we add the arcs (u, e_{uv}) and (v, e_{vu}) to time step 4 and add the arcs (e_{uv}, v) and (e_{vu}, u) to time step 5. This completes the construction of $\widetilde{\mathcal{G}}$. An example of the arcs added to $\widetilde{\mathcal{G}}$ is shown in Figure 2. Note that the first three snapshots of $\widetilde{\mathcal{G}}$ are edgeless. This construction is an adaptation of the reduction presented by Bhadra and Ferreira [6]

Table 1 For each vertex $v \in V(\mathcal{G}')$ a lower bound for $\text{out}_v^{\min}$ and an upper bound for $\text{in}_v^{\max}$.

	$\text{out}_v^{\min}$	$\text{in}_v^{\max}$
$v \in S$	2	5
$v \in V(\widetilde{\mathcal{G}}) \setminus S$	4	5
$v \in V \setminus S$	1	2
$v \in \{u_{\text{in}} \mid u \in S\}$	3	1

to the case of directed temporal graphs. Note that the temporal graph $\widetilde{\mathcal{G}}$ has the following properties that we make use of in our reduction:

1) $\widetilde{\mathcal{G}}$ is a proper and simple directed temporal graph,
2) the vertex set $\mathcal{V}$ of $\widetilde{\mathcal{G}}$ has size $\mathcal{O}(|S|^2)$ and contains all vertices of S,
3) each tcc of size at least $k-1$ in $\widetilde{\mathcal{G}}$ contains only vertices of S, and
4) each vertex set $X \subseteq S$ of size at least $k-1$ is a tcc in $\widetilde{\mathcal{G}}$ if and only if X is a clique in $G[S]$.

Note that the two last properties imply that the largest tcc of $\widetilde{\mathcal{G}}$ has size at most $k-1$, since $G[S]$ is $(k-1)$-partite.

Next, we describe how to extend the temporal graph $\widetilde{\mathcal{G}}$ to obtain a temporal graph $\mathcal{G}'$ which has a tcc of size k if and only if I is a yes-instance of Clique. Let $n := |V|$. Moreover, let $\mathcal{G}'$ be a copy of $\widetilde{\mathcal{G}}$. We extend the vertex set of $\mathcal{G}'$ by all vertices of $V \setminus S$, and a vertex v_{in} for each vertex $v \in S$.

For each vertex $v \in S$, we add the arc (v_{in}, v) to time step 3. For each vertex $v \in S$ and each neighbor $w \in V \setminus S$ of v in G, we add the arc (v, w) to time step 2 and the arc (w, v_{in}) to time step 1. This completes the construction of $\mathcal{G}'$. Let V' denote the newly added vertices, that is, $V' := (V \setminus S) \cup \{v_{\text{in}} \mid v \in S\}$.

Next, we show that there is a clique of size k in G if and only if there is a tcc of size k in $\mathcal{G}'$.

($\Rightarrow$) Let $K \subseteq V$ be a clique of size k in G. We show that K is a tcc in $\mathcal{G}'$. As discussed above, K contains exactly $k-1$ vertices of S and exactly one vertex w^* of $V \setminus S$. By construction of $\widetilde{\mathcal{G}}$, $K \setminus \{w^*\}$ is a tcc in $\widetilde{\mathcal{G}}$ and thus also a tcc in $\mathcal{G}'$. It thus remains to show that each vertex $K \setminus \{w^*\}$ can reach vertex w^* in $\mathcal{G}'$ and vice versa. Since each vertex of $K \setminus \{w^*\}$ is adjacent to w^* in G, by construction, w^* is an out-neighbor of each vertex of $K \setminus \{w^*\}$ in $\mathcal{G}'$. Hence, it remains to show that w^* can reach each vertex of $K \setminus \{w^*\}$ in $\mathcal{G}'$. Let v be a vertex of $K \setminus \{w^*\}$. Since v is adjacent to w^* in G, there is an arc (w^*, v_{in}) in $\mathcal{G}'$ that exists at time step 1. Hence, there is a temporal path from w^* to v in $\mathcal{G}'$, since the arc (v_{in}, v) exists at time step 3. Concluding, K is a tcc in $\mathcal{G}'$.

($\Leftarrow$) Let X be a tcc of size k in $\mathcal{G}'$. We show that X is a clique of size k in G. To this end, we first show that X contains only vertices of V. Afterwards, we show that X is a clique in G.

To show that X contains only vertices of V, we first analyze the reachability of vertices of $V(\mathcal{G}')$. For a vertex $v \in V(\mathcal{G}')$, we denote

- by $\text{out}_v^{\min}$ the smallest time label of any arc exiting v and
- by $\text{in}_v^{\max}$ the largest time label of any arc entering v.

Note that a vertex v cannot reach a distinct vertex w in $\mathcal{G}'$ if $\text{in}_w^{\max} < \text{out}_v^{\min}$. Table 1 shows for each vertex $v \in V(\mathcal{G}')$ a lower bound for $\text{out}_v^{\min}$ and an upper bound for $\text{in}_v^{\max}$.

Based on Table 1, we can derive the following properties about reachability in $\mathcal{G}'$.

▷ Claim 10.

a) No vertex of $V(\widetilde{\mathcal{G}}) \setminus S$ can reach any vertex of V' in $\mathcal{G}'$.
b) No vertex of $\{v_{\text{in}} \mid v \in S\}$ can reach any other vertex of $\{v_{\text{in}} \mid v \in S\}$ in $\mathcal{G}'$.

c) No vertex of $\{v_{\text{in}} \mid v \in S\}$ can reach any vertex of $V \setminus S$ in $\mathcal{G}'$.
d) No vertex of S can reach any vertex of $\{v_{\text{in}} \mid v \in S\}$ in $\mathcal{G}'$.
e) No vertex of $V \setminus S$ can reach any other vertex of $V \setminus S$ in $\mathcal{G}'$.

Proof. Based on Table 1, we derive Items a) to d). It remains to show Item e). To this end, observe that each arc with a vertex of $V \setminus S$ as source has a vertex of $\{v_{\text{in}} \mid v \in S\}$ as sink. Due to Item c), no vertex of $\{v_{\text{in}} \mid v \in S\}$ can reach any vertex of $V \setminus S$ in $\mathcal{G}'$. Hence, no vertex $V \setminus S$ can reach any other vertex of $V \setminus S$ in $\mathcal{G}'$. This implies that Item e) holds. $\lhd$

Since X is a tcc in $\mathcal{G}'$, Claim 10 implies that X contains at most one vertex of $V \setminus S$ (due to Item e)) and at most one vertex of $\{v_{\text{in}} \mid v \in S\}$ (due to Item b)). In other words, X contains at most two vertices of V'. Since $k > 6$, this then implies that X contains at least one vertex of $V(\widetilde{\mathcal{G}})$. Claim 10 thus further implies that X contains no vertex of $\{v_{\text{in}} \mid v \in S\}$ (due to Items a) and d)). This then implies that X contains at least $k-1$ vertices of $V(\widetilde{\mathcal{G}})$.

To show that X contains only vertices of V and is a clique in G we now show that the reachability between any two vertices of $V(\widetilde{\mathcal{G}})$ in $\mathcal{G}'$ is the same as in $\widetilde{\mathcal{G}}$. Let P be a temporal path between two distinct vertices of $V(\widetilde{\mathcal{G}})$ in $\mathcal{G}'$. We show that P is also a temporal path in $\widetilde{\mathcal{G}}$. Assume towards a contradiction that this is not the case. Hence, P visits at least one vertex of V'. Since no vertex of $V(\widetilde{\mathcal{G}})$ can reach any vertex of $\{v_{\text{in}} \mid v \in S\}$ (due to Items a) and d)), P visits no vertex of $\{v_{\text{in}} \mid v \in S\}$. Moreover, since each vertex of $V \setminus S$ has only out-neighbors in $\{v_{\text{in}} \mid v \in S\}$, P visits no vertex of $V \setminus S$ either. Consequently, P contains no vertex of V'; a contradiction.

Hence, P is a temporal path in $\widetilde{\mathcal{G}}$, which implies that for each vertex set $Y \subseteq V(\widetilde{\mathcal{G}})$, Y is a tcc in $\widetilde{\mathcal{G}}$ if and only if Y is a tcc in $\mathcal{G}'$. Recall that X contains at least $k-1$ vertices of $V(\widetilde{\mathcal{G}})$. Since the largest tcc in $\widetilde{\mathcal{G}}$ has size at most $k-1$ and each tcc of size $k-1$ in $\widetilde{\mathcal{G}}$ is a clique in G, this implies that $X \cap V(\widetilde{\mathcal{G}})$ is a clique of size $k-1$ in $G[S]$. Since X contains no vertex of $\{v_{\text{in}} \mid v \in S\}$, this implies that X contains exactly one vertex w^* of $V \setminus S$. Hence, it remains to show that each vertex $v \in X \setminus \{w^*\}$ is adjacent to w^* in G. Since X is a tcc in $\mathcal{G}'$, v can reach w^* in $\mathcal{G}'$. By construction and illustrated in Table 1, $\text{out}_v^{\min} \geq 2 \geq \text{in}_{w^*}^{\max}$. Since v reaches w^* and $\mathcal{G}'$ is a proper temporal graph, the arc (v, w^*) is contained in $\mathcal{G}'$. By construction, this implies that v and w^* are adjacent in G. Consequently, X is a clique in G. This completes the correctness proof of the reduction.

Parameter bounds. It thus remains to show that $\delta_{\text{vd}}(\mathcal{G}')$ and the vertex cover of the underlying graph of $\mathcal{G}'$ are at most $|S|^{\mathcal{O}(1)}$ each. Let $V^* := V(\mathcal{G}') \setminus (V \setminus S)$. Note that V^* has size $|V(\widetilde{\mathcal{G}})| + |S| \in \mathcal{O}(|S|^2)$ and is a vertex cover of the underlying graph of $\mathcal{G}'$. Hence, the vertex cover number of the underlying graph of $\mathcal{G}'$ is $\mathcal{O}(|S|^2)$. To show the parameter bounds, it thus suffices to show that V^* is a transitivity modulator of the reachability graph G_R of $\mathcal{G}'$. Due to Claim 10, $G_R - V^* = G_R[V \setminus S]$ is an independent set. Consequently, V^* is a transitivity modulator of G_R. Hence, $\delta_{\text{vd}}(\mathcal{G}') \in \mathcal{O}(|S|^2)$. By the fact that CLIQUE does not admit a polynomial kernel when parameterized by $|S| + k$, unless $\mathsf{NP} \subseteq \mathsf{coNP/poly}$, OPEN-TCC does not admit a polynomial kernel when parameterized by $\delta_{\text{vd}}(\mathcal{G}')$ plus the vertex cover number of the underlying graph of $\mathcal{G}'$ plus k, unless $\mathsf{NP} \subseteq \mathsf{coNP/poly}$. $\blacktriangleleft$

Note that our kernelization lower bounds do not include the non-strict undirected version of OPEN-TCC. An modification of Theorem 9 seems difficult, unfortunately. This is due to the fact that undirected edges can be traversed in both direction, which makes it very difficult to limit the possible reachable vertices in the temporal graph, while preserving a small transitivity modulator.

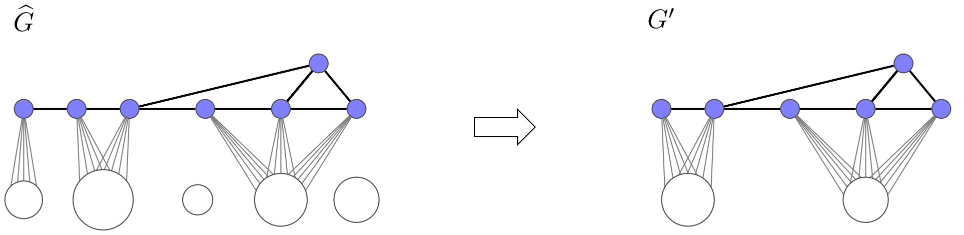

Figure 3 Left: the original instance of Clique from Theorem 12 constructed from the reachability graph of the considered temporal graph. Right: the obtained compressed instance of Clique after exhaustive application of all reduction rules. In both parts, the blue vertices are the vertices from the inherent transitivity modulator B and the cycles at the bottom indicate the white clusters. Note that in both graphs, each blue vertex has neighbors in at most one white cluster (see Claim 14). Intuitively, RR 1 ensures that small clusters are removed, RR 1 and RR 2 ensure that there are no isolated white clusters, and RR 3 reduces the size of each white cluster to at most $|B|+1$.

4 Arc-Modification Distance to Transitivity - A Polynomial Kernel

Next, we focus on the parameterized complexity of Open-TCC when parameterized by the size of a given arc-modification set towards a transitive reachability graph. As discussed earlier, for each arc-modification set M towards a transitive reachability graph, δ_{vd} does not exceed $2 \cdot |M|$, since removing the endpoints of all edges of M results in a transitivity modulator. This implies the following due to Theorem 7 and the fact that a minimum size arc-modification set towards a transitive graph can be computed in $2.57^{\delta_{\text{am}}} \cdot n^{\mathcal{O}(1)}$ time [25].

▶ **Corollary 11.** *Open-TCC can be solved in $4^{\delta_{\text{am}}} \cdot n^{\mathcal{O}(1)}$ time.*

In the remainder of this section, we thus consider this parameter with respect to kernelization algorithms. In contrast to parameterizations by δ_{vd}, we now show that a polynomial kernelization algorithm can be obtained for Open-TCC when parameterized by the size of a given arc-modification set towards a transitive reachability graph.

In fact, we show an even stronger result, since our kernelization algorithm does not need to know the actual arc-modification set but only its endpoints. To formulate this more general result, we need the following definition: Let $G=(V,A)$ be a directed graph. A transitivity modulator $S \subseteq V$ of G is called *inherent*, if there is an arc-modification set M with $M \subseteq S \times S$ for which $(V, A\Delta M)$ is a transitive graph. Note that the set of endpoint of an arc-modification set towards a transitive graph always forms an inherent transitivity modulator.

▶ **Theorem 12.** *Let $I=(\mathcal{G},k)$ be an instance of Open-TCC and let $G_R=(V,A)$ be the reachability graph of $\mathcal{G}$. Moreover, let $B \subseteq V$ be an inherent transitivity modulator of G_R. Then, for each version of Open-TCC, one can compute in polynomial time an equivalent instance of total size $\mathcal{O}(|B|^3)$.*

Proof. We first present a compression to Clique. Let $\widehat{G}=(V,E)$ be an undirected graph that contains an edge $\{u,v\}$ if and only if (u,v) and (v,u) are arcs of G_R. Due to Lemma 2, I is a yes-instance of Open-TCC if and only if $(\widehat{G},k)$ is a yes-instance of Clique. Let $W := V \setminus B$. We call the vertices of B *blue* and the vertices of W *white*. Note that $G_R[W]$ is a transitive graph, since B is a transitivity modulator of G_R. Moreover, there exists an arc set $M \subseteq B \times B$ such that $G'_R=(V, A\Delta M)$ is transitive, since B is an inherent transitivity modulator of G_R.

In the following, we present reduction rules to remove vertices from $\widehat{G}$ to obtain an equivalent instance (G', k') of Clique with $\mathcal{O}(|B|^2)$ vertices and where G' is an induced subgraph of $\widehat{G}$. The graphs $\widehat{G}$ and G' are conceptually depicted in Figure 3.

To obtain this smaller instance of Clique, we initialize G' as a copy of $\widehat{G}$ and k' as k and exhaustively applying three reduction rules. Our first two reduction rules are the following:

- RR 1: Remove a vertex v from G', if v has degree less than $k' - 1$ in G'.
- RR 2: If a white vertex has at least $k' - 1$ white neighbors in G', output a constant size yes-instance.

Note that the first reduction rule is safe, since no vertex of degree less than $k' - 1$ can be part of a clique of size at least k'. Moreover, each connected component in G' has size at least k' after this reduction rule is exhaustively applied. The safeness of the second reduction rule relies on the following observation.

▷ Claim 13. If two white vertices u and v are adjacent in G', then they are real twins in G'. That is, $N_{G'}[u] = N_{G'}[v]$.

Proof. Assume that u and v are adjacent in G' and assume towards a contradiction that there is a vertex w in G' which is adjacent to u in G' but not adjacent to v in G'. Since w and v are not adjacent in G', G_R contains at most one of the arcs (w, v) or (v, w). Assume without loss of generality that (w, v) is not an arc of G_R. Since u is adjacent to both v and w in G', G_R contains the arcs (v, u) and (u, w). Recall that both u and v are white vertices. This implies that the arc-modification set M contains no arc incident with any of these two vertices. Hence, M contains none of the arcs of $\{(v, u), (u, w), (v, w)\}$, which implies that $G'_R = (V, A\Delta M)$ is not a transitive graph; a contradiction. ◁

Note that this implies that each connected component in $G'[W]$ is a clique of real twins in G'. We call each such connected component in $G'[W]$ a *white cluster*.

Note that after exhaustive applications of the first two reduction rules, each white cluster has size at most $k' - 1$ and each connected component in G' has size at least k'. This implies that each connected component in G' contains at least one blue vertex. Since G' contains at most $|B|$ blue vertices, this implies that G' has at most $|B|$ connected components.

In the following, we show that no blue vertex has neighbors in more than one white cluster. This then implies that G' contains at most $|B| \cdot k'$ vertices. In a final step, we then show how to reduce the value of k'.

▷ Claim 14. No blue vertex has neighbors in more than one white cluster.

Proof. Assume towards a contradiction that there is a blue vertex w which is adjacent to two white vertices u and v in G', such that u and v are not part of the same white cluster. Since u and v are not part of the same white cluster, u and v are not adjacent in G' due to Claim 13. This implies that G_R contains at most one of the arcs (u, v) or (v, u). Assume without loss of generality that (u, v) is not an arc of G_R. Since w is adjacent to both u and v in G', G_R contains the arcs (u, w) and (w, v). By the fact that both u and v are white vertices, M contains no arc of $\{(u, w), (w, v), (u, v)\}$, which implies that $G'_R = (V, A\Delta M)$ is not a transitive graph; a contradiction. ◁

As mentioned above, this implies that G' contains at most $|B| \cdot k'$ vertices. Next, we show how to reduce the size of the white clusters if $k' > |B|$. To this end, we introduce our last reduction rule:

- RR 3: If $k' > |B| + 1$, remove an arbitrary white vertex from each white cluster and reduce k' by 1.

Note that RR 3 is safe: If $k' > |B| + 1$, a clique of size k' in G' has to contain at least two white vertices, since G' contains at most $|B|$ blue vertices. Since no clique in G' can contain vertices of different white clusters, we reduce the size of a maximal clique of size at least k' in G' by exactly one, when removing one vertex of each white cluster.

Hence, after all reduction rules are applied exhaustively, the resulting instance (G', k') of Clique contains at most $|B|$ blue vertices and at most $|B|$ white clusters. Each such white cluster hast size at most $|B| + 1$. This implies that the resulting graph G' contains $\mathcal{O}(|B|^2)$ vertices and $\mathcal{O}(|B|^3)$ edges, since each vertex has degree $\mathcal{O}(|B|)$.

Based on a known polynomial-time reduction [6], we can compute for an instance (G^*, k^*) of Clique, an equivalent instance $(\mathcal{G}^*, k^*)$ of Open-TCC, where $\mathcal{G}^*$ is a proper temporal graph and has $\mathcal{O}(n + m)$ vertices and edges, where n and m denote the number of vertices and the number of edges of G^*, respectively. Since G' has $\mathcal{O}(|B|^2)$ vertices and $\mathcal{O}(|B|^3)$ edges, this implies that we can obtain an equivalent instance of Open-TCC of total size $\mathcal{O}(|B|^3)$ in polynomial time. By the fact that $\mathcal{G}^*$ is a proper temporal graph, this works for all problem versions of Open-TCC. ◀

Based on the fact that the set B of endpoints of any arc-modification set M towards a transitive graph is an inherent transitivity modulator of size at most $2 \cdot |M|$, this implies the following for kernelization algorithms with respect to arc-modification sets towards a transitive graph.

▶ **Theorem 15.** *Let $I = (\mathcal{G}, k)$ be an instance of Open-TCC and let $G_R = (V, A)$ be the reachability graph of $\mathcal{G}$. Moreover, let $M \subseteq V \times V$ be a set of arcs such that $G'_R = (V, A \Delta M)$ is transitive. Then, for each version of Open-TCC, one can compute in polynomial time an equivalent instance of total size $\mathcal{O}(|M|^3)$.*

Moreover, if the arc-modification set M only adds arcs to the reachability graph, we can obtain the further even better kernelization result.

▶ **Lemma 16** (⋆). *Let $I = (\mathcal{G}, k)$ be an instance of Open-TCC and let $G_R = (V, A)$ be the reachability graph of $\mathcal{G}$. Moreover, let $M \subseteq V \times V$ be a set with $A \cap M = \emptyset$ of arcs such that $G'_R = (V, A \Delta M)$ is transitive. Then, for each version of Open-TCC, one can compute in polynomial time an equivalent instance of total size $\mathcal{O}(|M|^2)$.*

Hence, if we are given an arc-modification set M of size δ_{am}, we can compute a polynomial kernel. Unfortunately, finding a minimum-size arc-modification set of a given directed graph is NP-hard [25] and no polynomial-factor approximations are known that run in polynomial time. Hence, we cannot derive a polynomial kernel for the parameter δ_{am}. Positively, if we only consider arc-additions, we can compute the transitive closure of a given directed graph in polynomial time. This implies that we can find a minimum-size arc-modification set towards a transitive reachability graph in polynomial time among all such sets that only add arcs to to reachability graph. Consequently, we derive the following.

▶ **Corollary 17.** *Open-TCC admits a kernel of size $\mathcal{O}(\delta_{\text{aa}}^2)$, where δ_{aa} denotes the minimum number of necessary arc-additions to make the respective reachability graph transitive.*

5 Limits of these Parametrizations for Closed TCCs

So far, the temporal paths that realize the reachability between two vertices in a tcc could lie outside of the temporal connected component. If we impose the restriction that those temporal paths must be contained in the tcc, the problem of finding a large tcc becomes

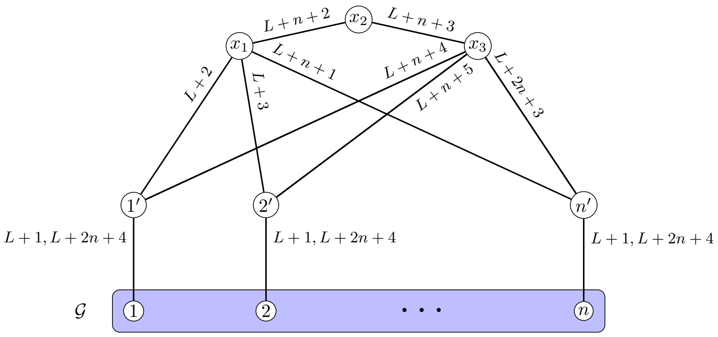

Figure 4 An illustration of the additional vertices and edges that are added to $\mathcal{G}$ in the reduction of Theorem 18. Here, L denotes the lifetime of $\mathcal{G}$ and the labels on the edges indicate in which snapshots the respective edges exist in the constructed temporal graph.

NP-hard even when the reachability graph is missing only a single arc to become a complete bidirectional clique: In other words, the problem becomes NP-hard even if $\delta_{\text{vd}} = \delta_{\text{am}} = 1$. On general temporal graphs, all versions of CLOSED-TCC are known to be NP-hard [8, 13].

▶ **Theorem 18.** *For each version of CLOSED-TCC, there is a polynomial time self-reduction that transforms an instance $(\mathcal{G}, k)$ with $k > 4$ of that version of CLOSED-TCC into an equivalent instance $(\mathcal{G}', k)$, such that the reachability graph of $\mathcal{G}'$ is missing only a single arc to be a complete bidirectional clique.*

Proof. Let $I := (\mathcal{G}, k)$ be an instance of CLOSED-TCC with underlying graph $G = (V, E)$ and let L be the lifetime of $\mathcal{G}$. Moreover, assume for simplicity that the vertices of V are exactly the natural numbers from $[1, n]$ with $n := |V|$. To obtain an equivalent instance $I' := (\mathcal{G}', k)$ of CLOSED-TCC, we extends $\mathcal{G}$ as follows: We initialize $\mathcal{G}'$ as a copy of $\mathcal{G}$ and for each vertex $v \in V$, we add a new vertex v' to $\mathcal{G}'$. Additionally, we add three vertices x_1, x_2, and x_3 to $\mathcal{G}'$. Furthermore, we append $2n + 4$ empty snapshots to the end of $\mathcal{G}'$ and add the following edges to $\mathcal{G}'$: For each vertex $v \in V$, we add the edge $\{v, v'\}$ to time steps $L + 1$ and $L + 2n + 4$, the edge $\{v', x_1\}$ to time step $L + 1 + v$, and the edge $\{v', x_3\}$ to time step $L + n + 3 + v$. Finally, we add the edge $\{x_1, x_2\}$ to time step $L + n + 2$ and the edge $\{x_2, x_3\}$ to time step $L + n + 3$. This completes the construction of $\mathcal{G}'$. An illustration of the additional vertices and edges is given in Figure 4.

Before we show the equivalence between the two instances of CLOSED-TCC, we first show that the reachability graph G'_R of $\mathcal{G}'$ only misses a single arc to be a bidirectional clique.

▷ Claim 19. The arc (x_3, x_1) is the only arc that is missing in G'_R.

Proof. First, we show that (x_3, x_1) is not an arc of G'_R. By construction of $\mathcal{G}'$, (i) no edge of $\mathcal{G}'$ that is incident with x_1 exists in any time step larger than $L + n + 2$, and (ii) no edge of $\mathcal{G}'$ that is incident with x_3 exists in any time step smaller than $L + n + 3$. This implies that no temporal path in $\mathcal{G}'$ that starts in x_3 can reach x_1. Hence, (x_3, x_1) is not an arc of G'_R.

Next, we show that G'_R contains all other possible arcs. To this end, we present strict temporal paths in $\mathcal{G}'$ that guarantee the existence of these arcs in G'_R. Let u and v be vertices of V. Consider the temporal path P that starts in vertex u and traverses

- the edge $\{u, u'\}$ in time step $L + 1$,
- the edge $\{u', x_1\}$ in time step $L + 1 + u$,
- the edge $\{x_1, x_2\}$ in time step $L + n + 2$,
- the edge $\{x_2, x_3\}$ in time step $L + n + 3$,

- the edge $\{x_3, v'\}$ in time step $L + n + 3 + v$, and
- the edge $\{v', v\}$ in time step $L + 2n + 4$.

Since each vertex of V is a natural number of $[1, n]$, the times steps in which these edges are traversed by P are strictly increasing, which implies that P is a strict temporal path of $\mathcal{G}'$. Note that each suffix and each prefix of P is also a strict temporal path in $\mathcal{G}'$. Hence, this implies that G'_R contains all the arcs $\{(u, v'), (u, v), (u', v'), (u', v)\} \cup \{(u', x_1), (u', x_1), (x_1, v'), (x_1, v) \mid i \in \{1, 2, 3\}\} \cup \{(x_1, x_3)\}$. Moreover, since $\{x_1, x_2\}$ and $\{x_2, x_3\}$ are edges in $\mathcal{G}'$, G'_R also contains the arcs $\{(x_1, x_2), (x_2, x_1), (x_2, x_3), (x_3, x_2)\}$. This implies that (x_3, x_1) is the unique arc that is missing in G'_R. ◁

Next, we show that I is a yes-instance of Closed-TCC if and only if I' is a yes-instance of Closed-TCC.

(⇒) This direction follows directly by the fact that $\mathcal{G}'$ is obtained by extending $\mathcal{G}$. Hence, a closed tcc S of size k in $\mathcal{G}$ is also a closed tcc in $\mathcal{G}'$.

(⇐) Let S be a closed tcc of size k in $\mathcal{G}'$. Recall that $k > 4$. We show that S only contains vertices of V. To this end, we first show that S does not contain x_2.

▷ Claim 20 (⋆). The set S does not contain x_2.

Next, we show that the vertex x_2 is required to have pairwise temporal paths between distinct vertices of $\{w' \mid w \in V\}$ in $\mathcal{G}'$.

▷ Claim 21 (⋆). Let u and v be distinct vertices of V with $u < v$. Then, each temporal path from v' to u' in $\mathcal{G}'$ visits x_2.

As a consequence, S contains at most one vertex of $\{w' \mid w \in V\}$, since S is a closed tcc that does not contain vertex x_2. Based on the above two claims, we now show that S contains only vertices of V.

▷ Claim 22 (⋆). Only vertices of V are contained in S.

Since no edge between any two vertices of V was added while constructing $\mathcal{G}'$ from $\mathcal{G}$, each temporal path in $\mathcal{G}'$ that visits only vertices of V is also a temporal path in $\mathcal{G}$. Together with Claim 22, this implies that S is a closed tcc in $\mathcal{G}$, which implies that I is a yes-instance of Closed-TCC. ◀

Recall that all versions of Closed-TCC are NP-hard [8, 13]. Moreover the strict undirected version of Closed-TCC is W[1]-hard when parameterized by k [8] and both directed versions of Closed-TCC are W[1]-hard when parameterized by k [13]. Together with Theorem 18, this implies the following intractability results for Closed-TCC.

▶ **Theorem 23.** *All versions of Closed-TCC are NP-hard even if $\delta_{\text{vd}} = \delta_{\text{am}} = 1$. More precisely, this hardness holds on instances where the reachability graph is missing only a single arc to be a complete bidirectional clique. Excluding the undirected non-strict version of Closed-TCC, all versions of Closed-TCC are W[1]-hard when parameterized by k under these restrictions*

6 Conclusion

We introduced two new parameters δ_{vd} and δ_{am} that capture how far the reachability graph of a given temporal graph is from being transitive. We demonstrated their applicability when the goal is to find open tccs in a temporal graph, presenting FPT-algorithms for each parameter individually, and a polynomial kernel with respect to δ_{am}, assuming that the corresponding arc-modification set of size δ_{am} is given. Computing such a set is NP-hard in general directed graphs [25]. An interesting question, also formulated in that paper, is whether this parameter is at least approximable to within a polynomial factor of δ_{am}. If so, our result implies a polynomial kernel for Open-TCC when parameterized by δ_{am}. Alternatively, the existence of a proper polynomial kernel for Open-TCC when parameterized by δ_{am} could also be shown by finding an approximation for a minimum-size inherent transitivity modulator due to Theorem 12 and the fact that the size of a minimum-size inherent transitivity modulator never exceeds $2 \cdot \delta_{\text{am}}$.

Another natural question is to identify what are other (temporal) reachability problems for which our transitivity parameters could be useful. For instance, consider a variant of the Open-TCC problem where we search for *d-tccs*, that is, tccs such that the fastest temporal path between the vertices has duration at most d. It is plausible that our positive results carry over to this version when applied to the *d-reachability graph*, i.e., the graph whose arcs represent temporal paths of duration at most d.

Regarding Closed-TCC, our intractability results show that neither δ_{vd} nor δ_{am} suffice to make this problem tractable. However, our results do not preclude the existence of an FPT-algorithm in the case that the arc modification operations are restricted to deletion only, which remains to be investigated. Nonetheless, we still believe that transitivity is a key aspect of the problem. The problem with Closed-TCC is that the reachability graph itself does not encode whether the paths responsible for reachability travel through internal or external vertices.

We would like to initiate the idea of considering further transitivity parameters based on modifications of the temporal graph itself, not only of the reachability graph. In particular, could FPT-algorithms for such parameters be achieved for reachability problems such as Open-TCC with similar performance as our FPT-algorithms for δ_{vd} and δ_{am}, and could these parameters make Closed-TCC tractable as well? And if so, how difficult is the computation of such parameters?

Abstract

This paper studies the recursion-theoretic aspects of large-scale geometries of infinite strings, a subject initiated by Khoussainov and Takisaka (2017). We investigate several notions of quasi-isometric reductions between recursive infinite strings and prove various results on the equivalence classes of such reductions. The main result is the construction of two infinite recursive strings α and β such that α is strictly quasi-isometrically reducible to β, but the reduction cannot be made recursive. This answers an open problem posed by Khoussainov and Takisaka.

1 Introduction

Quasi-isometry is an important concept in geometric group theory that has been used to solve problems in group theory. Loosely speaking, two metric spaces are said to be quasi-isometric iff there is a mapping (called a *quasi-isometry*) from one metric space to the other that preserves the distance between any two points in the first metric space up to some multiplicative and additive constants. Thus, for example, while the Euclidean plane is not isometric to $\mathbb{R}^2$ equipped with the taxicab distance, the two spaces are quasi-isometric to each other since the Euclidean distance between any two points does not differ from the

taxicab distance between them up to a multiplicative factor of $\sqrt{2}$. The study of group properties – where groups are represented by their Cayley graphs – that are invariant under quasi-isometries is quite a prominent theme in geometric group theory; examples of such group properties include hyperbolicity and growth rate [2].

This paper studies quasi-isometries of the ordered sets $(\mathbb{N}, <)$ with the objects being infinite strings, recursive functions from $\mathbb{N}$ to a finite alphabet or isomorphic copies of these structures defined with automatic functions in automata theory replacing recursive ones (the latter being delayed to the journal version of this paper). The notion of quasi-isometry for infinite strings was introduced by Khoussainov and Takisaka [6], enabling the study of global patterns on strings and linking the study of large-scale geometries with automata theory, computability theory, algorithmic randomness and model theory. Furthermore, quasi-isometries between hyperbolic metric spaces in general – an example of which is an infinite string when viewed as a colored metric space – are well-studied in geometric group theory. Isometries between computable metric spaces have also been studied by Melnikov [10].

Among the various questions investigated by Khoussainov and Takisaka was the computational complexity of the *quasi-isometry problem*: given any two infinite strings α and β, is there a quasi-isometry from α to β? They found that for any two quasi-isometric strings, a quasi-isometry that is recursive in the halting problem relative to α and β always exists between them, and that the quasi-isometry problem between any two recursive strings is Σ^0_2-complete [7][1]. In comparison, the corresponding problem for isometry with respect to recursive strings is Π^0_1-complete [10]. Khoussainov and Takisaka also had the following open problem which was mentioned in many talks and discussions: *if a quasi-isometric reduction from α to β exists, does there always exist a recursive quasi-isometric reduction?* This is a very natural question for computer science, specifically for computability theory, since it seeks to understand how complex such a reduction is. We answered this question in the negative, that is, there are cases where the reduction exists but cannot be made recursive. The fourth author's bachelor thesis [9] which contains this result was cited by Khoussainov and Takisaka in the journal version [7] of their paper [6].

To complete the picture, the present work examines, in more detail, the recursion-theoretic aspects of quasi-isometries between infinite strings. We study various natural restrictions on quasi-isometric reductions between strings: first, *many-one reductions*, where the quasi-isometric reduction is required to be *recursive* and *many-one*; second, *one-one reductions*, which are injective many-one reductions; third, *permutation quasi-isometric reductions*, which are surjective one-one reductions.

The main subjects of this work are the structural properties of the equivalence classes induced by the different types of reductions and the relationships between these reductions. In accordance with recursion-theoretic terminology, we call an equivalence class induced by a reduction type a *degree* of that reduction type. We show, for example, that within each many-one quasi-isometry degree, any pair of strings has a common upper bound as well as a common lower bound with respect to one-one reductions. Furthermore, there are two strings for which their many-one quasi-isometry degrees have a unique least common upper bound. The main result is the separation of quasi-isometry from *recursive* quasi-isometry, that is, we construct two recursive strings such that one is quasi-isometric reducible to the other but no recursive many-one quasi-isometry exists between them. This main result answers the above-mentioned open problem posed by Khoussainov and Takisaka.

[1] Note that [7] is the journal version of their paper [6], containing some corrections from the earlier paper.

2 Notation

Any unexplained recursion-theoretic notation may be found in [11, 13, 14]. The set of positive integers will be denoted by $\mathbb{N}$; $\mathbb{N} \cup \{0\}$ will be denoted by $\mathbb{N}_0$. The finite set Σ will denote the alphabet used. We assume knowledge of elementary computability theory over different size alphabets [1]. An infinite string $\alpha \in \Sigma^\omega$ can also be viewed as a Σ-valued function defined on $\mathbb{N}$. The length of an interval I is denoted by $|I|$. For $\alpha_i \in \Sigma^*$ and $i \in \mathbb{N}$, we write $(\alpha_i)_{i=1}^{\infty}$ to denote $\alpha_1\alpha_2\cdots$, a possibly infinite string.

3 Colored Metric Spaces and Infinite Strings

▶ **Definition 1** (Colored Metric Spaces, [6]). *A* colored metric space $(M; d_M, Cl)$ *consists of the* underlying metric space $(M; d_M)$ *with metric d_M and the color function $Cl : M \to \Sigma$, where Σ is a finite set of colors called an* alphabet*. We say that $m \in M$* has color $\sigma \in \Sigma$ *if $\sigma = Cl(m)$.*

▶ **Definition 2** (Quasi-isometries Between Colored Metric Spaces, [6]). *For any $A \geq 1$ and $B \geq 0$, an* (A, B)-quasi-isometry *from a metric space $\mathcal{M}_1 = (M_1; d_1)$ to a metric space $\mathcal{M}_2 = (M_2; d_2)$ is a function $f : M_1 \to M_2$ such that for all $x, y \in M_1$, $\frac{1}{A} \cdot d_1(x, y) - B \leq d_2(f(x), f(y)) \leq A \cdot d_1(x, y) + B$, and for all $y \in M_2$, there exists an $x \in M_1$ such that $d_2(f(x), y) \leq A$.*

Given two colored metric spaces $\mathcal{M}_1 = (M_1; d_1, Cl_1)$ and $\mathcal{M}_2 = (M_2; d_2, Cl_2)$, a function $f : M_1 \to M_2$ is a quasi-isometric reduction *from $\mathcal{M}_1$ to $\mathcal{M}_2$ iff for some $A \geq 1$ and $B \geq 0$, f is an (A, B)-quasi-isometry from $(M_1; d_1)$ to $(M_2; d_2)$ and f is* color-preserving*, that is, for all $x \in M_1$, $Cl_1(x) = Cl_2(f(x))$.*

An infinite string α can then be seen as a colored metric space $(\mathbb{N}; d, \alpha)$, where d is the metric on $\mathbb{N}$ defined by $d(i, j) = |i - j|$ and $\alpha : \mathbb{N} \to \Sigma$ is the color function. For any two infinite strings α and β, we write $\alpha \leq_{qi} \beta$ to mean that there is a quasi-isometric reduction from α to β. The relation $\leq_{qi}$ is a preorder on Σ^ω. For any pair of distinct letters $a_1, a_2 \in \Sigma$, a_1^ω and a_2^ω are incomparable with respect to $\leq_{qi}$, so this relation is not total.

The following proposition gives a useful simplification of the definition of quasi-isometry in the context of infinite strings.

▶ **Proposition 3.** *Given two infinite strings α and β, let $f : \mathbb{N} \to \mathbb{N}$ be a color-preserving function. Then f is a quasi-isometric reduction from α to β iff there exists a constant $C \geq 1$ such that for all x, y in the domain of α, the following conditions hold:*

(a) $d(f(x), f(x+1)) \leq C$;

(b) $x + C < y \Rightarrow f(x) < f(y)$.

Proof. First, suppose that $f : \mathbb{N} \to \mathbb{N}$ is a color-preserving quasi-isometric reduction from α to β. We show that there exists a constant $C \geq 1$ for which Conditions (a) and (b) hold for any $x, y \in \mathbb{N}$. By the definition of a quasi-isometric reduction, there exist constants $A \geq 1$ and $B \geq 0$ such that

$$\frac{1}{A} \cdot d(x, y) - B \leq d(f(x), f(y)) \leq A \cdot d(x, y) + B. \tag{1}$$

We first derive, for each of the two conditions, a choice of C satisfying it.

(i) Plugging $y = x + 1$ into the upper bound in (1) yields $d(f(x), f(x + 1)) \leq A + B$.

(ii) Assume for the sake of a contradiction that for all $C \geq 1$, there are $x \in \mathbb{N}$ and $C' > C$ such that $f(x + C') \leq f(x)$. We show that if C is chosen so that $A + B \leq \frac{1}{A} \cdot C - B$, then the existence of some $C' > C$ with $f(x + C') \leq f(x)$ would lead to a contradiction. Fix such a C, and suppose there were indeed some C' with $C' > C \geq 1$ and

$$f(x + C') \leq f(x)\,. \tag{2}$$

Then,

$$\begin{aligned} f(x + C' + 1) - f(x + C') &\leq d(f(x + C' + 1), f(x + C')) \\ &\leq A + B \quad \text{(by statement (i))} \\ &\leq \frac{1}{A} \cdot C - B \quad \text{(by the choice of } C\text{)} \\ &< \frac{1}{A} \cdot C' - B \quad \text{(since } C' > C\text{)} \\ &\leq f(x) - f(x + C') \quad \text{(by (1) and (2))}\,, \end{aligned}$$

giving $f(x + C' + 1) < f(x)$. One can repeat the preceding argument inductively, yielding the inequality $f(x + C' + k + 1) - f(x + C' + k) < f(x) - f(x + C' + k)$, or equivalently $f(x + C' + k + 1) < f(x)$, for each $k \geq 0$. But this is impossible since $f(x)$ is finite and $d(f(x + C' + k + 1), f(x + C' + k' + 1)) > 0$ whenever $|k - k'|$ is sufficiently large.

It follows from (i) and (ii) that Conditions (a) and (b) are satisfied for $C = A \cdot (A + 2B)$.

For a proof of the converse direction, fix a C satisfying Conditions (a) and (b). Suppose $x \in \mathbb{N}$. Then by Condition (a), $d(f(x), f(x + 1)) \leq C$. Inductively, assume that $d(f(x), f(x + n)) \leq n \cdot C$. Then by the inductive hypothesis and Condition (a), $d(f(x), f(x + n + 1)) \leq d(f(x), f(x+n)) + d(f(x+n), f(x+n+1)) \leq n \cdot C + C = (n+1) \cdot C$ where the first inequality follows from the triangle inequality. Consequently, for all $x, y \in \mathbb{N}$,

$$d(f(x), f(y)) \leq d(x, y) \cdot C\,. \tag{3}$$

Next, we establish a lower bound for $d(f(x), f(y))$. Without loss of generality, assume $x < y$. Write $y = x + i(C + 1) + j$ for some $i \in \mathbb{N}_0$ and $0 \leq j \leq C$. By a simple induction, one can show that $f(x + i(C + 1)) \geq f(x) + i$ and thus $d(f(x), f(x + i(C + 1)) \geq i$. Furthermore, $d(f(x + i(C + 1)), f(y)) \leq C^2$. Thus $d(f(x), f(y)) \geq i - C^2$ and $i \geq d(x, y)/(C + 1) - 1$. It follows that $d(f(x), f(y)) \geq d(x, y)/(C + 1) - 1 - C^2$. Thus one can select $A = (C + 1)$ and $B = C^2 + 1$ to establish the required bounds for the quasi-isometric mapping.

To establish that for all $y \in M_2$, there exists an $x \in M_1$ such that $d_2(f(x), y) \leq A$, one can choose any $A \geq max(C, f(1))$, as the distance between $f(x)$ and $f(x + 1)$ is bounded by C. ◀

By Proposition 3, we can now redefine quasi-isometric reduction in terms of one constant C, instead of two constants A and B as in Definition 2, reducing the number of constants by 1.

▶ **Definition 4.** *Suppose $C \geq 1$. Given infinite strings α and β, a C-*quasi-isometry *from α to β is a color-preserving function $f : \mathbb{N} \to \mathbb{N}$ such that for all x, y in the domain of α,*

(a) *$f(1) \leq C$ and $f(x) - C \leq f(x + 1) \leq f(x) + C$.*

(b) *$x + C < y \Rightarrow f(x) < f(y)$.*

For the rest of the paper, we shall use "Condition (a)" and "Condition (b)" to refer to the above conditions respectively, without necessarily mentioning the definition number.

A useful property of a C-quasi-isometry f from α to β is that any position of β has at most $C+1$ pre-images under f.

▶ **Lemma 5** ([6, Corollary II.4]). *Given two infinite strings α and β, suppose that f is a C-quasi-isometry from α to β. Then for all $y \in \mathbb{N}$, $|f^{-1}(y)| \leq C+1$.*

It was proven earlier that for any infinite strings α, β and any C-quasi-isometry f from α to β, there is a constant D such that each position of β is at most D positions away from some image of f. The next lemma states that each position of β in the range of f is at most C positions away from a different image of f. The proof is omitted due to space restrictions.

▶ **Lemma 6.** *Given two infinite strings α and β, suppose that f is a C-quasi-isometry from α to β. Then $\min\{f(x) : x \in \mathbb{N}\} \leq C$ and for each $y \in \mathbb{N}$, $min\{f(x) : x \in \mathbb{N}$ and $f(x) > f(y)\} \leq f(y) + C$. Hence for each $z \in \mathbb{N}$, there is some $x \in \mathbb{N}$ such that $d(f(x), z) \leq C$.*

▶ **Corollary 7.** *Let $\Sigma = \{a_1, \ldots, a_l\}$ and let α, β be two infinite strings. Let f be a C-quasi-isometry from α to β. Suppose that there is a positive integer K such that there is at least one occurrence of a_i in any interval of positions of α of length K. Then there is at least one occurrence of a_i in any interval of positions of β of length KC.*

A quasi-isometry f can fail to be order-preserving in that there are pairs $x, y \in \mathbb{N}$ with $x < y$ and $f(x) > f(y)$. Nonetheless, as Khoussainov and Takisaka noted [6, Lemma II.2], every quasi-isometry enforces a uniform upper bound on the size of a *cross-over* – the difference $f(x) - f(y)$ for such a pair $x, y \in \mathbb{N}$.

▶ **Lemma 8** (Small Cross-Over Lemma, [6, Lemma II.2]). *Given two infinite strings α and β, suppose that f is a C-quasi-isometry from α to β. Then for all $n, m \in \mathbb{N}$ with $n < m$, we have $f(n) - f(m) \leq C^2$.*

4 Recursive Quasi-Isometric Reductions

Khoussainov and Takisaka [6] investigated the structure of the partial-order Σ^{ω}_{qi} of the quasi-isometry degrees over an alphabet $\Sigma = \{a_1, \ldots, a_l\}$. They proved that Σ^{ω}_{qi} has a greatest element, namely the degree of $(a_1 \cdots a_n)^{\omega}$, and that Σ^{ω}_{qi} contains uncountably many minimal elements. Furthermore, they showed that Σ^{ω}_{qi} includes a chain of the type of the integers, and that it includes an antichain. In connection with computability theory, in particular with the arithmetical hierarchy, they established that the quasi-isometry relation on recursive infinite strings is Σ^0_2-complete [7]. In this section, we continue research into the recursion-theoretic aspects of quasi-isometries on infinite strings. We consider the notions of many-one and one-one recursive reducibilities first introduced by Post [12] as relations between recursive functions, and apply them to quasi-isometric reductions. We also define a third type of quasi-isometric reducibility – permutation reducibility – which is bijective. We then prove a variety of results on the degrees of such reductions.

▶ **Definition 9** (Many-One Reducibility). *A string α is* many-one reducible*, or* mqi-reducible*, to a string β iff there exists a quasi-isometric reduction f from α to β such that f is* recursive*. We call such an f a* many-one quasi-isometry (or mqi-reduction)*, and write $\alpha \leq_{mqi} \beta$ to mean that α is many-one reducible to β; if, in addition, f is a C-quasi-isometry, then we call f a* C-many-one quasi-isometry *(or* C-mqi-reduction*). We write $\alpha <_{mqi} \beta$ to mean that $\alpha \leq_{mqi} \beta$ and $\beta \not\leq_{mqi} \alpha$.*

▶ **Definition 10** (One-One Reducibility). *A string α is* one-one reducible*, or* 1qi-reducible*, to a string β iff there exists a many-one quasi-isometry f from α to β such that f is one-one. We call such an f a* one-one quasi-isometry (or 1qi-reduction)*, and write $\alpha \leq_{1qi} \beta$ to mean that α is one-one reducible to β; if, in addition, f is a C-quasi-isometry, then we call f a* C-one-one quasi-isometry *(or* C-1qi-reduction*). We write $\alpha <_{1qi} \beta$ to mean that $\alpha \leq_{1qi} \beta$ and $\beta \not\leq_{1qi} \alpha$.*

▶ **Definition 11** (Permutation Reducibility). *A string α is* permutation reducible*, or* pqi-reducible*, to a string β iff there exists a one-one quasi-isometry f from α to β such that f is surjective. We call such an f a* permutation quasi-isometry (or pqi-reduction)*, and write $\alpha \leq_{pqi} \beta$ to mean that α is permutation reducible to β; if, in addition, f is a C-quasi-isometry, then we call f a* C-permutation quasi-isometry *(or* C-pqi-reduction*). We write $\alpha <_{pqi} \beta$ to mean that $\alpha \leq_{pqi} \beta$ and $\beta \not\leq_{pqi} \alpha$. Here, note that it can be shown that $\alpha \leq_{pqi} \beta$ implies $\beta \leq_{pqi} \alpha$.*

Given an alphabet Σ, the relations $\leq_{mqi}$, $\leq_{1qi}$, $\leq_{pqi}$ and $\leq_{qi}$ are preorders on the class of infinite strings over Σ. Let $\equiv_{mqi}$ be the relation on Σ^ω such that $\alpha \equiv_{mqi} \beta$ iff $\alpha \leq_{mqi} \beta$ and $\beta \leq_{mqi} \alpha$. Then $\equiv_{mqi}$ is an equivalence relation on Σ^ω. We call an equivalence class on Σ^ω induced by $\equiv_{mqi}$ a *many-one quasi-isometry degree* (or *mqi-degree*), and denote the mqi-degree of an infinite string α by $[\alpha]_{mqi}$. Analogous definitions apply to $\equiv_{1qi}$, $[\alpha]_{1qi}$, $\equiv_{pqi}$, $[\alpha]_{pqi}$, $\equiv_{qi}$ and $[\alpha]_{qi}$.

We denote the partial orders induced by $\leq_{pqi}, \leq_{1qi}, \leq_{mqi}$ and $\leq_{qi}$ on the pqi-degrees, 1qi-degrees, mqi-degrees and qi-degrees by $\Sigma^\omega_{pqi}, \Sigma^\omega_{1qi}, \Sigma^\omega_{mqi}$ and Σ^ω_{qi} respectively.

By definition, Σ^ω_{pqi} is a refinement of Σ^ω_{1qi} in the sense that for all infinite strings α and β, $[\alpha]_{pqi} \leq_{pqi} [\beta]_{pqi} \Rightarrow [\alpha]_{1qi} \leq_{1qi} [\beta]_{1qi}$. In a similar manner, Σ^ω_{1qi} is a refinement of Σ^ω_{mqi}, which is in turn a refinement of Σ^ω_{qi}. The first subsection deals with the mqi-degrees, starting with the inner structure of each mqi-degree.

4.1 Structure of the mqi-Degrees

Fix any two distinct infinite strings β and γ belonging to $[\alpha]_{mqi}$. It can be shown that β and γ have a common upper bound as well as a common lower bound in $[\alpha]_{mqi}$ such that these bounds are witnessed by 1qi-reductions.

▶ **Proposition 12.** *For any two distinct infinite strings $\beta, \gamma \in [\alpha]_{mqi}$, there exists a $\delta \in [\alpha]_{mqi}$ such that $\beta \leq_{1qi} \delta$ and $\gamma \leq_{1qi} \delta$.*

Proof. Let f be a C-mqi-reduction from β to γ. Let δ be the infinite string obtained from γ by repeating $C+1$ times each letter of γ. Then $\gamma \leq_{1qi} \delta$ via a $(C+1)$-1qi-reduction g defined by $g(n) = (n-1)\cdot(C+1)+1$ for each $n \in \mathbb{N}$. Furthermore, $\delta \leq_{mqi} \gamma$ via a C-mqi-reduction g' defined by $g'(n) = \lceil \frac{n}{C+1} \rceil$. Thus $\delta \in [\alpha]_{mqi}$.

Next, one constructs a (C^2+2C)-1qi-reduction f' from β to δ using the function f. For each y in the range of f, map the pre-image of y under f, which by Lemma 5 has at most $C+1$ elements, to the set of positions of δ corresponding to the $C+1$ copies of the letter at position y. Formally, define

$$f'(n) = \begin{cases} g(f(n)), & \text{if } f(n) \neq f(n') \text{ for all } n' < n; \\ g(f(n)) + C', & \text{otherwise; where } 1 \leq C' < C+1 \text{ is minimum such that} \\ & g(f(n)) + C' \neq f'(n') \text{ for all } n' < n. \end{cases}$$

We verify that f' is an injective (C^2+2C)-quasi-isometry. Injectiveness follows from the definition of f': in the first case, the injectiveness of g ensures that $f'(x) \neq f'(x')$ for all $x' < x$; in the second case, it is directly enforced that $f'(x) \neq f(x')$ for all $x' < x$. Since f is a C-reduction, $x + C < y \Rightarrow f(x) < f(y) \Rightarrow g(f(x)) < g(f(y)) \Rightarrow f'(x) < f'(y)$, and so f' satisfies Condition (b) with constant C. Now we show that f' satisfies Condition (a) with constant C^2+2C. By Condition (a), $d(f(x), f(x+1)) \leq C$. Without loss of generality, assume that $f(x) \leq f(x+1)$. By the definition of f', $f'(x) \geq g(f(x))$ and $f'(x+1) \leq g(f(x+1)) + C$. Since $f(x) \leq f(x+1)$, it follows that $f'(x) \leq f'(x+1)$ and so

$$\begin{aligned} d(f'(x+1), f'(x)) &\leq g(f(x+1)) + C - g(f(x)) \\ &= (C+1)\cdot(f(x+1)-1) + 1 + C - (C+1)\cdot(f(x)-1) - 1 \\ &= (C+1)\cdot(f(x+1) - f(x)) + C \\ &\leq C\cdot(C+1) + C \\ &= C^2 + 2C\,. \end{aligned}$$

This completes the proof. ◀

Next, we prove a lower bound counterpart of Proposition 12.

▶ **Proposition 13.** *For any two distinct infinite strings $\beta, \gamma \in [\alpha]_{mqi}$, there exists a $\delta \in [\alpha]_{mqi}$ such that $\delta \leq_{1qi} \beta$ and $\delta \leq_{1qi} \gamma$.*

Proof. Suppose $\beta = \beta_1\beta_2\ldots$, where $\beta_i \in \Sigma$. Let $f : \mathbb{N} \to \mathbb{N}$ be a C-mqi-reduction from β to γ. Now define $\delta = \beta_{i_1}\beta_{i_2}\ldots$, where i_k is the minimum index such that $i_k \neq i_l$ for all $l < k$ and for all $j < i_k$, $f(j) \neq f(i_k)$. By Condition (b), the range of f is infinite and thus each i_k is well-defined. We verify that $\delta \leq_{1qi} \beta$ and $\delta \leq_{1qi} \gamma$.

Define $f'(n) = i_n$ for all $n \in \mathbb{N}$. We show that f' is a 1qi-reduction from δ to β. By the choice of the i_n's, $f'(n) > f'(m)$ whenever $n > m$; in particular, f' is injective and Condition (b) holds for f'. Furthermore, given any n, by applying Condition (b) to f and all $n' \leq n$, it follows that $f'(n+1) \leq f'(n) + C + 1$. Hence f' also satisfies Condition (a).

Next, define a 1qi-reduction f'' from δ to γ by $f''(n) = f(i_n)$. The injectiveness of f'' follows from the choice of the i_n's (though f'' is not necessarily strictly monotone increasing). Using the fact that $i_{n+1} \leq i_n + C + 1$, as well as applying Condition (a) $i_{n+1} - i_n$ times, $d(f''(n+1), f''(n)) = d(f(i_{n+1}), f(i_n)) \leq C \cdot d(i_{n+1}, i_n) \leq C \cdot (C+1)$. Hence f'' satisfies Condition (a) with constant $C \cdot (C+1)$. Since the i_n's are strictly increasing, $m + C < n \Rightarrow i_m + C < i_n \Rightarrow f(i_m) < f(i_n)$. Thus f'' is a $C \cdot (C+1)$-1qi-reduction.

Lastly, define a mqi-reduction g from β to δ by $g(n) = k$ where k is the minimum integer with $f(n) = f(i_k)$. As the i_n's cover the whole range of f, g is well-defined. For any given n, suppose $g(n) = k_1$ and $g(n+1) = k_2$, so that $f(n) = f(i_{k_1})$ and $f(n+1) = f(i_{k_2})$. By Condition (b), $d(n, i_{k_1}) \leq C$ and $d(n+1, i_{k_2}) \leq C$, and so

$$\begin{aligned} d(g(n), g(n+1)) &= d(k_1, k_2) \\ &\leq d(i_{k_1}, i_{k_2}) \\ &\leq d(n, i_{k_1}) + d(n, n+1) + d(n+1, i_{k_2}) \\ &\leq 2C + 1\,. \end{aligned}$$

Hence g satisfies Condition (a) with constant $2C+1$. To verify that g satisfies Condition (b) for some constant, fix any n and apply Condition (b) $C \cdot (C+1)$ times to f, giving $f(n) + C \cdot (C+1) \leq f(n + C \cdot (C+1)^2)$. Suppose $g(n) = i_{k_1}$ and $g(n + C \cdot (C+1)^2) = i_{k_2}$, so that $f(n) = f(i_{k_1})$ and $f(n + C \cdot (C+1)^2) = f(i_{k_2})$. Then $d(f(i_{k_1}), f(i_{k_2})) = d(f(n), f(n+

$C \cdot (C+1)^2)) \geq C \cdot (C+1)$. So by applying Condition (a) $d(i_{k_1}, i_{k_2})$ times to f, we have $C \cdot d(i_{k_1}, i_{k_2}) \geq d(f(i_{k_1}), f(i_{k_2})) \geq C \cdot (C+1)$. Dividing both sides of the inequality by C yields $d(i_{k_1}, i_{k_2}) \geq C+1$. Applying the contrapositive of Condition (b) to f then gives $f(i_{k_2}) \geq f(i_{k_1}) \Rightarrow i_{k_2} + C \geq i_{k_1}$. Since $d(i_{k_1}, i_{k_2}) \geq C+1$, this implies that $g(n + C \cdot (C+1)^2) = i_{k_2} > i_{k_1} = g(n)$. Thus g satisfies Condition (b) with constant $C \cdot (C+1)^2 - 1$. ◀

4.2 1qi-Degrees Within mqi-Degrees

We now investigate the structural properties of 1qi-degrees within individual mqi-degrees. As will be seen shortly, these properties can vary quite a bit depending on the choice of the mqi-degree.

▶ **Proposition 14.** *There exists an infinite string α such that $[\alpha]_{mqi}$ is the union of an infinite ascending chain of 1qi-degrees.*
