Proof. Let $\Sigma = \{0, 1\}$ and let $\alpha = 10^\omega$. Then $[\alpha]_{mqi}$ consists of all infinite strings with a finite, positive number of occurrences of 1. Given any infinite string β with $k \geq 1$ occurrences of 1, β is 1qi-equivalent to a string γ in $[\alpha]_{mqi}$ iff γ has exactly k occurrences of 1. If $1 \leq k < k'$, then each string $\beta \in [\alpha]_{mqi}$ with exactly k occurrences of 1 is 1qi-reducible to any string $\beta' \in [\alpha]_{mqi}$ with exactly k' occurrences of 1. Thus $[\alpha]_{mqi}$ is the union of an ascending chain $[\alpha]_{1qi} < [110^\omega]_{1qi} < [1110^\omega]_{1qi} < \ldots$, where the i-th term of this chain is $1^i 0^\omega$. ◀

▶ **Proposition 15.** *There exists an infinite string α such that the poset of 1qi-degrees within $[\alpha]_{mqi}$ is isomorphic to $\mathbb{N}^2$ with the componentwise ordering. That is, $[\alpha]_{mqi}$ is the union of infinitely many disjoint infinite ascending chains of 1qi-degrees such that every pair of these ascending chains has incomparable elements. Also, $[\alpha]_{mqi}$ does not contain infinite anti-chains of 1qi-degrees.*

Proof. Let $\Sigma = \{0, 1, 2\}$ and let $\alpha = 120^\omega$. Then $[\alpha]_{mqi}$ consists of all infinite strings with a finite, positive number of 1's and a finite, positive number of 2's. Furthermore, $[\alpha]_{1qi}$ consists of all infinite strings with exactly one occurrence of 1 and exactly one occurrence of 2.

Based on the proof of Proposition 14, $[\alpha]_{mqi}$ is the union, over all $k \geq 1$, of chains of the form $[12^k 0^\omega]_{1qi} < [1^2 2^k 0^\omega]_{1qi} < \ldots$, where the i-th term of each chain is $[1^i 2^k 0^\omega]_{1qi}$. Given any two chains $\Gamma_j = \{[1^i 2^j 0^\omega]_{1qi} : i \in \mathbb{N}\}$ and $\Gamma_k = \{[1^i 2^k 0^\omega]_{1qi} : i \in \mathbb{N}\}$, where $j < k$, the classes $[1^2 2^j 0^\omega]_{1qi} \in \Gamma_j$ and $[12^k 0^\omega]_{1qi} \in \Gamma_k$ are incomparable with respect to $\leq_{1qi}$.

It remains to show that any anti-chain of 1qi-degrees contained in $[\alpha]_{mqi}$ must be finite. Consider any anti-chain of 1qi-degrees containing the class $[1^i 2^j 0^\omega]_{1qi} \subsetneq [\alpha]_{mqi}$. Every element of this anti-chain that is different from $[1^i 2^j 0^\omega]_{1qi}$ is of the form $[1^{i'} 2^{j'} 0^\omega]_{1qi}$, where either $i < i'$ and $j > j'$, or $i > i'$ and $j < j'$. Thus, if the anti-chain were infinite, then it would contain at least 2 1qi-degrees, $[\beta]_{1qi}$ and $[\gamma]_{1qi}$, such that either β has the same number of occurrences of 1 as γ, or β has the same number of occurrences of 2 as γ. This is a contradiction as it would imply that either $\beta \leq_{1qi} \gamma$ or $\gamma \leq_{1qi} \beta$. ◀

4.3 pqi-Reductions

We now discuss pqi-reductions, which are the most stringent kind of quasi-isometric reductions considered in the present work. Pqi-reductions are 1qi-reductions that are surjective; an example of such a reduction is the mapping $2m-1 \mapsto 2m$, $2m \mapsto 2m-1$ from $(01)^\omega$ to $(10)^\omega$. We record a few elementary properties of pqi-reductions.

▶ **Lemma 16.** *If f is a pqi-reduction and if $x + D = f(x)$ for some $D \geq 1$ and some $x \in \mathbb{N}$, then there are at least D positions $y > x$ such that $f(y) < f(x)$.*

Proof. If $x + D = f(x)$ for some $D \geq 1$, then $\{1, \ldots, x + D - 1\} \setminus \{f(1), \ldots, f(x-1)\}$ must contain at least D elements as the former set contains D more elements than the latter. Thus, for f to be a bijection, there must exist at least D positions $y > x$ that are mapped by f into $\{1, \ldots, x + D - 1\} \setminus \{f(1), \ldots, f(x-1)\}$. ◀

We next observe that for any pqi-reduction f, there is a uniform upper bound on the difference $x - f(x)$.

▶ **Proposition 17.** *If f is a C-pqi-reduction, then for all $x \in \mathbb{N}$, $x - f(x) < 2C^2 + 1$.*

Proof. Assume, by way of contradiction, that there is some $x \in \mathbb{N}$ such that $x - f(x) \geq 2C^2 + 1$. First, suppose that there are at least $C^2 + 1$ numbers z such that $z > x$ and $f(z) \in \{f(x)+1, f(x)+2, \ldots, x-1\}$. Then there are at least $C^2 + 1$ numbers z' such that $z' < x$ and $f(z') > x > f(x)$, among which there is at least one z'_0 with $f(z'_0) \geq x + C^2 + 1$. This would contradict the fact that by the Small Cross-Over Lemma (Lemma 8), $z'_0 < x \Rightarrow f(z'_0) \leq f(x) + C^2 < x + C^2$.

Second, suppose that f maps at most C^2 numbers greater than x into $\{f(x)+1, f(x)+2, \ldots, x-1\}$. Then there are at least $C^2 + 1$ numbers less than x that are mapped into $\{f(x)+1, f(x)+2, \ldots, x-1\}$ and in particular, there is at least one number $y < x$ such that $f(y) \geq f(x) + C^2 + 1$, contradicting the Small Cross-over Lemma. Thus for all $x \in \mathbb{N}$, $x - f(x) < 2C^2 + 1$. ◀

Lemma 16 and Proposition 17 together give a uniform upper bound on the absolute difference between any position number and its image under a C-pqi-reduction.

▶ **Corollary 18.** *If f is a C-pqi-reduction, then for all $x \in \mathbb{N}$, $|x - f(x)| < 2C^2 + 1$.*

Proof. By Condition (b), there cannot be more than C numbers y such that $y > x$ and $f(y) < f(x)$. Lemma 16 thus implies that there cannot exist any $D > C$ such that $x + D = f(x)$, and so $f(x) - x \leq C$. Combining the latter inequality with that in Proposition 17 yields $|x - f(x)| < \max\{C+1, 2C^2+1\} = 2C^2 + 1$. ◀

Given any infinite string α, it was observed earlier that by the definitions of pqi, 1qi and mqi-reductions, $[\alpha]_{pqi} \subseteq [\alpha]_{1qi} \subseteq [\alpha]_{mqi}$. In the following example, we give instances of strings α where each of the two subset relations is proper or can be replaced with the equals relation.

▶ **Example 19.**

(a) $[\alpha]_{pqi} = [\alpha]_{1qi} = [\alpha]_{mqi}$. Set $\alpha = 0^\omega$. For any infinite string γ such that $\gamma \leq_{mqi} 0^\omega$, γ can only contain occurrences of 0, and therefore $[0^\omega]_{pqi} = [0^\omega]_{1qi} = [0^\omega]_{mqi} = \{0^\omega\}$.

(b) $[\alpha]_{1qi} = [\alpha]_{mqi}$ and $[\alpha]_{pqi} \subset [\alpha]_{1qi}$. Set $\alpha = (01)^\omega$. First, $(001)^\omega \leq_{1qi} (01)^\omega$, as witnessed by the 1qi-reduction $3n-2 \mapsto 4n-3, 3n-1 \mapsto 4n-1, 3n \mapsto 4n$ for $n \in \mathbb{N}$. We also have $(01)^\omega \leq_{1qi} (001)^\omega$ via the 1qi-reduction $2n-1 \mapsto 3n-2, 2n \mapsto 3n$ for $n \in \mathbb{N}$. However, $(001)^\omega \notin [(01)^\omega]_{pqi}$ because the density of 0's and 1's in the two strings are different, making it impossible to construct a permutation reduction between them. More formally, if there were a pqi-reduction from $(001)^\omega$ to $(01)^\omega$, then by Corollary 18, there would be a constant D such that for each n, the first $3n$ positions of $(001)^\omega$ are mapped into the first $3n + D$ positions of $(01)^\omega$. But the first $3n$ positions of $(001)^\omega$ contain $2n$ occurrences of 0 while the first $3n + D$ positions of $(01)^\omega$ contain at most $\lceil 1.5n + \frac{D}{2} \rceil$ occurrences of 0, and for large enough n, one has $2n > \lceil 1.5n + \frac{D}{2} \rceil$. Hence no pqi-reduction from $(001)^\omega$ to $(01)^\omega$ can exist, and so $[\alpha]_{pqi} \subset [\alpha]_{1qi}$.

To see that $[(01)^\omega]_{mqi} \subseteq [(01)^\omega]_{1qi}$, we first note that any string that is mqi-reducible to $(01)^\omega$ (or to any other recursive string) must be recursive. Thus if $\beta \leq_{mqi} (01)^\omega$, then a 1qi-reduction from β to $(01)^\omega$ can be constructed by mapping the n-th position of β to the position of the matching letter in the n-th occurrence of 01 in $(01)^\omega$. Next, suppose that f is a C-mqi-reduction from $(01)^\omega$ to β. By Corollary 7, f maps the positions of $(01)^\omega$ to a sequence of positions of β that contains 0 and 1 every $2C$ positions. Thus a 1qi-reduction can be constructed from $(01)^\omega$ to β by mapping, for each n, the $(2n-1)$-st and $(2n)$-th positions of $(01)^\omega$ to the positions of the first occurrence of 0 and first occurrence of 1 respectively in the interval $[2C(n-1)+1, 2Cn]$ of positions of β. Therefore $\beta \in [(01)^\omega]_{1qi}$.

(c) $[\alpha]_{1qi} \subset [\alpha]_{mqi}$ and $[\alpha]_{pqi} = [\alpha]_{1qi}$. Set $\alpha = 10^\omega$. We recall from the proof of Proposition 14 that $[10^\omega]_{pqi}$ and $[10^\omega]_{1qi}$ consist of all binary strings with a single occurrence of 1, while $[10^\omega]_{mqi}$ consists of all binary strings with a finite, positive number of occurrences of 1. Thus $[10^\omega]_{pqi} = [10^\omega]_{1qi}$ and $[10^\omega]_{pqi} \neq [10^\omega]_{mqi}$.

(d) $[\alpha]_{pqi} \subset [\alpha]_{1qi} \subset [\alpha]_{mqi}$. Set $\alpha = (0^n1)_{n=1}^\infty$, the concatenation of all strings 0^n1 where $n \in \mathbb{N}$. Then $\beta = (0^n11)_{n=1}^\infty \in [\alpha]_{mqi}$; however, $\beta \notin [\alpha]_{1qi}$ as each pair of adjacent positions of 1's in β must be mapped to distinct positions of 1's in α, but the distance between the n-th and $(n+1)$-st occurrences of 1 in α increases linearly with n, meaning that Condition (a) cannot be satisfied.

To construct an mqi-reduction from β to α, map the positions of the substring 0^n11 of β to the positions of the substring 0^n1 of α as follows: for $k \in \{1, \ldots, n\}$, the position of the k-th occurrence of 0 in 0^n11 is mapped to that of the k-th occurrence of 0 in 0^n1, while the two positions of 1's in 0^n11 are mapped to the position of the single 1 in 0^n1. For an mqi-reduction from α to β, for each substring 0^n1 of α and each substring 0^n11 of β, the positions of 0^n in 0^n1 are mapped to the corresponding positions of 0^n in 0^n11, while the position of 1 in 0^n1 is mapped to the position of the first occurrence of 1 in 0^n11. Thus $\beta \in [\alpha]_{mqi}$.

Furthermore, $\gamma = 1(0^n1)_{n=1}^\infty \in [\alpha]_{1qi}$ but $\gamma \notin [\alpha]_{pqi}$. The reason for γ not being pqi-reducible to α is similar to that given in Example (b). If such a pqi-reduction did exist, then by Corollary 18, there would exist a constant D such that for all n, the first $1 + \sum_{k=1}^n (k+1) = 1 + \frac{n(n+3)}{2}$ positions of γ are mapped into the first $1 + \frac{n(n+3)}{2} + D$ positions of α. But the first $1 + \frac{n(n+3)}{2}$ positions of γ contain $n+1$ occurrences of 1 and for large enough n, the first $1 + \frac{n(n+3)}{2} + D$ positions of α contain at most n occurrences of 1. Hence no pqi-reduction from γ to α is possible.

For a 1qi-reduction from γ to α, map the starting position of γ, where the letter 1 occurs, to the first occurrence of 1 in α. For subsequent positions of γ, for each $n \geq 1$, the set of positions of γ where the substring 0^n1 occurs can be mapped in a one-to-one fashion into the set of positions of α where the substring $0^{n+1}1$ occurs. To see that α is 1qi-reducible to γ, it suffices to observe that α is a suffix of γ, so one can map the positions of α in a one-to-one fashion to the positions of the suffix of γ corresponding to α. The 1qi-reduction from α to γ is trivial.

Proposition 21 extends the first example in Example 19 by characterising all recursive strings whose pqi, 1qi and mqi-degrees all coincide. In fact, there are only $|\Sigma|$ many such strings: those of the form a_i^ω, where $a_i \in \Sigma$. We call the pqi, 1qi and mqi-degrees of such strings *trivial*. Due to space constraint, the proof of Proposition 21 is omitted.

▶ **Definition 20.** *The pqi, 1qi and mqi-degrees of each string a_i^ω, where $a_i \in \Sigma$, will be called* trivial *pqi, 1qi and mqi-degrees respectively.*

▶ **Proposition 21.** *If, for some recursive string α, $[\alpha]_{pqi} = [\alpha]_{1qi} = [\alpha]_{mqi}$, then all three degree classes are trivial.*

We observe next that every non-trivial pqi degree must be infinite.

▶ **Proposition 22.** *All non-trivial pqi-degrees are infinite.*

Proof. Suppose that at least two distinct letters occur in α. Fix a letter, say a_1, that occurs infinitely often in α. Let a_2 be a letter different from a_1 that occurs in α. For each $n \in \mathbb{N}$, let $\beta_n = a_1^n a_2 \alpha^{(n+1)}$, where $\alpha^{(n+1)}$ is obtained from α by removing the first occurrence of a_2 as well as the first n occurrences of a_1. Since β_n is built from α by permuting the letters occurring at a finite set of positions of α, $\beta_n \in [\alpha]_{pqi}$. As the β_n's are all distinct, it follows that $[\alpha]_{pqi}$ is indeed infinite. ◀

We close this subsection by illustrating an application of Proposition 22, showing that if the mqi-degree of α contains at least two distinct strings such that one is 1qi-reducible to the other, then the first string is 1qi-reducible to infinitely many strings in $[\alpha]_{mqi}$.

▶ **Proposition 23.** *If there exist distinct $\beta \in [\alpha]_{mqi}$ and $\gamma \in [\alpha]_{mqi}$ such that $\beta \leq_{1qi} \gamma$, then β is 1qi-reducible to infinitely many strings in $[\alpha]_{mqi}$.*

Proof. Suppose that $\beta \leq_{1qi} \gamma$ and $\beta \neq \gamma$ for some $\beta \in [\alpha]_{mqi}$ and $\gamma \in [\alpha]_{mqi}$. Then $[\alpha]_{mqi}$ is non-trivial, so by Proposition 22, $[\gamma]_{pqi}$ is infinite. Since $[\gamma]_{pqi} \subseteq [\gamma]_{1qi}$, $[\gamma]_{1qi}$ is also infinite. Thus β is 1qi-reducible to each of the infinitely many strings in $[\gamma]_{1qi}$. ◀

4.4 The Partial Order of All mqi-Degrees

As discussed earlier, Khoussainov and Takisaka [6] observed that for any alphabet $\Sigma = \{a_1, \ldots, a_l\}$, the partial order Σ^ω_{qi} has a greatest element equal to $[(a_1 \cdots a_l)^\omega]_{qi}$. Their proof also extends to the partial order of all recursive mqi-degrees, showing that for each recursive string α, $[\alpha]_{mqi} \leq_{mqi} [(a_1 \cdots a_l)^\omega]_{mqi}$. We next prove that there is a pair of recursive mqi-degrees whose join is precisely the maximum recursive mqi-degree $[(a_1 \cdots a_l)^\omega]_{mqi}$.

▶ **Proposition 24.** *Suppose that $\Sigma = \{a_1, \ldots, a_l\}$. Then there exist two distinct infinite strings α and β such that $[(a_1 \cdots a_l)^\omega]_{mqi}$ is the unique recursive common upper bound of $[\alpha]_{mqi}$ and of $[\beta]_{mqi}$ under $\leq_{mqi}$.*

Proof. Let $\alpha = (a_1)^\omega$ and $\beta = (a_2 a_3 \cdots a_l)^\omega$. Suppose that for some recursive string γ, $\alpha \leq_{mqi} \gamma$ via a C-mqi-reduction. Since a_1 is the only letter occurring in α, Condition (a) implies that there must be at least one occurrence of a_1 in γ every C positions. Similarly, if $\beta \leq_{mqi} \gamma$ via a C'-mqi-reduction, then for each a_i with $i \geq 2$, since a_i occurs every $l-1$ positions, it must also occur in γ every $C' \cdot (l-1)$ positions. Hence there exists a constant C'' such that every substring of γ of length C'' contains at least one occurrence of a_i for every $i \in \{1, \ldots, l\}$, and therefore $(a_1 \cdots a_l)^\omega \leq_{mqi} \gamma$. Since $\gamma \leq_{mqi} (a_1 \cdots a_l)^\omega$ follows from the proof of [6, Proposition II.1], one has $\gamma \in [(a_1 \cdots a_l)^\omega]_{mqi}$, as required. ◀

Khoussainov and Takisaka [6] showed that the partial order Σ^ω_{qi} is not dense. In particular, given any distinct $a_i, a_j \in \Sigma$, there is no element $[\beta]_{qi}$ that is strictly between the minimal element $[(a_j)^\omega]_{qi}$ and the "atom" $[a_i(a_j)^\omega]_{qi}$ [6, Proposition II.1]. The next theorem shows similarly that the partial order Σ^ω_{mqi} is non-dense with respect to pairs of mqi-degrees. The high-level proof of the theorem is given below; the proofs of claims used are not shown due to space limitations.

▶ **Theorem 25.** *There exist two pairs (α, β) and (γ, δ) of recursive strings such that both α and β are mqi-reducible to γ as well as mqi-reducible to δ, but there is no string ξ such that $\alpha \leq_{mqi} \xi, \beta \leq_{mqi} \xi, \xi \leq_{mqi} \gamma$ and $\xi \leq_{mqi} \delta$.*

Proof. Let $\Sigma = \{0, 1\}$. Define the strings

$$\alpha = \sigma_1\sigma_2 \ldots, \quad \text{where } \sigma_n = (01)^{2^{2^n}} 0^n 1^n\,;$$

$$\beta = \tau_1\tau_2 \ldots, \quad \text{where } \tau_n = (01)^{2^{2^n}} 1^n 0^n\,;$$

$$\gamma = \mu_1\mu_2 \ldots, \quad \text{where } \mu_n = (01)^{2^{2^n}} 0^n\,;$$

$$\delta = \nu_1\nu_2 \ldots, \quad \text{where } \nu_n = (01)^{2^{2^n}} 1^n\,.$$

We first show that $\alpha \leq_{mqi} \gamma$. For each $i \in \mathbb{N}$, define the following intervals of positions.

- $K_i = [k_i, k_i + 2^{2^i+1} - 1]$ is the interval of positions of the substring $(01)^{2^{2^i}}$ of σ_i in α.
- $R_i = [r_i, r_i + 2i - 1]$ is the interval of positions of the substring 0^i1^i of σ_i in α.
- $L_i = [l_i, l_i + 2^{2^i+1} - 1]$ is the interval of positions of the substring $(01)^{2^{2^i}}$ of μ_i in γ.
- $L'_i = [l_i + 2^{2^i+1}, l_i + 2^{2^i+1} + i - 1]$ is the interval of positions of the substring 0^i of μ_i in γ.

Define an mqi-reduction g from α to γ as follows. For $i \in \mathbb{N}$,

$$g(k_i + 4w + 2u + x) = l_i + 2(i-1) + 2w + x\,, \quad 0 \leq w \leq i-2, u, x \in \{0, 1\}\,;$$

$$g(k_i + m) = l_i + m\,, \quad 4i - 4 \leq m \leq 2^{2^i+1} - 1\,;$$

$$g(r_i + m) = l_i + 2^{2^i+1} + m\,, \quad 0 \leq m \leq i - 1\,;$$

$$g(r_i + i + m) = l_{i+1} + 2m + 1\,, \quad 0 \leq m \leq i - 1.$$

The mqi-reduction g maps the interval K_i to the suffix of the interval L_i starting at its $(2i-1)$-st position such that each of the first $i-1$ pairs of positions of this suffix is the image of two consecutive pairs of positions of K_i, while the remaining $|K_i| - 2(i-1)$ positions of K_i is mapped by g to the remaining positions of the suffix of L_i in a one-to-one fashion. Thus g is a 4-mqi-reduction from α to γ. A similar mqi-reduction can be constructed from β to γ, from α to δ, as well from β to δ.

Assume, by way of contradiction, that there is a string ξ and there are mqi-reductions f_1 from α to ξ, f_2 from β to ξ, f_3 from ξ to γ and f_4 from ξ to δ with constants C_1, C_2, C_3 and C_4 respectively. Set $C = \max\{C_1, C_2, C_3, C_4\}$ and fix some $n > 2C^7 + 1$.

For $i \in \mathbb{N}$, let $K'_i = [k_i + C^2 + 2, k_i + 2^{2^i+1} - 3 - C^2]$ be the interval obtained from K_i by removing the first and last $C^2 + 2$ positions. We make the following observation. The proof is omitted due to space constraint.

▷ Claim 26. For all positions $m \in K'_n$, for $i \in \{1, 2\}$ and $j \in \{3, 4\}$, $f_j(f_i(m)) \in L_n$.

Define the sets $H_i = f_1(K'_i) \cup f_2(K'_i)$ for $i \in \mathbb{N}$. We show that the sets H_n and H_{n+1} are non-overlapping by proving $\max(H_n) < \min(H_{n+1})$. By Claim 26, for all $m \in H_n$ and $j \in \{3, 4\}$ we have $f_j(m) \in L_n$. Then, we have $f(\min(H_{n+1})) - f(\max(H_n)) \geq \min(L_{n+1}) - \max(L_n) = n + 1 > 2C^7 + 2 > C^2$. So by the Small Cross-Over Lemma, $\min(H_{n+1}) > \max(H_n)$.

Consider the interval $[\min(H_n), \max(H_n)]$ in the domain of ξ. By Claim 26, f_3 (resp. f_4) maps each element of H_n into L_n. Fix any other position z in the interval. Then f_3 cannot map z into L'_n, which is the set of positions in γ of the string 0^n. To see this, we note that if ℓ and $\ell + 1$ are the two largest values of K_n, then ℓ is at least $C^2 + 1$ more than the value x such that $f_i(x) = \max(H_n)$ for some $i \in \{1, 2\}$, and so by Condition (b), $z + C < \max(H_n) + C < f_k(\ell + 1)$ for $k \in \{1, 2\}$. Thus $f_3(z) < f_3(f_k(\ell + 1))$ for

$k \in \{1,2\}$. Furthermore, by applying Condition (a) repeatedly to f_3 and then to f_k, we have $d(f_3(f_k(\ell+1)), f_3(f_k(\max(K'_n)))) \leq C \cdot d(f_k(\ell+1), f_k(\max(K'_n))) \leq C^2 \cdot (C^2+2) = C^4+2C^2$. Since $f_3(f_k(\max(K'_n))) \in L_n$ and we fixed $n > 2C^7+1$, then $f_3(f_k(\ell+1)) \notin L_{n+1}$. Furthermore, the letter at position $f_3(f_k(\ell+1))$ of γ is 1. Thus $f_3(z)$ cannot lie in L'_n as there is no occurrence of 1 in L'_n. A similar argument, using position ℓ rather than position $\ell+1$, shows that $f_4(z)$ cannot lie in L'_n. One can also prove similarly that none of the positions in the interval $[\min(H_{n+1}), \max(H_{n+1})]$ is mapped by f_3 or f_4 into the interval L'_n.

Next, we consider the positions of ξ between $\max(H_n)$ and $\min(H_{n+1})$. Since none of the positions of ξ in the union $[\min(H_n), \max(H_n)] \cup [\min(H_{n+1}), \max(H_{n+1})]$ is mapped by f_3 into L'_n and L'_n is an interval of length $n > 2C^7$, Lemma 6 implies that there are at least $\lfloor \frac{n}{C_3} \rfloor$ positions of ξ between H_n and H_{n+1} which are mapped into L'_n. Then, we can make the following observations – the proofs of which are omitted due to space constraint.

▷ Claim 27. The string ξ contains a substring of 0's (resp. 1's) of length $\Omega(C^4)$ between H_n and H_{n+1} such that all positions of this substring are mapped by f_3 (resp. f_4) into L'_n.

▷ Claim 28. There cannot exist between H_n and H_{n+1} two $\Omega(C^4)$-long substrings of 0's (resp. 1's) such that an $\Omega(C^4)$-long substring of 1's (resp. 0's) lies between them.

Based on these two claims, there are exactly two maximal intervals J_1 and J_2, each of length $\Omega(C^4)$, such that the substrings of ξ occupied by J_1 and J_2 belong to $\{0\}^*$ and $\{1\}^*$ respectively. Then f_1 maps $\Omega(C^3)$ positions of $[r_n, r_n+n-1]$ into J_1 and $\Omega(C^3)$ positions of $[r_n+n, r_n+2n-1]$ into J_2; further, there are two positions that are $\Omega(C^3)$ positions apart, one in $[r_n, r_n+n-1]$ and the other in $[r_n+n, r_n+2n-1]$, such that f_1 maps the first position into J_1 and the second position into J_2. This implies that J_1 must precede J_2, for otherwise Condition (b) would be violated. Arguing similarly with f_2 in place of f_1 (that is, the mapping from β to ξ), it follows that J_2 must precede J_1, a contradiction. We conclude that the string ξ cannot exist. ◀

Example 19 established separations between various notions of recursive quasi-reducibility: pqi, 1qi and mqi-reducibilities. It remains to separate general quasi-isometry from its recursive counterpart. Due to space constraint, we only give a proof sketch of Theorem 29.

▶ **Theorem 29.** *There exist two recursive strings α and β such that $\alpha \leq_{qi} \beta$ but $\alpha \not\leq_{mqi} \beta$.*

Proof sketch. We begin with an overview of the construction of α and β. To ensure that only non-recursive quasi-isometries between α and β exist, we use a tool from computability theory, which is a Kleene tree [8] – an infinite uniformly recursive binary tree with no infinite recursive branches (see, for example, [11, §V.5]). The idea of the proof is to encode a fixed Kleene tree into β, and construct α such that for any quasi-isometry f from α to β, an infinite branch of the encoded Kleene tree can be computed recursively from f. Hence, f cannot be recursive, as otherwise the chosen infinite branch of the Kleene tree must be recursive, contradicting the definition of a Kleene tree.

We now describe the construction of α and β based on some fixed Kleene tree $T \subseteq \{0,1\}^*$. The building blocks for α and β are called *n-blocks*, which are strings of the following form for some $n \in \mathbb{N}$:

- $\lambda_{(n,0)} = 0^n 1^n$,
- $\lambda_{(n,i)} = 0^{\lfloor \frac{n+1}{2} \rfloor} 1^i 0^{\lceil \frac{n+1}{2} \rceil} 1^n$, for $1 \leq i \leq n-1$,
- $\lambda'_n = (01)^n 1^n$,

We may also call an n-block as simply a *block*.

To construct α and β we concatenate the blocks in stages, where in stage n we arrange n-blocks to form θ_n and ζ_n. Then, θ_n and ζ_n for $n \in \mathbb{N}$ are concatenated to form α and β respectively. That is, $\alpha = \theta_1\theta_2\dots$ and $\beta = \zeta_1\zeta_2\dots$ where θ_n and ζ_n are defined as follows:

- $\theta_1 = \zeta_1 = \lambda_{(1,0)}$.
- For $n \geq 2$, $\theta_n = v_{n,1}\ s_{n,1}\ v_{n,2}\ s_{n,2}\ v_{n,3}\ t_n\ v_{n,4}\ u_n$.
- For $n \geq 2$, $\zeta_n = v'_{n,1}\ s'_{n,1}\ v'_{n,2}\ s'_{n,2}\ v'_{n,3}\ t'_n\ v'_{n,4}\ u'_n$.

We now state the definitions of each variables $v_{n,1}$ and so on, and explain their purpose later. For $n \geq 2$, we define the following:

- Let $B^n_1, B^n_2, B^n_3, B^n_4, B^n_5, B^n_6, B^n_7, B^n_8$ be the number of blocks in α before the start of $v_{n,1},\ s_{n,1},\ v_{n,2},\ s_{n,2},\ v_{n,3},\ t_n,\ v_{n,4},\ u_n$ respectively.
- *Join segments* $v_{n,i} = v'_{n,i} = (\lambda_{(n,0)})^{3nB^n_{2i-1}}$.
- *Scaling segments* $s_{n,1}v_{n,2}s_{n,2}$ and $s'_{n,1}v'_{n,2}s'_{n,2}$, each containing two of the *scaling parts* $s_{n,i} = s'_{n,i} = (\lambda_{(n,1)})^{nB}(\lambda_{(n,2)})^{nB}\dots(\lambda_{(n,n-1)})^{nB}(\lambda_{(n,0)})^{2nB}$ where B means B^n_{2i}.
- *Branching segments* $t_n = (\lambda_{(n,0)})^{2nB^n_6+1}$ and $t'_n = (\lambda_{(n,0)})^{2nB^n_6}\lambda'_n$.
- *Selection segments* u_n and u'_n defined as follows. Let

$$S_n = \left\{ \sum_{m=1}^{n-1} b_m 4^{n-1-m} : b_1 \cdots b_{n-1} \in T \cap \{0,1\}^{n-1} \right\}.$$

  Then, each element $\sum_{m=1}^{n-1} b_m 4^{n-1-m}$ of S_n corresponds to the binary string $b_1 \cdots b_{n-1} \in T$. Define $u_n = \lambda_{(n,1)}(\lambda_{(n,0)})^{\max(S_n)}$. For $1 \leq i \leq \max(S_n)+1$, let the i-th block of u'_n be $\lambda_{(n,0)}$ if $i-1 \notin S_n$ and be $\lambda_{(n,1)}$ if $i-1 \in S_n$.

Note that the number of blocks in the respective segments of α and β are the same. So, for example, the number of blocks in α before $v_{n,i}$ is the same as that of β before $v'_{n,i}$.

Before we explain the purpose of each segment, we first describe some useful properties of the n-blocks. The proofs are omitted due to space restrictions. Let f be any C-quasi-isometric reduction from α to β. For all large enough n:

- No position of the i-th occurrence of an n-block in α is mapped by f to the position of an m-block in β with $m < n$.
- No position of a block $\lambda_{(n,1)}$ is mapped by f to a position of a block $\lambda_{(n,0)}$ occurring in β.
- For $i \leq n-2$, f maps the sequence of positions of each $\lambda_{(n,i)}$ block in a scaling segment of θ_n into either the sequence of positions of a $\lambda_{(n,i)}$ block in a scaling segment of ζ_n or the sequence of positions of a $\lambda_{(n,i+1)}$ block in a scaling segment of ζ_n.
- f can map the sequence of positions of a $\lambda_{(n,n-1)}$ block into the sequence of positions of exactly k blocks $\lambda_{(n,0)}$ iff $k = 2$.
- Up to $C+1$ blocks $\lambda_{(n,0)}$ can be mapped to a single λ'_n block.
- A single $\lambda_{(n,0)}$ block can be mapped across $\lambda_{(n,0)}\lambda'_n$.

We can now describe the purpose of each segment. As above, the proofs are omitted due to space restrictions. Let f be a C-quasi-isometric reduction from α to β. For sufficiently large $n \geq 2$:

- Each join segment $v_{n,i}$ has a non-negative *lead* ℓ such that for all $nB^n_{2i-1}+1 \leq j \leq 2nB^n_{2i-1}$, f maps the j-th $\lambda_{(n,0)}$ block of $v_{n,i}$ to the $(j+\ell)$-th $\lambda_{(n,0)}$ block of $v'_{(n,i)}$.
- The scaling part doubles the lead in the previous join segment. Since a scaling segment contains two scaling parts, the scaling segment multiplies the lead by four. Hence, if the lead of $v_{n,1}$ is ℓ, then the lead of $v_{n,3}$ is 4ℓ.
- The branching segment ensures that the lead is decreased by at most C or increased by 1. So, if the lead of $v_{n,3}$ is 4ℓ, then the lead of $v_{n,4}$ is between $4\ell - C$ and $4\ell + 1$ inclusive.
- The selection segment ensures that the lead in the previous join segment $v_{n,4}$ is in S_n.

Then, one can show that there is some constant c such that for large enough n, the leads ℓ_n and ℓ_{n+1} of the join segments $v_{n,4}$ and $v_{n+1,4}$ are contained in S_n and S_{n+1} respectively, and the binary strings $\sigma_n \in T \cap \{0,1\}^{n-1}$ and $\sigma_{n+1} \in T \cap \{0,1\}^n$, corresponding to ℓ_n and ℓ_{n+1} respectively have a common prefix of length $n-c$. Let τ_n be the prefix of σ_n of length $n-c$. Then, for some large enough n, $\tau_n \prec \tau_{n+1} \prec \tau_{n+2} \prec \ldots$ give an infinite branch of the Kleene tree T, which is non-recursive by definition of Kleene trees. Moreover, this infinite branch can be computed recursively from f. Hence, the quasi-isometric reduction f from α to β must be non-recursive. Hence, $\alpha \not\leq_{mqi} \beta$.

We now describe how to construct a quasi-isometric reduction f from α to β, using some fixed infinite branch $\mathcal{B}(1)\mathcal{B}(2)\cdots$ of the Kleene tree. Since $\theta_1 = \zeta_1 = \lambda_{(n,0)}$, we can map θ_1 to ζ_1 in a strictly increasing manner and the lead in the next segment is 0. We can now describe the mappings for each segment in θ_n for $n \geq 2$. Observe that each block $\lambda_{(n,i)}$ can be mapped to a block $\lambda_{(n,j)}$ in a strictly increasing manner if $j = i$ or $i+1$. For each join segment $v_{(n,i)}$ with lead ℓ_1 and $3nB^n_{2i-1}$ blocks, map the first $3nB^n_{2i-1} - \ell_1$ blocks of $v_{n,i}$ to the last $3nB^n_{2i-1} - \ell_1$ blocks of $v'_{(n,i)}$. Then, map the last ℓ_1 blocks of $v_{n,i}$ to the first ℓ_1 blocks of the following segment in ζ_n. The lead in the next segment is ℓ_1.

Next we describe the mapping for scaling part $s_{n,i}$ with lead ℓ_2. For each $1 \leq j \leq (n-1)nB^n_{2i} - \ell_2$, map the j-th block of $s_{n,i}$ to the $(j+\ell_2)$-th block of $s'_{n,i}$. Map each of the last ℓ_2 blocks $\lambda_{(n,n-1)}$ of $s_{n,i}$ to 2 blocks $\lambda_{(n,0)}$ of $s'_{n,i}$. Map the first $2nB^n_{2i} - 2\ell_2$ blocks $\lambda_{(n,0)}$ of $s_{n,i}$ to the remaining $2nB^n_{2i} - 2\ell_2$ blocks $\lambda_{(n,0)}$ of $s'_{n,i}$. Map the last $2\ell_2$ blocks $\lambda_{(n,0)}$ of $s_{n,i}$ to the first $2\ell_2$ blocks of the following join segment in ζ_n. The lead of the next join segment is $2\ell_2$.

For the branching segment, suppose that the current lead is ℓ_3. If $\mathcal{B}(n-1) = 1$, map the $(2nB^n_6 - \ell_3)$-th $\lambda_{(n,0)}$ block to the concatenation $\lambda_{(n,0)}\lambda'_n$ of two blocks in $t'_n v_{n,4}$. Otherwise, map the $(2nB^n_6 - \ell_3 + 1)$-st $\lambda_{(n,0)}$ block to the λ'_n block in t'_n. Map the rest of the $\lambda_{(n,0)}$ blocks such that f is strictly increasing. Then, the lead of the next join segment is $\ell_3 + \mathcal{B}(n-1)$.

For the selection segment, suppose that the current lead is ℓ_4. Map the $\lambda_{(n,1)}$ block to the (ℓ_4+1)-st block. By induction, $\ell_4 \in S_n$ and so the (ℓ_4+1)-st block in the selection segment of ζ_n is $\lambda_{(n,1)}$. Map the $\lambda_{(n,0)}$ blocks in a strictly increasing manner. ◀

5 Conclusions and Future Investigations

The present paper introduced finer-grained notions of quasi-isometries between infinite strings, in particular requiring the reductions to be recursive. We showed that permutation quasi-isometric reductions are provably more restrictive than one-one quasi-isometric reductions, which are in turn provably more restrictive than many-one quasi-isometric reductions. One result was that general many-one quasi-isometries are strictly more powerful than recursive many-one quasi-isometries, which answers Khoussainov and Takisaka's open problem.

This work also presented some results on the structures of the permutation, one-one and many-one quasi-isometric degrees. It was shown, for example, that there are two infinite strings whose many-one quasi-isometric degrees have a unique common upper bound. It was also proven that the partial order Σ^ω_{mqi} is non-dense with respect to pairs of mqi-degrees. We conclude with the simple observation that the class of mqi-degrees does not form a lattice; in particular, the mqi-degrees $[0^\omega]_{mqi}$ and $[1^\omega]_{mqi}$ do not have a common lower bound.

For future work, we consider an automata-theoretic version of quasi-isometric reduction. Note that Definition 4 defines quasi-isometric reduction based only on the ordering of the natural numbers, as well as adding and subtracting constants. Then we can define an automatic version of Definition 4 for any automatically-ordered set $(A, \leq_A)$ which is order-isomorphic to $(\mathbb{N}, \leq)$: we replace natural number i with the i-th smallest element of A, and study automatic functions $\mu, \nu : A \to \Sigma$ instead of infinite recursive strings $\alpha, \beta : \mathbb{N} \to \Sigma$. (The complete definitions of automatic functions and relations can be found in [3, 4, 5].) Note that the successor function is first-order definable in $(A, \leq_A)$ as follows: $succ(x) = x + 1 \coloneqq \min\{y : x <_A y\}$. So, adding and subtracting constants are automatic as well. Then this definition corresponds to the quasi-isometric reduction between colored metric spaces $(A; d_A, \mu)$ and $(A; d_A, \nu)$ where the metric function d_A is defined in terms of the order-isomorphism g from $(A, \leq_A)$ to $(\mathbb{N}, \leq)$; that is, $d_A(x, y) = |g(x) - g(y)|$.

Now one can ask, for which automatic functions $\mu, \nu : A \to \Sigma$, is there a quasi-isometric reduction from μ to ν? And can every quasi-isometric reduction between some given μ, ν be replaced by an automatic quasi-isometric reduction? The journal version of this paper will also study this automatic setting and show that the answer to the second question depends on $(A, \leq_A)$. Moreover, the expressibility, that is, which mappings from $\mathbb{N}$ to Σ correspond to automatic functions from A to Σ in $(A, \leq_A)$, also depends on the choice of $(A, \leq_A)$.

Abstract

A *path cover* of a digraph is a collection of paths collectively containing its vertex set. A path cover with minimum cardinality for a *directed acyclic graph* can be found in polynomial time [Fulkerson, AMS'56; Cáceres et al., SODA'22]. Moreover, Dilworth's celebrated theorem on chain coverings of partially ordered sets equivalently states that the minimum size of a path cover of a DAG is equal to the maximum size of a set of mutually unreachable vertices. In this paper, we examine how far these classic results can be extended to a dynamic setting.

A temporal digraph has an arc set that changes over discrete time-steps; if the underlying digraph is acyclic, then it is a *temporal DAG*. A temporal path is a directed path in the underlying digraph, such that the time-steps of arcs are strictly increasing along the path. Two temporal paths are temporally disjoint if they do not occupy any vertex at the same time. A *temporal path cover* is a collection $\mathcal{C}$ of temporal paths that covers all vertices, and $\mathcal{C}$ is *temporally disjoint* if all its temporal paths are pairwise temporally disjoint. We study the computational complexities of the problems of finding a minimum-size temporal (disjoint) path cover (denoted as Temporal Path Cover and Temporally Disjoint Path Cover).

On the negative side, we show that both Temporal Path Cover and Temporally Disjoint Path Cover are NP-hard even when the underlying DAG is planar, bipartite, subcubic, and there are only two arc-disjoint time-steps. Moreover, Temporally Disjoint Path Cover remains NP-hard even on temporal oriented trees. We also observe that natural temporal analogues of Dilworth's theorem on these classes of temporal DAGs do not hold.

In contrast, we show that Temporal Path Cover is polynomial-time solvable on temporal oriented trees by a reduction to Clique Cover for (static undirected) *weakly chordal* graphs (a subclass of perfect graphs for which Clique Cover admits an efficient algorithm). This highlights an interesting algorithmic difference between the two problems. Although it is NP-hard on temporal oriented trees, Temporally Disjoint Path Cover becomes polynomial-time solvable on temporal oriented *lines* and temporal *rooted directed* trees.

Motivated by the hardness result on trees, we show that, in contrast, Temporal Path Cover admits an XP time algorithm with respect to parameter $t_{\max} + tw$, where $t_{\max}$ is the maximum time-step and tw is the treewidth of the underlying static undirected graph; moreover, Temporally Disjoint Path Cover admits an FPT algorithm with respect to the same parameterization.

1 Introduction

A classic theorem of Dilworth from 1950 [14] states that in any partially ordered set (poset), the minimum number of chains required to cover all the elements is equal to the maximum size of an antichain. Dilworth's theorem is fundamental from the mathematical point of view; furthermore, an algorithmic proof (that enables to construct a chain cover and an antichain in polynomial time) was published by Fulkerson in 1956 [17]. This theorem and its algorithmic form have many applications, not only in combinatorics, but also in various fields such as bioinformatics [6], scheduling [32], databases [22], program testing [36], etc.

A collection $\mathcal{P}$ of (resp. pairwise vertex-disjoint) directed paths of a digraph D is a *path cover* (resp. *path partition*) of D if all vertices of D are contained in some path of $\mathcal{P}$. Dilworth's theorem can be restated in an equivalent form, equating the minimum cardinality of path covers on directed acyclic graphs (DAGs) and the maximum size of a set of pairwise "unreachable" vertices, or *antichain* vertices [4, 5, 16].

Fulkerson [17] showed that finding a minimum-size path cover of a DAG can be done in polynomial time. Moreover, by using similar methods, one can also find a minimum-size path *partition* in polynomial time for arbitrary DAGs (see [11, Probl. 26-2] or [15, Chapter 11.5]). Improving the best known algorithms for path cover and partitions of DAGs is still an active field of research, see for example [4, 5, 10, 28, 31] for some recent results.

The notions of directed paths and path covers naturally extends to *temporal (di)graphs*. Informally, the arc set of a temporal digraph changes over discrete time-steps and *labels* of an arc are the time-steps where the arc appears. Temporal (di)graphs have been extensively studied in the two last decades, with contributions from and applications to various fields, see [7, 21, 23, 34, 35, 37]. A *temporal path* of a digraph is a path that traverses edges appearing at strictly increasing time-steps. The asymmetric nature of temporal paths has motivated many recent algorithmic works on related reachability or path problems on temporal graphs, such as [1, 2, 3, 8, 24, 33].

Two temporal paths are *temporally disjoint* if they do not occupy a vertex at the same time-step. Motivated by applications in artificial intelligence, this definition was introduced by Klobas et al. [25] and has since then garnered some attention from the graph algorithmic community [29]. Even though the above notion was introduced in the context of temporal undirected graphs, it naturally extends to temporal digraphs and motivates the corresponding covering problems. The objective of Temporal Path Cover (resp. Temporally Disjoint Path Cover) is to cover an input temporal digraph by a minimum number of temporal paths (resp. temporally disjoint paths).

Main objectives. In this paper, we initiate the algorithmic study of Temporal Path Cover and Temporally Disjoint Path Cover and focus on *temporal directed acyclic graphs* (or simply, temporal DAGs). A temporal digraph is a *temporal DAG* if the union of all arcs across all time-steps induces a (static) DAG. We say that a temporal digraph satisfies the *Dilworth property* (resp. *temporally disjoint Dilworth property*, or *TD-Dilworth property* for short) if the largest size of a *temporal antichain* (understood as a set of pairwise temporally unreachable vertices) is equal to the smallest size of a temporal path cover (resp. temporally disjoint path cover). The main goals of this paper are the following:

(a) Determine classes of temporal DAGs satisfying the (TD-)Dilworth property.
(b) Study the computational complexities of Temporal Path Cover and Temporally Disjoint Path Cover on temporal digraphs.

Practical motivation. Similar to the problems studied by Klobas et al. [25], one natural application is *Multi-Agent Path Finding* (MAPF) [13, 40], which can be applied for example to crime prevention in transportation networks [44]. In this setting, k agents are assigned the task of surveying a location: collecting data, moving objects around, looking out for hazards, etc. When the changes over time are predictable (train network, irrigation periods in a field, departure and arrival of vehicles in a logistics area, blockades at given times in a post-disaster area, naturally occurring blockades such as tides, ...), the location is modeled as a temporal digraph. If the location digraph does not contain directed cycles, it is modeled by a temporal DAG (for example, if it is inherently directed from a start area towards a target area). The exploration path of an agent can be modeled by a temporal path. Now, Temporal Path Cover corresponds to the situation where the agents need to explore the whole location, while for Temporally Disjoint Path Cover, the agents also cannot be simultaneously at the same place, a scenario described as *vertex-conflicts* in the literature [39]. In both cases, we want to minimize the number k of agents.

Spatio-temporal security games [42, 43] are a natural example of applicability of MAPF. In these games, defenders want to protect spatially-located resources from attackers by covering them, and have to take time into account whenever they are moving (to be sure that the edges are available when they need to use them). In these games, the temporal dimension is generally represented by adding one layer of space per time-step. This representation induces a DAG, with as many vertices as the size of the initial graph multiplied by the number of time-steps. It seems natural to encode time through the more compact model of temporal graphs, which allows these games to be modeled by Temporal Path Cover and Temporally Disjoint Path Cover.

Our results. We begin by formally defining the problems studied in this paper.

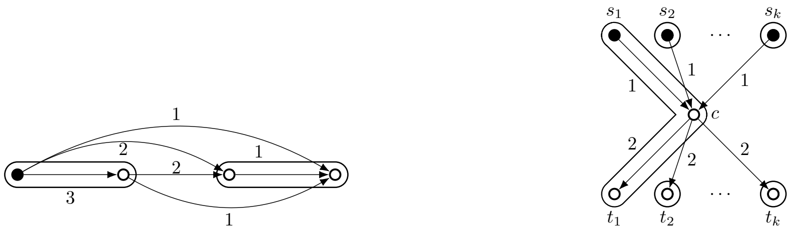
Temporal Path Cover (TPC)
Input: A temporal digraph D, an integer k.
Problem: Does there exist a set $\mathcal{C}$ of k temporal paths in D such that every vertex of D is covered by some path of $\mathcal{C}$?

Temporally Disjoint Path Cover (TD-PC)
Input: A temporal digraph D, an integer k.
Problem: Does there exist a set $\mathcal{C}$ of k temporally disjoint temporal paths in D such that every vertex of D is covered by some path of $\mathcal{C}$?

We observe that in general, temporal DAGs do not have the Dilworth property (see Figure 1a). Then, we prove the following negative result.

▶ **Theorem 1.** *Temporal Path Cover and Temporally Disjoint Path Cover are NP-hard on temporal DAGs, even if the input is planar, bipartite, subcubic, of girth 10, has only one time label per arc, and every label is either* 1 *or* 2*.*

A temporal DAG D is a *temporal oriented tree* if the underlying directed graph of D is a tree. On the positive side, we prove the following.



(a) A temporal DAG not having the Dilworth property.

(b) A temporal oriented tree not having the TD-Dilworth property.

Figure 1 Each encircled area is a path of a minimum-size (temporally disjoint) temporal path cover, vertices in a maximum-size temporal antichain are in black.

▶ **Theorem 2.** *There is an $\mathcal{O}(\ell n^2 + n^3)$-time algorithm for* Temporal Path Cover *on temporal oriented trees with n vertices and at most ℓ many labels per arc. Furthermore, temporal oriented trees satisfy the Dilworth property.*

We briefly describe the technique we use for proving Theorem 2. Two vertices of a temporal digraph are *temporally connected* if there exists a temporal path from one to the other. The *connectivity graph* of a temporal digraph D is an undirected (static) graph whose vertex set is the same as that of D, and whose edge set consists of all pairs of temporally connected vertices. To prove the above theorem, we show that the connectivity graph of a temporal oriented tree is a *weakly chordal graph* [19] (a subclass of *perfect graphs*). We show Temporal Path Cover can be reduced to Clique Cover on weakly chordal graphs. The above observation, combined with the Weak Perfect Graph Theorem (proved by Lovász [30]), proves that temporal oriented trees satisfy the Dilworth property. Moreover, the existing $\mathcal{O}(nm)$-time algorithm [20] to compute a minimum clique cover of a weakly chordal graph (having n vertices and m edges) completes the proof of Theorem 2. Our proof gives interesting structural information on the interaction between temporal paths in temporal oriented trees. Interestingly, another important class of perfect graphs plays an important role in connection with Dilworth's theorem and its translation to the setting of static DAGs: the class of comparability graphs, see [18, Chapter 5.7]. In our case, there does not appear to be any connection to comparability graphs.

On the other hand, temporal oriented trees do not satisfy the TD-Dilworth property (see Figure 1b for an example). Then, we prove the following negative result.

▶ **Theorem 3.** Temporally Disjoint Path Cover *is NP-hard on temporal oriented trees.*

To find classes that satisfy the TD-Dilworth property, we study *temporal oriented lines* (that is, where the underlying digraph is an oriented path) and *temporal rooted directed trees.* A tree is a *rooted directed tree* if it is an oriented tree with a single source vertex called the *root.* We prove the following result.

▶ **Theorem 4.** Temporal Path Cover *and* Temporally Disjoint Path Cover *can be solved in time:*
(a) *$\mathcal{O}(\ell n)$ on temporal oriented lines;*
(b) *$\mathcal{O}(\ell n^2)$ on temporal rooted directed trees;*
where ℓ is the maximum number of labels per arc and n is the number of vertices. Furthermore, both classes satisfy the TD-Dilworth property.

Note that some related problems remain NP-hard for temporal lines, such as Temporally Disjoint Walks [26]. Theorem 4(a) shows that this is not the case here. To prove

Table 1 Summary of our algorithmic results. For all polynomial-time solvable classes of temporal DAGs, we also show that the Dilworth property (or TD-Dilworth property for TD-PC) holds.

temporal graph class	TPC	TD-PC
temporal DAGs (planar bipartite subcubic, girth 10, two arc-disjoint time-steps)	NP-c.	NP-c.
temporal oriented trees	poly $\mathcal{O}(\ell n^2 + n^3)$	NP-c.
temporal rooted directed trees	poly $\mathcal{O}(\ell n^2)$	poly $\mathcal{O}(\ell n^2)$
temporal oriented lines	poly $\mathcal{O}(\ell n)$	poly $\mathcal{O}(\ell n)$
general temporal digraphs with bounded treewidth tw and number of time-steps $t_{\max}$	poly (XP w.r.t. tw and $t_{\max}$)	poly (FPT w.r.t. tw and $t_{\max}$)

Theorem 4(b), we begin by constructing a temporal path cover before transforming it into a temporally disjoint one of the same size. This is in contrast with general temporal oriented trees, for which, by Theorem 3, such an approach is not possible.

As Temporally Disjoint Path Cover is NP-hard even on temporal oriented trees and on temporal DAGs with two time-steps, a natural question is what happens when the number of time-steps is small *and* the underlying digraph is a tree. Motivated by this question, we study the case where both the number of time-steps and the treewidth of the underlying digraph are bounded (where we define the *treewidth* of a temporal digraph as the treewidth of the underlying static undirected graph). We show that both problems become tractable in this setting. More precisely, we give a fixed-parameter tractable (FPT) algorithm for Temporally Disjoint Path Cover with treewidth and number of time-steps as parameters. The same technique gives an XP algorithm for Temporal Path Cover.

▶ **Theorem 5.** *There is an algorithm for Temporally Disjoint Path Cover on general temporal digraphs that is FPT with respect to the treewidth of the underlying undirected graph and the maximum number of labels per arc. For Temporal Path Cover on general temporal digraphs, there is an XP algorithm for the same parameter.*

See Table 1 for a summary of our algorithmic results.

Further related work. Algorithms for solving several types of path and distance problems in temporal graphs have been developed, see for example [3, 24, 41]. Recently, the problem Temporally Disjoint Paths was introduced in [25], as a generalization of the notorious Disjoint Paths problem (also known as Linkage). In Temporally Disjoint Paths, one is given a temporal graph with k pairs of vertices called *terminals*, and the goal is to find a set of k pairwise temporally disjoint paths, each of them connecting one pair of terminals. Temporally Disjoint Paths is NP-hard, even for temporal lines and two paths [25] or temporal stars [29], but becomes FPT for trees when parameterized by the number of paths [25]. Algorithms that are FPT for certain structural parameters are given in [29].

Structure of the paper. We start with the hardness result for temporal DAGs (Theorem 1) in Section 3. We then prove our results for temporal oriented trees (Theorem 2 and Theorem 3) in Sections 4 and 5. We prove Theorem 4, the polynomial-time algorithms for special temporal oriented trees (temporal rooted directed trees and temporal oriented lines), in Section 6. We then prove our results for temporal digraphs of bounded treewidth and number of time-steps

(Theorem 5) in Section 7. We conclude in Section 8. Due to space constraints, proofs of propositions and lemmas marked with **(*)** are omitted here and can be found in the full version of the paper [9].

2 Preliminaries

A *temporal digraph* $\mathcal{D} = (V, A_1, \dots, A_{t_{\max}})$ is given by a sequence of arc-sets representing $t_{\max}$ discrete *time-steps* $\{1, \dots, t_{\max}\}$, where an arc in A_i is *active* at time-step i [25]. We denote by $D = (V, A)$, where $A = \cup_{i=1}^{t_{\max}} A_i$, the *underlying digraph* of $\mathcal{D}$ (sometimes called the *footprint (di)graph* [7]). Equivalently, one can view the time-steps as an arc-labelling function $\lambda : A(D) \to 2^{[t_{\max}]}$, where $\lambda(\overrightarrow{xy}) \subseteq [1, t_{\max}]$ is the set of time-steps where $\overrightarrow{xy}$ is active [24]. In that case, we denote the temporal digraph as $\mathcal{D} = (D, \lambda)$. We say that a temporal digraph has a given property $\mathcal{P}$ (planarity, given girth, ...) if the undirected graph obtained by forgetting the orientation of the arcs of its underlying digraph has property $\mathcal{P}$. Similarly, we call a temporal digraph a temporal DAG (resp. temporal oriented tree, temporal line, ...) if its underlying digraph is a DAG (resp. oriented tree, path, ...). For a given temporal digraph, we denote by ℓ the maximum number of labels per arc and by n the number of vertices in the underlying digraph.

For a (temporal) (di)graph $\mathcal{D}$ and subset S of its vertices (resp. edges), $\mathcal{D} \setminus S$ denotes the (temporal) (di)graph obtained by removing the vertices (resp. edges) in S from $\mathcal{D}$.

In a temporal digraph, a *temporal (directed) path* is a sequence $(v_1, v_2, t_1), (v_2, v_3, t_2), \dots,$ (v_{k-1}, v_k, t_{k-1}) such that for any i, j with $1 \leq i < j \leq k$, $v_i \neq v_j$ and for any i with $1 \leq i \leq k-1$, $t_i < t_{i+1}$ and there is an arc $\overrightarrow{v_i v_{i+1}}$ at time-step t_i. These paths are sometimes called *strict* in the literature.[1] For a temporal path $P = (v_1, v_2, t_1), \dots, (v_{k-1}, v_k, t_{k-1})$, we denote by $V(P)$ the set $\cup_{i=1}^{k} \{v_i\}$ and by $A(P)$ the set $\cup_{i=1}^{k-1} \{\overrightarrow{v_i v_{i+1}}\}$. Note that we allow a temporal path to contain exactly one vertex and no arc.

The *length* of a temporal path is the number of arcs it uses. We say that a temporal path $P = (v_1, v_2, t_1), \dots, (v_{k-1}, v_k, t_{k-1})$ *occupies* vertex v_i during the time interval $[t_{i-1}, t_i]$. Two temporal paths P_1, P_2 *temporally intersect* if there is a vertex $v \in V(P_1) \cap V(P_2)$ and two time intervals $[a_1, b_1], [a_2, b_2]$ where $[a_1, b_1] \cap [a_2, b_2] \neq \emptyset$ such that P_1 (resp. P_2) occupies v during $[a_1, b_1]$ (resp. $[a_2, b_2]$). Two temporal paths are *temporally disjoint* if they do not temporally intersect. In other words, they do not occupy the same vertex at the same time. A *temporal path cover* (resp. *temporally disjoint path cover*) of a temporal digraph D is a collection of temporal paths (resp. temporally disjoint paths) that cover all vertices of D. Two vertices are *temporally connected* in D if there exists a temporal path between them. A *temporal antichain* is a set of vertices that are pairwise not temporally connected.

▶ **Definition 6.** *A class $\mathcal{C}$ has the* Dilworth property *(resp.* TD-Dilworth property*) if, for every digraph $D \in \mathcal{C}$, the cardinality of a minimum temporal path cover (resp. temporally disjoint path cover) of D is equal to the maximum cardinality of a temporal anti-chain in D.*

A *hole* of a static undirected graph is an induced cycle of length at least 5, and an *anti-hole* is the complement of a hole. A hole or anti-hole is *even* (resp. *odd*) if it has an even (resp. odd) number of vertices. A graph G is *weakly chordal* if it has neither a hole nor an anti-hole. A *(minimum) clique cover* of a graph G is a (minimum cardinality) set of complete subgraphs of G that covers all vertices. A *(maximum) independent set* of a graph G is a (maximum cardinality) set of pairwise non-adjacent vertices. We shall use the following results for weakly chordal graphs.

[1] For non-strict paths, the condition $t_i < t_{i+1}$ is replaced with $t_i \leq t_{i+1}$; argued in [29], the strict definition is more natural for applications where an agent cannot traverse any number of arcs at once.

▶ **Theorem 7** ([20, 30, 38]). *Let H be a weakly chordal graph with n vertices and m edges. Then, a minimum clique cover of H can be found in $\mathcal{O}(nm)$-time. Furthermore, the maximum size of an independent set of H equals the minimum size of a clique cover of H.*

3 Temporal DAGs

We provide a reduction from a restricted variant of 3-Dimensional Matching to prove the following (proof deferred to the full version [9] due to space constraints).

▶ **Theorem 1.** *Temporal Path Cover and Temporally Disjoint Path Cover are NP-hard on temporal DAGs, even if the input is planar, bipartite, subcubic, of girth 10, has only one time label per arc, and every label is either 1 or 2.*

We also show the following.

▶ **Proposition 8** (*). *There are temporal DAGs (whose underlying digraph is a transitive tournament) that satisfy neither the Dilworth nor the TD-Dilworth property. Moreover, the ratio between the minimum-size temporal path cover and the maximum-size temporal antichain can be arbitrarily large.*

4 Temporal Path Cover on temporal oriented trees

In this section we prove the following theorem.

▶ **Theorem 2.** *There is an $\mathcal{O}(\ell n^2 + n^3)$-time algorithm for Temporal Path Cover on temporal oriented trees with n vertices and at most ℓ many labels per arc. Furthermore, temporal oriented trees satisfy the Dilworth property.*

For the rest of this section, $\mathcal{T} = (T, \lambda)$ shall denote a temporal oriented tree with n vertices and at most ℓ-many labels per edge. We construct the *connectivity graph of* $\mathcal{T}$, denoted by G, as follows: $V(G) = V(T)$ and $E(G) = \{uv \mid u \neq v \text{ and } u \text{ and } v \text{ are temporally connected}\}$. In other words, the connectivity graph of a temporal oriented tree connects vertices that are temporally connected. Observe that G can be constructed in $\mathcal{O}(\ell n^2)$-time. The next observation follows immediately from the definition.

▶ **Observation 9.** *A set S of vertices of $\mathcal{T}$ is a temporal antichain if and only if S induces an independent set in G.*

We have the following relationship between temporal paths in $\mathcal{T}$ and cliques in G.

▶ **Lemma 10.** *Let S be a set of vertices of $\mathcal{T}$. Then S is contained in a temporal path in $\mathcal{T}$ if and only if S is contained in a clique of G.*

Proof. Let S be contained in temporal path P in $\mathcal{T}$. Let $u_1, u_2, \ldots, u_k$ where $k = |S|$, be the ordering of the vertices in S as they are encountered while traversing P from the source to the sink. Notice that, for each $1 \leq i < j \leq k$, there is a temporal path from u_i to u_j. Therefore, u_i is adjacent to u_j in G. Hence, S is contained in a clique of G.

Let S be contained in a clique of G and S' be a maximal complete subgraph of G such that $S \subseteq V(S')$. Now, we orient the edges of S' to create a digraph $\overrightarrow{S'}$ as follows. For an edge $uv \in E(S')$, we introduce an arc $\overrightarrow{uv} \in A(\overrightarrow{S'})$ if there is a temporal path from u to v in $\mathcal{T}$. Since $\mathcal{T}$ is acyclic, $\overrightarrow{S'}$ is a transitive tournament. Hence, there is an ordering $u_1, u_2, \ldots, u_k$ of the vertices of S' where $k = |V(S')|$ such that for $1 \leq i < j \leq k$, there is a temporal path from u_i to u_j in $\mathcal{T}$. Now, consider any temporal path P from u_1 to u_k in $\mathcal{T}$. (P exists as $\overrightarrow{u_1u_k} \in A(\overrightarrow{S'})$. Since $\mathcal{T}$ is a temporal oriented tree, P will contain all vertices of S' and therefore of S. ◀

Following is an immediate corollary of the above.

▶ **Corollary 11.** *The minimum cardinality of a temporal path cover of $\mathcal{T}$ is equal to the minimum cardinality of a clique cover of G.*

We will often use the following lemma.

▶ **Lemma 12.** *Let $\{u, v, w, x\} \subseteq V(T)$ be four vertices such that there is a temporal path P_1 from u to v and a temporal path P_2 from w to x. If P_1 and P_2 have a vertex in common, then, there is a temporal path from u to x, or a temporal path from w to v, or both.*

Proof. Assume that there is no temporal path from u to x. Let y be the vertex of a temporal path from w to x that is closest to u in T. Let t be the smallest integer such that there is a temporal path from u to v that reaches y at time-step t. Observe that no temporal path from y to x can start at time-step $t' > t$ since, otherwise, there would be a temporal path from u to x. This implies that all temporal paths between w and x reach y at time-step $t'' \leq t$. Let P_1 be a temporal path from w to y which is also a subpath of a temporal path from w to x. Let P_2 be a temporal path from y to v which is also a subpath of a temporal path from u to v. The above arguments imply that the arc incident with y in P_1 has time-step at most t. Similarly, the arc incident with y in P_2 has time-step strictly greater than t. Hence, the concatenation of P_1 and P_2 is a temporal path in $\mathcal{T}$ from w to v. ◀

4.1 The case of holes

In this subsection, we will show that the connectivity graph G does not contain any holes. We use the following lemma.

▶ **Lemma 13.** *Let H be an induced cycle of length at least 4 in G. Then, for every vertex $v \in V(H)$ and every arc $\overrightarrow{a}$ of T incident with v, the vertices of $H \setminus \{v\}$ lie in the same weakly connected component of $T \setminus \{\overrightarrow{a}\}$.*

Proof. For the sake of contradiction, let there exist vertices $\{u, v, w\} \subseteq V(H)$ and an arc $\overrightarrow{a}$ of T incident with v such that u and w lie in two different connected components of $T' = T \setminus \{\overrightarrow{a}\}$. Let C_u and C_w be the sets of vertices of $H \setminus \{v\}$ contained in the same connected component as u and w, respectively. Since $H \setminus \{v\}$ is connected, there exist $u' \in C_u$ and $w' \in C_w$ such that $u'w' \in E(H)$ *i.e.* $u'w' \in E(G)$. Hence, there is a temporal path P from u' to w' or w' to u' in $\mathcal{T}$. Since T is a tree, P must contain v. Lemma 10 implies that $\{u', v, w'\}$ forms a subset of a clique in G, and therefore $\{u', v, w'\}$ forms a triangle. But this contradicts that H is a hole. ◀

Going forward, we need the following notations. For an edge $e = uv \in E(G)$, let Q_e denote a temporal path from u to v or v to u in $\mathcal{T}$. For an induced cycle H of length at least 4 in G, let T_H denote the smallest connected subtree of T containing all vertices of H. Lemma 13 implies that every vertex of H must be a leaf in T_H (that is, a vertex with degree 1 in the underlying undirected tree). For a vertex $v \in V(H)$, let $\overrightarrow{a}(v)$ be the arc incident with v in T_H. Let H be an induced cycle of length at least 4 in G. We can partition the vertex set of H into two sets $IN(H)$ and $OUT(H)$ as follows: a vertex $v \in V(H)$ is in

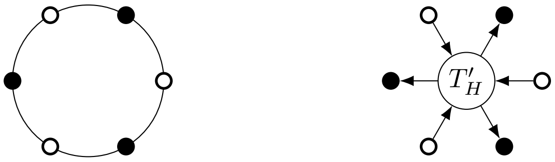


Figure 2 On the left, a hole H in the connectivity graph. On the right, its corresponding vertices in the oriented subtree T_H, with $T'_H = T_H \setminus V(H)$. Vertices in $IN(H)$ are in black.

$IN(H)$ if $\overrightarrow{a}(v)$ is directed towards v, and otherwise v is in $OUT(H)$ (see Figure 2 for an illustration of these definitions).

For a vertex $v \in IN(H)$, notice that both neighbors of v in H must lie in $OUT(H)$, and vice versa, since they must be connected by a directed path in T. Hence, H is bipartite, and therefore G does not contain any odd hole:

▶ **Lemma 14.** *The connectivity graph G does not contain any odd hole.*

Without loss of generality, we assume in the following that $OUT(H)$ (resp. $IN(H)$) contains every odd-indexed (resp. even-indexed) vertex of H. For an even hole H whose vertices are cyclically ordered as $u_1, u_2, \ldots, u_k$, we use a cyclic definition of addition, so $u_{k+1} = u_1$. We first prove the following lemmas.

▶ **Lemma 15.** *Let H be an even hole in the connectivity graph G. Then, for every i, $Q_{u_iu_{i+1}}$ and $Q_{u_{i+2}u_{i+3}}$ share a common vertex in T.*

Proof. Assume by contradiction that $Q_{u_iu_{i+1}}$ and $Q_{u_{i+2}u_{i+3}}$ are vertex-disjoint. Assume without loss of generality that $Q_{u_iu_{i+1}}$ goes from u_i to u_{i+1}. Note that, since each vertex of the hole is a leaf of T_H as a consequence of Lemma 13, the two paths $Q_{u_iu_{i+1}}$ and $Q_{u_{i+1}u_{i+2}}$ have to share a common vertex other than u_{i+1} (its neighbour in T_H). By the same reasoning, $Q_{u_{i+1}u_{i+2}}$ and $Q_{u_{i+2}u_{i+3}}$ share a common vertex other than u_{i+2}. Hence, since the three paths $Q_{u_iu_{i+1}}$, $Q_{u_{i+1}u_{i+2}}$ and $Q_{u_{i+2}u_{i+3}}$ are in T_H, and $Q_{u_iu_{i+1}}$ and $Q_{u_{i+2}u_{i+3}}$ are vertex-disjoint, there is an arc $\overrightarrow{a}$ contained in $Q_{u_{i+1}u_{i+2}}$ that separates $Q_{u_iu_{i+1}}$ and $Q_{u_{i+2}u_{i+3}}$.

Removing $\overrightarrow{a}$ from T partitions the vertices of H into two sets H_1 and H_2: H_1 (resp. H_2) contains the vertices of H that are in the same part of $T \setminus \overrightarrow{a}$ as u_{i+1} (resp. u_{i+2}). Now, since H is a cycle, there is an edge u_ju_{j+1} such that (without loss of generality) $u_j \in H_1$, $u_{j+1} \in H_2$ and $(j, j+1) \neq (i+1, i+2)$. This implies that the path $Q_{u_ju_{j+1}}$ has to use $\overrightarrow{a}$ in $\mathcal{T}$, and thus $Q_{u_{i+1}u_{i+2}}$ and $Q_{u_ju_{j+1}}$ share a common vertex. Hence, Lemma 12 implies that there is a temporal path from u_{j+1} to u_{i+1} or from u_{i+2} to u_j. However, since $j \neq i+3$ ($u_j \in H_1$ and $u_{i+3} \in H_2$) and $j+1 \neq i$ ($u_{j+1} \in H_2$ and $u_i \in H_1$), both temporal paths would induce a chord in H, a contradiction. ◀

▶ **Lemma 16.** *The connectivity graph G does not contain any hole of size 6.*

Proof. Assume by contradiction that there is a hole on six vertices $u_1, \ldots, u_6$. We know that $Q_{u_1u_2}$ and $Q_{u_4u_5}$ are vertex-disjoint (since otherwise, by Lemma 12, at least one of the chords u_1u_4 or u_2u_5 would exist). The u_i's are leaves of T_H, so $Q_{u_1u_2}$ and $Q_{u_1u_6}$, being paths with a common leaf in the same subtree, share at least one common vertex other than u_1 (its neighbour in T_H), let v be the last (with respect to the orientation of T) vertex in their common subpath. Now, $Q_{u_5u_6}$ has a common vertex with both $Q_{u_1u_2}$ (by Lemma 15) and $Q_{u_1u_6}$ (the neighbour of u_6 in T_H), so it has to contain v by the Helly property of subtrees of a tree. By the same reasoning, $Q_{u_4u_5}$ and $Q_{u_5u_6}$ share at least one common vertex other than u_5 (its neighbour in T_H), let w be the last vertex in their common subpath. The Helly property of subtrees of a tree again implies that both $Q_{u_2u_3}$ and $Q_{u_3u_4}$ have to contain w, since they pairwise intersect with $Q_{u_4u_5}$. But this means that $Q_{u_2u_3}$ and $Q_{u_5u_6}$ share both v and w as common vertices, and so by Lemma 12 there is at least one of the two chords u_2u_5 or u_3u_6, a contradiction. ◀

We can now prove that there is no even hole in G:

▶ **Lemma 17.** *The connectivity graph G does not contain any even hole.*

Proof. Assume by contradiction that G contains an even hole H on $k \geq 8$ vertices ($k = 6$ is impossible by Lemma 16). We know by Lemma 15 that both $Q_{u_3u_4}$ and $Q_{u_{k-1}u_k}$ intersect $Q_{u_1u_2}$, but do not intersect each other (otherwise, by Lemma 12, at least one of the edges u_3u_k or u_4u_{k-1} would exist, and both would be chords since $k \geq 8$), so there is an arc $\overrightarrow{a}$ in T that separates them. Removing $\overrightarrow{a}$ from T partitions the vertices of H into two sets H_1 and H_2: H_1 (resp. H_2) contains the vertices of H that are in the same part of $T \setminus \overrightarrow{a}$ as u_3 (resp. u_k). Now, since H is a cycle, there is an edge u_ju_{j+1} such that (without loss of generality) $u_j \in H_1$ and $u_{j+1} \in H_2$. This implies that the path $Q_{u_ju_{j+1}}$ has to use $\overrightarrow{a}$ in $\mathcal{T}$, and thus $Q_{u_1u_2}$ and $Q_{u_ju_{j+1}}$, both containing $\overrightarrow{a}$, share a common vertex. Hence, Lemma 12 implies that there is a temporal path from u_{j+1} to u_2 or from u_1 to u_j. However, since $j \neq k$ ($u_j \in H_1$ and $u_k \in H_2$) and $j + 1 \neq 3$ ($u_{j+1} \in H_2$ and $u_3 \in H_1$), by Lemma 12 both temporal paths would induce a chord in H, a contradiction. ◀

4.2 The case of anti-holes

In this subsection, we will show that the connectivity graph G does not contain any anti-hole. For an anti-hole H, let its vertices be circularly ordered as $u_1, u_2, \ldots, u_k$ as they are encountered while traversing the complement of H (which is a hole). Let $ODD(H)$ (resp. $EVEN(H)$) denote the set of vertices with odd (resp. even) indices.

▶ **Lemma 18.** *The connectivity graph G does not contain any anti-hole.*

Proof. Throughout this proof, recall that T is a tree, in particular, if two vertices are temporally connected, then there is a unique temporal path from one to the other. Assume by contradiction that G contains an anti-hole H with k vertices. If $k = 5$, then H is a hole, which contradicts Lemma 14; hence, assume $k \geq 6$.

When k is odd, let $F_1 = ODD(H) \setminus \{u_k\}, F_2 = EVEN(H)$. When k is even, let $F_1 = ODD(H), F_2 = EVEN(H)$. Observe that $|F_1| = |F_2| \geq 3$ and both sets induce (vertex-disjoint) cliques in G. By Lemma 10, there are temporal paths P_1 and P_2 in $\mathcal{T}$ containing F_1 and F_2, respectively, which we can assume are minimal vertex-inclusion-wise (so that, for each $i \in \{1, 2\}$, both end-vertices of P_i lie in F_i). For $i \in \{1, 2\}$, let v_i and w_i denote the source and sink of P_i, respectively. We have two cases.

Case 1: $V(P_1) \cap V(P_2) = \emptyset$. Let Q be the shortest temporal path that contains vertices from both P_1 and P_2 (note that, since every vertex in F_1 is temporally connected to at least one vertex in F_2, Q necessarily exists). Let p_1, p_2 be the end-vertices of Q that lie on P_1 and P_2, respectively. Since for each $i \in \{1, 2\}$ and $Z \in \{F_1, F_2\}$, $N_G(w_i) \cap Z \neq \emptyset$, Q is oriented from p_1 to p_2, or vice versa. Without loss of generality, assume that Q is oriented from p_2 to p_1. Then, necessarily $p_2 = w_2$, since otherwise w_2 is not temporally connected with any vertex of F_1, a contradiction. By a similar argument, we have $p_1 = v_1$. Now, consider the clique induced by $N_G(v_2) \cap F_1$. Due to Lemma 10, all vertices of $N_G(v_2) \cap F_1$ and v_2 itself are contained in a temporal path, which also necessarily contains w_2. Hence all of F_2 (P_2, even) is in a temporal path containing v_1, since the path has to go through v_1 to reach other vertices of F_1, and so $F_2 \cup \{v_1\}$ forms a clique. This is a contradiction as v_1 necessarily has at least one non-neighbor in F_2.

Case 2: $V(P_1) \cap V(P_2) \neq \emptyset$. Let Q denote the maximal vertex-inclusion-wise path that is common to both P_1 and P_2, *i.e.*, the path induced by the set $V(P_1) \cap V(P_2)$. Note that Q does not contain any vertex from H, since a vertex of H in Q would be temporally connected to every other vertex of $F_1 \cup F_2$, a contradiction. Let p denote source of Q and for each $i \in \{1, 2\}$ let Q_i (resp. Q'_i) be the subpath of P_i between p and w_i (resp. p and v_i).

Note that no vertex of $Q'_1 \setminus \{p\}$ can be in a directed path with any vertex of $Q'_2 \setminus \{p\}$. Similarly, no vertex of $Q_1 \setminus Q$ can be in a directed path with any vertex of $Q_2 \setminus Q$. Thus, the two subgraphs of the connectivity graph G induced by the vertices of $(V(Q_1) \cup V(Q_2)) \setminus V(Q)$ and $(V(Q'_1) \cup V(Q'_2)) \setminus \{p\}$ each induce the complement of a complete bipartite graph. As H does not contain any complement of a 4-cycle as an induced subgraph, this implies that there are exactly three vertices of H in each of these two subsets of vertices (since Q does not contain any vertex of H). In particular, H has size either 6 or 7.

Without loss of generality, we assume that Q'_1 contains only one vertex of H, which must be v_1. Thus, there are two vertices of H in Q'_2: v_2 and another vertex, say, v'_2. Since F_1 and F_2 both have size 3, the vertices of H in Q_1 are w_1 and (say) w'_1, and the only vertex of H in Q_2 is w_2. Now, observe that if v_2 is contained in a temporal path with w_1, then v_2, v'_2, w'_1 and w_1 are in a common temporal path. This is not possible, since in H, there is either one or two non-edges among these four vertices (depending on whether H has size 7 or 6). Thus, w_1 and v_2 are in no common temporal path. Since v_2 has no non-neighbour in H other than v_1 and w_1, v_2 and w'_1 are in a common temporal path, that also contains v'_2. Thus, $\{v_2, v'_2, w'_1\}$ form a clique in H. Similarly, $\{v'_2, w'_1, w_1\}$ also form a clique in H. If H had size 6, v'_2 and w'_1 would need to be non-neighbours in H (since w_1 already has two non-neighbours in H), a contradiction. Thus, H has size 7, and the two non-neighbours in H of u_7 (the vertex of H not in $F_1 \cup F_2$) are v'_2 and w'_1 (since they are the only ones without two non-neighbours in H). But u_7 has to be temporally connected to all of v_1, v_2, w_1 and w_2, so u_7 has to be in Q. But any temporal path from v_2 to a vertex of Q has to contain v'_2, and so u_7 and v'_2 are temporally connected, a contradiction. This completes the proof. ◀

4.3 Completion of the proof of Theorem 2

Lemmas 14, 17, and 18 imply that the connectivity graph of a temporal oriented tree is weakly chordal. Note that this cannot be strengthened to chordal, as there are temporal oriented trees whose connectivity graphs contain induced 4-cycles: let $\lambda(\overrightarrow{s_1c}) = \lambda(\overrightarrow{s_2c}) = 1$ and $\lambda(\overrightarrow{ct_1}) = \lambda(\overrightarrow{ct_2}) = 2$, the vertices s_1, t_1, s_2 and t_2 induce a C_4 in the connectivity graph. Corollary 11 implies the correspondence between a minimum temporal path cover of a temporal oriented tree and a minimum clique cover of the corresponding connectivity graph. We then conclude using Theorem 7 for the algorithm. Observation 9, Corollary 11 and Theorem 7 together give the Dilworth property.

5 Temporally Disjoint Path Cover on temporal oriented trees

We provide a reduction from Unary Bin Packing to prove the following (proof deferred to the full version [9] due to space constraints).

▶ **Theorem 3.** *Temporally Disjoint Path Cover is NP-hard on temporal oriented trees.*

We also show the following.

▶ **Proposition 19 (*).** *There are temporal oriented trees (whose underlying digraph is a star) that do not satisfy the TD-Dilworth property.*

6 Subclasses of temporal oriented trees

▶ **Theorem 4.** *Temporal Path Cover and Temporally Disjoint Path Cover can be solved in time:*

(a) *$\mathcal{O}(\ell n)$ on temporal oriented lines;*

(b) *$\mathcal{O}(\ell n^2)$ on temporal rooted directed trees;*

where ℓ is the maximum number of labels per arc and n is the number of vertices. Furthermore, both classes satisfy the TD-Dilworth property.

Proof. (a) Let $\mathcal{P} = (P, \lambda)$ be a temporal oriented line, and let v be a leaf of P. We construct $\mathcal{C}$ as follows. Assume that v is incident with an in-arc $\overrightarrow{uv}$. We construct a maximum-length temporal path that covers v. Set $(b, c) = (u, v)$, $\ell = \max \lambda(\overrightarrow{uv})$, and apply the following routine: while b is incident with an in-arc $\overrightarrow{ab}$, if there is a time label smaller than ℓ in $\lambda(\overrightarrow{ab})$, add $\overrightarrow{ab}$ to the path, update $(b, c) = (a, b)$ and $\ell = \max\{k \in \lambda(\overrightarrow{ab}) \mid k < \ell\}$. When the routine stops, add the path to $\mathcal{C}$, remove its vertices from P, and start again on a new leaf (or return $\mathcal{C}$ if P is empty). If v was incident with an out-arc, we would do the same but with out-arcs, start with the smallest possible time label, and update $\ell = \min\{k \in \lambda(\overrightarrow{ab}) \mid k > \ell\}$.

This algorithm computes its output in time $\mathcal{O}(\ell n)$: every arc is visited at most once, but we need to parse the time labels in order to see whether we can keep on extending the path or not. Furthermore, the set of leaves v where we start the routine are a temporal antichain: assume on the contrary that v_1 and v_2 are such vertices that are temporally connected, and assume without loss of generality that there is a path from v_1 to v_2 in the underlying oriented path; in this case, our algorithm would have added v_1 to the path that started being computed at v_2, a contradiction. Hence, $\mathcal{C}$ is a temporally disjoint path cover with the same size as a temporal antichain, proving that it is minimum-size and that temporal oriented lines satisfy the TD-Dilworth property.

(b) We give an algorithm that solves Temporal Path Cover on a temporal rooted directed tree $\mathcal{T} = (T, \lambda)$. First, we sort the vertices of T with respect to their topological distance from the root in T (with the highest distances first). Then, we construct a maximum-length temporal path covering the first uncovered vertex (which will be a sink of that path), and repeat until $\mathcal{T}$ is fully covered.

Note that this algorithm outputs $\mathcal{C}$ which is clearly a temporal path cover: every vertex is covered by some path of $\mathcal{C}$. Furthermore, it is an adaptation of the algorithm for temporal oriented lines: instead of successive leaves, we construct the paths from successive leaves with highest topological distance from the root. We will show that $\mathcal{C}$ is minimum-size, and later we will explain how to modify the algorithm in order to obtain a minimum-size temporally disjoint path cover.

Let S be the set of sinks of paths of $\mathcal{C}$. First, let v_i and v_j be two vertices of S (without loss of generality, assume that v_i was covered by the algorithm after v_j). They cannot be temporally connected, since otherwise, the graph being a temporal rooted directed tree, one of them is necessarily the predecessor of the other in a path from the root, and thus the maximum-length temporal path ending in v_j would necessarily contain v_i, since there is a temporal path from v_i to v_j, and thus v_i would have been covered at this step and cannot be in S. Hence, S is a temporal antichain. Furthermore, since $|\mathcal{C}| = |S|$, $\mathcal{C}$ is minimum-size and S is maximum-size, implying that temporal rooted directed trees satisfy the Dilworth property.

We now modify the algorithm to obtain a minimum-size temporally disjoint path cover. Indeed, we can see that the maximum-length temporal path construction, which is executed for every vertex of S, can re-cover some vertices that had already been covered at a previous step. Let v_i and v_j be two vertices of S such that their maximum-length temporal paths constructed by the algorithm P_i and P_j intersect. Since the graph is a temporal rooted directed tree, we can divide P_i and P_j into the following parts, without loss of generality: $P_i = P_i^{\text{top}} \cup (P_i \cap P_j) \cup P_i^{\text{bot}}$ and $P_j = (P_i \cap P_j) \cup P_j^{\text{bot}}$, where $P_i^{\text{top}} \cap P_j = P_i^{\text{bot}} \cap P_j = P_j^{\text{bot}} \cap P_i = \emptyset$ (note that we can have $P_i^{\text{top}} = \emptyset$). In other words, P_i^{top} (resp. P_i^{bot}) contains the vertices of $P_i \setminus P_j$ that are ancestors (resp. descendants) of $P_i \cap P_j$ in the underlying rooted tree, with the equivalent definition for P_j^{top} and P_j^{bot}. Hence, we can modify the algorithm by adding a loop that, for each such pair (P_i, P_j), defines these subpaths and then removes $P_i \cap P_j$ from P_j. Now, $\mathcal{C}$ will still be a temporal path cover, but the paths will be vertex-disjoint and thus temporally disjoint, and its size will not change. This implies that temporal rooted directed trees satisfy the TD-Dilworth property (contrasting the general temporal oriented trees), and thus the modified algorithm outputs the optimal solution for these two problems. The result of the algorithm and its modification is depicted in Figure 3.

Finally, one can check that the algorithm and its modification compute $\mathcal{C}$ in time $\mathcal{O}(\ell n^2)$. For each vertex in the antichain S, we have to construct the maximum-length temporal path. This can be done in time $\mathcal{O}(\ell n)$ by taking at every arc the largest label that allows to extend the path, thus we have to parse all the labels of every arc along the path, which can be of linear-size in the worst case. Since we can have a linear number of antichain vertices, we have a complexity of $\mathcal{O}(\ell n^2)$ to get the temporal path cover. The modification to make it temporally disjoint can be done in $\mathcal{O}(n^2)$ time afterwards, by considering all pairs of intersecting paths starting from the root. ◀

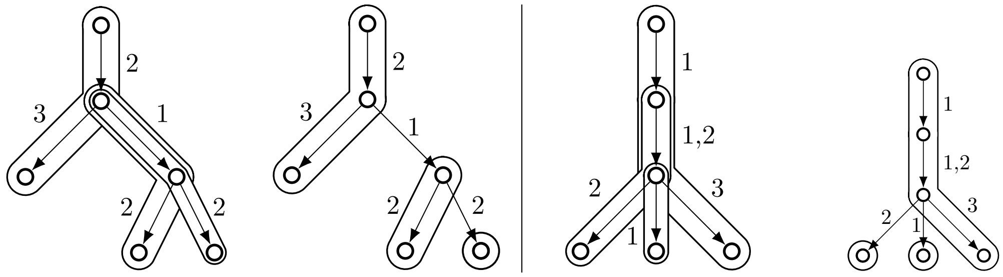

Figure 3 Minimum-size temporal path covers and temporally disjoint path covers of the same temporal rooted directed tree (on the left, with one label per arc; on the right, with any labels per arc), as computed by our algorithm and its modification in the proof of Theorem 4.

7 Algorithms for temporal digraphs of bounded treewidth

Recall that an algorithm is FPT with respect to some parameter k of the input, if it runs in time $f(k)n^{\mathcal{O}(1)}$ for inputs of size n, where f is any computable function; the algorithm is XP for this parameter if the running time is in $n^{f(k)}$ [12]. We prove the following theorem.

▶ **Theorem 5.** *There is an algorithm for* Temporally Disjoint Path Cover *on general temporal digraphs that is FPT with respect to the treewidth of the underlying undirected graph and the maximum number of labels per arc. For* Temporal Path Cover *on general temporal digraphs, there is an XP algorithm for the same parameter.*

Proof (sketch). To prove the theorem, we use the well-known concept of *nice tree decompositions* [27]. The algorithm is a classic bottom-up dynamic programming. To simplify the algorithm, we replace each arc by a set of parallel arcs, each of them with a distinct time-label. This makes it easier to deal with temporally disjoint paths, as in this representation, one arc cannot be used in two solution paths (for Temporally Disjoint Path Cover).

To give the intuition behind the algorithm, we informally describe the states of the dynamic programming. For a bag $X_v \subseteq V(G)$ corresponding to a node v of the tree decomposition, every state corresponds to a distinct way a potential solution interacts with X_v. Primarily, it consists of a set of (solution) subpaths that cover the vertices in X_v. Each subpath may consist of several disconnected parts (possibly, a part may have only one vertex). The order in which the vertices of each solution path appear is also specified. We also store the information, for every vertex, whether it is connected via an arc to one vertex (or two vertices) in its solution path, but lying outside the bag X_v, and whether this vertex lies in a lower (already handled) or upper (to be handled) part of the tree decomposition.

We show that this information is enough to encode a partial solution, and as there are at most $p = \binom{\text{tw}}{2} \cdot t_{\max}$ arcs in each bag, we deduce that the maximum possible number of states for a bag is at most $2^{O(p \log p)}$ in the case of Temporally Disjoint Path Cover (since every arc may appear in at most one solution path) and $n^{O(p \log p)}$ in the case of Temporal Path Cover (since a specific subpath may appear in any number of solution paths, so we must also encode the number of appearances of each subpath). The running times are essentially dominated by these functions.

Due to space constraints, the details are deferred to the full version [9]. ◀

8 Conclusion

We have initiated the study of two natural path covering problems in temporal DAGs, which, in the static case, are related to Dilworth's theorem and are polynomial-time solvable. Both problems become NP-hard for temporal DAGs, even in a very restricted setting. Interestingly, and somewhat unexpectedly, they behave differently on temporal oriented trees: we showed that Temporal Path Cover is polynomial-time solvable on temporal oriented trees (and a temporal version of Dilworth's theorem holds in this setting), while Temporally Disjoint Path Cover remains NP-hard for this class. On the other hand, this distinction is inverted in the parameterized case, where we obtained an FPT algorithm for Temporally Disjoint Path Cover but an XP algorithm for Temporal Path Cover. However, we do not know if our algorithms for treewidth and number of time-steps are optimal. In particular, can we obtain an FPT algorithm for Temporal Path Cover for this parameter? One could also explore other (structural) parameterizations of the problems.

To prove our polynomial-time algorithm for Temporal Path Cover on temporal oriented trees, we have reduced the problem to Clique Cover in a static undirected graph, which turns out to be weakly chordal. This is a powerful technique, and the correspondence between the two problems is quite enlightening for the structure of temporal paths in an oriented tree. Nevertheless, it seems unlikely that this particular technique can be used on temporal digraph classes that are far from trees, as it was essential for the proof that any two vertices are joined by only one path in the underlying tree. However, this general technique could likely be applied in other temporal settings.

We note that many of our results for Temporally Disjoint Path Cover also hold for its stricter vertex-disjoint version (note that a vertex-disjoint version of Temporally Disjoint Paths is studied in [24]), in particular, the NP-hardness result for restricted DAGs and the polynomial-time algorithms for rooted directed trees and oriented lines.

Abstract

Given a graph G, an *isometric path cover* of a graph is a set of isometric paths that collectively contain all vertices of G. An isometric path cover $\mathcal{C}$ of a graph G is also an *isometric path partition* if no vertex lies in two paths in $\mathcal{C}$. Given a graph G, and an integer k, the objective of Isometric Path Cover (resp. Isometric Path Partition) is to decide whether G has an isometric path cover (resp. partition) of cardinality k.

In this paper, we show that Isometric Path Partition is NP-complete even on split graphs, *i.e.* graphs whose vertex set can be partitioned into a clique and an independent set. In contrast, we show that both Isometric Path Cover and Isometric Path Partition admit polynomial time algorithms on cographs (graphs with no induced P_4) and chain graphs (bipartite graphs with no induced $2K_2$).

1 Introduction and results

Finding paths in graphs is of fundamental interest to the algorithmic graph theory community. An example is the Path Cover where the objective is to decide whether the vertex set of a graph can be covered by at most k paths. This problem is NP-hard even if $k = 1$ which is equivalent to Hamiltonian Path. Recently, researchers have studied the problem of covering graphs with *isometric paths* i.e. shortest path between its end-vertices. Given a graph G, an *isometric path cover* of a graph is a set of isometric paths that collectively contain all vertices of G. An isometric path cover $\mathcal{C}$ of a graph G is also an *isometric path partition* if no vertex lies in two paths in $\mathcal{C}$. Given a graph G, and an integer k, the objective of Isometric Path Cover (resp. Isometric Path Partition) is to decide whether G has an isometric path cover (resp. partition) of cardinality at most k. Besides algorithmic graph theory, Isometric Path Cover has been studied in different contexts like machine learning [14], combinatorial games [1] etc.

Despite being a natural covering problem, the algorithmic complexity of Isometric Path Cover has thus far remained mostly unexplored. Isometric Path Cover and Isometric Path Partition have been proven to be NP-hard in *chordal* graphs (i.e. graphs without induced cycles of order four or higher) and bipartite graphs of diameter 4 [5, 8]. Parameterized complexity of Isometric Path Cover has been studied with respect to various parameters like solution size, neighbourhood diversity, etc [7, 8]. Approximability of Isometric Path Cover has also been studied [4, 5]. It was shown that Isometric Path Cover admits constant factor approximation algorithms on graph classes like chordal graphs and more generally on graphs with bounded treelength and bounded hyperbolicity, outerstring graphs, universally-signable graphs and more generally on (theta, pyrmaid, prism)-free graphs [4, 5]. It was also shown that Isometric Path Cover admits $O(\log n)$-approximation algorithm on general graphs [14]. On the other hand, polynomial time solvability of Isometric Path Cover is only known for special graph classes such as block graphs [12] which is a subclass of chordal graphs. This motivated us to study the computational complexities of Isometric Path Cover and Isometric Path Partition on *split* graphs which is a popular subclass of chordal graphs.

A graph is a *split* graph if the vertex set can be partitioned into a clique C and an independent set I. In this paper, we prove that the Isometric Path Partition problem remains NP-hard on split graphs answering an open question in the literature [5]

▶ **Theorem 1.** *Isometric Path Partition is* NP*-hard on split graphs.*

Our reduction techniques deviate significantly from the known ones which typically reduce the problem of partitioning a graph into induced P_k (for appropriately chosen k, also known as Induced P_k Partition) by adding few vertices of large degree, so that a path in the reduced graph is isometric if and only if it was an induced P_k in the original graph. However, one difficulty in applying this technique is that the complexity of Induced P_k Partition for $k \in \{3, 4\}$ on split graphs is not known. The problems of partitioning split graphs into (non-induced) P_3's can be solved in polynomial time [15] by reducing it to finding a maximum matching in some auxiliary graph.

We reduce from the NP-complete problem 3-XSAT [13] where the input is a CNF formula that has exactly 3 positive literals in every clause and every variable occurs exactly 3 times, and the objective is to decide if there is an assignment that satisfies exactly one literal from every clause. As a biproduct of our proof, we also get the following corollary. Isometric $P_{\geq t}$ Partition denotes the problem of partitioning the vertex set of a graph into isometric paths with at least t vertices.

▶ **Corollary 2.** *For $t \leq 3$, Isometric $P_{\geq t}$ Partition is* NP*-hard on split graphs.*

We note that the computational complexity of Isometric Path Cover on split graphs remains open. Theorem 1 motivates the study of Isometric Path Partition on natural subclasses of split graphs. *Threshold* graphs, the class of split graphs without an induced P_4, is one of the well-studied subclass of split graphs [11]. We show that both Isometric Path Cover and Isometric Path Partition admit polynomial-time algorithms on threshold graphs. In fact, we prove the following more general result. Cographs were introduced in [6] and are exactly the class of graphs with no induced P_4.

▶ **Theorem 3.** *Isometric Path Cover and Isometric Path Partition admit polynomial time algorithms on cographs.*

Our algorithm for Isometric Path Partition on cographs is based on dynamic programming on *cotrees* [6], which also characterise cographs. The class of cographs contains the class of threshold graphs, which are exactly the class of split graphs whose vertices in the independent set can be linearly ordered under inclusion of their open neighbourhoods. We note that designing algorithms for cographs is a popular direction of research in algorithmic graph theory [2, 3, 9, 10].

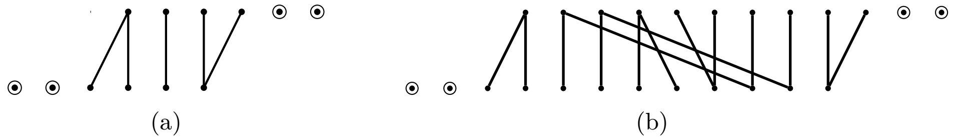

Figure 1 Normal forms of optimal solutions for Isometric Path Partition on chain graphs. Connected components or marked vertices indicate isometric paths in the solution.

Motivated by the success on cographs we then consider the class of *chain* graphs, the bipartite analogue of threshold graphs. A chain graph is a bipartite graph such that the vertices of each color class can be linearly ordered under inclusion of their open neighbourhoods. We show the following result:

▶ **Theorem 4.** *Isometric Path Cover and Isometric Path Partition admit polynomial time algorithms on chain graphs.*

Note that a path in a chain graph or a cograph is an isometric path if and only if it is induced. Due to Theorems 3 and 4, we have the following corollary.

▶ **Corollary 5.** *Induced Path Partition and Induced Path Cover admit polynomial time algorithms on cographs and chain graphs.*

Our algorithm for Isometric Path Partition on chain graphs is based on the observation that any (optimal) solution can be converted into one of three *normal forms*, two of which are illustrated in Figure 1 and where the induced paths can be thought of (roughly) as following the ordering of the vertices according to the neighbourhood inclusion relation. Obtaining the normal forms is also the main challenge behind the algorithm as it turned out to be surprising difficult to find the right order of operations required to transform any solution into one of these normal forms without sacrificing previously made progress. Once the normal form is obtained, however, Isometric Path Partition can be solved via a simple brute-force algorithm that guesses the important positions of a solution in normal form. Finally, a simple reduction from Isometric Path Cover to Isometric Path Partition on chain graphs then allows us to obtain the polynomial-time algorithm for Isometric Path Cover on chain graphs.

Structure of the paper. In Section 2 we introduce some definitions. In Section 3 and Section 4 we prove Theorems 3 and 4 respectively. In Section 5 we prove Theorem 1.

Statements whose full proofs are omitted due to space constraints can be found in the full version.

2 Preliminaries

All graphs considered here are finite, simple, and undirected. That is, a *graph* $G = (V, E)$ consists of a finite set V of *vertices* and a set $E \subseteq V^{(2)}$ of *edges*, where $V^{(2)}$ is the set of 2-element subsets of V. An edge $\{u, v\}$ will also be written as uv. The graph $H = (U, F)$ is a *subgraph* of $G = (V, E)$ if $U \subseteq V$ and $F \subseteq E$. The subgraph H is *induced* if $F = E \cap U^{(2)}$, denoted as $H = G[U]$. The *neighbourhood* $N_G(v)$, or simply $N(v)$ if G is clear from the context, of a vertex $v \in V$ in graph G is $\{u \mid uv \in E\}$. Moreover, for a subset V' of vertices, we denote by $N_G(V')$ the set $\bigcup_{v \in V'} N_G(v)$.

A *path* in G is a subgraph $P = (U, F)$ with $U = \{u_i \mid 0 \leq i \leq l\}$ and $F = \{u_{i-1}u_i \mid 1 \leq i \leq l\}$. We usually refer to P by the sequence $(u_0, u_1, u_2, \ldots, u_l)$. The *length* of this path is l, the number of edges in P.

The *distance* between two vertices u and v of G is the length of a shortest path between u and v. It is denoted by $d_G(u, v)$. A path $P = (u, \ldots, v)$ is *isometric* if $d_G(u, v) = d_P(u, v)$. Every isometric path is an induced path, and induced paths of length at most two are isometric.

3 Algorithms for Chain Graphs

Here, we provide our algorithms for Isometric Path Partition and Isometric Path Cover on chain graphs. A bipartite graph $G = (T, B, E)$ is a *chain graph* if, for every pair of vertices $v, u \in T$ or $v, u \in B$, we have $N(v) \subseteq N(u)$ or $N(v) \supseteq N(u)$, respectively; see also [16]. This implies an ordering $<$ of the vertices in T and the vertices in B such that $u < v$ if $N_G(u) \subseteq N_G(v)$. For convinience and by resolving ties arbitrarily, we will assume that $<$ is a total ordering on T and on B.

The main step of our proofingredient and the main challenge for the algorithms is to show that any solution to Isometric Path Partition on a chain graph can be transformed into an equally-sized solution that follows a certain normal form (Section 3.1). Assuming this normal form, then essentially allows us to solve Isometric Path Partition in polynomial-time via a brute-force approach (Section 3.2). Finally, our polynomial-time algorithm for Isometric Path Cover then uses a simple reduction from Isometric Path Cover to Isometric Path Partition (Section 3.2).

3.1 Normal Form

In this subsection we introduce our normal form for solutions to Isometric Path Partition on chain graphs and show that there is always an optimal solution adhering to this normal form. We start by introducing some important notation.

Let $G = (T, B, E)$ be a chain graph and let $\mathcal{P}$ be a set of isometric paths. A pattern can be thought of as a string over the symbols ∘, Λ, I, V, N, and ˚, where it is possible for symbols to overlap with each other; such as in NΛ or NV, which consists of two overlapping symbols N and Λ respectively N and V. We also allow special symbols to indicate that a symbol is repeated arbitrary many times, e.g., $\overset{*}{\circ}$, $\overset{*}{Λ}$, $\overset{*}{V}$, and $\overset{*}{˚}$ represent arbitrary many (non-crossing) ∘'s, Λ's, V's, and ˚'s, respectively. Moreover, ⌈-NN-⌋ represents arbitrary many N's that are pairwise in pattern ⌈NN⌋, e.g., ⌈NNNNN⌋ is an element of ⌈-NN-⌋.

We say that $\mathcal{P}$ *has pattern* α if the drawing of all paths in $\mathcal{P}$, *i.e.*, the drawing obtained by drawing all vertices in T from right to left in the order $<$ on top of all vertices in B drawn according to $<$ from left to right, looks like α. For instance, if $P \in \mathcal{P}$ is a single path, then P has pattern ∘, Λ, I, V, N, or ˚, if $|V(P) \cap T| = 0$ and $|V(P) \cap B| = 1$, $|V(P) \cap T| = 1$ and $|V(P) \cap B| = 2$, $|V(P) \cap T| = 1$ and $|V(P) \cap B| = 1$, $|V(P) \cap T| = 2$ and $|V(P) \cap B| = 1$, $|V(P) \cap T| = 2$ and $|V(P) \cap B| = 2$, or $|V(P) \cap T| = 1$ and $|V(P) \cap B| = 0$, respectively. Alternatively, we also say that P *is an α-path*, if P has pattern α. We denote by $\mathcal{P}_\alpha$ the set of all α-paths in $\mathcal{P}$ and we denote by $\mathcal{P}_\circ$ the set $\mathcal{P}_{{}_\circ} \cup \mathcal{P}^{\circ}$. Observe that since G is a chain graph every path in $\mathcal{P}$ is either a ∘-path, a Λ-path, an I-path, a V-path, a N-path, or a ˚-path.

We say that a path $P \in \mathcal{P}$ is *before (or to the left)* of a path $P' \in \mathcal{P}$ if $b < b'$ for every $b \in V(P) \cap B$ and $b' \in V(P') \cap B$ and moreover $t > t'$ for every $t \in V(P) \cap T$ and $t' \in V(P') \cap T$. We say that P is *after (or to the right of P')* if P' is before P. We say that P and P' *cross* if P is neither before nor after P'.

The main aim of this section is to show the following theorem.

▶ **Theorem 6.** *Let $G = (T, B, E)$ be a chain graph. G has an optimal isometric path partition that has one of the following patterns:*

(1) $\circ^*\wedge^*\vee^*{}^{\circ*}$, *i.e., any number of* ∘*-paths, followed by any number of* ∧*-paths, followed by any number of* ∨*-paths, followed by any number of* °*-paths,*

(2) $\circ^*\wedge^*\mathsf{I}\vee^*{}^{\circ*}$, *i.e., same as (1) but with exactly one* I*-path in the center,*

(3) $\circ^*\wedge^*\ulcorner\text{-}(\mathsf{N}\wedge^*\vee^*)\text{-}\urcorner\vee^*{}^{\circ*}$, *i.e., same as (2) but with the* I*-path replaced by any number of* ∧*-paths,* ∨*-paths, and* N*-paths such that every pair of those paths has one of the following patterns* ∧.∧, ∨.∨, ∧.∨, N∧, N∨, *or* NN.

Towards showing Theorem 6, we will introduce various intermediate normal forms and we will then show that a solution can be transformed step-by-step into more and more restrictive normal forms. Let $G = (T, B, E)$ be a chain graph and $\mathcal{P}$ be an isometric path partition of G. Most of our normal forms are based on the correct relationships between pairs of paths in $\mathcal{P}$. In particular, we say that two distinct paths P and P' in $\mathcal{P}$ are in *normal position* if either:

(1) If P or P' is a ∘-path, then $\{P, P'\}$ has pattern ∘∘, ∘∧, ∘∨, ∘N, or ∘°. In other words, all ∘-paths are to the left of all other paths in $\mathcal{P}$.

(2) If P or P' is a °-path, then $\{P, P'\}$ has pattern ∘°, ∧°, ∨°, N°, or °°. In other words, all °-paths are to the right of all other paths in $\mathcal{P}$.

(3) If P is a I-path and P' is a ∧-path (∨-path), then $\{P, P'\}$ has pattern ∧I (I∨). In other words, all I-paths are to the right of all ∧-paths and to the left of all ∨-paths in $\mathcal{P}$.

(4) If both P and P' are ∧-paths, then $\{P, P'\}$ has pattern ∧.∧. In other words, no two ∧-paths in $\mathcal{P}$ cross each other.

(5) If both P and P' are ∨-paths, then $\{P, P'\}$ has pattern ∨.∨. In other words, no two ∨-paths in $\mathcal{P}$ cross each other.

(6) If both P and P' are N-paths, then $\{P, P'\}$ has pattern NN.

(7) If P is a N-path and P' is a ∧-path (∨-path), then $\{P, P'\}$ has pattern ∧.N or N∧ (N.∨ or N∨).

(8) If P is a ∧-path and P' is a ∨-path, then $\{P, P'\}$ has pattern ∧.∨.

We say that $\mathcal{P}$ satisfies (i), $i \in [8]$, if condition (i) holds for every two distinct paths P and P' in $\mathcal{P}$. We are now ready to define our normal forms.

▶ **Definition 7.** *Let $\mathcal{P}$ be an isometric path partition of a chain graph G.*

- *We say that $\mathcal{P}$ is* NI-minimal *if either $\mathcal{P}_{\mathsf{N}} = \emptyset$ and $|\mathcal{P}_{\mathsf{I}}| \leq 1$ or $\mathcal{P}_{\mathsf{N}} \neq \emptyset$ and $\mathcal{P}_{\mathsf{I}} = \emptyset$.*
- *We say that $\mathcal{P}$ is in* S-normal form *if $\mathcal{P}$ is NI-minimal and $\mathcal{P}$ satisfies (1) and (2).*
- *We say that $\mathcal{P}$ is in* I-normal form, A-normal form, V-normal form, *or* N-normal form *if $\mathcal{P}$ satisfies (3), (4), (5), or (6), respectively.*
- *We say that $\mathcal{P}$ is in* mixed normal form *if $\mathcal{P}$ is in S-normal form and additionally $\mathcal{P}$ satisfies (7) and (8).*
- *We say that $\mathcal{P}$ is in* pair-normal form *if $\mathcal{P}$ is in mixed normal form, in I-normal form, in A-normal form, in V-normal form, and in N-normal form.*

All normal forms given above are purely defined in terms of restrictions on the relationships between pairs of paths in an isometric path partition. However, to obtain a normal form for the pattern given in Theorem 6 (3), we need to additionally put restrictions on the patterns allowed for triples of isometric paths. We say that $\mathcal{P}$ is in *AN-normal form* if there are no distinct $P_A \in \mathcal{P}_{\wedge}$, $P_N, P'_N \in \mathcal{P}_{\mathsf{N}}$ such that $\{P_N, P_A\}$ has pattern N∧ and $\{P'_N, P_A\}$ has pattern ∧.N. In other words, for every $P_A \in \mathcal{P}_{\wedge}$ it holds that either $\{P_A, P_N\}$ has pattern ∧.N for every $P_N \in \mathcal{P}_{\mathsf{N}}$ or $\{P_A, P_N\}$ has pattern N∧ for every $P_N \in \mathcal{P}_{\mathsf{N}}$. Similarily, we say that $\mathcal{P}$ is in

NV-normal form if and there are no distinct $P_V \in \mathcal{P}_{\mathsf{V}}$, $P_N, P'_N \in \mathcal{P}_{\mathsf{N}}$ such that $\{P_N, P_V\}$ has pattern N̸V and $\{P'_N, P_V\}$ has pattern NV. Finally, we say that $\mathcal{P}$ is in *normal form* if $\mathcal{P}$ is in pair-normal form, AN-normal form, and in NV-normal form.

Observe that any isometric path partition in normal form has one of the three patterns given in Theorem 6. To show Theorem 6, it therefore suffices to show the following.

▶ **Theorem 8** (⋆). *Let $G = (T, B, E)$ be a chain graph. There is an optimal isometric path partition of G in normal form.*

The main challenge for proving Theorem 8, whose proof turned out to be surprisingly difficult, is to define the right operations and to apply them in the right order to obtain more and more restricted normal forms while maintaining the progress already made. In particular, after defining the required operations, we will show how to obtain normal form in the following order: S-normal form, mixed normal form, I-normal form, A-normal form, N-normal form, V-normal form, AN-normal form, and finally NV-normal form.

We say that a pattern α implies a pattern β (denoted by $\alpha \to \beta$) if for any chain graph that contains a set $\mathcal{P}$ of pairwise disjoint isometric paths with pattern α there is a set $\mathcal{P}'$ of pairwise disjoint isometric paths with pattern β such that $V(\mathcal{P}) = V(\mathcal{P}')$. (Here $V(\mathcal{P})$ is the set of vertices covered by the paths in $\mathcal{P}$.) For a set Δ of patterns we write $\Delta \to \beta$ if $\delta \to \beta$ for every $\delta \in \Delta$.

For a pattern α, we denote by $\alpha^{\curvearrowright}$ the pattern obtained from α after rotating α by 180° degrees around the center of the pattern. For instance, Λ̸N$^{\curvearrowright}$ = N̸V, ΛN$^{\curvearrowright}$ = NV, ΛV$^{\curvearrowright}$ = ΛV, ΛI$^{\curvearrowright}$ = IV, and $\alpha = \alpha^{\curvearrowright\curvearrowright}$. Moreover, for a set of patterns Δ, we define $\Delta^{\curvearrowright}$ as $\{\, \delta^{\curvearrowright} \mid \delta \in \Delta \,\}$. The following observation is very useful to reduce the number of cases that have to be considered in the proofs and follows easily from the symmetry of chain graphs w.r.t. rotation by 180° degree around the center.

▶ **Observation 9.** *Let α and β be patterns. Then $\alpha \to \beta$ implies $\alpha^{\curvearrowright} \to \beta^{\curvearrowright}$.*

We say that a pattern α is *valid* if there is a set of pairwise disjoint isometric paths in some chain graph with pattern α. For a pattern α, we denote by $[\alpha]$, the set of all valid patterns that can be obtained from α after reordering the endpoints of the lines on the top and/or on the bottom of the pattern α in an arbitrary manner. For instance, [N∘] = {N∘, N̥, ∘N} and [ΛI] = {Λ\, /X, X, X, X\, /Λ}. Note that [N] does not contain any pattern where the lines of the N cross each other because those patterns are not valid.

The following auxiliary lemma provides the most important production rules on patterns that we will use to transform an arbitrary solution into a solution in normal form.

▶ **Lemma 10** (⋆). *The following holds:*

(a) [∘∘] → ∘∘ *and* [°°] → °°,

(b) [∘°] → ∘°,

(c) [∘I] → ∘I *and* [I°] → I°,

(d) [∘Λ] → ∘Λ *and* [V°] → V°,

(e) [Λ°] ∪ [II] → Λ° *and* [∘V] ∪ [II] → ∘V,

(f) [ΛI] ∪ [∘N] \ {∘N} → ΛI *and* [IV] ∪ [N°] \ {N°} → IV,

(g) [ΛΛ] → ΛΛ *and* [VV] → VV,

(h) [ΛV] ∪ [NI] → ΛV,

(i) [ΛN] \ {ΛN} → Λ̸N *and* [NV] \ {NV} → N̸V,

Sketch. (a) and (b) follow immediately because [∘∘] = {∘∘}, [⁚] = {⁚}, and [∘˚] = {∘˚}.

Let $G = (T, B, E)$ be a chain graph and let P and P' be two isometric paths in G. Let $(V(P) \cup V(P')) \cap T = \{t_1, \ldots, t_c\}$ and $(V(P) \cup V(P')) \cap B = \{b_1, \ldots, b_d\}$ such that $t_1 > \cdots > t_c$ and $b_1 < \cdots < b_d$.

Towards showing (e), assume that $\{P, P'\}$ has pattern α for some $\alpha \in$ [Λ˚] ∪ [‖]. Then, $c = 2$, $d = 2$ and b_1 must have degree at least 1 in G. Therefore, because $N_G(t_2) \subseteq N_G(t_1)$, it follows that $b_1 t_1 \in E(G)$, which in turn implies that $b_2 t_1 \in E(G)$ since $N_G(b_1) \subseteq N_G(b_2)$. Therefore, $\{(b_1, t_1, b_2), (t_2)\}$ is a pair of isometric paths with pattern Λ˚, as required. Because of Observation 9, we also obtain [∘V] ∪ [‖] → ∘V. The remaining cases can be shown in an analogous manner. ◀

The remainder of this subsection is about showing that there are optimal solutions that have more and more restrictive normal forms. As an illustrative example we show next how to obtain a mixed normal form from a solution in S-normal form. We start by stating the lemma required to obtain a S-normal form.

▶ **Lemma 11** (⋆). *Let $G = (T, B, E)$ be a chain graph. There is an optimal isometric path partition $\mathcal{P}$ which is in S-normal form.*

Building upon S-normal form, the following lemma now shows that we can achieve mixed normal form. The proof of the lemma is based on an exhaustive application of certain production rules from Lemma 10 combined with a potential function approach for showing that this process terminates.

▶ **Lemma 12** (⋆). *Let $G = (T, B, E)$ be a chain graph. There is an optimal isometric path partition of G in mixed normal form.*

Sketch. Let $G = (T, B, E)$ be a chain graph and let $\mathcal{P}$ be an optimal isometric path partition of G. Because of Lemma 11, we can assume that $\mathcal{P}$ is in S-normal form.

Let $\mathcal{P}'$ be the isometric path partition of G obtained from $\mathcal{P}$ after exhaustively applying the following transformation rules from Lemma 10:

(1) [ΛV] → ΛV,
(2) [ΛN] \ {ΛN} → NΛN, and
(3) [NV] \ {NV} → NVN,

Observe that if $\mathcal{P}'$ exists, then it trivially satisfies all the claims made in the statement of the lemma. It therefore suffices to show the existence of $\mathcal{P}'$ or in other words that the above rules can only be applied finitely often to $\mathcal{P}$.

Towards showing this we will define a potential function Φ that assigns a two dimensional vector of natural numbers to every isometric path partition of G. For the definition of Φ, we need the following additional notation. For two vertices u and v of G such that either $u, v \in B$ or $u, v \in T$, we denote by $[u, v]_G$ the set $\{u, v\} \cup \{\, w \mid u < w < v \,\}$ of vertices of G.

For a path $P = (p_1, p_2, p_3, p_4) \in \mathcal{P}_{\mathsf{N}}$, we denote by $W_G(P)$ the integer $|[p_1, p_3]_G| + |[p_2, p_4]_G|$. For a path $P = (p_1, p_2, p_3) \in \mathcal{P}_{\Lambda}$, we denote by $L_G(P)$ the integer $|[f_b, p_1]_G| + |[f_b, p_3]_G| + |[f_t, p_2]_G|$, where f_b is the smallest vertex in B and f_t is the largest vertex in T w.r.t. $<$.

For a path $P = (p_1, p_2, p_3) \in \mathcal{P}_{\mathsf{V}}$, we denote by $R_G(P)$ the integer $|[l_t, p_1]_G| + |[l_b, p_2]_G| + |[l_t, p_3]_G|$, where l_t is the smallest vertex in T and l_b is the largest vertex in B w.r.t. $<$.

For a isometric path partition $\mathcal{P}^\star$ of G, we define the first and second component of $\Phi(\mathcal{P}^\star)$ as follows.

$$\Phi(\mathcal{P}^\star)[1] = \sum_{P \in \mathcal{P}^\star_{\mathsf{N}}} W_G(P) \qquad \Phi(\mathcal{P}^\star)[2] = -\Big(\sum_{P \in \mathcal{P}^\star_{\Lambda}} L_G(P)\Big) - \Big(\sum_{P \in \mathcal{P}^\star_{\mathsf{V}}} R_G(P)\Big)$$

Let $\mathcal{P}^1$ and $\mathcal{P}^2$ be two isometric path partitions of G such that $\mathcal{P}^2$ is obtained from $\mathcal{P}^1$ by applying exactly one of the operations given in (1)–(3). We claim that $\Phi(\mathcal{P}^2) > \Phi(\mathcal{P}^1)$, where $>$ is the lexicographical ordering among two dimensional integer vectors. Because Φ is finite, *i.e.*, $(0, -|B||\mathcal{P}^\star_{\mathsf{\Lambda}} \cup \mathcal{P}^\star_{\mathsf{V}}|) \leq \Phi(\mathcal{P}^\star) \leq (|B||\mathcal{P}^\star_{\mathsf{N}}|, 0)$, this then shows that $\mathcal{P}'$ is well defined.

It suffices to show the claim for the cases that $\mathcal{P}^2$ is obtained from $\mathcal{P}^1$ using one of the operations (1)–(3). We show the case for operation (1) as an illustration and leave operations (2) and (3) for the full version. If $\mathcal{P}^2$ is obtained from $\mathcal{P}^1$ by applying operation (1) to two paths $\mathsf{P}_A \in \mathcal{P}^1_{\mathsf{\Lambda}}$ and $P_V \in \mathcal{P}^1_{\mathsf{V}}$, then $\Phi(\mathcal{P}^2)[1] = \Phi(\mathcal{P}^1)[1]$ and $\Phi(\mathcal{P}^2)[2] > \Phi(\mathcal{P}^1)[2]$ because no path in $\mathcal{P}^1$ other than P_A and P_V is changed and moreover because $\mathsf{\Lambda V}$ is the unique pattern that maximizes $\Phi(\{P, P'\})$ for any two paths $P \in \mathcal{P}^1_{\mathsf{\Lambda}}$ and $P' \in \mathcal{P}^1_{\mathsf{V}}$. ◀

Surprisingly, even after reaching mixed normal form, we are still rather far away from our final normal form. In particular, we will go through the following normal forms (in that order): I-normal form, A-normal form, N-normal form, V-normal form, AN-normal form, and finally NV-normal form ($\star$).

3.2 The Algorithms

Having developed our normal forms, we are now ready to show Theorem 4. We start by showing the result for Isometric Path Partition.

▶ **Lemma 13** ($\star$)**.** *Isometric Path Partition admits a polynomial-time algorithm on chain graphs.*

Sketch. Let $G = (T, B, E)$ be a chain graph. Theorem 6 implies that there is an optimal isometric path partition of G having pattern $\overset{*}{\circ}\overset{*}{\mathsf{\Lambda}}\overset{*}{\mathsf{V}}\overset{*}{\circ}$, $\overset{*}{\circ}\overset{*}{\mathsf{\Lambda}}\mathsf{I}\overset{*}{\mathsf{V}}\overset{*}{\circ}$, or $\overset{*}{\circ}\overset{*}{\mathsf{\Lambda}}\mathsf{N}\overset{*}{\mathsf{\Lambda}}\overset{*}{\mathsf{V}}\mathsf{N}\overset{*}{\mathsf{V}}\overset{*}{\circ}$. It therefore suffices to show that we can compute an optimal solution having any of these patterns in polynomial-time. It suffices to provide the proof for the most involved of those patterns, *i.e.*, the pattern $\overset{*}{\circ}\overset{*}{\mathsf{\Lambda}}\mathsf{N}\overset{*}{\mathsf{\Lambda}}\overset{*}{\mathsf{V}}\mathsf{N}\overset{*}{\mathsf{V}}\overset{*}{\circ}$, as the proof of the other two patterns is analogous. Hence, let $\mathcal{P}$ be an isometric path partition of G having pattern $\overset{*}{\circ}\overset{*}{\mathsf{\Lambda}}\mathsf{N}\overset{*}{\mathsf{\Lambda}}\overset{*}{\mathsf{V}}\mathsf{N}\overset{*}{\mathsf{V}}\overset{*}{\circ}$, then $\mathcal{P}$ can be defined by the following 6 numbers:

- the number p_1 of $\circ$-paths,
- the number p_2 of $\mathsf{\Lambda}$-paths that are to the left of any N-path,
- the number p_3 of N-paths,
- the number p_4 of $\mathsf{\Lambda}$-paths that are inside all N-paths,
- the number p_5 of V-paths that are inside all N-paths, and
- the number p_6 of V-paths that are to the right of any N-path.

We say that a tuple $U = (p_1, \ldots, p_6)$ of those six numbers is *valid* if there is an isometric path partition of G with pattern $\overset{*}{\circ}\overset{*}{\mathsf{\Lambda}}\mathsf{N}\overset{*}{\mathsf{\Lambda}}\overset{*}{\mathsf{V}}\mathsf{N}\overset{*}{\mathsf{V}}\overset{*}{\circ}$ with the number of paths as given by U. It is now straightforward to show that the validity of any tuple U can be verified in time $\mathcal{O}(|V(G)|)$ by checking the existence and non-existence of certain edges in G.

Putting everything together, we can solve Isometric Path Partition in time $\mathcal{O}(|V(G)|^7)$ by enumerating all of the at most $|V(G)|^6$ tuples U in time $\mathcal{O}(|V(G)|^6)$, testing their validity in time $\mathcal{O}(|V(G)|)$, and then returning the solution that corresponds to a valid tuple U minimizing $p_1 + p_2 + p_3 + p_4 + p_5 + p_6 + (|T| - p_2 - 2p_3 - p_4 - 2p_5 - 2p_6)$. ◀

We will now show that Isometric Path Cover on chain graphs can be reduced to Isometric Path Partition on chain graphs with the help of the following lemma.

▶ **Lemma 14** ($\star$)**.** *Let $G = (T, B, E)$ be a chain graph, $t \in T$ be a vertex such that $t > t'$ for all $t' \in T \setminus \{t\}$, and $b \in B$ be a vertex such that $b' < b$ for all $b' \in B \setminus \{b\}$. Then, there is an optimal isometric path cover $\mathcal{P}$ of G such that all vertices in $V(G) \setminus \{t, b\}$ appear in exactly one path in $\mathcal{P}$.*

Now to solve Isometric Path Cover on a chain graph $G = (T, B, E)$ we do the following. Fix two vertices $t \in T$ and $b \in B$ such that $t > t'$ for all $t' \in T \setminus \{t\}$, and $b' < b$ for all $b' \in B \setminus \{b\}$. From Lemma 14, we know that there is an optimal isometric path cover $\mathcal{C}$ such that no vertex in $V(G) \setminus \{t, b\}$ belongs to more than one path. Now we guess the numbers n_t and n_b such that the number of paths in $\mathcal{C}$ that contain t and b are n_t and n_b, respectively, and create a new graph G' by adding $n_t - 1$ copies $a_1, \ldots, a_{n_t-1}$ of t, and $n_b - 1$ copies $c_1, \ldots, c_{n_b-1}$ of b. Moreover, each vertex in $\{a_1, \ldots, a_{n_t-1}\}$ is adjacent to all the neighbours of t and each vertex in $\{c_1, \ldots, c_{n_b-1}\}$ is adjacent to all the neighbours of b. Then, clearly there is an isometric path partition $\mathcal{P}$ in G' of size $|\mathcal{C}|$. Also, any isometric path partition $\mathcal{Q}$ in G' can be converted into an isometric path cover in G of size $|\mathcal{Q}|$. Hence, we solve Isometric Path Partition on G' and output accordingly.

4 Algorithms on Cographs

Here we design polynomial time algorithms for Isometric Path Partition and Isometric Path Cover on cographs. Complement-reducible graphs (or *cographs* for short) were introduced in [6]. To define the class we use the operations *union* $\oplus$ and *join* $\otimes$ for graphs $G = (V, E)$ and $H = (U, F)$ with $V \cap U = \emptyset$, i.e., $G \oplus H = (V \cup U, E \cup F)$ and $G \otimes H = (V \cup U, E \cup F \cup \{vu \mid v \in V, u \in U\})$.

▶ **Definition 15.** *The cographs can be defined recursively:*

- *K_1 is a cograph.*
- *If G and H are cographs then so are $G \oplus H$ and $G \otimes H$.*
- *There are no other cographs.*

A *cotree* T of a graph $G = (V, E)$ can be defined as a rooted binary tree where the leaves are the vertices in V and the inner nodes are marked with $\oplus$ and $\otimes$ such that two vertices $u, v \in V$ are adjacent if and only if their least common ancestor in T is marked by $\otimes$. Then we say that G has a cotree.

▶ **Theorem 16** ([6])**.** *For every graph G the following conditions are equivalent.*

1. *G is a cograph.*
2. *G does not contain P_4 as induced subgraph.*
3. *G has a cotree.*

The following observations follow from the definition of cotrees.

▶ **Observation 17.** *Let T be a cotree of a cograph G. Let (v_1, v_2, v_3) be an induced path in G. Then, there is a node t labelled $\otimes$ in the tree such that the least common ancestor of v_1 and v_2, as well as v_2 and v_3 is t.*

▶ **Observation 18.** *Let T be a cotree of a cograph G. For a node t in T, let T_t be the subtree of T rooted at t. For a node t, if G_t is the cograph that has the cotree T_t, then G_t is the subgraph of G induced on $V(G_t)$. This implies that for any $u, v \in V(G_t)$, if $(u, v) \notin E(G_t)$, then $(u, v) \notin E(G)$.*

Now, we discuss an algorithm for Isometric Path Partition on cographs. For a cograph $G = (V, E)$ let $Q(G)$ denote the set of quadruples $(\ddot{p}, p_1, p_2, p_3)$ such that V has a partition $\mathcal{S}$ into $\ddot{p} + p_1 + p_2 + p_3$ subsets $S \subseteq V$ such that

- for $i \in \{1, 2, 3\}$, exactly p_i sets $S \in \mathcal{S}$ induce a graph $G[S]$ isomorphic to P_i, which is a path on i vertices, and
- for the remaining $\ddot{p}$ subsets $S \in \mathcal{S}$ the subgraph $G[S]$ is isomorphic to $2P_1$, which is an edgeless graph on two vertices.

Theorem 16 implies that each partition of a cograph into isometric paths consists of P_1s, P_2s and P_3s only.

▶ **Lemma 19.** *For a cograph G on n vertices we can compute $Q(G)$ in time $\mathcal{O}(n^{10})$.*

Proof. A cotree T of G can be computed in linear time [6]. We compute $Q(G)$ as follows:

$$\begin{aligned}
Q(K_1) &= \{(0, 1, 0, 0)\} \\
Q(G' \oplus H) &= \{(\ddot{p} + \ddot{q} + r, p_1 + q_1 - 2r, p_2 + q_2, p_3 + q_3) \mid 0 \le r \le \min\{p_1, q_1\}, \\
&\qquad (\ddot{p}, p_1, p_2, p_3) \in Q(G'), (\ddot{q}, q_1, q_2, q_3) \in Q(H)\} \\
Q(G' \otimes H) &= \{\big((\ddot{p} - k) + (\ddot{q} - l), (p_1 - i - l) + (q_1 - i - k), p_2 + q_2 + i, \\
&\qquad (p_3 + k) + (q_3 + l)\big) \mid 0 \le i, 0 \le k \le \ddot{p}, 0 \le i + k \le q_1, 0 \le l \le \ddot{q}, \\
&\qquad 0 \le i + l \le p_1, (\ddot{p}, p_1, p_2, p_3) \in Q(G'), (\ddot{q}, q_1, q_2, q_3) \in Q(H)\}
\end{aligned}$$

The equation for $\oplus$ holds because $G' \oplus H$ does not contain any edges between G' and H. Every path in $G' \oplus H$ is either a path in G' or in H. We can count a P_1 in G' and a P_1 in H as one $2P_1$ in the first coordinate or as two P_1 in the second. For $\otimes$ we can create i paths P_2 from a P_1 in G and a P_1 in H, k paths P_3 from one $2P_1$ in G and one P_1 in H, and l paths P_3 from one P_1 in G and one $2P_1$ in H. Using induction on the nodes of the cotree and the Observations 17 and 18, we prove that the above recursive formulae are correct.

Note that for any cograph G', the number of quadruples in $Q(G')$ is at most n^3, because, by knowing specific values for $\ddot{p}$, p_2 and p_3, we can determine p_1 through the equation $2\ddot{p} + p_1 + 2p_2 + 3p_3 = |V(G')|$. The cotree T has $2n - 1$ nodes. Now we estimate the time to compute $Q(G' \otimes H)$, which is asymptotically larger than that of $Q(G' \oplus H)$. For each $(\ddot{p}, p_1, p_2, p_3) \in Q(G')$ and $(\ddot{q}, q_1, q_2, q_3) \in Q(H)$, we run over three values k, l, i, each of them is upper bounded by n, and constructs tuples in $Q(G' \otimes H)$. The number of choices for k, l, i is at most n^3. Thus, for each each $(\ddot{p}, p_1, p_2, p_3) \in Q(G')$ and $(\ddot{q}, q_1, q_2, q_3) \in Q(H)$, we will be taking $O(n^3)$ time. Since the cardinalities of $Q(G')$ and $Q(H)$ are upper bounded by n^3 each, the total running time to compute $Q(G' \otimes H)$ is $O(n^9)$. Since the cotree has $2n - 1$ nodes, the total running time of our algorithm is $O(n^{10})$. ◀

▶ **Lemma 20.** *Isometric Path Partition can be solved in $\mathcal{O}(n^{10})$ time on cographs.*

Proof. The recurrence for Q leads to a dynamic programming algorithm computing the isometric path partition number of a cograph G, which is $\min\{p_1 + p_2 + p_3 \mid (0, p_1, p_2, p_3) \in Q(G)\}$. ◀

Next, we explain how to use the values in $Q(G)$ to solve Isometric Path Cover on connected cographs.

▶ **Lemma 21.** *Let G be a connected cograph. Let $Q(G)$ be the set defined before in this section. Then, the cardinality of an optimal isometric path cover of G is*

$$\min\{\ddot{p} + p_1 + p_2 + p_3 \mid (\ddot{p}, p_1, p_2, p_3) \in Q(G)\}.$$

Proof. Let $(\ddot{p}, p_1, p_2, p_3) \in Q(G)$. We claim that there is an isometric path cover of G of size $\ddot{p} + p_1 + p_2 + p_3$. Since $(\ddot{p}, p_1, p_2, p_3) \in Q(G)$, we know that $V(G)$ has a partition into $\ddot{p} + p_1 + p_2 + p_3$ subsets $S \subseteq V(G)$ of which,

(a) for $i \in \{1, 2, 3\}$, exactly p_i induced $G[S]$ is isomorphic to P_i, and

(b) for the remaining $\ddot{p}$ subsets we have $G[S]$ isomorphic to $2P_1$.

Since G is a connected cograph, in Case (b), there is an induced path of length 2 with the vertices in S being its end vertices. So these paths along with the paths in Case (a) forms an isometric path cover of G of size $\ddot{p} + p_1 + p_2 + p_3$.

Now we prove the reverse direction. Without loss of generality we assume that there is an optimal isometric path cover $\mathcal{P}$ of G where for each path $P \in \mathcal{P}$, its end vertices appear only in one path which is P. Let $\ell = |\mathcal{P}|$. Now we claim that there is a tuple $(\ddot{p}, p_1, p_2, p_3) \in Q(G)$ such that $\ddot{p} + p_1 + p_2 + p_3 = \ell$. Let $\mathcal{P} = \mathcal{P}_1 \cup \mathcal{P}_2 \cup \mathcal{P}_3$, where $\mathcal{P}_j$ contains all paths on j vertices from $\mathcal{P}$. Let $\mathcal{Q}_1 = \{V(P) \colon P \in \mathcal{P}_1\}$ and $\mathcal{Q}_2 = \{V(P) \colon P \in \mathcal{P}_2\}$. Now we construct $\ddot{\mathcal{Q}}$ and $\mathcal{Q}_3$. Initially, we set $\ddot{\mathcal{Q}} := \emptyset$ and $\mathcal{Q}_3 := \emptyset$. Consider a vertex z such that z is an intermediate vertex in a path in $\mathcal{P}_3$. Suppose z is present in n_z paths. Because of our assumption of $\mathcal{P}$, we know that z is the intermediate vertex in all those n_v paths in $\mathcal{P}_3$. Let $R_1, R_2, \ldots, R_{n_z}$ be these paths. Now let $S_{z,i}$ be the set containing the end vertices of R_i for all $i \in [n_z - 1]$ and $S_{z,n_z} = V(R_{n_z})$. Now we set $\ddot{\mathcal{Q}} := \ddot{\mathcal{Q}} \cup \{S_{z,i} : i \in [n_z - 1]\}$ and $\mathcal{Q}_3 := \mathcal{Q}_3 \cup \{S_{i,n_z}\}$. We do this procedure for each z such that it is an intermediate vertex of a path in $\mathcal{P}_3$. Let $\ddot{p} = |\ddot{\mathcal{Q}}|$ and $p_i = |\mathcal{Q}_i|$ for all $i \in \{1, 2, 3\}$. It is easy to see that $\ddot{p} + p_1 + p_2 + p_3 = \ell$ and the above construction of $\ddot{\mathcal{Q}}$ and $\mathcal{Q}_3$ implies that $(\ddot{p}, p_1, p_2, p_3) \in Q(G)$. ◀

Lemma 21 implies that Isometric Path Cover can be solved in time $O(n^{10})$ on cographs.

5 Hardness on Split Graphs

Here, we show that Isometric Path Partition is already NP-hard on split graphs.

▶ **Theorem 22** (⋆). *Isometric Path Partition is* NP*-hard on split graphs.*

Sketch. We provide a polynomial-time reduction from the NP-complete 3-XSAT problem [13, Lemma 5], where given a propositional formula Φ in CNF such that every clause of Φ has exactly 3 positive literals and every variable occurs exactly in 3 clauses of Φ, the task is to decide whether there is an assignment of the variables of Φ that satisfies exactly one literal from every clause. Let Φ be the given instance of 3-XSAT. We will construct a split graph $G = (T, B, E)$ where T is the independent set and B is the clique such that Φ has an assignment satisfying exactly one literal from every clause if and only if G has isometric path partition $\mathcal{P}$ of size at most $32n^2 - 4n$, where n is a number of clauses (and also the number of variables) of Φ. We shall frequently refer to B as "bottom" and T as "top".

Let $\mathcal{C} = \{C_1, \ldots, C_n\}$ be the set of clauses of Φ and let $\mathcal{X} = \{x_1, \ldots, x_n\}$ be the set of variables of Φ. G is constructed from three types of gadgets defined as follows and illustrated in Figure 2. For every variable x_a, G contains the gadget $G_{\mathcal{X}}(x_a)$ defined as follows. Let C_i, C_j and C_k with $1 \leq i < j < k \leq n$ be the 3 clauses that contain x_a. For every $b \in \{i, j, k\}$, $G_{\mathcal{X}}(x_a)$ has the vertices $x_{a,b}$, $\overline{x_{a,b}}$, $x^{\otimes}_{a,b}$ and $x^{\odot}_{a,b}$ with $x_{a,b}, \overline{x_{a,b}} \in B$ and $x^{\otimes}_{a,b}, x^{\odot}_{a,b} \in T$ and the edges $x_{a,b}x^{\otimes}_{a,b}$ and $\overline{x_{a,b}}x^{\odot}_{a,b}$. Additionally, $G_{\mathcal{X}}(x_a)$ contains the edges $\overline{x_{a,i}}x^{\otimes}_{a,j}$, $\overline{x_{a,j}}x^{\otimes}_{a,k}$, and $\overline{x_{a,k}}x^{\otimes}_{a,i}$. Intuitively, the gadget is used to ensure that all occurrences of the variable x_a are assigned in the same manner, which is achieved by forcing that any solution for G can cover all vertices in the gadget in only two manners, which are illustrated in Figure 2.

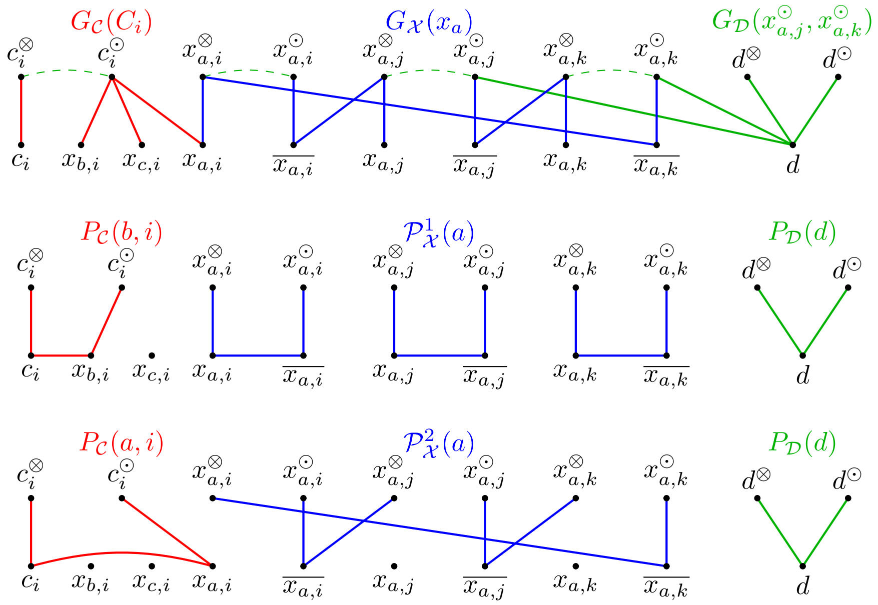

Figure 2 Illustration of the gadgets $G_{\mathcal{C}}(C_i)$, $G_{\mathcal{X}}(x_a)$, and $G_{\mathcal{D}}(x^{\odot}_{a,j}, x^{\odot}_{a,k})$ used in the proof of Theorem 1. The colors of the edges indicate, which gadget they belong to, *i.e.*, red, blue, and green edges are part of $G_{\mathcal{C}}(C_i)$, $G_{\mathcal{X}}(x_a)$, and $G_{\mathcal{D}}(x^{\odot}_{a,j}, x^{\odot}_{a,k})$, respectively. The top figure provides the edges that are part of each gadget (without the edges that are part of the clique on B). The dashed green edges indicate pairs of twin vertices, *i.e.*, the only pairs on the top that can be used as endpoints of isometric paths of length 3. The center and the bottom figure together provide the two possible configurations for how the vertices of the gadgets can be cover in an isometric path partition, which is also descripted in (1), (3), and (4). The center figure illustrates the case that the variable x_a is set to 0 and does not satisfy the clause C_i and the bottom figure illustrates the opposite case.

For every clause $C_i \in \mathcal{C}$, G contains the gadget $G_{\mathcal{C}}(C_i)$. The gadget $G_{\mathcal{C}}(C_i)$ consists of 1 new bottom vertex c_i, 2 new top vertices $c_i^{\otimes}$ and $c_i^{\odot}$, and the edges $c_i c_i^{\otimes}$ and $x_{a,i} c_i^{\odot}$ for every $x_a \in C_i$. This gadget $G_{\mathcal{C}}(C_i)$ will ensure that every clause in Φ is satisfied by exactly one literal. Given two distinct top vertices u and v, the last gadget $G_{\mathcal{D}}(u,v)$, which we call the *destroyer gadget*, has 1 bottom vertex $d_{u,v}$, 2 top vertices $d^{\otimes}_{u,v}$ and $d^{\odot}_{u,v}$ and the edges $d_{u,v} d^{\otimes}_{u,v}$, $d_{u,v} d^{\odot}_{u,v}$, $d_{u,v} u$ and $d_{u,v} v$. The purpose of the destroyer gadget is to ensure that the two top vertices u and v can not occur together in a path of length 3.

We are now ready to define the graph G. Let $G' = \bigcup_{x \in \mathcal{X}} G_{\mathcal{X}}(x) \cup \bigcup_{C \in \mathcal{C}} G_{\mathcal{C}}(C)$. Note that $|T(G')| = 6n + 2n = 8n$. We say that two top vertices v and v' from $T(G')$ are twins, if there exists $u \in B(G')$ such that $v = u^{\otimes}$ and $v' = u^{\odot}$. Then, G is the union of G' and an instance of the destroyer gadget $G_{\mathcal{D}}(u,v)$ for every two distinct top vertices u and v of $T(G')$ that are not twins. Let $B_{\mathcal{D}}$ be the set of all bottom vertices from all of the destroyer gadgets. Note that $|T(G)| = |T(G')|(|T(G')| - 2) + |T(G')| = 64n^2 - 8n$.

Consider an isometric path partition $\mathcal{P}$ of G with $|\mathcal{P}| = \frac{|T(G)|}{2} = 32n^2 - 4n$. The correctness of the reduction can now be shown rather straightforwardly from the following properties $(\star)$:

(1) For every $d \in B_{\mathcal{D}}$, the path $P_{\mathcal{D}}(d) = (d^{\otimes}, d, d^{\odot})$ is included in $\mathcal{P}$.

(2) If a path $P \in \mathcal{P}$ is of length 3, then its endpoints are twins.

(3) For every $i \in [n]$ there exists $a \in [n]$ such that $P_{\mathcal{C}}(a,i) = (c_i^{\otimes}, c_i, x_{a,i}, c^{\odot})$ is in $\mathcal{P}$.

(4) For any $a, i, j, k \in [n]$ with x_a belonging to $C_i \cap C_j \cap C_k$ and $i < j < k$, precisely one of the following scenarios occurs:

(a) The set of paths $\mathcal{P}^1_{\mathcal{X}}(a) = \{\, (x^{\otimes}_{a,\ell}, x_{a,\ell}, \overline{x_{a,\ell}}, x^{\odot}_{a,\ell}) \mid \ell \in \{i, j, k\} \,\}$ is a subset of $\mathcal{P}$, or

(b) $\mathcal{P}^2_{\mathcal{X}}(a) = \{\, (x^{\otimes}_{a,i}, \overline{x_{a,k}}, x^{\odot}_{a,k}), (x^{\otimes}_{a,j}, \overline{x_{a,i}}, x^{\odot}_{a,i}), (x^{\otimes}_{a,k}, \overline{x_{a,j}}, x^{\odot}_{a,j}) \,\}$ is a subset of $\mathcal{P}$.

(5) For every $a, i \in [n]$ and $P \in \mathcal{P}$, such that $x_a \in C_i$ and $x_{a,i} \in V(P)$, $P = P_{\mathcal{C}}(a, i)$ or $P \in \mathcal{P}^1_{\mathcal{X}}(a)$. ◀

6 Conclusion

In this paper we proved that Isometric Path Partition remains NP-hard on split graphs. We also showed that both Isometric Path Cover and Isometric Path Partition admit polynomial time algorithms on chain graphs and cographs. Algorithms faster than the ones provided in this paper would be interesting. Another direction of research is to look for other graph classes where Isometric Path Cover and Isometric Path Partition admit polynomial time algorithms. Graph classes like bipartite permutation graphs, proper interval graphs, strongly chordal split graphs, *etc.* are natural candidates. The computational complexities of Isometric Path Cover and Induced Path Cover on split graphs remain open.

Abstract

Given an Abelian group $\mathcal{G}$, a Boolean-valued function $f : \mathcal{G} \to \{-1, +1\}$, is said to be s-sparse, if it has at most s-many non-zero Fourier coefficients over the domain $\mathcal{G}$. In a seminal paper, Gopalan et al. [15] proved "Granularity" for Fourier coefficients of Boolean valued functions over $\mathbb{Z}_2^n$, that have found many diverse applications in theoretical computer science and combinatorics. They also studied structural results for Boolean functions over $\mathbb{Z}_2^n$ which are *approximately Fourier-sparse*. In this work, we obtain structural results for approximately Fourier-sparse Boolean valued functions over Abelian groups $\mathcal{G}$ of the form, $\mathcal{G} := \mathbb{Z}_{p_1}^{n_1} \times \cdots \times \mathbb{Z}_{p_t}^{n_t}$, for distinct primes p_i. We also obtain a lower bound of the form $1/(m^2 s)^{\lceil \varphi(m)/2 \rceil}$, on the absolute value of the *smallest* non-zero Fourier coefficient of an s-sparse function, where $m = p_1 \cdots p_t$, and $\varphi(m) = (p_1 - 1) \cdots (p_t - 1)$. We carefully apply probabilistic techniques from [15], to obtain our structural results, and use some non-trivial results from algebraic number theory to get the lower bound.

We construct a family of at most s-sparse Boolean functions over $\mathbb{Z}_p^n$, where $p > 2$, for arbitrarily large enough s, where the minimum non-zero Fourier coefficient is $o(1/s)$. The "Granularity" result of Gopalan et al. implies that the absolute values of non-zero Fourier coefficients of any s-sparse Boolean valued function over $\mathbb{Z}_2^n$ are $\Omega(1/s)$. So, our result shows that one *cannot* expect such a lower bound for general Abelian groups.

Using our new structural results on the Fourier coefficients of sparse functions, we design an efficient sparsity testing algorithm for Boolean function, which tests whether the given function is s-sparse, or ϵ-far from any sparse Boolean function, and it requires $\mathsf{poly}((ms)^{\varphi(m)}, 1/\epsilon)$-many queries. Further, we generalize the notion of *degree* of a Boolean function over an Abelian group $\mathcal{G}$. We use it to prove an $\Omega(\sqrt{s})$ lower bound on the query complexity of any adaptive sparsity testing algorithm.

1 Introduction

Boolean functions are fundamental objects of study in computer science. For a discrete domain $\mathcal{D}$, a Boolean function $f : \mathcal{D} \to \{+1, -1\}$ models a decision task where each member of $\mathcal{D}$ is classified into one of two classes. Boolean functions play a vital role in the study of digital circuits and computer hardware. They are also significant in the study of algorithms and complexity, particularly in problems where the set $\mathcal{D}$ of instances is endowed with an algebraic structure. Examples of such problems include matrix multiplication and polynomial evaluation.

The case of Boolean function complexity with $\mathcal{D} = \mathbb{Z}_2^n$ has been widely studied. These functions are often analyzed in connection with their Fourier transform (see Section 2) and a significant amount of research has focused on the structural properties of Fourier spectra of important classes of these functions. One such class that this work focuses on is that of Fourier-sparse functions. These are functions with only a few non-zero Fourier coefficients, formally defined in Definition 18. We will denote by s_f the Fourier sparsity of a Boolean function f. Fourier sparsity and Fourier-sparse functions have known connections with a variety of areas of Boolean function analysis and computational complexity like property testing [15], learning theory [20, 3], distance estimation [35] and communication complexity [23, 31, 19, 27, 22]. These connections provide enough motivation to comprehend the structure of Fourier coefficients for Fourier-sparse Boolean functions.

In this work, we extend the study of Fourier-sparse Boolean functions to the domains $\mathcal{D}$, which are Abelian groups of the form $\mathbb{Z}_{p_1}^{n_1} \times \cdots \times \mathbb{Z}_{p_t}^{n_t}$, where $p_1, \ldots, p_t$ are distinct prime numbers. Boolean functions over general Abelian groups have been studied in both mathematics and computer science. A celebrated result regarding such functions is Chang's Lemma [10]. Chang's lemma over $\mathbb{Z}_2^n$ has found numerous applications in complexity theory and algorithms [5, 9], analysis of Boolean functions [16, 31], communication complexity [31, 21], extremal combinatorics [13], and many more. Recently, [8] improved Chang's lemma over $\mathbb{Z}_2^n$ for some special settings of parameters, where Fourier sparsity played a crucial role. One motivation to study Fourier sparsity over a broader class of Abelian groups is to investigate possible generalizations of their bounds to those groups.

Fourier analysis over finite Abelian groups in cryptography. For the past three decades, the field of cryptography has been utilizing concepts derived from Fourier analysis, specifically over finite Abelian groups. Akavia, Goldwasser, and Safra [2] have combined some of these concepts to develop a comprehensive algorithm that can detect "large" Fourier coefficients of any concentrated function on finite Abelian groups, and compute a *sparse approximation* for the same. This algorithm has gained significant attention within the cryptography community, especially regarding the notion of "bit security" of the *discrete logarithm problem* (DLP), RSA, and learning with errors (LWE) problems; see [25, 14, 1]. In particular, the "nice" structural results on the Fourier coefficients of a Boolean-valued function over the general Abelian group are of utmost importance and interest from a crypto-theoretic point of view.

Interestingly, there are strong relationships between learning, sparsity, and sampling, in the context of Fourier-sparse Boolean functions. They have been rigorously studied in [28, 29, 30]. In [28], the authors asked the following:

▶ **Question 1.1.** *What can be said about the structure of the Fourier coefficients of a Boolean function f over an Abelian group $\mathcal{G} = \mathbb{Z}_p^n$, where the support is significantly smaller compared to $\mathcal{G}$?*

Gopalan et al. [15] proved that any non-zero Fourier coefficient of a Boolean function over $\mathbb{Z}_2^n$ with Fourier sparsity at most s_f, is *at least* $\frac{1}{s_f}$ in its absolute value. This gave a satisfactory answer of Question 1.1 over $\mathbb{Z}_2^n$. Furthermore, they proved *robust versions* of their result for functions which are *approximately Fourier-sparse*. Finally, their structural results were used to design a sample-efficient algorithm to test whether a function is Fourier-sparse.

In our work, we undertake the same task for Boolean functions over Abelian groups of the form $\mathbb{Z}_p^n$, for a prime $p \geq 3$. We prove lower bounds on the absolute value of any non-zero coefficient in terms of s_f and p. We also prove a tightness result that complements our lower bounds. In particular, our bound implies that a lower bound of $\frac{1}{\Theta(s_f)}$ that [15] showed *does not* hold anymore for $\mathbb{Z}_p^n$. Finally, we use our bounds to design a testing algorithm for Fourier-sparse Boolean functions over $\mathbb{Z}_{p_1}^{n_1} \times \cdots \times \mathbb{Z}_{p_t}^{n_t}$. This is probably the first time, we have advanced on understanding some structure on the Fourier-sparse coefficients over a general Abelian group, and shed some light on Question 1.1.

It is well-known that any Abelian group is isomorphic to a group of the form $\mathbb{Z}_{p_1^{n_1}} \times \cdots \times \mathbb{Z}_{p_t^{n_t}}$ where $p_1, \ldots, p_t$ are prime numbers and $n_1, \ldots, n_t$ are positive integers. Unfortunately, our techniques fall short of handling even a simpler case of $\mathbb{Z}_{p^2}$, fundamentally because of the *absence of a linear structure* on the solution space of systems of equations over $\mathbb{Z}_{p^2}$. Therefore, we are leaving the task of investigating the existence of similar bounds and algorithmic results when the domain of the function is a general Abelian group to future research.

Why care about Fourier-sparse Boolean functions over Abelian groups?

There has been a considerable amount of interest in studying the complexity of reconstructing or learning functions of the form $f : \mathcal{D} \to \mathbb{C}$, where $\mathcal{D}$ is a known domain (more general than a hypercube, such as a general finite Abelian group), and f is Fourier-sparse; see [30, 26, 24, 11, 34]. Fourier-sparse functions over various finite Abelian groups have gained much interest with the advancement in sparse Fourier transform algorithms [17, 18, 4]. These algorithms improve the efficiency of the standard Fast Fourier Transform algorithms by taking advantage of the sparsity itself. To reliably use sparse Fourier transform algorithms, it is beneficial to have a way to *test* if a function is s-sparse or, more generally, to *estimate* the distance of a function to the closest s-sparse function. In this work, we consider the problem of non-tolerant sparsity-testing of Boolean functions over finite Abelian groups.

Finally, apart from mathematical curiosity and potential cryptographic applications (as mentioned previously), structural results on Fourier-sparse functions $f : \mathbb{Z}_N \to \mathbb{C}$, for some $N \in \mathbb{N}$, have also found algorithmic applications in SOS-optimization and control theory. These applications have further implications in certifying maximum satisfiability (MAX-SAT) and maximum k-colorable subgraph (MkCS) problems; see [12, 33, 32].

1.1 Our results

Throughout the article, we will be working with the Abelian group $\mathcal{G} := \mathbb{Z}_{p_1}^{n_1} \times \cdots \times \mathbb{Z}_{p_t}^{n_t}$ where p_i are primes. Let $f : \mathcal{G} \to \{-1, +1\}$, and $f(x) = \sum_{\chi \in \hat{\mathcal{G}}} \widehat{f}(\chi)\chi(x)$ be the Fourier transform of f, where $\hat{\mathcal{G}}$ is the set of characters of the Abelian group $\mathcal{G}$.

We say a Boolean function is *s-sparse*, if it has at most s non-zero Fourier coefficients. [15] proved that for any s-sparse Boolean functions over $\mathbb{Z}_2^n$, the magnitude of the Fourier coefficients are k-granular where $k = \lceil \log_2 s \rceil + 1$. A real number is *$k$-granular* if it is an integer multiple of $1/2^k$. One wonders whether such a phenomenon still holds over a more general group $\mathcal{G}$.

This notion of granularity made sense over $\mathbb{Z}_2^n$, since in this case, all the Fourier coefficients are *rational* (and hence real) numbers. But when the domain of the function is a general group $\mathcal{G}$, the Fourier coefficients are necessarily complex numbers. So, we would like to suitably define granularity, and show that such a property still holds for s-sparse Boolean-valued functions over $\mathcal{G}$. Our first conceptual contribution in this paper is to generalize the notion of granularity appropriately.

▶ **Definition 1** (Granularity). *A complex number is said to be k-granular or has granularity k with respect to $\mathbb{Z}_p$ if it is of the form $\frac{g(\omega_p)}{p^k}$, where $g(X) \in \mathbb{Z}[X]$ and ω_p is a primitive p^{th} root of unity.*

More generally, a complex number is said to be $(m_1, \ldots, m_t)$-granular with respect to $(\mathbb{Z}_{p_1}, \ldots, \mathbb{Z}_{p_t})$ if it is of the form $\frac{g(\omega_{p_1}, \ldots, \omega_{p_t})}{p_1^{m_1} \cdots p_t^{m_t}}$, where $g(X_1, \ldots, X_t) \in \mathbb{Z}[X_1, \ldots, X_t]$ and ω_{p_i} is a primitive p_i^{th} root of unity, $i \in [k]$.

Note that, this goes well with the definition of granularity in [15] for the case of $\mathbb{Z}_2$ as ω_2 is either $+1$ or -1 and hence $g(\omega_2)$ is an integer for any $g(X) \in \mathbb{Z}[X]$.

A function $f : \mathcal{G} \to \{-1, +1\}$ is said to be $(m_1, \ldots, m_t)$-granular with respect to $(\mathbb{Z}_{p_1}, \ldots, \mathbb{Z}_{p_t})$ if each Fourier coefficient of f is $(m_1, \ldots, m_t)$-granular.

We will also need a *robust* version of the definition of granularity of a complex number.

▶ **Definition 2** (μ-close to k-granular). *A complex number v is said to be μ-close to k-granular with respect to $\mathbb{Z}_p$ if $|v - \frac{g(\omega_p)}{p^k}| \leq \mu$, for some non-zero polynomial $g(X) \in \mathbb{Z}[X]$.*

Note that a similar notion can be defined for the case of μ-close to $(m_1, \ldots, m_t)$-granular with respect to $(\mathbb{Z}_{p_1}, \ldots, \mathbb{Z}_{p_t})$.

Now, we are ready to formally state our two main structural results. All our results hold for Boolean-valued functions over the more general Abelian group $\mathcal{G}$. But for simplicity of presentation and ease of understanding, we first present the result for Boolean-valued functions over $\mathbb{Z}_p^n$. Later, we present more general versions of our results, see the archived version of the paper [7] for more details.

Our first theorem says that for any Boolean-valued function over $\mathbb{Z}_p^n$ that is *close* to being sparse, all its large Fourier coefficients are close to being granular. This is a generalization of the structural theorem of [15, Theorem 3.3], which was proved over $\mathbb{Z}_2^n$.

▶ **Theorem 3** (Structure theorem 1). *Let $f : \mathbb{Z}_p^n \to \{-1, +1\}$ be a Boolean-valued function and let B be the set of characters corresponding to the set of s-largest Fourier coefficients of f (in terms of magnitude). If $\sum_{\chi \in B} |\widehat{f}(\chi)|^2 \geq (1 - \mu)$ then for all $\chi \in B$, $\widehat{f}(\chi)$ is $\frac{\mu}{\sqrt{s}}$-close to $\lceil \log_p s \rceil + 1$-granular.*

For a function $f : \mathbb{Z}_p^n \to \{-1, +1\}$, $\sum_{\chi \in B} |\widehat{f}(\chi)|^2 \geq (1 - \mu)$ (where B is the set of characters corresponding to the set of s largest coefficients of f) can also be stated as "there is an s-sparse function $g : \mathbb{Z}_p^n \to \mathbb{C}$ with the ℓ_2-distance between f and g is at most $\sqrt{\mu}$". But note that this *does not* guarantee that there is an s-sparse Boolean-valued function $g : \mathbb{Z}_p^n \to \{-1, +1\}$ with ℓ_2-distance between f and g being at most $\sqrt{\mu}$. However, our second theorem proves that one can indeed find an s-sparse Boolean-valued function in a close enough vicinity, thus generalizing [15, Theorem 3.4].

▶ **Theorem 4** (Structure theorem 2). *Let $f : \mathbb{Z}_p^n \to \{-1, +1\}$ be a Boolean-valued function and let B be the set of characters corresponding to the set of s-largest Fourier coefficients of f (in terms of magnitude). If $\sum_{\chi \in B} |\widehat{f}(\chi)|^2 \geq (1 - \mu)$, with $\mu \leq \frac{1}{8(p^2 s)^{p-1}}$ then there exists an s-sparse Boolean-valued function $F : \mathbb{Z}_p^n \to \{-1, +1\}$ with ℓ_2 distance between f and F is at most $\sqrt{2}\mu$.*

Theorem 3 and Theorem 4 can be suitably generalized to functions from $\mathcal{G}$ to $\{-1,+1\}$. But for the clarity of presentation, we state the generalized theorems and present their proofs in the archived version of the paper [7].

One important corollary of Theorem 3 is that for any s-sparse Boolean function $f : \mathbb{Z}_2^n \to \{-1,+1\}$ the non-zero Fourier coefficients has magnitude at least $1/2^k$, where $k = \lceil \log_2 s \rceil + 1$. Unfortunately, such a simple corollary cannot be claimed for s-sparse functions $f : \mathbb{Z}_p^n \to \{-1,+1\}$ if $p \neq 2$. The main reason is that the definition of granularity is for complex numbers, rather than real numbers and hence such a lower bound cannot be directly deduced. However, borrowing results from algebraic number theory, we can obtain a lower bound on the Fourier coefficients of Boolean-valued functions from $\mathbb{Z}_p^n$ to $\{-1,+1\}$ for any arbitrary prime p.

▶ **Theorem 5** (Fourier coefficient lower bound). *Let $f : \mathbb{Z}_p^n \to \{-1,+1\}$, with Fourier sparsity s_f. Then, for any $\chi \in \operatorname{supp}(f)$, we have $|\hat{f}(\chi)| \geq \frac{1}{(p^2 s_f)^{\lceil (p-1)/2 \rceil}}$.*

▶ Remark. One can also prove a weaker lower bound of the form $1/((s_f+1)\sqrt{s_f})^{s_f}$, which is p-independent; for details, see the archived version of the paper [7].

Observe that the lower bound in Theorem 5 is much lower than $1/s_f$. One may wonder how tight our result is. It is known that $1/s$ is tight for the case when $p = 2$. For example, consider the function $AND : \mathbb{Z}_2^n \to \{-1,+1\}$. Its non-empty Fourier coefficients are either $\frac{1}{2^{n-1}}$ or $-\frac{1}{2^{n-1}}$, while the empty (constant) coefficient being $1 - \frac{1}{2^{n-1}}$.

To our pleasant surprise, we construct s-sparse Boolean-valued functions over $\mathbb{Z}_p^n$, for $p \geq 5$, such that they have nonzero Fourier coefficients with absolute value being $o(1/s)$.

▶ **Theorem 6** (Small Fourier coefficients). *For every prime $p \geq 5$, and large enough n, there exist a positive constant α_p that depends only on p and a function $f : \mathbb{Z}_p^n \to \{-1,+1\}$ with Fourier sparsity s_f satisfying the following property:*

$$\min_{\chi \in \operatorname{supp}(f)} \left| \widehat{f}(\chi) \right| \leq 1/s_f^{1+\alpha_p}.$$

We prove a generalized version of the lower bound result (Theorem 5) for Boolean-valued functions over $\mathcal{G}$. The above example (from Theorem 6) can also be easily extended to obtain Boolean-value functions over $\mathcal{G}$ demonstrating similar bounds on the absolute value of the non-trivial Fourier coefficients.

Finally, we design efficient algorithms for testing whether a function $f : \mathbb{Z}_p^n \to \{-1,+1\}$ is s-sparse or "far" from s-sparse-Boolean. To state our results we need to define what we mean by a function $f : \mathbb{Z}_p^n \to \{-1,+1\}$ is ϵ-far from s-sparse.

▶ **Definition 7.** *A function $f : \mathbb{Z}_p^n \to \{-1,+1\}$ is ϵ-far from s-sparse-Boolean if for every s-sparse function $g : \mathbb{Z}_p^n \to \{-1,+1\}$ the ℓ_2-distance of f and g is at least $\sqrt{\epsilon}$.*[1]

We say that an algorithm (property tester) $\mathcal{A}$ ϵ-tests $\mathcal{C}$, for a class of functions $f : \mathbb{Z}_p^n \to \{-1,+1\}$, if given access to the truth table of a function f, whether $f \in \mathcal{C}$, or f, is "ϵ-far from $\mathcal{C}$" can be tested using $\mathcal{A}$ with success probability (called the *confidence*) $\geq 2/3$. The number of queries to the truth-table of f made by $\mathcal{A}$ is called the query complexity of $\mathcal{A}$.

[1] In property testing usually the distance measure used is Hamming distance between two Boolean functions. But since we are using ℓ_2 distance in our other theorem, so for ease of presentation, we have defined the farness in terms of ℓ_2 instead of Hamming distance. Also, note that for a pair of Boolean-valued functions the square of the ℓ_2 distance and Hamming distance are the same up to a multiplicative factor of 4, see the archived version of the paper [7]

Using the structure theorems (Theorem 3 and Theorem 4), we prove the following theorem which tests sparsity of a Boolean-valued function $f : \mathbb{Z}_p^n \to \{-1, +1\}$.

▶ **Theorem 8** (Testing s-sparsity). *For a fixed prime p, there is a non-adaptive* $\mathsf{poly}(s, 1/\epsilon)$ *query algorithm with confidence $2/3$, which tests whether a given function $f : \mathbb{Z}_p^n \to \{-1, +1\}$, is s-sparse or ϵ-far from s-sparse-Boolean.*

We can also obtain a similar testing algorithm for sparsity, for a Boolean-valued function over $\mathcal{G}$. The generalized algorithm is discussed in the archived version of the paper [7].

We complement our result by showing a query-complexity lower bound for sparsity-testing algorithms. Gopalan et al. [15] gave a $\Omega(\sqrt{s})$ lower bound for s-sparsity testing algorithms over $\mathbb{Z}_2^n$. An important component of their proof was to cleverly use an alternative notion of *degree* (borrowed from [6]) of a Boolean function over $\mathbb{Z}_2$. We also give a similar lower bound over $\mathbb{Z}_p^n$, by appropriately generalizing the useful notion of degree. For details on the definition of degree, see proof idea of Theorem 9 in Section 1.2 and in the archived version of the paper [7].

▶ **Theorem 9.** *For Boolean valued functions on $\mathbb{Z}_p^n$, to adaptively test s-sparsity, the query lower bound of any algorithm is $\Omega(\sqrt{s})$.*

Theorem 9 can be generalized for Boolean valued functions on $\mathcal{G}$, which will give us the same lower bound.

1.2 Proof ideas

In this section, we briefly outline the proof ideas of our main theorems. Although some of the proofs are indeed inspired by [15] (which worked over $\mathbb{Z}_2$), the proof techniques *does not* directly generalize over $\mathbb{Z}_p$. So, we will first discuss the proof ideas, and then clarify the differences between [15] and our techniques (see Section 1.2.1). While doing so, we will try to convey the hurdles for generalizing over $\mathbb{Z}_p$. Let us first sketch the proof of Theorem 3.

Proof idea of Theorem 3. Our goal is to show that if f is μ-close to some s-sparse complex-valued function in ℓ_2, then there exists a non-zero polynomial $g(X) \in \mathbb{Z}[X]$ such that the following properties hold.

1. The sum of the absolute values of its coefficients is *at most* p^k, where $k := \lceil \log_p s \rceil + 1$.
2. The *distance* between the absolute value of each non-zero Fourier coefficient of f and $|g(\omega_p)|/p^k$ is at most $\mu/\sqrt{s}$.

To show the above, we first utilize a probabilistic method to prove that for each character $\chi_i \in B$ in the Fourier support of f, there exists a matrix $A \in \mathbb{Z}_p^{k \times n}$, and a column vector $b \in \mathbb{Z}_p^{n \times 1}$, such that – (1) χ_i is a solution of the linear system $A\chi = b$, and (2) *no other* character in the Fourier support of f is a solution of $A\chi = b$, where B be the set of s-largest Fourier coefficients of f. After establishing the existence of such A and b, we consider the Fourier transform of the projection operator for the solution space of $A\chi = b$ (see the archived version of the paper [7]). The projection operator, as the name suggests, is an operator that projects $\mathbb{Z}_p^n$ onto a linear subspace which yields a partition of the Fourier spectrum of f. Then we show that the ℓ_2 Fourier weight of $S \cap H$, i.e., $\sum_{\chi \in S \cap H} |\widehat{f}(\chi)|^2$ is upper bounded by $\mu/\sqrt{s}$, where $S = \overline{B}$, and H is a coset of $A^\perp$ that are solutions to the system of linear equations $A\chi = b$. For details, see the archived version of the paper [7].

Proof idea of Theorem 5. If we put $\mu = 0$ in Theorem 3, we get that there exists a $g \in \mathbb{Z}[X]$, with the sum of the absolute values of its coefficients is *at most* p^k, such that $|\widehat{f}(\chi)| \geq |g(\omega_p)/p^k|$, where $k = \lceil \log_p s_f \rceil + 1$, s_f being the sparsity of the Boolean valued function f. The remaining part of the proof is to show that for any polynomial g with the aforementioned properties, $|g(\omega_p)|/p^k \geq 1/(p^2 s_f)^{\lceil (p-1)/2 \rceil}$.

As stated earlier, we use a non-trivial result from algebraic number theory (Theorem 25), which states that if $f \in \mathbb{Z}[x]$, such that $f(\omega_n) \neq 0$, where ω_n be a primitive root of unity, then, $|\prod_{i \in \mathbb{Z}_n^*} f(\omega_n^i)| \geq 1$. We also use the fact that the sum of the absolute values of the coefficients of g is at most p^k, to get an upper bound on the quantities $|g(\omega_p^i)|$, for any $i \in [p-1]$. Combining these two facts, we obtain our lower bound; for details see the archived version of the paper [7].

Proof idea of Theorem 4. We first show that the given function $f : \mathbb{Z}_p^n \to \{-1, +1\}$, that is μ-close to some s-sparse complex-valued function in ℓ_2, can be written as the sum of two functions F and G, where the Fourier coefficients of F are $\lceil \log_p s \rceil + 1$-granular and the absolute value of the Fourier coefficients of G are upper bounded by $\mu/\sqrt{s}$, where p is an odd prime. This follows from Theorem 3. Then we show that the range of F is $\{-1, +1\}$, which uses the following facts:

1. $(F + G)^2 = f^2 = 1$ and
2. F^2 is $2\lceil \log_p s \rceil + 1$-granular.

We compute $\mathbb{E}[G(x)^2]$ in order to find an upper bound on the Fourier coefficients of $H := G(2f - G)$, which helps us to conclude that $\widehat{F^2}(\chi) = 0$ for all $\chi \neq \chi_0$, and $\widehat{F^2}(\chi_0) = 1$, where χ_0 is the character which takes the value 1 at all points in $\mathbb{Z}_p^n$. Then we complete the proof by showing that the $\Pr_x[x \in \mathbb{Z}_p^n | f(x) \neq g(x)]$ is $\leq \mu^2/2$, which implies that F is $\sqrt{2}\mu$ close to f in ℓ_2 (see Lemma 22). This idea has also been employed in [15]. We have also extended this proof to a more general Abelian group $\mathcal{G}$, (see the archived version of the paper [7]).

Proof idea of Theorem 6. The example that we construct to prove Theorem 6 is a simple one. The crucial observation in this regard is that there are functions from $\mathbb{Z}_p$ to $\{-1, +1\}$, whose Fourier coefficients are smaller than $1/p$. In this work, we work with one such function $\mathbb{I}_{\geq \frac{p+1}{2}} : \mathbb{Z}_p \to \{-1, +1\}$. We claim that the composition function $AND_n \circ \mathbb{I}_{\geq \frac{p+1}{2}}$ is one such desired function from $\mathbb{Z}_p^n$ to $\{-1, +1\}$, such that its minimum Fourier coefficient is less than $1/p^n$. Here, we assume a trivial bound of p^n on the Fourier sparsity of the function $AND_n \circ \mathbb{I}_{\geq \frac{p+1}{2}}$.

Proof idea of Theorem 8. We sketch the algorithmic idea over $\mathbb{Z}_p^n$, where p is an odd prime; this idea can be canonically extended to more general Abelian groups $\mathcal{G}$. The main idea of the algorithm is to partition the set of characters into buckets and estimate the *weights* of the individual buckets (that is the sum of the squares of the absolute values of the Fourier coefficients corresponding to the characters in the buckets). We know from Theorem 5 that all the coefficients of an s-sparse function are at least as large as $1/(p^2 s)^{\lceil (p-1)/2 \rceil}$. So, we are certain that if the weights of the buckets can be approximated within an additive error or $\tau/3$, where $\tau \geq 1/(p^2 s)^{p-1}$, then in the case the function is s-sparse, not more than s of the buckets can have weight more than $\tau/2$. On the other hand, we will show that if the function f is ϵ-far from any s-sparse Boolean function then with a high probability at least $(s + 1)$ buckets will have weight more than τ, making the estimated weight at least $2\tau/3$; see the archived version of the paper for more details [7].

The challenge is that estimating the weights of the buckets is not easy if the characters the randomly partitioned into buckets. Here we use the ideas from Gopalan et al [15] and appropriately modify them to handle the technicalities of working with $\mathbb{Z}_p^n$. We choose the buckets carefully. The buckets corresponds to the cosets of $H^\perp$ in $\mathbb{Z}_p^n$, where H is a random subspace of $\mathbb{Z}_p^n$ of dimension, $t = \Theta(s^2)$. For such kinds of buckets, we show that estimation of the weight can be done using a small number of samples. We also need to use the concept of "random shift", see the archived version of the paper [7], to avoid the corner case of characters being put into the trivial bucket.

Unlike [15], it becomes a bit more challenging to prove that if f is ϵ-far from any s-sparse Boolean function over $\mathbb{Z}_p^n$, then with high probability at least $(s+1)$ buckets will have weight more than τ. Since we partition the set of characters by cosets, the events whether two characters land in the same bucket (that is same coset) are *not independent* – since two characters (in the case $p \neq 2$) can be scalar multiple of each other; this is where some additional care is required (which was not the case in [15]). Under random shifts and case-by-case analysis, we can show that the two events are *not correlated*, i.e., the covariance of the corresponding indicator variables of the two events is 0; see the archived version of the paper [7]. Thus, we can use Chebyshev's inequality and then Markov's inequality to bound the number of buckets that can be of low weight, or in other words prove that the number of "heavy" weight buckets is more than $s+1$. The proof of Theorem 8 is given in the archived version of the paper [7].

Proof idea of Theorem 9. In [15], Gopalan et al. proved a query lower bound over $\mathbb{Z}_2^n$, by using a natural notion of *degree* of a Booelan function, denoted $\deg_2$. They crucially used the fact that for a Boolean function f over $\mathbb{Z}_2$, $2^{\dim(f)} \geq s_f \geq 2^{\deg_2(f)}$; this was originally proved in [6]. To define the degree, let us consider all possible restrictions $f|_{V_{b,r_1,\ldots,r_t}}$ of f, where $V_{b,r_1,\ldots,r_t}$ is a coset of $V_{0,r_1,\ldots,r_t}$ in $\mathbb{Z}_p^n$ as defined as

$$V_{b,r_1,\ldots,r_k} \;:=\; \{x \in \mathbb{Z}_p^n : r_j \cdot x \;=\; b_j \pmod{p}\ \forall j \in [t]\}\ .$$

Then the degree over $\mathbb{Z}_p$ of f, denoted by $\deg_p$, is defined in the following way.

$$\deg_p(f) \;=\; \max_{\ell}\{\ell \;= \dim(V_{b,r_1,\ldots,r_t}) \;:\; s_{f|_{V_{b,r_1,\ldots,r_t}}} \;=\; p^{\dim(V_{b,r_1,\ldots,r_t})}\},$$

where $s_{f|_{V_{b,r_1,\ldots,r_t}}}$ is the Fourier sparsity of the function $f|_{V_{b,r_1,\ldots,r_t}}$. [15] defined the degree over $\mathbb{Z}_2^n$ via similar restrictions. However, [15] argued that this is a natural definition of the degree over $\mathbb{Z}_2^n$. To argue, observe that $\widehat{f} = \frac{1}{2^n} H_n f$, where H_n is the $2^n \times 2^n$ Hadamard matrix, when $x_i \in \mathbb{Z}_2^n$ are seen in lexicographic order. Consider the restrictions $f|_{V_{b,r_1,\ldots,r_t}}$ that takes the value 1 at those points such that each entry of $\widehat{f}|_{V_{b,r_1,\ldots,r_t}}$ is nonzero. Then $\deg_2$ can be defined as the dimension of the coset $V_{b,r_1,\ldots,r_t}$ which is *largest* amongst them! In that case, all the Fourier coefficients of $f|_{V_{b,r_1,\ldots,r_t}}$ are nonzero.

Interestingly, we can also show that the above definition of $\deg_p$ is natural, mainly because $\widehat{f} = \frac{1}{p^n} V_n f$, where V_1 is a $p \times p$ *Vandermonde* matrix V_1, whose (i,j)-th entry is $(V_1)_{i,j} := \omega_p^{(i-1)(j-1)}$, and V_n is defined by taking n many *Kronecker products* of V_1, i.e., $V_n := V_1^{\otimes n} = V_1 \otimes \cdots \otimes V_1$. Note that $H_n = V_n$, over $\mathbb{Z}_2^n$. Similar to [6], one can also show that $p^{\dim(f)} \geq s_f \geq p^{\deg_p(f)}$ (see the archived version of the paper [7]). This plays a crucial role in the proof.

We first define two distributions $\mathcal{D}_{Yes}$ and $\mathcal{D}_{No}$ on the set of Boolean valued functions from $\mathbb{Z}_p^n$ to $\{-1,+1\}$. Let us choose a *random* t-dimensional subspace H of $\mathbb{Z}_p^{Ct}$, for some parameter C (to be fixed later). Let $\mathcal{C}$ be the set of all cosets of H. There are 2 main steps as follows.

1. We construct random functions f by making f a constant on each coset of $\mathcal{C}$. The constant is chosen randomly from $\{-1,+1\}$. We call this probability distribution $\boldsymbol{\mathcal{D}_{yes}}$.
2. We choose a random function f randomly from $\mathbb{Z}_p^{Ct}$, conditioned on the fact that f is $2-\tau$ far in ℓ_2 from any function which has $\deg_p = t$, where τ is as defined in Theorem 8. Let us call this distribution $\boldsymbol{\mathcal{D}_{No}}$.

We show that if an adaptive query algorithm makes less than $q < \Omega(p^{t/2})$ queries, then the total variation distance $||\mathcal{D}_{Yes} - \mathcal{D}_{No}||_{TV}$ between the two distributions $\mathcal{D}_{Yes}$ and $\mathcal{D}_{No}$ is $\leq \frac{1}{3}$. This proves that any adaptive query algorithm which distinguishes between $\mathcal{D}_{Yes}$ and $\mathcal{D}_{No}$, i.e., where $||\mathcal{D}_{Yes} - \mathcal{D}_{No}||_{TV} > \frac{1}{3}$, *must* make at least $\Omega(p^{t/2})$ queries. This essentially proves Theorem 9.

1.2.1 Comparison with Gopalan et al. [15]

In this section, we discuss the main differences and points between our proof and the one by Gopalan et al. [15]. Our proofs (and the analysis of the testing algorithm) are more elaborate, subtle, case-dependent, and complicated than [15].

Linear dependence is *bad*. [15] used the similar idea as in Theorem 3, see the archived version of the paper for more details [7]. However, their proof took advantage of the fact that any two distinct non-zero vectors in $\mathbb{Z}_2^n$ are *linearly independent*. This is *not true* for $\mathbb{Z}_p^n$, as distinct vectors can be scalar multiples of each other; e.g., $(1,\cdots,1)$ and $(2,\cdots,2)$ in $\mathbb{Z}_p^n$, for any $p \geq 3$. Thus, our proof technique is capable of handling and overcoming these difficulties effectively. This is also why our analysis of the structure theorems and algorithms are very much case-dependent.

Different granularity. In case of $\mathbb{Z}_2^n$, [15] defined a function $f : \mathbb{Z}_2^n \to \{-1,+1\}$ to be k-granular, where k is a positive integer, if all of its nonzero Fourier coefficients are an *integer multiple* of $\frac{1}{2^k}$. In the case of $\mathbb{Z}_p^n$, since the Fourier coefficients are truly complex numbers, we define a function $f : \mathbb{Z}_p^n \to \{-1,+1\}$ to be k-granular if all of its nonzero Fourier coefficients are of the form $\frac{g(\omega_p)}{p^k}$ (see Definition 1), where $g \in \mathbb{Z}[X]$ and ω_p is a primitive p^{th} root of unity.

Algebraic integer lower bounds are *harder*. While proving a lower bound on the absolute value of the Fourier coefficients, in the case of $\mathbb{Z}_2^n$, proving a lower bound on the magnitude of a Fourier coefficient [15] translates to proving a lower bound on $|g(-1)|/2^k$ (since $\omega_2 = -1$). Note that $|g(-1)| \geq 1$, because $g(-1) \in \mathbb{Z} \setminus \{0\}$; hence the lower bound follows. However, for a general prime p, ω_p is *truly* a complex number, and hence, $g(\omega_p)$ is *no longer* an integer (and therefore, there is no way to conclude that $|g(\omega_p)| \geq 1$). We use a non-trivial result from algebraic number theory (Theorem 25) to tackle this problem, in the proof of Theorem 5. We also crucially use the fact that the sum of the absolute values of the coefficients of g is at most p^k, to get an upper bound on the quantities $|g(\omega_p^i)|$, for any $i \in [p-1]$. Clearly, this part requires much more non-triviality than [15].

Do not expect a tight linear lower bound. For $p = 2$, it follows from [15] that the lower bound on the absolute value of the Fourier coefficients is equal to $\frac{1}{s_f}$. We show in Theorem 6 that there exists a family of Boolean valued functions on $\mathbb{Z}_p^n$, $p > 3$ such that $\min_{\chi \in \mathrm{supp}(f)} \left|\widehat{f}(\chi)\right| \leq 1/s_f^{1+\alpha_p}$, hence proving that the lower bound on the absolute value of the Fourier coefficients is not linear in $\frac{1}{s_f}$ in case of $p > 3$.

Generalizing the notion of degree. For functions from $\mathbb{Z}_2^n$ to $\{-1,+1\}$, it is known that $\widehat{f} = \frac{1}{p^n} H_n f$, where H_n denotes the Hadamard matrices (see [6]). Then, the degree $\deg_2$ is defined naturally in the case of $\mathbb{Z}_2^n$. The definition of $\deg_p$ becomes slightly challenging, since the relation $\widehat{f} = \frac{1}{p^n} H_n f$ is simply *false* over $\mathbb{Z}_p^n$. To define $\deg_p$ for Boolean valued functions on $\mathbb{Z}_p^n$ (see the archived version of the paper [7]), where p is an odd prime, we have defined the matrix V_1 using Vandermonde matrix, and have inductively defined the matrices V_n, where n is a positive integer, via Kronecker product. Then we have shown that $\widehat{f} = \frac{1}{p^n} V_n f$, which helps us to define $\deg_p(f)$. We claim that this is an appropriate generalization of degree, since $H_n = V_n$, over $\mathbb{Z}_2^n$.

Finally, we remark that because of the *absence of a linear structure* on the solution space of systems of equations over arbitrary Abelian groups (e.g. $\mathbb{Z}_{p^2}$), we could not generalize this to arbitrary Abelian groups.

2 Preliminaries

2.1 Fourier Analysis over $\mathbb{Z}_{p_1}^{n_1} \times \cdots \times \mathbb{Z}_{p_t}^{n_t}$

$\mathbb{Z}_{p_1}^{n_1} \times \cdots \times \mathbb{Z}_{p_t}^{n_t}$ forms a finite Abelian group under addition whose order is $p_1^{n_1} \cdots p_t^{n_t}$, where $p_1, \ldots, p_t$ are distinct primes. Its individual components form a vector space, that is, $\mathbb{Z}_{p_i}^{n_i}$ is a vector space over the field $\mathbb{Z}_{p_i}$ for all $i \in \{1, 2, \ldots t\}$ whenever p_i's are primes. Throughout this paper we will denote $\mathbb{Z}_{p_1}^{n_1} \times \cdots \times \mathbb{Z}_{p_t}^{n_t}$ by $\mathcal{G}$. So $\mathcal{G}$ is a finite Abelian group with $|\mathcal{G}| = p_1^{n_1} \cdots p_t^{n_t}$, where $|.|$ denotes the order of $\mathcal{G}$.

We will denote this root of unity by ω_p a p^{th} primitive root of unity, that is $e^{2\pi\iota/p}$.

Let us begine by defining the characters of $\mathcal{G}$.

▶ **Definition 10** (Character). *A character of $\mathcal{G}$ is a homomorphism $\chi : \mathcal{G} \to \mathbb{C}^\times$ of $\mathcal{G}$, that is, χ satisfies the following:*

$$\chi(x+y) = \chi(x)\chi(y), \;\; x, y \in \mathcal{G}.$$

Equivalently, a character χ of $\mathcal{G}$ can be defined by

$$\chi(x_1, \ldots, x_t) = \chi_{r_1}(x_1) \cdots \chi_{r_t}(x_t) = \omega_{p_1}^{r_1 \cdot x_1} \cdots \omega_{p_t}^{r_t \cdot x_t},$$

where χ_{r_i} is a character of $\mathbb{Z}_{p_i}^{n_i}$ for each i and is defined by $\chi_{r_i}(x_i) = \omega_{p_i}^{r_i \cdot x_i}$, $x_i, r_i \in \mathbb{Z}_{p_i}^{n_i}$ for all i, $r_i \cdot x_i = \sum_{j=1}^{n_i} r_{i(j)} x_{i(j)}$, $r_{i(j)}$ and $x_{i(j)}$ being the j^{th} component of r_i and x_i respectively (It follows from the fact that any character χ of $\mathcal{G}$ can be written as the product of characters of $\mathbb{Z}_{p_1}^{n_1}, \ldots, \mathbb{Z}_{p_t}^{n_t}$). Let us denote this character by $\chi_{r_1,\ldots,r_t}$.

Now let us look at some properties of characters.

▶ **Lemma 11.** *Let χ be a character of $\mathcal{G}$. Then,*

1. $\chi_0(x) = 1$ *for all* $x \in \mathcal{G}$.
2. $\chi(-x) = \chi(x)^{-1} = \overline{\chi(x)}$ *for all* $x \in \mathcal{G}$.
3. *For any character χ of $\mathcal{G}$, where $\chi \neq \chi_0$, $\sum_{x \in \mathcal{G}} \chi(x) = 0$.*
4. $|\chi_0(x)| = 1$ *for all* $x \in \mathcal{G}$.

Now let us define the dual group of $\mathcal{G}$.

▶ **Definition 12** (Dual group). *The set of characters of $\mathcal{G}$ forms a group under the operation $(\chi\psi)(x) = \chi(x)\psi(x)$ and is denoted by $\widehat{\mathcal{G}}$, where χ and ψ are characters of $\mathcal{G}$. $\widehat{\mathcal{G}}$ is called the dual group of $\mathcal{G}$.*

The following theorem states that $\mathcal{G}$ is isomorphic to its dual group.

▶ **Theorem 13.** *$\widehat{\mathcal{G}} \cong \mathcal{G}$.*

Let us look at the definition of Fourier transform for functions on $\mathcal{G}$.

▶ **Definition 14** (Fourier transform)**.** *For any function $f : \mathcal{G} \to \mathbb{C}$, the Fourier transform $\widehat{f} : \widehat{\mathcal{G}} \to \mathbb{C}$ is defined by*

$$\widehat{f}(\chi_{r_1,\dots,r_t}) = \frac{1}{|\mathcal{G}|} \sum_{x\in\mathcal{G}} f(x)\omega_{p_1}^{-r_1\cdot x_1} \cdots \omega_{p_t}^{-r_t\cdot x_t},$$

where $x_i, r_i \in \mathbb{Z}_{p_i}^{n_i}$ for all i, and $r_i \cdot x_i = \sum_{j=1}^{n_i} r_{i(j)}x_{i(j)}$, $r_{i(j)}$ and $x_{i(j)}$ being the j^{th} component of r_i and x_i respectively.

▶ Remark 15. The Fourier transform of a function $f : \mathcal{G} \to \mathbb{C}$ is defined by

$$\widehat{f}(\chi) = \frac{1}{|\mathcal{G}|} \sum_{x\in\mathcal{G}} f(x)\overline{\chi(x)},$$

where $\overline{\chi(x)}$ is the conjugate of $\chi(x)$. The Definition 14 follows from this, as $\chi = \chi_{r_1,\dots,r_t}$ for some $r_i \in \mathbb{Z}_{p_i}^{n_i}$, $i \in \{1, \dots, t\}$.

The following theorem states that any function from $\mathcal{G}$ to $\mathbb{C}$ can be written as a linear combination of characters of $\mathcal{G}$.

▶ **Theorem 16** (Fourier inversion formula)**.** *Any function $f : \mathcal{G} \to \mathbb{C}$ can be uniquely written as a linear combination of characters of $\mathcal{G}$, that is,*

$$f(x) = \sum_{\chi_{r_1,\dots,r_t}\in\widehat{\mathcal{G}}} \widehat{f}(\chi_{r_1,\dots,r_t})\omega_{p_1}^{r_1\cdot x_1} \cdots \omega_{p_t}^{r_t\cdot x_t},$$

where $x_i, r_i \in \mathbb{Z}_{p_i}^{n_i}$ for all i, $r_i \cdot x_i = \sum_{j=1}^{n_i} r_{i(j)}x_{i(j)}$, $r_{i(j)}$ and $x_{i(j)}$ being the j^{th} component of r_i and x_i respectively.

▶ **Theorem 17** (Parseval)**.** *For any two functions $f, g : \mathcal{G} \to \mathbb{C}$,*

$$\mathbb{E}_{x\in\mathcal{G}}[f(x)\overline{g(x)}] = \sum_{\chi\in\widehat{\mathcal{G}}} \widehat{f}(\chi)\overline{\widehat{g}(\chi)}.$$

More specifically, if $f : \mathcal{G} \to \{-1, +1\}$ is a Boolean-valued function then

$$\sum_{\chi\in\widehat{\mathcal{G}}} |\widehat{f}(\chi)|^2 = 1.$$

Now let us define the Fourier sparsity of a function f on $\mathcal{G}$.

▶ **Definition 18** (Sparsity and Fourier Support)**.**

- *The Fourier sparsity s_f of a function $f : \mathcal{G} \to \mathbb{C}$ is defined to be the number of non-zero Fourier coefficients in the Fourier expansion of f (Theorem 16). In this paper, by sparsity of a function, we will mean the Fourier sparsity of the function.*
- *Fourier support* $\mathrm{supp}(f)$ *of a function $f : \mathcal{G} \to \mathbb{C}$ denotes the set $\left\{\chi \mid \widehat{f}(\chi) \neq 0\right\}$.*

The following lemma states an important property of characters of a subgroup $H = H_1 \times \cdots \times H_t$ of $\mathcal{G}$.

▶ **Lemma 19.** *$\sum_{h\in H}\chi_h = |H|\cdot 1_{H^\perp}$, where $H = H_1\times\cdots\times H_t$ is a subgroup of $\mathcal{G}$, and $h = (h_1,\dots,h_t)$, $h_i\in H_i$ $\forall i$. That is,*

$$\sum_{h_1\in H_1,\dots,h_t\in H_t}\chi_{h_1}\cdots\chi_{h_t} = |H_1|\cdots|H_t|\cdot 1_{H_1^\perp}\cdots 1_{H_t^\perp}.$$

Here, for each i, H_i is a subgroup of $\mathbb{Z}_{p_i}^{n_i}$ and hence a subspace $\mathbb{Z}_{p_i}^{n_i}$, as $\mathbb{Z}_{p_i}^{n_i}$ is a vector space.

The proof of Lemma 19 is given in the archived version of the paper [7] due to lack of space.

▶ **Lemma 20.** *Let f, g be two Boolean valued functions from $\mathcal{G}$ to $\{-1,+1\}$. Then,*

$$|\widehat{fg}(\chi)| \le ||f||_2||g||_2,$$

for any character $\chi\in\widehat{\mathcal{G}}$.

The proof of Lemma 20 is given in the archived version of the paper [7] due to lack of space.

Now let us formally define the notion of ϵ-close and ϵ-far in ℓ_2 below.

▶ **Definition 21** (μ-close to s-sparse). *Let f and g be two functions with domain $\mathbb{Z}_p^n$ and range $\mathbb{C}$. Then the square of the ℓ_2 distance between f and g is defined as $\mathbb{E}_{x\in\mathcal{G}}[|f(x)-g(x)|^2]$. By Parseval's identity the square of the ℓ_2-distance between f and g can also be written as $\sum_{\chi\in\widehat{\mathbb{Z}_p^n}}|\widehat{(f-g)}(\chi)|^2$.*

We say that f is ϵ-close to g in ℓ_2 if the square of the ℓ_2 distance between f and g is less than ϵ. Similarly, f is ϵ-far from g in ℓ_2 if the square of the ℓ_2 distance between f and g is at least ϵ.

The following lemma gives us a relation between the ℓ_2 distance between two Boolean valued functions f and g defined in Definition 21 and $\Pr_x[x\in\mathcal{G}|f(x)\neq g(x)]$.

▶ **Lemma 22.** *The square of the ℓ_2 distance between two Boolean valued functions f and g defined in Definition 21 is equal to $4\Pr_x[x\in\mathcal{G}|f(x)\neq g(x)]$.* [2]

The proof of Lemma 22 is given in the archived version of the paper [7] due to lack of space.

Now let us define the total variation distance between two probability distributions.

▶ **Definition 23.** *Let $(\Omega,\mathcal{F})$ be a probability space, and P and Q be probability distributions defined on $(\Omega,\mathcal{F})$. The total variation distance between P and Q is defined in the following way.*

$$||P-Q||_{TV} = \sup_{A\in\mathcal{F}}|P(A)-Q(A)|.$$

▶ **Lemma 24.** *Given two probability distributions P and Q on a probability space $(\Omega,\mathcal{F})$, the total variation distance between P and Q is half of the L_1 distance between them. That is,*

$$||P-Q||_{TV} = \frac{1}{2}\sum_x|P(x)-Q(x)|.$$

[2] If f and g are two Booelan-valued functions then $\Pr_x[x\in\mathcal{G}|f(x)\neq g(x)]$ is also called the Hamming distance between the two functions. So the ℓ_2 norm between two Boolean-valued functions is 4 times the Hamming distance between two Boolean-valued functions.

3 Lower bound on the Fourier coefficients

In this section, we will prove Theorem 5 assuming Theorem 3, which gives us a lower bound on the Fourier coefficients of functions from $\mathbb{Z}_p^n$ to $\{-1,+1\}$, where p is a prime number. This is a generalization on the granularity of a function $f : \mathbb{Z}_2^n \to \mathbb{R}$ when the domain of the function is $\mathbb{Z}_p^n$. We will use the following theorem; for more details see the archived version of the paper [7].

▶ **Theorem 25.** *For $n \in \mathbb{Z}$, let ω_n be a primitive root of unity. Let $f \in \mathbb{Z}[x]$, such that $f(\omega_n) \neq 0$. Then,*

$$\left|\prod_{i\in\mathbb{Z}_n^*} f(\omega_n^i)\right| \geq 1 .$$

Proof of Theorem 5. If we put $\mu = 0$ in Theorem 3, we get that there exists a $g \in \mathbb{Z}[X]$, such that $|\widehat{f}(\chi)| \geq |g(\omega_p)/p^k|$, where $k = \lceil \log_p s_f \rceil + 1$, s_f being the sparsity of the Boolean valued function f. We know by Theorem 25 that $|\prod_{i=1}^{p-1} g(\omega_p^i)| \geq 1$. Therefore,

$$\left|\prod_{i=1}^{p-1} g(\omega_p^i)\right| \geq 1 \Rightarrow \prod_{i=1}^{p-1}\left|\frac{g(\omega_p^i)}{p^k}\right| \geq \left(\frac{1}{p^k}\right)^{p-1} \Rightarrow \left|\frac{g(\omega_p)}{p^k}\right| \geq \frac{1}{p^{k(p-1)}} \geq \frac{1}{(p^2 s_f)^{p-1}}.$$

For $p = 2$, $g(\omega_p^i)$ is an integer, so

$$\left|\frac{g(\omega_p)}{p^k}\right| \geq \frac{1}{4s_f} \tag{3.1}$$

For $p \neq 2$, the conjugate of $g(\omega_p^i)$, namely $\overline{g(\omega_p^i)}$, is nothing but $= g(\omega_p^{p-i})$. Since $|g|_1 \leq p^k$, it follows that for any $i \in [p-1]$, $|g(\omega_p^i)/p^k| \leq 1$. Therefore,

$$\begin{aligned}
\left|\prod_{i=1}^{p-1} g(\omega_p^i)\right| \geq 1 &\Rightarrow \prod_{i=1}^{(p-1)/2} |g(\omega_p^i)|^2 \geq 1 \\
&\Rightarrow \prod_{i=1}^{(p-1)/2} \left|\frac{g(\omega_p^i)}{p^k}\right|^2 \geq (\frac{1}{p^k})^{p-1} \\
&\Rightarrow \left|\frac{g(\omega_p)}{p^k}\right|^2 \geq \frac{1}{p^{k(p-1)}} \\
&\Rightarrow \left|\frac{g(\omega_p)}{p^k}\right| \geq \frac{1}{p^{k(p-1)/2}} \geq \frac{1}{(p^2 s_f)^{(p-1)/2}} .
\end{aligned} \tag{3.2}$$

So, from Equation (3.1) and Equation (3.2), we have

$$\left|\frac{g(\omega_p)}{p^k}\right| \geq \frac{1}{(p^2 s_f)^{\lceil (p-1)/2 \rceil}} . \qquad ◀$$

▶ Remark 26. Let p be a prime. The proof-technique of Theorem 5 gives the following. If the Fourier coefficients of a Boolean function f are k granular, where $k = \lceil \log_p s \rceil + 1$, then the Fourier coefficients of f^2 are $2k$-granular, and their absolute values are $\geq \frac{1}{(p^2 s)^{(p-1)}}$.

4 Sparse Boolean-valued function with small Fourier coefficients

In this section, for a fixed prime $p \geq 5$, and arbitrarily large s, we give an example of a function $f : \mathbb{Z}_p^n \to \{-1, +1\}$, such that the minimum of the absolute value of its Fourier coefficients is at most $o(1/s)$. In this section, we give the details of the construction of Theorem 6; see the archived version of the paper [7].

To prove Theorem 6 we define a function, which is basically composition of AND_n and univariate Threshold functions; we call AT.

▶ **Definition 27.** *Let us define function* $\mathsf{AT} : \mathbb{Z}_p^n \to \{-1, +1\}$ *by*

$$\mathsf{AT}(x_1, x_2, \ldots, x_n) \;:=\; \text{AND}_n\left(\mathbb{I}_{\geq \frac{p+1}{2}}(x_1), \mathbb{I}_{\geq \frac{p+1}{2}}(x_2), \ldots, \mathbb{I}_{\geq \frac{p+1}{2}}(x_n)\right),$$

where the univariate Threshold function $\mathbb{I}_{\geq \frac{p+1}{2}} : \mathbb{Z}_p \to \{-1, +1\}$, *is defined as:*

$$\mathbb{I}_{\geq \frac{p+1}{2}}(x) \;=\; \begin{cases} 1 & \text{for } x \geq \frac{p+1}{2} \\ -1 & \text{otherwise.} \end{cases}$$

▶ **Lemma 28.** *There is a Fourier coefficient of* AT, *whose absolute value is* $\frac{1}{p^{nc}}$, *where c is a constant* > 1.

The proof of Lemma 28 is given in the archived version of the paper [7]. Now we are ready to prove Theorem 6.

Proof of Theorem 6. This directly follows, as we can claim from Lemma 28 that there exists a family of functions in $\mathbb{Z}_p^n$ whose absolute value of the minimum coefficient is not linear in $\frac{1}{\text{sparsity}}$, but actually $= \Omega(\frac{1}{\text{sparsity}^{1+\epsilon_p}})$. where $\epsilon_p > 0$, is a p-dependent constant. ◀

▶ **Lemma 29.** *There exists a function whose one of the Fourier coefficients is less than that of* AT.

The proof of Lemma 29 is given in the archived version of the paper [7].

5 Testing Algorithm for Sparsity

Here we present the whole algorithm (Algorithm 1) for sparsity testing over $\mathbb{Z}_p^n$ (see next page). However, we describe the various steps of the algorithm in the archived version of the paper [7], including the correctness and the analysis of the algorithm in the archived version of the paper [7].

6 Conclusion

Gopalan et al. [15] was the first to study the problem of testing Fourier sparsity of Boolean function over $\mathbb{Z}_2^n$. Along the way, they were able to drive fundamental properties of Boolean functions over $\mathbb{Z}_2^n$, like *Granularity* of the Fourier spectrum, that have found many other applications [3]. In this work, we have extended their results for groups that can be written as $\mathbb{Z}_{p_1}^{n_1} \times \cdots \times \mathbb{Z}_{p_t}^{n_t}$.

The most natural question that arises from our work will be to study this problem for (finite) general Abelian groups. Unfortunately, our work does not extend to finite Abelian groups, because of the *absence* of the component-wise vector space structure. In particular, it would be nice to get a lower bound on the absolute value of non-zero Fourier coefficients of a sparse Boolean-valued function over $\mathbb{Z}_{p^2}^n$. In any way, our results in this paper should be seen as a first step toward solving the lower bound problem over finite Abelian group.

Finally, we ask whether it is possible to show a better (*p-dependent*) lower bound over $\mathbb{Z}_p^n$ on the query-complexity of any adaptive sparsity testing algorithm.

Algorithm 1 Test Sparsity.

```
Input: $s, \epsilon$, and query access to $f : \mathbb{Z}_p^n \to \{-1, +1\}$.
Output: YES, if $f$ is $s$-sparse, and NO, if it is $\epsilon$-far from any Boolean valued function.
Parameter setting: Set $t := \lceil 2\log_p s + \log_p 20 \rceil + 1, \tau := \min(\frac{\epsilon^2}{40p^t}, \frac{1}{(p^2 s)^{p-1}})$ $M := O(\log(p^t) \cdot \frac{1}{\tau^2})$
Choose $v_1, \ldots, v_t$ linearly independent vectors uniformly at random from $\mathbb{Z}_p^n$.
Let $H = \text{Span}\{v_1, \ldots, v_t\}$
Pick $(z_1, x_1), \ldots, (z_M, x_M)$ uniformly and independently from $H \times \mathbb{Z}_p^n$
Query $f(x_1), \ldots, f(x_M)$ and $f(x_1 - z_1), \ldots, f(x_M - z_M)$
for For every $r \in \mathbb{Z}_p^n$ do
    Let $\frac{1}{M}\sum_{i=1}^M \chi_r(z_i) f(x_i) f(x_i - z_i)$ be the estimate of $wt(r + H^\perp)$
end for
if number of $r$ for which the estimate of $wt(r + H^\perp)$ is $\geq \frac{2\tau}{3}$ is $\leq s$ then
    Output YES
else
    Output NO
end if
```

Krenn-Gu Conjecture for Sparse Graphs

University of California, Irvine, CA, USA

Abstract

Greenberger–Horne–Zeilinger (GHZ) states are quantum states involving at least three entangled particles. They are of fundamental interest in quantum information theory, and the construction of such states of high dimension has various applications in quantum communication and cryptography. Krenn, Gu and Zeilinger discovered a correspondence between a large class of quantum optical experiments which produce GHZ states and edge-weighted edge-coloured multi-graphs with some special properties called the *GHZ graphs*. On such GHZ graphs, a graph parameter called *dimension* can be defined, which is the same as the dimension of the GHZ state produced by the corresponding experiment. Krenn and Gu conjectured that the dimension of any GHZ graph with more than 4 vertices is at most 2. An affirmative resolution of the Krenn-Gu conjecture has implications for quantum resource theory. Moreover, this would save huge computational resources used for finding experiments which lead to higher dimensional GHZ states. On the other hand, the construction of a GHZ graph on a large number of vertices with a high dimension would lead to breakthrough results.

In this paper, we study the existence of GHZ graphs from the perspective of the Krenn-Gu conjecture and show that the conjecture is true for graphs of vertex connectivity at most 2 and for cubic graphs. We also show that the minimal counterexample to the conjecture should be 4-connected. Such information could be of great help in the search for GHZ graphs using existing tools like PyTheus. While the impact of the work is in quantum physics, the techniques in this paper are purely combinatorial, and no background in quantum physics is required to understand them.

1 Introduction

Quantum entanglement theory implies that two particles can influence each other, even though they are separated over large distances. In 1964, Bell demonstrated that quantum mechanics conflicts with our classical understanding of the world, which is local (i.e. information can be transmitted maximally with the speed of light) and realistic (i.e. properties exist prior to and independent of their measurement) [2]. Later, in 1989, Greenberger, Horne, and Zeilinger (abbreviated as GHZ) studied what would happen if more than two particles are entangled [8]. Such states in which three particles are entangled $(|GHZ_{3,2}\rangle = \frac{1}{\sqrt{2}}(|000\rangle + |111\rangle))$ were observed rejecting local-realistic theories [4, 21]. While the study of such states started purely out of fundamental curiosity [24, 16, 17], they are now used in many applications in quantum information theory, such as quantum computing [11]. They are also essential for early tests of quantum computing tasks [28], and quantum cryptography in quantum networks[22].

Zeilinger became a co-recipient of the Nobel Prize for Physics in 2022, for experiments with entangled photons, establishing the violation of Bell inequalities and pioneering quantum information science. We note that the work on experimentally constructing GHZ states is at the heart of Zeilinger's Nobel prize-winning work [1]. Increasing the number of particles involved and the dimension of the GHZ state is essential both for foundational studies and practical applications. Motivated by this, a huge effort is being made by several experimental groups around the world to push the size of GHZ states. Photonic technology is one of the key technologies used to achieve this goal [28, 27]. The Nobel Laureate himself, with some co-authors, proposed a scheme of optical experiments in order to achieve this, which gives an opportunity for graph theorists to get involved in this fundamental research: In 2017, Krenn, Gu and Zeilinger [14] discovered (and later extended [10, 9]) a bridge between experimental quantum optics and graph theory. They observed that large classes of quantum optics experiments (including those containing probabilistic photon pair sources, deterministic photon sources and linear optics elements) can be represented as an edge-coloured edge-weighted graph, though the edge-colouring goes a little beyond what graph theorists are used to. Conversely, every edge-coloured edge-weighted graph (also referred to as an experiment graph) can be translated into a concrete experimental setup. This technique has led to the discovery of new quantum interference effects and connections to quantum computing [10]. Furthermore, it has been used as the representation of efficient AI-based design methods for new quantum experiments [15, 23].

However, despite several efforts, a way to generate a GHZ state of dimension $d > 2$ with more than $n = 4$ photons with perfect quality and finite count rates without additional resources [13] could not be found. This led Krenn and Gu to conjecture that it is not possible to achieve this physically (stated in graph theoretic terms in Conjecture 6). They have also formulated this question purely in graph theoretic terms and publicised it widely among graph theorists for a resolution [19]. We now formally state this problem in graph-theoretic terms and explain its equivalence in quantum photonic terms. For a high-level overview of how the experiments are converted to edge-coloured edge-weighted graphs, we refer the reader to the appendix of [6]. For the exact details, the reader can refer to [14, 10, 9, 13].

1.1 Graph theoretic preliminaries and notations

We first define some commonly used graph-theoretic terms. For a graph G, let $V(G), E(G)$ denote the set of vertices and edges, respectively. We use $\kappa(G)$ to denote the vertex connectivity of G. For $S \subseteq V(G)$, $G[S]$ denotes the induced subgraph of G on S. $\mathbb{N}, \mathbb{N}_0, \mathbb{C}$ denote the set of natural numbers, non-negative numbers and complex numbers, respectively. The cardinality of a set $\mathcal{S}$ is denoted by $|\mathcal{S}|$. For a positive integer r, $[r]$ denotes the set $\{1, 2 \ldots, r\}$. Given a multi-graph, its skeleton is its underlying simple graph. We do not consider self-loops in multi-graphs.

Usually, in an edge colouring, each edge is associated with a natural number. However, in such edge colourings, the edges are assumed to be monochromatic. But in the graphs corresponding to experiments, we are allowed to have bichromatic edges, i.e. one half coloured by a certain colour and the other half coloured by a different colour. For example, in the graph shown in Figure 1a, the simple edge between vertices 4 and 6 is a bichromatic edge. We develop some new notation to describe bichromatic edges.

Each edge of a multi-graph can be thought to be formed by two half-edges, i.e., an edge e between vertices u and v, consists of the half-edge starting from the vertex u to the middle of the edge e (hereafter referred to as the u-half-edge of e) and the half-edge starting from the vertex v to the middle of the edge e (hereafter referred to as the v-half-edge e). Thus, the edge set E of the multi-graph gives rise to the set of half-edges H, with $|H| = 2|E|$. For an edge e between vertices u and v, we may denote the v-half-edge of e by e_v and u-half edge of e by e_u. Consider the edge e between vertices 4 and 6 in Figure 1a. The 4-half edge of e (e_4) is of colour red, and the 6-half edge (e_6) is of colour green.

The type of edge colouring that we consider in this paper is more aptly called a *half-edge colouring.* It is a function from H to $\mathbb{N}_0$, say $c : H \to \mathbb{N}_0$. (Note that we use non-negative numbers to name the colours.) In other words, each half-edge gets a colour. An edge is called monochromatic if both its half-edges get the same colour (in which case we may use $c(e)$ to denote this colour); otherwise, it is called a bi-chromatic edge. In Figure 1a, the colour 0 is shown in red, and the colour 1 is shown in green. It is easy to see that $c(e_4) = 0$ and $c(e_6) = 1$ (recall that e is the simple edge between vertices 4 and 6). Consider the edge e' between vertices 1 and 6. As $c(e'_1) = c(e'_6) = 0$, e' is monochromatic and moreover, $c(e') = 0$. We then assign a weight $w(e) \in \mathbb{C}$ to each such coloured edge e. We denote the multi-graph G with the edge colouring c and edge weights $w(e)$ as G_c^w.

We call a subset P of edges in this edge-weighted edge-coloured graph a perfect matching if each vertex in the graph has exactly one edge in P incident on it.

▶ **Definition 1.** *The weight of a perfect matching P, $w(P)$ is the product of the weights of all its edges* $\prod\limits_{e \in P} w(e)$

▶ **Definition 2.** *The weight of an edge-coloured edge-weighted multi-graph G_c^w is the sum of the weights of all perfect matchings in G_c^w.*

A vertex colouring vc associates a colour i to each vertex in the graph for some $i \in \mathbb{N}$. We use $vc(v)$ to denote the colour of vertex v in the vertex colouring vc. A vertex colouring vc *filters out* a sub-graph $\mathcal{F}(G_c, vc)$ of G_c on $V(G_c)$ where for an edge $e \in E(G_c)$ between vertices u and v, $e \in E(\mathcal{F}(G_c, vc))$ if and only if $c(e_u) = vc(u)$ and $c(e_v) = vc(v)$. Filtering also extends to weighted graphs where the weight of each edge in $\mathcal{F}(G_c^w, vc)$ is the same as its weight in G_c^w. Let vc be a vertex colouring in which $1, 2, 3, 6$ are associated with the colour green and $4, 5$ are associated with the colour red. The filtering operation of vc on the edge-coloured graph G_c^w shown in Figure 1a is given in Figure 1b. A vertex colouring vc is defined to be feasible in G_c^w if $\mathcal{F}(G_c^w, vc)$ has at least one perfect matching. It is easy to see that each perfect matching P is part of $\mathcal{F}(G_c^w, vc)$ for a unique vertex colouring vc. Such a P is said to induce vc. It is interesting to notice that there is a partition of perfect matchings (not edges) based on the vertex colourings.

▶ **Definition 3.** *The weight of a vertex colouring vc in the multi-graph G_c^w is denoted by $w(G_c^w, vc)$ and is equal to the weight of the graph $\mathcal{F}(G_c^w, vc)$.*

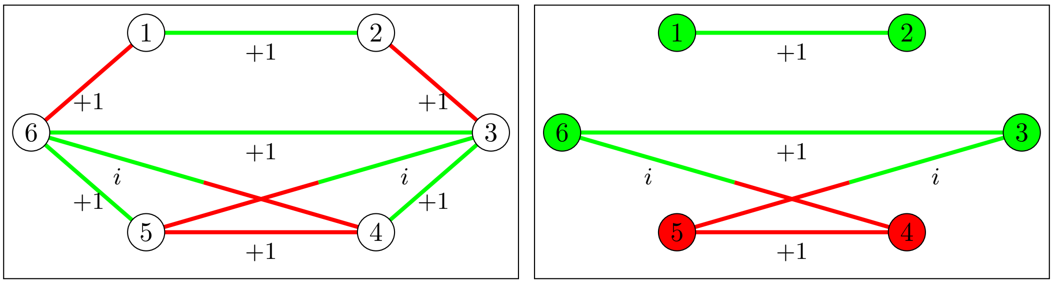
The weight of a vertex colouring, which is not feasible, is zero by default.

▶ **Definition 4.** *An edge-coloured edge-weighted graph is said to be GHZ, if:*
1. *All feasible monochromatic vertex colourings have a weight of* 1.
2. *All non-monochromatic vertex colourings have a weight of* 0.

An example of a GHZ graph is shown in Figure 1a.

▶ **Definition 5.** *The dimension of a GHZ graph G_c^w, $\mu(G, c, w)$ is the number of feasible monochromatic vertex colourings (having a weight of* 1*).*

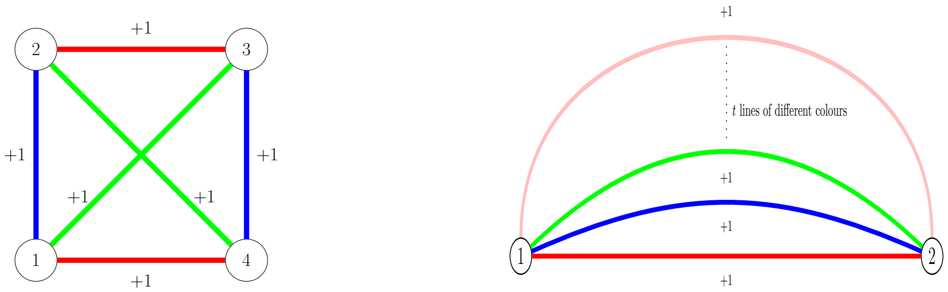
For a given multi-graph G (experimental set up), many possible edge-colourings (mode numbers of photons) and edge-weight (amplitude of photon pairs) assignments may lead it a GHZ graph (GHZ state). Finding a GHZ graph with n vertices and dimension d would



(a) An edge coloured edge-weighted graph G_c^w.

(b) $\mathcal{F}(G_c^w, vc)$, where $vc(i)$ is green for $i \in [1, 2, 3, 6]$ and red for $i \in [4, 5]$.

Figure 1 vc-Filtering of a graph.



(a) K_4 with 3 dimensions.

(b) K_2 with t dimensions.

Figure 2 GHZ graphs.

immediately lead to an experiment which result in a d-dimensional GHZ state with n particles. For each such GHZ graph, a dimension is achieved. The maximum dimension achieved over all possible GHZ graphs with the unweighted uncoloured simple graph G as their skeleton is known as the *matching index* of G, denoted by $\mu(G)$. In Figure 2b, we have an edge-coloured edge-weighted GHZ K_2 of dimension t. Note that t can be arbitrarily large. Therefore, $\mu(K_2) = \infty$. However, only two particles are involved; for a GHZ state to form, we need more than two particles. Therefore, such a construction will not give a GHZ state. We note that the matching index is defined for a simple graph G by taking the maximum over all possible multi-graphs with a skeleton G. For instance, the simple graph K_2 has only one edge. However, we considered all possible multi-graphs having a skeleton K_2 to define $\mu(K_2)$.

It is easy to see that if a graph has a perfect matching, it must contain an even number of vertices. So, we consider matching indices of graphs with even and at least 4 vertices for the rest of the manuscript. From Figure 2a, we know that $\mu(K_4) \geq 3$ and, despite the use of huge computational resources [15, 23, 20], this is the only (up to an isomorphism) known graph of the matching index at least 3. Any graph with a matching index of at least 3 and $n > 4$ vertices would lead to a new GHZ state of dimension at least 3 with $n > 4$ entangled particles. Motivated by this, this problem has been extensively promoted[19, 12]. Krenn and Gu conjectured that

▶ **Conjecture 6.** *If* $|V(G)| > 4$, *then* $\mu(G) \leq 2$

Several cash rewards were also announced for a resolution of this conjecture [12]. We note the following implications of resolving this conjecture

1. Finding a counterexample for this conjecture would uncover new peculiar quantum interference effects of a multi-photonic quantum system using which we can create new GHZ states

2. **a.** Proving this conjecture would immediately lead to new insights into resource theory in quantum optics
   b. Proving this conjecture for different graph classes would help us understand the properties of a counterexample and guide experimentalists in finding it. This is particularly important since huge computational efforts are going into finding such graphs [15, 23, 20].

A graph is matching covered if every edge of it is part of at least one perfect matching. If an edge e is not part of any perfect matching M, then we call the edge e to be redundant. By removing all redundant edges from the given graph G, we get its unique maximum matching covered sub-graph $mcg(G)$. Note that a colouring c and a weight assignment w of G induces a colouring and a weight assignment for every subgraph of G, respectively. When there is no scope for confusion, we use c, w itself to denote this induced colouring and weight assignment, respectively. It is easy to see that if c and w make G a GHZ graph, they also make $mcg(G)$ a GHZ graph and $\mu(G, c, w) = \mu(mcg(G), c, w)$. Therefore, $\mu(G) = \mu(mcg(G))$.

One can also notice that, if there are two edges, say e, e' between vertices u and v such that $c(e_u) = c(e'_u)$ and $c(e_v) = c(e'_v)$, then they can be replaced with an edge e'' such that $w(e'') = w(e) + w(e')$,$c(e''_u) = c(e_u)$ and $c(e''_v) = c(e_v)$. Such a reduction will retain the GHZ property and dimension of the graph. Therefore, in the rest of the manuscript, we only deal with such reduced graphs, i.e, between two vertices between vertices u and v and given $i, j \in [\mu(G)]$ there exists at most one edge e such that $c(e_u) = i$ and $c(e_v) = j$. We also note that, if an edge e has weight 0, it can be treated as if the edge were absent.

1.2 Related work

No destructive interference. The special case of all edges having a real positive weight corresponds to the case when there is no destructive interference. With this restriction, Krenn-Gu conjecture was resolved due to the following observation by Bogdanov [3].

▶ **Theorem 7.** *In a coloured multi-graph G_c with $|V(G)| > 4$, if there exist three monochromatic perfect matchings of different colours, then there must be a non-monochromatic perfect matching.*

Due to this result, when there is no destructive interference, every matching covered graph non-isomorphic to K_4 can achieve a maximum dimension of 1 or 2 and thus can be classified into Type 1 and Type 2 graphs(See [6] for detailed discussion). Chandran and Gajjala [6] gave a structural classification for Type 2 graphs. They further proved that for any half-edge colouring and edge weight assignment on a simple Type 2 unweighted uncoloured graph, a dimension of 3 or more can not be achieved! The computational aspects of the vertex colourings arising from these experiments were studied by Vardi and Zhang [25, 26]

Absence of bi-coloured edges. The problems get easier in the absence of bi-coloured edges and have opened up work in several directions. We list some of the known results in this direction. Cervera-Lierta et al. [5] used SAT solvers to prove that if the number of vertices is 6 or 8, the maximum dimension achievable is 2 or, at most, 3, respectively. Chandran and Gajjala [7] proved that the maximum dimension achievable for an $n > 4$ vertex graph is less than $\dfrac{n}{\sqrt{2}}$.

Unrestricted results. For the general case, the only known result is due to Mantey [18]. He proved the following theorem using the Gröbner basis.

▶ **Theorem 8.** *If $|V(G)| = 4$, then $\mu(G) \leq 3$. Moreover, if $\mu(G, c, w) = 3$, then between any pair of vertices in G_c^w, there is exactly one non-zero edge (and isomorphic to the coloured graph shown in Figure 2a).*

Surprisingly, there is no known analytical proof even for such *small* graphs. We encourage the reader to attempt to prove Theorem 8 to understand the difficulty arising due to multi-edges. One has to tune 54 variables which can be complex numbers (the number of possible edges when 3 colours are allowed) such that 81 equations (the number of possible vertex colourings when 3 colours are allowed) are satisfied, even for graphs as small as 4 vertex graphs.

1.3 Our results

We give the first results, which resolve the Krenn-Gu conjecture for a large class of graphs in the completely general setting, that is, when both bi-coloured edges and multi-edges are allowed. We prove that the Krenn-Gu conjecture is true for all graphs with vertex connectivity at most 2 in the full version.

▶ **Theorem 9.** *For a graph G, if $\kappa(G) \leq 2$, then $\mu(G) \leq 2$.*

Our next main contribution is a reduction technique, which implies Theorem 10. We explain and prove our reduction in Section 2. We introduce a scaling lemma in Section 1.4, which gives us an equivalent version of Krenn-Gu conjecture and which may turn out to be more useful in some situations.

▶ **Theorem 10.** *Given a graph G with $\kappa(G) \leq 3$ and $V(G) > 4$, there exists a graph G' with $|V(G')| \leq |V(G)| - 2$ and $\mu(G') \geq \mu(G)$.*

Due to Theorem 10, a minimal counter-example (a counter-example with the minimum number of vertices) to Krenn-Gu conjecture must be 4-connected. Using Theorem 10, we can resolve Krenn-Gu conjecture for some interesting graph classes like cubic graphs (that is, 3 regular graphs). We prove Theorem 11 and Theorem 12 in Section 2.3.

▶ **Theorem 11.** *If the maximum degree of a graph G is 3, Conjecture 6 is true.*

▶ **Theorem 12.** *If the minimum degree of a graph G is 3, then $\mu(G) \leq 3$*

1.4 Reformulation of Krenn-Gu conjecture

Recall that we denote the weight of the vertex colouring vc over a set of vertices $U \subseteq V(G)$ as $w(U, vc)$, which is the sum of weights of all perfect matching on $G[U]$ which induce the vertex colouring vc on U and we denote the monochromatic vertex colouring $vc : V \to \{i\}$ by $\mathbf{i}_V$.

For a graph G, let $U, U' \subseteq V(G)$. Let $vc : U \to \mathbf{N}$ and $vc' : U' \to \mathbf{N}$. If $vc(v) = vc'(v)$ for all $v \in U \cap U'$, we call vc, vc' to be compatible with each other. When vc, vc' are compatible, we define their union $[vc \cup vc'] : U \cup U' \to \mathbf{N}$ as follows: $[vc \cup vc'](v) = vc(v)$ for $v \in U$ and $[vc \cup vc'](v) = vc'(v)$ for $v \in U'$.

We broaden the definition of GHZ graphs to *g-GHZ* graphs. An edge-coloured edge-weighted graph G_c^w satisfying the following properties is defined to be g-GHZ

1. All feasible monochromatic vertex colourings have a non-zero weight (instead of necessarily being 1).
2. All non-monochromatic vertex colourings have a weight of 0.

Note that this generalization allows each of the monochromatic vertex colourings to have different weights. The dimension of a g-GHZ graph is the number of feasible monochromatic vertex colourings. For a graph G, the maximum dimension achievable over all possible g-GHZ colouring and weight assignments is its *generalized matching index* $\mu_g(G)$.

▶ **Conjecture 13.** *$\mu_g(K_4) = 3$ and for a graph G which is non-isomorphic to K_4, $\mu_g(G) \leq 2$.*

We prove that Conjecture 6 and Conjecture 13 are equivalent. Trivially, a counter-example to Conjecture 6 would immediately give a counter-example to Conjecture 13. We prove that any counter-example to Conjecture 13 would also yield a counter-example to Conjecture 6 in Lemma 14. This reformulation is more suitable for our proofs in the following sections.

▶ **Lemma 14** (Scaling lemma). *If there is a graph G_c^w, which is g-GHZ, then there is a graph $G_c^{w'}$, which is a GHZ graph with the same dimension.*

Proof. We denote the weight of the vertex colouring $w(\mathbf{i}_V, G)$ using $W(i)$. Note that by definition of g-GHZ graphs, the weight of a monochromatic colouring $W(i)$ is always non-zero. So, for each edge $e \in G_c$ whose half-edges are of colour i, j, we assign the weight

$$w'(e) = w(e)(W(i)W(j))^{-1/n}$$

Let M be a matching in G_c, which induces the vertex colouring vc_M. The weight of an edge $e \in M$ between vertices u, v will be,

$$w'(e) = w(e)(W(vc_M(u))W(vc_M(v)))^{-1/n}$$

As each vertex is incident by exactly one edge of the perfect matching M, the weight of M will be

$$w'(M) = w(M) \prod_{v \in V} W(vc_M(v))^{-1/n}$$

Since the weights of all perfect matchings which induce a vertex colouring, vc will increase by a factor of $\prod_{v \in V} W(vc(v))^{-1/n}$, the weight of the vertex colouring vc will be

$$w'(vc) = w(vc) \prod_{v \in V} W(vc(v))^{-1/n}$$

As $w(vc)$ is zero for all non-monochromatic vertex colourings, $w'(vc)$ will remain to be zero.

For a monochromatic vertex colouring $vc = \mathbf{i}_V$, we know that $vc(v) = i$ for all $v \in V$. Therefore, $w'(\mathbf{i}_V) = w(\mathbf{i}_V)((w(\mathbf{i}_V))^{-1/n})^n = 1$

Therefore, $G_c^{w'}$ is a GHZ graph. ◀

2 Reduction

We prove a stronger theorem than Theorem 10 as stated below.

▶ **Theorem 15.** *Let G be a multi-graph with a vertex cut S of size 3. Let V_1 and V_2 be a partition of $V(G) \setminus S$ such that V_1 and V_2 are non-empty and there are no edges between V_1 and V_2 in G. Moreover, let $|V_1|$ be odd and $|V_2|$ be even. There exists a graph G' such that $|V(G')| \leq |V_1| + 3 \leq |V(G)| - 2$ and $\mu(G') \geq \mu(G)$.*

Let w, c be a colouring and weight assignment of G for which $\mu(G, c, w) = \mu(G)$. Then G' would be a graph on the vertex set $V_1 \bigsqcup S$. The edge set, the edge weight function and the edge colouring of G' would be the same as in $G[V_1 \bigsqcup S]$ except for the edges with both endpoints inside S; We redefine the set of edges, edge-weight function, edge-colouring within S. Let c' and w' represent the edge-colouring and the edge-weight function of G'. We will show that $\mu(G') \geq \mu(G', c', w') = \mu(G, c, w) = \mu(G)$.

Let $V = V(G)$ and $S = \{u_1, u_2, u_3\}$. Note that any perfect matching of G, should match an odd number of vertices of S to V_1 (since $|S|$ is odd). Therefore the perfect matchings of G can be grouped into 4 types:

Type 0: Let $\mathcal{P}_0$ denote the set of all perfect matchings on $G[V_1 \cup S]$ in which all the three vertices of S are matched with vertices in V_1. Let $W_0(vc)$ denote the sum of weights of the perfect matchings from $\mathcal{P}_0$ that induce the vertex colouring vc on $V_1 \bigsqcup S$. Let $\mathcal{P}'_0$ denote the set of all perfect matchings on $G[V_2]$. Let $W'_0(vc)$ denote the sum of weights of the perfect matchings from $\mathcal{P}'_0$ that induce the vertex colouring vc on V_2. Type 0 perfect matchings of G are the perfect matchings that belong to $\mathcal{P}_0 \times \mathcal{P}'_0$. Clearly, the sum of the weights of Type 0 perfect matchings that induce the colouring vc equals $W_0(vc)W'_0(vc)$.

Type *i*: For $i \in \{1, 2, 3\}$, Let $\mathcal{P}_i$ denote the set of perfect matchings of $V_1 \bigsqcup \{u_i\}$, and let $\mathcal{P}'_i$ denote the set of perfect matchings of $V_2 \bigsqcup (S \setminus \{u_i\})$. Let $W_i(vc)$ denote the sum of weights of all perfect matchings from $\mathcal{P}_i$ that induce the vertex colouring vc on $V_1 \bigsqcup \{u_i\}$ and $W'_i(vc)$ denote the sum of weights of all perfect matchings from $\mathcal{P}'_i$ that induce the colouring vc on $V_2 \bigsqcup (S \setminus \{u_i\})$. Type i matchings of G are the perfect matchings that belong to $\mathcal{P}_i \times \mathcal{P}'_i$. Clearly, the sum of weights of Type i perfect matchings that induce the colouring vc equals $W_i(vc)W'_i(vc)$. From the above discussion, it is easy to see that

$$w(vc) = \sum_{i \in \{0,1,2,3\}} W_i(vc)W'_i(vc) \tag{1}$$

Recall that c_{V_2} denotes the monochromatic vertex colouring with the colour c on V_2. Let us partition $[\mu(G)]$ into $\mathcal{C}_1 \sqcup \mathcal{C}_2$ such that $c \in \mathcal{C}_1$, if and only if there exists some colouring c' on $V_1 \sqcup S$ such that $W'_0(c_{V_2})W_0(c') \neq 0$. The remaining colors from $[\mu(G)]$ belong to $\mathcal{C}_2$ (Note that this happens if $W'_0(c_{V_2}) = 0$ or if for all colourings c' on $V_1 \sqcup S$, $W_0(c') = 0$.). We will now prove Theorem 15 in two cases. When $\mathcal{C}_1 = \emptyset$ (Theorem 1) and $\mathcal{C}_1 \neq \emptyset$ (Theorem 2)

▶ **Theorem 1.** *Let G be a multi-graph with a vertex cut of size 3. If $\mathcal{C}_1 = \emptyset$ (as defined earlier), then $\mu(G) \leq \mu(K_4)$*

▶ **Theorem 2.** *Let G be a multi-graph with a vertex cut of size 3. If $\mathcal{C}_1 \neq \emptyset$ (as defined earlier), then there exists a graph G' such that $|V(G')| \leq |V_1| + 3 \leq |V(G)| - 2$ and $\mu(G') \geq \mu(G)$. Recall that V_1 and V_2 is a partition of $V(G) \setminus S$ such that V_1 and V_2 are non-empty and there are no edges between them. Moreover $|V_1|$ is odd and $|V_2|$ is even.*

2.1 Construction for Theorem 1

Let $V(G') = \{v_0, v_1, v_2, v_3\}$. The reader may mentally map the vertices v_1, v_2, v_3 to the vertices u_1, u_2, u_3 of the vertex cut S and v_0 to the set of vertices V_1. Note that G' is a multi-graph (without self loops) and each pair of vertices from $V(G')$ may have many edges between them. In fact, we would define $\mu(G)^2$ number of edges between each pair of vertices in $\{v_0, v_1, v_2, v_2\}$, one edge for each ordered pair in $[\mu(G)] \times [\mu(G)]$.

Let $i, j \in \{1, 2, 3\}$ with $i \neq j$. Let $(p, q) \in [\mu(G)] \times [\mu(G)]$. We will define an edge e for each such (p, q) between v_i and v_j. This edge e would be coloured such that the v_i-half edge of e (i.e., e_{v_i}) has colour p and the v_j-half edge of e (i.e., e_{v_j}) has colour q. The weight of the edge would be $w(e) = \sum_{c \in \mathcal{C}_2} w(c_{V_2} p_{u_i} q_{u_j})$ The reader may recall that $c_{V_2} p_{u_i} q_{u_j}$ represents the colouring in which V_2, u_i, u_j are coloured with c, p, q respectively. Its weight is the weight of the induced subgraph of G on $V_2 \cup \{u_i, u_j\}$ filtered out by the colouring $c_{V_2} p_{u_i} q_{u_j}$. In this case, $\mathcal{C}_1 = \emptyset$; so $\mathcal{C}_2 = [\mu(G)]$; and therefore there are $\mu(G)$ terms in the summation.

We will now consider the edges between v_0 and v_i, when $i \in \{1, 2, 3\}$. Let $(p, q) \in [\mu(G)] \times [\mu(G)]$. We will define an edge e for each such (p, q) between v_0 and v_i. This edge e would be coloured such that the v_0-half edge of e (i.e., e_{v_0}) has colour p and the v_i-half edge of e (i.e., e_{v_i}) has colour q. The weight of such an edge e is defined as $w(e) = w(p_{V_1} q_{u_i})$

2.2 Proof of construction for Theorem 1

Consider any vertex colouring $vc : V' \to \mathbf{N}$ on G'. We will prove that $w(V(G'), vc) = 0$, if vc is non-monochromatic and $w(V(G'), vc) = 1$, if vc is monochromatic.

Let the vertex colouring vc be $i_{v_0} j_{v_1} k_{v_2} l_{v_3}$. To find the weight of vc, we consider the subgraph of G' filtered out by vc. For instance, between the vertices v_2 and v_3, the colouring vc would filter exactly one edge, and such an edge would have the v_2-half edge of colour k and v_3-half edge of colour l. Clearly, this gives a graph which is isomorphic to K_4 (with some edges possibly getting a weight of zero). Observe that there are only three perfect matchings in K_4. So, it is now easy to find the weight of vc by enumeration.

As an example, consider the vertex colouring in which v_0, v_1 are coloured red and v_2, v_3 are coloured green and blue, respectively. Its filtering is shown in Figure 3. Its weight would be $w_1 w_1' + w_2 w_2' + w_3 w_3'$.

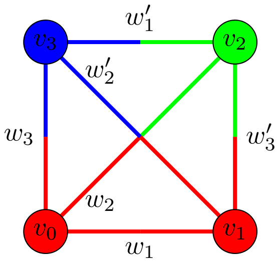


Figure 3 K_4 obtained by a filtering operation.

We will first compute the weight of perfect matching $\{\{v_0, v_1\}, \{v_2, v_3\}\}$ in vc. By substituting the edge weights from the construction, we get the weight of the perfect matching to be

$$= w(i_{V_1} j_{u_1}) \sum_{c \in [\mu(G)]} w(c_{V_2} k_{u_2} l_{u_3}) = \sum_{c \in [\mu(G)]} w(i_{V_1} j_{u_1}) w(c_{V_2} k_{u_2} l_{u_3})$$

As $w(i_{V_1} j_{u_1}) w(c_{V_2} k_{u_2} l_{u_3})$ is exactly the sum of weights of Type 1 perfect matchings for the vertex colouring $i_{V_1} j_{u_1} k_{u_2} l_{u_3} c_{V_2}$

$$= \sum_{c \in [\mu(G)]} W_1(i_{V_1} j_{u_1} k_{u_2} l_{u_3} c_{V_2}) W_1'(i_{V_1} j_{u_1} k_{u_2} l_{u_3} c_{V_2}) \tag{2}$$

Similarly, the weight of the weight of perfect matching $\{\{v_0, v_2\}, \{v_1, v_3\}\}$ in vc is

$$= \sum_{c\in[\mu(G)]} W_2(i_{V_1} j_{u_1} k_{u_2} l_{u_3} c_{V_2}) W_2'(i_{V_1} j_{u_1} k_{u_2} l_{u_3} c_{V_2}) \tag{3}$$

and the weight of the weight of perfect matching $\{\{v_0, v_3\}, \{v_1, v_2\}\}$ in vc is

$$= \sum_{c\in[\mu(G)]} W_3(i_{V_1} j_{u_1} k_{u_2} l_{u_3} c_{V_2}) W_3'(i_{V_1} j_{u_1} k_{u_2} l_{u_3} c_{V_2}) \tag{4}$$

As the weight of the vertex colouring vc' is the sum of these three perfect matchings, by adding the equations Equations (2)–(4), we get

$$w(vc') = \sum_{r\in\{1,2,3\}} \sum_{c\in[\mu(G)]} W_r(i_{V_1} j_{u_1} k_{u_2} l_{u_3} c_{V_2}) W_r'(i_{V_1} j_{u_1} k_{u_2} l_{u_3} c_{V_2})$$

By rearranging the summation and using Equation (1),

$$= \sum_{c\in[\mu(G)]} \sum_{r\in\{1,2,3\}} W_r(i_{V_1} j_{u_1} k_{u_2} l_{u_3} c_{V_2}) W_r'(i_{V_1} j_{u_1} k_{u_2} l_{u_3} c_{V_2}) = \sum_{c\in[\mu(G)]} w(i_{V_1} j_{u_1} k_{u_2} l_{u_3} c_{V_2})$$

First suppose that $vc = i_{v_0} j_{v_1} k_{v_2} l_{v_3}$ is non-monochromatic. Clearly, $i_{V_1} j_{u_1} k_{u_2} l_{u_3} c_{V_2}$ is also non-monochromatic for all $c \in [\mu(G)]$. Since the weight of all such colourings is zero, their sum is also zero. It now follows that $w(vc) = 0$

On the other hand, suppose $vc = i_{v_0} j_{v_1} k_{v_2} l_{v_3}$ is monochromatic, i.e., $i = j = k = l$. Clearly, if $c = i$, $i_{V_1} j_{u_1} k_{u_2} l_{u_3} c_{V_2}$ is also monochromatic and has weight 1. If $c \neq i$, $i_{V_1} j_{u_1} k_{u_2} l_{u_3} c_{V_2}$ is non-monochromatic and has weight 0. Since we take the sum over all c, it now follows that $w(vc) = 1$.

2.3 Applications of construction for Theorem 1

▶ **Corollary 16.** *If the minimum degree of a graph G is 3, then $\mu(G) \leq 3$*

Proof. Let u be a three-degree vertex, and x, y, z be its neighbours. Let $V_1 = \{u\}$, $S = \{x, y, z\}$ and $V_2 = V \setminus \{u, x, y, z\}$. Note that there are no Type 0 matchings as u can match with at most one vertex in S in any perfect matching. Therefore, $W_0(c)$ is zero for all $c \in [\mu(G)]$. It is now easy to see that $\mathcal{C}_1 = \emptyset$. Therefore, from Theorem 1, $\mu(G) \leq \mu(K_4)$. From Theorem 8, it is known that the matching index of graphs with 4 vertices is at most 3. Therefore, $\mu(G) \leq \mu(K_4) = 3$. ◀

▶ **Corollary 17.** *Conjecture 6 is true for all graphs whose maximum degree is at most* 3.

Proof. From Corollary 16, we know that $\mu(G) \leq 3$. Towards a contradiction, let $\mu(G) = 3$ for graph with $|V(G)|$ >4 and maximum degree 3. Therefore, there exists a colouring c and weight assignment w such that $\mu(G, c, w) = 3$. Let the three colours be $1, 2, 3$.

We first claim that between any pair of vertices, there is at most one non-zero edge incident on it. Suppose not. Then, there exist vertices u and x_1 with multiple non-zero edge between them. Since the maximum degree of the skeleton G is at most 3, there exists a vertex set (for instance, all neighbours of u if the degree is 3) $\{x_1, x_2, x_3\}$ which separates u from the $V - \{u, x_1, x_2, x_3\}$. Let $V_1 = \{u\}$, $S = \{x_1, x_2, x_3\}$ and $V_2 = V \setminus \{u, x_1, x_2, x_3\}$. Recall that $\mathcal{C}_1 = \emptyset$. By the construction from Section 2.1, the weights of edges between u and the vertices $\{x_1, x_2, x_3\}$ remain unchanged. Therefore, we obtain a graph with 4 vertices of dimension 3 such that a pair of vertices have multiple non-zero edges between them. But this is not possible from Theorem 8. Therefore, there are no multi-edges in G_c^w.

Since the matching index is 3, there are perfect matchings (of non-zero edges) of colours $1, 2, 3$. Therefore, from Theorem 7, there must be at least one non-monochromatic perfect matching M (of non-zero edges), say inducing the non-monochromatic vertex colouring vc. But there is exactly one non-zero edge of colours $1, 2, 3$ incident on u. Therefore, for any vertex colouring vc, there can be at most one perfect matching M' inducing vc. It now follows that $w'(M) = w'(vc) = 0$. Therefore, there must be an edge, say of colour 1, whose weight is zero; hence, the monochromatic vertex colouring of 1 must be zero. Contradiction.

Therefore, $\mu(G) \leq 2$ when $|V(G)| > 4$. ◀

2.4 Construction for Theorem 2

Recall that $S = \{u_1, u_2, u_3\}$ is a vertex cut separating V_1 from V_2 in the graph G, where $|V_1|$ is odd, $|V_2|$ is even. Assume that $\mathcal{C}_1 \neq \emptyset$. For this case, we will construct an edge-weighted, edge coloured multi-graph G' with $V(G') = V_1 \cup S$ and $\mu(G') \geq \mu(G)$. Since $|V_2| \geq 2$, $|V(G')| \leq |V(G)| - 2$.

If a pair of vertices is such that at least one of them lies in V_1, then the set of edges in G' between this pair of vertices is the same as those in G with the same weights and colours. Between the pairs of vertices with both vertices from S, we define one edge for each pair of colours in $[\mu(G)] \times [\mu(G)]$. Thus there would be $(\mu(G))^2$ edges between each pair, $\{u_i, u_j\}, i \neq j$.

We now describe how to assign weight to a coloured edge e between the vertices u_i and u_j, where $i < j$ and $i, j \in \{1, 2, 3\}$ such that the u_i-half of e is coloured p and the u_j-half of e is coloured q.

$$w'(e) = \sum_{c \in \mathcal{C}_2} W(c_{V_2} p_{u_i} q_{u_j}) + \frac{1}{|\mathcal{C}_1|} \sum_{c \in \mathcal{C}_1} \frac{W(c_{V_2} p_{u_i} q_{u_j})}{W(c_{V_2})} \tag{5}$$

▶ Remark 18. Recall that our plan is to remove V_2 and the edges incident on V_2 completely in order to get the reduced graph G'. This should be done without losing the information about the weights of monochromatic vertex colourings of V_2 to make sure that $\mu(G')$ does not become smaller than $\mu(G)$. The weight assignment is similar in spirit to the weight assignment done for the construction of Theorem 1. The expression here is more complicated in this case, because of the adjustments required to make it work: This will be clear when the reader goes through the proof carefully.

2.5 Proof of the construction for Theorem 2

Consider any vertex colouring $vc' : V_1 \cup S \to \mathbf{N}$ of G'. Let us denote vc' more explicitly, using the notation describe in Section 2.1, as $(\alpha)_{V_1} i_{u_1} j_{u_2} k_{u_3}$. Note that α here is the vertex colouring induced on V_1 by the vertex colouring vc', i, j, k are the colours of u_1, u_2, u_3 respectively under the vertex colouring vc'. (Note that we use the notation $(\alpha)_{V_1}$ to emphasize that this is not necessarily a monochromatic colouring of V_1, using a single colour named α; rather it can be any vertex colouring, monochromatic or non-monochromatic.) We will use the notation of w' to denote the weights of vertex colourings of G' and its subgraphs and w to denote the weights of vertex colourings of G and its subgraphs. For example, $w(i_{V_1} j_S)$ is the weight of the vertex colouring $i_{V_1} j_S$ with respect to the edge-set of G, whereas $w'(i_{V_1} j_S)$ denotes the weight of the same vertex colouring with respect to the edge-set of G'. Our intention is to prove that $w'((\alpha)_{V_1} i_{u_1} j_{u_2} k_{u_3}) = 0$, whenever $(\alpha)_{V_1} i_{u_1} j_{u_2} k_{u_3}$ is non-monochromatic and $w'((\alpha)_{V_1} i_{u_1} j_{u_2} k_{u_3}) \neq 0$, whenever $(\alpha)_{V_1} i_{u_1} j_{u_2} k_{u_3}$ is monochromatic, i.e. $i = j = k$ and α is a monochromatic vertex colouring of V_1 using colour i, i.e. $(\alpha)_{V_1} = i_{V_1}$. The reader may note that we are not insisting the weight to be equal to 1 in the monochromatic case; non-zero is sufficient since we can then use the Scaling Lemma (Lemma 14) to scale the weights of the monochromatic vertex colourings to 1, thus constructing an edge-weight function w' and edge-colouring c' of G' such that $\mu(G', c', w') = \mu(G)$ implying $\mu(G') \geq \mu(G)$.

Recall that $vc' = (\alpha)_{V_1} i_{u_1} j_{u_2} k_{u_3}$ filters out a simple graph from G' and the weight of vc' is the sum of weights of all the perfect matchings (PMs) in this filtered out simple graph. Perfect matchings (PMs) of this graph can be grouped into 4 categories: (1) Type $0'$: PMs containing none of the edges with both endpoints in S. (2) Type $1'$: PMs containing the edge (u_2, u_3) (3) Type $2'$: PMs containing the edge (u_1, u_3) (4) Type $3'$: PMs containing the edge (u_1, u_2) For $t = 0, 1, 2, 3$, we denote the total weight of Type t' PMs by W'_t. Clearly $w'(vc') = \sum_{0 \leq t \leq 3} W'_t$.

Now let us consider a corresponding vertex colouring of G, $vc = (\alpha)_{V_1} i_{u_1} j_{u_2} k_{u_3} c_{V_2}$, which is obtained by taking the same vertex colouring vc' for $V_1 \cup S$, and then extending it by the monochromatic vertex colouring c_{V_2} of V_2, using the colour c. Since we may use any colour $c \in [\mu(G)]$ to extend the vertex colouring vc' of $V_1 \cup S$ to a vertex colouring of $V_1 \cup S \cup V_2$, it is more appropriate to call the extended colouring $(\alpha)_{V_1} i_{u_1} j_{u_2} k_{u_3} c_{V_2}$, it is better to denote $vc(c)$, rather than just vc.

The weight of vc on G can also be decomposed into 4 terms corresponding to 4 different groups of perfect matchings of the subgraph filtered out by vc from G.

(1) Type 0: The PMs in which all the three vertices of S are matched to vertices in V_1.

(2) Type t for $t = 1, 2, 3$: The PMs in which only u_t is matched to some vertex of V_1, and the remaining two vertices of S are either matched to each other or to vertices of V_2.

The total weight of the perfect matchings (in the the subgraph of G filtered out by the vertex colouring $vc(c)$) of Type$t, 0 \leq t \leq 3$ will be denoted by $W_t(c)$ where $c \in [u(G)]$. Clearly $w(vc(c)) = \sum_{0 \leq t \leq 3} W_t(c)$. Now we show that W'_t can be expressed as a (weighted) sum of $W_t(c)$ over the colours $c \in [\mu(G)]$.

▶ **Observation 19.** *For* $t = 1, 2, 3 : W'_t = \sum_{c \in \mathcal{C}_2} W_t(c) + \frac{1}{|\mathcal{C}_1|} \sum_{c \in \mathcal{C}_1} \frac{W_t(c)}{w(c_{V_2})}$

Proof. Let us calculate the total weight W'_1 of Type 1 perfect matchings of the vertex colouring $\alpha_{V_1} i_{u_1} j_{v_2} k_{v_3}$. (The case when $t = 2, 3$ is similar.) Clearly these PMs are obtained by adding the edge (u_2, u_3) of colour (j, k) to each perfect matching of the induced subgraph on $V_1 \cup \{u_1\}$ (after filtering out by the vertex colouring $\alpha_{V_1} i_{u_1}$). Therefore the total weight of these PMs can be written as $W'_1 = w'(\alpha_{V_1} i_{u_1}) w'(e)$ where e is the edge between u_2 and u_3 of colour (i, j), that is, the edge e with u_2-half of e coloured j and u_3-half of e coloured k. Now substituting for $w'(e)$, the right hand side of equation 5, we get

$$W'_1 = w'(\alpha_{V_1} i_{u_1}) \left(\sum_{c \in \mathcal{C}_2} w(c_{V_2} j_{u_2} k_{u_3}) + \frac{1}{|\mathcal{C}_1|} \sum_{c \in \mathcal{C}_1} \frac{w(c_{V_2} j_{u_2} k_{u_3})}{w(c_{V_2})} \right) \tag{6}$$

Note that $w'((\alpha)_{V_1} i_{u_1}) = w((\alpha)_{V_1} i_{u_1})$ since in the induced subgraph on $V_1 \cup \{u_1\}$ the edge set, weights and colour are same for both G and G'. It follows that,

$$W'_1 = \sum_{c \in \mathcal{C}_2} w((\alpha)_{V_1} i_{u_1})) w(c_{V_2} j_{u_2} k_{u_3}) + \frac{1}{|\mathcal{C}_1|} \sum_{c \in \mathcal{C}_1} \frac{w((\alpha)_{V_1} i_{u_1})) w(c_{V_2} j_{u_2} k_{u_3})}{w(c_{V_2})} \tag{7}$$

Noting that $w(\alpha_{V_1} i_{u_1}) w(c_{V_2} j_{u_2} k_{u_3}) = w(\alpha_{V_1} i_{u_1} j_{u_2} k_{u_3} c_{V_2}) = W_1(c)$ we get,

$$W'_1 = \sum_{c \in \mathcal{C}_2} w(\alpha_{V_1} i_{u_1} c_{V_2} j_{u_2} k_{u_3}) + \frac{1}{|\mathcal{C}_1|} \sum_{c \in \mathcal{C}_1} \frac{w(\alpha_{V_1} i_{u_1} c_{V_2} j_{u_2} k_{u_3})}{w(c_{V_2})} = \sum_{c \in \mathcal{C}_2} W_1(c) + \frac{1}{|\mathcal{C}_1|} \sum_{c \in \mathcal{C}_1} \frac{W_1(c)}{w(c_{V_2})}$$

Similar arguments allow us establish the required result for $t = 2, 3$ also. ◀

▶ **Observation 20.** $w(vc') = \sum_{c \in \mathcal{C}_2} w(vc(c)) + \dfrac{1}{|\mathcal{C}_1|} \sum_{c \in \mathcal{C}_1} \dfrac{w(vc(c))}{w(c_{V_2})}$

Proof. Now $w'(vc') = W_0' + W_1' + W_2' + W_3'$

$= W_0' + \sum_{c \in \mathcal{C}_2} (W_1(c) + W_2(c) + W_3(c)) + \dfrac{1}{|\mathcal{C}_1|} \sum_{c \in \mathcal{C}_1} \dfrac{W_1(c) + W_2(c) + W_3(c)}{w(c_{V_2})}$

Recall that for any colour $c \in [\mu(G)]$, $w(vc(c)) = W_0(c) + W_1(c) + W_2(c) + W_3(c)$. Note that for colours $c \in \mathcal{C}_2$, $W_0(c) = W_0'.w(c_{V_2})$; and therefore $W_1(c) + W_2(c) + W_3(c) = w(vc(c))$, the weight of the vertex colouring $\alpha_{V_1} i_{u_1} j_{u_2} k_{u_3} c_{V_2}$. Now W_0' can be trivially rewritten as $\dfrac{1}{|\mathcal{C}_1|} \sum_{c \in \mathcal{C}_1} \dfrac{W_0'.w(c_{V_2})}{w(c_{V_2})}$. Since $W_0'.w(c_{V_2}) = W_0(c)$, this expression can be rewritten as $\dfrac{1}{|\mathcal{C}_1|} \sum_{c \in \mathcal{C}_1} \dfrac{W_0(c)}{w(c_{V_2})}$.

So we can combine the terms of this expression, term by term with the terms inside the sum over $c \in \mathcal{C}_1$ and rewrite the expression as follows:

$$= \sum_{c \in \mathcal{C}_2} w(vc(c)) + \frac{1}{|\mathcal{C}_1|} \sum_{c \in \mathcal{C}_1} \frac{W_0(c) + W_1(c) + W_2(c) + W_3(c)}{w(c_{V_2})} \tag{8}$$

Since for colours $c \in \mathcal{C}_1$, $W_0(c) + W_1(c) + W_2(c) + W_3(c) = w(vc(c))$ we get the required result. ◀

If vc' is non-monochromatic, then $vc(c)$ is also non-monochromatic for any $c \in [\mu(G)]$. Therefore, $w(vc(c)) = 0$ for all c and hence $w'(vc') = 0$ from Observation 20.

If vc' is monochromatic, say of colour i, $vc(c)$ will be monochromatic if and only if $c = i$. Therefore, if $i \in \mathcal{C}_2$, then $w(vc') = w(vc(i)) = 1$. Similarly, if $i \in \mathcal{C}_1$, then $w'(vc') = \dfrac{1}{|\mathcal{C}_1| w(\mathbf{i}_{V_2})}$ from Observation 20. In both the cases this will be non-zero as required.

The weights can now be readjusted by the Scaling Lemma (Lemma 14) to get a GHZ graph.

2.6 Limitations of our reduction

A careful reader might observe that the difficulty in extending our reduction technique to cuts of larger size comes from the case when two newly introduced edges are part of the same perfect matching. For instance, for the case when there is a 4 vertex cut $\{u_1, u_2, u_3, u_4\}$ separating V_1, V_2 (both of even size) in G, one could try to extend our ideas and capture the weights from $V_2 \cup \{u_3, u_4\}$ and $V_2 \cup \{u_1, u_2\}$ on the edges $(v_3, v_4), (v_1, v_2)$ of G', respectively. However, this would create some extra terms in G' due to the perfect matchings in which (v_1, v_2) and (v_3, v_4) are contained. Such terms could destroy the GHZ property of G'. We believe that finding a way to bypass this difficulty and finding a more general reduction will resolve Krenn and Gu's conjecture for all graphs.

Abstract

In this paper we give several applications of Littlestone dimension. The first is to the model of Angluin and Dohrn [1], where we extend their results for learning by equivalence queries with random counterexamples. Second, we extend that model to infinite concept classes with an additional source of randomness. Third, we give improved results on the relationship of Littlestone dimension to classes with extended d-compression schemes, proving the analog of a conjecture of Floyd and Warmuth [4] for Littlestone dimension.

1 Introduction

In query learning, a learner attempts to identify an unknown concept from a collection via a series of data requests called queries. Typically, algorithms designed for learning in this setting attempt to bound the number of required queries to identify the target concept in the worst-case scenario. If one imagines the queries of the learner being answered by a teacher, the usual setup imagines the teacher answering queries in an adversarial manner, with minimally informative answers. Alternatively, for a given algorithm, the bounds for the traditional model are on the *worst-case answers* over *all potential targets*. In variations of the model, one of these two factors is usually modified.

For instance, Kumar, Chen, and Singla [7] study the case in which the answers are assumed to be maximally informative in a certain sense. In this manuscript, we first work in the setup originating with Angluin and Dohrn [1], where we assume that the answers to the queries are randomly selected with respect to some fixed probability distribution.

Consider a concept class $\mathcal{C} = \{C_1, \dots, C_n\}$, subsets of a fixed set X. Fix a target concept $A \in \mathcal{C}$. An *equivalence query* consists of the learner submitting a hypothesis $B \in \mathcal{C}$ to a teacher, who either returns *yes* if $A = B$, or a counterexample $x \in A \triangle B$. In the former case, the learner has learned A, and in the latter case, the learner uses the new information to update and submit a new hypothesis.

Angluin and Dohrn [1] fix a probability distribution μ on X and assume that the teacher selects the counterexamples randomly with respect to μ restricted to $A \triangle B$. They show that for a concept class $\mathcal{C}$ of size n, there is an algorithm in which the expected number of queries to learn any concept is at most $\log_2(n)$. It is natural to wonder whether there is a combinatorial notion of dimension which can be used to bound the expected number of queries independent of the size of the class - perhaps even in infinite classes. In fact, Angluin and Dohrn [1] (Theorem 25) already consider this and show that the VC-dimension of the concept class is a lower bound on the number of expected queries. On the other hand, Angluin and Dohrn [1] (Theorem 26), using an example of [9], show that the VC-dimension *cannot* provide an upper bound for the number of queries.

The motivation for bounds depending on some notion of dimension rather than the number of concepts is two-fold:

- Many combinatorial notions of dimension (e.g. Littlestone or VC) of a class $\mathcal{C}$ can be small while $|\mathcal{C}|$ is large.
- Investigating this model of learning in settings where $\mathcal{C}$ is an infinite class will require methods and bounds that do not use $|\mathcal{C}|$.

Roughly speaking, the *Littlestone dimension* (or Ldim) [9] of a concept class $\mathcal{C}$ over domain X is the maximal depth of a complete binary decision tree T such that T's nodes are associated with elements of X and T's edges are associated with binary labels such that each root-to-leaf path in T agrees in the labeling of its respective elements with some concept in $\mathcal{C}$. If we require all nodes of T at the same depth to be associated with the same element of X, this yields the definition of VC dimension.

We show that the Littlestone dimension provides such an upper bound; we give an algorithm that yields a bound that is linear in the Littlestone dimension for the expected number of queries needed to learn any concept. In Section 2 we establish the bounds for finite concept classes $\mathcal{C}$.

In Section 3 we give a specific example that shows finite Littlestone dimension of an infinite class $\mathcal{C}$ is not sufficient to guarantee the learnability of the class in the model of Angluin and Dohrn [1]. That is, we show the expected number of queries is impossible to bound over all target concepts, even in very simple infinite classes. Suppose that the target concept is itself selected randomly with respect to some (perhaps unrelated to the feedback mechanism) probability distribution. In this case, we give an algorithm so that the expected number of queries (over both sources of randomness) is at most $\tilde{O}(d)$ where d is the Littlestone dimension of the class $\mathcal{C}$. This result uses the bounds developed in Section 2 in an essential way, in particular by using the finite class's Littlestone dimension instead of its size.

In Section 4, we give another application of Littlestone dimension - to compression schemes, which answers a question of Johnson and Laskowski [6] on d-compression with b extra bits, a notion originating with Floyd and Warmuth [4]. The existence of a d-compression is closely related to various notions of learning; d-compressibility of a class $\mathcal{C}$ implies the class has VC-dimension at most d. A famous conjecture of Floyd and Warmuth [4] asks if every VC-class has a d-compression where d is the VC-dimension.[1] Our result in Section 4 proves a strong version of the conjecture for Littlestone dimension. In Section 4 we also explain some of the many variants of this problem which have been previously solved.

2 Random counterexamples and EQ-learning

In this section, we essentially work in the setting of Angluin and Dohrn [1] with slightly different notation. Throughout this section, let X be a finite set, let $\mathcal{C}$ be a set system on X, and let μ be a probability measure on X. For $A, B \in \mathcal{C}$, let

$$\Delta(A, B) = \{x \in X \mid A(x) \neq B(x)\}$$

denote the symmetric difference of A and B.

▶ **Definition 2.1.** *We denote, by $\mathcal{C}_{\bar{x}=\bar{i}}$ for $\bar{x} \in X^n$ and $\bar{i} \in \{0,1\}^n$, the set system $\{A \in \mathcal{C} \mid A(x_j) = i_j, j = 1, \ldots, n\}$. For $A \in \mathcal{C}$ and $a \in X$, we let*

$$u(A, a) = \mathrm{Ldim}(\mathcal{C}) - \mathrm{Ldim}(\mathcal{C}_{a=A(a)}).$$

For any $a \in X$, either $\mathcal{C}_{a=1}$ or $\mathcal{C}_{a=0}$ has Littlestone dimension strictly less than that of $\mathcal{C}$ and so:

▶ **Lemma 2.2.** *For $A, B \in \mathcal{C}$ and $a \in X$ with $A(a) \neq B(a)$,*

$$u(A, a) + u(B, a) \geq 1.$$

Next, we define a directed graph that is similar to the *elimination graph* of Angluin and Dohrn [1].

▶ **Definition 2.3.** *We define the* thicket query graph *$G_{TQ}(\mathcal{C}, \mu)$ to be the weighted directed graph on vertex set $\mathcal{C}$ such that the directed edge from A to B has weight $d(A, B)$ equal to the expected value of* $\mathrm{Ldim}(\mathcal{C}) - \mathrm{Ldim}(\mathcal{C}_{x=B(x)})$ *over $x \in \Delta(A, B)$ with respect to the distribution $\mu|_{\Delta(A,B)}$.* [2]

▶ **Definition 2.4.** *The* query rank *of $A \in \mathcal{C}$ is defined as:* $\inf_{B \in \mathcal{C}}(d(A, B))$.

▶ **Lemma 2.5.** *For any $A \neq B \in \mathcal{C}$, $d(A, B) + d(B, A) \geq 1$.*

Proof. Noting that $\Delta(A, B) = \Delta(B, A)$, and using Lemma 2.2:

$$\begin{aligned} d(A, B) + d(B, A) &= \sum_{a \in \Delta(A,B)} \frac{\mu(a)}{\mu(\Delta(A, B))}(u(A, a) + u(B, a)) \\ &\geq \sum_{a \in \Delta(A,B)} \frac{\mu(a)}{\mu(\Delta(A, B))} \\ &= 1. \end{aligned}$$ ◀

▶ **Definition 2.6** (Angluin and Dohrn [1], Definition 14)**.** *Let G be a weighted directed graph and $l \in \mathbb{N}$, $l > 1$. A* deficient l-cycle *in G is a sequence $v_0, \ldots v_{l-1}$ of distinct vertices such that for all $i \in [l]$, $d(v_i, v_{(i+1) (\mod l)}) \leq \frac{1}{2}$ with strict inequality for at least one $i \in [l]$.*

[1] Resolving whether there is an $O(d)$ compression has a reward of 600 dollars [12].

[2] Here one should think of the query by the learner as being A, and the actual hypothesis being B. The teacher samples from $\Delta(A, B)$, and the learner now knows the value of the hypothesis on x.

The next result is similar to Theorems 16 (the case $l = 3$) and Theorem 17 (the case $l > 3$) of Angluin and Dohrn [1], but our proof is rather different (note that the case $l = 2$ follows easily from Lemma 2.5).

▶ **Theorem 2.7.** *The thicket query graph $G_{TQ}(\mathcal{C}, \mu)$ has no degenerate l-cycles for $l \geq 2$.*

The analogue of Theorem 16 of Angluin and Dohrn [1] can be adapted in a very similar manner to the technique employed by them. However, the analogue of the proof of Theorem 17 of Angluin and Dohrn [1] falls apart in our context; the reason is that Lemma 2.2 is analogous to their Lemma 6 (and Lemma 2.5 is analogous to their Lemma 13), but our lemmas involve inequalities instead of equations. The inductive technique of Angluin and Dohrn [1, Theorem 17] is to shorten degenerate cycles by considering the weights of a particular edge in the elimination graph along with the weight of the edge in the opposite direction. Since one of those weights being large forces the other to be small (by the *equalities* of their lemmas), the induction naturally separates into two useful cases. In our thicket query graph, things are much less tightly constrained - one weight of an edge being large does not force the weight of the edge in the opposite direction to be small. However, the technique employed in our proof seems to be flexible enough to adapt to prove Theorems 16 and 17 of Angluin and Dohrn [1].

Proof. Suppose the vertices in the degenerate l-cycle are $A_0, \dots, A_{l-1}$. By the definition of degenerate cycles and $d(-,-)$, we have, for each $i \in \mathbb{Z}/l\mathbb{Z}$, that

$$\sum_{a \in \Delta(A_i, A_{i+1})} \frac{\mu(a)}{\mu(\Delta(A_i, A_{i+1}))} u(A_i, a) \leq \frac{1}{2}.$$

Clearing the denominator we have

$$\sum_{a \in \Delta(A_i, A_{i+1})} \mu(a) u(A_i, a) \leq \frac{1}{2} \mu(\Delta(A_i, A_{i+1})). \tag{2.1}$$

Note that throughout this argument, the coefficients are being calculated modulo l. Notice that for at least one value of i, the inequality in 2.1 must be strict.

Let G, H be a partition of

$$\mathcal{X} = \{A_1, \dots, A_l\}.$$

Now define

$$D(G,H) := \{a \in X \mid \forall A_1, B_1 \in G, \forall A_2, B_2 \in H, A_1(a) = B_1(a), A_2(a) = B_2(a), A_1(a) \neq A_2(a)\}.$$

The following fact follows from the definition of $\Delta(A, B)$ and $D(-,-)$.

▶ **Fact 2.8.** *The set $\Delta(A_i, A_{i+1})$ is the disjoint union, over all partitions of $\mathcal{X}$ into two pieces G, H such that $A_i \in G$ and $A_{i+1} \in H$ of the sets $D(G, H)$.*

Now, take the sum of the inequalities 2.1 as i ranges from 1 to l. On the LHS of the resulting sum, we obtain

$$\sum_{i=1}^{l} \left(\sum_{G,H \text{ a partition of } \mathcal{X},\, A_i \in G, A_{i+1} \in H} \left(\sum_{a \in D(G,H)} \mu(a) u(A_i, a) \right) \right).$$

On the RHS of the resulting sum, we obtain

$$\frac{1}{2}\sum_{i=1}^{l}\left(\sum_{G,H\text{ a partition of }\mathcal{X},\, A_i\in G, A_{i+1}\in H}\left(\sum_{a\in D(G,H)}\mu(a)\right)\right).$$

Given a partition G, H of $\{A_1, \dots, A_l\}$ we note that the term $D(G,H) = D(H,G)$ appears exactly once as an element of the above sum for a fixed value of i exactly when $A_i \in G$ and $A_{i+1} \in H$ or $A_i \in H$ and $A_{i+1} \in G$.

Consider the partition G, H of $\mathcal{X}$. Suppose that $A_j, A_{j+1}, \dots, A_k$ is a block of elements each contained in G, and that A_{j-1}, A_{k+1} are in H. Now consider the terms $i = j - 1$ and $i = k$ of the above sums (each of which where $D(G,H)$ appears).

On the left hand side, we have $\sum_{a\in D(G,H)} \mu(a)u(A_{j-1}, a))$ and $\sum_{a\in D(G,H)} \mu(a)u(A_k, a))$. Note that for $a \in D(G,H)$, we have $a \in \Delta(A_{j-1}, A_k)$. So, by Lemma 2.2, we have

$$\sum_{a\in D(G,H)} \mu(a)u(A_{j-1}, a) + \sum_{a\in D(G,H)} \mu(a)u(A_k, a) \geq \sum_{a\in D(G,H)} \mu(a).$$

On the RHS, we have

$$\frac{1}{2}\left(\sum_{a\in D(G,H)} \mu(a) + \sum_{a\in D(G,H)} \mu(a)\right) = \sum_{a\in D(G,H)} \mu(a).$$

For each G, H a partition of X, the terms appearing in the above sum occur in pairs as above by Fact 2.8, and so, we have the LHS is at least as large as the RHS of the sum of inequalities 2.1, which is impossible since one of the inequalities must have been strict by our degenerate cycle. ◀

▶ **Theorem 2.9.** *There is at least one element $A \in \mathcal{C}$ with query rank at least $\frac{1}{2}$.*

Proof. If not, then for every element $A \in \mathcal{C}$, there is some element $B \in \mathcal{C}$ such that $d(A, B) < \frac{1}{2}$. So, pick, for each $A \in \mathcal{C}$, an element $f(A)$ such that $d(A, f(A)) < \frac{1}{2}$. Now, fix $A \in \mathcal{C}$ and consider the sequence of elements of $\mathcal{C}$ given by $(f^i(A))$; since $\mathcal{C}$ is finite, at some point the sequence repeats itself. So, take a list of elements $B, f(B), \dots, f^n(B) = B$. By construction, this yields a bad cycle, contradicting Theorem 2.7. ◀

2.1 The thicket max-min algorithm

In this subsection we show how to use the lower bound on query rank proved in Theorem 2.9 to give an algorithm that yields the correct concept in linearly (in the Littlestone dimension) many queries from $\mathcal{C}$. The approach is fairly straightforward – essentially the learner repeatedly queries the highest query rank concept. The approach is similar to that taken in Angluin and Dohrn [1, Section 5] but with query rank in place of their notion of *informative*.

Now we informally describe the thicket max-min-algorithm. At stage i, the learner is given information of a concept class $\mathcal{C}_i$. The learner picks the query

$$A = \text{argmax}_{A\in\mathcal{C}_i}\left(\min_{B\in\mathcal{C}_i} d_{\mathcal{C}_i}(A, B)\right).$$

The algorithm halts if the learner has picked the actual concept C. If not, the teacher returns a random element $a_i \in \Delta(A, C)$ at which point the learner knows the value of $C(a_i)$. Then

$$\mathcal{C}_{i+1} = (\mathcal{C}_i)_{a_i=C(a_i)}.$$

Let $T(\mathcal{C})$ be the expected number of queries before the learner correctly identifies the target concept.

▶ **Theorem 2.10.** *The expected number of queries to learn a concept in a class $\mathcal{C}$ is less than or equal to* $2\,\mathrm{Ldim}(\mathcal{C})$.

Proof. The expected drop in the Littlestone dimension of the concept class induced by any query before the algorithm terminates is at least $1/2$ by Theorem 2.9; so the probability that the drop in the Littlestone dimension is positive is at least $1/2$ for any given query. So, from $2n$ queries, one expects at least n drops in Littlestone dimension, at which point the class is learned. ◀

3 Equivalence queries with random counterexamples and random targets

Let $\mathcal{C}$ consist the collection of intervals $\left\{\left(\frac{1}{n+1}, \frac{1}{n}\right) \mid n \in \mathbb{N}\right\}$ with μ the Lebesgue measure on the unit interval. This concept class has Littlestone dimension one since any two concepts are disjoint. There is no upper bound on the number of expected queries (using the model with random counterexamples of the previous section) that is uniform over all targets.

To see why, suppose the learner guesses interval $\left(\frac{1}{n+1}, \frac{1}{n}\right)$ for some n. For any $\epsilon > 0$ there is $N \in \mathbb{N}$ such that with probability greater than $1-\epsilon$, the learner gets a counterexample from the interval they guessed, $\left(\frac{1}{n+1}, \frac{1}{n}\right)$. Of course, even with this additional information, no matter the learner's guess at any stage at which they have received only negative counterexamples, this is clearly still the case. Thus, there can be no bound on expected queries which is uniform over all target concepts.

In this section we introduce an additional source of randomness, which allows for learning over infinite classes $\mathcal{C}$.[3] So, suppose $\mathcal{C}$ is a (possibly infinite) set of concepts on a set X. Suppose that we have probability measures μ on X and τ on $\mathcal{C}$. Suppose a target $A \in \mathcal{C}$ is selected randomly according to the distribution τ and the counterexamples to equivalence queries are selected randomly according to the distribution μ.

▶ **Theorem 3.1.** *Suppose that $\mathcal{C}$ is countable with finite Littlestone dimension d. There is an algorithm such that the expected number of queries over distributions μ on X and τ on $\mathcal{C}$ is at most $\tilde{O}(d)$.*

Proof. Let $\epsilon_k = \frac{1}{2^{k+1}}$ for $k \in \mathbb{N}$. The idea of the algorithm is to run our earlier algorithm on a $1-\epsilon_k$ fraction of the concepts with respect to the measure τ.

At stage k of the algorithm, we observe the following. Since $\mathcal{C}$ is countable, enumerate the collection $\mathcal{C} = \{C_i\}_{i \in \mathbb{N}}$. Then since $\sum_{i=1}^{\infty} P(C_i) = 1$, for any $\epsilon_k > 0$, there is $N_k = N(\epsilon_k) \in \mathbb{N}$ such that $\sum_{i=1}^{\infty} P(C_i) \geq 1 - \epsilon_k$.

Conditional on the target being among the first N_k concepts, the next idea is to run the algorithm from the previous section on this finite set for n steps where n is such that the probability that we have not identified the target after n steps is less than ϵ, for some $0 < \epsilon < 1$. This number $n = n_{d,\epsilon}$ depends only on the Littlestone dimension and ϵ, but not on N as we will explain.

We now bound the probability that the algorithm has not terminated after n steps, conditional on the target being in the first N_k many concepts. Since at any step, the probability that the Littlestone dimension drops is at least $\frac{1}{2}$ by Theorem 2.9, the probability that the algorithm has not terminated after n steps is at most the probability of a binomial random variable with probability $\frac{1}{2}$ achieving at most $d-1$ successes in n attempts, which is

[3] One might also think of the random EQ learning of Angluin and Dohrn as analyzing the maximum number of expected number of queries over all possible targets, while our model will analyze the *expected* number of queries where the expectation is taken over the concepts (with a fixed but arbitrary distribution) and over the counterexamples.

$$\sum_{k=0}^{d-1} \binom{n}{k} \left(\frac{1}{2}\right)^n \leq n^d/2^n.$$

Note that $n^d/2^n < \epsilon$ whenever $n - d\log n > \log\left(\frac{1}{\epsilon}\right)$. Hence,

$$n \geq \tilde{O}(d + \log(1/\epsilon))$$

is sufficient.

So at stage k, we run the algorithm for n steps as specified above. Either the target concept is found or we continue to stage $k+1$ on the larger concept class N_k. Since

$$(1-\epsilon_1)\left(\sum_{k=1}^{\infty} \epsilon_k\right) = 1/2\sum_{k=1}^{\infty} 1/2^{k+1} < 1,$$

the expected total number of queries is still bounded by $\tilde{O}(d + \log(1/\epsilon))$.[4] ◀

4 Compression schemes and stability

In this section, we follow the notation and definitions given in Johnson and Laskowski [6] on *compression schemes*, a notion due to Littlestone and Warmuth [10]. Roughly speaking, $\mathcal{C}$ admits a *d-dimensional compression scheme* if, given any finite subset F of X and some $f \in \mathcal{C}$, there is a way of encoding the set F with only d-many elements of F in such a way that F *can be recovered.*

We will give a formal definition, but we note that numerous variants of this idea appear throughout the literature, including as size d-array compression [2], extended compression schemes with b extra bits [4], and as unlabeled compression schemes [8]. In the definitions below, we let $dom(f)$ denote the domain of f and $\mathcal{C}_{\text{fin}}$ the restriction of $\mathcal{C}$ to finite subsets.

The following definition gives the notion of compression we consider within this section; the notion is equivalent to the notion of a d-compression with b extra bits [4]. The equivalence of these two notions is proved by Johnson and Laskowski [6, Proposition 2.1]. In our compression schemes, the role of the b extra bits is played by the reconstruction functions, and of course, the number of extra bits can be bounded in terms of the number of reconstruction functions (and vice versa). Of course, one is interested in optimizing both the size of the compression and the number of reconstruction functions (extra bits) in general.

▶ **Definition 4.1.** *We say that a concept class $\mathcal{C}$ has a d-*compression *if there is a compression function $\kappa : \mathcal{C}_{\text{fin}} \to X^d$ and a finite set $\mathcal{R}$ of reconstruction functions $\rho : X^d \to 2^X$ such that for any $f \in \mathcal{C}_{\text{fin}}$*

1. *$\kappa(f) \subseteq dom(f)$*
2. *$f = \rho(\kappa(f))|_{dom(f)}$ for at least one $\rho \in \mathcal{R}$.*

We work with the above notion mainly because it is the notion used in Johnson and Laskowski [6], and our goal is to improve a result therein. That result was later improved by Laskowski and appears in the unpublished notes of Guingona [5] (Theorem 4.1.3). When the original work on this result was completed, we were not aware of the work of Guingona [5], but as it turns out, our result improves both of these (the latter uses exponentially many reconstruction functions, while we use linearly many).

[4] There isn't anything particularly special about the sequence ϵ_k that we chose. Any sequence (ϵ_k) going to zero whose sum converges can be seen to work in the algorithm and affects only the constants in the expected number of steps, which we are not optimizing.

Johnson and Laskowski [6] prove that a concept class with finite Littlestone dimension has an extended d-compression for some d.[5] The precise value of d is not determined there, but was conjectured to be the Littlestone dimension. In Theorem 4.4, we will show that d can be taken to be the Littlestone dimension and $d + 1$ many reconstruction functions suffice.[6]

The question in Johnson and Laskowski [6] is the analogue (for Littlestone dimension) of a well-known open question from VC-theory [4]: is there a bound $A(d)$ linear in d such that every class of VC-dimension d has a compression scheme of size at most $A(d)$? In general, there is known to be a bound that is at most exponential in d [11].

▶ **Definition 4.2.** *Suppose* $\mathrm{Ldim}(\mathcal{C}) = d$*. Given a partial function* f*, say that* f *is* exceptional *for* $\mathcal{C}$ *if for all* $a \in \mathrm{dom}(f)$*,*

$$\mathcal{C}_{(a,f(a))} := \{g \in \mathcal{C} \mid g(a) = f(a)\}$$

has Littlestone dimension d*.*

▶ **Definition 4.3.** *Suppose* $\mathrm{Ldim}(\mathcal{C}) = d$*. Let* $f_{\mathcal{C}}$ *be the partial function given by*

$$f_{\mathcal{C}}(x) = \begin{cases} 0 & \mathrm{Ldim}(\mathcal{C}_{(x,0)}) = d \\ 1 & \mathrm{Ldim}(\mathcal{C}_{(x,1)}) = d \\ \text{undefined} & \text{otherwise.} \end{cases}$$

It is clear that $f_{\mathcal{C}}$ extends any partial function exceptional for $\mathcal{C}$.

▶ **Theorem 4.4.** *Any concept class* $\mathcal{C}$ *of Littlestone dimension* d *has an extended* d*-compression with* $(d + 1)$*-many reconstruction functions.*

Proof. If $d = 0$, then $\mathcal{C}$ is a singleton, and one reconstruction function suffices. So we may assume $d \geq 1$.

Fix some $f \in \mathcal{C}_{\text{fin}}$ with domain F. We will run an algorithm to construct a tuple of length at most d from F by adding one element at each step of the algorithm. During each step of the algorithm, we also have a concept class $\mathcal{C}_i$, with $\mathcal{C}_0 = \mathcal{C}$ initially.

If f is exceptional in $\mathcal{C}_{i-1}$, then the algorithm halts. Otherwise, pick either:

- $a_i \in F$ such that $f(a_i) = 1$ and

  $$(\mathcal{C}_{i-1})_{(a_i,1)} := \{g \mid g \in \mathcal{C}_{i-1},\, g(a_i) = 1\}$$

  has Littlestone dimension less than $\mathrm{Ldim}(\mathcal{C}_{i-1})$. In this case, set $\mathcal{C}_i := (\mathcal{C}_{i-1})_{(a_i,1)} = \{g \mid g \in \mathcal{C}_{i-1},\, g(a_i) = 1\}$.
- $d_i \in F$ such that $f(d_i) = 0$ and

  $$(\mathcal{C}_{i-1})_{(d_i,0)} := \{g \mid g \in \mathcal{C}_{i-1},\, g(d_i) = 0\}$$

  has Littlestone dimension less than $\mathrm{Ldim}(\mathcal{C}_{i-1})$. In this case, set $\mathcal{C}_i := (\mathcal{C}_{i-1})_{(d_i,0)}$.

[5] Their result is formulated for the sets of realizations of first-order formulas that are *stable*, but their proofs work for general concept classes, and Chase and Freitag [3] explain that stability is equivalent to finite Littlestone dimension.

[6] After proving this, we became aware of the unpublished result of Laskowski appearing as [5, Theorem 4.1.3] which shows one can take d to be the Littlestone dimension and uses 2^d many reconstruction functions.

We allow the algorithm to run for at most d steps. There are two distinct cases. If our algorithm has run for d steps, let $\kappa(f)$ be the tuple $(\bar{a}, \bar{d})$ of all of the elements a_i as above followed by all of the elements d_i as above for $i = 1, \ldots, d$. By choice of a_i and d_i, this tuple consists of d distinct elements. By construction the set

$$\mathcal{C}_{(\bar{a},\bar{d})} := \{g \in \mathcal{C} | \, g(a_i) = 1, \, g(d_i) = 0\}$$

has Littlestone dimension 0, that is, there is a unique concept in this class. So, given $(c_1, c_2, \ldots, c_n) \in X^d$ consisting of distinct elements, for $i = 0, \ldots, d$, we let $\rho_i(c_1, \ldots, c_n)$ be some g belonging to

$$\{g \in \mathcal{C} \, | \, g(c_j) = 1 \text{ for } j \leq i, \, g(c_j) = 0 \text{ for } j > i\},$$

if such a g exists. By construction, for some i, the Littlestone dimension of the concept class $\{g \in \mathcal{C} \cap F \, | \, g(c_j) = 1 \text{ for } j \leq i, \, g(c_j) = 0 \text{ for } j > i\}$ is zero, and so g is uniquely specified and will extend f.

We handle cases where the algorithm halts early by augmenting two of the reconstruction functions ρ_0 and ρ_1 defined above. Because ρ_0 and ρ_1 have so far only been defined for tuples consisting of d distinct elements, we can extend these to handle exceptional cases by generating tuples with duplicate elements.

If the algorithm stops at some step $i > 1$, then it has generated a tuple of length $i - 1$ consisting of some elements a_j and some elements d_k. Let $\bar{a}$ consist of the elements a_j chosen during the algorithm, and let $\bar{d}$ consist of the elements d_k chosen during the running of the algorithm. Observe that f is exceptional for $\mathcal{C}_{(\bar{a},\bar{d})}$.

If $\bar{a}$ is not empty, with initial element a', then let $\kappa(f) = (\bar{a}, a', \bar{d}, a', \ldots, a') \in F^d$. From this tuple, one can recover $(\bar{a}, \bar{d})$ (assuming $\bar{a}$ is nonempty), so we let $\rho_1(\bar{a}, a', \bar{d}, a', \ldots, a')$ be some total function extending $f_{\mathcal{C}_{(\bar{a},\bar{d})}}$, which itself extends f. So $\rho_1(\bar{a}, \bar{d})$ extends f whenever the algorithm halts before step d is completed *and* some a_i was chosen at some point. If $\bar{a}$ is empty, then let $\kappa(f) = (\bar{d}, d', \ldots, d') \in F^d$, where d' is the initial element of $\bar{d}$. From this tuple, one can recover $(\emptyset, \bar{d})$ (assuming $\bar{a}$ is empty), so we let $\rho_0(\bar{d}, d', \ldots, d')$ be total function extending $f_{\mathcal{C}_{(\emptyset,\bar{d})}}$, which itself extends f. Finally, if the algorithm terminates during step 1, then it has generated the empty tuple. In this case, let $\kappa(f) = (c, \ldots, c)$ for some $c \in F$. Then $\text{Ldim}(\mathcal{C}) = \text{Ldim}(\mathcal{C}_{(c,l)})$ for some $l \in \{0, 1\}$. In particular, if we have defined $\kappa(f') = (c, \ldots, c)$ above for some f' where the algorithm only returns c (rather than the empty tuple), then $1 - l = f'(c) \neq f(c)$, and so any such f' is handled by ρ_{1-l}. So we may overwrite ρ_l to set $\rho(c, \ldots, c)$ to be a total function extending $f_{\mathcal{C}}$, which itself extends f. For any tuple output by our algorithm, one of the reconstruction functions produces an extension of the original concept. ◀

Abstract

Finding a simple path of even length between two designated vertices in a directed graph is a fundamental NP-complete problem [24] known as the EvenPath problem. Nedev [28] proved in 1999, that for directed planar graphs, the problem can be solved in polynomial time. More than two decades since then, we make the first progress in extending the tractable classes of graphs for this problem. We give a polynomial time algorithm to solve the EvenPath problem for classes of H-minor-free directed graphs,[1] where H is a single-crossing graph.

We make two new technical contributions along the way, that might be of independent interest. The first, and perhaps our main, contribution is the construction of small, planar, *parity-mimicking networks*. These are graphs that mimic parities of all possible paths between a designated set of terminals of the original graph.

Finding vertex disjoint paths between given source-destination pairs of vertices is another fundamental problem, known to be NP-complete in directed graphs [14], though known to be tractable in planar directed graphs [34]. We encounter a natural variant of this problem, that of finding disjoint paths between given pairs of vertices, but with constraints on parity of the total length of paths. The other significant contribution of our paper is to give a polynomial time algorithm for the 3-*disjoint paths with total parity problem*, in directed planar graphs with some restrictions (and also in directed graphs of bounded treewidth).

1 Introduction

Given a directed graph G, and two vertices s and t in it, checking for the existence of a a simple directed path from s to t is a fundamental problem in graph theory, known as the Reachability problem. The EvenPath problem is a variant of Reachability, where given a directed graph G and two vertices s and t we need to answer whether there exists a simple path of even length from s to t. EvenPath was shown to be NP-complete by LaPaugh and Papadimitriou [24] via a reduction from an NP-complete problem, the Path-Via-A-Vertex problem. On the other hand, they also show in [24] that its undirected counterpart is solvable in linear time. Several researchers have recently studied both the space, and simultaneous time-space complexity of EvenPath for special classes of graphs [5, 10]. A similar problem, that of finding a simple directed cycle of even length, called EvenCycle (which easily reduces to EvenPath), has also received significant attention. While polynomial-time algorithms have been known since long for the undirected version ([24, 39]), the question of tractablility of the directed version was open for over two decades before polynomial-time algorithms were given by McCuiag, and by Robertson, Seymour and Thomas [27]. More recently, Björklund, Husfeldt and Kaski [3] gave a randomized polynomial-time algorithm for finding a *shortest* even directed cycle in directed graphs.

Although EvenPath is NP-complete for general directed graphs, it is natural and interesting to investigate the classes of graphs for which it can be solved efficiently. In 1994, before the algorithm of [27], Gallucio and Loebl [15] gave a polynomial-time algorithm for EvenCycle in planar directed graphs. They did so by developing a routine for a restricted variant of EvenPath (when s, t lie on a common face, and there are no even directed cycles left on removal of that face). Following that, Nedev in 1999, showed that EvenPath in planar graphs is polynomial-time solvable [28]. Planar graphs are an example of a *minor-closed* family, which are families of graphs that are closed under edge contraction and deletion. Minor-closed families include many more natural classes of graphs, like graphs of bounded genus, graphs of bounded treewidth, apex graphs. A theorem of Robertson-Seymour [33] shows that every minor-closed family can be characterized by a set of finite forbidden minors. Planar graphs, for example, are exactly graphs with $K_{3,3,}, K_5$ as forbidden minors [38]. In this paper, we consider the family of H-minor-free graphs, where H is any fixed single-crossing graph, i.e., H can be drawn on the plane with at most one crossing. Such families are called single-crossing-minor-free graphs. They include well-studied classes of graphs like K_5-minor-free graphs, $K_{3,3}$-minor-free graphs.[2] Robertson and Seymour showed that single-crossing-minor free graphs admit a decomposition by (upto) 3-clique-sums, into pieces that are either of bounded treewidth, or planar [30]. This is a simpler version of their more general theorem regarding decomposition of H-minor free graphs, (where H is any fixed graph) by clique sums, into more complex pieces, involving apices and vortices [32]. Solving EvenPath on single-crossing-minor free graphs would therefore be a natural step to build an attack on more general minor closed familes.

Many results on problems like reachability, matching, coloring, isomorphism, for planar graphs have been extended to $K_{3,3}$-minor-free graphs and K_5-minor-free graphs as a next step (see [36, 21, 22, 37, 35, 11, 2]). Chambers and Eppstein showed in [6] that using the results of [4, 17] for maximum flows in planar and bounded treewidth graphs, respectively, maximum flows in single-crossing-minor-free graphs can be computed efficiently. Following the result of [1] which showed that perfect matching in planar graphs can be found in NC, Eppstein and Vazirani in [13], extended the result to single-crossing-minor-free graphs.

[2] Both $K_5, K_{3,3}$ have crossing number one. Also, note that both the families, K_5-minor-free, and $K_{3,3}$-minor-free, have graphs of $O(n)$ genus.

1.1 Our Contributions

From here onwards, we will drop the term "directed" and assume by default that the graphs we are referring to are directed, unless otherwise stated. Operations like clique sums, decomposing the graphs along separating triples, pairs, etc., will be applied on the underlying undirected graphs. The following is the main theorem we prove in this paper:

▶ **Theorem 1.** *Given an H-minor-free graph G for any fixed single-crossing graph H, the* EvenPath *problem in G can be solved in polynomial time.*

We first apply the theorem of Robertson-Seymour (theorem 3), and decompose G using 3-clique sums into pieces that are either planar or of bounded treewidth. Though EvenPath is tractable in planar graphs, and can also be solved in bounded treewidth graphs by Courcelle's theorem, straightforward dynamic programming does not yield a polynomial-time algorithm for the problem, as we will explain in subsequent sections. One of the technical ingredients that we develop to overcome the issues is that of *parity-mimicking networks*, which are graphs that preserve the parities of various paths between designated terminal vertices of the graph it mimics. We construct them for upto three terminal vertices. The idea of mimicking networks has been used in the past in other problems, like flow computation [6, 7, 17, 20, 23], and in perfect matching [13]. The ideas we use for constructing parity mimicking networks however, do not rely on any existing work that we know of. For technical reasons, we require our parity mimicking networks to be of bounded treewidth *and* planar, with all terminals lying on a common face. These requirements make it more challenging to construct them (or even to check their existence), than might seem at a first glance. One of our main contributions is to show (in lemma 8) the construction of such networks, for upto three terminals. It might be of independent interest to see if a more simpler construction exists (perhaps a constructive argument to route paths, that has eluded us so far), that avoids the hefty case analysis we do, and also if they can be constructed for more than three terminals.

We also come across a natural variant of another famous problem. Suppose we are given a graph G and vertices $s_1, t_1, s_2, t_2 \ldots s_k, t_k$ (we may call them terminals) in it. The problem of finding pairwise vertex disjoint paths, from each s_i to t_i is a well-studied problem called the disjoint paths problem. In undirected graphs, the problem is in P when k is fixed [31, 29], but NP-complete otherwise [26]. For (directed) graphs, the problem is NP-complete even for $k = 2$ [14]. In planar graphs, it is known to be in P for fixed k [34, 9, 25]. We consider this problem, with the additional constraint that the sum of lengths of the s_i-t_i paths must be of specified parity. We hereafter refer to the parity of the sum of lengths as total parity, and refer to the problem as DisjPathsTotalParity. In the undirected setting, a stricter version of this problem has been studied, where each s_i-t_i path must have parity p_i that is specified in input. This problem was shown to be in P for fixed k, by Kawarabayashi et al. [18]. However much less is known in directed setting. While DisjPathsTotalParity can be solved for fixed k in bounded treewidth graphs using Courcelle's theorem [8], we do not yet know if it is tractable in planar graphs, even for $k = 2$. The other main technical contribution of our paper is in lemma 10, where we show that in some special cases, i.e., when there are four terminals, three of which lie on a common face of a planar graph, DisjPathsTotalParity can be solved in polynomial time for $k = 3$. We do this by showing that under the extra constraints, the machinery developed by [28] can be further generalized and applied to find a solution in polynomial time. The question of tractability of DisjPathsTotalParity in planar graphs, without any constraint of some terminals lying on a common face is open, and would be interesting to resolve. A polynomial-time algorithm for it (for fixed k), would yield a polynomial-time algorithm for EvenPath in graphs with upto k crossings, which is currently unknown.

Though the proofs of lemmas 8,10 form the meat of technical contributions of the paper, we give a proof idea, deferring the proofs to the full version of the paper.

2 Preliminaries

From now onwards we will refer to simple, directed paths as just paths. For a path P, and a pair of vertices u and v on P, such that u occurs before v in P, $P[u, v]$ denotes the subpath of P from u to v. If P_1 and P_2 are two paths that are vertex disjoint, except possibly sharing starting or ending vertices, then we say that P_1, P_2 are *internally disjoint* paths. If P_1's ending vertex is same as the starting vertex of P_2, then we denote the concatenation of P_1 and P_2 by $P_1.P_2$. We will use the numbers $0, 1$ to refer to *parities*, 0 for even parity and 1 for odd parity. We say a path P is of *parity* p ($p \in \{0, 1\}$), if its length modulo 2 is p. We will use a well-known structural decomposition of H-minor-free graphs due to [30]. We recall the definition of clique sums:

▶ **Definition 2.** *A k-clique-sum of two graphs G_1, G_2 can be obtained from the disjoint union of G_1, G_2 by identifying a clique in G_1 of at most k vertices with a clique of the same number of vertices in G_2, and then possibly deleting some of the edges of the merged clique.*

Thus when separating G along a separating pair/triplet, we can add virtual edges if needed, to make the separating pair/triplet a clique. The virtual edges will not be used in computation of path parities, they are only used to compute the decomposition. We can keep track of which edges in the graph are virtual edges and which are the real edges throughout the algorithm. We can repeatedly apply this procedure to decompose any graph G into smaller pieces. The following is a theorem from [30].

▶ **Theorem 3** (Robertson-Seymour [30]). *For any single-crossing graph H, there is an integer τ_H such that every graph with no minor isomorphic to H is either*

1. *the proper* 0-, 1-, 2- *or* 3-*clique-sum of two graphs, or*
2. *planar*
3. *of treewidth $\leq \tau_H$.*

Thus, every H-minor-free graph, where H is a single-crossing graph, can be decomposed by 3-clique sums into graphs that are either planar or have treewidth at most τ_H. Polynomial time algorithms are known to compute this decomposition [12, 19, 16] (and also NC algorithms [13]). The decomposition can be thought of as a two colored tree (see [12, 6, 13] for further details on the decomposition), where the blue colored nodes represent *pieces* (subgraphs that are either planar or have bounded treewidth), and the red nodes represent cliques at which two or more pieces are attached. We call these nodes of the tree decomposition as *piece nodes* and *clique nodes*, respectively. The edges of the tree describe the incidence relation between pieces and cliques (see Figure 2). We will denote this decomposition tree by T_G. We will sometimes abuse notation slightly and refer to a piece of T_G (and also phrases like *leaf* piece, *child* piece), when it is clear from the context that we mean the piece represented by the corresponding node of T_G. Note that the bounded treewidth and planarity condition on the pieces we get in the decomposition, is along with their virtual edges. As explained in [6, 13], we can assume that in any planar piece of the decomposition, the vertices of a separating pair or triplet lie on a common face (Else we could decompose the graph further).

Suppose G decomposes via a 3-clique sum at clique c into G_1 and G_2. Then we write G as $G_1 \oplus_c G_2$. More generally, if $G_1, G_2, \ldots, G_\ell$ all share a common clique c, then we use $G_1 \oplus_c G_2 \oplus_c \ldots \oplus_c G_\ell$ to mean $G_1, G_2, \ldots, G_\ell$ are glued together at the shared clique. If it is clear from the context which clique we are referring to, we will sometimes drop the subscript

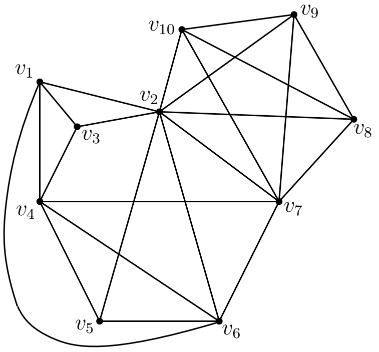

Figure 1 An example of a graph G. We ignore directions here.

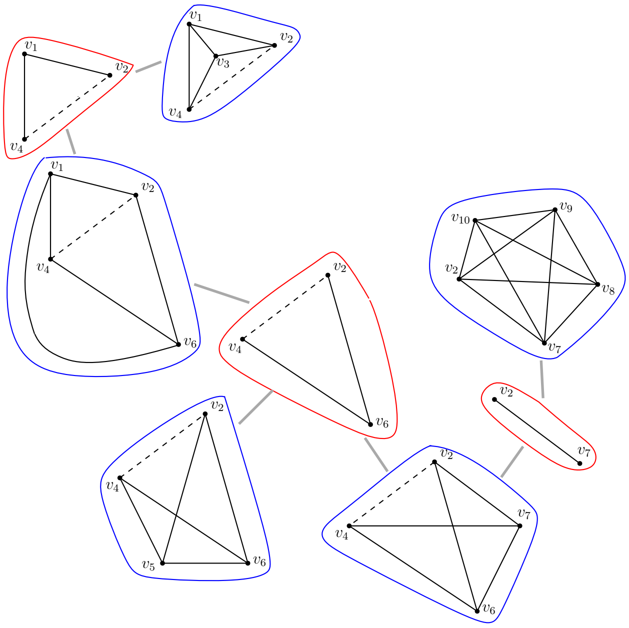

Figure 2 A clique sum decomposition of G. Red nodes are the clique nodes and blue node the piece nodes. Dashed edges denote virtual edges.

and simply use $G_1 \oplus G_2 \oplus \ldots \oplus G_\ell$ instead. Suppose G'_2 is a graph that contains the vertices of the clique c shared by G_1 and G_2. We denote by $G[G_2 \rightarrow G'_2]$, the graph $G_1 \oplus_c G'_2$, i.e., replacing the subgraph G_2 of G, by G'_2, keeping the clique vertices intact. We will also use the notion of *snapshot* of a path in a subgraph. If G can be decomposed into G_1 and G_2 as above, and P is an s-t path in G, its snapshot in G_1 is the set of maximal subpaths of P, restricted to vertices of G_1. Within a piece, we will sometimes refer to the vertices of separating cliques, and s and t, as *terminals*.

In figures, we will generally use the convention that a single arrow denotes a path segment of odd parity and double arrow denotes a path segment of even parity, unless there is an explicit expression for the parity mentioned beside the segment.

3 Overview and Technical Ingredients

We first compute the 3-clique sum decomposition tree of G, T_G. We can assume that s, t, each occur in only one piece of T_G, S and T, respectively.[3] We call the pieces S and T, along with the pieces corresponding to nodes that lie in the unique path in T_G joining S and T, as the *main* pieces of T_G, and the remaining pieces are called the *branch* pieces of T_G. We will assume throughout that T_G is rooted at S.

The high level strategy of our algorithm follows that of [6]. The algorithm has two phases. In the first phase, we simplify the branch pieces of the decomposition tree. Any s-t even path P must start and end inside the main pieces S and T, respectively. However, it may

[3] If they are part of a separating vertex/pair/triplet then they may occur in multiple pieces of T_G. Say s is a part of many pieces in T_G. To handle that case, we can introduce a dummy s' and add an edge from s' to s and reduce the problem to finding an odd length path from s' to t. The vertex s' now will occur in a unique piece in T_G. Vertex t can be handled similarly.

take a detour into the branch pieces. Suppose L is a leaf branch piece of T_G, attached to its parent piece, say G_i, via a 3-clique c. Using Nedev's algorithm or Courcelle's theorem, we can find paths of various parities between vertices of c in L, which constitutes the *parity configuration* of L with respect to c (formally defined in next subsection). We will replace L by a parity mimicking network of L with respect to vertices of c, L'. L' will mimic the parity configuration of L and hence preserve the parities of all s-t paths of original graph. The parity mimicking networks we construct are small and planar, with the terminals (vertices of c) all lying on a common face, as decribed in lemma 8. Therefore, if G_i is of bounded treewidth, then $G_i \oplus L'$ will be of bounded treewidth. And if G_i is planar, then we can plug L' in the face of G_i that is common to vertices of c, and $G_i \oplus L'$ will be planar. This allows us compute the parity configurations of the merged piece, and repeat this step until a single branch, i.e. a path, remains in the decomposition tree, consisting only of the main pieces (connected by cliques), including S and T.

In the second phase, we start simplifying the main pieces, starting with the leaf piece T. Instead of a single mimicking network for T, we will store a set of small networks, each of them mimicking a particular snapshot of a solution. We call them *projection networks.* Since a snapshot of an s-t even path in T can possibly be a set of disjoint paths between the (upto) four terminals in T, we require the DisjPathsTotalParity routine of lemma 10 to compute these projection networks. We combine the parent piece with each possible projection network. The merged piece will again be either planar or of bounded treewidth, allowing us to continue this operation towards the root node until a single piece containing both s and t remains. We query for an s-t even path in this piece and output yes iff there exists one. At each step, the number of projection networks used to replace the leaf piece, and their combinations with its parent piece will remain bounded by a constant number.

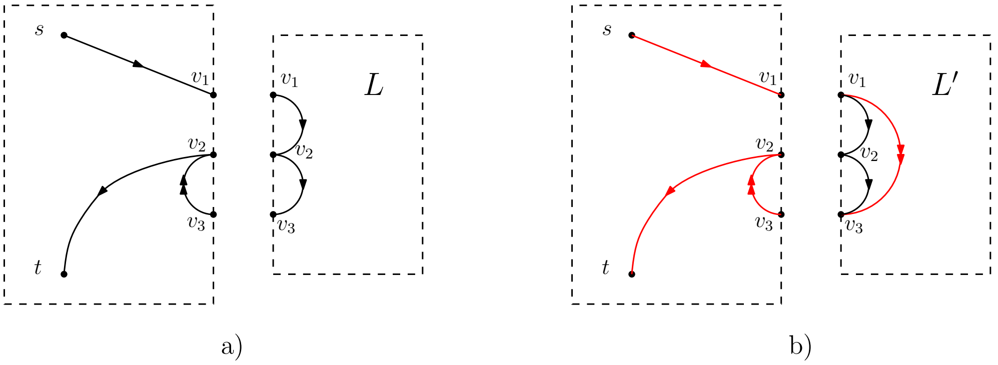
Once we have the decision version of EvenPath, we show a poly-time self-reduction using the decision oracle of EvenPath to construct a solution, in the full version of the paper.

Necessity of a two phased approach

We mention why we have two phases and different technical ingredients for each.

- Instead of a single parity mimicking network, we need a set of projection networks for the leaf piece in the second phase because it can have upto four terminals (three vertices of the separating clique and the vertex t), and we do not yet know how to find (or even the existence of) parity mimicking networks with the constraints we desire, for graphs with four terminals.
- We cannot however use a set of networks for each piece in phase I because of the unbounded degree of T_G. Suppose a branch piece G_i is connected to its parent piece by clique c, and suppose G_i has child pieces $L_1, L_2, \ldots, L_\ell$, attached to G_i via disjoint cliques $c_1, c_2, \ldots, c_\ell$, respectively. An even s-t path can enter G_i via a vertex of c, then visit any of $L_1, L_2, \ldots, L_\ell$ in any order and go back to the parent of G_i via another vertex of c. If we store information regarding parity configurations of $L_1, L_2, \ldots, L_\ell$ as sets of projection networks, we could have to try exponentially many combinations to compute information of parity configurations between vertices of c in the subtree rooted at G_i (note that ℓ could be $O(n)$). Therefore, we compress the information related to parity configurations of L_i into a single parity mimicking network L'_i, while preserving solutions, so that the combined graph $(((G_i \oplus_{c_1} L'_1) \oplus_{c_2} L'_2 \ldots) \oplus_{c_\ell} L'_\ell)$ is either planar or of bounded treewidth.

We will now describe these ingredients formally in the remaining part of this section.



a)

b)

Figure 3 Figure a) shows the input graph and b) shows the graph with L replaced by an erroneous mimicking network L'. Suppose the original graph in a) has no s-t even path but does have an s-t even walk as shown in the figure, using vertex v_2 twice. If we query for a path from v_1 to v_3 in L, and add a direct v_1 to v_3 path of that parity in L', we end up creating a false solution since v_2 is freed up to be used outside L'. Hence there must be equality between corresponding direct sets.

3.1 Parity Mimicking Networks

We first define the parity configuration of a graph, which consists of subsets of $\{0, 1\}$ for each pair, triplet of terminals, depending on whether there exists “direct” or “via” paths of parity even, odd, or both (we use 0 for even parity and 1 for odd). We formalise this below.

▶ **Definition 4.** *Let L be a directed graph and $T(L) = \{v_1, v_2, v_3\}$ be the set of terminal vertices of L. Then, $\forall i, j, k \in \{1, 2, 3\}$, such that i, j, k are distinct, we define the sets* $\mathrm{Dir}_L(v_i, v_j)$*, and* $\mathrm{Via}_L(v_i, v_k, v_j)$ *as:*

- $\mathrm{Dir}_L(v_i, v_j) =$*{p | there exists a path of parity p from v_i to v_j in $L - v_k$ }*
- $\mathrm{Via}_L(v_i, v_k, v_j) =$*{p | there exists a path of parity p from v_i to v_j via v_k* and *there does not exist a path of parity p from v_i to v_j in $L - v_k$}*

We say that the $\mathrm{Dir}_L, \mathrm{Via}_L$ *sets constitute the* parity configuration *of the graph L with respect to $T(L)$. We call the paths corresponding to elements in* $\mathrm{Dir}_L, \mathrm{Via}_L$ *sets as* Direct paths *and* Via paths*, respectively.*

The parity configuration of a graph can be visualised as a table. We have defined it for three terminals, it can be defined in a similar way for two terminals. It is natural to ask the question that given a parity configuration $\mathcal{P}$ independently with respect to some terminal vertices, does there exist a graph with those terminal vertices, realising that parity configuration. If not, we say that $\mathcal{P}$ is unrealisable. It is easy to see that the number of parity configurations for a set of three terminals is bounded by 4^{12}, many of which are unrealizable. We now define parity mimicking networks.

▶ **Definition 5.** *A graph L' is a parity mimicking network of a another graph L (and vica versa), if they share a common set of terminals, and have the same parity configuration, $\mathcal{P}$, w.r.t. the terminals. We also call them parity mimicking networks of parity configuration $\mathcal{P}$.*

The reason we differentiate between direct paths and via paths while defining parity configurations is to ensure that no false solutions are introduced on replacing a leaf piece of T_G by its mimicking network (see Figure 3). Note that in our definition of *Via* sets, we exclude parity entries of via paths between two terminals if that parity is already present in *Dir* set between the same terminals. We do so because this makes the parity configurations easier to enumerate in our construction of parity mimicking networks. In Figure 4, we describe why doing this will still preserve solutions.

We also need to consider the case where multiple leaf pieces, in T_G are attached to a common parent piece via a shared clique (as seen in Figure 2). In this case, we will replace the entire subgraph corresponding to the clique sum of the sibling leaf pieces by one parity mimicking network. To compute the parity configuration of the combined subgraph of leaf pieces, we make the following observation:

▶ **Observation 6.** *Let $L_1, L_2, \ldots, L_\ell$ be leaf branch pieces that are pairwise disjoint except for a common set of terminal vertices, say $\{v_1, v_2, v_3\}$. Let $L = L_1 \oplus L_2 \oplus \ldots \oplus L_\ell$. Then the parity configuration of L with respect to $\{v_1, v_2, v_3\}$ can be computed by:*

$$\mathrm{Dir}_L(v_i, v_j) = \bigcup_{a=1}^{\ell} \mathrm{Dir}_{L_a}(v_i, v_j) \tag{1}$$

$$\mathrm{Via}_L(v_i, v_k, v_j) =$$
$$\left(\bigcup_{a=1}^{\ell} \mathrm{Via}_{L_a}(v_i, v_k, v_j) \cup \bigcup_{a,b=1}^{\ell} (\mathrm{Dir}_{L_a}(v_i, v_k) \boxplus \mathrm{Dir}_{L_b}(v_k, v_j)) \right) \backslash \mathrm{Dir}_L(v_i, v_j) \tag{2}$$

where $A \boxplus B$ denotes the set formed by addition modulo 2 between all pairs of elements in sets A, B, and $i, j, k \in \{1, 2, 3\}$ are distinct.

The intuition behind the observation is simple. Any direct path in L from v_i to v_j must occur as a direct path in one of $L_1, L_2 \ldots L_\ell$ since they are disjoint except for terminal vertices. Any via path in L from v_i to v_j via v_k can occur in two ways, either as a v_i-v_k-v_j via path in one of $L_1, L_2 \ldots L_\ell$, or as a concatenation of two direct paths, one from v_i to v_k in some piece L_i, and another from v_k to v_j in another piece L_j. Note that although the observation is for the case when all $L_1, L_2, \ldots, L_\ell$ share a common 3-clique $\{v_1, v_2, v_3\}$, it is easy to see it can be tweaked easily to handle the cases when some of the $L_i's$ are attached via a 2-clique that is a subset of the 3-clique.

The next lemma states that replacing leaf piece nodes in T_G by parity mimicking networks obeying some planarity conditions, will preserve the existence of s-t paths of any particular parity, and also preserve conditions on treewidth and planarity for the combined piece.

▶ **Lemma 7.** *Let G be a graph with clique sum decomposition tree T_G, and let $L_1, L_2 \ldots, L_\ell$ be set of leaf branch pieces of T_G, attached to their parent piece G_1 via a common clique c. Let L' be a parity mimicking network of $L_1 \oplus L_2 \oplus \ldots L_\ell$ with respect to c, such that L' is planar, and vertices of c lie on a common face in L'. Then:*

1. *There is a path of parity p from s to t in G iff there is a path of parity p from s to t in $G[L_1 \oplus L_2 \oplus \ldots L_\ell \rightarrow L']$.*
2. *If G_1 is planar, then $G_1 \oplus L'$ is also planar.*
3. *If G_1 has treewidth τ_H, and L' has treewidth $\tau_{L'}$, then $G_1 \oplus L'$ has treewidth max$(\tau_H, \tau_{L'})$*

Proof.

1. The proof essentially follows from the definition of parity mimicking networks and observation 6, since we can replace the snapshot of any s-t path P in L_i by a path of corresponding parity in L'_i and vice-versa.
2. This follows since in the decomposition, vertices of separting cliques in every piece lie on the same face, and so is the case for L' by assumption. Therefore we can embed L' inside the face in G_1, on the boundary of which v_1, v_2, v_3 lie.
3. This follows since we can merge tree decompositons of G_1, L' along bags consisting of the common clique. ◀

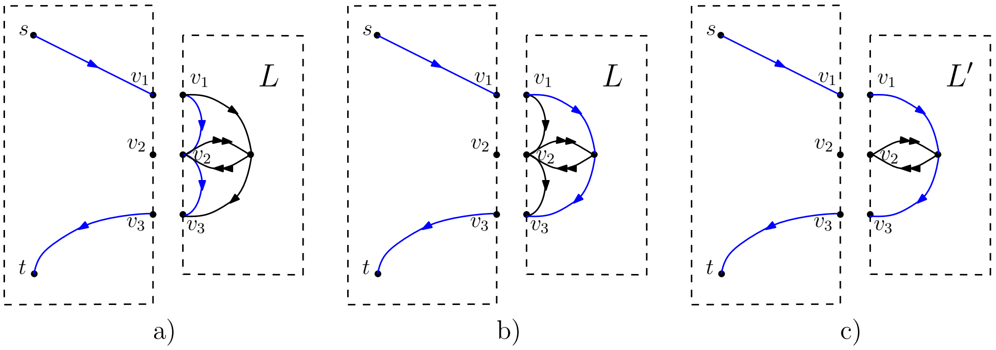


Figure 4 Figure a) denotes the original graph which has both a direct path, as well as a via path of even parity from v_1 to v_3. Suppose the via path is part of an even s-t path solution, as marked by blue. Then in L itself, we could replace the via path by the direct path and it would still be a valid even s-t path, as marked in blue in b). Hence in the mimicking network L', too (shown in c)), we could use the direct v_1 to v_3 path of the same parity. Therefore we do not need to put the parity of the v_1-v_2-v_3 path in $Via_L(v_1, v_2, v_3)$, since the same parity is already present in $Dir_L(v_1, v_3)$, and $Dir_L(v_1, v_3) = Dir_{L'}(v_1, v_3)$.

Now we will show how to compute parity mimicking networks that are small in size (and hence of bounded treewidth), and also planar, with terminal vertices lying on the same face, for a given parity configuration of a graph L.

▶ **Lemma 8.** *Suppose L is a graph with terminals $T(L) = \{v_1, v_2, v_3\}$, and suppose we know the parity configuration of L with respect to $\{v_1, v_2, v_3\}$. We can in polynomial-time, find a parity mimicking network L' of L, with respect to $\{v_1, v_2, v_3\}$ which consists of at most* 18 *vertices, and is also planar, with v_1, v_2, v_3 lying on a common face.*

Proof. We give a brief idea of the proof and defer the full proof to the full version of this paper.As noted above, the number of possible parity configurations are finite (bounded by 4^{12} for three terminals), but the number is too large to enumerate over all of them and individually construct the mimicking networks. We use some observations to make the case analysis tractable. We refer to elements of sets $Dir_L(v_i, v_j)$ as *entries*. But we abuse notation slightly and distinguish them from the boolean values $0, 1$. For example, we always distinguish between an entry of $Dir_L(v_1, v_2)$, and an entry of $Dir_L(v_2, v_3)$, even if they have the same *value* (0 or 1). A natural constructive approach would be to iteratively do the following step for all i, j, p : add a path of length $2 - p$ from v_i to v_j in L', disjoint from existing paths of L', if there is an entry of parity p present in $\mathrm{Dir}_{L'}(v_i, v_j)$. Its easy to check that this will result in a planar L' with terminals on a common face. However, this could lead to wrong parity configurations in L'. For example, L could have a direct paths of parity 1 from v_1 to v_2, and a direct path of parity 0 from v_2 to v_3, but no path of parity 1 from v_1 to v_3, either direct or via v_2 (see Figure 5). We will call pairs of such entries as *bad pairs.* The entries that are part of *any* bad pair are called *bad entries.* Though the example in Figure 5 has a simple fix for the bad pair, it becomes more complicated to maintain the planarity conditions as the number of bad pairs increase. Let $\mathcal{P}_L$ be the parity configuration of L. The idea of the proof is to define a *bad kernel* of $\mathcal{P}_L$, as the *sub-configuration* consisting of all the *bad entries* of $\mathcal{P}_L$. The *closure* of the bad kernel is defined as the parity configuration obtained from it by adding “minimal” number of entiries to make it realizable. We observe that the closure remains a sub-configuration of $\mathcal{P}_L$. Suppose that we can somehow construct a planar mimicking network for the *closure* of the *bad kernel* of $\mathcal{P}_L$, with terminals lying on a

Figure 5 Fig a) denotes a graph L with its parity configuration table (only relevant sets). Fig b) denotes a "parity mimicking network", if for each pair of terminals, we just independently put paths of correct parity, disjoint from each other. It leads to an extra path (highlighted in red) from v_1 to v_3 via v_2 in L', of odd parity. Pairs of such entries, for which we cannot add disjoint paths are called bad entries as marked by the dashed red line in the parity configuration table in a). Fig c) outlines the approach used to construct the correct mimicking network. The two paths corresponding to bad pair entries, form the bad kernel, for which we construct a mimicking network by enumerating cases. The remaining paths can be added iteratively, disjoint from all existing paths, on the outer face.

Figure 6 An example of a more non-trivial bad kernel, and a mimicking network realising its closure. This is a subcase of case $(4,0)$ described in the full proof. We give a list of paths along with their lengths, for ease of reader to check that the network obeys the parity configuration.

common face. Then we show that paths corresponding to leftover parity entries of L can be safely added using the constructive approach described above. Hence it suffices to construct parity mimicking networks for closures of all possible bad kernels. We use some observations to show that the number of possible types of bad kernels cannot be too large, and enumerate over each type, explicitly constructing the parity mimicking networks of their closures. ◀

3.2 Disjoint Paths with Parity Problem

In this section, we will define and solve the DisjPathsTotalParity problem for some special cases and types of graphs. We define the problem for three paths between four terminals.

▶ **Definition 9.** *Given a graph G and four distinct terminals v_1, v_2, v_3, and v_4 in $V(G)$, the* DisjPathsTotalParity *problem is to find a set of three pairwise disjoint paths, from v_1 to v_2, v_2 to v_3, and from v_3 to v_4, such that the total parity is even, if such a set of paths exist, and output no otherwise.*

The problem where total parity must be odd can be easily reduced to this by adding a dummy neighbour to v_4. The problem is NP-hard in general graphs since the even path problem trivially reduces to this. We show that the above problem can be solved in polynomial time in following two cases:

▶ **Lemma 10.** *Let G be a graph, and v_1, v_2, v_3, v_4 be four vertices of G. Both decision as well as search versions of* DisjPathsTotalParity *for these vertices as defined above can be solved in polynomial time in the following cases:*

1. *If G has constant treewidth.*
2. *If G is planar and v_1, v_2, v_3 lie on a common face of G.*

Proof. Proofs of both parts can be found in the full version of the paper. We give a high level idea of the proof of the second part. The argument of Nedev for EvenPath uses two main lemmas. One lemma states that if there are two paths P_1, P_2, of different parities from s to t, then their union forms a (at least one) structure, which they call an *odd list superface*. It (roughly) consists of two internally disjoint paths of different parities, with a common starting vertex, say b and a common ending vertex, say e. Let F denote such a superface. They show that there exist two disjoint paths in $P_1 \cup P_2 - F$, one from s to b, and one from e to t. This provides a "switch" in $P_1 \cup P_2$, and if we can find this switch efficiently, then we can use existing 2-disjoint path algorithms to connect s and t via this switch. But the number of odd list superfaces in a graph can be exponential. The second lemma of Nedev says that we can exploit the structure of planarity and show that each of the odd list superfaces formed by $P_1 \cup P_2$, "contain" a "minimal" odd list superface, which they call a *simple* odd list superface, that obeys the same conditions. The set of simple odd list superfaces is small and can be enumerated in polynomial time. In our setting, we start from the case that two instances of three disjoint paths between the specified terminals exist, such that they have different total parity. Say the instances are P_1, P_2, P_3, and P'_1, P'_2, P'_3. At least one of P_i, P'_i must be of different parity. We show that using the constraints of three terminals on a face, and using ideas of *leftmost* (and rightmost) paths of $P_i \cup P'_i$, for each case of $i \in \{1, 2, 3\}$, there does exist an analogous structure: a simple odd list super face, and four disjoint path segments connecting the required vertices. A point to note is that in Nedev's argument, *any* odd list superface formed by P_1, P_2 could be trimmed to a simple odd list superface that would give a valid solution. That does not hold true here. We generalise their lemma, and argue that there does exist *at least one* odd list superface between P_i, P'_i that will work in our setting. ◀

4 Main Algorithm

We now explain the two phases of the algorithm.

4.1 Phase 1

1. Find the 3-clique sum decomposition tree T_G. Mark the piece that contains the vertex s as the root of T_G.
2. Pick any maximal set of leaf branch pieces of T_G, say $L_1, L_2, \ldots, L_\ell$, which are attached to a parent piece G_i via a common clique. Compute their parity configurations using Nedev's algorithm, or using Courcelle's theorem.Then compute the parity configuration of $L_1 \oplus L_2 \oplus \ldots \oplus L_\ell$ using observation 6.
3. Compute the parity mimicking network, L', of $L_1 \oplus L_2 \oplus \ldots \oplus L_\ell$ using lemma 8. Replace $L_1 \oplus L_2 \oplus \ldots \oplus L_\ell$ by L' and merge it with G_i.
4. Since $G_i \oplus L'$ is either of bounded treewidth or is planar by lemma 7, we can repeat this step until no branch pieces remain.

4.2 Phase II

Let G' denote the graph after phase I. After phase I, the modified tree $T_{G'}$ looks like a path of pieces, $G_1, G_2, \ldots, G_m$, joined at cliques $c_1, c_2 \ldots c_{m-1}$.[4] The vertex s is in root piece G_1, and t in leaf piece G_m (we use G_1, G_m instead of S, T here for notational convenience). We can write $G' = G_1 \oplus_{c_1} G_2 \oplus_{c_2} \ldots \oplus_{c_{m-1}} G_m$. Since it is clear in this phase that c_i is the clique joining G_i, G_{i+1}, we will omit the subscript for notational convenience and just write $G_1 + G_2 + \ldots + G_m$ instead. Let $c_{m-1} = \{v_1, v_2, v_3\}$ and let $i, j, k \in \{1, 2, 3\}$ be distinct. The snapshot of any even s-t path P in G_m, can be one of the following four types (see figure 7):

- Type 1 : A path from v_i to t without using v_j, v_k.
- Type 2 : A path from v_i to t via v_j, without using v_k.
- Type 3 : A path from v_i to t via v_j, v_k.
- Type 4 : A path from v_i to v_j and a path from v_k to t, both disjoint from each other.

We call any path/set of paths in G_m of one of the above types as a *potential snapshot* of G_m. We now construct the *projection networks* of potential snapshots of G_m.

▶ **Definition 11.** *Let G_m be the leaf piece as described above with clique $c_{m-1} = \{v_1, v_2, v_3\}$, and vertex t present in G_m.*

- *For each of the types described above, for all $i \in \{1, 2, 3\}$, and for all $p \in \{0, 1\}$, find a potential snapshot (if it exists) in G_m from v_i to t, of total parity p, using lemma 10.*
- *Let J be a potential snapshot found in the previous step, Its* projection network*, is defined as the* graph *obtained from J by keeping terminal vertices intact, and replacing every terminal to terminal path in J by a path of length $2 - p$.*

The type of the projection network is the type of the corresponding potential snapshot.
The set of projection networks *of G_m, denoted by $\mathcal{N}(G_m)$, is the set of all projection networks obtained for G_m by the above procedure.*

See Figure 7 for an example. Since the total number of terminals is at most 4 (with one fixed as t), it is easy to see that the number of possible projections networks for G_m is bounded. Therefore $\mathcal{N}(G_m)$ can be computed in polynomial time. Note that $\mathcal{N}(G_m)$ is not uniquely defined. But it is sufficient for our purpose, to compute any one of the various possible choices of the set $\mathcal{N}(G_m)$ as explained in Figure 7. The next lemma shows that the projection networks of G_m preserve solutions, and also maintain invariants on planarity and treewidth, when merged with the parent piece.

▶ **Lemma 12.** *Given $G' = G_1 + \ldots + G_m$ as described above.*

1. *Given a $\mathcal{N}(G_m)$, there is an s-t path in G' of parity p iff $\exists N \in \mathcal{N}(G_m)$ such that $G'[G_m \to N]$ has an s-t path of parity p.*
2. *If G_{m-1} is planar/of bounded treewidth, then for any projection network $N \in \mathcal{N}(G_m)$, $G_{m-1} + N$ is planar/of bounded treewidth, respectively.*

Proof.

1. This follows from the definition of projection networks. The only minor technical point to note is that $\mathcal{N}(G_m)$ is not unique. For example, suppose there are two potential snaphots in G_m of type 4. One is J_1, consisting of a path P_1 from v_1 to v_2 of even parity, and a path P_2 from v_3 to t of odd parity. The other is J_2, consisting of a path P_1' from v_1 to v_2

[4] Note that the vertices of a clique, say c_i need no longer lie on the same face of G_i after phase I, since we might have merged the parity mimicking network of the branch pieces incident at c_i into the face corresponding to c_i.

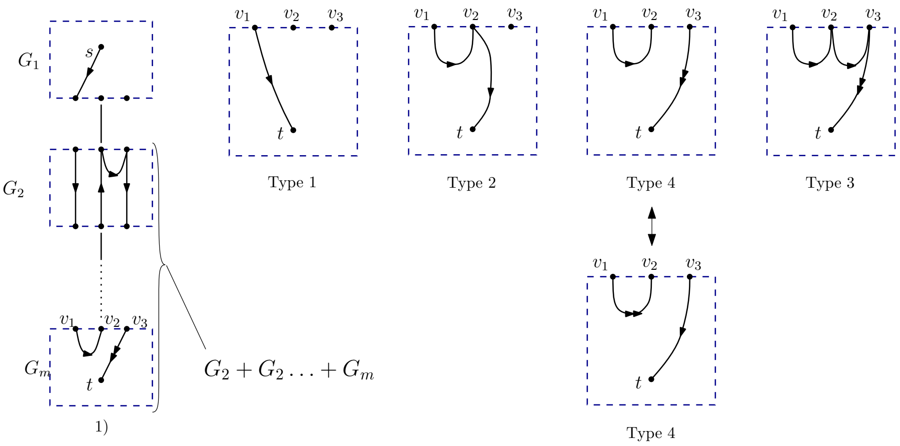

Figure 7 Fig 1) Denotes the decomposition tree after phase 1, with $G_1, G_2 \ldots, G_m$ denoting the pieces. We skip drawing clique nodes here. On the right are examples of projection networks of different types. In fig 1), the snapshot of the s-t path in G_m is of type 4. The two projection networks of type 4 drawn on the right have same total parity, but different parities of individual segments. It is sufficient for our purpose to find any one of them since they are interchangeable.

of odd parity, and a path P_2' from v_3 to t, of even parity. Since the total parity of J_1 and J_2 is same, Lemma 10 could output either one of them. We don't have control over it to find both. But finding any one of them is sufficient for us, since if J_1 is a snapshot of an actual solution, then replacing J_1 by J_2 would also give a valid solution and vice versa.(See Figure 7)

2. Suppose $c_{m_1} = \{v_1, v_2, v_3\}$ is the clique where G_{m-1}, G_m are attached. The argument of treewidth bound is same as that of Lemma 7 in previous phase, when we attached mimicking networks to parent pieces. However if G_{m-1} is planar, there could have been a parity mimicking network L' attached to G_{m-1} via c_{m-1} during phase I. Hence v_1, v_2, v_3 might not lie on a common face in G_{m-1} after phase I. We observe however, since L' was attached at a 3-clique, c_{m-1}, every pair v_i, v_j of vertices of c_{m-1}, must share a common face in G_{m-1}. Now, the projection networks consist of at most three paths, two between v_1, v_2, v_3, and one from them to t. For any v_i, v_j, we can embed the path between v_i, v_j in N, in the face in G_{m-1} shared by v_i, v_j, and finally just add the path leading to t. Therefore if G_{m-1} is planar, all projection networks of G_m can be embedded in their parent nodes. ◀

We make the following observation to compute a $\mathcal{N}(G_i + \ldots G_m)$ recursively:

$$\mathcal{N}(G_i + \ldots G_m) = \bigcup_{N \in \mathcal{N}(G_{i+1} + \ldots G_m)} \mathcal{N}(G_i + N) \tag{3}$$

Thus we can proceed as follows:

1. Compute $\mathcal{N}(G_m)$ using lemma 10
2. For all $N \in \mathcal{N}(G_m)$, compute $G_{m-1} + N$, and hence compute $\mathcal{N}(G_m + G_{m-1})$ using the observation above.
3. For all $N \in \mathcal{N}(G_m + G_{m-1})$, compute $G_{m-2} + N$, and hence compute $\mathcal{N}(G_m + G_{m-1} + G_{m-2})$. Repeat until we reach G_1.

Abstract

We present a new technique to encode Post's Correspondence Problem into automaton semigroups and monoids. The encoding allows us to precisely control whether there exists a relation in the generated semigroup/monoid and thus show that the freeness problems for automaton semigroups and for automaton monoids (listed as open problems by Grigorchuk, Nekrashevych and Sushchanskĭi) are undecidable. The construction seems to be quite versatile and we obtain the undecidability of further problems: Is a given automaton semigroup (monoid) (left) cancellative? Is it equidivisible (which – together with the existence of a (proper) length function – characterizes free semigroups and monoids)? Does a given map extend into a homomorphism between given automaton semigroups? Finally, our construction can be adapted to show that it is undecidable whether a given automaton generates a free monoid whose basis is given by the states (but where we allow one state to act as the identity). In the semigroup case, we show a weaker version of this.

1 Introduction

In the 1980s, Grigorchuk solved a famous question by Milnor (see [20] for a nice introduction) by presenting the first group with intermediate growth: the number of elements that can be written as a word of length at most n over the generators grows sub-exponentially but super-polynomially. The group has even more noteworthy properties. It is amenable but not elementary amenable (e. g. [24]) and an infinite 2-group (giving a counter-example to Burnside's problem, e. g. [33, 3]). Its peculiar properties stirred interest in Grigorchuk's group and groups of similar form where it soon became important that Grigorchuk's group has a nice description using what is simply called an *automaton* in this context (e. g. [33] or [3]). The simplicity of this presentation (the automaton only uses a binary alphabet and four states – with an additional identity state) contrasts the complex nature of the group. An "automaton" here is what more precisely is called a finite-state letter-to-letter transducer (i. e. an automaton with input and output). The idea is that in such an automaton every state induces a mapping of input to output words and the closure of these functions under composition forms a semigroup. If the automaton is additionally invertible, the functions are bijections and we may consider the generated group. This leads to the classes of *automaton semigroups* and *groups*, which contain further noteworthy examples (e. g. Gupta-Siki p-groups [22], the lamplighter group [21] and more general lamplighter-like groups [37, 38]).

Being able to finitely describe groups without classical finite presentations (consisting of generators and relations) additionally highlights the usefulness of considering (semi)groups generated by automata. Starting from Grigorchuk's group, the study of automaton groups and semigroups is nowadays a thriving research field with important connections to many neighboring areas (such as geometry, dynamical systems and symbolic dynamics; see e. g. [33, 3] for more background information). The extensive research in Mathematics and Computer Science on the semigroup (and monoid) case (e. g. [9, 26, 7, 34, 1, 15]) arises naturally from the group case for example via the *dual automaton* where states and input/output letters swap places. The connection between an automaton and its dual has been exploited algebraically and algorithmically (e. g. [18, 41, 42, 26, 27, 11]).

In this work, we look further at the algorithmic aspects of this interesting class by showing that its *freeness problem* is undecidable. This problem asks whether a given automaton generates a free semigroup (or monoid). It has been studied extensively for other classes of groups and semigroups. Since freeness is a Markov property, the problem is undecidable for classical finite group (and, thus, semigroup) presentations (see e. g. [29]). Further important results include the undecidability of the freeness problem for matrix semigroups, originally shown using a reduction from Post's Correspondence Problem [25], which has been improved and contrasted in many further publications (e. g. [31, 10, 4]). Interestingly, matrix (semi)groups and automaton (semi)groups are connected in the sense that the former can be presented as subgroups of the latter [8] (see also [40, 12, 43]) but this does not help to prove the freeness problem undecidable for automaton (semi)groups [13].

With our result, we continue this line of research but also further contribute to the study of freeness in self-similar (i. e. generated by infinite automata) and automaton structures as well as their algorithmic aspects. For the former, we refer the reader to the survey [36] and only point out that, while it is known that free groups are automaton groups [41, 42, 39], these constructions are usually deemed rather difficult. For automaton semigroups and monoids, the situation seems to be simpler: every free semigroup of (finite) rank at least two can be generated by an automaton (see [9] or Example 2.5) but the free semigroup of rank one cannot [9]. All free monoids of finite rank are automaton semigroups, though.

Regarding algorithmic questions for automaton (semi)groups, we point out that, while one may easily be misled into believing that using a finite automaton as the generating combinatorial object should be rather simple, the situation is actually quite complex and only a few natural algorithmic problems are known to be undecidable while many others notoriously remain open problems. An exception here seems to be that the word problem for automaton (semi)groups is PSPACE-complete. Interestingly, this was first known for semigroups [14] and was later extended to groups [43]. Some subclasses have simpler word problems. For example, using finitary automata to present finite groups results in a coNP-complete word problem [28] and the word problem of an automaton group of polynomial activity is in polylogarithmic space [5] (see [44] for more information). On the other hand, there is an automaton group with an undecidable conjugacy problem [40] ("are two given group elements conjugate in the group?"). The construction used there also shows that the isomorphism problem for automaton groups ("are the groups generated by two given automata isomorphic?") and, thus, automaton semigroups is undecidable.[1] There are two constructions for an automaton group with undecidable order problem ("has a given group

[1] Unfortunately, this does not seem to be written down explicitly anywhere.

element finite or infinite order?") [17, 2]. The latter of the two even yields a contracting automaton. The undecidability was also first known for automaton semigroups [16] and the problem is decidable for bounded automaton groups [6] and monoids [1].

All these constructions encoding Turing machines in automaton (semi)groups make a statement about individual (semi)group elements. Since the interaction between the generating automaton and generated algebraic structure is often surprising and still not well understood, it is much more challenging to construct reductions where the entire generated (semi)group (or monoid) has a certain property (based on whether we input a positive or negative problem instance). The only known result of this kind seems to be that the finiteness problem for automaton semigroups ("Is the semigroup generated by a given automaton finite?") is undecidable [16]. The corresponding group problem is still open [19].

Our reduction from Post's Correspondence Problem [35] to the freeness problems for automaton semigroups and for monoids in this paper is a second result of this form. It solves the corresponding open problem by Grigorchuk, Nekrashevych and Sushchanskiĭ [19, 7.2 b)] and, despite previous attempts [12, 13] and a positive result for semigroups generated by invertible and reversible automata with two states [26] as well as a negative result on testing for relations of the form $w = \mathbb{1}$ [12], the problem had remained open quite a while for groups and for semigroups. The main challenge seems to be that we need very precise control over the relations in the generated semigroup (which seems to be much more difficult than, e. g., ensuring that the semigroup is finite or infinite) while the interaction between the structure of the generating automaton and the semigroup/monoid relations is highly non-obvious.

Our construction yields further results beyond the freeness problem(s). Namely, testing whether a given automaton generates a (left) cancellative semigroup/monoid and whether the semigroup/monoid generated by a given automaton is equidivisible (a notion strongly related to freeness by Levi's lemma, see Fact 2.2) are undecidable. We also obtain that it is undecidable whether a given automaton generates a free semigroup with a given basis and whether a given map between the state sets of two given automata can be extended into an iso- or homomorphism. The latter problem is connected to the (undecidable, see above) isomorphism problem for automaton semigroups in the sense that it asks whether all relations of the first automaton semigroup also hold in the second one.

Finally, the construction seems to be flexible enough to be adapted to similar problems, which gives us hope that our results could also contribute towards showing that the freeness problem is undecidable in the group case. For example, it can be adapted to show that the free presentation problem for automaton monoids is undecidable: does a given automaton generate a free monoid whose rank is equal to the number of its states (minus an identity state)? In other words, we cannot test whether a given automaton monoid contains any relations (although this is semi-decidable as the word problem is decidable, see above).

Adapting our construction for this is necessary because the construction in the semigroup case always yields semigroup relations since we need to use a result on the closure of the class of automaton semigroups under (certain) free products [30] in order to construct some kind of "partial" powers of the generating automaton. However, no details of this construction will be required to understand our results. More generally, the presentation in this work is meant to be self-contained (although the construction may be considered to be rather technical).

2 Preliminaries

Fundamentals, Semigroups and Monoids. We write $A \uplus B$ for the disjoint union of sets and consider the set of natural numbers $\mathbb{N}$ to contain 0. We assume the reader to be familiar with fundamental notions of semigroup theory (see e. g. [23]). We write $\mathbb{1}_M$ for the neutral element of a monoid M or, if M is clear from the context, simply $\mathbb{1}$. For a monoid M, we let $M^{\mathbb{1}} = M$ and, if S is a semigroup but not a monoid, we may adjoin a neutral element $\mathbb{1} \notin S$ to S by letting $\mathbb{1}\mathbb{1} = \mathbb{1}$ and $\mathbb{1}s = s = s\mathbb{1}$ for all S and denote the resulting monoid by $S^{\mathbb{1}}$.

Words, Free Semigroups and Free Monoids. Let B be a finite, non-empty set, which we call an *alphabet.* A *word* w over B is a finite sequence $a_1 \dots a_n$ with $a_1, \dots, a_n \in B$, whose *length* is $|w| = n$. We denote the unique word of length 0 (i. e. the *empty word*) by ε. The set of all words over B is denoted by B^*. Words have the natural operation of juxtaposition (where we let $uv = a_1 \dots a_m b_1 \dots b_n$ for $u = a_1 \dots a_m$ and $v = b_1 \dots b_n$ with $a_1, \dots, a_m, b_1, \dots, b_n \in B$), which turns B^* into a monoid with the neutral element ε. This monoid B^* is *the free monoid* with *basis* B (or *over* B) and a monoid M is *free* (with basis B) if it is isomorphic to B^* (for some alphabet B). Closely related to the free monoid is *the free semigroup* B^+, which is formed by the set of all non-empty words (i. e. $B^+ = B^* \setminus \{\varepsilon\}$) and (again) juxtaposition as operation. Similarly, a semigroup S is *free* (with basis B) if it is isomorphic to B^+ (for some alphabet B). Note that B^* is (isomorphic to) $(B^+)^{\mathbb{1}}$ and that the basis of a free monoid or semigroup is unique (see e. g. [23, Proposition 7.1.3]). The *rank* of a free monoid or semigroup is the cardinality $|B|$ of its basis B. We will use common conventions from formal language theory and, e. g., write q^+ and q^* for $\{q\}^+$ and $\{q\}^*$.

Properties of Free Semigroups and Monoids. We will need some properties of free semigroups and monoids. A (general) semigroup S is *left cancellative* if $st = st'$ implies $t = t'$ for all $s, t, t' \in S$. Symmetrically, it is *right cancellative* if $st = s't$ implies $s = s'$ for all $s, s', t \in S$ and, finally, it is *cancellative* if it is both left and right cancellative. It is easy to see that B^* and, thus, B^+ are cancellative (see, e. g. [23, Proposition 7.1.1]).

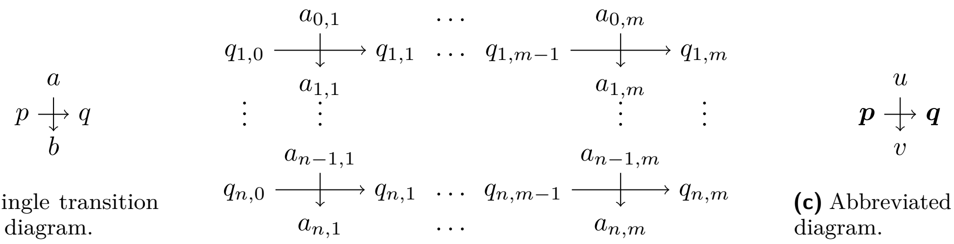
▶ **Fact 2.1.** *Free semigroups and free monoids are cancellative.*

A *length function* of a semigroup S is a homomorphism $S \to \mathbb{N}_{>0}$ where $\mathbb{N}_{>0}$ is the additive semigroup of strictly positive natural numbers. A monoid M has a *proper length function* if there is a monoid homomorphism $M \to \mathbb{N}$ (where $\mathbb{N}$ is the additive monoid of the natural numbers including 0) such that $\mathbb{1}$ is the only pre-image of 0 (i. e. only $\mathbb{1}$ has length 0, all other elements have strictly positive length). A semigroup S that is not a monoid has a length function if and only if $S^{\mathbb{1}}$ has a proper one and free semigroups and monoids do have (proper) length functions (mapping a word to its length).

A semigroup (or monoid) S is *equidivisable* if, for all $s_1, s_2, s_1', s_2' \in S$ with $s_1 s_2 = s_1' s_2'$, there is some $x \in S^{\mathbb{1}}$ with $s_1 = s_1' x$ and $x s_2 = s_2'$ or with $s_1 x = s_1'$ and $s_2 = x s_2'$. It is not difficult to see that free semigroups and monoids are equidivisible (see e. g. [23, Proposition 7.1.2]). Together with having a (proper) length function, this turns out to characterize free semigroups and monoids (see e. g. [23, Proposition 7.1.8]).

▶ **Fact 2.2** (Levi's Lemma). *A semigroup (monoid) S is free if and only if it is equidivisible and has a (proper) length function.*

Free Products of Semigroups. A *semigroup presentation* is a pair $\langle Q \mid \mathcal{R} \rangle_{\mathscr{S}}$ of a set of *generators* Q and a (possibly infinite) set of *relations* $\mathcal{R} \subseteq Q^+ \times Q^+$. We will only consider presentations where Q is finite and non-empty. If we denote by $\mathcal{C}$ the smallest congruence $\mathcal{C} \subseteq Q^+ \times Q^+$ with $\mathcal{R} \subseteq \mathcal{C}$, the semigroup *presented* by such a presentation is $S = Q^+/\mathcal{C}$ formed by the congruence classes $[\cdot]$ of $\mathcal{C}$ with the (well-defined!) operation $[u] \cdot [v] = [uv]$. Every semigroup generated by a finite, non-empty set Q is presented by some semigroup presentation of this form.



(a) Single transition cross diagram.

(b) Multiple crosses combined in one diagram.

(c) Abbreviated cross diagram.

Figure 1 Combined and abbreviated cross diagrams.

The free product of the semigroups $S = \langle Q \mid \mathcal{S} \rangle_{\mathscr{S}}$ and $T = \langle P \mid \mathcal{R} \rangle_{\mathscr{S}}$ is the semigroup $S \star T = \langle Q \uplus P \mid \mathcal{S} \cup \mathcal{R} \rangle_{\mathscr{S}}$. For example, we have $\{p, q\}^+ = p^+ \star q^+$.

▶ Remark. Of course, there is also the free product of monoids (and monoid presentations). However, we will only consider free products of semigroups (in particular: $\{p, q\}^* \not\simeq p^* \star q^*$).

Automata. In the current context, an *automaton* is a triple $\mathcal{T} = (Q, \Sigma, \delta)$ consisting of a non-empty, finite set of *states* Q, an *alphabet* Σ and a set $\delta \subseteq Q \times \Sigma \times \Sigma \times Q$ of *transitions*.

▶ Remark. What we simply call an automaton here would rather be called a finite-state, letter-to-letter transducer in more general automaton-theoretic terms. However, simply using the term "automaton" is standard terminology in the area. We also do not use initial or final states as they do not interact nicely with the self-similar nature of the semigroups and monoids generated by automata we are about to define.

For transitions, we will use the graphical notation $p \xrightarrow{a/b} q$ to denote $(p, a, b, q) \in Q \times \Sigma \times \Sigma \times Q$. Such a transition *starts* in p, *ends* in q, its *input* is a and its *output* is b. This reflects the common way of depicting automata (see e. g. Figure 2). When dealing with an automaton $\mathcal{T} = (Q, \Sigma, \delta)$, we are actually dealing with two alphabets (Q and Σ). In order to avoid confusion, we call the elements of Q *states* and the elements of Q^* *state sequences*, while reserving the terms *letters* and *words* for the elements of Σ and Σ^*, respectively.

Another somewhat graphical tool that we will make heavy use of are *cross diagrams*. Here, a cross diagram as given in Figure 1a indicates the existence of a transition $p \xrightarrow{a/b} q$ in the automaton. Cross diagrams can be stacked together in order to create larger ones. For example, the diagram in Figure 1b indicates the existence of the transition $q_{i,j-1} \xrightarrow{a_{i-1,j}/a_{i,j}} q_{i,j}$ for all $0 < i \leq n$ and $0 < j \leq m$. When combining cross diagrams, we will sometimes omit unnecessary states and letters. Additionally, we will also abbreviate them: for example, if we let $\boldsymbol{p} = q_{n,0} \dots q_{1,0}$, $u = a_{0,1} \dots a_{0,m}$, $v = a_{n,1} \dots a_{n,m}$ and $\boldsymbol{q} = q_{n,m} \dots q_{1,m}$, the cross diagram in Figure 1c is an abbreviation of the cross diagram in Figure 1b. It is important here to note the order we write the state sequences in: in our example, $q_{1,0}$ is the first state in the top left of the cross diagram but it is the rightmost state in the sequence $\boldsymbol{p}$. This order will later be more natural as we will define a left action based on cross diagrams.

An automaton $\mathcal{T} = (Q, \Sigma, \delta)$ is called *complete and deterministic* if, for every $p \in Q$ and every $a \in \Sigma$, there is exactly one $q \in Q$ and exactly one $b \in \Sigma$ such that the cross diagram in Figure 1a holds (i. e. in every state p and for every letter $a \in \Sigma$, there is exactly one transition starting in p with input a). We call such an automaton a *complete $\mathscr{S}$-automaton* (as they naturally generate semigroups).

An automaton $\mathcal{S} = (P, \Sigma, \sigma)$ is a *subautomaton* of another automaton $\mathcal{T} = (Q, \Gamma, \delta)$ if $P \subseteq Q$, $\Sigma \subseteq \Gamma$ and $\sigma \subseteq \delta$. In this case, any cross diagram of $\mathcal{S}$ is also valid for $\mathcal{T}$.

Automaton Semigroups and Monoids. Let $\mathcal{T} = (Q, \Sigma, \delta)$ be a complete $\mathscr{S}$-automaton. By induction, there is exactly one $v \in \Sigma^+$ and exactly one $\boldsymbol{q} \in Q^+$ for every $\boldsymbol{p} \in Q^+$ and $u \in \Sigma^+$ such that the cross diagram in Figure 1c holds. This allows us to define a left action of Q^+ on Σ^+ by letting $\boldsymbol{p} \circ u = v$ and to define a right action of Σ^+ on Q^+, called the *dual action*, by letting $\boldsymbol{p} \cdot u = \boldsymbol{q}$. The reader may verify that this indeed defines well-defined actions by the way cross diagrams work. We may extend these into an action of Q^* on Σ^* and an action of Σ^* on Q^* by letting $\varepsilon \circ u = u$ for all $u \in \Sigma^*$, $\boldsymbol{p} \circ \varepsilon = \varepsilon$ for all $\boldsymbol{p} \in Q^*$, $\varepsilon \cdot u = \varepsilon$ again for all $u \in \Sigma^*$ and, finally, $\boldsymbol{p} \cdot \varepsilon = \boldsymbol{p}$ for (again) all $\boldsymbol{p} \in Q^*$.

By the way cross diagrams work, there is an interaction between the two actions: for all $\boldsymbol{p}, \boldsymbol{q} \in Q^*$ and all $u, v \in \Sigma^*$, we have $\boldsymbol{p} \circ uv = (\boldsymbol{p} \circ u)[(\boldsymbol{p} \cdot u) \circ v]$ and $\boldsymbol{qp} \cdot u = [\boldsymbol{q} \cdot (\boldsymbol{p} \circ u)](\boldsymbol{p} \cdot u)$.

The action $\boldsymbol{p} \circ u$ allows us to define the congruence $=_\mathcal{T} \subseteq Q^* \times Q^*$ by $\boldsymbol{p} =_\mathcal{T} \boldsymbol{q} \iff \forall u \in \Sigma^* : \boldsymbol{p} \circ u = \boldsymbol{q} \circ u$. We denote the class of $\boldsymbol{p} \in Q^*$ with respect to $=_\mathcal{T}$ by $[\boldsymbol{p}]_\mathcal{T}$. The set $\mathscr{M}(\mathcal{T}) = Q^*/{=_\mathcal{T}}$ of these classes forms a monoid, which is called the *monoid generated* by $\mathcal{T}$. In other words, it is the faithful quotient of Q^* with respect to the action $\boldsymbol{q} \circ u$. Note that ε acts like the identity on all $u \in \Sigma^*$ and the class of ε, thus, forms the neutral element of $\mathscr{M}(\mathcal{T})$. A monoid arising in this way is called a *complete automaton monoid*.

Similarly, the *semigroup generated* by $\mathcal{T}$ is the semigroup $\mathscr{S}(\mathcal{T}) = Q^+/{=_\mathcal{T}}$ and any such semigroup is a *complete automaton semigroup*. Note that monoid and semigroup generated by a complete $\mathscr{S}$-automaton coincide if there is a non-empty state sequence acting trivially.

▶ Remark 2.3. We only consider complete $\mathscr{S}$-automata in this work but will make this explicit by talking about complete $\mathscr{S}$-automata and complete automaton semigroups and monoids. In the literature, these objects are often simply called "automaton semigroups" (the term "automaton monoid" is less common). This is a convention that we could also follow here but choose not to since the concepts generalize naturally also to non-complete automata, yielding (partial) automaton semigroups and monoids. It is not known whether the two classes coincide (see [15] for more details).

▶ Remark 2.4. There is a subtle difference between an automaton monoid and an automaton semigroup which happens to be a monoid. In the latter, the neutral element not necessarily acts as the identity map. In fact, it is not known whether the two classes coincide (see [9, Proposition 3.1] for the analogue for groups).

Free Semigroups (Monoids) as Automaton Semigroups (Monoids). As examples of complete automaton semigroups and monoids, we will next look at how to generate free semigroups and monoids. The free monoid of rank one is generated by an automaton known as the *adding machine* (see e. g. [33] or [3]), which turns it into both a complete automaton monoid and a complete automaton semigroup. The free semigroup of rank one, on the other hand, is neither [9, Proposition 4.3] (see also [7, Theorem 15], [15, Theorem 19] and [43, Theorem 1.2.1.4]).

However, free semigroups of higher rank (and their monoid counter-parts) are indeed complete automaton semigroups [9, Proposition 4.1]:

▶ **Example 2.5.** Let R be a finite set with $|R| \geq 2$. Consider the automaton $\mathcal{R} = (R, R, \rho)$ with $\rho = \{a \xrightarrow{b/a} b \mid a, b \in R\}$ (see Figure 2 for the binary case). One easily verifies that $\mathcal{R}$ is a complete $\mathscr{S}$-automaton and we claim that it generates R^+. For this, it suffices to show that, for every $\boldsymbol{p}, \boldsymbol{q} \in R^+$ with $\boldsymbol{p} \neq \boldsymbol{q}$, there is some $u \in R^*$ with $\boldsymbol{p} \circ u \neq \boldsymbol{q} \circ u$. We may assume $|\boldsymbol{p}| \geq |\boldsymbol{q}|$ and there needs to be some $a \in R$ with $\boldsymbol{p} \neq \boldsymbol{q}a^{|\boldsymbol{p}|-|\boldsymbol{q}|}$ (we just need to take a different to the last letter of $\boldsymbol{p}$ if the lengths differ). Now, observe that, for all $n \geq 1$ and

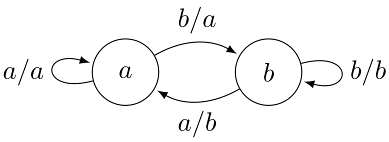


Figure 2 A complete $\mathscr{S}$-automaton generating $\{a, b\}^+$.

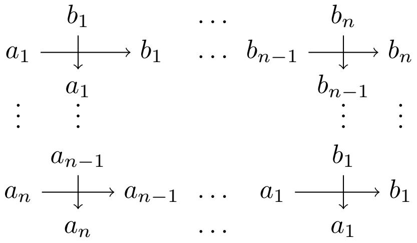

Figure 3 Cross diagram of $\mathcal{R}$.

all $a_1, \dots, a_n, b_1, \dots, b_n \in R$, we have the cross diagram in Figure 3 by the construction of $\mathcal{R}$. This shows, in particular, $\boldsymbol{p} \circ a^{|\boldsymbol{p}|} = \boldsymbol{p}$ and $\boldsymbol{p} \cdot a^{|\boldsymbol{p}|} = a^{|\boldsymbol{p}|}$. By a similar cross diagram, we obtain $\boldsymbol{p} \neq_{\mathcal{R}} \boldsymbol{q}$ (since $\boldsymbol{q} \circ a^{|\boldsymbol{p}|} = (\boldsymbol{q} \circ a^{|\boldsymbol{q}|})(a^{|\boldsymbol{q}|} \circ a^{|\boldsymbol{p}|-|\boldsymbol{q}|}) = \boldsymbol{q}a^{|\boldsymbol{p}|-|\boldsymbol{q}|} \neq \boldsymbol{p} = \boldsymbol{p} \circ a^{|\boldsymbol{p}|}$).

There is no state sequence which acts like the identity and this means that $\mathscr{M}(\mathcal{R})$ is $\mathscr{S}(\mathcal{R})^{\mathbb{1}} \simeq R^*$, which shows that R^* is a complete automaton monoid.

The construction presented in Example 2.5 is clearly computable and we obtain:

▶ **Fact 2.6.** *For every finite set R with $|R| \geq 2$, one can compute an $\mathscr{S}$-automaton $\mathcal{R} = (R, R, \rho)$ with $\mathscr{S}(\mathcal{R}) \simeq R^+$ and $\mathscr{M}(\mathcal{R}) \simeq R^*$.*

Automaton Operations. The *union* of two automata $\mathcal{T}_1 = (Q_1, \Sigma_1, \delta_1)$ and $\mathcal{T}_2 = (Q_2, \Sigma_2, \delta_2)$ is the automaton $\mathcal{T}_1 \cup \mathcal{T}_2 = (Q_1 \cup Q_2, \Sigma_1 \cup \Sigma_2, \delta_1 \cup \delta_2)$. If $\mathcal{T}_1$ and $\mathcal{T}_2$ are both complete $\mathscr{S}$-automaton with non-intersecting state sets ($Q_1 \cap Q_2 = \emptyset$) but a common alphabet $\Sigma_1 = \Sigma_2$, their union $\mathcal{T}_1 \cup \mathcal{T}_2$ is also a complete $\mathscr{S}$-automaton (which allows us, for example, to consider the semigroup $\mathscr{S}(\mathcal{T}_1 \cup \mathcal{T}_2)$). Similarly, the union of two complete $\mathscr{S}$-automata with the same state set but disjoint alphabets is again a complete $\mathscr{S}$-automaton. This operation basically adds the transitions of $\mathcal{T}_2$ to the existing transitions of $\mathcal{T}_1$.

The *composition* of two automata $\mathcal{T}_2 = (Q_2, \Sigma, \delta_2)$ and $\mathcal{T}_1 = (Q_1, \Sigma, \delta_1)$ over a common alphabet Σ is the automaton $\mathcal{T}_2 \circ \mathcal{T}_1 = (Q_2Q_1, \Sigma, \delta_2 \circ \delta_1)$ with

$$\delta_2 \circ \delta_1 = \left\{ p_2p_1 \xrightarrow{a/c} q_2q_1 \,\middle|\, \exists b \in \Sigma : p_1 \xrightarrow{a/b} q_1 \in \delta_1 \text{ and } p_2 \xrightarrow{b/c} q_2 \in \delta_2 \right\}$$

(where $Q_2Q_1 = \{q_2q_1 \mid q_1 \in Q_1, q_2 \in Q_2\}$ is the cartesian product of Q_2 and Q_1). If $\mathcal{T}_2$ and $\mathcal{T}_1$ are complete $\mathscr{S}$-automata, also their composition is.

The *k-th power* $\mathcal{T}^k$ of an automaton $\mathcal{T}$ is the k-fold composition of $\mathcal{T}$ with itself. It is computable and, if $\mathcal{T}$ (and, thus, $\mathcal{T}^k$) is a complete $\mathscr{S}$-automaton, the actions of some $\boldsymbol{p} \in Q^*$ of length $|\boldsymbol{p}| = k$ seen as a state of $\mathcal{T}^k$ or seen as a state sequence over $\mathcal{T}$ coincide. Thus (and by an analogue for the dual action), the notations $\boldsymbol{p} \circ u$ and $\boldsymbol{p} \cdot u$ remain unambiguous and we have $\mathscr{S}(\mathcal{T}) = \mathscr{S}(\mathcal{T} \cup \mathcal{T}^k)$ for all $k \geq 1$, which is usually used to ensure that any fixed state sequence $\boldsymbol{p} \in Q^+$ may be assumed to be congruent to a single state under $=_{\mathcal{T}}$ (i. e. equal in the semigroup or monoid).

Finally, the *dual* of an automaton $\mathcal{T} = (Q, \Sigma, \delta)$ is the automaton $\partial\mathcal{T} = (\Sigma, Q, \partial\delta)$ with $\partial\delta = \left\{ a \xrightarrow{p/q} b \,\middle|\, p \xrightarrow{a/b} q \in \delta \right\}$ (i. e. we swap the roles of the states Q and the letters Σ). Clearly, the dual of a complete $\mathscr{S}$-automaton is again a complete $\mathscr{S}$-automaton.

The dual automaton can make it sometimes more accessible to understand how a letter is transformed by a state sequence: we just have to follow a path in the graphical representation of the dual automaton. For example, from Figure 5, it is obvious that the only way for $\boldsymbol{p} \circ \alpha = \boldsymbol{q} \circ \beta$ to hold is for both of them to be equal to f.

Adding Free Generators. For our results, we will need to add new free generators to existing automaton semigroups S computationally (in the sense that we do not change the behavior of existing state sequences but add a new state q such that the new automaton generates the (semigroup) free product $S \star q^+$). More precisely, we will use the following statement, which follows from the construction used for [30, Theorem 13].

▶ **Proposition 2.7.** *On input of a complete $\mathscr{S}$-automaton $\mathcal{S} = (P, \Sigma, \sigma)$, one can compute a complete $\mathscr{S}$-automaton $\mathcal{T} = (Q, \Gamma, \delta)$ with $Q = P \uplus \{q\}$ such that the identity on Q extends into a well-defined isomorphism $\mathscr{S}(\mathcal{T}) \to \mathscr{S}(\mathcal{S}) \star q^+$ (for the free product of semigroups).*

3 The Freeness Problem for Semigroups

We reduce Post's Correspondence Problem[2] PCP

Constant: an alphabet Λ
Input: homomorphisms $\varphi, \psi : I = \{1, \dots, n\} \to \Lambda^+$
Question: $\exists \boldsymbol{i} \in I^+ : \varphi(\boldsymbol{i}) = \psi(\boldsymbol{i})$?

to (the complement of) the freeness problem for automaton semigroups. For this, we fix an instance φ, ψ, I for PCP[3] over an alphabet Λ and describe how to map it to a complete $\mathscr{S}$-automaton $\mathcal{T} = (Q, \Sigma, \delta)$ in such a way that $\mathcal{T}$ can be computed and the PCP instance has a solution if and only if $\mathscr{S}(\mathcal{T})$ is **not** a free semigroup.

Starting from the free semigroup, we will construct $\mathcal{T}$ (in steps) such that the semigroup has a relation $\#_1 \boldsymbol{i} \#_1 =_{\mathcal{T}} \#_1 \boldsymbol{i} \#_2$ for $\boldsymbol{i} \in I^+$ if and only if $\boldsymbol{i}$ belongs to a PCP solution (if there is no solution, $\mathscr{S}(\mathcal{T})$ is free). Throughout this process, the reader may find it convenient to refer to Table 1 for the various symbols we are going to use.

The rough idea is to add an input symbol ι whose dual action turns $\boldsymbol{i}\#_1$ into $\varphi(\boldsymbol{i})$ and $\boldsymbol{i}\#_2$ into $\psi(\boldsymbol{i})$. But we also have to be careful not to introduce any unwanted relations and to keep the underlying free semigroup structure intact.

Without loss of generality, we may assume $|I| = n \geq 1$, $|\Lambda| \geq 2$ and $I \cap \Lambda = \emptyset$. In the following, we let $L = \max\{|\varphi(i)|, |\psi(i)| \mid i \in I\}$, $\hat{\Lambda} = \cup_{\ell=1}^{L} \Lambda^\ell$, $R = \Lambda \cup I$ and $\hat{R} = \hat{\Lambda} \cup I$.

Definition of $\hat{\mathcal{R}}$. First, we compute a complete $\mathscr{S}$-automaton $\hat{\mathcal{R}}$ with state set $\hat{R}$ generating the free semigroup over R:

▶ **Proposition 3.1.** *On input I, Λ and L, one can compute a complete $\mathscr{S}$-automaton $\hat{\mathcal{R}} = (\hat{R}, \Gamma, \rho)$ with state set $\hat{R} = \hat{\Lambda} \cup I$ (for $\hat{\Lambda} = \cup_{\ell=1}^{L} \Lambda^\ell$) and $\mathscr{S}(\hat{\mathcal{R}}) \simeq R^+ = (\Lambda \cup I)^+$ (where the isomorphism is given by $\hat{\lambda} \mapsto \hat{\lambda}$ for all $\hat{\lambda} \in \hat{\Lambda}$ and $i \mapsto i$ for all $i \in I$).*

Proof. Let $\mathcal{R}_1$ be an $\mathscr{S}$-automaton with state set Λ generating the free semigroup Λ^+ (see Fact 2.6) and let $\hat{\mathcal{R}}_1 = \bigcup_{\ell=1}^{L} \mathcal{R}_1^\ell$ be the union of the first L powers of $\mathcal{R}_1$. Note that the state set of $\hat{\mathcal{R}}_1$ is $\hat{\Lambda} = \cup_{\ell=1}^{L} \Lambda^\ell$ and that we still have $\mathscr{S}(\hat{\mathcal{R}}_1) \simeq \Lambda^+$ (where an isomorphism is induced by $\hat{\Lambda} \ni \hat{\lambda} \mapsto \hat{\lambda} \in \Lambda^+$). Now, we may apply Proposition 2.7 sequentially for every element of $I = \{1, \dots, n\}$, which yields the sought automaton $\hat{\mathcal{R}}$ with state set $\hat{R} = \hat{\Lambda} \cup I$ whose generated semigroup is isomorphic to $\Lambda^+ \star \bigstar_{i \in I} i^+ = \Lambda^+ \star I^+ = (\Lambda \cup I)^+$. ◀

[2] Post's statement of the problem [35] is equivalent to ours. In particular, we may assume $\varphi(i), \psi(i) \neq \varepsilon$.

[3] It is worth mentioning that we may assume I to only contain five elements [32] and Λ to be a binary alphabet (using standard encoding techniques). Note that we may only allow non-empty entries, however.

The states in $\hat{R}$ of $\hat{\mathcal{R}}$ do not form a basis of the free semigroup. To simplify working with this fact, we make the following definition(s).

▶ **Definition 3.2** (natural projection). *There is a natural projection $\pi : \hat{\Lambda}^* \to \Lambda^*$ where $\hat{\Lambda} = \bigcup_{\ell=1}^{L} \Lambda^\ell$, which interprets a letter $\hat{\lambda} \in \hat{\Lambda}$ as the corresponding word over Λ. We extend this projection into a homomorphism $\pi : \hat{R}^* \to R^*$ by setting $\pi(i) = i$ for all $i \in I$. Two elements $\hat{\boldsymbol{r}}_1, \hat{\boldsymbol{r}}_2 \in \hat{R}^*$ are* R-equivalent *(written as $\hat{\boldsymbol{r}}_1 =_R \hat{\boldsymbol{r}}_2$) if $\pi(\hat{\boldsymbol{r}}_1) = \pi(\hat{\boldsymbol{r}}_2)$. Finally, $|\hat{\boldsymbol{r}}|_R$ for $\boldsymbol{r} \in \hat{R}^*$ is $|\hat{\boldsymbol{r}}|_R = |\pi(\hat{\boldsymbol{r}})|$.*

Note that we have $\hat{\boldsymbol{r}}_1 =_R \hat{\boldsymbol{r}}_2$ if and only if $\hat{\boldsymbol{r}}_1 =_{\hat{\mathcal{R}}} \hat{\boldsymbol{r}}_2$ for all $\hat{\boldsymbol{r}}_1, \hat{\boldsymbol{r}}_2 \in \hat{R}^*$ as $\mathscr{S}(\hat{\mathcal{R}}) \simeq R^+$.

Definition of $\mathcal{S}$. We use the automaton $\hat{\mathcal{R}} = (\hat{R}, \Gamma, \rho)$ as a building block for our target automaton $\mathcal{T} = (Q, \Sigma, \delta)$ for the reduction. We fix some arbitrary element $\lambda_\# \in \Lambda \subseteq \hat{R}$. To compute $\mathcal{S}$ from $\hat{\mathcal{R}}$, we duplicate the state $\lambda_\#$ twice and call these copies $\#_1$ and $\#_2$. Formally, we have $\mathcal{S} = (Q, \Gamma, \sigma)$ where $Q = \hat{R} \uplus \{\#_1, \#_2\}$ for the new symbols $\#_1$ and $\#_2$ and $\sigma = \rho \cup \{\#_1 \xrightarrow{c/d} q, \#_2 \xrightarrow{c/d} q \mid \lambda_\# \xrightarrow{c/d} q \in \rho\}$. Thus, the new states $\#_1$ and $\#_2$ act in the same way as $\lambda_\#$ and we have $\mathscr{S}(\mathcal{S}) = \mathscr{S}(\hat{\mathcal{R}}) \simeq R^+$.

Definition of $\mathcal{T}$. The next step is to fix another $\lambda_R \in \Lambda \subseteq Q$ arbitrarily but different to $\lambda_\#$ and take $\mathcal{T}_1 = (Q, \Gamma \cup \{a, b\}, \delta_1) = \mathcal{S} \cup \mathcal{T}_1'$ where $\mathcal{T}_1'$ is given via its dual in Figure 4 (i. e. we add two new letters a, b to the alphabet and some additional transitions). Note that we have the transitions $\lambda_\# \xrightarrow{a/a} \lambda_R$ and the self-loops $\lambda_R^\ell \xrightarrow{a/a} \lambda_R^\ell$ for all $1 \leq \ell \leq L$ in $\mathcal{T}_1$.

The idea for this part is that we may factorize a state sequence $\boldsymbol{q} \in Q^*$ into blocks from $\hat{R}^*$ and symbols $\#_1$ and $\#_2$ and then remove the blocks one after another using the letter a. We will explain this precisely later in Fact 3.3.

Finally, we let $\mathcal{T} = (Q, \Sigma, \delta) = \mathcal{T}_1 \cup \mathcal{T}_2$ where $\mathcal{T}_2$ is given via its dual in Figure 5. Note, in particular, that we have $\varphi(i), \psi(i) \in \bigcup_{\ell=1}^{L} \Lambda^\ell = \hat{\Lambda} \subseteq \hat{R}$.

In other words, we obtain $\mathcal{T}$ from $\mathcal{T}_1$ by adding new symbols to the alphabet resulting in $\Sigma = \Gamma \cup \{a, b\} \cup \{\iota, \alpha, \alpha', f_\alpha, \beta, \beta', f_\beta, f\}$ and adding the transitions depicted in Figure 5 for all $i \in I$ and $\hat{\lambda} \in \hat{\Lambda}$. Clearly, $\mathcal{T}$ can be computed and is a complete $\mathscr{S}$-automaton.

The Role of a and b in $\mathcal{T}$. As already mentioned above, we may use the letter a to remove a block from a certain factorization of a state sequence (the proof is by induction on μ):

▶ **Fact 3.3.** *Let $\boldsymbol{p} \in Q^*$ and factorize it as $\boldsymbol{p} = (\boldsymbol{p}_s \#_{x_s}) \dots (\boldsymbol{p}_1 \#_{x_1}) \boldsymbol{p}_0$ for $\boldsymbol{p}_0, \dots, \boldsymbol{p}_s \in \hat{R}^*$ and $x_1, \dots, x_s \in \{1, 2\}$. Then, for any $1 \leq \mu \leq s$, we have (in $\mathcal{T}$):*

$$\boldsymbol{p} \cdot a^\mu = (\boldsymbol{p}_s \#_{x_s}) \dots (\boldsymbol{p}_{\mu+1} \#_{x_{\mu+1}}) \boldsymbol{p}_\mu \, \lambda_\# \lambda_R^{\mu-1+|\boldsymbol{p}_{\mu-1} \dots \boldsymbol{p}_0|_R}$$

Correctness. It remains to show that the `PCP` instance φ, ψ, I has a solution if and only if $\mathscr{S}(\mathcal{T})$ is **not** a free semigroup. We start with the (easier) "only if" direction and show that the additional transitions from $\mathcal{T}_1$ and $\mathcal{T}_2$ do not affect the subautomaton $\hat{\mathcal{R}}$: if two state sequences are R-equivalent, they are also equal with respect to $\mathcal{T}$.

▶ **Lemma 3.4.** *Let $\hat{\boldsymbol{r}}_1, \hat{\boldsymbol{r}}_2 \in \hat{R}^*$ with $\hat{\boldsymbol{r}}_1 =_R \hat{\boldsymbol{r}}_2$. Then, we have $\hat{\boldsymbol{r}}_1 =_{\mathcal{T}} \hat{\boldsymbol{r}}_2$.*

Proof Sketch. We need to show $\hat{\boldsymbol{r}}_1 \circ u = \hat{\boldsymbol{r}}_2 \circ u$ for all $u \in \Sigma^*$ and this can be done by induction on u. Thus, write $u = cu'$ for some $c \in \Sigma = \Gamma \cup \{a, b\} \cup \{\iota, \alpha, \alpha', f_\alpha, \beta, \beta', f_\beta, f\}$ and $u' \in \Sigma^*$.

Most cases for c are straight-forward (for example, for $c \in \Gamma$ – the alphabet of $\hat{\mathcal{R}}$ – we inherit this property from $\hat{\mathcal{R}}$) and we only demonstrate the case $c \in \{\alpha, \alpha', \beta, \beta'\}$. Here, we factorize $\hat{\boldsymbol{r}}_1 = \hat{\boldsymbol{s}}_1 \hat{\lambda}_1 \boldsymbol{i}_1$ with $\boldsymbol{i}_1 \in I^*$ maximal, $\hat{\lambda}_1 \in \hat{\Lambda} \cup \{\varepsilon\}$ and $\hat{\boldsymbol{s}}_1 \in \hat{R}^*$ with

Figure 6 Cross diagrams for Lemma 3.4.

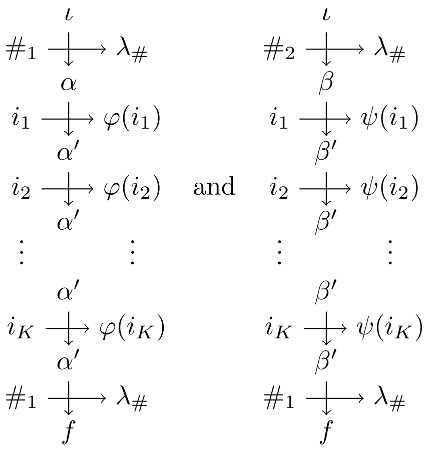

Figure 7 Cross diagrams for Lemma 3.5.

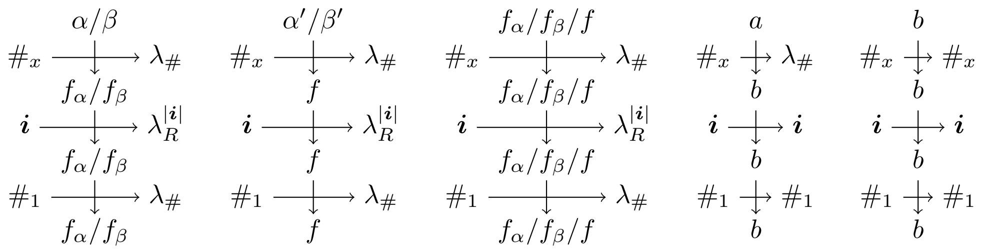
$\lambda_1 = \varepsilon \implies \hat{\boldsymbol{s}}_1 = \varepsilon$. Analogously, we factorize $\hat{\boldsymbol{r}}_2 = \hat{\boldsymbol{s}}_2\hat{\lambda}_2\boldsymbol{i}_2$. Observe that, since we have $\hat{\boldsymbol{r}}_1 =_R \hat{\boldsymbol{r}}_2$, we must have $\boldsymbol{i}_1 = \boldsymbol{i}_2 = \boldsymbol{i}$, $\hat{\boldsymbol{s}}_1\hat{\lambda}_1 =_R \hat{\boldsymbol{s}}_2\hat{\lambda}_2$ and $\hat{\lambda}_1 = \varepsilon \iff \hat{\lambda}_2 = \varepsilon$. This yields the cross diagrams in Figure 6 where the shaded parts only exist if $\hat{\lambda}_1, \hat{\lambda}_2 \neq \varepsilon$ and where we have α' after applying $\boldsymbol{i}$ if $\boldsymbol{i} \neq \varepsilon$. In both diagrams, we have the same state sequence on the right hand side (because of $\hat{\boldsymbol{s}}_1\hat{\lambda}_1 =_R \hat{\boldsymbol{s}}_2\hat{\lambda}_2$) and, thus, are done. The case $c \in \{\beta, \beta'\}$ is analogous (using ψ). ◀

Finally, we show that a solution for the PCP instance implies a proper relation in the semigroup generated by $\mathcal{T}$ and, thus, that it is not free.

▶ **Lemma 3.5.** *If $\boldsymbol{i} \in I^+$ is a solution for the* PCP *instance, then we have $\#_1\boldsymbol{i}\#_1 =_\mathcal{T} \#_1\boldsymbol{i}\#_2$.*

Proof Sketch. We show $\#_1\boldsymbol{i}\#_1 \circ u = \#_1\boldsymbol{i}\#_2 \circ u$ for all $u \in \Sigma^*$. For $u = \varepsilon$, there is nothing to show. So, let $u = cu'$ for some $c \in \Sigma = \Gamma \cup \{a, b\} \cup \{\iota, \alpha, \alpha', f_\alpha, \beta, \beta', f_\beta, f\}$ and $u' \in \Sigma^*$. Again, we only fully demonstrate the most interesting case $c = \iota$ (the other cases may be found in Figure 8 where Figure 8e requires induction). Writing $\boldsymbol{i} = i_K \dots i_2 i_1$ for $i_1, \dots, i_K \in I$, we obtain the diagrams in Figure 7. Since $\boldsymbol{i} = i_K \dots i_2 i_1$ is a solution, we have $\varphi(i_K) \dots \varphi(i_2)\varphi(i_1) =_R \psi(i_K) \dots \psi(i_2)\psi(i_1)$. Thus, Lemma 3.4 implies $\lambda_\#\varphi(i_K) \dots \varphi(i_2)\varphi(i_1)\lambda_\# =_\mathcal{T} \lambda_\#\psi(i_K) \dots \psi(i_2)\psi(i_1)\lambda_\#$. ◀



(a) $c \in \{\alpha, \beta\}$ **(b)** $c \in \{\alpha', \beta'\}$ **(c)** $c \in \{f_\alpha, f_\beta, f\}$ **(d)** $c = a$ **(e)** $c = b$

Figure 8 Various cases for $c \in \Sigma$. The cross diagrams hold for $x \in \{1, 2\}$.

▶ **Proposition 3.6.** *If the* PCP *instance has a solution, $\mathscr{S}(\mathcal{T})$ is not (left) cancellative and, thus, not a free semigroup.*

Converse Direction. To show that the PCP instance has a solution if the semigroup is not free, we introduce the notion of compatibility and observe that every relation is compatible. The proof relies on Fact 3.3 for removing blocks from the factorization used in Definition 3.7 and that $\mathcal{S}$ (generating R^+) survives as a subautomaton of $\mathcal{T}$. The latter allows us to use the cancellativity of R^+ to show that the individual blocks are the same in R^+.

▶ **Definition 3.7** (compatible state sequences). *Factorize $\boldsymbol{p}, \boldsymbol{q} \in Q^*$ (uniquely) as $\boldsymbol{p} = (\boldsymbol{p}_s\#_{x_s}) \dots (\boldsymbol{p}_1\#_{x_1})\, \boldsymbol{p}_0$ and $\boldsymbol{q} = (\boldsymbol{q}_t\#_{y_t}) \dots (\boldsymbol{q}_1\#_{y_1})\, \boldsymbol{q}_0$ with $\boldsymbol{p}_0, \dots, \boldsymbol{p}_s, \boldsymbol{q}_0, \dots, \boldsymbol{q}_t \in \hat{R}^*$ and $x_1, \dots, x_s, y_1, \dots, y_t \in \{1, 2\}$. They are* compatible *if $s = t$ and $\forall\, 0 \leq i \leq s = t : \boldsymbol{p}_i =_R \boldsymbol{q}_i$.*

▶ **Lemma 3.8.** *Let $\boldsymbol{p}, \boldsymbol{q} \in Q^*$ with $\boldsymbol{p} =_{\mathcal{T}} \boldsymbol{q}$. Then, we have that $\boldsymbol{p}$ and $\boldsymbol{q}$ are compatible.*

Proof. We factorize $\boldsymbol{p}$ and $\boldsymbol{q}$ in the same way as in Definition 3.7 and show the statement by induction on $s + t$. For $s = t = 0$, we have $\boldsymbol{p}_0 = \boldsymbol{p} =_{\mathcal{T}} \boldsymbol{q} = \boldsymbol{q}_0$. Since $\hat{\mathcal{R}}$ is a subautomaton of $\mathcal{T}$, this implies $\boldsymbol{p}_0 =_{\hat{\mathcal{R}}} \boldsymbol{q}_0$ and, equivalently, $\boldsymbol{p} = \boldsymbol{p}_0 =_R \boldsymbol{q}_0 = \boldsymbol{q}$.

For the inductive step ($s + t > 0$), we may assume $s > 0$ (due to symmetry) or, in other words, that $\boldsymbol{p}$ contains at least one $\#_1$ or $\#_2$. We have $\boldsymbol{p} \circ a = b$ (compare to Figure 4) and, thus, due to $\boldsymbol{p} =_{\mathcal{T}} \boldsymbol{q}$, also $\boldsymbol{q} \circ a = \boldsymbol{p} \circ a = b$. This is only possible (again, compare to Figure 4) if $\boldsymbol{q}$ also contains at least one $\#_1$ or $\#_2$, i. e. if $t > 0$.

From Fact 3.3 (with $\mu = 1$), we obtain (for both $\boldsymbol{p}$ and $\boldsymbol{q}$):

$$\begin{aligned} \boldsymbol{p} \cdot a &= \boldsymbol{p}' \lambda_\# \lambda_R^{|\boldsymbol{p}_0|_R} \\ &\qquad \text{for } \boldsymbol{p}' = (\boldsymbol{p}_s\#_{x_s}) \dots (\boldsymbol{p}_2\#_{x_2})\, \boldsymbol{p}_1 \text{ and} \\ \boldsymbol{q} \cdot a &= \boldsymbol{q}' \lambda_\# \lambda_R^{|\boldsymbol{q}_0|_R} \\ &\qquad \text{for } \boldsymbol{q}' = (\boldsymbol{q}_t\#_{x_t}) \dots (\boldsymbol{q}_2\#_{x_2})\, \boldsymbol{q}_1 \end{aligned}$$

Now, $\boldsymbol{p} =_{\mathcal{T}} \boldsymbol{q}$ implies $\boldsymbol{p}' \lambda_\# \lambda_R^{|\boldsymbol{p}_0|_R} = \boldsymbol{p} \cdot a =_{\mathcal{T}} \boldsymbol{q} \cdot a = \boldsymbol{q}' \lambda_\# \lambda_R^{|\boldsymbol{q}_0|_R}$ and we may apply the induction hypothesis, which yields that $\boldsymbol{p}' \lambda_\# \lambda_R^{|\boldsymbol{p}_0|_R}$ and $\boldsymbol{q}' \lambda_\# \lambda_R^{|\boldsymbol{q}_0|_R}$ are compatible. This means that we have $s = t$, $\boldsymbol{p}_\mu =_R \boldsymbol{q}_\mu$ for all $2 \leq \mu \leq s = t$ and $\boldsymbol{p}_1 \lambda_\# \lambda_R^{|\boldsymbol{p}_0|_R} =_R \boldsymbol{q}_1 \lambda_\# \lambda_R^{|\boldsymbol{q}_0|_R}$. Observe that the latter implies $\boldsymbol{p}_1 =_R \boldsymbol{q}_1$ (as we have chosen $\lambda_\#$ and λ_R as different elements of Λ). In particular, we also obtain $\boldsymbol{p}_s \lambda_\# \boldsymbol{p}_{s-1} \dots \lambda_\# \boldsymbol{p}_1 =_R \boldsymbol{q}_t \lambda_\# \boldsymbol{q}_{t-1} \dots \lambda_\# \boldsymbol{q}_1$.

Since $\mathcal{S}$ is a subautomaton of $\mathcal{T}$, $\boldsymbol{p} =_{\mathcal{T}} \boldsymbol{q}$ implies $\boldsymbol{p} =_{\mathcal{S}} \boldsymbol{q}$. As $\#_1$ and $\#_2$ act in the same way as $\lambda_\#$ in $\mathcal{S}$ by construction, this shows $\boldsymbol{p}_s \lambda_\# \dots \boldsymbol{p}_1 \lambda_\# \boldsymbol{p}_0 =_{\mathcal{S}} \boldsymbol{q}_t \lambda_\# \dots \boldsymbol{q}_1 \lambda_\# \boldsymbol{q}_0$ and, because of $\mathscr{S}(\mathcal{S}) \simeq R^+$, also $\boldsymbol{p}_s \lambda_\# \dots \boldsymbol{p}_1 \lambda_\# \boldsymbol{p}_0 =_R \boldsymbol{q}_t \lambda_\# \dots \boldsymbol{q}_1 \lambda_\# \boldsymbol{q}_0$. Now, because R^* as a free monoid is cancellative (see Fact 2.1) and because we have $\boldsymbol{p}_s \lambda_\# \boldsymbol{p}_{s-1} \dots \lambda_\# \boldsymbol{p}_1 =_R \boldsymbol{q}_t \lambda_\# \boldsymbol{q}_{t-1} \dots \lambda_\# \boldsymbol{q}_1$ (from above), we obtain $\lambda_\# \boldsymbol{p}_0 =_R \lambda_\# \boldsymbol{q}_0$ and, finally, $\boldsymbol{p}_0 =_R \boldsymbol{q}_0$, which concludes the proof that $\boldsymbol{p}$ and $\boldsymbol{q}$ are compatible. ◀

On the other hand, not every compatible pair forms a semigroup relation. However, this is true by Lemma 3.4 if, additionally, the subsequence containing only $\#_1$ and $\#_2$ is the same in both entries. To formalize this, we introduce the following definition.

▶ **Definition 3.9** (projection on $\{\#_1, \#_2\}$). *Let $\pi_\# : Q^* \to \{\#_1, \#_2\}^*$ be the homomorphism given by $\pi_\#(\#_x) = \#_x$ for both $x \in \{1, 2\}$ and $\pi_\#(\hat{r}) = \varepsilon$ for all other $\hat{r} \in Q \setminus \{\#_1, \#_2\} = \hat{R}$.*

▶ **Lemma 3.10.** *Let $\boldsymbol{p}, \boldsymbol{q} \in Q^*$ be compatible with $\pi_\#(\boldsymbol{p}) = \pi_\#(\boldsymbol{q})$. Then, we have $\boldsymbol{p} =_{\mathcal{T}} \boldsymbol{q}$.*

Combining the last two lemmas, we obtain that $\mathscr{S}(\mathcal{T})$ is a free semigroup if all its relations have the same projection under $\pi_\#$. Most importantly, we will later on apply the contraposition of the “only if” direction of the following lemma to obtain a relation with different images under the projection if the semigroup is not free.

▶ **Lemma 3.11.** *Let $\pi' : Q^* \to (R \cup \{\#_1, \#_2\})^*$ be the extension of the natural projection π (from Definition 3.2) with $\pi'(\#_x) = \#_x$ for $x \in \{1, 2\}$. The following are equivalent:*

1. *For all $\boldsymbol{p}, \boldsymbol{q} \in Q^+$ with $\boldsymbol{p} =_{\mathcal{T}} \boldsymbol{q}$, we have $\pi_\#(\boldsymbol{p}) = \pi_\#(\boldsymbol{q})$.*
2. *The map π' induces a well-defined homomorphism $\mathscr{S}(\mathcal{T}) \to (R \cup \{\#_1, \#_2\})^+$.*
3. *The map π' induces a well-defined isomorphism $\mathscr{S}(\mathcal{T}) \to (R \cup \{\#_1, \#_2\})^+$.*

In particular, $\mathscr{S}(\mathcal{T})$ is isomorphic to $(R \cup \{\#_1, \#_2\})^+$ if we have $\pi_\#(\boldsymbol{p}) = \pi_\#(\boldsymbol{q})$ for all $\boldsymbol{p}, \boldsymbol{q} \in Q^+$ with $\boldsymbol{p} =_{\mathcal{T}} \boldsymbol{q}$.

Now a relation whose sides have different images under $\pi_\#$ yields a `PCP` solution.

▶ **Lemma 3.12.** *If there are $\boldsymbol{p}, \boldsymbol{q} \in Q^+$ with $\boldsymbol{p} =_{\mathcal{T}} \boldsymbol{q}$ but $\pi_\#(\boldsymbol{p}) \neq \pi_\#(\boldsymbol{q})$, then the* `PCP` *instance has a solution.*

Proof. We factorize these $\boldsymbol{p}$ and $\boldsymbol{q}$ in the same way as in Definition 3.7 and observe that $\boldsymbol{p}$ and $\boldsymbol{q}$ are compatible by Lemma 3.8. We may assume that there is some $1 \leq \mu_0 \leq s = t$ with $\#_{x_{\mu_0}} = \#_1$ but $\#_{y_{\mu_0}} = \#_2$ (due to symmetry).

We may assume $\mu_0 = 1$ without loss of generality. This is because we may substitute $\boldsymbol{p}$ by $\boldsymbol{p}' = \boldsymbol{p} \cdot a^{\mu_0 - 1}$ and $\boldsymbol{q}' = \boldsymbol{q} \cdot a^{\mu_0 - 1}$ (we still have $\boldsymbol{p}' =_{\mathcal{T}} \boldsymbol{q}'$) by Fact 3.3 (for $\mu_0 > 1$).

With these assumptions, we apply $\boldsymbol{p}$ and $\boldsymbol{q}$ to ι and obtain (see Figure 5) the cross diagrams depicted in Figure 9 for $\tilde{\boldsymbol{p}} = \boldsymbol{p}_s \#_{x_s} \dots \boldsymbol{p}_3 \#_{x_3} \boldsymbol{p}_2$, $\tilde{\boldsymbol{q}} = \boldsymbol{q}_t \#_{y_t} \dots \boldsymbol{q}_3 \#_{y_3} \boldsymbol{q}_2$ and some $\boldsymbol{p}_1', \tilde{\boldsymbol{p}}', \boldsymbol{q}_1', \tilde{\boldsymbol{q}}' \in Q^*$, $p_2', q_2' \in Q$ and $c_1, c_2, c, d_1, d_2, d \in \Gamma$. Since we have $\boldsymbol{p} =_{\mathcal{T}} \boldsymbol{q}$, we must have $c = d$ and, by the construction of $\mathcal{T}$, this is only possible if $c = f = d$ (see Figure 5). This, in turn, is only possible if we have $\boldsymbol{p}_1 = \boldsymbol{i} \in I^+$ and $\boldsymbol{q}_1 = \boldsymbol{j} \in I^+$. Since $\boldsymbol{p}$ and $\boldsymbol{q}$ are compatible, we must even have $\boldsymbol{i} = \boldsymbol{p}_1 =_R \boldsymbol{q}_1 = \boldsymbol{j}$, which implies $\boldsymbol{i} = \boldsymbol{j}$. Additionally, we also obtain $\boldsymbol{p}_1' =_R \varphi(\boldsymbol{i})$, $c_1 = \alpha'$, $p_2' = \lambda_\#$, $c_2 = f$, $\boldsymbol{q}_1' =_R \psi(\boldsymbol{i})$, $d_1 = \beta'$, $q_2' = \lambda_\#$, $d_2 = f$ and $\tilde{\boldsymbol{p}}' = \lambda_R^{|\boldsymbol{p}_s|_R} \lambda_\# \dots \lambda_R^{|\boldsymbol{p}_3|_R} \lambda_\# \lambda_R^{|\boldsymbol{p}_2|_R}$ as well as $\tilde{\boldsymbol{q}}' = \lambda_R^{|\boldsymbol{q}_t|_R} \lambda_\# \dots \lambda_R^{|\boldsymbol{q}_3|_R} \lambda_\# \lambda_R^{|\boldsymbol{q}_2|_R}$ from the construction of $\mathcal{T}$. This shows

$$\begin{aligned} &\lambda_R^{|\boldsymbol{p}_s|_R} \lambda_\# \dots \lambda_R^{|\boldsymbol{p}_3|_R} \lambda_\# \lambda_R^{|\boldsymbol{p}_2|_R} \, \lambda_\# \varphi(\boldsymbol{i}) \lambda_\# \, \lambda_R^{|\boldsymbol{p}_0|_R} \\ =_{\mathcal{T}} &\lambda_R^{|\boldsymbol{q}_t|_R} \lambda_\# \dots \lambda_R^{|\boldsymbol{q}_3|_R} \lambda_\# \lambda_R^{|\boldsymbol{q}_2|_R} \, \lambda_\# \psi(\boldsymbol{i}) \lambda_\# \, \lambda_R^{|\boldsymbol{q}_0|_R} \end{aligned}$$

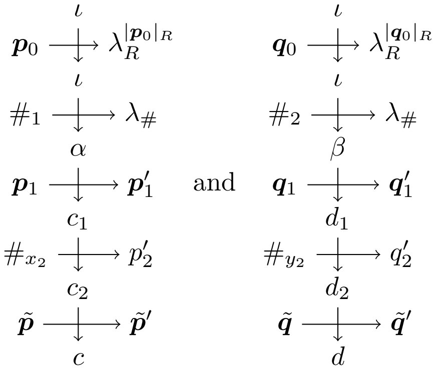


Figure 9 Cross diagrams for Lemma 3.12.

and, by Lemma 3.8, also that both sides are R-equivalent. Since $\boldsymbol{p}$ and $\boldsymbol{q}$ are compatible, we have $\lambda_R^{|\boldsymbol{p}_\mu|_R} =_R \lambda_R^{|\boldsymbol{q}_\mu|_R}$ for all $0 \leq \mu \leq s = t$. Combining this with the cancellativity of R^*, we obtain $\varphi(\boldsymbol{i}) =_R \psi(\boldsymbol{i})$ and, thus, that $\boldsymbol{i}$ is a solution for the PCP instance. ◀

We have now shown that the PCP instance has a solution if the semigroup generated by $\mathcal{T}$ is not free. A careful analysis of the proof yields more, however, which we collect in Proposition 3.14 (which follows from the lemmas and propositions above). For one part of this statement, we will first state another consequence of Lemma 3.8:

▶ **Proposition 3.13.** *Mapping $\hat{r}$ to $|\hat{r}|_R$ for every $\hat{r} \in \hat{R}$ and $\#_x$ to 1 for $x \in \{1, 2\}$ induces a well-defined proper length function of $\mathscr{M}(\mathcal{T})$ (and a well-defined length function of $\mathscr{S}(\mathcal{T})$).*

▶ **Proposition 3.14.** *The following statements are equivalent:*

1. *The* PCP *instance has a solution $\boldsymbol{i} \in I^+$.*
2. *We have $\#_1\boldsymbol{i}\#_1 =_{\mathcal{T}} \#_1\boldsymbol{i}\#_2$ for some $\boldsymbol{i} \in I^+$.*
3. *There are $\boldsymbol{p}, \boldsymbol{q} \in Q^+$ with $\boldsymbol{p} =_{\mathcal{T}} \boldsymbol{q}$ but $\pi_\#(\boldsymbol{p}) \neq \pi_\#(\boldsymbol{q})$.*
4. *$\mathscr{S}(\mathcal{T})$ is not a free semigroup.*
5. *$\mathscr{S}(\mathcal{T})$ is not isomorphic to $(R \cup \{\#_1, \#_2\})^+$.*
6. *$\mathscr{S}(\mathcal{T})$ is not (left[4]) cancellative.*
7. *$\mathscr{S}(\mathcal{T})$ is not equidivisible.*

4'. *$\mathscr{M}(\mathcal{T})$ is not a free monoid.*
5'. *$\mathscr{M}(\mathcal{T})$ is not isomorphic to $(R \cup \{\#_1, \#_2\})^*$.*
6'. *$\mathscr{M}(\mathcal{T})$ is not (left) cancellative.*
7'. *$\mathscr{M}(\mathcal{T})$ is not equidivisible.*

Main Theorem and other Consequences. Proposition 3.14 shows that we have reduced PCP to (the complements of) the freeness problem for (complete) automaton semigroups and monoids (as the construction of $\mathcal{T}$ is computable). Since PCP is undecidable [35], we obtain:

▶ **Theorem 3.15.** *The freeness problem for automaton semigroups*

Input: *a (complete) $\mathscr{S}$-automaton $\mathcal{T}$*
Question: *is $\mathscr{S}(\mathcal{T})$ a free semigroup?*

and the freeness problem for automaton monoids

Input: *a (complete) $\mathscr{S}$-automaton $\mathcal{T}$*
Question: *is $\mathscr{M}(\mathcal{T})$ a free monoid?*

are undecidable.

▶ **Theorem 3.16.** *The following problems are undecidable:*

Input: *a complete $\mathscr{S}$-automaton $\mathcal{T}$*
Question: *is $\mathscr{S}(\mathcal{T})$ (left) cancellative/equidivisible?*

Input: *a complete $\mathscr{S}$-automaton $\mathcal{T}$*
Question: *is $\mathscr{M}(\mathcal{T})$ (left) cancellative/equidivisible?*

Finally, we obtain that it is undecidable whether a given map on the generators induces a homomorphism (or an isomorphism) between two automaton semigroups (using $\mathcal{T}$ from above as $\mathcal{T}_1$ and an automaton generating $(R \cup \{\#_1, \#_2\})^+$ for $\mathcal{T}_2$). Note that the isomorphism problem for automaton groups (and, thus, also for automaton semigroups and monoids) is known to be undecidable (as it follows from [40]).

[4] Recall that we defined automaton semigroups by a left action here.

▶ **Theorem 3.17.** *The following two problems are undecidable:*

Input: *two (complete)* $\mathscr{S}$*-automata* $\mathcal{T}_1 = (Q_1, \Sigma_1, \delta_1)$ *and* $\mathcal{T}_2 = (Q_2, \Sigma_2, \delta_2)$ *and a map* $f : Q_1 \to Q_2$
Question: *does* f *extend into a homomorphism* $\mathscr{S}(\mathcal{T}_1) \to \mathscr{S}(\mathcal{T}_2)$*?*

Input: *two (complete)* $\mathscr{S}$*-automata* $\mathcal{T}_1 = (Q_1, \Sigma_1, \delta_1)$ *and* $\mathcal{T}_2 = (Q_2, \Sigma_2, \delta_2)$ *and a map* $f : Q_1 \to Q_2$
Question: *does* f *extend into an isomorphism* $\mathscr{S}(\mathcal{T}_1) \to \mathscr{S}(\mathcal{T}_2)$*?*

For our construction, we need that all $\varphi(i)$ and $\psi(i)$ are states in the automaton. This immediately yields relations of the form $u\,v =_{\hat{\mathcal{R}}} uv$ for $u, v, uv \in \hat{\Lambda}$ that still exist in the eventual automaton $\mathcal{T}$. In the monoid case, however, we may use the neutral element as a "padding symbol" and thus avoid using a power automaton. This then yields:

▶ **Theorem 3.18.** *The free presentation problem for automaton monoids is undecidable:*

Input: *a (complete)* $\mathscr{S}$*-automaton* $\mathcal{T} = (Q, \Sigma, \delta)$ *with a dedicated state* $e \in Q$ *acting as the identity map*
Question: *is* $\mathscr{M}(\mathcal{T}) \simeq (Q \setminus \{e\})^*$*?*

In the semigroup case, we only get a weaker form of this result (using $P = R \cup \{\#_1, \#_2\}$):

▶ **Theorem 3.19.** *The following problem is undecidable:*

Input: *a (complete)* $\mathscr{S}$*-automaton* $\mathcal{T} = (Q, \Sigma, \delta)$ *and a subset* $P \subseteq Q$
Question: *is* $\mathscr{S}(\mathcal{T}) \simeq P^+$*?*

4 Open Problems

Theorem 3.18 immediately raises the question whether the corresponding problem for automaton semigroups is also undecidable:

▶ **Open Problem 4.1.** *Is the following problem decidable?*

Input: *a (complete)* $\mathscr{S}$*-automaton* $\mathcal{T} = (Q, \Sigma, \delta)$
Question: *is* $\mathscr{S}(\mathcal{T}) \simeq Q^+$*?*

In Theorem 3.16, we have also shown that it is not possible to test whether a given automaton semigroup (or monoid) is equidivisible. By Levi's lemma (Fact 2.2) this is one part of a semigroup (monoid) being free while the other one is the existence of a (proper) length function. So, the following question naturally arises.

▶ **Open Problem 4.2.** *Is the following problem decidable?*

Input: *a (complete)* $\mathscr{S}$*-automaton* $\mathcal{T}$
Question: *does* $\mathscr{S}(\mathcal{T})$ *(*$\mathscr{M}(\mathcal{T})$*) admit a (proper) length function?*

We highly suspect this problem to be undecidable and it seems likely that our construction can be adapted to show this.

Of course, it also remains open whether the freeness problem for automaton groups [19, 7.2 b)] is decidable.

Abstract

Flow sparsification is a classic graph compression technique which, given a capacitated graph G on k terminals, aims to construct another capacitated graph H, called a *flow sparsifier*, that preserves, either exactly or approximately, every *multicommodity flow* between terminals (ideally, with size as a small function of k). Cut sparsifiers are a restricted variant of flow sparsifiers which are only required to preserve maximum flows between bipartitions of the terminal set. It is known that exact cut sparsifiers require $2^{\Omega(k)}$ many vertices [Krauthgamer and Rika, SODA 2013], with the hard instances being *quasi-bipartite* graphs, where there are no edges between non-terminals. On the other hand, it has been shown recently that exact (or even $(1+\varepsilon)$-approximate) flow sparsifiers on networks with just 6 terminals require unbounded size [Krauthgamer and Mosenzon, SODA 2023, Chen and Tan, SODA 2024].

In this paper, we construct exact flow sparsifiers of size 3^{k^3} and exact cut sparsifiers of size 2^{k^2} for quasi-bipartite graphs. In particular, the flow sparsifiers are contraction-based, that is, they are obtained from the input graph by (vertex) contraction operations. Our main contribution is a new technique to construct sparsifiers that exploits connections to polyhedral geometry, and that can be generalized to graphs with a small separator that separates the graph into small components. We also give an improved reduction theorem for graphs of bounded treewidth [Andoni et al., SODA 2011], implying a flow sparsifier of size $\mathrm{O}(k \cdot w)$ and quality $\mathrm{O}\left(\frac{\log w}{\log\log w}\right)$, where w is the treewidth.

1 Introduction

Graph sparsification is a classic and influential technique in algorithm design. The idea behind graph sparsification is to compress a given graph into a "smaller" graph (the notion of small depends on the context) which preserves certain crucial properties of the graph. The notion of edge sparsification dates back to the work of Gomory and Hu [21] and to Nagamochi and Ibaraki [32], who developed techniques to find a sparser graph – that is, with fewer edges – preserving s-t-cuts and k-edge-connectivity, respectively. This work was continued by Benczur and Karger [5] and Spielman and Teng [35], who extended the techniques to preserving cut values, or more generally the Laplacian spectrum, up to a factor of $1+\varepsilon$.

Relatively recent is the study of vertex sparsification. Arguably, the most extensively explored notions here are flow sparsification and cut sparsification. Specifically, suppose we are given an undirected graph $G = (V, E)$ along with a capacity function u on the edges and a subset of vertices T called terminals, with $|T| = k$. A cut sparsifier H of quality $q \geq 1$ is a graph on (potentially) fewer vertices which preserves the minimum cut value between every possible bipartition of the terminal set, up to a factor of q. A more general notion is flow sparsification where the sparsifier must preserve all multicommodity flows between the terminals (formal definitions are introduced in Section 2). Hence, we can see cut sparsification as a special case where it is only required to preserve the single-commodity flows between bipartitions of terminals.

The main focus in cut and flow sparsification research is to strike the ideal trade-off between the size of H and its quality q. In their seminal work, Moitra [31] and later Moitra and Leighton [29] showed that there is a flow sparsifier on just the terminal set (that is with size k) of quality $\mathrm{O}\big(\frac{\log k}{\log \log k}\big)$, and their work was later made constructive by different works [9, 16, 30]. These works also showed that any sparsifier of size k would have a quality loss of at least $\Omega(\sqrt{\log k / \log \log k})$ [30]. Hence, a significant improvement in the quality would either require more vertices in the sparsifier or special properties of the graph.

Considerable research effort has been dedicated to cut and flow sparsification in more restricted settings. For instance, one can construct a flow sparsifier on only the terminals with quality $\mathrm{O}(r)$ for graphs that exclude $K_{r,r}$ as a minor by exploiting connections between flow sparsification and the 0-extension problem [8, 31]. For general graphs, Chuzhoy [12] gave a construction with quality $O(1)$ and size $C^{\mathrm{O}(\log \log C)}$, where C is the total capacity of edges incident on terminals (and hence might be as large is $\Omega(nk)$). On the other hand, one can construct quality-1 cut sparsifiers of size $\mathrm{O}(2^{2^k})$ for general graphs [22, 24], of size $\mathrm{O}(k^2 \cdot 2^k)$ for planar graphs [27] and $\mathrm{O}(k) \cdot 2^{2^{\mathrm{O}(w)}}$ for graphs with treewidth w [10] (such sparsifiers are also known as mimicking networks or exact sparsifiers in the literature). The scenario is drastically different for exact flow sparsifiers. Recent breakthroughs have ruled out the existence of exact flow sparsifiers [26], as well as contraction-based quality-$(1 + \varepsilon)$ flow sparsifiers [11], with size as a function of k, which is achieved by demonstrating hard instances on 6 terminal networks. On the other hand, contraction-based flow sparsifiers of quality $1 + \varepsilon$ and size $2^{\mathtt{poly}(1/\varepsilon)}$ exist for every 5-terminal network [11].

For the special case of *quasi-bipartite graphs* [34], where non-terminals form an independent set, Andoni et al. [2] improved the bound of Chuzhoy significantly: they give a quality-$(1 + \varepsilon)$ flow sparsifier of size $\mathrm{poly}(k/\varepsilon)$, recently improved to size $k \cdot \mathrm{poly}(\log k, \varepsilon^{-1})$ [1, 23]. The significance of these result lies in the fact that for the simpler case of cut sparsification, these graphs present some of the hardest known instances [24, 27], where a quality-1 cut sparsifier requires $2^{\Omega(k)}$ vertices [24, 27]. Thus, their result raises hope that we can overcome the lower bounds by designing quality-$(1 + \varepsilon)$ sparsifiers, even in the flow sparsification setting.

Andoni et al. also prove a second result where they show a generic reduction from graphs of bounded treewidth to general graphs in the following sense: They give a construction whereby the existence of any quality-$q(k)$ sparsifier of size $S(k)$ implies a quality-$q(6w)$ sparsifier of size $k^4 \cdot S(6w)$ where w is the treewidth of the graph.

Our Results. We give the following results on quasi-bipartite graphs and their extensions:

1. A cut sparsifier of size 2^{k^2} for quasi-bipartite graphs (Theorem 3.1);
2. A contraction-based flow sparsifier of size 3^{k^3} for quasi-bipartite graphs (Theorem 3.2);
3. A cut sparsifier of size $k + 2^{c^2}$ and a flow sparsifier of size $k + 3^{c^3}$ when the graph has a vertex cover of size c (Theorem 4.1);
4. A cut sparsifier of size $kd + 4^{d^3}$ when G has vertex integrity d [4, 19], that is, a separator $X \subseteq V$ such that $|X| + |C| \leq d$ for every component C of $G - X$ (Corollary 4.3).

Note that our result almost matches the lower bound given by Krauthgamer and Rika [27] (up to a polynomial in the exponent). Further, our result on flow sparsifiers shows that instances on quasi-bipartite graphs are not hard for flow sparsification, as they admit better bounds than general graphs.

Our main contribution lies in developing a novel tool for constructing sparsifiers that is based on connections to polyhedral geometry. We show that this technique can be applied to obtain cut and flow sparsifiers, and even when the terminal set separates the graph into small components. Furthermore, we show that the size of the sparsifier actually grows with the size of the separator whose removal leaves only small components, thus obtaining improved results for bounded vertex cover and vertex integrity, two structural graph parameters that have recently gained popularity in the parameterized community [7, 18, 19, 20, 28, 33]. These have particular relevance when studying problems that are hard for more general parameters, such as treewidth [17] and treedepth [7, 19]; they also allow for stronger meta-theorems [20, 28] compared to the classic theorem of Courcelle for bounded-treewidth graphs [14].

We give an additional result for graphs with treewidth w, improving the results of Andoni et al. [2] and Chaudhuri et al. [10]: we construct a flow sparsifier of size $k \cdot S(2w)$ and quality $g(2w)$ provided that every k-terminal network admits a quality $g(k)$ flow sparsifier with size $S(k)$ (see Section 5). This implies an $\mathrm{O}(\frac{\log w}{\log \log w})$-quality sparsifier with size $\mathrm{O}(k \cdot w)$ for graphs with treewidth w using results from [16, 29].

Due to space constraints, we defer some proofs to the full version; the corresponding lemmas are marked with an asterisk (*).

Techniques. The main idea behind our construction of cut and flow sparsifiers for bipartite graphs is to consider them as a union of stars centered on Steiner vertices, which can be handled independently as they do not share any edges. By showing that the number of different ways that stars can participate in cuts is bounded, we get a sparsifier with the same bound on the size, as equivalent stars can be contracted together. Thus, it is sufficient to show how to put stars into a bounded number of classes.

Our approach is based on polyhedral theory. We represent each star by a vector in $\mathbb{R}^k_{\geq 0}$ where each coordinate is the capacity of an edge between the center of the star and a terminal. We show that there are 2^{k^2} stars, which we refer to as *basic stars*, such that any star is the conic combination of at most k of them. Using this idea, we obtain two constructions: the first is to construct H from the terminals and the set of *basic stars* with appropriately scaled-up capacities; whereas the second (slightly larger) is to simply contract vertices that are the conic combination of the same set of basic stars. Since the second construction is contraction-based, a consequence of our results is that optimal algorithm for contraction-based sparsifiers presented by Khan et al. [24] obtains a sparsifier of size at most 2^{k^3} for bipartite graphs.

The construction of the flow sparsifiers is much more involved. A first attempt would be to use our result for cut sparsifier along with a result from Andoni et al. [2, Theorem 7.1] which roughly implies that if the flow-cut gap for the given graph is γ, then an exact contraction-based cut sparsifier is also a flow sparsifier of quality γ. Unfortunately, bipartite networks can have a flow-cut gap of $\Omega(\log k)$ and hence this approach fails.

We rather take a more direct approach: by relying on the above mentioned polyhedral tool to define equivalence classes on the stars, we show that we can contract the stars in each equivalence class into a single one. Applying this technique is much more challenging in the case of flow sparsifiers, since one has to ensure that every multicommodity flow between terminals (and not just bipartitions) must be preserved.

The main technical difficulty is to show that merging two stars preserves the routing of multicommodity flows, and in particular, that if a demand can be routed in the merged star, then it can also be routed in the original stars (if the original stars are in the same equivalence class). We achieve this by splitting the demand so that each part can be routed in a different star, by a process which iteratively adds demand to one of the two stars, and if that is no longer possible, refines the partition by globally switching demands between the two stars. We show that when the process can no longer introduce new demand, then there is a saturated cut in the merged star, and thus all of the demand must be already routed.

2 Preliminaries

A network $G = (V, E, u)$ is a graph (V, E) with edge capacities $u\colon E(G) \to \mathbb{R}_{\geq 0}$. It is usually associated with a set of *terminals* $K \subseteq V(G)$, whose size we denote by k. We refer to vertices in $V(G) \setminus K$ as *non-terminal* or *Steiner* vertices, and say that two networks G_1, G_2 are *Steiner-disjoint* if $V(G_1) \cap V(G_2) \subseteq K$.

We consider a cut to be a subset of vertices $X \subset V$, with cut edges $\delta(X) = E(X, V - X)$. For convenience, we usually write $u(X)$ to mean $u(\delta(X))$ for any $X \subseteq V$. A cut X *separates* $A \subseteq K$ if $A \subseteq X$ and $K - A \subseteq V - X$, and it is a min-cut for A if it minimizes the capacity among all cuts separating A. We denote by $\mathrm{mc}_G(A)$ the smallest (minimum $|X|$) min-cut (in G) that separates A, and $\kappa_G(A)$ its capacity. If the network is clear from context, we drop the subscript in $\mathrm{mc}(A)$, $\kappa(A)$.

Cut sparsifiers. A *cut sparsifier* of quality $q \geq 1$ for a network G with terminals K is a network H such that $K \subseteq V(H)$ and for every subset $A \subset K$, the capacity of the min-cut separating A is q-approximated, that is,

$$\kappa_G(A) \leq \kappa_H(A) \leq q \cdot \kappa_G(A).$$

Unless specified, a cut sparsifier is of quality 1.

Flow sparsifiers. A *flow sparsifier* of quality $q \geq 1$ for a network G with terminals K is a network H that q-approximately preserves the multi-commodity flows for any demand. We use the formal description in the work of Andoni et al. [2].

We say that a demand $\mathbf{d} \in \mathbb{R}^{K \times K}_{\geq 0}$ *is routed* in G by flow $f \geq 0$ if $\sum_{P \in \mathcal{P}_{s,t}} f_P = d(s,t)$ and $\sum_{P \ni e} f_P \leq u(e)$, where f is defined over paths and $\mathcal{P}_{s,t}$ is the set of all s-t-paths. We consider both demands and paths as symmetric, that is, $d(s,t) = d(t,s)$, but $\mathcal{P}_{s,t} = \mathcal{P}_{t,s}$ so the same flows can satisfy both demands.

The demand polytope [2] for a network is the set all demands that can be routed in G, $\mathcal{D}(G) = \{\mathbf{d} : \mathbf{d} \text{ can be routed in } G\}$. Given a demand vector $\mathbf{d}$, its *flow factor* is the value $\lambda_G(\mathbf{d}) = \sup\{\lambda \geq 0 : \lambda\mathbf{d} \in \mathcal{D}(G)\}$.

We formally define *flow sparsifiers* as follows: H is a quality-q flow sparsifier for G with terminals K if for all demand vectors $\mathbf{d}$,

$$\lambda_G(\mathbf{d}) \leq \lambda_H(\mathbf{d}) \leq q \cdot \lambda_G(\mathbf{d}).$$

In particular for $q = 1$, we have that $\mathbf{d} \in \mathcal{D}(G)$ if and only if $\mathbf{d} \in \mathcal{D}(H)$.

Treewidth. A tree decomposition $(T, \mathcal{B})$ of a graph G is a tree T together with a collection of subsets of vertices $\mathcal{B} = \{B_i\}_{i \in V(T)}$ called *bags*, such that:

- For each edge $uv \in E(G)$, there is a bag B_i containing both u and v.
- For each vertex $v \in V(G)$, the collection of bags containing v induces a non-empty subtree of T.

The *width* of $(T, \mathcal{B})$ is $w(T, \mathcal{B}) = \max_{i \in V(T)}(|B_i| - 1)$. The *treewidth* of G is the minimum width achievable by any tree decomposition.

We assume that there are no two identical bags in the decomposition, as otherwise we can simply contract the edge connecting the corresponding nodes. We consider that each edge uv is associated with a single node of T, namely the node closest to the root whose bag contains both u and v. The collection of edges associated with a node $i \in T$ is denoted by E_i, and the subgraph induced by a bag is $G[i] = (B_i, E_i)$. This notation is particularly useful when talking about the graph induced by collections of bags, and thus for a subset $R \subseteq V(T)$ we write $B(R) = \bigcup_{i \in R} B_i$, $E(R) = \bigcup_{i \in R} E_i$, and $G[R] = (B(R), E(R))$. We remark that $G[R]$ and $G[B(R)]$ are subgraphs on the same subset of vertices but with different sets of edges.

Computing the treewidth of a graph, together with the corresponding tree decomposition, is an NP-hard problem [3], but can be computed in time $w^{O(w^3)} \cdot n$ [6] for a graph of treewidth w. For a faster running time, we can get a tree decomposition with width $2w + 1$ in time $2^{O(w)} \cdot n$ due to the recent work by Korhonen [25]. For a more detailed introduction to treewidth, see e.g. the book by Cygan et al. [15].

2.1 Basic Tools

▶ **Lemma 2.1** **(*).** *Let G be a network. If H is a quality-q sparsifier for G with terminals K, and L is a quality-r sparsifier for H with terminals K', $K' \subseteq K$, then L is a quality-qr sparsifier for G with terminals K', where the statement works if H, L are cut sparsifiers or flow sparsifiers.*

We recall the splicing lemma of Andoni et al. [2] for flow sparsifiers, which shows that it is sufficient for a sparsifier to preserve routings along terminal-free paths.

▶ **Lemma 2.2** ([2, Lemma 5.1])**.** *Let G and H be two networks with the same set of terminals K, and fix $\rho \geq 1$. Suppose that whenever a demand $\mathbf{d}$ between terminals in K can be routed in G using terminal-free flow paths, demand $\mathbf{d}/\rho$ can be routed in H (by arbitrary flow paths).*

Then for every demand $\mathbf{d}$ between terminals in K that can be routed in G, demand $\mathbf{d}/\rho$ can be routed in H.

Finally, we show the following generalization of the composition lemma to both cut and flow sparsifiers.

▶ **Lemma 2.3** **(*).** *Let G_1 and G_2 be Steiner-disjoint networks for terminal set K.*

If H_1 and H_2 are quality-q (cut or flow) sparsifiers for G_1, and G_2 with terminal set $K \cap V(G_1)$, $K \cap V(G_2)$, respectively, then $H := H_1 \uplus H_2$ is a quality-q (cut or flow, resp.) sparsifier for $G := G_1 \uplus G_2$ (parallel edges in K are joined and their capacities summed).

The proof for flow sparsifiers is given by Andoni et al. [2, Lemma 5.2]; the proof for cut sparsifiers follows using similar arguments.

Let G/vw be the network obtained from G by contracting v and w into a vertex denoted vw, that is, removing v and w, adding a vertex vw with edges to vertices $(N(v) \cup N(w)) \setminus \{v, w\}$, and setting the capacity of each new edge $\{vw, x\}$ to $w_{G/vw}(\{vw, x\}) = u_G(vx) + u_G(wx)$, where $u_G(vx) = 0$ if the edge does not exist.

▶ **Lemma 2.4** **(*).** *Let v, w be vertices such that for every $A \subseteq K$, there is a min-cut X separating A that either contains both v and w or neither of them.*

Then G/vw is an exact cut sparsifier for G with terminals K.

3 Sparsifiers for Quasi-Bipartite Graphs

In this section we show how to compute cut and flow sparsifiers for quasi-bipartite graphs, where the left side is the set of terminals. In a later section we show how to improve this to a more general case of bounded vertex cover. Our results are formalized in the following theorems:

▶ **Theorem 3.1.** *Let $G = (V, E, u)$ be a network with terminal set K of size k.*
If G is bipartite with partition $V = K \uplus (V \setminus K)$, then G has a cut sparsifier of size 2^{k^2} and a contraction-based cut sparsifier of size 2^{k^3}.

▶ **Theorem 3.2.** *Let $G = (V, E, u)$ be a network with terminal set K of size k.*
If G is bipartite with partition $V = K \uplus (V \setminus K)$, then G has a contraction-based flow sparsifier of size 3^{k^3}.

We remark that quasi-bipartite and bipartite graphs are equally hard to handle, as we can simply consider a quasi-bipartite graph as the Steiner-disjoint union of $G[K]$ and $G - E(K)$.

▶ **Corollary 3.3.** *Quasi-bipartite networks (with no edges between Steiner vertices) have cut sparsifiers of size 2^{k^2} and flow sparsifiers of size 3^{k^3}.*

3.1 Cut Sparsifiers

This section is dedicated to proving Theorem 3.1.

Let v be the center of a star, and $(c(1), c(2), \dots, c(k))$ be the capacity vector of the edges to the terminals (with some ordering $K = \{t_1, \dots, t_k\}$). For each cut $S \subseteq K$, either $c(S) \leq c(K - S)$, $c(S) = c(K - S)$, or $c(S) \geq c(K - S)$. Using the inequalities for c and each subset $S \subseteq K$, we can define a polyhedron P_c of all the capacity vectors that cut the star in the same way as c. Thus, the capacity vector c is a conic combination of the extreme rays of P_c, and therefore we can replace it in the graph by a conic combination of the stars corresponding to the extreme rays, which we call *basic stars*. Finally, we show that since c agrees on every inequality with the basic stars in its conic combination, the replacement preserves the value of min-cuts, and so by replacing every star we obtain a sparsifier of G.

Basic stars. Let $c \in \mathbb{R}^k$ be a capacity vector. We define $\mathcal{S}_c$ to be the collection of subsets $S \subseteq K$ such that $c(S) \leq c(K - S)$, i.e. $\mathcal{S}_c = \{S \subseteq K : c(S) \leq c(K - S)\}$, and the *star cone* of c to be:

$$P_c := \left\{ x \in \mathbb{R}^k_{\geq 0} : \ x(S) \leq x(K - S) \ \forall S \in \mathcal{S}_c \right\}$$

We say that a vector x *agrees with* c (on every cut) if $x(S) \leq x(K - S)$ for all $S \in \mathcal{S}_c$, and thus P_c is the polyhedron containing all of the capacity vectors that agree with c. It is a cone since it is defined by constraints of the form $\alpha^T x \leq 0$. We remark that for every $S \subseteq K$, $S \in \mathcal{S}_c$ or $K - S \in \mathcal{S}_c$, and both are present if and only if $x(S) = x(K - S)$.

We define the set of basic stars as stars constructed from extreme rays of any such cone. For a given c, the extreme rays of the cone P_c are found at the intersection of $k - 1$ tight inequalities: $x_i \geq 0$ for some indices $i \in I$, and $x(S) = x(K - S)$ for some $S \in J$, with $|I| + |J| = k - 1$ (see e.g. [13, Sec. 3.12]). Notice that, regardless of the capacity vector c, the extreme rays of P_c are all found using a tight subset of the same collection of inequalities. However, not every extreme ray belongs to every P_c, as they might disagree on some inequalities outside of J. For convenience, we represent each ray by a vector with coordinates summing to 1.

Let Q be the set of extreme rays of any cone as obtained above, that is, the set of extreme rays obtained from intersection of $k-1$ independent tight constraints with $x(K)=1$. Formally, let $\mathcal{I}_k$ be the collection of pairs (I,J), $|I|+|J|=k-1$, such that the constraints $x(i)=0$ for $i\in I$, $x(S)=x(K-S)$ for $S\in J$ and $x(K)=1$ are all independent. Then

$$Q=\big\{q_{IJ}\in\mathbb{R}^k_{\geq 0}: q_{IJ}(K)=1; q_{IJ}(I)=0; \\ q_{IJ}(S)=q_{IJ}(K-S)\ \forall S\in J; (I,J)\in\mathcal{I}_k\big\}.$$

For each $q\in Q$, we can construct a star with center denoted v_q and an edge to each terminal $t_i\in K$ with capacity q_i. These stars are denoted *basic stars* and are referred to by their center v_q.

The size of Q is determined by the possible sets of inequalities that define each of its elements. As the tight inequalities for S and $K\setminus S$ are the same, there are effectively at most $2^{k-1}+k\leq 2^k$ inequalities to choose from. Each element of Q is defined by $k-1$ of these, and thus $|Q|\leq\binom{2^k}{k-1}\leq 2^{k^2}$.

▶ **Lemma 3.4.** *Any capacity vector c can be written as the conic combination of at most k points in Q, all of which agree with c.*

Formally, there are $q_1,\ldots,q_k\in Q$, $\lambda(q_1),\ldots,\lambda(q_k)\geq 0$ such that :

$$\sum_{i=1}^{k}\lambda(q_i)\cdot q_i=c \qquad \textit{and} \qquad q_i(S)\leq q_i(K-S) \qquad \forall i\in[k], S\in\mathcal{S}_c$$

Proof. Let P_c be the star cone corresponding to c. By Carathéodory's theorem (see e.g. [13, Sec. 3.14]), c is a conic combination of at most k extreme rays of P_c (which are contained in Q). In other words, there are $q_1,\ldots,q_k\in P_c\cap Q$ and $\lambda(q_1),\ldots,\lambda(q_k)\geq 0$ such that $c=\sum_{i=1}^{k}\lambda(q_i)\cdot q_i$.

All it remains to show is that every q_i agrees with c on every cut. Indeed, since every q_i is an extreme ray of P_c, it must satisfy the inequalities defining P_c, and thus agree with c. ◀

We obtain a sparsifier for G as follows: for each $v\in V-K$, write the capacity vector c_v of the star centered at v as a conic combination of the points in Q, i.e. as $c_v=\sum_{q\in Q}\lambda_v(q)q$. Then, define $V_Q=\{v_q:q\in Q\}$ and take $H=(K\cup V_Q, K\times V_Q, u')$; the capacity vector for each v_q is q scaled up by the sum of the corresponding values λ_v: $u'(v_q,\cdot)=q\cdot\sum_v\lambda_v(q)$.

To determine the values λ_v, we can use the constructive proof of Carathéodory's theorem, starting by computing the set Q by enumeration in time $2^{k^2}\cdot\text{poly}(k)$. Given a capacity vector c, start by finding $q_1\in Q\cap P_c$ that agrees with c on every cut; then, find the maximum value of $\lambda(q_1)$ such that $c-\lambda(q_1)q_1\in P_c$; finally, set $c'=c-\lambda(q_1)q_1$ and repeat the process for c' to find the remaining $q_2,\ldots$ and $\lambda_2,\ldots$ Notice that at each step, c' has at least one more tight inequality than c (otherwise we could increase $\lambda(q_1)$), and thus the process stops after k iterations. In conclusion, the process of computing the set Q takes time $2^{O(k^2)}$, and the process of finding the coefficients for each star takes time $2^{O(k^2)}$ (per star).

The following lemma allows us to relate a star to its conic combination using basic stars.

▶ **Lemma 3.5.** *Let v be a vertex with degree k and capacity vector c for its incident edges.*

If c can be written as the conic combination of points $q_1,q_2,\ldots,q_\ell\in Q$, all of which agree with c, then G has a sparsifier given by $G-\{v\}+\{w_1,\ldots,w_\ell\}$, where the neighbors of vertices $w_1,\ldots,w_\ell$ are also neighbors of v and the capacities of the edges incident on each vertex w_i are given by $\lambda(q_i)\cdot q_i$.

Proof. We will use the fact that the definition of sparsifier is reflexive, and thus show that G is a sparsifier for $G - \{v\} + \{w_1, \ldots, w_\ell\}$. We will iteratively contract two vertices in $\{w_1, \ldots, w_\ell\}$, until we have the original graph. We assume that each vertex w_i has the same neighbors as v by adding edges with capacity 0.

Let $G' = G - \{v\} + \{w_1, \ldots, w_\ell\}$ so that $u_G(v) = \sum_{i=1}^{\ell} u_{G'}(w_i)$. For any $i \in [\ell]$, q_i agrees with c, so $u_{G'}(w_i) = \lambda(q_i) \cdot q_i$ also agrees with c, as P_c is a cone (and thus scale-invariant). We observe that if some $A \in \mathcal{S}_c$, then $c(A) \leq c(K - A)$, and thus there is a min-cut separating A that does not contain v, as it is at least as cheap to cut the edges to A as to $K - A$; the same argument applies to any vertex whose capacities agree with c, such as any w_i. Therefore, for any $A \subseteq K$, there is a min-cut separating A that contains both $w_{\ell-1}$ and w_ℓ (if $K - A \in \mathcal{S}_c$) or neither (if $A \in \mathcal{S}_c$), and thus we can apply Lemma 2.4 to merge $w_{\ell-1}$ and w_ℓ to obtain a new vertex $w'_{\ell-1}$ with capacities $u_{G'}(w_{\ell-1}) + u_{G'}(w_\ell)$. This ensures that $u_G(v) = \sum_{i=1}^{\ell-2} u_{G'}(w_i) + u_{G'}(w'_{\ell-1})$, and thus we can repeat the process until we only have a single w'_1 left, with capacities $u_{G'}(w'_1) = \sum_{i=1}^{\ell} u_{G'}(w_i) = u_G(v)$, which is equivalent to the original graph. ◀

We can now finish the proof of Theorem 3.1.

Proof of Theorem 3.1. We start by computing the basic stars Q for k terminals, and then computing the coefficients $\lambda_v : Q \to \mathbb{R}_{\geq 0}$ for each $v \in V \setminus K$. We can now obtain two different constructions for a sparsifier, one that replaces all the vertices with basic stars, and another which simply contracts vertices that have the same cut profile.

Basic star sparsifier. We take $V_Q = \{v_q : q \in Q\}$ as the set of all basic stars, and construct our sparsifier by adding edges from every $v_q \in Q$ to every terminal $t \in K$. The capacities are given by summing over the λ_v as follows: $u'(v_q, t_i) = q_i \cdot \sum_v \lambda_v(q)$. The sparsifier is then given by $H = (K \cup V_Q, K \times V_Q, u')$.

This construction is equivalent to decomposing each v into a conic combination of basic stars using Lemma 3.5, and then (iteratively) contracting all of the vertices created for the same $q \in Q$ (and different $v \in V \setminus K$) using Lemma 2.4. This also proves correctness of the sparsifier.

Contraction-based sparsifier. For this variant of the sparsifier, we will only use Lemma 2.4 and Carathéodory's theorem [13, Sec. 3.14], as well as the algorithm introduced by Hagerup et al. [22], in which we compute all 2^k minimum cuts, and contract any two vertices whose capacity vectors agree with each other.

The running time is $O(2^k \cdot n^2)$ to compute the set $\mathcal{S}_c$ for each of the at most n stars, and then comparing the sets for each pair of stars to decide whether to contract them. Alternatively, the sets $\mathcal{S}_c$ can be computed in time $O(2^k \cdot kn)$ and the vertices placed in buckets according to their set $\mathcal{S}_c$, after which the vertices in each bucket can be contracted.

Thus, all that we need to do is to show that if two capacity vectors are the conic combination of the same basic stars, then they agree, and thus can be contracted.

▶ **Lemma 3.6.** *If capacity vectors c and c' can be written as the conic combination of points $q_1, q_2, \ldots, q_\ell \in Q$ and each q_i agrees with both c and c', then c and c' agree with each other.*

Proof. As the lemma is symmetric, we will simply show that if $S \in \mathcal{S}_c$, then $S \in \mathcal{S}_{c'}$. If $S \in \mathcal{S}_c$, then $S \in \mathcal{S}_{q_i}$ and so $q_i(S) \leq q_i(K \setminus S)$ by definition of agreement. Therefore,

$$c'(S) - c'(K \setminus S) = \sum_i \lambda_{c'}(q_i) \cdot \big(q_i(S) - q_i(K \setminus S)\big) \leq 0 \quad \Rightarrow \quad S \in \mathcal{S}_{c'}.$$ ◀

Given Lemma 3.6, it is sufficient to bound the number of possible ways that capacity vectors can be written as conic combinations, as vectors that are written as a conic combination of the same basic stars are always on the same minimal min-cuts, and thus can be contracted by Lemma 2.4. As there are 2^{k^2} basic stars, and by Carathéodory's theorem each capacity vector can be written as the conic combination of at most k of them, there are at most 2^{k^3} such combinations, and thus after contraction, we are left with a sparsifier of size at most 2^{k^3}. ◀

3.2 Flow Sparsifiers

We will show that a slight modification to the contraction-based sparsifier in Section 3.1 increases its size to 3^{k^3} but makes it a flow sparsifier on bipartite graphs, proving Theorem 3.2.

Let c be a capacity vector. The only modification we need is to consider all inequalities of the form $c(A) \leq c(B)$ for $A, B \subseteq K$, $A \cap B = \emptyset$. Surprisingly, the cut sparsifiers of Theorem 3.1 preserve min-cuts separating a subset $A \subseteq K$ from a disjoint subset $B \subseteq K$ without requiring these inequalities. However, for the construction of flow sparsifiers it is necessary that the vertices we contract agree on the inequalities for each pair (A, B).

We define $\mathcal{S}'_c = \{(A, B) \subseteq K : c(A) \leq c(B)\}$ and say that c' *strongly agrees* with c if $c'(A) \leq c'(B)$ for all $(A, B) \in \mathcal{S}'_c$. Notice that $\mathcal{S}'_c$ has at most 3^k sets, as an element can be placed in A, B or neither.

The *strong star cone* of c is defined as $P'_c := \left\{x \in \mathbb{R}^k_{\geq 0} : \; x(A) \leq x(B) \; \forall (A, B) \in \mathcal{S}'_c\right\}$, and the set of extreme rays $Q' := \{q \in \mathbb{R}^k_{\geq 0} : q \text{ is an extreme ray of some } P'_c\}$. The size of Q' is upper-bounded by the possible combinations of $k - 1$ tight inequalities, which implies that $|Q'| \leq 3^{k^2}$.

We use the contraction-based construction of Section 3.1 using the concept of strong agreement. As before, we can show that each capacity vector is the conic combination of k extreme rays.

▶ **Lemma 3.7.** *Any capacity vector c can be written as the conic combination of at most k points in Q', all of which strongly agree with c.*

Formally, there are $q_1, \ldots, q_k \in Q'$, $\lambda(q_1), \ldots, \lambda(q_k) \geq 0$ such that :

$$\sum_{i=1}^{k} \lambda(q_i) \cdot q_i = c \qquad \text{and} \qquad q_i(A) \leq q_i(B) \qquad \forall i \in [k], (A, B) \in \mathcal{S}'_c$$

Proof. Let P'_c be the star cone corresponding to c. By Carathéodory's theorem, c is a conic combination of at most k extreme rays of P'_c (contained in Q'). Each q_i is in P'_c, and thus strongly agrees with c. ◀

As Q' has at most 3^{k^2} extreme rays, this means that there are at most 3^{k^3} classes where capacity vectors can be placed according to which set of extreme rays produce it as a conic combination. As part of our proof, we need to show that if two capacity vectors are in the same class, then they strongly agree.

▶ **Lemma 3.8.** *If capacity vectors c and c' can be written as the conic combination of points $q_1, q_2, \ldots, q_\ell \in Q'$ and both strongly agree with each q_i on every cut, then c and c' strongly agree.*

Proof. As the lemma is symmetric, we will simply show that if $(A, B) \in \mathcal{S}'_c$, then $(A, B) \in \mathcal{S}_{c'}$. If $(A, B) \in \mathcal{S}_c$, then $(A, B) \in \mathcal{S}_{q_i}$ and so $q_i(A) \leq q_i(B)$ by definition of agreement. Therefore,

$$c'(A) - c'(B) = \sum_i \lambda_{c'}(q_i) \cdot \big(q_i(A) - q_i(BS)\big) \leq 0 \quad \Rightarrow \quad (A, B) \in \mathcal{S}_{c'}. \qquad ◀$$

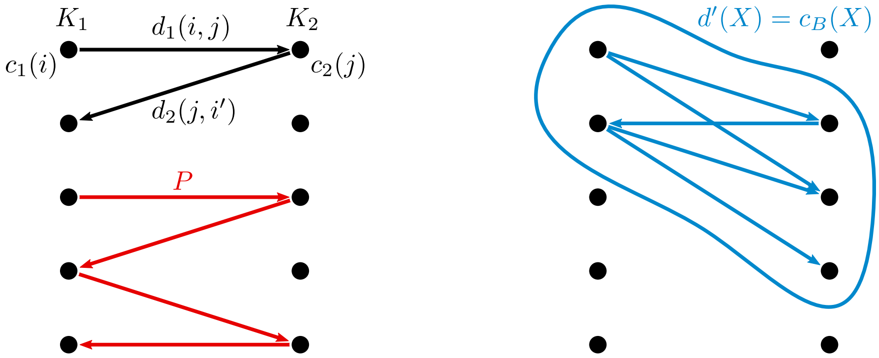

Figure 1 Representation of the graph G_B; a path (left, red) as found in Step 3a; a cut (right, blue) representing the situation in which no path is found.

We then show that if we have two stars where their capacity vectors agree, we can contract them to obtain a flow sparsifier. By repeating the process until we have at most 1 vertex per class, we obtain a flow sparsifier of size 3^{k^3}.

▶ **Lemma 3.9.** *Let v_1, v_2 be centers of stars with leaves K and let $c_1, c_2 \in \mathbb{R}^k_{\geq 0}$ be their capacity vectors (respectively).*

If c_1 and c_2 strongly agree with each other, that is $\mathcal{S}'_{c_1} = \mathcal{S}'_{c_2}$, then G/v_1v_2 is an exact flow sparsifier for G with terminals K.

Proof. Let $c := c_1 + c_2$, and $v := v_1v_2$ be the vertex created in $G' := G/v_1v_2$. We will show that if we can route a demand $\mathbf{d}$ in G then we can route it G' and vice-versa. If we can route a demand in G, then any demand routed on v_1w or v_2w can be routed instead on vw, as $c_1(w) + c_2(w) = c(w)$. We now show that a demand routed in G' can also be routed in G.

By Lemma 2.2, and since the neighbors of v_1 and v_2 are terminals, we can “splice” the flows so that any demand is routed only through (internally) terminal-free paths. Thus, we focus on the demands that are routed through paths t_ivt_j, $t_i, t_j \in K$ in G'. Let $\mathbf{d}$ be any such demand that can be routed in $K \cup \{v\}$, and we will construct vectors $\mathbf{d}_1$, $\mathbf{d}_2$ of the demands that will be routed through v_1, v_2, such that $\mathbf{d}_1 + \mathbf{d}_2 = \mathbf{d}$.

▶ **Observation 3.10.** *In a star $K \cup \{v\}$ with capacities c, a demand $\mathbf{d}$ can be routed if and only if for every $i \in [k]$, $\mathbf{d}(i) := \sum_j d(t_i, t_j) \leq c(i)$.*

We use the following directed bipartite graph G_B to assist us in the algorithm and proof: G_B has as vertices two copies of K, $V(G_B) = K_1 \cup K_2$, and has arcs $A(G_B) = (K_1 \times K_2) \cup (K_2 \times K_1)$. We also impose node capacities for outgoing arcs, with capacity vector c_1 for the vertices in K_1 and c_2 for vertices in K_2; we represent the capacity vector for G_B as c_B (so $c_B(K_1) = c_1$, $c_B(K_2) = c_2$). See Figure 1 for a visual representation of the graph.

Our goal is to add demand to the graph in the form of demands on arcs, with arcs from K_1 to K_2 representing $\mathbf{d}_1$, and arcs from K_2 to K_1 representing $\mathbf{d}_2$. We will use $\mathbf{d}'$ to represent the demand in the graph (so $\mathbf{d}_1 = \mathbf{d}'(K_1, K_2)$, $\mathbf{d}_2 = \mathbf{d}'(K_2, K_1)$), and $\tilde{\mathbf{d}}$ to represent leftover demand (initially $\mathbf{d}' = 0$, $\tilde{\mathbf{d}} = \mathbf{d}$). Whenever we say to add some demand to $d_\iota(i,j)$, it is implied that we add the demand to $d'(i_\iota, j_{3-\iota})$ and remove it from $\tilde{d}(i,j)$, as well as make the same changes to (j,i) (increase $d_\iota(j,i)$ and $d'(j_\iota, i_{3-\iota})$, decrease $\tilde{d}(j,i)$), where $i_1, j_1 \in K_1$, $i_2, j_2 \in K_2$ are the copies of i and j in K_1, K_2, respectively.

We repeat the following steps until $\tilde{\mathbf{d}} = 0$:

1. if there is $\tilde{d}(i,j) > 0$ such that $\mathbf{d}_1(i) < c_1(i)$ and $\mathbf{d}_1(j) < c_1(j)$, add to $d_1(i,j)$ a value of $\varepsilon := \min(\tilde{d}(i,j), c_1(i) - \mathbf{d}_1(i), c_1(j) - \mathbf{d}_1(j))$;
2. similarly for $\mathbf{d}_2$, if there is (i,j) such that $\varepsilon := \min(\tilde{d}(i,j), c_2(i) - \mathbf{d}_2(i), c_2(j) - \mathbf{d}_2(j)) > 0$, add ε to $d_2(i,j)$;
3. let $\tilde{d}(i,j) > 0$, and assume w.l.o.g. that $\mathbf{d}_2(i) = c_2(i)$:
   a. find a path $P = (i_2 = \ell_0, \ell_1, \ell_2, \dots \ell_p)$ such that for all $0 < r < p$, $\mathbf{d}'(\ell_r) = c_B(\ell_r)$, $d'(\ell_r, \ell_{r+1}) > 0$, and for the endpoint, $d'(\ell_p) < c_B(\ell_p)$;
   b. switch demand between $\mathbf{d}_1$ and $\mathbf{d}_2$ as follows: let $\varepsilon := \min\big(c_1(i) - \mathbf{d}_1(i), c_B(\ell_p) - \mathbf{d}'(\ell_p), \min_r d'(\ell_r, \ell_{r+1})\big)$; for any arc $(x_1, y_2) \in K_1 \times K_2$ (resp. $(x_2, y_1) \in K_2 \times K_1$) in P, decrease $d'(x_1, y_2)$ (resp. $d'(x_2, y_1)$) and increase $d'(x_2, y_1)$ (resp. $d'(y_1, x_2)$) by ε;
   c. add $\min(\tilde{d}(i,j), \varepsilon, c_2(j) - \mathbf{d}_2(j))$ to $d_2(i,j)$.

We will show that such a path always exists as long as there is demand to be routed, but first, let us show that these operations maintain the invariants that $\mathbf{d}'(i) \le c_B(i)$, for all $i \in V(G_B)$. For the first two steps, $\mathbf{d}_1(i)$ (resp. $\mathbf{d}_2(i)$) increases by at most $c_1(i) - \mathbf{d}_1(i)$ (resp. $c_2(i) - \mathbf{d}_2(i)$), which maintains the invariant. For the third step, notice that every ℓ_i except the endpoints has two arcs in the path, one corresponding to $\mathbf{d}_1$ and the other to $\mathbf{d}_2$, hence the decrease on $\mathbf{d}_1$ on one edge is compensated by the increase on the other, and the same for $\mathbf{d}_2$. Furthermore, as we choose ε to be the smallest value on the path, no demand can go below 0. Finally, for the endpoints, we know that ℓ_p has spare capacity by definition, and for i we decrease $\mathbf{d}_2(i)$ and increase $\mathbf{d}_1(i)$, but $\mathbf{d}_2(i) = c_2(i)$ implies that $\mathbf{d}_1(i) < c_1(i)$, as $\tilde{\mathbf{d}}(i) + \mathbf{d}_1(i) + \mathbf{d}_2(i) = \mathbf{d}(i) \le c(i) = c_1(i) + c_2(i)$ and $\tilde{\mathbf{d}}(i) > 0$.

We will now show by contradiction that a path must exist. Assume that the process above cannot complete, i.e. there is some demand $\tilde{d}(i,j) > 0$ that cannot be placed in $\mathbf{d}_1$ or $\mathbf{d}_2$, and there is no path P as specified above. Then there is a set $X \subseteq V(G_B)$ of vertices reachable from i by edges with positive demand in $\mathbf{d}'$, all of which have saturated capacity $\mathbf{d}'(\ell_r) = c_B(\ell_r)$. Writing $X_1 = X \cap K_1$, $X_2 = X \cap K_2$, we get that $\mathbf{d}_1(X_1) = \sum_{\ell \in X_1} \mathbf{d}_1(\ell) = c_1(X_1)$ and $\mathbf{d}_2(X_2) = c_2(X_2)$. We can furthermore deduce that $\mathbf{d}_1(X_1) \le \mathbf{d}_1(X_2)$, since all of the demand in $\mathbf{d}_1$ incident on X_1 is represented as demand in an arc (X_1, X_2), which is thus also incident on X_2. Similarly, we know that $\mathbf{d}_2(X_2) \le \mathbf{d}_2(X_1)$. Putting these facts together, we conclude that:

$$c_1(X_1) = \mathbf{d}_1(X_1) \le \mathbf{d}_1(X_2) \le c_1(X_2) \quad \text{and} \quad c_2(X_2) = \mathbf{d}_2(X_2) \le \mathbf{d}_2(X_1) \le c_2(X_1)$$

Since $\mathcal{S}'_{c_1} = \mathcal{S}'_{c_2}$, it must be the case that $c_1(X_1) = c_1(X_2)$ and $c_2(X_2) = c_2(X_1)$, and thus from the inequalities above we can conclude that $\mathbf{d}_1(X_2) = c_1(X_2)$, and in particular, since $i_2 \in X_2$, it must be that $\mathbf{d}_1(i) = c_1(i)$. But this is a contradiction, as $\mathbf{d}(i) = \tilde{\mathbf{d}}(i) + \mathbf{d}_1(i) + \mathbf{d}_2(i) = \tilde{\mathbf{d}}(i) + c_1(i) + c_2(i) > c(i)$, and thus $\mathbf{d}$ would not be routable in G'.

We conclude that, as long as $\tilde{\mathbf{d}} \ne \mathbf{0}$, the process above finds a path and thus makes progress in each iteration. Therefore, $\mathbf{d}$ is routable in G by splitting it into demands $\mathbf{d}_1$ for v_1 and $\mathbf{d}_2$ for v_2 as described above. ◀

4 Sparsifiers for Small Vertex Cover and Integrity

The vertex cover number c of a graph G is the size of the smallest set X such that $G - X$ contains no edges. The vertex integrity d of a graph extends this by allowing $G - X$ to have small components, and it is the smallest number for which there is a set X such that $G - X$ has components of size at most $d - |X|$ (i.e. the size of a component plus X does not exceed

d). We show that if either of these parameters is bounded, the exponential complexity in the size of the sparsifier is limited to an *additive* term depending only on the parameter. The result of Section 3.1 corresponds to the case of $c = k$ (or $d = k + 1$).

Our formal results are the following:

▶ **Theorem 4.1.** *Let $G = (V, E, u)$ be a network with terminal set K of size k.*

If G has a vertex cover of size c, it has a cut sparsifier of size $k + 2^{c^2}$ and a flow sparsifier of size $k + 3^{c^3}$.

Proof. Let X be a vertex cover of size c. We will start by splitting the graph into a subgraph with all of the terminals and another containing only X and non-terminals. Let $G_K = G[K \cup X]$ be the first of these graphs, and $G_S = G[(V \setminus K) \cup X] - E(X)]$ be the second. Notice that the graphs are Steiner-disjoint for terminal set $K \cup X$, and thus we can use Lemma 2.3. Furthermore, if we compute a sparsifier H_S for G_S (with terminal set X) and take the sparsifier $H = G_K \uplus H_S$ for G, the size of H is $k + |V(H)|$. All that remains is to apply Theorem 3.1 to obtain a cut sparsifier H_S of size 2^{c^2} or Theorem 3.2 to obtain a flow sparsifier H_S of size 3^{c^3}, which completes the proof of the theorem. ◀

▶ **Theorem 4.2.** *Let $G = (V, E, u)$ be a network with terminal set K of size k.*

If G has a separator $X \subseteq V$ of size a and $|C| \leq b$ for every component C of $G - X$, then it has a sparsifier of size $kb + 4^{b(a+b)^2}$.

As a corollary, we get that small sparsifiers exist when vertex integrity is bounded.

▶ **Corollary 4.3.** *Let $G = (V, E, u)$ be a network with terminal set K of size k.*

If G has a separator $X \subseteq V$ such that $|X| + |C| \leq d$ for every component C of $G - X$, then it has a cut sparsifier of size $kd + 4^{d^3}$.

The rest of the section is dedicated to proving Theorem 4.2.

We use the same strategy of separating out the terminals, though in this case we need to show a new bound when $G - X$ has small connected components. We will use similar polyhedral techniques adjusted for the case of small components.

Let $X \subseteq V$ be a separator of size a such that $G - X$ has components of size at most b. Let $\mathcal{C} = \mathrm{cc}(G - X)$, and let $\mathcal{C}_K$ be the set of connected components containing any terminals. We define $G_K = G[X \cup \bigcup\{C \in \mathcal{C}_K\}]$ and $G_S = G[(V(G) \setminus V(G_K)) \cup X]$. The graphs are Steiner-disjoint for terminals $X \cup K$, and $|V(G_K) \setminus V(G_S)| \leq kb$, thus by Lemma 2.3, $H = G_K \uplus H_S$ is a sparsifier for G of size $kb + |V(H_S)|$, where H_S is a sparsifier for G_S.

All that is left is then to show that G_S with terminal set X has a sparsifier of size $4^{b(a+b)^2}$. Though on stars (components of size 1), there are only two possible cuts for each subset of terminals, here there are more possibilities for cuts, and thus we need multiple inequalities for each subset of terminals. Therefore, we show that there are at most $4^{b(a+b)^2}$ *basic components* of size at most b, such that any connected component can be written as the conic combination of these. We then replace each component by a conic combination of basic components, and contract all of the components of the new graph corresponding to the same basic component.

Basic components. Let C be a component with vertices $v_1, \ldots, v_b$, and let the terminals be ordered $K = \{t_1, \ldots, t_k\}$. To simplify the analysis, we consider that every component has size b by adding isolated vertices if needed. We represent the edge capacities for C as a vector $c \in \mathbb{R}_{\geq 0}^{C \times (C \cup X)}$ (where $c(v_i, v_j) = c(v_j, v_i)$ for all $v_i, v_j \in C$, $c(v_i, v_i) = 0$ for all $v_i \in C$).

We define $\mathcal{S}_c$ to be the collection of triples (A, B, B'), $A \subseteq K$, $B, B' \subseteq V(C)$, such that $c(A \cup B) \le c(A \cup B')$, i.e. $\mathcal{S}_c = \{(A, B, B') \subseteq K \times V(C)^2 : c(A \cup B) \le c(A \cup B')\}$, and the *cut cone* of c to be:

$$P_c := \Big\{x \in \mathbb{R}_{\ge 0}^{C\times(C\cup X)} : x(A \cup B) \le x(A \cup B') \ \forall (A, B, B') \in \mathcal{S}_c; \\ x(v_i, v_j) = x(v_j, v_i), x(v_i, v_i) = 0 \ \forall v_i, v_j \in V(C)\Big\}$$

We say that a vector x *agrees with* c if $c(A \cup B) \le c(A \cup B')$ for all $(A, B, B') \in \mathcal{S}_c$, and thus P_c is the polyhedron containing all of the capacity vectors that agree with c. It is a cone since it is defined by constraints of the form $\alpha^T x \le 0$.

We can now define the set Q of extreme rays similarly to the star case, as the set of all capacity vectors that satisfy $b(a+(b-1)/2)$ many linearly independent constraints. For each $q \in Q$, we can construct a corresponding *basic component* C_q with vertices $X \cup \{v_{q,1}, v_{q,2}, \dots, v_{q,b}\}$ and capacities defined according to q.

The size of Q is determined by the possible sets of inequalities that define each of its elements. Out of the 2^{a+2b}, we choose at most $b(a + b/2)$, which gives us an upper bound of $|Q| \le 2^{b(a+2b)(a+b)} \le 4^{b(a+b)^2}$.

The following lemma expresses components as conic combinations of basic components:

▶ **Lemma 4.4.** *Any capacity vector c for a component C can be written as the conic combination of at most $\ell = b(a + b/2)$ points in Q, all of which agree with c.*

Formally, there are $q_1, \dots, q_\ell \in Q$, $\lambda(q_1), \dots, \lambda(q_\ell) \ge 0$ such that :

$$\sum_{i=1}^{\ell} \lambda(q_i) \cdot q_i = c \qquad \textit{and} \qquad q_i(A \cup B) \le q_i(A \cup B') \qquad \forall i \in [\ell], (A, B, B') \in \mathcal{S}_c$$

Proof. The proof mimics that of Lemma 3.4, with some slight adjustments to consider the different definition of $\mathcal{S}_c$, P_c and Q.

Let P_c be the cut cone corresponding to c. Notice that P_c always includes equality constraints to ensure symmetry ($x(v_i, v_j) = x(v_j, v_i)$, $x(v_i, v_i) = 0$), and these $\binom{b}{2} + b$ constraints are independent. Thus, by Carathéodory's theorem c is a conic combination of at most $\ell = ab - \binom{b}{2} - b \le b(a + b/2)$ extreme rays of P_c (which are contained in Q). In other words, there are $q_1, \dots, q_k \in P_c \cap Q$ and $\lambda(q_1), \dots, \lambda(q_k) \ge 0$ such that $c = \sum_{i=1}^{k} \lambda(q_i) \cdot q_i$.

Furthermore, each q_i agrees with c on every cut since it is an extreme ray of P_c, and thus satisfies its inequalities. ◀

We obtain a sparsifier H for G as follows: given a separator X, $|X| \le a$ such that $G - X$ only has connected components of size at most b, we start by partitioning G into $G_K = G[X \cup \bigcup\{C \in \mathcal{C}_K\}]$ and $G_S = G[(V(G) \setminus V(G_K)) \cup X]$. We then compute Q and the coefficients λ_C for each component C of $G_S - X$, in time $2^{O(b(a+b)^2)}$. Then, we define the collection of graphs $\mathcal{C}_Q(G_S) = \{C'_q : q \in Q\}$, where $C'_q = C_q \cdot \sum_{C\in\mathcal{C}} \lambda_C(q)$ is C_q with the capacities scaled up by $\sum_{C\in\mathcal{C}} \lambda_C(q)$. The sparsifier is obtained by doing the Steiner-disjoint union of the graphs in $\mathcal{C}_Q(G_S)$ and G_K, that is, $H = G_K \uplus \biguplus_{C'_q\in\mathcal{C}_Q(G_S)} C'_q$.

The analysis follows similarly to Section 3.1, by applying Lemmas 4.4 and 4.5 to G_S.

▶ **Lemma 4.5 (*).** *Let G be a network with a separator $X \subseteq V(G)$ of size a and $|C| \le b$ for every component C of $G - X$.*

Then $H = G_K \uplus \biguplus_{C'_q\in\mathcal{C}_Q(G_S)} C'_q$ is a sparsifier for G of size at most $4^{b(a+b)^2}$.

5 Reduction Theorem for Bounded-Treewidth Graphs

In this section, we show that given a graph G with k terminals and a tree decomposition for G of width w, we can compute in linear time a sparsifier for G with size linear in k. In particular, by using as a black-box algorithm for computing a sparsifier with size $S(k)$ and quality $g(k)$, we obtain a sparsifier of size $O(k) \cdot S(2w)$ and quality $g(2w)$, which can be computed with $O(k)$ calls to the original sparsifier algorithm. The result is formalized in Theorem 5.1.

▶ **Theorem 5.1.** *Let $G = (V, E, u)$ be a network with terminal set K of size k. Let $S : \mathbb{N} \to \mathbb{N}$, $g \colon \mathbb{N} \to \mathbb{R}_{\geq 1}$ be functions such that every network (of treewidth w) has a quality-$g(k)$ cut (resp. flow) sparsifier of size $S(k)$.*

Then any network of treewidth at most w has a cut (resp. flow) sparsifier with quality $g(2w)$ and size $O(k) \cdot S(2w)$.

Furthermore, given a tree decomposition of width w, the sparsifier can be computed in time $O(nw)$ plus $O(k)$ calls to an algorithm computing sparsifiers on edge-disjoint subgraphs of G with at most $2w$ terminals.

As an immediate consequence of Theorem 5.1 and work on flow sparsifiers [9, 16, 30], we obtain the following corollary:

▶ **Corollary 5.2.** *Any network with treewidth at most w has a quality-$O(\log w)$ flow sparsifier of size $O(k \cdot w)$, which can be computed in polynomial time.*

Let $(T, \mathcal{B})$ be a tree decomposition for G of width w. We recall that we associate each edge with a single bag, and that we assume that no two identical bags exist.

Let $Y \subseteq V(T)$ be a subset of bags obtained as follows: first, for each terminal $t \in K$, add to Y a node $u \in V(T)$ containing t, i.e. $t \in B_u$; then add the lowest common ancestors of any two nodes Y to Y as well.

The algorithm first constructs the set Y, and then partitions T into a set of regions $\mathcal{R}(T, Y)$ as follows: consider the components of $T - Y$, and group them into regions according to their neighboring nodes. Finally, it returns the sparsifier $H = G[Y] \uplus \biguplus_{R \in \mathcal{R}(T,Y)} H_R$, where H_R is a sparsifier for the subgraph $G[R]$ with terminal set $G[R] \cap B(Y)$, computed using the black-box algorithm.

Since T has $O(n)$ nodes, constructing Y as well as the graphs $G[R]$ for every region can be done in time $O(nw)$, and computing the sparsifiers simply requires $|\mathcal{R}(T, Y)|$ calls to the given sparsifier algorithm. We remark that the calls to the sparsifier algorithm are run on subgraphs $G[R]$ for disjoint R, and thus induce edge-disjoint subgraphs of G.

We will now show that the size of Y and $\mathcal{R}(T, Y)$ is bounded, before showing that each $G[R]$ has a small sparsifier, and that all of these can be joined into H.

▶ **Lemma 5.3.** *There are at most $2k$ nodes in Y and $2|Y|$ regions in $\mathcal{R}(T, Y)$, with each region neighboring at most two nodes of Y.*

Proof. Let T' be the tree obtained from T by iteratively contracting every edge that does not connect to nodes in Y. T' has (at most) one node for every terminal in K, plus nodes for the lowest common ancestors. In particular, the nodes for the lowest common ancestors have at least 2 children, as they were added to Y because there are terminals in two of its children subtrees. As there are at most k nodes with at most 1 child, T' must have at most $2k - 1$ nodes.

We now show that every region neighbors at most two nodes of Y. Assume that there is a region R neighboring more than 2 nodes in Y. If there are two nodes u, v such that one is not the ancestor of the other, then their lowest common ancestor a is also in Y and in

R, since the u-v-path in T is contained in R. But then a is a cut in T which splits R into smaller regions, and thus R cannot be a region in $\mathcal{R}(T, Y)$. The remaining possibility is that the nodes neighboring R all are ancestors or descendants of one another, and thus are all contained in a root-leaf path in T. However, in that case, the middle points (not the highest or lowest neighbor of R) are all vertex cuts which would split R into smaller regions. We conclude that each region neighbors at most two nodes of Y, and that one is the parent of the other in T'.

As a consequence of the above, there can be at most $|Y|$ regions that have only a single node as neighbor, and $|Y|$ regions that have two neighbors in Y (a node u and its parent). ◀

We now show that we can apply a sparsifier to $G[R]$ to obtain a good sparsifier.

▶ **Lemma 5.4.** *Given $R \in \mathcal{R}(T, Y)$, its induced subgraph $G[R]$ with terminal set $G[R] \cap B(Y)$ has a sparsifier H_R of quality $g(2w)$ and size $S(2w)$.*

Proof. As G has treewidth w, any of its subgraphs has treewidth w as well. Thus, we only need to prove that $|G[R] \cap B(Y)| \le 2w$, as we assume that every graph of treewidth w has a quality-$g(k)$ sparsifier of size $S(k)$, with $k = |G[R] \cap B(Y)|$ for $G[R]$.

If R has only one neighbor $y \in V(T)$, then $|G[R] \cap B(Y)| = |G[R] \cap B_y| \le w + 1 \le 2w$, as the only neighboring bag to R is y and thus $G[R]$ and $G[T - R]$ only intersect in B_y.

Otherwise, R has two neighbors $y_1, y_2 \in V(T)$. Let u_1, u_2 be the nodes of R neighboring y_1, y_2, respectively. Notice that R must correspond to a single connected component of $T - Y$, as there is a single path connecting y_1 and y_2 in T, and thus y_1 and y_2 each have a single neighbor in R.

By the properties of the tree decomposition, any vertex v that is simultaneously in $G[R]$ and $G[T - R]$ must either be contained in B_{y_1} and B_{u_1}, or be contained in B_{y_2} and B_{u_2}, as the subtree induced by the bags containing v must connect R and $T - R$ and thus must contain the edge y_1u_1 or the edge y_2u_2. Since no two bags are the same, $|B_{y_1} \cap B_{u_1}| \le w$, $|B_{y_2} \cap B_{u_2}| \le w$, and thus $|G[R] \cap B(Y)| \le |B_{y_1} \cap B_{u_1}| + |B_{y_2} \cap B_{u_2}| \le 2w$. ◀

We complete the proof by taking the sparsifier $H = G[Y] \uplus \biguplus_{R \in \mathcal{R}(T,Y)} H_R$. H is a sparsifier for G because $G = G[Y] \uplus \biguplus_{R \in \mathcal{R}(T,Y)} G[R]$ and, by Lemma 5.4, each H_R is a sparsifier for $G[R]$, thus by (repeated application of) Lemma 2.3, H is a sparsifier for G with terminal set $B(Y) \supseteq K$. The size of H is at most $2k(w + 1) + 2kS(2w) = O(k) \cdot S(2w)$, by using Lemma 5.3 and it can be computed in running time $O(nw)$ plus $O(k)$ calls to edge-disjoint subgraphs of G.

Abstract

Which dynamic queries can be maintained efficiently? For constant-size changes, it is known that constant-depth circuits or, equivalently, first-order updates suffice for maintaining many important queries, among them reachability, tree isomorphism, and the word problem for context-free languages. In other words, these queries are in the dynamic complexity class DynFO. We show that most of the existing results for constant-size changes can be recovered for batch changes of polylogarithmic size if one allows circuits of depth $\mathcal{O}(\log \log n)$ or, equivalently, first-order updates that are iterated $\mathcal{O}(\log \log n)$ times.

1 Introduction

Dynamic descriptive complexity [23, 10] is a framework for studying the amount of resources that are necessary to *maintain* the result of a query when the input changes slightly, possibly using additional auxiliary data (which needs to be maintained as well). Its main class DynFO contains all queries for which the update of the query result (and possibly of further useful

auxiliary data) can be expressed in first-order logic FO. Equivalently[1], the updates can be computed using (DLOGTIME) uniform circuits with constant-depth and polynomial size that consist of $\neg$- as well as $\wedge$- and $\vee$-gates with unbounded fan-in, that is, within uniform AC^0.

It is known that many important queries can be maintained in DynFO if only one bit of the input changes in every step. This includes reachability for acyclic graphs [11, 23], undirected graphs [23, 12, 17], and general directed graphs [6], tree isomorphism [14] and every problem definable in monadic second-order logic MSO for graphs of bounded treewidth [8], all under insertions and deletions of single edges. Also, membership in context-free languages can be maintained under changes of single positions of the input word [15].

Some of these results have been extended to changes beyond single-bit changes: reachability in undirected graphs is in DynFO if simultaneously $\text{polylog}(n) = (\log n)^{\mathcal{O}(1)}$ edges can be inserted or deleted [7], where n is the size of the graph; regular languages are in DynFO under changes of $\text{polylog}(n)$ positions at once [24]. Reachability in directed graphs can be maintained under insertions and deletions of $\mathcal{O}(\frac{\log n}{\log\log n})$ many edges [9].

Thus, only for few problems it is known that changes of polylogarithmic size (or: even non-constant size) can be handled in DynFO, or, equivalently, by AC^0-updates. Trivially, if a problem can be maintained in DynFO under single-bit changes it can also be maintained under $\text{polylog}(n)$ changes using AC-circuits of $\text{polylog}(n)$-depth. This is achieved by processing the changed bits “sequentially” by “stacking” $\text{polylog}(n)$ copies of the constant-depth circuit for processing single-bit changes.

The starting point for the present paper is the question which problems can be maintained by AC-circuits of less than $\text{polylog}(n)$ depth under $\text{polylog}(n)$-sized changes, in particular which of the problems known to be in DynFO under single-bit changes. The answer is short: for almost all of them circuits of depth $\mathcal{O}(\log\log n)$ suffice.

A first observation is that directed reachability under polylogarithmic changes can be maintained by AC-circuits of depth $\mathcal{O}(\log\log n)$. This can be derived by analyzing the proof from [9] (see Section 3). For this reason, we introduce the dynamic complexity class[2] DynFOLL of problems that can be maintained using circuits with polynomial size and depth $\mathcal{O}(\log\log n)$ or, equivalently, by first-order formulas that are iterated $\mathcal{O}(\log\log n)$ times. We investigate its power when changes affect $\text{polylog}(n)$ input bits and prove that almost all problems known to be maintainable in DynFO for constant-size changes fall into this class for changes of $\text{polylog}(n)$-size, see Table 1. One important problem left open is whether all MSO-definable queries for bounded treewidth graphs can be maintained in DynFOLL under $\text{polylog}(n)$ changes. We present an intermediate result and show that tree decompositions can be maintained within DynFOLL (see Section 5).

This power of depth-$\mathcal{O}(\log\log n)$ update circuits came as a surprise to us. Statically, circuits of this depth and polynomial size still cannot compute the parity of n bits due to Håstad's famous lower bound for parity: depth-$(d+1)$ AC-circuits with alternating $\wedge$- and $\vee$-layers require $2^{\Omega(n^{1/d})}$ gates for computing parity (see, e.g., [20, Theorem 12.3]). Dynamically, while such update circuits are powerful for changes of non-constant size, they seem to provide not much more power for single-bit changes. As an example, the parity-exists query from [26] is conjectured to not be in DynFO, and it also cannot easily be seen to be in DynFOLL.

[1] assuming that first-order formulas have access to numeric predicates $\leq, +, \times$

[2] The class could equally well be called (uniform) $\mathsf{DynAC}[\log\log n]$. We opted for the name DynFOLL as it extends DynFO and its static variant was introduced as FOLL [2].

Table 1 Overview of results for DynFO and DynFOLL. Entries indicate the size of changes that can be handled by DynFO and DynFOLL programs, respectively.

regular languages	$(\log n)^{\mathcal{O}(1)}$	[24]	$(\log n)^{\mathcal{O}(\log\log n)}$	(Theorem 4)
context-free languages	$\mathcal{O}(1)$	[15]	$(\log n)^{\mathcal{O}(1)}$	(Theorem 9)

The obtained bounds are almost optimal. For all mentioned problems, DynFO can handle changes of size at most polylog(n) and DynFOLL can handle changes of size at most $(\log n)^{\mathcal{O}(\log\log n)}$. This is an immediate consequence of Håstad's lower bound for parity and standard reductions from parity to these problems. For the queries that are known to be maintainable under polylog(n) changes in DynFO, we show that they can be maintained under $(\log n)^{\mathcal{O}(\log\log n)}$ changes in DynFOLL.

Our results rely on two main techniques for handling changes of polylogarithmic size:

- In the *small-structure technique* (see Section 3), it is exploited that on structures of polylogarithmic size, depth-$\mathcal{O}(\log\log n)$ circuits have the power of NC^2 circuits. Dynamic programs that use this technique first construct a substructure of polylogarithmic size depending on the changes and the current auxiliary data, then perform a NC^2-computation on this structure, and finally combine the result with the rest of the current auxiliary data to obtain the new auxiliary data. This technique is a slight generalization of previously used techniques for DynFO.
- In the *hierarchical technique* (see Section 4), it is exploited that auxiliary data used in dynamic programs is often "composable". Dynamic programs that use this technique first construct polynomially many structures depending on the current auxiliary data, each of them associated with one of the changes (in some cases, known dynamic programs for single changes can be exploited for this step). Then, in $\mathcal{O}(\log\log n)$ rounds, structures are combined hierarchically such that after ℓ rounds the program has computed polynomially many structures, each associated with 2^ℓ changes.

2 Preliminaries and setting

We introduce some notions of finite model theory, circuit complexity and the dynamic complexity framework.

Finite model theory & circuit complexity. A (relational) schema σ is a set of relation symbols and constant symbols. A relational structure $\mathcal{S}$ over a schema σ consists of a finite domain D, relations $R^{\mathcal{S}} \subseteq D^k$ for every k-ary relation symbol $R \in \sigma$, and interpretations $c^{\mathcal{S}} \in D$ of every constant symbol $c \in \sigma$. We assume in this work that every structure has a linear order $\leq$ on its domain. We can therefore identify D with the set $\{0, \ldots, n-1\}$.

First-order logic FO is defined in the usual way. Following [19], we allow first-order formulas to access the linear order on the structures and corresponding relations $+$ and $\times$ encoding addition and multiplication. We write $\mathsf{FO}(\leq, +, \times)$ to make this explicit. $\mathsf{FO}(\leq, +, \times)$ can express iterated addition and iterated multiplication for polylogarithmically many numbers that consist of polylog(n) bits, see [18, Theorem 5.1].

First-order logic with $\leq, +, \times$ is equivalent to (DLOGTIME) uniform AC^0, the class of problems decidable by uniform families of constant-depth circuits with polynomially many "not"-, "and"- and "or"-gates with unbounded fan-in. We write $\mathsf{AC}[f(n)]$ for the class that allows for polynomial-sized circuits of depth $\mathcal{O}(f(n))$, where n is the number of input bits. For polynomially bounded and first-order constructible functions f, the class $\mathsf{AC}[f(n)]$ is equal to $\mathsf{IND}[f(n)]$, the class of problems that can be expressed by inductively applying an $\mathsf{FO}(\leq, +, \times)$ formula $\mathcal{O}(f(n))$ times [19, Theorem 5.22]. So, we can think of an $\mathsf{AC}[f(n)]$ circuit as being a stack of $\mathcal{O}(f(n))$ copies of some AC^0 circuit. The class FOLL, see [2], is defined as $\mathsf{IND}[\log \log n] = \mathsf{AC}[\log \log n]$.

The circuit complexity classes uniform NC^i and SAC^i are defined via uniform circuits of polynomial size and depth $\mathcal{O}((\log n)^i)$; besides "not"-gates, NC circuits use "and"- and "or"-gates with fan-in 2, SAC circuits allow for "or"-gates with unbounded fan-in.

Dynamic complexity. The goal of a *dynamic program* Π is to maintain the result of a query applied to an input structure $\mathcal{I}$ that is subject to changes. In this paper, we consider changes of the form $\textsc{ins}_R(P)$, the insertion of a set P of tuples into the relation R of $\mathcal{I}$, and $\textsc{del}_R(P)$, the deletion of the set P from R. We usually restrict the size of the set P to be bounded by a function $s(n)$, where n is the size of the domain of $\mathcal{I}$. Most of the time, the bound is polylogarithmic in n, so $s(n) = \log(n)^c$ for some constant c. A pair (Q, Δ) of a query Q and a set Δ of (size-bounded) change operation $\textsc{ins}_R, \textsc{del}_R$ is called a *dynamic query.*

To maintain some dynamic query over σ-structures, for some schema σ, Π stores and updates a set $\mathcal{A}$ of auxiliary relations over some schema σ_{aux} and over the same domain as the input structure. For every auxiliary relation symbol $A \in \sigma_{\text{aux}}$ and every change operation δ, Π has an update program $\varphi_\delta^A(\bar{x})$, which can access input and auxiliary relations. Whenever an input structure $\mathcal{I}$ is changed by a change $\delta(P)$, resulting in the structure $\mathcal{I}'$, the new auxiliary relation $A^{\mathcal{A}'}$ in the updated auxiliary structure $\mathcal{A}'$ consists of all tuples $\bar{a}$ such that $\varphi_\delta^A(\bar{a})$ is satisfied in the structure $(\mathcal{I}', \mathcal{A})$.

We say that a dynamic program Π *maintains* a dynamic query (Q, Δ), if after applying a sequence α of changes over Δ to an initial structure $\mathcal{I}_0$ and applying the corresponding update programs to $(\mathcal{I}_0, \mathcal{A}_0)$, where $\mathcal{A}_0$ is an initial auxiliary structure, a dedicated auxiliary relation is always equal to the result of evaluating Q on the current input structure. Following Patnaik and Immerman [23], we demand that the initial input structure $\mathcal{I}_0$ is *empty*, so, has empty relations. The initial auxiliary structure is over the same domain as $\mathcal{I}_0$ and is defined from $\mathcal{I}_0$ by some first-order definable initialization.

The class DynFO is the class of all dynamic queries that are maintained by a dynamic program with $\mathsf{FO}(\leq, +, \times)$ formulas as update programs[3]. Equivalently, we can think of the update programs as being AC^0 circuits. The class $\mathsf{DynFO}[f(n)]$ allows for $\mathsf{AC}[f(n)]$ circuits as update programs. We often use the equivalence $\mathsf{AC}[f(n)] = \mathsf{IND}[f(n)]$ and think of update programs that apply an $\mathsf{FO}(\leq, +, \times)$ update formula $f(n)$ times. In this paper, we are particularly interested in the class $\mathsf{DynFOLL} = \mathsf{DynFO}[\log \log n]$.

3 The small-structure technique

The small-structure technique has been used for obtaining maintenance results for DynFO for non-constant size changes [7, 24]. The idea is simple: for changes of size m, (1) compute a structure with a domain of size roughly m, depending on the changes and the current auxiliary data, then (2) compute information about this structure (as $m \ll n$, this computation can be more powerful than AC^0), and (3) combine the result with the current auxiliary data to obtain the new auxiliary data.

For DynFO and changes of polylogarithmic size, one can use SAC^1-computations in step (2), as formalized in the next lemma.

▶ **Lemma 1** ([24, Corollary 3]). *Let Q be a k-ary query on σ-structures, for some $k \in \mathbb{N}$. If Q is uniform SAC^1-computable, then there is an $\mathsf{FO}(\leq, +, \times)$ formula φ over schema $\sigma \cup \{C\}$ such that for any σ-structure $\mathcal{S}$ with n elements, any subset C of its domain of size* $\text{polylog}(n)$ *and any k-tuple $\bar{a} \in C^k$ it holds that: $\bar{a} \in Q(\mathcal{S}[C])$ if and only if $(\mathcal{S}, C) \models \varphi(\bar{a})$. Here, $\mathcal{S}[C]$ denotes the substructure of $\mathcal{S}$ induced by C.*

For DynFOLL, this generalizes in two directions: (a) for structures of size $\text{polylog}(n)$ one can use NC^2-computations, (b) for structures of size $(\log n)^{\mathcal{O}(\log \log n)}$ one can use SAC^1-computations. This is captured by the following lemma.

▶ **Lemma 2.** *Let Q be a k-ary query on σ-structures, for some $k \in \mathbb{N}$.*

(a) *If Q is uniform NC^2-computable, then there is an FOLL formula φ over schema $\sigma \cup \{C\}$ such that for any σ-structure $\mathcal{S}$ with n elements, any subset C of its domain of size* $\text{polylog}(n)$ *and any k-tuple $\bar{a} \in C^k$ it holds that: $\bar{a} \in Q(\mathcal{S}[C])$ if and only if $(\mathcal{S}, C) \models \varphi(\bar{a})$.*

(b) *If Q is uniform SAC^1-computable, then there is an FOLL formula φ over schema $\sigma \cup \{C\}$ such that for any σ-structure $\mathcal{S}$ with n elements, any subset C of its domain of size $(\log n)^{\mathcal{O}(\log \log n)}$ and any k-tuple $\bar{a} \in C^k$ it holds that: $\bar{a} \in Q(\mathcal{S}[C])$ if and only if $(\mathcal{S}, C) \models \varphi(\bar{a})$.*

Proof.

(a) Let C have size m, which is polylogarithmically bounded in n. The NC^2-circuit for Q has polynomial size in m and depth $\mathcal{O}((\log m)^2)$, so its size is polylogarithmic in n and the depth is $\mathcal{O}((\log \log n)^2)$. It is well-known[4] that for every NC-circuit of depth $f(n)$ there is an equivalent AC-circuit of depth $\mathcal{O}(\frac{f(n)}{\log \log n})$ and size polynomial in the original circuit, so we can obtain an AC-circuit for answering Q on C with depth $\mathcal{O}(\log \log n)$.

[3] Other papers write DynFO for the class that uses FO update formulas without a priori access to the arithmetic relations $\leq, +, \times$ and $\mathsf{DynFO}(\leq, +, \times)$ for the class that uses $\mathsf{FO}(\leq, +, \times)$ update formulas. If changes only affect single tuples, there is no difference for most interesting queries, see [6, Proposition 7]. For changes that affect sets of tuples of non-constant size, all DynFO maintainability results use $\mathsf{FO}(\leq, +, \times)$ update formulas, as FO update formulas without arithmetic are not strong enough to maintain interesting queries. We therefore just write DynFO and omit the suffix $(\leq, +, \times)$ to avoid visual clutter.

[4] Divide the circuit into layers of depth $\log \log n$. Each layer depends only on $\log n$ gates of the previous layer, as each gate has fan-in at most 2, and can be replaced by a constant-depth circuit for the CNF of the layer, which has polynomial size.

(b) The proof of [1, Lemma 8.1] can easily be extended towards the following statement: if a language L is decided by a non-deterministic Turing machine with polynomial time bound m^c and polylogarithmic space bound $(\log m)^d$ then for every positive, non-decreasing and first-order constructible function $t(n)$ there is a uniform AC circuit family for L with depth $\mathcal{O}(t(n))$ and size $2^{\mathcal{O}(m^{\frac{c}{t(n)}}(\log m)^d)}$. For $m = \log n^{e \log\log n}$ and $t(n) = 2ce \log\log n$, the size is exponential in $\sqrt{\log n}\,(\log\log n)^{\mathcal{O}(1)}$, and therefore, as this function grows slower than $\log n$, polynomial in n. The statement follows as all SAC^1 languages can be decided by a non-deterministic Turing machine with polynomial time bound and space bounded by $(\log n)^2$, see [4]. ◀

A straightforward application of the technique to dynamic programs from the literature yields the following DynFOLL-programs. For directed reachability, adapting the DynFO-program for $\mathcal{O}(\frac{\log n}{\log\log n})$ changes from [9] yields (with more proof details in the full version):

▶ **Theorem 3.** *Reachability in directed graphs is in* DynFOLL *under insertions and deletions of* $\text{polylog}(n)$ *edges.*

For undirected reachability and regular languages, replacing Lemma 1 by Lemma 2(b) in the DynFO maintainability proofs for $\text{polylog}(n)$ changes from [7, 24] directly yields:

▶ **Theorem 4.**

(a) *Reachability in undirected graphs is in* DynFOLL *under insertions and deletions of* $(\log n)^{\mathcal{O}(\log\log n)}$ *edges.*

(b) *Membership in regular languages is in* DynFOLL *under symbol changes at* $(\log n)^{\mathcal{O}(\log\log n)}$ *positions.*

The small-structure technique has further applications beyond graph reachability and regular languages. We mention a few here. The proofs are deferred to the full version.

▶ **Theorem 5.**

(a) *A minimum spanning forest for weighted graphs can be maintained*

  (i) *in* DynFO *under changes of* $\text{polylog}(n)$ *edges, and*

  (ii) *in* DynFOLL *under changes of* $(\log n)^{\mathcal{O}(\log\log n)}$ *edges.*

(b) *A maximal matching can be maintained in* DynFOLL *under changes of* $\text{polylog}(n)$ *edges.*

(c) *For graphs with maximum degree bounded by a constant* δ*, a proper* $(\delta+1)$*-colouring can be maintained in* DynFO *under changes of* $\text{polylog}(n)$ *edges.*

4 The hierarchical technique

In this section we describe and use a simple, yet powerful hierarchical technique for handling polylogarithmic changes in DynFOLL. After changing $m \overset{\text{def}}{=} (\log n)^c$ many tuples, auxiliary data $\mathcal{R}^1, \ldots, \mathcal{R}^k$ is built in $k \overset{\text{def}}{=} d \log\log n$ rounds, for suitable d. The auxiliary data $\mathcal{R}^{\ell-1}$ after round $\ell - 1$ encodes information for certain subsets of the changes of size $2^{\ell-1}$. This information is then combined, via first-order formulas, to information on 2^ℓ changes in round ℓ. The challenge for each concrete dynamic query is to find suitable auxiliary data which is defined depending on a current instance as well as on subsets of changes, and can be combined via first-order formulas to yield auxiliary data for larger subsets of changes.

We apply this approach to maintaining distances in acyclic and undirected graphs, context-free language membership, and tree-isomorphism under polylogarithmic changes. In these applications of the hierarchical technique, information is combined along paths, binary trees, and arbitrary trees, respectively.

4.1 Undirected and acyclic reachability and distances

The articles that introduced the class DynFO showed that reachability for undirected and for acyclic graphs is in DynFO under single-edge changes [10, 23]. For these classes of graphs, also distances, that is, the number of edges in a shortest path between two reachable nodes, can be maintained. For undirected graphs, this was proven in [17], for acyclic graphs it is a straightforward extension of the proof for reachability from [10].

While reachability for undirected graphs is in DynFO under polylogarithmically many edge changes [7], we only know the general $\mathcal{O}(\frac{\log n}{\log \log n})$ bound for acyclic graphs [9]. It is unknown whether distances can be maintained in DynFO under changes of non-constant size, both for undirected and for directed, acyclic graphs.

▶ **Theorem 6.** *Distances can be maintained in* DynFOLL *under insertions and deletions of* $\text{polylog}(n)$ *edges for*

(a) *undirected graphs,*

(b) *acyclic directed graphs.*

To maintain distances, a dynamic programs can use a relation of the form $\text{DIST}(u, v, d)$ with the meaning "the shortest path from u to v has length d". The proof of Theorem 6 is then a direct application of the hierarchical technique on paths. After inserting polylogarithmically many edges, distance information for two path fragments can be iteratively combined to distance information for paths fragments that involve more changed edges. Thus $\text{polylog}\, n$ path fragments (coming from so many connected components before the insertion) can be combined in $\log \log n$ many iterations.

To handle edge deletions, we observe that some distance information is still guaranteed to be valid after the deletion: the shortest path from u to v surely has still length d after the deletion of some edge e if there was no path of length d from u to v that used e. These "safe" distances can be identified using the DIST relation. We show that after deleting polylogarithmically many edges, shortest paths can be constructed from polylogarithmically many "safe" shortest paths of the original graph. We make this formal now.

▶ **Lemma 7.** *Let $G = (V, E)$ be an undirected or acyclic graph, $e \in E$ an edge and $u, v \in V$ nodes such that there is a path from u to v in $G' = (V, E - e)$. For every shortest path $u = w_0, w_1, \dots, w_{d-1}, w_d = v$ from u to v in G' there is an edge (w_i, w_{i+1}) such that no shortest path from u to w_i and no shortest path from w_{i+1} to v in the original graph G uses e.*

Proof. For undirected graphs, this was proven in [22, Lemma 3.5c]. We give the similar proof for acyclic graphs. If no node w_{i+1} on a shortest path $u = w_0, w_1, \dots, w_{d-1}, w_d = v$ from u to v in G' exists such that some shortest path from u to w_{i+1} in G uses the edge e, the edge (w_{d-1}, v) satisfies the lemma statement. Otherwise, let w_{i+1} be the first such node on the path. It holds $i + 1 \geq 1$, as the shortest path from u to u trivially does not use e. So, no shortest path from u to w_i in G uses e. There is no shortest path from w_{i+1} to v in G that uses e: otherwise, there would be a path from e to w_{i+1} and a path from w_{i+1} to e in G, contradicting the assumption that G is acyclic. ◀

▶ **Corollary 8.** *Let $G = (V, E)$ be an undirected or acyclic graph and $\Delta E \subseteq E$ with $|\Delta E| = m$. For all nodes u and v such that v is reachable from u in $G' \overset{\text{def}}{=} (V, E \setminus \Delta E)$ there is a shortest path in G' from u to v that is composed of at most m edges and $m + 1$ shortest paths of G, each from some node u_i to some node v_i for $i \leq m + 1$, such that no shortest path from u_i to v_i in G uses an edge from ΔE.*

Proof idea. Via induction over m. For $m = 1$, this follows from Lemma 7. For $m > 1$ this is immediate from the induction hypothesis. ◀

We can now prove that distances in undirected and in acyclic graphs can be maintained in DynFOLL under changes of polylogarithmic size.

Proof of Theorem 6. We construct a DynFOLL program that maintains the auxiliary relation $\textsc{dist}(u, v, d)$ with the meaning "the shortest path from u to v has length d".

Suppose $m \stackrel{\text{def}}{=} (\log n)^c$ edges ΔE are changed in $G = (V, E)$ yielding the graph $G' = (V, E')$. W.l.o.g. all edges in ΔE are either inserted or deleted. In both cases, the program executes a first-order initialization, yielding auxiliary relations $\textsc{dist}^0(u, v, d)$, and afterwards executes a first-order procedure for $k \stackrel{\text{def}}{=} c \log\log n$ rounds, yielding auxiliary relations $\textsc{dist}^1, \ldots, \textsc{dist}^k$. The superscripts on the relations are for convenience, they are all subsequently stored in $\textsc{dist}$.

For insertions, we use the standard inductive definition of reachability and distances. Set $\textsc{dist}^0(u, v, d) \stackrel{\text{def}}{=} \textsc{dist}(u, v, d)$, where $\textsc{dist}(u, v, d)$ is the distance information of the unchanged graph G. Then, for k rounds, the distance information is combined with the new edges ΔE, doubling the amount of used edges from ΔE in each round. Thus $\textsc{dist}^\ell(u, v, d)$ is computed from $\textsc{dist}^{\ell-1}$ by including $\textsc{dist}^{\ell-1}$ and all tuples which satisfy the formula:

$$\varphi_{\text{INS}} \stackrel{\text{def}}{=} \exists z_1 \exists z_2 \exists d_1 \exists d_2 (\Delta E(z_1, z_2) \wedge d_1 + d_2 + 1 = d \wedge \textsc{dist}^{\ell-1}(u, z_1, d_1) \wedge \textsc{dist}^{\ell-1}(z_2, v, d_2))$$

For deletions, the program starts from shortest paths $u, \ldots, v$ in G such that no shortest path from u to v uses edges from ΔE and then combines them for k rounds, which yields the correct distance information for G' according to Corollary 8. Thus, the first-order initialization yields $\textsc{dist}^0(u, v, d)$ via

$$\textsc{dist}(u, v, d) \wedge \neg \exists z_1 \exists z_2 \exists d_1 \exists d_2 (d = d_1 + d_2 + 1 \wedge \Delta E(z_1, z_2) \wedge \textsc{dist}(u, z_1, d_1) \wedge \textsc{dist}(z_2, v, d_2))$$

Then $\textsc{dist}^\ell(u, v, d)$ is computed from $\textsc{dist}^{\ell-1}(u, v, d)$ via a formula similar to φ_{INS}, using E instead of ΔE. ◀

4.2 Context-free language membership

Membership problems for formal languages have been studied in dynamic complexity starting with the work of Gelade, Marquardt, and Schwentick [15]. It is known that context-free languages can be maintained in DynFO under single symbol changes [15] and that regular languages can even be maintained under polylog changes [25, 24].

It is an open problem whether membership in a context-free language can be maintained in DynFO for changes of non-constant size. We show that this problem is in DynFOLL under changes of polylogarithmic size.

▶ **Theorem 9.** *Every context-free language can be maintained in* DynFOLL *under changes of size* polylog n.

Suppose $G = (V, \Sigma, S, \Gamma)$ is a grammar in Chomsky normal form with $L \stackrel{\text{def}}{=} L(G)$. For single changes, 4-ary auxiliary relations $R_{X \to Y}$ are used for all $X, Y \in V$ [15], with the intention that $(i_1, j_1, j_2, i_2) \in R_{X \to Y}$ iff $X \Rightarrow^* w[i_1, j_1) Y w(j_2, i_2]$, where $w \stackrel{\text{def}}{=} w_1 \ldots w_n$ is the current string. Let us call $I = (i_1, j_1, j_2, i_2)$ a *gapped interval*. For a gapped interval I and a set P of changed positions, denote by $\#(I, P)$ the number of changed positions $p \in P$ with $p \in [i_1, j_1) \cup (j_2, i_2]$.

The idea for the DynFOLL program for handling polylog changes is simple and builds on top of the program for single changes. It uses the same auxiliary relations and, after changing a set P of positions, it collects gapped intervals I into the relations $R_{X\to Y}$ for increasing $\#(I,P)$ in at most $\mathcal{O}(\log\log n)$ rounds. Initially, gapped intervals with $\#(I,P)\leq 1$ are collected using the first-order update formulas for single changes. Afterwards, in each round, gapped intervals I with larger $\#(I,P)$ are identified by splitting I into two gapped intervals I_1 and I_2 with $\#(I,P)=\#(I_1,P)+\#(I_2,P)$ such that I can be constructed from I_1 and I_2 with a first-order formula.

To ensure that $\mathcal{O}(\log\log n)$ many rounds suffice, we need that the intervals I_1 and I_2 can always be chosen such that $\#(I_1,P)$ and $\#(I_2,P)$ are of similar size. This will be achieved via the following simple lemma, which will be applied to parse trees. For a binary tree $T=(V,E)$ with red coloured nodes $R\subseteq V$, denote by $\#(T,R)$ the number of red nodes of T. For a tree T and a node v, let T_v be the subtree of T rooted at v.

▶ **Lemma 10.** *For all rooted binary trees $T=(V,E,r)$ with red coloured nodes $R\subseteq V$, there is a node $v\in V$ such that:*

- $\#(T_v,R)\leq\frac{2}{3}\cdot\#(T,R)$ *and*
- $\#(T\setminus T_v,R)\leq\frac{2}{3}\cdot\#(T,R)$

Proof idea. Walk down the tree starting from its root by always choosing the child whose subtree contains more red coloured nodes. Stop as soon as the conditions are satisfied. ◀

We now provide the detailed proof of Theorem 9.

Proof (of Theorem 9). We construct a DynFOLL program that maintains the auxiliary relations $R_{X\to Y}$ for all $X,Y\in V$. Suppose $m\overset{\text{def}}{=}(\log n)^c$ positions P are changed. The program executes a first-order initialization, yielding auxiliary relations $R^0_{X\to Y}$, and afterwards executes a first-order procedure for $k\overset{\text{def}}{=}d\log\log n$ rounds, for $d\in\mathbb{N}$ chosen such that $(\frac{3}{2})^k>m$, yielding auxiliary relations $R^1_{X\to Y},\dots,R^k_{X\to Y}$. The superscripts on the relations are for convenience, they are all subsequently stored in $R_{X\to Y}$.

For initialization, the DynFOLL program includes gapped intervals (i_1,j_1,j_2,i_2) into the relations $R^0_{X\to Y}$ for which

- no position in $[i_1,j_1)\cup(j_2,i_2]$ has changed and (i_1,j_1,j_2,i_2) was previously in $R_{X\to Y}$, or
- exactly one position in $[i_1,j_1)\cup(j_2,i_2]$ has changed and the dynamic program for single changes from [15] includes the tuple (i_1,j_1,j_2,i_2) into $R_{X\to Y}$.

Afterwards, for k rounds, the DynFOLL program applies the following first-order definable procedure to its auxiliary relations. A gapped interval $I=(i_1,j_1,j_2,i_2)$ is included into $R^\ell_{X\to Y}$ in round ℓ if it was included in $R^{\ell-1}_{X\to Y}$ or one of the following conditions hold (see Figure 1 for an illustration):

(a) There are gapped intervals $I_1=(i_1,u_1,u_2,j_2)$ and $I_2=(u_1,j_1,j_2,u_2)$ and a non-terminal $Z\in V$ such that $I_1\in R^{\ell-1}_{X\to Z}$ and $I_2\in R^{\ell-1}_{Z\to Y}$. This can be phrased as first-order formula as follows:

$$\varphi_a\overset{\text{def}}{=}\exists u_1,u_2\Bigg[(i_1\leq u_1\leq j_1\leq j_2\leq u_2\leq i_2)\wedge\bigvee_{Z\in V}\Big(R_{X\to Z}(i_1,u_1,u_2,i_2)\wedge R_{Z\to Y}(u_1,j_1,j_2,u_2)\Big)\Bigg]$$

Figure 1 Illustration of when a gapped interval (i_1, j_1, j_2, i_2) is added to $R_{X\to Y}$ in the proof of Theorem 9.

(b) There are gapped intervals $I_1 = (i_1, v_1, v_3, i_2)$, $I_2 = (v_1, u_1, u_2, v_2)$, and $I_3 = (v_2, j_1, j_2, v_3)$ and non-terminals $Z, Z_1, Z_2, Z' \in V$ such that $Z \to Z_1Z_2 \in \Gamma$ and $I_1 \in R^{\ell-1}_{X\to Z}$, $I_2 \in R^{\ell-1}_{Z_1\to Z'}$, $I_3 \in R^{\ell-1}_{Z_2\to Y}$ and $w[u_1, u_2]$ can be derived from Z'. This can be phrased as first-order formula as follows:

$$\varphi_b \overset{\text{def}}{=} \exists u_1, u_2, v_1, v_2, v_3 \Bigg[(i_1 \leq v_1 \leq u_1 \leq u_2 \leq v_2 \leq j_1 \leq j_2 \leq v_3 \leq i_2) \land \bigvee_{\substack{Z,Z_1,Z_2,Z'\in V\\ Z\to Z_1Z_2\in\Gamma}} \Big(R_{X\to Z}(i_1, v_1, v_3, i_2) \land R_{Z_1\to Z'}(v_1, u_1, u_2, v_2) \land R_{Z'}(u_1, u_2) \land R_{Z_2\to Y}(v_2, j_1, j_2, v_3) \Big) \Bigg]$$

Here, $R_{Z'}(u_1, u_2)$ is an abbreviation for the formula stating that $w[u_1, u_2]$ can be derived from Z', i.e. $R_{Z'}(u_1, u_2) \overset{\text{def}}{=} \exists v \bigvee_{W\to\sigma\in\Gamma} (R_{Z'\to W}(u_1, v, v, u_2) \land \sigma(v))$.

(c) Symmetrical to (b), with gapped intervals $I_1 = (i_1, v_1, v_3, i_2)$, $I_2 = (v_1, j_1, j_2, v_2)$, and $I_3 = (v_2, u_1, u_2, v_3)$ and non-terminals $Z, Z_1, Z_2, Z' \in V$ such that $Z \to Z_1Z_2 \in \Gamma$ and $I_1 \in R^{\ell-1}_{X\to Z}$, $I_2 \in R^{\ell-1}_{Z_1\to Y}$, $I_3 \in R^{\ell-1}_{Z_2\to Z'}$ and $w[u_1, u_2]$ can be derived from Z'.

Note that $\#(I, P) = \#(I_1, P) + \#(I_2, P)$ in case (a) and $\#(I, P) = \#(I_1, P) + \#(I_2, P) + \#(I_3, P)$ in cases (b) and (c). Using Lemma 10, the intervals I_j can be chosen such that $\#(I_j, P) \leq \frac{2}{3} \cdot \#(I, P)$ and thus k rounds suffice. ◀

It is known that for single tuple changes one can maintain for edge-labeled, acyclic graphs whether there is a path between two nodes with a label sequence from a fixed context-free language [21]. The techniques we have seen can be used to also lift this result to changes of polylogarithmic size.

▶ **Proposition 11.** *Context-free path queries can be maintained under changes of polylogarithmic size in* DynFOLL *on acyclic graphs.*

4.3 Tree isomorphism

The dynamic tree isomorphism problem – given a forest $F = (V, E)$ and two nodes $x, x^* \in V$, are the subtrees rooted at x and x^* isomorphic? – has been shown to be maintainable in DynFO under single edge insertions and deletions by Etessami [14].

It is not known whether tree isomorphism can be maintained in DynFO under changes of size $\omega(1)$. We show that it can be maintained in DynFOLL under changes of size $\text{polylog}\, n$:

▶ **Theorem 12.** *Tree isomorphism can be maintained in* DynFOLL *under insertion and deletion of* polylog n *edges.*

Intuitively, we want to use Etessami's dynamic program as the base case for a DynFOLL-program: (1) compute isomorphism information for pairs of subtrees in which only one change happened, then (2) combine this information in $\log\log n$ many rounds. Denote by $\text{subtree}_x(r)$ the subtree rooted at r, in the tree rooted at x, within the forest F. The main ingredient in Etessami's program is a 4-ary auxiliary relation T-ISO for storing tuples (x, r, x^*, r^*) such that $\text{subtree}_x(r)$ and $\text{subtree}_{x^*}(r^*)$ are isomorphic and disjoint in F. It turns out that this information is not "composable" enough for step (2).

We therefore slightly extend the maintained auxiliary information. A *(rooted) context* $C = (V, E, r, h)$ is a tree (V, E) with root $r \in V$ and one distinguished leaf $h \in V$, called the *hole*. Two contexts $C = (V, E, r, h)$, $C^* = (V^*, E^*, r^*, h^*)$ are isomorphic if there is a root- and hole-preserving isomorphism between them, i.e. an isomorphism that maps r to r^* and h to h^*. For a forest F and nodes x, r, h occurring in this order on some path, the context $C(x, r, h)$ is defined as the context we obtain by taking $\text{subtree}_x(r)$, removing all children of h, and taking r as root and h as hole. Our dynamic program uses

- a 6-ary auxiliary relation C-ISO for storing tuples $(C, C^*) \overset{\text{def}}{=} (x, r, h, x^*, r^*, h^*)$ such that the contexts $C \overset{\text{def}}{=} C(x, r, h)$ and by $C^* \overset{\text{def}}{=} C(x^*, r^*, h^*)$ are disjoint and isomorphic,
- a ternary auxiliary relation DIST for storing tuples (x, y, d) such that the distance between nodes x and y is d, and
- a 4-ary auxiliary relation #ISO-SIBLINGS for storing tuples (x, r, y, m) such that y has m isomorphic siblings within $\text{subtree}_x(r)$.

The latter two relations have also been used by Etessami. From distances, a relation PATH(x, y, z) with the meaning "y is on the unique path between x and z" is FO-definable on forests, see [14]. The relation T-ISO(x, r, x^*, r^*) can be FO-defined from C-ISO.

We will now implement the steps (1) and (2) with these adapted auxiliary relations. Suppose a forest $F \overset{\text{def}}{=} (V, E)$ is changed into the forest $F' \overset{\text{def}}{=} (V, E')$ by changing a set ΔE of edges. A node $v \in V$ is *affected* by the change, if v is adjacent to some edge in ΔE. The DynFOLL program iteratively collects isomorphic contexts C and C^* of F' with more and more affected nodes. Denote by $\#(C, C^*, \Delta E)$ the number of nodes in contexts C and C^*, excluding hole nodes, affected by change ΔE.

The following lemma states that C-ISO can be updated for pairs of contexts with at most one affected node each. Its proof is very similar to Etessami's proof.

▶ **Lemma 13.** *Given* C-ISO, DIST, *and* #ISO-SIBLINGS *and a set of changes* ΔE, *the set of pairs* (C, C^*) *of contexts such that* C, C^* *are disjoint and isomorphic and such that both* C *and* C^* *contain at most one node affected by* ΔE *is* FO-*definable.*

The dynamic program will update the auxiliary relation C-ISO for contexts with at most one affected node per context using Lemma 13. Isomorphic pairs (C, C^*) of contexts with larger $\#(C, C^*, \Delta E)$ are identified by splitting both C and C^* into smaller contexts.

The splitting is done such that the smaller contexts have fewer than $\frac{2}{3} \cdot \#(C, C^*, \Delta E)$ affected nodes. To this end, we will use the following simple variation of Lemma 10. For a tree $T = (V, E)$ and a function $p : V \to \{0, 1, 2\}$ which assigns each a node number of pebbles, let $\#(T, p)$ be the total number of pebbles assigned to nodes in T.

▶ **Lemma 14.** *Let T be a tree of unbounded degree and p such that either (i) $\#(T, p) > 2$, or (ii) $\#(T, p) = 2$ and $p(v) \leq 1$ for all $v \in V$. Then there is a node v such that either:*

(1) $\#(T \setminus T_v, p) \leq \frac{2}{3} \cdot \#(T, p)$ *and* $\#(T_v, p) \leq \frac{2}{3} \cdot \#(T, p)$*, or*

(2) $\#(T \setminus T_v, p) \leq \frac{1}{3} \cdot \#(T, p)$ *and* $\#(T_u, p) \leq \frac{1}{3} \cdot \#(T, p)$ *for any child u of v.*

Proof idea. Use the same approach as for Lemma 10. If no node v of type (1) is found, a node of type (2) must exist. ◀

We now prove that tree isomorphism can be maintained in DynFOLL under changes of polylogarithmic size.

Proof (of Theorem 12). We construct a DynFOLL program that maintains the auxiliary relations C-ISO, DIST, and #ISO-SIBLINGS. Suppose $m \overset{\text{def}}{=} (\log n)^c$ edges ΔE are changed. As a preprocessing step, the auxiliary relation DIST is updated in depth $\mathcal{O}(\log\log n)$ via Theorem 6. Then, C-ISO is updated by first executing a first-order initialization for computing an initial version C-ISO^0. Afterwards a first-order procedure is executed for $k \overset{\text{def}}{=} d \log\log n$ rounds, for $d \in \mathbb{N}$ chosen such that $(\frac{3}{2})^k > m$, yielding auxiliary relations $\{\text{C-ISO}^\ell\}_{\ell \le k}$ and $\{\#\text{ISO-SIBLINGS}^\ell\}_{\ell \le k}$. The superscripts on the relations are for convenience, they are all subsequently stored in C-ISO, DIST, and #ISO-SIBLINGS.

The goal is that after the ℓth round

- C-ISO^ℓ contains all pairs C, C^* with $\#(C, C^*, \Delta E) \le (\frac{3}{2})^\ell$ which are isomorphic and disjoint, and
- $\#\text{ISO-SIBLINGS}^\ell$ contains the number of isomorphic siblings identified so far (i.e., with respect to C-ISO^ℓ).

Round ℓ first computes C-ISO^ℓ with a first-order procedure, and afterwards computes $\#\text{ISO-SIBLINGS}^\ell$. For initialization, the DynFOLL program first computes C-ISO^0, using Lemma 13, and $\#\text{ISO-SIBLINGS}^0$. Afterwards, for k rounds, the DynFOLL program combines known pairs of isomorphic contexts into pairs with more affected nodes and adapts C-ISO and #ISO-SIBLINGS accordingly.

Computing C-ISO$^\ell$. In the ℓth round, the program tests whether contexts $C \overset{\text{def}}{=} C(x, r, h)$ and $C^* \overset{\text{def}}{=} C(x^*, r^*, h^*)$ with $\#(C, C^*, \Delta E) \le (\frac{3}{2})^\ell$ are isomorphic by splitting both C and C^* into contexts with fewer affected nodes. The splitting is done by selecting suitable nodes $z \in C$ and $z^* \in C^*$, and splitting the context depending on these nodes.

We first provide some intuition of how z and z^* are intended to be chosen. Suppose C and C^* are isomorphic via isomorphism π. With the goal of applying Lemma 14, let p be the function that assigns to each non-hole node v of C a number of pebbles from $\{0, 1, 2\}$ indicating how many of the two nodes v and $\pi(v)$ have been affected by the change ΔE. Note that if (C, p) does not fulfill the precondition of Lemma 14, then (C, C^*) must have already been included in C-ISO^0 during the initialization. Therefore, assume the precondition holds for (C, p). Let C_z denote the subcontext of C rooted at z. Now, applying Lemma 14 to (C, p) yields a node z such that one of the following cases holds:

(1) $\#(C \setminus C_z, p) \le \frac{2}{3} \cdot \#(C, p)$ and $\#(C_z, p) \le \frac{2}{3} \cdot \#(C, p)$, or

(2) $\#(C \setminus C_z, p) \le \frac{1}{3} \cdot \#(C, p)$ and $\#(C_u, p) \le \frac{1}{3} \cdot \#(C, p)$ for any child u of z.

Intuitively our first-order procedure tries to guess this node z and its image $z^* \overset{\text{def}}{=} \pi(z)$ and split the contexts C and C^* at these nodes.

For testing that C and C^* are isomorphic, the program guesses two nodes z and z^* and (disjunctively) chooses case (1) or (2). Note that the program cannot be sure that it has correctly guessed z and z^* according to the above intuition. For this reason, the program first tests that the size restrictions from the chosen case (1) or (2) are fulfilled, which is easily possible in $\mathsf{FO}(\le, +, \times)$ as there are at most polylogarithmically many affected nodes. Since $\#(C, C^*, \Delta E) \le \left(\frac{3}{2}\right)^\ell$, this ensures that, by induction, $\text{C-ISO}^{\ell-1}$ is fully correct for all pairs of contexts that will be compared when testing isomorphism of C and C^*. Note that in case (2) the subtrees of any pair of children u_1 and u_2 of z have at most $\frac{2}{3} \cdot \#(C, C^*, \Delta E)$ affected nodes.

Next, the procedure tests that there is an isomorphism between C and C^* that maps z to z^*. The following claim is used:

▷ Claim 15. Suppose z and z^* are nodes in C and C^* that satisfy Condition (1) or (2) with children $Z \uplus Y$ and $Z^* \uplus Y^*$, respectively, with $|Y| = |Y^*|$ constant. Then a first-order formula can test whether there is an isomorphism between the forests $\{\text{subtree}_z(u) \mid u \in Z\}$ and $\{\text{subtree}_{z^*}(u^*) \mid u^* \in Z^*\}$ using the relations $\textsc{c-iso}^{\ell-1}$ and $\#\textsc{iso-siblings}^{\ell-1}$.

Proof. The forests are isomorphic iff for each $u \in Z$ there is a $u^* \in Z^*$ such that $\text{subtree}_z(u) \cong \text{subtree}_{z^*}(u^*)$ and such that the number of nodes $v \in Z$ with $\text{subtree}_z(u) \cong \text{subtree}_z(v)$ is the same as the number of nodes v^* with subtrees $\text{subtree}_{z^*}(u^*) \cong \text{subtree}_{z^*}(v^*)$, and vice versa with roles of u and u^* swapped.

Because z and z^* satisfy condition (1) or (2), $\textsc{c-iso}^{\ell-1}$ is correct on the forest $\{\text{subtree}_z(u) \mid u \in Z\} \cup \{\text{subtree}_{z^*}(u^*) \mid u^* \in Z^*\}$ by induction. Additionally, $\#\textsc{iso-siblings}^{\ell-1}$ is consistent with $\textsc{c-iso}^{\ell-1}$ by induction. From $\textsc{c-iso}^{\ell-1}$, the tree isomorphism relation $\textsc{t-iso}^{\ell-1}$ – storing tuples (x, r, x^*, r^*) such that $\text{subtree}_x(r)$ and $\text{subtree}_{x^*}(r^*)$ are isomorphic and disjoint – is FO-definable.

For testing whether a node $u \in Z$ satisfies the above condition, a first-order formula existentially quantifies a node $u^* \in Z^*$ and checks that $\textsc{t-iso}^{\ell-1}(z, u, z^*, u^*)$. The number of isomorphic siblings of u, u^* is compared using $\#\textsc{iso-siblings}^{\ell-1}$ and subtracting any siblings $y \in Y$ for which $\textsc{t-iso}^{\ell-1}(z, u, z, y)$ (and, respectively, $y^* \in Y^*$ for which $\textsc{t-iso}^{\ell-1}(z^*, u^*, z^*, y^*)$). This is possible in FO because (a) $|Y|$ is constant and (b) $\#\textsc{iso-siblings}^{\ell-1}$ is consistent with $\textsc{c-iso}^{\ell-1}$ (even though $\textsc{c-iso}^{\ell-1}$ is not necessarily complete on subtrees in Y, Y^*). ◁

For testing whether there is an isomorphism between C and C^* mapping z to z^*, the program distinguishes the cases (1) and (2) from above. Further, in each of the cases it distinguishes (A) $\textsc{path}(r, z, h)$ and $\textsc{path}(r^*, z^*, h^*)$, or (B) $\neg\textsc{path}(r, z, h)$ and $\neg\textsc{path}(r^*, z^*, h^*)$. For all these first-order definable cases, a first-order formula can test whether there is an isomorphism between C and C^* mapping z to z^*. The detailed case analysis is deferred to the full version of the paper.

Computing #ISO-SIBLINGS$^\ell$. The relation $\#\textsc{iso-siblings}^\ell$ can be first-order defined from $\textsc{c-iso}^\ell$ and the 4-ary relation $\#\textsc{iso-sibling}_{\text{unchanged}}$ containing tuples

- (x, r, y, m) with $m > 0$ if $\text{subtree}_x(y)$ has no affected nodes and the number of isomorphic siblings of y in $\text{subtree}_x(r)$ with no affected nodes is m; and
- $(x, r, y, 0)$ if $\text{subtree}_x(y)$ contains an affected node.

Thus the relation $\#\textsc{iso-sibling}_{\text{unchanged}}$ contains isomorphism counts for "unchanged" siblings. It is FO-definable from the old auxiliary data (from before the change) and the set of changes.

Given $\#\textsc{iso-sibling}_{\text{unchanged}}$ and $\textsc{c-iso}^\ell$, the relation $\#\textsc{iso-sibling}^\ell$ is FO-definable as follows. Include a tuple (x, r, y, m) into $\#\textsc{iso-sibling}^\ell$ if $m = m_1 + m_2$ where m_1 is the number of unchanged, isomorphic siblings of y and m_2 is the number of isomorphic siblings of y affected by the change (but by at most $(\frac{3}{2})^{\ell-1}$ changes).

The number m_1 can be checked via distinguishing whether $\text{subtree}_x(y)$ has changed or not. If $\text{subtree}_x(y)$ has not changed, the formula checks that m_1 is such that $(x, r, y, m_1) \in \#\textsc{iso-sibling}_{\text{unchanged}}$. If $\text{subtree}_x(y)$ has changed, find a sibling y^* of y with an unchanged, isomorphic subtree. If y^* exists then the formula checks that m_1 is such that $(x, r, y^*, m_1) \in \#\textsc{iso-sibling}_{\text{unchanged}}$, and otherwise that m_1 is 0.

For checking m_2, let $S(y)$ be the set of siblings y^* of y in $\text{subtree}_x(r)$ that contain at least one affected node and where $\textsc{t-iso}^\ell(x, y, x, y^*)$. Since there are at most $\text{polylog}\, n$ changes, $|S(y)| = \mathcal{O}(\text{polylog}\, n)$. Therefore, $|S(y)|$ can be counted and compared to m_2 in FO. ◀

5 Tree decompositions of bounded-treewidth graphs

One of the best-known algorithmic meta-theorems is Courcelle's theorem, which states that all graph properties expressible in monadic second-order logic MSO can be decided in linear time for graphs with tree-width bounded by some constant k [5]. The tree-width is a graph parameter and measures how "tree-like" a graph is and is defined via tree decompositions, see below for details. Courcelle's theorem is based on Bodlaender's theorem, stating that in linear time (1) one can decide whether a graph has tree-width at most k and (2) one can compute a corresponding tree decomposition [3].

Elberfeld, Jakoby and Tantau [13] proved variants of these results and showed that "linear time" can be replaced with "logarithmic space" in both theorem statements. A dynamic version of Courcelle's theorem was proven in [8]: every MSO-definable graph property is in DynFO under changes of single edges. The proof of the latter result circumvented providing a dynamic variant of Bodlaender's theorem, by using the result of Elberfeld et al. that tree decompositions can be computed in LOGSPACE, showing that a tree decomposition can be used to decide the graph property if only logarithmically many single-edge changes occurred after its construction, and that this is enough for maintenance in DynFO.

It is an open problem to generalize the DynFO maintenance result of [8] from single-edge changes to changes of polylogarithmically many edges, even for DynFOLL. Here, we provide an intermediate step and show that tree decompositions for graphs of bounded treewidth can be maintained in DynFOLL. This result may lead to a second strategy for maintaining MSO properties dynamically, in addition to the approach of [8].

A *tree decomposition* (T, B) of a graph $G = (V, E)$ consists of a rooted tree T and a mapping B from the nodes of T to subsets of V. For a tree node t, we call the set $B(t)$ the *bag* of t. A tree decomposition needs to satisfy three conditions. First, every vertex $v \in V$ needs to be included in some bag. Second, for every edge $(u, v) \in E$ there needs to be bag that includes both u and v. Third, for each vertex $v \in V$, the nodes t of T such that $v \in B(t)$ form a connected subgraph in T. The *width* of a tree decomposition is the maximal size of a bag $B(t)$, over all tree nodes t, minus 1. The *treewidth* of a graph G is the minimal width of a tree decomposition for G.

In addition to the width, important parameters of a tree decomposition are its *depth*, the maximal distance from the root to a leaf, and its *degree*, the degree of the tree T. Often, a binary tree decomposition of depth $\mathcal{O}(\log |V|)$ is desirable, while width $\mathcal{O}(k)$ for a graph of treewidth k is tolerable. We show that one can maintain in DynFOLL a tree decomposition of logarithmic depth but with unbounded degree. The proof is deferred to the full version of the paper. It does not use the hierarchical technique; a tree decomposition is defined in FOLL from auxiliary information that is maintained in DynFO.

▶ **Theorem 16.** *For every k, there are numbers $c, d \in \mathbb{N}$ such that a tree decomposition of width ck and depth $d \log n$ can be maintained in* DynFOLL *under changes of* $\text{polylog}(n)$ *edges for graphs of treewidth k, where n is the size of the graph.*

6 Conclusion and discussion

We have shown that most existing maintenance results for DynFO under single tuple changes can be lifted to DynFOLL for changes of polylogarithmic size. A notable exception are queries expressible in monadic second-order logic, which can be maintained on graphs of bounded treewidth under single-tuple changes.

Thus it seems very likely that one can find large classes of queries such that: If a query from the class can be maintained in DynFO for changes of size $\mathcal{O}(1)$, then it can be maintained in DynFOLL for polylogarithmic changes. Identifying natural such classes of queries is an interesting question for future research.

Preservation Theorems on Sparse Classes Revisited

Abstract

We revisit the work studying homomorphism preservation for first-order logic in sparse classes of structures initiated in [Atserias et al., JACM 2006] and [Dawar, JCSS 2010]. These established that first-order logic has the homomorphism preservation property in any sparse class that is monotone and addable. It turns out that the assumption of addability is not strong enough for the proofs given. We demonstrate this by constructing classes of graphs of bounded treewidth which are monotone and addable but fail to have homomorphism preservation. We also show that homomorphism preservation fails on the class of planar graphs. On the other hand, the proofs of homomorphism preservation can be recovered by replacing addability by a stronger condition of amalgamation over bottlenecks. This is analogous to a similar condition formulated for extension preservation in [Atserias et al., SiCOMP 2008].

1 Introduction

Preservation theorems have played an important role in the development of finite model theory. They provide a correspondence between the syntactic structure of first-order sentences and their semantic behaviour. In the early development of finite model theory it was noted that many classical preservation theorems fail when we limit ourselves to finite structures. An important case in point is the Łoś-Tarski or *extension* preservation theorem, which asserts that a first-order formula is preserved by embeddings between all structures if, and only if, it is equivalent to an existential formula. Interestingly, this was shown to fail on finite structures [15] much before the question attracted interest in finite model theory [12]. On the other hand, the *homomorphism* preservation theorem, asserting that formulas preserved by homomorphisms are precisely those equivalent to existential-positive ones, was remarkably shown to hold on finite structures by Rossman [14], spurring applications in constraint satisfaction and database theory.

However, even before Rossman's celebrated result, these preservation properties were investigated on subclasses of the class of finite structures. In the case of both the extension and homomorphism preservation theorems, the direction of the theorem stating that the syntactic restriction implies the semantic closure condition is easy and holds in restriction to any class of structures. It is the other direction that may fail and, restricting to a subclass weakens both the hypothesis and the conclusion, therefore leading to an entirely new question. Thus, while the class of all finite structures is combinatorially wild, it contains *tame* classes which are both algorithmically and model-theoretically better behaved [6]. A study of

preservation properties for such restricted classes of finite structures was initiated in [3] and [2], which looked at homomorphism preservation and extension preservation respectively. The focus was on tame classes defined by *sparsity* conditions, which allows for methods based on the *locality* of first-order logic. In particular, the sparsity conditions were based on what have come to be called wideness conditions.

We recall the formal definition of wideness in Section 4 below but, informally, a class of structures $\mathcal{C}$ is called *wide* if in any large enough structure in $\mathcal{C}$ we can find a large set of elements that are pairwise far away from each other. The class $\mathcal{C}$ is *almost wide* if there is a constant s so that in any large enough structure in $\mathcal{C}$, removing at most s elements gives a structure in which we can find a large set of elements that are pairwise far away from each other. Finally, $\mathcal{C}$ is said to be *quasi-wide* if there is a function s so that in any large enough structure in $\mathcal{C}$, removing at most $s(d)$ elements gives a structure in which we can find a large set of elements that are pairwise at distance d from each other. In the latter two cases, we refer to a set of elements whose removal yields a large scatterd set as a *bottleneck* set.

The main result asserted in [3] is that homomorphism preservation holds in any class $\mathcal{C}$ which is almost wide and is *monotone* (i.e. closed under substructures) and *addable* (i.e. closed under disjoint unions). From this, it is concluded that homomorphism preservation holds for any class $\mathcal{C}$ whose Gaifman graphs exclude some graph G as a minor, as long as $\mathcal{C}$ is monotone and addable. The result was extended from almost wide to quasi-wide classes in [7], from which homomorphism preservation was deduced for classes that locally exclude minors and classes that have bounded expansion, again subject to the proviso that they are monotone and addable. Quasi-wide classes were later identified with *nowhere dense* classes, which are now central in structural and algorithmic graph theory [13].

The main technical construction in [3] is concerned with showing that classes of graphs which exclude a minor are indeed almost wide. The fact that homomorphism preservation holds in monotone and addable almost wide classes is deduced from a construction of Ajtai and Gurevich [1] which shows the "density" of minimal models of a first-order sentence preserved by homomorphisms, and the fact that in an almost wide class a collection of such dense models must necessarily be finite. While the Ajtai and Gurevich construction is carried out within the class of all finite structures, it is argued in [3] that it can be carried out in any monotone and addable class because of "the fact that disjoint union and taking a substructure are the only constructions used in the proof" [3, p. 216]. This argument is sketched in a bit more detail in [7, Lemma 7]. The starting point of the present paper is that this argument is flawed. The construction requires us to take not just disjoint unions, but unions that identify certain elements: in other words *amalgamations* over sets of points. On the other hand, we can relax the requirement of monotonicity to just hereditariness (i.e. closure under induced substructures). The conclusion is that homomorphism preservation holds in any class $\mathcal{C}$ that is quasi-wide, hereditary and closed under amalgamation over bottleneck points. The precise statement is given in Theorem 9 below. We also show that the requirements formulated in [3] are insufficient by constructing a class that is almost wide (indeed, has bounded treewidth), is monotone and addable, but fails to have the homomorphism preservation property.

Interestingly, the requirement of amalgamations over bottlenecks is similar to that used to define classes on which the extension preservation property holds in [2], even though the construction uses rather different methods. The result there can be understood, in our terms, as showing that the extension preservation theorem holds in any almost wide, hereditary class with amalgamation over bottlenecks. As we observe below (in Corollary 3), this implies that homomorphism preservation holds in all such classes. Our Theorem 9 then strengthens this to quasi-wide classes, where we do not know if extension preservation holds. The class of planar graphs is an interesting case as it is used in [2] as an example of a hereditary, addable class with excluded minors in which extension preservation fails. We show here that homomorphism preservation also fails in this class, strengthening the result of [2].

In the rest of this paper, we introduce notation and necessary background in Section 2. We construct a monotone, addable class of graphs of small treewidth in Section 3, providing the first counterexample to the claims of [3]. Section 4 states and proves the corrected version of the preservation theorems and Section 5 shows the failure of homomorphism preservation in the class of planar graphs.

2 Preliminaries

We assume familiarity with the standard notions of finite model theory and structural graph theory, and refer to [10] and [13] for reference. We henceforth fix a finite relational vocabulary τ; by a structure we implicitly mean a τ-structure. We often abuse notation and do not distinguish between a structure and its domain. Given two structures A, B, a homomorphism $f : A \to B$ is a map such that for all relation symbols R and tuples $\bar{a}$ from A we have $\bar{a} \in R^A \implies f(\bar{a}) \in R^B$. If moreover $f(\bar{a}) \in R^B \implies \bar{a} \in R^A$ then f is said to be *strong*. An injective strong homomorphism is called an *embedding*. We also call a homomorphism $f : A \to B$ *full* if it is surjective and for any relation symbol R and tuple $\bar{b}$ from B we have $\bar{b} \in R^B \implies \exists \bar{a} \in R^A$ with $f(\bar{a}) = \bar{b}$.

A structure B is said to be a *weak substructure* of a structure A if $B \subseteq A$ and the inclusion map $\iota : B \hookrightarrow A$ is a homomorphism. Likewise, B is an *induced substructure* of A if the inclusion map is an embedding. Given a structure A and a subset $S \subseteq A$ we write $A[S]$ for the unique induced substructure of A with underlying set S. An induced substructure B of A is said to be *free in* A if there is some structure C such that A is the disjoint union $B + C$. Finally, a substructure B of A is said to be *proper* if the inclusion map is not full. We say that a class of structures is *monotone* if it is closed under weak substructures, and it is *hereditary* if it is closed under induced substructures. Moreover a class is called *addable* if it is closed under taking disjoint unions. We often consider classes of undirected graphs. Seen as a relational structure, this is a set with an irreflexive symmetric relation E on it. A weak substructure of such a graph need not be a graph. However, when we speak of a monotone class of undirected graphs, we mean it in the usual sense of a class of graphs closed under the operations of removing edges and vertices.

Given a structure A and an equivalence relation $E \subseteq A \times A$ we define the quotient structure A/E as the structure whose domain $A/E = \{[a]_E : a \in A\}$ is the set of E-equivalence classes and such that for every relation symbol R of arity n we have $R^{A/E} = \{([a_1], \dots, [a_n]) \in A/E : (a_1, \dots, a_n) \in R^A\}$. Clearly, the quotient map $\pi_E : A \twoheadrightarrow A/E$ is a full homomorphism which we call the *quotient homomorphism*. Given structures A, B and a set $S \subseteq A \cap B$ such that $A[S] = B[S]$, we write $A \oplus_S B$ for the *free amalgam of A and B over S*. This can be defined as the quotient of the disjoint union $A + B$ by the equivalence relation generated by $\{(\iota_A(s), \iota_B(s)) : s \in S\}$, where $\iota_A : S \to A$ and $\iota_B : S \to B$ are the inclusion maps. Evidently, there is an injective homomorphism $A \to A \oplus_S B$ given by composing the inclusion $A \to A + B$ with the quotient $A + B \to A \oplus_S B$, and a full homomorphism $A + A \to A$ which descends to a full homomorphism $A \oplus_S A \to A$.

By the *Gaifman graph* of a structure A we mean the undirected graph $\mathsf{Gaif}(A)$ with vertex set A such that two elements are adjacent if, and only if, they appear together in some tuple of a relation of A. Given a structure A, $r \in \mathbb{N}$, and $a \in A$, we write $B^r_A(a)$ for the *ball of radius r around a in A*, that is, the set of elements of M whose distance from a

in $\mathsf{Gaif}(A)$ is at most r; we shall often abuse notation and write $B^r_A(a)$ to mean the induced substructure $A[B^r_A(a)]$ of A, possibly with a constant for the element a. A set $S \subseteq A$ is said to be *r-independent* if $b \notin B^r_A(a)$ for any $a, b \in S$.

For $r \in \mathbb{N}$, let $\mathrm{dist}(x, y) \leq r$ be the first-order formula expressing that the distance between x and y in the Gaifman graph is at most r, and $\mathrm{dist}(x, y) > r$ its negation. Evidently, the quantifier rank of $\mathrm{dist}(x, y) \leq r$ less than r. A *basic local sentence* is a sentence

$$\exists x_1, \ldots, x_n(\bigwedge_{i \neq j} \mathrm{dist}(x_i, x_j) > 2r \wedge \bigwedge_{i \in [n]} \psi^{B^r(x_i)}(x_i)),$$

where $\psi^{B^r(x_i)}(x_i)$ denotes the relativisation of ψ to the r-ball around x_i, i.e. the formula obtained from ψ by replacing every quantifier $\exists x\ \theta$ with $\exists x(\mathrm{dist}(x_i, x) \leq r \wedge \theta)$, and likewise every quantifier $\forall x\ \theta$ with $\forall x(\mathrm{dist}(x_i, x) \leq r \to \theta)$. We call r the *locality radius*, n the *width*, and ψ the *local condition* of ϕ. Recall the Gaifman locality theorem [10, Theorem 2.5.1].

▶ **Theorem 1** (Gaifman Locality). *Every first-order sentence of quantifier rank q is equivalent to a Boolean combination of basic local sentences of locality radius 7^q.*

We say that a formula ϕ is preserved by homomorphisms (resp. extensions) over a class of structures $\mathcal{C}$ if for all $A, B \in \mathcal{C}$ such that there is a homomorphism (resp. embedding) from A to B, $A \models \phi$ implies that $B \models \phi$. We say that a class of structures $\mathcal{C}$ has the *homomorphism preservation property* (resp. *extension preservation property*) if for every formula ϕ preserved by homomorphisms (resp. extensions) over $\mathcal{C}$ there is an existential-positive (resp. existential) formula ψ such that $M \models \phi \iff M \models \psi$ for all $M \in \mathcal{C}$.

Given a formula ϕ and a class of structures $\mathcal{C}$, we say that $M \in \mathcal{C}$ is a *minimal induced model* of ϕ in $\mathcal{C}$ if $M \models \phi$ and for any proper induced substructure N of M with $N \in \mathcal{C}$ we have $N \not\models \phi$. The relationship between minimal models and preservation theorems is highlighted by the following lemma, which is standard, and combines [3, Theorem 3.1] and [2, Lemma 2.1]

▶ **Lemma 2.** *Let $\mathcal{C}$ be a hereditary class of finite structures. Then a sentence preserved by homomorphisms (resp. extensions) in $\mathcal{C}$ is equivalent to an existential-positive (resp. existential) sentence over $\mathcal{C}$ if and only if it has finitely many minimal induced models in $\mathcal{C}$.*

▶ **Corollary 3.** *Let $\mathcal{C}$ be a hereditary class of finite structures. If $\mathcal{C}$ has the extension preservation property, then $\mathcal{C}$ has the homomorphism preservation property.*

Proof. If a formula ϕ is preserved by homomorphisms then, in particular, it is preserved by extensions. It follows that ϕ is equivalent to an existential sentence over $\mathcal{C}$, and so by Lemma 2 it has finitely many minimal induced models in $\mathcal{C}$. Consequently, the same lemma implies that ϕ is equivalent to an existential-positive sentence over $\mathcal{C}$ as required. ◀

Another immediate consequence of the above is that both preservation properties hold over any class $\mathcal{C}$ that is *well-quasi-ordered* by the induced substructure relation, i.e. for every infinite subclass $\{M_i : i \in I\} \subseteq \mathcal{C}$ there are $i \neq j \in I$ such that either M_i is an induced substructure of M_j or vice versa. In fact, any property (i.e. not necessarily definable by a first-order formula) preserved by homomorphisms (resp. extensions) is equivalent to an existential positive (resp. existential) formula over a well-quasi-ordered class. In particular, this applies to classes of cliques or more generally classes of bounded shrub-depth [11].

3 Preservation can fail on classes of small treewidth

Theorem 4.4 of [3] can be paraphrased in the language of this paper as saying that *homomorphism preservation holds over any monotone and addable class of bounded treewidth.* In this section we provide a simple counterexample to this, exhibiting a monotone and addable class of graphs of treewidth 3 where homomorphism preservation fails. More generally, this contradicts Corollary 3.3 of [3] and Theorem 9 of [7]. To witness failure of preservation, we must exhibit the relevant class, a formula preserved by homomorphisms over this class, and an infinite collection of minimal induced models in the class. We then conclude by Lemma 2.

▶ **Definition 4.** *Fix $k \in \mathbb{N}$ and $n_i \geq 3$ for every $i \in [k]$. We define the bouquet of cycles of type $(n_1, \dots, n_k)$, denoted by $W_{n_1,\dots,n_k}$, as the graph obtained by taking the disjoint union of k cycles of length $n_1, \dots, n_k$ respectively, and adding an apex vertex, i.e. a vertex adjacent to every vertex in these cycles. When $k = 1$, we refer to the graph W_n as the wheel of order n.*

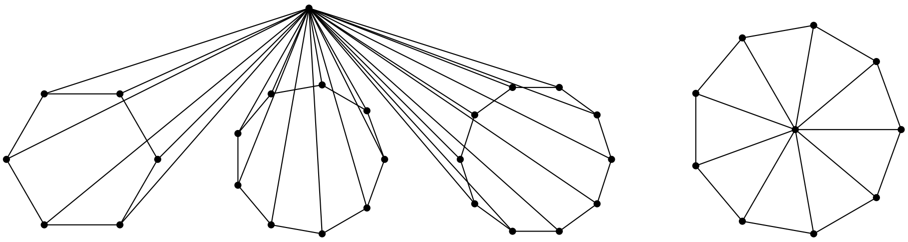

Figure 1 The bouquet of cycles of type $(6, 9, 10)$ and the wheel of order 9 respectively.

▶ **Lemma 5.** *Fix $n, m \in \mathbb{N}$ odd. Then the wheel W_n has chromatic number 4, while its proper subgraphs have chromatic number 3. Consequently, any homomorphism $W_n \to W_m$ is full.*

Proof. Fix $n, m \in \mathbb{N}$ odd. Clearly, any proper colouring of W_n must use a unique colour for the apex as it is adjacent to every other node in W_n. Moreover, we require an additional three colours to colour the vertices in the odd-length cycle of W_n. It follows that $\chi(W_n) = 4$. Now, let W be a proper subgraph of W_n. It follows that there is at least one edge (u, v) present in W_n which is not in W. If u and v are both in the cycle of odd length then we may define a proper 3-colouring of W by giving u and v the same colour, alternating between this and a second colour along the cycle, and using a final third colour for the apex. If one of u or v is the apex of W_n, then we once again colour u and v with the same colour and use an additional two colours to alternate between along the cycle. In particular, it follows that the chromatic number of any homomorphic image of W_n is at least 4, and so it cannot be a proper substructure of W_m. This implies that any homomorphism $f : W_n \to W_m$ is full. ◀

The advantage of working with bouquets of cycles is that, unlike single cycles, there is a formula that asserts the existence of such a structure as a free induced subgraph. Indeed, let

$$\phi := \exists x \exists y [E(x, y) \wedge \forall z (z \neq x \wedge \mathrm{dist}(x, z) \leq 2 \to E(x, z) \wedge \psi(x, z)], \text{ where}$$

$$\psi(x, z) := \exists u \exists v [u \neq v \wedge u \neq x \wedge v \neq x \wedge E(z, u) \wedge E(z, v) \wedge \forall w (E(w, z) \to w = u \vee w = v \vee w = x)]$$

Intuitively, ϕ asserts the following: “there is a vertex x of degree at least one such that every other vertex reachable from x by a path of length two is adjacent to x and has exactly two distinct neighbours which are not x”.

▶ **Lemma 6.** *Let G be an arbitrary finite graph. Then $G \models \phi$ if, and only if, it contains a bouquet of cycles as a free induced subgraph.*

Proof. Suppose that G contains a bouquet W as a free induced subgraph. Then the apex of the bouquet is a vertex of degree at least one, while every vertex reachable from the apex by a path of length two must be in one of the cycles, since W is free in G. Since all vertices in the cycles have degree exactly two, not considering the apex itself, it follows that $G \models \phi$.

Conversely, suppose that $G \models \phi$, and let x be the vertex that is guaranteed to exist by ϕ. Let $S \subseteq V(G)$ be the vertices that are adjacent to x. Since x has degree at least one it follows that S is non-empty. Partition S into k classes $S_1, \ldots, S_k$, by putting two vertices in the same class if, and only if, there is a path between them in $G \setminus \{x\}$. We argue that for each $i \in [k]$, S_i is a free induced cycle in $G \setminus \{x\}$. First, notice that since every vertex reachable from x by a path of length two has degree exactly two in $G \setminus \{x\}$, it follows that S_i induces a cycle in $G \setminus \{x\}$. Moreover, there is no $y \in G \setminus (\{x\} \cup S_i)$ which is adjacent to S_i. Indeed, if $y \neq x$ is adjacent to some $v \in S_i$ then y is reachable from x by a path of length two. It follows that y is itself adjacent to x, and therefore y is in S; in particular, y and v are in the same class and so $y \in S_i$. Consequently each S_i is a free induced cycle in $G \setminus \{x\}$, and so the connected component of x is a free induced bouquet of cycles in G. ◀

It is evident that ϕ is not preserved by homomorphisms in general as every W_n maps homomorphically to the structure $W_n \cup \{c\}$ with an additional vertex adjacent to the apex, and while the latter contains a bouquet as an induced subgraph, it does not contain a bouquet as a free induced subgraph. However, when restricting to subgraphs of disjoint unions of wheels we no longer have non-free-occurring bouquets. This is the core of the next argument.

▶ **Theorem 7.** *Let $\mathcal{C}$ be the monotone and addable closure of $\{W_{2n+1} : n \in \mathbb{N}\}$. Then homomorphism preservation fails over $\mathcal{C}$.*

Proof. Let ϕ be as above; we argue that it is preserved by homomorphisms over $\mathcal{C}$. Indeed, if some $G \in \mathcal{C}$ is such that $G \models \phi$ then by Lemma 6 it contains a bouquet of cycles as a free induced subgraph. By the choice of $\mathcal{C}$, this necessarily implies that G contains W_n as a free induced subgraph for some odd n. Let $H \in \mathcal{C}$ and $f : G \to H$ be a homomorphism. Then f restricts onto a homomorphism $W_n \to H$ which, by the connectivity of W_n and the fact that $H \in \mathcal{C}$, descends to a homomorphism $\hat{f} : W_n \to W_m$ for some odd $m \in \mathbb{N}$. It follows by Lemma 5 that $\hat{f}$ is full, and therefore H contains W_m as a subgraph. The choice of $\mathcal{C}$ once again ensures that W_m is a free induced subgraph of H, and so Lemma 6 implies that $H \models \phi$ as required. Finally, Lemma 6 implies that every W_n is a model of ϕ, while every proper subgraph of W_n cannot possibly contain a bouquet of cycles as a free induced subgraph, and so it cannot model ϕ. Consequently, each W_n is a minimal model of ϕ in $\mathcal{C}$, and so we conclude by Lemma 2 that ϕ is not equivalent to an existential-positive formula over $\mathcal{C}$. ◀

Finally, observe that each graph W_n has treewidth 3 (in fact even pathwidth 3). Indeed, taking a tree decomposition of the cycle C_n of width 2, and adding the apex to every bag in the decomposition gives the required tree decomposition of W_n.

4 Preservation under bottleneck amalgamation

The results of [3] were later extended to classes that are *quasi-wide*. Recall that a class is called quasi-wide if for every $r \in \mathbb{N}$ there exist $k_r \in \mathbb{N}$ and $f_r : \mathbb{N} \to \mathbb{N}$ such that for all $m \in \mathbb{N}$ and $M \in \mathcal{C}$ of size at least $f_r(m)$ there are disjoint sets $A, S \subseteq M$ with $|A| \geq m$, $|S| \leq k_r$ and such that A is r-independent in $M \setminus S$. Intuitively, quasi-wideness ensures that, for every choice of distance, we may find in suitably large structures a large set of elements that are pairwise far away after removing a small set of *bottleneck points*. This notion was introduced for the purpose of extending the arguments of [3] to more general sparse classes, such as classes of bounded expansion, or classes that locally exclude a minor. Paraphrased into the language of this paper, Theorem 9 of [7] asserts that: *homomorphism preservation holds over any monotone and addable quasi-wide class.* Evidently, this is violated by Theorem 7 above. Nonetheless, we may salvage the proof by replacing additivity by the stronger assumption of closure under amalgamation over the bottleneck points that witness quasi-wideness.

The proof proceeds by arguing that any suitably large model M of a sentence ϕ preserved by homomorphisms over a class $\mathcal{C}$ satisfying our assumptions, has a proper induced substructure N which also models ϕ. We thus obtain a concrete bound on the size of minimal models of ϕ, and conclude by Lemma 2. The existence of this bound is guaranteed by quasi-wideness, as any large enough structure contains a large scattered set after removing a small number of bottleneck points. To isolate the bottleneck points $\bar{p}$ of M we consider a structure $\bar{p}M$ in an expanded language which is bi-interpretable with M, and work with the corresponding interpretation ϕ^k of ϕ; in particular $\bar{p}M$ contains a large scattered set itself and it models ϕ^k. Then, by removing a carefully chosen point from the scattered set of $\bar{p}M$, we obtain a proper induced substructure $\bar{p}N$ of $\bar{p}M$ such that $N \in \mathcal{C}$ by hereditariness. To argue that this still models ϕ^k, we use a relativisation of the locality argument of Ajtai and Gurevich from [1]. While in its original version the argument only considers disjoint copies of M, working with the interpretation $\bar{p}M$ of M corresponds to taking free amalgams of M over the set of bottleneck points; this is precisely the subtlety that was missed in [3] and [7].

We now define the structure $\bar{p}M$; in the following we only consider the case of undirected graphs for simplicity. For arbitrary relational structures the idea is analogous, in that we isolate the tuple $\bar{p}$ by forgetting any relation that contains some p_i, and introduce new relation symbols of smaller arities to recover the forgotten relations.

▶ **Definition 8.** *Fix $k \in \mathbb{N}$, and let $\sigma = \{E, P_1, \dots, P_k, Q_1, \dots, Q_k\}$ be the expansion of the language of graphs with $2k$ unary predicates. Given a graph $G = (V, E)$ and a tuple $\bar{p} \in V^k$, define the σ-structure $\bar{p}G$ on the same domain V such that for all $i \in [k]$:*

- $E^{\bar{p}G} = \{(u, v) \in E : u, v \notin \{p_1, \dots, p_k\}\}$;
- $P_i^{\bar{p}G} = \{p_i\}$;
- $Q_i^{\bar{p}G} = \{v \in V : (p_i, v) \in E\}$.

Consider the formula $\epsilon(x, y) := \bigvee_{i\in[k]}(P_i(x) \wedge Q_i(y)) \vee E(x, y)$. Given a sentence ϕ, write ϕ^k for the σ-sentence obtained by ϕ by replacing every atom $E(x, y)$ by $(\epsilon(x, y) \vee \epsilon(y, x))$. It is then clear that for every $G = (V, E)$ and $\bar{p} \in V^k$ as above $G \models \phi \iff \bar{p}G \models \phi^k$.

With this, we turn to our main theorem in this section. Instead of proving a base case and invoking that for the interpretation step as in [2], [3], and [7], we opt for a direct proof to illustrate the relevance of our assumptions on the class.

▶ **Theorem 9.** *Let $\mathcal{C}$ be hereditary such that for every $r \in \mathbb{N}$ there exist $k_r \in \mathbb{N}$ and $f_r : \mathbb{N} \to \mathbb{N}$ so that for every $m \in \mathbb{N}$ and $M \in \mathcal{C}$ of size $\geq f_r(m)$ there are disjoint sets $A, S \subseteq M$ with:*

- *$|A| \geq m$ and $|S| \leq k_r$;*
- *A being r-independent in $M \setminus S$;*
- *$\oplus_S^n M := \underbrace{M \oplus_S M \oplus_S \cdots \oplus_S M}_{n \text{ times}} \in \mathcal{C}$ for every $n \in \mathbb{N}$.*

Then homomorphism preservation holds over $\mathcal{C}$.

Proof. Let $\mathcal{C}$ be as above, and fix ϕ which is preserved by homomorphisms over $\mathcal{C}$. Denote the quantifier rank of ϕ by q, and let $r = 2 \cdot 7^q$. It follows that there is some $k \in \mathbb{N}$ and some $f : \mathbb{N} \to \mathbb{N}$ such that for every $m \in \mathbb{N}$ and every M in $\mathcal{C}$ of size at least $f(m)$, there are disjoint sets $A, S \subseteq M$ such that $|A| \geq m$, $|S| \leq k$, $|A|$ is r-independent in $M \setminus S$, and $\oplus^n_S M \in \mathcal{C}$ for every $n \in \mathbb{N}$. We consider the formula ϕ^k: by Gaifman locality, there is a set $\{\phi_1, \dots, \phi_s\}$ of basic local sentences such that ϕ^k is equivalent to a Boolean combination of these. For $i \in [s]$, let r_i and n_i be the radius and width of locality respectively of ϕ_i, and ψ_i its local condition. Observe that ϕ and ϕ^k have the same quantifier rank, and so $2 \cdot \max_{i \in [s]} r_i \leq r$. Set $n := \max_{i \in [s]} n_i$ and $m := 2^s + 1$. We argue that every minimal model $M \in \mathcal{C}$ of ϕ has size $< f(m)$.

Let M be a minimal model of ϕ, and assume for a contradiction that $|M| \geq f(m)$. It follows that there is a set $S \subseteq M$ of size k such that $M \setminus S$ contains an r-independent set A of size m. Let $\bar{p} \in M^k$ be an enumeration of S; this implies that $\bar{p}M \models \phi^k$ and A is an r-independent set in $\bar{p}M$. For each $i \in [s]$ define

$$\Psi_i(x) := \exists y(\mathrm{dist}(x, y) \leq r_i \wedge \psi_i^{B^{r_i}(y)}(y)).$$

Since $|A| \geq m = 2^s + 1$, it follows that there are at least two vertices $u, v \in A$ satisfying

$$B^{2r_i}_{\bar{p}M}(u) \models \Psi_i(u) \iff B^{2r_i}_{\bar{p}M}(v) \models \Psi_i(v)$$

for all $i \in [s]$. Let N' be the substructure of $\bar{p}M$ induced on $\bar{p}M \setminus \{u\}$. Since A does not intersect the vertices in S, the substructure N of M induced on $M \setminus \{u\}$ satisfies that $N' = \bar{p}N$. We shall argue that $\bar{p}N \models \phi^k$ and so $N \models \phi$, contradicting that M is a minimal induced model of ϕ.

By our closure assumptions on $\mathcal{C}$, $N_n := \oplus^n_S N$ and $M_n := M \oplus_S (\oplus^n_S N)$ are both in $\mathcal{C}$, as the latter is an induced substructure of $\oplus^{n+1}_S M$. Since there is a homomorphism $M \to M_n$ we obtain that $M_n \models \phi$ and thus $\bar{p}M_n \models \phi^k$. We shall argue that

$$\bar{p}M_n \models \phi_i \iff \bar{p}N_n \models \phi_i$$

for all basic local sentences ϕ_i of ϕ^k. In particular, this implies that $\bar{p}N_n \models \phi^k$, and so $N_n \models \phi$. Since there is a homomorphism $N_n \to N$, the preservation of ϕ implies that $N \models \phi$ as claimed.

Clearly, if $\bar{p}N_n \models \phi_i$ then $\bar{p}M_n \models \phi_i$ by the fact that ϕ_i is a local sentence and $\bar{p}N_n$ a free induced substructure of $\bar{p}M_n$. Conversely, if $\bar{p}M_n \models \phi_i$ then there is a $2r_i$-independent subset X of size n_i such that $B^{r_i}_{\bar{p}M_n}(x) \models \psi_i(x)$ for every $x \in X$. Observe that if $X \subseteq S$ then clearly $\bar{p}N_n \models \phi_i$. So, since S is isolated in $\bar{p}M_n$ and $\bar{p}N_n$, we focus on elements of $X \setminus S$, which we may assume to be non-empty. We therefore distinguish two cases.

If $|X \setminus S| > 1$ then, by the $2r_i$-independence of X, there is at least one $x \in X \setminus S$ such that $u \notin B^{r_i}_{\bar{p}M_n}(x)$. It follows that the r_i-ball centered at x is isomorphic to an r_i-ball centered at an element in a disjoint copy of $N \setminus S$. Since $\bar{p}N_n$ contains $n \geq n_i$ such copies, it follows that there is a $2r_i$-independent subset Y of N_n of size n_i such that $B^{r_i}_{\bar{p}N_n}(y) \models \psi_i(y)$ for every $y \in Y$, i.e. $\bar{p}N_n \models \phi_i$.

On the other hand if $|X \setminus S| = 1$, let x be the unique element of $X \setminus S$. Clearly if $u \notin B^{r_i}_{\bar{p}M_n}(x)$ then the r_i-ball centered at x is isomorphic to the r_i-ball centered at an element in $\bar{p}N_n$, and so $\bar{p}N_n \models \phi_i$. If $u \in B^{r_i}_{\bar{p}M_n}(x)$, then $\bar{p}M \models \Psi_i(u)$, and so by the choice of u and v, $\bar{p}M \models \Psi_i(v)$. Consequently, there is some $y \in B^{r_i}_{\bar{p}M}(v)$ such that $B^{r_i}_{\bar{p}M}(v) \models \psi_i(v)$. Observe that because v and u are $2r_i$-independent, $u \notin B^{r_i}_{\bar{p}M_n}(y)$. As before, this implies that $\bar{p}(B_n) \models \phi_i$.

The above implies that there are finitely many minimal induced models of ϕ in $\mathcal{C}$, and so we conclude that ϕ is equivalent to an existential-positive formula over $\mathcal{C}$ by Lemma 2. ◀

Going back to bouquets of cycles, it is easy to see that if a bouquet has more than $m^2 \cdot (r+1)$ vertices then after removing the apex it either contains m disjoint cycles or it contains a cycle of size at least $m \cdot (r+1)$; in either case it contains an r-independent set of size m. In this case the apex is the only bottleneck point, and so amalgamating over this corresponds to adding more cycles to the bouquet. Consequently, homomorphism preservation holds for the hereditary closure of the class of bouquets of cycles by Theorem 9 above.

Closure under amalgamation over bottlenecks is a technical condition and one might consider if it could be replaced by more natural conditions. For example, we could strengthen it by considering closure under arbitrary amalgamation. However, this is a condition that does not sit well with sparsity requirements. Indeed, any hereditary class of undirected graphs that is also closed under arbitrary amalgamation contains arbitrarily large 1-subdivided cliques, and hence, cannot be quasi-wide. Nonetheless, there are naturally defined sparse families of structures that satisfy the conditions of Theorem 9. One such class is known to exist by [2], that is, the class $\mathcal{T}_k$ of all graphs of treewidth bounded by k, for any value of $k \in \mathbb{N}$. Indeed, for any suitably large graph of bounded treewidth we may pick a set of bottleneck points that comes from the same bag in a tree decomposition of the graph, and so amalgamating over this set of points does not increase the treewidth. Another naturally defined such class is the class of outerplanar graphs. For our purposes, we may define outerplanar graphs as those omitting K_4 and $K_{2,3}$ as minors [4]. The quasi-wideness of this class follows by the following fact, which moreover permits some control over the bottleneck points.

▶ **Theorem 10** ([3]). *For every $k, r, m \in \mathbb{N}$ there is an $N = N(k, r, m) \in \mathbb{N}$ such that if G is a graph of size at least N excluding K_k as a minor, then there are disjoint sets $A, S \subseteq V(G)$ with $|A| \geq m$ and $|S| \leq k-2$ such that A is $2r$-independent in $G \setminus S$. Moreover, the bipartite graph $K_{A,S}$ with parts A and S defined by putting an edge between $a \in A$ and $s \in S$ if and only if there is some $u \in B^r_{G\setminus S}(a)$ such that $(u, s) \in E(G)$ is complete.*

▶ **Theorem 11.** *Homomorphism preservation holds for the class of outerplanar graphs.*

Proof. Since outerplanar graphs are K_4-minor-free, it follows by Theorem 10 that for every $r, m \in \mathbb{N}$ there exists an $N = N(r, m) \in \mathbb{N}$ such that if G is an outerplanar graph of size at least N, then there are disjoint sets $A, S \subseteq V(G)$ with $|A| \geq m, |S| \leq 2$, A r-independent in $G \setminus S$, and $K_{A,S}$ complete. Since outerplanar graphs also forbid $K_{2,3}$ as a minor, this implies that $|S| \leq 1$. It is then clear that for any such G and $S \subseteq V(G)$, the graph $\oplus^n_S G$ is still outerplanar for all $n \in \mathbb{N}$, as no 1-point free amalgams can create K_4 or $K_{2,3}$ minors. We thus conclude by Theorem 9. ◀

Interestingly, the examples exhibited above are in fact *almost-wide*, that is, the number of the bottleneck points does not depend on the radius of independence. It would be interesting to find natural quasi-wide classes which are not almost-wide, and which are closed under bottleneck amalgamation. One potential candidate might be the class of all graphs whose local treewidth is bounded by the same constant.

5 Homomorphism preservation fails on planar graphs

In this section we witness that homomorphism preservation fails on the class of planar graphs. Previously, it was established [2] that the extension preservation property fails on planar graphs. Since extension preservation implies homomorphism preservation on hereditary classes by Corollary 3, our result strengthens the above. Recall that by Wagner's theorem [16] a graph is planar if and only if it omits $K_{3,3}$ and K_5 as minors. Our construction, in fact, also reveals that homomorphism preservation fails on the class of K_5-minor-free graphs.

▶ **Definition 12.** *Fix $n \in \mathbb{N}$. Define G_n as the undirected graph on vertex set $V(G_n) = \{v_1, v_2\} \cup \{a_i : i \in [n]\} \cup \{b_i : i \in [n]\}$ and edge set*

$$E(G_n) = \{(v_1, a_i) : i \in [n]\} \cup \{(v_2, b_i) : i \in [n]\} \cup \{(a_i, b_i) : i \in [n]\}$$

$$\cup \{(a_i, a_{i+1}) : i \in [n-1]\} \cup \{(b_i, b_{i+1}) : i \in [n-1]\} \cup \{(a_{i+1}, b_i) : i \in [n-1]\}.$$

We define D_n as the extension of G_n on the same vertex set, with

$$E(D_n) = E(G_n) \cup \{(a_1, a_n), (b_1, b_n), (a_1, b_n)\}.$$

We also define A_n as the graph obtained from G_n by taking the quotient over the equivalence relation generated by (a_1, a_n), and we write $\alpha_n : G_n \to A_n$ for the corresponding quotient homomorphism. Likewise, we let $B_n := G_n/(a_1, b_n)$ and $C_n := G_n/(b_1, b_n)$, and write $\beta_n : G_n \to B_n$ and $\gamma_n : G_n \to C_n$ for the respective quotient homomorphisms.

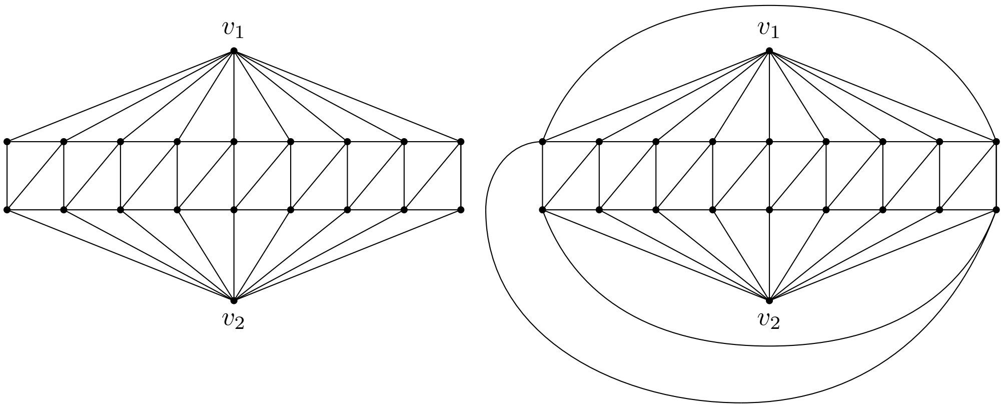

Figure 2 Planar embeddings of G_9 and D_9 respectively.

Consider the following observations. First, for every $n \geq 3$ the graphs G_n, D_n, A_n, B_n, C_n are all planar and 4-chromatic. In particular D_n, B_n, C_n are maximal planar. For $n = 3$ the graphs D_n and B_n contain a copy of K_4, while for $n \geq 4$ they are K_4-free. Likewise, for $n \in \{3, 4\}$ the graphs A_n and C_n contain a copy of K_4, while for $n \geq 5$ they are K_4-free. Finally, for $3 \leq m \leq n$ there is a homomorphism $\delta_{n,m} : G_n \to D_m$ that "wraps" G_n around D_m. Labelling their vertices as above, this satisfies

$$\delta_{n,m}(v_1) = v_1, \delta_{n,m}(v_2) = v_2, \delta_{n,m}(a_i) = a_{i \bmod m} \text{ and } \delta_{n,m}(b_i) = b_{i \bmod m},$$

for all $i \in [n]$.

We proceed to characterise the K_5-minor-free homomorphic images of D_n. We argue that these either contain K_4, or an induced copy of D_m for some m with $m|n$. The proof proceeds by first characterising the K_5-minor-free homomorphic images of G_n by induction, and then using that G_n is a subgraph of D_n. While this requires a fair amount of book-keeping, it is not conceptually difficult. The base case of the induction is the following lemma.

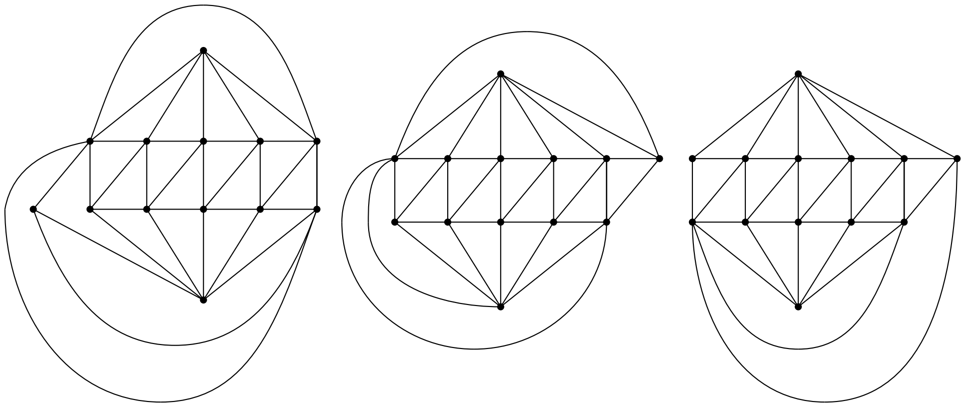

Figure 3 Planar embeddings of A_6, B_6, and C_6 respectively.

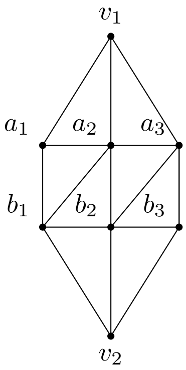
▶ **Lemma 13.** *Let $f : G_3 \to H$ be a homomorphism. If H is K_4-free then f is injective.*

Proof. Let H be a K_4-free graph, and $f : G_3 \to H$ a homomorphism. Label the vertices of G_3 as in the picture below; we shall argue that f is injective.



First, notice that f is injective on $\{v_2, b_1, b_2\}$ since they form a triangle in G_3. If $f(a_2) = f(v_2)$ then the set $\{f(v_2), f(b_2), f(a_3), f(b_3)\}$ induces K_4 in H; it follows that $f(a_2) \neq f(v_2)$, and so f is injective on $\{v_2, b_1, b_2, a_2\}$. Likewise, $f(b_3) \neq f(a_2)$ as otherwise $\{f(b_1), f(b_2), f(b_3), f(v_2)\}$ induce K_4 in H. Moreover, $f(b_3) \neq f(b_1)$ as $\{f(b_1), f(b_2), f(a_2), f(a_3)\}$ would otherwise induce K_4 in H. It follows that f is injective on $\{v_2, b_1, b_2, b_3, a_2\}$. From this we deduce that $f(a_3) \neq f(b_1)$ as otherwise $\{f(v_2), f(b_1), f(b_2), f(b_3)\}$ would induce K_4 in H, and that $f(a_3) \neq f(v_2)$ as otherwise $\{f(v_2), f(b_1), f(b_2), f(a_2)\}$ would also induce K_4. Hence, f is injective on $\{v_2, b_1, b_2, b_3, a_2, a_3\}$. By symmetry, it follows that f is also injective on $\{v_1, a_1, a_2, a_3, b_1, b_2\}$. Notice that $f(a_1) \neq f(b_3)$ and $f(v_1) \neq f(b_3)$ since otherwise $\{f(a_2), f(a_3), f(b_2), f(b_3)\}$ would induce K_4 in H. Finally, $f(a_1) \neq f(v_2)$ and $f(v_1) \neq f(v_2)$ as otherwise $\{f(a_2), f(b_1), f(b_2), f(v_2)\}$ would induce K_4 in H. Putting all the above together, we conclude that f is injective on all of G_3 as required. ◀

We now proceed to the general case.

▶ **Lemma 14.** *Fix $n \geq 3$. Let $f : G_n \to H$ be a homomorphism, where H is K_4-free and K_5-minor-free. Then one of the following is true:*

1. *f is injective;*
2. *there is some $m \in [4, n-1]$ and an embedding $\hat{f} : D_m \to H$ such that $f = \hat{f} \circ \delta_{n,m}$;*
3. *$n \geq 5$ and there is an injective homomorphism $\hat{f} : A_n \to H$ such that $f = \hat{f} \circ \alpha_n$;*
4. *$n \geq 4$ and there is an embedding $\hat{f} : B_n \to H$ such that $f = \hat{f} \circ \beta_n$;*
5. *$n \geq 5$ and there is an embedding $\hat{f} : C_n \to H$ such that $f = \hat{f} \circ \gamma_n$;*

Proof. We prove the claim by induction on n. The base case $n = 3$ follows by Lemma 13. So, fix a K_4-free and K_5-minor-free graph H and consider a homomorphism $f : G_{n+1} \to H$. Evidently, this restricts to a homomorphism $f' : G_n \to H$. By the induction hypothesis, we may assume that f' satisfies one of the five conditions of this proposition.

Assume that f' satisfies (1), i.e. f is injective on $G_n = G_{n+1} \setminus \{a_{n+1}, b_{n+1}\}$. We consider the images of the vertices a_{n+1} and b_{n+1} under f. Observe that $(a_{n+1}, b_{n+1}) \in E(G_{n+1})$ so $f(a_{n+1}) \neq f(b_{n+1})$. Clearly, if $f(a_{n+1})$ and $f(b_{n+1})$ are not any of the vertices in $f[G_n]$, then f is itself injective and (1) holds. We hence distinguish three cases.

First, suppose that $f(a_{n+1}) \in f[G_n]$ and $f(b_{n+1}) \notin f[G_n]$. Since there are edges (v_1, a_{n+1}), (a_n, a_{n+1}), and (b_n, a_{n+1}), it follows that $f(a_{n+1}) \notin \{f(v_1), f(a_n), f(b_n)\}$. Moreover, $f(a_{n+1}) \neq f(v_2)$ as otherwise $\{f(b_{n-1}), f(b_n), f(a_n), f(v_2)\}$ would induce K_4 in H. Similarly, $f(a_{n+1}) \neq f(a_{n-1})$, as otherwise $\{f(a_{n-1}), f(b_{n-1}), f(a_n), f(b_n)\}$ would induce K_4, and $f(a_{n+1}) \neq f(b_{n-1})$, as otherwise $\{f(v_1), f(a_{n-1}), f(a_n), f(b_{n-1})\}$ would induce K_4. In addition, $f(a_{n+1}) \notin \{f(a_i) : 2 \leq i \leq n-2\}$ as otherwise an edge $(f(a_i), f(a_n))$ for some $i \in [2, n-2]$ would produce a K_5-minor in H, namely the minor arising from $S_1 = \{f(v_1)\}, S_2 = \{f(a_i)\}, S_3 = \{f(a_n)\}, S_4 = \{f(a_j) : i+1 \leq j \leq n-1\}, S_5 = \{f(v_2), f(b_1), f(a_1), f(b_i), f(b_{i+1}), f(b_n)\}$. A similar argument reveals that $f(a_{n+1}) \notin \{f(b_i) : 2 \leq i \leq n-2\}$. It follows that $f(a_{n+1}) = f(b_1)$ or $f(a_{n+1}) = f(a_1)$. The former case would produce a copy of K_4, namely $\{f(v_1), f(a_1), f(a_2), f(b_1)\}$, leading to a contradiction. Hence $f(a_{n+1}) = f(a_1)$. Since $f(b_{n+1}) \notin f[G_n]$, it follows that f factors through the quotient homomorphism α_n, i.e. case (3) is true.

Next, suppose that $f(a_{n+1}) \in f[G_n]$ and $f(b_{n+1}) \in f[G_n]$. As before, we deduce from the first assumption that $f(a_{n+1}) = f(a_1)$. This implies that there are edges $(f(a_1), f(a_n))$ and $(f(a_1), f(b_n))$ in H. Since there are edges $(a_{n+1}, b_{n+1}), (b_n, b_{n+1}), (v_2, b_{n+1})$ in G_{n+1} we deduce that $f(b_{n+1}) \notin \{f(a_1), f(b_n), f(v_2)\}$. Moreover, $f(b_{n+1}) \neq f(v_1)$ as otherwise the edge $(f(v_1), f(v_2))$ would produce a K_5-minor in H, namely $S_1 = \{f(v_1)\}, S_2 = \{f(a_1)\}, S_3 = \{f(a_n)\}, S_4 = \{f(a_j) : j \in [2, n-1]\}, S_5 = \{f(v_2), f(b_1), f(b_2), f(b_n)\}$. Similarly, a K_5-minor arises in H if $f(b_{n+1}) \in \{f(a_i), f(b_i) : i \in [2, n-1]\}$. We thus deduce that $f(b_{n+1}) = f(b_1)$, from which we conclude that $f[G_{n+1}]$ induces a copy of D_n in H, and more precisely, case (2) holds.

So, suppose that $f(a_{n+1}) \notin f[G_n]$ and $f(b_{n+1}) \in f[G_n]$. We consider the possible images of b_{n+1} under f. Since there are edges $(a_{n+1}, b_{n+1}), (v_2, b_{n+1}), (b_n, b_{n+1})$ in G_{n+1} we deduce that $f(b_{n+1}) \notin \{f(a_{n+1}), f(v_2), f(b_n)\}$. Moreover, $f(b_{n+1}) \neq f(v_1)$ as otherwise $\{f(v_1), f(a_n), f(a_{n+1}), f(b_n)\}$ would induce K_4 in H. Likewise, $f(b_{n+1}) \neq f(a_n)$ as otherwise $\{f(v_2), f(a_{b-1}), f(b_n), f(a_n)\}$ would induce K_4 in H. Moreover $f(b_{n+1}) \notin \{f(a_i) : i \in [2, n-1]\}$ as otherwise the edge $(f(a_i), f(a_{n+1}))$ would produce a K_5-minor in H, namely $S_1 = \{f(v_1)\}, S_2 = \{f(a_i)\}, S_3 = \{f(a_{n+1})\}, S_4 = \{f(a_j) : j \in [i+1, n]\}, S_5 = \{f(v_2), f(b_1), f(a_1), f(b_i), f(b_{i+1}), f(b_n)\}$. Very similarly, we deduce that $f(b_{n+1}) \notin \{f(b_i) : i \in [2, n-1]\}$. It follows that $f(b_{n+1}) = f(a_1)$ or $f(b_{n+1}) = f(b_1)$. In the former case, it follows that f factors through the quotient homomorphism β_n, and so (4) is true, while in the latter case, it follows that f factors through γ_n, and so (5) is true.

Next, assume that f' satisfies (2), i.e. there is some $m \in [4, n-1]$ and and an embedding $\hat{f} : D_m \to H$ such that $f' = \hat{f} \circ \delta_{n,m}$. Arguing as before, it is easy to see that the assumptions on H force $f(a_{n+1})$ to be equal to $\hat{f}(a_{n+1 \bmod m})$, and likewise $f(b_{n+1}) = \hat{f}(b_{n+1 \bmod m})$, implying that $f = \hat{f} \circ \delta_{n+1,m}$. Hence f also satisfies (2).

Finally, we argue that f' cannot satisfy any of (3), (4), and (5). Indeed, assume for a contradiction that f' satisfies (3) and write f' as $\hat{f} \circ \alpha_n$ for some injective homomorphism $\hat{f} : A_n \to H$. In particular, we know that $n \geq 5$. Consider the image of a_{n+1} under f; this is some vertex adjacent to $f(a_n) = f(a_1), f(v_1)$, and $f(b_n)$. If $f(a_{n+1}) \notin f[G_n]$, then we obtain a K_5-minor in H, namely $S_1 = \{f(v_1)\}, S_2 = \{f(a_1)\}, S_3 = \{f(a_{n-1})\}, S_4 = \{f(a_i) : i \in [2, n-1]\}, S_5 = \{f(v_2), f(b_1), f(b_2), f(b_{n-1}), f(b_n), f(a_{n+1})\}$. So $f(a_{n+1}) \in f[G_n]$. If $f(a_{n_1}) = f(a_i)$ for some $i \in [2, n-2]$ then we obtain a K_5-minor in H by picking some $j \in [2, n-2] \setminus \{i\}$ and letting $S_1 = \{f(v_1), f(a_j)\}, S_2 = \{f(a_1)\}, S_3 = \{f(a_{n-1})\}, S_4 = \{f(b_i) : i \in [n-1]\}, S_5 = \{f(v_2), f(b_n), f(a_i)\}$. Likewise, if $f(a_{n+1}) = f(a_{n-1})$ then we obtain the K_5-minor $S_1 = \{f(v_1)\}, S_2 = \{f(a_1)\}, S_3 = \{f(b_{n-1}), f(b_{n-2}), f(a_{n-2})\}, S_4 = \{f(a_i) : i \in [2, n-3]\}, S_5 = \{f(v_2), f(b_n), f(a_{n-1})\}$. Consequently, $f(a_{n+1}) = f(b_i)$ for some $i \in [1, n-1]$. This produces an edge $(f(v_1), f(b_i))$ and thus gives rise to the K_5-minor $S_1 = \{f(v_1)\}, S_2 = \{f(a_j) : j \in [1, i-1]\}, S_3 = \{f(a_i)\}, S_4 = \{f(a_j) : j \in [i+1, n-1]\}, S_5 = \{f(v_2), f(b_1), f(b_i), f(b_{n-1})\}$. It follows that f' cannot satisfy (3); via very similar reasoning, we exclude cases (4) and (5). ◀

Having established the above, our characterisation of the K_5-minor-free homomorphic images of D_n follows easily.

▶ **Proposition 15.** *Fix $n \geq 4$. Then any K_4-free and K_5-minor-free homomorphic image of D_n contains an induced copy of D_m for some $m \geq 4$ such that $m|n$.*

Proof. Consider a homomorphism $f : D_n \to H$ where H is K_4-free and K_5-minor-free. Then f descends to a homomorphism $f' : G_n \to H$. It follows that one of the five cases of Lemma 14 holds. If f' is injective, then in particular f is injective; since the addition of any edge in D_n creates a K_5-minor, it follows that f is in fact an embedding as required. Suppose that case (2) is true, and let $m \in [4, n-1]$ and $\hat{f} : D_m \to H$ be such that $f' = \hat{f} \circ \delta_{n,m}$. In particular, D_m is an induced subgraph of H and $m|n$. Finally, case (3) leads to a contradiction as the edge (a_1, a_n) in D_n implies that $f(a_1) \neq f(a_n)$, case (4) leads to a contradiction as the edge (a_1, b_n) implies that $f(a_1) \neq f(b_n)$, and likewise, case (5) leads to a contradiction as the edge (b_1, b_n) implies that $f(b_1) \neq f(b_n)$. ◀

We also define G_∞ as the countably infinite analogue of G_n, i.e. the graph on the vertex set $V(G_\infty) = \{v_1, v_2\} \cup \{a_i : i \in \mathbb{N}_{>0}\} \cup \{b_i : i \in \mathbb{N}_{>0}\}$ and edge set

$$E(G_n) = \{(v_1, a_i) : i \in \mathbb{N}_{>0}\} \cup \{(v_2, b_i) : i \in \mathbb{N}_{>0}\} \cup \{(a_i, b_i) : i \in \mathbb{N}_{>0}\}$$

$$\cup \{(a_i, a_{i+1}) : i \in \mathbb{N}_{>0}\} \cup \{(b_i, b_{i+1}) : i \in \mathbb{N}_{>0}\} \cup \{(a_{i+1}, b_i) : i \in \mathbb{N}_{>0}\}.$$

Likewise, we define the homomorphism $\delta_{\infty,m} : G_\infty \to D_m$ in analogy to the homomorphisms $\delta_{n,m} : G_n \to D_m$. Lemma 14 allows us to also characterise the finite K_5-minor-free homomorphic images of G_∞.

▶ **Lemma 16.** *Let $f : G_\infty \to H$ be a homomorphism where H is finite, K_4-free, and K_5-minor-free. Then there is some $m \geq 4$ and an embedding $\hat{f} : D_m \to H$ such that $f = \hat{f} \circ \delta_{\infty,m}$.*

Proof. Fix f as above and let $n := |H|$. It follows that f restricts to a homomorphism $f' : G_n \to H$; this satisfies one of the five cases of Lemma 14. Clearly, cases (1),(3),(4), and (5) are ruled out due to size restrictions. Consequently, case (2) holds and the claim follows. ◀

With the above, we show that the existence of the graphs D_n as induced subgraphs is definable among K_4-free K_5-minor-free graphs by a simple first-order formula. Indeed, let

$$\chi(x_1, x_2, y_1, z_1, y_2, z_2) = E(x_1, y_2) \wedge E(y_1, y_2) \wedge E(z_1, y_2) \wedge E(z_1, z_2) \wedge E(y_2, z_2) \wedge E(z_2, x_2), \text{ and}$$

$$\phi = \exists x_1, x_2, y, z[E(x_1, y) \wedge E(y, z) \wedge E(z, x_2) \wedge \forall a, b(E(x_1, a) \wedge E(a, b) \wedge E(b, x_2))$$
$$\to \exists c, d\ \chi(x_1, x_2, a, b, c, d))]$$

▶ **Lemma 17.** *Let H be a finite K_4-free and K_5-minor free graph. If $H \models \phi$ then there is some $n \geq 4$ such that H contains D_n as an induced subgraph.*

Proof. Fix a graph H as above, and suppose that $G \models \phi$. We inductively define a chain of partial homomorphisms $f_1 \subseteq f_2 \subseteq f_3 \subseteq \ldots$ from $G_\infty \to H$ such that $\text{dom}(f_n) = G_n$. Then the map $f = \cup_{n=1}^{\infty} f_n$ is a homomorphism $G_\infty \to H$, and hence Lemma 16 implies that H contains some D_n as an induced subgraph.

Since $H \models \phi$ it follows that there are $x_1, x_2, y, z \in V(H)$ such that

$$H \models E(x_1, y) \wedge E(y, z) \wedge E(z, x_2).$$

Consequently, the map $f_1 : G_1 \to H$ given by $f(v_1) = x_1, f(v_2) = x_2, f(a_1) = y, f(b_1) = z$ is a homomorphism as required. So, suppose that f_n has been defined. Since

$$H \models E(x_1, f(a_n)) \wedge E(f(a_n), f(b_n)) \wedge E(f(b_n), x_2)$$

it follows that

$$H \models \exists c, d\ \chi(x_1, x_2, f(a_n), f(b_n), c, d).$$

We consequently extend $f_n : G_n \to H$ to $f_{n+1} : G_{n+1} \to H$ by letting $f_{n+1}(a_{n+1}) = c$ and $f_{n+1}(b_{n+1}) = d$; this is easily seen to be a valid homomorphism by the choice of χ. ◀

▶ **Lemma 18.** *Let H be a K_5-minor-free graph. If H contains some D_n for $n \geq 3$ as an induced subgraph then $H \models \phi$.*

Proof. Let $D_n \leq H$ be as above. Clearly, $H \models E(v_1, a_1) \wedge E(a_1, b_1) \wedge E(b_1, v_2)$ So, let $a, b \in V(H)$ be arbitrary vertices such that $H \models E(v_1, a) \wedge E(a, b) \wedge E(b, v_2)$; we first argue that $a \in \{a_i : i \in [n]\}$ and $b \in \{b_i : i \in [n]\}$. Towards this, observe first that $b \notin \{a_i : i \in [n]\} \cup \{v_1\}$ as otherwise the edge (v_2, a_i) or (v_2, v_1) would contradict that D_n is induced in H. So, assume for a contradiction that $a \notin \{a_i : i \in [n]\}$. Since there is an edge (v_1, a) it follows that $a \neq v_1$, and so in particular the sets $S_1 = \{v_1\}, S_2 = \{a_1\}, S_3 = \{a_n\}, S_4 = \{a_j : j \in [2, n-1]\}, S_5 = \{v_2, b_1, b_n, a, b\}$ produce a K_5-minor in H. With a symmetric argument we obtain that $b \in \{b_i : i \in [n]\}$. Now, since there is an edge (a, b) it follows that there is some $i \in [n]$ such that $a = a_i$ and $b = b_i$ or $b = b_{i-1 \bmod n}$. In these two respective cases we have that

$$H \models \chi(v_1, v_2, a, b, a_{i+1 \bmod n}, b_{i+1 \bmod n}), \text{ or } H \models \chi(v_1, v_2, a, b, a_{i-1 \bmod n}, b_{i-2 \bmod n}).$$

In either case, $H \models \exists c, d\ \chi(v_1, v_2, a, b, c, d)$, and since the choice of $a, b \in V(H)$ was arbitrary we obtain that $H \models \phi$ as required. ◀

Putting all the above together, we deduce the main theorem of this section.

▶ **Theorem 19.** *The class of planar graphs does not have the homomorphism preservation property.*

Proof. Let $\hat{\phi}$ be the disjunction of ϕ with the formula that induces a copy of K_4, i.e.

$$\hat{\phi} := \phi \vee \exists x_1, x_2, x_3, x_4 \bigwedge_{i \neq j} E(x_i, x_j).$$

We argue that $\hat{\phi}$ is preserved by homomorphisms over the class of planar graphs. Indeed, let $f : G \to H$ be a homomorphism with G, H planar such that $G \models \hat{\phi}$. Clearly, if H contains a copy of K_4 then $H \models \hat{\phi}$. So, without loss of generality we may assume that $G \models \phi$ and G, H are K_4-free. It follows by Lemma 17 that there exists some $n \geq 4$ such that G contains D_n as a subgraph. Consequently, Proposition 15 implies that there is some $m \geq 4$ such that H contains D_m as a subgraph. Lemma 18 then implies that $H \models \phi$, and thus $H \models \hat{\phi}$ as required. To conclude, observe that the minimal models of $\hat{\phi}$ over the class of planar graphs are K_4 and the graphs D_n for $n \geq 4$; since these are infinitely many Lemma 2 implies that $\hat{\phi}$ is not equivalent to an existential-positive formula over the class of planar graphs. ◀

Since we only use exclusion of K_5-minors in the above, we additionally obtain the following.

▶ **Theorem 20.** *The class of all K_5-minor-free graphs does not have the homomorphism preservation property.*

Finally, while we have not referred to topological minors to simplify our arguments, an easy check reveals that the above are still valid when considering graphs that forbid K_5 as a topological minor, implying that homomorphism preservation also fails on the class of K_5-topological-minor-free graphs.

6 Conclusion

Much work in finite model theory explores *tame* classes of finite structures. In [6], two related notions of tameness are identified: algorithmic tameness and model-theoretic tameness. The former is centred around the tractability of model-checking for first-order logic while the latter is illustrated by preservation theorems and it was argued that these occurred together in sparse classes of structures. More recently, algorithmic tameness has been explored extensively for dense classes as well (see [8] for example). On the other hand, the results here show that the status of preservation theorems on sparse classes is more subtle and relies on closure properties that are not always present in natural classes such as planar graphs. Nonetheless, it is an interesting question whether the recent understanding of tame dense classes, such as *monadically stable* and more generally *monadically dependent* classes, can also cast light on preservation theorems. The arguments for homomorphism and extension preservation rely on quasi-wideness and almost-wideness respectively. Similar wideness phenomena occur for dense classes, by replacing deletion of bottleneck points with performing *flips*, that is, edge-complementations within subsets of the domain (see Table 1 in [9]). A question inspired by this is whether, for every $k \in \mathbb{N}$, the class of all graphs of cliquewidth at most k has the extension preservation property. For $k \leq 2$ this follows from the fact that cographs are well-quasi-ordered by the induced subgraph relation [5].

Abstract

The goal of local certification is to locally convince the vertices of a graph G that G satisfies a given property. A prover assigns short certificates to the vertices of the graph, then the vertices are allowed to check their certificates and the certificates of their neighbors, and based only on this local view and their own unique identifier, they must decide whether G satisfies the given property. If the graph indeed satisfies the property, all vertices must accept the instance, and otherwise at least one vertex must reject the instance (for any possible assignment of certificates). The goal is to minimize the size of the certificates.

In this paper we study the local certification of geometric and topological graph classes. While it is known that in n-vertex graphs, planarity can be certified locally with certificates of size $O(\log n)$, we show that several closely related graph classes require certificates of size $\Omega(n)$. This includes penny graphs, unit-distance graphs, (induced) subgraphs of the square grid, 1-planar graphs, and unit-square graphs. These bounds are tight up to a constant factor and give the first known examples of hereditary (and even monotone) graph classes for which the certificates must have linear size. For unit-disk graphs we obtain a lower bound of $\Omega(n^{1-\delta})$ for any $\delta > 0$ on the size of the certificates, and an upper bound of $O(n \log n)$. The lower bounds are obtained by proving rigidity properties of the considered graphs, which might be of independent interest.

1 Introduction

Local certification is an emerging subfield of distributed computing where the goal is to assign short certificates to each of the nodes of a network (some connected graph G) such that the nodes can collectively decide whether G satisfies a given property (i.e., whether it belongs

to some given graph class $\mathcal{C}$) by only inspecting their unique identifier, their certificate and the certificates of their neighbors. This assignment of certificates is called a *proof labeling scheme*, and its *complexity* is the maximum number of bits of a certificate (as a function of the number of vertices of G, which is usually denoted by n in the paper). If a graph class $\mathcal{C}$ admits a proof labeling scheme of complexity $f(n)$, we say that $\mathcal{C}$ has *local complexity* $f(n)$. Proof labelling schemes are distributed analogues of traditional non-deterministic algorithms, and graph classes of logarithmic local complexity can be considered as distributed analogues of classes whose recognition is in NP [7]. The notion of proof labeling scheme was formally introduced by Korman, Kutten and Peleg in [17], but originates in earlier work on self-stabilizing algorithms (see again [7] for the history of local certification and a thorough introduction to the field). While every graph class has local complexity $O(n^2)$ [17],[1] the work of [13] identified three natural ranges of local complexity for graph classes:

- $\Theta(1)$: this includes k-colorability for fixed k, and in particular bipartiteness;
- $\Theta(\log n)$: this includes non-bipartiteness and acyclicity; and
- $\Theta(\text{poly}(n))$: this includes non-3-colorability and problems involving symmetry.

It was later proved in [19] that any graph class which can be recognized in linear time (by a centralized algorithm) has an "interactive" proof labeling scheme of complexity $O(\log n)$, where "interactive" means that there are several rounds of interaction between the prover (the entity which assigns certificates) and the nodes of the network (see also [16] for more on distributed interactive protocols). A natural question is whether the interactions are necessary or whether such graph classes have classical proof labeling schemes of complexity $O(\log n)$ as defined above, that is, without multiple rounds of interaction. This question triggered the work of [9] on planar graphs, which have a well-known linear time recognition algorithm. The authors of [9] proved that the class of planar graphs indeed has local complexity $O(\log n)$, and asked whether the same holds for any proper minor-closed class.[2] This was later proved for graphs embeddable on any fixed surface in [10] (see also [6]) and in [2] for classes excluding small minors, while it was proved in [12] that classes excluding a planar graph H as a minor have local complexity $O(\log^2 n)$. The authors of [12] also proved the related result that any graph class of bounded treewidth which is expressible in second order monadic logic has local complexity $O(\log^2 n)$ (this implies in particular that for any fixed k, the class of graphs of treewidth at most k has local complexity $O(\log^2 n)$). Similar meta-theorems involving graph classes expressible in some logic were proved for graphs of bounded treedepth in [8] and graphs of bounded cliquewidth in [11].

Closer to the topic of the present paper, the authors of [14] obtained proof labeling schemes of complexity $O(\log n)$ for a number of classes of geometric intersection graphs, including interval graphs, chordal graphs, circular-arc graphs, trapezoid graphs, and permutation graphs. It was noted earlier in [15] (which proved various results on interactive proof labeling schemes for geometric graph classes) that the "only" classes of graphs for which large lower bounds on the local complexity are known (for instance non-3-colorability, or some properties involving symmetry) are not *hereditary*, meaning that they are not closed under taking induced subgraphs. It turns out that an example of a hereditary class with polynomial local complexity had already been identified in [4] a couple of years earlier: triangle-free graphs (the lower bound on the local complexity given there was sublinear). It was speculated in [15]

[1] Give to every vertex the adjacency matrix of the graph.

[2] Note that it is easy to show that for any minor-closed class $\mathcal{C}$, the complement of $\mathcal{C}$ has local complexity $O(\log n)$, using Robertson and Seymour's Graph Minor Theorem [21].

that any class of geometric intersection graphs has small local complexity, as such classes are both hereditary and well-structured.

Results

In this paper we identify a key rigidity property in graph classes and use it to derive a number of *linear* lower bounds on the local complexity of graph classes defined using geometric or topological properties. These bounds are all best possible, up to $n^{o(1)}$ factors. So our main result is that for a number of classical hereditary graph classes studied in structural graph theory, topological graph theory, and graph drawing, the local complexity is $\Theta(n)$. These are the first non-trivial examples of hereditary classes (some of our examples are even monotone) with linear local complexity. Interestingly, all the classes we consider are very close to the class of planar graphs (which is known to have local complexity $\Theta(\log n)$ [9, 6]): most of these classes are either subclasses or superclasses of planar graphs. Given the earlier results on graphs of bounded treewidth [12] and planar graphs, it is natural to try to understand which sparse graph classes have (poly)logarithmic local complexity. It would have been tempting to conjecture that any (monotone or hereditary) graph class of *bounded expansion* (in the sense of Nešetřil and Ossona de Mendez [20]) has polylogarithmic local complexity, but our results show that this is false, even for very simple monotone classes of linear expansion.

We first show that every class of graphs that contains at most $2^{f(n)}$ unlabeled graphs of size n has local complexity $f(n) + O(\log n)$. This implies all the upper bounds we obtain in this paper, as the classes of graphs we consider usually contain $2^{O(n)}$ or $2^{O(n \log n)}$ unlabeled graphs of size n.

We then turn to lower bounds. Using rigidity properties in the classes we consider, we give a $\Omega(n)$ bound on the local complexity of *penny graphs* (contact graphs of unit-disks in the plane), *unit-distance graphs* (graphs that admit an embedding in $\mathbb{R}^2$ where adjacent vertices are exactly the vertices at Euclidean distance 1), and (induced) subgraphs of the square grid. We then consider *1-planar graphs*, which are graphs admitting a planar drawing in which each edge is crossed by at most one edge. This superclass of planar graphs shares many similarities with them, but we nevertheless prove that it has local complexity $\Theta(n)$ (while planar graphs have local complexity $\Theta(\log n)$).

Next, we consider *unit-square graphs* (intersection graphs of unit-squares in the plane). We obtain a linear lower bound on the local complexity of triangle-free unit-square graphs (which are planar) and of unit-square graphs in general. Finally, we consider *unit-disk graphs* (intersection of unit-disks in the plane), which are widely used in distributed computing as a model of wireless communication networks. For this class we reuse some key ideas introduced in the unit-square case, but as unit-disk graphs are much less rigid we need to introduce a number of new tools, which might be of independent interest in the study of rigidity in geometric graph classes. In particular we answer questions such as: what is asymptotically the minimum number of vertices in a unit-disk graph G such that in any unit-disk embedding of G, two given vertices u and v are at Euclidean distance at least n and at most $n+1$? Or at distance at least n and at most $n+\varepsilon$, for $\varepsilon \ll n$? Using our constructions we obtain a lower bound of $\Omega(n^{1-\delta})$ (for every $\delta > 0$) on the local complexity of unit-disk graphs. As there are at most $2^{O(n \log n)}$ unlabelled unit-disk graphs on n vertices [18], our first result implies that the local complexity of unit-disk graphs is $O(n \log n)$, so our results are nearly tight.

Techniques

All our lower bounds are inspired by the set-disjointness problem in non-deterministic communication complexity. This approach was already used in earlier work in local certification, in order to provide lower bounds on the local complexity of computing the diameter [3], or for certifying non-3-colorability [13]. Here the main challenge is to translate the technique into geometric constraints. The key point of the set-disjointness problem is informally the following: let $A, B \subseteq \{1, \dots, N\}$ be the input of some kind of "two-party system" that must decide whether A and B are disjoint, given that one party knows A and the other knows B; then at least N bits of shared (or exchanged) information are necessary for them to decide correctly. Otherwise, there are fewer bit combinations than the 2^N entries of the form $(A, \overline{A})$, hence the two parties can be fooled to accept a negative instance built from two particular positive instances sharing the same bit combination. In the setting of non-deterministic communication complexity, the two parties are Alice and Bob; in our setting, the two parties will be two subsets of vertices covering the graph and with small intersection (the intersection must be a small cutset of the whole graph): in the following, we refer to those two connected subsets of vertices as respectively the "left" part and the "right" part of the graph. The "shared" bits of information will be the certificates given to their intersection (and to its neighborhood). To express the sets A, B and their disjointness, the left (resp. right) part of the graph will be equipped with a path P_A (resp. P_B) of length $\Omega(N)$, such that P_A and P_B only intersect in their endpoints.[3] The crucial rigidity property which we will require is that in any embedding of G as a geometric graph from some class $\mathcal{C}$, the two paths P_A and P_B will be very close, in the sense that if $P_A = a_1, \dots, a_\ell$ and $P_B = b_1, \dots, b_\ell$, then a_i is close to b_i for any $1 \leq i \leq \ell$. Using this property, we will attach some gadgets to the vertices of the path P_A (resp. P_B) depending on A (resp. B), in such a way that the resulting graph lies in the class $\mathcal{C}$ if and only if A and B are disjoint. As there is little connectivity between the left and the right part, the endpoints of the paths will have to contain very long certificates in order to decide whether A and B are disjoint, hence whether $G \in \mathcal{C}$ or not.

We present the results in increasing order of difficulty. Subgraphs or induced subgraphs of infinite graphs such as grids are perfectly rigid in some sense, with some graphs having unique embeddings up to symmetry. Unit-square graphs are much less rigid but we can use nice properties of the ℓ_∞-distance and the uniqueness of embeddings of 3-connected planar graphs. We conclude with unit-disk graphs, which is the least rigid class we consider. The Euclidean distance misses most of the properties enjoyed by the ℓ_∞-distance and we must work much harder to obtain the desired rigidity property.

Outline

We start with some preliminaries on graph classes and local certification in Section 2. We prove our general upper bound result in Section 3. Section 4 introduces the notion of *disjointness-expressing* class of graphs, highlighting the key properties needed to derive our local certification lower bounds. We deduce in Section 5 linear lower bounds on the local complexity of subgraphs of the grid, penny graphs, and 1-planar graphs. Section 6 is devoted for the linear lower bound on the local complexity of unit-square graphs, while Section 7 contains our main result, a quasi-linear lower bound on the local complexity of unit-disk graphs. We conclude in Section 8 with a number of questions and open problems.

Due to the limit on the number of pages of the submission, most of the proofs have been omitted in this version. They are available in the full version of the paper [5].

[3] We note here that the proof for 1-planar graphs diverges from this approach, but it is the only one.

2 Preliminaries

In this paper logarithms are binary, and graphs are assumed to be simple, loopless, undirected, and connected. The *length* of a path P, denoted by $|P|$, is the number of edges of P. The *distance* between two vertices u and v in a graph G, denoted by $d_G(u, v)$ is the minimum length of a path between u and v. The *neighborhood* of a vertex v in a graph G, denoted by $N_G(v)$ (or $N(v)$ if G is clear from the context), is the set of vertices at distance exactly 1 from v. The *closed neighborhood* of v, denoted by $N_G[v] := \{v\} \cup N_G(v)$, is the set of vertices at distance at most 1 from v. For a set S of vertices of G, we define $N_G[S] := \bigcup_{v\in S} N_G[v]$.

2.1 Local certification

The vertices of any n-vertex graph G are assumed to be assigned distinct (but otherwise arbitrary) identifiers $(\mathrm{id}(v))_{v\in V(G)}$ from $\{1, \ldots, \mathrm{poly}(n)\}$. When we refer to a subgraph H of a graph G, we implicitly refer to the corresponding labeled subgraph of G. Note that the identifiers of each of the vertices of G can be stored using $O(\log n)$ bits, where log denotes the binary logarithm. We follow the terminology introduced by Göös and Suomela [13].

Proofs and provers

A *proof* for a graph G is a function $P : V(G) \to \{0, 1\}^*$ (as G is a labeled graph, the proof P is allowed to depend on the identifiers of the vertices of G). The binary words $P(v)$ are called *certificates*. The *size* of P is the maximum size of a certificate $P(v)$, for $v \in V(G)$. A *prover* for a graph class $\mathcal{G}$ is a function that maps every $G \in \mathcal{G}$ to a proof for G.

Local verifiers

A *verifier* $\mathcal{A}$ is a function that takes a graph G, a proof P for G, and a vertex $v \in V(G)$ as inputs, and outputs an element of $\{0, 1\}$. We say that v *accepts* the instance if $\mathcal{A}(G, P, v) = 1$ and that v *rejects* the instance if $\mathcal{A}(G, P, v) = 0$.

Consider a graph G, a proof P for G, and a vertex $v \in V(G)$. We denote by $G[v]$ the subgraph of G induced by $N[v]$, the closed neighborhood of v, and similarly we denote by $P[v]$ the restriction of P to $N[v]$.

A verifier $\mathcal{A}$ is *local* if for any $v \in G$, the output of v only depends on its identifier and $P[v]$.

Note that our lower bounds hold in the stronger model of *locally checkable proofs* of Göös and Suomela [13], where in addition the output of v is allowed to depend on $G[v]$, that is $\mathcal{A}(G, P, v) = \mathcal{A}(G[v], P[v], v)$ for any vertex v of G.

Proof labeling schemes

A *proof labeling scheme* for a graph class $\mathcal{G}$ is a prover-verifier pair $(\mathcal{P}, \mathcal{A})$ where $\mathcal{A}$ is local, with the following properties.

Completeness: If $G \in \mathcal{G}$, then $P := \mathcal{P}(G)$ is a proof for G such that for any vertex $v \in V(G)$, $\mathcal{A}(G, P, v) = 1$.

Soundness: If $G \notin \mathcal{G}$, then for every proof P' for G, there exists a vertex $v \in V(G)$ such that $\mathcal{A}(G, P', v) = 0$.

In other words, upon looking at its closed neighborhood (labeled by the identifiers and certificates), the local verifier of each vertex of a graph $G \in \mathcal{G}$ accepts the instance, while if $G \notin \mathcal{G}$, for every possible choice of certificates, the local verifier of at least one vertex rejects the instance.

The *complexity* of the proof labeling scheme is the maximum size of a proof $P = \mathcal{P}(G)$ for an n-vertex graph $G \in \mathcal{G}$, and the *local complexity* of $\mathcal{G}$ is the minimum complexity of a proof labeling scheme for $\mathcal{G}$. If we say that the complexity is $O(f(n))$, for some function f, the $O(\cdot)$ notation refers to $n \to \infty$. See [7, 13] for more details on proof labeling schemes and local certification in general.

2.2 Geometric graph classes

In this section we collect some useful properties that are shared by most of the graph classes we will investigate in the paper.

A *unit-disk graph* (respectively *unit-square graph*) is the intersection graph of unit-disks (respectively unit-squares) in the plane. That is, G is a unit-disk graph if every vertex of G can be mapped to a unit-disk in the plane so that two vertices are adjacent if and only if the corresponding disks intersect, and similarly for squares. A *penny graph* is the contact graph of unit-disks in the plane, i.e., in the definition of unit-disk graphs above we additionally require the disks to be pairwise interior-disjoint. A *unit-distance* graph is a graph whose vertices are points in the plane, where two points are adjacent if and only if their Euclidean distance is equal to 1. Unit-distance graphs clearly form a superclass of penny graphs.

A *drawing* of a graph G in the plane is a mapping from the vertices of G to distinct points in the plane and from the edges of G to Jordan curves, such that for each edge uv in G, the curve associated to uv joins the images of u and v and does not contain the image of any other vertex of G. A graph is *planar* if it has a drawing in the plane with no edge crossings (such a drawing will also be called a *planar graph drawing* in the remainder). Every planar graph drawing of a graph G gives a clockwise cyclic ordering of the neighbors around each vertex of G. We say that that two planar graph drawings of G are *equivalent* if the corresponding cyclic orderings are the same. A *planar graph embedding* of a graph G is an equivalence class of planar graph drawings of G. Given a planar graph embedding of a graph G, all the corresponding (equivalent) planar drawings of G have the same set of faces (but different choices of outerface yield different planar drawings).

A graph is *1-planar* if it has a drawing in the plane such that for each edge e of G, there is at most one edge e' of G distinct from e such that the interior of the curve associated to e intersects the interior of the curve associated to e'.

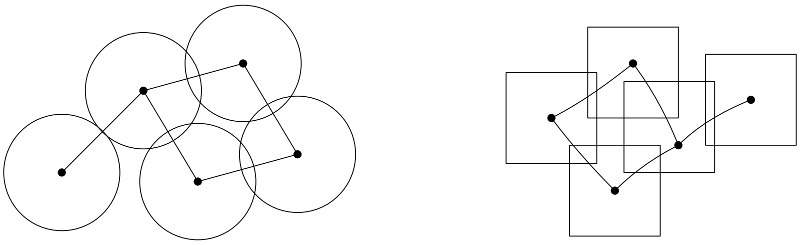

Figure 1 Triangle-free intersection graphs of unit-disks and unit-squares in the plane, and the associated planar graph embeddings.

The following well-known proposition will be useful (see Figure 1 for an illustration).

▶ **Proposition 2.1.** *Consider a family of unit-disks or a family of unit-squares in the plane, and assume that the intersection graph G of the family is connected and triangle-free. Then G is planar, and moreover each representation of G as such an intersection graph of unit-disks or unit-squares in the plane gives rise to a planar graph embedding of G in a natural way (see for instance Figure 1). Furthermore, the representation of G as an intersection graph (of unit-disks or unit-squares) and the resulting planar graph embedding are equivalent, in the sense that the clockwise cyclic ordering of the neighbors around each vertex is the same.*

We will often need to argue that some planar graphs have unique planar embeddings. The following classical result of Whitney will be crucial.

▶ **Theorem 2.2** ([22]). *If a planar graph G is 3-connected (or can be obtained from a 3-connected simple graph by subdividing some edges), then it has a unique planar graph embedding, up to the reversal of all cyclic orderings of neighbors around the vertices.*

We note that the reversal of all cyclic orderings in the statement of Theorem 2.2 corresponds to a reflection of the corresponding planar drawings.

3 Linear upper bounds for tiny classes

Given a class of graphs $\mathcal{C}$ and a positive integer n, let $\mathcal{C}_n$ be the set of all unlabeled graphs of $\mathcal{C}$ having exactly n vertices (i.e., we consider graphs up to isomorphism).

If there is a constant $c > 0$ such that for every positive integer n, $|\mathcal{C}_n| \leq c^n$, then the class $\mathcal{C}$ is said to be *tiny*. This is the case for all proper minor-closed classes (for instance planar graphs). On the other hand, unit-interval graphs and unit-disk graphs do not form tiny classes as proved in [18]. The local complexity and the number of unlabeled graphs in a class are related by the following simple result.

▶ **Theorem 3.1** ([5]). *Any class $\mathcal{C}$ of connected graphs has local complexity at most $\log(|\mathcal{C}_n|) + O(\log n)$. In particular if $\mathcal{C}$ is a tiny class, then the local complexity is $O(n)$.*

Proof (sketch). The prover gives each vertex v the same description of G (as an unlabelled graph, so using $\log(|\mathcal{C}_n|)$ bits), together with the name of the image of v in this description, and the number n of vertices of G. Each vertex checks that its neighborhood is consistent with its image in the description of G, and if so the graph under consideration must have a locally bijective homomorphism to G. The vertices then check that the number of vertices of the graph is indeed $n = |V(G)|$, which implies that this locally bijective homomorphism is an isomorphism to G, as desired. ◀

As a consequence, we immediately obtain the following.

▶ **Corollary 3.2.** *The following classes have local complexity $O(n)$: the class of all (induced) subgraphs of the square grid, penny graphs, 1-planar graphs, triangle-free unit-square graphs, and triangle-free unit-disk graphs.*

The next result directly follows from a bound of order $2^{O(n \log n)}$ on the number of unit-square graphs and unit-disk graphs [18], and on the number of unit-distance graphs [1].

▶ **Corollary 3.3.** *The classes of unit-distance graphs, unit-square graphs, and unit-disk graphs have local complexity $O(n \log n)$.*

The remainder of the paper consists in proving lower bounds of order $\Omega(n)$ (or $\Omega(n^{1-\delta})$, for any $\delta > 0$), for all the classes mentioned in Corollaries 3.2 and 3.3, except triangle-free unit-disk graphs (our quasi-linear lower bound only applies to unit-disk graphs).

4 Disjointness-expressing graph classes

In this section we describe the framework relating the disjointness problem to proof labeling schemes. Our main source of inspiration is [13], where a lower bound on the local complexity of non-3-colorability is proved using a similar approach, and [3] where an explicit reduction to the non-deterministic communication complexity of the disjointness problem is used.

Here we adapt the disjointness problem to fit in our local certification setting. A class $\mathcal{C}$ of graphs is said to be (s, κ)-*disjointness-expressing* if for some constant $\alpha > 0$, for every positive integer N and every $X \subseteq \{1, \dots, N\}$, one can define graphs $L(X)$ (referred to as the "left part") and $R(X)$ ("right part"), each containing a labeled set S of special vertices such that for every $A, B \subseteq \{1, \dots, N\}$ the following holds:

1. the graph $g(L(A), R(B))$ obtained by identifying vertices of S in $L(A)$ to the corresponding vertices of S in $R(B)$ is connected and has at most $\alpha N^{1/\kappa}$ vertices;
2. the subgraph of $g(L(A), R(B))$ induced by the closed neighborhood $N_{g(L(A),R(B))}[S]$ of S is independent[4] of the choice of A and B and has at most s vertices; and
3. $g(L(A), R(B))$ belongs to $\mathcal{C}$ if and only if $A \cap B = \emptyset$.

The idea is that S is a small cutset between vertices of $L(A)$, having information on A, and vertices of $R(B)$, having information on B. Deciding whether the graph $g(L(A), R(B))$ belongs to $\mathcal{C}$ amounts to deciding whether A and B are disjoint, which requires N bits of information even in a non-deterministic setting, thus the small cutset at the frontier between $L(A)$ and $R(B)$ must receive long certificates. Otherwise, there are fewer bit combinations at the frontier than the 2^N entries of the form $(A, \overline{A})$, hence the vertices can be fooled to accept a negative instance built from two particular positive instances sharing the same bit combination.

The role of s and κ is explained by the result below.

▶ **Theorem 4.1** ([5]). *Let $\mathcal{C}$ be a (s, κ)-disjointness-expressing class of graphs. Then any proof labeling scheme for the class $\mathcal{C}$ has complexity $\Omega\left(\frac{n^\kappa}{s}\right)$. In particular if s is a constant and $\kappa = 1$, the complexity is $\Omega(n)$.*

Proof (sketch). Let $(\mathcal{P}, \mathcal{A})$ be a proof labeling scheme for the class $\mathcal{C}$ and let $p \colon \mathbb{N} \to \mathbb{N}$ be its complexity. For every $A \subseteq \{1, \dots, N\}$, let $G_A = g(L(A), R(\overline{A}))$. Clearly $G_A \in \mathcal{C}$ so the verifier $\mathcal{A}$ accepts the proof $P_A = P(G_A)$ on every vertex of G_A. Let n denote the maximum order of G_A for $A \subseteq \{1, \dots, N\}$.

There are 2^N choices for the set A. On the other hand, in G_A there are at most $2^{s \cdot p(n)}$ different ways to assign certificates to the vertices of $N[S]$. By the Pigeonhole Principle, if $2^N > 2^{sp(n)}$ there are two sets $A, A' \subseteq \{1, \dots, N\}$ such that the proofs P_A and $P_{A'}$ coincide on the subgraph of G_A and $G_{A'}$ induced by $N[S]$. Since $A \neq A'$, we may assume without loss of generality that $A \cap \overline{A'} \neq \emptyset$. So the graph $G = g(L(A), R(\overline{A'}))$ does not belong to $\mathcal{C}$. We now consider a proof P for G defined as follows: if $v \in V(L(A))$ then $P(v) := P_A(v)$ and if $v \in V(R(\overline{A'}))$ then $P(v) := P_{A'}(v)$. The verifier $\mathcal{A}$ will accept P on every vertex of G, contradiction. Therefore $2^N \leq 2^{s \cdot p(n)}$. Recall that $n \leq \alpha N^{1/\kappa}$, by the definition of disjointness-expressibility. Hence $p(n) = \Omega(n^\kappa / s)$, as claimed. ◀

[4] i.e., for every $A, A', B, B' \subseteq \{1, \dots, N\}$ there is an isomorphism from $g(L(A), R(B))[N_{g(L(A),R(B))}[S]]$ to $g(L(A'), R(B'))[N_{g(L(A'),R(B'))}[S]]$ that is the identity on S.

5 Linear lower bounds in rigid classes

In this section we obtain linear lower bounds on the local complexity of several graph classes using the framework described in Section 4. We only sketch the argument in the case of penny graphs.

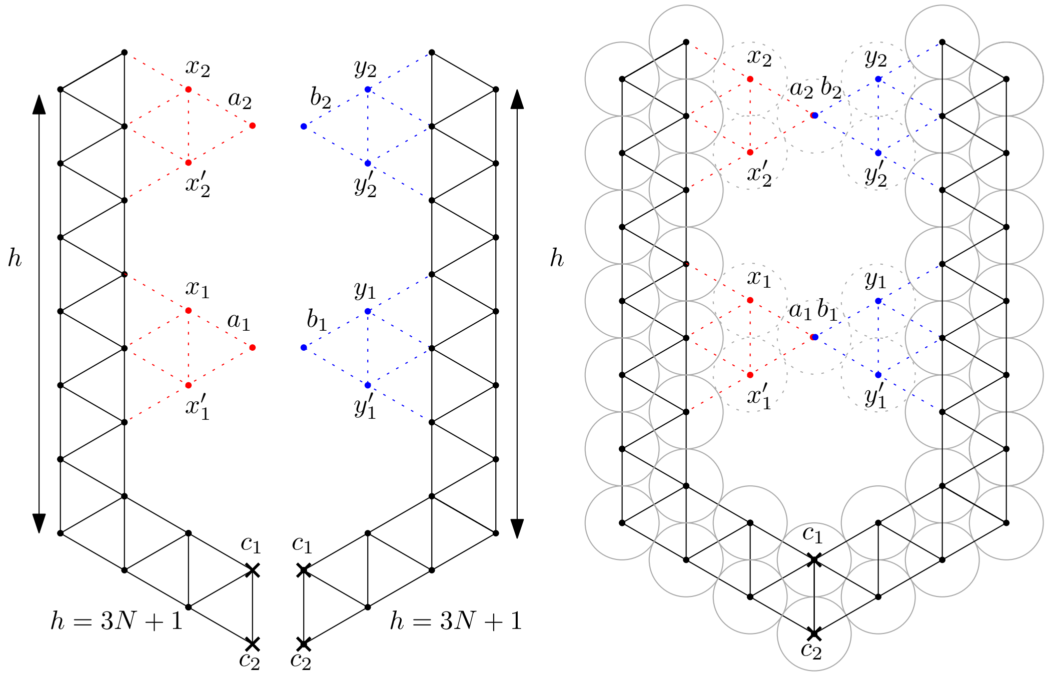

Figure 2 Construction of L, R and g for penny graphs in the case where $N = 2$, with $A, B \subseteq \{1, \ldots, N\}$. Color red highlights vertices and edges that depend on the choice of A, and color blue highlights vertices and edges that depend on the choice of B.

▶ **Theorem 5.1** ([5]). *The class of penny graphs is $(6, 1)$-disjointness-expressing.*

Proof (sketch). The proof is illustrated in Figure 2. The graph $g(L(A), R(B))$ (on the right) is obtained by identifying each c_i $(i = 1, 2)$ in $L(A)$ with the corresponding vertex in $R(B)$. The graphs $L(A)$ and $R(B)$ are depicted on the left. Vertices a_j, x_j, x'_j are added to the graph $L(A)$ if and only if $j \in A$, and similarly vertices b_j, y_j, y'_j are added to the graph $R(B)$ if and only if $j \in B$. The crucial properties of the construction are that (1) the graph without the added gadgets has a unique embedding as a penny graph, and (2) there is a small cut separating the left and right parts ($\{c_1, c_2\}$, which is far from the gadgets on both sides), and (3) if two gadgets a_i, x_i, x'_i and b_j, y_j, y'_j are added with $i = j$, then the graph is not a penny graph. The last item follows from the fact that a_i and b_j would be mapped to the same point in the plane, and thus a_i would also need to be adjacent to y_j and y'_j in the graph (which they are not). ◀

From Theorems 5.1 and 4.1, together with Corollary 3.2, we immediately deduce the following.

▶ **Theorem 5.2.** *The local complexity of the class of penny graphs is $\Theta(n)$.*

Using our framework we obtain the following results (whose proofs are available in appendix).

▶ **Theorem 5.3.** *The class of unit-distance graphs is* $(6, 1)$*-disjointness-expressing.*

▶ **Theorem 5.4** ([5])**.** *The class of subgraphs of the square grid is* $(6, 1)$*-disjointness-expressing.*

▶ **Theorem 5.5** ([5])**.** *The class of 1-planar graphs is* $(20, 1)$*-disjointness-expressing.*

We immediately deduce the following.

▶ **Theorem 5.6.** *The classes of subgraphs of the square grid, unit-distance graphs and 1-planar graphs all have local complexity* $\Theta(n)$*.*

6 Unit-square graphs

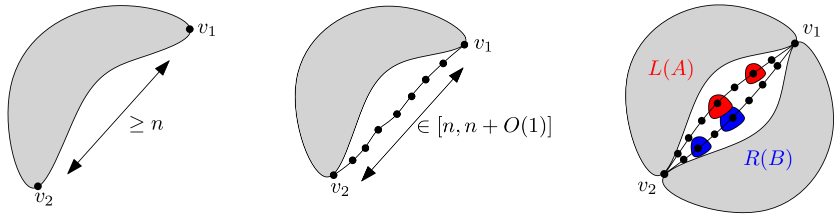

Figure 3 A sketch of the general approach to prove Theorems 6.1 and 7.1.

The graph we constructed in the previous section had some perfect rigidity properties: if the images of a constant number of vertices in the plane were fixed, then the whole graph had at most one embedding in the plane. This does not hold in unit-square graphs, but for our framework it is enough to make sure that once a constant number of vertices are fixed, each vertex of the graph can only be mapped to a small fixed region in any embedding. More precisely, we construct for any n a unit-square graph with $O(n)$ vertices with two specific vertices v_1, v_2 that are at ℓ_∞-distance at least n in any embedding. We add a shortest path connecting v_1 and v_2, so that the resulting graph is still a unit-square graph with $O(n)$ vertices, and the ℓ_∞-distance between v_1 and v_2 is at least n and at most $n + O(1)$ in any embedding. This is illustrated in Figure 3 above, where the path between v_1 and v_2 is close from being mapped to the line segment between the image of v_1 and the image of v_2. This path is then used as an interface to add gadgets expressing any set A for part $L(A)$ and any set B for part $R(B)$, very much as in the proof of Theorem 5.1. The difficulty lies in proving this approximate rigidity property, which follows from the rigidity of the ℓ_∞ norm.

▶ **Theorem 6.1** ([5])**.** *The classes of triangle-free unit-square graphs and unit-square graphs are both* $(6, 1)$*-disjointness-expressing.*

Using Theorem 4.1, together with Corollaries 3.2 and 3.3, we immediately deduce the following.

▶ **Theorem 6.2.** *The local complexity of the class of triangle-free unit-square graphs is* $\Theta(n)$*, and the local complexity of the class of unit-square graphs is* $\Omega(n)$ *and* $O(n \log n)$*.*

We note that the proof approach of Theorem 6.1 naturally extends to higher dimension.

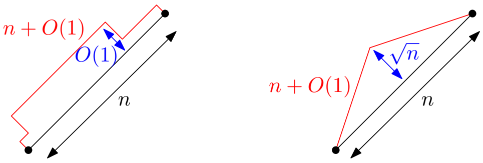

Figure 4 The difference between the ℓ_∞-distance (left) and the ℓ_2-distance (right).

7 Unit-disk graphs

We would like to prove a variant of Theorem 6.1 for unit-disk graphs, but there are two major obstacles. The first is that there does not seem to be a simple unit-disk graph with $O(n)$ vertices with two specified vertices that are at Euclidean distance at least n in any unit-disk embedding. Our construction of such a graph will be significantly more involved (and thus the number of vertices will be only upper bounded by $O(n^{1+\varepsilon})$ for any $\varepsilon > 0$, rather than $O(n)$). The second obstacle comes from Pythagoras' theorem: In the unit-square case, if we consider a path P of length $n + O(1)$ between two vertices u, v embedded in the plane such that their x- and y-coordinates both differ by exactly n, then in any unit-square embedding of P, the vertices of P deviate by at most a constant from the line segment $[u, v]$ between u and v. This is what we used in the proof of Theorem 6.1 to make sure that $L(A)$ and $R(B)$ are so close that the i-th gadget cannot exist both on $L(A)$ and $R(B)$ simultaneously when $i \in A \cap B$. However, as illustrated in Figure 4, Pythagoras' theorem implies that in the Euclidean case, when the Euclidean distance between u and v is equal to n, the vertices of P can deviate by $\Theta(\sqrt{n})$ from the line segment $[u, v]$, which is too much for our purpose (we need a constant deviation). So we need different ideas to make sure the gadgets are embedded sufficiently close to each other.

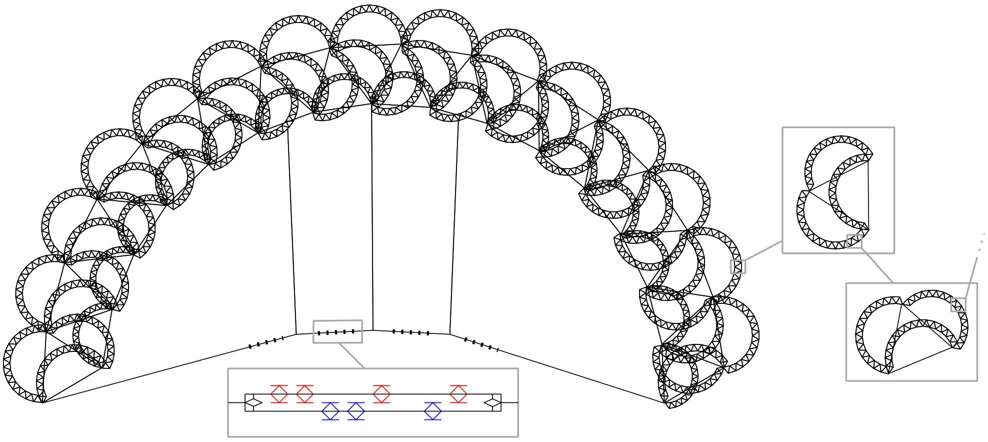

Figure 5 A summary of the construction used in the proof of Theorem 7.1.

The main result of this paper is the following.

▶ **Theorem 7.1** ([5]). *For any $\delta > 0$, the class of unit-disk graphs is $(O(\log n), 1 - \delta)$-disjointness-expressing.*

Proof (sketch). A summary of our construction is depicted in Figure 5. The first component of the construction is the arch-shaped part, which is defined recursively and has the property that its endpoints lie at Euclidean distance $\Omega(n)$ in any unit-disk embedding, while the graph only contains $O(n^{1+\varepsilon})$ vertices (for any $\varepsilon > 0$). We then add a shortest possible path P between the endpoints of the arch (with the condition that the resulting graph is still a unit-disk graph) and we would like to argue that the path P is *tight*, in the sense that in any embedding, all the unit-disks corresponding to the vertices of P lie at distance $O(1)$ from the line segment between the endpoints of P. For this we need to add a number of paths connecting P to the arch to make P even tighter. These paths delimit subpaths of P and the construction forces *at least one of* those subpaths to be tight. Since we do not know which subpath will be tight, we add gadgets, called *decorated corridors*, along all these subpaths. When a subpath is tight, the corresponding corridor is sufficiently narrow so that gadgets of $L(A)$ and $R(B)$ along the corridor can emulate the disjointness problem between A and B, as in the proof of Theorem 5.1. There is a gadget of $L(A)$ at position j of every corridor if and only if $j \in A$ and similarly for $R(B)$, and the gadgets of $L(A)$ and $R(B)$ intersect at position j of some corridor if and only if $j \in A \cap B$. Since these gadgets are not adjacent in the graph, this shows that the graph is a unit-disk graph if and only if $A \cap B = \emptyset$, as desired. ◀

Using Theorem 4.1, together with Corollary 3.3, we immediately deduce the following.

▶ **Theorem 7.2.** *The local complexity of the class of unit-disk graphs is $O(n \log n)$ and $\Omega(n^{1-\delta})$ for any $\delta > 0$.*

8 Open problems

In this paper we have obtained a number of optimal (or close to optimal) results on the local complexity of geometric graph classes. Our proofs are based on a new notion of rigidity. It is natural to ask which other graph classes enjoy similar properties. A natural candidate is the class of segment graphs (intersection graphs of line segments in the plane), which have several properties in common with unit-disk graphs. In particular the recognition problems for these classes are complete for the existential theory of the reals, and the minimum bit size for representing an embedding of some of these graphs in the plane is at least exponential in their number of vertices. We believe that the local complexity of segment graphs (and that of the more general class of string graphs) is at least polynomial in their number of vertices. More generally, is it true that all classes of graphs for which the recognition problem is hard for the existential theory of the reals have polynomial local complexity?

It might also be interesting to investigate the smaller class of *circle graphs* (intersection graphs of chords of a circle). The authors of [14] proved that the closely related class of permutation graphs has logarithmic local complexity. It is quite possible that the same holds for circle graphs. See [15] for results on interactive proof labeling schemes for this class and related classes.

We proved that 1-planar graphs have local complexity $\Theta(n)$. What can we say about the local complexity of other graph classes defined with constrained on their drawings in the plane? For instance is it true that for every $k \geq 2$, the local complexity of the class of graphs with queue number at most k is polynomial? What about graphs with stack number at most k?

We have given the first example of non-trivial hereditary (and even monotone) classes of local complexity $\Omega(n)$. Can this be improved? Are there hereditary (or even monotone) classes of local complexity $\Omega(n^c)$ for $c > 1$?

Efficient Computation in Congested Anonymous Dynamic Networks*

Giuseppe A. Di Luna[1]
DIAG, Sapienza University of Rome, Italy

Giovanni Viglietta[1]
Department of Computer Science and Engineering, University of Aizu, Japan

Abstract

An *anonymous dynamic network* is a network of indistinguishable processes whose communication links may appear or disappear unpredictably over time. Previous research has shown that deterministically computing an arbitrary function of a multiset of input values given to these processes takes only a linear number of communication rounds (Di Luna–Viglietta, FOCS 2022).

However, fast algorithms for anonymous dynamic networks rely on the construction and transmission of large data structures called *history trees*, whose size is polynomial in the number of processes. This approach is unfeasible if the network is *congested*, and only messages of logarithmic size can be sent through its links. Observe that sending a large message piece by piece over several rounds is not in itself a solution, due to the anonymity of the processes combined with the dynamic nature of the network. Moreover, it is known that certain basic tasks such as all-to-all token dissemination (by means of single-token forwarding) require $\Omega(n^2/\log n)$ rounds in congested networks (Dutta et al., SODA 2013).

In this work, we develop a series of practical and efficient techniques that make it possible to use history trees in congested anonymous dynamic networks. Among other applications, we show how to compute arbitrary functions in such networks in $O(n^3)$ communication rounds, greatly improving upon previous state-of-the-art algorithms for congested networks.

1 Introduction

Dynamic networks. In recent years, distributed computing has seen a remarkable increase in research on the algorithmic aspects of networks that constantly change their topology [7, 30, 32]. The study of these *dynamic networks* is motivated by technologies such as wireless sensors networks, software-defined networks, and networks of smart devices. Typically, the distributed system consists of n processes that communicate with each other in synchronous rounds. At each round, the network topology is rearranged arbitrarily, and communication links appear or disappear unpredictably.

[*] A preliminary version of this paper appeared as a Brief Announcement in the Proceedings of PODC 2023 [16].

Anonymity and leadership. There are efficient algorithms for various tasks that work under the assumption that processes have *unique IDs* [6, 27, 28, 29, 32, 34]. However, unique IDs may not be available due to operational limitations [34] or to protect user privacy; for instance, assigning temporary random IDs to users of COVID-19 tracking apps was not sufficient to eliminate privacy concerns [40]. Systems where processes are indistinguishable are called *anonymous*.

It is known that many fundamental problems for anonymous networks cannot be solved without additional "symmetry-breaking" assumptions: A notable example is the *Counting problem*, i.e., determining the total number of processes n. The most typical symmetry-breaking choice is assuming the presence of a single distinguished process in the system, called *leader* [1, 2, 3, 4, 14, 19, 21, 23, 31, 39, 42]. A leader process may represent a base station in a sensor network, a super-node in a P2P network, etc.

Disconnected networks. Another common assumption is that the network is connected at every round [28, 34]. However, this assumption appears somewhat far-fetched when one considers the highly dynamic nature of some real-world networks, such as P2P networks of smart devices moving unpredictably. A weaker and more reasonable assumption is that the union of all the network's links across any T consecutive rounds induces a connected (multi)graph on the processes [25, 36]. Such a network is said to be *T-union-connected*, and $T \geq 1$ is its *dynamic disconnectivity* [17].

Congested networks. Almost all previous research on anonymous dynamic networks pertains to models that impose no limit on the size of messages exchanged by processes [11, 15, 21, 22, 23, 24, 26, 34, 36]. Unfortunately, in most mobile networks, sending small-size messages is not only desirable but also a necessity; for example, in sensor networks, short communication times significantly increase battery life. A more realistic model assumes the network to be "congested" and limits the size of every message to $O(\log n)$ bits, where n is the number of processes [38].[2]

General computation. A recent innovation in the study of anonymous dynamic networks with leaders was the introduction of *history trees* in [15], which led to an optimal deterministic solution to the *Generalized Counting problem*[3] in the non-congested network model. This problem is "complete" for a large class of functions called *multiset-based functions*, which in turn are the only computable functions in this model. The theory of history trees was extended in [17] to *leaderless* networks, providing optimal algorithms for the *Frequency problem*:[4] This problem is complete for the class of *frequency-based* functions, which are the only computable functions in leaderless systems. Thus, the computational landscape for the non-congested network model is fully understood, and optimal linear-time algorithms are known for anonymous dynamic systems with and without leaders. No previous research exists on the congested network model, except for a recent preprint that gives a Counting algorithm in $\widetilde{O}(n^{2T(1+\epsilon)+3})$ rounds for networks with leaders [25]. Note that its running time is exponential in the dynamic disconnectivity T and becomes $\widetilde{O}(n^{5+\epsilon})$ for connected networks.

[2] This $O(\log n)$ limit on message sizes does not imply that the processes have a-priori information about n. The size limit is not explicitly given to the processes, and it is up to the algorithm to automatically prevent larger messages from being sent.

[3] In the Generalized Counting problem, each process starts with a certain input, and the goal is to determine how many processes have each input. That is, each process has to compute the *multiset* of all inputs.

[4] In the Frequency problem, the goal is to determine the percentage of processes that have each input.

1.1 Contributions and Techniques

Contributions. In this paper, we provide a state-of-the-art general algorithmic technique for T-union-connected anonymous dynamic *congested* networks, with and without leaders. The resulting algorithms run in $O(Tn^3)$ rounds, where n is the (initially unknown) total number of processes.

In Section 4 we give a basic and slightly inefficient Counting algorithm that applies to a limited setting but already contains all of the key ideas of our technique. In Section 5 we sketch its correctness (the technical details of the proof are found in the arXiv version linked in the title page), and in Section 6 we discuss optimizations and extensions of the basic algorithm to several other settings. This includes the computation of all multiset-based functions. Section 7 concludes the paper with some directions for future research.

Technical background. Informally, a *history tree* is a way of representing the history of a network in the form of an infinite tree. Each node in a history tree represents a set of anonymous processes that are "indistinguishable" at a certain round, where two processes become "distinguishable" as soon as they receive different sets of messages (see Section 3).

The theory of history trees developed in [15, 17] yields optimal general algorithms for anonymous dynamic networks with and without leaders, assuming the network is not congested. The idea is that processes can work together to incrementally construct the history tree by repeatedly exchanging and merging together their respective "views" of it. Once they have a sufficiently large portion of the history tree (i.e., a number of "levels" proportional to n), each process can locally analyze its structure and perform arbitrary computations on the multiset of input values originally assigned to the processes.

Challenges. Unfortunately, implementing the above idea requires sending messages containing entire "views" of the history tree. The size of a view is $\Theta(n^3 \log n)$ bits in the worst case, and is therefore unsuitable for the congested network model [15]. There is a major difficulty in dealing with this problem deterministically, which stems from the lack of unique IDs combined with the dynamic nature of the network.

It is worth noting that the "naive" approach of breaking down large messages into smaller pieces to be sent in different rounds does not work. Indeed, it is not clear how the original message can then be reconstructed, because the pieces carry no IDs and a process' neighbors may change at every round. This may result in messages from different processes being mixed up and non-existent messages being reconstructed.

Methodology. Our main contribution is a general method that allows history trees to be transmitted reliably and deterministically between anonymous processes in a dynamic *congested* network with a leader. To overcome the fundamental issues outlined above, we devised a basic protocol combining different techniques, as well as a number of extensions, including leaderless ones. Although the techniques introduced in this paper are self-contained and do not rely on the results of [15], they effectively allow us to reduce the congested network model to the non-congested one, making it possible to apply the Counting algorithm in [15] as a "black box".

Firstly, we developed a method for dynamically assigning temporary (non-unique) IDs to processes; this method is an essential part of the history tree transmission algorithm. In fact, the nodes of our history trees are now augmented with IDs, meaning that each node represents the set of processes with a certain ID. When processes with equal IDs get disambiguated, they get new IDs.

The transmission of history trees occurs level by level, one edge at a time. Since the total ordering between IDs induces a total ordering on the history tree's edges, the processes can collectively transmit sets of edges with a method reminiscent of *Token Dissemination* [28].

Essentially, all processes participate in a series of broadcasts; the goal of each broadcast is to transmit the next "highest-value" edge to the whole network. The problem is that no upper bound on the *dynamic diameter* of the network is known, and so there is no way of knowing how many rounds it may take for all processes to receive the edge being broadcast.

We adopt a self-stabilizing approach to ensure that all messages are successfully broadcast. We give a communication protocol based on acknowledgments by the leader, where failure to broadcast a message alerts at least one process. Alerted processes start broadcasting error messages, which eventually cause a reset of the broadcast that caused the error. A mechanism that dynamically estimates the diameter of the network guarantees that no more than $O(\log n)$ resets are performed.

Finally, in order to achieve a cubic running time, we do not construct the history tree of the actual network, but a more compact history tree corresponding to a *virtual network*. The virtual network is carefully derived from the real one in such a way as to amortize the number of edges in the resulting history tree and further reduce the final worst-case running time by a factor of n.

2 Previous Work

Non-congested networks. The study of computation in anonymous dynamic networks has been mainly devoted to two fundamental problems: The *Counting problem* in networks with a leader [11, 12, 13, 21, 22, 23, 24, 26] and the *Average Consensus problem* in leaderless networks [5, 8, 9, 10, 24, 33, 35, 37, 41, 43]. This research thread produced a series of algorithms for these problems; the underlying technique used is a local averaging or mass-distribution method coupled with refined termination strategies.

A radically different technique based on history trees was recently used to optimally compute arbitrary multiset-based functions in $3n$ rounds in networks with a leader [15]. This approach was successfully extended to multi-leader, leaderless, and disconnected networks [17].

Congested networks. As for the congested model, the only paper that has ever studied deterministic algorithms for anonymous dynamic networks, to the best of our knowledge, is the recent preprint [25], which solves the Counting problem in $\widetilde{O}(n^{2T(1+\epsilon)+3})$ rounds. As usual, T is the dynamic disconnectivity of the network and ϵ is an arbitrarily small positive constant. By comparison, our main algorithm has a running time of $O(Tn^3)$ rounds; hence, its dependence on T is linear (as opposed to exponential) and, for connected networks (i.e., when $T = 1$), the improvement is a factor of $\Theta(n^{2+\epsilon}\log^k n)$.

Most previous research efforts on congested networks in the dynamic setting have focused on randomized algorithms or processes with unique IDs [18, 20, 28]. In this context, a problem similar to Counting is *Token Dissemination*, where each process starts with a token and the goal is for every process to collect all tokens. In connected networks, this problem is solved in $O(n^2)$ rounds by a simple *token-forwarding* algorithm (i.e., no manipulation is done on tokens other than storing, copying, and individually transmitting them) [28]. Interestingly, solving the Token Dissemination problem by token-forwarding algorithms requires at least $\Omega(n^2/\log n)$ rounds [18].

It is worth remarking that the randomized algorithm in [28] only solves the Counting problem approximately and assumes a-priori knowledge of an upper bound on n. Moreover, this algorithm only works with high probability. These are three key differences that make our contribution preferable. Furthermore, assuming processes to have unique IDs (or randomly generating unique IDs) as in [28] defeats the purpose of safeguarding user privacy, which is a motivation of our work.

3 Definitions and Fundamentals

Computation model. A *dynamic network* is modeled by an infinite sequence $\mathcal{G} = (G_t)_{t\geq 1}$, where $G_t = (V, E_t)$ is an undirected multigraph whose vertex set $V = \{p_1, p_2, \dots, p_n\}$ is a system of n *anonymous processes* and E_t is a multiset of edges representing *links* between processes. Hence, there may be multiple links between two processes, or even from a process to itself.[5]

If there is a constant $T \geq 1$ such that, for every $t \geq 1$, the multigraph $G_t^\star = \left(V, \bigcup_{i=t}^{t+T-1} E_i\right)$ is connected, the network is said to be T*-union-connected*, and the smallest such T is its *dynamic disconnectivity*.[6]

Each process p_i starts with an *input*, which is assigned to it at *round* 0. It also has an internal state, which is initially determined by its input. At each *round* $t \geq 1$, every process composes a message (as a function of its internal state) and sends it to its neighbors in G_t through all its incident links.[7] In the congested network model, only messages of $O(\log n)$ bits can be sent.[8] By the end of round t, each process reads all messages coming from its neighbors and updates its internal state according to a local algorithm $\mathcal{A}$. Note that $\mathcal{A}$ is the same for all processes, and is a deterministic function of the internal state and the multiset of messages received in the current round.

The input of each process also includes a *leader flag*. In Section 4, we will assume that the leader flag of exactly one process is set (this process is the *unique leader*); in Section 6, we will discuss the *leaderless* case, where none of the processes has the leader flag set.

A process may return an *output* at the end of a round, which must be a function of its current internal state. A process may also *terminate* execution after returning an output. An algorithm $\mathcal{A}$ solves the *Counting problem* if executing $\mathcal{A}$ at every round eventually causes all processes to simultaneously output n and terminate. The (worst-case) *running time* of $\mathcal{A}$, as a function of n, is the maximum number of rounds it takes for $\mathcal{A}$ to solve the problem, across all possible dynamic networks of size n and all possible input assignments.

History trees. *History trees* were introduced in [15] as a tool of investigation for anonymous dynamic networks; an example is found in Figure 1. A history tree is a representation of a dynamic network given some inputs to the processes. It is an infinite graph whose nodes are partitioned into *levels* L_t, with $t \geq -1$; each node in L_t represents a class of processes

[5] Each self-loop in G_t represents a single link, hence a single message being sent and received by the same process.

[6] A similar parameter for dynamic networks is the *dynamic diameter* D, defined as the maximum number of rounds it may take for a message to be broadcast from a process to all other processes. The parameters T and D are related by the inequalities $T \leq D \leq T(n-1)$, which are best possible [17].

[7] Contrary to static networks, where processes may be allowed to send different messages to different neighbors, dynamic networks usually require processes to "broadcast" the same message through all incident links due to the lack of unique port numbers. This is the case, for instance, in wireless radio communications, where messages are sent to all processes within communication range, and the anonymity of the network prevents destinations from being specified.

[8] We may want to assume that the total number of links in a network multigraph G_t (counted with their multiplicities) is bounded by a polynomial in n. In fact, when dealing with congested networks, we explicitly make this assumption, as it ensures that the multiplicity of a link can always fit in a single $O(\log n)$-sized message.

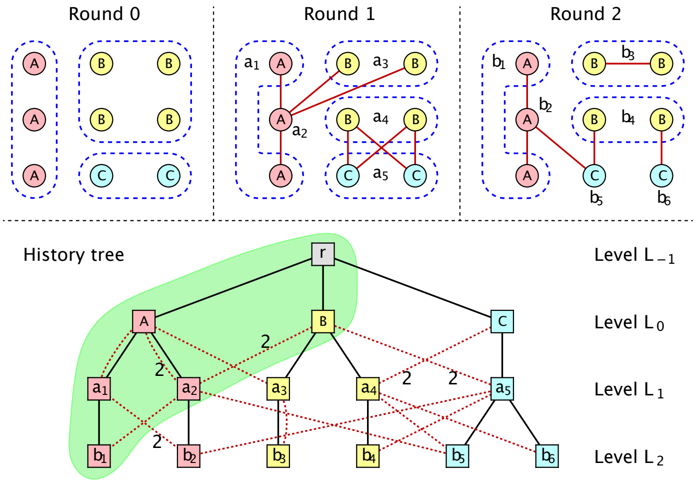

Figure 1 The first rounds of a dynamic network with $n = 9$ processes and the corresponding levels of the history tree. Level L_t consists of the nodes at distance $t + 1$ from the root r, which represent indistinguishable processes after the tth communication round. There are no leaders in the network, but each process has an input from the set $\{A, B, C\}$. Only the nodes in L_0 have explicit labels; all labels of the form a_i and b_i were added for the reader's convenience, and indicate classes of indistinguishable processes (in contrast, the nodes of the *virtual history tree* introduced in Section 4 do have IDs). Note that the two processes in b_4 are still indistinguishable at the end of round 2, although they are linked to the distinguishable processes b_5 and b_6. This is because such processes were in the same class a_5 at round 1. The subgraph induced by the nodes in the green blob is the *view* of the two processes in b_1. We remark that a history tree does not contain any explicit information about how many processes each node represents.

that are *indistinguishable* at the end of round t (with the exception of L_{-1}, which contains a single node r representing all processes). The definition of distinguishability is inductive: At the end of round 0, two processes are distinguishable if and only if they have different inputs. At the end of round $t \geq 1$, two processes are distinguishable if and only if they were already distinguishable at round $t - 1$ or if they have received different multisets of messages at round t. (We refer to "multisets" of messages, as opposed to sets, because multiple copies of identical messages may be received; each message has a *multiplicity*.)

Each node in level L_0 has a label indicating the input of the processes it represents. There are also two types of edges connecting nodes in adjacent levels. The *black edges* induce an infinite tree spanning all nodes, rooted at node $r \in L_{-1}$. The presence of a black edge $\{v, v'\}$, with $v \in L_t$ and $v' \in L_{t+1}$, indicates that the *child node* v' represents a subset of the processes represented by the *parent node* v. The *red multi-edges* represent communications between processes. The presence of a red edge $\{v, v'\}$ with multiplicity m, with $v \in L_t$ and $v' \in L_{t+1}$, indicates that, at round $t+1$, each process represented by v' receives m (identical) messages from processes represented by v.

The *view* of a process p at round $t \geq 0$ as the subgraph of the history tree which is spanned by all the shortest paths (using black and red edges indifferently) from the root r to the node in L_t representing p (Figure 1 shows an example of a view).

Applications of history trees. As proved in [15], the view of any process at round $3n$ contains enough information to determine the multiset of the initial inputs (i.e., how many processes have each input value). Thus, once a process is able to locally construct a view spanning $3n$ levels of a history tree, it can immediately do any computation on the inputs, and in particular determine n and solve the Generalized Counting problem.

History trees were adopted in [15, 17], where it is shown how processes can construct their views of the history tree in real time. For the algorithm to work, each process is required to repeatedly send its current view to all its neighbors at every round, merging it with all the views it receives from them.

This approach is not feasible in the congested network model, because a view at round t has size $\Theta(tn^2 \log n)$ in the worst case, since there may be $\Theta(n^2)$ red edges in each level. In the following, we will develop a strategy whereby processes can construct a history tree one red edge at a time. The core idea is that the nodes of the history tree are assigned unique IDs, and therefore a single red edge can be encoded in only $O(\log n)$ bits as a pair of IDs and a multiplicity.

4 Basic Counting Algorithm

In this section we describe our deterministic Counting algorithm for congested anonymous dynamic networks in its most basic version. The algorithm assumes the network to be connected ($T = 1$), to have a unique leader, and execution terminates in $O(n^3 \log n)$ rounds with the leader reporting the total number of processes in the system, n. The complete pseudocode is found in the arXiv version of this paper.

In Section 6, we will optimize this basic algorithm, making it terminate in $O(n^3)$ rounds. We will also extend the algorithm in several directions, for instance by making all processes (as opposed to the leader only) simultaneously output n and terminate. Furthermore, we will show how to not only count the number of processes, but also compute arbitrary (multiset-based, cf. [15]) functions, assuming that input values are assigned to the processes. Finally, we will extend the algorithm to leaderless networks and T-union-connected networks.

4.1 Algorithm Outline

The only input given to each process is whether or not it is the leader. Each process also has some private memory which is used to permanently store information in the form of internal variables.

Virtual history tree (VHT). The overall goal of the algorithm is for the processes to implicitly agree on the first $O(n)$ levels of a particular history tree, called *virtual history tree (VHT)*, which corresponds to a dynamic network $\mathcal{N}$ of n processes. Once the construction of each new level of the VHT is complete (refer to Section 4.5), the leader locally runs the Counting algorithm from [15] on the VHT. If this algorithm successfully returns a number (as opposed to "Unknown"), the leader outputs it; otherwise, the construction of a new level of the VHT is initiated.

Virtual network ($\mathcal{N}$). The dynamic network $\mathcal{N} = (N_1, N_2, \dots)$ represented by the VHT is in fact a *virtual network*, in the sense that none of the multigraphs N_t necessarily coincides with any multigraph of links actually occurring in the real communication network $\mathcal{G} = (G_1, G_2, \dots)$. However, each N_t is obtained by carefully adding and removing links from some G_{i_t} (see Figure 2). This manipulation has the purpose of reducing the size of the resulting VHT by a factor of n (see Section 4.4).

Temporary IDs. To cope with the fact that processes are anonymous and information can only be sent in small chunks of size $O(\log n)$, each process has a *temporary ID* stored in a local variable called `MyID`. Each node v in the VHT also has an ID, indicating that v

represents all processes having that ID. Thus, a *red-edge triplet* of the form $(\mathtt{ID1}, \mathtt{ID2}, \mathtt{Mult})$ can be used to unambiguously represent a red edge of multiplicity `Mult` between the nodes of the VHT whose IDs are `ID1` and `ID2`. Since a red-edge triplet has size $O(\log n)$, it can be included in a single message. Note that the variable `MyID` of each process may be modified over time as the VHT acquires more nodes.

Broadcast phases. The construction of the VHT is carried out level by level, and is done through several *broadcast phases*, which are indirectly coordinated by the leader (see Section 4.3). At first, each process knows the red edges incident to its corresponding node of the VHT. Then, ideally every two broadcast phases, the whole network learns a new red edge of the VHT. The broadcast phases continue until all processes know all red edges in the level (see Section 4.6).

Estimating the diameter. In order to guarantee the success of a broadcast phase, all processes must keep sending each other information for a certain number of rounds, which depends on the *dynamic diameter* of the network, and is $n - 1$ in the worst case [28]. Since the processes do not initially possess any information at all, they can only make estimations on the dynamic diameter. The current estimate is stored by each process in the variable `DiamEstimate`. Its value is initially 1, and it is doubled every time the processes detect an error in a broadcast.

Error phases. Detecting broadcasting errors and consistently reacting to them is by no means a trivial task, and is discussed in Section 4.7. Our broadcasting technique ensures that, if some red-edge triplet fails to be broadcast to the entire network and does not become part of the local VHT of all processes, at least one process becomes aware of this fact. Such a process enters an *error phase*, sending a high-priority message at every round containing the level number at which the error occurred. Error messages supersede the regular ones and eventually reach the leader.

Reset phases. When the leader finally receives an error message, it initiates a *reset phase*, whose goal is to force the whole network to restore a previous state of the VHT and continue from there. This is achieved by broadcasting a high-priority reset message. Since the error must have occurred because `DiamEstimate` was too small, its value is doubled at the end of the reset phase.

Note that there is no obvious way for the leader to tell if any level of the VHT is actually missing some parts: At any time, there may be processes in an error phase unbeknownst to the leader. One of the challenges of our method is to ensure that the leader will not terminate with an incorrect guess on n due to the VHT being incomplete.

4.2 Communication and Priority

Counting rounds. The processes have to implicitly synchronize with one another to start and finish each broadcast phase at the same time. Part of the synchronization is achieved by the function `SendAndReceive`, which is called by each process at every communication round. This function simply sends a given message to all neighbors, collects all messages coming from the neighbors, and increments the internal variable `CurrentRound`. Since communications in the network are synchronous, all processes always agree on the value of `CurrentRound`.

Message types. The processes use messages of various types to share information with one another. Each message has a *label* describing its type, as well as at most three additional integer parameters. As it will turn out in the analysis of the algorithm, each parameter has size $O(\log n)$ bits.[9] The message types and their parameters are as follows.

- **Null message.** Label: "Null". No parameters.
- **Level-begin message.** Label: "Begin". Parameters: `ID`.
- **Level-end message.** Label: "End". No parameters.
- **Done message.** Label: "Done". Parameters: `ID`.
- **Red-edge message.** Label: "Edge". Parameters: `ID1`, `ID2`, `Mult`.
- **Error message.** Label: "Error". Parameters: `ErrorLevel`.
- **Reset message.** Label: "Reset". Parameters: `ResetLevel`, `StartingRound`, `NewDiam`.

Priority. Messages have *priorities* that determine how they are handled during a broadcast. The priority of a message is defined as follows:

$$\text{Null} < \text{Begin} < \text{End} < \text{Done} < \text{Edge} < \ldots < \text{Reset } k+1 < \text{Error } k < \text{Reset } k < \ldots < \text{Error } 1 < \text{Reset } 1$$

That is, the message with lowest priority is the Null message, followed by all possible Level-begin messages, then the Level-end message, etc. The priority of a Level-begin message is independent of its parameter. For all other message types, however, the priority is also a function of the parameters.

As for Done messages, different `ID` parameters yield different priorities. Thus, priority induces a total ordering on the set of all possible Done messages; the precise ordering is irrelevant, as long as all processes implicitly agree on it. All Done messages have greater priority than Null, Level-begin and Level-end messages. The same goes for Red-edge messages: Different parameters yield different priorities, and all processes agree on the priority function. All Red-edge messages have greater priority than all Done messages, and lower priority than all Error and Reset messages.

An Error message (respectively, a Reset message) with a smaller `ErrorLevel` (respectively, `ResetLevel`) has a greater priority. Moreover, the priorities of Error and Reset messages are interleaved: The priority of an Error message with `ErrorLevel` $= k$ is strictly between the priority of a Reset message with `ResetLevel` $= k+1$ and the priority of a Reset message with `ResetLevel` $= k$.

4.3 Broadcasting Data

During the execution of the algorithm, a non-leader process may have a particular piece of information that it wishes to send to the leader. Similarly, the leader may have some information that it wishes to share with all processes in the network. Both operations are performed via a *broadcast* spanning several rounds.

The broadcast technique used to construct the VHT is implemented as follows. It is assumed that all processes participating in the broadcast are *synchronized*, i.e., they start at the same round and continue broadcasting for the same number of rounds (which is equal to `DiamEstimate`). Each process is also assumed to have the information it wishes to share packed in a message of the appropriate type (see Section 4.6), which is passed to the function `BroadcastPhase` as the argument `Message`.

[9] As already remarked, the algorithm spontaneously creates $O(\log n)$-sized messages without any a-priori knowledge on n.

At each broadcast round, each process sends its message to all its neighbors. Then it examines the messages received from the neighbors, as well as its own message, and keeps only the message with highest priority, discarding all others (function `BroadcastStep`). This is the message the process will send in the next round, and so on.[10]

Ideally, if the broadcast is continued for a sufficiently large number of rounds, all processes participating in the broadcast will eventually obtain the message having the highest priority among the ones initially owned by the processes (note that this may be an Error or Reset message, as well).

4.4 Defining the Virtual Network

Definition. Recall that the VHT is the history tree of the virtual network $\mathcal{N} = (N_1, N_2, N_3, \dots)$. We will now define N_t by induction on t. That is, assuming that the multigraphs N_1, N_2, …, N_{t-1} are already known, we will construct N_t based on the multigraph G_{i_t}, which represents the real communication network $\mathcal{G}$ at a selected round i_t (Section 4.6 explains how i_t is selected).

Since the first $t-1$ rounds of the virtual network are known, we can construct the first levels of the VHT up to level L_{t-1}. By definition of history tree, each node $v \in L_{t-1}$ represents a class P_v of processes that are indistinguishable after the first $t-1$ "virtual rounds" modeled by the communication networks N_1, N_2, …, N_{t-1}.

Consider the simple undirected graph $H = (V, E)$, where $V = L_{t-1}$ and $\{u, v\} \in E$ if and only if $u \neq v$ and there is at least one link in G_{i_t} between a process in P_u and one in P_v. Recall that we are assuming that G_{i_t} is connected, and therefore H is connected, as well (disconnected networks will be discussed in Section 6). Let $S = (V, E')$ be an arbitrary spanning tree of H.

Now, N_t is the network having the following links (refer to Figure 2):

- For every edge $\{u, v\} \in E'$ of S, the multigraph N_t contains all the links in G_{i_t} having an endpoint in P_u and an endpoint in P_v (with the respective multiplicities).
- For every $v \in V$, the multigraph N_t contains a cycle C_v spanning all the processes in P_v. In the special case where P_v contains exactly two processes p_1 and p_2, C_v is a double link between p_1 and p_2. If P_v contains a single process p, C_v is a double self-loop on p.

Note that, in every case, C_v induces a 2-regular multigraph on P_v. The purpose of these (possibly degenerate) cycles C_v is to ensure that N_t is connected. On the other hand, the purpose of using a spanning tree S, as opposed to the full graph H, is to reduce the size of the VHT.

Implementation. In the actual algorithm, N_t is defined only implicitly in a distributed manner (because the ultimate goal is merely the construction of the VHT). The implicit construction of N_t starts at round i_t, where each process (not in an error phase) invokes the function `SetUpNewLevel` and sends a Begin message containing its own ID to each neighbor. As a result, each process learns the IDs of all its neighbors in G_{i_t}, as well as their multiplicities, and stores this information as a list of pairs of the form $(\texttt{ID}, \texttt{Mult})$ in the internal variable `ObsList`. It should be noted that a process discards all Begin messages from processes with the same ID as its own. These are replaced by the single pair $(\texttt{MyID}, 2)$, which accounts for the two edges of the cycle C_v incident to the process in N_t.

[10] Note that our broadcasting strategy implements a token-forwarding mechanism, and the sequence of all broadcast phases is akin to a Token Dissemination algorithm. It is known that any such algorithm must have a worst-case running time of at least $\Omega(n^2/\log n)$ rounds [18].

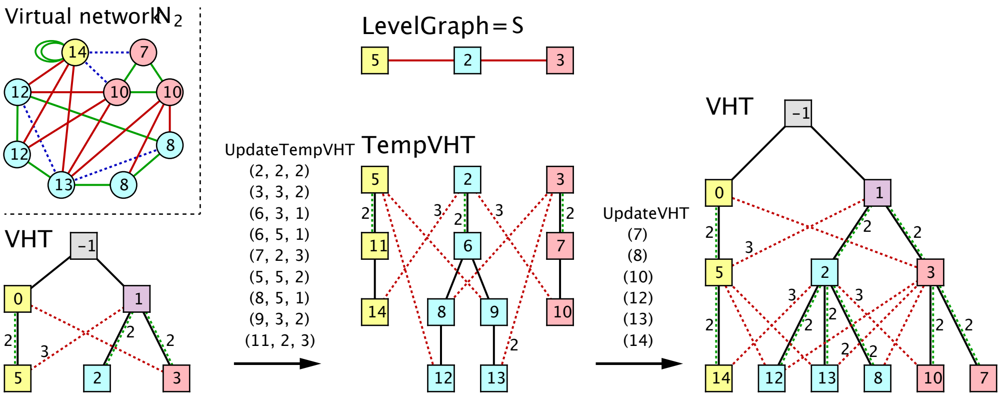

Figure 2 Construction of the virtual network N_2 and level L_2 of the virtual history tree (VHT). The real network G_{i_2} consists of the $n = 9$ processes in the upper-left picture, connected by the red and blue links (not the green ones). Before the construction starts, the IDs in the network are 5, 2, and 3. Same-colored processes have equal IDs when the construction of L_2 starts; the labels indicate their IDs when the construction finishes. Accordingly, level L_1 of the VHT has three nodes with IDs 5, 2, 3. The graph H is a triangle on these three nodes, while its spanning tree S is the same as `LevelGraph`. Therefore, to construct N_2 we remove the blue edges from G_{i_2} and keep the red ones (see Section 4.4). For example, after the triplets $(6, 3, 1)$ and $(6, 5, 1)$ are accepted, any elements of `ObsList` corresponding to the two blue edges incident to the yellow process are deleted and are never broadcast. We also have to add the green edges, which represent the cycles C_v. Note that failing to add them would result in a disconnected network, because the process with ID 7 would be isolated. For clarity, the edges of the (temporary) VHT are colored red or green to match the edges of the virtual network that they represent (although technically they are all red edges).

The choice of links to be included in N_t (which directly reflects on the red edges included in the VHT) is guided by the construction and maintenance of an *auxiliary graph* stored in each process' internal variable `LevelGraph`. The auxiliary graph is a graph on $V = L_{t-1}$ and starts with no edges at all; it gradually acquires more edges until it becomes the spanning tree S (as defined above). This is carried out as part of the function `UpdateTempVHT`, which is invoked every time a red-edge triplet $(\texttt{ID1}, \texttt{ID2}, \texttt{Mult})$ is selected to become a new red edge of the VHT at the end of a broadcast phase. Among other operations (described in Section 4.5), this function adds an edge to the auxiliary graph which connects the two nodes corresponding to `ID1` and `ID2`. Then the function `PreventCyclesInLevelGraph` is called, which deletes all the pairs in `ObsList` whose selection would cause the creation of a cycle in the auxiliary graph. This guarantees that, eventually, `LevelGraph` will be a tree (representing S).

4.5 Constructing the Virtual History Tree (VHT)

Initialization. The VHT is initialized by the function `InitializeVariables`. At first, the VHT only contains level L_{-1} (a single root node whose ID is -1) and level L_0 (two nodes with IDs 0 and 1, representing the leader and the non-leader processes, respectively). Accordingly, the leader initializes its own `MyID` variable to 0 and the non-leaders to 1.

Temporary VHT. Then, for all $t \geq 1$, the level L_t of the VHT is constructed based on the virtual network N_t as in Figure 2. When the construction begins, all processes (that are not in an error phase) acquire new pairs of the form $(\texttt{ID}, \texttt{Mult})$ at the same round i_t and store them in `ObsList`, as explained in Section 4.4. The construction of a new level is not carried out directly on the VHT, but in a separate *temporary VHT* stored in the internal variable TempVHT. Initially, this is just a copy of level L_{t-1} of the VHT, i.e., a set of nodes, each with a distinct ID, and no edges.

Adding red edges. In order to determine how TempVHT should be updated, several broadcast phases are performed, allowing the processes to share their red-edge triplets with one another. Note that a process can transform each element of ObsList of the form (ID, Mult) into a red-edge triplet by simply adding its own ID as the first element. Every time a red-edge triplet (ID1, ID2, Mult) has been broadcast by a process to the entire network and has been "accepted" (see Section 4.6 for details), the function UpdateTempVHT is called. The result is that the node v of TempVHT whose ID is ID1 gets a new child v' with a new unique ID. Pictorially, a black edge is created connecting v' to v. Also, a red edge with multiplicity Mult is added to TempVHT, connecting the new node with the node whose ID is ID2.

Updating IDs. By definition, the red-edge triplet (ID1, ID2, Mult) indicates that *some* processes whose ID is ID1 have received exactly Mult messages from processes whose ID is ID2. These processes, which were previously represented by the node v, are now represented by v'. Therefore, every process whose ID is ID1 that has the pair (ID2, Mult) in its local ObsList removes it from the list and modifies its own ID from ID1 to the ID of v'.[11]

Updating the VHT. When a process has no more red-edge triplets to share (that is, its ObsList is empty), it broadcasts a Done message containing its current ID. Recall that Done messages have lower priority than Red-edge messages (see Section 4.2). When the final result of a broadcast is a Done message containing a certain ID, all processes assume that *some* processes with that ID have sent all their red-edge triplets. Therefore, the node of the temporary VHT with that ID is ready to be added to the VHT.

To this end, the function UpdateVHT is called with the ID contained in the Done message. This function creates a new node v in level L_t of VHT corresponding to the node v' of TempVHT whose ID is the one passed to the function (refer to Figure 2). The node v gets the same ID as v' and becomes a child of the node $u \in L_{t-1}$ having the same ID as the root v'' of the tree containing v'. Then, v takes all the red edges found along the path from v' to v''.

Finalizing the level. When the ObsList of a process is empty and the VHT already contains a node with its ID, the process broadcasts an Level-end message, which has lower priority than Done and Red-edge messages. When the result of a broadcast is an Level-end message, the construction of the level is finished.

4.6 Main Loop

The entry point of the algorithm is the function Main. After initializing the internal variables as already explained, the function goes through a loop that constructs the VHT level by level. At several points in this loop there may be errors that cause some of the levels to be undone and execution to resume from the beginning of the loop; we will discuss errors in Section 4.7. Next, we will describe an ideal error-free execution.

[11] To clarify, the nodes of the VHT have unique IDs. Each node represents a class of "indistinguishable" processes, all of which have the same ID as the node itself. When processes disambiguate in the virtual network, they obtain different IDs. However, it is not necessarily true that all processes will have distinct IDs eventually. For example, if the network is the (static) complete graph, all non-leader processes will always have the same ID (which is incremented at every virtual round).

Level initialization. With each iteration of the main loop, a new level of the VHT is constructed. At the beginning, the function `SetUpNewLevel` is executed by all processes: This marks a selected round G_{i_t} as defined in Section 4.4 (the non-trivial fact that all processes always call this function at the same round will become apparent from our analysis of the algorithm, in Section 5).

VHT broadcast. Then an inner loop is entered; the purpose of each iteration is for all processes to learn new information, which causes an update of the temporary VHT or the VHT itself. At first, each process calls the function `MakeVHTMessage`, which picks an element from `ObsList`, converts it into a red-edge triplet by adding its own ID to it, and wraps it in a Red-edge message. If `ObsList` is empty, a Done message containing the process' ID is generated instead. The resulting message is used in a first broadcast phase which, after a number of rounds equal to `DiamEstimate`, returns the highest-priority message circulating in the network. This message is stored in the variable `VHTMessage`.

Acknowledgment broadcast. Note that, in the presence of a faulty broadcast, different processes may end up having different versions of `VHTMessage`. To ensure that all processes (that are not in an error phase) update their local copies of the (temporary) VHT in a consistent way, an "acknowledgment" broadcast phase is performed. Its purpose is for the leader to inform all other processes of the *accepted message*; by definition, the accepted message is the leader's version of `VHTMessage`.

In the acknowledgment phase, all non-leader processes broadcast a low-priority Null message, while the leader broadcasts the accepted message. The message resulting from the broadcast is then stored in the variable `AckMessage`.

Updating the level. Now, each process compares the contents of the two messages `VHTMessage` and `AckMessage`. If they are the same (hence not Null), then this is indeed the accepted message coming from the leader, and the data therein is used to update the temporary VHT or the VHT. Specifically, if `AckMessage` is a Red-edge message, the red-edge triplet therein is used to update the temporary VHT. If it is a Done message, the VHT is updated instead.

Finalizing the level. When a process is done broadcasting red-edge triplets and the VHT already contains a node representing it, the process broadcasts a low-priority Level-end message. As soon as the accepted message is the Level-end message, the level is considered complete and the inner loop is exited.

Counting processes. Now the leader extracts its own view from the VHT and locally runs the Counting algorithm from [15] on it (function `CountFromView`). By "extracts its own view" we mean that it makes a copy of the VHT and deletes all nodes that are not on a shortest path from the root to the deepest leader's node.

If the value returned by `CountFromView` is a number, this is taken as the correct number n of processes in the virtual network $\mathcal{N}$ (and hence in the real network $\mathcal{G}$) and becomes the leader's output. Otherwise, a new iteration of the main loop starts, a new level of the VHT is constructed, and so on.

4.7 Handling Errors and Resets

Detecting errors. As mentioned, a broadcast phase lasts a number of rounds indicated by the variable `DiamEstimate`. If this number happens to be smaller than the dynamic diameter of the network, the broadcast may be unsuccessful, in the sense that not all processes may end up agreeing on the same highest-priority message. Fortunately, the protocol described in Section 4.6 makes error detection very simple: At the end of every acknowledgment broadcast, if the contents of a process' variables `VHTMessage` and `AckMessage` are different, the broadcast was unsuccessful. Any process that detects this event enters an error phase.

Error phase. When a process enters an error phase, it runs the function `BroadcastError`; as it turns out, only non-leader processes ever execute this function. During an error phase, a process continually broadcasts an Error message containing the index of the level of the VHT where the error was detected. This message is replaced by any other message of higher priority received by the process during the error phase (see Section 4.2). As soon as the process receives a Reset message for a level of smaller or equal depth than the one indicated by the current Error message (i.e., a Reset message of higher priority), it ends the error phase and enters a reset phase.

Another situation where a non-leader process enters an error phase is when it receives an Error message from some other process. In this case, it calls the function `HandleError` and starts broadcasting a new Error message containing the smaller between the index of the current level and the one contained in the received Error message. This causes higher-priority error messages to propagate through the network and eventually reach the leader.

Reset phase. This phase is initiated by the leader at the end of a broadcast phase (or after sending a Begin message) in case it received an Error message. The leader first waits for $2 \cdot \texttt{DiamEstimate} + 1$ rounds, sending only Null messages. This is to ensure that all non-leader processes finish any broadcast phase and enter an error phase. In turn, this prevents any possible conflicts between different broadcast phases before and after a reset.

Then the leader creates a Reset message containing the index of the VHT level where the error occurred, the current round number, and the new estimate on the dynamic diameter, i.e., twice the current one, since the error occurred because the estimate was too small.

Now the leader calls the function `BroadcastReset`, where it broadcasts the Reset message; any process that receives this message starts broadcasting it as well (provided that it has higher priority than the Error message it is currently broadcasting, as usual). The broadcast continues for a total number of rounds equal to the new dynamic diameter estimate. All processes that receive the Reset message are able to synchronize with one another and finish the reset phase at the same round, thanks to the information contained in the message itself.

At the end of the reset phase, the reset is actually performed: Every process that got the Reset message deletes the most recent levels of the VHT up to the level where the error occurred (this information is contained in the Reset message) and reverts its ID to the one it had at the beginning of the construction of that level. The variable `DiamEstimate` is also updated with the new estimate. At this point, the network is ready to resume construction of the VHT.

5 Proof of Correctness

We will now sketch a proof of correctness for the Counting algorithm in Section 4. The interested reader may refer to the arXiv version for a detailed and technically rigorous proof.

We say that two processes *agree* on a variable at a certain round if their local instances of that variable are equal. As it turns out, all processes that are not in an error phase must always agree on the variable `DiamEstimate`: this can be proved by induction on the number of reset phases that the leader has completed.

In turn, this implies that all processes (that are not in an error phase) are able to implicitly synchronize their broadcast phases with the leader, since these phases have a duration of `DiamEstimate` rounds. As a consequence, all processes (not in an error phase) also agree on the variables `CurrentLevel`, `VHT`, `TempVHT`, `LevelGraph`, and `NextFreshID`, because these variables are updated either at the beginning or at the end of a broadcast or reset phase.

Thus, we can unambiguously refer to phases and variables with no explicit mention of any individual process, because these phases and variables are the same throughout the whole network (excluding the processes in an error phase).

The goal of the algorithm is to construct the first levels of the VHT, i.e., the history tree of the virtual network $\mathcal{N}$. However, information on the virtual network is shared by all processes through several broadcast phases, and there is no guarantee that every broadcast phase will have the correct outcome (some data may fail to be communicated if `DiamEstimate` is smaller than the network's actual dynamic diameter). Thus, we distinguish between the *ideal VHT*, i.e., the "correct" history tree corresponding to $\mathcal{N}$, and the *effective VHT*, i.e., the one that is actually being constructed by the processes, which may be missing some information.

It is a byproduct of our protocol that, whenever a node is added to the effective VHT, then all red edges incident to it (and to nodes in the previous level of the ideal VHT) are also included. In particular, extracting the leader's view from the effective VHT yields a graph isomorphic to the view of the leader in the ideal VHT. This implies that the function `CountFromView` is always given as input a view of the history tree of a connected network of n processes. As proved in [15], this function must return either "Unknown" or n; in particular, it returns n when the input view spans at least $3n$ levels.

Hence, our algorithm cannot return an incorrect number. It remains to prove that it does terminate within the desired number of rounds. Every time a faulty broadcast is detected and the leader is notified of it, a reset phase is initiated and `DiamEstimate` is doubled. It follows that no more than $O(\log n)$ reset phases ever occur, and `DiamEstimate` is always $O(n)$; this is also the duration of each broadcast phase.

Recall that links are not included in the virtual network if they cause cycles to appear in `LevelGraph` (see Section 4.4). Although this strategy may not guarantee that every level of the VHT has $O(n)$ red edges, it does amortize the total number of red edges over several levels. In fact, the first $O(n)$ levels of the ideal VHT only contain $O(n^2)$ red edges (as opposed to $O(n^3)$, which may be the case for the history tree of a generic network).

Summarizing, it takes $O(n^2)$ broadcast phases to construct the first $3n$ levels of the VHT, resulting in a total of $O(n^3)$ rounds. The construction process is partially undone and repeated at most $O(\log n)$ times due to resets, and so the final running time is $O(n^3 \log n)$.

It is straightforward to prove that the algorithm works in the congested network model, because all the data contained in a message are binary representations of values that are polynomial in n, e.g., round numbers, estimates of the dynamic diameter, or temporary IDs of processes. Since each message contains at most three of these values, its size is $O(\log n)$.

6 Extensions and Improvements

Simultaneous termination. In Section 4 we showed how the leader can determine n. If we want all processes, not just the leader, to simultaneously output n and terminate, we can use the following protocol. As soon as the leader knows n, it broadcasts a message of maximum priority containing n and the current round number c. Any process that receives this message keeps forwarding it until round $c+n$. By this round they all have it, and thus can output n and terminate simultaneously.

General computation. If each process is assigned an $O(\log n)$-sized input (other than the leader flag), we can also perform general computations on the multiset of inputs. We only have to adapt the algorithm of Section 4 to work with history trees whose level L_0 contains one node per input occurring in the system, and then run the algorithm in [15] on this extended history tree. This can easily be done with the techniques developed in Section 4: We can construct L_0 like any other level, except that we use broadcast phases to transmit inputs instead of red edges.

Optimized running time. We can sightly speed up our algorithm at the cost of some additional bookkeeping. The idea is to refine the error and reset mechanism by resuming the construction of the VHT not from the *level* that caused an error, but from the *broadcast phase* that caused it.

The processes have to remember the order in which the leader accepted Red-edge and Done messages, as well as the Begin messages received at every begin round. When a process detects an error, it broadcasts an Error message containing not the current level number, but the number of messages that the leader has accepted up to that time. The advantage is that the reset phase can rewind the (temporary) VHT exactly to the desired point without erasing entire levels. Furthermore, by looking up the Begin messages received in the appropriate begin round, each process is also able to reconstruct its local `ObsList` at the desired time.

If a broadcast phase causes an error, the leader receives a notification after less than n rounds, and so it only has to undo the work done in $O(n)$ rounds. Since there can be at most $O(\log n)$ resets, the total time spent in reset phases or doing work that later gets undone is $O(n \log n)$ rounds. Thus, the new algorithm runs in $O(n^3) + O(n \log n) = O(n^3)$ rounds.

Leaderless computation. It is known that doing any non-trivial computation in a leaderless network requires some extra assumptions, for example the knowledge of an upper bound D on its dynamic diameter [17]. However, knowing D allows processes to reliably broadcast messages in phases of D rounds. This immediately yields an extension of our algorithm to leaderless networks in $O(Dn^2)$ rounds, where no acknowledgment phases or error and reset phases are needed.

Disconnected networks. We can extend our algorithm to T-union-connected networks, assuming the parameter T is known. As discussed in [17], the idea is to divide the sequence of rounds into blocks of size T. Within every block, each process keeps sending the same message and stores all incoming messages. At the end of a block, each process runs the algorithm from Section 4 (or its optimization) pretending that all the stored messages arrived in a single round. This is equivalent to running the algorithm on the dynamic network $\mathcal{G}^\star = (G_1^\star, G_{T+1}^\star, G_{2T+1}^\star, \dots)$, which is always connected ($G_t^\star$ is defined in Section 3). The running time is simply $O(Tn^3)$ rounds.

7 Concluding Remarks

In this paper we have extended the theory of history trees by introducing the tools necessary for the distributed construction and transmission of history trees in the congested network model. This resulted in a new state of the art for general computation in disconnected anonymous dynamic congested networks, with or without leaders.

Our history tree construction technique leads to general algorithms whose running time is cubic in the size of the network. An immediate open problem is whether this running time can be reduced. Since our algorithm broadcasts information using a token-forwarding approach, and by virtue of the $\Omega(n^2/\log n)$ lower bound of [18], we believe that it would be unlikely to achieve a better running time without a radical change in the technique used.

Understanding whether the Counting problem has as a super-linear lower bound in congested networks is of special importance, because it would mark a computational difference between anonymous dynamic networks in the congested and non-congested models.

It would be interesting to do a thorough fine-grained tradeoff analysis of our algorithm. For instance, it is not difficult to show that, if messages have size $O(n \log n)$, the running time of our algorithm can be reduced to $O(n^2)$.

An Oracle with no UP-Complete Sets, but NP = PSPACE

David Dingel

Abstract

We construct an oracle relative to which NP = PSPACE, but UP has no many-one complete sets. This combines the properties of an oracle by Hartmanis and Hemachandra [25] and one by Ogiwara and Hemachandra [38].

The oracle provides new separations of classical conjectures on optimal proof systems and complete sets in promise classes. This answers several questions by Pudlák [43], e.g., the implications $\mathsf{UP} \implies \mathsf{CON}^{\mathsf{N}}$ and $\mathsf{SAT} \implies \mathsf{TFNP}$ are false relative to our oracle.

Moreover, the oracle demonstrates that, in principle, it is possible that TFNP-complete problems exist, while at the same time SAT has no p-optimal proof systems.

1 Introduction

We investigate relationships between the following classical conjectures on NP, optimal proof systems, and complete sets in promise classes. They are deeply rooted in formal logic, but also have far reaching practical implications. Each of these conjectures remains open.

$\mathsf{P} \neq \mathsf{NP}$:	P does not equal NP [12, 35]
$\mathsf{NP} \neq \mathsf{coNP}$:	NP does not equal coNP [16]
CON:	p-optimal proof systems for TAUT do not exist [34]
$\mathsf{CON}^{\mathsf{N}}$:	optimal proof systems for TAUT do not exist [34]
SAT:	p-optimal proof systems for SAT do not exist [34]
TFNP:	TFNP does not contain many-one complete problems [36]
$\mathsf{NP} \cap \mathsf{coNP}$:	NP ∩ coNP does not contain many-one complete problems [30]
UP:	UP does not contain many-one complete problems [25]
DisjNP:	DisjNP does not contain many-one complete pairs [45]
$\mathsf{DisjCoNP}$:	DisjCoNP does not contain many-one complete pairs [37, 42]

We refer to Pudlák [41] for a comprehensive elaboration of the conjectures and their context.

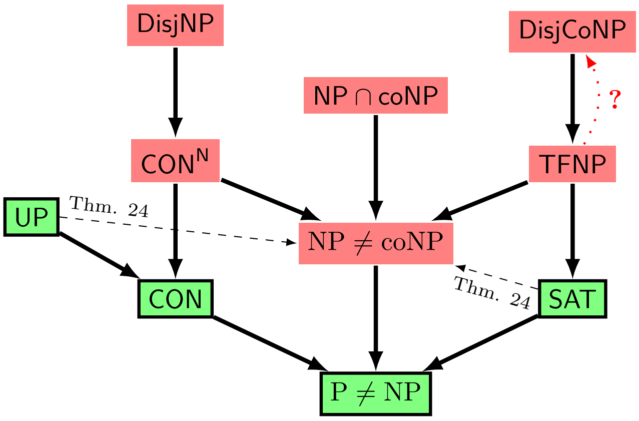

Figure 1 Hypotheses that are true relative to our oracle are filled green and have borders, whereas those that are false relative to the oracle are red without borders. Solid arrows mean relativizable implications. A dashed arrow from one conjecture A to another conjecture B means that there is an oracle X against the implication A ⇒ B, meaning that A ∧ ¬B holds relative to X. For clarity, we only depict the two strongest separations proved in this paper, and omit those that either follow from these, as well as those already known before. All possible separations have now been achieved, except for the one depicted as the red dotted arrow.

Pudlák's program. The known implications between these conjectures are shown in Figure 1. They raise the question of whether further implications can be recognized with the currently available methods. Pudlák [43] therefore initiated a research program to either prove further implications or to disprove them relative to an oracle. The latter shows that the implication is beyond the reach of current methods. Hence, from today's perspective, the corresponding conjectures are not mere reformulations of one another, but instead deserve individual attention.

So far several implications have been disproved relative to an oracle. The following selection of oracles covers all previously known disproofs of implications, in the sense that each such implication fails relative to at least one of these oracles:

$\mathsf{CON}^{\mathsf{N}} \wedge \neg\mathsf{DisjNP}$	(Glaßer, Selman, Sengupta, Zhang [20])
$\mathsf{DisjCoNP} \wedge \neg\mathsf{CON}$	(Khaniki [31])
$\mathsf{DisjNP} \wedge \mathsf{NP} \cap \mathsf{coNP} \wedge \neg\mathsf{UP}$	(Dose, Glaßer [15])
$\mathsf{NP} \cap \mathsf{coNP} \wedge \neg\mathsf{CON}$	(Dose [13])
$\mathrm{P} \neq \mathrm{NP} \wedge \neg\mathsf{CON} \wedge \neg\mathsf{SAT}$	(Dose [13])
$\mathsf{DisjNP} \wedge \mathsf{UP} \wedge \mathsf{NP} \cap \mathsf{coNP} \wedge \neg\mathsf{SAT}$	(Dose [14])
$\mathsf{DisjNP} \wedge \mathsf{UP} \wedge \mathsf{DisjCoNP} \wedge \neg\mathsf{NP} \cap \mathsf{coNP}$	(Egidy, Ehrmanntraut, Glaßer [17])

Optimal proof systems. The hypotheses CON, CON$^{\mathsf{N}}$, and SAT are concerned with the existence of (p-)optimal proof systems. The study of proof systems was initiated by Cook and Reckhow [11] and motivated by the NP $\overset{?}{=}$ coNP question, because the set of tautologies TAUT has a proof system with polynomially bounded proofs if and only if NP = coNP. Krajíček and Pudlák [34, 33, 44] link questions about proof systems to questions in bounded arithmetic. Especially the notions of optimal and p-optimal proof systems have gained much attention in research. They are closely connected to the separation of fundamental complexity classes, e.g., Köbler, Messner, and Torán [32] show that the absence of optimal proof systems for TAUT implies NEE ≠ coNEE. Moreover, (p-)optimal proof systems have tight connections to promise classes, e.g., if TAUT has p-optimal proof systems, then UP has many-one complete sets [32]. Many more relationships are known between proof systems and promise classes [3, 4, 5, 6, 7, 8, 21, 22, 32, 43, 45].

TFNP-complete problems. The class TFNP contains a multitude of problems that are of central importance to various practical applications, and as such is currently being researched with great intensity. The search for a complete problem in TFNP is of primary concern to certain fields such as cryptography, but it remains open whether such a problem exists.

For instance, the security of RSA [46] is primarily based on the hardness of integer factorization, which is a TFNP problem. However, no solid argument is known that factorization actually is a particularly hard problem within TFNP, i.e., being able to solve factorization might not require being able to solve arbitrary TFNP problems. RSA is now widely considered to no longer represent the state of the art in modern cryptography. Hence researchers develop cryptoschemes whose security is based on the hardness of other problems. However, it is still not clear whether these are strictly harder than factorization. A TFNP-complete problem would allow cryptoschemes that are at least as hard to break as any TFNP problem, i.e., schemes with optimal security guarantees.

Since the search for TFNP-complete problems has been unsuccessful, various subclasses were defined and studied in order to construct at least a complete problem for those subclasses. Their definitions are based on the proof of totality used to show the membership to TFNP. Prominent examples are PLS [29], based on the argument that *every dag has a sink*, PPA [39], based on the fact that *every graph has an even number of nodes with odd degree*, PPAD [39] and PPADS, based on slight variations of PPA for directed graphs, and PPP [40], based on the polynomial pigeonhole principle.[1] All of them have complete problems [29, 40] and can be defined in a syntactical way too [40]. Beame et al. [2] constructed oracles relative to which these classes are not a subset of P, and no inclusions exist beyond the few that are already known. The classes are significant to various practical applications like polynomially hard one way functions [9, 19], collision resistant hash functions [23], computing square roots modulo n [28], and the security of prominent homomorphic encryption schemes [27].

Our Contribution

1. Oracle with NP = PSPACE, but UP has no many-one complete sets.

Hartmanis and Hemachandra [25] construct an oracle relative to which UP does not have many-one complete sets. Ogiwara and Hemachandra [38] construct an oracle relative to which UP $\neq$ NP = PSPACE. Our oracle provides both properties at the same time, but this is achieved using completely different methods. Due to the far-reaching collapse NP = PSPACE and the close connection between UP-completeness and optimality of proof systems, we obtain a number of useful properties summarized in Corollary 25.

2. Consequences for Pudlák's program.

Regarding the conjectures shown in Figure 1, all known implications are presented in the figure, while for some of the remaining implications there exist oracles relative to which the implications do not hold. From the implications that were left open, our oracle refutes all but one. The key to this observation was to take the conjecture NP $\neq$ coNP into consideration. As we make sure that our oracle satisfies NP = coNP, the conjectures $\mathsf{CON}^{\mathsf{N}}$ and TFNP are

[1] For precise definitions we refer to recent papers [23], [24, notably Figure 1].

false, while the conjectures CON and SAT are equivalent. In addition, the oracle satisfies the conjecture UP, which implies CON, and thereby in summary refutes all of the following previously open implications:

$$\begin{array}{rlrlrl}
\mathsf{UP} \Longrightarrow \mathsf{CON}^{\mathsf{N}} & & \mathsf{UP} & \Longrightarrow \mathrm{NP} \neq \mathrm{coNP} & \mathsf{UP} & \Longrightarrow \mathsf{DisjNP} \\
\mathsf{CON} \Longrightarrow \mathsf{CON}^{\mathsf{N}} & & \mathsf{CON} & \Longrightarrow \mathrm{NP} \neq \mathrm{coNP} & \mathsf{SAT} & \Longrightarrow \mathsf{DisjCoNP} \\
\mathsf{SAT} \Longrightarrow \mathsf{TFNP} & & \mathsf{SAT} & \Longrightarrow \mathrm{NP} \neq \mathrm{coNP} & &
\end{array}$$

3. Consequences for TFNP-complete problems.
Regarding the search for TFNP-complete problems, our oracle demonstrates that, in principle, it is possible that NP = coNP and hence TFNP-complete problems exist, while at the same time SAT has no p-optimal proof systems.

Open questions

Hemaspaandra, Jain, and Vereshchagin [26] improve the oracle of Hartmanis and Hemachandra [25]. They show the existence of an oracle relative to which FewP [1] does not have Turing-hard sets for UP [26, Thm. 3.1]. They note that the theorem still holds when replacing the class FewP by Few [10]. Since UP $\subseteq$ FewP $\subseteq$ Few and many-one reducibility implies Turing reducibility, this raises the following questions (in ascending order of difficulty):
Does there exist an oracle relative to which

1. NP = PSPACE and UP has no set that is Turing-hard for UP?
2. NP = PSPACE and FewP has no set that is Turing-hard for UP?
3. NP = PSPACE and Few has no set that is Turing-hard for UP?

Regarding Pudlák's research program, all implications that are not presented in Figure 1 fail relative to some oracle, except for one single implication, which we leave as open question:

$$\mathsf{TFNP} \overset{?}{\Longrightarrow} \mathsf{DisjCoNP}$$

We suspect that such construction of an oracle with TFNP and ¬DisjCoNP is a particular challenge.

2 Preliminaries

2.1 Basic Definitions and Notations

This section covers the notation of this paper and introduces well-known complexity theoretic notions.

Words and sets. All sets and machines in this paper are defined over the alphabet $\Sigma = \{0, 1\}$. Σ^* denotes the set of all strings of finite length, and for a string $w \in \Sigma^*$ let $|w|$ denote the length of w. We write $\mathbb{N}$ for the set of non-negative integers, $\mathbb{N}^+$ for the set of positive integers, and $\emptyset$ for the empty set. For a set A and $k \in \mathbb{N}$ we write $A^{=k} := \{x \in A \mid |x| = k\}$ as the subset of A containing only words of length k. We define this analogously for $\leq$. For a clearer notation, we use the abbreviations $\Sigma^k := \Sigma^{*=k}$ and $\Sigma^{\leq k} := \Sigma^{*\leq k}$. Let $<_{\mathrm{lex}}$ denote the quasi-lexicographic (i.e., "shortlex") ordering of words over Σ^*.

Functions. Let enc be a polynomial-time computable, polynomial-time invertible order-isomorphism between $(\Sigma^*, <_{\mathrm{lex}})$ and $(\mathbb{N}, <)$, i.e., a variant of the dyadic representation. The domain and range of a function f are denoted by $\mathrm{dom}(f)$ and $\mathrm{ran}(f)$. For a function f and $A \subseteq \mathrm{dom}(f)$, we define $f(A) \coloneqq \{f(x) \mid x \in A\}$. We define certain polynomial functions $p_i \colon \mathbb{N} \to \mathbb{N}$ for $i \in \mathbb{N}$ by $p_i(n) \coloneqq n^i + i$ for $i \in \mathbb{N}^+$, and $p_i(n) \coloneqq 1$ for $i = 0$.

Let $\langle\cdot\rangle \colon \bigcup_{i \geq 0}(\Sigma^*)^i \to \Sigma^*$ be an injective, polynomial-time computable and polynomial-time invertible sequence encoding function[2] such that $|\langle u_1, \ldots, u_n\rangle| = 2(|u_1|+\cdots+|u_n|+n)+1$. The sequence encoding function has the following property.

▷ Claim 1. Let $w, x \in \Sigma^*$. If $|w| \geq |x| + 3$, then $|w| \geq |\langle x, w\rangle|/4$.

Proof. The following calculation proves the claimed statement:

$$|\langle x, w\rangle| = 2(|x| + |w| + 2) + 1 = 2|x| + 5 + 2|w| \leq 2|w| + 2|w| = 4|w| \qquad \lhd$$

Machines. We use the default model of a Turing machine in the deterministic as well as in the non-deterministic variant, abbreviated by DTM, resp., NTM. The language decided by a Turing machine M is denoted by $L(M)$. We use Turing transducers to compute functions. For a Turing transducer F we write $F(x) = y$ when on input x the transducer outputs y. We sometimes refer to the function computed by F as 'the function F'.

Complexity Classes and Reductions. The classes P, NP, coNP, FP and PSPACE denote the standard complexity classes. Furthermore, we are interested in several promise classes. Originally defined by Valiant [50], UP denotes the set of languages that can be decided by so called UP-machines, i.e., NTMs that have at most one accepting path on every input. The common polynomial-time many-one reducibility for sets $A, B \subseteq \Sigma^*$ is denoted by $\leq_{\mathrm{m}}^{\mathrm{p}}$, i.e., $A \leq_{\mathrm{m}}^{\mathrm{p}} B$ if there exists an $f \in \mathrm{FP}$ such that $x \in A \Leftrightarrow f(x) \in B$. If $\leq$ is some notion of reducibility for some class $\mathcal{C}$, then we call a set A $\leq$-complete for $\mathcal{C}$, if $A \in \mathcal{C}$ and for all $B \in \mathcal{C}$ the reduction $B \leq A$ holds.

Oracle-specific definitions and notations. An oracle B is a subset of Σ^*. We relativize the concept of Turing machines and Turing transducers by giving them access to a write-only oracle tape as proposed by Simon [48][3]. Furthermore, we relativize complexity classes, proof systems, reducibilities and (p-)simulation by defining them over machines with oracle access, i.e., whenever a Turing machine or Turing transducer is part of a definition, we replace them by an oracle Turing machine or an oracle Turing transducer. We indicate the access to some oracle B in the superscript of the mentioned concepts, i.e., P^B, NP^B, FP^B, ... for complexity classes, M^B for a Turing machine or Turing transducer M, and $\leq_{\mathrm{m}}^{\mathrm{p},B}$ for reducibility. We sometimes omit the oracles in the superscripts, e.g., when sketching ideas in order to convey intuition, but never in the actual proof.

Let $\{F_i\}_{i \in \mathbb{N}}$ be a standard enumeration of polynomial-time oracle Turing transducers, such that relative to any oracle B, F_i^B has running time exactly p_i and for any function $f \in \mathrm{FP}^B$, there is some i such that F_i^B computes f. Since the functions computed by $\{F_i^B\}_{i \in \mathbb{N}}$ form exactly FP^B, we call such machines FP^B-machines. Similarly, let $\{N_i\}_{i \in \mathbb{N}}$ be

[2] Notice that the sequence encoding function explicitly is not surjective, so invertibility is meant in the sense that $\mathrm{ran}(\langle\cdot\rangle) \in \mathrm{P}$, and there is a function $f \in \mathrm{FP}$ such that $\langle f(y)_1, \ldots, f(y)_n\rangle = y$ for all $y \in \mathrm{ran}(\langle\cdot\rangle)$.

[3] When considering time-bounded computation, this machine model reflects the usual relativization of Turing machines. For space-bounded computations, the oracle tape is also subject to the space-bound.

a standard enumeration of polynomial-time non-deterministic oracle Turing machines, such that relative to any oracle B, N_i^B has running time exactly p_i on each path and for any set $L \in \mathrm{NP}^B$, there is some i such that $L(N_i^B) = L$. Since the sets decided by $\{N_i^B\}_{i\in\mathbb{N}}$ form exactly NP^B, we call such machines NP^B-machines. If p is an encoding of a computation path, then $Q(p)$ denotes the set of oracle queries on p. For a Turing transducer F, an NTM N and some word x, let $Q(N(F(x))$ denote the set of oracle queries of the computations $F(x)$ and $N(F(x))$. Hence, we interpret $N(F(x))$ as one computation which computes $F(x)$ first, followed by the computation N on input $F(x)$.

Relativized QBF. For any oracle B, we define the relativized problem QBF^B as the typical QBF problem as defined by Shamir [47], but the boolean formulas are extended by expressions $B(w)$ for $w \in \Sigma^*$, which evaluate to true if and only if $w \in B$. It holds that for any oracle B, QBF^B is $\leq_{\mathrm{m}}^{\mathrm{p},B}$-complete for PSPACE^B.

Throughout the remaining sections, M will be a polynomial-space oracle Turing machine which, given access to oracle B, accepts QBF^B. Choose $k \geq 3$ such that M on input $x \in \Sigma^*$ completes using at most $t(x) := |x|^k + k$ space (including queries to the oracle).

2.2 Notions for the Oracle Construction

In this section we define all necessary objects and properties for the oracle construction and convey their intuition.

Tools for UP. In order to achieve that UP^Φ has no complete set, we will ensure that for any set $L(N_i^\Phi) \in \mathrm{UP}^\Phi$ a set $W_i^\Phi \in \mathrm{UP}^\Phi$ exists such that W_i^Φ does not reduce to $L(N_i^\Phi)$, i.e., $W_i^\Phi \not\leq_{\mathrm{m}}^{\mathrm{p},\Phi} L(N_i^\Phi)$. Here, W_i^Φ is a witness that $L(N_i^\Phi)$ is not complete for UP^Φ. For this, we injectively assign countably infinitely many levels of the oracle to each set W_i, where a level consists of certain words of the same length as follows.

► **Definition 2** (H_i).
Let $e(0) := 2,\ e(i+1) := 2^{e(i)}$ and $H_i := \{e(2^i \cdot 3^j) \mid j \in \mathbb{N}\}$ for $i \in \mathbb{N}$.

► **Corollary 3** (Properties of H_i).

(i) *For every $i \in \mathbb{N}$, the set H_i is countably infinite and a subset of the even numbers.*
(ii) *$H_i \in \mathrm{P}$ for all $i \in \mathbb{N}$.*
(iii) *For $i, j \in \mathbb{N}$ with $i \neq j$, it holds that $H_i \cap H_j = \emptyset$.*

► **Definition 4** (Witness language W_i^B).
For $i \in \mathbb{N}$ and an oracle B, we define the set

$$W_i^B := \{0^n \mid n \in H_i \text{ and there exists } x \in \Sigma^n \text{ with } x \in B\}$$

► **Corollary 5** (Sufficient condition for $W_i^B \in \mathrm{UP}^B$).
For any oracle B and any $i \in \mathbb{N}$, the following implication holds:

$$|B^{=n}| \leq 1 \text{ for all } n \in H_i \Longrightarrow W_i^B \in \mathrm{UP}^B$$

Proof. Let B and i be arbitrary. Since $H_i \in \mathrm{P}$, an NP-machine can reject on all inputs except 0^n with $n \in H_i$. On these inputs 0^n the machine can non-deterministically query all words $x \in \Sigma^n$ and accept if $x \in B$. Now, this machine accepts W_i^B, and if $|B^{=n}| \leq 1$, then it has at most one accepting path on all inputs. Hence, $W_i^B \in \mathrm{UP}^B$. ◄

We can control the membership of W_i to UP in the oracle construction. We will never add more than one word on the levels H_i, except for when we can rule out N_i as a UP-machine.

Tools for NP = PSPACE. In order to achieve that $\mathrm{NP}^\Phi = \mathrm{PSPACE}^\Phi$, we will encode QBF^Φ into the oracle Φ, such that $\mathrm{QBF}^\Phi \in \mathrm{NP}^\Phi$, from which $\mathrm{NP}^\Phi = \mathrm{PSPACE}^\Phi$ follows.

▶ **Definition 6** (Coding set Z^B).
For any oracle B, we define the set

$$Z^B := \{x \in \Sigma^* \mid \exists w \in \Sigma^{t(x)} \colon \langle x, w\rangle \in B\}$$

▶ **Corollary 7.** *For any oracle B, it holds that $Z^B \in \mathrm{NP}^B$.*

We will assemble the oracle Φ in such a way that $Z^\Phi = \mathrm{QBF}^\Phi$, i.e., Z^Φ will be PSPACE^Φ-hard, and thus $\mathrm{NP}^\Phi = \mathrm{PSPACE}^\Phi$.

Goals of the construction.

▶ **Definition 8** (Desired properties of Φ).
The later constructed oracle Φ should satisfy the following properties:

P1 $\forall x \in \Sigma^* \colon (x \in \mathrm{QBF}^\Phi \iff x \in Z^\Phi)$.

(Meaning: $\mathrm{QBF}^\Phi \in \mathrm{NP}^\Phi$*.)*

P2 $\forall i \in \mathbb{N}$, *at least one of the following statements holds:*

- **(I)** $\exists x \in \Sigma^* \colon N_i^\Phi(x)$ *accepts on more than one path.*

  (Meaning: N_i^Φ is not a UP^Φ*-machine.)*
- **(II)** *Both of the following statements hold:*
  - **(a)** $\forall n \in H_i \colon \ |\Phi^{=n}| \leq 1$

    (Meaning: $W_i^\Phi \in \mathrm{UP}^\Phi$.)
  - **(b)** $\forall j \in \mathbb{N}\ \exists x \in \Sigma^* \colon N_i^\Phi(F_j^\Phi(x))$ *accepts if and only if $x \notin W_i^\Phi$.*

    (Meaning: W_i^Φ does not reduce to $L(N_i^\Phi)$ via F_j^Φ.)

The following lemma shows that these properties imply our desired structural properties of complexity classes.

▶ **Lemma 9.** *Let $\Phi \subseteq \Sigma^*$.*

(i) *If statement* P1 *is satisfied relative to Φ, then* $\mathrm{NP}^\Phi = \mathrm{PSPACE}^\Phi$*.*

(ii) *If statement* P2 *is satisfied relative to Φ, then there is no $\leq_\mathrm{m}^{\mathrm{p},\Phi}$-complete set for* UP^Φ*.*

Proof. To (i): Recall that QBF^Φ is $\leq_\mathrm{m}^{\mathrm{p},\Phi}$-complete for PSPACE^Φ. Since property P1 holds relative to Φ, $Z^\Phi = \mathrm{QBF}^\Phi$. From Corollary 7 we get $Z^\Phi \in \mathrm{NP}^\Phi$ and thus $\mathrm{NP}^\Phi = \mathrm{PSPACE}^\Phi$.

To (ii): Assume there is a $\leq_\mathrm{m}^{\mathrm{p},\Phi}$-complete set C for UP^Φ. Let N_i^Φ be a UP^Φ-machine such that $L(N_i^\Phi) = C$. Then property P2.I cannot hold for i, because N_i would not be a UP-machine. Hence, property P2.II holds for i. By P2.II.a and Corollary 5, we get $W_i^\Phi \in \mathrm{UP}^\Phi$. Since $L(N_i^\Phi)$ is complete, there is some $j \in \mathbb{N}$ such that for all $x \in \Sigma^*$ we have

$$x \in W_i^\Phi \iff F_j^\Phi(x) \in L(N_i^\Phi).$$

This is a contradiction to the satisfaction of property P2.II.b, because there has to be some x where this equivalence does not hold. Hence, the assumption has to be false and there is no $\leq_\mathrm{m}^{\mathrm{p},\Phi}$-complete set for UP^Φ. ◀

Stages. We choose certain stages on which we will deal with property P2.II.b. They are chosen as the range of a certain function m. We will call the values of m 'UP-stages', since only on these we will contribute to enforcing property P2.II.b and consequently UP^{Φ}. For now, it suffices to know that the stages will be chosen 'sufficiently large'.

We choose a total injective function $m : \mathbb{N} \times \mathbb{N} \to \mathbb{N}$, $(i, j) \mapsto m(i, j)$ which meets the following requirements:

M1 $m(i, j) \in H_i$.

(Meaning: UP-stages $m(i, \cdot)$ are important to the witness-language W_i.)

M2 $2^{m(i,j)/4} > 4(p_i(p_j(m(i, j))))^2 + 2p_i(p_j(m(i, j))) + 1$.

(Meaning: The number of words of length $m(i, j)$ is far bigger than the number of words the computation $N_i(F_j(0^{m(i,j)}))$ can query.)

M3 $m(i, j) > m(i', j') \implies m(i, j) > p_{i'}(p_{j'}(m(i', j')))$.

(Meaning: The stages are sufficiently distant from another such that for no $i', j' \in \mathbb{N}$, the computation $N_{i'}(F_{j'}(0^{m(i',j')}))$ can query any word of the UP-stages following $m(i', j')$.)

▶ **Observation 10.** *For all $k \in \operatorname{ran}(m)$: $\operatorname{ran}(\langle\cdot\rangle) \cap \Sigma^k = \emptyset$, because $\langle\cdot\rangle$ only maps to odd lengths. In particular, if $|x| = m(i, j)$ for some $i, j \in \mathbb{N}$, then $x \notin \operatorname{ran}(\langle\cdot\rangle)$.*

3 Oracle Construction

In this section we will construct an oracle Φ such that UP^{Φ} has no complete set and $\mathrm{NP}^{\Phi} = \mathrm{PSPACE}^{\Phi}$.

Construction of Φ. We construct the oracle Φ sequentially. For each $x \in \Sigma^*$, we decide whether to add some words to the oracle. We give a brief sketch of the construction and its ideas:

To P1: Whenever the input x has the form $\langle x', 0^{t(x')}\rangle$, we add $\langle x', w\rangle$ for some $w \in \Sigma^{t(x')}$ to the oracle if and only if $x' \in \mathrm{QBF}$. Since $M(x')$ cannot query words of length $|\langle x', w\rangle|$, the membership of x' to QBF does not change after adding $\langle x', w\rangle$. From then on, we never add shorter words to Φ, thus the encoding persists correct for the finished oracle.

To P2: On every UP-stage $n := m(i, j)$, we try to achieve property P2.I or P2.II. For this, we differentiate between three cases.

1. If $N_i(F_j(0^n))$ accepts relative to the oracle constructed so far, we leave the stage n empty. In subsequent iterations, we ensure that added words will not interfere with this accepting path. This achieves property P2.II, because $0^n \notin W_i$ and $F_j(0^n) \in L(N_i)$.
2. If $N_i(F_j(0^n))$ rejects relative to the oracle constructed so far, we add a word of length n to the oracle such that this computation keeps rejecting. This achieves property P2.II, because $0^n \in W_i$ and $F_j(0^n) \notin L(N_i)$. Notice that finding appropriate words may not be possible.
3. If $N_i(F_j(0^n))$ rejects relative to the oracle constructed so far, and there is no choice of a word to add such that $N_i(F_j(0^n))$ keeps rejecting (i.e., case 2 is not possible), then we force $N_i(F_j(0^n))$ to accept on two different paths (which is possible, as we will show). In subsequent iterations, we ensure that added words will not interfere with these accepting paths. This achieves property P2.I.

In iterations after a UP-stage, if we have to add words to maintain P1, we choose them in such a way that property P2 still remains upheld for the previous stage. This is captured in Procedure 3, `handle_UP_stage_aftercare`. Once the next stage is reached, our word length will have increased enough such that the stage before cannot be affected anymore.

▶ **Definition 11** (Oracle construction).
Define $\Phi_0 := \emptyset$*. For* $k \in \mathbb{N}^+$*, define* $\Phi_{k+1} := \Phi_k \cup \mathtt{construct}(\mathrm{enc}(k), \Phi_k)$ *according to Procedure 1. Finally, define* $\Phi := \bigcup_{k \in \mathbb{N}} \Phi_k$*.*

Procedure 1 `construct(x,B)`.

```
1  If x = $\langle$x',$0^{t(x')}\rangle$ and $M^B$(x') accepts:
2      If the largest UP-stage m(i,j) < |x| exists:
3          Return handle_UP_stage_aftercare(x',i,j,B)
4      Return {x}
5  Elif x = $0^{m(i,j)}$ for some i,j $\in \mathbb{N}$:
6      Return handle_UP_stage(i,j,B)
7  Else:
8    Return $\emptyset$.
```

Procedure 2 `handle_UP_stage(i,j,B)`.

```
1  n := m(i,j)
2  If $N_i^B(F_j^B(0^n))$ accepts:
3    Return $\emptyset$
   // Here, $N_i^B(F_j^B(0^n))$ rejects
4  If $\exists y \in \Sigma^n$ s.th. $N_i^{B\cup\{y\}}(F_j^{B\cup\{y\}}(0^n))$ rejects:
5    Return {y}
6  Else:
7    Let y,z $\in \Sigma^n$ s.th. $N_i^{B\cup\{y,z\}}(F_j^{B\cup\{y,z\}}(0^n))$ accepts on $\geq 2$ paths
8    Return {y,z}
```

Procedure 3 `handle_UP_stage_aftercare(x',i,j,B)`.

```
1  n := m(i,j)
2  If $N_i^B(F_j^B(0^n))$ accepts on at least one path $p_1$:
3    $Q := \begin{cases} Q(p_1) \cup Q(p_2) & \text{if } N_i^B(F_j^B(0^n)) \text{ accepts on another path } p_2 \neq p_1 \\ Q(p_1) & \text{else} \end{cases}$
4    Choose w $\in \Sigma^{t(x')}$ s.th. $\langle$x',w$\rangle \notin$ Q
5    Return {$\langle$x',w$\rangle$}
   // Here, $N_i^B(F_j^B(0^n))$ rejects
6  If $\exists y \in \{\langle x',w\rangle \mid w \in \Sigma^{t(x')}\}$ s.th. $N_i^{B\cup\{y\}}(F_j^{B\cup\{y\}}(0^n))$ rejects:
7    Return {y}
8  Let $y,z \in \{\langle x',w\rangle \mid w \in \Sigma^{t(x')}\}$ s.th. $N_i^{B\cup\{y,z\}}(F_j^{B\cup\{y,z\}}(0^n))$ accepts on $\geq 2$ paths
9  Return {y,z}
```

Notice that in `handle_UP_stage` reaching line 3 corresponds to case 1 of the construction sketch for P2, reaching line 5 corresponds to case 2, and reaching lines 7–8 corresponds to case 3. In lines 2–4 of `construct`, because M accepts, we need to add at least one word $\langle x', w\rangle$ to the oracle in order to achieve P1. Procedure 3, `handle_UP_stage_aftercare`, ensures that a previous UP-stage either remains unaffected by this (lines 2–7), or at least i now satisfies property P2.I instead (lines 8–9).

It is not clear that the oracle construction can be performed as stated, because lines 4 and 8 in `handle_UP_stage_aftercare` and line 7 in `handle_UP_stage` claim the existence of words with complex properties. The following claims attend to this problem.

▷ Claim 12 (Line 7 in `handle_UP_stage` can be performed).
If the line 7 is reached in `handle_UP_stage` in the step $\mathtt{construct}(\mathrm{enc}(k), \Phi_k)$, then y and z can be chosen as stated.

Proof. Let $x \coloneqq \mathrm{enc}(k)$. When reaching this line, then for some $i, j \in \mathbb{N}$ with $n \coloneqq m(i,j)$ we have that $N_i^{\Phi_k}(F_j^{\Phi_k}(0^n))$ rejects, and for all extensions $\Phi_k \cup \{x'\}$ with $x' \in \Sigma^n$, $N_i^{\Phi_k \cup \{x'\}}(F_j^{\Phi_k \cup \{x'\}}(0^n))$ accepts. Since the accepting paths appear after adding x' to Φ_k, these paths must query x'. There are 2^n words of length n and an accepting path can query at most $p_i(p_j(n)) + p_j(n) \leq 2p_i(p_j(n))$ of these words. Let X be a set consisting of $4(p_i(p_j(n)))^2 + 2p_i(p_j(n)) + 1$ pairwise different words x' of length n. By M2,

$$2^{n/4} > 4(p_i(p_j(n)))^2 + 2p_i(p_j(n)) + 1,$$

whereby such a set exists. We show that there must be two different words $y, z \in X$ such that $N_i^{\Phi_k \cup \{y\}}(F_j^{\Phi_k \cup \{y\}}(0^n))$ (resp., $N_i^{\Phi_k \cup \{z\}}(F_j^{\Phi_k \cup \{z\}}(0^n))$) accepts and does not query z (resp., y) on some accepting path.

To choose y, we look at $X' \subseteq X$ consisting of $2p_i(p_j(n)) + 1$ pairwise different words. When extending Φ_k by a word from X' for each word in X' separately, the resulting leftmost accepting paths query at most

$$2p_i(p_j(n)) \cdot |X'| = 2p_i(p_j(n)) \cdot (2p_i(p_j(n)) + 1) = 4(p_i(p_j(n)))^2 + 2p_i(p_j(n))$$

different words in total. Hence, there is at least one unqueried word $y \in X$.

To choose z, consider $N_i^{\Phi_k \cup \{y\}}(F_j^{\Phi_k \cup \{y\}}(0^n))$, which on the leftmost accepting path queries at most $p_i(p_j(n)) + p_j(n) \leq 2p_i(p_j(n))$ words. Hence, there is some unqueried word $z \in X' \subseteq X$.

So, $N_i^{\Phi_k \cup \{y\}}(F_j^{\Phi_k \cup \{y\}}(0^n))$ accepts on a path which queries y but not z, and $N_i^{\Phi_k \cup \{z\}}(F_j^{\Phi_k \cup \{z\}}(0^n))$ accepts on a path which queries z but not y (because $z \in X'$). Thus, $y \neq z$, both accepting paths are different and both are preserved when extending by both y and z, resulting in at least two different accepting paths for $N_i^{\Phi_k \cup \{y,z\}}(F_j^{\Phi_k \cup \{y,z\}}(0^n))$. ◁

▷ Claim 13 (Line 8 in `handle_UP_stage_aftercare` can be performed).
If the line 8 is reached in `handle_UP_stage_aftercare` in the step `construct`$(\mathrm{enc}(k), \Phi_k)$, then y and z can be chosen as stated.

Proof. Let $x \coloneqq \mathrm{enc}(k)$. When reaching this line, then for $x = \langle x', 0^{t(x')} \rangle$ and the biggest UP-stage $n \coloneqq m(i,j) \leq |x|$ we have that $N_i^{\Phi_k}(F_j^{\Phi_k}(0^n))$ rejects, but for all extensions $\Phi_k \cup \{y\}$ with $y \in \{\langle x', w \rangle \mid w \in \Sigma^{t(x')}\} =: Y$, the computation $N_i^{\Phi_k \cup \{y\}}(F_j^{\Phi_k \cup \{y\}}(0^n))$ accepts. Since the accepting paths appear after adding y to Φ_k, these paths must query y. By Claim 1, $|t(x')| \geq |x|/4 \geq n/4$. Hence, there are $\geq 2^{n/4}$ words $w \in \Sigma^{t(x')}$, and thus $|Y| \geq 2^{n/4}$. An accepting path can query at most $p_i(p_j(n)) + p_j(n) \leq 2p_i(p_j(n))$ of these words. Let X be a set consisting of $4(p_i(p_j(n)))^2 + 2p_i(p_j(n)) + 1$ pairwise different words $y \in Y$. By M2,

$$2^{n/4} > 4(p_i(p_j(n)))^2 + 2p_i(p_j(n)) + 1,$$

whereby such a set exists. From here on, we can proceed exactly as in the proof of Claim 12 to find two fitting words y and z. ◁

▷ Claim 14 (Line 4 in `handle_UP_stage_aftercare` can be performed).
If the line 4 is reached in `handle_UP_stage_aftercare` in the step `construct`$(\mathrm{enc}(k), \Phi_k)$, then w can be chosen accordingly.

Proof. Let $x \coloneqq \mathrm{enc}(k)$. When reaching this line, then for $x = \langle x', 0^{t(x')} \rangle$ and the biggest UP-stage $n \coloneqq m(i,j) \leq |x|$ it holds that $N_i^{\Phi_k}(F_j^{\Phi_k}(0^n))$ accepts. In the worst case, there are at least two accepting paths. Up to two accepting paths p_1 and p_2 query at most $2p_i(p_j(n)) + 2p_j(n) \leq 4p_i(p_j(n))$ words in total. Together with M2, we get

$$|Q(p_1) \cup Q(p_2)| \leq 4p_i(p_j(n)) \leq 4(p_i(p_j(n)))^2 + 2p_i(p_j(n)) < 2^{n/4}.$$

By Claim 1, $|t(x')| \geq |x|/4 \geq n/4$ and thus

$$|\Sigma^{t(x')}| \geq 2^{n/4} > 4(p_i(p_j(n)))^2 + 2p_i(p_j(n)) + 1 \geq |Q(p_1) \cup Q(p_2)|.$$

Consequently, there is some $w \in \Sigma^{t(x')}$ with $\langle x', w\rangle \notin (Q(p_1) \cup Q(p_2))$. ◁

The Claims 12, 13, and 14 show that $\Phi_{k+1} := \Phi_k \cup \texttt{construct}(\mathrm{enc}(k), \Phi_k)$ is well-defined. We make three further observations about `construct`.

▶ **Observation 15.** *For $k \in \mathbb{N}$, $\texttt{construct}(\mathrm{enc}(k), \Phi_k)$ only adds words of length $|\mathrm{enc}(k)|$.*

The next two observations follow from Observation 15 combined with Observation 10.

▶ **Observation 16.** *Let $n \in H_i$ for some $i \in \mathbb{N}$ and $k := \mathrm{enc}^{-1}(0^n)$.*
Then only the step $\texttt{construct}(0^n, \Phi_k)$ can add words of length n to Φ.

▶ **Observation 17.** *Let $x := \langle x', 0^{t(x')}\rangle$ for $x' \in \Sigma^*$ and $k := \mathrm{enc}^{-1}(x)$.*
Then only the step $\texttt{construct}(x, \Phi_k)$ can add words of the form $\langle x', w\rangle$ with $w \in \Sigma^{t(x')}$ to Φ.

Proving the Properties. Finally, we show that the properties P1 and P2 hold relative to Φ. We start with property P1.

▶ **Lemma 18.** *The oracle Φ satisfies property* P1*.*

Proof. First, recall that by definition of Z,

$$x \in Z^\Phi \iff \exists w \in \Sigma^{t(x)} \colon \langle x, w\rangle \in \Phi \tag{1}$$

Let $x \in \Sigma^*$ be arbitrary, and consider the step of the oracle construction where Φ_k is defined as $\texttt{construct}(\langle x, 0^{t(x)}\rangle, \Phi_{k-1})$. By Observation 17, only $\texttt{construct}(\langle x, 0^{t(x)}\rangle, \Phi_{k-1})$ may add words of the form $\langle x, w\rangle$ for $w \in \Sigma^{t(x)}$ to Φ. From this we can draw $x \notin Z^{\Phi_{k-1}}$, and further, together with $\Phi_k \subseteq \Phi$,

$$\exists w \in \Sigma^{t(x)} : \langle x, w\rangle \in \Phi \iff \exists w \in \Sigma^{t(x)} \colon \langle x, w\rangle \in \Phi_k \tag{2}$$

The lines 5 and 6 in $\texttt{construct}(\langle x, 0^{t(x)}\rangle, \Phi_{k-1})$ are skipped, since, by M1, $m(i,j)$ is always even, whereas $\langle x, 0^{t(x)}\rangle$ has odd length (see Observation 10). Hence, `handle_UP_stage` will not be entered. Since at the lines 2–4 of `construct` always at least one word is added to the oracle, $\texttt{construct}(\langle x, 0^{t(x)}\rangle, \Phi_{k-1})$ adds a word $\langle x, w\rangle$ with $w \in \Sigma^{t(x)}$ to Φ_{k-1} if and only if the condition in line 1 is met and these lines are entered, i.e., if $M^{\Phi_{k-1}}(x)$ accepts. This gives

$$x \in \mathrm{QBF}^{\Phi_{k-1}} \iff \exists w \in \Sigma^{t(x)} \colon \langle x, w\rangle \in \Phi_k \tag{3}$$

Since $M^{\Phi_{k-1}}(x)$ has a space bound of $t(x)$, it cannot ask words longer than $t(x)$. Thereby $M^{\Phi_{k-1}}(x)$ cannot notice a transition to the oracle Φ_k, because we only add words $\langle x, w\rangle$ with $w \in \Sigma^{t(x)}$, which have length $> t(x)$. So, $M^{\Phi_k}(x)$ accepts if and only if $M^{\Phi_{k-1}}(x)$ accepts. For the same reason, $M^{\Phi_k}(x)$ cannot notice a transition to the oracle Φ, because by Observation 15, all words in the set $\Phi \setminus \Phi_k$ have length $\geq |\langle x, 0^{t(x)}\rangle|$, and thus $M^\Phi(x)$ accepts if and only if $M^{\Phi_k}(x)$ accepts. Combining these two facts gives

$$x \in \mathrm{QBF}^\Phi \iff x \in \mathrm{QBF}^{\Phi_{k-1}} \tag{4}$$

In total, we conclude

$$\begin{aligned} x \in \mathrm{QBF}^{\Phi} &\overset{(4)}{\iff} x \in \mathrm{QBF}^{\Phi_{k-1}} \overset{(3)}{\iff} \exists w \in \Sigma^{t(x)} \colon \langle x, w\rangle \in \Phi_k \\ &\overset{(2)}{\iff} \exists w \in \Sigma^{t(x)} \colon \langle x, w\rangle \in \Phi \\ &\overset{(1)}{\iff} x \in Z^{\Phi} \end{aligned}$$

Since $x \in \Sigma^*$ was chosen arbitrarily, property P1 holds. ◀

Before proving Lemma 21, i.e., proving that property P2 holds, we state the helpful claim that `construct` does not alter certain accepting paths.

▷ Claim 19. Let $i, j, k \in \mathbb{N}$ such that $k > \mathrm{enc}^{-1}(0^{m(i,j)})$, and $n := m(i,j)$. If $N_i^{\Phi_k}(F_j^{\Phi_k}(0^n))$ accepts (resp., accepts on more than one path), then so does $N_i^{\Phi_{k+1}}(F_j^{\Phi_{k+1}}(0^n))$.

Proof. If $\mathrm{enc}(k) \geq_{\mathrm{lex}} 0^{p_i(p_j(n))+1}$, then by Observation 15, only words of length $> p_i(p_j(n))$ are added to Φ_k. Hence, all paths of $N_i^{\Phi_k}(F_j^{\Phi_k}(0^n))$ and $N_i^{\Phi_{k+1}}(F_j^{\Phi_{k+1}}(0^n))$ are the same, from which the claimed statement follows.

Otherwise, $\mathrm{enc}(k) \leq_{\mathrm{lex}} 1^{p_i(p_j(n))}$. By M3, $m(i,j)$ has to be the biggest UP-stage $\leq |\mathrm{enc}(k)|$. Consider the step `construct`$(\mathrm{enc}(k), \Phi_k)$. Either $\Phi_{k+1} = \Phi_k$ and the claim holds, or some words are added to Φ_k. The procedure `handle_UP_stage` is not entered, because $\mathrm{enc}(k) >_{\mathrm{lex}} 0^n$, so the condition in line 5 of `construct` is false, whereby any added words would need to be added by `handle_UP_stage_aftercare`. Further, since $N_i^{\Phi_k}(F_j^{\Phi_k}(0^n))$ accepts, this can only happen via the lines 3 to 5. Here, line 4 makes sure that $N_i^{\Phi_{k+1}}(F_j^{\Phi_{k+1}}(0^n))$ remains accepting (resp., remains accepting on more than one path), since the respective paths do not query the chosen words. ◁

▶ **Corollary 20.** *Let $i, j, k \in \mathbb{N}$ such that $k > \mathrm{enc}^{-1}(0^{m(i,j)})$, and $n := m(i,j)$. If $N_i^{\Phi_k}(F_j^{\Phi_k}(0^n))$ accepts (resp., accepts on more than one path), then so does $N_i^{\Phi}(F_j^{\Phi}(0^n))$.*

▶ **Lemma 21.** *The oracle Φ satisfies property* P2*.*

Proof. Let $i \in \mathbb{N}$ be arbitrary. Assume that for i the property P2.I does not hold. Then we show that property P2.II holds.

▷ Claim 22. The property P2.II.a holds.

Proof. Let $n \in H_i$ be arbitrary and $k := \mathrm{enc}^{-1}(0^n)$. By Observation 16, only the step `construct`$(0^n, \Phi_k)$ adds words of length n to Φ. Since n has even and $\langle \cdot, \cdot \rangle$ has always odd length (see Observation 10), the condition in line 1 of `construct` evaluates to 'false'. So, only if line 8 in `handle_UP_stage` is executed, more than one word of length n is added to Φ_k and consequently to Φ. In this case, since the sets $H_0, H_1, \ldots$ are disjoint, there is some $j \in \mathbb{N}$ with $m(i,j) = n$ where $N_i^{\Phi_{k+1}}(F_j^{\Phi_{k+1}}(0^n))$ accepts on more than one path. Invoking Corollary 20 with i, j and $k+1$, we get that also $N_i^{\Phi}(F_j^{\Phi}(0^n))$ accepts on more than one path. This is a contradiction to the assumption that the property P2.I does not hold for i. Hence, line 8 in `handle_UP_stage` cannot be executed during `construct`$(0^n, \Phi_k)$. This gives $|\Phi^{=n}| \leq 1$, as required. ◁

▷ Claim 23. The property P2.II.b holds.

Proof. Let $j \in \mathbb{N}$ be arbitrary, $n := m(i,j)$, and $k := \mathrm{enc}^{-1}(0^n)$. Consider the step `construct`$(0^n, \Phi_k)$. Since n has even length, the condition in line 1 of `construct` evaluates to 'false'. But the condition in line 5 is satisfied, so `handle_UP_stage` will define which words are added to the oracle. Also recall that only at this step words of length n are added to Φ (Observation 16), i.e., $\Phi_{k+1}^{=n} = \Phi^{=n}$. We distinguish between the three cases on how Φ_{k+1} can be defined in `handle_UP_stage`.

If Φ_{k+1} is defined via line 3, then $\Phi^{=n} = \emptyset$ and $N_i^{\Phi_{k+1}}(F_j^{\Phi_{k+1}}(0^n))$ accepts. By Corollary 20, $N_i^{\Phi}(F_j^{\Phi}(0^n))$ accepts too. Hence, $N_i^{\Phi}(F_j^{\Phi}(0^n))$ accepts and $0^n \notin W_i^{\Phi}$, i.e., 0^n satisfies property P2.II.b.

If Φ_{k+1} is defined via line 8, then $N_i^{\Phi_{k+1}}(F_j^{\Phi_{k+1}}(0^n))$ accepts on more than one path. By Corollary 20, $N_i^{\Phi}(F_j^{\Phi}(0^n))$ also accepts on more than one path. But then, property P2.I holds for i, a contradiction to the assumption at the start of Lemma 21. Hence, this case cannot occur.

If Φ_{k+1} is defined by line 5, then $|\Phi^{=n}| = 1$ and $N_i^{\Phi_{k+1}}(F_j^{\Phi_{k+1}}(0^n))$ rejects. Let $k' > k+1$ be the smallest number such that $N_i^{\Phi_{k'}}(F_j^{\Phi_{k'}}(0^n))$ accepts. Either k' does not exist and hence, $N_i^{\Phi}(F_j^{\Phi}(0^n))$ rejects, satisfying property P2.II.b.

Otherwise $\mathrm{enc}(k') \leq_{\mathrm{lex}} 1^{p_i(p_j(n))}$, because $N_i(F_j(0^n))$ can query only words of length $\leq p_i(p_j(n))$, and for bigger k', only words of length $> p_i(p_j(n))$ are added (Observation 15). Consider the step `construct`$(\mathrm{enc}(k'-1), \Phi_{k'-1})$. By M3, $m(i,j)$ is the biggest UP-stage $\leq |\mathrm{enc}(k'-1)|$. Since

$$0^n = \mathrm{enc}(k) <_{\mathrm{lex}} \mathrm{enc}(k+1) \leq_{\mathrm{lex}} \mathrm{enc}(k'-1),$$

the condition in line 5 is not met, thus `handle_UP_stage` is skipped. Since by the minimality of k' the computation $N_i^{\Phi_{k'-1}}(F_j^{\Phi_{k'-1}}(0^n))$ rejects, $\Phi_{k'}$ can only be defined via line 9 in `handle_UP_stage_aftercare`. But then, $N_i^{\Phi_{k'}}(F_j^{\Phi_{k'}}(0^n))$ accepts on more than one path. Invoking Corollary 20 for i, j, k', we get that also $N_i^{\Phi}(F_j^{\Phi}(0^n))$ accepts on more than one path. Consequently, property P2.I holds for i, a contradiction to the assumption at the start of Lemma 21. Hence, this case cannot occur. ◁

Since i is arbitrary, the Claims 22 and 23 show that if property P2.I does not hold, property P2.II does. Thus, property P2 holds. ◀

4 Conclusion

The oracle from the previous section gives the following result.

▶ **Theorem 24.** *There exists an oracle relative to which* UP *has no* $\leq_{\mathrm{m}}^{\mathrm{p}}$*-complete sets and* NP = PSPACE.

Proof. This follows from the Lemmas 9, 18, and 21. ◀

We summarize the properties of the oracle from Theorem 24 relating to the hypotheses of Pudlák [43] and mention a few more.

▶ **Corollary 25.** *Relative to the oracle from Theorem 24, all of the following hold:*
1. NP = coNP, *i.e.,* ¬NP ≠ coNP.
2. UP *does not have* $\leq_{\mathrm{m}}^{\mathrm{p}}$*-complete sets, i.e.,* UP.
3. TAUT *does not have p-optimal proof systems, i.e.,* CON.
4. SAT *does not have p-optimal proof systems, i.e.,* SAT.
5. TFNP *has a complete problem, i.e.,* ¬TFNP.

6. TAUT *has optimal proof systems, i.e.,* $\neg\mathsf{CON}^{\mathsf{N}}$.
7. DisjNP *has* $\leq_{\mathrm{m}}^{\mathrm{pp}}$*-complete pairs, i.e.,* $\neg\mathsf{DisjNP}$.
8. DisjCoNP *has* $\leq_{\mathrm{m}}^{\mathrm{pp}}$*-complete pairs, i.e.,* $\neg\mathsf{DisjCoNP}$.
9. NP ∩ coNP *has* $\leq_{\mathrm{m}}^{\mathrm{p}}$*-complete sets, i.e.,* $\neg\mathsf{NP} \cap \mathsf{coNP}$.
10. $\mathrm{P} \subsetneq \mathrm{UP} \subsetneq \mathrm{NP} \cap \mathrm{coNP} = \mathrm{NP}$.
11. *The conjecture Q does not hold* [18, Def. 2].
12. *The conjecture Q′ does not hold* [18, Def. 3].
13. $\mathrm{TFNP} \not\subseteq_c \mathrm{PF}$.

Proof. To 1 and 2: Follows from Theorem 24.
To 3: Follows from 2 by Köbler, Messner, and Torán [32, Cor. 4.1].
To 4: Follows from 3 and 1.
To 5: Follows from 1 by Megiddo and Papadimitrou [36, Thm. 2.1].
To 6: Follows from 1 and the fact that NP has optimal proof systems [37, Thm. 3.1].
To 7: Follows from 6 by Köbler, Messner, Torán [32, Cor. 6.1].
To 8: Follows from 7 and 1.
To 9: Follows from 1 and that NP^{Φ} has $\leq_{\mathrm{m}}^{\mathrm{p}}$-complete sets.
To 10: Follows from P ⊆ UP ⊆ NP, P has complete sets, UP^{Φ} does not have complete sets (2), NP has complete sets and $\mathrm{NP}^{\Phi} = \mathrm{coNP}^{\Phi}$ (1).
To 11 and 12: Follows from $\mathrm{P} \neq \mathrm{NP} \cap \mathrm{coNP}$ (which is implied by 10), as shown by Fenner et al. [18, Thm. 2,Prop. 9].
To 13: Follows from 11, as shown by Fenner et al. [18, Prop. 7]. ◀

Abstract

We study half-space separation in the convexity of chordless paths of a graph, i.e., monophonic convexity. In this problem, one is given a graph and two (disjoint) subsets of vertices and asks whether these two sets can be separated by complementary convex sets, called half-spaces. While it is known this problem is NP-complete for geodesic convexity – the convexity of shortest paths – we show that it can be solved in polynomial time for monophonic convexity.

1 Introduction

A (finite) convexity space is a pair $(V, \mathcal{C})$ where V is a (finite) groundset and $\mathcal{C}$ a collection of subsets of V, called *convex sets*, containing $\emptyset$, V and closed under taking intersections. Graphs provide a wide variety of different convexity notions, known as graph convexities. These are usually defined based on paths and include for instance the geodesic convexity [20], the monophonic convexity [10, 12, 15], the m^3-convexity [11], the triangle-path convexity [5], the toll convexity [1], or the weakly toll convexity [9].

In this paper, we are interested in the *half-space separation* problem: with an implicitly given convexity space $(V, \mathcal{C})$ and two (convex) subsets A, B of V, are there complementary convex sets $H, \overline{H}$ – the so-called *half-spaces* – such that $A \subseteq H$ and $B \subseteq \overline{H}$? This problem is a generalization to abstract convexity of the half-space separation problem in $\mathbb{R}^d$, being well-studied in machine learning [3, 16, 25]. Half-space separation has motivated the study of structural separation properties of convexity spaces. Among these properties, two have received particular attention, notably within graph convexities (see e.g. [2, 7, 14, 18, 23]): the S_3 property stating that any convex set C can be separated from any element of V not in C; and the S_4 or Kakutani property stating that any pair of disjoint convex sets can be separated. Besides, the study of the half-space separation problem on its own has recently been brought to the context of graph convexities [21, 22]. In particular, Seiffarth et al. [21] show that half-space separation is NP-complete for geodesic convexity, the convexity induced by the shortest paths of a graph. To our knowledge though, the complexity status of half-space separation for the other aforementioned graph convexities is still unknown.

In our contribution, we follow this latter line of research and study half-space separation for the monophonic convexity. Given a graph G with vertices $V(G)$, a set $C \subseteq V(G)$ is monophonically convex if for any two vertices u, v of C, all the vertices on a chordless path u and v lie in C. We prove that half-space separation can be decided in polynomial time for monophonic convexity. More formally, our main theorem reads as follows:

▶ **Theorem 1.** *Given a graph G and two subsets A, B of $V(G)$, whether A, B are separated by monophonic half-spaces can be decided in polynomial time.*

Theorem 1 contrasts with the NP-completeness of half-space separation for geodesic convexity [21] and suggests to study separation in further graph convexities. Besides, half-space separation also relates to the p-partition problem (in graph convexities). In the p-partition problem, one is given a graph G and has to decide whether $V(G)$ can be partitioned into p convex sets, where the meaning of convex depends on the convexity at hand. For monophonic convexity, Gonzalez et al. [17] show that p-partition is NP-complete for $p \geq 3$, but they leave open the case $p = 2$. Since 2-partition is possible if and only if there exists two separable vertices, Theorem 1 proves that 2-partition can be decided in polynomial time.

▶ Remark 2. In very recent contributions, Chepoi [8] and Bressan et al. [4] also showed that half-space separation can be decided in polynomial time for monophonic convexity. Their results have been obtained independently and using different approaches, even though they share some common points with the technique used in this paper.

Organization of the paper

In Section 2 we provide definitions, notations and we formally define the problem we investigate in the paper. In Section 3 we prove Theorem 1 by giving an algorithm which decides whether two sets can be separated by half-spaces. We conclude in Section 4.

▶ Remark 3. Due to space limitations, most proofs are omitted. All of them can found in the `arXiv` version of the present contribution [13].

2 Preliminaries

All the objects considered in this paper are finite. Let V be a set. The powerset of V is denoted $\mathbf{2}^V$. Given $X \subseteq V$, we write $\overline{X}$ the complement of X in V, i.e., $\overline{X} = V \setminus X$. Sometimes, we shall write a set X as the concatenation of its elements, e.g., uv instead of $\{u, v\}$. As a result, $X \cup uv$ and $X \cup v$ stands for $X \cup \{u, v\}$ and $X \cup \{v\}$ respectively.

Graphs

We assume the reader is familiar with standard graph terminology. We consider loopless undirected graphs. Let G be a graph with vertices $V(G)$ and edge set $E(G)$. A subgraph of G is any graph H such that $V(H) \subseteq V(G)$ and $E(H) \subseteq E(G)$. The *(open) neighborhood* of a vertex v in G is denoted $N(v)$ and is defined as $N(v) = \{u \in V(G) : uv \in E(G)\}$. The *closed neighborhood* of v in G is $N[v] = N(v) \cup v$. For $X \subseteq V(G)$, we put similarly $N(X) = \{u \in V(G) \setminus X : xu \in E(G) \text{ for some } x \in X\}$ and $N[X] = N(X) \cup X$. The subgraph of G *induced* by X is $G[X] = (X, E(G[X]))$, where $E(G[X]) = \{uv \in E(G) : u, v \in X\}$. If this is clear from the context, we identify X with $G[X]$, and we use $G - X$ to denote $G[V(G) - X]$. A *path* in G is a subgraph P of G with $V(P) = \{v_1, \ldots, v_k\}$ and such that $v_i v_{i+1} \in E(P)$ for each $1 \leq i < k$. Putting $u = v_1$ and $v = v_k$, P is an *uv-path* of G. An *induced uv-path* or *chordless uv-path* of G is an induced subgraph of G being an uv-path. A shortest path is an induced path with the least possible number of vertices. For simplicity we will identify a path P with the sequence $v_1, \ldots, v_k$ of its vertices. Let $A, B \subseteq V(G)$ be non-empty. The *(inner) frontier* of A with respect to B is $F(A, B) = A \cap N[B]$. We note that if A, B are disjoint, we obtain $F(A, B) = A \cap N(B)$. Remark that for every $X \subseteq V(G)$, $F(\overline{X}, X) = N(X)$.

Convexity spaces

We refer the reader to [24] for a thorough introduction to convexity theory. A *convexity space* is a pair $(V, \mathcal{C})$, with $\mathcal{C} \subseteq \mathbf{2}^V$, such that $\emptyset, V \in \mathcal{C}$ and for every $C_1, C_2 \in \mathcal{C}$, $C_1 \cap C_2 \in \mathcal{C}$. The sets in $\mathcal{C}$ are *convex* sets. A convexity space $(V, \mathcal{C})$ induces a *(convex) hull* operator $h \colon \mathbf{2}^V \to \mathbf{2}^V$ defined for all $X \subseteq V$ by:

$$h(X) = \bigcap \{C \in \mathcal{C} : X \subseteq C\}$$

The operator h satisfies, for all $X, Y \subseteq V$: $X \subseteq h(X)$; $h(X) \subseteq h(Y)$ if $X \subseteq Y$; and $h(h(X)) = h(X)$. The *Carathéodory number* of $(V, \mathcal{C})$ is the least integer d such that for every $X \subseteq V$ and $v \in V$, if $v \in h(X)$, there exists a subset Y of X such that $v \in h(Y)$ and $|Y| \leq d$. A *half-space* of $(V, \mathcal{C})$ is a convex set H whose set complement $\overline{H}$ is convex, that is, $H, \overline{H} \in \mathcal{C}$. Let A, B be two subsets of V. We say that A and B are *(half-space) separable* if there exists half-spaces $H, \overline{H}$ satisfying $A \subseteq H$ and $B \subseteq \overline{H}$. This is equivalent to $h(A) \subseteq H$ and $h(B) \subseteq \overline{H}$. The *shadow of A with respect to B* [6, 7] is the set $A/B = \{v \in V : h(B \cup v) \cap A \neq \emptyset\}$. Observe that $A \subseteq A/B$ and $B \subseteq B/A$.

▶ Remark 4. Usually, A/B is defined for disjoint sets. Here, it is more convenient to extend this definition to sets that may intersect. If $A \cap B \neq \emptyset$, then $A/B = V$ vacuously.

Monophonic convexity

We introduce monophonic convexity. We redirect the reader to [24, 20] for further details on graph and interval convexities. Let G be a graph, and let $u, v \in V(G)$. The *monophonic closed interval* of u, v is the set of all vertices that lie on a chordless uv-path, denoted by $J[u, v]$. For $X \subseteq V(G)$, we put $J[X] = \bigcup_{u,v \in X} J[u, v]$. A set C is *monophonically convex* if $J[C] = C$. Throughout the paper, if there is no ambiguity, we use the term convex sets as a shortening for monophonically convex sets. With $\mathcal{C} = \{C \subseteq V(G) : C \text{ is monophonically convex}\}$, the pair $(V(G), \mathcal{C})$ is a convexity space, the *monophonic convexity* of G. Its convex hull operator h is defined for all $X \subseteq V(G)$ by:

$$h(X) = \bigcup_{k=0}^{\infty} X_k$$

where $X_0 = X$ and $X_i = J[X_{i-1}]$ for $i \geq 1$. We now gather existing results regarding monophonic convexity that will be useful throughout the paper. These statements are rephrased to match our terminology.

▶ **Observation 5** (see also [12]). *In a connected graph G, every convex set is connected.*

▶ **Theorem 6** ([12], Theorem 5.1)**.** *The monophonic convexity of a connected graph has Carathéodory number is* 1 *if the graph is a clique and* 2 *otherwise.*

▶ **Theorem 7** ([10], Theorem 4.1)**.** *Let G be a graph and let $X \subseteq V(G)$. Then, $h(X)$ can be computed in polynomial time in the size of G.*

▶ **Theorem 8** ([10], Theorem 2.1)**.** *Let G be a connected graph and let $C \subseteq V$. The set C is convex if and only if for every connected component S of $G - C$, $F_G(C, S)$ is a clique.*

▶ **Lemma 9** ([17], Lemma 14)**.** *Let G be a connected graph, K a clique separator of G, and X the union of some of the connected components of $G - K$. Then $X \cup K$ is convex.*

We end these preliminaries by stating the problem we investigate in this paper. It is the problem of separating two sets of vertices by half-spaces. Its decision version is:

Half-space separation in monophonic convexity
Input: A graph G and two (non-empty and disjoint) subsets A, B of $V(G)$.
Question: Are A and B half-space separable?

Since h can be computed in polynomial time by Theorem 7 and A, B are separable if and only if $h(A)$, $h(B)$ are separable, we can assume w.l.o.g. that the sets A and B are convex.

3 Half-space separation

In this section, we prove Theorem 1, which we first restate.

▶ **Theorem 1.** *Given a graph G and two subsets A, B of $V(G)$, whether A, B are separated by monophonic half-spaces can be decided in polynomial time.*

Remark that if the input graph is not connected, one just has to solve the problem for each connected component. Thus, we can consider without loss of generality that the graphs we consider are connected. Hence, for the section, we fix a connected graph G. Let A, B be two (disjoint) convex sets of G. To prove Theorem 1, we give a polynomial time algorithm that decides whether A, B are separable. The algorithm first computes a shortest path $a = v_1, \ldots, v_k = b$ for some $a \in A$ and $b \in B$ in polynomial time. We show in Lemma 11 that A and B are separable if and only if there exists $1 \leq i < k$ such that $A_i := h(A \cup \{v_1, \ldots, v_i\})$ and $B_i := h(B \cup \{v_{i+1}, \ldots, v_k\})$ are separable. This step is the *linkage* of A and B. Then, for each i, the algorithm does the subsequent operations:

(1) It computes the *saturation* $A'_i := S(A_i, B_i)$, $B'_i := S(B_i, A_i)$ of A_i, B_i (resp.) with respect to h (see Subsection 3.2). Informally, the saturation step extends A_i and B_i with vertices that are forced on one of the two sides by the hull operator h. Lemma 13 shows that A_i, B_i are separable if and only if A'_i, B'_i are separable. Corollary 16 proves that computing saturation takes polynomial time.

(2) From A'_i and B'_i, it builds an equivalence relation $\equiv_{A'_iB'_i}$ on $\overline{A'_i \cup B'_i}$ and an associated graph $G_{A'_iB'_i}$. Theorem 31 states that A'_i and B'_i are separable if and only if $G_{A'_iB'_i}$ is bipartite and no equivalence class of $\equiv_{A'_iB'_i}$ contains a so-called *forbidden pair* of vertices. Finally, Theorem 32 proves that the conditions of Theorem 31 can be tested in polynomial time.

The algorithm outputs that A and B are separable if there is an integer i for which step (2) succeeds. Otherwise, A and B are not separable. The correctness of the algorithm follows from Lemma 11, Lemma 13 and Theorem 31. The fact that it runs in polynomial time is a consequence of Corollary 16 and Theorem 32. This proves Theorem 1.

The rest of the section is dedicated to the proof of the aforementioned statements.

3.1 Linkage along a shortest path

Let A, B be two non-empty disjoint convex subsets of $V(G)$. Assume that A and B are separable and let $H, \overline{H}$ be half-spaces separating A and B. Then for each $a \in A$, and each $b \in B$, all the vertices on the shortests ab-paths are distributed among H and $\overline{H}$. We show that, in fact, for each shortest ab-path, there is a vertex before which all vertices are assigned one half-space and all vertices after which are assigned the other half-space.

▶ **Proposition 10.** *Let $a \in A$, $b \in B$ and let $a = v_1, \dots, v_k = b$ be a shortest ab-path. For every half-space separation $H, \overline{H}$ of A and B with $A \subseteq H$ and $B \subseteq \overline{H}$, there exists $1 \leq i < k$ such that $\{v_1, \dots, v_i\} \subseteq H$ and $\{v_{i+1}, \dots, v_k\} \subseteq \overline{H}$.*

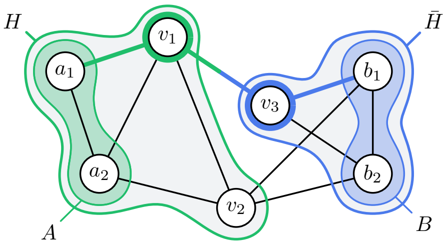

Figure 1 A graph G with two disjoint convex sets $A = \{a_1, a_2\}$ and $B = \{b_1, b_2\}$ (circled in green and blue resp.). A and B are not linked, but they can be linked along the path a_1, v_1, v_3, b_1 (in bold green / bold blue). Namely, $A \cup v_1$ and $B \cup v_3$ are linked and convex. Two half-spaces $H, \overline{H}$ separating $A \cup v_1$ and $B \cup v_3$ (hence A and B) are drawn.

Following Proposition 10, we say that A and B are *linked* if there exists $a \in A$, $b \in B$ such that $ab \in E(G)$. Linked sets and Proposition 10 are illustrated in Figure 1. The next lemma is a direct consequence of Proposition 10.

▶ **Lemma 11.** *Let G be a connected graph and let A, B be two non-empty disjoint convex subsets of $V(G)$. Let $a \in A$, $b \in B$ and let $a = v_1, \dots, v_k = b$ be a shortest ab-path. Then, A and B are separable if and only if there exists $1 \leq i < k$ such that $h(A \cup \{v_1, \dots, v_i\})$ and $h(B \cup \{v_{i+1}, \dots, v_k\})$ are separable.*

Given $a \in A$ and $b \in B$, finding a shortest ab-path can be done in polynomial time. Hence, making A and B linked can be done efficiently. Moreover, if A and B are linked, then for any disjoint $A', B' \subseteq V$ such that $A \subseteq A'$ and $B \subseteq B'$, A' and B' must be linked too. In what follows, we will thus consider disjoint, convex and linked subsets of $V(G)$.

3.2 Saturation with the hull operator

Let A, B be two disjoint, linked and convex subsets of $V(G)$. In this part, we use the hull operator h to define two sets $S(A, B)$ and $S(B, A)$ – the saturation of A and B (see below) – with $A \subseteq S(A, B)$, $B \subseteq S(B, A)$ and such that A, B are separable if and only if their saturation is separable. Informally, we use h to identify vertices that will appear in the same half-space as A in any possible half-space separation of A (and similarly with B), if any. We use two properties built on h:

(1) **Shadow-closing.** Remind that A/B, the shadow of A with respect to B, is defined by $A/B = \{v \in V(G) : h(B \cup v) \cap A \neq \emptyset\}$. In particular, $A \subseteq A/B$.

(2) **Forbidden sets.** Let $X \subseteq \overline{A \cup B}$ and assume that $h(X) \cap A \neq \emptyset$ and $h(X) \cap B \neq \emptyset$. Since $h(v) = \{v\}$ for all $v \in V$, we have $|X| \geq 2$. Thus, separating A, B implies to split the vertices of X. We say that X is a *forbidden set* of A and B with respect to G. A set X is forbidden if and only if it includes an inclusion-wise minimal forbidden set as a subset. Henceforth, in order to use forbidden sets, we need only consider the family of inclusion-wise minimal forbidden sets, denoted $\mathrm{MFS}(A,B)$. Formally,

$$\mathrm{MFS}(A,B) = \min_{\subseteq}\{X \subseteq \overline{A \cup B} : h(X) \cap A \neq \emptyset \text{ and } h(X) \cap B \neq \emptyset\}.$$

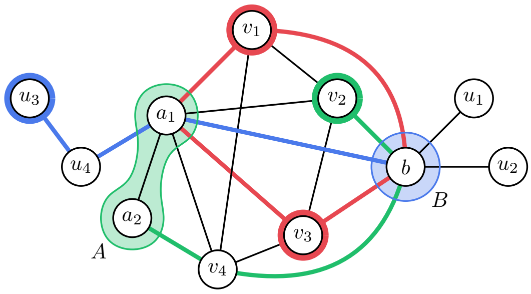

Figure 2 A graph G in which we seek to separate A and B (in circled green/blue resp.). The vertex a_1 is on a chordless u_3b-path (bold blue), so that $u_3 \in A/B$. Dually, b is on a chordless v_2a_2-path (bold green), i.e., $v_2 \in B/A$. Besides, $h(v_1v_3)$ intersects both A and B (bold red). Thus, v_1, v_3 must be separated to separate A and B, and $v_1v_3 \in \mathrm{MFS}(A,B)$ holds.

We illustrate shadows and forbidden sets in Figure 2. Now, we use A/B (resp. B/A) and $\mathrm{MFS}(A,B)$ in view of separating A and B. On the one hand, A/B cannot be separated from A by definition. On the other hand, for each $X \in \mathrm{MFS}(A,B)$ and every half-spaces $H, \bar{H}$ separating A and B with $A \subseteq H$, there exists at least one $x \in X$ such that $x \in H$, so that, $\bigcap_{x \in X} h(A \cup x) \subseteq H$ always hold. Based on the previous arguments, we define the *pre-saturation* of A with respect to B in G, denoted by $\sigma(A,B)$, by:

$$\sigma(A,B) = h\left(A/B \cup \bigcup \left\{ \bigcap_{x \in X} h(A \cup x) : X \in \mathrm{MFS}(A,B) \right\}\right)$$

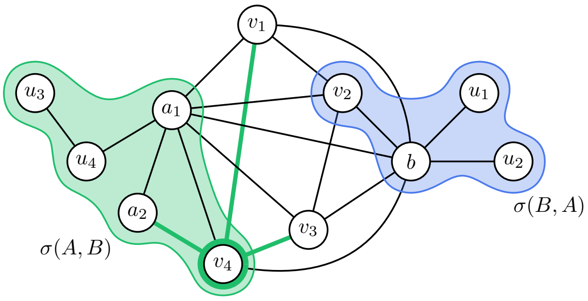
Observe that if $A \cap B \neq \emptyset$, then $\sigma(A,B) = \sigma(B,A) = V(G)$ as $A/B = B/A = V(G)$. In this case though, A and B cannot be separated. We prove in the next statement that $\sigma(A,B)$ preserves separation. Remark that it holds regardless of the disjointness of A and B.

▶ **Lemma 12.** *Let G be a connected graph, and let A, B be linked and convex subsets of $V(G)$. Then, A, B are separable if and only if $\sigma(A,B)$ and $\sigma(B,A)$ are separable.*

Proof. The if part follows from $A \subseteq A/B \subseteq \sigma(A,B)$ and $B \subseteq B/A \subseteq \sigma(B,A)$. We show the only if part. Suppose that A and B are separable and let $H, \overline{H}$ be half-spaces such that $A \subseteq H$, $B \subseteq \bar{H}$. Let $v \in A/B$. By definition, $h(B \cup v) \cap A \neq \emptyset$, hence $H \cap \overline{H} = \emptyset$ entails $v \in H$. Now let $X \in \mathrm{MFS}(A,B)$. By definition of forbidden sets, $X \cap H \neq \emptyset$ and $X \not\subseteq H$. Thus, there exists $x \in X$ such that $x \in H$, which entails $h(A \cup x) \subseteq H$ as H is convex. Since $\bigcap_{x' \in X} h(A \cup x') \subseteq h(A \cup x)$ for each $x \in X$, we deduce

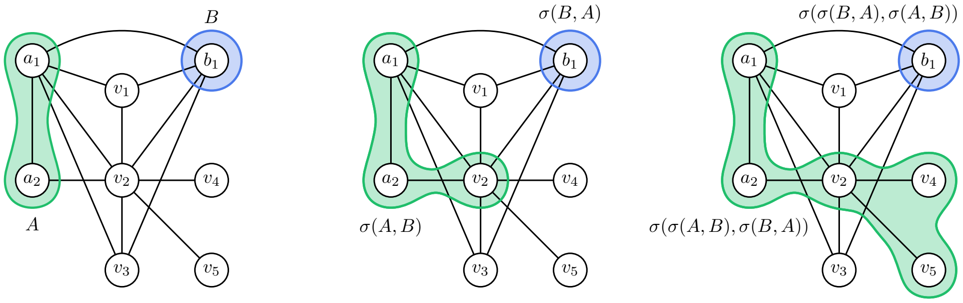
$$A/B \cup \bigcup \left\{ \bigcap_{x \in X} h(A \cup x) : X \in \mathrm{MFS}(A,B) \right\} \subseteq H.$$

As H is convex, we get $\sigma(A,B) \subseteq H$. Applying the symmetric reasoning on $\sigma(B,A)$ yields $\sigma(B,A) \subseteq \overline{H}$. This concludes the proof. ◀



■ **Figure 3** Pre-saturation applied to the sets A and B of Figure 2. For $\sigma(B,A)$, $u_1,u_2 \in B/A$ are added. For $\sigma(A,B)$, we have $u_3,u_4 \in A/B$ and $v_4 \in h(A\cup v_1)\cap h(A\cup v_3)$ (paths in bold green) with $v_1v_3 \in \mathrm{MFS}(A,B)$.

We illustrate pre-saturation in Figure 3, where the operation is applied to the set A and B of Figure 2. In this example, once pre-saturation has been applied, no further vertices can be assigned by applying pre-saturation once more. There are cases however where applying pre-saturation twice yields new vertices to assign. Figure 4 illustrates this situation.



■ **Figure 4** An example where pre-saturation can be applied twice. For $\sigma(A,B)$, v_2 is obtained from the forbidden pair v_1v_3. Once v_2 is added, v_4,v_5 become part of $\sigma(A,B)/\sigma(B,A)$. Observe that $B=\sigma(B,A)=\sigma(\sigma(B,A),\sigma(A,B))$. The remaining vertices v_1,v_3 can be separated in any way.

This suggests to iteratively apply the pre-saturation operator until no more vertices are added. For $A,B\subseteq V$, the *saturation* of A with respect to B, denoted by $S(A,B)$ is defined as follows:

$$S(A,B)=\bigcup_{i=0}^{\infty}\sigma(A_i,B_i)$$

where $A_0=A$, $B_0=B$ and for all $1\le i$, $A_i=\sigma(A_{i-1},B_{i-1})$ and $B_i=\sigma(B_{i-1},A_{i-1})$. Given $A,B\subseteq V(G)$, we say that A and B are *saturated* if $A=S(A,B)$ and $B=S(B,A)$. Since σ is increasing, the procedure for computing $S(A,B)$ terminates after $|V(G)|$ steps at most. Applying Lemma 12 inductively on $1\le i$, we get:

▶ **Lemma 13.** *Let G be a connected graph, and let A,B be two linked and convex subsets of $V(G)$. Then, A,B are separable if and only if $S(A,B)$, $S(B,A)$ are separable.*

▶ Remark 14. If $A_i\cap B_i\neq\emptyset$ for some i, then $S(A,B)=S(B,A)=V(G)$, and no separation can distinguish $S(A,B)$ and $S(B,A)$. In particular, A,B are thus not separable.

To conclude this paragraph, we argue that $S(A, B)$ can be computed in polynomial time in the size of G. Since S is at most $|V(G)|$ applications of σ on subsets of $V(G)$, it is sufficient to show that σ can be computed in polynomial time. The bottleneck of computing σ lies in finding $\mathrm{MFS}(A, B)$. However, the fact that the Carathéodory number of monophonic convexity is 2 by Theorem 6 makes the sets in $\mathrm{MFS}(A, B)$ of constant size.

▶ **Proposition 15.** *Given $A, B \subseteq V(G)$, $\sigma(A, B)$ can be computed in polynomial time in the size of G.*

▶ **Corollary 16.** *Given $A, B \subseteq V(G)$, $S(A, B)$ can be computed in polynomial time in the size of G.*

We note that saturation is not sufficient to decide separability, as suggested by Figure 5. This motivates the last step of the algorithm.

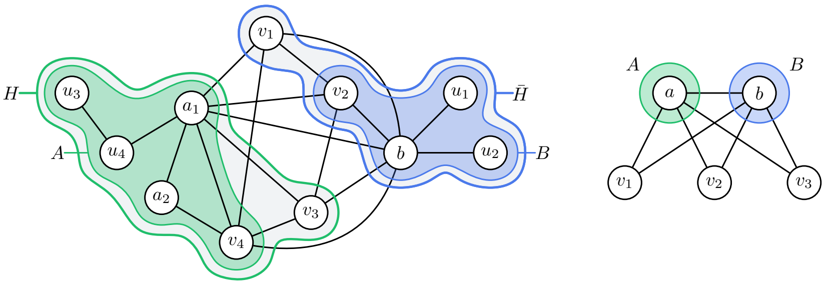


Figure 5 Two cases where A and B are linked, convex and saturated. On the left (follow-up of Figure 3), A and B can be separated (two half-spaces are drawn). On the right, any bipartition of the vertices will contain one of the forbidden pair v_1v_2, v_1v_3 or v_2v_3. Thus, A and B are not separable.

3.3 Testing bipartiteness

Let A, B be two linked, disjoint and saturated subsets of $V(G)$. By definition of saturation, A and B are convex. We characterize the separability of A and B using an equivalence relation $\equiv_{AB}$ on $\overline{A \cup B}$ and a graph G_{AB} defined from $\equiv_{AB}$. More precisely, we prove in Theorem 31 that A and B are separable if and only if G_{AB} is bipartite and no two $\equiv_{AB}$-equivalent vertices form a forbidden pair of $\mathrm{MFS}(A, B)$.

As a preliminary step though, we give properties of G and $N(A \cup B)$ in terms of A and B. We start with a statement that holds for every convex set.

▶ **Proposition 17.** *Let $C \subseteq V(G)$ be a convex set, and let u, v be two distinct vertices of $V(G) \setminus C$. Then:*

(1) *if u, v are not adjacent, then $h(uv) \cap C \neq \emptyset$ if and only if there exists $u', v' \in N(C)$ such that $u'v' \notin E(G)$ and $u', v' \in h(uv)$;*

(2) *if u, v are adjacent, then $F(C, u) \setminus F(C, v) \neq \emptyset$ entails $u \in h(C \cup v)$.*

Leveraging from the fact that A, B are linked and saturated, we use Proposition 17 to show that every vertex in $N(A \cup B)$ is adjacent to both A and B.

▶ **Lemma 18.** *For every $v \in N(A \cup B)$, $F(A, B) \cup F(B, A) \subseteq N(v)$. Therefore, the following properties hold for A (and symmetrically for B):*

(1) *$N(A) = F(B, A) \cup N(A \cup B)$;*

(2) *$F(A, \overline{A}) = F(A, N(A \cup B))$ is a clique.*

Proof. Assume for contradiction there exists $v \in N(A \cup B)$ such that $F(A,B) \cup F(B,A) \nsubseteq N(v)$. We have two cases:

(1) $F(A,B) \nsubseteq N(v)$ and $F(B,A) \nsubseteq N(v)$. Suppose w.l.o.g. that $v \in N(A)$. There exists $b \in F(B,A)$ such that $b \notin N(v)$. Then, we deduce by Proposition 17 that $h(bv) \cap A \neq \emptyset$ and $v \in A/B$.

(2) $F(A,B) \subseteq N(v)$ and $F(B,A) \nsubseteq N(v)$ (w.l.o.g.). Since $F(A,B) \subseteq N(v)$, $v \in N(A)$ holds. Thus, $v \in A/B$ again follows from Proposition 17.

In both cases, we obtain $v \in A/B$ with $v \notin A$. This contradicts A being saturated. We derive $F(A,B) \cup F(B,A) \subseteq N(v)$. Therefore, every $v \in N(A) \setminus B$ also lies in $N(B) \setminus A$ so that $N(A) \cap N(B) = N(A \cup B)$ holds along with $N(A) = F(B,A) \cup N(A \cup B)$ and $F(A, \overline{A}) = F(A, N(A \cup B))$. To see that $F(A, \overline{A})$ is a clique, observe that $B \cup N(A \cup B)$ is connected since B is convex. We deduce that $B \cup N(A \cup B)$ is included in a connected component of $G - A$. Since $F(A, \overline{A}) = F(A, N(A \cup B))$ and A is convex as it saturated, we obtain from Theorem 8 that $F(A, \overline{A})$ is a clique. ◀

Proposition 17 and Lemma 18 have two consequences. First, we can characterize $\mathrm{MFS}(A,B)$ as the set of pairs uv the closure of which contains non-adjacent vertices of $N(A \cup B)$, or in other words, a forbidden pair within $N(A \cup B)$.

▶ **Lemma 19.** *Let G be a connected graph and let A, B be two linked, disjoint and saturated subsets of $V(G)$. The following equality holds:*

$$\mathrm{MFS}(A,B) = \{uv \subseteq \overline{A \cup B} : h(uv) \cap N(A \cup B) \text{ is not a clique}\}$$

In particular, $X \subseteq \overline{A \cup B}$ is forbidden if and only if it includes a forbidden pair of $\mathrm{MFS}(A,B)$.

As another consequence, we can describe $N(A \cup B)$ and its interactions with A and B depending on whether it is a clique or not.

▶ **Lemma 20.** *Let G be a connected graph and let A, B be two linked, disjoint and saturated subsets of $V(G)$. Then either $N(A \cup B)$ is a clique or for every $u, v \in N(A \cup B)$, $F(A,v) = F(A,u)$ and $F(B,v) = F(B,u)$.*

Proof. Suppose that $N(A \cup B)$ is not a clique and let u, v be two non-adjacent vertices of $N(A \cup B)$. We first prove that $F(A,v) = F(A,u)$ and $F(B,v) = F(B,u)$. Assume for contradiction that $F(A,v) \neq F(A,u)$. We have $F(A,v) \setminus F(A,u) \neq \emptyset$ or $F(A,u) \setminus F(A,v) \neq \emptyset$. By Proposition 17, we deduce $v \in h(A \cup u)$ or $u \in h(A \cup v)$. Since u, v are not adjacent, $uv \in \mathrm{MFS}(A,B)$ by Lemma 19 and we obtain $h(A \cup u) \cap B \neq \emptyset$ or $h(A \cup v) \cap B \neq \emptyset$. Thus, either $u \in A/B$ or $v \in A/B$. This contradicts A being saturated. We obtain $F(A,v) = F(A,u)$, and $F(B,v) = F(B,u)$ using the same argument on B.

Now, let $w \in N(A \cup B)$ such that $w \neq u, v$. If w is not adjacent to u or v, then $F(A,w) = F(A,u) = F(A,v)$ and $F(B,w) = F(B,u) = F(B,v)$ readily holds by previous argument. Therefore, suppose that w is adjacent to both u and v. We prove that: (1) $F(A,w) \setminus F(A,u) = \emptyset$ and (2) $F(A,u) \setminus F(A,w) = \emptyset$.

(1) Assume for contradiction that $F(A,w) \setminus F(A,u) \neq \emptyset$. Then, $w \in h(A \cup u)$ by Proposition 17. But since, $F(A,u) = F(A,v)$, we deduce $F(A,w) \setminus F(A,v) \neq \emptyset$ and hence $w \in h(A \cup v)$. Because $uv \in \mathrm{MFS}(A,B)$ and $w \in h(A \cup u) \cap h(A \cup v)$, $w \notin A$ is a contradiction with A being saturated. We deduce that $F(A,w) \setminus F(A,u) = \emptyset$ must hold.

(2) Again, suppose for contradiction that $F(A,u) \setminus F(A,w) \neq \emptyset$. By Proposition 5, we obtain $u \in h(A \cup w)$ and since $F(A,u) = F(A,v)$, $v \in h(A \cup w)$ also holds. Since $uv \in \mathrm{MFS}(A,B)$, we obtain $w \in B/A$, a contradiction with B being saturated.

We conclude that $F(A,w) = F(A,u)$ holds, and similarly $F(B,w) = F(B,u)$. This concludes the proof. ◀

The two situations obtained from Lemma 20 are illustrated in Figure 6. In the case where

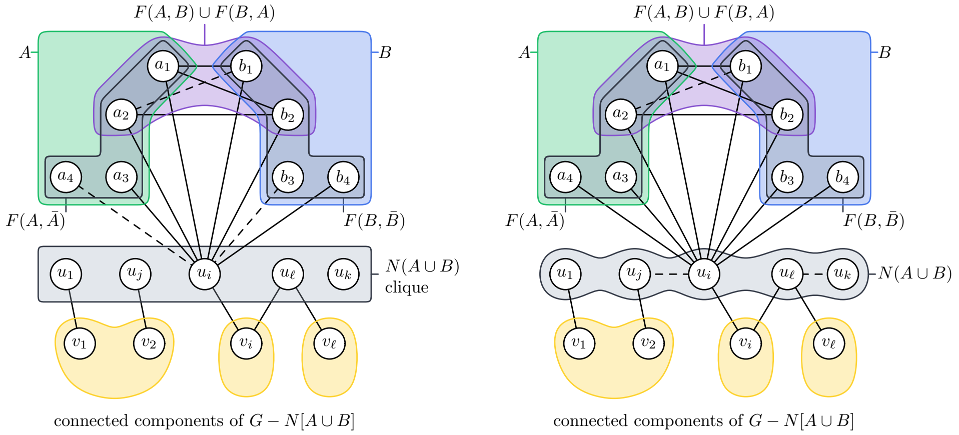

Figure 6 The two possible situations of Lemma 20. On the left, $N(A \cup B)$ is a clique. Each vertex of $N(A \cup B)$, is connected to each vertex of $F(A,B) \cup F(B,A)$ (circled in purple), modelled by u_i. However, it needs not be adjacent to all the vertices of the cliques $F(A,\bar{A})$ and $F(B,\bar{B})$ (the dotted line $u_i a_4$ indicates a non-edge). On the right, $N(A \cup B)$ is not a clique (for instance, u_i, u_j are not adjacent). Each vertex of $N(A \cup B)$ is complete to $F(A,\bar{A}) \cup F(B,\bar{B})$, including $F(A,B) \cup F(B,A)$.

$N(A \cup B)$ is not a clique, Lemma 20 together with Lemma 18 yields the subsequent corollary that will be useful later on.

▶ **Corollary 21.** *If $N(A \cup B)$ is not a clique, then for every clique $K \subseteq N(A \cup B)$, $F(A,\overline{A}) \cup K$ (resp. $F(B,\overline{B}) \cup K$) is a clique.*

Thanks to Lemmas 19 and 20, we are in position to relate the separability of A, B with (co)bipartiteness. We first address the case where all the vertices left to assign lie in $N(A \cup B)$, i.e., when $\overline{A \cup B} = N(A \cup B)$. Although restricted, this case gives some insights for the general one.

If $N(A \cup B)$ is a clique, then $\mathrm{MFS}(A,B) = \emptyset$ by Lemma 19. Hence every bipartition X, Y of $N(A \cup B)$ readily satisfies $h(A \cup X) \cap B = \emptyset$ and $h(B \cup Y) \cap A = \emptyset$. Therefore, X and Y need only satisfy $h(A \cup X) \cap Y = \emptyset$ and $h(B \cup X) \cap Y = \emptyset$. The trivial bipartition $X = \emptyset$ and $Y = N(A \cup B)$ vacuously obeys this requirement.

On the other hand, when $N(A \cup B)$ is not a clique, the subsequent lemma implies that for any bipartition X, Y of $N(A \cup B)$ into cliques, $A \cup X$ and $B \cup Y$ are convex.

▶ **Lemma 22.** *Let G be a connected graph and let A, B be two linked, disjoint and saturated subsets of $V(G)$ such that $N(A \cup B)$ is not a clique. Then for every clique $K \subseteq N(A \cup B)$, both $A \cup K$ and $B \cup K$ are convex.*

Proof. To check that $A \cup K$ is convex, we verify that $J[u,v] \subseteq A \cup K$ for every $u, v \in A \cup K$. If $u, v \in A$ or $u, v \in K$, then the result holds since A is convex and K is a clique. Consider instead $u \in A, v \in K$. Assume for contradiction $J[u,v] \nsubseteq K \cup A$. There exists a chordless uv-path $u = v_1, \ldots, v_k = v$ such that $v_i \notin K \cup A$ for some $1 < i < k$. Consider the least such i. By assumption $v_i \in N(A)$ and $v_{i-1} \in F(A, v_i)$. Morever, since A, B are saturated, $v_i \in N(A \cup B)$ must hold. As $N(A \cup B)$ is not a clique, we obtain by Lemma 20 that $F(A, v_i) = F(A, v)$, meaning that v_{i-1} is adjacent to v. This contradicts v_i being on a chordless uv-path. We deduce that $J[u,v] \subseteq A \cup K$ and $A \cup K$ is convex. ◀

We finally arrive at the following intermediate claim.

▶ **Lemma 23.** *Let G be a connected graph and let A, B be two disjoint, linked and saturated subsets of $V(G)$. If $\overline{A \cup B} = N(A \cup B)$, then A and B are separable if and only if $N(A \cup B)$ is cobipartite.*

Proof. We start with the only if part. Let $H = A \cup X$, $\overline{H} = B \cup Y$ be half-spaces separating A and B. By assumption, X contains no forbidden pair of $\mathrm{MFS}(A, B)$. Since $X \subseteq N(A \cup B)$, we deduce from Lemma 19 that X is a clique. In the same way, we deduce that Y is a clique. As X, Y is a bipartition of $\overline{A \cup B} = N(A \cup B)$, we deduce that $N(A \cup B)$ is cobipartite.

We proceed to the if part. If $N(A \cup B)$ is cobipartite, we have two cases: either $N(A \cup B)$ is a clique or it is not. If $N(A \cup B)$ is a clique, then (resp. $A \cup N(A \cup B)$ and B) are half-spaces separating A and B. If $N(A \cup B)$ is not a clique, the fact that $A \cup X$ and $B \cup Y$ are half-spaces for all bipartitions X, Y of $N(A \cup B)$ into cliques follows from Lemma 22. ◀

Let us consider now that there are vertices outside of $N(A \cup B)$, i.e., $N(A \cup B) \subset \overline{A \cup B}$. First, if $N(A \cup B)$ is a clique, $\mathrm{MFS}(A, B) = \emptyset$ still holds by Lemma 19. In this case, the same reasoning as before applies, and $A, B \cup \overline{A \cup B}$ is a half-space separation of A, B. Suppose on the other hand that $N(A \cup B)$ is not a clique. If it is not cobipartite, then any bipartition of $N(A \cup B)$ will contain a pair of non-adjacent vertices, and hence a forbidden pair, again due to Lemma 19. In other words, if $N(A \cup B)$ is not cobipartite, A and B are not separable. However, there are also cases where $N(A \cup B)$ is cobipartite, yet A and B are not separable. This is the case for the graphs of Figure 7, that we will use to illustrate the steps of the upcoming discussion. This happens because when picking an element v in a connected component S of $G - N[A \cup B]$, $h(A \cup v)$ and $h(B \cup v)$ will share elements from $N(S)$, regardless of the structure of $N(A \cup B)$ (clique or not).

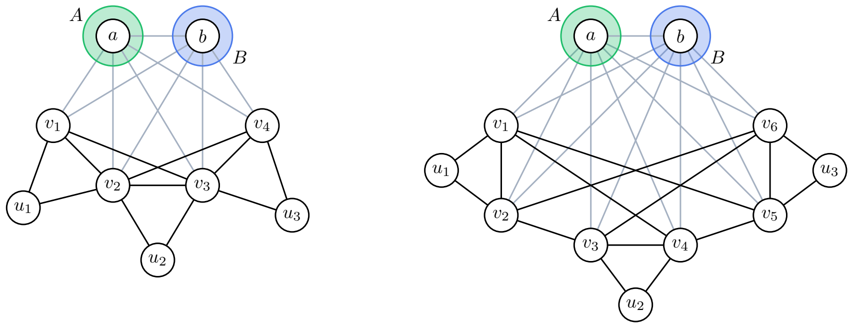

Figure 7 Two examples where A and B are linked and saturated, yet not separable despite $N(A \cup B)$ being cobipartite. For readability, the edges incident to a and b are clearer. Remark that since $N(A \cup B)$ is not a clique, both a and b are complete to $N(A \cup B)$ in virtue of Lemma 20.

▶ **Lemma 24.** *Let G be a connected graph and let A, B be two linked, disjoint and saturated subsets of $V(G)$. Let S be a connected component of $G - N[A \cup B]$. Then, for every $v \in S$, $N(S) \subseteq h(A \cup v) \cap h(B \cup v) \cap N(A \cup B)$.*

Using Lemma 24, we define an equivalence relation on $\overline{A \cup B}$ that will help us characterize the separability of A and B. Every half-space separation H, $\overline{H}$ of A and B, if any, can be written as $H = A \cup X$ and $\overline{H} = B \cup Y$ where X, Y is a bipartition of $\overline{A \cup B}$. Since $H \cap \bar{H} = \emptyset$, we have $H \cap Y = h(A \cup X) \cap Y = \emptyset$ and similarly $\overline{H} \cap X = h(B \cup Y) \cap X = \emptyset$. As a direct application of Lemma 24, we deduce:

(1) For each connected component S of $G - N[A \cup B]$, either $N[S] \subseteq X$ or $N[S] \subseteq Y$;

(2) If $S_1, \dots, S_k$ is a sequence of (not necessarily distinct) connected components of $G - N[A \cup B]$ such that $N(S_i) \cap N(S_{i+1}) \neq \emptyset$ for each $1 \leq i < k$, then $\bigcup_{i=1}^{k} N[S_i]$ must be included in one of X or Y. We call such a sequence an intersecting sequence of connected components.

Given an intersecting sequence $S_1, \dots, S_k$ of connected components of $G - N[A \cup B]$, we say for brevity that u, v belongs to the sequence $S_1, \dots, S_k$ if there exists $1 \leq i, j \leq k$ such that $u \in N[S_i]$ and $v \in N[S_j]$. Let us define the equivalence relation $\equiv_{AB}$ on $\overline{A \cup B}$ such that, for all $u, v \in \overline{A \cup B}$:

$$u \equiv_{AB} v \iff u = v \text{ or } u, v \text{ belong to an intersecting sequence of}$$
$$\text{connected components of } G - N[A \cup B]$$

▶ **Proposition 25.** *The relation $\equiv_{AB}$ is an equivalence relation.*

▶ Remark 26. The definition of $\equiv_{AB}$ encompasses the vertices that do not belong to the closed neighborhood of any connected component of $G - N[A \cup B]$, i.e., those vertices v in $N(A \cup B)$ such that $N[v] \subseteq N[A \cup B]$. By definition of $\equiv_{AB}$, they are equivalent to themselves only.

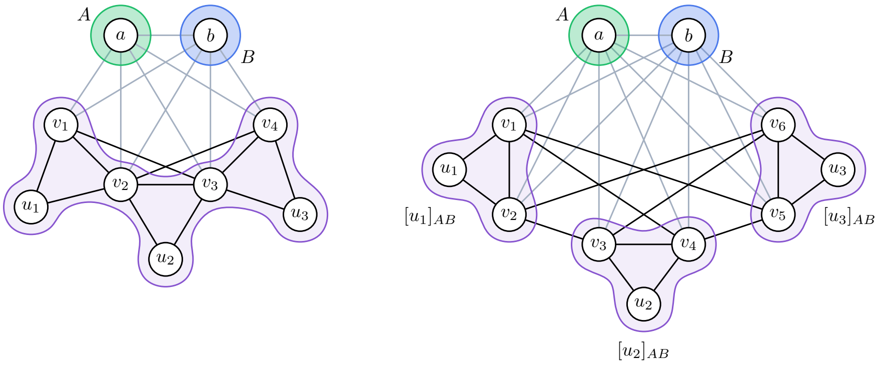

Figure 8 The equivalence relation $\equiv_{AB}$ applied to the graphs of Figure 7. The classes are circled (purple). On the left, there is a unique equivalence class. Remark that, as a consequence, v_1v_4 is a forbidden pair all the while $v_1 \equiv_{AB} v_4$. On the right, there are three classes, $[u_1]_{AB}$, $[u_2]_{AB}$, and $[u_3]_{AB}$.

For $u \in \overline{A \cup B}$, let $[u]_{AB}$ be the equivalence class of u: $[u]_{AB} = \{v \in \overline{A \cup B} : u \equiv_{AB} v\}$. In Figure 8, we give the equivalence classes induced by $\equiv_{AB}$ on the graphs of Figure 7. The next lemma is a direct yet important consequence of the above discussion and Lemma 24.

▶ **Lemma 27.** *Let G be a connected graph and let A, B be two disjoint, linked and saturated subsets of $V(G)$. For every bipartition X, Y of $\overline{A \cup B}$, we have $h(A \cup X) \cap Y = \emptyset$ and $h(B \cup Y) \cap X = \emptyset$ only if for each $v \in \overline{A \cup B}$, either $[v]_{AB} \subseteq X$ or $[v]_{AB} \subseteq Y$.*

We consider $\equiv_{AB}$ together with $\mathrm{MFS}(A, B)$. Remind that $\mathrm{MFS}(A, B)$ consists in pairs of vertices only, thanks to Lemma 19. Hence, a forbidden pair $uv \in \mathrm{MFS}(A, B)$ falls into exactly one of the following cases regarding equivalence classes:

(1) Either $u \equiv_{AB} v$ so that the equivalence class $[u]_{AB}$ prevents separation of A and B on its own (see Proposition 28 below). This case happens for instance in the graph on the left of Figure 8: $v_1 \equiv_{AB} v_4$ yet $v_1v_4 \in \mathrm{MFS}(A, B)$.

(2) Or $u \not\equiv_{AB} v$, so that $[u]_{AB}$ and $[v]_{AB}$ cannot be taken together in any separation of A and B. For example in the graph on the right of Figure 8 we have $v_1 \not\equiv_{AB} v_3$ and $v_1v_3 \in \mathrm{MFS}(A, B)$, which makes $[u_1]_{AB}$ and $[u_2]_{AB}$ incompatible for separating A and B. In this example, all equivalence classes are incompatible, so that A and B not separable.

As for the first case, we have the direct property:

▶ **Proposition 28.** *If $uv \in \mathrm{MFS}(A, B)$ and $u \equiv_{AB} v$, then A, B are not separable.*

For the second case, we can build a graph G_{AB} on the equivalence classes of $\equiv_{AB}$ that makes adjacent every two distinct equivalence classes sharing a forbidden pair. More formally:

$$V(G_{AB}) = \{[v]_{AB} : v \in \overline{A \cup B}\}$$
$$E(G_{AB}) = \{[u]_{AB}[v]_{AB} : u \not\equiv_{AB} v \text{ and } uv \in \mathrm{MFS}(A, B)\}.$$

For the graph on the right of Figure 8, the corresponding graph G_{AB} will be a clique. Figure 9 illustrates the graph G_{AB} on an other example.

▶ Remark 29. In the case where $\overline{A \cup B} = N(A \cup B)$, the equivalence classes $[v]_{AB}$ are precisely the singletons $\{v\}$ for all $v \in N(A \cup B)$. Identifying $[v]_{AB}$ with v, G_{AB} turns out to be precisely the complement of $G[N(A \cup B)]$.

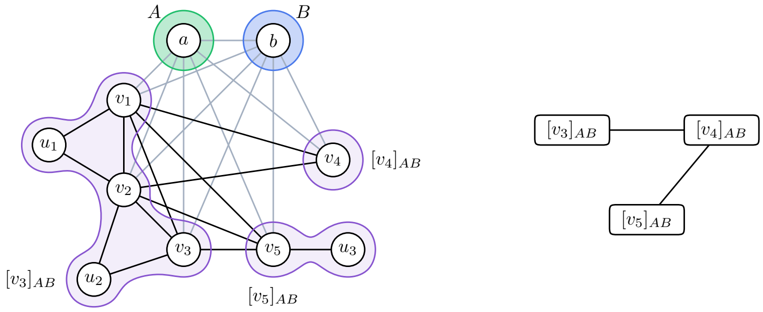

Figure 9 On the left, a graph with linked A and B where the equivalence class are highlighted. Again, the edges incident to a and b are clearer for readability. On the right, the corresponding graph G_{AB}.

Before characterizing the separability of A and B we give a lemma extending Lemma 22.

▶ **Lemma 30.** *Let G be a connected graph and let A, B be two disjoint, linked and saturated subsets of $V(G)$ such that $N(A \cup B)$ is not a clique. Then, for every collection $\mathcal{X}$ of equivalence classes of $\equiv_{AB}$, if $\bigcup \mathcal{X} \cap N(A \cup B)$ is a clique, then both $A \cup \bigcup \mathcal{X}$ and $B \cup \bigcup \mathcal{X}$ are convex.*

Proof. Let $\mathcal{X}$ be a collection of equivalences classes such that $\bigcup \mathcal{X} \cap N(A \cup B)$ is a clique and let $C = A \cup \bigcup \mathcal{X}$. We show that C is convex. We put $K = F(A, \bar{A}) \cup (N(A \cup B) \cap C)$. Now, by assumption, $N(A \cup B) \cap C$ is a clique, A and B are linked and saturated and $N(A \cup B)$ is not a clique. Therefore, K is a clique by Corollary 21. In view of Lemma 9, we show that K is a clique separator of G and that $C \setminus K$ is a union of connected components of $G - K$. First, since $F(A, \bar{A}) \subseteq K$ and K is a clique, we have that $G - K$ disconnects $A \setminus K$ from $\overline{A \cup B} \setminus K$. Hence K is a clique separator of G and moreover, $A \setminus K$ is indeed a union of connected components of $G - K$ since $F(A, \bar{A}) \subseteq K$. Now we consider $C \setminus (K \cup A)$. If $C \setminus (K \cup A) = \emptyset$, we deduce $C \subseteq A \cup K$ and the result holds by Lemma 22. Assume that $C \setminus (K \cup A) \neq \emptyset$ and let $S_1, \ldots, S_k$ be the connected components of $G - N[A \cup B]$ such that $C \cap S_i \neq \emptyset$ for each $1 \leq i \leq k$. We have $C \setminus (A \cup K) \subseteq \bigcup_{i=1}^{k} S_i$. We show that $\bigcup_{i=1}^{k} S_i \subseteq C \setminus (A \cup K)$. Let $v \in S_i$ for some $1 \leq i \leq k$. By definition of $\equiv_{AB}$, $S \subseteq [v]_{AB}$ and since $\mathcal{X}$ is a collection of equivalence classes, we obtain $S \subseteq [v]_{AB} \subseteq C \setminus (K \cup A)$. We deduce $C \setminus (A \cup K) \subseteq \bigcup_{i=1}^{k} S_i$ and hence $C \setminus (A \cup K) = \bigcup_{i=1}^{k} S_i$. It remains to show that S_i is a connected component of $G - K$. Since S_i is a connected component of $G - N[A \cup B]$, it is a connected component of

$G - N(S_i)$. Moreover, $N(S_i) \subseteq N(A \cup B)$ by construction. Finally, again by definition of C and $\equiv_{AB}$, $N(S_i) \subseteq C$. Henceforth, $N(S_i) \subseteq N(A \cup B) \cap C$ from which we deduce that S_i is a connected component of $G - K$. Hence, $C = K \cup (A \setminus K) \cup (C \setminus (K \cup A))$ is the union of a clique separator K of G and connected components of $G - K$. Applying Lemma 9, we deduce that C is convex, which concludes the proof. ◀

We can characterize the separability of A, B by generalizing Lemma 23.

▶ **Theorem 31.** *Let G be a connected graph and let A, B be two disjoint, linked and saturated subsets of V. Then A and B are separable if and only if the next conditions hold:*

(1) *for every $v \in \overline{A \cup B}$, $[v]_{AB}$ contains no forbidden pairs;*

(2) *G_{AB} is bipartite.*

Proof. We start with the only if part. Assume A and B are separable and let $H, \bar{H}$ be a half-space separation of A and B with $A \subseteq H$ and $B \subseteq \bar{H}$. Put $X = H \setminus A$ and $Y = \overline{H} \setminus B$. By assumption, $H \cap Y = h(A \cup X) \cap Y = \emptyset$. Hence, by Lemma 27, for each $v \in \overline{A \cup B}$, either $[v]_{AB} \subseteq X$ or $[v]_{AB} \subseteq Y$. Let $\mathcal{X} = \{[v]_{AB} \in V(G_{AB}) : [v]_{AB} \subseteq X\}$ and $\mathcal{Y} = \{[v]_{AB} \in V(G_{AB}) : [v]_{AB} \subseteq Y\}$. Since $H, \overline{H}$ are half-spaces separating A and B, and $X \subseteq H$, $Y \subseteq \overline{H}$, we deduce that neither X nor Y contain a forbidden pair of $\mathrm{MFS}(A, B)$. We derive:

(1) for each $[v]_{AB}$, $[v]_{AB}$ contains no forbidden pair, i.e., item (1) holds;

(2) for each pair of distinct classes $[u]_{AB}, [v]_{AB}$ in X (resp. Y), $[u]_{AB}$ and $[v]_{AB}$ are not adjacent in G_{AB}, i.e., that $\mathcal{X}$ (resp. $\mathcal{Y}$) is an independent set of G_{AB}. Since $\mathcal{X}$, $\mathcal{Y}$ is a partition of G_{AB} into two independent sets, we conclude that G_{AB} is bipartite, and that item (2) of the theorem holds.

We move to the if part. Assume both items (1) and item (2) are satisfied. In particular, if $N(A \cup B)$ is a clique, $\mathrm{MFS}(A, B) = \emptyset$ by Lemma 19. Hence, $A \cup N(A \cup B)$ and B (resp. $B \cup N(A \cup B)$ and A) are half-spaces separating A and B. Assume $N(A \cup B)$ is not a clique and let $\mathcal{X}, \mathcal{Y}$ be any bipartition of $V(G_{AB})$ into two independent sets. We show that $\bigcup \mathcal{X}$ contains no forbidden pair. Assume for contradiction there exists a forbidden pair $uv \in \bigcup \mathcal{X}$. We have two cases:

(1) $u \equiv_{AB} v$, but this would contradict item (1) of the statement;

(2) $u \not\equiv_{AB} v$, but this would contradict $\mathcal{X}_A$ being an independent set of G_{AB} by definition of G_{AB}.

By Lemma 19 we deduce that $\bigcup \mathcal{X}$ contains no forbidden pair, and hence that $\bigcup \mathcal{X} \cap N(A \cup B)$ is a clique. Applying Lemma 30, $A \cup \bigcup \mathcal{X}$ is convex. The same reasoning on $B \cup \mathcal{Y}$ yields that $A \cup \bigcup \mathcal{X}$ and $B \cup \mathcal{Y}$ are half-spaces separating A and B. This concludes the proof. ◀

Figure 10 illustrate the conditions of Theorem 31 on the example of Figure 9. We finally argue that the conditions of Theorem 31 can be checked in polynomial time. Since $\mathrm{MFS}(A, B)$ consists in pairs only, it can be computed in polynomial time. Then, we identify the connected components of $G - N[A \cup B]$ in polynomial time by traversing $G - N[A \cup B]$. We then identify the equivalence relation $\equiv_{AB}$ and build G_{AB} accordingly. Testing that no equivalent class contains a forbidden pair can be done in polynomial as well as checking that G_{AB} is bipartite. We deduce:

▶ **Theorem 32.** *Let G be a connected graph and let A, B be two disjoint, linked and saturated subsets of V. Whether A, B can be separated by half-spaces can be checked in polynomial time in the size of G.*

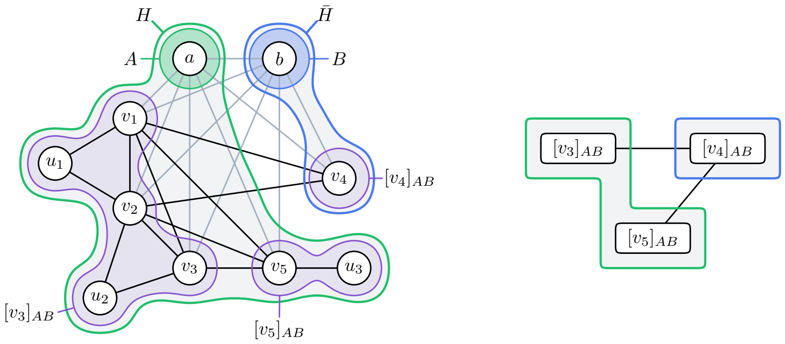

Figure 10 Illustration of Theorem 31 on the graph of Figure 9. A half-space separation of A and B is drawn. Observe that it corresponds to a bipartition of G_{AB} into independent sets.

4 Conclusion

We proved that half-space separability can be tested in polynomial time for monophonic convexity. Using Lemma 30, the algorithm we propose can be adapted to generate a pair of half-spaces separating two sets of vertices, if any. Moreover, we deduce as a corollary that the 2-partition problem can be solved in polynomial time for monophonic convexity, thus answering an open problem in [17].

To decide separability, we used the underlying graph together with the fact that the Carathéodory number is constant for monophonic convexity (Theorem 6, [12]). A natural question is then to investigate to what extent the Carathéodory number can be used to decide separability. However, relying on the problem of 2-coloring 3-uniform hypergraphs [19], we can show that already with Carathéodory number 3, half-space separation in general convexity spaces is out of reach.

▶ **Theorem 33.** *Half-space separation is NP-complete for convexity spaces $(V, \mathcal{C})$ given by V and a hull operator h that computes $h(X)$ in polynomial time in the size of V for all $X \subseteq V$, even if $(V, \mathcal{C})$ has Carathéodory number 3.*

Theorem 33 together with Theorem 1 motivate the next intriguing open problem.

▶ **Open Problem 34.** *Find a natural (graph) convexity with Carathéodory number 2 (e.g. triangle-path convexity [5]) where half-space separation is hard, or show that for all such convexities, half-space separation is tractable.*

Abstract

Temporal graphs provide a useful model for many real-world networks. Unfortunately, the majority of algorithmic problems we might consider on such graphs are intractable. There has been recent progress in defining structural parameters which describe tractable cases by simultaneously restricting the underlying structure and the times at which edges appear in the graph. These all rely on the temporal graph being sparse in some sense. We introduce temporal analogues of three increasingly restrictive static graph parameters – cliquewidth, modular-width and neighbourhood diversity – which take small values for highly structured temporal graphs, even if a large number of edges are active at each timestep. The computational problems solvable efficiently when the temporal cliquewidth of the input graph is bounded form a subset of those solvable efficiently when the temporal modular-width is bounded, which is in turn a subset of problems efficiently solvable when the temporal neighbourhood diversity is bounded. By considering specific temporal graph problems, we demonstrate that (up to standard complexity theoretic assumptions) these inclusions are strict.

1 Introduction

Temporal graphs, in which the set of active edges changes over time, are a useful formalism for modelling numerous real-world phenomena, from social networks in which friendships evolve over time to transport networks in which a particular connection is only available on particular days and times. This has inspired a large volume of research into the algorithmic aspects of such graphs in recent years [8, 26, 34], but unfortunately in many cases even problems which admit polynomial-time algorithms on static graphs become intractable in the temporal setting.

This has motivated the study of computational problems on restricted classes of temporal graphs, with mixed success: in a few cases, restricting the structure of the underlying static graph (e.g. to be a path or a tree) is effective, but numerous natural temporal problems remain intractable even when the underlying graph is very strongly restricted (e.g. when it is required to be a path [33] or a star [2]). Recently, several promising new parameters have been introduced that simultaneously restrict properties of the static underlying graph and the times at which edges are active in the graph; these include several analogues of treewidth for temporal graphs [18, 30], the temporal feedback edge/connection number [23], the timed vertex feedback number [7] and the (vertex-)interval-membership-width of the temporal graph [6]. However, all of these new temporal parameters are only small for temporal graphs that are, in some sense, sparse: none of them can be bounded on a temporal graph which has a superlinear (in the number of vertices) number of active edges at every timestep.

In this paper, we attempt to fill this gap in the toolbox of parameters for temporal graphs by introducing three new parameters which can take small values on temporal graphs which are dense but are sufficiently highly structured. Specifically, we define natural temporal analogues of cliquewidth, modular-width and neighbourhood diversity, all of which have proved highly effective in the design of efficient algorithms for static graphs.

Importantly, the neighbourhood diversity of a static graph upper bounds its modular-width, which upper bounds its cliquewidth. Both cliquewidth (introduced by Courcelle et al. [13]) and modular-width (introduced by Gajarský et al. [19], using the long-standing notion of modular decompositions [20]) can be defined in terms of width measures over composition trees allowing particular operations. Cliquewidth constructions have greater flexibility due to the fact that we are allowed to use an additional "relabelling" operation; this makes it possible, for example, to build long induced paths, which cannot exist in graphs of small modular width. Courcelle et al. [11] show that any graph property expressible in monadic second order is solvable in linear time on graphs of bounded cliquewidth. Gajarský et al. [19] provide examples of problems (Hamilton Path and Colouring) that are hard with respect to cliquewidth but tractable with respect to the more restrictive parameter modular-width. Neighbourhood diversity is a highly restrictive parameter, introduced by Lampis [28], which requires that large sets of vertices have identical neighbourhoods. Cordasco [9] demonstrated that Equitable Colouring is hard with respect to modular-width but tractable with respect to neighbourhood diversity.

These three static parameters are the inspiration for our temporal parameters. Informally, our new parameters are defined as follows:

- A temporal graph has *temporal neighbourhood diversity (TND)* at most k if its vertices can be partitioned into at most k classes such that each class induces either an independent set or a clique in which all edges are active at exactly the same times, and any two vertices in the same class have exactly the same neighbours outside the class at each timestep.
- *Temporal modular-width (TMW)* is a generalisation of TND: a temporal graph has TMW at most k if its vertices can be partitioned into modules such that two vertices in the same module must have the exactly the same neighbours outside the class at each timestep, but now each module need only be a temporal graph which itself has TMW at most k, rather than a clique or independent set.
- Like the static version, *temporal cliquewidth (TCW)* is defined to be the minimum number of labels needed to construct a temporal graph using four operations (create a vertex with a new label; take a disjoint union of two graphs; add all edges between vertices of two specified labels; relabel all occurrences of one label to another); the difference from the static case is that when adding edges between two sets of vertices these edges must all be active at exactly the same times.

We note that in every case we will recover the corresponding static parameter if all edges are active at the same times. It is immediate that the TND of a temporal graph is an upper bound on its TMW, and it is straightforward to show (see Section 3) that the TMW is an upper bound on the TCW. Thus, the most general algorithmic result we hope to obtain is to show that a problem is tractable when the TCW of the input temporal graph is bounded, but we expect to be able to show tractability for more problems as we impose stronger restictions on the input by bounding respectively the TMW and the TND.

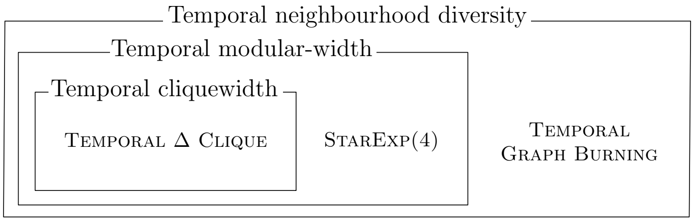

Figure 1 A diagram of our parameters and the problems we show to be tractable with respect to each. A problem is in a rectangle if it is tractable with respect to the parameter it is labelled with. Assuming P≠NP, each problem is in the rectangle for the most general of the three parameters for which it is tractable.

To illustrate the value of considering this hierarchy of parameters, we provide examples of problems which can be solved efficiently when each of our three new parameters is bounded, but which (in the case of TND and TMW) remain intractable when we restrict only the next most restrictive parameter, as illustrated in Figure 1. Specifically, we prove that:

- Temporal Clique is solvable in linear time when a temporal cliquewidth decomposition of constant width is given (see Section 2).
- StarExp(4) (the problem of deciding whether there is a closed temporal walk visiting all vertices in a star when each edge is active at no more than four times) remains NP-hard on graphs with TCW at most three, but is solvable in polynomial time when the TMW of the input graph is bounded by a constant; in fact we provide an fpt-algorithm[1] with respect to TMW (see Section 3).
- Graph Burning is NP-hard on temporal graphs with constant TMW, but is solvable in polynomial time when the TND of the input graph is bounded by a constant; again this is an fpt-algorithm with respect to TND (see Section 4).

We also (in Section 4) provide an fpt-algorithm to solve SingMinReachDelete parameterised by TND (when the number of appearances of each edge is bounded), in order to illustrate additional techniques that may be used when working with this new temporal parameter. This problem asks, for a given source vertex, what the cardinality of the smallest set of time-edges is such that their deletion leaves at most r vertices temporally reachable from the source. We conjecture that SingMinReachDelete is another example of a problem that is tractable with respect to TND but intractable when only the TMW is restricted.

The remainder of the paper is organised as follows. We conclude this section by introducing some key notation and definitions used throughout the paper. The following three sections are devoted to TCW, TMW and TND respectively, with each section containing the formal definition of a parameter as well as results about problems which can be solved efficiently when that parameter is bounded. Many proof details are omitted due to space constraints. A full version of the paper can be found on arXiv. Statements with proofs omitted are highlighted with a ($\star$).

[1] We use fpt (lowercase) as a descriptor of algorithms witnessing the inclusion of a problem in the parameterised complexity class FPT.

1.1 Notation and definitions

We use a number of standard notations for temporal graphs and related notions. A *temporal graph* $\mathcal{G} = (G, \lambda)$ consists of an underlying static graph $\mathcal{G}_{\downarrow} = G$, and a time-labeling function $\lambda : E \to 2^{\mathbb{N}}$, assigning to each edge a set of timesteps at which it is active. We refer to a pair (e, t) consisting of an edge $e \in E(G)$ and time $t \in \lambda(e)$ as a *time-edge*. The set of all time-edges of a temporal graph is denoted by $\varepsilon(\mathcal{G})$ and the *lifetime* Λ of a temporal graph refers to the final time at which any edge is active, i.e. $\Lambda = \max\{\max \lambda(e) : e \in E(G)\}$. The *snapshot* $\mathcal{G}_t$ of a temporal graph $\mathcal{G}$ at time t is the static graph $G = (V, E_t)$ where E_t is the set of edges active at time t.

A *temporal path* on the temporal graph $\mathcal{G} = (G, \lambda)$ is a sequence of edge, time pairs $(e_1, t_1), ..., (e_\ell, t_\ell)$, such that $e_1, ..., e_\ell$ is a path on G, and $t_i \in \lambda(e_i)$ for every $i \in [\ell]$, and $t_1, ..., t_\ell$ is a strictly increasing sequence of times. Given a temporal path $(e_1, t_1), ..., (e_\ell, t_\ell)$ we refer to the time t_1 as its *departure time*, and t_ℓ as its *arrival time*.

We refer the reader to [15] for standard definitions from the field of parameterised complexity.

2 Tractability with respect to Temporal Cliquewidth

In this section we give the formal definition of the first of our new parameters, temporal cliquewidth, and demonstrate that the problem of finding a temporal clique admits an fpt-algorithm parameterised by temporal cliquewidth. Before defining temporal cliquewidth, we start by recalling the definition of cliquewidth in the static setting, as introduced by Courcelle and Olariu [14].

▶ **Definition 1** (Cliquewidth). *The* cliquewidth *of a static graph $G = (V, E)$ is the number of labels required to construct G using only the following operations:*

1. *Creating a new vertex with label i.*
2. *Taking the disjoint union of two labeled graphs.*
3. *Adding edges to join all vertices labeled i to all vertices labeled j, where $i \neq j$.*
4. *Renaming label i to label j.*

We refer to an algorithm which constructs a graph G using the above operations as a cliquewidth construction *of G.*

Computing the cliquewidth of a graph is NP-hard [17], although there exists a polynomial-time algorithm to recognise graphs of cliquewidth at most three [10].

Translating this definition into the temporal setting, and preserving the idea that vertices with the same label should be indistinguishable when we add edges – which imposes additional restrictions on the times at which new edges are active – we obtain our definition of temporal cliquewidth.

▶ **Definition 2** (Temporal Cliquewidth). *The* temporal cliquewidth *of a temporal graph $\mathcal{G} = (G, \lambda)$ is the number of labels required to construct $\mathcal{G}$ using only the following operations:*

1. *Creating a new vertex with label i.*
2. *Taking the disjoint union of two labeled graphs.*
3. *Adding edges to join all vertices labeled i to all vertices labeled j, where $i \neq j$, such that all the added edges are active at the same set of times T.*
4. *Renaming label i to label j.*

We refer to an algorithm which constructs a temporal graph $\mathcal{G}$ using the above operations as a temporal cliquewidth construction *of $\mathcal{G}$.*

We note that, if temporal graph $\mathcal{G}$ has bounded temporal cliquewidth k, then the underlying graph $G_{\downarrow}$ of $\mathcal{G}$ has cliquewidth at most k. The construction of the underlying graph is found by adding a static edge (if one does not already exist) whenever a time-edge is added in the construction of the temporal graph. In addition, the snapshot of $\mathcal{G}$ at any time t, G_t, also has cliquewidth at most k. This follows from a similar argument. If we have a temporal graph where the edges all appear at the same times, the cliquewidth of the underlying graph is the same as the temporal cliquewidth and the cliquewidth of any snapshots where edges are active. It follows immediately that it is NP-hard to compute temporal cliquewidth, as the NP-hard problem of computing the cliquewidth of a static graph is a special case.

The remainder of this section is devoted to proving that the problem Temporal Δ Clique is in FPT parameterised by the temporal cliquewidth of the input graph. This problem was introduced by Viard et al. [37] and asks, in any interval of times of size Δ, whether there is a set of at least h vertices such that there is an appearance of an edge between every pair of vertices in every sub-interval of Δ times. Hermelin et al. [25] investigate the variant of this problem where the interval in question is the entire lifetime of the temporal graph. More formally, it asks if there exists a set V' of cardinality at least h such that for each pair of distinct vertices $u, v \in V'$ and each time $0 \leq i \leq \Lambda - \Delta$ where Λ is the lifetime of $\mathcal{G}$, there exists a time-edge at time $t' \in [i, \Delta + i]$.

Hermelin et al. note that this is the case if and only if there is a set of vertices of size at least k such that they form a clique on the static graph consisting of edges that appear in every interval of Δ timesteps. They name this static graph a Δ-*association graph.* It is more formally defined as $G = \left(V, \bigcap_{i=1}^{\Lambda(\mathcal{G})-\Delta+1} \bigcup_{j=i}^{i+\Delta-1} E_j\right)$ where E_j is the set of edges active at time j. This reformulates the problem as follows.

Temporal Δ Clique

Input: A temporal graph $\mathcal{G} = (V, E, \lambda)$ and two integers Δ and h where $\Delta \leq T(\mathcal{G})$.
Output: Is there a set $V' \subseteq V$ of vertices such that $|V'| \geq h$ and V' is a clique in the Δ-association graph G of $\mathcal{G}$?

Note that a temporal graph $\mathcal{G}$ with integers Δ and h is a yes-instance of Temporal Δ Clique if and only if its Δ-association graph G and h are a yes-instance of Clique.

▶ **Proposition 1** (⋆). *If a temporal graph $\mathcal{G}$ has temporal cliquewidth k, then the Δ-association graph G of $\mathcal{G}$ has cliquewidth at most k.*

Gurski [22, Theorem 4.4] shows that Clique is solvable in linear time in graphs of bounded cliquewidth if its construction is given. This gives us the following result.

▶ **Theorem 2.** *Given a cliquewidth construction of the Δ-association graph of a temporal graph $\mathcal{G}$, Temporal Δ Clique can be solved in linear time.*

3 Tractability with respect to Temporal Modular-width

We now introduce a more restrictive parameter, temporal modular-width, and show (in Section 3.1) that there exist problems which are efficiently solvable when this parameter is bounded even though they remain intractable on temporal graphs with constant temporal cliquewidth.

We begin with the formal definition of the parameter. Again, we start by recalling the definition of the corresponding static parameter on which our definition is based.

▶ **Definition 3** (Modular-width, Section 2.5 [19]). *Suppose a static graph G can be constructed by the algebraic expression A which uses the following operations:*

1. *Creating an isolated vertex.*
2. *Taking the disjoint union of two graphs.*
3. *Taking the complete join of two graphs. That is, for graphs $G_1 = (V_1, E_1)$ and $G_2 = (V_2, E_2)$, $V(G_1 \otimes G_2) = V(G_1) \cup V(G_2)$ and $E(G_1 \otimes G_2) = E(G_1) \cup E(G_2) \cup \{(v, w) : v \in V(G_1)$ and $w \in V(G_2)\}$.*
4. *The substitution of graphs $G_1, \ldots, G_n$ into a graph G' with vertices $v_1, \ldots, v_n$. This gives the graph $G'(G_1, \ldots, G_n)$ with vertex set $\bigcup_{1 \leq i \leq n} V(G_i)$ and edge set $\bigcup_{1 \leq i \leq n} E(G_i) \cup \{(v, w) : v \in V(G_i), w \in V(G_j),$ and $(v_i, v_j) \in E(G')\}$.*

The width of an expression A is the maximum number of operands in an occurrence of the operation 4 in A. The modular-width *of G, written $MW(G)$, is this minimum width of an expression A which constructs G.*

We refer to the graphs $G_1, \ldots, G_n$ which we substitute into G' as *modules*. It is known that for any graph G an algebraic expression of modular-width $MW(G)$ can be found in linear time [31, 36]. Observe that operations 2 and 3 are special cases of operation 4.

We now define our temporal analogue of this parameter. For simplicity we do not explicitly include the disjoint union and complete join operations, noting that once again these are special cases of the substitution operation.

▶ **Definition 4** (Temporal Modular-width). *Suppose a temporal graph $\mathcal{G}$ can be constructed by the algebraic expression A which uses the following operations:*

1. *Creating an isolated vertex.*
2. *Taking the disjoint union of two temporal graphs.*
3. *Taking the complete join of two temporal graphs at a set of times T. That is, for graphs $\mathcal{G}_1 = ((V_1, E_1), \lambda_1)$ and $\mathcal{G}_2 = ((V_2, E_2), \lambda_2)$, $V(\mathcal{G}_1 \otimes \mathcal{G}_2) = V(\mathcal{G}_1) \cup V(\mathcal{G}_2)$ and $\varepsilon(\mathcal{G}_1 \otimes \mathcal{G}_2) = \varepsilon(\mathcal{G}_1) \cup \varepsilon(\mathcal{G}_2) \cup \{(vw, t) : v \in V(\mathcal{G}_1), w \in V(\mathcal{G}_2)$ and $t \in T\}$.*
4. *The substitution of temporal graphs $\mathcal{G}_1, \ldots, \mathcal{G}_n$ into a temporal graph $\mathcal{G}'$ with vertices $v_1, \ldots, v_n$. This gives the graph $\mathcal{G}'(\mathcal{G}_1, \ldots, \mathcal{G}_n)$ with vertex set $\bigcup_{1 \leq i \leq n} V(\mathcal{G}_i)$ and time-edge set $\bigcup_{1 \leq i \leq n} \varepsilon(\mathcal{G}_i) \cup \{(vw, t) : v \in V(\mathcal{G}_i), w \in V(\mathcal{G}_j),$ and $(v_i v_j, t) \in \varepsilon(\mathcal{G}')\}$.*

The width of an expression A is the maximum number of operands in an occurrence of the operation 4 in A. The temporal modular-width *of G is this minimum width of an expression A which constructs G.*

As for temporal cliquewidth, we observe that the temporal modular-width of a temporal graph is equal to the modular-width of the underlying graph if all edges have the same temporal assignment. It follows that, as in the static case, the temporal modular-width bounds the length of the longest induced path in the underlying graph.

We now argue that, as claimed, bounding the temporal modular-width of a temporal graph is a strictly stronger restriction than bounding the temporal cliquewidth.

▶ **Theorem 3** ($\star$). *For any temporal graph $\mathcal{G} = (G, \lambda)$, the temporal cliquewidth is upper bounded by the temporal modular-width.*

Habib and Paul [24] describe a simple algorithm for finding the modular decomposition of a static graph. This operates by finding and repeatedly adding *splitters* to a candidate module - intuitively, splitters are vertices outside of a module that distinguish between vertices inside of a candidate module. We can use a similar splitter-closure method to find the unique maximal temporal modular decomposition:

▶ **Theorem 4** (⋆). *We can find the maximal temporal modular decomposition in time $O(n^4\Lambda)$, where n is the number of vertices in the temporal graph.*

3.1 Star Exploration

In this section we consider the following problem, demonstrating that it remains NP-hard even on temporal graphs with temporal cliquewidth at most three, but that it is solvable in constant time on graphs with bounded temporal modular-width (provided we are given the temporal modular-width of the graph). This problem was first introduced by Akrida et al. [2].

StarExp(τ)

Input: A temporal star (S_n, λ) where $|\lambda(e)| \leq \tau$ for every edge e in the star S_n.
Output: Is there a strict temporal walk, starting and finishing at the centre of the star, which visits every vertex of S_n?

We begin with a simple observation about the temporal cliquewidth of temporal graphs whose underlying graph is a star.

▶ **Lemma 5** (⋆). *A temporal star S_n has temporal cliquewidth at most 3.*

StarExp(τ) is known to be NP-hard even for constant τ [2, 6]. Then, by Lemma 5, StarExp(τ) is an example of a problem which is NP-hard on graphs of bounded temporal cliquewidth. We now show that StarExp(τ) is tractable on graphs of bounded temporal modular-width. We begin with the following lemma.

▶ **Lemma 6** (⋆). *If a temporal star S_n has temporal modular-width at most k, the leaves of S_n can be partitioned into $k-1$ subsets such that, if u and v are in the same subset and c is the central vertex in the star, the edges uc and cv are active at the same times.*

▶ **Lemma 7.** *If there are strictly more than $\tau/2$ leaves of S_n whose incident edges are active at the same times, we have a no-instance of StarExp(τ).*

Proof. By definition of the problem StarExp(τ), each edge in the star is active at most τ times. Therefore, if there are $\lfloor\tau/2\rfloor + 1$ vertices $u_1, \ldots, u_{\lfloor\tau/2\rfloor+1}$ such that $\lambda(u_1c) = \cdots = \lambda(u_{\lfloor\tau/2\rfloor+1}c)$ where c is the central vertex in the star, there is no temporal walk which starts at c and visits all of $u_1, \ldots, u_{\lfloor\tau/2\rfloor+1}$. To see this, note that visiting a leaf and returning requires the use of two distinct time-edges. Therefore, a walk visiting any $\lfloor\tau/2\rfloor + 1$ leaves which departs from and returns to c must consist of at least $\tau + 1$ distinct time-edges. This is not possible if these vertices have incident edges are active at the same times and $|\lambda(uc)| \leq \tau$. ◀

▶ **Theorem 8.** *StarExp(τ) is solvable in $(k\tau)!(k\tau)^{O(1)}$ time when the temporal modular-width of the graph is at most k.*

Proof. Given that the temporal modular-width of the graph is at most k, we check whether the number of leaves is more than $(k-1)\lfloor\tau/2\rfloor$. If the number of leaves is at least $(k-1)\lfloor\tau/2\rfloor+1$ then, by the pigeon-hole principle and Lemma 6, there must be at least $\lfloor\tau/2\rfloor + 1$ leaves whose edges to the central vertex are active at exactly the same times. In this case, by Lemma 7, we conclude that we have a no-instance of StarExp(τ).

Else, we have at most $(k-1)\lfloor\tau/2\rfloor < k\tau$ leaves. Note that, given an ordering of leaves to visit, we can check whether such a walk is valid in time polynomial in k and τ: we need only check for each leaf in order whether there are two appearances of its incident edge following the time-edges used to visit the previous leaf (and if so, greedily use the first two such appearances). Since there are fewer than $(k\tau)!$ possible orderings of the leaves, we can check each possibility in turn in time $(k\tau)!(k\tau)^{O(1)}$. ◀

4 Tractability with respect to Temporal Neighbourhood Diversity

We now turn our attention to our final parameter, temporal neighbourhood diversity, which is the most restrictive and hence allows for the most problems to be solved efficiently. In Section 4.1 we demonstrate that Temporal Graph Burning is solvable in polynomial time when the temporal neighbourhood diversity is bounded by a constant (in fact we give an fpt-algorithm with respect to this parameterisation), even though the problem remains NP-hard when restricted to temporal graphs with constant temporal modular-width. To illustrate further techniques that may be used to design efficient algorithms on graphs of bounded temporal neighbourhood diversity, in Section 4.2 we also give an fpt-algorithm for the problem SingMinReachDelete with a single source vertex.

We begin with the formal definition of temporal neighbourhood diversity. Once again, the definition is modelled on that for static graphs, which was first introduced by Lampis [28] and adpated by Ganian [21] to describe uncoloured graphs. In a static graph, we define the *neighbourhood* $N(v)$ of a vertex v as the set of vertices which share an edge with v.

▶ **Definition 5** (Type, Definition 2.2 [21])**.** *Two vertices v, v' have the same* type *if and only if $N(v) \setminus \{v'\} = N(v') \setminus \{v\}$.*

▶ **Definition 6** (Neighbourhood Diversity, Definition 2 [28])**.** *A graph $G = (V, E)$ has* neighbourhood diversity *at most k if and only if there exists a partition of $V(G)$ into at most k sets where all vertices in each set have the same type. We refer to this partition as a* neighbourhood partition.

We note that the neighbourhood diversity of a graph can be computed in linear time [28].

We now define the analogous temporal parameter, where we require that the edges between sets are all active at the same times.

▶ **Definition 7** (Temporal Neighbourhood)**.** *The* temporal neighbourhood *of a vertex v in a temporal graph (G, λ) is the set $TN(v)$ of vertex time pairs (w, t) where $(w, t) \in TN(V)$ if and only if $vw \in E(G)$ and $t \in \lambda(vw)$.*

▶ **Definition 8** (Temporal Type)**.** *Two vertices u, v have the same* temporal type *if and only if $\{(w, t) \in TN(v) : w \neq v\} = \{(w, t) \in TN(v') : w \neq u\}$.*

▶ **Definition 9** (Temporal Neighbourhood Diversity)**.** *A graph $\mathcal{G}$ has* temporal neighbourhood diversity *at most k if and only if there exists a partition of $V(\mathcal{G})$ into at most k sets where all vertices in each set have the same temporal type. We refer to this partition as a* temporal neighbourhood partition.

It is immediate from this definition that, when all edges are assigned the same times, the temporal neighbourhood diversity of the graph is the same as the neighbourhood diversity of the underlying graph. We now argue that, as in the static case, the subgraph induced by any class must form a clique or independent set; moreover, in the temporal setting, this must be true at every timestep.

▶ **Lemma 9** ($\star$)**.** *At any snapshot $\mathcal{G}_t$ of $\mathcal{G}$, the subgraph induced by the vertices in a class X of a temporal neighbourhood partition of $\mathcal{G}$ either forms an independent set or a clique.*

As stated, temporal neighbourhood diversity is the most restrictive parameter in our hierarchy. Observe that for any temporal graph $\mathcal{G}$ the temporal modular-width is upper bounded by the temporal neighbourhood diversity: each class in the temporal neighbourhood partition forms a module, and it follows from Lemma 9 that each of these modules can be constructed by operations 1, 2, and 3 of temporal modular-width construction.

Finally, we argue that we can compute the temporal neighbourhood diversity efficiently.

▶ **Proposition 10** ($\star$). *The temporal neighbourhood diversity of a temporal graph (G, λ) can be calculated in $O(\Lambda n^3)$ time.*

4.1 Temporal Graph Burning

In this section we define Temporal Graph Burning, a temporal analogue of the static Graph Burning problem first proposed by Bonato et al.[5]. Informally, a fire is placed at a new vertex in each time-step and the fire spreads along incident active edges. The problem asks if, after h placements of fire, all vertices are burning. Static Graph Burning is NP-hard on general graphs [4] and was recently shown to be in FPT parameterised by static modular width [27]. In contrast, we prove that Temporal Graph Burning remains NP-hard on graphs with constant temporal modular-width. This difference arises from the fact that, in the static setting, the length of a longest induced path in the graph (which is upper bounded by the modular-width) gives an upper bound on the time taken to burn the graph. In the temporal setting, on the other hand, the times assigned to edges mean that even graphs with small diameter may take many steps to burn. In contrast, we show that Temporal Graph Burning can be solved in time $O(n^5 \Lambda k! 4^k)$ on temporal graphs with n vertices, lifetime Λ and temporal neighbourhood diversity k.

The Temporal Graph Burning problem asks how quickly a fire can be spread over the vertices of a temporal graph in the following discrete time process, where a fire is placed at a vertex of a graph on each timestep.

1. At time $t = 0$ a fire is placed at a chosen vertex. All other vertices are unburnt.
2. At all times $t \geq 1$, the fire spreads, burning all vertices u adjacent to an already burning vertex v where the edge between u and v is active at time t. Then, another fire is placed at a chosen vertex.
3. This process ends once all vertices are burning.

We refer to a sequence of vertices at which fires are placed as a strategy.

▶ **Definition 10** (Burning Strategy). *A* burning strategy *for a temporal graph (G, λ) is a sequence of vertices $S = s_1, s_2, ..., s_h$ such that $s_i \in V(G)$ for all $i \leq h$, and on each timestep i a fire is placed at s_i.*

We say that a strategy $S = s_1, s_2, ..., s_h$ has length h. For convenience, we allow for strategies that place fires at already burning vertices, although it is worth noting that such moves may be omitted. If every vertex in the graph is burning after a strategy is played, we say that strategy is successful.

▶ **Definition 11** (Successful Burning Strategy). *A burning strategy $S = s_1, s_2, ..., s_h$ for a temporal graph (G, λ) is* successful *if every vertex in G is burning on timestep h when the moves from S are played.*

The decision problem asks how many timesteps it takes to burn a given temporal graph.

Temporal Graph Burning

Input: A temporal graph (G, λ) and an integer h.
Output: Does there exist a successful burning strategy for (G, λ) of length less than or equal to h?

This problem is in NP, with a strategy providing a certificate. Given a strategy it can be checked in polynomial time if it is successful and of length less than or equal to h by simulating temporal graph burning on the input graph.

We show that Temporal Graph Burning is NP-hard even on graphs of bounded temporal modular-width. This is achieved by reducing from (3, 2B)-SAT, an NP-hard variant of the Boolean satisfiability problem in which each variable appears exactly twice both positively and negatively [3]. Our reduction produces a graph where each edge is active on exactly one timestep, and furthermore every connected component has a bounded temporal neighbourhood diversity, and hence the graph has bounded temporal modular-width by our earlier observation.

▶ **Theorem 11** ($\star$). *Temporal Graph Burning is NP-hard even when restricted to graphs with constant temporal modular-width.*

We now show that Temporal Graph Burning is solvable efficiently when the temporal neighbourhood diversity of the input graph is bounded. Throughout we assume that the lifetime Λ of the input temporal graph is at most the number of vertices n, as it is possible to burn any temporal graph in n timesteps by placing a fire at every vertex in turn. We begin by defining notation for the burning set of vertices on a given timestep when a strategy is played.

▶ **Definition 12** (Burning Set). *Given a strategy S the* burning set *$B_t(S)$ at timestep t is the set of burning vertices immediately after a fire is placed on timestep t when S is played.*

We now give a number of results about how successful strategies can be modified to have certain desirable properties; these results allow us to bound the number of possible strategies we must check to determine whether there is a successful strategy of the desired length.

▶ **Lemma 12** ($\star$). *Let S be a successful strategy for (G, λ). Suppose that there is some timestep $t_1 < |S|$ and strategy R with $|R| = |S|$ such that $B_{t_1}(S) \subseteq B_{t_1}(R)$ and on every timestep after t_1, R places a fire at the same vertex as S. Then R is also successful.*

▶ **Lemma 13** ($\star$). *Let (G, λ) be a temporal graph with temporal neighbourhood partition $(X_i)_{i \in I}$. Now let S be a strategy that burns this graph, and let u be a vertex at which S places a fire on a timestep t_1, and X_i be the class to which this vertex belongs. Let S' be a strategy which plays as follows until t_2, for any timestep $t_2 > t_1$:*

$$s'_t = \begin{cases} s_t & \text{if } t < t_1 \\ s_{t+1} & \text{if } t_1 \leq t < t_2 \\ u & \text{if } t = t_2 \end{cases}$$

Providing there exists a vertex $w \in X_i$ which is burning before the end of timestep t_1 when S' is played, we have that $B_{t_2}(S) \subseteq B_{t_2}(S')$.

▶ **Lemma 14** ($\star$). *Let (G, λ) be a temporal graph with temporal neighbourhood partition $(X_i)_{i \in I}$. Let S and S' both be strategies with $|S'| = |S|$, such that on every timestep, S and S' both place fires in the same class, that is, for any $i \leq |S|$ we have that $\{s_i, s'_i\} \subseteq X_j$.*

Furthermore, assume that S' places a fire at an already burning vertex on a timestep i if and only if S also places a fire at an already burning vertex on timestep i. Then S is successful if and only if S' is.

▶ **Definition 13** (Placement Classes). *The placement classes for a strategy S denoted $C(S)$ is the set of classes from the temporal neighbourhood partition in which S places fires.*

▶ **Lemma 15** ($\star$). *Given a temporal graph (G, λ), let S be any successful strategy. There is then a successful strategy S' with $|S'| = |S|$, and $C(S') = C(S)$, such that the first $|C(S')|$ burns are in distinct equivalence classes in the temporal neighbourhood partition.*

Finally we show that, given a strategy S that places fires only in distinct classes for the first $|C(S)|$ moves, we can arbitrarily reorder all subsequent moves made after timestep $|C(S)|$.

▶ **Lemma 16** ($\star$). *Let (G, λ) be a temporal graph, and S a successful strategy such that the first $|C(S)|$ fires placed by S are placed in distinct classes from the temporal neighbourhood partition. Let $f : [|C(S)| + 1, |S|] \to [|C(S)| + 1, |S|]$ be any bijection. Then the strategy S' given by*

$$s'_t = \begin{cases} s_t & \text{if } t \leq |C(S)| \\ s_{f(t)} & \text{otherwise} \end{cases}$$

is successful, and burns the graph in the same or less time as S.

We now present an algorithm for Temporal Graph Burning (Algorithm 1), and show that this algorithm is an fpt-algorithm with respect to temporal neighbourhood diversity.

Algorithm 1 TND Graph Burning Algorithm.

```
Input: A temporal graph $\mathcal{G}$, and an integer $k$.
Output: True if and only if there exists a successful burning strategy of length at most $h$.
Compute the temporal neighbourhood partition $\Theta$ of $(G, \lambda)$.
for all possible subsets $A \subseteq \Theta$ do
    for all possible orderings of $A$ do
        for all possible subsets $B \subseteq A$ do
            Compute a strategy that first places a fire in order in every class from $A$, and
            then places fires at every unburnt vertex in $B$ in any order.
            if this strategy is successful and consists of $k$ or fewer moves then
                return true.
If no such strategy is found, return false.
```

▶ **Lemma 17** ($\star$). *The TND Graph Burning Algorithm returns true for a temporal graph (G, λ) and integer h if and only if there exists a strategy S that burns the graph in h or fewer timesteps.*

This allows us to obtain fixed parameter tractability, as bounding the temporal neighbourhood diversity bounds the number of such strategies that we have to check.

▶ **Theorem 18** ($\star$). *Temporal Graph Burning is solvable in time $O(n^5 \Lambda k! 4^k)$, where n is the size of the input temporal graph $\mathcal{G}$, Λ the lifetime, and k the temporal neighbourhood diversity. If the temporal neighbourhood partition is given, we obtain a runtime of $O(n^2 \Lambda k! 4^k)$.*

4.2 Minimum Reachability Edge Deletion

Here we give another problem which is tractable with respect to temporal neighbourhood diversity. Given a specified source vertex, we seek a minimum set of edge appearances that can be deleted to limit the number of vertices reachable from that source.

We say a vertex v is *temporally reachable* from a vertex u in $\mathcal{G}$ if there exists a temporal path from u to v. We say a vertex v is temporally reachable from a set S if there is a vertex in S from which v is temporally reachable. The *reachability set* $\text{reach}(v)$ of a vertex v is the set of vertices temporally reachable from v. We can now give the formal problem definition; this is a special case of the problem MinReachDelete studied by Molter et al. [35] in which multiple sources are allowed.

Singleton Minimum Temporal Reachability Edge Deletion (SingMinReachDelete)

Input: A temporal graph $\mathcal{G} = (G, \lambda)$, a vertex $v_s \in V(G)$ and positive integer r.
Output: What is the cardinality of the smallest set of time-edges E such that the vertex v_s has temporal reachability at most r after their deletion from $\mathcal{G}$?

SingMinReachDelete was shown by Enright et al. [16] to be NP-hard (and W[1]-hard parameterised by the maximum number of vertices that are allowed to be reached following deletion) even when the lifetime of the input temporal graph is 2 and every edge is active at exactly one timestep. In their problem, they ask if there exists a deletion such that no vertex in the resulting temporal graph reaches more than r vertices. While the result of [16] is for a version of the problem when the source set S is the entire vertex set, it is clear from the construction that hardness also holds with a single source vertex.

We show that this problem is in FPT when parameterised by temporal neighbourhood diversity and the *temporality* of the input graph $\tau(\mathcal{G})$, which was defined by Mertzios et al. [32] to be the maximum number of times any edge appears. When the temporal graph in question is clear from context, we just refer to τ. We note that it remains open whether the problem belongs to FPT parameterised by temporal neighbourhood diversity alone, or indeed parameterised by temporal modular width or temporal cliquewidth; the techniques we use here do not extend naturally to these less restrictive settings.

We now give a formal statement of our result.

▶ **Theorem 19** ($\star$). *SingMinReachDelete is solvable in time $g(k,\tau)\log^{O(1)} r + \Lambda n^3$, where g is a computable function. If a temporal neighbourhood decomposition is given, we can solve the problem in time $g(k,\tau)\log^{O(1)} r$.*

Note that, given two vertices of the same temporal type, their reachability sets must consist of the same vertices except for the vertices themselves; as a result, the reachability sets of vertices in a given class all have the same cardinality. Moreover, all vertices of the same type are first reached from the source at the same time (where we say a vertex is "first reached" at time t if the final time-edge in an earliest-arriving temporal path from the source is at time t). Our strategy for solving SingMinReachDelete is then as follows. We partition each class according to the time at which the vertices are first reached after the deletion of time-edges, and consider all possibilities for which of these subclasses are non-empty. Given a function ϕ telling us which subclasses are non-empty, we argue that we can determine efficiently whether there is indeed a deletion such that precisely these subclasses are non-empty, and if so compute exactly the pairs of subclasses between which we must delete time-edges to achieve this. For a fixed ϕ, we then encode the problem as an instance of Integer Quadratic Programming, where the variables are the sizes of the subclasses and the objective function seeks to minimise the number of time-edges we must delete, and use the algorithm of Lokshtanov [29].

5 Conclusion and Open Questions

We have described three temporal parameters that form a hierarchy mirroring the one formed by their static analogues, and that can all be small when the temporal graph is dense at every timestep. We provide examples of problems demonstrating that there is a separation between the classes of problems admitting efficient algorithms when each of the parameters is bounded. As is the case for the corresponding static parameters, we expect that there will be many problems for which these temporal parameters give fixed-parameter tractability, and suggest exploration of temporal extensions of static problems for which there are known fpt-algorithms as future work. From a practical perspective, it would also be interesting to investigate the values of these new parameters on dense real-world temporal networks.

One of the most celebrated results involving static cliquewidth is a metatheorem due to Courcelle et al. [11] which guarantees the existence of a linear-time algorithm for any problem expressible in a suitable fragment of logic (MSO_1) on graphs of bounded cliquewidth. It is a natural question whether an analogous metatheorem exists for temporal cliquewidth. A promising approach might be to encode a temporal graph as an arbitrary relational structure (as has been done for a temporal version of treewidth [18]). A major challenge here, however, is that to the best of our knowledge there is no single notion of cliquewidth for relational structures: several alternatives have been introduced [1, 12], but none has all of the desirable properties. Moreover, we believe that any encoding of a temporal graph of bounded temporal cliquewidth as a relational structure that preserves all the information in the original is unlikely to have bounded width for any cliquewidth-style measure unless we also bound the lifetime of the temporal graph. Nevertheless, this general direction merits further investigation, and there is potential for a useful metatheorem even if it is necessary to further restrict the fragment of logic considered or the structure of the temporal graph.

Abstract

Families of DFAs (FDFAs) are a computational model recognizing ω-regular languages. They were introduced in the quest of finding a Myhill-Nerode theorem for ω-regular languages and obtaining learning algorithms. FDFAs have been shown to have good qualities in terms of the resources required for computing Boolean operations on them (complementation, union, and intersection) and answering decision problems (emptiness and equivalence); all can be done in non-deterministic logarithmic space. In this paper we study FDFAs with a new type of acceptance condition, *duo-normalization*, that generalizes the traditional *normalization* acceptance type. We show that duo-normalized FDFAs are advantageous to normalized FDFAs in terms of succinctness as they can be exponentially smaller. Fortunately this added succinctness doesn't come at the cost of increasing the complexity of Boolean operations and decision problems — they can still be preformed in NLOGSPACE.

An important measure of the complexity of an ω-regular language is its position in the Wagner hierarchy (aka the Rabin Index). It is based on the inclusion measure of Muller automata, and for the common ω-automata there exist algorithms computing their position. We develop a similarly robust measure for duo-normalized (and normalized) FDFAs, which we term the *diameter measure*. We show that the diameter measure corresponds one-to-one to the position in the Wagner hierarchy. We show that computing it for duo-normalized FDFAs is PSPACE-complete, while it can be done in NLOGSPACE for traditional FDFAs.

1 Introduction

Regular languages of finite words possess a natural canonical representation — the unique minimal DFA. The essence of the representation lies in a right congruence relation for a language L saying that two words x and y are *equivalent*, denoted $x \sim_L y$, if and only if $xz \in L \iff yz \in L$ for every finite word $z \in \Sigma^*$. The famous Myhill-Nerode theorem [20, 21] relates the equivalence classes of $\sim_L$ to the set of words reaching a state of the minimal DFA.

For regular languages of infinite words the situation is more complex. First, there is no unique minimal automaton for any of the common ω-automata acceptance conditions (Büchi, Muller, Rabin, Streett and parity). Second, one can indeed define two finite words x and y to be *equivalent* with respect to an ω-regular language L, denoted $x \sim_L y$, if $xz \in L \iff yz \in L$

for every infinite word $z \in \Sigma^\omega$. However, there is no one-to-one correspondence between these equivalence classes and a minimal ω-automaton for L. Consider for instance the language L_1 stipulating that aab occurs infinitely often. The right congruence relation $\sim_{L_1}$ has only one equivalence class, yet clearly an automaton for L_1 needs more than one state.

A quest for a characterization of an ω-regular language L, relating equivalence classes of a semantic definition of L to states of an automaton for L, has led to the development of families of right concurrences (FORCs) [19] and families of DFAs (FDFAs) [14, 2]. Several canonical FDFAs were introduced over the years, the periodic FDFA [7], the syntactic FDFA [19], the recurrent FDFA [2], and the limit FDFA [17]. All these representations have a one-to-one correspondence between the equivalence classes of semantic right congruence relations and the states of the respective automata. This is very satisfying in the sense that they induce a semantic canonical representation, ie one that is agnostic to a particular automaton; and this is a beneficial property when it comes to learning [2, 18]. FDFAs have additional good qualities — computing Boolean operations on them (complementation, union, and intersection) and answering decision problems (emptiness and equivalence) can all be done cheaply, in non-deterministic logarithmic space [1].

Loosely speaking, an FDFA is composed of a *leading automaton* $\mathcal{Q}$ and a family of *progress DFAs* $\{\mathcal{P}_q\}$, one for each state q of $\mathcal{Q}$. FDFAs consider only ultimately periodic words, ie words of the form $u(v)^\omega$ for $u \in \Sigma^*$ and $v \in \Sigma^+$. Since two ω-regular languages recognize the same language if and only if they agree on the set of ultimately periodic words [6, 7], this is not really a limitation. Exact acceptance of an ultimately periodic word (u, v) representing uv^ω is determined by checking acceptance of v in the progress DFA corresponding to the state reached in the leading automaton by reading u. Normalized acceptance is done by first *normalizing* the word wrt the leading automaton — this means considering a decomposition (uv^i, v^j) of uv^ω such that v^j loops on the state of the leading automaton reached by reading uv^i. This normalization was introduced as it leads to an exponential save in the number of states [2]. In this paper we consider a new acceptance condition for FDFAs, which we term *duo-normalization*, which considers decompositions (uv^i, v^j) where in addition v^j closes a loop on the state it arrives at in the respective progress DFA. We term FDFAs with this new type of acceptance *duo-normalized* FDFAs. The notion of duo-normalization has appeared in the literature before [27, 9, 1, 5] and was suggested as an acceptance condition for FDFAs in the future work of [5].

We show that duo-normalized FDFAs also enjoy the good qualities of computing Boolean operations and answering decision problems in non-deterministic logarithmic space. In terms of succinctness we show that they can be exponentially smaller than normalized FDFAs.

We are also interested in the problem of finding their position in the *Wagner hierarchy*, a hierarchy reflecting the complexity of ω-regular properties, that often correlates to the complexity of algorithms on ω-regular languages and games [29, 13, 3]. It is noted in [10, Sec. 5] that while for ω-automata there are algorithms for computing their position in the Wagner hierarchy, there is no clear way to relate the structure of a particular FDFA to its Wagner position.

In [26] Wagner defined a complexity measure on Muller automata: the *inclusion measure*. Wagner showed that the inclusion measure is robust in the sense that any two Muller automata for the same language (minimal or not) have the same inclusion measure. This is thus a semantic property of the language. Since the inclusion measure is unbounded it induces an infinite hierarchy. The position on the Wagner hierarchy has been shown to be tightly related to the minimal number of colors required in a parity automaton, and the minimal number of pairs required in a Rabin/Street automaton. Deterministic Büchi and coBüchi (which are less expressive than deterministic Muller/Rabin/Streett/parity automata, that are capable of recognizing all the ω-regular languages) lie in the bottom levels of the hierarchy. Given a deterministic ω-automaton (Büchi, coBüch, Muller, Rabin, Streett, or parity), its position in the Wagner hierarchy can be computed in polynomial time [28, 8, 22].

We develop a syntactic notion of a measure on FDFAs, that we term *the diameter measure*. Loosely speaking it relates to chains of prefixes $v_1 \prec v_2 \prec \ldots \prec v_k$ such that $u(v_i)^\omega \in L$ iff $u(v_{i+1})^\omega \notin L$, and moreover, each of the words v_i is *persistent* in the progress DFA of some $u \in \Sigma^*$. The precise definition of the term *persistent* and *persistent chains* is deferred to § 4. We show there that this measure is robust in the sense that computing it on two FDFAs for the same language will give the same result. The proof is by relating it to the position on the Wagner hierarchy. We show that computing the Wagner position of a duo-normalized FDFA can be done in PSPACE and it is PSPACE-complete, whereas for normalized FDFAs this computation can be done in NLOGSPACE. So this is one place where the added succinctness of duo-normalized FDFAs comes at a price.

The rest of the paper is organized as follows. We give some basic definitions and explain the Wagner hierarchy in § 2. We introduce duo-normalized FDFAs in § 3 where we show that it is not more expensive to compute the Boolean operations on them, or to answer emptiness and equivalence about them. § 4 is devoted to defining the *diameter measure* and proving that its computation is PSPACE-complete. § 5 provides several succinctness results relating duo-normalized FDFAs and normalized FDFAs, including results regarding succinctness of previously studied canonical FDFAs and the *Colorful FDFA*, a canonical duo-normalized FDFA. We conclude with a short discussion in § 6. Due to space limitations, proofs are deferred to the appendix of the full version [12].

2 Preliminaries

We use $[i..j]$ for the set $\{i, i+1, \ldots, j\}$. A (complete deterministic) *automaton structure* is a tuple $\mathcal{A} = (\Sigma, Q, q_0, \delta)$ consisting of an alphabet Σ, a finite set Q of states, an initial state q_0, and a complete transition function $\delta : Q \times \Sigma \to Q$. A run of an automaton on a finite word $v = a_1 a_2 \cdots a_n$ is a sequence of states $q_0, q_1, \ldots, q_n$, starting with the initial state, such that for each $i \geq 0$, $q_{i+1} = \delta(q_i, a_i)$. A run on an infinite word is defined similarly and results in an infinite sequence of states. Let $\mathcal{A} = (\Sigma, Q, q_0, \delta)$ be an automaton structure. We say that a word $w \in \Sigma^*$ reaches state q if the run of $\mathcal{A}$ on w ends in q, and use $\mathcal{A}(w)$ to denote q.

By augmenting an automaton structure with an acceptance condition α, obtaining a tuple $(\Sigma, Q, q_0, \delta, \alpha)$, we get an *automaton*, a machine that accepts some words and rejects others. An automaton accepts a word if the run on that word is accepting. For finite words the acceptance condition is a set $F \subseteq Q$ and a run on a word v is accepting if it ends in an accepting state, ie a state $q \in F$. For infinite words, there are various acceptance conditions in the literature. The common ones are Büchi, coBüchi, Muller, Rabin, Streett and parity. They are all defined with respect to the set of states visited infinitely often during a run. For a run $\rho = q_0 q_1 q_2 \ldots$ we define $\mathit{inf}(\rho) = \{q \in Q \mid \forall i \in \mathbb{N}.\ \exists j > i.\ q_j = q\}$. We focus here on the most common types — Büchi, coBüchi, Muller and parity.

- A *Büchi* (resp. *coBüchi*) acceptance condition is a set $F \subseteq Q$. A run of a Büchi (resp. coBüchi) automaton is accepting if it visits F infinitely (resp. finitely) often. That is, if $\mathit{inf}(\rho) \cap F \neq \emptyset$ (resp. $\mathit{inf}(\rho) \cap F = \emptyset$).
- A *parity* acceptance condition is a mapping $\kappa : Q \to \{0, 1, \ldots, k\}$ of a state to a number (referred to as a *color*). For a subset $Q' \subseteq Q$, we use $\kappa(Q')$ for the set $\{\kappa(q) \mid q \in Q'\}$. A run ρ of a parity automaton is accepting if the **minimal** color in $\kappa(\mathit{inf}(\rho))$ is **even**.

- A *Muller* acceptance condition is a set $\alpha = \{F_1, \dots, F_k\}$ where $F_i \subseteq Q$ for all $1 \leq i \leq k$. A run ρ of a Muller automaton is accepting if $\mathit{inf}(\rho) \in \alpha$. That is, if the set of states visited infinitely often by the run ρ is exactly one of the sets F_i specified in α.

We use DBA, DCA, DPA, and DMA as acronyms for deterministic (complete) Büchi, coBüchi, parity, and Muller automata, respectively. We use $[\![\mathcal{A}]\!]$ to denote the set of words accepted by a given automaton $\mathcal{A}$. Two automata $\mathcal{A}$ and $\mathcal{B}$ are *equivalent* if $[\![\mathcal{A}]\!]$=$[\![\mathcal{B}]\!]$. Let $\mathcal{A} = (\Sigma, Q, q_0, \delta, F)$ be a DFA and $q \in Q$. We use $\mathcal{A}_{[q}$ for $(\Sigma, Q, q, \delta, F)$, namely a DFA for the words exiting state q of $\mathcal{A}$.

The *syntactic right congruence relation* for an ω-language L relates two finite words x and y if there is no infinite suffix z differentiating them, that is, for $x, y \in \Sigma^*$, $x \sim_L y$ if $\forall z \in \Sigma^\omega (xz \in L \iff yz \in L)$. We use $[u]_{\sim_L}$ (or simply $[u]$) for the equivalence class of u induced by $\sim_L$. A right congruence $\sim$ can be naturally associated with an automaton structure (Σ, Q, q_0, δ) as follows: the set of states Q are the equivalence classes of $\sim$. The initial state q_0 is the equivalence class $[\epsilon]$. The transition function δ is defined by $\delta([u], \sigma) = [u\sigma]$. We use $\mathcal{A}[\sim]$ to denote the automaton structure induced by $\sim$.

2.1 The Wagner Hierarchy

Let $\mathcal{M} = (\Sigma, Q, q_0, \delta, \alpha)$ be a complete deterministic Muller automaton, where all states are reachable. We use the term *strongly connected component (SCC)* for a set of states $S \subseteq Q$ such that there is a non-empty path between every pair of states in S. Thus, if S is a singleton $\{q\}$ we require a self-loop on q for S to be an SCC. We use the term *MSCC* for a *maximal SCC*, that is, an SCC S such that no set $S' \supset S$ is an SCC. We say that an SCC $S \subseteq Q$ is *accepting* iff $S \in \alpha$. Otherwise we say that S is *rejecting.* We define the *positive inclusion measure* of $\mathcal{M}$, denoted $|\mathcal{M}|^+_\subset$, to be the maximal length of an inclusion chain $S_1 \subset S_2 \subset S_3 \subset \cdots \subset S_k$ of SCCs with alternating acceptance where S_1 is accepting. (Therefore for each $1 \leq i \leq k$ if i is odd then S_i is accepting, and if it is even then S_i is rejecting.) Likewise, we define the *negative inclusion measure* of $\mathcal{M}$, denoted $|\mathcal{M}|^-_\subset$, to be the maximal length of an inclusion chain where the first SCC is rejecting. Note that for any $\mathcal{M}$ the difference between $|\mathcal{M}|^+_\subset$ and $|\mathcal{M}|^-_\subset$ may be at most one, since by omitting the first element of a chain we remain with a chain shorter by one, and of the opposite sign. We use $L_{\infty aa \wedge \neg \infty bb}$ in Ex. 2.2 to illustrate the concepts explained throughout this section.

Wagner [26] showed that this measure is robust in the sense that any two DMAs that recognize the same language have the same positive and negative inclusion measures.

▶ **Theorem 2.1** (Robustness of the inclusion measures [26]). *Let $\mathcal{M}_1$, $\mathcal{M}_2$ be two DMAs where $[\![\mathcal{M}_1]\!] = [\![\mathcal{M}_2]\!]$. For $i \in \{1, 2\}$, let $|\mathcal{M}_i|^+_\subset = p_i$ and $|\mathcal{M}_i|^-_\subset = n_i$. Then $p_1 = p_2$ and $n_1 = n_2$.*

Since this measure is robust and since one can construct DMAs with arbitrarily long inclusion chains, the inclusion measure yields an infinite hierarchy of ω-regular languages. Formally, the classes of the Wagner hierarchy are defined as follows for a positive integer k:

$$\begin{aligned}
\mathbb{DM}^+_k &= \{L \mid \exists \text{ DMA } \mathcal{M} \text{ s.t. } [\![\mathcal{M}]\!] = L \text{ and } |\mathcal{M}|^+_\subset \leq k \text{ and } |\mathcal{M}|^-_\subset < k\} \\
\mathbb{DM}^-_k &= \{L \mid \exists \text{ DMA } \mathcal{M} \text{ s.t. } [\![\mathcal{M}]\!] = L \text{ and } |\mathcal{M}|^+_\subset < k \text{ and } |\mathcal{M}|^-_\subset \leq k\} \\
\mathbb{DM}^\pm_k &= \{L \mid \exists \text{ DMA } \mathcal{M} \text{ s.t. } [\![\mathcal{M}]\!] = L \text{ and } |\mathcal{M}|^+_\subset \leq k \text{ and } |\mathcal{M}|^-_\subset \leq k\}
\end{aligned}$$

The hierarchy is depicted in Fig. 3.1 (left). Note that if $\mathcal{A}$ is an ω-automaton, for any of the ω-automata types, then it can be recognized by a Muller automaton on the same structure. Transforming a Büchi $\mathcal{B}$ automaton with accepting states F to a Muller automaton $\mathcal{M}_\mathcal{B}$ yields an acceptance condition $\alpha_\mathcal{B} = \{F' \mid F' \cap F \neq \emptyset\}$. Note that for any $F' \in \alpha_\mathcal{B}$ and $F'' \supseteq F'$ it holds that $F'' \in \alpha_\mathcal{B}$. Therefore $|\mathcal{M}_\mathcal{B}|^+_\subset = 1$ and $|\mathcal{M}_\mathcal{B}|^-_\subset = 2$ (unless $[\![\mathcal{B}]\!] = \Sigma^\omega$ or

$[\![\mathcal{B}]\!] = \emptyset$). Hence all languages recognized by a DBA are in $\mathbb{DM}_2^-$. Dually, one can see that all languages recognized by a DCA are in $\mathbb{DM}_2^+$. It can be shown that a parity automaton for a language in $\mathbb{DM}_k^-$ can suffice with colors $\{1,\dots,k\}$ if k is odd and $\{0,\dots,k-1\}$ if it is even [22]. Likewise, a DPA for a language in $\mathbb{DM}_k^+$ can suffice with colors $\{0,\dots,k-1\}$ if k is odd and with $\{1,\dots,k\}$ otherwise. A DPA in $\mathbb{DM}_k^\pm$ requires $k+1$ colors starting with 0.

▶ **Example 2.2.** Fig. 3.1 (middle) shows a Muller automaton $\mathcal{M}$ for the language $L_{\infty aa \wedge \neg \infty bb}$. The inclusion chain $\{q_1,q_2\} \subset \{q_1,q_2,q_3\} \subset \{q_1,q_2,q_3,q_4\}$ is a negative inclusion chain of length 3 (since $\{q_1,q_2\}$ is rejecting, $\{q_1,q_2,q_3\}$ is accepting, and $\{q_1,q_2,q_3,q_4\}$ is rejecting). There are no negative inclusion chains of length 4, and there are no positive inclusion chains of length 3. (Note that $\{q_3\} \subset \{q_2,q_3\} \subset \{q_1,q_2,q_3\}$ is not an inclusion chain since $\{q_2,q_3\}$ is not an SCC.) We can thus conclude that $L_{\infty aa \wedge \neg \infty bb} \in \mathbb{DM}_3^-$. Consider the parity automaton $\mathcal{P}$ for $L_{\infty aa \wedge \neg \infty bb}$ defined on the same structure as $\mathcal{M}$. It uses the three colors $\{1,2,3\}$ in accordance with our conclusion that $L_{\infty aa \wedge \neg \infty bb} \in \mathbb{DM}_3^-$.

3 FDFAs with duo-normalized acceptance condition

As already mentioned, none of the common ω-automata has a unique minimal automaton, and the number of states in the minimal automaton may be bigger than the number of equivalence classes in $\sim_L$. For example, $L_2 = (\Sigma^* abc)^\omega$ has one equivalence class under $\sim_{L_2}$, since for any finite word x, an infinite extension xw for $w \in \Sigma^\omega$ is in the language iff $w \in L_2$.

The quest for finding a correspondence between equivalence classes of the language and an automaton model led to the development of *Families of Right Congruences* (FORCs) [19] and *Families of DFAs* (FDFAs) [2]. These definitions consider only ultimately periodic words (ie words of the form uv^ω) building on the well-known result that two ω-regular languages are equivalent if and only if they agree on the set of ultimately periodic words [6, 7]. We also consider only such words, and represent them as pairs (u,v) for $u \in \Sigma^*$ and $v \in \Sigma^+$.

Several canonical FDFAs were introduced over the years, the periodic FDFA [7], the syntactic FDFA [19], the recurrent FDFA [2], and the limit FDFA [17]. We do not go into the details of their definition but summarize the succinctness relations among them. It was shown in [2] that the syntactic and recurrent FDFAs can be exponentially more succinct than the periodic FDFA, while the translations in the other direction are at most polynomial. Further, the recurrent FDFA is never bigger, and can be quadratically more succinct, than the syntactic FDFA [2]. Limit FDFAs are the duals of recurrent FDFAs and similarly can also be at most quadratically bigger than the syntactic; and there are examples of quadratic blowups in the transformation from the recurrent to the limit and vice versa [17].

The gain in succinctness in going from the syntactic to the recurrent (or limit) FDFAs originates from removing the requirement that $x \approx^u y$ implies that $ux \sim uy$, which comes from the definition of a FORC.[1] The gain in succinctness of the syntactic/recurrent/limit FDFAs compared to the periodic FDFA is due to the use of a different type of acceptance condition.

An FDFA is a pair $\mathcal{F} = (\mathcal{Q}, \{\mathcal{P}_q\}_{q\in Q})$ consisting of a *leading* automaton structure $\mathcal{Q}$ and of a *progress* DFA $\mathcal{P}_q$ for each state q of $\mathcal{Q}$. There are a few ways to define acceptance on FDFAs. They differ on what decompositions (u,v) of an infinite word w are considered. We

[1] A FORC is a pair $\mathcal{F} = (\sim, \{\approx^u\})$ where $\sim$ is a right congruence, $\approx^u$ is a right congruence for every equivalence class u of $\sim$, and it satisfies that $x \approx^u y$ implies $ux \sim uy$. An ω-language L is recognized by $\mathcal{F}$ if it can be written as a union of sets of the form $[u]([v]_u)^\omega$ s.t. $uv \sim_L u$. Every FORC corresponds to an FDFA, but the other direction many not hold. This is since there is no requirement on the relation between the progress DFAs and the leading automaton in an FDFA, while there is in a FORC.

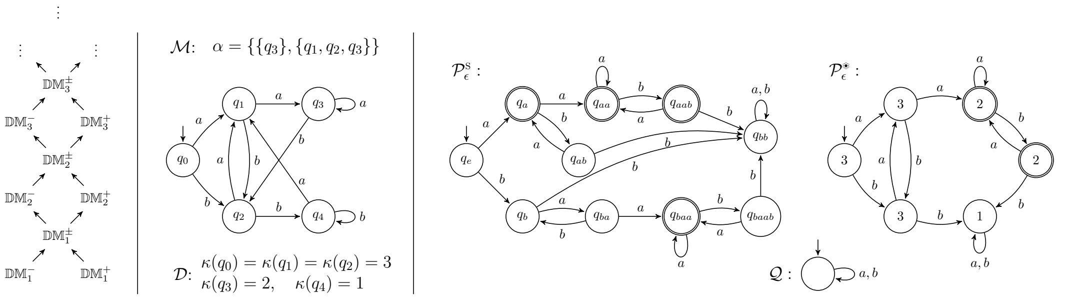

Figure 3.1 Left: The Wagner hierarchy. **Middle:** A DMA $\mathcal{M}$ and a DPA $\mathcal{D}$ for the language $L_{\infty aa \wedge \neg \infty bb}$. **Right:** Two FDFAs $\mathcal{F}^{\mathrm{S}} = (\mathcal{Q}, \{\mathcal{P}_\epsilon^{\mathrm{S}}\})$ and $\mathcal{F}^{\circledast} = (\mathcal{Q}, \{\mathcal{P}_\epsilon^{\circledast}\})$ for the language $L_{\infty aa \wedge \neg \infty bb}$ where $\mathcal{Q}$ is a one-state leading automaton. $\mathcal{F}^{\mathrm{S}}$ uses normalized acceptance, $\mathcal{F}^{\circledast}$ uses duo-normalized acceptance.

provide a definition for such decompositions in Def. 3.1. Once an α-decomposition is defined, an ω-word w is accepted by an FDFA using α-acceptance if there exists an α-decomposition (u, v) of w which is accepted. That is, the word v is accepted by $\mathcal{P}_{\mathcal{Q}(u)}$ where $\mathcal{P}_{\mathcal{Q}(u)}$ is the progress DFA corresponding to the state $\mathcal{Q}(u)$ reached by the leading automaton after reading u. We henceforth use $\mathcal{P}_u$ for $\mathcal{P}_{\mathcal{Q}(u)}$.

In exact acceptance, that is used in the periodic FDFA, any decomposition of the ω-word into an ultimately periodic word is considered. In normalized acceptance, used by the other three canonical FDFAs, only decompositions (u, v) in which the periodic part v loops in the leading automaton (ie $\mathcal{Q}(u) = \mathcal{Q}(uv)$) are considered.

As shown in [2] this acceptance condition, termed *normalization*, can yield an exponential save in the number of states. The intuition is that some periods are easier to verify as good periods if one considers some repetitions of them. For instance, in the language $(121 + 212)^\omega$ it is harder to figure out that $(\epsilon, 12)$ should be accepted than it is for $(\epsilon, 121{\cdot}212)$ though both represent the same ω-word.

For similar reasons, one may wonder if considering only decompositions that also close a loop in the progress automaton might lead to an exponential save as well. In the following we define FDFAs with such an acceptance condition, which we term *duo-normalization*. The notion of duo-normalization has appeared in the literature before. In particular, it resembles the notion of a linked-pair in ω-semigroups and Wilke-algebras [27, 9], it is used in [1, Proof of Thm. 5.8] and it is termed *idempotent* in [5].

▶ **Definition 3.1** (ω-words decomposition wrt an FDFA). *Let $u \in \Sigma^*$, $v \in \Sigma^+$ and $w \in \Sigma^\omega$. Let $\mathcal{F} = (\mathcal{Q}, \{\mathcal{P}_q\}_{q \in Q})$ be an FDFA.*

- *(u, v) is a decomposition of w if $uv^\omega = w$.*
- *A decomposition (u, v) is* normalized *if $\mathcal{Q}(u) = \mathcal{Q}(uv)$.*
- *A normalized decomposition is* duo-normalized *if $\mathcal{P}_u(v) = \mathcal{P}_u(vv)$.*

▶ **Definition 3.2** (Exact, Normalized, and Duo-Normalized acceptance). *Let $\mathcal{F} = (\mathcal{Q}, \{\mathcal{P}_q\}_{q \in Q})$ be an FDFA, $u \in \Sigma^*$, $v \in \Sigma^+$. We define three types of acceptance conditions: We say that $(u, v) \in [\![\mathcal{F}]\!]$ using* exact acceptance *if $v \in [\![\mathcal{P}_u]\!]$. We say that $(u, v) \in [\![\mathcal{F}]\!]$ using* normalized *(resp. duo-normalized) acceptance if there exists a normalized (resp. duo-normalized) decomposition (x, y) of uv^ω such that $y \in [\![\mathcal{P}_x]\!]$.*

An FDFA $\mathcal{F}$ is said to be α-*saturated* if for every ultimately periodic word w, all its α-decompositions agree on membership in $\mathcal{F}$. Assuming saturation, and an efficient α-normalization process (as suggested by Claim 3.3) we can alternatively define α-acceptance as in [2] using the efficient procedure that given any (u, v) returns a particular (x, y) that is α-normalized and satisfies $uv^\omega = xy^\omega$. Henceforth, all FDFAs are presumed to be saturated.

▷ Claim 3.3. Let $x \in \Sigma^*$ and $y \in \Sigma^+$. The word xy^ω has an α-decomposition of the form (xy^i, y^j) for i and j quadratic in the size of $\mathcal{F}$ for all $\alpha \in \{\text{exact, normalized, duo-normalized}\}$.

Clearly, if $\mathcal{F}$ is saturated using exact acceptance and it recognizes L then it is also saturated and recognizes L when using normalized acceptance instead. The same is true when going from normalized acceptance to duo-normalized acceptance.

▶ **Corollary 3.4.** *Duo-normalized FDFAs recognize all ω-regular languages.*

▶ **Example 3.5.** Fig. 4.1 (left) shows two FDFAs. The FDFA $\mathcal{F}_1 = (\mathcal{Q}, \{\mathcal{P}_\epsilon, \mathcal{P}_b\})$ has a leading automaton with two states $[\epsilon]$ and $[b]$, and the corresponding progress automata are $\mathcal{P}_\epsilon$ and $\mathcal{P}_b$. Consider the ultimately periodic word a^ω; since (ϵ, a) is a normalized decomposition of a^ω and $a \in [\![\mathcal{P}_\epsilon]\!]$, the word a^ω is accepted by $\mathcal{F}_1$ using normalized acceptance. The FDFA $\mathcal{F}_2 = (\mathcal{Q}, \{\mathcal{P}'_\epsilon, \mathcal{P}_b\})$ uses duo-normalization and $\mathcal{P}'_\epsilon$ as the progress DFA for $[\epsilon]$. The pair (ϵ, aa) is a duo-normalized decomposition of a^ω wrt $\mathcal{F}_2$ and it holds that $a \in [\![\mathcal{P}'_\epsilon]\!]$ thus the word a^ω is accepted by $\mathcal{F}_2$. Observe that the normalized (rather than duo-normalized) decomposition (ϵ, a) is not accepted by $\mathcal{P}'_\epsilon$. In this example the FDFA using duo-normalization has more states. Later on we provide an example where an FDFA using duo-normalization has fewer states, and even exponentially fewer.

▶ **Theorem 3.6.** *The following holds for saturated FDFAs using duo-normalized acceptance: complementation can be computed in constant space; intersection, union and membership can be computed in logarithmic space; emptiness, universality, containment and equivalence can be computed in non-deterministic logarithmic space.*

From now on, unless stated otherwise, we work with duo-normalization. That is, when we say $(u, v) \in [\![\mathcal{F}]\!]$ or $w \in [\![\mathcal{F}]\!]$ we mean according to duo-normalized acceptance condition.

As we later show duo-normalized FDFAs can be exponentially more succinct than all previously defined FDFAs. This is essentially because it considers fewer or more specific decompositions. One might wonder if considering even more specific decompositions will lead to more succinct FDFAs, and can this still be done in the same complexity as for normalized and duo-normalized FDFAs. We come back to this point in the next section, see Prop. 4.3.

4 The Diameter Measure — A Robust Measure on FDFAs

In the following section we define a measure on FDFAs that is tightly related to the inclusion measure of the Wagner hierarchy. The defined measure is robust among FDFAs in the same way that the inclusion measure is robust among DMAs. That is, every pair of FDFAs $\mathcal{F}_1$ and $\mathcal{F}_2$ recognizing the same language agree on this measure.

To devise this measure we would like to understand what the inclusion measure entails on an FDFA for the language. If a DMA has an inclusion chain $S_1 \subset S_2 \subset S_3$ then there is a state q_u in S_1 reachable by some word u from which there are words v_1, v_2, v_3 looping on q_u while traversing the states of S_1, S_2 and S_3, respectively (all and only these states). We term this state a *pivot* state. Assume S_1 is rejecting, then $u(v_1)^\omega \notin L$, $u(v_2)^\omega \in L$ and

$u(v_3)^\omega \notin L$. Since they all loop back to q_u, we have that $u(v_1v_2)^\omega$ also loops in S_2 and is thus accepted and $u(v_1v_2v_3)^\omega$ also loops in S_3 and is thus rejected. Since $v_1 \prec v_1v_2 \prec v_1v_2v_3$ (where $\prec$ denotes the prefix relation) tracing the run on $v_1v_2v_3$ in a progress DFA for u we expect the state reached after v_1 to be rejecting, the one after v_1v_2 to be accepting and the one after $v_1v_2v_3$ to be rejecting. To be precise, we should expect this only if the words v_1, v_1v_2 and $v_1v_2v_3$ are α-normalized, where α is the normalization used by the FDFA.

Let's inspect this on our running example $L_{\infty aa\wedge\neg\infty bb}$ with the DMA in Fig. 3.1 (middle) and the inclusion chain $S_1 = \{q_1, q_2\}$, $S_2 = \{q_1, q_2, q_3\}$, and $S_3 = \{q_1, q_2, q_3, q_4\}$. We can choose q_1 for the pivot state q_u of S_1 and the words $v_1 = ba$, $v_2 = aba$ and $v_3 = abba$, that loop respectively in S_1, S_2 and S_3. Fig. 3.1 (right) provides two FDFAs for this language. The FDFA $\mathcal{F}^{\text{s}}$ uses normalization and $\mathcal{F}^{\circledast}$ uses duo-normalization. Looking at $\mathcal{P}^{\text{s}}_\epsilon$, we see that v_1, v_1v_2 and $v_1v_2v_3$ are normalized and the states reached after reading them (q_{ba}, q_{baa}, q_{bb}) are rejecting or accepting as expected. The same is true for $\mathcal{P}^{\circledast}_\epsilon$.

Should we entail from this discussion and example that the maximal number of alternations between rejecting and accepting states along any path in an FDFA for a language in $\mathbb{DM}^-_k$ is at most $k-1$? This is true in the progress DFA $\mathcal{P}^{\circledast}_\epsilon$, but the progress DFA $\mathcal{P}^{\text{s}}_\epsilon$ clearly refutes it, since it has strongly connected accepting and rejecting states (eg, q_a and q_{ab}) and so we can create paths with an unbounded number of alternations between them.

Take such a path with say $k+1$ prefixes $z_1 \prec z_2 \prec \ldots \prec z_{k+1}$ alternating between accepting and rejecting states. Are the words z_i normalized? They can be. Take for instance $z_1 = a$, $z_2 = ab$, and so on ($z_{k+1} = z_k \cdot b$ if k is even and $z_{k+1} = z_k \cdot a$ otherwise).

Can they all be duo-normalized? They can be as we show in Fig. 4.1 (right). It shows a progress DFA $\mathcal{P}_\epsilon$ for an FDFA using duo-normalization and a one-state leading automaton. The FDFA recognizes the language ∞aa. The words $a \prec ab \prec abaa$ are all duo-normalized and reach alternating accepting/rejecting states though the language is in $\mathbb{DM}^-_2$. To fix this issue we introduce the notion of a *persistent decomposition.*

▶ **Definition 4.1** (persistent decomposition wrt an FDFA). *Let $u \in \Sigma^*$, $v \in \Sigma^+$. Let $\mathcal{F} = (\mathcal{Q}, \{\mathcal{P}_q\}_{q\in Q})$ be an FDFA. A duo-normalized decomposition (u, v) is* persistent *if for every $z \in \Sigma^*$ there exists $i > 1$ such that $\mathcal{P}_u(zv) = \mathcal{P}_u(zv^i)$.*

As in Claim 3.3 there exist i and j quadratic in the size of $\mathcal{F}$ such that (uv^i, v^j) is persistent.

▷ Claim 4.2. For every $x\in\Sigma^*$ and $y\in\Sigma^+$ the word xy^ω has a persistent decomposition of the form (xy^i, y^j) where i and j are of size quadratic in $\mathcal{F}$.

One might try to define an additional acceptance condition using the persistent decomposition as was done above, but as stated by the following claim this is futile.

▶ **Proposition 4.3.** *Every FDFA defined with persistent acceptance recognizes the same language when defined with duo-normalized acceptance instead.*

Back to the issue of finding the position on the Wanger hierarchy, we can look for chains of prefixes with alternating acceptance such that each prefix in the chain is persistent.

▶ **Definition 4.4** (Persistent Chain). *Let $\mathcal{F}$ be an FDFA and $u \in \Sigma^*$. We say that $v_1 \prec v_2 \prec \ldots \prec v_k$ for $v_i \in \Sigma^*$ is a u-*persistent chain *of length k wrt $\mathcal{F}$ if (u, v_i) is persistent for every $1 \leq i \leq k$ and $(u, v_{i+1}) \in [\![\mathcal{F}]\!]$ iff $(u, v_i) \notin [\![\mathcal{F}]\!]$ for every $1 \leq i < k$. We say the chain is* positive *(resp.* negative*) if $(u, v_1) \in [\![\mathcal{F}]\!]$ (resp. $(u, v_1) \notin [\![\mathcal{F}]\!]$). We use simply* persistent chain *when u is clear from the context.*

We can now state the measure on FDFAs that relates them to the Wagner hierarchy.

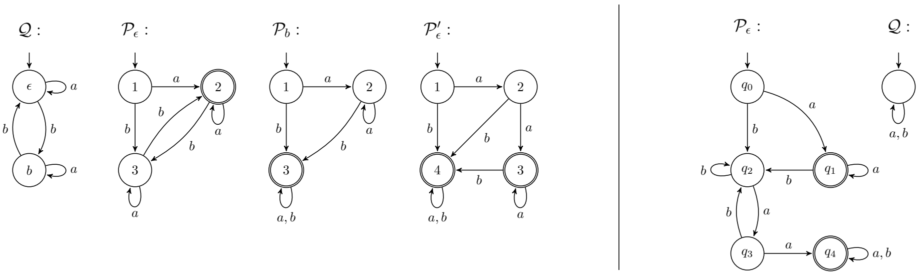

Figure 4.1 Left: Two FDFAs $\mathcal{F}_1 = (\mathcal{Q}, \{\mathcal{P}_\epsilon, \mathcal{P}_b\})$ and $\mathcal{F}_2 = (\mathcal{Q}, \{\mathcal{P}'_\epsilon, \mathcal{P}_b\})$ for the language $(\Sigma^* b)^\omega \cup (bb)^* a^\omega$ using normalized and duo-normalized acceptances, respectively. **Right:** The progress DFA $\mathcal{P}_\epsilon$ for an FDFA accepting ∞aa that uses duo-normalization and a one-state leading automaton.

▶ **Definition 4.5** (The Diameter Measure). *Let $\mathcal{F}$ be an FDFA and $u \in \Sigma^*$. We define the* positive *(resp.* negative*)* diameter measure *of the progress DFA $\mathcal{P}_u$, denoted $|\mathcal{P}_u|^+_\rightsquigarrow$ (resp. $|\mathcal{P}_u|^-_\rightsquigarrow$), as the maximal k for which there exists a* positive *(resp. negative) persistent chain of length k in $\mathcal{P}_u$. We define $|\mathcal{F}|^+_\rightsquigarrow$ as* $\max\{|\mathcal{P}_q|^+_\rightsquigarrow : q \in Q\}$ *and $|\mathcal{F}|^-_\rightsquigarrow$ as* $\max\{|\mathcal{P}_q|^-_\rightsquigarrow : q \in Q\}$.

We show that the diameter measure is robust among all FDFAs for the language by relating it to the Wagner hierarchy as formally stated below.

▶ **Theorem 4.6** (Correlation to Wagner's hierarchy). *Let $\mathcal{F}$ be an FDFA using any of the acceptance types $\alpha \in \{$exact, normalized, duo-normalized$\}$.*

- $[\![\mathcal{F}]\!] \in \mathbb{DM}^\pm_k$ *iff* $|\mathcal{F}|^+_\rightsquigarrow \leq k$ *and* $|\mathcal{F}|^-_\rightsquigarrow \leq k$
- $[\![\mathcal{F}]\!] \in \mathbb{DM}^+_k$ *iff* $|\mathcal{F}|^+_\rightsquigarrow \leq k$ *and* $|\mathcal{F}|^-_\rightsquigarrow < k$
- $[\![\mathcal{F}]\!] \in \mathbb{DM}^-_k$ *iff* $|\mathcal{F}|^-_\rightsquigarrow < k$ *and* $|\mathcal{F}|^-_\rightsquigarrow \leq k$

In the proof of Thm. 4.6, given a persistent chain $v_1 \prec v_2 \prec \ldots \prec v_k$ in $\mathcal{P}_u$ in some FDFA, we would like to find an inclusion chain of length k in some DMA recognizing the same language. The SCCs visited infinitely often by the words $u(v_1)^\omega, \ldots, u(v_k)^\omega$ might not correspond to an inclusion chain in the DMA. Roughly speaking, to obtain a persistent chain for which this does hold, we make sure every element of the chain has already reached its final SCC and traversed it. Using the following lemma we can create such a persistent chain.

▶ **Lemma 4.7** (Pumping Persistent Periods). *Let $\mathcal{A}$ be an automaton and let $v \in \Sigma^+$ be $\mathcal{A}$-persistent.*[2] *For every $n \in \mathbb{N}$ there exists $l \geq n$ such that for every extension $z \in \Sigma^*$, if vz is $\mathcal{A}$-persistent then $v^l z$ is also $\mathcal{A}$-persistent.*

Following [10] a word $v \in \Sigma^*$ is said to be a *suffix-invariant* of $u \in \Sigma^*$ (in short *u-invariant*) with respect to L if $u \sim_L uv$. That is, no suffix distinguishes between u and the word obtained by concatenating v to u.

Proof of Thm. 4.6. We prove the claim regarding the positive measure. The claim regarding the negative measure is proven symmetrically. We show that

1. $|L|^+_\subset \geq k$ implies $|\mathcal{F}|^+_\rightsquigarrow \geq k$ and
2. $|\mathcal{F}|^+_\rightsquigarrow \geq k$ implies $|L|^+_\subset \geq k$.

The two claims together entail that $|\mathcal{F}|^+_\rightsquigarrow = |L|^+_\subset$.

[2] We say that v is $\mathcal{A}$-persistent if $\mathcal{A}(v) = \mathcal{A}(vv)$ and for every $z \in \Sigma^*$ there exists an $i > 1$ such that $\mathcal{A}(zv) = \mathcal{A}(zv^i)$.

1. We start by showing that if $|L|^{+}_{\subset} \geq k$ then $|\mathcal{F}|^{+}_{\rightsquigarrow} \geq k$. Let $\mathcal{M}$ be a DMA for L. From $|L|^{+}_{\subset} \geq k$ we know that there exists an MSCC of $\mathcal{M}$ subsuming SCCs $S_1, S_2, \ldots, S_k$ such that $S_1 \subsetneq S_2 \subsetneq \ldots \subsetneq S_k$ and S_i is an accepting component if and only if i is odd. Pick a state s in S_1. For $1 \leq i \leq k$ let v_i be a word that loops on s while traversing all the states of S_i and no other states. Let u be a word reaching s from the initial state. Consider the progress DFA of u, $\mathcal{P}_u$. By Claim 4.2 there exists l_1 such that $y_1 = (v_1)^{l_1}$ is $\mathcal{P}_u$-persistent. Similarly, there exists l_2 such that $y_2 = (y_1 v_2)^{l_2}$ is $\mathcal{P}_u$-persistent. In the same way we define $y_i = (y_{i-1} v_i)^{l_i}$ for all $i \in [2..k]$. Consider the words $w_i = u(y_i)^{\omega}$ for $i \in [1..k]$. Since the set of states visited infinitely often when reading w_i is exactly S_i, it follows that w_i is in L if and only if i is odd. Since all the infixes y_i loop back to s it follows that all the y_i's are u-invariants and thus the (u, y_i) are persistent in $\mathcal{F}$. Since $y_1 \prec y_2 \prec \ldots \prec y_k$ we have found a positive alternating persistent chain in $\mathcal{P}_u$ of length k. Hence, $|\mathcal{P}_u|^{+}_{\rightsquigarrow} \geq k$, which in turn gives that $|\mathcal{F}|^{+}_{\rightsquigarrow} \geq k$.
2. Next we show that if $|\mathcal{F}|^{+}_{\rightsquigarrow} \geq k$ then $|L|^{+}_{\subset} \geq k$. Let u be such that $|\mathcal{P}_u|^{+}_{\rightsquigarrow} \geq k$. Then there exists a persistent chain $v_1 \prec v_1 v_2 \prec \ldots \prec v_1 v_2 \cdots v_k$ of length k in $\mathcal{P}_u$, starting with an accepting state. For $i \in [1..k]$ let q_i be the state reached after reading $v_1 v_2 \cdots v_i$. Note that q_i is accepting iff i is odd.

   Let $\mathcal{M}$ be a DMA for L and let n be its number of states. Let $l_1 \geq n$ be the number promised by Lemma 4.7 for v_1. Consider $(v_1)^{l_1} v_2$. As v_1 and $v_1 v_2$ are both $\mathcal{P}_u$-persistent, it follows from the lemma that $(v_1)^{l_1} v_2$ is $\mathcal{P}_u$-persistent as well. Since v_1 is $\mathcal{P}_u$-persistent it loops on q_1 and it holds that $(v_1)^{l_1} v_2$ reaches and loops on q_2. Continuing in the same manner, let $y_1 = v_1$ and $y_i = (y_{i-1})^{l_{i-1}} \cdot v_i$ for $i \in [2..k]$ where $l_{i-1} \geq n$ is the number from Lemma 4.7 for y_{i-1}. Then y_i is $\mathcal{P}_u$-persistent, reaching and looping on q_i. Moreover $u(v_1 v_2 \cdots v_i)^{\omega} \in L$ iff $u(y_i)^{\omega} \in L$ iff $x(y_i)^{\omega} \in L$ for any $x \sim_L u$. Let $x_i = u \cdot y_k^n \cdot y_{k-1}^n \cdots y_i^n$ for $i \in [1..k]$. As the v_i's are u-invariant it holds that the x_i's are $\sim_L u$. For $i \in [1..k]$ let $w_i = x_i (y_i)^{\omega}$. Thus, w_i is in L iff i is odd. For every such i, consider the run of $\mathcal{M}$ on w_i, and let $\mathit{inf}(w_i) = S_i$ be the states of the SCC that $\mathcal{M}$ eventually traverses in. Since n bounds the number of states of $\mathcal{M}$ it follows that after reading x_i the automaton already traversed the SCC S_i and reading y_i again, it will stay in S_i. Because $x_{i-1} = x_i \cdot y_{i-1}^n$ and $y_{i-1}^n \prec y_i$ it holds that $S_1 \subseteq S_2 \subseteq \ldots \subseteq S_k$.

   From the acceptance of the words w_i we conclude S_i is accepting iff i is odd. Therefore the inclusions are strict, namely $S_1 \subsetneq S_2 \subsetneq \ldots \subsetneq S_k$. This proves $|L|^{+}_{\subset} \geq k$. ◀

With Thm. 4.6 in place we conclude the robustness of the diameter measure.

▶ **Corollary 4.8.** *Let $\mathcal{F}_1$ and $\mathcal{F}_2$ be two FDFAs recognizing the same language. Then $|\mathcal{F}_1|^{+}_{\rightsquigarrow} = |\mathcal{F}_2|^{+}_{\rightsquigarrow}$ and $|\mathcal{F}_1|^{-}_{\rightsquigarrow} = |\mathcal{F}_2|^{-}_{\rightsquigarrow}$.*

Next we show that given an FDFA we can compute its diameter measure in polynomial space. The proof shows that with each progress DFA $\mathcal{P}_u$ we can associate a DFA $\mathbb{P}_u$, which we term the *persistent DFA*. Broadly speaking, $\mathbb{P}_u$ is the product of the leading automaton and copies of the progress automaton, starting from each of its states. The states of $\mathbb{P}_u$ can be classified into *significant* and *insignificant* where significant states are those that are reached by persistent words and only such words. The classification can easily be done by inspecting the "state vector". The persistent DFA need not be built, instead a persistent chain can be non-deterministically guessed and verified in polynomial space.

▶ **Theorem 4.9.** *The diameter measure of a duo-normalized FDFA can be computed in PSPACE.*

Since normalized and exact FDFAs are also duo-normalized, this upper bound holds for them as well. However, in Prop. 4.12 we show that for normalized (and exact) FDFAs the diameter measure can be computed in NLOGSPACE. For the case of duo-normalized FDFAs, we provide a matching lower bound.

▶ **Theorem 4.10.** *The problem of determining whether the diameter measure of a duo-normalized FDFA is at least k is PSPACE-hard.*

Proof sketch. The proof uses a reduction from non-emptiness of intersection of DFAs, which is known to be PSPACE-hard [15]. Let $D_1, D_2, \ldots, D_k$ be k DFAs over Σ. We construct an FDFA with a one-state leading automaton and a progress DFA $\mathcal{P}$ over $\Sigma' = \Sigma \cup \{1, \ldots, k\} \cup \{\sharp\}$ as depicted in Fig. 5.1 (left), see the full version for a complete description. To see that the FDFA is saturated, we show in the full version that not only every two duo-normalized decompositions (u, v) and (u', v') of the same ultimately periodic word w agree on acceptance, but their periods also traverse the same MSCC in $\mathcal{P}$.

We claim that if there is a word $v \in \Sigma$ in the intersection of all D_i's, then $\sharp v \prec \sharp v1 \prec \sharp v12 \prec \sharp v123 \prec \ldots \prec \sharp v12 \cdots k \prec \sharp v12 \cdots k\sharp\sharp$ is a persistent chain in $\mathcal{P}$ of length $k+2$. Let $y_0 = \sharp v$, $y_i = \sharp v12 \cdots i$ for $i \in [1..k]$, and $y_{k+1} = y_k\sharp\sharp$. Then y_i reaches s_i^i, and reading y_i from s_i^i reaches s_i^i again. Thus y_i is duo-normalized and y_i is accepted iff i is even. To see that y_i is persistent it remains to show that from any state q reading y_i and reading $(y_i)^2$ the automaton reaches the same state q' for some q'. Observe that reading y_i from any state s_j^j for $j \leq i$ will still reach s_i^i. If y_i is read from s_j^j for $i < j \leq k+1$ or any other state (as there are no other outgoing $\sharp$-transitions) it will reach s_{k+1}^{k+1} and stay there forever. Thus y_i is persistent for any i. Hence, $y_0 \prec y_1 \prec y_2 \prec \ldots \prec y_k \prec y_{k+1}$ is a persistent chain in $\mathcal{P}$ of length $k+2$.

For the other direction, we claim that if there exists a persistent chain of length $k+2$ in $\mathcal{P}$, then the intersection of all D_i's is non-empty. Let $w_0 \prec w_2 \prec \ldots \prec w_{k+1}$ be such a chain. First, we note that from the structure of $\mathcal{P}$, since the MSCCs corresponding to the D_i's are of alternating acceptance, it follows that w_0 reaches s_0^0, w_{k+1} reaches s_{k+1}^{k+1} and all other w_i reach some state in the i-th MSCC. Second, if reading w_i reaches a state in the i-th MSCC, then since w_i is duo-normalized, reading w_i for the second time must loop back to the same state. For $i \in [1..k]$ this can only occur if w_i is a rotation of $v_1 12 \cdots i\sharp v_2 12 \cdots i\sharp \cdots v_m 12 \cdots i\sharp$ for some $v_1, \ldots, v_m \in D_i$. This is since w_i must contain the letter 1 and it can only be read from final states of D_i. Note that there can't be an infix of any w_i for $1 \leq i \leq k$ where the letter $\sharp$ appears after a letter lower than i, as this would lead from the i-th MSCC to s_{k+1}^{k+1}. As the w_i's form a chain, w_1 is a prefix of all the w_i's for $1 < i \leq k$. It follows that w_1 is exactly of the form $\sharp v1$, and as v is common to all the following w_i's, v is in the intersection of all the D_i's. ◀

The following proposition shows that there exists FDFAs where the smallest elements of a persistent chain are inevitably of exponential length. The idea is to take the construction of the FDFA in the proof of Thm. 4.10 and let the DFA D_i count modulo the i-th prime.

▶ **Proposition 4.11.** *There exists a family of languages $\{L_n\}$ with an FDFA with number of states polynomial in n where any persistent chain of maximal length must include a word of length exponential in n.*

Computing the Wagner position on normalized (rather than duo-normalized) FDFAs, can be done more efficiently, specifically in NLOGSPACE.

▶ **Proposition 4.12.** *The position in the Wagner hierarchy of an FDFA using normalized acceptance can be computed in NLOGSPACE.*

For the sake of the proof we define two sub-classes of normalized FDFAs. The smallest one is a generalization studied in [5] of the syntactic FDFA for a language L [19].

▶ **Definition 4.13** (∼-syntactic FDFA). *Let $L \subseteq \Sigma^\omega$ and let $\sim$ be a right congruence refining the syntactic right congruence $\sim_L$. The* ∼-syntactic FDFA*, denoted $(\mathcal{Q}^\sim, \mathcal{P}_u^\sim)$, is defined as follows. The leading automaton $\mathcal{Q}^\sim$ is $\mathcal{A}[\sim]$, and the progress automaton $\mathcal{P}_u^\sim$ is $\mathcal{A}[\approx_u]$ where $x \approx_u y$ if (a) $ux \sim uy$ and (b) for every $z \in \Sigma^*$ it holds that $uxz \sim u$ implies $u(xz)^\omega \in L$ iff $u(yz)^\omega \in L$.*[3]

It is shown in [5, Lemma 21] that if x is duo-normalized wrt $\sim$ and $\approx_u$ then for every $y \approx_u x$ we have that y is also duo-normalized. We can thus refer to a state as being duo-normalized. It is then showed that two duo-normalized states in the same SCC of a ∼-syntactic progress DFA agree on acceptance [5, Lemma 23]. These properties allow defining a polynomial procedure that associates with every state of a *∼-syntactic FDFA* a color that tightly correlates to position on the Wagner hierarchy [5].

It follows that on *∼-syntactic FDFAs* the Wagner position can be determined in polynomial time. The proof can be generalized to any FDFA using normalization in which the right congruence $x \approx_u y$ implies $x \sim_L y$. We call such FDFAs *projective FDFAs*.

▶ **Definition 4.14.** *An FDFA $(\mathcal{A}[\sim], \{\mathcal{A}[\approx_u]\})$ is termed* projective *if for every progress DFA, the respective right congruence $\approx_u$ satisfies that $x \approx_u y$ implies $x \sim_L y$.*

Fig. 5.1 (left) depicts the inclusions among these classes. (In the meantime ignore the text in blue, and the arrow; we will come back to this in the next section.) Since any FDFA using normalization can be transformed with a quadratic blowup into a *projective FDFA* (by multiplying the progress DFAs by the leading automaton) we have that the Wagner position on normalized FDFAs can be computed in polynomial time. In the full version of the paper we show that it can also be computed in NLOGSPACE.

5 Succinctness Results

We turn to provide some succinctness results regarding FDFAs with duo-normalized acceptance. The results compare duo-normalized FDFAs with normalized FDFAs, as well as canonical FDFAs using these acceptance conditions. We already mentioned four canonical FDFAs: the periodic FDFA [7] that uses exact acceptance; and the syntactic [19], recurrent [2] and limit FDFAs [17] that use normalized acceptance. A canonical FDFA that uses duo-normalization can be extracted from notions of [5]. We term it the *Colorful FDFA*, since it relies on the notion of natural colors [10].

Loosely speaking, [10] shows that given an ω-regular language L one can associate with every word $w \in \Sigma^\omega$ a natural color. If w is given color k wrt L, then there is no parity automaton for L that would visit a color lower than k infinitely often when reading w. Consider again the language $L_{\infty aa \wedge \neg\infty bb}$ requiring infinitely many aa and finitely many bb for which a DPA is given in Fig. 3.1 (middle). The colors of $(ab)^\omega$, $(a)^\omega$, $(aab)^\omega$, $(aabb)^\omega$ and $(b)^\omega$ are 3, 2, 2, 1 and 1, resp. The intuition is that the color is 1 if bb occurs infinitely often, it is 2 if aa occurs infinitely often but bb occurs only finitely often, and it is 3 if neither aa nor bb occur infinitely often. We use $\mathsf{Color}(w)$ for the natural color of w. Note that the language L is implicit in the notation.

A related definition provided in [5, Def 2.] can be viewed as giving colors for finite words v wrt to an ω-regular language L and an equivalence class $[u]$. We use $\mathsf{Color}_u(v)$ to denote the color of the finite word $v \in \Sigma^+$ wrt a finite word $u \in \Sigma^*$. The definition satisfies that

[3] *Canonical FORC* is the term used in [5] for the FORC underlying the ∼-syntactic FDFA.

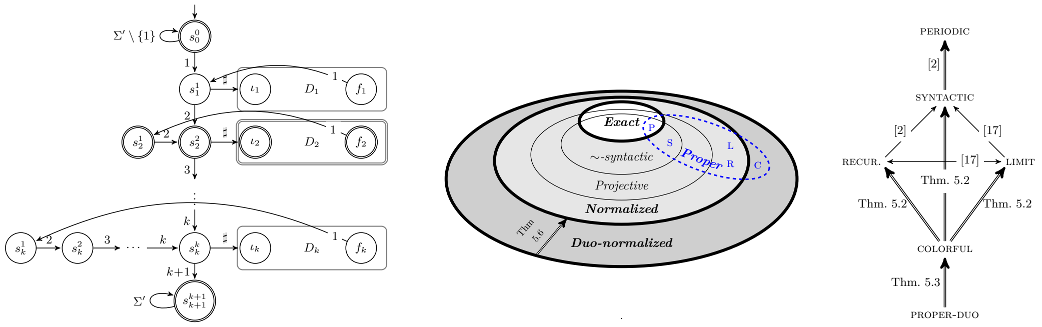

Figure 5.1 Left: The progress DFA $\mathcal{P}$ used in the proof of Thm. 4.10. Its alphabet is $\Sigma' = \Sigma \cup \{1, \ldots, k, k+1\} \cup \{\sharp\}$ where Σ is the alphabet of the DFAs $D_1, \ldots, D_k$. Transitions to the sink state s_{k+1}^{k+1} are omitted. The figure assumes k is odd; for $j \in [1..k]$, ι_j is initial and f_j is accepting. **Middle:** The inclusions among these classes of FDFAs (in black), as well as the placement of the canonical FDFAs in these classes (in blue). The letters P,S,R,L,C abbreviate PERIODIC, SYNTACTIC, RECURRENT, LIMIT, and COLORFUL, resp. **Right:** Picture summarizing succinctness results on proper FDFAs. A double-line (resp. one-line) arrow from C to D indicates that C can be exponentially (resp. quadratically) more succinct than D.

$\mathsf{Color}_u(v)$ returns $\max\{\mathsf{Color}(u(vz)^\omega) \mid z \in \Sigma^*\}$. Note that it is possible that $u(v')^\omega = u(v'')^\omega$ for some $u \in \Sigma^*$ and $v', v'' \in \Sigma^+$, though $\mathsf{Color}_u(v') \neq \mathsf{Color}_u(v'')$. Indeed in the example of $L_{\infty aa \wedge \neg \infty bb}$ we have $(a)^\omega = (aa)^\omega$, yet $\mathsf{Color}_\epsilon(a) = 3$ while $\mathsf{Color}_\epsilon(aa) = 2$.

The reason is that if the period contains a followed by some z the resulting color may be 3 or 2 or 1 while if the period contains aa followed by some z the color can be 2 or 1 but it cannot be 3 since aa surely occurs infinitely often.

These colors can be used to define equivalence classes $\approx_u^{\circledast}$ for each word $u \in \Sigma^*$ by differentiating between words x and y if there is a word z such that the respective extensions xz and yz disagree on the color (wrt u).[4] The Colorful FDFA uses the automaton for $\sim_L$ for the leading automaton as the other canonical FDFAs do. For the progress DFA for u it takes a DFA whose automaton structure is derived by the equivalence relation $\approx_u^{\circledast}$, and the accepting states are those with an even color. The acceptance type of the Colorful FDFA is duo-normalization.

▶ **Definition 5.1** (The Colorful FDFA). *Let $u, x, y \in \Sigma^*$. We define $x \approx_u^{\circledast} y$ if for every $z \in \Sigma^*$ we have $\mathsf{Color}_u(xz) = \mathsf{Color}_u(yz)$. The* colorful FDFA *for a language L, denoted $\mathcal{F}^{\circledast}(L)$, uses duo-normalized acceptance and consists of $(\mathcal{A}[\sim_L], \{\mathcal{P}_u^{\circledast}\})$ where $\mathcal{P}_u^{\circledast}$ is a DFA with the automaton structure $\mathcal{A}[\approx_u^{\circledast}]$ where state q_v is accepting if $\mathsf{color}_u(v)$ is even.*

The Colorful FDFA $\mathcal{F}^{\circledast} = (\mathcal{Q}, \{\mathcal{P}_\epsilon^{\circledast}\})$ for our running example $L_{\infty aa \wedge \neg \infty bb}$ is given in Fig. 3.1 (right).

We are now ready to discuss the succinctness results. Recall that the canonical FDFAs using normalized acceptance have been shown to be exponentially more succinct than the canonical model using exact acceptance [2]. We first show that using duo-normalization a similar succinctness gain is achieved, namely that the Colorful FDFA can be exponentially more succinct than all other canonical representations.

[4] These equivalence classes correspond to the precise family of weak priority mappings wrt to $\sim_L$ from [5, Def. 17].

▶ **Theorem 5.2.** *The Colorful FDFA can be exponentially more succinct than the syntactic/recurrent/limit FDFA.*

The proof uses the family of languages $\{L_n\}_{n\in\mathbb{N}}$ over $\Sigma = \{a, b, \langle, \rangle\}$ defined as follows.

$$L_n = \left\{ w \in \{a,b,\langle,\rangle\}^\omega \;\middle|\; \begin{array}{l} w \text{ has inf. many occurrences of } \langle a^k b^m \rangle \text{ for some } k \in [1..n] \\ \text{and } m \text{ that is divisible by the } k\text{-th prime.} \end{array} \right\}$$

The idea is that using duo-normalization the Colorful FDFA can look only for prefixes of the form $\langle a^k b^m\rangle$, whereas the syntactic/recurrent/limit FDFA must also answer correctly for prefixes of the form $b^m\rangle\langle a^k$ due to using normalized acceptance. Recognizing prefixes of the latter form is much harder.

Next we show that the Colorful FDFA is not the most succinct among the duo-normalized FDFAs. The essence of the proof is that the Colorful FDFA must keep track of all infixes of interest seen in order to maintain the real color of the word. On the other hand, a duo-normalized FDFA, similarly to a DBA, can choose an arbitrary order to look for such infixes. The proof uses the family $\{L'_n\}_{n\in\mathbb{N}}$ over $\Sigma = \{a_1, \ldots, a_n\}$ defined as follows.[5]

$$L'_n = \{w \in \{a_1, \ldots, a_n\}^\omega \;\mid \text{for all } i \in [1..n] \text{ the letter } a_i \text{ appears inf. often in } w\}$$

▶ **Theorem 5.3.** *Duo-normalized FDFAs can be exponentially more succinct than the Colorful FDFA.*

An FDFA in general can use any leading automaton $\mathcal{A}[\sim]$ for a right congruence $\sim$ that refines $\sim_L$. We note that all the canonical models (the periodic, syntactic, recurrent, limit and colorful) use $\mathcal{A}[\sim_L]$ for the leading automaton, we term such FDFAs, *proper*.

▶ **Definition 5.4** (Proper FDFAs). *An FDFA recognizing a language L is termed* proper *if its leading automaton is $\mathcal{A}[\sim_L]$.*

The FDFA used in the proof of Thm. 5.3 is proper. We can thus strengthen the claim as follows.

▶ **Corollary 5.5.** *Proper duo-normalized FDFAs can be exponentially more succinct than the Colorful FDFA.*

Surprisingly, Klarlund has shown that non-proper normalized FDFAs may be exponentially more succinct than proper normalized FDFAs [14]. One may thus wonder if non-proper normalized FDFAs can be as succinct as duo-normalized FDFAs. That is, if duo-normalization adds succinctness when considering non-proper FDFAs. The following theorem shows that duo-normalization does add succinctness even relative to non-proper normalized FDFAs (and even when limiting duo-normalized FDFAs to proper ones).

▶ **Theorem 5.6.** *(Proper) duo-normalized FDFAs can be exponentially more succinct than (not necessarily proper) normalized FDFAs.*

The proof uses the following family of languages $\{L''_n\}_{n\in\mathbb{N}}$ over $\Sigma = \Sigma_a \cup \Sigma_s$ where $\Sigma_a = \{a_1, \ldots, a_n\}$ and $\Sigma_s = \{s_1, \ldots, s_n\}$.

$$L''_n = \left\{ w \in (\Sigma^*\Sigma_a)^\omega \;\middle|\; \begin{array}{l} \text{Let } m = \max\{j \mid a_j \in \Sigma_a \cap \mathit{inf}(w)\}. \\ \text{Then } s_m \in \Sigma_s \text{ appears inf. often in } w. \end{array} \right\}.$$

[5] This family is used in [4] to show DBAs can be exponentially more succinct than combinations of DFAs.

The challenge in the language can be observed in periods where s_m occurs before a_m was seen (for m being the maximal index of an a_i letter in the period). The duo-normalized FDFA has the privilege of looking for duo-normalized decompositions in which s_m is observed after the maximal a_m is seen. As the normalized FDFA has to consider all prefixes, specifically prefixes for every subset of Σ_s, it must grow to an exponential size.

6 Discussion

We have shown that FDFAs with duo-normalized acceptance can be exponentially more succinct than FDFAs using (standard) normalization. At the same time the common operations procedures and decision problems on them can still be done in NLOGSPACE. Fig. 5.1 (right) summarizes the results regarding succinctness among the canonical FDFAs suggested thus far. It shows that the Colorful FDFA can be exponentially more succinct than all other canonical models. At the same time, a minimal duo-normalized FDFA can be exponentially more succinct than the Colorful FDFA.

The figure might raise the question whether a duo-normalized FDFA can be doubly-exponentially more succinct than the periodic FDFA (the least succinct canonical representation). However this cannot be since a duo-normalized FDFA can be translated into a non-deterministic Büchi automaton (NBA) using exactly the same procedure as the one transforming a normalized FDFA into an NBA [1]. The reason is that the construction actually looks for a duo-normalized decomposition (which by saturation exists).

▶ **Proposition 6.1.** *If L has a duo-normalized FDFA $\mathcal{F}$ then it has an NBA of size polynomial in the number of states of $\mathcal{F}$.*

Since an NBA can be converted into a periodic FDFA in an exponential blowup [7, 16] we get an overall exponential translation from duo-normalized FDFAs to the periodic FDFA, showing no doubly-exponential lower bound can be achieved. Since NBAs can be converted to DPAs with an exponential blow up [24, 23, 25, 11] and DPAs can be polynomially converted into non-proper FDFAs [1] we can conclude the following.

▶ **Corollary 6.2.** *The periodic FDFA and the minimal (non-proper) normalized FDFAs and DPAs of a language L are at most exponentially larger than a duo-normalized FDFA for L.*

We also answer a question posed by [10] regarding the relation of the structure of an FDFA to its position in the Wagner hierarchy. Specifically, we have provided a measure on FDFAs that corresponds to the Wagner hierarchy. We have shown that its computation is PSPACE-complete for duo-normalized FDFAs, and is in NLOGSPACE for normalized FDFAs. The measure is based on the notion of a persistent chain. Since the Wagner hierarchy correlates to the minimal color required by a parity automaton, we can define a notion of chains that relates to natural colors of [10, 5], and is thus a semantic notion (defined wrt to the language regardless of a particular acceptor for it). In the full version we show that the existence of one type of chain implies the existence of the other type of chain, and vice versa.

The notion of duo-normalization decomposition seems to be related to the notion of a *linked-pair* in ω-semigroups and Wilke-algebras [27, 9], in which (s, e) is a linked pair if $se = s$ and e is idempotent. It seems that there are two main differences; the first is that a linked pair relates to one relation $\sim$, while a duo-normalized decomposition relates to a pair of relations $(\sim, \approx)$ (one for the leading automaton and one for the respective progress DFA). The second is that the relation $\sim$ used in Wilke-algebras is a two-sided congruence, while the relations used by FDFAs are one-sided. Both differences suggest that duo-normalized FDFAs would be more succinct, but this deserves further study.

Abstract

Romeo and Juliet is a two player Rendezvous game played on graphs where one player controls two agents, *Romeo* ($\mathcal{R}$) and *Juliet* ($\mathcal{J}$) who aim to meet at a vertex against k adversaries, called *dividers*, controlled by the other player. The optimization in this game lies at deciding the minimum number of dividers sufficient to restrict $\mathcal{R}$ and $\mathcal{J}$ from meeting in a graph, called the *dynamic separation number*. We establish that Romeo and Juliet is EXPTIME-complete, settling a conjecture of Fomin, Golovach, and Thilikos [Inf. and Comp., 2023] positively. We also consider the game for directed graphs and establish that although the game is EXPTIME-complete for general directed graphs, it is PSPACE-complete and co-W[2]-hard for directed acyclic graphs.

1 Introduction

The study of *Rendezvous Games* was initiated by Alpern [2] where two agents, that are randomly placed in some known search region and move at unit speed, aim to meet each other in least expected time. Since then, several variants of rendezvous games have been considered on graphs [3, 10, 24]. Fomin, Golovach, and Thilikos [12] introduced the rendezvous game on graph with *adversaries* where a team of *dividers* aim to prevent the meeting of two passionate lovers, say *Romeo* and *Juliet*. We refer to this game as Romeo and Juliet.

Romeo and Juliet is played on finite, connected, and undirected graphs between two players: *facilitator* and *divider*. The facilitator has two agents, *Romeo*, denoted by $\mathcal{R}$, and *Juliet*, denoted by $\mathcal{J}$, that start the game at two designated vertices s and t of G, respectively. The divider has k agents, $D_1, \ldots D_k$, and their starting position is selected by the divider from vertices in $V(G) \setminus \{s, t\}$. Several divider agents can occupy the same vertex. Afterwards, the divider player and the facilitator player make alternate moves, starting with the facilitator. In a move, a player, for each of its agents, either moves the agent to an adjacent vertex not occupied by any agent of the other player or keeps it on the same vertex. A situation where $\mathcal{R}$ and $\mathcal{J}$ are on the same vertex is a *meet*. The facilitator wins if $\mathcal{R}$ and $\mathcal{J}$ meet, and the divider wins if it succeeds in preventing the meet of $\mathcal{R}$ and $\mathcal{J}$ forever. Accordingly, we have the following decision version of the problem. We define the game formally in Section 2.

Romeo and Juliet
Input: A graph G with two specified vertices s and t, and an integer $k \in \mathbb{N}$.
Question: Can the facilitator win on G starting from s and t against the divider with k agents?

We consider the computational complexity of this game and establish that Romeo and Juliet is EXPTIME-complete, resolving a conjecture of Fomin, Golovach, and Thilikos [12] positively. We further define the game for directed graphs and extend our EXPTIME-completeness result to directed graphs as well. We then establish that the game stays PSPACE-complete for directed acyclic graphs.

Rules of Romeo and Juliet are very similar to the rule of classical Cops and Robber game introduced by Nowakowski and Winkler [20], and Quilliot [21]. Cops and Robber fall in the broad range of *Graph Searching*, where a a set of agents, called *pursuers*, plan to catch one or multiple *evaders* in a graph under some movement rules. We refer to the annotated bibliography by Fomin and Thilikos [13] and recent monographs [6, 7] for further references on this topic.

Observe that if $s = t$ or s and t are adjacent vertices, then the facilitator wins trivially. For distinct non-adjacent vertices s and t, let s, t*-dynamic separation number* be the minimum k such that k dividers have a winning strategy against $\mathcal{R}$ and $\mathcal{J}$ starting at s and t, respectively. Since the dividers have a winning strategy by placing a divider on each vertex of a minimum size s, t-vertex cut (for distinct and non-adjacent vertices), the s, t-dynamic separation number is a well-defined graph invariant for s, t.

Fomin, Golovach, and Thilikos [12] proved that Romeo and Juliet is PSPACE-hard for general graphs. They conjectured that the game is, in fact, EXPTIME-complete. We resolve their conjecture positively by providing the following theorem.

▶ **Theorem 1.** *Romeo and Juliet is EXPTIME-complete for undirected graphs.*

Fomin, Golovach, and Thilikos [12] gave a backtracking based $n^{\mathcal{O}(k)}$ time algorithm for Romeo and Juliet, which is also a $2^{\mathcal{O}(n \log n)}$ time algorithm. Hence, to prove the EXPTIME-completeness, we only need to prove EXPTIME-hardness of Romeo and Juliet. To this end, we provide a non-trivial reduction from GuardUndir (a *guarding game* on undirected graphs), which is known to be EXPTIME-complete [22].

Several graph-searching games have a natural generalization to directed graphs and are well-studied [4, 5, 8, 9, 15, 16, 17]. Romeo and Juliet can also be considered on directed graphs where the agents can only move along the orientations of the arcs. We begin by establishing that the Romeo and Juliet game stays EXPTIME-complete on directed graphs. To this end, we provide a rather easy and straightforward reduction from Guard (a guarding game on directed graphs), which is known to be EXPTIME-complete [23], to Romeo and Juliet on directed graphs.

▶ **Theorem 2.** *Romeo and Juliet is EXPTIME-complete for oriented graphs.*

Next, we consider Romeo and Juliet on directed acyclic graphs (DAGs). Fomin, Golovach, and Thilikos [12] also considered a variant of this game, Romeo and Juliet in Time, where the question is whether $\mathcal{R}$ and $\mathcal{J}$ can meet in at most τ rounds. They established that this game is PSPACE-hard and co-W[2]-hard parameterized by k (for undirected graphs). We provide a general framework to establish computational complexity results for Romeo and Juliet on DAGs. In particular, we define a relaxation of the game –Relaxed Romeo and Juliet– where the dividers have an added relaxation that they can move to a vertex occupied by $\mathcal{R}$ or $\mathcal{J}$, but $\mathcal{R}$ or $\mathcal{J}$ cannot finish a move by occupying the same vertex as a divider. We present a reduction from Romeo and Juliet in Time on general graphs to Romeo and Juliet on directed acyclic graphs. This helps us to translate the hardness results proved for Romeo and Juliet in Time on general graphs to Romeo and Juliet on DAGs. In particular, this establishes that Romeo and Juliet remains PSPACE-hard and co-W[2]-hard parameterized by k even on DAGs. To prove PSPACE-completeness for DAGs, we also provide a polynomial-space algorithm for Romeo and Juliet on DAGs. We show the following results.

▶ **Theorem 3.** *Romeo and Juliet is PSPACE-complete when restricted to directed acyclic graphs.*

▶ **Theorem 4.** *Romeo and Juliet is co-W[2]-hard parameterized by k when restricted to directed acyclic graphs.*

Brief Survey. The study of rendezvous games with adversaries was initiated by Fomin, Golovach, and Thilikos [12] and they conducted an extensive study of the computational complexity of this problem and established the following results. Romeo and Juliet, as well as Romeo and Juliet in Time, are PSPACE-hard and co-W[2]-hard parameterized by k, and both of these problems admit a $n^{\mathcal{O}(k)}$ algorithm. This algorithm is optimal in the sense that, assuming ETH , none of these problems can be solved in $n^{o(k)}$ time. Moreover, Romeo and Juliet in Time is co-NP-complete even for $\tau = 2$, and admit a FPT algorithm parameterized by τ and the neighbourhood diversity of the graph, combined. Interestingly, for chordal graphs and P_5-free graphs, the s, t-dynamic separation number is same as the minimum size of a s, t-vertex cut, which establishes that Romeo and Juliet is polynomial time solvable for these classes.

Misra et al. [18] conducted further analysis of this game from a parameterized complexity perspective and established the following interesting results. Romeo and Juliet is co-para-NP-hard parameterized by the treewidth of the input graph. Further, Romeo and Juliet remains co-W[1]-hard when parameterized by the feedback vertex set number and the solution size (combined), and when parameterized by the pathwidth and the solution size (combined). On the positive side, they established that Romeo and Juliet is FPT when parameterized by the vertex cover number and solution size (combined) by the design of an exponential kernel, and complemented this result by proving that it is unlikely to obtain a polynomial kernel by these parameters. Finally, Romeo and Juliet can be solved in polynomial time for treewidth-2 graphs and grids.

An important part of our result is related to the so-called *guarding game*, introduced by Fomin et al. [11], is played on a graph G by two alternating players, the *cop-player* and the *robber-player*, each having their pawns (c cops and one robber, respectively). The vertex set $V(G)$ is partitioned into a *cop region* C and a *robber region* $R = V(G) \setminus C$, and the goal of the cops is to prevent the robber, who starts at some vertex of R, from entering a vertex of C. The computational complexity of the guarding game depends heavily on the chosen restrictions on the graph G. In particular, if Robber's region (R) is only a path, then the problem can be solved in polynomial time, and when robber moves in a tree (or even in a star), then the problem is NP-complete, and if Robber is moving in a DAG, the problem becomes PSPACE-complete [11]. Later Fomin, Golovach and Lokshtanov [14] studied the *reverse guarding game* with the same rules as in the guarding game, except that the cop-player plays first. They proved that the related decision problem is PSPACE-hard on undirected graphs. Nagamochi [19] has also shown that that the problem is NP-complete even if C induces a 3-star and that the problem is polynomially solvable if R induces a cycle. Also, Reddy, Krishna and Rangan [25] proved that if the robber-region is an arbitrary undirected graph, then the decision problem is PSPACE-hard. Šámal and Valla established that the guarding game is, in fact, ETIME-complete under log-space reductions for both directed [23] as well undirected graphs [22].

Organization. We begin with formal preliminaries and definitions in Section 2. In Section 3 we establish the EXPTIME-completeness of Romeo and Juliet for undirected graphs. In Section 4, we extend our EXPTIME-completeness result to directed graphs. We conclude in Section 5. To respect the space restrictions the section concerning Romeo and Juliet on DAGs has been omitted.

2 Preliminaries

For $\ell \in \mathbb{N}$, let $[\ell] = \{1, \ldots, \ell\}$.

Graph Theory. For a graph G, we denote its vertex set by $V(G)$ and edge set by $E(G)$. We denote the size of $V(G)$ by n and size of $E(G)$ by m. In this paper, we consider finite, connected, and simple graphs. Let v be a vertex of a graph G. Then, by $N(v)$ we denote the *open neighbourhood* of v, that is, $N(v) = \{u \mid uv \in E(G)\}$. By $N[v]$ we denote the *closed neighbourhood* of v, that is, $N[v] = N(v) \cup \{v\}$. For $X \subseteq V(G)$, we define $N_X(v) = N(v) \cap X$ and $N_X[v] = N[v] \cap X$. The *length* of a path or cycle is the number of edges in it. A *u, v-path* is a path with endpoints u and v. For $u, v \in V(G)$, let $d(u, v)$ denote the length of a shortest u, v-path. A path is *isometric* if it is a shortest path between its endpoints.

Computational complexity. The complexity class PSPACE is the set of all decision problems that can be solved by a Turing machine using a polynomial amount of space. The class EXPTIME (sometimes denoted EXP) is the set of all decision problems that are solvable by a deterministic Turing machine in the $O(2^{p(n)})$ time where $p(n)$ is a polynomial of n.

Romeo and Juliet. Romeo and Juliet is played on a graph G, where the input prescribes the number of dividers k, and the starting positions s_0 and t_0 of $\mathcal{R}$ and $\mathcal{J}$, respectively. The game starts with $\mathcal{R}$ and $\mathcal{J}$ occupying the initial vertices s_0, and t_0, respectively. Then, the divider player places its agents $D_1, \ldots, D_k$ on vertices $d_0^1, \ldots, d_0^k$, respectively, such that $\{d_0^1, \ldots, d_0^k\} \cap \{s_0, t_0\} = \emptyset$. We call this state $\mathcal{S}_0 = (s_0, t_0, d_0^1, \ldots, d_0^k)$. For $i \geq 0$, let $\mathcal{D}_i$ denote the set $\{d_i^1, \ldots, d_i^k\}$. Multiple dividers may occupy the same vertex, and $|\mathcal{D}_i|$ may be less than k. After this, the game proceed in *rounds*, where each round consists of a divider move, followed by a facilitator move. In round i, $i \geq 1$, first the facilitator moves $\mathcal{R}$ to a vertex $s_i \in N[s_{i-1}] \setminus \mathcal{D}_{i-1}$ and $\mathcal{J}$ to a vertex $t_i \in N[t_{i-1}] \setminus \mathcal{D}_{i-1}$. Then, the divider moves each divider D_p, $p \in [k]$, to a vertex $d_i^p \in N[d_{i-1}^p] \setminus \{s_i, t_i\}$. This gives us a game state $\mathcal{S}_i = (s_i, t_i, d_i^1, \ldots, d_i^k)$. If the facilitator can ensure that for some $i \geq 0$, $s_i = t_i$, we say that the facilitator has a winning strategy. On the other hand, if the divider player can ensure that for each $i \geq 0$, $s_i \neq t_i$, then the divider player has a winning strategy. For directed graphs, the rules are exactly the same with the only difference that the agents can only move along the orientations of the arcs. Fomin et al. [12] gave an algorithm for Romeo and Juliet with running time $\mathcal{O}(2^{\mathcal{O}(n \log n)})$. It is easy to see that the algorithm works for directed graphs as well. Hence, we have the following proposition.

▶ **Proposition 5** ([12]). *Romeo and Juliet is in class EXPTIME on directed as well as undirected graphs.*

We have the following trivial observation that shall be useful to us.

▶ **Observation 6.** *Let $\mathcal{S}_i = (s_i, t_i, d_i^1, \ldots, d_i^k)$ be a game state in some graph G, and let $y \in V(G)$. If there is a s_i, y-path (resp., t_i, y-path) P such that (i) P is an isometric path of length ℓ, (ii) and for each vertex $v \in V(P)$ and $u \in \mathcal{D}_i$, $d(s_i, v) \leq d(u, v)$ (resp., $d(t_i, v) \leq d(u, v)$), then the facilitator player can ensure that $\mathcal{S}_{i+\ell} = (s_{i+\ell} = y, t_{i+\ell}, d_{i+\ell}^1, \ldots, d_{i+\ell}^k)$ (resp., $\mathcal{S}_{i+\ell} = (s_{i+\ell}, t_{i+\ell} = y, d_{i+\ell}^1, \ldots, d_{i+\ell}^k)$).*

Guarding Game. The GuardUndir game is played on an undirected graph G, where $V(G)$ is partitioned into two regions: *Cop region* $C \subset V(G)$, and *Robber region* $R = V(G) \setminus C$. There is a prescribed vertex $r_0 \in R$, where the robber starts. The games begins with the robber occupying the vertex r_0. Then, k cops occupy vertices $c_0^1, \dots, c_0^k$ such that for each $j \in [k]$, $c_0^j \in C$. More than one cop may occupy the same vertex. This gives us game state $\mathcal{G}_0 = (r_0, c_0^1, \dots, c_0^k)$. Let $\mathcal{C}_i$ denote the set of vertices $\{c_0^i, \dots, c_k^i\}$. Then, the game proceeds in rounds. In round i, $i > 0$, first the robber moves to a vertex $r_i \in N[r_{i-1}] \setminus \mathcal{C}_{i-1}$. Then, the cop player moves the cop C_j, $j \in [k]$, to a vertex $c_i^j \in N_C[c_{i-1}^j] \setminus \{r_i\}$. If the robber can ensure that for some $i \geq 0$, $r_i \in C$, then the robber has a winning strategy. Otherwise, if the cops can ensure that for each $i \geq 0$, $r_i \notin C$, then the cop player has a winning strategy.

It is worth noting that the GuardUndir game where the starting position of the robber is not specified is also studied. But for our purposes, we consider the variant where the starting position of the robber, i.e., r_0 is fixed. Furthermore, we assume that $G[C]$ as well as $G[R]$ are connected subgraphs of G.

The Guard game is analog of GuardUndir on directed graphs. The rules of the game are exactly the same as the undirected case with the only change that the agents can only move along the orientations of the arcs. Šámal and Valla [22, 23] proved the following.

▶ **Proposition 7** ([23, 22]). *Guard and GuardUndir are EXPTIME-complete.*

3 Romeo and Juliet is EXPTIME-complete

In this section, we establish that Romeo and Juliet is EXPTIME-complete for undirected graphs. To prove this, we provide a non-trivial reduction from GuardUndir to Romeo and Juliet on undirected graphs. We begin by providing an overview of our reduction.

Overview. First, we make two copies of the cop region C as $C_\mathcal{R}$ and $C_\mathcal{J}$, and two copies of the robber region R as $R_\mathcal{R}$ and $R_\mathcal{J}$ such that $\mathcal{R}$ starts in $R_\mathcal{R}$ and $\mathcal{J}$ starts in $R_\mathcal{J}$. We will have $2k$ dividers. Moreover, we use some gadgets, that we call *secret gardens*, which ensure that after each round, if each of $C_\mathcal{R}$ and $C_\mathcal{J}$ does not host at least k dividers each, $\mathcal{R}$ and $\mathcal{J}$ will meet in one of the secret gardens after a finite number of rounds. Moreover, given that both $C_\mathcal{R}$ and $C_\mathcal{J}$ host at least k dividers each, if $\mathcal{R}$ and $\mathcal{J}$ are able to enter the vertices of $C_\mathcal{R}$ and $C_\mathcal{J}$, respectively, then they will be able to meet in the next round. Hence, for dividers to win, the game is, more or less, similar to restricting $\mathcal{R}$ and $\mathcal{J}$ to enter $C_\mathcal{R}$ and $C_\mathcal{J}$, respectively, where both $C_\mathcal{R}$ and $C_\mathcal{J}$ host exactly k dividers each. Below, we provide our construction in detail.

Construction. Let (H, k, r) be an instance of the GuardUndir, where r is the starting position of the robber and $V(H)$ consists of the cop region C and the robber region $R = V(H) \setminus C$. We assume that $H[C]$ as well as $H[R]$ is connected. We will construct an instance $(G, 2k)$ of Romeo and Juliet in the following manner. Since the construction has several components, we will define the components of our construction (reduction) individually. Our graph G will have following components.

1. $C_\mathcal{R}$, $C_\mathcal{J}$, $R_\mathcal{R}$, and $R_\mathcal{J}$. We begin by constructing two copies of the graph H as $G_\mathcal{R}$ and $G_\mathcal{J}$, corresponding to $\mathcal{R}$ and $\mathcal{J}$, respectively. See Figure 1 for an illustration. More specifically, $G_\mathcal{R}$ (resp., $G_\mathcal{J}$) contains a copy $C_\mathcal{R}$ (resp., $C_\mathcal{J}$) of C and $R_\mathcal{R}$ (resp., $R_\mathcal{J}$) of R. Formally, $V(G_\mathcal{R}) = \{u_\mathcal{R} \mid u \in V(H)\}$ and, $V(G_\mathcal{J}) = \{u_\mathcal{J} \mid u \in V(H)\}$. Moreover,

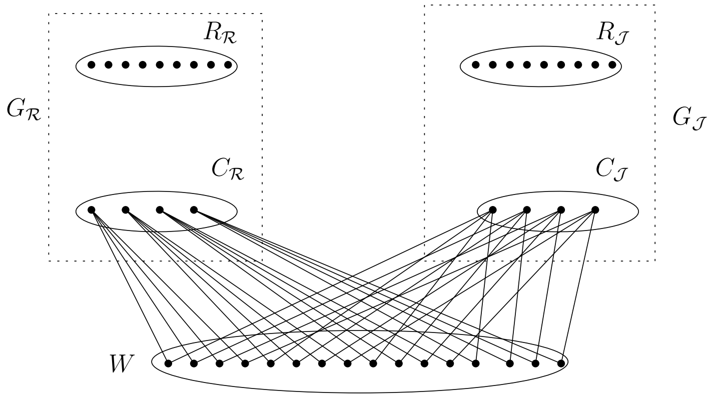

Figure 1 The graphs $G[R_{\mathcal{R}} \cup C_{\mathcal{R}}]$ (i.e., $G_{\mathcal{R}}$) as well as $G[R_{\mathcal{J}} \cup C_{\mathcal{J}}]$ (i.e., $G_{\mathcal{J}}$) are isomorphic to H. Here, we do not display edges in $G_{\mathcal{R}}$ and $G_{\mathcal{J}}$ to ease the illustration.

$E(G_{\mathcal{R}}) = \{u_{\mathcal{R}}v_{\mathcal{R}} \mid uv \in E(H)\}$ and $E(G_{\mathcal{J}}) = \{u_{\mathcal{J}}v_{\mathcal{J}} \mid uv \in E(H)\}$. Finally, the starting position of $\mathcal{R}$ is $r_{\mathcal{R}}$ and $\mathcal{J}$ is $r_{\mathcal{J}}$ (where r is the starting position of the robber in the GuardUndir), i.e., $s_0 = r_{\mathcal{R}}$ and $t_0 = r_{\mathcal{J}}$.

2. Connecting $C_{\mathcal{R}}$ to $C_{\mathcal{J}}$. For each vertex $x \in C_{\mathcal{R}}$ and each vertex $y \in C_{\mathcal{J}}$, we connect x and y using a path $P_{xy} = xw_{xy}y$ of length 2. Let W be the set of vertices that lie in the middle of these paths, i.e., $W = \{w_{xy} \mid x \in C_{\mathcal{R}}, y \in C_{\mathcal{J}}\}$. Moreover, each vertex of W has degree exactly 2 in G. See Figure 1 for an illustration. We have the following trivial observation, which follows from the fact that each vertex in W have degree exactly 2.

▶ **Observation 8.** *Consider a game state $S_i = \{s_i, t_i, d_i^1, \ldots, d_i^{2k}\}$, $i > 0$, such that $s_i \in C_{\mathcal{R}}$ and $t_i \in C_{\mathcal{J}}$, and $w_{s_i t_i} \notin \mathcal{D}_{i-1}$, then $\mathcal{R}$ and $\mathcal{J}$ can meet at $w_{s_i t_i}$ in the next round.*

Proof. The proof follows from the fact that if $w_{s_i t_i} \notin \mathcal{D}_{i-1}$, then $w_{s_i t_i} \notin \mathcal{D}_i$ since $w_{s_i t_i}$ is connected only to s_i and t_i and $\{s_i, t_i\} \cap \mathcal{D}_i = \emptyset$. ◀

3. *Secret Gardens*. Next, we construct $2k+2$ secret gardens $S_1, \ldots, S_{2k+2}$, the goal of which is to ensure that after each round, both $C_{\mathcal{R}}$ and $C_{\mathcal{J}}$ must host exactly k dividers each. See Figure 2 for an illustration. Each S_i, $i \in [2k+2]$, consists of k independent vertices.

4. *Bridges*. Next, we construct $2k+2$ *divider bridges* $B_1, \ldots B_{2k+2}$, where each B_i ($i \in [2k+2]$) consists of k independent vertices, and $2k+2$ *lover bridges* $L_1, \ldots, L_{2k+2}$, where each L_i consists of two independent vertices a_i and b_i. See Figure 2 for an illustration.

5. Connecting bridges and gardens. For each $i \in [2k+2]$, $G[S_i \cup B_i]$ induces a complete bipartite graphs. Next, for $i \in [k+1]$, we connect each vertex of S_i to a_i via an edge and each vertex of b_i to S_i via a path of length 2. Symmetrically, for $k+2 \le i \le 2k+2$, we connect each vertex of S_i to a_i via a path of length 2 and each vertex of S_i to b_i via an edge.

6. Connecting bridges to rest of the graph. Let β_H, β_C, and β_R be the diameter of graph H, graph $H[C]$, and graph $H[R]$, respectively. Then, let $\alpha = \max(\beta_H, \beta_C, \beta_R)$. For each vertex $x \in C_{\mathcal{R}}$ and each vertex $y \in \bigcup_{i \in [k+1]} B_i$, we connect x and y using a path of length α. Similarly, for each vertex $x \in C_{\mathcal{J}}$ and each vertex $y \in \bigcup_{k+1 < i \le 2k+2} B_i$, we connect x and y using a path of length α. Next, for $i \in [k+1]$, we connect each vertex $x \in R_{\mathcal{R}}$ to

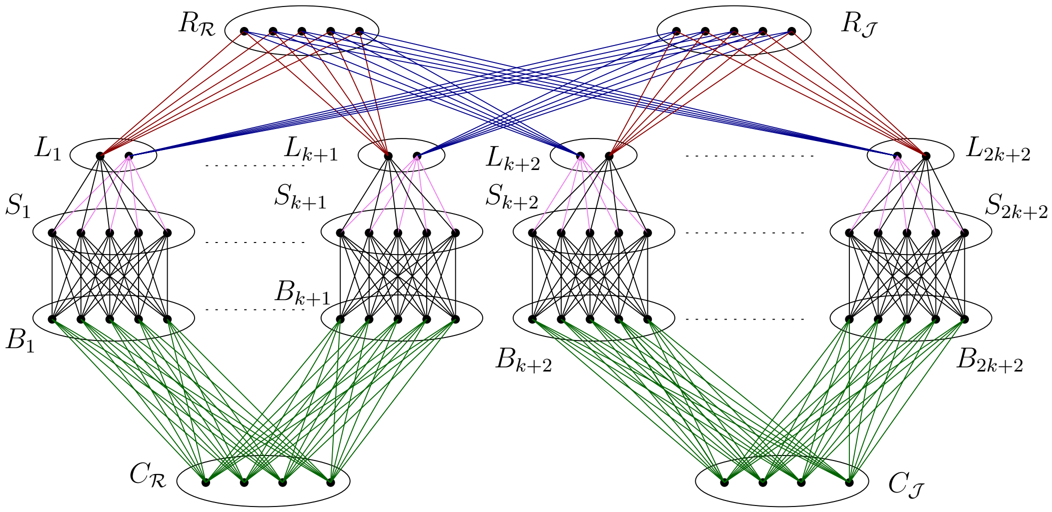

Figure 2 Illustration of secret gardens and bridges. Each black connection signifies an edge, blue, red, green, and violet connections signify paths of length $\alpha+2$, $\alpha+1$, α, and 2, respectively. Note that, due to our choice of α, no shortcuts are created in the original graph.

a_i using a path of length $\alpha+1$ and each vertex $y \in R_{\mathcal{J}}$ to b_i using a path of length $\alpha+2$. Symmetrically, for $k+2 \leq i \leq 2k+2$, we connect each vertex $x \in R_{\mathcal{R}}$ to a_i using a path of length $\alpha+2$ and each vertex $y \in R_{\mathcal{J}}$ to b_i using a path of length $\alpha+1$. See Figure 2 for an illustration. This completes our construction of G.

Subgraphs of G. For the ease of exposition, we name some of the induced subgraphs of G. Consider the induced subgraph $G' = G[V(G) \setminus (R_{\mathcal{R}} \cup R_{\mathcal{J}} \cup W)]$. Observe that G' has two connected components: one containing $C_{\mathcal{R}}$, say $G'_{\mathcal{R}}$, and the other containing $C_{\mathcal{J}}$, say $G'_{\mathcal{J}}$. Moreover, consider the induced subgraph $G'' = G'[V(G') \setminus (C_{\mathcal{R}} \cup C_{\mathcal{J}})]$. Observe that G'' contains exactly $2k+2$ connected components, say $G_1, \ldots, G_{2k+2}$, and let G_i be the connected component containing S_i (and hence, B_i and L_i).

The following observation follows directly from the construction of G

▶ **Observation 9.** *The following statements follow from the construction.*

1. *For distinct $i, j \in [2k+2]$, for a vertex $x \in V(G_i)$ and $y \in S_j$, $d(x,y) > \alpha+1$.*
2. *Let $x \in S_i$ for $i \in [k+1]$. For each vertex $y \in C_{\mathcal{R}}$, there is a x,y-path of length $\alpha+1$, and for each vertex $z \in C_{\mathcal{J}}$, there is a x,z-path of length $\alpha+3$.*
3. *Let $x \in S_i$ for $k+2 \leq i \leq 2k+2$. For each vertex $y \in C_{\mathcal{R}}$, there is a x,y-path of length $\alpha+3$, and for each vertex $z \in C_{\mathcal{J}}$, there is a x,z-path of length $\alpha+1$.*

The following lemma establishes that if $\mathcal{R}$ and $\mathcal{J}$ are in $R_{\mathcal{R}}$ and $R_{\mathcal{J}}$, respectively, then both $G'_{\mathcal{R}}$ and $G'_{\mathcal{J}}$ must host at least k dividers, else $\mathcal{R}$ and $\mathcal{J}$ meet in at most $\alpha+2$ rounds.

▶ **Lemma 10.** *Consider a game state $\mathcal{S}_i = (s_i, t_i, d_i^1, \ldots, d_i^{2k})$ for $i \geq 0$. If $s_i \in R_{\mathcal{R}}$ and $t_i \in R_{\mathcal{J}}$, and at least one of $G'_{\mathcal{R}}$ or $G'_{\mathcal{J}}$ hosts less than k dividers, then $s_{i+\alpha+3} = t_{i+\alpha+3}$.*

Proof. Without loss of generality, let us assume that $G'_{\mathcal{R}}$ hosts at most $k-1$ dividers at the end of round i (i.e., $\mathcal{D}_i \cap V(G'_{\mathcal{R}}) < k$). Therefore, at least one of $G_1, \ldots, G_{k+1}$ does not host any divider (as $G_1, \ldots, G_{k+1}$ are disjoint subgraphs of G'_R). Let G_p, $p \in [k+1]$, be such a component, i.e., $V(G_p) \cap \mathcal{D}_i = \emptyset$. To ease the presentation, let $x = s_i$ and $y = t_i$. Moreover, let P_x be the unique isometric x, a_p-path of length $\alpha+1$, and let P_y be the unique isometric

y, b_p-path of length $\alpha + 2$. Furthermore, let the vertices of S_p be marked as $v_1, \dots, v_k$ and let, for $j \in [k]$, the (degree-2) vertex connecting v_j and b_p be u_j. We have the following crucial claim that proves our lemma.

▷ Claim 11. $\mathcal{R}$ and $\mathcal{J}$ can move along the paths P_x and P_y such that $s_{i+\alpha+2} \in S_p$, $t_{i+\alpha+2} = b_p$. Moreover, if $s_{i+\alpha+2} = v_j$, where $j \in [k]$, then $u_j \notin \mathcal{D}_{i+\alpha+2}$.

Proof of Claim. First, we establish that $\mathcal{R}$ can move to the vertex a_p in $\alpha + 1$ rounds. Due to Observation 6, to show that $\mathcal{R}$ can ensure that $s_{i+\alpha+1} = a_p$, it is sufficient to show that for each vertex $v \in V(P_x)$, $d(x, v) \leq \min_{u \in \mathcal{D}_i}(d(u, v))$. We distinguish the following cases depending on where u is in G.

1. $u \in C_{\mathcal{R}} \cup C_{\mathcal{J}} \cup W$: Observe that for each vertex $u \in C_{\mathcal{R}} \cup C_{\mathcal{J}} \cup W$ and each vertex $v \in V(P_x)$, $d(u, v) \geq \alpha + 1$ and $d(x, v) \leq \alpha + 1$. Hence, $d(x, v) \leq \min_{u \in \mathcal{D}_i}(d(u, v))$.
2. $u \in R_{\mathcal{R}} \cup R_{\mathcal{J}}$: Observe that for each vertex $u \in R_{\mathcal{R}} \cup R_{\mathcal{J}}$ and each vertex $v \in V(P_x)$, any u, v-path contains either x or a_p. In the former case, trivially $d(x, v) \leq d(u, v)$, and in the latter case, observe that $d(u, v) \geq \alpha + 1 \geq d(x, v)$. Hence, $d(x, v) \leq \min_{u \in \mathcal{D}_i}(d(u, v))$.
3. $u \in G_j$, for some $j \in [2k+2]$: Due to our choice of p, clearly $u \notin V(G_p)$ (since we choose G_p such that $V(G_p) \cap \mathcal{D}_i = \emptyset$). Hence, $j \neq p$. Since G_j and G_p are disjoint components in $G[V(G) \setminus \{C_{\mathcal{R}} \cup C_{\mathcal{J}} \cup R_{\mathcal{R}} \cup R_{\mathcal{J}}\}]$, each u, v-path passes through a vertex of $u' \in C_{\mathcal{R}} \cup C_{\mathcal{J}} \cup R_{\mathcal{R}} \cup R_{\mathcal{J}}$, and hence this case is implied by the previous two cases.

Thus, the facilitator can ensure that $s_{i+\alpha+1} = a_p$. Finally, since $G'_{\mathcal{R}}$ hosts at most $k - 1$ dividers and for each vertex $u \in V(G) \setminus V(G'_{\mathcal{R}})$ and $v \in S_p$, $d(u, v) > \alpha + 1$, at most $k - 1$ dividers can reach the vertices of S_p in $\alpha + 1$ moves of dividers. Therefore, $|\mathcal{D}_{i+\alpha+1} \cap S_p| < k$. Hence, there is at least one $j \in [k]$ such that $v_j \in S_p \setminus \mathcal{D}_{i+\alpha+1}$, and hence $\mathcal{R}$ can move to v_j in this round, i.e., $s_{i+\alpha+2} = v_j \in S_p$.

The proof that of the claim $t_{i+\alpha+2} = b_p$ is symmetric to the proof that $s_{i+\alpha+1} = a_p$.

Next, we establish that $u_j \notin \mathcal{D}_{i+\alpha+2}$. Recall that $v_j \notin \mathcal{D}_{i+\alpha+1}$ and, due to our choice of p, $V(G_p) \cap \mathcal{D}_i = \emptyset$. It follows from our construction that for each vertex $w \in V(G) \setminus (G_p \cup C_{\mathcal{R}})$, $d(w, u_j) > \alpha + 2$ and for $w' \in C_{\mathcal{R}}$, $d(w', u_j) = \alpha + 2$ and each w', u_j-path of length $\alpha + 2$ passes through v_j. Since $\mathcal{D}_i \cap V(G_p) = \emptyset$, if a divider, say D_ℓ, has to ensure that $d^{\ell}_{i+\alpha+2} = u_j$, D_ℓ has to ensure that $d^{\ell}_{i+\alpha+1} = v_j$, which is not possible since $v_j \notin \mathcal{D}_{i+\alpha+1}$. Hence, $u_j \notin \mathcal{D}_{i+\alpha+2}$. This completes the proof of our claim. ◁

Finally, since $s_{i+\alpha+2} = v_j \in S_p$ (for some $j \in [k]$), $t_{i+\alpha+2} = b_p$ and $u_j \notin \mathcal{D}_{i+\alpha+2}$ (Claim 11), the facilitator can ensure that $\mathcal{R}$ and $\mathcal{J}$ meet in the next round at u_j. ◀

Next, we have the following lemma which establishes that as long as $\mathcal{R}$ and $\mathcal{J}$ are in $R_{\mathcal{R}}$ and $R_{\mathcal{J}}$, respectively, both $C_{\mathcal{R}}$ and $C_{\mathcal{J}}$ must host exactly k dividers each.

▶ **Lemma 12.** *Consider a game state $\mathcal{S}_i = (s_i, t_i, d^1_i, \dots, d^{2k}_i)$ for $i \geq 0$ such that $s_i \in R_{\mathcal{R}}$ and $t_i \in R_{\mathcal{J}}$. If $|\mathcal{D}_i \cap C_{\mathcal{R}}| \neq k$ or $|\mathcal{D}_i \cap C_{\mathcal{J}}| \neq k$, then the facilitator can ensure that $s_{i+\alpha+3} = t_{i+\alpha+3}$.*

Proof. The proof is similar to the proof of Lemma 10. Due to Lemma 10, we know that both $G'_{\mathcal{R}}$ and $G'_{\mathcal{J}}$ host exactly k dividers, and thus, $|\mathcal{D}_i \cap C_{\mathcal{R}}| \leq k$ and $|\mathcal{D}_i \cap C_{\mathcal{J}}| \leq k$, else $\mathcal{R}$ and $\mathcal{J}$ meet in $\alpha + 3$ rounds. At this point, let one of $C_{\mathcal{R}}$ or $C_{\mathcal{J}}$ hosts less that k dividers. Without loss of generality, let $|\mathcal{D}_i \cap C_{\mathcal{R}}| < k$. In this case, similarly to the proof of Lemma 10, there is at least one G_p, $p \in [k+1]$, such that G_p does not contain any divider . Moreover, similarly to the proof of Lemma 10, only the dividers on $C_{\mathcal{R}}$ can reach S_p in $\alpha + 2$ rounds and hence at most $k - 1$ dividers can reach the vertices of S_p in $\alpha + 2$ rounds. Therefore, $\mathcal{R}$ and $\mathcal{J}$ have a strategy to ensure that $s_{i+\alpha+2} = z \in S_p$ and $t_{i+\alpha+2} = b_p$ such that the unique vertex on the isometric $s_{i+\alpha+2}, t_{i+\alpha+2}$-path does not any divider in this round. Hence, $s_{i+\alpha+3} = t_{i+\alpha+3}$. ◀

Next, we prove the following lemma which implies one side of our reduction.

▶ **Lemma 13.** *If the robber has a winning strategy in H against k cops, then $\mathcal{R}$ and $\mathcal{J}$ have a winning strategy in G against $2k$ dividers.*

Proof. The game starts with $\mathcal{R}$ and $\mathcal{J}$ placed on $r_{\mathcal{R}}$ and $r_{\mathcal{J}}$, respectively. Due to Lemma 12, we can assume that as long as $\mathcal{R}$ and $\mathcal{J}$ are in $R_{\mathcal{R}}$ and $R_{\mathcal{J}}$, respectively, both $C_{\mathcal{R}}$ and $C_{\mathcal{J}}$ must host exactly k dividers each, else $\mathcal{R}$ and $\mathcal{J}$ win. First, we will show that after a finite number of rounds $\mathcal{R}$ can enter $C_{\mathcal{R}}$. Observe that any move of dividers in $C_{\mathcal{R}}$ (in G) corresponds to a valid move of cops in C (in H) and $\mathcal{R}$ can make any move in $G[C_{\mathcal{R}} \cup R_{\mathcal{R}}]$ against dividers in G that is accessible to the robber in H against the corresponding position of the cops. Hence, using the winning strategy of the robber, $\mathcal{R}$ can enter $C_{\mathcal{R}}$ after a finite number of rounds (since $C_{\mathcal{R}}$ hosts exactly k dividers). Similarly, $\mathcal{J}$ can move to $C_{\mathcal{J}}$ in a finite number of rounds.

But, observe that since the dividers in $C_{\mathcal{R}}$ and $C_{\mathcal{J}}$ may be using different strategies, $\mathcal{R}$ and $\mathcal{J}$ may not be able to simultaneously move to $C_{\mathcal{R}}$ and $C_{\mathcal{J}}$, respectively. Hence, we distinguish the following two cases.

1. $\mathcal{R}$ and $\mathcal{J}$ move simultaneously to $x \in C_{\mathcal{R}}$ and $y \in C_{\mathcal{J}}$, respectively. Due to Lemma 12, we may assume that when $\mathcal{R}$ and $\mathcal{J}$ made this move, both $C_{\mathcal{R}}$ and $C_{\mathcal{J}}$ hosted exactly k dividers each, and hence no vertex of W was occupied by any divider. Hence, $\mathcal{R}$ and $\mathcal{J}$ can meet in the next round due to Observation 8.
2. $\mathcal{R}$ moves to $x \in C_{\mathcal{R}}$ while $\mathcal{J}$ is on some vertex $y \in R_{\mathcal{J}}$. Similarly to the previous case, due to Lemma 12, we may assume that when $\mathcal{R}$ and $\mathcal{J}$ made this move, both $C_{\mathcal{R}}$ and $C_{\mathcal{J}}$ hosted exactly k dividers each. In the next move of the dividers, observe that there will be at least one G_p, $p \in [k+1]$, such that G_p does not contain any dividers. In the next $\alpha + 2$ rounds, $\mathcal{J}$ moves towards the vertex b_p and $\mathcal{R}$ moves first towards a vertex in S_p, and then to a neighbour of b_p. We note that $\mathcal{R}$ and $\mathcal{J}$ can make these moves following the same arguments presented in the proof of Lemma 10. Hence, $\mathcal{R}$ and $\mathcal{J}$ meet in the next round since they are they are at adjacent vertices.
3. $\mathcal{J}$ moves to $x \in C_{\mathcal{J}}$ while $\mathcal{R}$ is on some vertex $y \in R_{\mathcal{R}}$. This case is symmetric to Case 2.

This completes our proof. ◀

To complete our reduction, we need to establish that if k cops have a winning strategy in H, then $2k$ dividers have a winning strategy in G. To aid the presentation of the proof of this lemma, we need the following notion of *safe states*.

Safe states. Consider the GUARDUNDIR on graph H and consider some game state $\mathcal{G}_i = (r_i, c_i^1, \ldots, c_i^k)$ such that $r_i \in R$. We say that $\mathcal{G}_i$ is a *safe state* if the cops have a strategy to ensure that robber cannot enter C in any round $i' > i$. Similarly, consider the game ROMEO AND JULIET on graph G and some game state $\mathcal{S}_j = (s_j, t_j, d_j^1, \ldots, d_j^{2k})$. We say that $\mathcal{S}_j$ is *$\mathcal{R}$-safe state* (resp., *$\mathcal{J}$-safe state*) if (1) $s_j \in R_{\mathcal{R}}$ (resp., $t_j \in R_{\mathcal{J}}$), (2) $\{d_1^j, \ldots, d_k^j\} \subseteq C_{\mathcal{R}}$ (resp., $\{d_j^{k+1}, \ldots, d_j^{2k}\} \subseteq C_{\mathcal{J}}$), and (3) the dividers $D_1, \ldots, D_k$ (resp., $D_{k+1}, \ldots, D_{2k}$) can ensure that if $\mathcal{R}$ (resp., $\mathcal{J}$) is restricted to $G_{\mathcal{R}}$ (resp., $G_{\mathcal{J}}$), then $\mathcal{R}$ (resp., $\mathcal{J}$) cannot enter a vertex of $C_{\mathcal{R}}$ (resp., $C_{\mathcal{J}}$) in any round $j' > j$. We say that a game state $\mathcal{S}_j$ is *almost-$\mathcal{R}$-safe state* if $\mathcal{R}$ is in some G_i, $i \in [2k+2]$, and the dividers $D_1, \ldots, D_k$ have a strategy that ensures that if for some $j' > j$, $s_{j'} \in V(G_{\mathcal{R}}) \cup V(G_{\mathcal{J}})$ (i.e., $\mathcal{R}$ enters a vertex in $V(G_{\mathcal{R}}) \cup V(G_{\mathcal{J}})$), then $\mathcal{S}_{j'}$ is a $\mathcal{R}$-safe state. We define *almost-$\mathcal{J}$-safe state* analogously. We have the following easy, but useful, observations.

▶ **Observation 14.** *Consider a game state $\mathcal{S}_j = (s_j, t_j, d_j^1, \dots, d_j^{2k})$ of* Romeo and Juliet *on G such that $s_j \in R_{\mathcal{R}}$ and $\{d_j^1, \dots, d_j^k\} \subseteq C_{\mathcal{R}}$. Now, consider a corresponding game state $\mathcal{G}_i = (r_i, c_i^1, \dots, c_i^k)$ of* GuardUndir *on H such that if $s_j = u_{\mathcal{R}}$, then $r_i = u$, and if, for $\ell \in [k]$, $d_j^\ell = v_{\mathcal{R}}$, then $c_j^\ell = v$. If $\mathcal{G}_i$ is a safe state then $\mathcal{S}_j$ is a $\mathcal{R}$-safe state.*

Proof. To prove our statement, we need to show that if $\mathcal{R}$ is restricted to $G_{\mathcal{R}}$, then the dividers have a strategy to ensure that, for $j' > j$, $\mathcal{R}$ cannot enter a vertex of $C_{\mathcal{R}}$. The dividers $D_1, \dots, D_k$ can do so by mimicking the winning strategy of the cops from H in the following manner. Whenever $\mathcal{R}$ moves from a vertex $u_{\mathcal{R}}$ to $w_{\mathcal{R}}$ in $G_{\mathcal{R}}$, we move the robber in H from u to w, and then each cop C_ℓ, for $\ell \in [k]$, moves as per its winning strategy. Notice that this gives us a safe state $\mathcal{S}_{i+1}$. Then, each divider D_ℓ, for $\ell \in [k]$, copies the move of C_i such that if C_i moved from v to x, then D_i moves from $v_{\mathcal{R}}$ to $x_{\mathcal{R}}$. Using this strategy, the dividers $D_1, \dots, D_k$ can ensure that, as long as $\mathcal{R}$ is restricted to $G_{\mathcal{R}}$, $\mathcal{R}$ can never enter a vertex of $C_{\mathcal{R}}$. Hence, $\mathcal{S}_j$ is a $\mathcal{R}$-safe state. ◀

Analogously, we can have the following observation for $\mathcal{J}$-safe states.

▶ **Observation 15.** *Consider a game state $\mathcal{S}_j = (s_j, t_j, d_j^1, \dots, d_j^{2k})$ of* Romeo and Juliet *on G such that $t_j \in R_{\mathcal{J}}$ and $\{d_j^{k+1}, \dots, d_j^{2k}\} \subseteq C_{\mathcal{J}}$. Now, consider a corresponding game state $\mathcal{G}_i = (r_i, c_i^1, \dots, c_i^k)$ of* GuardUndir *on H such that if $t_j = u_{\mathcal{J}}$, then $r_i = u$, and if, for $k+1 \leq \ell \leq 2k$, $d_j^\ell = v_{\mathcal{J}}$, then $c_j^{\ell - k} = v$. If $\mathcal{G}_i$ is a safe state then $\mathcal{S}_j$ is a $\mathcal{J}$-safe state.*

▶ **Observation 16.** *Let k cops have a winning strategy in H against the robber starting at r. Then, for each vertex $v \in R$ ($\subseteq V(H)$), there exists a set of (not necessarily distinct) vertices $u_1, \dots, u_k \in C$ such that the game state $\mathcal{G} = (v, u_1, \dots, u_k)$ is a safe state.*

Proof. Targeting contradiction, let there be a vertex $v \in C$ such that for every $u_1, \dots, u_k \in C$ (possibly $u_i = u_j$ for distinct i, j), $\mathcal{G} = (v, u_1, \dots, u_k)$ is a not a safe state. Let $d(r, v) = \ell \leq \alpha$. Then, the robber have a strategy to reach a game state $\mathcal{G}_\ell = (r_\ell = v, c_\ell^1, \dots, c_\ell^k)$, which is not a safe state (by our contradiction assumption). Hence, the cops do not have any strategy that can restrict the robber to R for each round $\ell' > \ell$, a contradiction to the fact that k cops have a winning strategy in H against the robber starting at r. ◀

Next, we have the following lemma.

▶ **Lemma 17.** *Let k cops have a winning strategy in H against the robber starting at r. Moreover, let $\mathcal{S}_j = (s_j, t_j, d_j^1, \dots, d_j^{2k})$ be a game state in G. Then, the following are true.*

1. *If $s_j = a_p$ for some $p \in [k+1]$ and each vertex of S_p is occupied by a divider from $D_1, \dots, D_k$, then $\mathcal{S}_j$ is an almost-$\mathcal{R}$-safe state.*
2. *If $s_j = a_p$ for some $k+2 \leq p \leq 2k+2$, and each vertex of B_p is occupied by some divider from $D_1, \dots, D_k$, then $\mathcal{S}_j$ is an almost-$\mathcal{R}$-safe state.*

Proof. First, we will show that if $s_j = a_p$ for some $p \in [k+1]$ and each vertex of S_p is occupied by a divider from $D_1, \dots, D_k$, then $\mathcal{S}_j$ is an almost-$\mathcal{R}$-safe state. Let the vertices of S_p be marked $v_1, \dots, v_k$, and without loss of generality, let us assume that $d_j^i = v_i$, for $i \in [k]$. The dividers will maintain the following invariant for $\ell \geq j$: $d(d_\ell^i, v_i) = d(s_\ell, a_p)$. (We have that $d(d_j^i, v_i) = d(s_j, a_p) = 0$.) This invariant will ensure that whenever $\mathcal{R}$ is at the vertex a_p, each vertex of S_p is occupied by some divider, and hence, $\mathcal{R}$ can never access a vertex of S_p. Let $j' > j$ be the smallest integer such that $s_{j'} \in V(G_{\mathcal{R}}) \cup V(G_{\mathcal{C}})$. If no such j' exists, then $\mathcal{S}_j$ is trivially almost-$\mathcal{R}$-safe state, and hence we assume that j' exists. To establish that $\mathcal{S}_j$ is an almost-$\mathcal{R}$-safe state, we need to show the following:

1. $s_{j'} \in R_{\mathcal{R}}$: This is easy to see since $S_p \cup R_{\mathcal{R}}$ separates a_p from each vertex in $R_{\mathcal{J}} \cup C_{\mathcal{R}} \cup C_{\mathcal{J}}$ and whenever $\mathcal{R}$ is at a_p, all vertices of S_p are occupied by the dividers.
2. $\mathcal{S}_{j'}$ is a $\mathcal{R}$-safe state: To ensure this, the dividers implement the following strategy which maintains the invariant $d(d^i_\ell, v_i) = d(s_\ell, a_p)$ (for $\ell \geq j$ and $i \in [k]$). Let $\gamma \geq j$ be the least integer such that $s_\gamma = a_p$ and $s_{\gamma+1} \neq a_p$. Observe that there is a unique vertex $v_{\mathcal{R}}$ in $R_{\mathcal{R}}$ such that $d(s_{\gamma+1}, v_{\mathcal{R}}) = \alpha$. (For every other vertex $w_{\mathcal{R}} \in R_{\mathcal{R}} \setminus \{v_{\mathcal{R}}\}$, $\alpha + 1 \leq d(s_{\gamma+1}, v_{\mathcal{R}}) \leq \alpha + 2$). Since k cops have a winning strategy in H, due to Observation 16, we know that there exists a safe state $\mathcal{G} = (v, u_1, \dots, u_k)$ in H such that $u_1, \dots, u_k \in C$. Moreover, due to Observation 14, we know that, a game state $\mathcal{S}_{j''} = (s_{j''} = v_{\mathcal{R}}, t_{j''}, d^1_{j''}, \dots, d^{2k}_{j''})$ such that, for $i \in [k]$, $d^i_{j''} = u_{i\mathcal{R}}$ is a $\mathcal{R}$-safe state. Now, each divider D_i chooses chooses a $v_i, u_{i\mathcal{R}}$-path, say P_i, of length $\alpha + 1$ and move on this path to maintain the invariant $d(d^i_\ell, v_i) = d(s_\ell, a_p)$ (for $\ell \geq j$ and $i \in [k]$). Now, we distinguish the following two cases:
   a. For $\gamma < \gamma' < j'$, $s_{\gamma'} \neq a_p$. In this case, observe that $s_{j'} = v_{\mathcal{R}}$ and $d^i_{j'} = u_{i\mathcal{R}}$, for $i \in [k]$, which gives a $\mathcal{R}$-safe state.
   b. There is some $\gamma < \gamma' < j'$, such that $s_{\gamma'} = a_p$. Observe that the game state $\mathcal{S}_{\gamma'}$ is identical to the state $\mathcal{S}_j$ from the perspective of $\mathcal{R}$ and $D_1, \dots, D_k$ (due to our invariant). Hence, the dividers $D_1, \dots, D_k$ can restart their strategy that they had starting from $\mathcal{S}_j$.

Second, we will establish that if $s_j = a_p$ for some $k+2 \leq p \leq 2k+2$ and each vertex of B_p is occupied by a divider from $D_1, \dots, D_k$, then $\mathcal{S}_j$ is an almost-$\mathcal{R}$-safe state. It follows directly from our construction of G that for each vertex $y \in C_{\mathcal{R}}$ and $z \in B_p$, there is a y, z-path of length $\alpha + 2$ (that passes through W and $C_{\mathcal{J}}$). Similarly, for each vertex $z \in R_{\mathcal{R}}$, there is a a_p, z-path of length $\alpha + 2$. The proof is similar to the proof of the first case and hence we will provide the proof in a succinct manner. Let the vertices of B_p be marked $v_1, \dots, v_k$, and without loss of generality let us assume that $d^i_j = v_i$ (for $i \in [k]$). Furthermore, let the vertices of S_p be marked $x_1, \dots, x_k$ and let the unique vertex connected a_p and x_i be y_i. Now, the dividers will use the following strategy for $j' \geq j$ while always maintaining the invariant: $d(s_{j'}, a_p) = d(d^i_{j'}, v_i)$ for $i \in [k]$.

- If $s_{j'} = y_q$ for some $q \in [k]$, then for each $i \in [k]$, the divider D_i moves to the vertex x_i, i.e., $d^i_{j'} = x_i$. Observe that this ensures that $\mathcal{R}$ can never reach a vertex of S_p, and hence, whenever $\mathcal{R}$ will enter a vertex of $C_{\mathcal{R}} \cup C_{\mathcal{J}} \cup R_{\mathcal{R}} \cup R_{\mathcal{J}}$, it will do so at a vertex of $R_{\mathcal{R}}$.
- If $s_{j'-1} = a_p$ and $s_{j'} \notin \{a_p\} \cup \{y_1, \dots, y_p\}$. Then, let v be the unique vertex in $R_{\mathcal{R}}$ such that $d(v, s_{j'}) = \alpha + 1$. Since k cops have a winning strategy in H, due to Observation 16, we know that there exists a safe state $\mathcal{G} = (v, u_1, \dots, u_k)$ in H such that $u_1, \dots, u_k \in C$. Moreover, due to Observation 14, we know that, a game state $\mathcal{S}_{j''} = (s_{j''} = v_{\mathcal{R}}, t_{j''}, d^1_{j''}, \dots, d^{2k}_{j''})$ such that, for $i \in [k]$, $d^i_{j''} = u_{i\mathcal{R}}$ is a $\mathcal{R}$-safe state. Now, each divider D_i chooses chooses a $v_i, u_{i\mathcal{R}}$-path, say P_i, of length $\alpha + 2$ and move on this path to maintain the invariant $d(d^i_\ell, v_i) = d(s_\ell, a_p)$ (for $\ell \geq j$ and $i \in [k]$). If $\mathcal{R}$ reaches the vertex $v_{\mathcal{R}}$, then observe that we have reached a safe state. Otherwise, if $\mathcal{R}$ reaches to a_p in some round $\gamma > j'$, then we restart our strategy.

This completes our proof. ◀

Next, we have the following lemma, whose proof is identical to the proof of Lemma 17.

▶ **Lemma 18.** *Let k cops have a winning strategy in H against the robber starting at r. Moreover, let $\mathcal{S}_j = (s_j, t_j, d^1_j, \dots, d^{2k}_j)$ be a game state in G. Then, the following are true.*

1. *If $t_j = a_p$ for some $p \in [k+1]$ and each vertex of B_p is occupied by a divider from $D_{k+1}, \dots, D_{2k}$, then $\mathcal{S}_j$ is an almost-$\mathcal{J}$-safe state.*
2. *If $s_j = a_p$ for some $k+2 \leq p \leq 2k+2$, and each vertex of S_p is occupied by some divider from $D_{k+1}, \dots, D_{2k}$, then $\mathcal{S}_j$ is an almost-$\mathcal{J}$-safe state.*

The following observation is directly implied by our construction.

▶ **Observation 19.** *Consider the connected components of the graph $G[V(G) \setminus (C_{\mathcal{R}} \cup C_{\mathcal{J}} \cup S_1 \cup \cdots \cup S_{2k})]$. The components containing $R_{\mathcal{R}}$ and the component containing $R_{\mathcal{J}}$ are disjoint, and let them be named $F_{\mathcal{R}}$ and $F_{\mathcal{J}}$, respectively.*

Due to Observation 19, if we can show that k of the dividers, say $D_1, \ldots, D_k$, can restrict $\mathcal{R}$ from entering any vertex of $C_{\mathcal{R}} \cup C_{\mathcal{J}} \cup S_1 \cup \cdots \cup S_{2k}$, and the other k dividers, say $D_{k+1}, \ldots, D_{2k}$ can restrict $\mathcal{J}$ from entering any vertex of $C_{\mathcal{R}} \cup C_{\mathcal{J}} \cup S_1 \cup \cdots \cup S_{2k}$, then $\mathcal{R}$ and $\mathcal{J}$ never be able to meet as they will be restricted to disjoint subgraphs $F_{\mathcal{R}}$ and $F_{\mathcal{J}}$, respectively, of G. We use a similar strategy to prove the following lemma, which proves the other side of our reduction.

▶ **Lemma 20.** *If k cops have a winning strategy in H against the robber starting at r, then $2k$ dividers have a winning strategy in G against $\mathcal{R}$ and $\mathcal{J}$ starting at $r_{\mathcal{R}}$ and $r_{\mathcal{J}}$, respectively.*

Proof. Since k cops have a winning strategy against the robber starting at r in H, there is a safe state $\mathcal{G}_0 = (r_0 = r, c_0^1, \ldots, c_0^k)$. Now, we begin Romeo and Juliet on G with the game state $\mathcal{S}_0 = (s_0 = r_{\mathcal{R}}, t_0 = r_{\mathcal{J}}, d_0^1, \ldots, d_0^{2k})$ such that if $c_0^\ell = v$, for $\ell \in [k]$, then $d_0^\ell = v_{\mathcal{R}}$ and $d_0^{\ell+k} = v_{\mathcal{J}}$. It follows from Observations 14 and 15 that $\mathcal{S}_0$ is $\mathcal{R}$-safe state as well as $\mathcal{J}$-safe state. Therefore, as long as $\mathcal{R}$ (resp., $\mathcal{J}$) is restricted to $G_{\mathcal{R}}$ (resp., $G_{\mathcal{J}}$), they cannot enter a vertex of $C_{\mathcal{R}}$ (resp., $C_{\mathcal{J}}$). Hence, unless at least one of $\mathcal{R}$ or $\mathcal{J}$ leaves $G_{\mathcal{R}}$ or $G_{\mathcal{J}}$, respectively, to move to some G_i, for $i \in [2k+2]$, they cannot meet. First, we prove the following claim.

▷ Claim 21. Let $\mathcal{S}_j$ be a $\mathcal{R}$-safe state such that $s_{j+1} \notin R_{\mathcal{R}}$. Then, for $j' > j$, the dividers $D_1, \ldots, D_k$ have a strategy that can ensure the following:

1. $s_{j'} \in F_{\mathcal{R}}$.
2. If $s_{j'} \in R_{\mathcal{R}}$, then $\mathcal{S}_{j'}$ is a $\mathcal{R}$-safe state.

Proof of Claim. Let P_x be the unique x, a_p-path that contains s_{j+1}. For $\ell \in [k]$, let $d_j^\ell = y_\ell$ (i.e., in round j, the divider D_ℓ occupies the vertex $y_\ell \in C_{\mathcal{R}}$). We distinguish the following two cases depending on whether $p \leq k$ or $p > k$.

Case 1: $p \leq k$. Let the vertices of S_p be marked $v_1, \ldots, v_k$. It follows from the construction that $d(y_\ell, v_\ell) = \alpha + 1$ and $d(x, a_p) = \alpha + 1$. Each D_ℓ chooses a y_ℓ, v_ℓ-path of length $\alpha + 1$, say P_ℓ, and move along it to maintain the following invariant for $j' > j$: $d(s_{j'}, a_p) = d(d_{j'}^\ell, v_\ell)$. Again, we have the following cases depending on the moves of $\mathcal{R}$.

1. $\mathcal{R}$ never reaches the vertex a_p: In this case observe that when $\mathcal{R}$ moves to $R_{\mathcal{R}}$, say in round j', it can only move to the vertex x (i.e., $s_{j'} = x$). In this case, observe that $d_{j'}^\ell = y_\ell$. Since this state is identical to $\mathcal{S}_j$ with respect to the placement of $\mathcal{R}$ and the dividers $D_1, \ldots D_k$, $\mathcal{S}_{j'}$ is a $\mathcal{R}$-safe state. Moreover, it is easy to see that $\mathcal{R}$ was restricted to $F_{\mathcal{R}}$ for each round $j \leq j'' \leq j'$.
2. $\mathcal{R}$ reaches the vertex a_p in some round j'': In this case, observe that each vertex v_ℓ of S_p is occupied by the divider D_ℓ (due to our invariant), and hence, $\mathcal{R}$ cannot move to a vertex of S_p in round $j'' + 1$. Observe that the game state $\mathcal{S}_{j''}$ is an almost-$\mathcal{R}$-safe state due to Lemma 17. Therefore $\mathcal{R}$ is restricted to $F_{\mathcal{R}}$ and whenever $\mathcal{R}$ reaches a vertex of $R_{\mathcal{R}}$ in some round j', then $\mathcal{S}_{j'}$ is a $\mathcal{R}$-safe state due to the definition of almost-$\mathcal{R}$-safe state.

Case 2: $p > k$. The proof of this case is similar to the proof of Case 1. Let the vertices of B_p be marked $v_1, \ldots, v_k$. It follows from the construction that $d(y_\ell, v_\ell) = \alpha + 2$ and $d(x, a_p) = \alpha + 2$. Each D_ℓ chooses a y_ℓ, v_ℓ-path of length $\alpha + 2$, say P_ℓ, and move along it to maintain the following invariant for $j' > j$: $d(s_{j'}, a_p) = d(d^\ell_{j'}, v_\ell)$. If $\mathcal{R}$ never reaches the vertex a_p, then our invariant implies that whenever $\mathcal{R}$ will enter $R_\mathcal{R}$, it will enter at a safe state. If $\mathcal{R}$ reaches the vertex a_p, then each vertex of B_p is occupied by a divider (due to our invariant), which is an almost-$\mathcal{R}$-safe state due to Lemma 17. Hence, if $\mathcal{R}$ enters a vertex $R_\mathcal{R}$ in some round j', then $\mathcal{S}_{j'}$ is a $\mathcal{R}$-safe state. Further, observe that in all these rounds, $\mathcal{R}$ is restricted to $F_\mathcal{R}$. This completes the proof of this case. ◁

Next, we have the following claim whose proof is symmetric to the proof of Claim 21.

▷ Claim 22. Let $\mathcal{S}_j$ be a $\mathcal{J}$-safe state such that $t_{j+1} \notin R_\mathcal{J}$. Then, for $j' > j$, the dividers $D_{k+1}, \ldots, D_{2k}$ have a strategy that can ensure the following:

1. $t_{j'} \in F_\mathcal{J}$.
2. If $t_{j'} \in R_\mathcal{J}$, then $\mathcal{S}_{j'}$ is a $\mathcal{J}$-safe state.

Finally, our proof follows from the following facts. Since we start from a state that is $\mathcal{R}$-safe state as well as $\mathcal{J}$-safe state, as long as $\mathcal{R}$ (resp., $\mathcal{J}$) is restricted to $G_\mathcal{R}$ (resp., $G_\mathcal{J}$), they cannot enter a vertex of $C_\mathcal{R}$ (resp., $C_\mathcal{J}$). Moreover, even if $\mathcal{R}$ (resp., $\mathcal{J}$) leave $G_\mathcal{R}$ (resp., $G_\mathcal{J}$), it is restricted to $F_\mathcal{R}$ (resp. $F_\mathcal{J}$), and whenever $\mathcal{R}$ (resp., $\mathcal{J}$) return to $G_\mathcal{R}$ (resp., $G_\mathcal{J}$), it returns to a $\mathcal{R}$-safe state (resp., $\mathcal{J}$-safe state), due to Claim 21 (resp., Claim 22). Since this strategy restricts $\mathcal{R}$ and $\mathcal{J}$ to two disjoint subgraphs $F_\mathcal{R}$ and $F_\mathcal{J}$, respectively, of G, $\mathcal{R}$ and $\mathcal{J}$ will never be able to meet. Hence, $2k$ dividers have a winning strategy in G against $\mathcal{R}$ and $\mathcal{J}$ starting at $r_\mathcal{R}$ and $r_\mathcal{J}$, respectively. This completes our proof. ◀

Finally, we haven the following theorem due to our construction of G from H, Propositions 5 and 7, and Lemmas 13 and 20.

▶ **Theorem 1.** *Romeo and Juliet is EXPTIME-complete for undirected graphs.*

4 EXPTIME-Completeness for Directed Graphs

In this section, we establish that Romeo and Juliet is EXPTIME-complete on directed graphs. Due to Proposition 5, to complete our proofs, we only need to establish that Romeo and Juliet is EXPTIME-hard. To this end, we will reduce Guard to Romeo and Juliet on directed graphs. This is a rather straightforward and easy construction.

Construction. Let $(\overrightarrow{G}, k, r)$ be an instance of Guard (where r is the starting position of the robber and $V(\overrightarrow{G})$ consists of the $C \cup R$). We construct an instance $(\overrightarrow{H}, k, s, t)$ in the following manner. Let $V(\overrightarrow{H}) = V(\overrightarrow{G}) \cup \{s, t, d_1, \ldots, d_k\}$, and let $D = \{d_1, \ldots, d_k\}$. Next, $E(\overrightarrow{H}) = E(\overrightarrow{G}) \cup \{\overrightarrow{sr}, \overrightarrow{sd_1}, \ldots, \overrightarrow{sd_k}, \overrightarrow{d_1t}, \ldots, \overrightarrow{d_kt}\}$. Moreover, for each d_i, $i \in [k]$, and $v \in C$, we add an arc $\overrightarrow{d_ic}$. Furthermore, for each vertex $u \in C$, we add an arc $\overrightarrow{ut}$. See Figure 3 for an illustration. Finally, the starting position for $\mathcal{R}$ is s and for $\mathcal{J}$ is t. This completes the construction. The following observation follows directly from our construction.

▶ **Observation 23.** *The following statements are true.*

1. *The vertex t is a sink, and hence $\mathcal{J}$ cannot move throughout the game.*
2. *If at any point in the game $\mathcal{R}$ is on a vertex in C, then $\mathcal{R}$ and $\mathcal{J}$ meet in the next step.*
3. *If there are less than k dividers, then $\mathcal{R}$ and $\mathcal{J}$ meet in at most 2 rounds.*

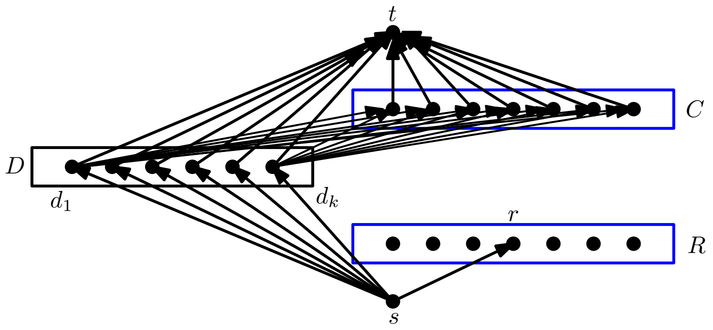

Figure 3 Here, we do not show edges of $\overrightarrow{G}$ to ease the presentation.

Proof. The proof of (1) and (2) follows directly from the construction and the game definition. To see the proof of (3), observe that if there are less than k dividers, there is at least one vertex in D, say x, that is not occupied by any of the dividers (since $|D| = k$). Hence, $\mathcal{R}$ can move to x in the first round, and since $\overrightarrow{xt}$ is an edge, $\mathcal{R}$ and $\mathcal{J}$ meet in the next round. ◀

The following lemma proves the soundness of our reduction.

▶ **Lemma 24.** *In $\overrightarrow{G}$, k cops have winning strategy against the robber starting at r if and only if k dividers have a winning strategy in $\overrightarrow{H}$ against $\mathcal{R}$ and $\mathcal{J}$ starting at s and t, respectively.*

Proof. In one direction, let k cops have a strategy to prevent the robber, who starts at r, from entering C. Then, we prove that k dividers have a winning strategy $\overrightarrow{H}$ against $\mathcal{R}$ and $\mathcal{J}$ starting at s and t, respectively. The k dividers begin with occupying each vertex of D. This restricts $\mathcal{R}$ from entering a vertex of D. Recall that $\mathcal{J}$ cannot move throughout the game (due to Observation 23). Now, the only move possible for $\mathcal{R}$ is to move to vertex r from s. Whenever $\mathcal{R}$ moves to r, the dividers move to the vertices in C where the cops begin in their winning strategy in $\overrightarrow{G}$. Now, observe that $\mathcal{R}$ cannot access s or any vertex in D. Hence, the dividers can restrict $\mathcal{R}$ and $\mathcal{J}$ from meeting by simply restricting $\mathcal{R}$ to ever enter C. Note that the the dividers can do so following the winning strategy for the cops as the rules of movement are the same for both of the games. Hence, k dividers have a winning strategy in $\overrightarrow{H}$ against $\mathcal{R}$ and $\mathcal{J}$ starting at s and t, respectively.

In the other direction, let the robber has a strategy to enter C in G starting from r. In this case, observe that in the beginning, k dividers have to occupy the vertices of D, else $\mathcal{R}$ and $\mathcal{J}$ meet in at most two steps ($\mathcal{R}$ moves to a vertex in D and then meet $\mathcal{J}$ in the next round). Now, $\mathcal{R}$ moves to r from s. Now, at most k dividers move to C. Since the dividers can make the same moves as cops and the robber have a winning strategy against any strategy of k cops to enter C starting from r, $\mathcal{R}$ can use the same strategy to enter C. Hence, $\mathcal{R}$ can enter C after a finite number of rounds, and then meet $\mathcal{J}$ in the next round at t (due to Observation 23). ◀

Hence, we have the following theorem as a consequence of our reduction, Propositions 5 and 7, and Lemma 24.

▶ **Theorem 2.** *Romeo and Juliet is EXPTIME-complete for oriented graphs.*

5 Conclusion

In this work, we considered Romeo and Juliet on directed as well as undirected graphs and established that the game is EXPTIME-complete in both cases, and that the game remains PSPACE-complete even for directed acyclic graphs. Moreover, we defined a game Relaxed Romeo and Juliet that provides a framework for extending the hardness results of Romeo and Juliet in Time on undirected graphs to Romeo and Juliet on DAGs.

It may be an interesting question to figure out if Romeo and Juliet in Time is also EXPTIME-complete as conjectured by Fomin, Golovach, and Thilikos [12]. Moreover, it is known that, assuming ETH, Romeo and Juliet cannot be solved in $n^{o(k)}$ (i.e., $2^{o(k \log n)}$) time [12]. It might be interesting to see if this result can be extended to a lower bound of the form $2^{o(n)}$. Note that this result will be incomparable to the current known bound as k can be $\mathcal{O}(n)$. Aigner and Fromme [1] established that the cop number for planar graphs is at most 3 by the use of a guarding lemma that states that 1 cop can guard the vertices of an isometric path. It is easy to see that the dynamic separation number of planar graphs is unbounded, for eg., consider $K_{2,n}$ and let s, t be the vertices of the partition with two vertices. It might be interesting to figure out the computational complexity of Romeo and Juliet on planar graphs, and more generally, graphs on surfaces.

Abstract

For graphs G and H, an H-coloring of G is an edge-preserving mapping from $V(G)$ to $V(H)$. Note that if H is the triangle, then H-colorings are equivalent to 3-colorings. In this paper we are interested in the case that H is the five-vertex cycle C_5.

A minimal obstruction to C_5-coloring is a graph that does not have a C_5-coloring, but every proper induced subgraph thereof has a C_5-coloring. In this paper we are interested in minimal obstructions to C_5-coloring in F-free graphs, i.e., graphs that exclude some fixed graph F as an induced subgraph. Let P_t denote the path on t vertices, and let $S_{a,b,c}$ denote the graph obtained from paths $P_{a+1}, P_{b+1}, P_{c+1}$ by identifying one of their endvertices.

We show that there is only a finite number of minimal obstructions to C_5-coloring among F-free graphs, where $F \in \{P_8, S_{2,2,1}, S_{3,1,1}\}$ and explicitly determine all such obstructions. This extends the results of Kamiński and Pstrucha [Discr. Appl. Math. 261, 2019] who proved that there is only a finite number of P_7-free minimal obstructions to C_5-coloring, and of Dębski et al. [ISAAC 2022 Proc.] who showed that the triangle is the unique $S_{2,1,1}$-free minimal obstruction to C_5-coloring.

We complement our results with a construction of an infinite family of minimal obstructions to C_5-coloring, which are simultaneously P_{13}-free and $S_{2,2,2}$-free. We also discuss infinite families of F-free minimal obstructions to H-coloring for other graphs H.

1 Introduction

Out of a great number of interesting and elegant graph problems, the notion of graph coloring is, arguably, among the most popular and well-studied ones, not only from combinatorial, but also from algorithmic point of view. For an integer $k \geq 1$, a *k-coloring* of a graph G is a function $c : V(G) \to \{1, \ldots, k\}$ such that for every edge $uv \in E(G)$ it holds that $c(u) \neq c(v)$. For a fixed integer $k \geq 1$, the k-Coloring problem is a computational problem in which an instance is a graph G and we ask whether there exists a k-coloring of G.

The k-Coloring problem is known to be polynomial-time solvable if $k \leq 2$ and NP-complete for larger values of k. Still, even if $k \geq 3$, it is often possible to obtain polynomial-time algorithms that solve k-Coloring if we somehow restrict the class of input instances, for example, to perfect graphs [14, 15], bounded-treewidth graphs [1] or intersection graphs of geometric objects [11].

Observe that these example classes are *hereditary*, i.e., closed under deleting vertices. Such a property is very useful in algorithm design, as it combines well with standard algorithmic techniques, like branching or divide-&-conquer. Therefore, if we want to study some computational problem in a restricted graph class $\mathcal{G}$, choosing $\mathcal{G}$ to be hereditary appears to be reasonable. For a fixed graph F, we say that a graph G is *F-free* if it does not contain F as an induced subgraph. If $\mathcal{F}$ is a family of graphs, we say that a graph G is *$\mathcal{F}$-free* if G is F-free for every $F \in \mathcal{F}$. Each hereditary class of graphs can be characterized by a (possibly infinite) family $\mathcal{F}$ of forbidden induced subgraphs.

Coloring hereditary graph classes. As a first step towards understanding the complexity of k-Coloring in hereditary classes it is natural to consider classes defined by a single induced subgraph F. If F contains a cycle or a vertex of degree at least 3, it follows from the classical results by Emden-Weinert [9], Holyer [20], and Leven and Galil [25] that for every $k \geq 3$, k-Coloring remains NP-complete when restricted to F-free graphs. Thus we are left with the case that F is a *linear forest*, i.e., every component of F is a path.

However, if F is a linear forest, the situation becomes more complicated. For simplicity, let us focus on the case when F is connected, i.e., F is a path on t vertices, denoted by P_t. Then, k-Coloring is polynomial-time-solvable in P_t-free graphs if $t \leq 5$, or if $(k, t) \in \{(3, 6), (3, 7), (4, 6)\}$ [21, 30, 2, 18]. On the other hand, for any $k \geq 4$, the k-Coloring problem is NP-complete in P_t-free graphs for all other values of t [21]. The complexity of the remaining cases, i.e., 3-Coloring of P_t-free graphs where $t \geq 8$, remains unknown: we do not know polynomial-time algorithms nor any hardness proofs. The general belief is that all these cases are in fact tractable, which is supported by the existence of a quasipolynomial-time algorithm for 3-Coloring in P_t-free graphs, for every fixed t [29]. For the summary of the results on the complexity of k-Coloring P_t-free graphs see Figure 1. Let us remark that there are also some results for disconnected forbidden linear forests [24, 6].

Figure 1 The complexity of k-Coloring P_t-free graphs.

Minimal obstructions to k-coloring. One can look at k-Coloring from another, purely combinatorial perspective. Instead of asking whether a graph G admits a k-coloring, we can ask whether it contains a *dual object*, i.e., some structure that forces the chromatic number to be at least $k + 1$. For example, 2-Coloring can be equivalently expressed as a question whether a graph contains an odd cycle. As another example, k-Coloring restricted to perfect graphs is equivalent to the question of the existence of a $(k + 1)$-clique, i.e., the complete graph on $k + 1$ vertices, denoted by K_{k+1}.

In other words, odd cycles are *minimal non-2-colorable graphs* and $(k + 1)$-cliques are *minimal non-k-colorable perfect graphs* (where minimality is defined with respect to the induced subgraph relation). Formally, if a graph G is not k-colorable, but every proper induced subgraph of it is k-colorable, we say that G is *vertex-$(k + 1)$-critical* or is a *minimal obstruction to k-coloring*. We denote by $\mathsf{Obstructions}(k)$ the set of all minimal obstructions to k-coloring. Note that $\mathsf{Obstructions}(k)$ naturally forms a family of dual objects – a graph is k-colorable if and only if it does not contain any graph from $\mathsf{Obstructions}(k)$ as an induced subgraph.

Suppose that, for some k, there is a polynomial-time algorithm Alg_k that takes as an input a graph G and answers whether it contains any graph from $\mathsf{Obstructions}(k)$ as an induced subgraph (i.e., whether G is *not* $\mathsf{Obstructions}(k)$-free). From the discussion above it follows that the existence of Alg_k yields a polynomial-time algorithm for k-Coloring. Thus it is unlikely that Alg_k exists for any $k \geq 3$. However, it is still possible when we restrict the input graphs to a certain class $\mathcal{G}$ (like perfect graphs in the example above). Recall that we are interested in the case that $\mathcal{G} = F$-free, where F is a path. Let us denote such a restriction Alg_k to F-free graphs by $\mathsf{Alg}_{k,F}$.

Note that the existence of $\mathsf{Alg}_{k,F}$ is trivial if $(\mathsf{Obstructions}(k) \cap F\text{-free})$ is finite; indeed, brute force works in this case. This line of arguments allows us to further refine cases that are polynomial-time solvable: into pairs (k, F), where $(\mathsf{Obstructions}(k) \cap F\text{-free})$ is finite, and the others. Recall that the algorithm for k-Coloring obtained for the former ones is able to produce a *negative certificate*: a small (constant-size) witness that the input graph is *not* k-colorable. We refer the reader to the survey of McConnell et al. [27] for more information about certifying algorithms.

It turns out that we can fully characterize all pairs (k, F) for which $\mathsf{Obstructions}(k) \cap F$-free is finite. It is well-known that P_4-free graphs (also known as *cographs*) are perfect and thus the only minimal obstruction to k-coloring is the $(k + 1)$-clique. Bruce et al. [3] proved that there is a finite number of minimal obstructions to 3-coloring among P_5-free graphs. The result was later extended by Chudnovsky et al. [4] who showed that the family of P_6-free minimal obstructions to 3-coloring is is also finite, and that this is no longer true among P_7-free graphs (and thus for P_t-free graphs for every $t \geq 7$). If the number of colors is larger, things get more difficult faster: Hoàng et al. [19] showed that for each $k \geq 4$ there exists an infinite family of P_5-free minimal obstructions to k-coloring. See also Figure 1.

H-coloring F-free graphs and minimal obstructions to H-colorings. Graph colorings can be seen as a special case of *graph homomorphisms.* For graphs G and H, an *H-coloring* of G is a function $c : V(G) \to V(H)$ such that for every edge $uv \in E(G)$ it holds that $c(u)c(v) \in E(H)$. The graph H is usually called the *target graph.* It is straightforward to verify that homomorphisms from G to the k-clique, are in one-to-one correspondence to k-colorings of G. For this reason one often refers to the vertices of H as *colors.*

For a fixed graph H, by H-Coloring we denote the computational problem that takes as an input a graph G and asks whether G admits a homomorphism to H. The complexity dichotomy for H-Coloring was proven by Hell and Nešetřil [16]: the problem is polynomial-time solvable if H is bipartite, and NP-complete otherwise.

The complexity landscape of H-Coloring in F-free graphs for non-complete target graphs is far from being fully understood. Chudnovsky et al. [5] proved that if H is an odd cycle on at least 5 vertices, then H-Coloring is polynomial-time solvable in P_9-free graphs; they also showed a number of hardness results for more general variants of the homomorphism problem. Feder and Hell [10] and Dębski et al. [8] studied the case when H is an *odd wheel*, i.e., an odd cycle with universal vertex added. The most general algorithmic results were provided by Okrasa and Rzążewski [28] who showed that

(OR1) if H does not contain C_4 as a subgraph, then H-Coloring can be solved in quasi-polynomial time in P_t-free graphs for any fixed t (note that a better running time here would also mean progress for 3-Coloring P_t-free graphs),

(OR2) if H is of girth at least 5, then H-Coloring can be solved in subexponential time in F-free graphs, where F is any fixed *subdivided claw*, i.e., any graph obtained from the three-leaf star by subdividing edges.

While these are not polynomial-time algorithms, no NP-hardness proofs for these cases are known either. To complete the picture, from [28] it also follows that if H is a so-called *projective core* that contains C_4 as a subgraph, then there exists a t such that H-Coloring is NP-complete in P_t-free graphs (and thus also in graphs excluding some fixed subdivided claw). Furthermore, the hardness reductions even exclude any subexponential-time algorithms for these cases, assuming the Exponential Time Hypothesis (ETH). Let us skip the definition of a projective core, as it is quite technical and not really relevant for this paper. However, it is worth pointing out that almost all graphs are projective cores [26, 17].

Since we are interested in a finer classification of polynomial-time-solvable cases, we should be looking at pairs (H, F) of graphs such that the H-Coloring problem is *not* known to be NP-complete in F-free graphs. From the discussion above it follows that there are two natural families of such pairs to consider:

(i) when H does not contain C_4 as a subgraph and F is a path,

(ii) when H is of girth at least 5 and F is a subdivided claw.

It is straightforward to generalize the notion of minimal obstructions to the setting of H-colorings. A graph G is called a *minimal obstruction to H-coloring* if there is no H-coloring of G, but every proper induced subgraph of G can be H-colored.

The area of minimal obstructions to H-coloring is rather unexplored. In the setting of (i), Kamiński and Pstrucha [23] showed that for any $t \geq 5$, there are finitely many minimal obstructions to C_{t-2}-coloring among P_t-free graphs.[1] In particular, the family of P_7-free

[1] While in [23] the authors consider minimality with respect to the *subgraph* relation, it is not hard to observe that bounded number of subgraph-minimal obstructions is equivalent to the bounded number of induced-subgraph-minimal obstructions.

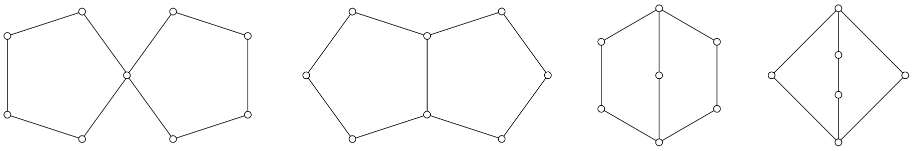

Figure 2 Graphs Q_1, Q_2, Q_3, and Q_4 (left to right).

minimal obstructions to C_5-coloring is finite. In the setting of (ii), Dębski et al. [8] showed that the triangle is the only minimal obstruction to C_5-coloring among graphs that exclude the *fork*, i.e., the graph obtained from the three-leaf star by subdividing one edge once.

Our contribution. As our first result, we show the following strengthening of the result of Kamiński and Pstrucha.

▶ **Theorem 1.** *There are 19 minimal obstructions to C_5-coloring among P_8-free graphs.*

Let us sketch the proof of Theorem 1. Note that K_3 is a minimal obstruction for C_5-coloring, so from now on we focus on graphs that are $\{P_8, K_3\}$-free. For $i \in \{1, 2, 3, 4\}$, by Q_i we denote the graph obtained from two copies of C_5 by identifying an i-vertex subpath of one cycle with an i-vertex subpath of the other one, see Figure 2. In the proof we separately consider minimal obstructions that contain some Q_i as an induced subgraph, and those that are $\{Q_1, Q_2, Q_3, Q_4\}$-free.

The intuition behind this is as follows. Notice that if G contains an induced 5-vertex cycle, the vertices of this cycle must be mapped to the vertices of C_5 bijectively, respecting the ordering along the cycle. Consequently, if G contains some Q_i, the colorings of the vertices in Q_i are somehow restricted. Combining several Q_i's we might impose some contradictory constraints and thus build a graph that is not C_5-colorable. However, as each Q_i already contains quite long induced paths, we might hope that by combining several Q_i we are either forced to create an induced P_8 (if we add only few edges between different Q_i's) or K_3 (if we add too many such edges). Thus the possibilities of building non-C_5-colorable graphs using this approach are somehow limited. It turns out that this intuition is correct: there are 18 graphs that are $\{P_8, K_3\}$-free and contain Q_i, for some $i \in \{1, 2, 3, 4\}$, as an induced subgraph. Together with K_3, they are shown in Figure 3. This part of the proof is computer-aided.

For the second step, we assume that our graph does not contain any Q_i, i.e., we consider graphs that are $\{P_8, K_3, Q_1, Q_2, Q_3, Q_4\}$-free. We show that such graphs are always C_5-colorable. Consequently, each minimal obstruction to C_5-coloring (and, in general, every graph that is not C_5-colorable) was discovered in step 1.

Before we discuss the second result, let us introduce the notation for subdivided claws. For integers $a, b, c \geq 1$, by $S_{a,b,c}$ we denote the graph obtained from the three-leaf star by subdividing each edge, respectively, $a - 1$, $b - 1$, and $c - 1$ times. Equivalently, $S_{a,b,c}$ is obtained from three paths $P_{a+1}, P_{b+1}, P_{c+1}$ by identifying one of their endpoints.

As our second result we show the following extension of the result of Dębski et al. [8].

▶ **Theorem 2.** *There are 3 minimal obstructions to C_5-coloring among $S_{2,2,1}$-free graphs, and 5 minimal obstructions to C_5-coloring among $S_{3,1,1}$-free graphs.*

These graphs are shown in Figure 4. The proof is similar to the proof of Theorem 1. First, we consider minimal obstructions that contain an induced C_5 and, using the computer search, we show that there is only a finite number of them. Then, we show that graphs that

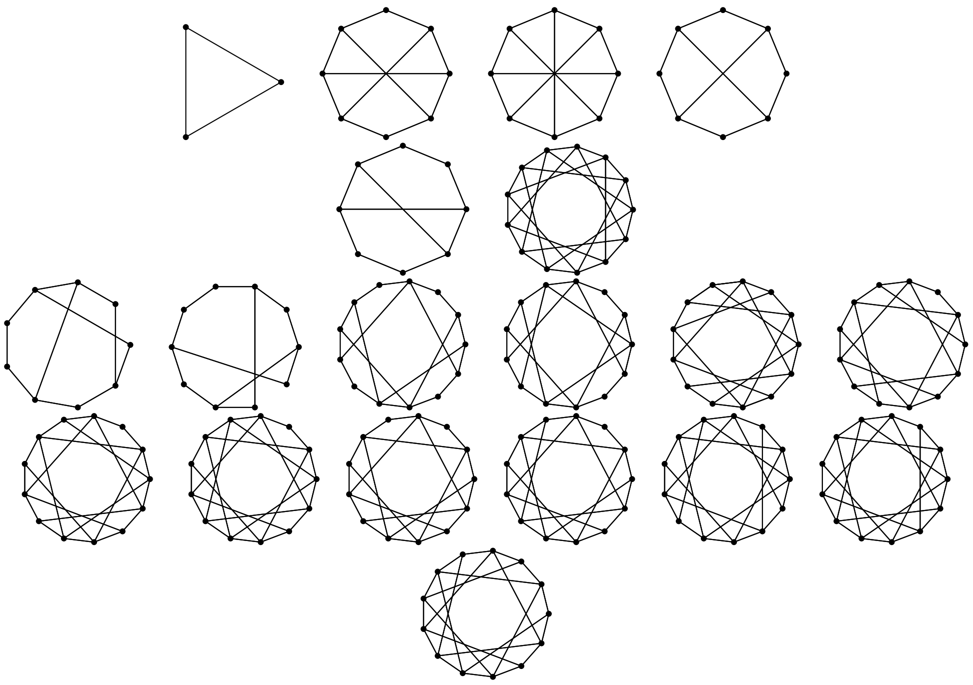

Figure 3 All P_8-free minimal obstructions to C_5-coloring. The graphs in the first row are P_6-free. The graphs in the second row are P_7-free, but not P_6-free. All other graphs are P_8-free, but not P_7-free.

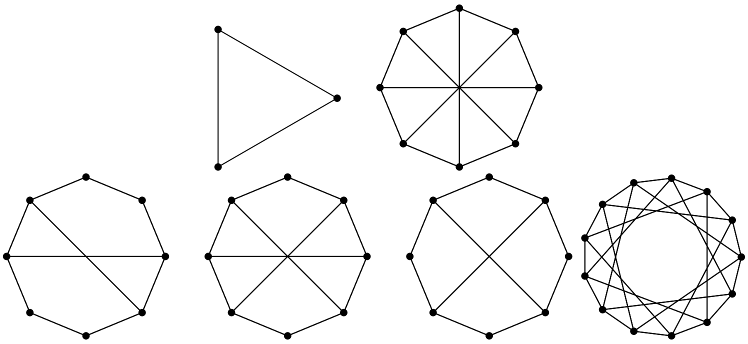

Figure 4 All $S_{2,2,1}$-free and all $S_{3,1,1}$-free minimal obstructions to C_5-coloring. The graphs in the first row are both $S_{2,2,1}$-free and $S_{3,1,1}$-free, whereas the first three graphs in the second row are $S_{3,1,1}$-free, but not $S_{2,2,1}$-free and the last graph in the second row is $S_{2,2,1}$-free, but not $S_{3,1,1}$-free.

exclude K_3 (as it is a minimal obstruction by itself), C_5, and also one of $S_{2,2,1}, S_{3,1,1}$, are either bipartite or are "blown-up cycles" – in both cases C_5-colorability is straightforward to show.

We complement these results with a construction of an infinite family of minimal obstructions to C_5-coloring.

▶ **Theorem 3.** *There is an infinite family of minimal obstructions to C_5-coloring, which simultaneously exclude P_{13}, $S_{2,2,2}$, $S_{5,5,1}$, $S_{11,1,1}$, and $S_{8,2,1}$ as an induced subgraph.*

The construction from Theorem 3 is obtained by generalizing the infinite family of P_7-free minimal obstructions to 3-coloring, provided by Chudnovsky et al. [4]. The idea can be further generalized. Let the *odd girth* of H be the length of a shortest odd cycle in H (and keep it undefined for bipartite graphs).

▶ **Theorem 4.** *Let $q \geq 3$ be odd, and let H be a graph of odd girth q that does not contain C_4 as a subgraph. There is an infinite family of minimal obstructions to H-coloring that are $\{P_{3q-1}, S_{2,2,2}, S_{3(q-1)/2,3(q-1)/2,1}\}$-free.*

Note that Theorem 4 gives a bound for every graph H that was discussed in (OR1) and (OR2). An astute reader might notice that applying Theorem 4 for $H = C_5$, i.e., $q = 5$, yields a family of obstructions that are in particular P_{14}-free and $S_{6,6,1}$-free, which does not match the bounds from Theorem 3. Indeed, obtaining the refined result from Theorem 3 requires some additional work, which again uses a mixture of combinatorial observations and computer search.

Organization of the paper. In Section 2 we introduce some notation and preliminary observations. In Section 3 we explain the algorithm that is later used to generate minimal obstructions. In Sections 4 and 5 we present, respectively, the overview of the proofs of Theorems 1 and 2 In Section 6 we provide constructions of infinite families of graphs that are then used to prove Theorems 3 and 4.

We refer the interested reader to the full version of this paper [12] for the proofs that were omitted due to space limitations (marked by (♠)), and for implementation details of our algorithms and how they were tested for correctness.

2 Preliminaries

For an integer $n \geq 1$ we denote by $[n]$ the set $\{1, \ldots, n\}$, and by $[n]_0$ the set $[n] \cup \{0\}$. For a graph $G = (V, E)$ and a vertex set $U \subseteq V$, the graph $G[U]$ denotes the subgraph of G induced by U. The graph $G - U$ denotes $G[V(G) \setminus U]$. The set $N_G(u)$ denotes the neighborhood of vertex u in the graph G. For $U \subseteq V(G)$ we define $N_G(U) = \bigcup_{u \in U} N_G(u) \setminus U$. If the graph G is clear from the context, we omit the subscript and write $N(u)$ and $N(U)$.

If there exists an H-coloring of G, we denote this fact by $G \to H$. It is straightforward to verify that if $G \to H$, then $\mathsf{odd\text{-}girth}(G) \geq \mathsf{odd\text{-}girth}(H)$. In particular, K_3 has no C_5-coloring and is actually a minimal obstruction to C_5-coloring. Consequently, every other minimal obstruction to C_5-coloring is K_3-free.

For any two graphs G and H such that G is H-colorable, the graph $\mathsf{hull}(G, H)$ denotes the graph with vertex set $V(G)$ and edge set $\{uv : u, v \in V(G)$ and for every H-coloring c of G, we have $c(u)c(v) \in E(H)\}$. Note that $\mathsf{hull}(G, H)$ is a supergraph of G that is H-colorable and that for every induced subgraph G' of G we have $E(\mathsf{hull}(G', H)) \subseteq E(\mathsf{hull}(G, H))$. Note that $\mathsf{hull}(G, H)$ might contain some induced subgraphs that do not appear in G.

3 Generating F-free minimal obstructions to H-coloring

In this section we describe an algorithm that can be used to generate all F-free minimal obstructions to H-coloring. We emphasize that this approach is robust in the sense that it does not assume that $H = C_5$ and F is a path or a subdivided claw, as needed for Theorems 1 and 2.

Throughout the section graphs H and F are fixed. We will use the term *minimal obstruction* for *minimal obstruction to H-coloring*. The algorithm takes as an input "the current candidate graph" I that it tries to extend to a minimal obstruction by adding a new vertex x and some edges between x and $V(I)$. In particular, the algorithm can be used to generate all F-free minimal obstructions by choosing I as the single-vertex graph.

This algorithm is similar to the algorithm for k-Coloring by [13], but we formulate it in a more general way. In case there are infinitely many minimal obstructions, the generation algorithm will never terminate. If there are only finitely many minimal obstructions, then the algorithm might still not terminate, since the prunning rules might not be strong enough. However, if the algorithm terminates, it is guaranteed that there are only finitely many minimal obstructions and that the algorithm outputs all of them.

Let us explain the algorithm, see also the pseudocode in Algorithm 1.

Algorithm 1 Expand.

```
Constants: target graph $H$, forbidden graph $F$
Input    : current graph $I$
Output   : exhaustive list of $F$-free minimal obstructions to $H$-coloring

if $I$ is $F$-free and not generated before then
    if $I$ is not $H$-colorable then
        if $I$ is a minimal obstruction to $H$-coloring then output $I$
else
    if $I$ contains comparable vertices $(u, v)$ then
        foreach graph $I'$ obtained from $I$ by adding a new vertex $x$ and edges between
          $x$ and vertices in $V(I)$ in all possible ways, such that $ux \in E(I')$, but
          $vx \notin E(\mathsf{hull}(I' - u, H))$ do
            Expand($I'$)
    else if $I$ contains comparable edges $(uv, u'v')$ then
        foreach graph $I'$ obtained from $I$ by adding a new vertex $x$ and edges between
          $x$ and vertices in $V(I)$ in all possible ways, such that $rx \in E(I')$, but
          $r'x \notin E(\mathsf{hull}(I' - \{u, v\}, H)))$ for some $r \in \{u, v\}$ do
            Expand($I'$)
    else
        foreach graph $I'$ obtained from $I$ by adding a new vertex $x$ and edges between
          $x$ and vertices in $V(I)$ in all possible ways do
            Expand($I'$)
```

It starts from a graph I and recursively expands this graph by adding a vertex and edges between this new vertex and existing vertices in each recursive step. The expansion is based on expansion rules that aim at reducing the search space while ensuring that no minimal obstructions are lost in this operation. For example, if an expansion leads to a graph I' that is not F-free, the recursion can be stopped, because all further expansions of I' will not be F-free either (note that we do not add any edges inside $V(I)$ and that the class of F-free graphs is hereditary). Another way to restrict the search space is based on Lemma 5. This lemma and its proof follow Lemma 5 from [4] concerning k-Coloring, but generalizing it to H-Coloring required some adjustments.

▶ **Lemma 5 (♠).** *Let $G = (V, E)$ be a minimal obstruction to H-coloring and let U and W be two non-empty disjoint vertex subsets of G. Let $J := \mathsf{hull}(G - U, H)$. If there exists a homomorphism ϕ from $G[U]$ to $J[W]$, then there exists a vertex $u \in U$ for which $N_G(u) \setminus U \not\subseteq N_J(\phi(u))$.*

As isomorphism is a special type of a homomorphism, Lemma 5 immediately yields the following corollary.

▶ **Corollary 6.** *Let G be an H-colorable graph that is an induced subgraph of a minimal obstruction G'. Let $U, W \subseteq V(G)$ be two non-empty disjoint vertex subsets and let $J := \mathsf{hull}(G - U, H)$. If there exists an isomorphism $\phi : G[U] \to J[W]$ such that $N_G(u) \setminus U \subseteq N_J(\phi(u))$ for all $u \in U$, then there exists a vertex $x \in V(G') \setminus V(G)$ such that x is adjacent to some vertex $u \in U$, but x is not adjacent to $\phi(u)$ in $\mathsf{hull}(G' - U, H)$ (and thus also not adjacent to $\phi(u)$ in $\mathsf{hull}(G'[V(G) \cup \{x\} \setminus U], H)$).*

Actually, we will only use the restricted version of Corollary 6. In what follows we use the notation and assumptions of the Corollary. In case that $|U| = |W| = 1$, say $U = \{u\}$ and $W = \{w\}$, we call the pair (u, w) *comparable vertices*. In case that $G[U]$ and $J[W]$ are both isomorphic to K_2 and, say, $U = \{u, u'\}$ and $W = \{w, w'\}$, we call the pair (uu', ww') *comparable edges*. The algorithm concentrates on finding comparable vertices and edges for computational reasons.

We refer the interested reader to the full version of this paper [12] for additional details about the efficient implementation of this algorithm, independent correctness verifications and sanity checks.

4 Minimal obstructions to C_5-coloring with no long paths

In this section we still only discuss C_5-colorings, thus we will keep writing *minimal obstructions* for *minimal obstructions for C_5-coloring*.

The algorithm from Section 3 was implemented for $H = C_5$ (the source code is made publicly available at [22]). We used the algorithm, combined with some purely combinatorial observations, to generate an exhaustive list of P_t-free minimal obstructions, where $t \leq 8$; see also Figure 3. The minimal obstructions can also be obtained from the database of interesting graphs at the *House of Graphs* [7] by searching for the keywords "minimal obstruction to C5-coloring".

4.1 P_t-free minimal obstructions for $t \in \{6, 7\}$

As a warm-up, let us reprove the result of Kamiński and Pstrucha [23] (in a slightly stronger form, as they did not provide the explicit list of minimal obstructions). It will also serve as a demonstration of the way how the algorithm from 3 is intended to be used.

An exhaustive list for $t \leq 6$ can be obtained by running the algorithm from Section 3 with parameters $(I = K_1, H = C_5, F = P_6)$.[2] This leads to the following observation.

▶ **Observation 7.** *There are four minimal obstructions for C_5-coloring among P_6-free graphs. All of these obstructions, except for the triangle K_3, are P_6-free and not P_5-free.*

Unfortunately, the same simple strategy already fails for $t = 7$. Indeed, the algorithm as presented in Section 3 does not terminate after running for several hours after calling it with parameters $(I = K_1, H = C_5, F = P_7)$. However, with relatively small adjustments, the algorithm is able to produce an exhaustive list of minimal obstructions in a few seconds.

The first adjustment has to do with the order in which the expansion rules are used. Note that the order in which the algorithm checks whether it can find comparable vertices and comparable edges does not affect the correctness of the algorithm, but it might affect

[2] Let us remark that it is a simple exercise to find this list by hand.

whether the algorithm terminates or not. For example, it could happen that by expanding in order to get rid of a pair of comparable vertices, a new pair of comparable vertices is introduced (and this could continue indefinitely). By applying a different expansion rule first, this can be avoided sometimes. For $F = P_7$, the algorithm was run by first looking for comparable vertices and then for comparable edges, except when $|V(I)| = 10$, in which case the algorithm first looks for comparable edges and then for comparable vertices.

The second adjustment is based on the following observation.

▶ **Observation 8 (♠).** *Every P_7-free minimal obstruction to C_5-coloring, except for the graph K_3, contains the cycle C_5 or the cycle C_7 as an induced subgraph.*

By Observation 8, the set of P_7-free minimal obstructions can be partitioned into three subsets:

(i) the triangle K_3,
(ii) minimal obstructions that are P_7-free but contain C_5 as an induced subgraph,
(iii) minimal obstructions that are P_7-free but contain C_7 as an induced subgraph.

Thus, running the algorithm for $(I = C_5, H = C_5, F = P_7)$ and $(I = C_7, H = C_5, F = P_7)$, respectively, we can generate the families (ii) and (iii). This yields the following result; recall that the finiteness of the family of minimal obstructions was already shown by Kamiński and Pstrucha [23].

▶ **Observation 9.** *There are six P_7-free minimal obstructions to C_5-coloring. Two of these obstructions are P_7-free, but not P_6-free.*

4.2 P_8-free minimal obstructions

This section is devoted to the proof of Theorem 1, which we restate below (see also Figure 3).

▶ **Theorem 1.** *There are 19 minimal obstructions to C_5-coloring among P_8-free graphs.*

Similarly to the P_7-free case, the proof uses the algorithm from Section 3, but this time it requires a lot more purely combinatorial insights. For $i \in [4]$, let Q_i be the graph obtained from two disjoint copies of C_5 by identifying i pairs of consecutive corresponding vertices of the cycles (see Figure 2). Let G be a P_8-free minimal obstruction; we aim to understand the structure of G and show that is must be one of 19 graphs in Figure 3. We split the reasoning into two cases: first, we assume that G contains Q_i, for some $i \in [4]$, as an induced subgraph. Then, in the second case, we assume that G is $\{Q_1, Q_2, Q_3, Q_4\}$-free.

Case 1: G contains Q_i for some $i \in [4]$ as an induced subgraph. We deal with this case using the algorithm from Section 3. The algorithm terminates in a few minutes when it is called with the parameters $(I = Q_i, H = C_5, F = P_8)$ for all $i \in [4]$. All minimal obstructions obtained this way are listed in Figure 3.

Case 2: G does not contain Q_i for any $i \in [4]$. As K_3 is a minimal obstruction, from now on we can assume that G is $\{P_8, K_3, Q_1, Q_2, Q_3, Q_4\}$-free. We aim to show that all such graphs are C_5-colorable, i.e., the list obtained in Case 1, plus the triangle, is exhaustive.

▶ **Lemma 10 (♠).** *Let G be a $\{P_8, K_3, Q_1, Q_2, Q_3, Q_4\}$-free graph. Then G is C_5-colorable.*

5 Minimal obstructions to C_5-coloring with no long subdivided claws

This section is devoted to the proof of Theorem 2.

▶ **Theorem 2.** *There are 3 minimal obstructions to C_5-coloring among $S_{2,2,1}$-free graphs, and 5 minimal obstructions to C_5-coloring among $S_{3,1,1}$-free graphs.*

The minimal obstructions are shown in Figure 4 and can also be obtained from the database of interesting graphs at the *House of Graphs* [7] by searching for the keywords “S221-free minimal obstruction to C5-coloring” and “S311-free minimal obstruction to C5-coloring”, respectively. As in this section the target graph is always C_5, we will keep writing *minimal obstructions* for *minimal obstructions to C_5-coloring.* We proceed similarly as in the proof of Theorem 1. Let G be an $S_{2,2,1}$-free (respectively, $S_{3,1,1}$-free) minimal obstruction. We again consider two cases.

Case 1: G contains C_5 as an induced subgraph. This case is solved using the algorithm from Section 3. The algorithm is called with the parameters $(I = C_5, H = C_5, F = S_{2,2,1})$ and then with parameters $(I = C_5, H = C_5, F = S_{3,1,1})$. Both calls terminate, returning a finite list of minimal obstructions.

Case 2: G does not contain C_5 as an induced subgraph. Similarly as in the proof of Theorem 1, note that K_3 is a minimal $\{F, C_5\}$-free obstruction for $F \in \{S_{2,2,1}, S_{3,1,1}\}$. Thus, from now on, we assume that G is K_3-free and prove that there are no more minimal obstructions satisfying this case, i.e., the following result.

▶ **Lemma 11 (♠).** *Let $F \in \{S_{2,2,1}, S_{3,1,1}\}$ and let G be a $\{F, C_5, K_3\}$-free graph. Then G is C_5-colorable.*

Combining the cases, we obtain the statement of Theorem 2.

6 An infinite family of minimal obstructions

In this section we construct infinite families of graphs that will be later used to prove Theorems 3 and 4. The construction is a generalization of the one designed for 3-Coloring [4]; the authors attribute it to Pokrovskiy.

The construction. For every odd $q \geq 3$ and every $p \geq 1$, let $G_{q,p}$ be the graph on vertex set $[qp-3]_0$ (all arithmetic operations on $[qp-3]_0$ here are done modulo $qp-2$), such that for every $i \in [qp-3]_0$ it holds that

$$N(i) = \{i-1, i+1\} \cup \{i + qj - 1 \mid j \in [p-1]\}.$$

To simplify the arguments, we partition $V(G_{q,p})$ into q sets $V_s = \{i \mid i = s \mod q\}$, where $s \in [q-1]_0$. Next observation follows immediately from the definition of $E(G_{q,p})$.

▶ **Observation 12.** *Let $q \geq 3$ be odd, and let $ij \in E(G_{q,p})$ be such that $i \in V_s$ for some $s \in [q-1]_0$. If $i < j$, then $j \in V_{s-1}$, or $j = i+1$, or $i = 0$ and $j = qp-3$. Analogously, if $j > i$, then $j \in V_{s+1}$, or $j = i-1$, or $i = qp-3$ and $j = 0$.*

We now show that graphs $G_{q,p}$ are minimal obstructions to H-coloring for a rich family of graphs H.

▶ **Lemma 13 (♠).** *Let $q \geq 3$ be an odd integer, and let H be graph of odd girth q that does not contain C_4 as a subgraph. For every $p \geq 1$ the graph $G_{q,p}$ is a minimal obstruction to H-coloring.*

Excluded induced subgraphs of $G_{q,p}$. Now let us show an auxiliary lemma that will be helpful in analyzing induced subgraphs that (do not) appear in $G_{q,p}$. In particular, it implies that in order to prove that for each p, the graph $G_{q,p}$ is F-free for some graph F, it is sufficient to show that this statement holds for some small values of p.

▶ **Lemma 14.** *Let q be a fixed constant and F be a graph. Let $p \geq |V(F)| + 2$. If $G_{q,p-1}$ is F-free, then $G_{q,p}$ is F-free.*

Proof. Assume otherwise, and let $U \subseteq V(G_{q,p})$ induce a copy of F in $G_{q,p}$, in particular $|V(F)| = |U|$. Since $|V(F)| < qp-2$, we can assume without loss of generality that the vertex $qp-3$ does not belong to U. Since $|V(G_{q,p})| = qp-2 > q(|V(F)|+1)$, there exist $q+1$ consecutive vertices $\ell, \ldots, \ell+q$ that do not belong to U. Define $R = \{j \in U \mid j > \ell+q\}$, $R' = \{j-q \mid j \in R\}$, and let $L = U \setminus R$.

Now consider $U' = L \cup R'$, and note that $\ell \notin U'$. It is straightforward to verify that $U' \subseteq V(G_{q,p-1})$. We will show that U' induces a copy of F in $V(G_{q,p-1})$. Since this is a contradiction with our assumption, we then conclude that $G_{q,p}$ is F-free.

Let $i, j \in U'$, let $s \in [q-1]_0$ be such that $i \in V_s$. Assume without loss of generality that $i < j$. Note that it is enough to show that

- if $i, j < \ell$, then $ij \in E(G_{q,p-1})$ if and only if $ij \in E(G_{q,p})$,
- if $i, j > \ell$, then $ij \in E(G_{q,p-1})$ if and only if $(i+q)(j+q) \in E(G_{q,p})$,
- if $i < \ell < j$, then $ij \in E(G_{q,p-1})$ if and only if $i(j+q) \in E(G_{q,p})$.

The first item is straightforward.

For the second item, by Observation 12 we have that $ij \in E(G_{q,p-1})$ if and only if $j = i+1$ or $j \in V_{s-1}$. The first is equivalent to $j+q = (i+q)+1$, the latter is equivalent to $j+q \in V_{s-1}$. Hence again using Observation 12 we obtain that $ij \in E(G_{q,p-1})$ if and only if $(i+q)(j+q) \in E(G_{q,p})$.

For the last item, note that $i < \ell < j$ implies $i \in L$ and $j \in R'$. If $ij \in E(G_{q,p-1})$, then by Observation 12, either $j = i+1$ or $v_j \in V_{s-1}$. Since $i < \ell < j$, the first case is not possible. In the second case, if $v_j \in V_{s-1}$, then $j+q \in V_{s-1}$, so $i(j+q) \in E(G_{q,p})$. On the other hand, if $i(j+q) \in E(G_{q,p})$, then, since $i < \ell < j$, it cannot happen that $j+q = i+1$. If $j+q \in V_{s-1}$ then $j \in V_{s-1}$, so we conclude that $ij \in E(G_{q,p-1})$. That concludes the proof. ◀

The power of Lemma 14 is that in order to show that $G_{q,p}$ is F-free for *every* p, it is sufficient to prove it for a finite (and small) set of graphs. This is encapsulated in the following, immediate corollary.

▶ **Corollary 15.** *Let q be a fixed constant and F be a graph. If $G_{q,p}$ is F-free for every $p \leq |V(F)| + 1$, then $G_{q,p}$ is F-free for every p.*

Consequently, for every fixed q and F, Corollary 15 reduces the problem of showing that $G_{q,p}$ is F-free to a constant-size task that can be tackled with a computer.

Proof of Theorem 4 and Theorem 3. Now let us analyze what induced paths and subdivided claws appear in $G_{q,p}$. We start with showing that for every odd $q \geq 3$ and every $p \geq 1$ the graph $G_{q,p}$ is qK_2-free, i.e., they exclude an induced matching on q edges. Here, an induced matching is a set of edges that are not only pairwise disjoint, but also non-adjacent.

▶ **Lemma 16 (♠).** *Let $q \geq 3$ be an odd integer. For every $p \geq 1$ the graph $G_{q,p}$ is qK_2-free.*

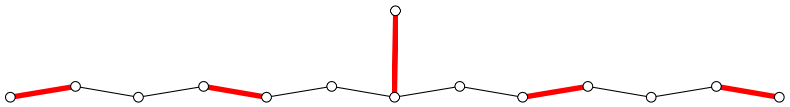

Figure 5 If a graph contains $S_{3(q-1)/2,3(q-1)/2,1}$ as an induced subgraph, then it also contains qK_2.

Let us remark that Lemma 16 is best possible, i.e., if p is large enough, then $G_{q,p}$ contains $(q-1)K_2$ as an induced subgraph. We do not prove it, as later, in Lemma 19, we will show a stronger result. Let us turn our attention to induced paths and subdivided claws that do not appear in $G_{q,p}$. In particular, using Lemma 16 we can exclude the existence of long paths and claws (see Figure 5).

▶ **Lemma 17** (♠). *Let $q \geq 3$ be an odd integer. For every $p \geq 1$ the graph $G_{q,p}$ is $\{P_{3q-1}, S_{2,2,2}, S_{3(q-1)/2,3(q-1)/2,1}\}$-free.*

Now, as an immediate consequence of Lemma 13 and Lemma 17, we obtain Theorem 4, which we restate below.

▶ **Theorem 4.** *Let $q \geq 3$ be odd, and let H be a graph of odd girth q that does not contain C_4 as a subgraph. There is an infinite family of minimal obstructions to H-coloring that are $\{P_{3q-1}, S_{2,2,2}, S_{3(q-1)/2,3(q-1)/2,1}\}$-free.*

Note that for $H = C_5$, i.e., for $q = 5$, Theorem 4 shows that the constructed graphs are in particular P_{14}-free and $S_{6,6,1}$-free. It turns out that they are actually P_{13}-free and $S_{5,5,1}$-free (and also exclude some other subdivided claws). Here we will make use of Corollary 15, combined with computer search.

Let us start with analyzing the length of a longest induced path in $G_{5,p}$. Thus we are interested in applying Corollary 15 to the case $q = 5$ and $F = P_{13}$. Actually, we can even exclude $F = P_{10} + P_2$, i.e., the graph with two components: one isomorphic to P_{10} and the other isomorphic to P_2. Note that $(P_{10} + P_2)$-free graphs are in particular P_{13}-free. Furthermore, the graph $G_{5,p}$ excludes the following subdivided claws: $S_{5,5,1}$, $S_{11,1,1}$, and $S_{8,2,1}$. These results, together with Lemma 13, give us Theorem 3.

▶ **Theorem 3.** *There is an infinite family of minimal obstructions to C_5-coloring, which simultaneously exclude P_{13}, $S_{2,2,2}$, $S_{5,5,1}$, $S_{11,1,1}$, and $S_{8,2,1}$ as an induced subgraph.*

Longest induced paths in $G_{q,p}$. Theorem 3, and the fact that from the result of Chudnovsky et al. [4] it follows that for every p, the graph $G_{3,p}$ is P_7-free (while Lemma 17 only gives P_8-freeness), suggest that the bound on the length of a longest induced path given by Theorem 4 is not optimal also in the other cases. This evidence suggests the following conjecture.

▶ **Conjecture 18.** *Let $q \geq 3$ be odd. For every $p \geq 1$, the graph $G_{q,p}$ is P_{3q-2}-free.*

We conclude this section by showing that the bound from Conjecture 18, if true, is best possible.

▶ **Lemma 19** (♠). *Let $q \geq 3$ be odd. If $p \geq 2q + 1$, then $G_{q,p}$ contains P_{3q-3} as an induced subgraph.*

Abstract

We are interested in the following validation problem for computational reductions: for algorithmic problems P and $P^\star$, is a given candidate reduction indeed a reduction from P to $P^\star$? Unsurprisingly, this problem is undecidable even for very restricted classes of reductions. This leads to the question: Is there a natural, expressive class of reductions for which the validation problem can be attacked algorithmically? We answer this question positively by introducing an easy-to-use graphical specification mechanism for computational reductions, called cookbook reductions. We show that cookbook reductions are sufficiently expressive to cover many classical graph reductions and expressive enough so that SAT remains NP-complete (in the presence of a linear order). Surprisingly, the validation problem is decidable for natural and expressive subclasses of cookbook reductions.

1 Introduction

Computational reductions are one of the most powerful concepts in theoretical computer science. They are used, among others, to establish undecidability in computability theory and hardness of algorithmic problems in computational complexity theory. In practical applications, reductions help to harness the power of modern SAT solvers for other problems.

For teaching reductions in introductory courses, instructors often design learning tasks for (i) understanding the computational problems involved, (ii) exploring existing reductions via examples, and (iii) designing reductions between computational problems. Technological teaching support so far is only provided for (i) and (ii), likely because these tasks are typically easy to illustrate and checking student solutions is algorithmically straightforward.

Providing teaching support for (iii) requires to address the foundational question: Is there a language for specifying reductions that can express a variety of reductions, but is also algorithmically accessible? In particular, it should be possible to test whether a candidate for a reduction provided by a student is indeed a valid reduction, preferably also providing a counterexample in case a submitted answer is incorrect.

In this paper, we propose such a specification language for reductions and study variants of the following algorithmic problem, parameterized by a class $\mathcal{R}$ of reductions and complexity classes $\mathcal{C}$ and $\mathcal{C}^*$:

Problem: Reduction?$(\mathcal{C}, \mathcal{C}^\star, \mathcal{R})$
Input: Algorithmic problems $P \in \mathcal{C}$, $P^\star \in \mathcal{C}^\star$, and a reduction $\rho \in \mathcal{R}$.
Question: Is ρ a reduction from P to $P^\star$?

More precisely, our contributions are twofold:

- We propose a graphical and modular specification language for reductions, which we call *cookbook reductions* (Section 3). Its design is inspired by "building blocks" such as local replacement of nodes, edges, ... [6] that are used in the context of many standard reductions. Cookbook reductions allow these building blocks to be combined in a simple, stepwise fashion. We compare the expressive power of cookbook reductions with standard methods of specifying reductions. Specifically, we relate cookbook reductions to quantifier-free first-order interpretations (Section 4.2) and observe that SAT remains NP-hard under cookbook reductions, assuming the presence of a linear order (Corollary 3).
- We study variants of the decision problem Reduction?, obtained by choosing different classes of reduction candidates and by either fixing the algorithmic problems $P, P^\star$ or by fixing complexity classes $\mathcal{C}, \mathcal{C}^\star$ and letting $P \in \mathcal{C}, P^\star \in \mathcal{C}^\star$ be part of the input (Section 5). Not surprisingly, Reduction? is undecidable for many restricted variants (Theorem 4). To our surprise, several interesting variants remain decidable: for example, Reduction? is decidable for an arbitrary fixed problem P and fixed $P^\star$ expressible in monadic second-order logic[1], if reduction candidates are from the subclass of cookbook reductions that allows local replacements of edges by a gadget graph (Theorem 10). Also, for some concrete choices of problems $P, P^\star$, we characterize valid reductions; the characterizations can be used to generate counterexamples for invalid candidates, which is particularly relevant in teaching contexts.

Related work. Restricted specification languages have also been used in [3, 9] in the context of learning reductions algorithmically. Reductions that are similar in spirit to cookbook reductions due to their stepwise fashion are pp-constructions and gadget reductions in the realm of (finite) constraint satisfaction problems [1, 5, 2].

2 Preliminaries

We assume familiarity with basic notions from finite model theory [10].

A *(purely relational) schema* $\sigma = \{R_1, \dots, R_m\}$ is a set of relation symbols R_i with associated *arities* $\mathrm{Ar}(R_i)$. A (finite) σ-structure $\mathcal{S} = (U, R_1^{\mathcal{S}}, \dots, R_m^{\mathcal{S}})$ consists of a finite set U, called the *universe* or the *domain* of $\mathcal{S}$, and relations $R_i^{\mathcal{S}} \subseteq U^{\mathrm{Ar}(R_i)}$. If clear from the context, we sometimes omit the superscript $\mathcal{S}$. We also refer to the domain of $\mathcal{S}$ as $\mathrm{dom}(\mathcal{S})$. We write FO_k for the set of all first-order formulas with quantifier depth at most k. The FO_k*-type* of a σ-structure $\mathcal{S}$ is the set of all FO_k formulas over schema σ that $\mathcal{S}$ satisfies. Two structures $\mathcal{S}_1, \mathcal{S}_2$ are FO*-similar* up to quantifier depth k, written $\mathcal{S}_1 \equiv_k^{\mathsf{FO}} \mathcal{S}_2$, if they have the same FO_k-type.

An *isomorphism type* of σ-structures is an equivalence class of the equivalence relation "is isomorphic to". We represent an isomorphism type by an arbitrarily fixed σ-structure $\mathfrak{t}$ with universe $\{1, \dots, k\}$, for the appropriate number k, from that equivalence class. The

[1] This logic extends first-order logic with quantification over sets and can express for example the NP-complete problem 3-Colorability.

Problem: Clique
Input: Undirected graph $G = (V, E)$, $k \in \mathbb{N}$
Question: Is there a set $U \subseteq V$ of size k with $(u, v) \in E$ for all $u, v \in U$?

Problem: IndependentSet
Input: Undirected graph $G = (V, E)$, $k \in \mathbb{N}$
Question: Is there a set $U \subseteq V$ of size k with $(u, v) \notin E$ for all $u, v \in U$?

Problem: VertexCover
Input: Undirected graph $G = (V, E)$, $k \in \mathbb{N}$
Question: Is there a set $U \subseteq V$ of size at most k such that $u \in U$ or $v \in U$ for all $(u, v) \in E$?

Problem: FeedbackVertexSet
Input: Undirected graph $G = (V, E)$, $k \in \mathbb{N}$
Question: Is there a set $U \subseteq V$ of size at most k such that removing U from G yields a cycle-free graph?

Problem: $\textsc{HamCycle}_{\textsc{u}}$
Input: Undirected graph $G = (V, E)$
Question: Is there an undirected cycle in G that passes each node exactly once?

Problem: $\textsc{HamCycle}_{\textsc{d}}$
Input: Directed graph $G = (V, E)$
Question: Is there a directed cycle in G that passes each node exactly once?

Figure 1 Collection of algorithmic problems considered in the paper.

arity of an isomorphism type is the universe size of its representative. Often, we identify an isomorphism type with its representative $\mathfrak{t}$. Given a structure $\mathcal{S}$ and a subset A of its universe, we write $\mathfrak{tp}_{\mathcal{S}}(A)$ for the isomorphism type of $\mathcal{S}[A]$, so, the isomorphism type of the substructure of $\mathcal{S}$ that is induced by A. We write $\mathfrak{tp}(A)$ if $\mathcal{S}$ is clear from the context and call $\mathfrak{tp}(A)$ the isomorphism type of A.

An *embedding* π of a structure $\mathcal{S}$ into a structure $\mathcal{S}^\star$ is an injective mapping from the domain of $\mathcal{S}$ into the domain of $\mathcal{S}^\star$ that is an isomorphism between $\mathcal{S}$ and the substructure of $\mathcal{S}^\star$ that is induced by the image of π. So, an embedding π witnesses that $\mathcal{S}^\star$ contains an isomorphic copy of $\mathcal{S}$ as an induced substructure.

An (*algorithmic*) *problem* P is an isomorphism-closed set of σ-structures, for some schema σ. A *reduction* ρ from a problem P over schema σ to a problem $P^\star$ over schema $\sigma^\star$ is a mapping from σ-structures to $\sigma^\star$-structures such that $\mathcal{S} \in P \Leftrightarrow \rho(\mathcal{S}) \in P^\star$, for every σ-structure $\mathcal{S}$. A *d-dimensional first-order interpretation* from σ-structures to $\sigma^\star$-structures is a tuple $\Psi = (\varphi_U(\bar{x}), \varphi_\sim(\bar{x}_1, \bar{x}_2), (\varphi_R(\bar{x}_1, \ldots, \bar{x}_{\mathrm{Ar}(R)}))_{R \in \sigma^\star})$ of first-order formulas over schema σ, where each tuple $\bar{x} = (x_1, \ldots, x_d), \bar{x}_i = (x_{i,1}, \ldots, x_{i,d})$ consists of d variables. For a given σ-structure $\mathcal{S}$ with universe U, let $\hat{\Psi}(\mathcal{S})$ be the $\sigma^\star$-structure with universe $\hat{U} = \{\bar{a} \in U^d \mid \mathcal{S} \models \varphi_U(\bar{a})\}$ and relations $R^{\hat{\Psi}(\mathcal{S})} = \{(\bar{a}_1, \ldots, \bar{a}_{\mathrm{Ar}(R)}) \in \hat{U}^{\mathrm{Ar}(R)} \mid \mathcal{S} \models \varphi_R(\bar{a}_1, \ldots, \bar{a}_{\mathrm{Ar}(R)})\}$ for each $R \in \sigma^\star$. We demand that for every σ-structure $\mathcal{S}$, the binary relation $\sim^{\hat{\Psi}(\mathcal{S})} = \{(\bar{a}_1, \bar{a}_2) \in \hat{U}^2 \mid \mathcal{S} \models \varphi_\sim(\bar{a}_1, \bar{a}_2)\}$ is a congruence relation on $\hat{\Psi}(\mathcal{S})$, that is, an equivalence relation on the universe that is compatible with the relations of the structure. For a given σ-structure $\mathcal{S}$, the interpretation Ψ defines the $\sigma^\star$-structure $\Psi(\mathcal{S})$ that is the quotient structure of $\hat{\Psi}(\mathcal{S})$ with respect to $\sim^{\hat{\Psi}(\mathcal{S})}$, that is, the structure that results from $\hat{\Psi}(\mathcal{S})$ by restricting the universe to only one element for every equivalence class of $\sim^{\hat{\Psi}(\mathcal{S})}$.

Most of our examples will be drawn from the algorithmic problems from Figure 1. We also consider variants of some of these problems where k is a fixed parameter, e.g. k-Clique asks, given a graph G, whether there is a k-clique in G.

For a natural number n, we sometimes write $[n]$ for the set $\{1, \ldots, n\}$.

3 Cookbook reductions: A specification language for reductions

When looking for a reduction, one approach by typical experts is to subsequently try building blocks that they have encountered in the context of other reductions before. For example, Garey and Johnson [6, Section 3.2] discuss common proof techniques like local replacements that occur in many standard reductions. An example is the standard reduction from the problem of finding a directed Hamiltonian cycle to finding an undirected Hamiltonian cycle that transforms a directed graph into an undirected graph by mapping each node  to a small gadget . Constructing such node gadgets is one of the typical building blocks when designing reductions.

Our approach towards constructing a specification language for reductions is to (1) identify common building blocks used in computational reductions between graph problems, and to (2) abstract these building blocks into a more general specification language. The resulting language is reasonably broad and, due to its modular and graphical nature, easy to use.

3.1 Building blocks and recipes

Many computational reductions can be crafted from a small set of common building blocks. For reductions between graph problems, some such building blocks are the following:

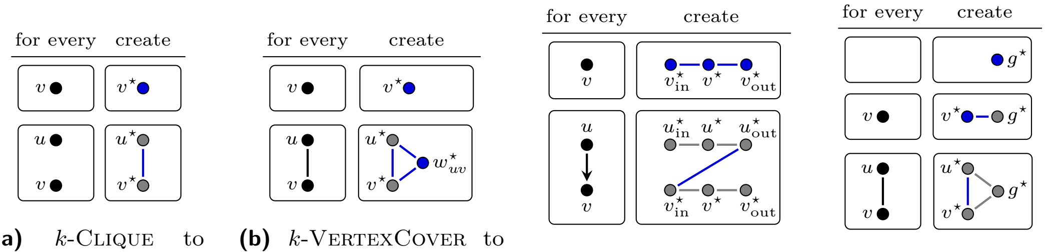
- *Edge gadgets* replace each edge (u, v) of the source instance uniformly by a graph. For example, in the standard reduction from VertexCover to FeedbackVertexSet, every edge  in the source instance is replaced by a triangle .
- *Node gadgets* replace each node of the source instance uniformly by a graph and specify how these graphs are connected. For example, in the standard reduction from HamCycle$_d$ to HamCycle$_u$, every node in the source instance is replaced by a path  and if there is an edge (u, v) in the source instance, then the paths for u and v are connected via .
- *Global gadgets* introduce a (global) graph and specify how each node of this graph is connected to the nodes of the source instance. For example, in the simple reduction from 3-Clique to 4-Clique, a single node is introduced as global graph and each node v of the source instance is connected to g via an edge .

These building blocks have in common that target instances of reductions are obtained from source instances by following simple, recipe-like steps of the form "for every occurrence of a substructure $\mathfrak{t}$ in the source instance, create a copy of the substructure $\mathfrak{t}^\star$ in the target structure". For example, the recipes for the above reductions are as follows:

- Reducing k-VertexCover to k-FeedbackVertexSet: For every node v in the source instance, create a node $v^\star$ in the target instance. For every edge (u, v) in the source instance, create a node $w^\star_{uv}$ and edges $(u^\star, v^\star), (v^\star, w^\star_{uv}), (w^\star_{uv}, u^\star)$ in the target instance.
- Reducing HamCycle$_d$ to HamCycle$_u$: For every node v in the source instance, create nodes $v^\star_{\text{in}}, v^\star, v^\star_{\text{out}}$ in the target instance and connect them as a path. For every directed edge (u, v) in the source instance, create the undirected edge $(u^\star_{\text{out}}, v^\star_{\text{in}})$ in the target instance.
- Reducing 3-Clique to 4-Clique: Create a node $g^\star$ in the target instance. For every node v of the source instance, create a node $v^\star$ in the target instance and add the edge $(v^\star, g^\star)$. Copy all edges (u, v) of the source instance as edges $(u^\star, v^\star)$ to the target instance.

Other reductions can also be phrased in this form, for instance:

- Reducing k-Clique to k-IndependentSet: First, for every node v of the source instance, create a node $v^\star$ in the target instance. Then, for every pair u, v of nodes that are not connected by an edge in the source instance, create an edge $(u^\star, v^\star)$ in the target instance.



(a) k-Clique to k-IndependentSet.

(b) k-VertexCover to k-FeedbackVertexSet.

(c) HamCycle$_d$ to HamCycle$_u$.

(d) 3-Clique to 4-Clique.

Figure 2 Graphical representations of four reductions. The reductions are applied stepwise, from the top-most step to the bottom-most step. Nodes and edges coloured blue are created in this step, grey nodes and edges were created in a previous step.

Reductions specified this way capture building blocks such as the ones from [6] and are usually easy to understand, often much more than their presentation as algorithms or as logical interpretations. Such reductions can also easily be specified graphically, see Figure 2.

3.2 Cookbook reductions: Formalization

We now formalize cookbook reductions as such recipe-style descriptions of computational reductions. In general, graphical representations as in Figure 2 can be used to specify a cookbook reduction. In this section, we discuss the formal syntax and semantics.

Intuitively, a reduction specified in our formalism builds, based on a source structure, the target structure in a sequence of stages, starting from an empty structure. At first, independent of the source structure, some global elements and tuples over these elements may be introduced to the target structure. Then, for every element of the source structure, a set of elements may be added, together with tuples that may also incorporate the elements that were introduced in the step before. The added elements and tuples depend on the (atomic) type of the respective element of the source structure. In further stages, elements are analogously introduced for every set of two, three, . . . , elements of the source structure, depending on the type of these sets.

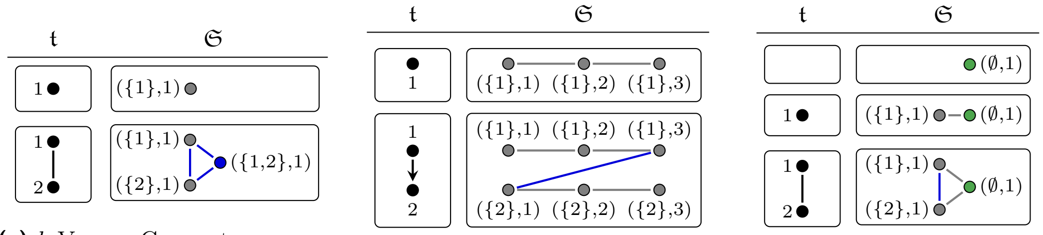
Syntactically, a *cookbook reduction* ρ from σ-structures to $\sigma^\star$-structures is a finite set $\rho = \{(\mathfrak{t}_1, \mathfrak{S}_1), \ldots, (\mathfrak{t}_m, \mathfrak{S}_m)\}$ of pairs which we call *instructions*. The structures $\mathfrak{t}_i$ are σ-structures with universe $\{1, \ldots, k_i\}$, for some natural number $k_i \geq 0$, that represent pairwise distinct isomorphism types of σ-structures. The set $\{\mathfrak{t}_1, \ldots, \mathfrak{t}_m\}$ is the *support* of ρ. The *arity* of ρ is the maximal arity of an isomorphism type in the support of ρ. The structures $\mathfrak{S}_i$ are over the schema $\sigma^\star$. For $(\mathfrak{t}_i, \mathfrak{S}_i) \in \rho$, we also refer to $\mathfrak{S}_i$ as $\mathfrak{S}(\mathfrak{t}_i)$. Each instruction $(\mathfrak{t}, \mathfrak{S})$, where $\mathfrak{t}$ has the universe $[k] = \{1, \ldots, k\}$, satisfies the following properties:

(P1) The universe $\text{dom}(\mathfrak{S})$ of $\mathfrak{S}$ consists of elements (A, j), where $A \subseteq [k]$ and $j \geq 1$. If $(A, j) \in \text{dom}(\mathfrak{S})$ with $j > 1$, then also $(A, 1), \ldots, (A, j-1)$ are in $\text{dom}(\mathfrak{S})$.

(P2) For any $(A, j) \in \text{dom}(\mathfrak{S})$ with $A \subsetneq [k]$, the isomorphism type $\mathfrak{t}' = \mathfrak{tp}_{\mathfrak{t}}(A)$ is in the support of ρ and $(\{1, \ldots, |A|\}, j)$ is in $\text{dom}(\mathfrak{S}(\mathfrak{t}'))$.

(P3) For any tuple $((A_1, j_1), \ldots, (A_\ell, j_\ell))$ in any relation of $\mathfrak{S}$ with $\bigcup_{i \leq \ell} A_i \subsetneq [k]$, the isomorphism type $\mathfrak{tp}_{\mathfrak{t}}(\bigcup_{i \leq \ell} A_i)$ is in the support of ρ.

(P4) For any $(\mathfrak{t}', \mathfrak{S}') \in \rho$ and any $A \subsetneq [k]$ with $\mathfrak{tp}_{\mathfrak{t}}(A) = \mathfrak{t}'$, there is an isomorphism π from $\mathfrak{t}'$ to $\mathfrak{t}[A]$ such that the injective mapping $\hat{\pi}$ with $\hat{\pi}((A', j')) = (\pi(A'), j')$, for all (A', j') in $\text{dom}(\mathfrak{S}')$, is an embedding from $\mathfrak{S}'$ into $\mathfrak{S}$.



(a) k-VertexCover to k-FeedbackVertexSet. **(b)** HamCycle$_d$ to HamCycle$_u$. **(c)** 3-Clique to 4-Clique.

Figure 3 Three reductions formalized as cookbook reductions. Nodes introduced for type $\mathfrak{t}_\emptyset$ are coloured green, nodes and edges introduced for type $\mathfrak{t}_\bullet$ are coloured grey, and nodes and edges introduced for types $\mathfrak{t}_{\bullet-\bullet}$ and $\mathfrak{t}_{\bullet\to\bullet}$ are coloured blue. Compare to Figure 2(b), (c), and (d).

A cookbook reduction has to satisfy a further, semantic property, which we state after defining the semantics.

See Figure 3 for examples of cookbook reductions.

We give some more explanations for the conditions (P1)–(P4). Intuitively, an instruction $(\mathfrak{t}, \mathfrak{S}) \in \rho$ means that for every occurrence of the type $\mathfrak{t}$ in the source structure, a copy of the structure $\mathfrak{S}$ is included in the target structure. The conditions (P1) and (P2) are concerned with the universe $\mathrm{dom}(\mathfrak{S})$ of $\mathfrak{S}$. If $\mathfrak{t}$ is an isomorphism type of k elements, the universe of $\mathfrak{S}$ partly consists of elements $([k], 1), \dots, ([k], m)$, for some number m. These elements are added to the target structure for every occurrence of the type $\mathfrak{t}$. We also call these m elements *fresh* and write $\#_{\text{fresh}}(\mathfrak{t}) = m$ (and $\#_{\text{fresh}}(\mathfrak{t}) = 0$ if no such element exists). The universe of $\mathfrak{S}$ also contains further elements of the form (A, j) with $A \subsetneq [k]$. These represent elements that are added for sets of elements with size $k' < k$ (in the intuitive explanation: in previous stages). If such an element (A, j) occurs in the universe of $\mathfrak{S}$, there has to be a corresponding instruction to add this element, that is, the type $\mathfrak{t}'$ of the set A in $\mathfrak{t}$ has to be in the support of ρ and the element $([k'], j)$ has to be a fresh element in $\mathfrak{S}(\mathfrak{t}')$.

The conditions (P3) and (P4) concern the relations of $\mathfrak{S}$. A tuple $((A_1, j_1), \dots, (A_\ell, j_\ell))$ with $\bigcup_{i \le \ell} A_i = [k]$ in a relation of $\mathfrak{S}$ says that this tuple is to be added to the target structure for every set of elements of type $\mathfrak{t}$. No further conditions on these tuples are imposed by (P3) and (P4). If $A' \overset{\text{def}}{=} \bigcup_{i \le \ell} A_i$ is a proper subset of $[k]$, this tuple is added for the subset A' of elements (intuitively: in a previous stage). Again, there needs to be another instruction that adds this tuple, that is, the isomorphism type $\mathfrak{t}'$ of A' needs to be in the support of ρ.

If a subtype $\mathfrak{t}'$ of $\mathfrak{t}$ is in the support of ρ then the corresponding instruction $(\mathfrak{t}', \mathfrak{S}')$ needs to be respected: for every occurrence of $\mathfrak{t}'$ in $\mathfrak{t}$, a copy of the structure $\mathfrak{S}'$ needs to be present in $\mathfrak{S}$. Formally, if a set $A \subsetneq [k]$ with $|A| = k'$ has type $\mathfrak{t}'$ in $\mathfrak{t}$, as witnessed by some isomorphism π from $\mathfrak{t}'$ to $\mathfrak{t}[A]$, the substructure of $\mathfrak{S}$ that is induced by the set $\{(A_i, j_i) \mid A_i \subseteq \pi([k'])\}$ is isomorphic to $\mathfrak{S}'$.

We now define the semantics of cookbook reductions. A cookbook reduction $\rho = \{(\mathfrak{t}_1, \mathfrak{S}_1), \dots, (\mathfrak{t}_m, \mathfrak{S}_m)\}$ maps a σ-structure $\mathcal{S}$ to a set $\rho(\mathcal{S})$ of $\sigma^\star$-structures, where σ is the schema of the isomorphism types $\mathfrak{t}_i$ and $\sigma^\star$ is the schema of the structures $\mathfrak{S}_i$. For some σ-structure $\mathcal{S}$, the $\sigma^\star$-structure $\mathcal{S}^\star$ is in $\rho(\mathcal{S})$ if the following conditions hold:

(S1) The universe $\mathrm{dom}(\mathcal{S}^\star)$ of $\mathcal{S}^\star$ consists of exactly those elements (A, j) with $A \subseteq \mathrm{dom}(\mathcal{S})$ such that

- the isomorphism type $\mathfrak{t} = \mathfrak{tp}_{\mathcal{S}}(A)$ is in the support of ρ, and
- the structure $\mathfrak{S}$ with $(\mathfrak{t}, \mathfrak{S}) \in \rho$ has the element $(\{1, \dots, |A|\}, j)$ in its universe.

(S2) If a tuple $((A_1, j_1), \dots, (A_\ell, j_\ell))$ is in some relation $R^{\mathcal{S}^\star}$ of $\mathcal{S}^\star$, for any $R \in \sigma^\star$, then the isomorphism type $\mathfrak{tp}_{\mathcal{S}}(\bigcup_{i \le \ell} A_i)$ is in the support of ρ.

(S3) For any $(\mathfrak{t}, \mathfrak{S}) \in \rho$ and any $A \subseteq \text{dom}(\mathcal{S})$ with $\mathfrak{tp}_{\mathcal{S}}(A) = \mathfrak{t}$, there is an isomorphism π from $\mathfrak{t}$ to $\mathcal{S}[A]$ such that the injective mapping $\hat{\pi}$ with $\hat{\pi}((A', j')) = (\pi(A'), j')$, for all (A', j') in the universe of $\mathfrak{S}$, is an embedding from $\mathfrak{S}$ into $\mathcal{S}^\star$.

Intuitively, these conditions state that the elements (S1) and tuples (S3) of $\mathcal{S}^\star$ can be obtained by transforming occurrences of an isomorphism type $\mathfrak{t}$ in $\mathcal{S}$ into $\mathfrak{S}$, for any $(\mathfrak{t}, \mathfrak{S}) \in \rho$, and that no other tuples are present (S2).

A cookbook reduction ρ needs to satisfy the following semantic property[2].

(P5) For every σ-structure $\mathcal{S}$, the set $\rho(\mathcal{S})$ is a non-empty set of isomorphic structures.

Abusing notation, we usually write $\rho(\mathcal{S})$ to denote some arbitrary structure $\mathcal{S}^\star \in \rho(\mathcal{S})$.

4 The expressive power of cookbook reductions

In this section we study the expressive power of cookbook reductions. First, we explain how the building blocks from Section 3 are captured by restricted cookbook reductions. Afterwards, we discuss the expressive power of general cookbook reductions and relate them to quantifier-free first-order interpretations.

4.1 From building blocks to cookbook reductions

Cookbook reductions are a versatile reduction concept and as we have seen in the examples depicted in Figure 2 and Figure 3, many reductions have a small and easily understandable representation as cookbook reductions that have only few isomorphism types in their support.

In fact, the building blocks for graph problems that we discussed as motivation for cookbook reductions can be recovered as restricted variants of cookbook reductions. For undirected graphs with only the binary edge relation E and no self-loops, only four isomorphism types of arity at most 2 are relevant: the type $\mathfrak{t}_\emptyset$ of the graph with 0 nodes, the type $\mathfrak{t}_\bullet$ of a single node, the type $\mathfrak{t}_{\bullet\!-\!\bullet}$ of an undirected edge, and the type $\mathfrak{t}_{\bullet\,\bullet}$ of non-edges.

We obtain the following characterization:

- For a *global gadget reduction*, the inserted global graph $\mathfrak{S}(\mathfrak{t}_\emptyset)$ is arbitrary. Nodes of the source instance are copied, so we fix $\#_{\text{fresh}}(\mathfrak{t}_\bullet) = 1$, but allow $\mathfrak{S}(\mathfrak{t}_\bullet)$ to arbitrarily select nodes from the global graph that are connected to every source node. Edges of the source are copied, so $\#_{\text{fresh}}(\mathfrak{t}_{\bullet\!-\!\bullet}) = 0$ and $\mathfrak{S}(\mathfrak{t}_{\bullet\!-\!\bullet})$ just adds the edge.
- A *node gadget reduction* replaces every node by some gadget, so $\mathfrak{S}(\mathfrak{t}_\bullet)$ is arbitrary. The reduction can define how these gadgets are connected in case there is an edge between the corresponding nodes in the source instance, resulting in $\#_{\text{fresh}}(\mathfrak{t}_{\bullet\!-\!\bullet}) = 0$ and $\mathfrak{S}(\mathfrak{t}_{\bullet\!-\!\bullet})$ being arbitrary apart from that.
- An *edge gadget reduction* replaces edges by some gadget. As every node from the source is copied to the target, $\mathfrak{S}(\mathfrak{t}_\bullet)$ is a single node. We allow any symmetric $\mathfrak{S}(\mathfrak{t}_{\bullet\!-\!\bullet})$.

Only the mentioned isomorphism types are in the support of the cookbook reduction.

A similar characterization holds if the source graph is directed.

Global, node or edge gadget reductions constitute expressive subclasses of cookbook reductions that are relatively easy to comprehend. More fragments can be defined by, e.g., setting an upper bound for $\#_{\text{fresh}}(\mathfrak{t}_\bullet)$ in a node gadget reduction, or selecting a different set

[2] For global and node gadget reductions as introduced in Section 3.1, this property is trivially satisfied, for edge gadget reductions it is satisfied if the gadget graph is symmetric. In general, the following syntactic restriction is necessary: For every $(\mathfrak{t}, \mathfrak{S}) \in \rho$ and any automorphism π of $\mathfrak{t}$ there is an automorphism $\hat{\pi}$ of $\mathfrak{S}$ with $\hat{\pi}((A, j)) = (\pi(A), j')$, for any (A, j) in the universe of $\mathfrak{S}$.

of isomorphism types $\mathfrak{t}$ for which $\mathfrak{S}(\mathfrak{t})$ needs to be provided. This modularity of cookbook reductions helps finding decidable cases of the Reduction? problem. In a teaching context, instructors can select the degree of freedom students have.

4.2 Relating cookbook reductions to quantifier-free interpretations

Quantifier-free first-order (FO) interpretations constitute a widely-used class of reductions with very low complexity, see, e.g., [7]. They are still expressive enough to show hardness of problems: SAT, the satisfiability problem for propositional formulas, is NP-hard even under quantifier-free FO interpretations [4].

In this section, we show that cookbook reductions can be expressed as quantifier-free FO interpretations. If we assume a linear order on the input structures, mildly restricted quantifier-free FO interpretations can be expressed as cookbook reductions. It follows that if input structures are linearly ordered, SAT is NP-hard under cookbook reductions.

We say that two reductions ρ_1 and ρ_2 are *equivalent* for a source structure $\mathcal{S}$ over the appropriate schema, if the target structures $\rho_1(\mathcal{S})$ and $\rho_2(\mathcal{S})$ are isomorphic.

▶ **Theorem 1.** *For every cookbook reduction ρ there is a d-dimensional quantifier-free first-order interpretation Ψ, for some number d, such that ρ and Ψ are equivalent for every structure with at least* 2 *elements.*

Proof idea. Suppose that for a cookbook reduction $\rho = \{(\mathfrak{t}_1, \mathfrak{S}_1), \dots, (\mathfrak{t}_m, \mathfrak{S}_m)\}$ the maximal arity of an isomorphism type $\mathfrak{t}_i$ is k and ℓ is the maximal size of the universe of a structure $\mathfrak{S}_i$. The interpretation Ψ intuitively creates for each set of elements of type $\mathfrak{t}_i$ a copy of the structure $\mathfrak{S}_i$, so, defines a universe of elements of the form (A, i), where $|A| \leq k$ and $i \leq \ell$. Such elements can be encoded by tuples of length $d \overset{\text{def}}{=} k + \ell + 1$. Quantifier-free formulas can determine the isomorphism type of a set of elements and, by the properties of a cookbook reduction, whether a tuple $((A, i_1), \dots, (A, i_r))$ exists in the interpreted structure only depends on the isomorphism type of A. ◀

We call a first-order interpretation *set-respecting* if, for the equivalence relation defined by the formula $\varphi_\sim(\bar{x}_1, \bar{x}_2)$, two tuples $\bar{a}_1, \bar{a}_2$ are only in the same equivalence class if $\bar{a}_1$ and $\bar{a}_2$ contain the same set of elements.

▶ **Theorem 2.** *For every set-respecting quantifier-free first-order interpretation Ψ there is a cookbook reduction ρ such that ρ and Ψ are equivalent for every structure with a linearly ordered universe.*

Proof idea. Let d be the dimension of Ψ. For every isomorphism type $\mathfrak{t}$ of $k \leq d$ elements, the number ℓ of elements $([k], 1), \dots, ([k], \ell)$ in the universe of $\mathfrak{S}(\mathfrak{t})$, so, the number of elements added to the target structure because of a set of elements with isomorphism type $\mathfrak{t}$, is equal to the number of equivalence classes of the congruence defined by $\varphi_\sim$ on the set of d-tuples that contain exactly the k elements of $\mathfrak{t}$ and satisfy the formula φ_U of Ψ. We identify each of the ℓ elements with a particular d-tuple over the set $[k]$, which is possible as $[k]$ is linearly ordered. The structure $\mathfrak{S}(\mathfrak{t})$ is then defined as dictated by Ψ. ◀

As SAT is NP-hard under set-respecting quantifier-free FO interpretations [4], we obtain:

▶ **Corollary 3.** *Assuming that input structures are linearly ordered,* SAT *is* NP*-hard under cookbook reductions.*

Note that in descriptive complexity theory one often studies relational input structures that are not linearly ordered (although Immerman usually assumes a linear order to be present [7, Proviso 1.14]). However, when considering Turing machines as models of computation in complexity theory, inputs are binary string encodings and therefore linearly ordered.

5 Towards automated correctness tests and feedback

We now turn to the problem of checking whether a given reduction candidate is a valid reduction between two computational problems P and $P^\star$. In a first variation of this problem, a corresponding algorithm gets as input the reduction candidate $\rho \in \mathcal{R}$ as well as the two problems $P \in \mathcal{C}$ and $P^\star \in \mathcal{C}^\star$, for a fixed class $\mathcal{R}$ of reductions and fixed complexity classes $\mathcal{C}$ and $\mathcal{C}^\star$. Formally, this corresponds to solving the following algorithmic problem Reduction?$(\mathcal{C}, \mathcal{C}^\star, \mathcal{R})$, parameterized by $\mathcal{C}$, $\mathcal{C}^\star$, and $\mathcal{R}$. Also fixing the problems P and $P^\star$ yields the special case Reduction?$(P, P^\star, \mathcal{R})$.

Problem: Reduction?$(\mathcal{C}, \mathcal{C}^\star, \mathcal{R})$
Input: Algorithmic problems $P \in \mathcal{C}$, $P^\star \in \mathcal{C}^\star$, and a reduction $\rho \in \mathcal{R}$.
Question: Is ρ a reduction from P to $P^\star$?

Problem: Reduction?$(P, P^\star, \mathcal{R})$
Input: A reduction $\rho \in \mathcal{R}$.
Question: Is ρ a reduction from P to $P^\star$?

We are slightly vague here, as for the moment we leave open how algorithmic problems and reductions are represented. It will be clear how these are represented for all classes $\mathcal{C}$, $\mathcal{C}^\star$ and $\mathcal{R}$ we will consider. For standard classes of reductions, – including reductions computable in polynomial time or logarithmic space, as well as first-order definable reductions – already the second, more restricted problem is clearly undecidable for all non-trivial P and $P^\star$. Already testing whether a quantifier-free interpretation or even an edge gadget reduction reduces from some problem P to another problem $P^\star$ is undecidable, for simple P and $P^\star$. As soon as P or $P^\star$ are part of the input, the Reduction? problem is undecidable in most cases in which one of the classes $\mathcal{C}$ or $\mathcal{C}^\star$ is defined by an undecidable fragment of second-order logic, even for very simple classes of reductions.

▶ **Theorem 4.**

1. *Reduction?$(P, P^\star, \mathcal{R})$ is undecidable for the following parameters:*
   - **a.** *The class $\mathcal{R}$ of first-order interpretations, $P = \emptyset$ and arbitrary $P^\star$ (or vice versa, i.e. arbitrary P and $P^\star = \emptyset$).*
   - **b.** *The class $\mathcal{R}$ of edge gadget reductions, $P = \emptyset$ and some graph problem $P^\star$ definable in first-order logic with arithmetic.*
   - **c.** *The class $\mathcal{R}$ of quantifier-free interpretations, $P = \emptyset$ and the graph problem $P^\star$ defined by the first-order formula $\varphi^\star \overset{def}{=} \forall x \exists y E(x, y)$.*
2. *Reduction?$(\mathcal{C}, \mathcal{C}^\star, \mathcal{R})$ is undecidable for the following parameters:*
   - **a.** *A class $\mathcal{R}$ containing the identity mapping, a class $\mathcal{C}$ containing the empty problem, and a class $\mathcal{C}^\star$ defined by a fragment of second-order logic with undecidable finite satisfiability problem.*
   - **b.** *A class $\mathcal{R}$ containing the identity mapping, a class $\mathcal{C}$ defined by a fragment of second-order logic with undecidable finite satisfiability problem, and a class $\mathcal{C}^\star$ containing the empty problem.*

In the rest of this section, we explore how to overcome the undecidability barriers. That is, we explore for which parameters one can obtain algorithms for solving Reduction?$(P, P^\star, \mathcal{R})$ and Reduction?$(\mathcal{C}, \mathcal{C}^\star, \mathcal{R})$. Our focus is on (restrictions of) cookbook reductions.

We start by exhibiting toy examples for algorithms for Reduction?$(P, P^\star, \mathcal{R})$ for concrete algorithmic problems P and $P^\star$ in Section 5.1. For these examples, counterexamples can be provided if the input is not a correct reduction. A generalized view is taken in Section 5.2, where we exhibit algorithm templates for Reduction?$(P, P^\star, \mathcal{R})$ for algorithmic problems P and $P^\star$ selected from classes of problems. Then, in Section 5.3, we consider algorithmic problems as part of the input by studying Reduction?$(\mathcal{C}, \mathcal{C}^\star, \mathcal{R})$.

5.1 Warm-up: Reductions between explicit algorithmic problems

In this section we provide toy examples of how Reduction?$(P, P^\star, \mathcal{R})$ can be decided for very restricted classes $\mathcal{R}$: (1) for reducing k-Clique to ℓ-Clique via global gadgets, for $k < \ell$, (2) for reducing k-VertexCover to k-FeedbackVertexSet via edge gadgets, and (3) for reducing HamCycle$_d$ to HamCycle$_u$ via restricted node gadgets. In all cases, the decision procedures are obtained by characterizing the class of correct gadgets.

While not deep, these characterizations and the algorithms resulting from them are a first step towards more general results.

We start by characterizing those global gadgets that reduce k-Clique to ℓ-Clique. For simplicity, we represent global gadget reductions ρ by a global gadget $\mathfrak{g}_\rho$ and a distinguished subset A of its nodes. When applying ρ to a graph $G = (V, E)$, the gadget $\mathfrak{g}_\rho$ is disjointly added to G and edges (u, v) are introduced for all $u \in A$ and all $v \in V$.

▶ **Proposition 5.** *Let ρ be a global gadget reduction with global gadget $\mathfrak{g}_\rho$ and a distinguished subset A of its nodes. Let $k, \ell \in \mathbb{N}$ with $k < \ell$. Then the following are equivalent:*

1. *ρ is a reduction from k-Clique to ℓ-Clique*
2. *$\mathfrak{g}_\rho$ and A satisfy the following conditions:*
   a. *$\mathfrak{g}_\rho$ has no ℓ-clique*
   b. *$\mathfrak{g}_\rho$ has an $(\ell - k)$-clique contained in A*
   c. *$\mathfrak{g}_\rho$ has no $(\ell - k + 1)$-clique contained in A*

Furthermore, if ρ is not a reduction from k-Clique to ℓ-Clique, then a counterexample can be computed efficiently.

We next characterize those edge gadgets that constitute a reduction from k-VertexCover to k-FeedbackVertexSet. We represent edge gadget reductions ρ by an edge gadget $\mathfrak{g}_\rho$ with two distinguished nodes c and d. When applying ρ to a graph $G = (V, E)$, all edges $(u, v) \in E$ are replaced by disjoint copies of $\mathfrak{g}_\rho$, where u, v are identified with c, d, respectively.

▶ **Proposition 6.** *Let ρ be an edge gadget reduction based on the edge gadget $\mathfrak{g}_\rho$ with distinguished nodes c and d. Then the following are equivalent:*

1. *ρ is a reduction from k-VertexCover to k-FeedbackVertexSet*
2. *$\mathfrak{g}_\rho$ satisfies the following conditions:*
   a. *$\{c\}$ and $\{d\}$ are feedback vertex sets of $\mathfrak{g}_\rho$*
   b. *$\emptyset$ is not a feedback vertex set of $\mathfrak{g}_\rho$.*

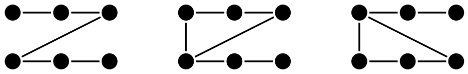
Furthermore, if ρ is not a reduction from k-VertexCover to k-FeedbackVertexSet, then a counterexample can be computed efficiently.

Lastly, we characterize restricted node gadget reductions from the directed Hamiltonian cycle problem HamCycle$_d$ to the undirected variant HamCycle$_u$. For simplicity, we represent node gadget reductions ρ by node gadgets $\mathfrak{g}_\rho$. A node gadget $\mathfrak{g}_\rho$ consists of two copies of a *node graph* $\mathfrak{S}(\mathfrak{t}_\bullet)$ and a set of additional edges between these copies. As an example, the standard reduction from HamCycle$_d$ to HamCycle$_u$ is represented by the node gadget  consisting of two copies of the node graph  with one additional edge between them (cf. Figures 2(c) and 3(b)). When applying $\mathfrak{g}_\rho$ to a graph $G = (V, E)$, all nodes in V are replaced by a copy of the node graph and two such copies for nodes u, v are connected accordingly by the additional set of edges, if $(u, v) \in E$.

As a first step towards characterizing node gadget reductions between HamCycle$_d$ and HamCycle$_u$, we characterize all correct node gadget reductions whose node graph has at most three nodes.

▶ **Proposition 7.** *Let ρ be a node gadget reduction with node gadget $\mathfrak{g}_\rho$ whose node graph has at most three nodes. Then the following are equivalent:*

1. *ρ is a reduction from* HamCycle$_d$ *to* HamCycle$_u$
2. *$\mathfrak{g}_\rho$ is either of the following node gadgets (with the two copies of the node graphs depicted at top and bottom), up to symmetries:*



Furthermore, if ρ is not a reduction from HamCycle$_d$ *to* HamCycle$_u$*, a counterexample can be computed efficiently.*

5.2 Decidable cases for classes of (fixed) algorithmic problems

In this section, we study the question whether there are classes $\mathcal{C}$ and $\mathcal{C}^\star$ of algorithmic problems as well as classes $\mathcal{R}$ of reductions, such that after fixing $P \in \mathcal{C}$ and $P^\star \in \mathcal{C}^\star$ there is an algorithm that tests correctness of inputs $\rho \in \mathcal{R}$.

We first give an example that decidability results are possible for non-trivial classes of reductions and problems. Afterwards, we sketch how the technique employed in the proof can be generalized.

▶ **Theorem 8.** *Reduction?($P, P^\star, \mathcal{R}$) is decidable for the class $\mathcal{R}$ of cookbook reductions with arity bounded by some $r > 0$, arbitrary P, and $P^\star$ definable in first-order logic.*

The proof idea is to represent cookbook reductions ρ by "recipe structures" recipe(ρ) such that $\rho(\mathcal{A})$ can be constructed from the disjoint union $\mathcal{A} \uplus \text{recipe}(\rho)$ of $\mathcal{A}$ and recipe(ρ) via an FO-interpretation which depends on the arity and schema of ρ, but is independent of ρ itself. Then we prove that correctness of reductions in the setting of Theorem 8 only depends on the FO-similarity type of their recipe.

Intuitively, the recipe of a cookbook reduction ρ is the disjoint union of the structures $\mathfrak{S}(\mathfrak{t})$ for all relevant isomorphism types $\mathfrak{t}$, where additional unary relations indicate the source structure and an additional binary relation identifies inherited elements (those (A, j) where A is a strict subset of the domain of $\mathfrak{t}$) with their origin. Formally, fix two schemas σ and $\sigma^\star$, an arity $r \in \mathbb{N}$, and define $\mathfrak{T}_{\leq r}$ to be the finite set of all isomorphism types $\mathfrak{t}$ over the schema σ of arity at most r. The *recipe* recipe(ρ) of a cookbook reduction ρ of arity at most r from σ to $\sigma^\star$ is a structure over the schema $\sigma^\star \cup \{\approx\} \cup \{C_\mathfrak{t} \mid \mathfrak{t} \in \mathfrak{T}_{\leq r}\}$, where $\approx$ is binary and all $C_\mathfrak{t}$ are unary. The restriction of recipe(ρ) to the schema $\sigma^\star \cup \{C_\mathfrak{t} \mid \mathfrak{t} \in \mathfrak{T}_{\leq r}\}$ is the disjoint union $\biguplus_{\mathfrak{t} \in \mathfrak{T}_{\leq r}} \mathfrak{S}(\mathfrak{t})$, where we set $\mathfrak{S}(\mathfrak{t}) = \rho(\mathfrak{t})$ if $\mathfrak{t}$ is not in the support of ρ, and each $C_\mathfrak{t}$ is interpreted as the universe of $\mathfrak{S}(\mathfrak{t})$. The relation $\approx$ "identifies" inherited elements and their original version: for every $\mathfrak{t}, \mathfrak{t}' \in \mathfrak{T}_{\leq r}$ such that $\mathfrak{t}$ is the type of a strict subset of the elements of $\mathfrak{t}'$, if a' is an element of $\mathfrak{S}(\mathfrak{t}')$ inherited from $\mathfrak{S}(\mathfrak{t})$'s element a, then $a' \approx a$ holds in recipe(ρ).

The structure recipe(ρ) representing the cookbook reduction ρ from 3-Clique to 4-Clique given in Figure 3 can be found in Figure 4.

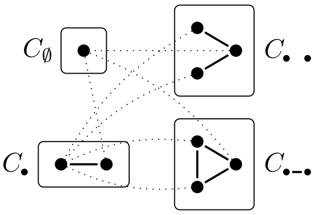


Figure 4 The recipe recipe(ρ) for the cookbook reduction of arity 2 from 3-Clique to 4-Clique from Figure 3. There are four unary relations for the types $\mathfrak{t}_{\emptyset}$, $\mathfrak{t}_{\bullet}$, $\mathfrak{t}_{\bullet\!-\!\bullet}$, and $\mathfrak{t}_{\bullet\;\bullet}$ of loopless undirected graphs. The dotted edges represent the binary inheritance relation $\approx$.

There is an FO-interpretation that applies a recipe recipe(ρ) to a structure $\mathcal{A}$ by interpreting $\mathcal{A} \uplus \text{recipe}(\rho)$.

▶ **Lemma 9.** *Fix $r > 0$ and two schemas $\sigma, \sigma^\star$. There is an* FO*-interpretation $\mathcal{I}^r_{\sigma,\sigma^\star}$ such that $\rho(\mathcal{A})$ and $\mathcal{I}^r_{\sigma,\sigma^\star}(\mathcal{A} \uplus \textit{recipe}(\rho))$ are isomorphic, for every cookbook reduction ρ from σ to $\sigma^\star$ of arity at most r and for every σ-structure $\mathcal{A}$.*

As FO-interpretations preserve FO-similarity, there is a function $f^r_{\sigma,\sigma^\star} : \mathbb{N} \to \mathbb{N}$ such that for every $k \in \mathbb{N}$, $\mathcal{A} \equiv^{\mathsf{FO}}_{f^r_{\sigma,\sigma^\star}(k)} \mathcal{A}'$ entails $\mathcal{I}^r_{\sigma,\sigma^\star}(\mathcal{A}) \equiv^{\mathsf{FO}}_k \mathcal{I}^r_{\sigma,\sigma^\star}(\mathcal{A}')$ (see, e.g., [8, Section 3.2]).

We now prove Theorem 8.

Proof of Theorem 8. We show that whether a cookbook reduction ρ is a reduction from P to $P^\star$ solely depends on the FO_m-type of recipe(ρ), for some large enough m that depends only on r, P, and $P^\star$. As there are only finitely many such FO_m-types and because the type of recipe(ρ) can be determined, the statement follows.

Let k be the quantifier rank of a formula $\varphi^\star \in \mathsf{FO}$ defining $P^\star$. If the recipes of two reductions ρ and ρ' of arity at most r are $f^r_{\sigma,\sigma^\star}$-similar, then so are $\mathcal{A} \uplus \text{recipe}(\rho)$ and $\mathcal{A} \uplus \text{recipe}(\rho')$ for all σ-structures $\mathcal{A}$ (due to a simple Ehrenfeucht-Fraïsse argument). But then $\mathcal{I}^r_{\sigma,\sigma^\star}(\mathcal{A} \uplus \text{recipe}(\rho))$ and $\mathcal{I}^r_{\sigma,\sigma^\star}(\mathcal{A} \uplus \text{recipe}(\rho'))$ – and therefore also $\rho(\mathcal{A})$ and $\rho'(\mathcal{A})$ –, are k-similar. In particular, the reductions ρ and ρ' behave in the same way for all σ-structures $\mathcal{A}$, that is $\rho(\mathcal{A}) \models \varphi^\star$ if and only if $\rho'(\mathcal{A}) \models \varphi^\star$.

We conclude that whether $\rho(\mathcal{A})$ satisfies $\varphi^\star$ only depends on the $\mathsf{FO}_{f^r_{\sigma,\sigma^\star}(k)}$-type of recipe($\rho$) for all $\mathcal{A}$. Hence, the recipe of positive instances of Reduction?($P, P^\star, \mathcal{R}$) is a union of equivalence classes for $\equiv^{\mathsf{FO}}_{f^r_{\sigma,\sigma^\star}(k)}$. For a reduction ρ it can now be evaluated whether its recipe satisfies the type of one of these equivalence classes. ◀

In the rest of this section, we explore how the technique used in the proof above can be generalized to logics beyond FO. Our focus is on monadic-second order logic (MSO), which extends FO by quantifiers for sets of elements. One of the key ingredients, that FO-interpretations preserve FO-similarity, does not translate to MSO for interpretations of dimension greater than one (not even for quantifier-free interpretations). Yet, decidability is retained for problems $P^\star \in \mathsf{MSO}$ if we restrict ourselves to *edge gadget reductions* (on graphs), instead of general cookbook reductions. This generalizes Proposition 6.

▶ **Theorem 10.** *Reduction?($P, P^\star, \mathcal{R}$) is decidable for the class $\mathcal{R}$ of edge gadget reductions, arbitrary P, and $P^\star$ definable in monadic second-order logic.*

The proof exploits compositionality of MSO and can be generalized to other subclasses of cookbook reductions. A discussion of such subclasses is postponed to the long version of this paper.

Proof sketch. An edge gadget reduction ρ is specified as a graph $\mathfrak{g}_\rho$, with two distinguished nodes. As in the proof of Theorem 8, the idea is to show that there is an integer m such that whether ρ is a reduction from P to $P^\star$ only depends on the MSO_m-type of $\mathfrak{g}_\rho$. More precisely, for all gadget graphs $\mathfrak{g}_\rho$ and $\mathfrak{g}_{\rho'}$ with $\mathfrak{g}_\rho \equiv_m^{\mathsf{MSO}} \mathfrak{g}_{\rho'}$, one proves that $\rho(G) \equiv_k^{\mathsf{MSO}} \rho'(G)$ for all graphs G, where k is the quantifier rank of an MSO-sentence describing $P^\star$.

For proving MSO_k-similarity of $\rho(G)$ and $\rho'(G)$, one can use Ehrenfeucht-Fraïssé games for MSO (see, e.g., [10, Section 7.2]). The graphs $\rho(G)$ and $\rho'(G)$ are a composition of G with the edge gadgets $\mathfrak{g}_\rho$ and $\mathfrak{g}_{\rho'}$, respectively. Duplicator has a winning strategy for the MSO-game played on (G, G) as well as for the MSO-game played on $(\mathfrak{g}_\rho, \mathfrak{g}_{\rho'})$. Her strategy for the game on $\rho(G)$ and $\rho'(G)$ is to combine these two winning strategies. For instance, if Spoiler moves on $\rho(G)$ and part of his move is on the edge gadget inserted for an edge (u, v) of G, then Duplicator's response for this part of the move is derived from her strategy for the game on $(\mathfrak{g}_\rho, \mathfrak{g}_{\rho'})$. The partial answers for individual edges are then combined. ◀

For both FO and MSO, the proof uses that the respective classes of reductions can be finitely partitioned into similarity classes and that all reductions in one class are either correct or not correct. This provides a basis for characterizations akin to the ones in Section 5.1 for concrete, arbitrary problems P and concrete $P^\star$ definable in FO or MSO.

5.3 Algorithmic problems as input: decidable cases

We now explore decidability when source and/or target problems are part of the input. We consider classes $\mathcal{C}$ and $\mathcal{C}^\star$ captured by logics $\mathcal{L}$ and $\mathcal{L}^\star$, respectively, and write, e.g., Reduction?$(\mathcal{L}, \mathcal{L}^\star, \mathcal{R})$ for the algorithmic problem where we ask, given $\varphi \in \mathcal{L}$, $\varphi^\star \in \mathcal{L}^\star$ and $\rho \in \mathcal{R}$, whether ρ is a reduction from the problem defined by φ to the one defined by $\varphi^\star$.

One approach for obtaining decidability for the problem Reduction?$(\mathcal{L}, \mathcal{L}^\star, \mathcal{R})$ is by restating it as a satisfiability question for a decidable logic. For a quantifier-free interpretation $\mathcal{I}$ from σ-structures to $\sigma^\star$-structures, denote by $\mathcal{I}^{-1}(\varphi^\star)$ the σ-formula obtained from a $\sigma^\star$-formula $\varphi^\star$ by replacing atoms in $\varphi^\star$ according to their definition in $\mathcal{I}$. Whether a quantifier-free interpretation $\mathcal{I}$ is a reduction from the algorithmic problem defined by $\varphi \in \mathcal{L}$ to the one defined by $\varphi^\star \in \mathcal{L}^\star$ is equivalent to whether $\mathcal{A} \models \varphi$ if and only if $\mathcal{I}(\mathcal{A}) \models \varphi^\star$, for all structures $\mathcal{A}$. This in turn is equivalent to checking whether $\varphi \leftrightarrow \mathcal{I}^{-1}(\varphi^\star)$ is a tautology.

These observations yield, for instance, the following decidable variants, some involving the class QF of quantifier-free first-order interpretations, a class that includes all cookbook reductions, see Theorem 1. See the full version for the proof.

▶ **Theorem 11.**

1. *Reduction?*$(\exists^*\mathsf{FO}, \exists^*\mathsf{FO}, QF)$ *is decidable.*
2. *Reduction?*$(P, \exists^*\mathsf{FO}, QF)$ *is decidable for every fixed algorithmic problem* P*.*
3. *Reduction?*$(\exists^*\mathsf{FO}, P^\star, \mathcal{R})$ *is decidable for every fixed algorithmic problem* $P^\star$ *definable in* MSO *and the class* $\mathcal{R}$ *of edge gadget reductions.*

6 Summary and discussion

We studied variants of the algorithmic problem Reduction? which asks whether a given mapping is a computational reduction between two algorithmic problems. In addition to studying this problem for standard classes of reductions, we also proposed a graphical and compositional language for computational reductions, called cookbook reductions, and compared their expressive power to quantifier-free first-order interpretations. While Reduction? is undecidable in many restricted settings, we identified multiple decidable cases involving (restricted) cookbook reductions and quantifier-free first-order interpretations. Due to its graphical and compositional nature, cookbook reductions are well-suited to be used in teaching support systems for learning tasks tackling the design of computational reductions.

A prototype[3] of our formal framework has been integrated into the teaching support system *Iltis* [11]. Recently it has been used in introductory courses *Theoretical Computer Science* with > 300 students at Ruhr University Bochum and TU Dortmund in workflows covering (i) understanding computational problems, (ii) exploring reductions via examples, and (iii) designing reductions.

Abstract

Dependency pairs constitute a series of very effective techniques for the termination analysis of term rewriting systems. In this paper, we adapt the static dependency pair framework to logically constrained simply-typed term rewriting systems (LCSTRSs), a higher-order formalism with logical constraints built in. We also propose the concept of universal computability, which enables a form of open-world termination analysis through the use of static dependency pairs.

1 Introduction

Logically constrained simply-typed term rewriting systems (LCSTRSs) [12] are a formalism of higher-order term rewriting with logical constraints (built on its first-order counterpart [19]). Proposed for program analysis, LCSTRSs offer a flexible representation of programs owing to – in contrast with traditional TRSs – their support for primitive data types such as (arbitrary-precision or fixed-width) integers and floating-point numbers. Without compromising the ability to directly reason about these widely used data types, LCSTRSs bridge the gap between the abundant techniques based on term rewriting and automatic program analysis.

We consider *termination* analysis in this paper. The termination of LCSTRSs was first discussed in [12] through a variant of the higher-order recursive path ordering (HORPO) [14]. This paper furthers that discussion by introducing dependency pairs [1] to LCSTRSs. As a broad framework for termination, this method was initially proposed for unconstrained first-order term rewriting, and was later generalized in a variety of higher-order settings (see, e.g., [31, 23, 30, 2]). Modern termination analyzers rely heavily on dependency pairs.

In higher-order termination analysis, dependency pairs take two forms: the dynamic [31, 23] and the static [30, 2, 24, 7]. This paper concentrates on *static* dependency pairs, and is based on the definitions in [7, 24]. First-order dependency pairs with logical constraints have been informally defined by the third author [15], from which we also take inspiration.

For program analysis, the traditional notion of termination can be inefficient, and arguably insufficient. It assumes that the whole program is known and analyzed, i.e., *closed-world* analysis. This way even small programs that happen to import a large standard library need sophisticated analysis; local changes in a multipart, previously verified program also require the entire analysis to be redone. As O'Hearn [26] argues (in a different context), studying *open-world* analysis opens up many applications. In particular, it is practically desirable to analyze the termination of standard libraries – or modules of a larger program in general – without prior knowledge of how the functions they define may be used.

It is tricky to characterize such a property, especially in the presence of higher-order arguments. For example, map and fold are usually considered "terminating", even though passing a non-terminating function to them can surely result in non-termination. Hence, we need to narrow our focus to certain "reasonable" calls. On the other hand, the function $\mathsf{app}\ (\mathsf{lam}\ f) \to f$ where $\mathsf{app} : \mathsf{o} \to \mathsf{o} \to \mathsf{o}$ and $\mathsf{lam} : (\mathsf{o} \to \mathsf{o}) \to \mathsf{o}$ would generally be considered "non-terminating", because if we define $\mathsf{w}\ x \to \mathsf{app}\ x\ x$, an infinite rewrite sequence starts from $\mathsf{app}\ (\mathsf{lam}\ \mathsf{w})\ (\mathsf{lam}\ \mathsf{w})$ – this encodes the famous Ω in the untyped λ-calculus. The property we are looking for must distinguish map and fold from app.

To capture this property, we propose a new concept, called *universal computability.* In light of information hiding, this concept can be further generalized to *public computability.* We will see that static dependency pairs are a natural vehicle for analyzing these properties.

Various modular aspects of term rewriting have been studied by the community. Our scenario roughly corresponds to hierarchical combinations [27, 28, 29, 6], where different parts of a program are analyzed separately. We follow this terminology so that it will be easier to compare our work with the literature. However, our setup – higher-order constrained rewriting – is separate from the first-order and unconstrained setting in which hierarchical combinations were initially proposed. Furthermore, our approach has a different focus – namely, the use of static dependency pairs.

Contributions. We recall the formalism of LCSTRSs and the predicate of computability in Section 2. Then the contributions of this paper follow:

- We propose in Section 3 the first definition of *dependency pairs* for higher-order logically constrained TRSs. This is also the first DP approach for constrained rewriting as the prior work on first-order constrained dependency pairs [15] has never been formally published.
- We define in Section 4 the *constrained DP framework* for termination analysis with five classes of *DP processors*, which can be used to simplify termination problems.
- We extend the notion of a *hierarchical combination* [27, 28, 29, 6] to LCSTRSs and define *universal* and *public computability* in Section 5. We also fine-tune the DP framework to support these properties, and provide extra DP processors for public computability. This allows the DP framework to be used for open-world analysis. We base Section 5 on LCSTRSs to emphasize those notions in real-world programming, but they are new and of theoretical interest in higher-order term rewriting even without logical constraints.
- We have implemented the DP framework for both termination and public computability in our open-source analyzer Cora. We describe the experimental evaluation in Section 6.

2 Preliminaries

In this section, we collect the preliminary definitions and results we need from the literature. First, we recall the definition of an LCSTRS [12]. In this paper, we put a restriction on rewrite rules: ℓ is always a pattern in $\ell \to r\ [\varphi]$. Next, we recall the definition of computability (with accessibility) from [7]. This version is particularly tailored for static dependency pairs.

2.1 Logically Constrained STRSs

Terms Modulo Theories. Given a non-empty set $\mathcal{S}$ of *sorts* (or *base types*), the set $\mathcal{T}$ of simple types over $\mathcal{S}$ is generated by the grammar $\mathcal{T} ::= \mathcal{S} \mid (\mathcal{T} \to \mathcal{T})$. Right-associativity is assigned to → so we can omit some parentheses. Given disjoint sets $\mathcal{F}$ and $\mathcal{V}$, whose elements we call *function symbols* and *variables*, respectively, the set $\mathfrak{T}$ of *pre-terms* over $\mathcal{F}$ and $\mathcal{V}$ is generated by the grammar $\mathfrak{T} ::= \mathcal{F} \mid \mathcal{V} \mid (\mathfrak{T}\ \mathfrak{T})$. Left-associativity is assigned to the juxtaposition operation, called *application*, so $t_0\ t_1\ t_2$ stands for $((t_0\ t_1)\ t_2)$, for example.

We assume every function symbol and variable is assigned a unique type. Typing works as expected: if pre-terms t_0 and t_1 have types $A \to B$ and A, respectively, $t_0\ t_1$ has type B. The set $T(\mathcal{F}, \mathcal{V})$ of *terms* over $\mathcal{F}$ and $\mathcal{V}$ consists of pre-terms that have a type. We write $t : A$ if a term t has type A. We assume there are infinitely many variables of each type.

The set $\mathrm{Var}(t)$ of variables in $t \in T(\mathcal{F}, \mathcal{V})$ is defined by $\mathrm{Var}(f) = \emptyset$ for $f \in \mathcal{F}$, $\mathrm{Var}(x) = \{\, x \,\}$ for $x \in \mathcal{V}$ and $\mathrm{Var}(t_0\ t_1) = \mathrm{Var}(t_0) \cup \mathrm{Var}(t_1)$. A term t is called *ground* if $\mathrm{Var}(t) = \emptyset$.

For constrained rewriting, we make further assumptions. First, we assume that there is a distinguished subset $\mathcal{S}_\vartheta$ of $\mathcal{S}$, called the set of *theory sorts*. The grammar $\mathcal{T}_\vartheta ::= \mathcal{S}_\vartheta \mid (\mathcal{S}_\vartheta \to \mathcal{T}_\vartheta)$ generates the set $\mathcal{T}_\vartheta$ of *theory types* over $\mathcal{S}_\vartheta$. Note that a theory type is essentially a non-empty list of theory sorts. Next, we assume that there is a distinguished subset $\mathcal{F}_\vartheta$ of $\mathcal{F}$, called the set of *theory symbols*, and that the type of every theory symbol is in $\mathcal{T}_\vartheta$, which means that the type of any argument passed to a theory symbol is a theory sort. Theory symbols whose type is a theory sort are called *values*. Elements of $T(\mathcal{F}_\vartheta, \mathcal{V})$ are called *theory terms*.

Theory symbols are interpreted in an underlying theory: given an $\mathcal{S}_\vartheta$-indexed family of sets $(\mathfrak{X}_A)_{A \in \mathcal{S}_\vartheta}$, we extend it to a $\mathcal{T}_\vartheta$-indexed family by letting $\mathfrak{X}_{A \to B}$ be the set of mappings from $\mathfrak{X}_A$ to $\mathfrak{X}_B$; an *interpretation* of theory symbols is a $\mathcal{T}_\vartheta$-indexed family of mappings $(\llbracket\cdot\rrbracket_A)_{A \in \mathcal{T}_\vartheta}$ where $\llbracket\cdot\rrbracket_A$ assigns to each theory symbol of type A an element of $\mathfrak{X}_A$ and is bijective if $A \in \mathcal{S}_\vartheta$. Given an interpretation of theory symbols $(\llbracket\cdot\rrbracket_A)_{A \in \mathcal{T}_\vartheta}$, we extend each indexed mapping $\llbracket\cdot\rrbracket_B$ to one that assigns to each *ground theory term* of type B an element of $\mathfrak{X}_B$ by letting $\llbracket t_0\ t_1\rrbracket_B$ be $\llbracket t_0\rrbracket_{A \to B}(\llbracket t_1\rrbracket_A)$. We write just $\llbracket\cdot\rrbracket$ when the type can be deduced.

▶ **Example 1.** Let $\mathcal{S}_\vartheta$ be $\{\, \mathsf{int} \,\}$. Then $\mathsf{int} \to \mathsf{int} \to \mathsf{int}$ is a theory type over $\mathcal{S}_\vartheta$ while $(\mathsf{int} \to \mathsf{int}) \to \mathsf{int}$ is not. Let $\mathcal{F}_\vartheta$ be $\{\, - \,\} \cup \mathbb{Z}$ where $- : \mathsf{int} \to \mathsf{int} \to \mathsf{int}$ and $n : \mathsf{int}$ for all $n \in \mathbb{Z}$. The values are the elements of $\mathbb{Z}$. Let $\mathfrak{X}_{\mathsf{int}}$ be $\mathbb{Z}$, $\llbracket\cdot\rrbracket_{\mathsf{int}}$ be the identity mapping and $\llbracket - \rrbracket$ be the mapping $\lambda m.\, \lambda n.\, m - n$. The interpretation of $(-)\ 1$ is the mapping $\lambda n.\, 1 - n$.

Substitutions, Contexts and Subterms. Type-preserving mappings from $\mathcal{V}$ to $T(\mathcal{F}, \mathcal{V})$ are called *substitutions*. Every substitution σ extends to a type-preserving mapping $\bar{\sigma}$ from $T(\mathcal{F}, \mathcal{V})$ to $T(\mathcal{F}, \mathcal{V})$. We write $t\sigma$ for $\bar{\sigma}(t)$ and define it as follows: $f\sigma = f$ for $f \in \mathcal{F}$, $x\sigma = \sigma(x)$ for $x \in \mathcal{V}$ and $(t_0\ t_1)\sigma = (t_0\sigma)\ (t_1\sigma)$. Let $[x_1 := t_1, \ldots, x_n := t_n]$ denote the substitution σ such that $\sigma(x_i) = t_i$ for all i, and $\sigma(y) = y$ for all $y \in \mathcal{V} \setminus \{\, x_1, \ldots, x_n \,\}$.

A context is a term containing a hole. Let $\Box$ be a special terminal symbol and assign to it a type A; a *context* $C[]$ is an element of $T(\mathcal{F}, \mathcal{V} \cup \{\, \Box \,\})$ such that $\Box$ occurs in $C[]$ exactly once. Given a term $t : A$, let $C[t]$ denote the term produced by replacing $\Box$ in $C[]$ with t.

A term t is called a (maximally applied) *subterm* of a term s, written as $s \trianglerighteq t$, if either $s = t$, $s = s_0\ s_1$ where $s_1 \trianglerighteq t$, or $s = s_0\ s_1$ where $s_0 \trianglerighteq t$ and $s_0 \neq t$; i.e., $s = C[t]$ for $C[]$ that is not of form $C'[\Box\ t_1]$. We write $s \triangleright t$ and call t a *proper subterm* of s if $s \trianglerighteq t$ and $s \neq t$.

Constrained Rewriting. Constrained rewriting requires the theory sort bool: we henceforth assume that $\mathsf{bool} \in \mathcal{S}_\vartheta$, $\{\, \mathfrak{f}, \mathfrak{t} \,\} \subseteq \mathcal{F}_\vartheta$, $\mathfrak{X}_{\mathsf{bool}} = \{\, 0, 1 \,\}$, $\llbracket \mathfrak{f} \rrbracket_{\mathsf{bool}} = 0$ and $\llbracket \mathfrak{t} \rrbracket_{\mathsf{bool}} = 1$. A *logical constraint* is a theory term φ such that φ has type bool and the type of each variable in $\mathrm{Var}(\varphi)$

is a theory sort. A (constrained) *rewrite rule* is a triple $\ell \to r\ [\varphi]$ where ℓ and r are terms which have the same type, φ is a logical constraint, the type of each variable in $\mathrm{Var}(r) \setminus \mathrm{Var}(\ell)$ is a theory sort and ℓ is a pattern that takes the form $f\ t_1 \cdots t_n$ for some function symbol f and contains at least one function symbol in $\mathcal{F} \setminus \mathcal{F}_\vartheta$. Here a *pattern* is a term whose subterms are either $f\ t_1 \cdots t_n$ for some function symbol f or a variable. A substitution σ is said to *respect* $\ell \to r\ [\varphi]$ if $\sigma(x)$ is a value for all $x \in \mathrm{Var}(\varphi) \cup (\mathrm{Var}(r) \setminus \mathrm{Var}(\ell))$ and $[\![\varphi\sigma]\!] = 1$.

A *logically constrained simply-typed term rewriting system* (LCSTRS) collects the above data – $\mathcal{S}$, $\mathcal{S}_\vartheta$, $\mathcal{F}$, $\mathcal{F}_\vartheta$, $\mathcal{V}$, $(\mathfrak{X}_A)$ and $[\![\cdot]\!]$ – along with a set $\mathcal{R}$ of rewrite rules. We usually let $\mathcal{R}$ alone stand for the system. The set $\mathcal{R}$ induces the *rewrite relation* $\to_\mathcal{R}$ over terms: $t \to_\mathcal{R} t'$ if and only if there exists a context $C[]$ such that either (1) $t = C[\ell\sigma]$ and $t' = C[r\sigma]$ for some rewrite rule $\ell \to r\ [\varphi] \in \mathcal{R}$ and some substitution σ which respects $\ell \to r\ [\varphi]$, or (2) $t = C[f\ v_1 \cdots v_n]$ and $t' = C[v']$ for some theory symbol f and some values $v_1, \ldots, v_n, v'$ with $n > 0$ and $[\![f\ v_1 \cdots v_n]\!] = [\![v']\!]$. When no ambiguity arises, we may write $\to$ for $\to_\mathcal{R}$.

If $t \to_\mathcal{R} t'$ due to the second condition above, we also write $t \to_\kappa t'$ and call it a *calculation step*. Theory symbols that are not a value are called *calculation symbols*. Let $t{\downarrow_\kappa}$ denote the (unique) κ-normal form of t, i.e., the term t' such that $t \to_\kappa^* t'$ and $t' \not\to_\kappa t''$ for any t''. For example, $(f\ (7 * (3 * 2))){\downarrow_\kappa} = f\ 42$ if f is not a calculation symbol, or if $f : \mathsf{int} \to A \to B$.

A rewrite rule $\ell \to r\ [\varphi]$ is said to *define* a function symbol f if $\ell = f\ t_1 \cdots t_n$. Given an LCSTRS $\mathcal{R}$, f is called a *defined symbol* if some rewrite rule in $\mathcal{R}$ defines f. Let $\mathcal{D}$ denote the set of defined symbols. Values and function symbols in $\mathcal{F} \setminus (\mathcal{F}_\vartheta \cup \mathcal{D})$ are called *constructors*.

▶ **Example 2.** Below is the factorial function in continuation-passing style as an LCSTRS:

$$\begin{array}{lll} \mathsf{fact}\ n\ k \to k\ 1 & [n \leq 0] & \mathsf{comp}\ g\ f\ x \to g\ (f\ x) \\ \mathsf{fact}\ n\ k \to \mathsf{fact}\ (n - 1)\ (\mathsf{comp}\ k\ ((*)\ n)) & [n > 0] & \mathsf{id}\ x \to x \end{array}$$

We use infix notation for some binary operators, and omit the logical constraint of a rewrite rule when it is $\mathfrak{t}$. An example rewrite sequence is $\mathsf{fact}\ 1\ \mathsf{id} \to \mathsf{fact}\ (1 - 1)\ (\mathsf{comp}\ \mathsf{id}\ ((*)\ 1)) \to_\kappa \mathsf{fact}\ 0\ (\mathsf{comp}\ \mathsf{id}\ ((*)\ 1)) \to \mathsf{comp}\ \mathsf{id}\ ((*)\ 1)\ 1 \to \mathsf{id}\ ((*)\ 1\ 1) \to_\kappa \mathsf{id}\ 1 \to 1$.

2.2 Accessibility and Computability

We recall the notion of computability with accessibility – which originates from [3] and is reformulated in [7] to couple with static dependency pairs – and adapt the notion of accessible function passing [7] to LCSTRSs.

Accessibility. Assume given a *sort ordering* – a quasi-ordering $\succsim$ over $\mathcal{S}$ whose strict part $\succ\, = \,\succsim \setminus \precsim$ is well-founded. We inductively define two relations $\succsim_+$ and $\succ_-$ over $\mathcal{S}$ and $\mathcal{T}$: given a sort A and a type $B = B_1 \to \cdots \to B_n \to C$ where C is a sort and $n \geq 0$, $A \succsim_+ B$ if and only if $A \succsim C$ and $\forall i.\, A \succ_- B_i$, and $A \succ_- B$ if and only if $A \succ C$ and $\forall i.\, A \succsim_+ B_i$.

Given a function symbol $f : A_1 \to \cdots \to A_n \to B$ where B is a sort, the set $\mathrm{Acc}(f)$ of the *accessible argument positions* of f is defined as $\{\, 1 \leq i \leq n \mid B \succsim_+ A_i \,\}$. A term t is called an *accessible subterm* of a term s, written as $s \trianglerighteq_{\mathrm{acc}} t$, if either $s = t$, or $s = f\ s_1 \cdots s_m$ for some $f \in \mathcal{F}$ and there exists $k \in \mathrm{Acc}(f)$ such that $s_k \trianglerighteq_{\mathrm{acc}} t$. An LCSTRS $\mathcal{R}$ is called *accessible function passing* (AFP) if there exists a sort ordering such that for all $f\ s_1 \cdots s_m \to r\ [\varphi] \in \mathcal{R}$ and $x \in \mathrm{Var}(f\ s_1 \cdots s_m) \cap \mathrm{Var}(r) \setminus \mathrm{Var}(\varphi)$, there exists k such that $s_k \trianglerighteq_{\mathrm{acc}} x$.

▶ **Example 3.** An LCSTRS $\mathcal{R}$ is AFP (with $\succsim$ equating all the sorts) if for all $f\ s_1 \cdots s_m \to r\ [\varphi] \in \mathcal{R}$ and $i \in \{\, 1, \ldots, m \,\}$, the type of each proper subterm of s_i is a sort. Rewrite rules for common higher-order functions, e.g., map and fold, usually fit this criterion.

Consider $\{\,\mathsf{complst}\ \mathsf{fnil}\ x \to x, \mathsf{complst}\ (\mathsf{fcons}\ f\ l)\ x \to \mathsf{complst}\ l\ (f\ x)\,\}$, where $\mathsf{complst} : \mathsf{funlist} \to \mathsf{int} \to \mathsf{int}$ composes a list of *functions*. This system is AFP with $\mathsf{funlist} \succ \mathsf{int}$.

The system $\{\,\mathsf{app}\ (\mathsf{lam}\ f) \to f\,\}$ in Section 1 is not AFP since $\mathsf{o} \succ \mathsf{o}$ cannot be true.

Computability. A term is called *neutral* if it takes the form $x\ t_1 \cdots t_n$ for some variable x. A set of *reducibility candidates*, or an *RC-set*, for the rewrite relation $\to_{\mathcal{R}}$ of an LCSTRS $\mathcal{R}$ is an $\mathcal{S}$-indexed family of sets $(I_A)_{A \in \mathcal{S}}$ (let I denote $\bigcup_A I_A$) satisfying the following conditions:

(1) Each element of I_A is a terminating (with respect to $\to_{\mathcal{R}}$) term of type A.

(2) Given terms s and t such that $s \to_{\mathcal{R}} t$, if s is in I_A, so is t.

(3) Given a neutral term s, if t is in I_A for all t such that $s \to_{\mathcal{R}} t$, so is s.

Given an RC-set I for $\to_{\mathcal{R}}$, a term t_0 is called *I-computable* if either the type of t_0 is a sort and $t_0 \in I$, or the type of t_0 is $A \to B$ and $t_0\ t_1$ is I-computable for all I-computable $t_1 : A$.

We are interested in a specific RC-set $\mathbb{C}$, whose existence is guaranteed by Theorem 4.

▶ **Theorem 4** (see [7]). *Given a sort ordering and an RC-set I for $\to_{\mathcal{R}}$, let $\Rrightarrow_I$ be the relation over terms such that $s \Rrightarrow_I t$ if and only if both s and t have a base type, $s = f\ s_1 \cdots s_m$ for some function symbol f, $t = s_k\ t_1 \cdots t_n$ for some $k \in \mathrm{Acc}(f)$ and t_i is I-computable for all i.*

Given an LCSTRS $\mathcal{R}$ with a sort ordering, there exists an RC-set $\mathbb{C}$ for $\to_{\mathcal{R}}$ such that $t \in \mathbb{C}_A$ if and only if $t : A$ is terminating with respect to $\to_{\mathcal{R}} \cup \Rrightarrow_{\mathbb{C}}$, and for all t' such that $t \to_{\mathcal{R}}^* t'$, if $t' = f\ t_1 \cdots t_n$ for some function symbol f, t_i is $\mathbb{C}$-computable for all $i \in \mathrm{Acc}(f)$.

Thus, given a $\mathbb{C}$-computable term $f\ t_1 \cdots t_n$, all its reducts and the accessible arguments – t_i for $i \in \mathrm{Acc}(f)$ – are also $\mathbb{C}$-computable. We consider $\mathbb{C}$-computability throughout this paper.

3 Static Dependency Pairs for LCSTRSs

Originally proposed for unconstrained first-order term rewriting, the dependency pair approach [1] – a methodology that analyzes the recursive structure of function calls – is at the heart of most modern automatic termination analyzers for various styles of term rewriting. There follow multiple higher-order generalizations, among which we adopt here the *static* branch [24, 7]. As we shall see in Section 5, this approach extends well to open-world analysis.

In this section, we adapt static dependency pairs to LCSTRSs. We start with a notation:

▶ **Definition 5.** *Given an LCSTRS $\mathcal{R}$, let $\mathcal{F}^\sharp$ be $\mathcal{F} \cup \{\, f^\sharp \mid f \in \mathcal{D}\,\}$ where $\mathcal{D}$ is the set of defined symbols in $\mathcal{R}$ and $f^\sharp$ is a fresh function symbol for all f. Let dp be a fresh sort, and for each defined symbol $f : A_1 \to \cdots \to A_n \to B$ where $B \in \mathcal{S}$, we assign $f^\sharp : A_1 \to \cdots \to A_n \to \mathsf{dp}$. Given a term $t = f\ t_1 \cdots t_n \in T(\mathcal{F}, \mathcal{V})$ where $f \in \mathcal{D}$, let $t^\sharp$ denote $f^\sharp\ t_1 \cdots t_n \in T(\mathcal{F}^\sharp, \mathcal{V})$.*

In the presence of logical constraints, a dependency pair should be more than a pair. Two extra components – a logical constraint and a set of variables – keep track of what substitutions are expected by the dependency pair.

▶ **Definition 6.** *A* static dependency pair *(SDP) is a quadruple $s^\sharp \Rightarrow t^\sharp\ [\varphi \mid L]$ where $s^\sharp$ and $t^\sharp$ are terms of type dp, φ is a logical constraint and $L \supseteq \mathrm{Var}(\varphi)$ is a set of variables whose types are theory sorts. Given a rewrite rule $\ell \to r\ [\varphi]$, let $\mathrm{SDP}(\ell \to r\ [\varphi])$ denote the set of SDPs of form $\ell^\sharp\ x_1 \cdots x_m \Rightarrow g^\sharp\ t_1 \cdots t_q\ y_{q+1} \cdots y_n\ [\varphi \mid \mathrm{Var}(\varphi) \cup (\mathrm{Var}(r) \setminus \mathrm{Var}(\ell))]$ such that*

(1) *$\ell^\sharp : A_1 \to \cdots \to A_m \to \mathsf{dp}$ while $x_i : A_i$ is a fresh variable for all i,*

(2) *$r\ x_1 \cdots x_m \trianglerighteq g\ t_1 \cdots t_q$ for $g \in \mathcal{D}$, and*

(3) *$g^\sharp : B_1 \to \cdots \to B_n \to \mathsf{dp}$ while $y_i : B_i$ is a fresh variable for all $i > q$.*

Let $\mathrm{SDP}(\mathcal{R})$ be $\bigcup_{\ell \to r\ [\varphi] \in \mathcal{R}} \mathrm{SDP}(\ell \to r\ [\varphi])$. A substitution σ is said to respect *an SDP $s^\sharp \Rightarrow t^\sharp\ [\varphi \mid L]$ if $\sigma(x)$ is a ground theory term for all $x \in L$ and $[\![\varphi\sigma]\!] = 1$.*

The component L is new compared to [15]. We shall see its usefulness in Section 4.4, as it gives us more freedom to manipulate dependency pairs. We introduce two shorthand notations for SDPs: $s^\sharp \Rightarrow t^\sharp\ [\varphi]$ for $s^\sharp \Rightarrow t^\sharp\ [\varphi \mid \mathrm{Var}(\varphi)]$, and $s^\sharp \Rightarrow t^\sharp$ for $s^\sharp \Rightarrow t^\sharp\ [\mathsf{t} \mid \emptyset]$.

▶ **Example 7.** Consider the system $\mathcal{R}$ consisting of the following rewrite rules, in which $\mathsf{gcdlist} : \mathsf{intlist} \to \mathsf{int}$, $\mathsf{fold} : (\mathsf{int} \to \mathsf{int} \to \mathsf{int}) \to \mathsf{int} \to \mathsf{intlist} \to \mathsf{int}$ and $\mathsf{gcd} : \mathsf{int} \to \mathsf{int} \to \mathsf{int}$.

$$\begin{array}{lllll}
\mathsf{gcdlist} \to \mathsf{fold}\ \mathsf{gcd}\ 0 & & \mathsf{fold}\ f\ y\ \mathsf{nil} \to y & \mathsf{fold}\ f\ y\ (\mathsf{cons}\ x\ l) \to f\ x\ (\mathsf{fold}\ f\ y\ l) & \\
\mathsf{gcd}\ m\ n \to \mathsf{gcd}\ (-m)\ n & [m < 0] & \mathsf{gcd}\ m\ n \to \mathsf{gcd}\ m\ (-n) & & [n < 0] \\
\mathsf{gcd}\ m\ 0 \to m & [m \geq 0] & \mathsf{gcd}\ m\ n \to \mathsf{gcd}\ n\ (m \bmod n) & & [m \geq 0 \wedge n > 0]
\end{array}$$

The set $\mathrm{SDP}(\mathcal{R})$ consists of (1) $\mathsf{gcdlist}^\sharp\ l' \Rightarrow \mathsf{gcd}^\sharp\ m'\ n'$, (2) $\mathsf{gcdlist}^\sharp\ l' \Rightarrow \mathsf{fold}^\sharp\ \mathsf{gcd}\ 0\ l'$, (3) $\mathsf{fold}^\sharp\ f\ y\ (\mathsf{cons}\ x\ l) \Rightarrow \mathsf{fold}^\sharp\ f\ y\ l$, (4) $\mathsf{gcd}^\sharp\ m\ n \Rightarrow \mathsf{gcd}^\sharp\ (-m)\ n\ [m < 0]$, (5) $\mathsf{gcd}^\sharp\ m\ n \Rightarrow \mathsf{gcd}^\sharp\ m\ (-n)\ [n < 0]$, and (6) $\mathsf{gcd}^\sharp\ m\ n \Rightarrow \mathsf{gcd}^\sharp\ n\ (m \bmod n)\ [m \geq 0 \wedge n > 0]$. Note that in (1), m' and n' occur on the right-hand side of $\Rightarrow$ but not on the left while they are *not* required to be instantiated to ground theory terms ($L = \emptyset$). This is normal for SDPs [7, 24].

Termination analysis via SDPs is based on the notion of a chain:

▶ **Definition 8.** *Given a set $\mathcal{P}$ of SDPs and a set $\mathcal{R}$ of rewrite rules, a* $(\mathcal{P}, \mathcal{R})$-chain *is a (finite or infinite) sequence $({s_0}^\sharp \Rightarrow {t_0}^\sharp\ [\varphi_0 \mid L_0], \sigma_0), ({s_1}^\sharp \Rightarrow {t_1}^\sharp\ [\varphi_1 \mid L_1], \sigma_1), \ldots$ such that for all i, ${s_i}^\sharp \Rightarrow {t_i}^\sharp\ [\varphi_i \mid L_i] \in \mathcal{P}$, σ_i is a substitution which respects ${s_i}^\sharp \Rightarrow {t_i}^\sharp\ [\varphi_i \mid L_i]$, and ${t_{i-1}}^\sharp \sigma_{i-1} \to_{\mathcal{R}}^* {s_i}^\sharp \sigma_i$ if $i > 0$. The above $(\mathcal{P}, \mathcal{R})$-chain is called* computable *if $u\sigma_i$ is $\mathbb{C}$-computable for all i and u such that $t_i \rhd u$.*

▶ **Example 9.** Following Example 7, $(1, [l := \mathsf{nil}, m := 42, n := 24]), (6, [m := 42, n := 24]), (6, [m := 24, n := 18]), (6, [m := 18, n := 6])$ is a computable $(\mathrm{SDP}(\mathcal{R}), \mathcal{R})$-chain.

The key to establishing termination is the following result:

▶ **Theorem 10.** *An AFP system $\mathcal{R}$ is terminating if there exists no infinite computable* $(\mathrm{SDP}(\mathcal{R}), \mathcal{R})$*-chain.*

The proof (see [11, Appendix A.1]) is very similar to that for unconstrained SDPs [24, 7].

4 The Constrained DP Framework

In this section, we present several techniques based on SDPs, each as a class of *DP processors*; formally, we call this collection of DP processors the *constrained (static) DP framework*. In general, a DP framework [9, 7] constitutes a broad method for termination and non-termination. The presentation here is not complete – for example, we do not consider non-termination – and a complete one is beyond the scope of this paper. We rather focus on the most essential DP processors and those newly designed to handle logical constraints.

For presentation, we fix an LCSTRS $\mathcal{R}$.

▶ **Definition 11.** *A* DP problem *is a set $\mathcal{P}$ of SDPs. A DP problem $\mathcal{P}$ is called* finite *if there exists no infinite computable $(\mathcal{P}, \mathcal{R})$-chain. A* DP processor *is a partial mapping which possibly assigns to a DP problem a set of DP problems. A DP processor ρ is called* sound *if a DP problem $\mathcal{P}$ is finite whenever $\rho(\mathcal{P})$ consists only of finite DP problems.*

Following Theorem 10, in order to establish the termination of an AFP system $\mathcal{R}$, it suffices to show that $\mathrm{SDP}(\mathcal{R})$ is a finite DP problem. Given a collection of sound DP processors, we have the following procedure: (1) $Q := \{\, \mathrm{SDP}(\mathcal{R}) \,\}$; (2) while Q contains a DP problem $\mathcal{P}$ to which some sound DP processor ρ is applicable, $Q := (Q \setminus \{\, \mathcal{P} \,\}) \cup \rho(\mathcal{P})$. If this procedure ends with $Q = \emptyset$, we can conclude that $\mathcal{R}$ is terminating.

4.1 The DP Graph and Its Approximations

The interconnection of SDPs via chains gives rise to a graph, namely, the DP graph [1], which models the reachability between dependency pairs. Since this graph is not computable in general, we follow the usual convention and consider its (over-)approximations:

▶ **Definition 12.** *Given a set $\mathcal{P}$ of SDPs, a* graph approximation (G_θ, θ) *for $\mathcal{P}$ consists of a finite directed graph G_θ and a mapping θ which assigns to each SDP in $\mathcal{P}$ a vertex of G_θ so that there is an edge from $\theta(p_0)$ to $\theta(p_1)$ whenever $(p_0, \sigma_0), (p_1, \sigma_1)$ is a $(\mathcal{P}, \mathcal{R})$-chain for some substitutions σ_0 and σ_1.*

Here (G_θ, θ) approximates the true DP graph by allowing θ to assign a single vertex to multiple (possibly, infinitely many) SDPs, and by allowing G_θ to contain an edge from $\theta(p_0)$ to $\theta(p_1)$ even if p_0 and p_1 are not connected by any $(\mathcal{P}, \mathcal{R})$-chain. In practice, we typically deal with only a finite set $\mathcal{P}$ of SDPs, in which case we usually take a bijection for θ.

This graph structure is useful because we can leverage it to decompose the DP problem.

▶ **Definition 13.** *Given a DP problem $\mathcal{P}$, a* graph processor *computes a graph approximation (G_θ, θ) for $\mathcal{P}$ and the strongly connected components (SCCs) of G_θ, then returns $\{\, \{\, p \in \mathcal{P} \mid \theta(p)$ belongs to $S \,\} \mid S$ is a non-trivial SCC of $G_\theta \,\}$.*

▶ **Example 14.** Following Example 7, a (tight) graph approximation for SDP($\mathcal{R}$) is in Figure 1. If a graph processor produces this graph as the graph approximation, it will return the set of DP problems $\{\, \{\, 3 \,\}, \{\, 4, 5 \,\}, \{\, 6 \,\} \,\}$.

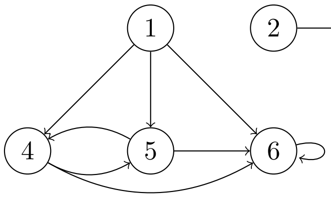

Figure 1 A graph approximation for SDP($\mathcal{R}$) from Example 7.

Implementation. To compute a graph approximation, we adapt the common Cap approach [10, 33] and take theories into account. Considering theories allows us, for example, *not* to have an edge from (6) to (4) in Figure 1.

We assume given a finite set of SDPs and let θ be a bijection. Whether there is an edge from $\theta({s_0}^\sharp \Rightarrow {t_0}^\sharp\ [\varphi_0 \mid L_0])$ to $\theta({s_1}^\sharp \Rightarrow {t_1}^\sharp\ [\varphi_1 \mid L_1])$ – we rename variables if necessary to avoid name collisions between the two SDPs – is determined by the satisfiability (which we check by an SMT solver) of $\varphi_0 \wedge \varphi_1 \wedge \zeta({t_0}^\sharp, {s_1}^\sharp)$ where $\zeta(u, v)$ is defined as follows:

- If $u = f\ u_1 \cdots u_n$ where $f \in \mathcal{F}^\sharp$ and no rewrite rule in $\mathcal{R}$ takes the form $f\ \ell_1 \cdots \ell_k \to r\ [\varphi]$ for $k \leq n$, we define $\zeta(u, v)$ in two cases:
  (1) $\zeta(u, v) = \zeta(u_1, v_1) \wedge \cdots \wedge \zeta(u_n, v_n)$ if $v = f\ v_1 \cdots v_n$.
  (2) $\zeta(u, v) = \mathfrak{f}$ if $v = g\ v_1 \cdots v_m$ for some function symbol g other than f, and either f is not a theory symbol or g is not a value.
- Suppose $\zeta(u, v)$ is not defined above; $\zeta(u, v) = (u \equiv v)$ if $u \in T(\mathcal{F}_\vartheta, L_0)$ has a base type and v is a theory term in which the type of each variable is a theory sort, and $\zeta(u, v) = \mathfrak{t}$ otherwise.

See [11, Appendix A.2] for the proof that this approach produces a graph approximation.

Then strongly connected components can be computed by Tarjan's algorithm [32].

▶ **Example 15.** In Figure 1, since $(m_0 \geq 0 \wedge n_0 > 0) \wedge m_1 < 0 \wedge (n_0 \equiv m_1 \wedge m_0 \bmod n_0 \equiv n_1)$ is unsatisfiable, there is no edge from (6) to (4).

4.2 The Subterm Criterion

The subterm criterion [13, 24] handles structural recursion and allows us to remove decreasing SDPs without considering rewrite rules in $\mathcal{R}$. We start with defining projections:

▶ **Definition 16.** *Let* heads$(\mathcal{P})$ *denote the set of function symbols heading either side of an SDP in $\mathcal{P}$. A* projection *ν for a set $\mathcal{P}$ of SDPs is a mapping from* heads$(\mathcal{P})$ *to integers such that $1 \leq \nu(f^\sharp) \leq n$ if $f^\sharp : A_1 \to \cdots \to A_n \to \mathsf{dp}$. Let $\bar{\nu}(f^\sharp\ t_1 \cdots t_n)$ denote $t_{\nu(f^\sharp)}$.*

A projection chooses an argument position for each relevant function symbol so that arguments at those positions do not increase in a chain.

▶ **Definition 17.** *Given a set $\mathcal{P}$ of SDPs, a projection ν is said to* $\rhd$-orient *a subset $\mathcal{P}'$ of $\mathcal{P}$ if $\bar{\nu}(s^\sharp) \rhd \bar{\nu}(t^\sharp)$ for all $s^\sharp \Rightarrow t^\sharp\ [\varphi \mid L] \in \mathcal{P}'$ and $\bar{\nu}(s^\sharp) = \bar{\nu}(t^\sharp)$ for all $s^\sharp \Rightarrow t^\sharp\ [\varphi \mid L] \in \mathcal{P} \setminus \mathcal{P}'$. A* subterm criterion processor *assigns to a DP problem $\mathcal{P}$ the singleton $\{\, \mathcal{P} \setminus \mathcal{P}' \,\}$ for some non-empty subset $\mathcal{P}'$ of $\mathcal{P}$ such that there exists a projection for $\mathcal{P}$ which $\rhd$-orients $\mathcal{P}'$.*

▶ **Example 18.** Following Example 14, a subterm criterion processor is applicable to $\{\, 3 \,\}$. Let $\nu(\mathsf{fold}^\sharp)$ be 3 so that $\bar{\nu}(\mathsf{fold}^\sharp\ f\ y\ (\mathsf{cons}\ x\ l)) = \mathsf{cons}\ x\ l \rhd l = \bar{\nu}(\mathsf{fold}^\sharp\ f\ y\ l)$. The processor returns $\{\, \emptyset \,\}$, and the empty DP problem can (trivially) be removed by a graph processor.

Implementation. The search for a suitable projection can be done through SMT and is standard: we introduce an integer variable $N_{f^\sharp}$ that represents $\nu(f^\sharp)$ for each $f^\sharp \in \mathrm{heads}(\mathcal{P})$, and a boolean variable strict_p for each $p \in \mathcal{P}$; then we encode the requirement per SDP.

4.3 Integer Mappings

The subterm criterion deals with recursion over the structure of terms, but not recursion over, say, integers, which requires us to utilize the information in logical constraints. In this subsection, we assume that $\mathsf{int} \in \mathcal{S}_\vartheta$ and $\mathcal{F}_\vartheta \supseteq \{\, \geq, >, \wedge \,\}$, where $\geq : \mathsf{int} \to \mathsf{int} \to \mathsf{bool}$, $> : \mathsf{int} \to \mathsf{int} \to \mathsf{bool}$ and $\wedge : \mathsf{bool} \to \mathsf{bool} \to \mathsf{bool}$ are interpreted in the standard way.

▶ **Definition 19.** *Given a set $\mathcal{P}$ of SDPs, for all $f^\sharp \in$* heads$(\mathcal{P})$ *(see Definition 16) where $f^\sharp : A_1 \to \cdots \to A_n \to \mathsf{dp}$, let $\iota(f^\sharp)$ be the subset of $\{\, 1, \ldots, n \,\}$ such that $i \in \iota(f^\sharp)$ if and only if $A_i \in \mathcal{S}_\vartheta$ and the i-th argument of any occurrence of $f^\sharp$ in an SDP $s^\sharp \Rightarrow t^\sharp\ [\varphi \mid L] \in \mathcal{P}$ is in $T(\mathcal{F}_\vartheta, L)$. Let $\mathcal{X}(f^\sharp)$ be a set of fresh variables $\{\, x_{f^\sharp,i} \mid i \in \iota(f^\sharp) \,\}$ where $x_{f^\sharp,i} : A_i$ for all i. An* integer mapping *$\mathcal{J}$ for $\mathcal{P}$ is a mapping from* heads$(\mathcal{P})$ *to theory terms such that for all $f^\sharp$, $\mathcal{J}(f^\sharp) : \mathsf{int}$ and $\mathrm{Var}(\mathcal{J}(f^\sharp)) \subseteq \mathcal{X}(f^\sharp)$. Let $\bar{\mathcal{J}}(f^\sharp\ t_1 \cdots t_n)$ denote $\mathcal{J}(f^\sharp)[x_{f^\sharp,i} \coloneqq t_i]_{i \in \iota(f^\sharp)}$.*

With integer mappings, we can handle decreasing integer values.

▶ **Definition 20.** *Given a set $\mathcal{P}$ of SDPs, an integer mapping $\mathcal{J}$ is said to* $>$-orient *a subset $\mathcal{P}'$ of $\mathcal{P}$ if $\varphi \models \bar{\mathcal{J}}(s^\sharp) \geq 0 \wedge \bar{\mathcal{J}}(s^\sharp) > \bar{\mathcal{J}}(t^\sharp)$ for all $s^\sharp \Rightarrow t^\sharp\ [\varphi \mid L] \in \mathcal{P}'$, and $\varphi \models \bar{\mathcal{J}}(s^\sharp) \geq \bar{\mathcal{J}}(t^\sharp)$ for all $s^\sharp \Rightarrow t^\sharp\ [\varphi \mid L] \in \mathcal{P} \setminus \mathcal{P}'$, where $\varphi \models \varphi'$ denotes that $[\![\varphi\sigma]\!] = 1$ implies $[\![\varphi'\sigma]\!] = 1$ for each substitution σ which maps variables in $\mathrm{Var}(\varphi) \cup \mathrm{Var}(\varphi')$ to values. An* integer mapping processor *assigns to a DP problem $\mathcal{P}$ the singleton $\{\, \mathcal{P} \setminus \mathcal{P}' \,\}$ for some non-empty subset $\mathcal{P}'$ of $\mathcal{P}$ such that there exists an integer mapping for $\mathcal{P}$ which $>$-orients $\mathcal{P}'$.*

▶ **Example 21.** Following Example 14, an integer mapping processor is applicable to $\{\,6\,\}$. Let $\mathcal{J}(\mathsf{gcd}^\sharp)$ be $x_{\mathsf{gcd}^\sharp,2}$ so that $\bar{\mathcal{J}}(\mathsf{gcd}^\sharp\ m\ n) = n$, $\bar{\mathcal{J}}(\mathsf{gcd}^\sharp\ n\ (m \bmod n)) = m \bmod n$ and $m \geq 0 \wedge n > 0 \models n \geq 0 \wedge n > m \bmod n$. The processor returns $\{\,\emptyset\,\}$, and the empty DP problem can (trivially) be removed by a graph processor.

Implementation. There are several ways to implement integer mapping processors. In our implementation, we generate a number of "interpretation candidates" and use an SMT encoding to select for each $f^\sharp \in \mathrm{heads}(\mathcal{P})$ one candidate that satisfies the requirements. Candidates include forms such as $\mathcal{J}(f^\sharp) = x_{f^\sharp,i}$ and those that are generated from the SDPs' logical constraints – e.g., given $\mathsf{f}^\sharp\ x\ y \Rightarrow \mathsf{g}^\sharp\ x\ (y+1)\ [y < x]$, we generate $\mathcal{J}(\mathsf{f}^\sharp) = x_{\mathsf{f}^\sharp,1} - x_{\mathsf{f}^\sharp,2} - 1$ because $y < x$ implies $x - y - 1 \geq 0$.

4.4 Theory Arguments

Integer mapping processors have a clear limitation: what if some key variables do not occur in the set L? This is observed in the remaining DP problem $\{\,4, 5\,\}$ from Example 7. It is clearly finite but no integer mapping processor is applicable since $\iota(\mathsf{gcd}^\sharp) = \emptyset$.

This restriction exists for a reason. Variables that are not guaranteed to be instantiated to theory terms may be instantiated to *non-deterministic* terms – e.g., $\{\,\mathsf{f}^\sharp\ x\ y\ z \Rightarrow \mathsf{f}^\sharp\ x\ (x+1)\ (x-1)\ [y < z]\,\}$ is not a finite DP problem if $\mathcal{R} \supseteq \{\,\mathsf{c}\ x\ y \to x, \mathsf{c}\ x\ y \to y\,\}$.

The problem of $\{\,4, 5\,\}$ arises because each SDP focuses on only one argument: for example, the logical constraint (with the component L) of (5) only concerns n so in principle we cannot assume anything about m. Yet, if (5) follows (4) in a chain, we *can* derive that m must be instantiated to a ground theory term (we call such an argument a *theory argument*). We explore a way of propagating this information.

▶ **Definition 22.** *A* theory argument (position) mapping τ *for a set* $\mathcal{P}$ *of SDPs is a mapping from* $\mathrm{heads}(\mathcal{P})$ *(see Definition 16) to subsets of* $\mathbb{Z}$ *such that* $\tau(f^\sharp) \subseteq \{\,1 \leq i \leq m \mid A_i \in \mathcal{S}_\vartheta\,\}$ *if* $f^\sharp : A_1 \to \cdots \to A_m \to \mathsf{dp}$, s_i *is a theory term and the type of each variable in* $\mathrm{Var}(s_i)$ *is a theory sort for all* $f^\sharp\ s_1 \cdots s_m \Rightarrow t^\sharp\ [\varphi \mid L] \in \mathcal{P}$ *and* $i \in \tau(f^\sharp)$*, and* t_j *is a theory term and* $\mathrm{Var}(t_j) \subseteq L \cup \bigcup_{i \in \tau(f^\sharp)} \mathrm{Var}(s_i)$ *for all* $f^\sharp\ s_1 \cdots s_m \Rightarrow g^\sharp\ t_1 \cdots t_n\ [\varphi \mid L] \in \mathcal{P}$ *and* $j \in \tau(g^\sharp)$*. Let* $\bar{\tau}(f^\sharp\ s_1 \cdots s_m \Rightarrow t^\sharp\ [\varphi \mid L])$ *denote* $f^\sharp\ s_1 \cdots s_m \Rightarrow t^\sharp\ [\varphi \mid L \cup \bigcup_{i \in \tau(f^\sharp)} \mathrm{Var}(s_i)]$*.*

By a theory argument mapping, we choose a subset of the given set of SDPs from which the theory argument information is propagated.

▶ **Definition 23.** *Given a set* $\mathcal{P}$ *of SDPs, a theory argument mapping* τ *is said to* fix *a subset* $\mathcal{P}'$ *of* $\mathcal{P}$ *if* $\bigcup_{i \in \tau(f^\sharp)} \mathrm{Var}(t_i) \subseteq L$ *for all* $s^\sharp \Rightarrow f^\sharp\ t_1 \cdots t_n\ [\varphi \mid L] \in \mathcal{P}'$*. A* theory argument processor *assigns to a DP problem* $\mathcal{P}$ *the pair* $\{\,\{\,\bar{\tau}(p) \mid p \in \mathcal{P}\,\}, \mathcal{P} \setminus \mathcal{P}'\,\}$ *for some non-empty subset* $\mathcal{P}'$ *of* $\mathcal{P}$ *such that there exists a theory argument mapping for* $\mathcal{P}$ *which fixes* $\mathcal{P}'$*.*

▶ **Example 24.** Following Example 14, a theory argument processor is applicable to $\{\,4, 5\,\}$. Let $\tau(\mathsf{gcd}^\sharp)$ be $\{\,1\,\}$ so that τ fixes $\{\,4\,\}$. The processor returns the pair $\{\,\{\,4, (7)\ \mathsf{gcd}^\sharp\ m\ n \Rightarrow \mathsf{gcd}^\sharp\ m\ (-n)\ [n < 0 \mid \{m, n\}]\,\}, \{\,5\,\}\,\}$. The integer mapping processor with $\mathcal{J}(\mathsf{gcd}^\sharp) = -x_{\mathsf{gcd}^\sharp,1}$ removes (4) from $\{\,4, 7\,\}$. Then $\{\,7\,\}$ and $\{\,5\,\}$ can be removed by graph processors.

Implementation. To find a valid theory argument mapping, we simply start by setting $\tau(f^\sharp) = \{\,1, \ldots, m\,\}$ for all $f^\sharp$, and choose one SDP to fix. Then we iteratively remove arguments that do not satisfy the condition until no such argument is left.

4.5 Reduction Pairs

Although it is not needed by the running example, we present a constrained variant of *reduction pair processors*, which are at the heart of most unconstrained termination analyzers.

▶ **Definition 25.** *A* constrained relation *R is a set of quadruples (s, t, φ, L) where s and t are terms which have the same type, φ is a logical constraint and $L \supseteq \mathrm{Var}(\varphi)$ is a set of variables whose types are theory sorts. We write $s\ R^L_\varphi\ t$ if $(s, t, \varphi, L) \in R$. A binary relation R' over terms is said to* cover *a constrained relation R if $s\ R^L_\varphi\ t$ implies that $(s\sigma)\downarrow_\kappa R'\ (t\sigma)\downarrow_\kappa$ for each substitution σ such that $\sigma(x)$ is a ground theory term for all $x \in L$ and $[\![\varphi\sigma]\!] = 1$.*

A constrained reduction pair *$(\succeq, \succ)$ is a pair of constrained relations such that $\succeq$ is covered by some reflexive relation $\sqsupseteq$ which includes $\rightarrow_\kappa$ and is monotonic (i.e., $s \sqsupseteq t$ implies $C[s] \sqsupseteq C[t]$), $\succ$ is covered by some well-founded relation $\sqsupset$, and $\sqsupseteq ; \sqsupset \subseteq \sqsupset^+$.*

▶ **Definition 26.** *A* reduction pair processor *assigns to a DP problem $\mathcal{P}$ the singleton $\{\,\mathcal{P}\backslash\mathcal{P}'\,\}$ for some non-empty subset $\mathcal{P}'$ of $\mathcal{P}$ such that there exists a constrained reduction pair $(\succeq, \succ)$ where (1) $s^\sharp \succ^L_\varphi t^\sharp$ for all $s^\sharp \Rightarrow t^\sharp\ [\varphi \mid L] \in \mathcal{P}'$, (2) $s^\sharp \succeq^L_\varphi t^\sharp$ for all $s^\sharp \Rightarrow t^\sharp\ [\varphi \mid L] \in \mathcal{P} \setminus \mathcal{P}'$, and (3) $\ell \succeq^{\mathrm{Var}(\varphi)\cup(\mathrm{Var}(r)\setminus\mathrm{Var}(\ell))}_\varphi r$ for all $\ell \rightarrow r\ [\varphi] \in \mathcal{R}$.*

While a variety of reduction pairs have been proposed for unconstrained rewriting, it is not yet the case in a higher-order and constrained setting: so far the only one is a limited version of HORPO [12], which is adapted into a weakly monotonic reduction pair [18] and then implemented in the DP framework. This is still a prototype definition.

We have included reduction pair processors here because their definition allows us to start designing constrained reduction pairs. In particular, as unconstrained reduction pairs can be used as the covering pair $(\sqsupseteq, \sqsupset)$, it is likely that many of them (such as variants of HORPO and weakly monotonic algebras) can be adapted.

We conclude this section by the following result (see [11, Appendix A.2]):

▶ **Theorem 27.** *All the DP processors defined in Section 4 are sound.*

5 Universal Computability

Termination is not a *modular* property: given terminating systems $\mathcal{R}_0$ and $\mathcal{R}_1$, we cannot generally conclude that $\mathcal{R}_0 \cup \mathcal{R}_1$ is also terminating. As computability is based on termination, it is not modular either. For example, both $\{\,\mathsf{a} \rightarrow \mathsf{b}\,\}$ and $\{\,\mathsf{f}\ \mathsf{b} \rightarrow \mathsf{f}\ \mathsf{a}\,\}$ are terminating, and $\mathsf{f} : \mathsf{o} \rightarrow \mathsf{o}$ is computable in the second system; yet, combining the two yields $\mathsf{f}\ \mathsf{a} \rightarrow \mathsf{f}\ \mathsf{b} \rightarrow \mathsf{f}\ \mathsf{a} \rightarrow \cdots$, which refutes the termination of the combination and the computability of f.

On the other hand, functions like map and fold are prevalently used; the lack of a modular principle for the termination analysis of higher-order systems involving such functions is painful. Moreover, if such a system is non-terminating, this is seldom attributed to those functions, which are generally considered "terminating" regardless of how they may be called.

In this section, we propose *universal computability*, a concept which corresponds to the termination of a function in all "reasonable" uses. First, we rephrase the notion of a hierarchical combination [27, 28, 29, 6] in terms of LCSTRSs:

▶ **Definition 28.** *An LCSTRS $\mathcal{R}_1$ is called an* extension *of a base system $\mathcal{R}_0$ if the two systems' interpretations of theory symbols coincide over all the theory symbols in common, and function symbols in $\mathcal{R}_0$ are not defined by any rewrite rule in $\mathcal{R}_1$. Given a base system $\mathcal{R}_0$ and an extension $\mathcal{R}_1$ of $\mathcal{R}_0$, the system $\mathcal{R}_0 \cup \mathcal{R}_1$ is called a* hierarchical combination.

In a hierarchical combination, function symbols in the base system can occur in the extension, but cannot be (re)defined. This forms the basis of the modular programming scenario we are interested in: think of the base system as a library containing the definitions of, say, map and fold. We further define a class of extensions to take information hiding into account:

▶ **Definition 29.** *Given an LCSTRS $\mathcal{R}_0$ and a set of function symbols – called* hidden symbols *– in $\mathcal{R}_0$, an extension $\mathcal{R}_1$ of $\mathcal{R}_0$ is called a* public extension *if hidden symbols do not occur in any rewrite rule in $\mathcal{R}_1$.*

Now we present the central definitions of this section:

▶ **Definition 30.** *Given an LCSTRS $\mathcal{R}_0$ with a sort ordering $\succsim$, a term t is called* universally computable *if for each extension $\mathcal{R}_1$ of $\mathcal{R}_0$ and each extension $\succsim'$ of $\succsim$ to sorts in $\mathcal{R}_0 \cup \mathcal{R}_1$ (i.e., $\succsim'$ coincides with $\succsim$ over sorts in $\mathcal{R}_0$), t is $\mathbb{C}$-computable in $\mathcal{R}_0 \cup \mathcal{R}_1$ with $\succsim'$; if a set of hidden symbols in $\mathcal{R}_0$ is also given and the above universal quantification of $\mathcal{R}_1$ is restricted to* public *extensions, such a term t is called* publicly computable*.*

The base system $\mathcal{R}_0$ is called universally computable if all its terms are; it is called publicly computable if all its public *terms – terms that contain no hidden symbol – are.*

With an empty set of hidden symbols, the two notions – universal computability and public computability – coincide. Below we state common properties in terms of public computability.

In summary, we consider passing $\mathbb{C}$-computable arguments to a defined symbol in $\mathcal{R}_0$ the "reasonable" way of calling the function. To establish the universal computability of higher-order functions such as map and fold – i.e., to prove that they are $\mathbb{C}$-computable in *all* relevant hierarchical combinations – we will use SDPs, which are about $\mathbb{C}$-computability.

▶ **Example 31.** The system $\{\,\mathsf{app}\ (\mathsf{lam}\ f) \to f\,\}$ in Section 1 is not universally computable due to the extension $\{\,\mathsf{w}\ x \to \mathsf{app}\ x\ x\,\}$.

5.1 The DP Framework Revisited

To use SDPs for universal – or public – computability, we need a more general version of Theorem 10. We start with defining public chains:

▶ **Definition 32.** *An SDP $f^\sharp\ s_1 \cdots s_m \Rightarrow t^\sharp\ [\varphi \mid L]$ is called public if f is not a hidden symbol. A $(\mathcal{P}, \mathcal{R})$-chain is called public if its first SDP is public.*

Now we state the main result of this section:

▶ **Theorem 33.** *An AFP system $\mathcal{R}_0$ with sort ordering $\succsim$ is publicly computable with respect to a set of hidden symbols in $\mathcal{R}_0$ if there exists no infinite computable $(\mathrm{SDP}(\mathcal{R}_0), \mathcal{R}_0 \cup \mathcal{R}_1)$-chain that is* public *for each public extension $\mathcal{R}_1$ of $\mathcal{R}_0$ and each extension $\succsim'$ of $\succsim$ to sorts in $\mathcal{R}_0 \cup \mathcal{R}_1$.*

While this result is not surprising and its proof (see [11, Appendix A.3]) is standard, it is not obvious how it can be used. The key observation which enables us to use the DP framework for public computability is that among the DP processors in Section 4, only reduction pair processors rely on the rewrite rules of the underlying system $\mathcal{R}$ (depending on how it computes a graph approximation, a graph processor does not have to know all the rewrite rules). Henceforth, we fix a base system $\mathcal{R}_0$, a set of hidden symbols in $\mathcal{R}_0$ and an arbitrary, unknown public extension $\mathcal{R}_1$ of $\mathcal{R}_0$. Now $\mathcal{R}$ is the hierarchical combination $\mathcal{R}_0 \cup \mathcal{R}_1$.

First, we generalize the definition of a DP problem:

▶ **Definition 34.** *A* (universal) DP problem $(\mathcal{P}, \mathtt{p})$ *consists of a set $\mathcal{P}$ of SDPs and a flag* $\mathtt{p} \in \{ \mathfrak{an}, \mathfrak{pu} \}$ *(for* any *or* public*). A DP problem $(\mathcal{P}, \mathtt{p})$ is called* finite *if either (1)* $\mathtt{p} = \mathfrak{an}$ *and there exists no infinite computable $(\mathcal{P}, \mathcal{R}_0 \cup \mathcal{R}_1)$-chain, or (2)* $\mathtt{p} = \mathfrak{pu}$ *and there exists no infinite computable $(\mathcal{P}, \mathcal{R}_0 \cup \mathcal{R}_1)$-chain which is* public*.*

DP processors are defined in the same way as before, now for universal DP problems. The goal is to show that $(\mathrm{SDP}(\mathcal{R}_0), \mathfrak{pu})$ is finite, and the procedure for termination in Section 4 also works here if we change the initialization of Q accordingly.

Next, we review the DP processors presented in Section 4. For each ρ of the original graph, subterm criterion and integer mapping processors, the processor ρ' such that $\rho'(\mathcal{P}, \mathtt{p}) = \{ (\mathcal{P}', \mathfrak{an}) \mid \mathcal{P}' \in \rho(\mathcal{P}) \}$ is sound for universal DP problems. For theory argument processors, we can do better when the input flag is $\mathfrak{pu}$ (when it is $\mathfrak{an}$, we just handle $\mathcal{P}$ in the same way as we do in Section 4 and the output flags are obviously $\mathfrak{an}$): if the subset $\mathcal{P}'$ of $\mathcal{P}$ fixed by a theory argument mapping τ contains all the public SDPs in $\mathcal{P}$, the processor should return the singleton $\{ (\{ p \mid p \in \mathcal{P} \text{ is public} \} \cup \{ \bar{\tau}(p) \mid p \in \mathcal{P} \text{ is not public} \}, \mathfrak{pu}) \}$; otherwise, the pair $\{ (\{ \bar{\tau}(p) \mid p \in \mathcal{P} \}, \mathfrak{an}), (\mathcal{P} \setminus \mathcal{P}', \mathfrak{pu}) \}$. Reduction pair processors require knowledge of the extension $\mathcal{R}_1$ so we do not adapt them.

New Processors. Last, we propose two classes of DP processors that are useful for public computability. Processors of the first class do not actually simplify DP problems; they rather alter their input to allow other DP processors to be applied subsequently.

▶ **Definition 35.** *Given sets $\mathcal{P}_1$ and $\mathcal{P}_2$ of SDPs, $\mathcal{P}_2$ is said to* cover *$\mathcal{P}_1$ if for each SDP $s^\sharp \Rightarrow t^\sharp\ [\varphi_1 \mid L_1] \in \mathcal{P}_1$ and each substitution σ_1 which respects $s^\sharp \Rightarrow t^\sharp\ [\varphi_1 \mid L_1]$, there exist an SDP $s^\sharp \Rightarrow t^\sharp\ [\varphi_2 \mid L_2] \in \mathcal{P}_2$ and a substitution σ_2 such that σ_2 respects $s^\sharp \Rightarrow t^\sharp\ [\varphi_2 \mid L_2]$, $s\sigma_1 = s\sigma_2$ and $t\sigma_1 = t\sigma_2$. A* constraint modification processor *assigns to a DP problem $(\mathcal{P}, \mathtt{p})$ the singleton $\{ (\mathcal{P}', \mathtt{p}) \}$ for some $\mathcal{P}'$ which covers $\mathcal{P}$.*

Now combined with the information of hidden symbols, the DP graph allows us to remove SDPs that are unreachable from any public SDP.

▶ **Definition 36.** *A* reachability processor *assigns to a DP problem $(\mathcal{P}, \mathfrak{pu})$ the singleton $\{ (\{ p \in \mathcal{P} \mid \theta(p)$ is reachable from $\theta(p_0)$ for some public SDP $p_0 \}, \mathfrak{pu}) \}$, given a graph approximation (G_θ, θ) for $\mathcal{P}$.*

These two classes of DP processors are often used together: a constraint modification processor can split an SDP into simpler ones, some of which may be removed by a reachability processor. In our implementation, a constraint modification processor is particularly used to break an SDP $s^\sharp \Rightarrow t^\sharp\ [u \neq v \mid L]$ into two SDPs with logical constraints $u < v$ and $u > v$, respectively (see Example 37); similarly for $s^\sharp \Rightarrow t^\sharp\ [u \vee v \mid L]$.

▶ **Example 37.** Consider an alternative implementation of the factorial function from Example 2, which has SDPs (1) $\mathsf{fact}^\sharp\ n\ k \Rightarrow \mathsf{comp}^\sharp\ k\ ((*)\ n)\ x'\ [n \neq 0]$, (2) $\mathsf{fact}^\sharp\ n\ k \Rightarrow \mathsf{fact}^\sharp\ (n-1)\ (\mathsf{comp}\ k\ ((*)\ n))\ [n \neq 0]$, and (3) $\mathsf{init}^\sharp\ k \Rightarrow \mathsf{fact}^\sharp\ 42\ k$. Assume that fact is a hidden symbol. Note that $(\{ 1, 2, 3 \}, \mathfrak{pu})$ is not finite without this assumption. A constraint modification processor can replace (2) with (4) $\mathsf{fact}^\sharp\ n\ k \Rightarrow \mathsf{fact}^\sharp\ (n-1)\ (\mathsf{comp}\ k\ ((*)\ n))\ [n < 0]$, and (5) $\mathsf{fact}^\sharp\ n\ k \Rightarrow \mathsf{fact}^\sharp\ (n-1)\ (\mathsf{comp}\ k\ ((*)\ n))\ [n > 0]$. A reachability processor can then remove (4). The remaining DP problem $(\{ 1, 3, 5 \}, \mathfrak{pu})$ can easily be handled by a graph processor and an integer mapping processor.

We conclude this section by the following result (see [11, Appendix A.4]):

▶ **Theorem 38.** *All the DP processors defined in Section 5 are sound.*

6 Experiments and Future Work

All the results in this paper have been implemented in our open-source analyzer Cora [20]. We have evaluated Cora on three groups of experiments, and the results are in Table 1.

Table 1 Cora experiment results.

	Custom	STRS	ITRS
Termination	20/28	72/140	69/117
Computability	20/28	66/140	68/117
Wanda	–	105/140	–
AProVE	–	–	102/117

The first group contains examples in this paper and several other LC(S)TRS benchmarks we have collected. The second group contains all the λ-free problems from the higher-order category of TPDB [5]. The third group contains problems from the first-order "integer TRS innermost" category. The computability tests analyze public computability; since there are no hidden symbols in TPDB, the main difference from a termination check is that reduction pair processors are disabled. A full evaluation page is available through the link:

`https://www.cs.ru.nl/~cynthiakop/experiments/mfcs2024`

Unsurprisingly, Cora is substantially weaker than Wanda [16] on unconstrained higher-order TRSs, and AProVE [8] on first-order integer TRSs: this work aims to be a starting point for *combining* higher-order term analysis and theory reasoning, and cannot yet compete with dedicated tools that have had years of development. Nevertheless, we believe that these results show a solid foundation with only a handful of simple techniques.

Future Work. Many of the existing techniques used in the analyses of integer TRSs and higher-order TRSs are likely to be extensible to our setting, leaving many encouraging avenues for further development. We highlight the most important few:

- Usable rules with respect to an argument filtering [10, 17]. To effectively use reduction pairs, being able to discard some rewrite rules is essential (especially for universal computability, if we can discard the unknown ones). Closely related is the adaptation of more reduction pairs such as weakly monotonic algebras [36, 34], tuple interpretations [22, 35] and more sophisticated path orderings [4], all of which have higher-order formulations.
- Transformation techniques, such as narrowing, and chaining dependency pairs together (as used for instance for integer transition systems [8, Secion 3.1]). This could also be a step toward using the constrained DP framework for non-termination.
- Handling the innermost or call-by-value strategy. Several functional languages adopt call-by-value evaluation, and applying this restriction may allow for more powerful analyses. In the first-order DP framework, there is ample work on the innermost strategy to build on (see, e.g., [9, 10]).
- Theory-specific processors for popular theories other than integers, e.g., bit vectors [25].

Abstract

Vertex integrity is a graph parameter that measures the connectivity of a graph. Informally, its meaning is that a graph has small vertex integrity if it has a small separator whose removal disconnects the graph into connected components which are themselves also small. Graphs with low vertex integrity are very structured; this renders many hard problems tractable and has recently attracted interest in this notion from the parameterized complexity community. In this paper we revisit the NP-complete problem of computing the vertex integrity of a given graph from the point of view of structural parameterizations. We present a number of new results, which also answer some recently posed open questions from the literature. Specifically, we show that unweighted vertex integrity is W[1]-hard parameterized by treedepth; we show that the problem remains W[1]-hard if we parameterize by feedback edge set size (via a reduction from a Bin Packing variant which may be of independent interest); and complementing this we show that the problem is FPT by max-leaf number. Furthermore, for weighted vertex integrity, we show that the problem admits a single-exponential FPT algorithm parameterized by vertex cover or by modular width, the latter result improving upon a previous algorithm which required weights to be polynomially bounded.

1 Introduction

The *vertex integrity* of a graph is a vulnerability measure indicating how easy it is to break down the graph into small pieces. More precisely, the vertex integrity $\mathrm{vi}(G)$ of a graph G is defined as $\mathrm{vi}(G) = \min_{S \subseteq V(G)}\{|S| + \max_{D \in \mathsf{cc}(G-S)} |D|\}$, that is, to calculate the vertex integrity of a graph we must find a separator that minimizes the size of the separator itself plus the size of the largest remaining connected component. Intuitively, a graph has low vertex integrity not only when it contains a small separator, but more strongly when it contains a small separator such that its removal leaves a collection of small connected components.

Vertex integrity was first introduced more than thirty years ago by Barefoot et al. [1], but has recently received particular attention from the parameterized complexity community since it can be considered as a very natural structural parameter: when a graph has vertex

integrity k, large classes of NP-hard problems admit FPT[1] algorithms with running times of the form $f(k)n^{\mathcal{O}(1)}$ [27]. Note that vertex integrity has a clear relationship with other, well-known structural parameters (see also Figure 1): it is more restrictive than treedepth, pathwidth, and treewidth (all these parameters are upper-bounded by vertex integrity) but more general than vertex cover (a graph of vertex cover k has vertex integrity at most $k+1$). "Price of generality" questions, where one seeks to discover for a given problem the most general parameter for which an FPT algorithm is possible, are a central topic in structural parameterized complexity, and vertex integrity therefore plays a role as a natural stepping stone in the hierarchy of standard parameters [3, 15, 16, 20, 22, 27].

The investigation of the parameterized complexity aspects of vertex integrity is, therefore, an active field of research, but it is important to remember that a prerequisite for any such parameter to be useful is that it should be tractable to calculate the parameter itself (before we try to use it to solve other problems). Since, unsurprisingly, computing the vertex integrity exactly is NP-complete [6], in this paper we focus on this problem from the point of view of parameterized complexity. We consider both the unweighted, as well as a natural weighted variant of the problem. Formally, we want to solve the following:

Unweighted (Weighted) Vertex Integrity

Instance: A graph G (with binary vertex weights $w : V(G) \to \mathbb{Z}^+$), an integer k.

Goal: Determine whether $\mathrm{vi}(G) \leq k$ ($\mathrm{wvi}(G) \leq k$).

The point of view we adopt is that of structural parameterized complexity, where vertex integrity is the target problem we are trying to solve, and not necessarily the parameter. Instead, we parameterize by standard structural width measures, such as variations of treewidth. The questions we would like to address are of several forms:

1. For which structural parameters is it FPT to compute the vertex integrity?
2. For which such parameters is it possible to obtain an FPT algorithm with single-exponential complexity?
3. For which parameters can the weighted version of the problem be handled as well as the unweighted version?

To put these questions in context, we recall some facts from the state of the art. When the parameter k is the vertex integrity itself, Fellows and Stueckle show an $\mathcal{O}(k^{3k}n)$-time algorithm for Unweighted Vertex Integrity [13], and later Drange et al. proposed an $\mathcal{O}(k^{k+1}n)$-time algorithm even for Weighted Vertex Integrity [9], so this problem is FPT. More recently, Gima et al. [21] took up the study of vertex integrity in the same structurally parameterized spirit as the one we adopt here and presented numerous results which already give some answers to the questions we posed above. In particular, for the first question they showed that Unweighted Vertex Integrity is W[1]-hard by pathwidth (and hence by treewidth); for the second question they showed that the problem admits a single-exponential algorithm for parameter modular-width; and for the third question they showed that the problem is (weakly) NP-hard on sub-divided stars, which rules out FPT algorithms for most structural parameters.

[1] We assume the reader is familiar with the basics of parameterized complexity, as given e.g. in [7]. We give precise definitions of all parameters in the next section.

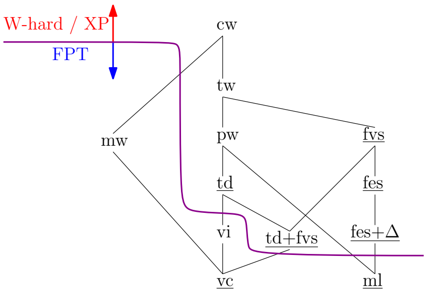

Figure 1 The parameterized complexity of Unweighted Vertex Integrity, with the underlined parameters indicating our results. A connection between two parameters implies that the one above generalizes the one below; that is, the one above is upper-bounded by a function of the one below. Regarding the presented parameters, vc, vi, td, pw, tw, cw, ml, fes, fvs, Δ, and mw stand for vertex cover, vertex integrity, treedepth, pathwidth, treewidth, cliquewidth, max-leaf number, feedback edge set, feedback vertex set, maximum degree, and modular width respectively. All of our FPT algorithms have single-exponential parametric dependence, while the ones for vc and mw extend to the weighted case as well.

Our results. Although the results of [21] are rather comprehensive, they leave open several important questions about the complexity of vertex integrity. In this paper we resolve the questions explicitly left open by [21] and go on to present several other results that further clarify the picture for vertex integrity. In particular, our results are as follows (see also Figure 1):

The first question we tackle is an explicit open problem from [21]: is Unweighted Vertex Integrity FPT parameterized by treedepth? This is a very natural question, because treedepth is the most well-known parameter that sits between pathwidth, where the problem is W[1]-hard by [21], and vertex integrity itself, where the problem is FPT. We resolve this question via a reduction from Bounded Degree Vertex Deletion, showing that Unweighted Vertex Integrity is W[1]-hard for treedepth (Theorem 2).

A second question left open by [21] is the complexity of Unweighted Vertex Integrity for parameter feedback vertex set. Taking a closer look at our reduction from Bounded Degree Vertex Deletion, which is known to be W[1]-hard for this parameter, we observe that it also settles this question, showing that Unweighted Vertex Integrity is also hard. However, in this case we are motivated to dig a little deeper and consider a parameter, feedback edge set, which is a natural restriction of feedback vertex set and typically makes most problems FPT. Our second result is to show that Unweighted Vertex Integrity is in fact W[1]-hard even when parameterized by feedback edge set and the maximum degree of the input graph (Theorem 7). We achieve this via a reduction from Unary Bin Packing parameterized by the number of bins, which is W[1]-hard [23]. An aspect of our reduction which may be of independent interest is that we use a variant of Unary Bin Packing where we are given a choice of only two possible bins per item (we observe that the reduction of [23] applies to this variant).

We complement these mostly negative results with a fixed-parameter tractability result for a more restrictive parameter: we show that Unweighted Vertex Integrity is FPT by max-leaf number (Theorem 10) indeed by a single-exponential FPT algorithm. Note that when a graph has bounded max-leaf number, then it has bounded degree and bounded feedback edge set number, therefore this parameterization is a special case of the one considered in Theorem 7. Hence, this positive result closely complements the problem's hardness in the more general case.

Moving on, we consider the parameterization by modular width, and take a second look at the $2^{\mathcal{O}(\mathrm{mw})}n^{\mathcal{O}(1)}$ algorithm provided by [21], which is able to handle the weighted case of the problem, but only for polynomially-bounded weights. Resolving another open problem posed by [21], we show how to extend their algorithm to handle the general case of weights encoded in binary (Theorem 13).

Finally, we ask the question of whether a single-exponential FPT algorithm is possible for parameters other than max-leaf and modular width. We answer this affirmatively for vertex cover, even in the weighted case (Theorem 16), obtaining a faster and simpler algorithm for the unweighted case (Theorem 14).

Related work. The concept of vertex integrity is natural enough that it has appeared in many slight variations under different names in the literature. We mention in particular, the fracture number [10], which is the minimum k such that it is possible to delete k vertices from a graph so that all remaining components have size at most k, and the starwidth [29], which is the minumum width of a tree decomposition that is a star. Both of these are easily seen to be at most a constant factor away from vertex integrity. Similarly, the safe set number [2, 14] seeks a separator such that every component of the separator is only connected to smaller components. These concepts are so natural that sometimes they are used as parameters without an explicit name, for example [4] uses the parameter "size of a deletion set to a collection of components of bounded size". As observed by [21], despite these similarities, sometimes computing these parameters can have different complexity, especially when weights are allowed. Another closely related computational problem, that we also use, is the Component Order Connectivity [9] problem, where we are given explicit distinct bounds on the size of the separator sought and the allowed size of the remaining components.

2 Preliminaries

Throughout the paper we use standard graph notation [8] and assume familiarity with the basic notions of parameterized complexity [7]. All graphs considered are undirected without loops. Given a graph G, Δ denotes its maximum degree; if we are additionally given $S \subseteq V(G)$, $G[S]$ denotes the subgraph induced by S, while $G - S$ denotes $G[V(G) \setminus S]$. Furthermore, given a weight function $w : V(G) \to \mathbb{Z}^+$, $w(S)$ denotes the sum of the weights of the vertices of S, that is $w(S) = \sum_{s \in S} w(s)$. For $x, y \in \mathbb{Z}$, let $[x, y] = \{z \in \mathbb{Z} : x \leq z \leq y\}$, while $[x] = [1, x]$. For a set of integers $S \subseteq \mathbb{Z}^+$, let $\Sigma(S)$ denote the sum of its elements, i.e. $\Sigma(S) = \sum_{s \in S} s$, while $\binom{S}{c}$ denotes the set of subsets of S of size c, i.e. $\binom{S}{c} = \{S' \subseteq S : |S'| = c\}$. Proofs of statements marked with $(\star)$ are presented in the full version of the paper.

2.1 Vertex Integrity

For a vertex-weighted graph G with $w : V(G) \to \mathbb{Z}^+$, we define its *weighted vertex integrity*, denoted by $\mathrm{wvi}(G)$, as

$$\mathrm{wvi}(G) = \min_{S \subseteq V(G)} \left\{ w(S) + \max_{D \in \mathtt{cc}(G-S)} w(D) \right\},$$

where $\mathtt{cc}(G - S)$ is the set of connected components of $G - S$. A set S such that $w(S) + \max_{D \in \mathtt{cc}(G-S)} w(D) \leq k$ is called a $\mathrm{wvi}(k)$-set. The *vertex integrity* of an unweighted graph G, denoted by $\mathrm{vi}(G)$, is defined in an analogous way, by setting $w(v) = 1$ for all $v \in V(G)$. In that case, $S \subseteq V(G)$ is a $\mathrm{vi}(k)$-set if $|S| + \max_{D \in \mathtt{cc}(G-S)} |D| \leq k$.

A vertex $v \in S$ is called *redundant* if at most one connected component of $G - S$ contains neighbors of v. A set $S \subseteq V(G)$ is *irredundant* if S contains no redundant vertex. Notice that it suffices to only search for irredundant wvi(k)-sets when solving Vertex Integrity, since if $v \in S$ is redundant and S is a wvi(k)-set, that is the case for set $S \setminus \{v\}$ as well.

▶ **Proposition 1** ([9, 21])**.** *A graph with a* wvi(k)*-set has an irredundant* wvi(k)*-set.*

2.2 Graph Parameters

We use several standard graph parameters, so we recall here their definitions and known relations between them. A graph G has *feedback vertex* (respectively *edge*) *set* k if there exists a set of k vertices (respectively edges) such that removing them from G destroys all cycles. We use fvs(G) and fes(G) to denote these parameters. Note that even though computing fvs(G) is NP-complete [24], in all connected graphs with m edges and n vertices fes(G) $= m - n + 1$. The *vertex cover* of a graph G, denoted by vc(G), is the size of the smallest set whose removal destroys all edges. The *treedepth* of a graph G can be defined recursively as follows: $\mathrm{td}(K_1) = 1$; if G is disconnected td(G) is equal to the maximum of the treedepth of its connected components; otherwise $\mathrm{td}(G) = \min_{v \in V(G)} \mathrm{td}(G - v) + 1$. The *max-leaf number* of a graph G, denoted by ml(G), is the maximum number of leaves of any spanning tree of G.

A module of a graph $G = (V, E)$ is a set of vertices $M \subseteq V$ such that for all $x \in V \setminus M$ we have that x is either adjacent to all vertices of M or to none. The *modular width* of a graph $G = (V, E)$ ([17, 18]) is the smallest integer k such that, either $|V| \leq k$, or V can be partitioned into at most $k' \leq k$ sets $V_1, \ldots, V_{k'}$, with the following two properties: (i) for all $i \in [k']$, V_i is a module of G, (ii) for all $i \in [k']$, $G[V_i]$ has modular width at most k.

Let us also briefly explain the relations depicted in Figure 1. Clearly, for all G, we have fvs(G) $\leq$ fes(G), because we can remove from the graph one endpoint of each edge of the feedback edge set. It is known that if a graph has ml(G) $= k$, then G contains at most $\mathcal{O}(k)$ vertices of degree 3 or more (Lemma 8), and clearly such a graph has maximum degree at most k. Since vertices of degree at most 2 are irrelevant for fes, we conclude that the parameterization by ml is more restrictive than that for fes $+ \Delta$. It is also not hard to see that for all G, td(G) $\leq$ vi(G) $\leq$ vc(G) $+ 1$. Note also that even though vc can be seen as a parameter more restrictive than mw, when a graph has vertex cover k, the best we can say is that its modular width is at most $2^k + k$ [26]. As a result, the algorithm of Theorem 13 does not imply a single-exponential FPT algorithm for parameter vc (but does suffice to show that the problem is FPT). We also note that the reductions of Theorem 2 (for td) and Theorem 7 (for fes $+ \Delta$) are complementary and cannot be subsumed by a single reduction. The reason for this is that if in a graph we bound simultaneously the treedepth and the maximum degree, then we actually bound the size of the graph (rendering all problems FPT).

3 Treedepth

Our main result in this section is the following theorem, resolving a question of [21]. We obtain it via a parameter-preserving reduction from Bounded Degree Vertex Deletion, which is known to be W[1]-hard parameterized by treedepth plus feedback vertex set [19].

▶ **Theorem 2.** Unweighted Vertex Integrity *is W[1]-hard parameterized by* td + fvs*. Moreover, it cannot be solved in time* $f(\mathrm{td})n^{o(\mathrm{td})}$ *under the ETH.*

Proof. First we define the closely related Component Order Connectivity problem: given a graph G as well as integers ℓ and p, we want to determine whether there exists $S \subseteq V(G)$ such that $|S| \leq p$ and all components of $G - S$ have size at most ℓ. We will proceed in two steps: we first reduce Bounded Degree Vertex Deletion to Component Order Connectivity, and then employ the reduction of [21] that reduces the latter to Unweighted Vertex Integrity. Notice that [21, Lemma 4.4] creates an equivalent instance of Unweighted Vertex Integrity by solely adding disjoint stars and leaves in the vertices of the initial graph, therefore it suffices to prove the statement for Component Order Connectivity instead.

We give a parameterized reduction from Bounded Degree Vertex Deletion, which is W[1]-hard by treedepth plus feedback vertex set number [19] and cannot be solved in time $f(\text{td})n^{o(\text{td})}$ under the ETH [28]. In Bounded Degree Vertex Deletion we are given a graph $G = (V, E)$ and two integers k and d, and we are asked to determine whether there exists $S \subseteq V$ of size $|S| \leq k$ such that the maximum degree of $G - S$ is at most d. In the following, let $n = |V(G)|$ and $m = |E(G)|$.

Given an instance (G, k, d) of Bounded Degree Vertex Deletion, we construct an equivalent instance (G', ℓ, p) of Component Order Connectivity. We construct G' from G as follows: We subdivide every edge $e = \{u, v\} \in E(G)$ three times, thus replacing it with a path on vertices u, u_v, y_e, v_u, and v, where $T_e = \{u_v, y_e, v_u\}$. Next, we attach $d - 1$ leaves to y_e (see Figure 2). This concludes the construction of G'. Notice that the subdivision of the edges three times and the attachment of pendant vertices does not change the feedback vertex set number, while the treedepth is only increased by an additive constant. Thus, it holds that $\text{fvs}(G') = \text{fvs}(G)$ and $\text{td}(G') = \text{td}(G) + \mathcal{O}(1)$.

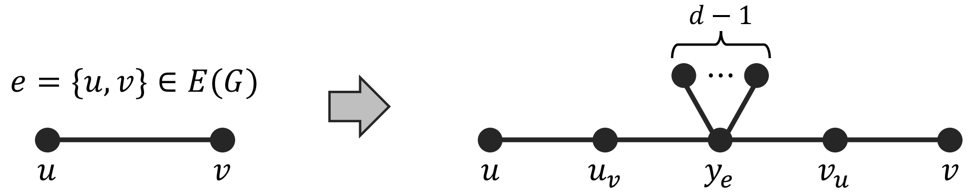

Figure 2 Edge gadget for edge $e = \{u, v\} \in E(G)$.

In the following, we show that (G, k, d) is a yes-instance of Bounded Degree Vertex Deletion if and only if (G', ℓ, p) is a yes-instance of Component Order Connectivity, where $\ell = d + 1$ and $p = k + m$.

For the forward direction, let S be a set of vertices of size at most k such that the maximum degree of $G - S$ is at most d. We will construct a set $S' \subseteq V(G')$ such that $|S'| \leq p$ and every connected component of $G' - S'$ has size at most ℓ. Initially set $S' = S$. Then, add one vertex to S' per edge $e = \{u, v\} \in E(G)$ as follows. If $u, v \in S$ or $u, v \notin S$, we add y_e to S'. Otherwise, if $u \in S$ and $v \notin S$, we add v_u to S'; symmetrically, if $u \notin S$ and $v \in S$, we add u_v instead. Notice that $|S'| = |S| + m \leq k + m = p$, therefore it suffices to show that the size of each connected component of $G' - S'$ is at most $\ell = d + 1$.

Consider a connected component D of $G' - S'$. Assume that D does not contain any vertices of $V \setminus S$. If D is a leaf it holds that $|D| \leq d + 1$. Alternatively, D is a subgraph of the graph induced by u_v (or v_u), y_e, and its attached leaves, for some $e = \{u, v\} \in E(G)$, in which case $|D| \leq d + 1$. Now assume that D contains $u \in V \setminus S$. Notice that u is the only vertex of $V \setminus S$ present in D, since $S' \cap T_e \neq \emptyset$ for all $e \in E(G)$. Moreover, let $N(u) \setminus S = \{u_i : i \in [q]\}$ denote its neighbors in $G - S$, where $q \leq d$ since the maximum degree of $G - S$ is at most d. In that case, it follows that D consists of u, as well as the vertices u_{u_i} for all $i \in [q]$. Consequently, $|D| = q + 1 \leq d + 1$.

For the converse direction, assume there exists $S' \subseteq V(G')$ such that $|S'| \leq p = k + m$ and $|D| \leq \ell = d + 1$, for all connected components $D \in \mathsf{cc}(G' - S')$. Assume that S' does not contain any leaves; if it does, substitute them with their single neighbor. Moreover, $S' \cap T_e \neq \emptyset$ for all $e \in E(G)$, since otherwise $G' - S'$ has a component of size at least $d + 2 > \ell$, which is a contradiction. Assume without loss of generality that $|S' \cap T_e| = 1$, for all $e = \{u, v\} \in E(G)$; if that is not the case, there is always a vertex of $\{u_v, v_u\}$, say u_v, such that $u_v \in S'$ and $S' \cap \{y_e, v_u\} \neq \emptyset$, in which case one may consider the deletion set $(S' \cup \{u\}) \setminus \{u_v\}$ instead (the argument is symmetric in case $v_u \in S'$).

Let $S = S' \cap V$, where $|S| \leq k$. We will prove that $G - S$ has maximum degree at most d. Let D_u denote the connected component of $G' - S'$ that contains $u \in V \setminus S'$; in fact this is the only vertex of $V \setminus S'$ present in D_u, since $S' \cap T_e \neq \emptyset$ for all $e \in E(G)$. Notice that for all $e = \{u, v\} \in E(G)$ where $u, v \notin S'$, it holds that $y_e \in S'$: if that were not the case, then either D_u or D_v contains at least $d + 2 > \ell$ vertices, due to $\{u, u_v, y_e\}$ or $\{v, v_u, y_e\}$ and the leaves of y_e respectively. For $u \in V \setminus S$, let $N(u) \setminus S = \{u_i : i \in [q]\}$, for some integer q, denote its neighbors in $G - S$, where $e_i = \{u, u_i\} \in E(G)$ for $i \in [q]$. It suffices to show that $q \leq d$. Assume that this is not the case, i.e. $q > d$. Then, since $S' \cap T_{e_i} = \{y_{e_i}\}$ for $i \in [q]$, it follows that D_u contains vertices u and u_{u_i}, therefore $|D_u| \geq q + 1 > d + 1 = \ell$, which is a contradiction. Consequently, $|N(u) \setminus S| \leq d$ for all $u \in V \setminus S$, i.e. $G - S$ has maximum degree d. ◀

4 Feedback Edge Set plus Maximum Degree

In this section we prove that Vertex Integrity is W[1]-hard parameterized by fes + Δ. Since our reduction is significantly more involved than the one of Theorem 2, we proceed in several steps. We start from an instance of Unary Bin Packing where the parameter is the number of bins and consider a variant where we are also supplied in the input, for each item, a choice of two possible bins to place it. We first observe that the reduction of [23] shows that this variant is also W[1]-hard. We then reduce this to a *semi-weighted* version of Vertex Integrity, where placing a vertex in the separator always costs 1, but vertices have weights which they contribute to their components if they are not part of the separator, and where we are prescribed the size of the separator to use (this is called the Component Order Connectivity problem). Subsequently, we show how to remove the weights and the prescription on the separator size to obtain hardness for Vertex Integrity.

4.1 Preliminary Tools

Unary Bin Packing. Given a set $S = \{s_1, \dots, s_n\}$ of integers in unary (i.e. $s_i = \mathcal{O}(n^c)$ for some constant c), as well as $k \in \mathbb{Z}^+$, Unary Bin Packing asks whether we can partition S into k subsets $S_1, \dots, S_k$, such that $\Sigma(S_i) = \Sigma(S)/k$, for all $i \in [k]$. This problem is well known to be W[1]-hard parameterized by the number of bins k [23]. We formally define a restricted version where every item is allowed to choose between *exactly two* bins, and by delving deeper into the proof of [23] we observe that an analogous hardness result follows.

Restricted Unary Bin Packing

Instance: A set $S = \{s_1, \dots, s_n\}$ of integers in unary, $k \in \mathbb{Z}^+$, as well as a function $f : S \to \binom{[k]}{2}$.

Goal: Determine whether we can partition S into k subsets $S_1, \dots, S_k$, such that for all $i \in [k]$ it holds that (i) $\Sigma(S_i) = \Sigma(S)/k$, and (ii) $\forall s \in S_i$, $i \in f(s)$.

▶ **Theorem 3** ($\star$)**.** Restricted Unary Bin Packing *is W[1]-hard parameterized by the number of bins.*

Semi-weighted problems. In this section we study semi-weighted versions of Component Order Connectivity and Vertex Integrity, which we first formally define. Then, we prove that the first can be reduced to the latter, while retaining the size of the minimum feedback edge set and the maximum degree.

Semi-Weighted Component Order Connectivity

Instance: A vertex-weighted graph $G = (V, E, w)$, as well as integers $\ell, p \in \mathbb{Z}^+$.
Goal: Determine whether there exists $S \subseteq V$ of size $|S| \leq p$, such that $w(D) \leq \ell$ for all $D \in \mathtt{cc}(G - S)$.

Semi-Weighted Vertex Integrity

Instance: A vertex-weighted graph $G = (V, E, w)$, as well as an integer $\ell \in \mathbb{Z}^+$.
Goal: Determine whether there exists $S \subseteq V$ such that $|S| + w(D) \leq \ell$ for all $D \in \mathtt{cc}(G - S)$.

▶ **Theorem 4** ($\star$)**.** Semi-Weighted Component Order Connectivity *parameterized by* $\text{fes} + \Delta$ *is fpt-reducible to* Semi-Weighted Vertex Integrity *parameterized by* $\text{fes} + \Delta$.

4.2 Hardness Result

Using the results of Section 4.1, we proceed to proving the main theorem of this section. To this end, we present a reduction from Restricted Unary Bin Packing to Semi-Weighted Component Order Connectivity such that for the produced graph G it holds that $\text{fes}(G) + \Delta(G) \leq f(k)$, for some function f and k denoting the number of bins of the Restricted Unary Bin Packing instance.

We first provide a sketch of our reduction. For every bin of the Restricted Unary Bin Packing instance, we introduce a clique of $\mathcal{O}(k)$ heavy vertices, and then connect any pair of such cliques via two paths. The weights are set in such a way that an optimal solution will only delete vertices from said paths. In order to construct a path for a pair of bins, we compute the set of all subset sums of the items that can be placed in these two bins, and introduce a vertex of medium weight per such subset sum. Moreover, every such vertex corresponding to subset sum s is preceded by exactly s vertices of weight 1. An optimal solution will cut the path in such a way that the number of vertices of weight 1 will be partitioned between the two bins, encoding the subset sum of the elements that are placed on each bin. The second path that we introduce has balancing purposes, allowing us to exactly count the number of vertices of medium weight that every connected component will end up with.

▶ **Theorem 5** ($\star$)**.** Semi-Weighted Component Order Connectivity *is W[1]-hard parameterized by* $\text{fes} + \Delta$.

By Theorems 4 and 5, the hardness of Semi-Weighted Vertex Integrity follows.

▶ **Theorem 6.** Semi-Weighted Vertex Integrity *is W[1]-hard parameterized by* $\text{fes} + \Delta$.

Moreover, we can easily reduce an instance (G, w, k) of Semi-Weighted Vertex Integrity to an instance (G', k) of Unweighted Vertex Integrity by attaching a path on $w(v) - 1$ vertices to each vertex v (we assume that $w(v) \leq k$, otherwise v belongs to the deletion set). Thus, $\text{fes}(G') = \text{fes}(G)$ and $\Delta(G') = \Delta(G) + 1$, and due to Theorem 6 the main result of this section follows.

▶ **Theorem 7.** *Unweighted Vertex Integrity is W[1]-hard parameterized by* $\text{fes} + \Delta$.

5 Max-Leaf Number

In this section, we consider Unweighted Vertex Integrity parameterized by the max-leaf number. For a connected graph G we denote by $\text{ml}(G)$ the maximum number of leaves of any spanning tree of G. This is a well-studied but very restricted parameter [11, 12, 26]. In particular, it is known that if a graph G has $\text{ml}(G) \leq k$, then in fact G is a subdivision of a graph on $\mathcal{O}(k)$ vertices [25]. We are motivated to study this parameter because in a sense it lies close to the intractability boundary established in Section 4. Observe that if a graph is a sub-division of a graph on k vertices, then it has maximum degree at most k and feedback edge set at most k^2; however, graphs of small feedback edge set and small degree do not necessarily have small max-leaf number (consider a long path where we attach a leaf to each vertex). Interestingly, the graphs we construct in Section 4.2 *do* have small max-leaf number, if we consider semi-weighted instances. However, adding the necessary simple gadgets in order to simulate weights increases the max-leaf number of the graphs of our reduction. It is thus a natural question whether this is necessary. In this section, we show that indeed this is inevitable, as Vertex Integrity is FPT parameterized by ml.

We start with a high-level overview of our approach. As mentioned, we will rely on the result of Kleitman and West [25] who showed that if a graph $G = (V, E)$ has $\text{ml}(G) \leq k$, then there exists a set X of size $|X| = \mathcal{O}(k)$ such that all vertices of $V \setminus X$ have degree at most 2. Our main tool is a lemma (Lemma 9) which allows us to "rotate" solutions: whenever we have a cycle in our graph, we can, roughly speaking, exchange every vertex of S in the cycle with the next vertex, until we reach a point where our solution removes strictly more vertices of X. We therefore guess the largest intersection of an optimal separator with X, and can now assume that in every remaining cycle, the separator S is not using any vertices. This allows us to simplify the graph in a way that removes all cycles and reduces the case to a tree, which is polynomial-time solvable.

Let us now give more details. We first recall the result of [25].

▶ **Lemma 8** ($\star$). *In any graph G, the set X of vertices of degree at least 3 has size at most* $|X| \leq 12\text{ml}(G) + 32$.

We will solve Component Order Connectivity: for a given ℓ we want to calculate the minimum number of vertices p such that there exists a separator S of size at most p with all components of $G - S$ having size at most ℓ. To obtain an algorithm for Unweighted Vertex Integrity, we will try all possible values of ℓ and select the solution which minimizes $\ell + p$.

Our main lemma is now the following:

▶ **Lemma 9** ($\star$). *Let $G = (V, E)$ be a graph and X be a set of vertices such that all vertices of $V \setminus X$ have degree at most 2 in G. For all positive integers ℓ, p, if there exists a separator S of size at most p such that all components of $G - S$ have size at most ℓ, then there exists such a separator S that also satisfies the following property: for every cycle C of G with $C \cap X \neq \emptyset$ we either have $C \cap S = \emptyset$ or $C \cap X \cap S \neq \emptyset$.*

We are now ready to state the main result of this section.

▶ **Theorem 10** (⋆). Unweighted Vertex Integrity *can be solved in time* $2^{\mathcal{O}(\mathrm{ml})}n^{\mathcal{O}(1)}$.

6 Modular Width

In this section we revisit an algorithm of [21] establishing that Weighted Vertex Integrity can be solved in time $2^{\mathcal{O}(\mathrm{mw})}n^{\mathcal{O}(1)}$, on graphs of modular width mw, but only if weights are polynomially bounded in n (or equivalently, if weights are given in unary). It was left as an explicit open problem in [21] whether this algorithm can be extended to the case where weights are given in binary and can therefore be exponential in n. We resolve this problem positively, by showing how the algorithm of [21] can be modified to work also in this case, without a large increase in its complexity.

The high-level idea of the algorithm of [21] is to perform dynamic programming to solve the related Weighted Component Order Connectivity problem. In this problem we are given a target component weight ℓ and a deletion budget p and are asked if it is possible to delete from the graph a set of vertices with total weight at most p so that the maximum weight of any remaining component is at most ℓ. Using this algorithm as a black box, we can then solve Weighted Vertex Integrity by iterating over all possible values of ℓ, between 1 and the target vertex integrity. If vertex weights are polynomially bounded, this requires a polynomial number of iterations, giving the algorithm of [21]. However, if weights are given in binary, the target vertex integrity could be exponential in n, so in general, it does not appear possible to guess the weight of the heaviest component in an optimal solution.

Our contribution to the algorithm of [21] is to observe that for graphs of modular width mw the weight of the heaviest component may take at most $2^{\mathcal{O}(\mathrm{mw})}n$ distinct possible values. Hence, for this parameter, guessing the weight of the heaviest component in an optimal solution can be done in FPT time. We can therefore plug in this result to the algorithm of [21] to obtain an algorithm for Weighted Vertex Integrity with binary weights running in time $2^{\mathcal{O}(\mathrm{mw})}n^{\mathcal{O}(1)}$.

Our observation is based on the following lemma.

▶ **Lemma 11** (⋆). *Let $G = (V, E)$ be an instance of* Weighted Vertex Integrity. *There exists an optimal solution using a separator S such that for all connected components D of $G - S$ and modules M of G we have one of the following: (i) $M \cap D = \emptyset$, (ii) $M \subseteq D$, or (iii) $D \subseteq M$.*

We also recall the algorithmic result of [21].

▶ **Theorem 12** ([21]). *There exists an algorithm that takes as input a vertex-weighted graph $G = (V, E)$ and an integer ℓ and computes the minimum integer p such that there exists a separator S of G of weight at most p such that each component of $G - S$ has weight at most ℓ. The algorithm runs in time $2^{\mathcal{O}(\mathrm{mw})}n^{\mathcal{O}(1)}$, where n is the size of the input.*

Putting Lemma 11 and Theorem 12 together we obtain the main result of this section.

▶ **Theorem 13** (⋆). *There exists an algorithm that solves* Weighted Vertex Integrity *in time $2^{\mathcal{O}(\mathrm{mw})}n^{\mathcal{O}(1)}$, where* mw *is the modular width of the input graph, n is the size of the input, and weights are allowed to be written in binary.*

7 Vertex Cover Number

In this section, we design single-exponential algorithms for Vertex Integrity parameterized by vertex cover number. We suppose that a minimum vertex cover C of size vc is given since it can be computed in time $\mathcal{O}(1.2738^{\text{vc}} + \text{vc}n)$ [5]. We start by presenting an algorithm for Unweighted Vertex Integrity, before moving on to the weighted version of the problem.

▶ **Theorem 14** ($\star$). Unweighted Vertex Integrity *can be solved in time* $5^{\text{vc}} n^{\mathcal{O}(1)}$.

We now move on to the weighted case of the problem. It is clear that Weighted Vertex Integrity is FPT parameterized by vertex cover, due to Theorem 13 and the relation between modular-width and vertex cover. However, this gives a double-exponential dependence on vc, as $\text{mw} \leq 2^{\text{vc}} + \text{vc}$ and there are some graphs for which this is essentially tight. We would like to obtain an algorithm that is as efficient as that of Theorem 14. The algorithm of Theorem 14, however, cannot be applied to the weighted case because the case of the branching where we place a vertex of the independent set in the separator is not guaranteed to make much progress (the vertex could have very small weight compared to our budget).

Before we proceed, it is worth thinking a bit about how this can be avoided. One way to obtain a faster FPT algorithm would be, rather than guessing only the intersection of the optimal separator S with the vertex cover C, to also guess how the vertices of $C \setminus S$ are partitioned into connected components in the optimal solution. This would immediately imply the decision for all vertices of the independent set: vertices with neighbors in two components must clearly belong to S, while the others cannot belong to S if S is irredundant. This algorithm would give a complexity of $\text{vc}^{\mathcal{O}(\text{vc})} n^{\mathcal{O}(1)}$, however, because the number of partitions of C is slightly super-exponential.

Let us sketch the high level idea of how we handle this. Our first step is, similarly to Theorem 13, to calculate the weight $w_{\max}$ of the most expensive connected component of the optimal solution. For this, there are at most $2^{\text{vc}} + n$ possibilities, because this component is either a single vertex, or it has a non-empty intersection with C. However, if we fix its intersection with C, then this fixes its intersection with the independent set: the component must contain (by irredundancy) exactly those vertices of the independent set all of whose neighbors in C are contained in the component. Having fixed a value of $w_{\max}$ we simply seek the best separator so that all components have weight at most $w_{\max}$. The reason we perform this guessing step is that this version of this problem is easier to decompose: if we have a disconnected graph, we simply calculate the best separator in each part and take the sum (this is not as clear for the initial version of Vertex Integrity).

Suppose then that we have fixed $w_{\max}$, how do we find the best partition of C into connected components? We apply a win/win argument: if the optimal partition has a connected component that contains many (say, more than vc/10) vertices of C, we simply guess the intersection of the component with C and complete it with vertices from the independent set, as previously, while placing vertices with neighbors inside and outside the component in the separator. If the weight of the component is at most $w_{\max}$, we recurse in the remaining instance, which has vertex cover at most 9vc/10. The complexity of this procedure works out as $T(\text{vc}) \leq 2^{\text{vc}} \cdot T(9\text{vc}/10) = 2^{\mathcal{O}(\text{vc})}$.

What if the optimal partition of C only has components with few vertices of C? In that case we observe that we do not need to compute the full partition (which would take time vc^{vc}), but it suffices to guess a good bipartition of C into two sets, of roughly the same size (say, both sets have size at least 2vc/5), such that the two sets are a coarsening of the optimal partition. In other words, we compute two subsets of C, of roughly equal size, such that the intersection of each connected component with C is contained in one of the two sets. This is always possible in this case, because no connected component has a very large intersection with C. Now, all vertices of I which have neighbors on both sides of the bipartition of C must be placed in the separator. But once we do this, we have disconnected the instance into two independent instances, each of vertex cover at most $3\text{vc}/5$. The complexity of this procedure again works out as $T(\text{vc}) \leq 2^{\text{vc}} \cdot 2 \cdot T(3\text{vc}/5) = 2^{\mathcal{O}(\text{vc})}$.

Let us now proceed to the technical details. To solve Weighted Vertex Integrity, we first define the annotated and optimization version of the problem.

Annotated Weighted Vertex Integrity with Vertex Cover

Instance: A vertex-weighted graph $G = (V, E, w)$, a vertex cover C of G, an integer $w_{\max}$.

Goal: Find a minimum weight irredundant wvi-set $S \subseteq V \setminus C$ such that $w(D) \leq w_{\max}$ for all $D \in \texttt{cc}(G - S)$. If there is no such S, report NO.

Then we give an algorithm that solves Annotated Weighted Vertex Integrity with Vertex Cover.

▶ **Theorem 15** ($\star$). Annotated Weighted Vertex Integrity with Vertex Cover *can be solved in time* $2^{\mathcal{O}(|C|)}n^{\mathcal{O}(1)}$.

▶ **Theorem 16** ($\star$). Weighted Vertex Integrity *can be solved in time* $2^{\mathcal{O}(\text{vc})}n^{\mathcal{O}(1)}$.

8 Conclusion

We have presented a number of new results on the parameterized complexity of computing vertex integrity. The main question that remains open is whether the slightly super-exponential $k^{\mathcal{O}(k)}n^{\mathcal{O}(1)}$ algorithm, where k is the vertex integrity itself, can be improved to single-exponential. Although we have given such an algorithm for the more restricted parameter vertex cover, we conjecture that for vertex integrity the answer is negative. Complementing this question, it would be interesting to consider approximation algorithms for vertex integrity, whether trying to obtain FPT approximations in cases where the problem is W[1]-hard, or trying to obtain almost-optimal solutions via algorithms that run with a better parameter dependence. Again, a constant-factor or even $(1+\varepsilon)$-approximation running in time $2^{\mathcal{O}(k)}n^{\mathcal{O}(1)}$ would be the ideal goal. Do such algorithms exist or can they be ruled out under standard complexity assumptions?

The Complexity of (P_3, H)-Arrowing and Beyond

Zohair Raza Hassan
Rochester Institute of Technology, Rochester, NY, USA

Abstract

Often regarded as the study of how order emerges from randomness, Ramsey theory has played an important role in mathematics and computer science, giving rise to applications in numerous domains such as logic, parallel processing, and number theory. The core of graph Ramsey theory is arrowing: For fixed graphs F and H, the (F, H)-Arrowing problem asks whether a given graph, G, has a red/blue coloring of the edges of G such that there are no red copies of F and no blue copies of H. For some cases, the problem has been shown to be coNP-complete, or solvable in polynomial time. However, a more systematic approach is needed to categorize the complexity of all cases.

We focus on (P_3, H)-Arrowing as $F = P_3$ is the simplest meaningful case for which the complexity question remains open, and the hardness for this case likely extends to general (F, H)-Arrowing for nontrivial F. In this pursuit, we also gain insight into the complexity of a class of matching removal problems, since (P_3, H)-Arrowing is equivalent to H-free Matching Removal. We show that (P_3, H)-Arrowing is coNP-complete for all 2-connected H except when $H = K_3$, in which case the problem is in P. We introduce a new graph invariant to help us carefully combine graphs when constructing the gadgets for our reductions. Moreover, we show how (P_3, H)-Arrowing hardness results can be extended to other (F, H)-Arrowing problems. This allows for more intuitive and palatable hardness proofs instead of ad-hoc constructions of SAT gadgets, bringing us closer to categorizing the complexity of all (F, H)-Arrowing problems.

1 Introduction and related work

At what point, if ever, does a system get large enough so that certain patterns become unavoidable? This question lies at the heart of Ramsey theory, which, since its inception in the 1930s, aims to find these thresholds for various combinatorial objects. Ramsey theory has played an important role in mathematics and computer science, finding applications in fields such as cryptography, algorithms, game theory, and more [11]. A key operator within Ramsey theory is the arrowing operator, which is defined for graphs like so: given graphs F, G, and H, we say that $G \to (F, H)$ (read, G *arrows* F, H) if every red/blue coloring of G's edges contains a red F or a blue H. In this work, we analyze the complexity of computing this operator when F and H are fixed graphs. The general problem is defined as follows.

▶ **Problem 1** ((F, H)-Arrowing). *For fixed F and H, given a graph G, does $G \to (F, H)$?*

The problem is clearly in coNP; a red/blue coloring of G's edges with no red F and no blue H forms a certificate that can be verified in polynomial time since F and H are fixed graphs. Such a coloring is referred to as an (F, H)-good coloring. The computational complexity of (F, H)-Arrowing has been categorized for several – but not all – pairs (F, H). For instance, (P_2, H)-Arrowing is in P for all H, where P_2 is the path graph on 2 vertices. This is because any coloring of an input graph G that does not contain a red P_2 must be entirely blue, and thereby (P_2, H)-Arrowing is equivalent to determining whether G is

H-free. Burr showed that (F, H)-Arrowing is coNP-complete when F and H are 3-connected graphs – these are graphs which remain connected after the removal of any two vertices, e.g., (K_5, K_6)-Arrowing [3]. More results of this type are discussed in Section 2.

In this work, we explore the simplest nontrival case for F, $F = P_3$, and provide a complete classification of the complexity when H is a 2-connected graph – a graph that remains connected after the removal of any one vertex. In particular, we prove:

▶ **Theorem 1.** *(P_3, H)-Arrowing is coNP-complete for all 2-connected H except when $H = K_3$, in which case the problem is in P.*

We do this by reducing an NP-complete SAT variant to (P_3, H)-Arrowing's complement, (P_3, H)-Nonarrowing (for fixed H, does there exist a (P_3, H)-good coloring of a given graph?), and showing how to construct gadgets for any 2-connected H. It is important to note that combining different copies of H can be troublesome; it is possible to combine graphs in a way so that we end up with more copies of it than before, e.g., combining two P_n's by their endpoints makes several new P_n's across the vertices of both paths. Results such as Burr's which assume 3-connectivity avoid such problems, in that we can combine several copies of 3-connected graphs without worrying about forming new ones. If G is 3-connected with vertices $u, v \in V(G)$ and we construct a graph F by taking two copies of G and identifying u across both copies, then identifying v across both copies, no new copies of G are constructed in this process; if a new G is created then it must be disconnected by the removal of the two identified vertices, contradicting F's 3-connectivity. This makes it easier to construct gadgets for reductions. To work with 2-connected graphs and show how to combine them carefully, we present a new measure of intra-graph connectivity called **edge pair linkage**, and use it to prove sufficient conditions under which two copies of a 2-connected graph G can be combined without forming new copies of G.

By targeting the (P_3, H) case we gain new insight and tools for the hardness of (F, H)-Arrowing in the general case since $F = P_3$ is the simplest case for F. We conjecture that if (P_3, H)-Arrowing is hard, then (F, H)-Arrowing is also hard for all nontrivial F, but this does not at all follow immediately. Towards the goal of categorizing the complexity of all (F, H)-Arrowing problems, we show how to extend the hardness results of (P_3, H)-Arrowing to other (F, H)-Arrowing problems in Section 5. These extensions are more intuitive and the resulting reductions are more palatable compared to constructing SAT gadgets. We believe that techniques similar to the ones shown in this paper can be used to eventually categorize the complexity of (F, H)-Arrowing for all (F, H) pairs.

The rest of the paper is organized as follows. Related work is discussed in Section 2. We present preliminaries in Section 3, wherein we also define and analyze edge pair linkage. Our complexity results for (P_3, H)-Arrowing are proven in Section 4. We show how our hardness results extend to other arrowing problems in Section 5, and we conclude in Section 6. All proofs omitted in the main text are provided in the appendix.

2 Related work

Complexity of (F, H)-Arrowing. Burr showed that (F, H)-Arrowing is in P when F and H are both star graphs, or when F is a matching [3]. Hassan et al. showed that (P_3, P_3)- and (P_3, P_4)-Arrowing are also in P [6]. For hardness results, Burr showed that (F, H)-Arrowing is coNP-complete when F and H are members of Γ_3, the family of all 3-connected graphs and K_3. The generalized (F, H)-Arrowing problem, where F and H are also part of the input, was shown to be Π_2^p-complete by Schaefer, who focused on constructions where F is a tree and H is a complete graph [13].[1] Hassan et al. recently showed that (P_k, P_ℓ)-Arrowing is coNP-complete for all k and ℓ aside from the exceptions listed above [6]. We note that (P_4, P_4)-Arrowing was shown to be coNP-complete by Rutenburg much earlier [12].

Matching removal. A matching is a collection of disjoint edges in a graph. Interestingly, there is an overlap between matching removal problems, defined below, and (P_3, H)-Arrowing.

▶ **Problem 2** (Π-Matching Removal [9]). *Let Π be a fixed graph property. For a given graph G, does there exist a matching M such that $G' = (V(G), E(G) - M)$ has property Π?*

Let Π be the property that G is H-free for some fixed graph H. Then, this problem is equivalent to (P_3, H)-Nonarrowing; a lack of red P_3's implies that only disjoint edges can be red, as in a matching, and the remaining (blue) subgraph must be H-free. Lima et al. showed that the problem is NP-complete when Π is the property that G is acyclic [7], or that G contains no odd cycles [8, 9].

Ramsey and Folkman numbers. The major research avenue involving arrowing is that of finding Ramsey and Folkman numbers. Ramsey numbers are concerned with the smallest complete graphs with arrowing properties, whereas Folkman numbers allow for any graph with some extra structural constraints. We refer the reader to surveys by Radziszowski [10] and Bikov [2] for more information on Ramsey and Folkman numbers, respectively.

3 Preliminaries

3.1 Notation and terminology

All graphs discussed in this work are simple and undirected. $V(G)$ and $E(G)$ denote the vertex and edge set of a graph G, respectively. We denote an edge in $E(G)$ between $u, v \in V(G)$ as (u, v). For two disjoint subsets $A, B \subsetneq V(G)$, $E_G(A, B)$ refers to the edges with one vertex in A and one vertex in B. For a subset $A \subseteq V(G)$, $G[A]$ denotes the induced subgraph on A. The neighborhood of a vertex $v \in V(G)$ is denoted as $N_G(v) = \{u \mid (u, v) \in E(G)\}$ and its degree as $d_G(v) := |N_G(v)|$. A connected graph is called k-connected if it has more than k vertices and remains connected whenever fewer than k vertices are removed.

Vertex identification is the process of replacing two vertices u and v with a new vertex w such that w is adjacent to all remaining neighbors $N(u) \cup N(v)$. For edges (u, v) and (p, q), edge identification is the process of identifying u with p, and v with q.

The path, cycle, and complete graphs on n vertices are denoted as P_n, C_n, and K_n, respectively. The complete graph on n vertices missing an edge is denoted as J_n. $K_{1,n}$ is the star graph on $n+1$ vertices. For $n \geq 3$, we define TK_n (tailed K_n) as the graph obtained by identifying a vertex of a K_2 and any vertex in K_n. The vertex of degree one in a TK_n is called the tail vertex of TK_n.

We introduce a new notion, defined below, to measure how "connected" a pair of edges in a graph is, which will be useful when identifying edges between multiple copies of the same graph. Examples have been shown in Figure 1.

▶ **Definition 2.** *For a pair of edges $e, f \in E(G)$, we define its* ***edge pair linkage****, $\mathrm{epl}_G(e, f)$, as the number of edges adjacent to both e and f. It is infinity if e and f share at least one vertex. Note that $\mathrm{epl}_G(e, f) \leq 4$ when e and f share no vertices. For a graph G, we define $\mathrm{mepl}(G) := \min_{e,f \in E(G)} \mathrm{epl}(e, f)$ as the minimum edge pair linkage across all edge pairs.*

[1] $\Pi_2^p = \mathrm{coNP}^{\mathrm{NP}}$, the class of all problems whose complements are solvable by a nondeterministic polynomial-time Turing machine having access to an NP oracle.

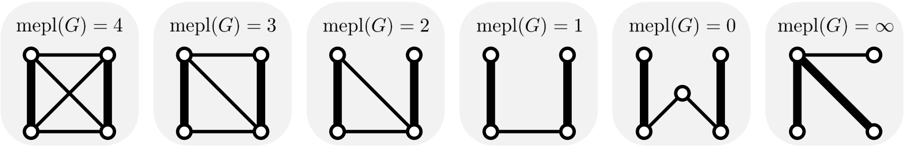

Figure 1 Graphs with different $\mathrm{mepl}(G)$ values. Bold edges have $\mathrm{epl}_G = \mathrm{mepl}(G)$.

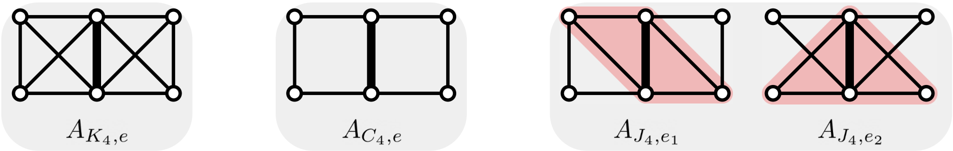

Figure 2 Proof for Lemma 3 when $|V(H)| = 4$. It is easy to see that $A_{H,e}$ for $H \in \{C_4, K_4\}$ has exactly two copies of H for arbitrary e. Moreover, constructing $A_{J_4,e}$ introduces a new J_4 (highlighted in red) for both nonisomorphic choices of $e \in E(J_4)$. Identified edges are bolded.

It is easy to see that the only graphs with $\mathrm{mepl}(G) = \infty$ are the star graphs, $K_{1,n}$, and K_3 since these are the only graphs that do not have disjoint edges. When the context is clear, the subscript G for $\mathrm{epl}_G(\cdot)$, $d_G(\cdot)$, etc. will be omitted.

An (F, H)-good coloring of a graph G is a red/blue coloring of $E(G)$ where the red subgraph is F-free, and the blue subgraph is H-free. We say that G is (F, H)-good if it has at least one (F, H)-good coloring. When the context is clear, we will omit (F, H) and refer to the coloring as a good coloring.

3.2 Combining graphs

Suppose H is a 3-connected graph. Consider the graph $A_{H,e}$, obtained by taking two disjoint copies of H and identifying some arbitrary $e \in E(H)$ from each copy. Observe that no new copy of H – referred to as a rogue copy of H in $A_{H,e}$ – is constructed during this process; if a new H is created then it must be disconnected by the removal of the two identified vertices, contradicting H's 3-connectivity. This is especially useful when proving the existence of good colorings; to show that a coloring of $A_{H,e}$ has no blue H, we know that only two copies of H need to be looked at, without worrying about any other rogue H. Unfortunately, this property does not hold for all 2-connected graphs. Instead, we use minimum edge pair linkage to explore sufficient conditions that allow us to combine multiple copies of graphs without concerning ourselves with any potential rogue copies.

▶ **Lemma 3.** *Suppose H is a 2-connected graph such that $|V(H)| \geq 4$ and $\mathrm{mepl}(H) \geq 2$. Given H and $e \in E(H)$, let $A_{H,e}$ be the graph obtained by taking two disjoint copies of H and identifying e from each copy. For all such H, except J_4, there exists $e \in E(H)$ such that $A_{H,e}$ has exactly two copies of H, i.e., no new copy of H is formed after identifying e.*

Proof. For $|V(H)| = 4$, the statement is easily observed as the only cases to consider are C_4, J_4, and K_4. See Figure 2. Suppose $|V(H)| \geq 5$. We will first construct $A_{H,e}$ using an arbitrary $e = (u, v) \in E(H)$ and assume that a new copy of H is constructed after identifying e. Let X and Y denote the subgraphs of $A_{H,e}$ corresponding to the two copies of H in $A_{H,e}$ that identify (u, v). It follows that, $V(X) \cap V(Y) = \{u, v\}$ and $V(X) \cup V(Y) = V(A_{H,e})$. Similarly, $E(X) \cap E(Y) = \{e\}$ and $E(X) \cup E(Y) = E(A_{H,e})$. Suppose Z is a subgraph corresponding to another copy of H in $A_{H,e}$, i.e. $V(Z) \neq V(X)$

and $V(Z) \neq V(Y)$. Let $V_{Z_X} = (V(X) - V(Y)) \cap V(Z)$ be the vertices of Z only in X, and $E_{Z_X} = \{(p,q) \in E(Z) \mid p,q \in V_{Z_X}\}$. V_{Z_Y} and E_{Z_Y} are defined similarly. In the following claim, we observe the properties of Z and the original graph H with $\text{mepl}(H) \geq 2$.

▷ Claim 4. If Z exists in $A_{H,e}$, the following must be true: *(1)* Both V_{Z_X} and V_{Z_Y} are nonempty, *(2)* $u \in V(Z)$ and $v \in V(Z)$, *(3)* at least one of E_{Z_X} and E_{Z_Y} is empty, and *(4)* there exists $w \in V(H)$ with $d_H(w) = 2$.

The proof of Claim 4 is given in Appendix A. Now, let $e = (u,v) \in E(H)$ such that $d_H(v) = 2$. Consider the graph $A_{H,e}$. Note that since $d_H(v) = 2$, we have $d_{A_{H,e}}(v) = d_H(v) + d_H(v) - 1 = 3$. Let w_X and w_Y be the neighbors of v in $V(X) - V(Y)$ and $V(Y) - V(X)$, respectively. We know that $V(Z)$ includes u and v from Claim 4(2). We now show that w_X and w_Y must also belong to $V(Z)$: if neither belong to $V(Z)$, then $d_Z(v) = 1$, contradicting H's 2-connectivity (removing u disconnects H). Suppose w.l.o.g., that $w_X \notin V(Z)$. Since V_{Z_X} is nonempty and H is connected, there is at least one vertex in V_{Z_X} connected to u. However, removing u would disconnect Z, again contradicting H's 2-connectivity. Thus, $\{u, v, w_X, w_Y\} \subseteq V(Z)$. Using a similar argument, we can also show that both (v, w_X) and (v, w_Y) must belong to $E(Z)$.

Let p be a vertex in $V(Z) - \{u, v, w_X, w_Y\}$. We know p exists since $|V(H)| \geq 5$. W.l.o.g., we assume that $p \in V_{Z_X}$. Note that p cannot be adjacent to v since $N_{A_{H,e}}(v) = \{u, w_X, w_Y\}$. We now consider the neighborhood of p in Z. If p has a neighbor $q \in V_{Z_X} - \{w_X\}$, then $\text{epl}_Z((p,q),(v,w_Y)) = 0$, contradicting our assumption that $\text{mepl}(H) \geq 2$. Since $d_Z(p) = d_H(p) \geq 2$ and the only options remaining for p's neighborhood are u and w_X, we must have that p is connected to both u and w_X. In this case, we have that $\text{epl}_Z((p,w_X),(v,w_Y)) \leq 1$, which is still a contradiction. ◀

4 The complexity of $(\mathrm{P}_3, \mathrm{H})$-Arrowing

In this section, we discuss our complexity results stated in Theorem 1. We first show that (P_3, K_3)-Arrowing is in P (Theorem 5). The rest of the section is spent setting up our hardness proofs for all 2-connected $H \neq K_3$, which we prove formally in Theorems 13 and 14.

▶ **Theorem 5.** *(P_3, K_3)-Arrowing is in P.*

Proof. Let G be the input graph. Let $\gamma : E(G) \to \mathbb{Z}_{\geq 0}$ be a function that maps each edge to the number of triangles it belongs to in G. Note that γ can be computed in $O(|E(G)|^3)$ time via brute-force. Let t be the number of triangles in G. Clearly, any (P_3, K_3)-good coloring of G corresponds to a matching of total weight $\geq t$; otherwise, there would be some K_3 in G in the blue subgraph of G. Now, suppose there exists a matching M with weight at least t that does not correspond to a (P_3, K_3)-good coloring of G. Then, there must exist a copy of K_3 in G with at least two of its edges in M. However, since K_3's maximal matching contains only one edge, M must contain a P_3, which is a contradiction. Thus, we can solve (P_3, K_3)-Arrowing by finding the maximum weight matching of (G, γ), which can be done in polynomial time [5], and checking if said matching has weight equal t. ◀

To show that (P_3, H)-Arrowing is coNP-complete we show that its complement, (P_3, H)-Nonarrowing, is NP-hard. We reduce from the following NP-complete SAT variant:

▶ **Problem 3** ($(2,2)$-3SAT [1]). *Let ϕ be a 3CNF formula where each clause has exactly three distinct variables, and each variable appears exactly four times: twice unnegated and twice negated. Does there exist a satisfying assignment for ϕ?*

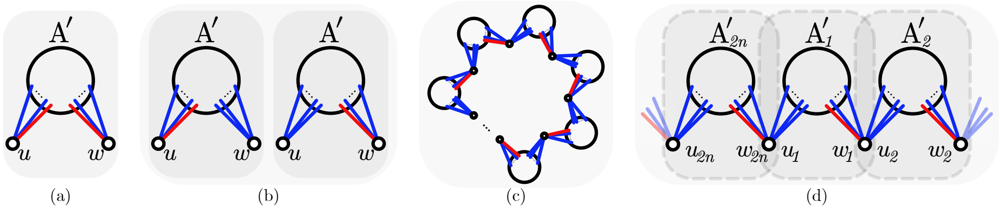

Figure 3 **(a)** The graph A' when u and w are adjacent to a red edge. **(b)** The graph A' when either u or w is adjacent to a red edge. **(c)** The graph B. **(d)** A zoomed in look at B.

Important definitions and the idea behind our reduction are provided in Section 4.1, while the formal proofs are presented in Section 4.2.

4.1 Defining special graphs and gadgets for proving hardness

We begin by defining a useful term for specific vertices in a coloring, after which we describe and prove the existence of some special graphs. We then define the two gadgets necessary for our reduction and describe how they provide a reduction from $(2, 2)$-3SAT.

▶ **Definition 6.** *For a graph G and a coloring c, a vertex $v \in V(G)$ is called a **free vertex** if it is not adjacent to any red edge in c. Otherwise, it is called a **nonfree vertex.***

Note that in any (P_3, H)-good coloring, a vertex can be adjacent to at most one red edge, otherwise, a red P_3 is formed. Intuition suggests that, by exploiting this restrictive property, we could freely force "any" desired blue subgraph if we can "append red edges" to it. This brings us to our next definition, borrowed from Schaefer's work on (F, H)-Arrowing [13]:

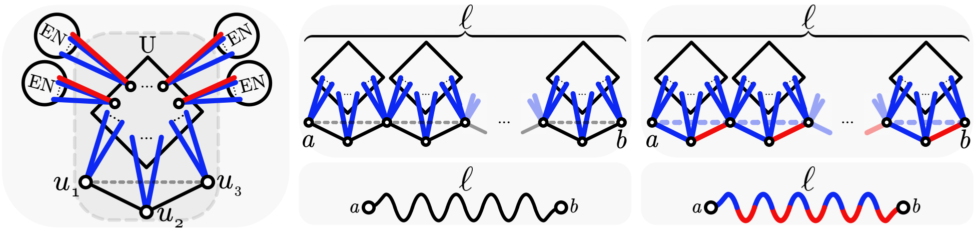
▶ **Definition 7** ([13]). *A graph G is called an **(F, H)-enforcer** with **signal vertex v** if it is (F, H)-good and the graph obtained from G by attaching a new edge to v has the property that this edge is colored blue in all (F, H)-good colorings.*

Throughout our text, when the context is clear, we will use the shorthand **append an enforcer to $u \in V(G)$** to mean we will add an (F, H)-enforcer to G and identify its signal vertex with u. We prove the existence of (F, H)-enforcers when $F = P_3$ below. This proof provides a good example of the role 2-connectivity plays while constructing our gadgets, showcasing how we combine graphs while avoiding constructing new copies of H. The arguments made are used frequently in our other proofs as well.

▶ **Lemma 8.** *(P_3, H)-enforcers exist for all 2-connected H.*

Proof. We extend an idea presented by Burr [3]. Let A be a "minimally bad" graph such that $A \to (P_3, H)$, but removing any edge e from A gives a (P_3, H)-good graph. Let $e = (u, w)$ and $A' = A - e$. This graph is illustrated in Figure 3. Observe that in any (P_3, H)-good coloring of A', at least one edge adjacent to u or w must be red; otherwise, such a coloring and a red (u, w) gives a good coloring for A, contradicting the fact that $A \to (P_3, H)$. If both u and w are adjacent to red edges in all good colorings, then A' is a (P_3, H)-enforcer, and either u or w can be the signal vertex .

If there exists a coloring where only one of $\{u, w\}$ is adjacent to a red edge, then we can construct an enforcer, B, as follows. Let $n = |V(H)|$. Make $2n$ copies of A', where u_i and w_i refer to the vertex u and w in the i^{th} copy of A', called A'_i. Now, identify each w_i with u_{i+1} for $i \in \{1, 2, \ldots, 2n - 1\}$, and identify w_{2n} with u_1 (see Figure 3). Although w_i and



(a) (b) (c)

Figure 4 **(a)** The (P_3, H)-signal extender described in Lemma 10, where enforcers are labeled EN and the copy of H is labeled U. Edges whose colors are fixed in all (P_3, H)-good colorings have been pre-colored. The edge (u_1, u_3) is dashed to signify it may or may not exist in the construction. **(b)** At the top, we show how extenders can be connected sequentially to form arbitrarily large extenders. The enforcers have been removed from the illustration for clarity. The in- and out-vertices are marked a and b, respectively. At the bottom, we show how signal extenders will be depicted in our figures, where ℓ is the number of concatenated constructed extenders. **(c)** At the top, we show the coloring of the signal extender when vertex a is a free vertex. At the bottom, we show the corresponding coloring of our representation of signal extenders.

u_{i+1} are now the same vertex in B, we will use their original names to make the proof easier to follow. It is easy to see that when w_1 is adjacent to a red edge in A'_1, then u_2 cannot be adjacent to any red edge in A'_2, causing w_2 to be adjacent to a red edge in A'_2, and so on. A similar argument holds when considering the case where u_1 is adjacent to a red edge in A'_1. Since every u_i and w_i is adjacent to a red edge, any of them can be our desired signal vertex.

Note that B must be (P_3, H)-good because each A'_i is (P_3, H)-good, and no new H is made during the construction of the graph; since H is 2-connected, H cannot be formed between two copies of A'_i's, otherwise there is a single vertex that can be removed to disconnect such an H, contradicting 2-connectivity. Thus, any new copy of H must go through all A_i's, which is not possible since such an H would have $\geq 2|V(H)|$ vertices. ◀

Using enforcers, we construct another graph that plays an important role in our reductions.

▶ **Definition 9.** *A graph G is called a* ***(P_3, H)-signal extender*** *with* ***in-vertex a*** *and* ***out-vertex b*** *if it is (P_3, H)-good and, in all (P_3, H)-good colorings, b is nonfree if a is free.*

▶ **Lemma 10.** *(P_3, H)-signal extenders exist for all 2-connected H.*

Proof. Let $n = |V(H)|$. Construct a graph G like so. Take a copy of H, and let $u_1, u_2, \ldots, u_n \in U$ be the vertices of H in G, such that (u_1, u_2) and (u_2, u_3) are edges of H. For each u_i for $i \in \{4, 5, \ldots, n\}$, append an enforcer to u_i. Observe that no "new" H is constructed during this process since H is 2-connected. Since each vertex except u_1, u_2, and u_3 is connected to an enforcer, each edge in $G[U]$, except (u_1, u_2), (u_2, u_3), and (u_1, u_3) must be blue. However, not all of them can be blue, otherwise $G[U]$ is a blue H. Therefore, in any good coloring, if u_1 is a free vertex, (u_2, u_3) must be red, making u_3 a nonfree vertex. Thus, u_1 is our in-vertex, and u_3 is our out-vertex. We illustrate G in Figure 4(a). ◀

Observe that multiple copies of these extenders can be used to form larger ones (see Figure 4). With the enforcer and extender graphs defined, we are ready to construct the gadgets for our reductions. Below, we define variable and clause gadgets and describe how they are used in our proofs. Recall that we are reducing from $(2, 2)$-3SAT. We will explain how our graphs encode clauses and variables after the definitions.

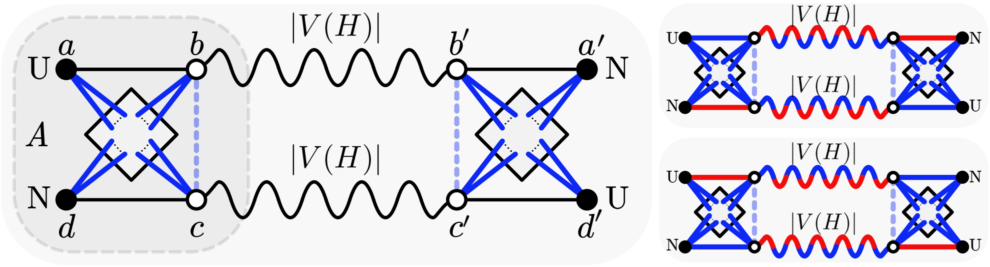


Figure 5 On the left, we show the variable gadget constructed using two copies of A as described in Theorem 13's proof and signal extenders. The vertices in the square are the vertices of A which had enforcers appended to them. The edge (b, c) is dashed to signify that it may or may not exist. Edges have been precolored wherever possible. Note that if (b, c) exists, it must be blue: if (b, c) is red, the attached signal extenders will force (a', b'), (b', c'), and (c', d') to be blue, forming a blue H. By symmetry, (b', c') must also be blue. Now, observe that at least one edge in $\{(a, b), (c, d)\}$ must be red, otherwise we form a blue H in A. Suppose (a, b) is red: the signal extender forces (a', b') to be blue. To avoid a blue H, (c', d') must be red, which forces (c, d) to be blue. In this case, the vertices marked **U** are nonfree vertices, and the vertices marked **N** are free. A similar pattern can be observed when we color (c, d) red instead, giving us colorings where vertices marked **U** are free and vertices marked **N** are nonfree.

▶ **Definition 11.** *For a fixed H, a **clause gadget** is a (P_3, H)-good graph CG containing vertices i_1, i_2, and i_3 – referred to as **input vertices**, such that if vertices outside the gadget, o_1, o_2 and o_3, are connected to i_1, i_2, and i_3, respectively, then each of the eight possible combinations of (o_j, i_j)'s colors should allow a (P_3, H)-good coloring for CG, except the coloring where all (o_j, i_j)'s are red, which should not allow a good coloring of CG.*

▶ **Definition 12.** *For a fixed H, a **variable gadget** is a (P_3, H)-good graph VG containing four **output vertices**: two **unnegated output vertices**, u_1 and u_2, and two **negated output vertices**, n_1 and n_2, such that:*

1. *In each (P_3, H)-good coloring of VG:*
   a. *If u_1 or u_2 is a free vertex, then n_1 and n_2 must be nonfree vertices.*
   b. *If n_1 or n_2 is a free vertex, then u_1 and u_2 must be nonfree vertices.*
2. *There exists at least one (P_3, H)-good coloring of VG where u_1 and u_2 are free vertices.*
3. *There exists at least one (P_3, H)-good coloring of VG where n_1 and n_2 are free vertices.*

Note how clause gadgets and their input vertices correspond to OR gates and their inputs; the external edges, denoted as (o_j, i_j)'s in the definition, behave like true or false signals: blue is true, and red is false. Similarly, output vertices of variable gadgets behave like sources for these signals. The reduction is now straightforward: for a formula ϕ, construct G_ϕ like so. For each variable and clause, add a corresponding gadget. Then, identify the output and input vertices according to how they appear in each clause. It is easy to see that any satisfying assignment of ϕ corresponds to a (P_3, H)-good coloring of G_ϕ, and vice versa. To complete the proof we must show that the gadgets described exist and that no new H is formed while combining the gadgets during the reduction.

Note that it is possible for a variable gadget to have a coloring where both unnegated and negated output vertices are nonfree. This does not affect the validity of the gadgets. A necessary restriction is that if variable x appears unnegated in clause L_1 and negated in L_2, then x cannot satisfy both clauses. Our gadgets clearly impose that restriction.

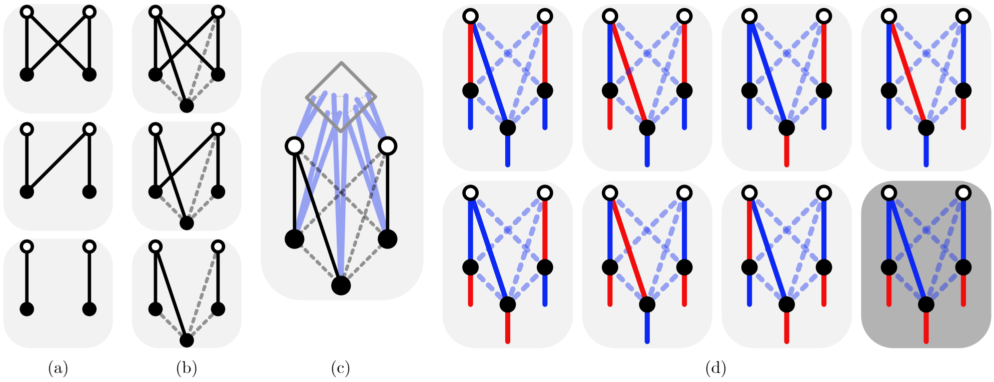

Figure 6 This figure shows the clause gadget used in the proofs of Theorem 13 and 14. **(a)** Each block represents the induced subgraph in a H when: *(1)* $\text{mepl}(H) = 2$ and H has an induced C_4, *(2)* $\text{mepl}(H) = 1$, and *(3)* $\text{mepl}(H) = 0$. **(b)** Each block represents how a fifth vertex, denoted e in the proofs of Theorems 13 and 14, may be connected to the induced subgraphs from (a). For each case, the solid line going from e represents an edge that must exist in $E(H)$ since $d_H(v) \geq 2$ for all $v \in H$ due to 2-connectivity. In the first case, any edge can be chosen w.l.o.g. due to the symmetry of C_4. The dashed edges may or may not exist, but their existence is inconsequential to the correctness of our gadget. **(c)** An illustration of the clause gadget, where each vertex of H attached to an enforcer is in the square. The input vertices have been filled in. **(d)** We show the eight possible combinations of inputs that can be given to the gadget. Observe that a (P_3, H)-good coloring is always possible unless the input is three red edges.

4.2 Hardness proofs

Using the ideas and gadgets presented in Section 4.1, we provide our hardness results below.

▶ **Theorem 13.** *(P_3, H)-Arrowing is coNP-complete when H is a 2-connected graph on at least four vertices with* $\text{mepl}(H) \leq 1$.

Proof. We reduce $(2, 2)$-3SAT to (P_3, H)-Nonarrowing as described in the end of Section 4.1; given a $(2, 2)$-3SAT formula ϕ, we construct a graph G_ϕ such that G_ϕ is (P_3, H)-good if and only if ϕ is satisfiable. Since we have $\text{mepl}(H) \leq 1$, we must have two edges $(a, b), (c, d) \in E(H)$ that have at most one edge adjacent to both. We construct a graph A like so: take a copy of H and append an enforcer to each vertex of H except a, b, c, and d. We construct the variable gadget using two copies of A joined by signal extenders, as shown in Figure 5. The vertices labeled **U** (resp., **N**) correspond to unnegated (resp., negated) output vertices. Note that there are no rogue H's made during this construction. Recall that because of 2-connectivity, a copy of H cannot go through a single vertex. Thus, if a copy of H other than the ones in A and the signal extenders exists, it must go through both copies of A and the signal extenders. However, this is not possible because by including the two signal extenders, we would have a copy of H with at least $2|V(H)|$ vertices.

We now describe our clause gadget. As observed in Section 3.2, there is no 2-connected graph with $\text{mepl}(\cdot) \leq 1$ on four vertices so we assume $|V(H)| \geq 5$. Let (a, b) and (c, d) be the edges that achieve this $\text{epl}(\cdot)$. Let e be a fifth vertex connected to at least one of $\{a, b, c, d\}$. We construct a clause gadget by taking a copy of H and appending an enforcer to each vertex except a, b, c, d, and e. In Figure 6 – which also includes a special case for $\text{mepl}(H) = 2$ used in Theorem 14 – we show how e and two vertices from $\{a, b, c, d\}$ can be used as input vertices so that a blue H is formed if and only if all three input vertices are connected to red external edges. Observe that we can make the clause gadget arbitrarily large by attaching

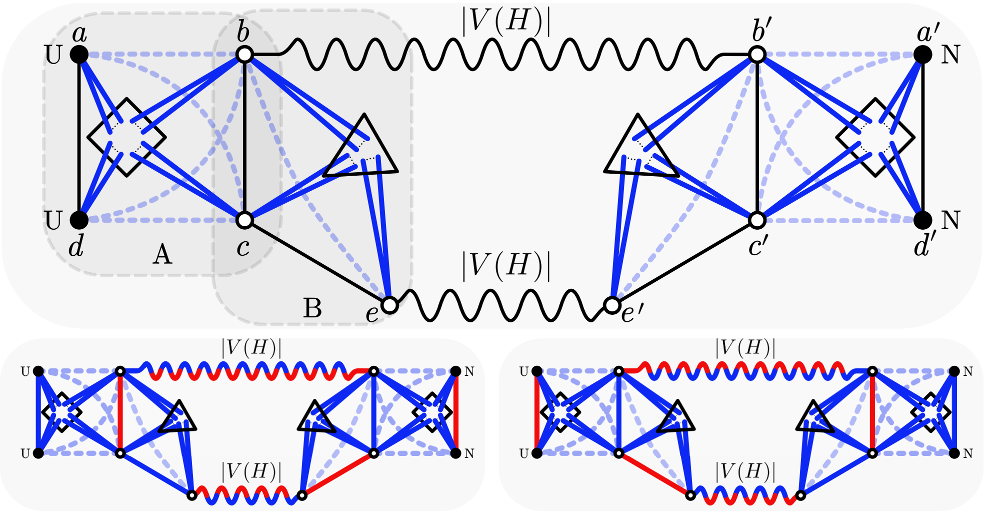

Figure 7 On the top, we show the variable gadget constructed using two copies of F as described in Theorem 13's proof and signal extenders. A and B have been marked. The vertices in the square (resp., triangle) are the vertices of A (resp., B) which had enforcers appended to them. Dashed edges signify edges that may or may not exist. Edges have been precolored wherever possible. Observe that (b, e) must be blue: if (b, e) is red, the attached extenders will force (b', c'), (b', e'), and (c', e') to be blue, forming a blue H in the copy of B on the right. We show that (a, b), (a, c), (b, d), and (c, d) must always be blue. Observe that at least one edge in $\{(b, c), (c, e)\}$ must be red, otherwise we form a blue H in B. Note that if (b, c) is red, the edges (a, b), (a, c), (b, d), and (c, d) must be blue. If (b, c) is blue, (c, e) is red. Thus, (c, d) and (a, c) are blue. Moreover, a red (c, e) forces (c', e') to be blue via the extender. Thus, (b', c') must be red to avoid a blue H. The extender on the top will in turn force edge (a, b) and (b, d) to be blue. Therefore, (a, b), (a, c), (b, d), and (c, d) are blue in all good colorings. By symmetry, (a', b'), (a', c'), (b', d'), (c', d'), and (b', e') must also be blue in all good colorings. Observe that when a vertex marked **U** is nonfree, i.e., (a, d) is blue, (b, c) must be red. Thus, (b', c') is blue, and (a', d') must be red, making the vertices marked **N** nonfree. A similar pattern can be observed when vertices marked **N** are free, wherein the vertices marked **U** are forced to be nonfree. These colorings are shown at the bottom of the figure.

the out-vertex of a signal extender to each input vertex of a clause gadget. We attach a signal extender with at least $|V(H)|$ vertices to each input vertex. This ensures that no copies of H other than the ones in each gadget and extender are present in G_ϕ. ◀

▶ **Theorem 14.** *(P_3, H)-Arrowing is coNP-complete when H is a 2-connected graph on at least four vertices with* $\operatorname{mepl}(H) \geq 2$.

Proof. We follow the same argument as in the proof of Theorem 13. We first discuss the variable gadget. Using Lemma 3 and the fact that $\operatorname{mepl}(H) \geq 2$, we know that we can construct a graph F with exactly two copies of H that share a single edge, unless $H = J_4$. The variable gadget for this exception is shown in Appendix A. For now, we assume $H \neq J_4$. Let A and B the copies of H in F and let (b, c) be the edge that was identified. Let $e \neq b$ be a vertex in B adjacent to c, and let (a, d) be an edge in A where $a, d \notin \{b, c\}$. Note that if such an (a, d) does not exist in H, then (b, c) must be an edge that shares a vertex with every other edge in H. However, it is easy to see that in this case two copies of H cannot be identified on (b, c) without forming new copies of H. Thus, (a, d) must exist. We now append enforcers to each vertex in A and B except a, b, c, d, and e. Our variable gadget is constructed using two copies of F joined via signal extenders as shown in Figure 7.

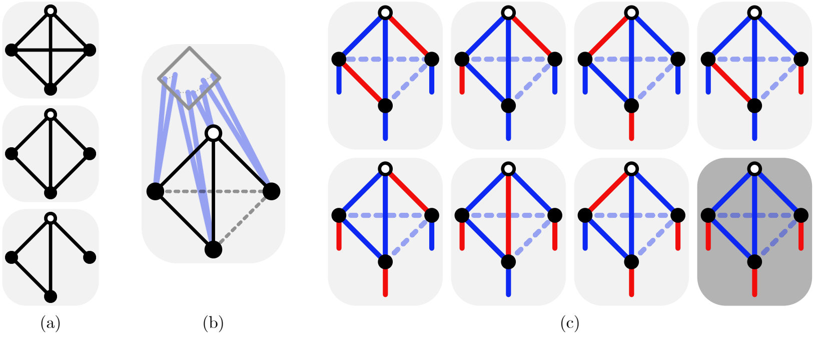

Figure 8 This figure shows the clause gadget used in Theorem 14 when H contains a TK_3. **(a)** Each block represents the induced subgraph in a H when: *(1)* $\mathrm{mepl}(H) = 4$, *(2)* $\mathrm{mepl}(H) = 3$, and *(3)* $\mathrm{mepl}(H) = 2$ and H has an induced TK_3. **(b)** An illustration of the clause gadget, where each vertex of H attached to an enforcer is in the square. The input vertices have been filled in. Dashed edges may or may not exist, but their existence is inconsequential to the correctness of our gadget. **(c)** We show the eight possible combinations of inputs that can be given to the gadget. Observe that a (P_3, H)-good coloring is always possible unless the input is three red edges.

We use a clause gadget similar to the one used in Theorem 13, but with some modifications. Since $\mathrm{mepl}(H) \geq 2$, we know that H must contain a C_4 or a TK_3. If H contains a TK_3, we can use the gadget shown in Figure 8. However, if $\mathrm{mepl}(H) = 2$ and we only have induced C_4's, we can use the gadget shown in Figure 6 when $|V(H)| \geq 5$ using the induced C_4 and another vertex e. The only case left is $H = C_4$, which is discussed in Appendix A. ◀

5 Extending the hardness of $(\mathrm{P_3}, \mathrm{H})$-Arrowing

In this section, we discuss how hardness results for (P_3, H)-Arrowing can be extended to other (F, H)-Arrowing problems. We believe this provides an easier method for proving hardness compared to constructing SAT gadgets. We discuss two methods in which our results can be extended: *(1)* showing that $G \to (P_3, H) \iff G \to (P_3, H')$ for some pairs of H and H' (Section 5.1), and *(2)* given a graph G, showing how to construct a graph G' such that $G \to (P_3, H) \iff G' \to (F, H)$ for some F (Section 5.2).

5.1 $\mathrm{P_3}$ versus tailed complete graphs

We first observe that edges not belonging to H can be removed while working on (P_3, H)-Arrowing for a graph G; we can always color said edge blue without forming a blue H.

▶ **Observation 15.** *Let G be a graph and $e \in E(G)$. If e does not belong to a copy of H in G, then $G \to (P_3, H)$ if an only if $G - e \to (P_3, H)$.*

▶ **Theorem 16.** *For $n \geq 3$, $G \to (P_3, TK_n)$ if and only if $G \to (P_3, K_n)$.*

Proof. Clearly if $G \to (P_3, TK_n)$ then $G \to (P_3, K_n)$ since K_n is a subgraph of TK_n. For the other direction, consider a graph G such that $G \to (P_3, K_n)$ but is (P_3, TK_n)-good. By Observation 15, we can assume that each edge in G belongs to a K_n. We can also assume that G is connected. Let c be a (P_3, TK_n)-good coloring of G. Since $G \to (P_3, K_n)$ there must exist a blue K_n in c. Let $U = \{u_1, u_2, \ldots, u_n\}$ be the vertices of said K_n. Let $e = (u_i, v)$ be an edge going from some $u_i \in U$ to a vertex $v \notin U$. We know that such an edge exists otherwise G is just a K_n, and a K_n is (P_3, K_n)-good, so this would contradict our assumption.

W.l.o.g., let $u_i = u_1$. Note that (u_1, v) must be red, otherwise, we have a blue TK_n. Since (u_1, v) is part of a K_n (Observation 15), at least one vertex w must be connected to both u_1 and v. Note that (u_1, w) and (v, w) must be blue to avoid a red P_3. If $w \in U$, then U and (v, w) form a blue TK_n. If $w \in V(G) - U$, then U and (u_1, w) form a blue TK_n. ◀

▶ **Corollary 17.** *(P_3, TK_n)-Arrowing is coNP-complete when $n \geq 4$ and in P when $n = 3$.*

With this result, we have categorized the complexity of all (P_3, H)-Arrowing problems for connected H with $|V(H)| \leq 4$; the star and path graphs were shown to be in P [4, 6].

5.2 Stars versus 2-connected graphs

Note that $P_3 = K_{1,2}$. Given a graph G, suppose we construct a graph G' by taking a copy of G and appending an edge (one for each vertex in G) to each vertex, where each appended edge is forced to be red in all colorings. It is easy to see that if a coloring of G contains a red $K_{1,2}$, then said coloring in G' contains a red $K_{1,3}$, using the appended red edge. Thus, if we can find a $(K_{1,3}, H)$-good graph F with an edge (u, v) such that, in all good colorings, (u, v) is red and no other edge adjacent to v is red, we could reduce $(K_{1,2}, H)$-Arrowing to $(K_{1,3}, H)$-Arrowing by appending a copy of F (identifying v) to each vertex of G. Recall that we do not have to worry about new copies of H due to its 2-connectivity.

Generalizing this argument, if we attach k red edges to each vertex of G, then a coloring of G with a red $K_{1,\ell}$ corresponds to a coloring of G' with a red $K_{1,k+\ell}$. In Appendix B, we show that for all $n \geq 3$, there exists some m for which there is a $(K_{1,n}, H)$-good graph with a vertex v that is always the center of a $K_{1,m}$ for some $1 \leq m < n$. This allows us to reduce $(K_{1,n-m}, H)$-Arrowing to $(K_{1,n}, H)$-Arrowing. Thus, we can assert the following:

▶ **Lemma 18.** *Suppose H is a 2-connected graph. If $(K_{1,k}, H)$-Arrowing is coNP-hard for all $2 \leq k < n$, then $(K_{1,n}, H)$-Arrowing is also coNP-hard.*

Also in Appendix B, we reduce $(2, 2)$-3SAT to $(K_{1,3}, K_3)$-Nonarrowing and show how that result can be extended to $(K_{1,n}, K_3)$-Arrowing for $n \geq 4$, giving us the following result:

▶ **Theorem 19.** *For all 2-connected H and $n \geq 2$, $(K_{1,n}, H)$-Arrowing is coNP-complete with the exception of $(K_{1,2}, K_3)$-Arrowing, which is in P.*

Finally, recall that (P_3, H)-Nonarrowing is equivalent to H-free Matching Removal. We can assert a similar equivalence between H-free b-Matching Removal and $(K_{1,b+1}, H)$-Nonarrowing, giving us the following corollary:

▶ **Corollary 20.** *For all 2-connected H, H-free b-Matching Removal is NP-complete for all $b \geq 1$, except the case where $b = 1$ and $H = K_3$, which is in P.*

6 Conclusion and future work

This paper provided a complete categorization for the complexity of (P_3, H)-Arrowing when H is 2-connected. We provided a polynomial-time algorithm when $H = K_3$, and coNP-hardness proofs for all other cases. Our gadgets utilized a novel graph invariant, minimum edge pair linkage, to avoid unwanted copies of H. We showed that our hardness results can be extended to (P_3, TK_n)- and $(K_{1,n}, H)$-Arrowing using easy-to-understand graph transformations.

Our ultimate goal is to categorize the complexity of all (F, H)-Arrowing problems. Our first objective is to categorize the complexity of (P_3, H)-Arrowing for all H, and to find more graph transformations to extend hardness proofs between different arrowing problems.

A Proof of Claim 4 and missing gadgets

▷ Claim 4. If Z exists in $A_{H,e}$, the following must be true: *(1)* Both V_{Z_X} and V_{Z_Y} are nonempty, *(2)* $u \in V(Z)$ and $v \in V(Z)$, *(3)* at least one of E_{Z_X} and E_{Z_Y} is empty, and *(4)* there exists $w \in V(H)$ with $d_H(w) = 2$.

Proof.

1. This follows from our definition of Z.
2. If at most one vertex in $\{u, v\}$ were in Z, deleting it would disconnect said copy of H, contradicting the fact that H is 2-connected.
3. Suppose that both E_{Z_X} and E_{Z_Y} are nonempty. Let $f_1 \in E_{Z_X}$ and $f_2 \in E_{Z_Y}$. We have $\text{epl}_{A_{H,e}}(f_1, f_2) = 0$ since, by construction, $E_{A_{H,e}}(X - Y, Y - X) = \emptyset$. Since both of these edges belong to Z, which is isomorphic to H, we also have $\text{epl}_H(f_1, f_2) = 0$, which contradicts our assumption that $\text{mepl}(H) \geq 2$.
4. Note that k-connected graphs must have minimum degree at least k as a vertex with fewer neighbors could be disconnected from the rest of the graph with fewer than k vertex deletions. So, we have $d_H(w) \geq 2$ for each $w \in V(H)$. W.l.o.g., assume that $E_{Z_X} = \emptyset$. Then, each vertex in $w \in Z_X$ can only be connected to u and v. Thus, we have $d_H(w) = d_Z(w) \leq 2$, and consequently $d_H(w) = 2$. ◁

Missing gadgets for $(\mathbf{P_3}, \mathbf{H})$-Nonarrowing. In Figure 9 we show the variable gadget for (P_3, J_4)-Nonarrowing. In Figure 10 we show the clause gadget for (P_3, C_4)-Nonarrowing.

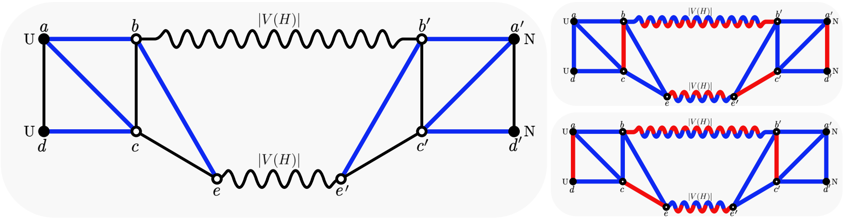

Figure 9 The variable gadget for (P_3, J_4)-Nonarrowing is shown on the left. The colorings on the right show that when vertices marked **U** (resp., **N**) are free, those marked **N** (resp., **U**) are nonfree.

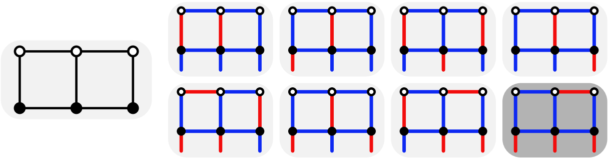

Figure 10 The clause gadget for (P_3, C_4)-Nonarrowing is shown on the left. Possible inputs for the gadget are shown on the right. A good coloring is possible unless the input is three red edges.

B Extending to stars

We first define the following special graph which will be used in our extension proof.

▶ **Definition 21.** *A graph G is called an (F, H)-leaf sender with leaf-signal edge (u, v) if it is (F, H)-good, (u, v) is red in all good colorings, and there exists a good coloring where (u, v) is not adjacent to any other red edge.*

When the context is clear, we will use the shorthand **append a leaf sender to $\boldsymbol{u} \in \boldsymbol{V(G)}$** to mean we will add an (F, H)-leaf sender to G and identify a vertex of its leaf-signal edge with u. This graph essentially simulates "appending a red edge" as described in Section 5.2.

B.1 Proof of Lemma 18

▶ **Lemma 18.** *Suppose H is a 2-connected graph. If $(K_{1,k}, H)$-Arrowing is coNP-hard for all $2 \le k < n$, then $(K_{1,n}, H)$-Arrowing is also coNP-hard.*

Proof. Suppose we are trying to prove the hardness of $(K_{1,n}, H)$-Arrowing for 2-connected H and $n \ge 3$. Let A be a "minimally bad" graph such that $A \to (K_{1,n}, H)$, but removing any edge e from A gives a $(K_{1,n}, H)$-good graph. Let $e = (u, w)$ and $A' = A - e$. Let $\mathcal{C}$ be the set of all good colorings of A'. For a coloring $c \in \mathcal{C}$ and vertex v, let $r_c(v)$ be the number of red edges that v is adjacent to in c. Let $r_{\mathcal{C}}(v) = \min_{c \in \mathcal{C}} r_c(v)$. We consider different cases for $r_{\mathcal{C}}(u)$. Since c is a good coloring, we know that $r_{\mathcal{C}}(u) \le n - 1$.

1. $r_{\mathcal{C}}(u) = n - 1$. In this case, it is easy to see that A' is a $(K_{1,n}, H)$-enforcer with signal vertex u. Let $(p, q) \in V(H)$. Construct a graph B like so. Take a copy of H and append an enforcer to each vertex of H except p and q. It is easy to see that (p, q) must be red in all good colorings, i.e., B is a $(K_{1,n}, H)$-leaf sender with leaf-signal edge (p, q). For any graph G, we append a leaf-sender to each of G's vertices to obtain a graph G' such that $G' \to (K_{1,n}, H) \iff G \to (K_{1,n-1}, H)$, as discussed in Section 5.2.
2. $r_{\mathcal{C}}(u) = 0$. Let $m = |V(H)|$. In this case, we can construct a $(K_{1,n}, H)$-enforcer, B, by combining $2m$ copies of A' as we did in Lemma 8. Note that in any good coloring c of A', we have that $r_c(u) \ge n - 1$ or $r_c(w) \ge n - 1$; if not, such a coloring and a red (u, w) gives

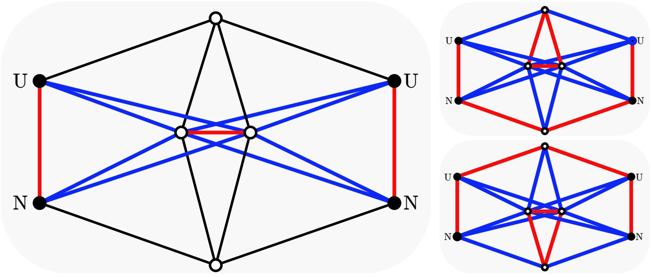

Figure 11 The variable gadget for $(K_{1,3}, K_3)$-Nonarrowing is shown on the left. Edges with the same color in all good colorings have been pre-colored. Both good colorings are shown on the right.

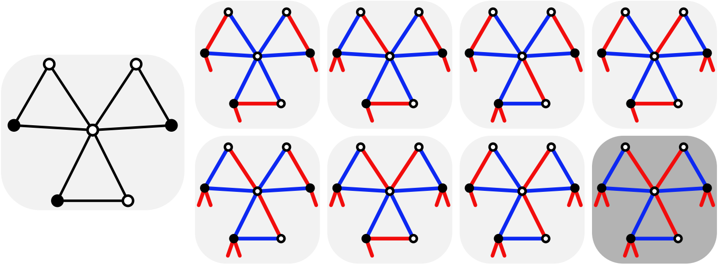

Figure 12 The clause gadget for $(K_{1,3}, K_3)$-Nonarrowing is shown on top. The eight combinations of inputs that can be given to the gadget are shown on the bottom. Observe that a $(K_{1,3}, K_3)$-good coloring is always possible unless the input is three red $K_{1,2}$'s.

a good coloring for A, contradicting the fact that $A \to (K_{1,n}, H)$. Make $2m$ copies of A', where u_i (resp., w_i) refers to the vertex u (resp., w) in the i^{th} copy of A', referred to as A'_i. Now, identify each w_i with u_{i+1} for $i \in \{1, 2, \ldots, 2m-1\}$, and identify w_{2m} with u_1. Observe that when w_1 is adjacent to $n-1$ red edges in A'_1, then u_2 cannot be adjacent to any red edge in A'_2, causing w_2 to be adjacent to $n-1$ red edges in A'_2, and so on. Since every u_i and w_i is adjacent to $n-1$ red edges, any of them can be our signal vertex v. We can now proceed as we did in the previous case to reduce from $(K_{1,n-1}, H)$-Arrowing.

3. $r_{\mathcal{C}}(u) \in \{1, 2, \ldots, n-2\}$. For any graph G, we can attach a copy of A' to each of G's vertices – identifying $u \in V(A')$ with each vertex – to obtain a graph G' such that $G' \to (K_{1,n}, H) \iff G \to (K_{1,n-r_{\mathcal{C}}(u)}, H)$, as discussed in Section 5.2, thereby providing a reduction from $(K_{1,n-r_{\mathcal{C}}(u)}, H)$-Arrowing. ◀

B.2 Hardness of $(\mathbf{K_{1,n}}, \mathbf{K_3})$-Nonarrowing for $n \geq 3$

To show that $(K_{1,3}, K_3)$-Arrowing is coNP-complete, we provide gadgets as we did for (P_3, H)-Arrowing. We provide gadgets in Figures 11 and 12 to show that $(2,2)$-3SAT can be reduced to $(K_{1,3}, K_3)$-Nonarowing. Note that the output vertices are either attached to a single red edge or two red edges. When they are attached to a single red edge, they behave like true output signals. When adjacent to two red edges, they behave like a false output signal. The clause gadget behaves like an OR gate, in that it has no good coloring when the three input vertices all have false inputs.

Recall that in the hardness proofs for (P_3, H)-Arrowing, we also had to show that no new H is constructed while combining gadget graphs to construct G_ϕ. It is easy to see that no new K_3 is constructed when our gadgets are combined; since each clause has unique literals, a cycle formed while constructing G_ϕ would have to go through at least two clause gadgets and at least two variable gadgets, but this cycle has more than three vertices (see Figure 13).

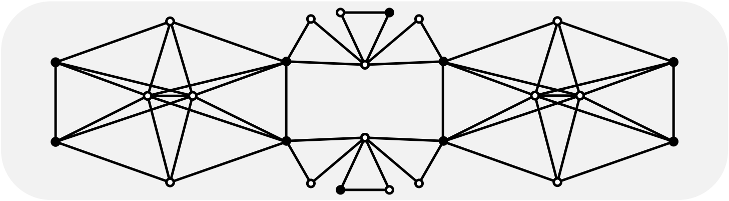

Figure 13 The smallest cycle made when joining $(K_{1,3}, K_3)$ variable and clause gadgets is a C_6.

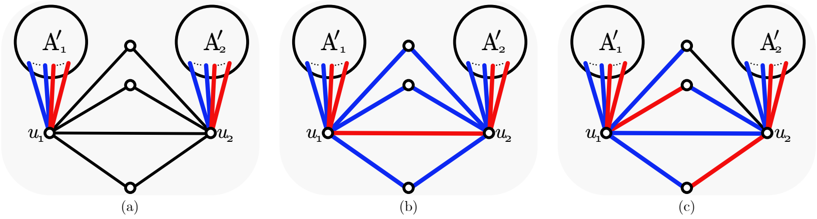

Figure 14 A'_1 and A'_2 are graphs with $r_{\mathcal{C}}(u_i) = n-2$. We show how to construct a new graph using these in **(a)**. In **(b)**, we show a good coloring where u_i's are now adjacent to $n-1$ red edges. Finally, in **(c)**, we observe that the coloring in **(b)** is the only good coloring since at most one edge from outside A'_i that is adjacent to u_i can be red.

To show the hardness of $(K_{1,n}, K_3)$-Arrowing for $n \geq 4$, we can proceed exactly as we did in Lemma 18. The only case where the proof fails is when $r_{\mathcal{C}}(u) = n-2$, because now the proof says we have to reduce $(K_{1,2}, K_3)$-Arrowing to $(K_{1,n}, K_3)$-Arrowing, which is unhelpful since $(K_{1,2}, K_3)$-Arrowing is in P. In Figure 14 we show how vertices attached to $n-2$ red edges can be combined to make a $(K_{1,n}, K_3)$-enforcer. Using the enforcer, we can create a $(K_{1,n}, K_3)$-leaf sender and reduce from $(K_{1,n-1}, K_3)$-Arrowing.

On the Complexity of Community-Aware Network Sparsification

Abstract

In the NP-hard Π-Network Sparsification problem, we are given an edge-weighted graph G, a collection $\mathcal{C}$ of c subsets of $V(G)$, called *communities*, and two numbers ℓ and b, and the question is whether there exists a spanning subgraph G' of G with at most ℓ edges of total weight at most b such that $G'[C]$ fulfills Π for each community $C \in \mathcal{C}$. We study the fine-grained and parameterized complexity of two special cases of this problem: Connectivity NWS where Π is the connectivity property and Stars NWS, where Π is the property of having a spanning star.

First, we provide a tight $2^{\Omega(n^2+c)}$-time running time lower bound based on the ETH for both problems, where n is the number of vertices in G even if all communities have size at most 4, G is a clique, and every edge has unit weight. For the connectivity property, the unit weight case with G being a clique is the well-studied problem of computing a hypergraph support with a minimum number of edges. We then study the complexity of both problems parameterized by the feedback edge number t of the solution graph G'. For Stars NWS, we present an XP-algorithm for t answering an open question by Korach and Stern [Discret. Appl. Math. '08] who asked for the existence of polynomial-time algorithms for $t = 0$. In contrast, we show for Connectivity NWS that known polynomial-time algorithms for $t = 0$ [Korach and Stern, Math. Program. '03; Klemz et al., SWAT '14] cannot be extended to larger values of t by showing NP-hardness for $t = 1$.

1 Introduction

A common goal in network analysis is to decrease the size of a given network to speed up downstream analysis algorithms or to decrease the memory footprint of the graphs. This leads to the task of network sparsification where one wants to reduce the number of edges of a network while preserving some important property Π [6, 31, 35]. Similarly, in network

design the task is often to construct a minimum-size or minimum-weight network fulfilling a given property, the most famous example being Minimum-Weight Spanning Tree.

In many applications the input contains, in addition to a network, a hypergraph on the same vertex set [17, 24, 32]. The hyperedges of this hypergraph represent, for example, communities that are formed within the network. In presence of such community data, the sparsified network should preserve a property not for the whole network but instead for each community, that is, for each hyperedge of the hypergraph. Gionis et al. [19] called this task *community-aware network sparsification* and formalized it as follows.

Π-Network Sparsification (Π-NWS)

Input: A graph G, a collection $\mathcal{C}$ of c subsets of $V(G)$, called *communities*, an edge-weight function $\omega : E(G) \to \mathbb{R}_+$, an integer ℓ, and a positive real number b.
Question: Is there a graph $G' = (V(G), E')$ with $E' \subseteq E(G)$, $|E'| \leq \ell$, and total edge weight at most b such that for each community $C_i \in \mathcal{C}$ the subgraph of G' induced by C_i satisfies Π?

We say that a graph G' fulfilling the requirements is a *solution* for the instance I. A very well-studied property Π, considered by Gionis et al. [19] but also in many previous works [2, 7, 13, 15, 28] is that every community should induce a connected subgraph. A graph G that has this property for some hypergraph H, is called a *support* for H [4, 5, 28]. We denote the corresponding special case of Π-NWS as Connectivity NWS. Another variant of Π-NWS, also studied by Gionis et al. [19], is to demand that every community not only induces a connected subgraph but more strongly that it contains a *spanning star*. In other words, in the solution graph G', every community must be contained in the neighborhood of at least one of its vertices, called a *center vertex*. We refer to this variant as Stars NWS. An example instance and solutions for both problems are given in Figure 1.

Connectivity NWS and Stars NWS are both NP-hard [13, 10, 9, 19]. Motivated by this, we study both problems in terms of their parameterized and fine-grained complexity. We also investigate the versions of both problems where each edge has unit weight and refer to them as Unweighted Connectivity NWS and Unweighted Stars NWS.

Our two main results are as follows:

- We show that, based on the Exponential Time Hypothesis (ETH), Connectivity NWS and Stars NWS do not admit algorithms with running time $2^{o(n^2)+c}$, even if the input graph is a clique with unit weights and each community has size at most 4. This bound is matched by simple brute-force algorithms.
- We show that Stars NWS admits an XP-algorithm when parameterized by t, the feedback edge number of the solution graph. This positively answers the question of Korach and Stern [30] who asked whether there is a polynomial-time algorithm for finding an optimal solution for Stars NWS that is a tree. In fact, our algorithm extends the polynomial-time solvable cases to solutions that are tree-like.

We obtain several further results, for example a complexity dichotomy for Stars NWS and Unweighted Stars NWS parameterized by c, the number of communities.

Known results. Already the most basic variant of Connectivity NWS, where the edges have unit weights and the input graph G is a clique, appears in many applications, ranging from explanation of protein complexes [32] to combinatorial auctions [10] to the construction of P2P overlay networks in publish/subscribe systems [8, 24]. Thus, the problem has been studied intensively under various names [2, 7, 8, 13, 15, 24] from a parameterized complexity [7, 15, 24] and an approximation algorithms [2, 8, 24] perspective. For example, the problem is NP-hard even for instances with maximum community size 3 [13], and admits FPT-algorithms for the number of communities and for the largest community size plus the feedback edge number t of a solution [7]. A particular restriction of the problem is to determine whether there is an acyclic solution, called *tree support* or *clustered spanning tree.* It can be determined in polynomial time whether a hypergraph has a tree support and different polynomial-time algorithms have been described over the years [3, 10, 14, 16, 20, 27, 33, 34].

Unweighted Connectivity NWS with general input graphs G, has applications in the context of placing green bridges [17, 22]. Unweighted Connectivity NWS is NP-hard even when the maximum degree of G is 3 [22] and even for seven communities [17]. On the positive side, one can construct in polynomial time a tree support if one exists [21, 28, 29].

For Connectivity NWS where we may have arbitrary edge-weights, the distinction whether or not G is restricted to be a clique vanishes: any non-clique input graph G may be transformed into a clique by adding the missing edges with a prohibitively large edge weight. The problem of finding a minimum-weight tree support received attention due to its applications in network visualization [28]. As shown by Korach and Stern [29] and Klemz et al. [28], one can compute minimum-weight tree supports in polynomial time. Gioinis et al. [19] provided approximation algorithms for the general problem.

Stars NWS has received less attention than Connectivity NWS. Gionis et al. [19] showed NP-hardness and provided approximation algorithms. Korach and Stern [30] studied a variant of Stars NWS where the input graph is a clique and the solution is constrained to be a tree T where the closed neighborhood of the center vertex of a community C_i is exactly the community C_i. This implies that two different communities need to have different center vertices and thus restricts the allowed set of solution graphs strictly compared to Stars NWS. Korach and Stern [30] showed that this problem is solvable in polynomial time. As an open question, they ask whether this positive result can be lifted to Stars NWS.

Cohen et al. [9] studied the Minimum $\mathcal{F}$-Overlay problem which can be viewed as the following special case of Π-NWS: The input graph G is a clique and all edges have unit weight; $\mathcal{F}$ is a family of graphs and the property Π is to have some spanning subgraph which is contained in $\mathcal{F}$. Unweighted Connectivity NWS and Unweighted Stars NWS with clique input graphs are special cases of Minimum $\mathcal{F}$-Overlay. Cohen et al. [9] provide a complexity dichotomy with respect to properties of $\mathcal{F}$. For most cases of $\mathcal{F}$, Minimum $\mathcal{F}$-Overlay is NP-hard. In particular, Unweighted Stars NWS is NP-hard even when G is a clique [9]. Gionis et al. [19] also studied Π being that each community needs to induce a subgraph exceeding some prespecified density. Fluschnik and Kellerhals [17] considered further properties Π, for example the property of having small diameter.

Our results and organization of the work. To put our main results into context, we first summarize in Section 2 some complexity results that follow from simple observations or from previous work. They imply in particular that Stars NWS and Connectivity NWS have an FPT-algorithm for the parameter solution size ℓ and that they are W[1]-hard with respect to the dual parameter $k := m - \ell$ even in the unit weight case when G is a clique. Then,

</table>

in Section 3 we show that Unweighted Connectivity NWS and Unweighted Stars NWS do not admit algorithms with running time $2^{o(n^2+c)}$ even when G is a clique unless the Exponential Time Hypothesis (ETH) [26] is false.

In Section 4, we consider parameterization by t, the feedback edge number of the solution graph G'. This is the minimum number of edges that need to be deleted to transform the solution into a forest.[1] The study of t is motivated as follows: The solution size ℓ is essentially at least as large as $n - 1$, and thus neither small in practice nor particularly interesting from an algorithmic point of view. Thus, t can be seen as a parameterization above the lower bound $n - 1$. Our first main result is an XP-algorithm for Stars NWS. This positively answers the question of Korach and Stern [30] who asked whether there is a polynomial-time algorithm for $t = 0$ and extends the tractability further to every constant value of t. We then show that, in contrast, Unweighted Connectivity NWS is NP-hard already if $t = 1$. Thus, the polynomial-time algorithms for $t = 0$ [29, 28] cannot be lifted to larger values of t.

Finally, in Section 5 we study Stars NWS parameterized by the number c of input communities. We obtain the following complexity classification: Unweighted Stars NWS is FPT with respect to c and Stars NWS is W[1]-hard in the most restricted case when G is a clique and all edges have weight 1 or 2 and in XP in the most general case.

For an overview of the parameterized complexity results, refer to Table 1.

Due to lack of space several proofs (marked with ($\star$)) are deferred to the full version.

2 Preliminaries and Basic Observations

Preliminaries. For a set X, we denote by $\binom{X}{2}$ the collection of all size-two subsets of X. Moreover, for positive integers i and j with $i \leq j$, we denote by $[i, j] := \{k \in \mathbb{N} : i \leq k \leq j\}$.

An *undirected graph* $G = (V, E)$ consists of a set of vertices V and a set of edges $E \subseteq \binom{V}{2}$. We denote by $V(G)$ and $E(G)$ the vertex and edge set of G, respectively, and let $n = n(G) := |V(G)|$ and $m := |E(G)|$. For a vertex set $V' \subseteq V$, we denote by $E_G(V') := \{\{u, v\} \in E : u, v \in V'\}$ the edges between the vertices of V' in G. If G is clear from the context, we may omit the subscript. A graph G' is a *subgraph* of G if $V(G') \subseteq V(G)$ and $E(G') \subseteq E(G)$. Moreover, G' is *spanning* if $V(G') = V(G)$. For a vertex set V', we denote by $G[V'] := (V', E_G(V'))$ the *subgraph of G induced by V'*. A set $S \subseteq V(G)$ with

[1] The parameter t can be computed in polynomial time as discussed in Section 2.

$E_G(S) = \binom{S}{2}$ is called a *clique*. A graph G is a *star* of size $n-1$ with *center* $z \in V(G)$ if $E(G) = \{\{z, v\} : v \in V(G) \setminus \{z\}\}$. A graph G contains a *spanning star* if some subgraph G' of G is a star of size $n-1$. The center of this star is *universal* for G.

An edge set $E' \subseteq E(G)$ is a *feedback edge set* of G, if the graph $G' := (V(G), E(G) \setminus E')$ is acyclic. Two vertices u and v are *connected* in G if G contains a path between u and v. A graph G is *connected* if each pair of vertices $u, v \in V(G)$ is connected. A set $S \subseteq V(G)$ is a *connected component* of G, if $G[S]$ is connected and S is maximal with this property. Connectivity in hypergraphs is defined similarly: Two vertices u and v are *connected* if there exists a sequence $C_1, C_2, \dots, C_p$ of hyperedges such that $u \in C_1$, $v \in C_p$, and consecutive communities have nonempty intersection. A *connected component* of a hypergraph is a maximal set of connected vertices. The number x of connected components of a hypergraph can be computed in polynomial time, for example by BFS. Note that for a minimal solution G' for Stars NWS and Connectivity NWS, the connected components of G' are exactly the connected components of the community hypergraph. Thus, $t = \ell - n + x$ and the parameter t can be computed in polynomial time for a given input instance.

For details about parameterized complexity and the ETH refer to [12, 11].

Basic observations. To put our main results for Connectivity NWS and Stars NWS into context, we state some results that either follow easily from previous work or from simple observations.

The naive brute-force approach for each Π-NWS is to perform an exhaustive search over the $\mathcal{O}(2^m)$ possibilities to select at most ℓ edges from the input graph G. This leads to the following general statement for Π-NWS problems.

▶ **Proposition 2.1.** *Let Π be a property which can be decided in $\operatorname{poly}(n)$ time. Then, Π-NWS is solvable in $2^m \cdot c \cdot \operatorname{poly}(n)$ time.*

For the solution size parameter ℓ, one can obtain the following running time.

▶ **Proposition 2.2** ($\star$). *Connectivity NWS and Stars NWS can be solved in $\ell^{\mathcal{O}(\ell)} \cdot \operatorname{poly}(n+c)$ time.*

The fixed-parameter tractability of Unweighted Connectivity NWS with respect to ℓ was also shown by Fluschnik and Kellerhals via a kernelization [17].

A further natural parameter that can be considered is $k := m - \ell$, a lower-bound on the number of edges of G that any solution must omit.

▶ **Proposition 2.3** ($\star$).

- *Connectivity NWS and Stars NWS are NP-hard for $k = 0$.*
- *Unweighted Connectivity NWS and Unweighted Stars NWS can be solved in $n^{2k} \cdot \operatorname{poly}(n)$ time and are $\mathrm{W}[1]$-hard with respect to k even if G is a clique and if each community has size at most 3.*

For Unweighted Connectivity NWS, Fluschnik and Kellerhals showed that a polynomial kernel for ℓ and (thus for n) is unlikely, even on planar series-parallel graphs [17]. This result can be also given for the case when the input graph G is a clique.

▶ **Proposition 2.4** ($\star$). *Unweighted Connectivity NWS and Unweighted Stars NWS do not admit a polynomial kernel for n even if G is a clique, unless NP $\subseteq$ coNP/poly.*

One can also show that the simple brute-force algorithm that considers all $\mathcal{O}(2^m)$ subsets of $E(G)$ cannot be improved substantially.

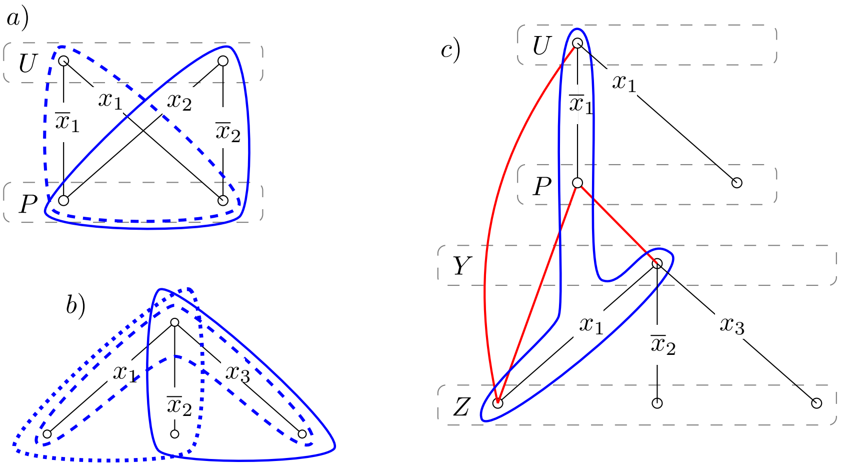

Figure 2 Sketch of the construction of Theorem 3.1. The communities are blue (solid, dashed and dotted). We only show edges which are contained in at least one community and only some fixed edges (red). *a)* Part of the variable gadget for x_1 and x_2. *b)* The variable communities for a clause $q = x_1 \vee \overline{x_2} \vee x_3$. *c)* The assignment gadget for the first literal x_1 of the clause q. Here, the red edges are the fixed edges with one endpoint in the variable gadget and one in the clause gadget.

▶ **Proposition 2.5** ($\star$). *If the ETH is true, then* Unweighted Stars NWS *and* Unweighted Connectivity NWS *cannot be solved in* $2^{o(n+m+c)} \cdot \mathrm{poly}(n+c)$ *time, even if restricted to instances with community size at most* 3.

3 A Stronger ETH-Bound

In Proposition 2.5 we observed that algorithms with running time $2^{o(n+m+c)}$ for Unweighted Connectivity NWS and Unweighted Stars NWS would violate the ETH. We now provide a stronger $2^{\Omega(n^2+c)}$-time lower bound for both problems. Notably, this lower bound also applies to the case when all communities have constant size.

First, we present the lower bound for Unweighted Stars NWS.

▶ **Theorem 3.1.** *If the ETH is true, then* Unweighted Stars NWS *cannot be solved in* $2^{o(n^2+c)}$ *time, even if* G *is a clique and if each community has size at most* 4.

Proof. We reduce from 3-SAT to Unweighted Stars NWS such that the resulting instance has $\mathcal{O}(\sqrt{|\phi|})$ vertices and $\mathcal{O}(|\phi|)$ communities, where ϕ denotes the total formula length. Then, the existence of an $2^{o(n^2+c)}$-time algorithm for Unweighted Stars NWS implies the existence of a $2^{o(|\phi|)}$-time algorithm for 3-SAT violating the ETH [25, 26]. The input formula ϕ is over the variable set X and each clause $q \in \Gamma$ contains exactly three literals. For a literal y, we denote by $\overline{y}$ its complement. A visualization of the construction is given in Figure 2. In all gadgets, we add several communities of size 2. These communities enforce that each solution has to contain the edge of this community. In the following we call such edges *fixed*.

Variable gadget G_X. Recall that G_X is a clique. The idea is to create for each variable a community C of size 3 with one *fixed* edge. The two remaining edges of C are called *selection* edges. The idea is that each solution contains exactly one selection edge of C. One selection edge represents the positive literal, the other one represents the negative literal. The fixed edge of the triangle is used to model that one literal must be set to `true`. The selection edges are arranged compactly, to guarantee that $|V(G_X)| \in \mathcal{O}(\sqrt{|\phi|})$. In the following, we describe the graph G_X together with communities fulfilling the above-described properties. An example of a variable gadget is shown in part $a)$ of Figure 2.

Let $V(G_X) = U \cup P$ where $U \coloneqq \{u_1, \dots, u_{n_x}\}$, $P = P_1 \cup P_2$, and $P_i \coloneqq \{p^i_1, \dots, p^i_{n_x}\}$ for $i \in [2]$ consist of $n_x = \lceil \sqrt{|X|} \rceil$ vertices each. It remains to describe the communities: For each variable $x \in X$, we add a community $C_x \coloneqq \{u_j, p^1_s, p^2_s\}$ for $j, s \in [\, n_x \,]$. This is possible since $n_x \cdot n_x \geq |X|$. These communities are called the *variable communities* $\mathcal{C}^X$. Afterwards, we set $\theta(x) \coloneqq \{u_j, p^1_s\}$ and $\theta(\overline{x}) \coloneqq \{u_j, p^2_s\}$ to assign the positive and negative literal of x to an edge of the variable gadget. Now, we fix the edges of $G[P] = G[P_1 \cup P_2]$. In other words, for each edge $\{p^{i_1}_{j_1}, p^{i_2}_{j_2}\}$ having both endpoints in $P_1 \cup P_2$, we add a community $\{p^{i_1}_{j_1}, p^{i_2}_{j_2}\}$.

Observe that the sets of selection edges corresponding to two distinct variables are disjoint:

▷ Claim 1 ($\star$). Each selection edge of $E(G_X)$ is contained in only one subgraph induced by a variable community in $\mathcal{C}^X$.

Clause gadget. We continue by describing the construction of the clause gadget G_Γ. The idea is that each clause is represented by four vertices of $V(G_\Gamma)$ in which a triangle is *fixed*. All three remaining edges of this size-4 clique are referred to as *free*. Note that these free edges form a star with three leaves. Each free edge represents one literal of the clause. For each pair containing two of these three edges, we then create a community containing the three endpoints of these two edges. As in the vertex gadget, these induced subgraphs are arranged compactly, to achieve a clause gadget with $|V(G_\Gamma)| \in \mathcal{O}(\sqrt{|\Gamma|})$.

Let $V(G_\Gamma) = Y \cup Z$ where $Y = \{y_1, \dots, y_{n_c}\}$, $Z = Z_1 \cup Z_2 \cup Z_3$, and $Z_i = \{z^1_1, \dots, z^i_{n_c}\}$ for $i \in [3]$ consist of $n_c = \lceil \sqrt{|\Gamma|} \rceil$ vertices each. In the following, we assign each clause to a clique of G_Γ having vertex set y_j, z^1_s, z^2_s, z^3_s for $j, s \in [n_c]$. This is possible since $n_c \cdot n_c \geq |\Gamma|$. In this clique, we *fix* the triangle having its endpoints in $Z_1 \cup Z_2 \cup Z_3$. Formally, for each clause $q = \{q_1, q_2, q_3\} \in \Gamma$ we add three communities $C^1_q = \{y_j, z^2_s, z^3_s\}$, $C^2_q = \{y_j, z^1_s, z^3_s\}$ and $C^3_q = \{y_j, z^1_s, z^2_s\}$. We refer to these communities as the *clause* communities $\mathcal{C}^\Gamma$. Afterwards, we set $\nu(q, q_1) \coloneqq \{y_j, z^1_s\}$, $\nu(q, q_2) \coloneqq \{y_j, z^2_s\}$, and $\nu(q, q_3) \coloneqq \{y_j, z^3_s\}$ to assign each literal in clause q to an edge of the clause gadget. These edges are referred to as *free*. Second, we fix the edges of the clique $Z_1 \cup Z_2 \cup Z_3$.

Observe that the sets of free edges corresponding to two distinct clauses are disjoint:

▷ Claim 2 ($\star$). Each free edge of $E(G_\Gamma)$ is contained in exactly one subgraph induced by a clause community in $\mathcal{C}^\Gamma$.

Connecting the gadgets. We complete the construction by connecting the variable and clause gadget, using new *assignment* communities. The idea is to add a new community containing the endpoints of a free edge describing a literal in a clause together with the endpoints of the selection edge describing the same opposite literal in the variable gadget. These communities model occurrences of variables in the clauses. Roughly speaking, these communities are satisfied if the selection edge of the variable gadget or the free edge of the clause gadget is part of the solution. To enforce this, we fix further edges of G.

We create for each clause $q = \{q_1, q_2, q_3\} \in \Gamma$ three assignment communities $C^{q_1}_q = \nu(q, q_1) \cup \theta(\overline{q_1})$, $C^{q_2}_q = \nu(q, q_2) \cup \theta(\overline{q_2})$, and $C^{q_3}_q = \nu(q, q_3) \cup \theta(\overline{q_3})$. We denote the assignment communities with $\mathcal{C}^X_\Gamma$. To enforce that each solution contains the selection edge or the free edge of each assignment community, we fix all edges between the vertex sets U and Z, between the vertex sets P and Y, and between the vertex sets P and Z.

Finally, we set $\ell \coloneqq |X| + 2 \cdot |\Gamma| + \binom{|P|}{2} + \binom{|Z|}{2} + |U| \cdot |Z| + |P| \cdot |Y| + |P| \cdot |Z|$.

Correctness. The correctness is based on the facts that each solution for I contains *a*) all fixed edges, *b*) exactly $|X|$ selection edges, and *c*) exactly $2|\Gamma|$ free edges. Fact *b*) ensures that this models an assignment β of the variables of X and fact *c*) ensures that each clause is satisfied by at least one literal of β. The detailed correctness proof is deferred to the full version. ◀

An adapted construction yields further results for d-DIAM NWS [17] (Π is "having diameter at most d") and DENSITY NWS [19] (Π is "exceeding some density threshold").

▶ **Corollary 3.2** ($\star$). *If the ETH is true, then UNWEIGHTED CONNECTIVITY NWS, d-DIAM NWS for each $d \geq 2$, and DENSITY NWS cannot be solved in $2^{o(n^2+c)}$ time even if G is a clique and each community has size at most* 4.

▶ **Corollary 3.3** ($\star$). *UNWEIGHTED STARS NWS remains NP-hard and, assuming the ETH, cannot be solved in $2^{o(n+m+c)}$ time on graphs with maximum degree six and community size at most* 4.

4 Parameterization by the Feedback Edge Number of a Solution

The parameter ℓ, the number of edges in the solution is in most cases not independent from the size of the input instance of STARS NWS or CONNECTIVITY NWS: if the hypergraph $(V, \mathcal{C})$ is connected, a solution G' has at least $n-1$ edges. In other words, $n-1$ is a lower bound for ℓ in this case. In this section, we study STARS NWS and CONNECTIVITY NWS parameterized above this lower bound. Formally, the parameter t is defined as the size of a minimum feedback edge set of any optimal solution of an instance of STARS NWS or CONNECTIVITY NWS. Thus, the parameter t measures how close the solution is to a forest. Formally, the definition is $t := \ell - n + x$ where x denotes the number of connected components of G'. Recall that t can be computed in polynomial time (see Section 2.).

4.1 An XP-Algorithm for Stars NWS

In this subsection, we show that STARS NWS parameterized by t admits an XP-algorithm.

▶ **Theorem 4.1.** *STARS NWS can be solved in $m^{4t} \cdot \mathrm{poly}(|I|)$ time.*

Our XP-algorithm exploits the fact that there are two different kinds of cycles in G': First, there are *global* cycles. These are the cycles in the solutions that are directly caused by cycles in the input hypergraph. No solution may avoid these cycles. Second, there are *local* cycles. These are cycles which are entirely contained in the subgraph induced by two communities. Since in each solution, each community contains a spanning star, local cycles can only have length 3 or 4. This allows us to bound the number of possible local cycles and thus to consider all possibilities for the local cycles in XP-time with respect to t. Then, the crux of our algorithm is that after all local cycles have been fixed, all remaining cycles added by our algorithm have to be global and are thus unavoidable. Using this fact, we show that in polynomial time we can compute an optimal solution with feedback edge number at most t that extends a fixed set of local cycles without introducing any further local cycles. To do this, for each community C, we store a set of *potential centers*, that is, vertices of C that may be the center of a spanning star of C in any solution that does not produce new local cycles. We define several *operations* that restrict the potential centers of each community. We show that after all operations have been applied exhaustively, one can greedily pick the best remaining center for each community.

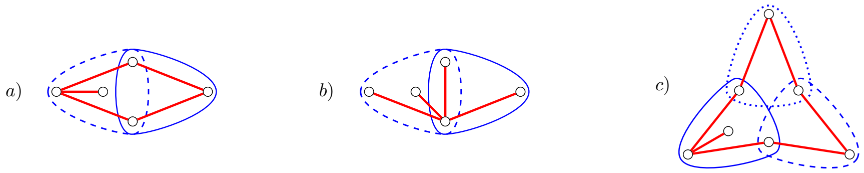

Figure 3 Examples for solutions with and without local cycles. Red edges indicate the edges of the solution. Part a) shows an example, where both communities induce a local cycle. Part b) shows an example, where the two communities do not induce local cycle. Finally, part c) shows an example, where the solution contains a (global) cycle but no two communities induce a local cycle.

Algorithm-specific notation. Next, we present the formal definition of local cycles; an example is shown in Figure 3. For a spanning subgraph H of G and a community $C \in \mathcal{C}$, let $\text{univ}_H(C)$ denote the vertices of C that are *universal* for C in H. Note that $\text{univ}_H(C) \subseteq \text{univ}_G(C)$. In the following, we assume that for each community $C \in \mathcal{C}$, $\text{univ}_G(C) \neq \emptyset$, as otherwise, there is no solution for the instance I of Stars NWS.

For a solution G', we say that two distinct communities C_1 and C_2 *induce a local cycle* if for each $i \in \{1,2\}$, there is a vertex $c_i \in \text{univ}_{G'}(C_i)$ such that the graph $S_1 \cup S_2$ contains a cycle. Here, for each $i \in \{1,2\}$, S_i is the spanning star of C_i with center c_i and $S_1 \cup S_2$ is the union of both these stars defined by $S_1 \cup S_2 := (C_1 \cup C_2, \{\{c_i, w_i\} \colon w_i \in C_i \setminus \{c_i\}, i \in \{1,2\}\})$. Moreover, we say that each cycle of $S_1 \cup S_2$ is a *local cycle* in G'. Note that each local cycle has length at most four, and if C_1 and C_2 induce a local cycle, then $|C_1 \cap C_2| \geq 2$.

As described above, the first step of the algorithm behind Theorem 4.1 is to test each possibility for the local cycles of the solution. For a fixed guess, we let E^* denote the set of all edges contained in at least one local cycle and in the following we refer to them as *local edges*. Moreover, we call a minimum solution G' *fitting for* E^* if each local cycle of G' uses only edges of E^* and each edge of E^* is contained in G'. Hence, to determine whether the choice of local edges E^* can lead to a solution, we only have to check, whether there is a fitting solution for E^*. In the following, we show that this can be done in polynomial time.

▶ **Theorem 4.2.** *Let $I = (G = (V,E), \mathcal{C}, \omega, \ell, b)$ be an instance of* Stars *NWS, and let $E^* \subseteq E$. In polynomial time, we can*

- *find a solution $G' = (V, E')$ for I with $E^* \subseteq E'$ or*
- *correctly output that there is no minimum solution that is fitting for E^*.*

Based on the definition of fitting solutions, we define for each community $C \in \mathcal{C}$ a set $\text{fit}_{E^*}(C)$ of possible centers. We initialize $\text{fit}_{E^*}(C) := \text{univ}_G(C)$ for each community $C \in \mathcal{C}$. The goal is to reduce $\text{fit}_{E^*}(C)$ of each community C as much as possible while preserving the following property, which trivially holds for the initial $\text{fit}_{E^*}(C)$ for each community $C \in \mathcal{C}$.

▶ **Property 1.** *For each minimum solution G' which is fitting for E^* and each community $C \in \mathcal{C}$, we have $\text{univ}_{G'}(C) \subseteq \text{fit}_{E^*}(C)$.*

Note that if Property 1 is fulfilled and if $\text{fit}_{E^*}(C) = \emptyset$ for some $C \in \mathcal{C}$, then we can correctly output that there is no fitting solution for E^*. Next, we define several operations that for some communities $C \in \mathcal{C}$ remove vertices from $\text{fit}_{E^*}(C)$ which – when taken as a center vertex for C – would introduce new local cycles, violating the properties of a fitting solution. We show that these operations preserve Property 1 and that after these operations are applied exhaustively, the task of Theorem 4.2 can be performed greedily based on fit_{E^*}. Examples for each of our operations are shown in Figure 5.

In the following, we say that a vertex $v \in V$ is *locally universal* for a vertex set $A \subseteq V$, if for each vertex $w \in A \setminus \{v\}$, the vertex pair $\{v, w\}$ is a local edge.

▶ **Operation 1.** *Let $C \in \mathcal{C}$ be a community and let $\{y, z\} \subseteq C$ be a local edge. Remove each vertex v from $\operatorname{fit}_{E^*}(C)$ which is not locally universal for $\{y, z\}$.*

The following lemma shows that Operation 1 preserves Property 1.

▶ **Lemma 4.3** (⋆). *Let G' be a minimum solution for I, let C be a community of $\mathcal{C}$ and let $x \in \operatorname{univ}_{G'}(C)$ such that x is not locally universal for some local edge $\{y, z\} \subseteq C$. Then, G' is not fitting for E^*.*

Note that after the exhaustive application of Operation 1, for each community $C \in \mathcal{C}$ with at least one local edge, the vertices of $\operatorname{fit}_{E^*}(C)$ induce a clique with only local edges.

Next, we define a partition $\mathfrak{C}$ of the communities of $\mathcal{C}$. The idea of this partition is that in each fitting solution for E^*, all communities of the same part of the partition $\mathfrak{C}$ have the same unique center. The definition of the partition $\mathfrak{C}$ is based on the following lemma.

▶ **Lemma 4.4** (⋆). *Let C and D be distinct communities of $\mathcal{C}$ with $|C \cap D| \geq 3$ and where no vertex $v \in C \cup D$ is locally universal for $C \cap D$. Let G' be a solution such that there is no vertex $w \in C \cap D$ with $\operatorname{univ}_{G'}(C) = \operatorname{univ}_{G'}(D) = \{w\}$. Then, C and D induce a local cycle in G' that uses at least one edge which is not a local edge.*

Consider the auxiliary graph $G_{\mathfrak{C}}$ with vertex set $\mathcal{C}$ and where two distinct communities C and D are adjacent if and only if *a*) $|C \cap D| \geq 3$ and *b*) there is no locally universal vertex for $C \cap D$ in $C \cup D$. The partition $\mathfrak{C}$ consists of the connected components of $G_{\mathfrak{C}}$ and for a community $C \in \mathcal{C}$, we denote by $\mathfrak{C}(C)$ the collection of communities in the connected component of C in $G_{\mathfrak{C}}$. An example is shown in Figure 4.

By Lemma 4.4 and due to transitivity, we obtain the following.

▶ **Corollary 4.5.** *For each community $C \in \mathcal{C}$ with $|\mathfrak{C}(C)| \geq 2$ and each fitting solution G' for E^*, there is a vertex $v \in \bigcap_{\widetilde{C} \in \mathfrak{C}(C)} \widetilde{C}$ such that $\operatorname{univ}_{G'}(\widetilde{C}) = \{v\}$ for each $\widetilde{C} \in \mathfrak{C}(C)$.*

This implies that the following operation preserves Property 1.

▶ **Operation 2.** *Let $C \in \mathcal{C}$. Remove each vertex v from $\operatorname{fit}_{E^*}(C)$ if v is not contained in $\bigcap_{\widehat{C} \in \mathfrak{C}(C)} \operatorname{fit}_{E^*}(\widehat{C})$.*

Next, we define an operation for each possibility how two communities may intersect.

▶ **Operation 3.** *Let $C \in \mathcal{C}$ such that C contains no local edge. Moreover, let $D \in \mathcal{C}$ such that $|C \cap D| \geq 2$. Remove all vertices from $\operatorname{fit}_{E^*}(C)$ that are not contained in $C \cap D$.*

▶ **Operation 4.** *Let $C \in \mathcal{C}$ such that C contains at least one local edge. Moreover, let $D \notin \mathfrak{C}(C)$ be a community, such that $|C \cap D| = 2$ and $\{x, y\} \coloneqq C \cap D$ is not a local edge.*

1. *If $\operatorname{fit}_{E^*}(C) \cap \{x, y\} = \emptyset$, then remove x and y from $\operatorname{fit}_{E^*}(D)$ or*
2. *if $\operatorname{fit}_{E^*}(C) \cap \{x, y\} = \{x\}$, then set $\operatorname{fit}_{E^*}(C) \coloneqq \{x\}$.*

▶ **Operation 5.** *Let $C \in \mathcal{C}$ be a community containing at least one local edge. Moreover, let $D \notin \mathfrak{C}(C)$ such that $|C \cap D| \geq 3$. For each pair of distinct vertices x and y of $C \cap D$, where $\{x, y\}$ is not a local edge, remove x and y from $\operatorname{fit}_{E^*}(D)$.*

▶ **Lemma 4.6** (⋆). *Operation 3 preserves Property 1. Moreover, if Operation 1 is exhaustively applied, then Operation 4 and Operation 5 preserve Property 1.*

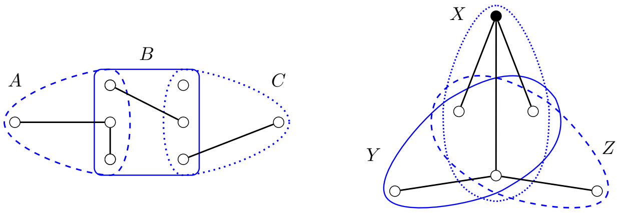

Figure 4 Examples for parts of the partition $\mathfrak{C}$. Only the local edges are shown. Note that $A, C \in \mathfrak{C}(B)$, since A and C share at least three vertices with B and no vertex of $A \cup B$ or $C \cup B$ is locally universal for $A \cap B$ or $C \cap B$, respectively. Hence, after exhaustive application of Operation 2, $\text{fit}_{E^*}(A) = \text{fit}_{E^*}(B) = \text{fit}_{E^*}(C) = \emptyset$, since A and C share no vertices. Furthermore, $Y \in \mathfrak{C}(Z)$, since no vertex of $Y \cup Z$ is locally universal for $Y \cap Z$. Note that $X \notin \mathfrak{C}(Z)$, since the black vertex of X is locally universal for $X \cap Y$ and $X \cap Z$. Observe that an exhaustive application of Operation 2 yields $\text{fit}_{E^*}(Z) \subseteq Y \cap Z$ and an exhaustive application of Operation 5 yields $\text{fit}_{E^*}(Z) \cap (X \cap Z) = \text{fit}_{E^*}(Z) \cap (Y \cap Z) = \emptyset$, since X contains at least one local edge and $X \cap Z$ contains no local edge. Hence, for both shown hypergraphs, there is no fitting solution for the given set of local edges.

Algorithm 1 Algorithm solving the problem described in Theorem 4.2.

```
Input  : $I = (G = (V, E), \mathcal{C}, \omega, \ell, b), E^* \subseteq E$
Output : A solution $G' = (V, E')$ with at most $\ell$ edges and total weight at most $b$, or
         no, if there is no minimal solution which is fitting for $E^*$
Compute the partition $\mathfrak{C}$ of $\mathcal{C}$
For each $C \in \mathcal{C}$, initialize $\text{fit}_{E^*}(C) \leftarrow \text{univ}_G(C)$ and apply Operation 1
Apply Operations 1–5 exhaustively
if $\text{fit}_{E^*}(C) = \emptyset$ for some $C \in \mathcal{C}$ then return no
$G_A \leftarrow (V, E^*)$
forall $\mathcal{L} \in \mathfrak{C}$ do
    $C \leftarrow$ some community of $\mathcal{L}$
    $V_{\mathcal{L}} \leftarrow \bigcup_{\widetilde{C} \in \mathcal{L}} \widetilde{C}$
    $y \leftarrow \arg\min_{u \in \text{fit}_{E^*}(C)} \omega(\{\{u, v\} : v \in V_{\mathcal{L}} \setminus \{u\}\} \setminus E^*)$
    add all edges of $\{\{y, v\} : v \in V_{\mathcal{L}} \setminus \{y\}\}$ to $G_A$
if $|E(G_A)| \leq \ell$ and $\omega(E(G_A)) \leq b$ then return $G_A$
return no
```

Based on these operations, we are now able to present the algorithm (see Algorithm 1) behind Theorem 4.2 working as follows: First, we apply Operations 1–5 exhaustively. Next, if there is a community $C \in \mathcal{C}$ with $\text{fit}_{E^*}(C) = \emptyset$, then we return no. This is correct, since Operations 1–5 preserve Property 1. Afterwards, we start with an auxiliary graph G_A with vertex set V and edge set E^* and we iterate over the partition $\mathfrak{C}$. Recall that since Operation 2 is exhaustively applied, for each $\mathcal{L} \in \mathfrak{C}$, $\text{fit}_{E^*}(C) = \text{fit}_{E^*}(D)$ for any two communities C and D of $\mathcal{L}$. For each $\mathcal{L} \in \mathfrak{C}$, we find a vertex $y \in \text{fit}_{E^*}(C)$ that minimizes the total weight of non-local edges required to make y the center of all communities of $\mathcal{L}$, where C is an arbitrary community of $\mathcal{L}$. Finally, we add all edges between y and each vertex of any community of $\mathcal{L}$ to G_A. After the iteration over the partition $\mathfrak{C}$ is completed, we output G_A if it contains at most ℓ edges and has total weight at most b. Otherwise, we return that there is no fitting solution for E^*. It remains to show that this greedy choice for the center vertices is correct.

▶ **Lemma 4.7.** *Algorithm 1 is correct.*

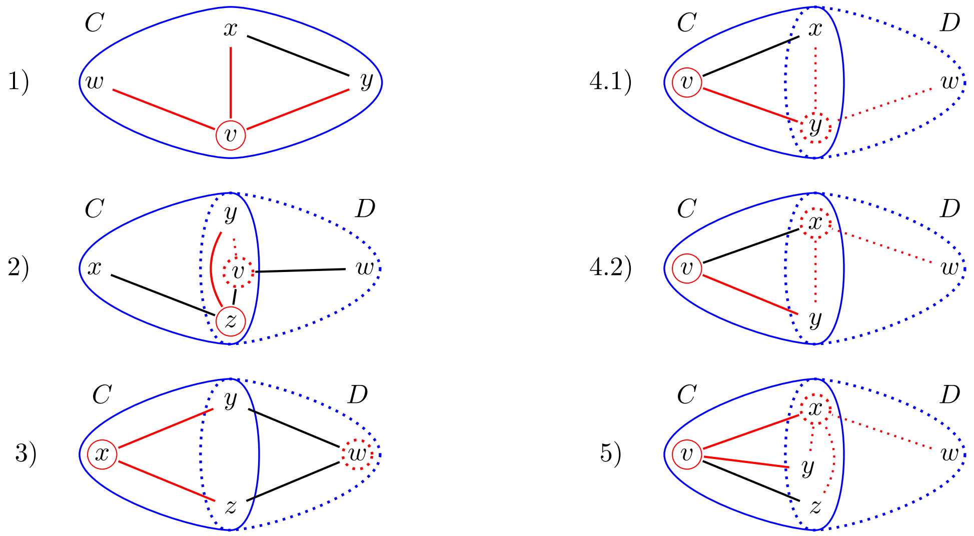

Figure 5 Examples of applications of Operations 1–5. The black edges represent the local edges, the solid (for C) or dashed (for D) red edges show the non-local edges resulting from choosing the respective center for community C or D. For example in 2), z is the center of community C and v is the center of community D, and the edges $\{z, y\}$ and $\{v, y\}$ are non-local edges in the solution. For each operation, the violation of the property of being a fitting solution is shown, if a vertex a is selected as a center of a community A where the application of the corresponding operation would remove a from $\mathrm{fit}_{E^*}(A)$. In 1), 2), 3), and 4.2), the vertex selected as center for community C is removed from $\mathrm{fit}_{E^*}(C)$ by the respective operation. For example, in 4.2), (assuming $\mathrm{fit}_{E^*}(C) \cap \{x, y\} = \{x\}$) Operation 4 removes v from $\mathrm{fit}_{E^*}(C)$, as otherwise selecting v as center of C results in the depicted non-fitting solution. In 4.1) and 5), the vertex selected as center for community D is removed from $\mathrm{fit}_{E^*}(D)$ by the respective operation. For example in 4.1), (assuming $\mathrm{fit}_{E^*}(C) \cap \{x, y\} = \emptyset$) Operation 4 removes y from $\mathrm{fit}_{E^*}(D)$, as otherwise selecting y as center of D results in the depicted non-fitting solution.

Proof. If Algorithm 1 outputs "no" in Line 4, then this is correct, since fit_{E^*} fulfills Property 1. Otherwise, let G_A denote the graph constructed by Algorithm 1 and let for each community $C \in \mathcal{C}$, $\mathrm{center}(C)$ denote the vertex y chosen to be the center of all communities of $\mathfrak{C}(C)$ in Line 9. By construction, G_A is a solution since for each community $C \in \mathcal{C}$, $\mathrm{center}(C)$ is a vertex of $\mathrm{fit}_{E^*}(C) \subseteq \mathrm{univ}_G(C)$. If G_A contains at most ℓ edges and has total weight at most b, then the algorithm correctly outputs the solution G_A which is fitting for E^*.

Thus, in the following we assume that G_A contains more than ℓ edges or has weight more than b. Assume towards a contradiction that there is a fitting solution G_F for E^* such that $\mathrm{Agree}(G_F) := \{C \in \mathcal{C} : \mathrm{center}(C) \in \mathrm{univ}_{G_F}(C)\}$ is as large as possible.

Case 1. $\mathrm{Agree}(G_F) = \mathcal{C}$**.** By construction, G_A contains all edges of E^* and only the required edges to achieve that for each community $C \in \mathcal{C}$, $\mathrm{center}(C) \in \mathrm{univ}_{G_A}(C)$. Consequently, G_A is a subgraph of G_F and thus G_F contains more than ℓ edges or has weight more than b, a contradiction.

Case 2. There is a community $C \in \mathcal{C} \setminus \mathrm{Agree}(G_F)$**.** In the following, we define a fitting solution G'_F for E^* with $\mathrm{Agree}(G'_F) \supsetneq \mathrm{Agree}(G_F)$. By definition, $\mathrm{center}(C) = \mathrm{center}(\widetilde{C})$ for each community $\widetilde{C} \in \mathfrak{C}(C)$. Let $V_C := \bigcup_{\widetilde{C} \in \mathfrak{C}(C)} \widetilde{C}$ and let $y := \mathrm{center}(C)$. Moreover, let x be an arbitrary vertex of V_C such that $x \in \mathrm{univ}_{G_F}(\widetilde{C})$ for each community $\widetilde{C} \in \mathfrak{C}(C)$. Due to Corollary 4.5 and since G_F is fitting for E^*, this vertex exists and is unique if $|\mathfrak{C}(C)| \geq 2$. Note that $C \in \mathcal{C} \setminus \mathrm{Agree}(G_F)$ implies that $x \neq y$. This also implies that C has size at least 3, and thus, each community of $\mathfrak{C}(C)$ has size at least 3. We obtain G'_F as follows: First, initialize G'_F as G_F. Second, for each community $\widetilde{C} \in \mathfrak{C}(C)$, remove all edges that are not local edges of $G_F[\widetilde{C}]$ from G'_F. Finally, for each community $\widetilde{C} \in \mathfrak{C}(C)$, add the minimum number of edges to G'_F such that $y \in \mathrm{univ}_{G'_F}(\widetilde{C})$, that is, the edges $\{\{y,v\} : v \in V_{\widetilde{C}} \setminus \{y\}\} \setminus E^*$.

First, we show that G'_F contains at most as many edges as G_F. To this end, we first observe the following.

▷ Claim 3 (⋆). For each $z \in V_C \setminus \{x, y\}$, the edge $\{x, z\}$ is a local edge if and only if $\{y, z\}$ is a local edge.

Recall that each edge which is in G'_F and not in G_F is incident with y and some vertex of $V_C \setminus \{x, y\}$. Hence, for each $z \in V_C \setminus \{x, y\}$ where the edge $\{y, z\}$ was added to obtain G'_F, the edge $\{x, z\}$ was removed to obtain G'_F. Thus, G'_F contains at most as many edges as G_F. This implies that the difference between the total weight of G'_F and the total weight of G_F is at most $\rho = \omega(\{\{y, z\} : z \in V_C \setminus \{y\}\} \setminus E^*) - \omega(\{\{x, z\} : z \in V_C \setminus \{x\}\} \setminus E^*)$. Due to Line 9, ρ is not positive. Thus, since G_F has total weight at most b, G'_F has total weight at most b.

To show that G'_F is a solution, it remains to show that each community $C \in \mathcal{C}$ has at least one center in G'_F. For this, it suffices to show that all communities outside of $\mathfrak{C}(C)$ have the same centers in G_F and G'_F, since y is a center of all communities of $\mathfrak{C}(C)$.

▷ Claim 4. For each community $D \in \mathcal{C} \setminus \mathfrak{C}(C)$, $\mathrm{univ}_{G_F}(D) = \mathrm{univ}_{G'_F}(D)$.

Proof. Due to symmetry, we only show that $\mathrm{univ}_{G_F}(D) \subseteq \mathrm{univ}_{G'_F}(D)$. Assume towards a contradiction that there is a vertex $z \in \mathrm{univ}_{G_F}(D) \setminus \mathrm{univ}_{G'_F}(D)$. Since $z \notin \mathrm{univ}_{G'_F}(D)$, there is an edge $\{z, w\}$ which is contained in G_F but not in G'_F. Moreover, $\{z, w\}$ is not a local edge, since G'_F contains all local edges. This further implies that there is a community $\widetilde{C} \in \mathfrak{C}(C)$ such that $\{z, w\} \subseteq \widetilde{C}$. Since G_F is fitting for E^*, x is one endpoint of $\{z, w\}$, as otherwise, $\widetilde{C}$ and D induce a local cycle in G_F on the vertices $\{x, z, w\}$ and the edge $\{z, w\}$ is not a local edge. Next, we distinguish the cases whether $\widetilde{C}$ contains a local edge.

Case 1. There is no local edge in $\widetilde{C}$**.** Since Operation 3 is exhaustively applied, $\{x, y\} \subseteq \mathrm{fit}_{E^*}(\widetilde{C}) \subseteq \widetilde{C} \cap D$. Hence, if $|\widetilde{C} \cap D| = 2$, then $x = z$ and $y = w$, or vice versa. Consequently, the edge $\{z, w\}$ is contained in G'_F, a contradiction. Otherwise, assume $|\widetilde{C} \cap D| \geq 3$. We show that in this case, there is no fitting solution for E^*. Since D is not in $\mathfrak{C}(C)$, there is some vertex of $\widetilde{C} \cup D$ which is locally universal for $\widetilde{C} \cap D$. Hence, $\mathrm{fit}_{E^*}(\widetilde{C}) \subseteq \widetilde{C} \cap D$, since $\widetilde{C}$ contains no local edge and Operation 3 is exhaustively applied. Moreover, since Operation 5 is exhaustively applied and there is no local edge between any two vertices of $\widetilde{C} \cap D$, $\mathrm{fit}_{E^*}(\widetilde{C}) \cap (\widetilde{C} \cap D) = \emptyset$. We conclude that $\mathrm{fit}_{E^*}(\widetilde{C}) = \emptyset$, which implies that there is no fitting solution for E^*, a contradiction to the fact that G_F is a fitting solution for E^*.

Case 2. There is some local edge in $\widetilde{C}$**.** Recall that Operation 4 and Operation 5 are applied exhaustively with respect to $\widetilde{C}$. If $x = z$ and $y = w$, or vice versa, then the edge $\{z, w\}$ is contained in G'_F, a contradiction. Otherwise, let w^* be the unique vertex of $\{z, w\} \setminus \{x\}$. Since $\{x, w^*\} = \{z, w\}$ is not a local edge, $x \in \mathrm{fit}_{E^*}(\widetilde{C})$, and Operation 1 is exhaustively applied, no vertex of $\mathrm{fit}_{E^*}(\widetilde{C})$ is locally universal for w^* and $w^* \notin \mathrm{fit}_{E^*}(\widetilde{C})$. Hence, if $|\widetilde{C} \cap D| = 2$, then since Operation 4 is exhaustively applied, $\mathrm{fit}_{E^*}(\widetilde{C})$ has size at most one, a contradiction. Otherwise, if $|\widetilde{C} \cap D| \geq 3$, then since Operation 5 is exhaustively applied $x \notin \mathrm{fit}_{E^*}(D)$ and $w^* \notin \mathrm{fit}_{E^*}(D)$. Consequently, $z \notin \mathrm{fit}_{E^*}(D)$, a contradiction. ◁

Since G_F is a solution, for each community $D \in \mathcal{C} \setminus \mathfrak{C}(C)$, Claim 4 implies that $\text{univ}_{G'_F}(D) = \text{univ}_{G_F}(D)$ is nonempty. Hence, G'_F is a solution. Moreover, since G_F is a minimum solution, Claim 3 implies that G'_F is a minimum solution.

Next, we show that G'_F is fitting for E^*. To show that G'_F is a fitting solution for E^*, it remains to show that each local cycle of G'_F uses only edges of E^*.

▷ Claim 5 (⋆). Each local cycle of G'_F uses only edges of E^*.

Finally, we show that $\text{Agree}(G'_F)$ is a proper superset of $\text{Agree}(G_F)$. By construction, $\mathfrak{C}(C) \subseteq \text{Agree}(G'_F)$, and due to Claim 4, for each community $D \in \mathcal{C} \setminus \mathfrak{C}(C)$, $\text{univ}_{G'_F}(D) = \text{univ}_{G_F}(D)$. Hence, $\text{Agree}(G_F) \subseteq \text{Agree}(G'_F)$. Moreover, since $C \notin \text{Agree}(G'_F) \setminus \text{Agree}(G_F)$ we obtain that $\text{Agree}(G'_F)$ is a proper superset of $\text{Agree}(G_F)$. Altogether, G'_F is a fitting solution for E^* with $\text{Agree}(G'_F) \supsetneq \text{Agree}(G_F)$. This contradicts our choice of G_F.

Hence, if G_A contains more than ℓ edges or has weight more than b, then the algorithm correctly outputs that there is no solution which is fitting for E^*. ◀

Proof of Theorem 4.2. Clearly, the partition $\mathfrak{C}$ of $\mathcal{C}$ and also the initialization of fit_{E^*} in Lines 1 and 2 can be computed in polynomial time. Note that Operations 1–5 can be exhaustively applied in polynomial time by iterating over all local edges and all pairs of communities, since for each community $C \in \mathcal{C}$, $\text{fit}_{E^*}(C)$ initially has size at most $|C| < n$ and each application of any operation may only remove elements from $\text{fit}_{E^*}(C)$. Hence, Lines 3–5 can be performed in polynomial time. Afterwards, Lines 6–10 can be performed in polynomial time since for each partite set of $\mathfrak{C}$ we compute the vertex y with minimal cost such that y serves as the center of all communities in this partite set. Finally, the check whether the solution has at most ℓ edges and weight at most b can be done in polynomial time. Thus, Algorithm 1 runs in polynomial time. ◀

Finding the correct edge set E^*. To solve Stars NWS, the main algorithmic difficulty now lies in finding an edge set E^* that contains all edges of local cycles of any optimal solution of I. Hence, to prove Theorem 4.1, it remains to show that such an edge set can be found in $m^{4t} \cdot \text{poly}(n + c)$ time, if it exists.

▶ **Lemma 4.8** (⋆). *If I is a yes-instance of Stars NWS, then for every optimal solution $G' = (V, E')$, there is an edge set $E^* \subseteq E'$ of size at most $4t$ such that the edge set of each local cycle of G' is a subset of E^*.*

Proof of Theorem 4.1. The algorithm works as follows: iterate over all possible edge sets E^* of size at most $4t$ and apply the algorithm behind Theorem 4.2. If I is a yes-instance, then for some edge set E^*, Theorem 4.2 yields an optimal solution for I with at most ℓ edges and weight at most b. Since there are $\mathcal{O}(m^{4t})$ edges sets of size at most $4t$, the algorithm achieves the stated running time. ◀

The concrete algorithm for $t = 0$. Recall that Theorem 4.1 affirmatively answers the question by Korach and Stern [30] who asked whether there is a polynomial-time algorithm for finding an optimal solution for Stars NWS with $t = 0$. For this case, the concrete algorithm is much simpler since most of the described operations are never applicable. This is due to the fact that for $t = 0$, no local edges exist and Operations 1, 4, and 5 require at least one local edge to be applicable. In the following, we give an intuitive description of the concrete much simpler algorithm for $t = 0$.

First, we set $E^* = \emptyset$ and initialize $\text{fit}_{E^*}(C) := \text{univ}_G(C)$ for each community $C \in \mathcal{C}$. Afterwards, we again compute the partition $\mathfrak{C}$ of the communities of $\mathcal{C}$. Recall that this is done by defining an auxiliary graph $G_{\mathfrak{C}}$ with vertex set $\mathcal{C}$ where two distinct communities C and D are adjacent if and only C and D have an intersection of size at least 3. Note that in the original definition one had to also check that no vertex is locally optimal for the intersection. This now always holds since there are no local edges. The partition $\mathfrak{C}$ then consists of the connected components of $G_{\mathfrak{C}}$.

Second, we exhaustively apply Operations 2 and 3. Operation 2 ensures that all communities of the same part of $\mathfrak{C}$ will have the same potential centers according to fit_{E^*}. Moreover, Operation 3 ensures that if two communities C and D have an intersection of size at least 2, then the potential centers of both communities will be within $C \cap D$ according to fit_{E^*}.

After exhaustive application of these two operations, the remaining lines of Algorithm 1 are executed, that is, if $\text{fit}_{E^*}(C) = \emptyset$ for at least one community $C \in \mathcal{C}$, we correctly output that the instance under consideration is a no-instance of Stars NWS. Otherwise, we greedily select for each part $\mathcal{L}$ of the partition $\mathfrak{C}$ a vertex y as center for all communities $\mathcal{L}$, such that y is a potential center of each community of $\mathcal{L}$ and such that the cost of selecting y as center of all these communities is minimum under all such potential centers. Finally, if these choices of center vertices result in more than ℓ edges or total weight more than b, we correctly output that the input instance is a no-instance of Stars NWS. Otherwise, the chosen center vertices induce a solution with $t = 0$.

4.2 Connectivity NWS

Korach and Stern presented an $\mathcal{O}(c^4 n^2)$-time algorithm for Connectivity NWS where G is a clique and $t = 0$ [29] which was improved by Klemz et al. [28] who provided an $\mathcal{O}(m \cdot (c + \log(n)))$-time algorithm for Connectivity NWS with $t = 0$. Guttmann-Beck et al. [21] presented a similar algorithm for Unweighted Connectivity NWS with $t = 0$.

Next, we show that the positive result for $t = 0$ cannot be lifted to $t = 1$; in this case Connectivity NWS is NP-hard. We obtain our result by reducing from the NP-hard Hamiltonian Cycle-problem [1, 18], which asks for a given graph $G = (V, E)$ if there is a *Hamiltonian cycle* in G, that is, a cycle containing each vertex of G exactly once.

▶ **Theorem 4.9** ($\star$)**.** *Let Π be a graph class on which Hamiltonian Cycle is* NP*-hard, then Unweighted Connectivity NWS is* NP*-complete on Π even if $t = 1$.*

Proof. Let $I := (V, E)$ be an instance of Hamiltonian Cycle containing at least three vertices. We obtain an equivalent instance $I' := (G = (V, E), \mathcal{C}, \ell)$ of Unweighted Connectivity NWS as follows: We start with an empty set $\mathcal{C}$ and add for each vertex $v \in V$ a community $C_v := V \setminus \{v\}$ to $\mathcal{C}$. Finally, we set $\ell := |V|$. Note that $t = \ell - n + x$, where x is the number of connected components of the graph. Thus, $t = n - n + 1 = 1$.

The detailed correctness proof is deferred to the full version. ◀

▶ **Corollary 4.10.** *Unweighted Connectivity NWS is NP-complete even if $t = 1$ on subcubic bipartite planar graphs.*

5 Stars NWS Parameterized by the Number of Communities

Unweighted Connectivity NWS is NP-hard even for $c = 7$ [17, Proposition 3]. In contrast, Stars NWS admits an XP-algorithm for c with running time $n^{\mathcal{O}(c)}$: For each community C, test each of the at most $|C| \leq n$ potential center vertices. Then, for each potential solution check whether it consists of at most ℓ edges of total weight at most b. For

Stars NWS, we show that it is unlikely that this brute-force algorithm can be improved, by showing W[1]-hardness. For Unweighted Stars NWS, we obtain an FPT-algorithm for c.

▶ **Theorem 5.1** (⋆). *Stars NWS is* W[1]*-hard when parameterized by c even if G is a clique and each edge weight is* 1 *or* 2*.*

Proof. We provide a parameter-preserving reduction from the W[1]-hard Regular Multicolored Clique problem [11]. The input consists of an r-regular graph G, an integer κ, and a partition $(V_1, \dots V_\kappa)$ of $V(G)$. The question is whether there exists a clique of size κ containing exactly one vertex of each partite set V_i.

We construct an equivalent instance $(G', \mathcal{C}, \omega, \ell, b)$ of Stars NWS as follows. The vertex set of $V(G')$ consists of a copy of $V(G)$ and κ additional vertex sets S_i, $i \in [\kappa]$, each of size $n(G)^3$. We make G' a clique by adding all edges between vertices of $V(G')$. To complete the construction, we specify the communities and edge weights. First, for each color class $i \in [1, \kappa]$, we add a community $C_i := V(G) \cup S_i$. Afterwards, we define the edge weights: For each edge $\{a, b\} \in E(G')$ such that $\{a, b\} \in E(G)$, we set $\omega(\{a, b\}) := 2$, for each edge $\{a, b\}$ with $a \in S_i$ and $b \notin V_i$, we set $\omega(\{a, b\}) := 2$, for each edge $\{a, b\}$ with $a \in S_i$ and $b \in S_j$, we set $\omega(\{a, b\}) := 2$, and for each remaining edge $\{a, b\} \in E(G')$ we set $\omega(\{a, b\}) := 1$. Finally, we set $\ell := \kappa \cdot (n(G)^3 + n(G) - 1) - \binom{\kappa}{2}$ and $b := \kappa \cdot (n(G)^3 + n(G) - 1 + r) - 2\binom{\kappa}{2}$. Note that $c = \kappa$, it thus remains to show the equivalence of the two instances. The detailed correctness proof is deferred to the full version. ◀

▶ **Theorem 5.2** (⋆). *Unweighted Stars NWS is solvable in $\mathcal{O}(4^{c^2} \cdot (n + m) + n^2 \cdot c)$ time.*

To complete the parameterized complexity picture, we show that a polynomial kernel for c is unlikely.

▶ **Theorem 5.3** (⋆). *Unweighted Stars NWS parameterized by c does not admit a polynomial kernel unless NP ⊆ coNP/poly.*

6 Conclusion

Presumably the most interesting open question is whether Stars NWS parameterized by t admits an FPT-algorithm. In Theorem 4.2 we showed that Stars NWS can be solved in polynomial time if for some optimal solution the edge set of all local cycles is known. Thus, to obtain an FPT-algorithm, it is sufficient to find such an edge set in FPT-time. Also, it is open whether Unweighted Connectivity NWS can be solved in polynomial time when t is constant and the input graph is a clique. In other words, it is open whether a minimum-edge hypergraph support can be found in polynomial time when it has a constant feedback edge number.

It is also interesting to close the gap between the running time lower bound of $2^{\Omega(c)} \cdot \mathrm{poly}(|I|)$ (see Proposition 2.5) and the upper bound of $2^{\mathcal{O}(c^2)} \cdot \mathrm{poly}(|I|)$ (see Theorem 5.2) for Unweighted Stars NWS. Also, we may ask the following: are there properties Π such that Π-NWS is NP-hard but can be solved in $2^{\mathcal{O}(n)} \cdot \mathrm{poly}(n + c)$ time?

$\mathcal{H}$-Clique-Width and a Hereditary Analogue of Product Structure

Petr Hliněný
Masaryk University, Brno, Czech Republic

Jan Jedelský
Masaryk University, Brno, Czech Republic

Abstract

We introduce a novel generalization of the notion of clique-width which aims to bridge the gap between classical hereditary width measures and the recently introduced graph product structure theory. Bounding the new $\mathcal{H}$-clique-width, in the special case of $\mathcal{H}$ being the class of paths, is equivalent to admitting a hereditary (i.e., induced) product structure of a path times a graph of bounded clique-width. Furthermore, every graph admitting the usual (non-induced) product structure of a path times a graph of bounded tree-width, has bounded $\mathcal{H}$-clique-width and, as a consequence, it admits the usual product structure in an induced way. We prove further basic properties of $\mathcal{H}$-clique-width in general.

Acknowledgements We acknowledge helpful discussions with Jakub Gajarský on the questions and problems posed in Section 5, and especially on the question of $\mathcal{H}$-clique-width possibly being complement-closed.

1 Introduction

A prominent structural result by Dujmović, Joret, Micek, Morin, Ueckerdt and Wood [11], known as the *Planar product structure theorem*, claims that every planar graph can be found as a subgraph in the strong product ($\boxtimes$) of a path and a graph of small tree-width. We refer to Section 2 and Theorem 2.3 for the definitions and details.

The original motivation for this rather recent Product structure theorem was to bound the queue number of planar graphs, but the theorem has quickly found interesting applications and follow-up results, among which we may mention [1,9,10,12,13,23]. Namely, the product structure theory has been used to study non-repetitive colourings [10], to design short labelling schemes [1,9], or to bound the twin-width of planar graphs [4,16,19].

The basic goal of the product structure theory can be seen in studying graph classes which admit such product structure, that is, they can be constructed as subgraphs of the strong product of a path and a graph of small tree-width. Within this setting, there are two major restrictions; first that the containment (subgraph) relation is not induced, and second that this kind of a superstructure can exist only for sparse graph classes.

We aim to give a different perspective on the product structure (Definition 2.1) addressing both mentioned issues, that is, getting graphs which admit the traditional product structure as *induced* subgraphs in such strong product, and allowing also dense graphs to occur.

Our alternative view is two-sided and is closely related to another classical structural notion in graph theory – the clique-width measure. On one hand, any graph admitting the traditional product structure can be obtained as an induced subgraph of the strong product of a path and a suitable graph of bounded clique-width and even bounded tree-width (Theorem 4.6). On the other hand, a graph G admits the induced product structure with bounded clique-width (of the relevant factor), if and only if G has bounded $\mathcal{H}$-clique-width where $\mathcal{H}$ is the class of reflexive paths (Theorem 4.1). This dual nature of our view is another promising enhancement. Moreover, we believe this view can contribute to finding potential algorithmic applications of product structure theory.

The wide scope of our definition suggests to study $\mathcal{H}$-clique-width for other graph families $\mathcal{H}$ in addition to paths, too. For instance, in relation to the aforementioned product-structure works, one may consider $\mathcal{H}$ to be the class of the graphs $P_n \boxtimes K_k$ or of $P_n \boxtimes P_m$.

We study and characterize relations of $\mathcal{H}$-clique-width to ordinary clique-width (Theorem 3.1), to local clique-width (Theorem 3.4), and in parts to twin-width (Corollary 4.3). The full potential of this new concept when $\mathcal{H}$ is a family of specific graphs other than paths is yet to be explored, especially in the case of $\mathcal{H}$ formed by suitable dense graphs. We conclude with a number of open questions related to the new concept (Section 5).

2 Preliminaries

We consider finite simple graphs, i.e., graphs without parallel edges or loops, but in one specific context (Definition 2.1) we allow graphs with optional (self-)loops, thereafter called loop graphs. Precisely, a *loop graph* is a multigraph allowing loops (at most one per vertex), but not allowing parallel edges. In the context of loop graphs, we specially call a graph G a *reflexive (loop) graph* if every vertex of G has a loop. We naturally use terms *reflexive path*, *reflexive clique*, and *reflexive independent set* to denote ordinary paths, cliques, and independent sets, respectively, with loops added to all vertices. We write $G_1 \subseteq_i G_2$ to say that G_1 is an induced subgraph of G_2. Note that if $G_1 \subseteq_i G_2$ for loop graphs, then possible loops of G_2 on vertices of G_1 are also inherited.

A graph G is a *matching* if G is simple and all vertex degrees in G are 1. A graph $G \subseteq K_{n,n}$ is an *antimatching* if G is obtained from $K_{n,n}$ by removing a matching of n edges. A graph G is a *half-graph* if G is a bipartite simple graph with the bipartition $\{u_1, \ldots, u_n\}$ and $\{v_1, \ldots, v_n\}$, such that $u_i v_j \in E(G)$ if and only if $i \leq j$.

Width measures. As a traditional structural decomposition, a *tree decomposition* of a graph G is a tuple $(T, \mathcal{X})$ where T is a tree, and $\mathcal{X} = \{X_t : t \in V(T)\}$ where $X_t \subseteq V(G)$ is a collection of *bags* which satisfy the following: (i) $\bigcup_{t \in V(T)} X_t = V(G)$, (ii) for every vertex $v \in V(G)$, the set of the nodes $t \in V(T)$ such that $v \in X_t$ forms a subtree in T, and (iii) for every edge $uv \in E(G)$, there exists $t \in V(T)$ such that $\{u, v\} \subseteq X_t$. The *tree-width* of G is the minimum of $\max_{t \in V(T)} |X_t| - 1$ over all tree decompositions of G.

Our work is closely related to another measure, which is a "dense counterpart" of tree-width. The *clique-width* of a graph G is the minimum integer ℓ such that G (irrespective of labelling) is the value of an algebraic *ℓ-expression* defined by the following operations:

- create a new vertex of label (colour) i for some $i \in \{1, \ldots, \ell\}$;
- take the disjoint union of two labelled graphs;
- for $1 \leq i \neq j \leq \ell$, add all (missing) edges between a vertex of label i and a vertex of label j;
- for $1 \leq i \neq j \leq \ell$, recolour each vertex of label i to have label j.

In the same direction, let the *local clique-width* of a graph G be the integer function λ defined as follows; for an integer distance $r \geq 1$, $\lambda(r)$ is the maximum clique-width of the r-neighbourhood of a vertex v in G, over all $v \in V(G)$. We say that a graph class $\mathcal{G}$ is of *bounded local clique-width* if there exists an integer function upper-bounding the local clique-width of every member of $\mathcal{G}$. For instance, the class of grids is of bounded local clique-width, but of unbounded clique-width.

The last measure we mention, twin-width, was introduced a few years ago by Bonnet et al. in [3]. A *trigraph* is a simple graph G in which some edges are marked as *red*, and with respect to the red edges only, we naturally speak about *red neighbours* and *red degree* in G. For a pair of (possibly not adjacent) vertices $x_1, x_2 \in V(G)$, we define a contraction of the pair x_1, x_2 as the operation creating a trigraph G' which is the same as G except that x_1, x_2 are replaced with a new vertex x_0 (said to *stem from* x_1, x_2) such that:

- the (full) neighbourhood of x_0 in G' (i.e., including the red neighbours), denoted by $N_{G'}(x_0)$, equals the union of the neighbourhoods $N_G(x_1)$ of x_1 and $N_G(x_2)$ of x_2 in G except x_1, x_2 themselves, that is, $N_{G'}(x_0) = (N_G(x_1) \cup N_G(x_2)) \setminus \{x_1, x_2\}$, and
- the red neighbours of x_0, denoted here by $N^r_{G'}(x_0)$, inherit all red neighbours of x_1 and of x_2 and add those in $N_G(x_1)\Delta N_G(x_2)$, that is, $N^r_{G'}(x_0) = \big(N^r_G(x_1) \cup N^r_G(x_2) \cup (N_G(x_1)\Delta N_G(x_2))\big) \setminus \{x_1, x_2\}$, where Δ denotes the symmetric set difference.

A *contraction sequence* of a trigraph G is a sequence of successive contractions turning G into a single vertex, and its width d is the maximum red degree of any vertex in any trigraph of the sequence. The *twin-width* of a trigraph G is the minimum width over all possible contraction sequences of G. The twin-width of a multigraph or a loop graph is defined as the twin-width of its simplification.

Introducing $\mathcal{H}$-clique-width. Our main contribution builds on the following new concept.

▶ **Definition 2.1** ($\mathcal{H}$-clique-width)**.** *Let $\mathcal{H}$ be a family of loop graphs, and $\ell > 0$ be an integer. Consider* labels *of the form (i, v) where $i \in \{1, \ldots, \ell\}$ and $v \in V(H)$ for some (fixed) $H \in \mathcal{H}$.*

a) *For $H \in \mathcal{H}$, let an* (H, ℓ)-expression *be an algebraic expression using the following four operations on vertex-labelled graphs:*
- *creating a new vertex with single label (i, v) for some $i \in \{1, \ldots, \ell\}$ and $v \in V(H)$;*
- *taking the disjoint union of two labelled graphs;*
- *for $1 \le i \ne j \le \ell$,* adding edges between i and j, *which means to add all edges between the vertices of label (i, v) and the vertices of label (j, w) over all pairs $(v, w) \in V(H)^2$ such that $vw \in E(H)$ (including the case of a single vertex $v = w$ with a loop, which will often be assumed to exist for the graphs H); and*
- *for $1 \le i \ne j \le \ell$,* recolouring i to j, *which means to relabel all vertices with label (i, v) where $v \in V(H)$ to label (j, v).*

b) *The* $\mathcal{H}$-clique-width $\mathcal{H}\text{-cw}(G)$ *of a simple graph G is defined as the smallest integer ℓ such that (some labelling of) G is the value of an (H, ℓ)-expression for some $H \in \mathcal{H}$. If it is not possible to build G this way, then let $\mathcal{H}\text{-cw}(G) = \infty$.*

Given an (H, ℓ)-expression of value (a labelled graph) G, we use the following terminology; the graph H is the parameter *of the expression, and when referring to a label (i, v) of $x \in V(G)$, the integer i is the* colour *and v the* parameter vertex *of x.*

Observe that, throughout an (H, ℓ)-expression φ valued G, the colours of vertices of G may arbitrarily change by the recolouring operations, but the parameter vertex of every $x \in V(G)$ stays the same (is uniquely determined for x) in φ.

It is obvious that $\mathcal{H}$-clique-width (similarly to ordinary clique-width) is monotone under taking induced subgraphs. On the other hand, it is not apriori clear whether $\mathcal{H}$-clique-width is (at least functionally) closed under taking the complement of a graph; we will address this interesting issue in the concluding section. Another remark concerns the family $\mathcal{H}$ which should be generally treated as an infinite class of (finite) loop graphs, due to $\mathcal{H}$-clique-width being asymptotically the same as ordinary clique-width in the case of finite $\mathcal{H}$ – see Theorem 3.1.

To further briefly illustrate Definition 2.1, we add few more easy observations:

▷ Claim 2.2.

a) If $\mathcal{H} = \{K_1\}$, then $\mathcal{H}$-cw$(G) < \infty$ if and only if G has no edges. If $\mathcal{H} = \{K_1^\circ\}$, where K_1° stands for a single vertex with a loop, then $\mathcal{H}$-cw$(G) = \mathrm{cw}(G) < \infty$.

b) If $\mathcal{H}$ contains a loop graph with at least one loop, then $\mathcal{H}$-cw$(G) \leq \mathrm{cw}(G)$.

c) If $\mathcal{H} = \{H\}$, then $\mathcal{H}$-cw$(H_1) \leq 2$ holds for every simple graph H_1 obtained from an induced subgraph of H by removing loops.

d) If $\mathcal{H} = \{H\}$ and H is disconnected, then for every connected simple graph G we have $\mathcal{H}$-cw$(G) = \{H_0\}$-cw(G) for some connected component H_0 of H.

e) If $\mathcal{H} = \{K_2\}$ (no loops), then $\mathcal{H}$-cw$(G) < \infty$ if and only if G is a simple bipartite graph. More generally, for any $\mathcal{H}$, we have $\mathcal{H}$-cw$(G) < \infty$ for a simple graph G, if and only if G has a homomorphism into some $H \in \mathcal{H}$.

f) For any $k \geq 3$ and $\mathcal{H} = \{K_k\}$, it is NP-hard to decide whether $\mathcal{H}$-cw$(G) < \infty$.

g) Let $\mathcal{H}$ be a family containing arbitrarily long reflexive paths. If G is any square grid, then $\mathcal{H}$-cw$(G) \leq 5$ (while cw(G) is unbounded in such case).

Proof.

a) There is no edge in K_1, and so Definition 2.1 cannot create an edge in G. On the other hand, (K_1°, ℓ)-expressions in Definition 2.1 exactly coincide with traditional ℓ-expressions of clique-width (replacing every label i with (i, v) where $\{v\} = V(K_1^\circ)$).

b) We pick $v \in V(H)$ for $H \in \mathcal{H}$ such that v has a loop in H. Then, in an ordinary cw(G)-expression for G, we replace every label i with (i, v) to get an $(H, \mathrm{cw}(G))$-expression for G, similarly to part a).

c) We simply make an $(H, 2)$-expression for H_1 as follows; in an arbitrary order $V(H_1) = \{v_1, \ldots, v_n\}$ of the vertices, for $k = 1, \ldots, n$, we add a new vertex labelled $(2, v_k)$, add edges between 1 and 2, and recolour 2 to 1. This creates exactly the non-loop edges of H_1.

d) This follows from the facts that the recolouring operation of Definition 2.1 does not allow to change the initially assigned parameter vertex of H, and hence every edge of G created within an (H, ℓ)-expression has a preimage edge in H. So, an expression creating connected G may only use parameter vertices of a connected component of H.

e) Considering the previous argument turned around, every edge created within an (H, ℓ)-expression has a unique homomorphic image in H (possibly a loop). In the opposite direction, for a homomorphism $h : G \to H \in \mathcal{H}$, we make an $(H, |V(G)|)$-expression starting with the disjoint union of vertices labelled $(i_x, h(x))$ for all $x \in V(G)$ where $i_x \neq i_y$ for $x \neq y$, and then simply add the edges of G one by one using the colours (i.e., i_x).

f) By e), we have $\mathcal{H}$-cw$(G) < \infty$ if and only if G is k-colourable.

g) Let G be an $a \times b$ grid, i.e., $|V(G)| = ab$. We take $H \in \mathcal{H}$ such that $|V(H)| \geq b$, choose a consecutive subpath on $\{v_1, \ldots, v_b\} \subseteq V(H)$, and make an $(H, 5)$-expression valued G as follows. As in c), we define an $(H, 3)$-(sub)expression creating a “vertical” copy P_1 of the path on b vertices, but now using three colours such that the resulting labels of P_1 are with alternating colours 2 and 3, precisely as $(2, v_1)$, $(3, v_2)$, $(2, v_3)$, $(3, v_4), \ldots$. We likewise create a copy P_2 of the same path with alternating colours in labels $(4, v_1)$, $(5, v_2)$, $(4, v_3)$, $(5, v_4), \ldots$. Then we make a disjoint union and add edges between colours $2, 4$ and between $3, 5$ – this creates precisely the “horizontal” edges between the labels $(2, v_i)$ and $(4, v_i)$, and between $(3, v_{i+1})$ and $(5, v_{i+1})$, for $i = 1, 3, \ldots$. In a subsequent round, we recolour colours $2, 3$ to 1 (this concerns only P_1), and continue the same process with adding a path P_3 with alternating colours again 2 and 3, and adding the "horizontal" edges. After $a - 1$ rounds, we build the desired $a \times b$ square grid G. ◁

Product structure theory. The *strong product* $G_1 \boxtimes G_2$ of two simple graphs is the graph G on the vertex set $V(G) := V(G_1) \times V(G_2)$ such that, for any $[u, u']$, $[v, v'] \in V(G)$, we have $\{[u, u'], [v, v']\} \in E(G)$ if and only if ($uv \in E(G_1)$ and $u'v' \in E(G_2)$) or ($u = v$ and $u'v' \in E(G_2)$) or ($uv \in E(G_1)$ and $u' = v'$).

For an illustration, the strong product $P \boxtimes Q$ of two paths P, Q is the square grid with diagonals. It may be interesting to observe that, in the context of loops graphs, if both G_1 and G_2 are reflexive, then the definition of the strong product $G_1 \boxtimes G_2$ could be shortened as "$uv \in E(G_1)$ and $u'v' \in E(G_2)$", and the result would be the same except that all vertices would have loops.

Origins of graph product structure theory go back to the mentioned seminal paper [11]:

▶ **Theorem 2.3** ([11], improved in [23]). *Every planar graph is a subgraph of the strong product $P \boxtimes M$ where P is a path and M is a planar graph of tree-width at most 6.*

There exist alternative refined formulations of Theorem 2.3, such as using the strong product $P \boxtimes K_3 \boxtimes M$ where M is now of tree-width at most 3 which is of importance in some applications (such as in refining the upper bound on the queue number of planar graphs).

Our main goal is to refine, using Definition 2.1, the statement of Theorem 2.3 with the induced subgraph relation in Theorem 4.6; admittedly, at the cost of worse absolute constants.

3 Properties of $\mathcal{H}$-Clique-Width

We first characterize the asymptotic difference between the ordinary clique-width and the $\mathcal{H}$-clique-width for families of loop graphs $\mathcal{H}$.

We recall the concept of neighbourhood diversity by Lampis [20]. Two vertices x, y of a simple graph G are of the same *neighbourhood type* if and only if they have the same set of neighbours in $V(G) \setminus \{x, y\}$. We shall use an adjusted version of this concept, suitable for our loop graphs; Two vertices x, y of a simple loop graph G are of the same *total neighbourhood type*, if and only if they have the same set of neighbours in $V(G)$ when x counts as a neighbour of x if there is a loop on x (and likewise with y). A loop graph G is of *total neighbourhood diversity* at most d if $V(G)$ can be partitioned into d parts such that every pair in the same part have the same total neighbourhood type.

The slight, but very important in our context, difference of these two notions in presence of loops can be observed, e.g., on: loopless cliques K_n (neighbourhood diversity 1 and total neighbourhood diversity n) vs. reflexive cliques K_n° (total neighbourhood diversity 1), or loopless stars $K_{1,n}$ (both neighbourhood diversities equal 2) vs. reflexive stars $K_{1,n}^\circ$ (total neighbourhood diversity n).

A loop graph class $\mathcal{G}$ is of *component-bounded* total neighbourhood diversity if there exists an integer d such that each connected component of every graph of $\mathcal{G}$ is of total neighbourhood diversity at most d.

▶ **Theorem 3.1.** *Let $\mathcal{H}$ be a family of loop graphs. There exists a function f such that,* $\mathrm{cw}(G) \leq f(\mathcal{H}\text{-}\mathrm{cw}(G))$ *holds for all simple graphs G, if and only if $\mathcal{H}$ is of component-bounded total neighbourhood diversity.*

Proof. In the "$\Leftarrow$" direction, we may assume G is connected (we will later take the maximum over connected components). By Claim 2.2 d), $\mathcal{H}$-cw$(G) = \{H_0\}$-cw$(G) = \ell$ for a connected component H_0 of some $H \in \mathcal{H}$. The total neighbourhood diversity of H_0 is at most some constant d, by the theorem assumption. Then, in an (H_0, ℓ)-expression for G, we may equivalently replace the parameter vertices of H_0 by d new colours, giving a $d\ell$-expression for G. So, $\mathrm{cw}(G) \leq d \cdot \mathcal{H}$-cw$(G)$.

A proof of the "$\Rightarrow$" direction is based on the following natural technical claim:

▷ Claim 3.2 (Ding et al. [7, Corollary 2.4]). For every k there exists m such that the following holds. If F is a bipartite connected simple graph with the bipartition $V(F) = A \cup B$, $|A| \geq m$ and the vertices of A have pairwise different neighbourhood types (in B), then F contains an induced subgraph isomorphic to one of the following graphs on $2k$ vertices: a matching, an antimatching, or a half-graph.

Having Claim 3.2 at hand, we continue as follows. Assume that $\mathcal{H}$ is *not* of component-bounded total neighbourhood diversity. Let $H \in \mathcal{H}$ (or a component thereof) be a connected loop graph of total neighbourhood diversity $\geq c_1$, and $C \subseteq V(H)$ be vertices representing these c_1 total neighbourhood types. By Ramsey theorem, for sufficiently large c_1 we find a subset $C_1 \subseteq C$, $|C_1| = 2c_2 - 1$, such that C_1 induces a clique or an independent set in G, and then we can select $C_2 \subseteq C_1$, $|C_2| = c_2$ such that either all vertices of C_2 have loops, or none has. We have got one of the two possibilities:

- C_2 is a reflexive independent set or a loopless clique in G.
- Or, all vertices of C_2 have the same total neighbourhood type in C_2 (empty or full C_2), and so they have pairwise different neighbourhood types in $D := V(G) \setminus C_2$. Consequently, we may apply Claim 3.2 to the bipartite subgraph "between" C_2 and D.

Regarding the second point, in more detail, we say that a bipartite graph F_1 with a fixed bipartition $V(F_1) = A_1 \cup B_1$ is a *bi-induced subgraph* of a graph H, if $F_1 \subseteq H$ such that every edge of H with one end in A_1 and the other end in B_1 belongs to F_1. Claim 3.2 hence implies that one of the three claimed subgraphs is bi-induced in H.

Altogether, for every k and sufficiently large c_1 depending on k, we have connected $H \in \mathcal{H}$ containing one of the five said substructures; an induced reflexive independent set or an induced loopless clique on k vertices, or a bi-induced matching, a bi-induced antimatching, or a bi-induced half-graph on $2k$ vertices. In each of these five cases, we can construct a "grid-like" graph of bounded $\mathcal{H}$-clique-width whose ordinary clique-width grows linearly with k. This is provided by subsequent Lemma 3.3, in which one can easily check that its assumptions cover all five cases of $H \in \mathcal{H}$ listed in this proof. ◀

▶ **Lemma 3.3.** *Let $k \geq 3$ be an integer, and H_1 be a loop graph satisfying the following:*

- *H_1 is connected.*
- *There exist sets $A, B \subseteq V(H_1)$, $|A| = |B| = k$, such that either $A = B$, or $A \cap B = \emptyset$.*
- *We can write $A = \{u_1, \dots, u_k\}$ and $B = \{u'_1, \dots, u'_k\}$ such that, for some of the following three conditions on integers $C(i,j) \in \{$'$i < j$','$i = j$','$i \neq j$'$\}$ we have; for all $(i,j) \in \{1, \dots, k\}^2$, $\{u_i, u'_j\} \in E(H_1)$ if and only if $C(i,j)$ is false. (Note that, if $A = B$, we assume $u_i = u'_i$ and deal also with loops.)*

Then, there exists a constant ℓ_0 independent of k such that the class of graphs of $\{H_1\}$-clique-width at most ℓ_0 has ordinary clique-width $\Omega(k)$.

Proof. We construct, via an $(H_1, \mathcal{O}(1))$-expression, a graph G_k of ordinary clique-width $\Omega(k)$ as follows.

Similarly as in Claim 2.2 c), we create a loopless copy G_1' of the graph H_1, such that every vertex $x \in V(G_1')$ which is a copy of a vertex $v \in B$ has the label with colour 2 and parameter vertex v and, if $A \neq B$, every vertex $x \in V(G_1')$ which is a copy of $w \in A$ has the label with colour 1 and parameter vertex w. Vertices of $V(G_i')$ that are not copies of $A \cup B$ have labels with colour 0 and the respective parameter vertex from $V(H_1) \setminus (A \cup B)$.

We set $G_1 := G_1'$, and for $a = 2, \ldots, k$ we do:

- We, likewise, create a loopless copy G_a' of H_1, now with colour 3 in the labels of the copy of A in $V(G_a')$ and, if $A \neq B$, with colour 4 in the labels of the copy of B in $V(G_a')$. The labels of $V(G_a')$ besides the copies of $A \cup B$ are again with colour 0.
- Then we make a disjoint union $G_a := G_{a-1} \mathbin{\dot\cup} G_a'$, and add edges between colours 2 and 3.
- If $A = B$, we recolour 2 to 1 and 3 to 2. If $A \neq B$, we recolour 2 and 3 to 1 and 4 to 2.

Altogether, the graph G_k has $k \cdot |V(H_1)|$ vertices, k disjoint copies G_a' of H_1, and every copy G_a' has k vertices which are, in a well-defined way – cf. condition $C(i,j)$, adjacent to corresponding k vertices of the subsequent copy G_{a+1}' (if $a < k$). There are no other edges in G_k. For clarity (and in resemblance to Theorem 4.1), we imagine the copy G_a' of H_1 as "column a" of G_k, and the set of the copies of u_i and u_i' of H_1 as "row i" of G_k. Possible remaining vertices of G_a' (those of colour 0 in their label) are not part of any row, as they do not participate in inter-column edges of G_k. Observe that, if $A \neq B$, the adjacency pattern occurring between columns a and $a+1$ is exactly the same as the edges between B and A in H_1, and so the same as the "mirrored" adjacency pattern between the copies of A and of B within column a (or $a+1$).

Now, assume we have an (ordinary) ℓ-expression φ valued G_k for some integer ℓ. We apply an argument which is folklore in this area. There must exist a subexpression φ_1 of φ making a subset of vertices $X \subseteq V(G_k)$ (it is irrelevant which of the edges of $G_k[X]$ this φ_1 makes), such that $\frac{1}{3}|V(G_k)| \leq |X| \leq \frac{2}{3}|V(G_k)|$. Let $\bar{X} = V(G_k) \setminus X$.

Consider any $1 \leq a < k$; then the columns a and $a+1$ differ with respect to X in at most 3ℓ rows ($\leq \ell$ if $A = B$); meaning that in $\leq 3\ell$ rows i we have a situation that a vertex of row i in one of the columns a or $a+1$ belongs to X, and a vertex of row i in the other column belongs to $\bar{X}$. This follows since we have at most ℓ different colours in φ_1 which can be used to further distinguish different adjacencies, as given by the condition $C(i,j)$ of the lemma, between the columns a and $a+1$, or within each one of the columns a or $a+1$ if $A \neq B$.

Likewise, at most ℓ columns are such that they intersect both X and $\bar{X}$. This follows similarly since every column is a copy of connected H_1, and so it needs in φ_1 a special colour for its (at least one) "private" edge from X to $\bar{X}$. The two latter conditions together are in a clear contradiction with $\frac{1}{3}|V(G_k)| \leq |X| \leq \frac{2}{3}|V(G_k)|$ if $\ell \in o(k)$. ◀

Secondly, there is an interesting relation to established concepts in the case of parameter families $\mathcal{H}$ of bounded degrees.

▶ **Theorem 3.4.** *Let $\mathcal{H}$ be a family of loop graphs of maximum degree Δ. Then the class of graphs of $\mathcal{H}$-clique-width at most ℓ is of bounded local clique-width in terms of Δ and ℓ.*

Proof. Let $H \in \mathcal{H}$ and G be a graph that is a value of an (H,ℓ)-expression φ. Choose $x \in V(G)$, and assume a vertex $y \in V(G)$ at distance at most r from x in G. Let $v, w \in V(H)$ be the parameter vertices in φ of x and y, respectively. As argued in Claim 2.2 e), there is a homomorphism $G \to H$ taking a path between x and y into a walk between v and w in H, and so the distance from v to w in H is at most r. Since $\Delta(H) \leq \Delta$, the r-neighbourhood of v in H has at most $(\Delta+1)^r$ vertices, and hence φ restricted to the r-neighbourhood of x in G uses only at most $(\Delta+1)^r$ parameter vertices which can be replaced in φ by unique colours.

This way we obtain an (ordinary) $\ell \cdot (\Delta+1)^r$-expression whose value is the r-neighbourhood of x in G. We can thus set $f(r) := \ell \cdot (\Delta+1)^r$ (independently of $H \in \mathcal{H}$ and G) to certify bounded local clique-width of every G such that $\mathcal{H}$-cw$(G) \leq \ell$. ◀

A similar structural relation of $\mathcal{H}$-clique-width to the parameter twin-width is stated later in Corollary 4.3, as a consequence of a product-structure-like characterization.

From Theorem 3.4 we, for instance, immediately get tractability of FO model checking, which is FPT for all classes of bounded local clique-width – this well-known fact follows by a combination of the ideas of Frick and Grohe [15] and of Dawar, Grohe and Kreutzer [5]:

▶ **Corollary 3.5.** *For every family $\mathcal{H}$ of loop graphs, the FO model checking problem of a graph G is in FPT when parameterized by the formula, the maximum degree of $\mathcal{H}$ and the $\mathcal{H}$-clique-width of G.* ◀

Furthermore, it may be interesting to ask to which extent Theorem 3.4 can be reversed. This cannot be done straightforwardly since there are families $\mathcal{H}$ of unbounded degrees, such that classes of bounded $\mathcal{H}$-clique-width not only have bounded local clique-width, but even bounded ordinary clique-width. One example is $\mathcal{H}_1$ the class of all reflexive cliques by Theorem 3.1. On the other hand, e.g., for $\mathcal{H}_2$ being the class of all reflexive stars, there are graphs whose $\mathcal{H}_2$-clique-width is bounded by a constant, and they contain arbitrarily large induced grids and a universal vertex adjacent to everything (a construction similar to Claim 2.2 g)). Such graph hence have unbounded local clique-width.

4 Approaching Induced Product Structure

In this section we restrict our attention to families $\mathcal{H}$ formed by *reflexive* loop graphs (i.e., all vertices have loops in the graphs of $\mathcal{H}$), which makes most natural sense with respect to the strong-product structure studied.

▶ **Theorem 4.1.** *Let $\mathcal{H}$ be a family of reflexive loop graphs, and $\mathcal{H}'$ be the family of simple graphs obtained from the graphs of $\mathcal{H}$ by removing all loops. For every integer $\ell \geq 2$ the following holds. A simple graph G is of $\mathcal{H}$-clique-width at most ℓ, if and only if G is isomorphic to an induced subgraph of the strong product $H' \boxtimes M$ where $H' \in \mathcal{H}'$ and M is a simple graph of clique-width at most ℓ.*

Proof. In the "$\Leftarrow$" direction, it is enough to show that $\mathcal{H}$-cw$(G) \leq \ell$ for $G := H' \boxtimes M$. Let φ be an ℓ-expression of the graph M, and let H° be obtained from H' by adding loops to all vertices. We are going to transform φ into an (H°, ℓ)-expression as follows. First, for each $x \in V(M)$ we independently construct a copy H'_x of H', using only $2 \leq \ell$ colours by Claim 2.2 c). That is, the parameter vertex of every $v_x \in V(H'_x)$ is the preimage $v \in V(H')$ of v_x. Then, at every moment the expression φ introduces a new vertex $y \in V(M)$ of colour i, we take (substitute) the copy H'_y and recolour it to i. The remaining operations (union, recolouring, and adding edges) stay in place in φ, but are now applied according to Definition 2.1.

We claim that the value G of the resulting transformed (H°, ℓ)-expression σ is $H' \boxtimes M$. Indeed, the vertex set is $V(G) = V(H') \times V(M)$, and for each $m \in V(M)$ the subgraph induced on $V(H') \times \{m\}$ is a copy of H'. For any $[v_1, m_1], [v_2, m_2] \in V(G)$ and $m_1 \neq m_2$; if $\{[v_1, m_1], [v_2, m_2]\} \in E(G)$, then $v_1v_2 \in E(H^\circ)$ by Definition 2.1, and $m_1m_2 \in E(M)$ by the definition of σ. Hence $\{[v_1, m_1], [v_2, m_2]\} \in E(H' \boxtimes M)$. Conversely, if $\{[v_1, m_1], [v_2, m_2]\} \in E(H' \boxtimes M)$, then, by the definition of $\boxtimes$, $v_1v_2 \in E(H')$ or $v_1 = v_2$, meaning $v_1v_2 \in E(H^\circ)$, and $m_1m_2 \in E(M)$. So, the edge $\{[v_1, m_1], [v_2, m_2]\}$ has been created by σ.

In the "⇒" direction, let σ be an (H°,ℓ)-expression valued G, for some $H^\circ \in \mathcal{H}$. Let $H' \in \mathcal{H}'$ be the simple graph of H°. We are going to construct an ℓ-expression φ valued M on the vertex $V(M) = V(G)$, such that $G \subseteq_i H' \boxtimes M$. The expression φ simply discards parameter vertices (cf. Definition 2.1) from the labels in σ. Hence, we clearly get $M \supseteq G$. To prove that $G \subseteq_i H' \boxtimes M$, consider any vertices $x \neq y \in V(G)$ labelled (i,v) and (j,w) by σ (for here, indefinite i and j are irrelevant, and v and w are uniquely determined by σ). We claim that the vertices x and y as of G can be represented by $[v,x]$ and $[w,y]$ of the product $H' \boxtimes M$. If $xy \in E(G)$, then $xy \in E(M)$ by previous $M \supseteq G$, and $vw \in E(H^\circ)$ by Definition 2.1. Consequently, $\{[v,x],[w,y]\} \in E(H' \boxtimes M)$ by $\boxtimes$. On the other hand, if $\{[v,x],[w,y]\} \in E(H' \boxtimes M)$, then $vw \in E(H')$ or $v = w$, and so $vw \in E(H^\circ)$. Moreover, $xy \in E(M)$ since $x \neq y$, and so $xy \in E(G)$ since the (original) (H°,ℓ)-expression σ creates the edge xy by Definition 2.1. ◀

Theorem 4.1 can be used also to bound the twin-width of graphs of bounded $\mathcal{H}$-clique-width. To show this, we first prove the following ad-hoc upper bound.

▶ **Proposition 4.2.** *Let P be a reflexive path and G a simple graph. Then the twin-width of G is at most $5 \cdot (\{P\}\text{-cw}(G)) - 2$. Consequently, denoting by $\mathcal{P}^\circ$ the class of all reflexive paths, the twin-width of any simple graph G is at most $5 \cdot (\mathcal{P}^\circ\text{-cw}(G)) - 2$.*

Proof. Let G be the value of a (P,ℓ)-expression φ, where $\ell = \{P\}\text{-cw}(G)$. When constructing a contraction sequence for G, we proceed recursively (bottom-up) along the expression tree of φ; processing only the union and recolouring nodes, and at each node contracting together all vertices of the same label.

Consider a situation at a node with a subexpression φ_0 of φ, where $X_0 \subseteq V(G)$ is the vertex set generated by φ_0, and let $x^0_{(i,v)}$ denote the vertex resulting from the contractions of all vertices of X_0 that are of label (i,v) by φ_0. The core observation is that every vertex of $V(G) \setminus X_0$ has the same adjacency to all vertices forming $x^0_{(i,v)}$ by Definition 2.1, and so the only possible red neighbours of $x^0_{(i,v)}$ in a contraction of G are those that stem from X_0.

The only possible neighbours of $x^0_{(i,v)}$ in the described contraction of the induced subgraph $G[X_0]$ are $x^0_{(j,w)}$ where $j \in \{1,\dots,\ell\}$ and $vw \in E(P)$ – altogether at most $3\ell - 1$ choices of potential red neighbours of $x^0_{(i,v)}$ in the contraction of $G[X_0]$. If a recolouring operation i to j is encountered after the node of φ_0, we simply contract each former $x^0_{(i,v)}$ with $x^0_{(j,v)}$ over all $v \in X_0$, not increasing the previous bound on the red degree.

Consider now a union node making $X_2 := X_0 \dot{\cup} X_1$, where X_1 has been generated by a sibling subexpression φ_1 of φ, and let $x^1_{(i,v)}$ analogously denote the vertices resulting from contractions of X_1. Let the vertices of P be $V(P) = (v_1,\dots,v_a)$ in the natural order along the path. For $k = 1,\dots,a$, and subsequently for $i = 1,\dots,\ell$, we make $x^2_{(i,v_k)}$ by contracting $x^0_{(i,v_k)}$ with $x^1_{(i,v_k)}$. Considering the corresponding successive contractions of the induced subgraph $G[X_2]$, the only possible red neighbours of $x^2_{(i,v_k)}$ are the ℓ vertices $x^2_{(i',v_{k-1})}$, the up to $2(\ell-1)$ vertices $x^2_{(j,v_k)}$ for $j < i$, or $x^0_{(j,v_k)}$, $x^1_{(j,v_k)}$ for $j > i$, and the 2ℓ vertices $x^2_{(i'',v_{k+1})}$, $x^2_{(i'',v_{k+1})}$. The maximum possible encountered red degree is thus $\ell + 2(\ell-1) + 2\ell = 5\ell - 2$. ◀

▶ **Corollary 4.3.** *Let $\mathcal{H}$ be a family of reflexive loop graphs of maximum degree Δ and twin-width at most t. Then the twin-width of any simple graph G is at most $\mathcal{O}(t + \Delta \cdot \mathcal{H}\text{-cw}(G))$.*

Proof. By Theorem 4.1, we have $G \subseteq_i H' \boxtimes M$, where H' is of maximum degree at most Δ and twin-width at most t and M is of clique-width at most $\ell := \mathcal{H}\text{-cw}(G)$. Since twin-width is monotone under taking induced subgraphs, it is enough to bound it for the graph $H' \boxtimes M$.

By Proposition 4.2 applied to P being a single reflexive vertex, and Claim 2.2 a), M is of twin-width at most $k := 5\ell - 2$. Then, by Bonnet et al. [2] (bounding twin-width of a strong product), $H' \boxtimes M$ is of twin-width at most $\max\{t + \Delta,\, k(\Delta + 1) + 2\Delta\} = \mathcal{O}(t + \Delta\ell)$. ◀

Notice that, for constant Δ, the bound $\mathcal{O}(t+\Delta\cdot\mathcal{H}\text{-cw}(G))$ in Corollary 4.3 is asymptotically best possible; a linear dependence on t (the maximum twin-width of $\mathcal{H}$) is necessary due to Claim 2.2 c), and a linear dependence on $\mathcal{H}$-cw(G) is, on the other hand, required already by the subcase of ordinary clique-width. It is not clear whether the linear dependence on Δ in the bound of Corollary 4.3 is really necessary, however, the next construction shows that the bound has to depend on Δ, the maximum degree of $\mathcal{H}$:

▶ **Proposition 4.4.** **(*)** *Let H_n denote the half-graph (cf. Section 2) on $2n$ vertices. Then the twin-width of the graphs $H_n \boxtimes H_n$ grows with n. Furthermore, the class $\{H_n \boxtimes H_n : n \in \mathbb{N}_+\}$ is monadically independent.*

Since Proposition 4.4 was not part of the reviewed MFCS submission, we leave its proof to the full preprint [17].

If $\mathcal{H}$ is the family of reflexive half-graphs (which is of unbouded maximum degree), then $\mathcal{H}$-cw$(H_n \boxtimes H_n) \leq$ cw$(H_n) \leq 3$ using Theorem 4.1 and a trivial 3-expression for H_n, and likewise the twin-width of $\mathcal{H}$ is constant. So, from Proposition 4.4 we get that the bound in Corollary 4.3 must grow with $n = \Delta(H_n)$, too.

4.1 Relations to the traditional product structure

In regard of the Planar product structure theorem, as introduced in Section 2, we are especially interested in $\mathcal{H}$-clique-width for $\mathcal{H} = \mathcal{P}^\circ$ where $\mathcal{P}^\circ$ is the *class of reflexive paths.* We get the following as another immediate consequence of Theorem 4.1:

▶ **Corollary 4.5.** *For every integer $\ell \geq 2$ the following holds. A graph G is isomorphic to an induced subgraph of the strong product $P \boxtimes M$ where P is a path and M is a simple graph of clique-width at most ℓ, if and only if $\mathcal{P}^\circ$-cw$(G) \leq \ell$.* ◀

There is, however, a more direct connection between our concept and the original Planar product structure theorem, which constitutes the main new contribution of the paper:

▶ **Theorem 4.6.** *Assume that a graph G is a subgraph (not necessarily induced) of the strong product $G \subseteq P \boxtimes M$ where P is a path and M is a simple graph of tree-width at most k. Then $\mathcal{P}^\circ$-cw$(G) \leq 6(k+1)\cdot 8^{k+1}$. Moreover, there exists a graph M_1 of tree-width at most $6(k+1)\cdot 8^{k+1}$ such that G is isomorphic to an* induced *subgraph of the strong product $P \boxtimes M_1$.*

Proof. We start with proving the first part of the statement, that $\mathcal{P}^\circ$-cw$(G) \leq 6(k+1)\cdot 8^{k+1}$. Although, we remark that we could as well jump straight into a proof of the second part, the product $P \boxtimes M_1$, and then refer to Theorem 4.1 to conclude with a bound (albeit weaker) on $\mathcal{P}^\circ$-cw(G). We believe that the presented approach to the proof is more accessible for the readers.

We assume a rooted tree decomposition $(T, \mathcal{X})$ of width k of the graph M, such that every node of T has at most two children. For a node $t \in V(T)$, let $X_t^+ \subseteq V(M)$ denote the union of X_s where s ranges over t and all descendants of t. Let $p(t)$ denote the parent node of t in T, and let $Y_t = X_t^+ \setminus X_{p(t)}$ denote the vertices of M which occur *only* in the bags of t and its descendants. For the root r of T, let specially $Y_r = X_r^+ = V(M)$. Observe that all neighbours of a vertex $m \in Y_t$ in $V(M) \setminus Y_t$ must belong to the set $X_t \setminus Y_t$, by the interpolation property of a tree decomposition. Let $q : V(M) \to \{0, 1, \dots, k\}$ be a function such that q is injective on each of the bags X_t over $t \in V(T)$ – such q is easily constructed along the tree T in the root-to-leaves order (in fact, q can be seen as a monotone cop search strategy on the decomposition of M).

Analogously to the treatment in the proof of Theorem 4.1, we refer to the vertices of $G \subseteq P \boxtimes M$ as to the pairs $[p, m]$ where $p \in V(P)$ and $m \in V(M)$ in the natural correspondence. When constructing an expression for the graph G, we follow on a high level the tree T; at a node $t \in V(T)$, we will construct precisely the subgraph G^t of G induced on the vertex set $(V(P) \times Y_t) \cap V(G)$. By the previous, all neighbours of $V(G^t)$ in the rest of G belong to the set $W_t := \big(V(P) \times (X_t \setminus Y_t)\big) \cap V(G)$ where $|X_t \setminus Y_t| \le |X_t| \le k + 1$. It will thus be enough to encode in the colour of each $x \in V(G^t)$ information about which vertices of W_t are actual neighbours of x in G and, moreover, the colours used can be "recycled modulo 3" along the path P. This way we will prove that $\mathcal{P}^\circ$-cw(G) is bounded in terms of k; more precisely, that $\{P^\circ\}$-cw$(G) \le 6(k + 1) \cdot 8^{k+1}$ for P° being the reflexive closure of P.

Let the vertices of P be $V(P) = (p_1, \dots, p_n)$ in the natural order along the path, and let $t_m \in V(T)$ for $m \in V(M)$ denote the node closest to the root such that $m \in X_{t_m}$ (so, $m \in Y_{t_m}$). In more detail, for each $m \in V(M)$ we create, in a trivial way, a subexpression for the subgraph G_m of G induced by $\big(V(P) \times \{m\}\big) \cap V(G)$ (which is a copy of a subpath of P), such that the labels in G_m are as follows.

For each vertex $x \in V(G_m)$ where $x = [p_i, m]$, we give x the label (c_x, p_i) such that the colour of x is a tuple $c_x = (0, i \bmod 3,\ b_0, b_1, \dots, b_k,\ d)$ satisfying the following:

- i is the index of p_i, and $b_j \in \{0, 1\}^3$ and $d \in \{0, \dots, k\}$ are prescribed below;
- for every $j \in \{0, 1, \dots, k\} \setminus q(X_{t_m})$ we let $b_j = (0, 0, 0)$;
- for every $j = q(m')$ where $m' \in X_{t_m}$ (recall that q is injective on each bag, and so m' is unique such), we define $b_j = (b^1, b^2, b^3)$ where
  - $b^1 = 1$ if and only if $\{x, [p_{i-1}, m']\} \in E(G)$,
  - $b^2 = 1$ if and only if $\{x, [p_i, m']\} \in E(G)$, and
  - $b^3 = 1$ if and only if $\{x, [p_{i+1}, m']\} \in E(G)$;
- we set $d = q(m'')$ where $m'' \in V(M)$ is a neighbour of m in M such that all neighbours of m belong to $Y_{t_{m''}}$ (informally, m'' is any topmost w.r.t. T neighbour of m in M).

For an informal explanation in relation the above "sketch of encoding", the colour c_x in the label of x covers all desired information about the neighbours of x in the set W_{t_m} in G, for which adjacencies will created later in the coming expression for G. And again on an informal level, the purpose of the component d of the colour c_x is to encode the moment at which all edges of m in M are already created going bottom-up along the tree T.

Let $\Gamma_k := \{0, 1\} \times \{0, 1, 2\} \times \{0, 1\}^{3 \cdot (k+1)} \times \{0, 1, \dots, k\}$ be our set of colours (where, as above, we have $c_x \in \Gamma_k$ for every x, and "a half" of the colour space – with the first component equal to 1, remains unused so far), and let $\ell = |\Gamma_k| = 2 \cdot 3 \cdot 2^{3(k+1)} \cdot (k + 1) = 6(k + 1) \cdot 8^{k+1}$. We construct a (P°, ℓ)-expression $\varphi = \varphi^r$ valued G recursively, making subexpressions φ^t valued G^t along the nodes $t \in V(T)$, as follows:

I. For a node $t \in V(T)$ (including leaves), in the leaf-to-root tree order, we start with an empty expression φ_0 and $G^t_0 = \emptyset$ if t is a leaf. If t has one child s, then we take the expression φ_0 already constructed at s, and $G^t_0 = G^s$. If t has two children s, s', then we let φ_0 be the union operation over the expressions constructed at s and s', and $G^t_0 = G^s \dot\cup G^{s'}$. Note that, in the latter case, M has no edges between the sets Y_s and $Y_{s'}$ by the interpolation property, and so there are no edges between the (disjoint) subgraphs G^s and $G^{s'}$ in G.

II. Subsequently, for $Y'_t := Y_t \cap X_t$ (informally, Y'_t are the vertices of M whose last bag in T is right at t) we choose an arbitrary order $Y'_t = (m_1, \dots, m_a)$, $a = |Y'_t|$, of these vertices – possibly $a = 0$ if $Y'_t = \emptyset$. For $i = 1, \dots, a$, we repeat the following:

a) We start the expression φ_i by making a union of previous φ_{i-1} (if nonempty) and of the above subexpression constructing G_{m_i}.

b) Now we add in φ_i all required edges between G_{m_i} and $\big(G^t_0 \cup G_{m_1} \cup \dots \cup G_{m_{i-1}}\big)$. Using information stored in the labels of φ_{i-1} and the labels of vertices of G_{m_i}, this is a routine task as follows. For simplicity, we write $*$ for an arbitrary value.

- Let $j = q(m_i)$. For $(\alpha, \beta) \in \{(0,2), (1,0), (2,1)\}$, we add edges between each colour $(1, \alpha,\ *, \dots, b_j, \dots, *,\ *)$ where $b_j = (1, *, *)$, and each colour $(0, \beta,\ *, \dots, *,\ *)$. (Note that only vertices of G_{m_i} may currently hold colours starting with 0.)
- Similarly, for $(\alpha, \beta) \in \{(0,0), (1,1), (2,2)\}$, we add edges between each colour $(1, \alpha,\ *, \dots, b_j, \dots, *,\ *)$ where $b_j = (*, 1, *)$, and each colour $(0, \beta,\ *, \dots, *,\ *)$.
- And again, for $(\alpha, \beta) \in \{(0,1), (1,2), (2,0)\}$, we add edges between each colour $(1, \alpha,\ *, \dots, b_j, \dots, *,\ *)$ where $b_j = (*, *, 1)$, and each colour $(0, \beta,\ *, \dots, *,\ *)$.

c) Then we recolour every colour $c = (0, \beta,\ b_0, \dots, b_k,\ d)$ in the previous, where $\beta \in \{0,1,2\}$ and $b_0, \dots, b_k,\ d$ are arbitrary, to colour $c' = (1, \beta,\ b_0, \dots, b_k,\ d)$. This finishes the expression φ_i constructing a subgraph on $V(G^t_0 \cup G_{m_1} \cup \dots \cup G_{m_i})$.

III. Continuing on the expression φ_a from the previous point, we for all $i \in \{1, \dots, a\}$ do the following. We recolour every colour $c = \big(1, \beta,\ b_0, \dots, b_k,\ q(m_i)\big)$ in φ_a, where $\beta \in \{0,1,2\}$ and $b_0, \dots, b_k$ are arbitrary, to colour $c' = \big(1, \beta,\ (0,0,0)^{k+1},\ q(m_i)\big)$. (The purpose is to prevent creation of further edges from the recoloured vertices which got finished.) This finishes the sought expression φ^t with intended value G^t at the node t.

Now, the constructed (P°, ℓ)-expression $\varphi = \varphi^r$ clearly creates (precisely) all vertices and (at least) all edges of G, and uses at most $\ell = 6(k+1) \cdot 8^{k+1}$ colours. The proof will be finished once we prove that no other edges than those of G have been created by φ in G^r.

There are three points in verification of the last task.

- First, colouring in the process of construction of φ ensures that no additional edges are created within each of the graphs G_m above, and no edges are ever created between G_m and $G_{m'}$ if $mm' \notin E(M)$. The only operation adding edges in φ, besides the subexpressions making each G_m, is as defined in item IIb) above, and so it always adds only edges from $V(G_{m_i})$ to the rest of the current subgraph.
- Second, the operations in IIb) indeed add precisely those edges between G_{m_i} and $\big(G^t_0 \cup G_{m_1} \cup \dots \cup G_{m_{i-1}}\big)$ which exist in G, thanks to our definition of the colours c_x.
- And third (which relates to both previous points), the "hash" function $q : V(M) \to \{0, 1, \dots, k\}$ used in the construction of our colours indeed unambiguously identifies neighbours we want to make adjacent as in G thanks to assumed injectivity of q on each bag of $(T, \mathcal{X})$ and the recolouring performed in item III.

Regarding the second part of the Theorem, the graph M_1, we cannot directly employ Theorem 4.1 since that would give us only a factor (of the strong product) of bounded clique-width, but containing unbounded bipartite cliques in the worst case. We instead provide an ad-hoc construction of the desired factor M_1 which is closely related to fine details of the (P°, ℓ)-expression φ^r of G described above.

Let $\Gamma'_k := \{0,1\} \times \{0,1,2\} \times \{0,1\}^{3\cdot(k+1)}$, i.e., we have got $\Gamma'_k \times \{0, 1, \dots, k\} = \Gamma_k$ as above. Recall also that $Y'_t := Y_t \cap X_t$ for $t \in V(T)$ denotes the vertices of the graph M whose last bag in T (going bottom-up) is right at t, and that, when defining the expression φ of G, we have ordered the members of Y'_t where $a = |Y'_t|$ as $Y'_t = (m_1, \dots, m_a)$.

We define the sought graph M_1 such that $V(M_1) := V(M) \times \Gamma'_k$, and $E(M_1) \subseteq F$ where $F = \{\{(m,c),(m',c')\} : m = m' \vee mm' \in E(M),\ c,c' \in \Gamma'_k\}$. This setting clearly implies that tree-width of M_1 is going to be at most $(k+1) \cdot |\Gamma'_k| < 6(k+1) \cdot 8^{k+1}$, regardless of the detailed definition of its edges. We finish the definition of M_1 as follows:

i. For each $m \in V(M)$ and $\iota \in \{0,1\}$, we have $\{(m,c),(m,c')\} \in E(M_1)$ if and only if $c = (\iota, *,\ *, \ldots, *)$ and $c' = (\iota, *,\ *, \ldots, *) \neq c$.

ii. For each $m \neq m' \in V(M)$ such that $mm' \in E(M)$, up to symmetry, we either have $m \in Y'_t$ and $m' \in Y'_u$ where u is closer to the root of T than t, or $m, m' \in Y'_t$ and m precedes m' in the order $Y'_t = (m_1, \ldots, m_a)$ mentioned above. We define $\{(m,c),(m',c')\} \in E(M_1)$ if and only if, for $j = q(m')$ and some $\alpha \in \{0,1,2\}$, one of the following holds:
- $c = (*, \alpha,\ *, \ldots, b_j, \ldots, *)$, $c' = (*, (\alpha+2) \bmod 3,\ *, \ldots, *)$ and $b_j = (1,*,*)$, or
- $c = (*, \alpha,\ *, \ldots, b_j, \ldots, *)$, $c' = (*, \alpha,\ *, \ldots, *)$ and $b_j = (*,1,*)$, or
- $c = (*, \alpha,\ *, \ldots, b_j, \ldots, *)$, $c' = (*, (\alpha+1) \bmod 3,\ *, \ldots, *)$ and $b_j = (*,*,1)$.

iii. No other edges exist in M_1.

It remains to identify an isomorphism of $G \subseteq P \boxtimes M$ to an induced subgraph of the product $P \boxtimes M_1$. To each vertex $x \in V(G)$ such that $x = [p_i, m]$ in $P \boxtimes M$, we assign $x \mapsto [p_i, (m, c_i)]$ in $P \boxtimes M_1$ where $c_i = (a_i,\ i \bmod 3,\ b_0, \ldots, b_k)$ is determined in the following:

(I) The first component a_i of c_i is defined inductively by i (for each fixed m) as follows; it is $a_1 = 0$, and for each $i > 1$ we let $a_i = 1 - a_{i-1}$ if there is $y = [p_{i-1}, m] \in V(G)$ such that $xy \notin E(G)$, and $a_i = a_{i-1}$ otherwise.

(II) For each $j \in \{0,1,\ldots,k\}$ where $j = q(m')$ for some $m' \in X_{t_m}$ (and recall that there is at most one such m' for j since q is injective on each bag), the component b_j is determined as $b_j = (b^1, b^2, b^3)$ where, for $k = 1,2,3,$ $b^k = 1$ if and only if $\{x, [p_{i+k-2}, m']\} \in E(G)$.

(III) If undetermined by the previous point, b_j may be chosen arbitrarily.

Let G' be the induced subgraph of $P \boxtimes M_1$ determined by the previous assignment $\mapsto$; our remaining task is to prove that $\mapsto$ is an isomorphism of G to G'. By $\boxtimes$ and the definition of M_1, we know that edges of G and of G' are of the form $e = \{[p_i, m], [p_j, m']\}$ and $e' = \{[p_i, (m,*)], [p_j, (m',*)]\}$, respectively, where $j \in \{i-1, i, i+1\}$ and $mm' \in E(M)$ or $m = m'$.

In the case of $m = m'$, we get $e \in E(G) \iff e' \in E(G')$ already by the definition of the component a_i (a_j) in the point (I). For $mm' \in E(M)$, we get the same straightforwardly from the definition of the edge set of M_1, precisely the point ii. above, and from the (matching) point (II) of the definition of $\mapsto$. ◀

▶ Remark 4.7. Theorem 4.6 has a natural and straightforward extension to graphs $P \in \mathcal{H}$ where $\mathcal{H}$ is any graph class of bounded maximum degree (instead of the class of paths). We skip details due to their additional technical difficulty.

5 Concluding Remarks

The primary focus of our paper is an introduction of a new concept of potential interest, and as such it naturally brings many questions and open problems, (some of) which we briefly survey in this last section.

From the TCS perspective, the probably most important question is about the complexity of computing the $\mathcal{H}$-clique-width. Computing traditional clique-width exactly is NP-hard [14], and hence the same holds for computing $\mathcal{H}$-clique-width exactly in general. However, a question is whether for some special classes $\mathcal{H}$ one could compute exact $\mathcal{H}$-clique-width faster. This is trivially possible, by Claim 2.2 c), when $\mathcal{H}$ is the class of all graphs – which is uninteresting. Is it true that computing $\mathcal{H}$-clique-width exactly is NP-hard for every fixed family $\mathcal{H}$ except in "similarly trivial" cases?

On the other hand, traditional clique-width can be approximated in FPT time with respect to the solution value [18,21]. A big goal would be to extend this approximation result to $\mathcal{H}$-clique-width, perhaps with an additional parameter capturing some properties of $\mathcal{H}$. In particular, with respect to Section 4, we emphasize:

▷ Problem 5.1. Let $\mathcal{P}^\circ$ denote the class of reflexive paths. Can one, for input graph G, approximate $\mathcal{P}^\circ$-cw(G) in FPT time with respect to the solution value?

Next group of questions concerns combinatorial properties proved in this paper. In regard of Section 3, we bring the following one:

▷ Problem 5.2 (cf. Theorem 3.4). Can we characterize families $\mathcal{H}$ of loop graphs such that, for all graphs, bounded $\mathcal{H}$-clique-width implies bounded local clique-width?
This question may be interesting even when restricted to particular graph classes which are of unbounded local clique-width.

A more interesting and natural question, however, comes in a direct relation to the Planar product structure theorem and to Theorem 4.6. We know that graphs of bounded clique-width that do not contain large $K_{t,t}$ subgraphs are as well of bounded tree-width. A natural counterpart of this claim in the context of $\mathcal{P}^\circ$-clique-width would be:

▷ Problem 5.3 (cf. Theorem 4.1, Theorem 4.6). Assume a fixed integer t and an arbitrary graph G such that $\mathcal{P}^\circ$-cw$(G) \leq t$ and G has no $K_{t,t}$ subgraph. Is it then true that $G \subseteq P \boxtimes M$ where P is a path and M is a suitable graph of tree-width bounded in terms of t?

Another question, already mentioned in Section 2, is whether $\mathcal{H}$-clique-width is (at least asymptotically) closed under taking graph complement. This is a prominent and desired property of ordinary clique-width. It would be natural to ask whether, having any simple graph G and its complement $\bar{G}$, we can bound $\mathcal{H}$-cw(G) in terms of $\mathcal{H}$-cw$(\bar{G})$. However, classes $\mathcal{H}$ of bounded degree have bounded local clique-width (Theorem 3.4) and this property is not closed under taking complement.

Instead, we ask whether, for every graph H, there is a graph H' such that for all graphs G, the $\{H'\}$-clique-width of the complement $\bar{G}$ is bounded by a function of the $\{H\}$-clique-width of G. Although we do not have a simple concrete counterexample at hand, we conjecture this is not possible with arbitrary H. One can thus, when being closed under complements is a desirable property, consider only classes $\mathcal{H}$ which are closed under complements themselves (but even that subcase is not trivial), or enrich Definition 2.1 with an operation of adding edges between labels (i, v) and (j, w) over all pairs $(v, w) \in V(H)^2$ such that $vw \notin E(H)$ (note that the latter is much stronger than simply requiring $\mathcal{H}$ to be complement-closed).

We also suggest to study the special case of $\mathcal{T}^\circ$-clique-width when $\mathcal{H} = \mathcal{T}^\circ$ is the family of (all) reflexive trees. The related question in the context of the traditional product structure – that is which graph classes (other than, say, planar graphs) can be expressed as subgraphs of the strong products $T \boxtimes M$ where T is an arbitrary tree and M is of bounded tree-width, does not seem to be explicitly studied yet. We, however, do not have any progress in this direction so far.

Our last batch of questions concerns possible relations of $\mathcal{H}$-clique-width to the currently hot trend of studying structural graph properties through the lens of FO logic on graphs and of FO transductions – transformations of one graph into another defined by FO formulas. In this we use some logic-oriented terms which are not formally defined here (such as, in particular, of *FO transductions*) and we refer for their definitions, e.g., to [6].

First, one may ask for which families $\mathcal{H}$, classes of bounded $\mathcal{H}$-clique-width are monadically dependent, i.e., such that one cannot FO-transduce all finite graphs from graphs of bounded $\mathcal{H}$-clique-width. A partial answer is provided by Theorem 3.4 and Proposition 4.4, but a full characterization of such classes $\mathcal{H}$ is currently out of our reach. As witnessed by Proposition 4.4, classes of bounded $\mathcal{H}$-clique-width can be monadically independent even if $\mathcal{H}$ itself is monadically dependent.

Second, it is interesting to investigate whether and when, having a graph class $\mathcal{G}$ obtained as an FO transduction of a class of bounded $\mathcal{H}$-clique-width, one can find a class $\mathcal{H}^+$ depending on $\mathcal{H}$ (e.g., $\mathcal{H}^+$ an FO transduction of $\mathcal{H}$), such that the $\mathcal{H}^+$-clique-width of $\mathcal{G}$ is bounded. In relation to the Planar product structure, we formulate the following two specific questions in this direction:

▷ Problem 5.4. Assume that a graph class $\mathcal{G}$ is obtained from the class of planar graphs by an FO transduction τ. Is it true that one can give an FO transduction σ, depending on τ, such that the $\mathcal{P}^\sigma$-clique-width of $\mathcal{G}$ is bounded where $\mathcal{P}^\sigma$ is the class of loop graphs obtained from the class of all paths by σ?

Problem 5.4 seems to be much easier if we, instead of requiring bounded $\mathcal{P}^\sigma$-clique-width of every member of $\mathcal{G}$, require only that every graph from $\mathcal{G}$ has a bounded perturbation of bounded $\mathcal{P}^\sigma$-clique-width. This is possibly extensible to classes $\mathcal{H}$ of bounded degree.

▷ Problem 5.5. Let $\mathcal{P}^\sigma$ be the class of loop graphs obtained from the class of all paths by an FO transduction σ. Assume that $\mathcal{G}$ is a graph class of bounded $\mathcal{P}^\sigma$-clique-width and $\mathcal{G}$ is monadically stable, meaning that one cannot define on graphs of $\mathcal{G}$ an arbitrarily long linear order using FO formulas. Is it then true that there exists an FO transduction τ, such that $\mathcal{G}$ is obtained, by τ, from a graph class that admits the traditional product structure?

Third, Theorem 3.4 and Corollary 3.5 can be read as that if a class $\mathcal{H}$ is of bounded degree, then the FO model checking problem is FPT on all classes of bounded $\mathcal{H}$-clique-width. Classes of bounded degree are a prime example of those having FO model checking in FPT [22]. Unfortunately, a bold conjecture claiming that for every class $\mathcal{H}$ having complexity of the FO model checking problem in FPT, the complexity of the FO model checking problem is again in FPT on every class of bounded $\mathcal{H}$-clique-width (perhaps assuming a given decomposition), is very likely false due to the construction given in Proposition 4.4 – the constructed graphs there actually FO transduce all graphs. Hence, it follows from the results of Dreier, Mählmann, and Toruńczyk [8] that FO model checking on classes of bounded $\mathcal{H}_{half}$-clique-width, where $\mathcal{H}_{half}$ denotes the class of reflexive half-graphs, is AW[⋆]-hard. However, a weaker version of this conjecture, with a suitable additional restriction on $\mathcal{H}$, might still be true.

Abstract

Speedable numbers are real numbers which are algorithmically approximable from below and whose approximations can be accelerated nonuniformly. We begin this article by answering a question of Barmpalias by separating a strict subclass that we will refer to as *superspeedable* from the speedable numbers; for elements of this subclass, acceleration is possible uniformly and to an even higher degree. This new type of benign left-approximation of numbers then integrates itself into a hierarchy of other such notions studied in a growing body of recent work. We add a new perspective to this study by juxtaposing this hierachy with the well-studied hierachy of algorithmic randomness notions.

1 Introduction

In theoretical computer science, the concepts of randomness and of computation speed, as well as their interactions with each other, play an important role. For example, one can study whether access to sources of random information can enable or simplify the computation of certain mathematical objects, for example by speeding up computations of difficult problems. This is a recurring paradigm of theoretical computer science, and there is more than one way of formalizing it, but the perhaps most well-known instance is the difficult open question in the field of complexity theory of whether P is equal to BPP.

A recent line of research could be seen as investigating the reverse direction: to what degree can objects that are random be quickly approximated? Before answering this question, we need to define what we understand by random. The answer is provided by the research field of information theory that deals with questions of compressibility of information, where randomly generated information will be difficult to compress, due to its lack of internal regularities. The subfield of algorithmic randomness, which set out to unify these and other topics and to understand what actually makes a mathematical object random, has produced a wealth of insights into questions about computational properties that random objects must, may, or may not possess. The general pattern in this area is that we put at our disposal algorithmic tools to detect regularities in sequences. Those sequences that are "random enough" to resist these detection mechanisms are then considered random. Many different "resistance levels" have been identified that give rise to randomness notions of different strengths.

For completeness, we define the two central randomness notions featuring in this article, introduced by Martin-Löf [12] and Schnorr [16] respectively: A *randomness test* is a sequence $(U_n)_{n\in\mathbb{N}}$ of uniformly effectively open subsets of $\mathbb{R}$ and we say that it *covers* an $x \in \mathbb{R}$ if and only if $x \in \bigcap_n U_n$. Write μ for the Lebesgue measure on $\mathbb{R}$; if $\mu(U_n) \leq 2^{-n}$ for all $n \in \mathbb{N}$, then we call $(U_n)_{n\in\mathbb{N}}$ a *Martin-Löf test*, and if an $x \in \mathbb{R}$ is not covered by any such test, then we call it *Martin-Löf random.* If we even require that $\mu(U_n) = 2^{-n}$ for all $n \in \mathbb{N}$, then we call $(U_n)_{n\in\mathbb{N}}$ a *Schnorr test*, and an $x \in \mathbb{R}$ that is not covered by any such test *Schnorr random.* It is well-known that Schnorr randomness is a strictly weaker notion than Martin-Löf randomness; that is, there exist more Schnorr random numbers than Martin-Löf random ones. For the rest of the article, we assume that the reader is familiar with these topics; see Calude [3], Downey and Hirschfeldt [4], Li and Vitányi [10], or Nies [14] for comprehensive overviews.

With those randomness paradigms in place, we can study the interactions between randomness and computation speeds. We will focus on a class of objects that can be approximated by an algorithm, and will be interested in the possible speeds of these approximations.

▶ **Definition 1.** *Let x be a real number. For a fixed sequence $(x_n)_n$ of real numbers converging to it from below, write $\rho(n)$ for the quantity $\frac{x_{n+1}-x_n}{x-x_n}$ for each $n \in \mathbb{N}$, and call $(\rho(n))_n$ the* speed quotients *of $(x_n)_n$.*

▶ **Definition 2.** *If there exists a* left-approximation *of x, that is, a computable increasing sequence of rational numbers converging to x, then we call x* left-computable*. If there even exists a left-approximation $(x_n)_n$ with speed quotients $(\rho(n))_n$ such that $\rho := \limsup_{n\to\infty} \rho(n) > 0$, then we call x* speedable*.*

Left-computable numbers can be Martin-Löf random; the standard example is *Chaitin's* Ω, the measure of the domain of an optimally universal prefix-free Turing machine. It is also known that there exist left-computable Schnorr randoms that are not Martin-Löf random.

The notion of speedability was introduced by Merkle and Titov. They made the interesting observation that speedability is incompatible with Martin-Löf randomness [13, Theorem 10] and asked the question whether the converse holds, that is, whether there exist left-computable numbers which are neither speedable nor Martin-Löf random. A positive answer would have been an interesting new characterization of Martin-Löf randomness; however, Hölzl and Janicki [8, Corollary 62] showed that such a characterization does *not* hold. They also introduced the term *benign approximations* when referring to subclasses of the left-computable numbers that possess special approximations that are in some sense better behaved than general approximations from below. One example is speedability; another that will play a role in this article is the following.

▶ **Definition 3** (Hertling, Hölzl, Janicki [7]). *A real number x is called* regainingly approximable *if there exists a computable increasing sequence of rational numbers $(x_n)_n$ converging to x with $x - x_n \leq 2^{-n}$ for infinitely many $n \in \mathbb{N}$.*

Obviously, every regainingly approximable number is left-computable and every computable number is regainingly approximable, but none of these implications can be reversed by results of Hertling, Hölzl, Janicki [7].

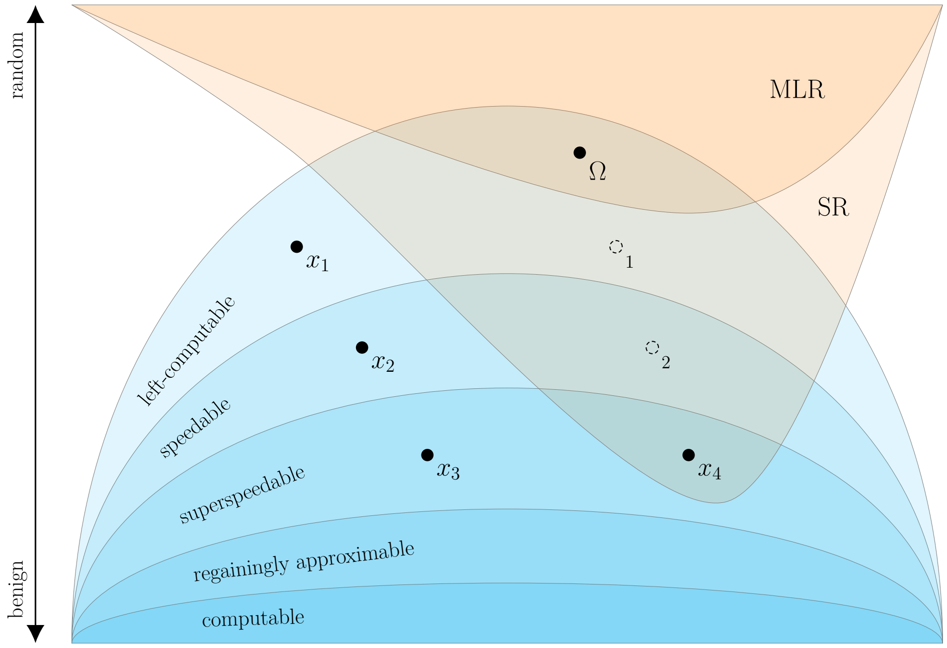

Figure 1 The number x_1 was constructed by Hölzl and Janicki [8, Corollary 62]; by construction it is nearly computable, thus weakly 1-generic by a result of Hoyrup [9], thus not Schnorr random (see, for instance, Downey and Hirschfeldt [4, Proposition 8.11.9]). The number x_2 constructed in Theorem 8 cannot be Schnorr random either, because it is by construction not immune. To see that x_3 exists, consider the example used in the proof of Corollary 16; it is strongly left-computable, thus not immune, thus not Schnorr random. Finally, x_4 is constructed in Theorem 21.
It is an open question whether numbers ◌$_1$ or ◌$_2$ exist; see the discussion in Section 6.

Merkle and Titov also showed that the property of being speedable does not depend on the choice of ρ, that is, if some left-computable number is speedable via some ρ witnessed by some left-approximation, it is also speedable via any other $\rho' < 1$ witnessed by some other left-approximation. However, their proof is highly nonuniform, which led to Barmpalias [1] asking whether every such number also has a *single* left-approximation with $\limsup_{n\to\infty} \rho(n) = 1$.

We answer this question negatively in this article by showing that the requirement to achieve $\limsup_{n\to\infty} \rho(n) = 1$ is a strictly stronger condition that defines a strict subset of the speedable numbers which we will call superspeedable. We then show that the regainingly approximable numbers are strictly contained in this subset. Thus within the speedable numbers there is a strict hierarchy of notions of benign approximations, namely computable implies regainingly approximable implies superspeedable implies speedable.

Wu [18] called finite sums of binary expansions of computably enumerable sets *regular reals*. We show that these reals are a strict subset of the superspeedable numbers as well; in particular every binary expansion of a computably enumerable set is superspeedable. Then we show that finite sums of left-computable numbers can only be superspeedable if at least one of their summands is superspeedable.

With this new approximation notion identified and situated in the hierarchy of benign approximability, it is then natural to wonder how it interacts with randomness. We will show that unlike the Martin-Löf randoms, which by the result of Merkle and Titov [13] cannot even be speedable, the Schnorr randoms may even be superspeedable; however they cannot be regainingly approximable.

2 Speedability versus immunity

Merkle and Titov [13] showed that all non-high and all strongly left-computable numbers are speedable. On the other hand they established that Martin-Löf randoms cannot be speedable. In this section we show that a left-computable number which is not immune has to be speedable.

We first observe that, as an alternative to Definition 2 above, speedability could also be defined using two other forms of speed quotients; this will prove useful in the following.

▶ **Proposition 4.** *Let $x \in \mathbb{R}$. For an increasing sequence of rational numbers $(x_n)_n$ converging to x with speed quotients $(\rho(n))_n$ the following statements are easily seen to be equivalent:*

1. $\limsup_{n\to\infty} \rho(n) > 0$*, that is,* $(x_n)_n$ *witnesses the speedability of* x*;*
2. $\limsup_{n\to\infty} \frac{x_{n+1}-x_n}{x-x_{n+1}} > 0$*;*
3. $\liminf_{n\to\infty} \frac{x-x_{n+1}}{x-x_n} < 1$. ◀

For any set $A \subseteq \mathbb{N}$, we define the real number $x_A := \sum_{n\in A} 2^{-(n+1)} \in [0,1]$. Clearly, A is computable if and only if x_A is computable. If A is only assumed to be computably enumerable, then x_A is a left-computable number; the converse is not true as pointed out by Jockusch (see Soare [17]). If there does exist a computably enumerable set $A \subseteq \mathbb{N}$ with $x_A = x$, then $x \in [0,1]$ is called *strongly left-computable.*

Recall that an infinite set $A \subseteq \mathbb{N}$ is *immune* if it does not have an infinite computably enumerable (or, equivalently, computable) subset. We call it *biimmune* if both A and its complement $\bar{A}$ are immune. A real number $x \in [0,1]$ is called *immune* if there exists an immune set $A \subseteq \mathbb{N}$ with $x_A = x$; analogously for *biimmune.*

▶ **Theorem 5.** *Every left-computable number that is not immune is speedable.*

Before we give the proof we mention that left-computable numbers

- whose binary expansion is not biimmune or
- whose binary expansion is of the form $A \oplus A$

can be shown to be speedable by similar arguments as below.

Proof of Theorem 5. Let x be a left-computable real that is not immune. If it is computable, the theorem holds trivially, thus assume otherwise. Let A be such that $x = x_A$; then there exists a computable increasing function $h\colon \mathbb{N} \to \mathbb{N}$ with $h(\mathbb{N}) \subseteq A$. Let $(B[n])_n$ be a computable sequence of finite sets of natural numbers such that the sequence $(x_{B[n]})_n$ is increasing and converges to x_A. Define the function $r\colon \mathbb{N} \to \mathbb{N}$ recursively via

$$r(0) := 0, \quad r(n+1) := \min\{m > r(n)\colon \{h(0), \dots, h(n)\} \subseteq B[m]\}.$$

It is easy to see that r is well-defined, computable and increasing. Let

$$s_n := \min\{m \in \mathbb{N}\colon\ m \in B[r(n+1)] \setminus B[r(n)]\}$$

for all $n \in \mathbb{N}$. Clearly, the sequence $(s_n)_n$ is well-defined and tends to infinity. Finally, define the sequence $(C[n])_n$ via

$$C[0] := \emptyset, \quad C[n+1] := B[r(n+1)] \restriction (s_n + 1),$$

for all $n \in \mathbb{N}$. Clearly, $(C[n])_n$ is a computable sequence of finite sets of natural numbers, which converge pointwise to A, and the sequence $(x_{C[n]})_n$ is increasing and converges to x.

We claim that there are infinitely many n such that $s_n < h(n)$; this is because otherwise, for almost all n, the sets $B[r(n)], B[r(n+1)], \dots$ would all mutually agree on their first $h(n) - 1$ bits, hence their limit A would be computable, contrary to our assumption. Thus, fix one of the infinitely many n with $s_n < h(n)$ and let $n' \geq n$ be maximal such that $s_{n'} < h(n)$. Then the sets $B[r(n'+1)], B[r(n'+2)], \ldots$ all contain $h(n)$ and, by definition of s and n', agree mutually on their first $(h(n)-1)$ bits; in other words, they even agree on their first $h(n)$ bits. But by choice of n', these sets also agree with the sets $C[n'+1], C[n'+2], \ldots$, respectively, on their first $h(n)$ bits; thus these latter sets must also contain $h(n)$ and agree mutually on their first $h(n)$ bits. By definition, the set $C[n']$ does *not* contain $h(n)$; thus, in summary, we have $x_{C[n'+1]} - x_{C[n']} \geq 2^{-h(n)}$ and $x - x_{C[n'+1]} \leq 2^{-h(n)}$, hence $\frac{x_{C[n'+1]}-x_{C[n']}}{x-x_{C[n'+1]}} \geq 1$.

Since there are infinitely many such n and corresponding n', the left-approximation $(x_{C[n]})_n$ of x witnesses that x is speedable. ◀

3 Superspeedability

We now strengthen the conditions in Proposition 4 to obtain the following new definition.

▶ **Definition 6.** *Let $x \in \mathbb{R}$. For an increasing sequence $(x_n)_n$ converging to x with speed quotients $(\rho(n))_n$ the following statements are easily seen to be equivalent:*

1. $\limsup_{n\to\infty} \rho(n) = 1$*;*
2. $\limsup_{n\to\infty} \frac{x_{n+1}-x_n}{x-x_{n+1}} = \infty$*;*
3. $\liminf_{n\to\infty} \frac{x-x_{n+1}}{x-x_n} = 0$.

We call x superspeedable *if it has a left-approximation $(x_n)_n$ with these properties.*

The following statement, which bears some similarity to Theorem 5, shows that one simple cause for a left-computable number to be superspeedable is for it to have a left-approximation which permanently leaves arbitrarily long blocks of bits fixed to 0.

▶ **Proposition 7.** *Fix a sequence $(I_i)_{i\in\mathbb{N}}$ of disjoint finite intervals in $\mathbb{N}$ with the property that $|I_i| \geq i$ for all n. If $x \in \mathbb{R}$ has a left-approximation $(x_n)_{n\in\mathbb{N}}$ consisting only of dyadic rationals and such that for all $i \in \mathbb{N}$ and $n \in \mathbb{N}$ we have $x_n(j) = 0$ for all $j \in I_i$, then x is superspeedable.*

Proof. Fix any i and let n be maximal such that $x_n(j) \neq x(j)$ for some $j < \min I_i$; that is, let $n+1$ be the last stage at which a bit left of I_i changes during the approximation of x. Then, on the one hand, $x_{n+1} - x_n \geq 2^{-\min(I_i)}$. On the other hand, by the maximality of n and by the assumptions on $(x_n)_{n\in\mathbb{N}}$, we must have $x - x_{n+1} \leq 2^{-\max(I_i)}$. Therefore we have

$$\frac{x-x_{n+1}}{x-x_n} \leq \frac{x-x_{n+1}}{x_{n+1}-x_n} \leq \frac{2^{-\max(I_i)}}{2^{-\min(I_i)}} \leq 2^{-(i-1)},$$

which tends to 0 as i tends to infinity. ◀

Obviously, every superspeedable number is speedable. Barmpalias [1] asked whether the converse is true as well. We give a negative answer with the following theorem and corollary.

▶ **Theorem 8.** *There is a left-computable number that is neither immune nor superspeedable.*

Proof. Let $r\colon \mathbb{N} \to \mathbb{N}$ be the function defined by $r(n) := \max\{\ell \in \mathbb{N}\colon\ 2^\ell \text{ divides } n+1\}$, that is, the characteristic sequence of r is the member of Baire space with the initial segment

0102010301020104010201 03 . . .

We construct a number α by approximating its binary expansion A. We will slightly abuse notation and silently identify real numbers with their infinite binary expansions; similarly we identify finite binary sequences σ with the rational numbers $0.\sigma$.

We approximate A in stages where during stage $s \in \mathbb{N}$ we define a set $A[s]$ such that the sets $A[s]$ converge pointwise to A. For all s and all n with $r(n) = 0$, let $A[s](n) = 0$; and for all s and all n with $r(n) = 1$, let $A[s](n) = 1$. We refer to all remaining bits as the *coding bits*. More precisely, we refer to all bits with $r(n) = e + 2$ as the *e-coding bits* and we let $(c_i^e)_i$ be the sequence of the positions of all e-coding bits in ascending order.

If $b = c_i^e$ for some e and i, then we say that position b is *threatened at stage s* if $A[s](b) = 0$ and $A[s]\restriction c_{i+1}^e = B_e[s]\restriction c_{i+1}^e$, where $(B_0[s])_s, (B_1[s])_s, \ldots$ is some fixed uniformly effective enumeration of all left-computable approximations.

Construction. At every stage s, if there exists a least coding bit $b \leq s$ that is threatened, then set $A[s+1](b) = 1$ and $A[s+1](c) = 0$ for all coding bits $c > b$. For all other $n \in \mathbb{N}$, leave bit n unchanged, that is, $A[s+1](n) = A[s](n)$.

Verification. By construction, once a coding bit has been set to 1, it can only be set back to 0 if a coding bit at an earlier position is set from 0 to 1. From this it follows by an obvious inductive argument that $A[s]$ converges to some limit A in a left-computable fashion; that is, interpreted as real numbers, the values $A[0], A[1], \ldots$ are nondecreasing. Thus α is left-computable.

As it contains all numbers n with $r(n) = 1$, the set A we are constructing is trivially not immune. All that remains to show is that it is not superspeedable. To that end, fix any e and assume that that the left-computable approximation $(B_e[s])_s$ converges to A; as otherwise there is nothing to prove for e. We will show that this left-computable approximation does not witness superspeedability of A.

▷ Claim. There are stages $s_0 < s_1 < \ldots$ such that for all $i \geq 0$, at stage s_i, the coding bit $b_i = c_i^e$ is threatened for the last time and is the least coding bit that is threatened at this stage, and such that A has already converged at this stage up to its $(b_i + 4)$-th bit; that is, for all $\ell \geq 1$ we have $A[s_i]\restriction(b_i + 4) = A[s_i + \ell]\restriction(b_i + 4) = A\restriction(b_i + 4)$.

Proof. Fix some e-coding bit $b_i = c_i^e$. By the discussion preceding the claim, there is some least stage s such that set A has already converged up to its b_i-th bit. By construction, it must hold that $A[s](b_i) = 0$ and since the left-approximation $(B_e[s])_s$ converges to A, there must be a stage $s' > s$ at which b_i becomes threatened and is the least threatened coding bit. Thus, during stage s', the bit $A(b_i)$ is set permanently to 1 and, because the two bits following b_i are no coding bits, A has now converged up to its $(b_i + 4)$-th bit. Therefore, it suffices to set $s_i = s'$ and to observe that we have $s_i < s_{i+1}$ for all i because e-coding bit c_{i+1}^e is set to 0 at stage s_i, hence is threatened again after stage s_i. ◁

Let $s_0, s_1, \ldots$ be the stages from the last claim.

▷ Claim. There is an $\rho_e < 1$ only depending on e such that for all i and $s \in \{s_i, \ldots, s_{i+1} - 1\}$,

$$\frac{B_e[s+1] - B_e[s]}{A - B_e[s]} \leq \rho_e.$$

Proof. Fix some i and some stage s as above. Let $b = c_i^e$ and let $b' = c_{i+1}^e$. Then A has already converged up to its b-th bit at stage s_i and by definition of a threat we must have $B_e[s_i]\restriction b = A[s_i]\restriction b$. But the left-approximation $(B_e[s])_s$ converges to A, hence can never "overshoot" A and thus at stage s_i has already converged up to its b-th bit as well. Consequently, we have $B_e[s+1] - B_e[s] \leq 2^{-(b-1)}$.

By construction and our assumptions,

- at stage s_{i+1}, bit b' is set from 0 to 1,
- bit $b'+1$ permanently maintains value 0 and,
- by definition of a threat, $A[s_{i+1}]$ and $B_e[s_{i+1}]$ agree on their first $b'+2 < c^e_{i+2}$ many bits.

This implies that

$$A - B_e[s+1] \geq A[s_{i+1}+1] - B_e[s_{i+1}] \geq 2^{-(b'+1)} = 2^{-(b+2^{e+3}+1)},$$

and in summary we have

$$\frac{B_e[s+1]-B_e[s]}{A-B_e[s]} = \frac{B_e[s+1]-B_e[s]}{(A-B_e[s+1])+(B_e[s+1]-B_e[s])} \leq \frac{2^{-(b-1)}}{2^{-(b+2^{e+3}+1)}+2^{-(b-1)}} \leq \frac{2^{2+2^{e+3}}}{1+2^{2+2^{e+3}}} < 1,$$

hence there is a constant $\rho_e < 1$ as claimed. ◁

Since e was arbitrary such that $(B_e[s])_s$ converges to A, there cannot be a left-approximation that witnesses superspeedability of A. ◀

By Theorem 5, the number α constructed in Theorem 8 is speedable.

▶ **Corollary 9.** *There exists a speedable number which is not superspeedable.* ◀

Thus, superspeedability is strictly stronger than speedability; we now proceed to identify interesting classes of numbers that have this property. We begin with the class of regainingly approximable numbers. It was shown by Hölzl and Janicki [8] that regainingly approximable numbers are speedable. This result can be strengthened; to show that regainingly approximable numbers are in fact superspeedable, we will use the following characterization.

▶ **Proposition 10** (Hertling, Hölzl, Janicki [7]). *For a left-computable number x the following are equivalent:*

(1) *x is regainingly approximable.*

(2) *For every computable unbounded function $f\colon \mathbb{N} \to \mathbb{N}$ there exists a computable increasing sequence of rational numbers $(x_n)_n$ converging to x with $x - x_n \leq 2^{-f(n)}$ for infinitely many $n \in \mathbb{N}$.*

▶ **Theorem 11.** *Every regainingly approximable number is superspeedable.*

Proof. Let x be a regainingly approximable number, and fix a computable increasing sequence $(x_n)_n$ of rational numbers that converges to x and satisfies $x - x_n \leq \frac{1}{(n+1)!}$ for infinitely many $n \in \mathbb{N}$. Define the sequence $(y_n)_n$ with $y_n := x_n - \frac{1}{n!}$ for all $n \in \mathbb{N}$. Surely, this sequence is computable, increasing and converges to x as well. Considering any of the $n \in \mathbb{N}$ with $x - x_n \leq \frac{1}{(n+1)!}$, we obtain

$$\frac{y_{n+1}-y_n}{x-y_n} = \frac{(x_{n+1}-x_n)+\frac{1}{n!}-\frac{1}{(n+1)!}}{(x-x_n)+\frac{1}{n!}} > \frac{\frac{1}{n!}-\frac{1}{(n+1)!}}{\frac{1}{n!}+\frac{1}{(n+1)!}} = \frac{\frac{n}{(n+1)!}}{\frac{n+2}{(n+1)!}} = \frac{n}{n+2}.$$

Thus we have $\limsup_{n\to\infty} \frac{y_{n+1}-y_n}{x-y_n} = 1$. Therefore, x is superspeedable. ◀

The next class of numbers that we investigate is the following.

▶ **Definition 12** (Wu). *A real number is called* regular *if it can be written as a finite sum of strongly left-computable numbers.*

Note that this includes in particular all binary expansions of computably enumerable sets. Using the following helpful definition and propositions, we now show that every regular number is superspeedable.

▶ **Definition 13.** *Let $f\colon \mathbb{N} \to \mathbb{N}$ be a function which tends to infinity. Then the function $u_f\colon \mathbb{N} \to \mathbb{N}$ is defined by $u_f(n) := |\{k \in \mathbb{N}\colon f(k) = n\}|$ for all $n \in \mathbb{N}$.*

If f is computable, then u_f possesses a computable approximation from below, namely $u_f[0](n) := 0$ and, for all $n, t \in \mathbb{N}$,

$$u_f[t+1](n) := \begin{cases} u_f[t](n) + 1 & \text{if } f(t) = n, \\ u_f[t](n) & \text{otherwise.} \end{cases}$$

▶ **Proposition 14.** *A real number x is regular if and only if there exists a computable function $f\colon \mathbb{N} \to \mathbb{N}$ with $\sum_{k=0}^{\infty} 2^{-f(k)} = x$, a so-called* name *of f, such that u_f is bounded by some constant.* ◀

▶ **Theorem 15.** *Every regular number is superspeedable; in particular this holds for every strongly left-computable number.*

Proof. Let x be a regular number. Fix some computable name $f\colon \mathbb{N} \to \mathbb{N}$ for x and some constant $c \in \mathbb{N}$ with $u_f(n) \leq c$ for all $n \in \mathbb{N}$. We define two sequences of natural numbers $(a_n)_n$ and $(b_n)_n$ and a sequence of sets of natural numbers $(I_n)_n$ by

$$a_n := \frac{n(n+1)}{2}, \quad b_n := a_n + n = a_{n+1} - 1, \quad I_n := \{a_n, \ldots, b_n\},$$

for all $n \in \mathbb{N}$. It is easy to verify that the set $\{I_n\colon n \in \mathbb{N}\}$ is a partition of $\mathbb{N}$ and that we also have $|I_n| = n + 1$ for all $n \in \mathbb{N}$.

We call a stage $s \in \mathbb{N}$ a *true stage* if we have $f(s) < f(t)$ for all $t > s$. Since f tends to infinity, there are infinitely many true stages. For any $n, s \in \mathbb{N}$, we say that the interval I_n is *incomplete* at stage s if there exists some stage $t > s$ with $f(t) \in I_n$. Otherwise, we say that I_n is *complete* at s. Since f tends to infinity, every interval is complete at some stage. Therefore, we can define the sequence $(\theta_n)_n$ with $\theta_n := \min\{t \in \mathbb{N}\colon I_n \text{ is complete at stage } t\}$ for all $n \in \mathbb{N}$. In order to show that x is superspeedable, we consider several cases:

- If there are infinitely many $n \in \mathbb{N}$ with $f(\mathbb{N}) \cap I_n = \emptyset$, then x is superspeedable for the reasons considered in Proposition 7; more explicitly, in this case, consider such an n with $a_n > \min_{k\in\mathbb{N}} f(k)$ and let $s \in \mathbb{N}$ be the latest true stage with $f(s) < a_n$. Then we have $\sum_{k=s+1}^{\infty} 2^{-f(k)} \leq c \cdot 2^{-b_n}$ due to $f(\mathbb{N}) \cap I_n = \emptyset$, and we obtain

$$\frac{2^{-f(s)}}{\sum_{k=s+1}^{\infty} 2^{-f(k)}} > \frac{2^{-a_n}}{c \cdot 2^{-b_n}} = \frac{2^{-a_n}}{c \cdot 2^{-(a_n+n)}} = \frac{2^n}{c}.$$

  As there exist infinitely many n as above, x is superspeedable.
- Otherwise, we can assume w.l.o.g. that $f(\mathbb{N}) \cap I_n \neq \emptyset$ for all $n \in \mathbb{N}$.
  Suppose that there are infinitely many $n \in \mathbb{N}$ with some stage $s \in \mathbb{N}$ at which I_n is incomplete and I_{n+1} is complete. Let $t > s$ be the earliest true stage at which $I_1, \ldots, I_n$ are all complete. On the one hand, we have $f(t) < a_{n+1}$. On the other hand we have $\sum_{k=t+1}^{\infty} 2^{-f(k)} \leq c \cdot 2^{-b_{n+1}}$, since, in particular, I_{n+1} is complete at stage t. We obtain

$$\frac{2^{-f(s)}}{\sum_{k=s+1}^{\infty} 2^{-f(k)}} > \frac{2^{-a_{n+1}}}{c \cdot 2^{-b_{n+1}}} = \frac{2^{-a_{n+1}}}{c \cdot 2^{-(a_{n+1}+n+1)}} = \frac{2^{n+1}}{c}.$$

  As there exist infinitely many n as above, x is superspeedable.

- Otherwise, we can assume w.l.o.g. that $(\theta_n)_n$ is an increasing sequence. This also implies that θ_n is a true stage for every $n \in \mathbb{N}$. Define the sequence $(d_n)_n$ by $d_n := b_n - f(\theta_n)$. Suppose that $(d_n)_n$ is unbounded; then for every $n \in \mathbb{N}$ we have

$$\frac{2^{-f(\theta_n)}}{\sum_{k=\theta_n+1}^{\infty} 2^{-f(k)}} = \frac{2^{-f(\theta_n)}}{c \cdot 2^{-b_n}} = \frac{2^{b_n - f(\theta_n)}}{c} = \frac{2^{d_n}}{c}.$$

  Therefore, x is superspeedable.

- Otherwise, $(d_n)_n$ is bounded. Fix some natural number $D \geq 1$ with $d_n \leq D$ for all $n \in \mathbb{N}$. Define the sequences $(T_n)_n$ and $(T_n[t])_{n,t}$ in $\{0, \ldots, c\}^D$ as follows:

$$T_n := (u_f(b_n - D + 1), \ldots, u_f(b_n)), \quad T_n[t] := (u_f[t](b_n - D + 1), \ldots, u_f[t](b_n))$$

  Clearly, we have $\lim_{t\to\infty} T_n[t] = T_n$ for all $n \in \mathbb{N}$. Fix some D-tuple $T \in \{0, \ldots, c\}^D$ satisfying $T_n = T$ for infinitely many $n \in \mathbb{N}$. Assume w.l.o.g. that there are infinitely many odd numbers n with this property, and recursively define the function $s\colon \mathbb{N} \to \mathbb{N}$ as follows: Let $s(0) := 0$, and define $s(m+1)$ as the smallest stage $t > s(m)$ such that there is some odd number $n \in \mathbb{N}$ with $T_n[t] = T$ and $T_n[t] \neq T_n[s(m)]$. Clearly, s is well-defined, computable and increasing. Finally, define the computable and increasing sequence $(x_n)_n$ by $x_n := \sum_{k=0}^{s(n)} 2^{-f(k)}$ for all $n \in \mathbb{N}$; this clearly converges to x. Let $n \in \mathbb{N}$ be an even number with $T_{n+1} = T$. By the previous assumption that $(\theta_n)_n$ is increasing, there exists a uniquely determined number $m \in \mathbb{N}$ with $s(m+1) = \theta_{n+1}$. Similarly, by the definition of s, we have $s(m) < \theta_n$. On the one hand, we have $x_{m+1} - x_m \geq 2^{-b_n}$. On the other hand, we have $x - x_{m+1} \leq c \cdot 2^{-b_{n+1}}$. So we finally obtain

$$\frac{x_{m+1} - x_m}{x - x_{m+1}} \geq \frac{2^{-b_n}}{c \cdot 2^{-b_{n+1}}} = \frac{2^{b_{n+1} - b_n}}{c} = \frac{2^{a_{n+1} - a_n + 1}}{c} = \frac{2^{n+2}}{c}.$$

  As there exist infinitely many n as above, x is superspeedable. ◀

As a corollary of the theorem, we obtain that the converse of Theorem 11 does not hold.

▶ **Corollary 16.** *Not every superspeedable number is regainingly approximable.*

Proof. By Theorem 15, every strongly left-computable number is superspeedable. However, Hertling, Hölzl, and Janicki [7] constructed a strongly left-computable number that is not regainingly approximable. ◀

Similarly, the converse of Theorem 15 is not true either, as the following observation shows.

▶ **Proposition 17.** *Not every superspeedable number is regular.*

Proof. Hertling, Hölzl, and Janicki [7] constructed a regainingly approximable number α such that for infinitely many n it holds that $K(\alpha\restriction n) > n$. By Theorem 11, this α is superspeedable. However, it cannot be regular, as it is easy to see that the initial segment Kolmogorov complexities of regular numbers must be logarithmic everywhere. ◀

4 Superspeedability and additivity

In this section we study the behaviour of superspeedability with regards to additivity. The following technical statement will be useful.

▶ **Lemma 18.** *Let α and β be left-computable numbers, and let $(c_n)_n$ be a computable increasing sequence of rational numbers converging to $\alpha + \beta$. Then there exist computable increasing sequences of rational numbers $(a_n)_n$ and $(b_n)_n$ converging to α and β, respectively, with $a_n + b_n = c_n$ for all $n \in \mathbb{N}$.*

Proof. Given two computable increasing sequences of rational numbers $(d_n)_n$ and $(e_n)_n$ converging to α and β, respectively, fix $N \in \mathbb{N}$ with

$$-N < \min\{d_0, e_0\} \quad \text{and} \quad -2N < c_0,$$

and define $a_{-1} := b_{-1} := -N$ and $c_{-1} := -2N$. We will inductively define an increasing function $s\colon \mathbb{N} \to \mathbb{N}$ as well as the desired sequences $(a_n)_n$ and $(b_n)_n$.

For every $n \in \mathbb{N}$, define $s(n)$ such that the inequalities

$$d_{s(n)} > a_{n-1}, \quad e_{s(n)} > b_{n-1}, \quad d_{s(n)} + e_{s(n)} \geq c_n$$

are satisfied; this is obviously always possible. Assume by induction that $a_{n-1} + b_{n-1} = c_{n-1}$. Note that the quantities $d_{s(n)} - a_{n-1}$ and $e_{s(n)} - b_{n-1}$ and $c_n - c_{n-1}$ are positive rational numbers. Thus there exist natural numbers $p_a, p_b, q \geq 1$ and $p_c \geq 2$ with

$$d_{s(n)} - a_{n-1} = \frac{p_a}{q}, \quad e_{s(n)} - b_{n-1} = \frac{p_b}{q}, \quad c_n - c_{n-1} = \frac{p_c}{q}.$$

This implies

$$\frac{p_a}{q} + \frac{p_b}{q} = \left(d_{s(n)} + e_{s(n)}\right) - (a_{n-1} + b_{n-1}) \geq c_n - c_{n-1} = \frac{p_c}{q},$$

hence $p_a + p_b \geq p_c$. Let $m := \min\{p_a, p_c - 1\}$, and finally define $a_n := a_{n-1} + \frac{m}{q}$ and $b_n := b_{n-1} + \frac{p_c - m}{q}$. It is easy to verify that $(a_n)_n$ and $(b_n)_n$ are both computable and increasing sequences, converge to α and β, respectively, and satisfy $a_n + b_n = c_n$ for all $n \in \mathbb{N}$. ◀

Using the lemma, we can establish the following result.

▶ **Theorem 19.** *Let α and β be left-computable numbers such that $\alpha + \beta$ is superspeedable. Then at least one of α or β must be superspeedable.*

We point out that it can be shown that the converse does not hold.

Proof. Suppose that neither α nor β are superspeedable. Let $\gamma := \alpha + \beta$, and let $(c_n)_n$ be a computable increasing sequence of rational numbers converging to γ. We show that there is some constant $\rho \in (0, 1)$ with $\frac{c_{n+1} - c_n}{\gamma - c_n} \leq \rho$ for all $n \in \mathbb{N}$. Due to Lemma 18, there exist computable increasing sequences of rational numbers $(a_n)_n$ and $(b_n)_n$ converging to α and β, respectively, with $a_n + b_n = c_n$ for all $n \in \mathbb{N}$. Since α and β are both not superspeedable, there is some constant $\rho \in (0, 1)$ satisfying both $\frac{a_{n+1} - a_n}{\alpha - a_n} \leq \rho$ and $\frac{b_{n+1} - b_n}{\beta - b_n} \leq \rho$ for all $n \in \mathbb{N}$. Considering some arbitrary $n \in \mathbb{N}$, we obtain

$$\begin{aligned}\frac{c_{n+1} - c_n}{\gamma - c_n} &= \frac{(a_{n+1} - a_n) + (b_{n+1} - b_n)}{(\alpha - a_n) + (\beta - b_n)} = \frac{\frac{a_{n+1} - a_n}{\alpha - a_n} \cdot (\alpha - a_n) + \frac{b_{n+1} - b_n}{\beta - b_n} \cdot (\beta - b_n)}{(\alpha - a_n) + (\beta - b_n)} \\ &\leq \frac{\max\left\{\frac{a_{n+1} - a_n}{\alpha - a_n}, \frac{b_{n+1} - b_n}{\beta - b_n}\right\} \cdot ((\alpha - a_n) + (\beta - b_n))}{(\alpha - a_n) + (\beta - b_n)} \leq \rho.\end{aligned}$$

Thus, γ is not superspeedable either. ◀

5 Benignness versus randomness

Recall that Merkle and Titov [13, Theorem 10] made the observation that Martin-Löf randomness is incompatible with speedability. In this section, we study the analogous question for the weaker randomness notion of Schnorr randomness. We begin with the easy observation that Schnorr randomness is incompatible with the rather demanding benignness notion of regaining approximability; the argument is a straight-forward modification of the result of Merkle and Titov.

▶ **Proposition 20.** *No regainingly approximable number can be Schnorr random.*

Proof. Let x be regainingly approximable, witnessed by its left-approximation $(x_n)_n$. Then x is covered by the Solovay test $(S_n)_n$ where $S_n = (x_n - 2^{-(n-1)}, x_n + 2^{-(n-1)})$ for all $n \in \mathbb{N}$. This test is *total*, that is, the sum of the measures of its components is computable; then, by a result of Downey and Griffiths [5, Theorem 2.4], x cannot be Schnorr random. ◀

In light of this result, it is natural to ask how far down into the hierarchy of benignness notions the class of Schnorr randoms reaches. The answer is given by the following theorem.

▶ **Theorem 21.** *There exists a superspeedable number which is Schnorr random.*

We point out that the number we construct will have the additional property that it is not partial computably random.

For an infinite set $A \subseteq \mathbb{N}$ we write p_A for the unique increasing function from $\mathbb{N}$ to $\mathbb{N}$ such that $p_A(\mathbb{N}) = A$. Recall, for instance from Odifreddi [15, Section III.3], that a set A is called *dense simple* if it is computably enumerable and $p_{\bar{A}}$ dominates every computable function. While the complement of a dense simple set must be very thin by definition, we claim that there does exist such a set A whose binary expansion contains arbitrarily long sequences of zeros. To see this, recall that a set B is called *maximal* if it is computably enumerable and coinfinite and for any computably enumerable set C with $B \subsetneq C$, we must have that C is cofinite or that $C \setminus B$ is finite; in other words, if B only has trivial computably enumerable supersets. Such sets exist, for instance see Odifreddi [15, Section III.4]. If we partition the natural numbers into a sequence $(I_n)_n$ of successive intervals of growing length by letting $I_0 := \{0\}$, and $I_{n+1} := \{\max I_n + 1, \ldots, \max I_n + n + 2\}$ for all $n \in \mathbb{N}$ and fix some maximal set B, then it is easy to check that we obtain a set A as required by letting

$$A := \left\{ n \colon \; \exists k, \ell \left[\begin{array}{c} (n \in I_k \wedge k \in B) \vee \\ (n \text{ is the } \ell\text{-th smallest element of } I_k \wedge \#(B{\restriction}k) \geq \ell) \end{array} \right] \right\}.$$

Proof of Theorem 21. Let A be a set that is dense simple and whose binary expansion contains arbitrarily long sequences of zeros. Define Ω_A bitwise via

$$\Omega_A(n) := \begin{cases} \Omega(m) & \text{if } n = p_A(m), \\ 0 & \text{else;} \end{cases}$$

for all $n \in \mathbb{N}$; that is, Ω_A contains all bits of Ω, but at those places that are elements of A; all other bits of Ω_A are zeros. Let $(A[t])_t$ be a computable enumeration of A and for all $n \in \mathbb{N}$ write $p_A(n)[t]$ for the n-th smallest element in $A[t]$, if it already exists. Then it is easy to see that $(\Omega_A[t])_t$ defined bitwise via

$$\Omega_A(n)[t] := \begin{cases} \Omega(m)[t] & \text{if } n = p_A(m)[t]\downarrow, \\ 0 & \text{else,} \end{cases}$$

for all $n \in \mathbb{N}$, is a left-approximation of Ω_A; namely, the individual bits of Ω are approximated in a left-computable fashion, and as more and more bits appear in the computable enumeration of A, the positions where the bits of Ω get stored in Ω_A may move to the left.

We claim that Ω_A is as required by the theorem.

- That Ω_A is superspeedable follows from Proposition 7. Namely, recall that A contains arbitrarily long blocks of bits that will permanently maintain value 0, that is, for all n in such a block and all t, we have $\Omega_A(n)[t] = 0$. As a consequence, the left-approximation of Ω_A described above witnesses superspeedability at the infinitely many stages where for the last time a bit left of one of these blocks changes.
- Note that the fact that $\bar{A}$ is dense immune implies that for every computable increasing function $f\colon \mathbb{N} \to \mathbb{N}$, there exists a number $m_f \in \mathbb{N}$ with $\left|\bar{A}\restriction f(n)\right| \le \frac{n}{4}$ for all $n \ge m_f$.
- Let $\alpha, \omega\colon \mathbb{N} \to \mathbb{N}$ be defined via

  $$\begin{aligned}\alpha(n) &:= \min\{t \in \mathbb{N}\colon\ \ A[t]\restriction(n+1) = A\restriction(n+1)\},\\ \omega(n) &:= \min\{t \in \mathbb{N}\colon\ \ \Omega[t]\restriction(n/4) \ \ = \Omega\restriction(n/4) \ \ \}\end{aligned}$$

  for all $n \in \mathbb{N}$. We claim that there exists a number $m_1 \in \mathbb{N}$ such that for every $n \ge m_1$ we have $\alpha(n) \le \omega(n)$. This is clear since the Kolmogorov complexity of computably enumerable sets grows logarithmically in the length of its initial segments, while that of Ω grows linearly.
- Let $\theta\colon \mathbb{N} \to \mathbb{N}$ be defined via

  $$\theta(n) := \min\{t \in \mathbb{N}\colon\ \Omega_A[t]\restriction n = \Omega_A\restriction n\}$$

  for all $n \in \mathbb{N}$. We claim that there exists a number $m_2 \in \mathbb{N}$ such that for every $n \ge m_2$ we have $\omega(n) \le \theta(n)$. To see this, fix some $n \ge m_{\text{id}}$ and such that $\Omega_A\restriction n$ contains at least one 1; write t_n for $\theta(n)$.

  First, it is easy to see that if we let ℓ_n denote the maximal ℓ such that $(\Omega_A[t_n]\restriction n)(\ell) = 1$, then we must already have $A[t_n]\restriction \ell_n = A\restriction \ell_n$. But then, since we chose $n \ge m_{\text{id}}$, the sets A and $A[t_n]$ contain exactly the same at least $\ell_n - {}^{n}\!/_{4}$ elements less than ℓ_n. Consequently, we must have $\Omega[t_n]\restriction(\ell_n - {}^{n}\!/_{4}) = \Omega\restriction(\ell_n - {}^{n}\!/_{4})$. If we choose $m_2 \ge m_{\text{id}}$ such that for all $n \ge m_2$ we have $\ell_n \ge {}^{n}\!/_{2}$, we are done. To see that such an m_2 exists, we argue as follows: For a given $n \ge m_{\text{id}}$, $\Omega_A\restriction n$ contains at least the first $k \ge {}^{3}\!/_{4} \cdot n$ bits of Ω; and thus if the last 1 in $\Omega_A\restriction n$ occurs before position ${}^{n}\!/_{2}$, then the last ${}^{k}\!/_{3}$ bits of Ω must be 0. But this can occur only for finitely many k as Ω is Martin-Löf random.
- Now we show that Ω_A is not partial computably random. We recursively define the partial martingale $d\colon \subseteq\Sigma^* \to \mathbb{Q}_{\ge 0}$ as follows: Let $d(\lambda) := 1$, and suppose that $d(\sigma)$ is defined for some $\sigma \in \Sigma^*$. Let $t_\sigma \in \mathbb{N}$ be the earliest stage with $\Omega_A[t_\sigma]\restriction|\sigma| = \sigma$, if it exists. Then define $d(\sigma 0)$ and $d(\sigma 1)$ via

  $$d(\sigma 0) := \begin{cases}\frac{3}{2}\cdot d(\sigma) & \text{if } |\sigma| \notin A[t_\sigma],\\ d(\sigma) & \text{otherwise,}\end{cases} \qquad d(\sigma 1) := \begin{cases}\frac{1}{2}\cdot d(\sigma) & \text{if } |\sigma| \notin A[t_\sigma],\\ d(\sigma) & \text{otherwise.}\end{cases}$$

  It is clear that d is a partial computable martingale. We claim that d succeeds on Ω_A. To see this, let $\ell \ge \max(m_{\text{id}}, m_1, m_2)$ and assume that d receives input $\sigma := \Omega_A\restriction\ell$. Let $t_\sigma \in \mathbb{N}$ be the first stage such that $\Omega_A[t_\sigma]\restriction\ell = \sigma$. Then, by choice of ℓ and σ, we have $\alpha(\ell) \le \omega(\ell) \le \theta(\ell) = t_\sigma$, thus $A[t_\sigma]\restriction(\ell+1) = A\restriction(\ell+1)$. Thus, $\ell \notin A[t_\sigma]$ if and only if $\ell \notin A$, and by construction, for each of the infinitely many $\ell \notin A$, we have $d(\Omega_A\restriction(\ell+1)) = \frac{3}{2}\cdot d(\sigma)$. On the other hand, for all other ℓ, we have $d(\Omega_A\restriction(\ell+1)) = d(\sigma)$. Thus, $\lim_{n\to\infty} d(\Omega_A\restriction n) = \infty$, and Ω_A is not partial computably random.

- It remains to show that Ω_A is Schnorr random. For the sake of a contradiction, assume this is not the case; then, according to a result of Franklin and Stephan [6], there exists a computable martingale $d\colon \Sigma^* \to \mathbb{Q}_{\geq 0}$ and a computable increasing function $f\colon \mathbb{N} \to \mathbb{N}$ with $d(\Omega_A \restriction f(n)) \geq 2^n$ for infinitely many $n \in \mathbb{N}$. W.l.o.g. we can assume $d(\lambda) = 1$.
  Let $m := \max(m_f, m_1)$ and define the partial computable martingale $d'\colon \subseteq\Sigma^* \to \mathbb{Q}_{\geq 0}$ recursively as follows: Let $d'(\sigma) := 1$ for each σ with $|\sigma| \leq m$. Now suppose that $d'(\sigma)$ is defined for some $\sigma \in \Sigma^*$, write $\ell := |\sigma|$, and let $t_\sigma \in \mathbb{N}$ be the earliest stage with $\Omega[t_\sigma]\restriction\ell = \sigma$, if it exists. To define how d' bets on the next bit, imitate the betting of d on the $p_A[t_\sigma](\ell+1)$-th bit of $\Omega_A[t_\sigma]$. It is clear that d' is computable.
  We claim that d' succeeds on Ω. To see this, fix any $\ell \geq m$ and assume that d' receives input $\sigma := \Omega\restriction\ell$. Let $t_\sigma \in \mathbb{N}$ be the first stage such that $\Omega[t_\sigma]\restriction\ell = \sigma$. By choice of m, this implies $p_A[t_\sigma](\ell+1) = p_A(\ell+1)$. By construction, d' bets in the same way on $\Omega\restriction(\ell+1)$ as d does on $\Omega_A\restriction p_A(\ell+1)$.
  Define the function $g\colon \mathbb{N} \to \mathbb{N}$ by $g(n) := f(n) - \left|\bar{A}\restriction f(n)\right|$, and pick any of the, by assumption, infinitely many n with $d(\Omega_A\restriction f(n)) \geq 2^n$. Recall that $\Omega_A\restriction f(n)$ contains at most $n/4$ bits which belong to $\bar{A}$ and each of them can at most double the starting capital. This implies that d', which omits exactly these bets but imitates all the others, must still at least achieve capital $2^{3/4\cdot n}$ on the initial segment $\Omega\restriction g(n)$. This contradicts the well-known fact that Ω is partial computably random. ◀

6 Future research

We finish the article by highlighting possible future research directions:

The first two open questions concern the positions marked ◌$_1$ and ◌$_2$ in Figure 1; in both cases it is unknown whether any such numbers can exist. Note that proving the existence of ◌$_1$ would give a negative answer to the open question posed by Hölzl and Janicki [8] whether the left-computable numbers are covered by the union of the Martin-Löf randoms with the speedable and the nearly computable numbers; in particular, it would provide an alternative way to obtain a counterexample to the question of Merkle and Titov discussed in the introduction. Concerning ◌$_2$, one might be tempted to believe that such a number could be constructed by an argument similar to that used to prove Theorem 21 but using a maximal computably enumerable set A; such a set would still be dense simple by a result of Martin [11], but it would only contain isolated zeros. However, it can be shown that an Ω_A constructed in this way would still end up being superspeedable.

Next, besides Schnorr randomness, there are numerous other randomness notions weaker than Martin-Löf randomness, such as computable randomness or weak s-randomness (see, for instance, Downey and Hirschfeldt [4, Definitions 13.5.6 and 13.5.8]). It is natural to ask which of them are compatible with which of the notions of benign approximability discussed in this article.

Finally, in this field, many relevant properties of the involved objects are not computable; one might ask *how far* from computable they are. One framework in which questions of this type can be studied is the Weihrauch degrees, a tool to gauge the computational difficulty of mathematical tasks by thinking of them as black boxes that are given *instances* of a problem and that have to find one of its admissible *solutions*. This model then allows comparing the "computational power" of such black boxes with each other (for more details see, for instance, the survey by Brattka, Gherardi, and Pauly [2]). In the context of this article, we could for example ask for the Weihrauch degrees of the following non-computable tasks, with many variants imaginable:

- Given an approximation that witnesses speedability of some number as well as a desired constant, determine infinitely many stages at which the speed quotients of the given approximation beat the constant.
- For a speedable number, given an approximation to it as well as a desired speed constant ρ, determine another approximation of that number which achieves speed constant ρ in the limit superior.
- For an approximation witnessing regaining approximability of some number, determine the sequence of n's at which the approximation "catches up."

Abstract

A classical problem in computational geometry and graph algorithms is: given a dynamic set $\mathcal{S}$ of geometric shapes in the plane, efficiently maintain the connectivity of the intersection graph of $\mathcal{S}$. Previous papers studied the setting where, before the updates, the data structure receives some parameter P. Then, updates could insert and delete disks as long as at all times the disks have a diameter that lies in a fixed range $[\frac{1}{P}, 1]$. As a consequence of that prerequisite, the aspect ratio ψ (i.e. the ratio between the largest and smallest diameter) of the disks would at all times satisfy $\psi \leq P$. The state-of-the-art for storing disks in a dynamic connectivity data structure is a data structure that uses $O(Pn)$ space and that has amortized $O(P \log^4 n)$ expected amortized update time. Connectivity queries between disks are supported in $O(\log n / \log \log n)$ time.

In the dynamic setting, one wishes for a more flexible data structure in which disks of any diameter may arrive and leave, independent of their diameter, changing the aspect ratio freely. Ideally, the aspect ratio should merely be part of the analysis. We restrict our attention to axis-aligned squares, and study fully-dynamic square intersection graph connectivity. Our result is fully-adaptive to the aspect ratio, spending time proportional to the current aspect ratio ψ, as opposed to some previously given maximum P. Our focus on squares allows us to simplify and streamline the connectivity pipeline from previous work. When n is the number of squares and ψ is the aspect ratio after insertion (or before deletion), our data structure answers connectivity queries in $O(\log n / \log \log n)$ time. We can update connectivity information in $O(\psi \log^4 n + \log^6 n)$ amortized time. We also improve space usage from $O(P \cdot n \log n)$ to $O(n \log^3 n \log \psi)$ – while generalizing to a fully-adaptive aspect ratio – which yields a space usage that is near-linear in n for any polynomially bounded ψ.

1 Introduction

Geometric intersection graphs are one of the most well-studied geometrically-flavoured graph classes: Their nodes are geometric shapes, and an edge between two such shapes exists if and only if they intersect. This makes the description complexity of a geometric intersection graph very compact; it is linear in the number of objects, while the underlying graph potentially has a quadratic number of edges. In this work, we consider square intersection graphs in the dynamic setting. Intersection graphs are one of the few examples of dynamic graphs where fully-dynamic insertion and deletion of vertices is motivated and interesting. Since a vertex can come or leave with $\Theta(n)$ edges, applying any existing edge-updatable dynamic graph algorithm in a blackbox manner would lead to $\Omega(n)$ update time. Yet, the geometric nature of these graphs often allows for sublinear or even polylogarithmic update times.

A classical problem in dynamic graph algorithms is dynamic connectivity. In this problem, we want to maintain a data structure under edge or node insertions and deletions that allows for fast queries that return whether a given pair of vertices is connected. Connectivity was one of the first problems to be studied in the dynamic setting dating back to the 80s [11, 25], and has received ample attention ever since. Dynamic connectivity in general graphs has been studied in many settings; randomised or deterministic, amortised or worst-case [11, 13, 29, 18, 24], and the partially dynamic incremental or decremental settings [26, 27, 28, 1]. Due to its fundamental nature, and its many applications, dynamic connectivity has also received much attention for simpler graph classes. Examples of such graph classes include trees [25, 3], planar graphs [10, 21], and graphs of bounded genus [9, 15].

Naturally, the dynamic connectivity problem also drew attention for the class of geometric intersection graphs. This setting is particularly interesting as a single node insertion can drastically change the number of connected components, as it can introduce a linear number of new edges. On the other hand, the geometric structure can be exploited in the data structures. The first result for geometric connectivity in geometric intersection graphs with update and query time independent of the object diameters is by Chan et al. [7] who presents a dynamic (Euclidean) disk intersection data structure with an update time of $O(n^{20/21+\varepsilon})$ and a query time of $O(n^{1/7+\varepsilon})$. This has recently been improved to $O(n^{7/8})$ amortized update time with constant query time [6]. As progress seemed difficult in this setting, the setting in which the disks in the data structure have restricted diameters was considered. For a fixed diameter range, where there is some value P given in advance and diameters have to be contained in an interval $[\frac{1}{P}, 1]$, Kaplan et al. [17] showed that there is a data structure with expected amortized $O(P^2 \log^{10} n)$ update time, query time $O(\log n / \log \log n)$, using $O(nP \log n)$ space. Recently, Kaplan et al. [16] improved this to $O(P \log^7 n)$ expected amortized update time with the same update time and $O(nP)$ space.

From disks to squares. While the above works are stated for Euclidean disks, we note that the approach in [16] can be combined with [30] to obtain a data structure that works for the simpler setting of connectivity between axis-aligned squares. The obtained update time is amortized $O(P \log^4 n)$. Disk intersection graphs are often motivated by communication networks where the disks are interpreted as some sort of transmission diameter. This is an idealization of a complicated physical process and actual ad-hoc communication networks do not correspond to perfectly circular disks [20]. Thus, it is reasonable to switch to a different metric for computational reasons while maintaining the core idea of the underlying problem. Recently, similar progress was made for computing a single-source shortest path tree in an intersection graph by assuming square regions instead of disks [19].

Table 1 Complexities are asymptotic. All update times are amortized. The query time for all approaches is $O(\log n/\log\log n)$. $\lambda_s(n)$ denotes the maximum length of a Davenport-Schinzel sequence of order s on n symbols.

Object	Aspect ratio	Update time	Space	Ref.

disks	fixed $[\frac{1}{P}, 1]$	$P \cdot \log^4$ exp.	nP	[16]+[22]
squares	fixed $[\frac{1}{P}, 1]$	$P \cdot \log^4 n$	nP	[16]+[30]
squares	adaptive ψ	$\psi \log^4 n + \log^6 n$	$n \log^3 n \log \psi$	Thm 10

We study the dynamic connectivity problem where the input S is a set of (axis-aligned) squares, while being fully adaptive to their aspect ratio. We let ψ denote the adaptive aspect ratio. Formally, if S is the input before an update and S' is the input after an update we define $\psi = \max\{\frac{\max_{\sigma \in S} |\sigma|}{\min_{\sigma' \in S} |\sigma'|}, \frac{\max_{\sigma \in S'} |\sigma|}{\min_{\sigma' \in S'} |\sigma'|}\}$. Our date structure maintains connectivity between squares with $O(\psi \log^4 n + \log^6 n)$ update time, $O(\log n/\log\log n)$ query time, and using $O(n \log^3 n \log \psi)$ space, see Table 1 for a comparison. our approach only requires near-linear space while maintaining near-linear update time and polylogarithmic query time.

Implications of adaptivity and our reduced space usage. To understand the implications of the adaptivity of our new solution, consider the scenario where the set of squares starts with a square A with diameter 1 and B with diameter $\frac{1}{n}$. Now, suppose the sequence of updates first removes B, then inserts a sequence of n squares of diameter 1, and finally reinserts B. Previous work [16] would require as input the interval $[\frac{1}{n}, 1]$ and the promise that all updates only insert squares in this interval. The space usage and the total update time of [16] is quadratic. In our case, since for almost all updates, the aspect ratio is constant. Moreover, the space usage and total update time is near-linear.

2 Problem statement and technical overview

Let $\mathcal{S} \subset \mathbb{R}^2$ be a set of axis-aligned squares. The intersection graph $G[\mathcal{S}]$ is the graph with vertex set $\mathcal{S}$ and with an edge between squares $\sigma, \sigma' \in \mathcal{S}$ whenever they intersect. We say that two squares σ, σ' are *connected* if there exists a path between their corresponding vertices in $G[\mathcal{S}]$. The set $\mathcal{S}$ is a fully dynamic set subject to (adversarial) insertions and deletions of squares. We wish to maintain $\mathcal{S}$ in a data structure supporting *connectivity queries* between squares in $\mathcal{S}$. We denote the diameter of square $\sigma \in \mathcal{S}$ by $|\sigma|$. We consider three settings with different restrictions on the square diameters in $\mathcal{S}$:

- The *fixed diameter range* setting. Here, the input specifies some P and each $\sigma \in \mathcal{S}$ has a diameter in $[\frac{1}{P}, 1]$ for some fixed P.
- The *bounded aspect ratio* setting. Here, the input specifies some P and at all times, for all $\sigma, \sigma' \in \mathcal{S}$ we have $\frac{|\sigma|}{|\sigma'|} \leq P$.
- The *adaptive aspect ratio* ψ setting in which arbitrary insertions and deletions may occur. Let S be the set of squares before an update and S' be the set of squares after an update. We define $\psi = \max\{\frac{\max_{\sigma \in S} |\sigma|}{\min_{\sigma' \in S} |\sigma'|}, \frac{\max_{\sigma \in S'} |\sigma|}{\min_{\sigma' \in S'} |\sigma'|}\}$ the aspect ratio relevant for the update.

We measure the algorithmic complexity in $n := |\mathcal{S}|$ and ψ, where n is the present size of the dynamic set $\mathcal{S}$. At all times, we maintain some minimal axis-aligned square F that contains $\mathcal{S}$, and the coordinates of F are powers of 2.

Results. The data structure of Kaplan et al. [16], when adapted to axis-aligned squares by applying Range Trees [30], can store a dynamic set of axis-aligned squares as follows: The input specifies some value P and all squares have fixed diameter range with ratio P. Their solution uses $O(nP)$ space and supports updates to $\mathcal{S}$ in $O(P \log^4 n)$ amortized time (Table 1). They answer connectivity queries in $O(\log n / \log \log n)$ worst-case time.

There are several reasons why [17] uses $O(nP)$ space and why their update bound cannot depend on the adaptive ψ instead of P (which we discuss further down). We present an adaption of their work that relies on the fact that $\mathcal{S}$ is a set of axis-aligned squares. Under this assumption, we adapt their data structure to work for adaptive ψ. We improve the space usage to near linear in n and $\log \psi$. In full generality, we also improve the performance: allowing for update times proportional to the density around the update σ. More concretely, we parameterize the runtime by the size of two sets $\mathcal{C}(\sigma)$ and $\mathcal{P}(\sigma)$. Intuitively, these sets contain squares in σ or squares around σ. These sets have size at most $O(\min\{\psi, n\})$.

Our result is a technical contribution, that examines and refines the data structure in [16] in the special case where $\mathcal{S}$ is a set of axis-aligned squares. To detail our contribution, we now present a technical overview, where we reference several concepts whose formal definitions are presented in their respective sections. The core component is a quadtree that stores $\mathcal{S}$.

The existing pipeline. We can describe the data structure of [16] (adapted to squares) on a high-level: They construct a quadtree $H(\mathcal{S})$ in which quadtree cells may store squares in $\mathcal{S}$. For any quadtree cell C, we denote by $\pi(C)$ the set of squares stored in C. A crucial definition is the concept of a *perimeter*. For a square σ, its perimeter $\mathbb{P}^*(\sigma, P)$ is intuitively a ring of $\Theta(P)$ quadtree cells of size at least $\frac{1}{4P}$ that are sufficiently close to the boundary of σ. Using this concept, their data structure is a pipeline of five components (Fig 1):

1. The set $\mathcal{S}$ gets stored in a compressed quadtree $H(\mathcal{S})$, such that for every $\sigma \in \mathcal{S}$, the quadtree contains $\mathbb{P}^*(\sigma, P)$.[1] This quadtree has $\Theta(P \cdot n)$ cells. For each $\sigma \in \mathcal{S}$, its storing cell is the maximal quadtree cell contained in σ.
2. They store all (maximal) quadtree cells contained in some $\sigma \in \mathcal{S}$ in a special ancestor data structure. We leave out the details of this structure, as we show that it suffices to use the well-studied marked-ancestor data structure by Alstrup, and Husfeldt, Rauhe [2].
3. For each square $\sigma \in \mathcal{S}$ with storing cell C_σ, for each quadtree cell $C_2 \in \mathbb{P}^*(\sigma, P)$, they store a square intersection data structure (a range tree). This data structure stores the squares $R \subset \pi(C_\sigma)$ that have C_2 in their perimeter (i.e. $R = \{\gamma \in \pi(C_\sigma) \mid C_2 \in \mathbb{P}^*(\sigma, P)\}$).
4. For each square σ with storing cell C_σ, for each quadtree cell $C_2 \in \mathbb{P}^*(\sigma, P)$, they store a maximal bichromatic matching (MBM) in the graph $G[R \cup B]$ with $B = \pi(C_2)$ with $R = \{\gamma \in \pi(C_\sigma) \mid C_2 \in \mathbb{P}^*(\sigma, P)\}$.
5. They store a *proxy graph* over the quadtree in the dynamic connectivity data structure by Holm, Lichtenberg, and Thorup (HLT) [14]. This graph contains an edge between two cells C_1, C_2 if and only if their maximal bichromatic matching is not empty.

They subsequently support connectivity queries for a query (σ, ρ) as follows. Given σ, obtain a pointer to its storing cell C_σ. Using their ancestor data structure, they obtain the largest ancestor C_a that is contained in a square $\sigma^* \in \mathcal{S}$. Let C^* be its storing cell. Doing the same procedure for ρ gives a cell R^*. They show that (σ, ρ) are connected in $G[\mathcal{S}]$ if and only if (C^*, R^*) are connected in the proxy graph; which they test in $O(\log n / \log \log n)$ time.

[1] Whilst originally their approach is a forest of quadtrees, we note that since each root of the forest is disjoint, the whole solution can be stored as a quadtree.

Why the space usage is high, and update times are not adaptive. For every $\sigma \in \mathcal{S}$, this pipeline creates a set of $\Theta(P)$ quadtree cells with sizes in $[\frac{1}{4P}, 1]$ which we denote by $\mathbb{P}^*(\sigma, P)$. For each quadtree cell $C_2 \in \mathbb{P}^*(\sigma, P)$, σ gets stored in a square intersection data structure, even if the quadtree cell C_2 is empty and/or has no other squares nearby. This approach makes it require a lot of space. Moreover, this approach fails when the aspect ratio becomes adaptive: suppose that $\mathcal{S}$ has $n-1$ squares with diameter $\frac{1}{P}$ and one unit square. We replace the unit square with a square of diameter $\frac{1}{P^2}$. The aspect ratio remains bounded by P. However (after rescaling the plane by a factor $\frac{1}{P}$) the quadtree no longer contains for every $\sigma \in \mathcal{S}$ the set $\mathbb{P}^*(\sigma, P)$ as (after rescaling the plane) it only contains quadtree cells of size 1. Reconstructing these requires $\Omega(Pn)$ time.

Our adaption. We improve this pipeline in several ways based on a few key insights: First, we revisit the definition of *perimeter*; presenting a new definition $\mathcal{P}(\sigma)$ which intuitively contains only cells in $\mathbb{P}^*(\sigma, \psi)$ that store at least one square. Since we only store data structures on cells that store at least one square, we save space and allow ψ to become fully adaptive. This introduces a new challenge, as we need to work with significantly fewer precomputed inormation. Concretely, we do the following (Figure 2):

1. We define a new type of quadtree $T(\mathcal{S})$ that uses only $O(n \log \psi)$ quadtree cells.
2. We replace their custom ancestor data structure by the well-studied Marked Ancestor Tree (MAT), simplifying the data structure.
3. For squares metric we create a new data structure that has deterministic guarantees and that avoids storing many copies.
4. For each square $\sigma \in \mathcal{S}$ with storing cell C_σ, for each quadtree cell C_2 in our new perimeter $\mathcal{P}(\sigma)$, we store a Maximal Bichromatic Matching (MBM*) in a graph $G[R \cup B]$. Using our new definition of perimeter, we define $R \leftarrow \{\gamma \in \pi(C_\sigma) \mid C_2 \in \mathcal{P}(\sigma)\}$ and $B \leftarrow \pi(C_2)$. We present a new algorithm to maintain this Maximal Bichromatic Matching.
5. Finally, we use HLT [14] on a proxy graph with an edge for every non empty MBM*.

We go through our data structures one by one in the order indicated in Figure 2.

3 Storing disks in quadtrees

Recall that F is a (dynamic) square bounding box of $\mathcal{S}$. By construction, the side length of F is 2^ω for some integer ω. We define the square F to be a *quadtree cell* and we recursively define quadtree cells to be any square obtained by *splitting* a cell into four equally sized closed squares. A *quadtree* T on F is any hierarchical decomposition obtained by recursively splitting cells. This hierarchical decomposition has a natural representation as a tree: the root is the cell F and every cell has either 0 or 4 children depending on whether it was split. We denote by $\mathbb{F}$ the (infinite) set of cells that are obtained by recursively splitting all cells, starting from F. We say that a cell $C \in \mathbb{F}$ is at *level* ℓ whenever its side length is 2^ℓ. We treat any quadtree T as a set of cells, i.e., $T \subset \mathbb{F}$.

Löffler, Simons, and Strash [23] use quadtrees to store arbitrary squares (or disks). Let F be fixed and σ be some square with center s. The unique *storing cell* $C_\sigma \in \mathbb{F}$ is a largest cell in $\mathbb{F}$ that contains the center s and that itself is contained in σ (if s lies at the intersection of multiple largest contained cells, we define the bottom left cell to be C_σ). Löffler, Simons and Strash subsequently say that C_σ *stores* σ. For a cell $C \in \mathbb{F}$, we denote by $\pi(C)$ all square of $\mathcal{S}$ stored in C. We will define five different cell sets to define our quadtree storing $\mathcal{S}$.

Quadtree cell sets. We assume that we have some bounding box F (which induces the set $\mathbb{F}$) and some set of storing cells in $\mathbb{F}$. We subsequently define two types of subsets of $\mathbb{F}$:

- definitions that originate from [16] and depend on some $P \in \mathbb{R}$ (blackboard font),
- and new definitions depending on only the storing cells (calligraphic font).

Quadtree cells C, C' are *neighboring* whenever they are not descendants of one another and intersect in their boundary. For any property, a quadtree cell C in $\mathbb{F}$ is *maximal* if there does not exist an ancestor of C in $\mathbb{F}$ with the same property.

Let $\sigma \in \mathcal{S}$ have a storing cell C_σ. We define (Figure 3):

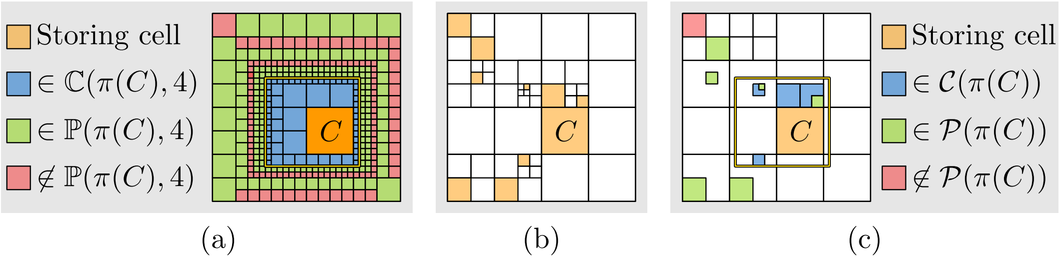
- $\mathcal{N}(\sigma) \subset \mathbb{F}$ as the cells of size $|C_\sigma|$ neighboring C_σ or a neighbor of C_σ.
- $\mathbb{C}^*(\sigma, P) \subset \mathbb{F}$ as the maximal cells $C' \in \mathbb{F}$ with $C' \subset \sigma$ and $|C| \in [\frac{1}{4P}, 1]$.
- $\mathcal{C}(\sigma) \subset \mathbb{F}$ as the maximal cells $C' \in \mathbb{F}$ with $C' \subset \sigma$ that contain at least one storing cell.
- $\mathbb{P}^*(\sigma, P) \subset \mathbb{F}$ as the *perimeter* of σ. These are all $C' \in \mathbb{F}$ contained in a cell in $\mathcal{N}(\sigma)$ with $|C'| \in [\frac{1}{4P}, 1]$ with the additional property that there exists a square $\rho \subset \mathbb{R}^2$ where C' would be the storing cell of ρ if $\rho \in S$, and, ρ intersects the boundary of σ.
- $\mathcal{P}(\sigma) \subset \mathbb{F}$ as all *storing cells* with diameter at most $|\sigma|$ that, when scaled around their center by a factor 5, intersect *the boundary* σ. Note that these may be contained in σ.

For $R \subseteq \mathcal{S}$, we define $\mathcal{N}(R)$ to be the union of all $\mathcal{N}(\sigma)$ with $\sigma \in R$. All other sets (e.g., $\mathcal{P}(R)$) are defined analogously. Let $\ell_{\min}$ (resp. $\ell_{\max}$) be the smallest (resp. largest) level that contains any cell in any of the five sets. Per definition, $\ell_{\max} - \ell_{\min} \in O(\log \psi)$.

▶ **Lemma 1** (Lemma 4.2 in [16]). *For any $\sigma \in \mathcal{S}$, if regions are disks under an L_p metric with a diameter in $[\frac{1}{4P}, 1]$ then:* $|\mathbb{C}^*(\sigma, P)| \in O(P)$ and $|\mathbb{P}^*(\sigma, P)| \in O(P)$.

Compressed quadtrees. Denote by $X \subset \mathbb{F}$ some set of cells. Denote by T_X the minimal quadtree over some bounding box F that contains all cells in X. The size of T_X can be arbitrarily large, even when $|X|$ is constant. To reduce quadtree space complexity, a quadtree may be *compressed* [12]. An α-compressed quadtree (for some variable $\alpha \geq 1$) is defined as follows: let C be a quadtree cell in T_X and C_α be the smallest descendant of C such that (1) $|C| \geq 2^\alpha |C_\alpha|$ and (2) all cells in X that are contained in C are also contained in C_α. Then C has not 4 children, but only C_α as its child. Given some constant α, every quadtree has a unique maximally compressed equivalent that has size linear in $|X|$ [12]. Given the above definitions, we want to mention two different quadtrees that store $\mathcal{S}$:

- [23] defines $L(\mathcal{S})$ as the compressed quadtree storing $\mathcal{N}(\mathcal{S})$.
- [16] defines $H(\mathcal{S})$ as the compressed quadtree storing $\mathcal{N}(\mathcal{S})$, $\mathbb{C}^*(\mathcal{S})$ and $\mathbb{P}^*(\mathcal{S})$.



Storing cell
$\in \mathbb{C}(\pi(C), 4)$
$\in \mathbb{P}(\pi(C), 4)$
$\notin \mathbb{P}(\pi(C), 4)$

Storing cell
$\in \mathcal{C}(\pi(C))$
$\in \mathcal{P}(\pi(C))$
$\notin \mathcal{P}(\pi(C))$

(a) (b) (c)

Figure 3 (a) We show for a square σ its storing cell in orange. We set $P = \psi = 2$ and show our sets. Many cells in $\mathbb{C}^*(\pi(C), 8)$ are also in $\mathbb{P}^*(\pi(C), 8)$. (b) The minimal quadtree that contains a set of storing cells. (c) Given the quadtree with storing cells, we illustrate our sets. Red cells are storing cells that occur in neither $\mathcal{C}(\pi(C))$ nor $\mathcal{P}(\pi(C))$.

Our quadtree. We define our quadtree $T(\mathcal{S})$ as the compressed quadtree storing $\mathcal{N}(\mathcal{S})$, where cells in $\mathcal{C}(\mathcal{S})$ are uncompressed. Note that any quadtree that contains $\mathcal{N}(\mathcal{S})$, also contains the cells in $\mathcal{C}(\mathcal{S})$. The key difference between $L(\mathcal{S})$ and $T(\mathcal{S})$ is that we decompress the cells in $\mathcal{C}(\mathcal{S})$, adding them to memory (i.e., we treat these cells as storing cells in the quadtree). Since these cells are uncompressed, this structure uses more space than the $O(n)$ cells in $\mathcal{N}(\mathcal{S})$. If we view quadtrees as a collection of (uncompressed) cells, then $L(\mathcal{S}) \subset T(\mathcal{S}) \subset H(\mathcal{S})$. By Lemma 1, Kaplan et al. [16] prove that $|\mathbb{C}^*(\mathcal{S}, P)|, |\mathbb{P}^*(\mathcal{S}, P)| \in O(Pn)$. It would be easy to show that $|\mathcal{C}(\mathcal{S})|, |\mathcal{P}(\mathcal{S})| \in O(n\psi)$. But through clever counting, we prove that storing $T(\mathcal{S})$ uses only $O(n \log \psi)$ space instead (Theorem 4).

3.1 Space complexity of the quadtree

We upper bound the size of $\mathcal{N}(\mathcal{S})$ and $\mathcal{C}(\mathcal{S})$ (and thus the size of $T(\mathcal{S})$).

▶ **Observation 2.** *There are $O(n)$ cells in $\mathcal{N}(\mathcal{S})$.*

▶ **Lemma 3.** *Let C be a storing cell. Denote by Z any cell, such that there could exist a σ stored in Z where an ancestor of C lies in $\mathcal{C}(\sigma)$. There are at most $O(\log \psi)$ such cells and we can report them in $O(\log \psi \log n)$ time.*

Proof. Let $|C| = 2^\ell$ (i.e., C is at level ℓ). By definition, Z is in a level $j \geq \ell$. Fix a level j. For any cell Z at level j, $\mathcal{C}(\pi(Z))$ contains an ancestor of C only if a square in $\pi(Z)$ intersects (or contains) C_j (the ancestor of C at level j). As the diameter of squares in $\pi(Z)$ is at most a factor 5 larger than the diameter of Z, there are at most $O(1)$ cells at level j that *could* store a square ρ that intersects C_j (the neighbors of C_j, their neighbors and possibly their neighbors). We can find these cells in $O(\log n)$ time by doing a point location in each cell for the level j. The fact that per definition of ψ, all storing cells and all cells in $\mathcal{C}(\mathcal{S})$ lie in a range of $O(\log \psi)$ levels concludes the proof. ◀

▶ **Theorem 4.** *At all times, the compressed quadtree $T(\mathcal{S})$ uses $O(n \log \psi)$ space.*

Proof. Since $T(\mathcal{S})$ is the quadtree that stores $\mathcal{N}(S)$ and $\mathcal{C}(S)$, and compressed quadtrees have linear space in the number of uncompressed cells, Observation 2 and Lemmas 3 immediately imply the theorem. ◀

We additionally upper bound the size of two more quadtree cell types:

▶ **Lemma 5.** *Let $\mathcal{S}$ be a set of squares with aspect ratio ψ. For all $\sigma \in \mathcal{S}$ with storing cell C_σ there are at most $O(\psi)$ cells in $\mathcal{C}(\sigma)$ and $\mathcal{P}(\sigma)$ and $O(\psi^2)$ cells in $\mathcal{P}(\pi(C_\sigma))$.*

Proof. Consider any set of squares S. We rescale the plane such that the diameter of squares in $\mathcal{S}$ lies in $[\frac{1}{\psi}, 1]$. We apply Lemma 1 to conclude that $|\mathbb{C}(\sigma, \psi)|, |\mathbb{P}(\sigma, \psi)| \in O(\psi)$. Note that the smallest storing cell in $T(\mathcal{S})$ then has size $\frac{1}{4\psi}$. Having rescaled, $\mathcal{C}(\sigma) \subseteq \mathbb{C}^*(\sigma, \phi)$.

Suppose that after rescaling there is a cell $C \in \mathcal{P}(\sigma)$ that is not in $\mathbb{P}^*(\sigma, \psi)$. Then C, scaled by a factor 5, intersects the boundary of σ. Yet if $C \notin \mathbb{P}^*(\sigma, \psi)$ then C cannot store any square ρ that intersects σ. Denote by C' a neighbor of C of size $2|C|$ that lies closer to the center of σ. It must be that $C' \in \mathbb{P}^*(\sigma, \psi)$ (indeed, we can construct a square with diameter $4|C|$ stored in C' that intersects σ). This way, each cell in $\mathbb{P}^*(\sigma, \psi)$ can get charged by at most $O(1)$ cells $C' \in \mathcal{P}(\sigma)$ where $C' \notin \mathbb{P}^*(\sigma, \psi)$. Thus, $|\mathcal{P}(\sigma)| \in O(\psi)$. The upper bound on $|\mathcal{P}(\pi(C_\sigma))|$ follows from the standard packing argument. ◀

▶ **Lemma 6.** *Let C be a storing cell. Denote by Z any cell, such that there could exist a σ stored in Z with $C \in \mathcal{P}(\sigma)$. We can report all $O(\log \psi)$ such cells in $O(\log \psi \log n)$ time.*

Proof. Let $|C| = 2^\ell$ (i.e., C is at level ℓ in the quadtree). By definition, every quadtree cell Z of the lemma statement is stored at a level $j \geq \ell$. Fix a level $j \geq \ell$ and let C_j be the ancestor of C at level j. If for any cell Z at level j, $C \in \mathcal{P}(\pi(Z))$ then it must be that the cells Z and C_j (when both are scaled around their center by a factor 5) intersect. There are at most $O(1)$ such cells Z at level j for which this can be true. We can find these cells at level j in $O(\log n)$ time by performing $O(1)$ point locations in the quadtree (querying a neighborhood of 25×25 around C_j). The fact that all cells in $\mathcal{P}(\mathcal{S})$ lie in a range of $O(\log \psi)$ levels concludes the proof. ◀

4 Maintaining and navigating quadtrees

A compressed quadtree T_X that stores a set X of quadtree cells can be dynamically maintained in $O(\log |X|)$ time per insertion and deletion [12]. Moreover, leaf location queries are supported in $O(\log |X|)$ time, which take as input some point $q \in \mathbb{R}^2$ and output the leaf of T_X that contains q. By Theorem 4, $|X| = O(n \log \psi)$ in our setting. Since we assume that $\psi \in O(n^c)$, see Section 2, we can say that our insertion, deletion and point location operations in the compressed quadtree take $O(\log n)$ time. Compressed quadtrees additionally support level locations where for any query point $q \in \mathbb{R}^2$ and level ℓ, the output is the quadtree cell at level ℓ that contains q; this can be used to dynamically maintain for all $\sigma \in \mathcal{S}$ the set $\mathcal{N}(\sigma)$ in our quadtree in $O(\log n)$ time per update in $\mathcal{S}$ [5].

We maintain $L(\mathcal{S})$ in $O(\log n)$ time per update to $\mathcal{S}$, while supporting point location queries. We maintain in $O(\log n)$ time per update in $\mathcal{S}$ the values $d_{\max}$ and $d_{\min}$ that denote the maximal and minimal diameter in $\mathcal{S}$ respectively. We apply 3 more data structures:

Marked Ancestor Trees (MAT). Alstrup, Husfeldt, and Rauhe [2] introduce marked-ancestor trees. Let T be a dynamic tree. Each node in T is either marked or unmarked. Given a node $v \in T$, the MAT supports changing the mark of v or updating T in $O(\log \log n)$ time. Additionally, given a node $v \in T$, one can find the lowest/highest marked node on the path from v to the root in $O(\log n / \log \log n)$ time. We augment our quadtree with a MAT.

Orthogonal range trees. Willard and Lueker [30] show a data structure to store a set of n squares using $O(n \log n)$ space. Given a query rectangle ρ, it can report an input square contained in ρ in $O(\log^4 n)$ time, if such a square exists. Given a query square ρ it can report the number of squares that contain ρ in $O(\log^4 n)$ time. We implement the range tree using general balanced trees [4], so that we can support updates in amortized $O(\log^4 n)$ time.

Segment trees. Segment trees [8] store a set of n horizontal segments using $O(n \log n)$ space, so that for a vertical query segment Q we obtain all k input segments that intersect Q in $O(\log^2 n + k)$ time. The data structure can again be made dynamic, supporting updates in $O(\log^2 n)$ amortized time. For any σ, we store the horizontal sides of C_σ (scaled by a factor 5) in such an orthogonal intersection data structure. Furthermore, we create a second such a data structure storing all vertical sides.

▶ **Theorem 7.** *Let $\mathcal{S}$ be a set of axis-aligned squares. We augment $T(\mathcal{S})$ with an $O(n \log n)$-size data structure using $O(n \log n)$ space, supporting inserting/deleting a square σ in $O(|\mathcal{C}(\sigma)| \cdot \log^4 n + \log^6 n)$ time, and*

- *all cells in $\mathcal{C}(\mathcal{S})$ are marked in our marked-ancestor tree;*
- *for any query square γ, we can obtain $\mathcal{P}(\gamma)$ in $O(\log^2 n + |\mathcal{P}(\gamma)|)$ time.*
- *for any query cell C, we obtain the set $\mathcal{Z}(C) := \{Z \mid C \in \mathcal{P}(\pi(Z))\}$ in $O(\log^5 n)$ time.*

Proof. By Theorem 4, our quadtree requires $O(n \log \psi)$ space. Using the standard operations on compressed quadtrees, we can maintain $\mathcal{N}(\mathcal{S})$ in $O(\log n)$ time per update. What remains for quadtree maintenance is to identify, decompress and mark all cells in $\mathcal{C}(\mathcal{S})$.

Maintaining $\mathcal{C}(\mathcal{S})$. Every cell $C \in \mathbb{F}$ has a counter that counts for how many $\sigma \in \mathcal{S}$, $C \in \mathcal{C}(\sigma)$. Whenever the counter is zero, we do not store it explicitly. Otherwise, $C \in \mathcal{C}(\mathcal{S})$ and we need to make sure that C is decompressed and marked. For each update of a square σ with storing cell C_σ, there are two types of counter updates:

1. updating counters of $C \in \mathcal{C}(\sigma)$, and
2. updating the counters of C_σ and its ancestors.

We start with the first case. Instead of increasing counters, we do something slightly stronger as we can report all of $\mathcal{C}(\sigma)$. By definition, $C_\sigma \in \mathcal{C}(\sigma)$ and we add it to our output. We split σ into eight rectangles that are bounded by σ and the boundary of C_σ, see Figure 4. We process each rectangle separately. Consider such a rectangle R. We query our orthogonal range tree to report a storing cell C_1 in R in $O(\log^4 n)$ time. Given C_1, we walk in $O(\log \psi)$ time up the quadtree to find its largest ancestor C_1' that is still contained in σ. By definition, $C_1' \in \mathcal{C}(\sigma)$ and we add it to our output. Subsequently, we partition R into nine rectangles that are bounded by the boundaries of C_1' and recurse. For each cell in $\mathcal{C}(\sigma)$ we perform eight orthogonal range queries. For each range query, we either conclude that the range contains no cells in $\mathcal{C}(\sigma)$, or we identify at least one cell in $\mathcal{C}(\sigma)$. As we recurse on rectangles that are bounded by cell boundaries and we explore all of R, we find all cells of $\mathcal{C}(\sigma)$ in $O(|\mathcal{C}(\sigma)| \cdot \log^2 n)$ time. As we find them, we may adjust their counters.

Now onto the second case, where we simply recompute all counters from scratch. There are at most $O(\log \psi)$ ancestors $C_\sigma, C_1, \ldots C_k$ of C_σ that may be contained in a square in $\mathcal{S}$. For each of these, we recompute their counters from scratch. Fix an ancestor C_i with parent C_{i+1}. By Lemma 3, there are at most $O(\log \psi)$ cells Z such that Z could store a square γ with $C_i \in \mathcal{C}(\gamma)$. We obtain all such Z in $O(\log \psi \log n)$ time and iterate over each of them. For a fixed Z, we use the range tree to count how many $\gamma \in \pi(Z)$ contain C_i in $O(\log^4 n)$ time. We then count how many $\gamma \in \pi(Z)$ contain C_{i+1}. The difference between these counts is the number of squares $\gamma^* \in \pi(Z)$ for which $C_i \in \mathcal{C}(\gamma^*)$. We compute and sum all these numbers to recompute the count of C_i. It follows from the fact that $O(\log \psi) \subset O(\log n)$ that we can maintain $\mathcal{C}(\mathcal{S})$ in $O(|\mathcal{C}(\sigma)| \cdot \log^2 n + \log^6 n)$ time.

Querying for $\mathcal{P}(\gamma)$. We show how to obtain for any query squares γ the set $\mathcal{P}(\gamma)$ in $O(\log^2 n + |\mathcal{P}(\gamma)|)$ time. For each storing cell C, we consider the cell C^* that is C scaled by a factor 5 around its center. We store each of the boundary segments of C^* in our Segment Tree. There is exactly one storing cell per square in $\mathcal{S}$, so maintaining the Segment Tree intersection data structure takes $O(\log^2 n)$ time per update and uses $O(n \log n)$ space. For any query square γ, we have $C \in \mathcal{P}(\gamma)$ if and only if one of the boundary segments of γ intersects one of the boundary segments of C^*. Thus, we can immediately use the intersection data structure to compute $\mathcal{P}(\gamma)$ in $O(\log^2 n + |\mathcal{P}(\gamma)|)$ time, as each cell in $\mathcal{P}(\gamma)$ is reported at most a constant number of times.

Querying for $\mathcal{Z}(C)$. Denote by Z any cell, such that there could exist a γ stored in Z with $C \in \mathcal{P}(\gamma)$. By Lemma 6, we can report all at $O(\log \psi)$ such cells in $O(\log \psi \log n)$ time. For every such Z, we conceptually rotate the plane such that Z lies above C. Let C^* be the cell C increased by a factor 5 around its center. Any square ρ in $\pi(Z)$ intersects C^* in its boundary if and only if one of two conditions hold: ρ contains the top left endpoint of C^* but not the bottom left endpoint, or ρ contains the top right endpoint of C^* but not the bottom right endpoint. We select the top right endpoint of C^* and we count how many squares in $\pi(Z)$ contain the top right endpoint in $O(\log^4 n)$ time. We do the same for the bottom right endpoint. If the counts differ, there is at least one square in $\pi(Z)$ that intersects C^* in its boundary and thus $C \in \mathcal{P}(\pi(Z))$. Doing this for all $O(\log \psi)$ levels takes $O(\log^5 n)$ time. ◀

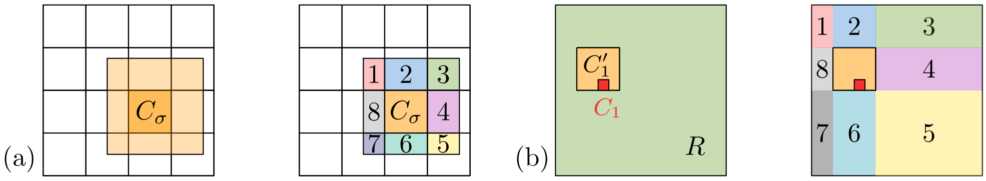

Figure 4 (a) Given a storing cell C_σ, we partition σ into nine rectangles (one being C_σ). (b) For each rectangle R, we do a range query to find a storing cell C_1 (if it exists). For the largest ancestor $C_1' \subset \sigma$ of C_1, we partition R into nine rectangles once again and recurse.

5 Specific square intersection data structures

In this section we develop a solution for the following data structure problem: Let $\mathcal{R}$ be a set of m squares. Let $R_1, \ldots, R_k$, be k subsets of $\mathcal{R}$ that we refer to as *conflict sets* and let $\ell \leq k$ be the maximum number of conflict sets that any square from $\mathcal{R}$ appears in. We want to store $\mathcal{R}$ and all the conflict sets $R_1, \ldots, R_k$ in a data structure that has size near linear in m and $z = \sum_i |R_i|$, and support the following operations in the following time:

Insert(ρ), ($O(l \cdot \log^3 m)$ time): Insert a square ρ into $\mathcal{R}$.

Delete(ρ), ($O(l \cdot \log^3 m)$ time): Delete a square ρ from $\mathcal{R}$ and every R_i that it occurs in.

Insert(ρ, R_i), ($O(\log^3 m)$ time): Insert a square ρ in the conflict set R_i. If $R_i = \emptyset$, create a new conflict set.

Delete(ρ, R_i), ($O(\log^3 m)$ time): Delete a square ρ from the conflict set R_i.

Query(σ, R_i, C), ($O(\log^3 m)$ time): Given a query σ whose center lies below all centers of all squares in $\mathcal{R}$, and a horizontal line segment C below σ, return (if it exists) a square $\rho \in \mathcal{R}$ that intersects σ, but is not in the conflict set R_i, and that does not contain C.

In Section 6 we solve this problem as follows: we map every square $\rho = [\ell_\rho, r_\rho] \times [b_\rho, t_\rho] \in \mathcal{R}$ to a point $p_\rho = (b_\rho, \ell_\rho, r_\rho)$ in $\mathbb{R}^3$, and store these points in a 3D-range tree T augmented for range counting queries [8]. Hence, every third-level subtree T_ν stores the number of points m_ν in T_ν. Furthermore, for each such subtree, and each conflict set R_i, consider the subset of points stored in the leaves of T_ν for which the corresponding square appears in R_i. If this set is non-empty then node ν also stores the size $m_{\nu,i} = |\{p_\rho \mid p_\rho \in T_\nu \wedge \rho \in R_i\}|$ of this set. Furthermore, we maintain a bipartite graph between the squares in $\mathcal{R}$ and the conflict sets R_i, so that given a square $\rho \in \mathcal{R}$ we can find the ℓ conflict sets it appears in in $O(\ell)$ time. We implement all trees using general balanced trees [4] so that we can perform updates efficiently. A 3D-range tree uses $O(m \log^2 m)$ space. Each square in the multiset $\bigcup_i R_i$ contributes to $O(\log^3 m)$ nodes of T, and hence the entire structure uses at most $O((m+z)\log^3 m)$ space (Lemma 8). In Section 7 we use this structure for connectivity queries.

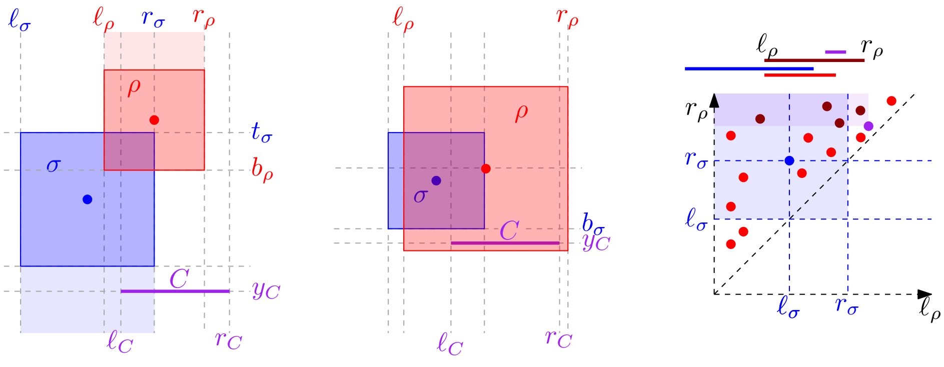
6 Square intersection data structure

Let $\mathcal{R}$ be a set of m squares. Let $R_1, \ldots, R_k$, be k subsets of $\mathcal{R}$ that we refer to as *conflict sets* and let $\ell \leq k$ be the maximum number of conflict sets that any square from $\mathcal{R}$ appears in. We want to store $\mathcal{R}$ and all the conflict sets $R_1, \ldots, R_k$ in a data structure that has size near linear in m and $z = \sum_i |R_i|$, and support the following operations:

Insert(ρ): Insert a square ρ into $\mathcal{R}$.
Delete(ρ): Delete a square ρ from $\mathcal{R}$ and every R_i that it occurs in.
Insert(ρ, R_i): Insert a square ρ in the conflict set R_i. If $R_i = \emptyset$, create a new conflict set.
Delete(ρ, R_i): Delete a square ρ from the conflict set R_i. If R_i becomes empty, delete R_i.
Query(σ, R_i, C): Given a query square σ whose center lies below all centers of all squares in $\mathcal{R}$, and a horizontal line segment C below σ, return (if it exists) a square $\rho \in \mathcal{R}$ that intersects σ, but is not in the conflict set R_i, and that also does not contain C.

We map every square $\rho = [\ell_\rho, r_\rho] \times [b_\rho, t_\rho] \in \mathcal{R}$ to a point $p_\rho = (b_\rho, \ell_\rho, r_\rho)$ in $\mathbb{R}^3$, and store these points in a 3D-range tree T augmented for range counting queries [8]. Hence, every third-level subtree T_ν stores the number of points m_ν in T_ν. Furthermore, for each such subtree, and each conflict set R_i, consider the subset of points stored in the leaves of T_ν for which the corresponding square appears in R_i. If this set is non-empty then node ν also stores the size $m_{\nu,i} = |\{p_\rho \mid p_\rho \in T_\nu \wedge \rho \in R_i\}|$ of this set. Furthermore, we maintain a bipartite graph between the squares in $\mathcal{R}$ and the conflict sets R_i, so that given a square $\rho \in \mathcal{R}$ we can find the ℓ conflict sets it appears in in $O(\ell)$ time. We implement all trees using general balanced trees [4] so that we can perform updates efficiently. A 3D-range tree uses $O(m \log^2 m)$ space. Each square in the multiset $\bigcup_i R_i$ contributes to $O(\log^3 m)$ nodes of T, and hence the entire structure uses at most $O((m+z)\log^3 m)$ space. We show how to answer our queries and how to update the data structure:

▶ **Lemma 8.** *Let $\mathcal{R}$ be a set of m squares, let $z = \sum |R_i|$, and let there be at most $k \leq m$ conflict sets. Let each $\rho \in \mathcal{R}$ appear in at most l conflict sets. There is a data structure $\mathcal{D}^*(\mathcal{R})$ of size $O((m+z)\log^3 m)$ that supports:*
Insert(ρ) *in $O(l \cdot \log^3 m)$ amortized deterministic time,*
Delete(ρ) *in $O(l \cdot \log^3 m)$ amortized deterministic time,*
Insert(ρ, R_i) *in $O(\log^3 m)$ amortized deterministic time,*
Delete(ρ, R_i) *in $O(\log^3 m)$ amortized deterministic time, and*
Query(σ, R_i, C) *in $O(\log^3 m)$ amortized deterministic time.*



(a) (b) (c)

Figure 5 (a) Since the center of ρ lies above the center of σ, we can essentially treat ρ as a rectangle unbounded from the top, and σ as a rectangle unbounded from the bottom. (b) A square ρ may intersect σ but is not allowed to contain C. (c) The x-extents of the objects map to points in $\mathbb{R}^2$. Squares (whose x-extent) intersects (the x-extent) of σ lie in the blue region, and are not allowed to lie in the purple region.

Proof. To insert a square $\rho \in \mathcal{R}$ we use the standard insertion procedure for (dynamic) 3D-range trees; we insert the point p_ρ into $O(\log^3 m)$ subtrees. If, one of our subtrees becomes too unbalanced, we rebuild it from scratch. Rebuilding a dD-range tree on a set P of n points can be done in $O(n \log^{d-1} n)$ time. However, we also still have to update the $m_{\nu,i}$ counts for each ternary subtree T_ν and each conflict list. We can do this in $O(ln \log^d n)$ time as follows. For each point $p_\rho \in P$ we obtain the at most l conflict sets R_i it appears in, and for each leaf corresponding to p_ρ we simply walk upward updating the $m_{\nu,i}$ counts appropriately. It follows that the amortized insertion time is $O(l \log^3 m)$. Deletions are handled similarly in $O(l \log^3 m)$ amortized time.

To insert or delete a square ρ in one of the conflict sets R_i we update the $m_{\nu,i}$ counts in the $O(\log^3 m)$ affected nodes (and we insert or delete the appropriate edge in the bipartite graph). If one of the $m_{\nu,i}$ counts reaches zero after a deletion, we stop storing it. Any counts that we do not store explicitly are considered to be zero.

Consider a query with square $\sigma = [\ell_\sigma, r_\sigma] \times [b_\sigma, t_\sigma]$, horizontal segment $C = [\ell_C, r_C] \times \{y_C\}$, and conflict set R_i (see also Figure 5). We will argue that there are $O(1)$ axis parallel boxes $Q_1, .., Q_{O(1)}$ such that the subset of squares from $\mathcal{R}$ that intersect σ but do not contain C is the subset of points that lies in $\bigcup_j Q_j$. Our range tree allows us to obtain $O(\log^3 m)$ ternary subtrees T_ν that together represent the points in this region (in $O(\log^3 m)$ time). For each such subtree we then consider the counts m_ν and $m_{\nu,i}$: if they are equal all points (squares) in T_ν also appear in R_i, and hence there are no candidate points (squares) to be found in T_ν. Otherwise, we have $m_\nu > m_{\nu,i}$, and hence T_ν does contain a point p_ρ for which ρ intersects σ, does not contain C, and for which $\rho \notin R_i$. Moreover, one of the two children of ν, say node μ, must then also have $m_\mu > m_{\mu,i}$. This way we can find p_ρ in time proportional to the height of T_ν. It follows that the total query time is $O(\log^3 m)$. All that remains is to describe the regions $Q_1, .., Q_{O(1)}$.

Since the center of σ is guaranteed to lie below all centers of squares in $\mathcal{R}$, and $y_C \leq b_\sigma$, we can essentially treat all squares as three-sided rectangles. In particular, a square $\rho \in \mathcal{R}$ intersects σ if and only if $p_\rho = (b_\rho, \ell_\rho, r_\rho)$ lies in the query range $Q = (-\infty, t_\sigma] \times (-\infty, r_\sigma] \times [\ell_\sigma, \infty)$ (see Figure 5). Using that $y_c \leq b_\sigma \leq (b_\rho + t_\rho)/2$, we find that $C \subset \rho$ if and only if p_ρ lies in the range $Q' = (\infty, y_C] \times (-\infty, \ell_C] \times [r_C, \infty)$. Hence, ρ intersects σ, but does not contain C if and only if $p_\rho \in Q \setminus Q'$. Since both Q and Q' are orthogonal boxes this region can be expressed as the union of $O(1)$ orthogonal ranges. ◀

7 Maximal Bichromatic Matchings

The Maximal Bichromatic Matching data structure (MBM) in [16] relies upon a square intersection data structure $\mathcal{D}$. Consider a pair of disjoint quadtree cells C_1, C_2 and two sets $R \subseteq \pi(C_1)$ and $B \subseteq \pi(C_2)$. The MBM stores two square intersection data structures: $\mathcal{D}(R)$ and $\mathcal{D}(B)$, plus a maximal bichromatic matching M_{RB} of the graph $G[R \cup B]$.

Given two such cells C_1, C_2, they dynamically maintain the matching as follows: For all edges in M_{RB}, dynamically remove the endpoints from the square intersection structures storing $\mathcal{D}(R \backslash M_{RB})$ and $\mathcal{D}(B \backslash M_{RB})$. When a new square σ gets inserted into B, query $\mathcal{D}(R \backslash M_{RB})$ to find a square in $R \backslash M_{RB}$ that intersects σ. If such a square ρ exists, add the edge (ρ, σ) to the matching M_{RB}. Subsequently delete ρ from $\mathcal{D}(R \backslash M_{RB})$. With a similar procedure for deletions, one can dynamically maintain M_{RB} in time proportional to the update and query time of the intersection data structure $\mathcal{D}$.

Defining the sets R and B. The sets R and B must be carefully chosen if we want to avoid spending quadratic space in n or ψ. Recall the pipeline of Kaplan et al. [16]. For each storing cell C_1, for each $C_2 \in \mathbb{P}^*(\pi(C_1))$, they store an MBM between the pair (C_1, C_2). We know that there may be $\Theta(\psi^2)$ cells in the set $\mathbb{P}^*(\pi(C_1))$. Suppose that for each pair C_1, C_2 they set $R \leftarrow \pi(C_1)$ and $B \leftarrow \pi(C_2)$. Every square in $\pi(C_1)$ may get stored $O(\psi^2)$ times and the total space usage is $O(\psi^2 n)$. To improve space and time usage, the authors of [16] instead set $R \leftarrow \{\sigma \in \pi(C_1) \mid C_2 \in \mathbb{P}^*(\sigma)\}$ and $B \leftarrow \pi(C_2)$, see Figure 6(a). Since each square $\sigma \in \pi(C_1)$ has $O(\psi)$ cells in its perimeter $\mathbb{P}^*(\sigma)$, each square σ is stored $O(\psi)$ times and the total space is $O(\psi \cdot |\pi(C_1)|)$. A charging argument then shows that the total space required is $O(\psi n)$. The data structures can be updated in $O(\psi)$ times: the update time of the intersection data structures $\mathcal{D}(R \backslash M_{RB})$ and $\mathcal{D}(B \backslash M_{RB})$.

Defining an MBM for adaptive ψ. When the aspect ratio is adaptive (or, even when it is bounded), the approach by Kaplan et al. [16] requires an update time linear in ψn, since, after increasing ψ, the perimeter $\mathbb{P}^*(\pi(\sigma))$ increases in size by $O(\psi)$ for every storing cell C_1. We could try to avoid this issue by replacing their definition of perimeter with ours. That is, for every cell C_1, we would consider the $O(\psi^2)$ cells C_2 in $\mathcal{P}(\pi(C_1))$. For the pair C_1, C_2, we want to maintain an MBM between sets $R \leftarrow \{\sigma \in \pi(C_1) \mid C_2 \in \mathcal{P}(\sigma)\}$ and $B \leftarrow \pi(C_2)$; by storing R and B each in their separate data structure for square intersection queries. However, such a structure can also not be efficiently dynamically maintained, see Figure 6(b). Thus, we must avoid storing the sets $R \backslash M_{RB}$ and $B \backslash M_{RB}$ explicitly in a data structure.

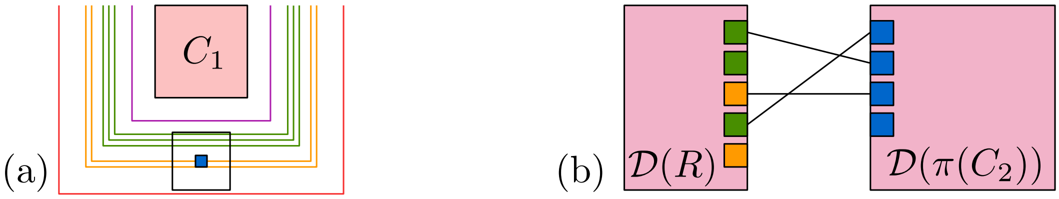


Figure 6 (a) C_1 with a blue $C_2 \in \mathbb{P}^*(\pi(C_1))$. The elements of the set $R = \{\sigma \in \pi(C_1) \mid C_2 \in \mathbb{P}^*(\sigma)\}$ are the green and yellow squares. (b) If we split C_2 to create a cell C', then the corresponding R' would consist only of the orange squares. Since there exists no efficient way to split intersection data structures, constructing the new data structure on R' takes linear time.

Applying our data structure problem. We now apply our previous data structure problem. Let C_1 be a storing cell in our quadtree $T(\mathcal{S})$. We maintain the data structure $\mathcal{D}^*(\pi(C_1))$ (i.e. we set $\mathcal{R} \leftarrow \pi(C_1)$). Let there be k cells in the perimeter $\mathcal{P}(\pi(C_1))$. Then by Lemma 5, we have $k \in O(\psi^2)$. Let C_i be some storing cell in $\mathcal{P}(\pi(C_1))$, we denote by M_i some maximal matching in the graph $G[R \cup B]$ for $R \leftarrow \{\gamma \in \pi(C_1) \mid C_i \in \mathcal{P}(\gamma)\}$ and $B \leftarrow \pi(C_i)$. Denote by R_i the squares in $\pi(C_1)$ that are part of M_i; we say that R_i is a conflict set. The result of this transformation are k conflict sets of $\pi(C_1)$. Moreover, each square ρ in $\pi(C_1)$ may appear in at most $l \in O(|\mathcal{P}(\rho)|) \subset O(\psi)$ conflict sets. We now apply Lemma 8 four times (one for each direction). We maintain for all C_1 this data structure $\mathcal{D}^*(\pi(C_1))$ and show:

▶ **Theorem 9.** *Let $\mathcal{S}$ be a set of n squares with adaptive aspect ratio ψ. We can maintain for pair of storing cells (C_1, C_2) a maximal bichromatic matching in $G[R \cup \pi(C_2)]$ with $R \leftarrow \{\gamma \in \pi(C_1) \mid C_2 \in \mathcal{P}(\gamma)\}$. Our solution uses $O(n \log \psi \log^3 n)$ space. Inserting/deleting a square σ requires $O(|\mathcal{P}(\sigma)| \cdot \log^3 n + \log^5 n)$ amortized time.*

Proof. We first analyse our space usage and then show how to maintain each matching.

Upper bounding size. For C_1, denote by z_1 the sum of all C_i, over all edges in the maximal matching of $G[R \cup \pi(C_i)]$ with $R \leftarrow \{\gamma \in \pi(C_1) \mid C_2 \in \mathbb{P}^*(\gamma)\}$. Lemma 8 presents a data structure with size $O((|\pi(C_1)| + z_1) \log^3 |\pi(C_1)|)$. Denote by $\mathcal{M}(\mathcal{S})$ the set of all edges, across all maximal bichromatic matchings, for all pairs of storing cells (C_1, C_2). Let $\mathcal{M}(\mathcal{S})$ contain z^* elements. It follows that all these data structures use at most $O((n + z^*) \cdot \log^3 n)$ total space. We upper bound the number of edges in z^* by charging each edge to one of their endpoints. Intuitively, we charge each matched edge to the squares of the smallest quadtree cell. Every square $\sigma \in \mathcal{S}$ receives at most $O(\log \psi)$ charges and z^* is upper bound by $n \log \psi$.

More formally, we over-estimate the edges in $\mathcal{M}(\mathcal{S})$. Fix for *every* pair (C_1, C_2) with $C_2 \in \mathcal{P}(\pi(C_1)))$ an arbitrary maximal bichromatic matching in the graph $G[\pi(C_1) \cup \pi(C_2)]$ (i.e., we ignore the fact that we match between sets $R \subseteq \pi(C_1)$ and $B \subseteq \pi(C_2)$, and fix some potentially larger matching in the bigger graph $G[\pi(C_1) \cup \pi(C_2)]$). Denote for C_1 by $\mathcal{M}_{\prec}(C_1)$ the set of all matchings between C_1 and C_2 where $|C_1| \prec |C_2|$ for $\prec \in \{<, =, >\}$. Any edge $e \in \mathcal{M}(\mathcal{S})$ is in $\mathcal{M}_{=}(C_1) \cup \mathcal{M}_{<}(C_1)$ for some storing cell C_1. First, we upper bound $|\mathcal{M}_{=}(C_1)|$. There are $O(1)$ cells C_2 with $|C_1| = |C_2|$ and $C_1 \in \mathcal{P}(\pi(C_2))$ or vice versa. For every such C_2, there can be at most $O(|\pi(C_1)|)$ edges in a MBM in $G[\pi(C_1) \cup \pi(C_2)]$. Thus, there are at most $O(|\pi(C_1)|)$ edges in $\mathcal{M}_{=}(C_1)$. Second, by Lemma 6, there are at most $O(\log \psi)$ cells C_2 with $C_1 \in \mathcal{P}(\pi(C_2))$ and $|C_1| < |C_2|$. Again, every matching in $G[\pi(C_1) \cup \pi(C_2)]$ has at most $O(|\pi(C_1)|)$ edges, thus $\mathcal{M}_{<}(C_1)$ contains at most $O(|\pi(C_1)| \cdot \log \psi)$ edges. Now:

$$z^* = |\mathcal{M}(\mathcal{S})| \leq \sum_{\text{storing cell } C_1} |\mathbb{M}_{=}(C_1)| + |\mathbb{M}_{<}(C_1)| \leq \sum_{\text{storing cell } C_1} |\pi(C_1)| \cdot \log \psi \leq n \log \psi$$

It follows we use at most $O((n + z^*) \cdot \log^3 n) \subset O(n \log \psi \log^3 n))$ space.

Maintaining the MBM. Suppose that we delete a square σ from $\mathcal{S}$ (this is the more difficult case). We can find its storing cell C_σ in $O(\log n)$ time using standard quadtree navigation. We obtain $\mathcal{D}^*(\pi(C_\sigma))$ with its $k \in O(\psi^2)$ conflict sets. Recall that σ appears in at most $l \in O(|\mathcal{P}(\sigma)|)$ conflict sets. By Lemma 8, we may remove σ from the data structure $\mathcal{D}^*(\pi(C_\sigma))$ in $O(l \log^2 n) \subseteq O(|\mathcal{P}(\sigma)| \cdot \log^2 n)$ amortized time. What remains is to update all the matchings. We recall that we maintain a matching between (C_σ, C_2) in two cases: either the cell $C_2 \in \mathcal{P}(\pi(C_\sigma))$ or $C_\sigma \in \mathcal{P}(\pi(C_2))$. There are at most $O(|\mathcal{P}(\pi(C_\sigma))|)$ cells of the first case, and $O(\log \psi)$ cells of the second case. By Theorem 7, we may obtain all such cells in $O(\log^5 n + |\mathcal{P}(\sigma)|)$ time.

Processing a cell C_2. Fix a cell C_2 with a corresponding conflict set R_2 in $\mathcal{D}^*(\pi(C_\sigma))$. We test if σ was an endpoint of the matching (σ, ρ) by searching over the conflict set R_2. If so, then we delete σ from the conflict set R_2. What remains is to try and rematch ρ.

Thus, we want to find a square in $R = \{\gamma \in \pi(\sigma) \mid C_2 \in \mathcal{P}(\gamma)\}$, that is not already in the conflict set R_2 (i.e. not already in the matching between $G[R \cup B]$). Denote by K the cell C_σ scaled by a factor 5 around its center and by $\underline{K}$ the bottom facet of K. We claim that ρ can be matched to a square in R if and only if Query$(\rho, R_2, \underline{K})$ from Lemma 8 is not empty.

Indeed, for any $\gamma \in \pi(C_\sigma)$ that intersects ρ and contains $\underline{K}$, must contain K. By definition, $C_2 \notin \mathcal{P}(\gamma)$ and thus $\gamma \notin R$. For any $\gamma \in \pi(C_\sigma)$ that intersects ρ where $\gamma \in R_2$, by definition $\gamma \notin R \backslash M_{RB}$. For any $\gamma \in \pi(C_\sigma)$ that does not intersect ρ, there is no edge between γ and ρ in $G[R \cup B]$. It follows that with one query we may rematch ρ in $O(\log^3 n)$ amortized time.

Since there are at most $O(|\mathcal{P}(\sigma)| + \log \psi)$ cells C_2 to consider, we can maintain every MBM in $O(|\mathcal{P}(\sigma)| \cdot \log^3 n + \log^5 n)$ time. ◀

8 Dynamic connectivity in square intersection graphs

Having formally introduced and analysed every component, we can now fully state what our data structure maintains. For an illustration, we refer back to Figure 2. We store a data structure that uses at most $O(n \log^3 n \log \psi)$ space:

(1) We store $\mathcal{S}$ in a quadtree $T(\mathcal{S})$.
- This quadtree contains for each cell $\sigma \in \mathcal{S}$ the neighborhood $\mathcal{N}(\sigma)$. Additionally, we
- maintain all $C \in \mathcal{C}(\mathcal{S})$ with $O(|\mathcal{C}(\sigma)| \cdot \log^4 n + \log^6 n)$ amortized time (Thm 7).
- This quadtree requires $O(n \log \psi)$ space (Thm 7).

(2) We augment our quadtree with a Marked-Ancestor Tree (MAT).
- We mark each cell $C \in \mathcal{C}(\mathcal{S})$ in the MAT (Thm 7).

(3) For any storing cell C, we define a conflict set R_i for all cells $C_i \in \mathcal{P}(\pi(C))$. We store $\pi(C)$ with the conflict sets in our square intersection data structure $\mathcal{D}^*(\pi(C))$.
- Let $z^* = \sum_C \sum_i |R_i|$, the total space required is $O((n + z^*) \log^3 n)$ (Lem 8).
- By the proof of Theorem 9, $z^* \in O(n \log \psi)$ so we use $O(n \log \psi \log^3 n)$ total space.

(4) For each storing cell C_1 and each $C_2 \in \mathcal{P}(\pi(C_1))$, we store a Maximal Bichromatic Matching (MBM) in $G[R \cup B]$.
- We set R as the set of squares in C_1 that have C_2 in their perimeter ($R \leftarrow \{\gamma \in \pi(C_1) \mid C_2 \in \mathcal{P}(\gamma)\}$ and $B \leftarrow \pi(C_2)$).
- Updates in $\mathcal{S}$ require $O(|\mathcal{P}(\sigma)| \cdot \log^3 n + \log^5 n)$ amortized time (Thm 9).

(5) Finally, for any pair (C_1, C_2), if their MBM is not empty, we store an edge between them.
- We maintain the resulting "proxy graph" in the HLT data structure [14].
- Inserting or deleting a square σ introduces at most $O(|\mathcal{P}(\sigma)| + \log \psi)$ new edges.

We finally show that this data structure implies the following:

▶ **Theorem 10.** *Let $\mathcal{S}$ be a set of squares with adaptive aspect ratio ψ. We can store $\mathcal{S}$ in a dynamic data structure of size $O(n \log^3 n \log \psi)$ with $O((|\mathcal{C}(\sigma)| + |\mathcal{P}(\sigma)|) \log^4 n + \log^6 n)$ amortized deterministic update time such that for any pair of squares (σ, ρ) we can query for the connectivity between σ and ρ in $O(\log n / \log \log n)$ time.*

Proof. Our pipeline functions identical to the pipeline of [16]. Given σ, we obtain a pointer to its storing cell C_σ in $O(1)$ time. We then query the marked-ancestor tree in $O(\log n / \log \log n)$ time to find the largest ancestor C_α of C_σ that is marked. The cell C_α is marked by at least one squares γ that contains C_α in its interior. We obtain a pointer to γ and its storing cell C^* in $O(1)$ time. We note that if there is also some squares γ' that marked C_α, we may arbitrarily get a pointer to either γ or γ'. Doing the same procedure for ρ gives a cell R^*. We test whether C^* and R^* are connected in the proxy graph $O(\log n/\log\log n)$ time. We now claim that these two cells are connected in the proxy graph if and only if (ρ, σ) are connected. The key observation to prove this claim is that, if we were to rescale the plane, our graph contains the proxy graph maintained by Kaplan et al. [16] as a subgraph. Indeed at the time of a query, ψ is fixed. Thus, we may rescale the plane such that every square has a diameter in $[\frac{1}{\psi}, 1]$. Let $H(\mathcal{S})$ be the quadtree of [16], then $T(\mathcal{S}) \subset H(\mathcal{S})$. Kaplan et al. maintain for every pair (C_1, C_2) with $C_2 \in \mathbb{P}^*(\pi(C_1))$ an Maximal Bichromatic Matching in the graph $G[R' \cup B']$ for $R' \leftarrow \{\gamma \in \pi(C_1) \mid C_2 \in \mathbb{P}^*(\gamma)\}$ and $B' \leftarrow \pi(C_2)$. For each nonempty MBM between a pair (C_1, C_2), they store an edge in the proxy graph.

Note that if the MBM is nonempty, then both C_1 and C_2 are storing cells. It follows that $C_2 \in \mathcal{P}(\pi(C_1))$; and that $R' = R$. Thus, we store for each non-empty MBM a maximal bichromatic matching in the graph $G[R \cup B] = G[R' \cup B']$ as in [16]. This implies that after rescaling, whenever there exists an edge in the proxy graph of [16], there exists an edge in our data structure. Thus, we may immediately apply the proof of Theorem 4.3 in [16] to conclude that (σ, ρ) are connected if and only if (C^*, R^*) are. ◀

Abstract

Analyzing refutations of the well known pebbling formulas $\mathrm{Peb}(G)$ we prove some new strong connections between pebble games and algebraic proof system, showing that there is a parallelism between the reversible, black and black-white pebbling games on one side, and the three algebraic proof systems Nullstellensatz, Monomial Calculus and Polynomial Calculus on the other side. In particular we prove that for any DAG G with a single sink, if there is a Monomial Calculus refutation for $\mathrm{Peb}(G)$ having simultaneously degree s and size t then there is a black pebbling strategy on G with space s and time $t+s$. Also if there is a black pebbling strategy for G with space s and time t it is possible to extract from it a MC refutation for $\mathrm{Peb}(G)$ having simultaneously degree s and size ts. These results are analogous to those proven in [14] for the case of reversible pebbling and Nullstellensatz. Using them we prove degree separations between NS, MC and PC, as well as strong degree-size tradeoffs for MC.

We also notice that for any directed acyclic graph G the space needed in a pebbling strategy on G, for the three versions of the game, reversible, black and black-white, exactly matches the variable space complexity of a refutation of the corresponding pebbling formula $\mathrm{Peb}(G)$ in each of the algebraic proof systems NS, MC and PC. Using known pebbling bounds on graphs, this connection implies separations between the corresponding variable space measures.

1 Introduction

The use of pebble games in complexity theory goes back many decades. They offer a very clean tool to analyze certain complexity measures, mainly space and time, in an isolated way on a graph, which can then be translated to specific computational models. Very good overviews of these results can be found in [26, 28, 23].

We consider several versions of the game, defined formally in the preliminaries. Intuitively, the goal of these games is to measure the minimum number of pebbles needed by a single player in order to place a pebble on the sink of a directed acyclic graph (DAG) following certain rules (this is called the pebbling price). A black pebble can only be placed on a vertex if it is a source or if all its direct predecessors already have a pebble on them, but these pebbles can be removed at any time. A white pebble (modelling non-determinism) can be placed on any vertex at any time but can only be removed if all its direct predecessors contain a pebble. In the reversible pebble game, pebbles can only be placed or removed from a vertex if all the direct predecessors of the vertex contain a pebble. These three games define a short hierarchy being reversible pebbling weaker than black pebbling and this in turn weaker than the black-white pebble game.

In proof complexity one tries to understand the resources needed for a proof of a mathematical statement in a formalized system. Pebbling games have also become one of the most useful tools for proving results in this area. The reason for this is that one can often

translate a certain measure for the pebbling game, mainly number of pebbles or pebbling time, into a suitable complexity measure for a concrete proof system. Very often the bounds for this measure in a graph translate accurately to bounds in the different proof systems for a certain kind of contradictory formulas mimicking the game, called pebbling formulas. These formulas were introduced in [6] and have been extremely useful for proving separations, upper and lower bounds as well as tradeoff results in basically all studied proof systems. See e.g. [22].

In the present paper we will concentrate on algebraic proof system. In these systems formulas are encoded as sets of polynomials over a field and the question of whether a formula is unsatisfiable is translated to the question of whether the polynomials have a common root. Powerful algebraic tools like the Gröbner Basis Algorithm can be used for this purpose. Several algebraic proof systems have been introduced in the literature (defined formally bellow). Well known are Nullstellensatz (NS) introduced in [3] and the more powerful Polynomial Calculus (PC) defined in [11]. The first one is usually considered as a static system in which a "one-shot" proof has to be produced, while in PC there are certain derivation rules like in a more standard proof system.

The best studied complexity measures for refutations in these systems are the degree (maximum degree of a polynomial) and size (number of monomials counted with repetitions). For studying the connections with the pebble games it is very useful to consider also space measures and the configurational refutations associated with space. We will use the variable space measure (number of variables that are simultaneously active in a refutation).

In [8] the Monomial Calculus system (MC) was identified. This system is defined by limiting the multiplication rule in PC to monomials and its power lies between NS and PC. Building on results from [2] for the Sherali-Adams proof system, the authors proved that for any pair of non-isomorphic graphs, the MC degree for the refutation of the corresponding isomorphism formulas exactly corresponds to the Weisfeiler-Leman bound for separating the graphs, a very important tool in graph theory and descriptive complexity. This equivalence (as well as the relations to pebbling shown here) motivates the study of Monomial Calculus as a natural proof system between NC and PC.

As mentioned above, connections between pebbling games and algebraic systems have been known. Already in [9] it was proved that for any directed acyclic graph (DAG) G the corresponding pebbling formula $\mathrm{Peb}(G)$ can be refuted with constant degree in PC but in NS it requires degree $\Omega(s)$, where s is the black pebbling price of $G, \mathsf{Black}(G)$. Using pebbling results, this automatically proves a strong degree separation between NS and PC. As a more recent example, the authors in [14] proved a very tight connection between NS and the reversible pebbling game. They showed that space and time in the game played on a DAG exactly correspond to the degree and size measures in a NS refutation of the corresponding pebbling formula. From this connection strong degree-size tradeoffs for NS follow. This result also improves degree separation from [9] since it is known that there are graphs for which the reversible pebbling price is a logarithmic factor larger than the black pebbling price.

We show in this paper that besides these results, there are further parallelisms between the reversible, black and black-white game hierarchy on one side, and the NS, MC and PC proof systems on the other side.

1.1 Our Results

In Section 3 we prove that very similar results to those given in [14] for NS and reversible pebbling are also true for the case of MC and black pebbling. More concretely we show in Theorem 13 that for any DAG G with a single sink, if there is a MC refutation for $\mathrm{Peb}(G)$

having simultaneously degree s and size t then there is a black pebbling strategy on G with space s and time $t+s$. This is done by proving that any Horn formula has a very especial kind of MC refutation, which we call input monomial refutation since it is the same concept as an input refutation in Resolution. Horn formulas constitute an important class with applications in many areas like program verification or logic programming. It is well known that input Resolution is complete for Horn formulas.

For the other direction, we show in Theorem 8 that from a black pebbling strategy for G with space s and time t it is possible to extract a MC refutation for $\mathrm{Peb}(G)$ having simultaneously degree s and size ts. The small loss in the time parameter compared to the results in [14] comes from the fact that size complexity is measured in slightly different ways in NS and MC. Using these results we are able to show degree separations between NS and MC as well as the first strong degree separations between MC and PC. We also use the simultaneous relation with time and space in the black pebbling game to obtain strong degree-size tradeoffs for MC in the same spirit as those in [14]. The results also show that strong degree lower bounds for MC refutations do not imply exponential size lower bounds as it happens in the PC proof system [19].

The degrees of the refutation for pebbling formulas in NS and MS correspond exactly to the space in reversible and black games respectively. It would be very nice if the same could be said about PC degree and space in the black-white game. Unfortunately this is not the case since as mentioned above, it was proven in [9] that for any DAG the corresponding pebbling formula can be refuted within constant PC degree. We notice however that if instead of the degree we consider the complexity measure of variable space, then the connection still holds. We notice that for for any single sink DAG G the variable space complexity of refuting $\mathrm{Peb}(G)$ in each of the algebraic proof systems NS, MC and PC is exactly the space needed in a strategy for pebbling G in each of the three versions Reversible, Black and Black-White of the pebble game. These results allow us to apply known separations between the pebbling space needed in the different versions of the the game, in order to obtain separations in the variable space measure between the different proof systems.

2 Preliminaries

2.1 Pebble Games

Black pebbling was first mentioned implicitly in [24], while black-white pebbling was introduced in [12]. Note, that there exist several variants of the (black-white) pebble game in the literature. For differences between these variants, we refer to [23]. For the following definitions, let $G=(V,E)$ be a DAG with a unique sink vertex z.

▶ **Definition 1** (Black and black-white pebble games). *The* black-white pebble game *on G is the following one-player game: At any time i of the game, there is a* pebble configuration *$\mathbb{P}_i := (B_i, W_i)$, where $B_i \cap W_i = \varnothing$ and $B_i \subseteq V$ is the set of black pebbles and $W_i \subseteq V$ is the set of white pebbles, respectively. A pebble configuration $\mathbb{P}_{i-1} = (B_{i-1}, W_{i-1})$ can be changed to $\mathbb{P}_i = (B_i, W_i)$ by applying exactly one of the following rules:*

Black pebble placement on v: *If all direct predecessors of an empty vertex v have pebbles on them, a black pebble may be placed on v. More formally, letting $B_i = B_{i-1} \cup \{v\}$ and $W_i = W_{i-1}$ is allowed if $v \notin B_{i-1} \cup W_{i-1}$ and $\mathrm{pred}_G(v) \subseteq B_{i-1} \cup W_{i-1}$. In particular, a black pebble can always be placed on an empty source vertex s, since $\mathrm{pred}_G(s) = \varnothing$.*

Black pebble removal from v: *A black pebble may be removed from any vertex at any time. Formally, if $v \in B_{i-1}$, then we can set $B_i = B_{i-1} \setminus \{v\}$ and $W_i = W_{i-1}$.*

- **White pebble placement on v:** *A white pebble may be placed on any empty vertex at any time. Formally, if $v \notin B_{i-1} \cup W_{i-1}$, then we can set $B_i = B_{i-1}$ and $W_i = W_{i-1} \cup \{v\}$.*
- **White pebble removal from v:** *If all direct predecessors of a white-pebbled vertex v have pebbles on them, the white pebble on v may be removed. Formally, letting $B_i = B_{i-1}$ and $W_i = W_{i-1} \setminus \{v\}$ is allowed if $v \in W_{i-1}$ and $\mathrm{pred}_G(v) \subseteq B_{i-1} \cup W_{i-1}$. In particular, a white pebble can always be removed from a source vertex.*

A black-white pebbling *of G is a sequence of pebble configurations $\mathcal{P} = (\mathbb{P}_0, \mathbb{P}_1, \ldots, \mathbb{P}_t)$ such that $\mathbb{P}_0 = \mathbb{P}_t = (\emptyset, \emptyset)$, for some $i \le t$, $z \in B_i \cup W_i$, and for all $i \in [t]$ it holds that $\mathbb{P}_i$ can be obtained from $\mathbb{P}_{i-1}$ by applying exactly one of the above-stated rules.*

A black pebbling *is a pebbling where $W_i = \varnothing$ for all $i \in [t]$. Observe that w.l.o.g. we can always assume that $B_{t-1} = \{z\}$. For convenience we will also use the dual notion of* white pebbling *game. A white (only) pebbling is a pebbling where $B_i = \varnothing$ for all $i \in [t]$. Notice that $\mathcal{P} = (\mathbb{P}_0, \mathbb{P}_1, \ldots, \mathbb{P}_t)$ is a black pebbling of G if and only if $\mathcal{P}' = (\mathbb{P}'_t, \ldots, \mathbb{P}'_0)$ is a white pebbling of G, where each configuration $\mathbb{P}'_i$ contains the same set of pebbled vertices as in $\mathbb{P}_i$, but with white pebbles instead of black pebbles. In a white pebbling we can always suppose that $W_1 = \{z\}$.*

▶ **Definition 2** (Pebbling time, space, and price). *The* time *of a pebbling $\mathcal{P} = (\mathbb{P}_0, \mathbb{P}_1, \ldots, \mathbb{P}_t)$ is $\mathsf{time}(\mathcal{P}) := t$ and the* space *of it is $\mathsf{space}(\mathcal{P}) := \max_{i \in [t]} |B_i \cup W_i|$. The* black-white pebbling price *(also known as the* pebbling measure *or* pebbling number*) of G, which we will denote by $\mathsf{BW}(G)$, is the minimum space of any black-white pebbling of G. The* black pebbling price *of G, denoted by $\mathsf{Black}(G)$, is the minimum space of any black pebbling of G. By the observation above, the white pebbling price $\mathsf{White}(G)$ coincides with $\mathsf{Black}(G)$*

Finally, we mention the reversible pebble game introduced in [7]. In the reversible pebble game, the moves performed in reverse order should also constitute a legal black pebbling, which means that the rules for pebble placements and removals have to become symmetric. This implies that reversible pebbling is a restricted version of black pebbling. The notions of reversible pebbling time, space, and price are defined as in the other pebbling variants.

2.2 Formulas and Polynomials

We will only consider propositional formulas in conjunctive normal form (CNF). Such a formula is a conjunction of clauses and a clause is a disjunction of literals. A literal is a variable or its negation. For a formula F, $\mathrm{Var}(F)$ denotes the set of its variables.

A Horn formula in a special type of CNF formula in which each clause has at most one positive literal. For a more detailed treatment of formulas as well as the well known Resolution proof system we refer the interested reader to some of the introductory texts in the area like [29]. We will basically only deal with pebbling formulas. These provide the connection between pebbling games and proof complexity.

▶ **Definition 3** (Pebbling formulas). *Let $G = (V, E)$ be a DAG with a set of sources $S \subseteq V$ and a unique sink z. We identify every vertex $v \in V$ with a Boolean variable x_v. For a vertex $v \in V$ we denote by $\mathrm{pred}(v)$ the set of its direct predecessors. In particular, for a source vertex v, $\mathrm{pred}(v) = \emptyset$. The* pebbling contradiction *over G, denoted $\mathrm{Peb}(G)$, is the conjunction of the following clauses:*

- *for all vertices v, the clause $\bigvee_{u \in \mathrm{pred}(v)} \bar{x}_u \vee x_v$,* (pebbling axioms)
- *for the unique sink z, the unit clause $\bar{x}_z$.* (sink axiom)

Observe that every clause in a pebbling formulas has at most one positive literal. These formulas are therefore Horn formulas.

A way to prove that a CNF formula is unsatisfiable is by translating it into a set of polynomials over a field $\mathbb{F}$ and then show that these polynomials do not have any common $\{0,1\}$-valued root. A clause $C = \bigvee_{x\in P} x \vee \bigvee_{y\in N} \bar{y}$ can be encoded as the polynomial $p(C) = \prod_{x\in P}(1-x)\prod_{y\in N} y$. A set of clauses $C_1,\ldots,C_m$ is translated as set of polynomials $p(C_1),\ldots,p(C_m)$. Adding the polynomials $x_i^2 - x_i$ (as axioms) for each variable x_i, there is no common $\{0,1\}$-valued root for all these polynomials if and only if the original set of clauses is unsatisfiable. The intuition here is to identify false with 1 and true with 0. A monomial is falsified by a Boolean assignment if all its variables get value 1, while it is satisfied if one of its variables gets value 0. In this context we will consider a monomial m as a set of variables and a polynomial p as a linear combination of monomials. A monomial with its coefficient in $\mathbb{F}$ is called a monomial term.

When encoding the pebbling formulas as polynomials, for a set $U \subseteq V$, we denote by m_U the monomial $\prod_{u\in U} x_u$. For $U = \emptyset$, $m_U = 1$. For every vertex $v \in V$ the axiom $\bigvee_{u\in \mathrm{pred}(v)} \bar{x}_u \vee x_v$ becomes the polynomial $A_v := m_{\mathrm{pred}(v)}(1-x_v)$, and the sink axiom $\bar{x}_z$ is transformed into the polynomial $A_{sink} := x_z$. Observe that every polynomial in the encoding of a pebbling formula has one or two monomials.

To avoid confusion we will denote the polynomial encoding of a CNF formula F by P_F.

2.3 Algebraic Proof Systems

Several proof systems that work with polynomials have been defined in the literature. The simplest one is *Nullstellensatz*, NS.

▶ **Definition 4.** *A Nullstellensatz refutation of the set of polynomials $p_1,\ldots,p_m$ in $\mathbb{F}[x_1,\ldots,x_n]$ consists of a set of polynomials $g_1,...,g_m,h_1,\ldots,h_n$ such that*

$$\sum_{j=1,\ldots,m} p_j g_j + \sum_{i=1,\ldots,n} h_i(x_i^2 - x_i) = 1.$$

As a consequence of Hilbert's Nullstellensatz, the NS proof systems is sound and complete for the set of encodings of unsatisfiable CNF formulas.

A stronger more dynamic algebraic refutational calculus also dealing with polynomials is the Polynomial Calculus (PC). As in the case of Nullstellensatz, PC is intended to prove the unsolvability of a set of polynomial equations.

▶ **Definition 5.** *The* PC *proof system uses the following rules:*

1. Linear combination

$$\frac{p \qquad q}{\alpha p + \beta q} \qquad \alpha,\beta \in \mathbb{F}.$$

2. Multiplication

$$\frac{p}{x_i p} \qquad i \in [n].$$

A refutation in PC *of an initial unsolvable set of polynomials $\mathcal{P}$ is a sequence of polynomials $\{q_1,\ldots,q_m\}$ such that each q_i is either a polynomial in $\mathcal{P}$, a Boolean axiom $x_i^2 - x_i$ or it is obtained by previous polynomials in the sequence applying one of the rules of the calculus.*

A less known algebraic proof system between NS and PC is Monomial Calculus, MC. This system was introduced in [8] identifying exactly the complexity of refuting graph isomorphism formulas. This proof system is defined like PC but the multiplication rule is only allowed to be applied to a monomial, or to a monomial times an axiom.

▶ **Definition 6.** *The* MC *proof system uses the following rules:*

1. Linear combination

$$\frac{p \qquad q}{\alpha p + \beta q} \qquad \alpha, \beta \in \mathbb{F}.$$

2. Multiplication

$$\frac{p}{x_i p} \qquad i \in [n], \quad p \quad \textit{is a monomial or the product of a monomial and an axiom.}$$

As is the case of PC, *a refutation in* MC *of an initial unsolvable set of polynomials $\mathcal{P}$ is a sequence of polynomials $\{q_1, \ldots, q_m\}$ where each one of them is either in $\mathcal{P}$, an axiom or is obtained by applying one of the rules of the calculus.*

As pointed out in [8], an equivalent definition of the Nullstellensatz system, but a dynamic one, would be to restrict the multiplication rule in the above definition even more, and only allow to apply it to polynomials that are a monomial multiplied by an axiom. In this way, the difference in the definition of the three systems NS, MC and PC is just a variation on how the multiplication rule can be applied. This alternative view of the definition also allows to consider configurational proofs in the NS system. In order to analyze and compare refutations we will consider several complexity measures on them.

▶ **Definition 7** (Complexity measures). *Let $\mathcal{C}$ be one of the mentioned systems $\mathcal{C} \in \{\text{NS}, \text{MC}, \text{PC}\}$ Let $\pi = \{q_1, \ldots, q_m\}$ be a $\mathcal{C}$ refutation. The degree of a polynomial q_i, $\deg(q_i)$ is the maximum degree of its monomials and the* degree *of π, $\deg_{\mathcal{C}}(\pi) = \max_{i=1,\ldots,n}(\deg(q_i))$. The size of π, denoted by $\text{Size}_{\mathcal{C}}(\pi)$ is the total number of monomials in π (counted with repetitions), when all polynomials p_i are fully expanded as linear combinations of monomials*[1].

For the space measures we need to define configurational proofs. Such a proof π in the system $\mathcal{C}$ is a sequence of configurations $\pi = C_0, \ldots C_t$ in which each C_i is a set of polynomials with $C_0 = \emptyset$ and $C_t = 1$. Each configuration C_i represents a set of polynomials that are kept simultaneously in memory at time i in the refutation, and for each $i, 0 < i \leq t$, C_i is either

- *$C_{i-1} \cup \{p\}$ for some axiom p (axiom download),*
- *$C_{i-1} \setminus \{p\}$ (erasure) or*
- *$C_{i-1} \cup \{p\}$ for some p inferred by the rules of $\mathcal{C}$ by some rule of the system (inference).*

The variable space of the proof π, $\text{VSpace}_{\mathcal{C}}(\pi)$ is defined as the maximum number of different variables appearing in any configuration of the proof.

For any of the defined complexity measures Comp and proof systems $\mathcal{C}$, and for every unsatisfiable set of polynomials P_F we denote by $Comp_{\mathcal{C}}(P_F \vdash)$ the minimum over all $\mathcal{C}$ refutations of P_F of $Comp_{\mathcal{C}}(\pi)$.

It is often convenient to consider a multilinear setting in which the multiplications in the mentioned algebraic systems are implicitly multilinearized. Clearly the degree and size measures can only decrease in this setting.

[1] Usually the size in the NS proof system is defined in a different way, for simplicity we keep this unifying definition although in some of the referenced results the size of NS refutations corresponds to the size definition given in the reference.

3 Monomial Calculus and pebbling formulas

In [14] it was shown that for any DAG G with a single sink, the reversible pebbling space and time of G, exactly coincides with the degree and the size of a NS refutation of Peb_G. We show that a very similar relation holds for the case of black pebbling and Monomial Calculus.

▶ **Theorem 8.** *Let G be a directed acyclic graph with a single sink z. If there is a black pebbling strategy of G with time t and space s then there is a MC refutation of* Peb_G *with degree s and size ts. The variable space of this refutation coincides with its degree.*

Proof. It is convenient to consider here the equivalent notion of white pebbling. Let $\mathcal{P} = (\mathbb{P}_0, \ldots, \mathbb{P}_t)$ be a white pebbling strategy for G with $\mathbb{P}_1 = \{z\}$ and $\mathbb{P}_t = \emptyset$ using s pebbles. We show that for each pebbling configuration $\mathbb{P}_i$, $i \in [t]$, $\mathbb{P}_i = \{v_{i_1}, \ldots, v_{i_{k_i}}\}$ the monomial $m_i = \prod_{v \in \mathbb{P}_i} x_v$ can be derived from Peb_G and m_{i-1} in degree s and size 1 if $\mathbb{P}_i$ adds a pebble, or size $2s-1$ if $\mathbb{P}_i$ removes a pebble. This proves the result since in the t steps of the pebbling strategy half of the steps add a pebble and the other half of the steps remove a pebble (each added pebble has to be removed). The total number of steps is therefore $\frac{t}{2} + \frac{t}{2}(2s-1) = ts$.

Pebble placement. If the configuration at pebbling step $i+1$ is reached after placing a white pebble on vertex v and $\mathbb{P}_i = \{u_{i_1}, \ldots, u_{i_{k_i}}\}$ with $k_i \leq s-1$ then $\mathbb{P}_{i+1} = \{v, u_{i_1}, \ldots, u_{i_{k_i}}\}$. Multiplying the monomial $m_i = \prod_{u \in \mathbb{P}_i} x_u$ by the variable x_v we obtain m_{i+1}. We have just added one more monomial of degree at most s to the proof.

Pebble removal. If the configuration at pebbling step $i+1$ is reached after removing a white pebble from vertex v and $\mathbb{P}_i = \{v, u_{i_1}, \ldots, u_{i_{k_i}}\}$ with $k_i \leq s-1$ then all predecessors of v are in the set $\{u_{i_1}, \ldots, u_{i_{k_i}}\}$. For the derivation of m_{i+1} we can multiply the axiom $(1 - x_v)\prod_{u \in \mathrm{pred}(v)} x_u$ by the variables in $\mathrm{Var}(m_i) \setminus (\bigcup_{u \in \mathrm{pred}(v)} x_u \cup \{x_v\})$, and add this polynomial to m_i obtaining m_{i+1}. Since there are at most $s-1$ variables in $\mathrm{Var}(m_i) \setminus (\bigcup_{u \in \mathrm{pred}(v)} x_u \cup \{x_v\})$, the number of intermediate monomials added to the proof (counting also monomial m_{i+1}) is at most $2(s-1)+1 = 2s-1$.

Observe that in all the steps in the refutation, at most two different monomials are active and the number of different variables in these monomials coincides with the largest of their degrees. This shows that the variable space of the MC refutation is also bounded by s. ◀

▶ **Observation 9.** *The size bound ts in the above proof comes from the way the MC rules are defined. As is the case of PC, in the multiplication rule only one variable at at time is multiplied, even when multiplying the axiom polynomials. When an axiom is multiplied by a monomial with several variables, all the intermediate polynomials contribute to the size of the MC refutation. This is different from the the usual way to measure the size in the NS case, where intermediate monomials are not counted. If we would define the MC rules as those in NS, that is, if a whole monomial could be multiplied by an axiom in one step, the size of the MC proof would be would avoid the s factor in the monomial size and obtain size $2t$ instead.*

In order to prove a result in the other direction we consider a very restricted kind of refutation in MC, similar to what is known as an input refutation in Resolution. It this kind of refutation in every Resolution step one of the parent clauses must be an axiom. Input Resolution is not complete, but it is complete for Horn formulas. We will show that the same is true for MC input refutations.

▶ **Definition 10.** *A MC refutation π of a contradictory set of polynomials F is called an* input refutation *if there is a sequence of monomials $M_0, \ldots, M_t$ such that M_0 is the product of a monomial and an axiom, $M_t = 1$ and for each i M_i is obtained by multiplying M_{i-1}*

times a variable, or by the linear combination rule from M_{i-1} and a monomial multiplied by an axiom polynomial. We will call the sequence of monomials $M_0, \dots, M_t$ the backbone of the proof.

▶ **Lemma 11.** *Let F be an unsatisfiable Horn formula and let P_F be the encoding of F as a set of polynomials. Let π be any MC refutation of P_F. There is an input MC refutation π' of P_F with at most the same size and degree as π.*

Proof. Let d and t be the degree and size of π. We can suppose that π is multilinear. We prove the result by induction on k, the number of times the multiplication rule is applied to a monomial derived in π. In the base case $k = 0$, π is just a NS refutation of P_F. This means that there is a linear combination of a set of polynomials S that adds up to 1. Each of these polynomials has the form of a polynomial axiom multiplied by a monomial and since F is a Horn formula, each polynomial in S has either one or two monomials. We will represent such a polynomial $p = \alpha_m m + \alpha_{m'} m'$ by the pair of monomials (m, m'). In all these polynomials the monomial terms have some coefficients α_m and $\alpha_{m'}$. Clauses without positive literals are encoded as single monomials. Some polynomial in S has a single monomial otherwise the whole set S would have a common root by setting all variables to 1. Moreover, there has to be a sequence of polynomials $p_1, \dots, p_\ell$ represented by the monomials $(\emptyset, m_1), (m_1, m_2), (m_2, m_3) \dots, (m_{\ell-1}, m)$ [2]. This is because the linear combination adds up to 1 and for this to happen, there has to be a polynomial $(\emptyset, m_1)$ in the linear combination since otherwise all monomials would have variables. Also the monomial m_1 in $(\emptyset, m_1)$ has to be cancelled and there has to be some other polynomial of the form (m_1, m_2) and so on. It must also hold that some polynomial in the sequence must have the form $(m_{\ell-1}, m)$ that can cancel with one of the polynomials with a single monomial m in S. We suppose that $p_1, \dots, p_\ell$ is a minimal sequence with these properties. Now we can define the input monomial refutation π starting at $M_0 = m$ and applying then ℓ linear combinations with axioms multiplied by monomials and deriving all the monomials $m_\ell, \dots, m_1$ until 1 is derived. Observe that the monomials $M_0, \dots M_t$ are exactly those appearing in $p_1, \dots, p_\ell$. By the minimality of the sequence we also know that the monomials in the backbone are all different.

All the monomials in π' belong also to π, therefore the degree of the new refutation is not larger than that in π. In fact all the polynomials in $p_1, \dots, p_\ell$ are already in π. Besides these polynomials π' contains also the ℓ new monomials in the backbone. Since the $p_1, \dots, p_\ell$ and m belong to π and in each linear combination of two polynomials at most one monomial vanishes, there are at least ℓ intermediate polynomials in π until 1 is reached. This means that the size of π' is bounded by t.

For the case $k > 0$ let m' be the first monomial in the proof that is the result of a multiplication from a derived monomial m and a variable x, $m' = xm$ in π. The same argument as above shows that there is a sequence of polynomials $p_1, \dots, p_\ell, \hat{m}$ in π from which we can extract an input monomial refutation that starts at $M_0 = \hat{m}$ and derives at some point $M_i = m$. In the next step the multiplication rule is applied to obtain $M_{i+1} = m'$. Observe that the set of polynomials $m' \cup P_F$ still has the Horn property and that there is sub-proof of π that refutes this set to the monomial 1 applying the multiplication rule at most $k - 1$ times. By induction hypothesis we know that there is a sequence of polynomials $p'_1, \dots, p'_{\ell'}$ in π represented by the monomials $(\emptyset, m'_1), (m'_1, m'_2), \dots, (m'_r, m')$ from which an input refutation of $P_F \cup m'$ can be extracted. We can put together both input MC refutations $M_0 \dots M_i$ and $M_{i+1}, \dots, 1$. Again we can assume that all the monomials in the backbone

[2] Since we are representing monomials by their set of variables, the monomial 1 is represented by $\emptyset$

are different since if $M_i = M_j$ for $i < j$, we could shorten π' by connecting M_i with M_{j+1}. By the same argument as in the base case the size and degree of the input MC refutation cannot be larger than that of π. ◀

Since pebbling formulas are Horn formulas we immediately obtain:

▶ **Corollary 12.** *Let G be a directed acyclic graph with a single sink vertex z and let π be a MC refutation of* $\mathrm{Peb}(G)$*. There is an input MC refutation π' of* $\mathrm{Peb}(G)$ *with at most the same size and degree as π.*

We consider next a result in the other direction.

▶ **Theorem 13.** *Let G be a directed acyclic graph with a single sink. Let π be a MC refutation of* $\mathrm{Peb}(G)$ *with degree s and size t. There is a black pebbling strategy with s pebbles and time $t + s$.*

Proof. Because of Corollary 12 we can suppose that there exits an input MC refutation with monomials $M_0, \dots M_t$ starting with $M_1 = mx_{\mathrm{sink}}$ for some monomial m and with $M_t = 1$. We describe a strategy for a white pebbling of G following π. At each step i only the vertices corresponding to variables in M_i have a pebble on them. In a multiplication step a new pebble is added, which is always possible in a white pebbling strategy. We only have to show that in case variables disappear when going from M_i to M_{i+1}, this is a correct pebbling move. But in this case, the step from i to $i + 1$ is a linear combination of M_i with the axiom for some vertex v, $m_{\mathrm{pred}(v)}(1 - x_v)$ multiplied by some monomial m. The only variable that can disappear in M_{i+1} is x_v and in this case $M_i = m_{\mathrm{pred}(v)}x_v$. Therefore all the vertices in $\mathrm{pred}(v)$ have pebbles on them and the pebble in x_v can be removed. At the end of the refutation, when the 1 monomial is reached there are no pebbles left on G. The number of pebbles present at any moment is the number of variables in any of the monomials and this is the degree of π. The number of pebbling steps needed is at most d steps to place a pebble in each variable of $M_1 = mx_{\mathrm{sink}}$ and then t more pebbling steps. ◀

▶ **Observation 14.** *For the case of Polynomial Calculus it is known that strong degree lower bounds imply size lower bounds. If a set of unsatisfiable polynomials P_F with n variables and constant degree requires PC refutations of degree s, then any PC refutation of P_F requires size at least $2^{\Omega(\frac{d^2}{n})}$ [19]. The previous results show that this does not hold for Monomial Calculus. This follows from the fact that there are graph families $\{G_n\}_{n=0}^{\infty}$ with n vertices and constant in-degree that require black pebbling space $\Omega(\frac{n}{\log n})$ [25]. Theorem 13 implies that the pebbling formulas for this graph family needs degree $\Omega(\frac{n}{\log n})$. On the other hand, for every single-sink DAG with n vertices there is a trivial black pebbling strategy using space n and pebbling time $2n$. By Theorem 8 this implies that the pebbling formulas corresponding to the graphs in $\{G_n\}_{n=0}^{\infty}$ have MC refutations of quadratic size in n. This is a family of formulas with MC refutation degree $\Omega(\frac{n}{\log n})$ but having quadratic size refutations, a very different situation from the PC case.*

3.1 Degree separations

The given relationships between MC and the black pebbling game allow for the immediate translation of pebbling results to Monomial Calculus. We start with some degree separations between MC and PC. The original motivation for introducing MC was the close connection between the degree complexity of the refutation of the graph isomorphism formulas in this proof system, and the Weisfeiler-Leman hierarchy [8]. Formulas corresponding to non-isomorphic graphs pairs that can only be distinguished using a large level of the WL algorithm, require a MC refutation with large degree. It was proven later in [1, 15], that the degree of a PC refutation of the isomorphism formulas cannot be much smaller than in the MC case, in fact the degrees of a MC and a PC refutation can only be a constant factor apart. We improve this separation and obtain an almost optimal degree separations by considering the pebbling formulas. In [9] it was shown that pebbling formulas have constant PC degree and that for any directed acyclic graph G with black pebbling price $B(G)$, the formula $\mathrm{Peb}(G)$ requires NS refutations with degree $\Omega(B(G))$. Since it is known that there are graph families $\{G_n\}_{n=0}^{\infty}$ with $\Theta(n)$ vertices and $B(G_n) = \Omega(\frac{n}{\log n})$ [25], this implies a degree separation of $\Omega(\frac{n}{\log n})$ between PC and NS. From Theorem 13 follows that this is in fact a degree separation between MC and PC.

▶ **Theorem 15.** *There is an unsatisfiable family of formulas $\{F_n\}_{n=0}^{\infty}$ with $\Theta(n)$ variables each, that have PC refutations of constant degree but require MC refutations of degree $\Omega(\frac{n}{\log n})$.*

For the case of NS, from Theorem 8 and the equivalence between reversible pebbling price and NS degree from [13], [14], follows that a separation between reversible and black pebbling price for a graph family implies a degree separation between NS and MC for the corresponding pebbling formulas. For example it is known that a directed path graphs with n vertices can be black pebbled with 2 pebbles but requires reversible pebbling number $\lceil \log n \rceil$ [7]. Translated to pebbling formulas this means:

▶ **Theorem 16.** *There is a family of unsatisfiable formulas $\{F_n\}_{n=0}^{\infty}$ with $\Theta(n)$ variables each, that have MC refutations of degree 2 but require NS refutations of degree $\lceil \log n \rceil$.*

There are other graph families for which a separation between the black and reversible pebbling prices by a logarithmic factor in the number of vertices is known, [10],[30]. The separations in pebbling for these graphs is translated into the next result.

▶ **Theorem 17.** *For any function $s(n) = O(n^{1/2-\epsilon})$ for constant $0 < \epsilon < \frac{1}{2}$ there is a family of unsatisfiable formulas $\{F_n\}_{n=0}^{\infty}$ with $\Theta(n)$ variables each, that have MC refutations of degree $O(s(n))$ but require NS refutations of degree $\Omega(s(n) \log n)$.*

The question of whether the separation between reversible and black pebbling space can be larger than a logarithmic factor in the number of nodes is open. The best known degree separation between NS and and MC is slightly better. This was obtained in [16] with very different methods. Using a classic result from descriptive complexity [18], the authors show that for for every constant $c \geq 1$ there are families of formulas F_n with O(n) variables that have a degree 3 MC refutation but require NS degree at least $\log^c(n)$. It is also open whether this degree separation between NS and MC is optimal.

3.2 Size-degree tradeoffs for MC

The close connections between black pebbling space and monomial calculus expressed in Theorems 8,13 make it possible to translate space-time tradeoffs for pebbling into degree-size tradeoffs for MC. There is a slight loss of the time parameter that comes from the extra space factor in the the MC refutation from Theorem 8. We present two such results as examples. The first one is an extreme tradeoff result that shows how decreasing the degree by one can make the size increase exponentially.

▶ **Theorem 18** ([28]). *There is a family of directed graphs $\{G_n\}_{n=0}^{\infty}$ having $\Theta(n^2)$ vertices each and with $\mathsf{Black}(G_n) = \Theta(n)$ for which any black pebbling strategy with $\mathsf{Black}(G_n)$ pebbles requires at least $2^{\Omega(n \log n)}$ steps while there is a pebbling strategy with $\mathsf{Black}(G_n) + 1$ pebbles and $O(n^2)$ steps.*

▶ **Corollary 19.** *There is a family of unsatisfiable formulas $\{F_n\}_{n=0}^{\infty}$ with F_n having $O(n^2)$ variables and $d_n \in O(n)$ such that F_n has a MC refutation of degree d_n but any MC refutation with this degree requires size $2^{\Omega(n \log n)}$. On the other side there is a MC refutation of F_n with degree $d_n + 1$ and size $O(n^3)$.*

As a second example we present a robust time-space result from [23].

▶ **Theorem 20.** *There is a family of directed graphs $\{G_n\}_{n=0}^{\infty}$ having $\Theta(n)$ vertices each and with $\mathsf{Black}(G_n) = O(\log^2 n)$, with a black pebbling strategy in space $O(n/\log n)$ and time $O(n)$. There is also a constant $c > 0$ for which any pebbling strategy using less than $cn/\log n$ pebbles requires at least $n^{\Omega(\log \log n)}$ steps.*

▶ **Corollary 21.** *There is a family of unsatisfiable formulas $\{F_n\}_{n=0}^{\infty}$ with F_n having $O(n)$ variables, and a constant $c > 0$ such that F_n has a MC refutation of degree $O(n/\log n)$ and size $O(n^2/\log n)$ but for which any MC refutation with degree smaller than $cn/\log n$ requires size at least $n^{\Omega(\log \log n)}$.*

4 Pebble Games and Variable Space

The equality between degree and pebbling price for the cases of Monomial Calculus and black pebbling from the previous section, as well as for Nullstellensatz and reversible pebbling from [14] cannot be extended to the case of Polynomial Calculus and black-white pebbling price since as already mentioned, it was proven in [9] that for any DAG G, $\deg_{\mathrm{PC}}(\mathrm{Peb}(G)) = O(1)$. We show in this section that the correspondence between the three pebbling variations and the proof systems holds if we consider the variables space measure instead.

It can be seen in the proof of Theorem 8, that not only the minimum degree of a monomial calculus refutation of $\mathrm{Peb}(G)$, but also the minimum variable space is bounded by the black pebbling price of G. The same can be observed in the proof of Theorem 3.1 in [14] for the case of Nullstellensatz and reversible pebbling. Considering the trivial fact that variable space measure is always greater or equal that the degree needed for the refutation of a formula in all three proof systems NS, MC and PC, and considering Theorems 13 as well as Theorem 3.4 in [14] this implies:

▶ **Observation 22.** *For every DAG G with a single sink,* $\mathrm{VSpace}_{\mathrm{NS}}(\mathrm{Peb}(G) \vdash) = \mathsf{Rev}(G)$ *and* $\mathrm{VSpace}_{\mathrm{MC}}(\mathrm{Peb}(G) \vdash) = \mathsf{Black}(G)$*.*

For the case of black-white pebbling it is known that for the Resolution proof system, the variable space needed in a refutation of $\mathrm{Peb}(G)$ equals $\mathsf{BW}(G)$. The inclusion from left to right is from [5] while the other inclusion appeared in [17]. This results can be extended to other proof systems using the following result:

▶ **Lemma 23** ([4], [27]). *Let S be a proof system that can simulate Resolution step by step without including new variables. For every unsatisfiable formula F,* $\mathrm{VSpace}_S(F \vdash) = \mathrm{VSpace}_{\mathrm{Res}}(F \vdash)$*.*

This implies:

▶ **Observation 24.** *For every DAG G with a single sink,* $\mathrm{VSpace}_{\mathrm{PC}}(\mathrm{Peb}(G) \vdash) = \mathsf{BW}(G)$*.*

Which together with Observation 22 shows the equivalence between variable space in the proof systems and the pebbling price in the three variations of the game.

4.1 Variable Space Separations

These observations allow us to use pebbling results to obtain separation in the variable space complexity in the algebraic proof systems. The reason why these results do not contradict Lemma 23, is that MC (or NS) cannot simulate Resolution step by step since the intermediate polynomials are not necessarily monomials.

For the variable space separations between NS and MC on pebbling formulas, the same degree separations given in Subsection 3.1 hold, since as we have seen, for this kind of formulas the variable space and the degree coincide in both proof systems. For the case of MC versus PC, it is known that for any DAG G, the separation between the black and the black-white pebbling prices can be at most quadratic [21]. This limits the variable space gap between MC and PC that can be obtained using pebbling formulas. In [31] a family of graphs is given that shows an asymptotic separation between the black-white and black pebbling prices. Translating this to our context we obtain:

▶ **Theorem 25.** *There is a family of unsatisfiable formulas* $\{F_n\}_{n=0}^{\infty}$ *with polynomially many variables (in* n*) such that* $\mathrm{VSpace}_{\mathrm{PC}}(F_n \vdash) = O(n)$ *and* $\mathrm{VSpace}_{\mathrm{MC}}(F_n \vdash) = \Omega(\frac{n \log n}{\log \log n})$.

An optimal quadratic separation between the black-white and black pebbling price was given in [20] but for a family of graphs having exponentially many vertices respect to their pebbling price. This implies:

▶ **Theorem 26.** *There is a family of unsatisfiable formulas* $\{F_n\}_{n=0}^{\infty}$ *with* $\exp(\Theta(n \log n))$ *many variables such that* $\mathrm{VSpace}_{\mathrm{PC}}(F_n \vdash) = O(n)$ *and* $\mathrm{VSpace}_{\mathrm{MC}}(F_n \vdash) = \Omega(n^2)$.

5 Conclusions and Open Questions

We have proven a strong connection between the black pebble game and the Monomial Calculus proof system by showing that the degree and size bounds required simultaneously in a MC refutation of the pebbling formula for a DAG G closely correspond to the number of pebbles and the time in a pebbling strategy for G. This improves the known relations between the complexities of pebble games and algebraic proof systems and implies strong degree-size tradeoffs for the MC system as well as degree separations between NS, MC and PC.

We have also shown that the variable space measure for the refutation of pebbling formulas in the three systems PC, MC and NS exactly corresponds to the number of pebbles in the black, black-white and reversible games. From this equivalence we obtain variable space separations between the proof systems.

It is open whether these separations are optimal or can be improved using other techniques. Finding out what is the optimal degree separation between the NS and MC proof systems is another interesting open question.

Punctual Presentability in Certain Classes of Algebraic Structures

Abstract

Punctual structure theory is a rapidly emerging subfield of computable structure theory which aims at understanding the primitive recursive content of algebraic structures. A structure with domain ℕ is punctual if its relations and functions are (uniformly) primitive recursive. One of the fundamental problems of this area is to understand which computable members of a given class of structures admit a punctual presentation. We investigate such a problem for a number of familiar classes of algebraic structures, paying special attention to the case of trees, presented both in a relational and functional signature.

1 Introduction

Computable structure theory is a vast research program which aims at analyzing the algorithmic content of algebraic structures through the tools of computability theory (for an excellent introduction to this field, see [15]). The fundamental concept of when a structure is computably presented dates back to the seminal work of Mal'cev [14] and Rabin [16] in the 1960s: A structure with domain the set ℕ of the natural numbers is computable if its relations and functions are uniformly Turing computable. Then, a countably infinite structure is computably presentable (or, it has computable copy) if it is isomorphic to some computable structure.

A classic problem in computable structure theory is to understand, for familiar classes of structures $\mathfrak{K}$, which members of $\mathfrak{K}$ are computably presentable. Sometimes the answer is that *every* member of $\mathfrak{K}$ has a computable copy: this is the case for, e.g., vector spaces over ℚ and algebraically closed fields of a given characteristic. On the other hand, it is an immediate consequence of Tennebaum's theorem that, among models of Peano Arithmetic, only one is computably presentable: the standard model. Yet, in most cases, characterizing the computable members of $\mathfrak{K}$ is a delicate task, which often requires to individuate nice invariants for $\mathfrak{K}$ (if any) and to determine how hard is to compute such invariants.

A parallel endeavour is to explore when a computable algebraic structure has a feasible presentation. The problem can be formalized in a number of different ways leading, e.g., to the study of algebraic structures presented by finite state automata [13], or to polynomial-time algebra [7, 1]. Kalimullin, Melnikov, and Ng [12] initiated the systematic study of punctual presentations, that lies somewhere in the between of computability and complexity theory:

▶ **Definition 1.** *A structure with domain* $\mathbb{N}$ *is* punctual *(or, fully primitive recursive) if its relations and functions are uniformly primitive recursive.*

Then, clearly, a structure is punctually presentable, if it is isomorphic to some punctual structure. Intuitively – and by relying on a sort of restricted Church-Turing thesis – a structure is punctual, if there is algorithmic with no unbounded search which is able to decide any quantifier-free question about the structure (that is, for any such question, one knows in advance how much time is needed to compute an answer).

Punctual structure theory rapidly emerged as an intriguing subfield of computable structure theory [10, 11, 4, 3] and it also serves as a theoretical underpinning for the study of online algorithms [2] (i.e., algorithms in which the input is received and processed piece by piece without having access from the start to the complete problem data).

One of notable results is that the index set of computable structures that are punctually presentable is Σ^1_1-complete [5]. However, if we restrict the class of structures is some natural way, it may be the case that every computable member from that class is punctually presentable (and thus the corresponding index set is trivial).

▶ **Definition 2.** *We say that a class of structures* $\mathfrak{K}$ *is* punctually robust*, if every computable member of* $\mathfrak{K}$ *admits a punctual presentation.*

In [12], it is proven that the following classes of structures are punctually robust: equivalence structures, linear orders, torsion-free abelian groups, Boolean algebras, and abelian p-groups; on the other hand, there are computable undirected graphs, computable torsion abelian groups, and computable Archimedean ordered abelian groups with no punctual copy. In this work, we contribute to this line of research, exhibiting new examples of both classes that are punctually robust and classes that are not.

Kalimullin, Melnikov, and Ng [12] showed that there exists a computable undirected graph with no punctual presentation. However, many natural classes of graphs admit such presentations. In Section 3, using a technique introduced in [12] for showing that equivalence structures are punctually presentable, we isolate one such class.

▶ **Proposition 3.** *Every computable digraph with an infinite semi-transversal is punctually presentable.*

For structures with a functional signature, the situation may change drastically. One of the simplest types of purely functional structures are the so-called injection structures. They are of the form $\mathcal{A} = (\mathbb{N}, f)$, where f is 1-1. Injection structures have already been considered in the computable setting (see, e.g., [6]) and in punctual structure theory with an emphasis on punctual categoricity in [10]. In Section 4 we prove the following:

▶ **Theorem 4.** *The class of injection structures is not punctually robust.*

The structure witnessing that injections structures are not punctually robust will consist only of cycles. One can observe that the relational counterpart of this structure is punctually presentable (this follows from Proposition 3). We supplement Theorem 4 by a list of sufficient conditions for an injection structure to be punctually presentable, as well as by a list of conditions equivalent to their punctual presentability. These supplementary results are omitted due to space constraints and will appear in the extended version.[1]

A similar contrast emerges for trees. We show that the punctual robustness (or, lack thereof) of the class of trees depends on how they are presented. More precisely, in Section 5 we consider the notion of a tree represented as a function mapping each child to its parent and looping back at the root. We then prove the main result of the paper:

▶ **Theorem 5.** *The class of functional trees is not punctually robust.*

2 Preliminaries

We denote the set of natural numbers by $\mathbb{N}$. We let $[a, b) = \{x \in \mathbb{N} : a \le x < b\}$. We assume a fixed computable enumeration $p_0, p_1, \dots$ of all primitive recursive unary functions. We abbreviate *primitive recursive* as *p.r.* By f^n be denote the n-fold composition of f with itself. If F is a partial function or a relation, χ_F denotes a graph of F. A structure is any tuple $\mathcal{A} = (A, (R_i)_{i\in I}, (f_j)_{j\in J}, (c_k)_{k\in K})$, where $A \neq \emptyset$ is the domain of $\mathcal{A}$, in symbols $dom(\mathcal{A})$, while R_i, f_j, c_k are relations, functions, constants on A. By $\mathcal{A} \cong \mathcal{B}$ we mean that $\mathcal{A}$ and $\mathcal{B}$ are isomorphic, and by $\mathcal{A} \hookrightarrow \mathcal{B}$ that $\mathcal{A}$ embeds into $\mathcal{B}$. All structures in this article are countably infinite, except finite structures that appear in constructions.

▶ **Definition 6** (computable structure)**.** *A structure is a computable if its domain, as well as all relations, functions, and constants from its signature are uniformly computable.*

Punctual structures were defined in the introduction (Definition 1).

Notice that $(\mathbb{N}, p_0), (\mathbb{N}, p_1), \dots$ is a computable enumeration of all punctual structures with just one unary functional symbol.

▶ **Definition 7** (punctual presentability)**.** *A structure $\mathcal{A}$ is a copy (presentation) of $\mathcal{B}$ if $\mathcal{A}$ and $\mathcal{B}$ are isomorphic. We say that $\mathcal{A}$ is punctually presentable if $\mathcal{A}$ has a punctual presentation.*

3 Directed graphs

In this section, we individuate a class of computable directed graphs (from now on, digraphs) which are punctually presentable. For a digraph $G = (\mathbb{N}, E_G)$, we denote by L_G the collection of G-nodes with loops, i.e., $L_G := \{x : (x, x) \in E_G\}$. We denote by $G \restriction_c$ the restriction of G to the initial segment $\{x : 0 \le x \le c\}$.

▶ **Definition 8** (semi-transversal)**.** *Let $G = (\mathbb{N}, E_G)$ be a computable digraph. The* semi-transversal *of G, denoted as τ_G, is the collection of numbers that are not adjacent to any smaller number, i.e.,*

$$\tau_G := \{x : (\forall y < x)(\{(y, x), (x, y)\} \cap E_G = \emptyset)\}.$$

It is immediate to observe that τ_G is computable, whenever G is computable. As aforementioned, the following result elaborates on ideas presented in [12] when dealing with equivalence structures. The proof may serve as a gentle introduction to the way of thinking about punctual copies and as a warm-up to the more complex constructions of this paper.

[1] Following a suggestion from one of the reviewers, the authors have realized that some results on injection structures were obtained earlier [8]. Essentially, Theorem 4 should be attributed to Cenzer and Remmel (see, Lemma 3.12 and Theorem 3.13 in [8]). For completeness of the presentation, we include our proof of this theorem in the punctual setting.

▶ **Proposition 3.** *Every computable digraph with an infinite semi-transversal is punctually presentable.*

Proof. Let $G = (\mathbb{N}, E_G)$ be a computable digraph so that τ_G is an infinite set. For the sake of exposition, we assume that both $L_G \cap \tau_G$ and $(\mathbb{N} \setminus L_G) \cap \tau_G$ are infinite (the other cases are treated similarly and are somehow simpler). We will build by stages a punctual copy P_G of G and a bijection $f : \mathbb{N} \to \mathbb{N}$ witnessing that $G \cong P_G$.

The underlying idea of the proof is rather straightforward: At any given stage of the construction, we monitor a finite fragment of G. In particular, we aim at determining if a given number c belongs to τ_G. This information is computable but, in general, not primitive recursive. So to ensure that P_G will be punctual, while waiting to know if $c \in \tau_G$, we let several numbers x to be inactive (meaning that such numbers will belong to the semi-transversal of P_G). If we see that $c \notin \tau_G$, we extend the desired isomorphism by letting $f(c)$ be a fresh number and ensuring that $G \restriction_c$ embeds into the active part of P_G. On the other hand, if $c \in \tau_G$, we will let $f(c)$ be a suitable inactive number z (which returns active right after this action). Let us now be formal.

Construction

To record which fragment of G is currently monitored, we use a parameter c that will be updated as the construction proceeds. Moreover, during the construction some numbers x will be marked as *inactive*: specifically, by declaring x to be *no loop-inactive* (*NL*-inactive), we let x be non-adjacent (in P_G) to any number $\leq x$; by declaring x as *loop-inactive* (L-inactive), we let x non-adjacent (in P_G) to any number $< x$ but we also let $(x, x) \in P_G$. *Active* numbers are those that are neither *NL*-inactive nor L-inactive.

At stage 0, all numbers in $\mathbb{N}$ are active; we let c be 0 and we immediately move to the next stage. At all stages $s > 0$, we see if the following condition holds:

$$(\forall x \leq c)(\chi_{E_G}(x, c)\downarrow \text{ and } \chi_{E_G}(c, x)\downarrow \text{ in less than } s \text{ stages}). \tag{$\star$}$$

If $(\star)$ is not met, we declare $2s$ to be *NL*-inactive and $2s + 1$ to be L-inactive. Then, we move to the next stage. Otherwise, if $(\star)$ is met, we can determine whether c belongs to τ_G. Then, we distinguish two cases:

1. If $c \notin \tau_G$, we define $f(c) = 2s$ and we mirror an initial segment of the G-neighborhood of c by forming the P_G-edges that are needed to ensure that, for all $x \leq c$, the following equation holds:

$$(x, c) \in E_G \Leftrightarrow (f(x), f(c)) \in E_{P_G} \ \&\ (c, x) \in E_G \Leftrightarrow (f(c), f(x)) \in E_{P_G}. \tag{$\dagger$}$$

   Finally, we declare $2s + 1$ *NL*-inactive.
2. We distinguish two subcases:
   a. If $c \in L_G \cap \tau_G$, we define $f(c) = z$ for the least number z which is L-inactive, and we mark z as active (if there is no such number, we define $f(c) = 2s + 1$). Then, we declare $2s$ to be NL-inactive.
   b. If $c \in (\mathbb{N} \setminus L_G) \cap \tau_G$, the situation is symmetric: We define $f(c) = z$ for the least number z which is NL-inactive, and we mark z as active (if there is no such number, we define $f(c) = 2s$), and we declare $2s + 1$ to be L-inactive.

In both cases 1. and 2., we increase c by one and we move to the next stage.

Verification

From the construction, it follows immediately that P_G is punctual: indeed, to decide if $(u,v) \in E_{P_G}$, for $u < v$, it suffices to run the construction until stage $\lfloor v/2 \rfloor$ and each stage s requires at most s steps to be completed. To see that P_G is isomorphic to G, we begin by arguing that f is bijection.

▶ **Lemma 9.** *The function $f : \mathbb{N} \to \mathbb{N}$ is a bijection.*

Proof. Say that a stage s is *expansionary*, if at stage s the condition $(\star)$ holds. It is not hard to see that there are infinitely many expansionary stages: indeed, since G is computable, for any choice of the parameter c, there will a stage at which we are able to entirely compute $G \restriction_c$. Now, observe that the parameter c starts as 0 and is increased by one whenever $f(c)$ is defined. Thus, f is total.

Next, let $u < v$ be numbers on which f is defined at stages $s_u < s_v$. By construction, $f(u) \in \{2s_u, 2s_{u+1}, z\}$, for some z which is *NL*-inactive or L-inactive at the beginning of stage s_u; on the other hand, $f(v) \in \{2s_v, 2s_{v+1}, z'\}$, for some z' which is NL-inactive or L-inactive at stage s_v. Observe that $z \neq z'$, since z returns active as soon as it enters the range of f. Thus, f is injective.

To deduce that f is surjective, it suffices to prove that all numbers are eventually active: indeed, if a number $z \in \{2s, 2s+1\}$ is active at all stages, then s must an expansionary stage at which z enters the range of f; similarly, if at stage s some number z returns active, after being *NL*-inactive or L-inactive, then z simultaneously enters the range of f. Towards a contradiction, suppose there is a least number u which is declared, say, L-inactive and eventually remains so. Since $L_G \cap \tau_G$ is infinite, then there must be a stage s at which the condition $(\star)$ is met and we perform action 2.a, by which z (being the least L-inactive number) enters the range of f, contradicting our hypothesis. Hence, f is surjective. ◀

Finally, we shall prove that the bijection f yields an isomorphism from G to P_G. Suppose that, for a pair of numbers $u < v$,

$$(u,v) \in E_G \not\Leftrightarrow (f(u), f(v)) \in E_{P_G}.$$

Let s_u and s_v be the stages at which $f(u)$ and $f(v)$ are, respectively, defined. By construction, $s_u < s_v$, so that $f(u)$ is already defined at stage s_v. Moreover, at stage s_v, we decide whether $(f(u), f(v)) \in E_{P_G}$: if $v \notin \tau_G$, then condition (†) ensures that $(f(u), f(v)) \in E_{P_G}$ if and only if $(u,v) \in E_G$; on the other hand, if $v \in \tau_G$, we have that $(u,v) \notin E_G$, but $f(v)$ is chosen from the inactive numbers so that $f(u)$ is non-adjacent to $f(v)$. Similarly, one proves that, for all u, $(u,u) \in E_G$ if and only $(f(u), f(u)) \in E_{P_G}$. So f is an isomorphism from G to E_{P_G}. ◀

As an immediate corollary of Proposition 3, one obtains that the following classes of algebraic structures $\mathfrak{K}$ are punctually robust: equivalence structures, strongly locally finite graphs, and – more generally – graphs with infinitely many components. In fact, Proposition 3 may serve to obtain the punctual robustness of the classes of locally finite graphs and of graph-theoretic trees (the analog result holds in the setting of feasible presentations, see Cenzer and Remmel [9]). Let us give a brief informal discussion of these cases.

Recall that a *dominating* set for a graph $G = (V_G, E_G)$ is a set $D \subseteq V_G$ so that all vertices of $V_G \setminus D$ has a neighbor in D. The *domination number* $\gamma(G)$ is the minimum size of a dominating set for G. It is simple to show that every computably presentable graph G with $\gamma(G) = \infty$ has a computable copy H with an infinite semi-transversal. Hence, by

Proposition 3, all computable graphs with infinite domination numbers admit a punctual copy. This comprises the class of infinite but locally finite graphs, as is shown by a simple application of the pigeonhole principle.

We conclude the section by observing that the class of graph-theoretic trees, (i.e., acyclic graphs) is also punctually robust. Let T be a such tree. If T has infinite domination number, then T must be punctually presentable. On the other hand, if $\gamma(T) < \infty$, then it must contain a vertex with infinite neighborhood; a standard construction proves that such T is punctually presentable (we omit the details for space reasons). In contrast, in Section 5 we will show that there is a computable functional tree which admits no punctual copy.

4 Injection structures

▶ **Definition 10** (injection structure). *(A, f) is an* injection structure*, if $f : A \to A$ is injective.*

Let $f : A \to A$. A finite sequence of pairwise distinct elements $a_1, ..., a_n \in A$ is an f-cycle of length n if, for each $i = 1, ..., n-1$, $f(a_i) = a_{i+1}$, and also $f(a_n) = a_1$. If f is clear from the context, we may refer to a cycle without specifying f.

▶ **Definition 11** (cyclic injection structure). *$f : A \to A$ is* cyclic*, if f is injective and every element of A belongs to some f-cycle. $\mathcal{A} = (\mathbb{N}, f)$ is a* cyclic injection structure*, if f is cyclic. Such $\mathcal{A}$ is called* simple*, if $\mathcal{A}$ contains at most one cycle of length l, for all $l \in \mathbb{N}$.*

▶ **Definition 12** ($\mathbb{N}$-chain, $\mathbb{Z}$-chain). *Let $f : A \to A$. If $(a_n)_{n \in I}$ is an indexed family of elements of A such that $a_i \neq a_j$ for all $i \neq j \in I$, and $f(a_n) = a_{n+1}$ for all $n \in I$, then we call (a_n) an* $\mathbb{N}$-chain *if $I = \mathbb{N}$ and there is no such x that $f(x) = a_0$, and a* $\mathbb{Z}$-chain *if $I = \mathbb{Z}$.*

If $f : \mathbb{N} \to \mathbb{N}$ is an injection, then every $n \in \mathbb{N}$ belongs to a cycle, an $\mathbb{N}$-chain, or a $\mathbb{Z}$-chain. In the remaining part of this section we prove the following:[2]

▶ **Theorem 4.** *The class of injection structures is not punctually robust.*

We construct by stages a computable simple cyclic injection structure $\mathcal{A} = (\mathbb{N}, f)$ not isomorphic to any $(\mathbb{N}, p_i)$. For each $i \in \mathbb{N}$, we have the following requirement:

$$\begin{aligned} R_i :\ & \text{if } (\mathbb{N}, p_i) \text{ is a simple cyclic injection structure, then there is} \\ & n \in \mathbb{N} \text{ so that } p_i \text{ has a cycle of length } n \text{ but } f \text{ does not.} \end{aligned}$$

Initially, for $\mathcal{A} = \emptyset$, and all requirement are inactive. At a given stage we have finitely many active requirements. Active requirements may later be deactivated: deactivating a requirement R_i will guarantee that R_i is, and will remain, satisfied. Some requirements R_i may stay eventually active, but we will argue that in that case they are satisfied vacuously (i.e., the antecedent of R_i is false).

[2] As a side remark, Theorem 3.16 from [8] says that *any* computable injective structure has a polynomial-time computable copy with the domain equal to $Bin(\omega)$, the set of all binary representations of natural numbers, or to $Tal(\omega)$, the set of all unary (tally) representations of natural numbers; call such a copy *fully polynomial-time*. The statement of Theorem 3.16 [8] turns out to be too general because the structures constructed in the proofs of our Theorem 3, or Theorem 3.13 [8] for that matter, are computable injection structures with no punctual presentation, and hence they cannot have fully polynomial-time copies either (as any fully polynomial-time structure is punctual). However, a slight weakening of the statement of Theorem 3.16 [8] can be achieved, namely: every computable injection structure which is not cyclic is punctually presentable. We omit the proof due to space constraints.

Stage s of the construction. Let $R_{i_1}, \dots, R_{i_k}$ be the list of active requirements, and let $c_{i_1}, \dots, c_{i_k}$ be the corresponding witnesses. If there is a fresh active requirement in the list, execute the strategy for the fresh requirement (see below). Then, for each active non-fresh requirement, execute the corresponding strategy (also see below). If the list of active requirements is empty or, during stage s, we have not discovered any cycle of length s while executing strategies for fresh or non-fresh R_{i_j}, then we add a fresh (i.e., composed from distinct least numbers $a_1, a_2, \dots, a_s \notin \mathcal{A}$) cycle of length s to $\mathcal{A}$ and add the least inactive requirement to the list of active requirements and call it fresh.

Strategy for non-fresh $R_{i,j}$. Compute $c_{i_j}, p_{i_j}(c_{i_j}), p^2_{i_j}(c_{i_j}), \dots, p^{s-1}_{i_j}(c_{i_j})$. The following outcomes are possible:

1. elements of the sequence are pairwise different from each other and then we shall call such a sequence a straight line of length s,
2. there is some l such that $1 \le l \le s-1$ and $p^l_{i_j}(c_{i_j}) = c_{i_j}$ and then for the least such l, we shall call $c_{i_j}, p_{i_j}(c_{i_j}), p^2_{i_j}(c_{i_j}), \dots, p^l_{i_j}(c_{i_j})$ a cycle of length l,
3. there are some l and l' such that $1 \le l < l' \le s-1$ and $p^l_{i_j}(c_{i_j}) = p^{l'}_{i_j}(c_{i_j})$ and then for the least such l' we shall call such sequence a cycle with a tail of length $l'+1$.

If precisely after $s-1$-th iteration of function p_{i_j} on its corresponding witness we close a cycle or a cycle with a tail, then we deactivate R_{i_j}.

Strategy for fresh $R_{i,j}$. We define α_p to be the sequence $a_p, p_{i_j}(a_p), p^2_{i_j}(a_p), \dots, p^{s-1}_{i_j}(a_p)$, for $p = 1, \dots s$, where a_p is the least number which is currently not in the domain of $\mathcal{A}$ and has not appeared anywhere in calculations of any of the sequences α_p.

Now we check if any of the following outcomes occurs and act accordingly:

- if some α_p is a line of length s, set $c_{i_j} := a_p$ as the witness for R_{i_j} and call R_{i_j} non-fresh,
- if some α_p is a cycle of length s or a cycle with a tail of any length, deactivate R_{i_j},
- if for every α_p we obtained a cycle of length smaller than s, deactivate R_{i_j}.

Verification

▶ **Lemma 13.** *$\mathcal{A}$ is a computable simple cyclic injection structure.*

Proof. Clearly, $\mathcal{A}$ is computable. It is a cyclic injection structure since whenever we add new elements to the structure, they are in a cycle. A cycle of length s can only be added at stage s and only once. Hence, the structure is simple. ◀

▶ **Lemma 14.** *If a requirement R_i is deactivated during some stage s, then from that moment it always remains satisfied.*

Proof. There are several possible cases of how R_i was deactivated at stage s. Below we consider all of them:

- We discovered a cycle with a tail generated by the function p_i starting from its corresponding witness. In this case R_i is satisfied because p_i is not a cyclic function,
- We discovered a cycle of length s generated by p_i during stage s. In this case R_i is satisfied because we do not have a cycle of such length in $\mathcal{A}$ and hence $\mathcal{A}$ is not isomorphic to $(\mathbb{N}, p_i)$.
- We tried s different witnesses $a_1, \dots, a_s$ for R_i and for each potential witness a we generated a cycle of length shorter than s starting with a. As a consequence of the pigeon-hole principle it is necessary that there are some witnesses a and b generating cycles of the same length. Furthermore, whenever we choose a new witness, we take a number which has not appeared anywhere in earlier calculations. Hence, the cycle containing a and the cycle containing b are not the same and they are both in $(\mathbb{N}, p_i)$. We conclude that this is not a simple cyclic injection structure and hence R_i is satisfied. ◀

▶ **Lemma 15.** *If a requirement R_i is not deactivated at any stage, then it is satisfied.*

Proof. We assume that R_i was activated at some stage s. Then at stage $s+1$ it acted as a fresh requirement and it was deactivated unless we discovered a witness c_i such that the sequence $c_i, p_i(c_i), p_i^2(c_i), \dots, p_i^s(c_i)$ is a straight line of length $s+1$. In that case, at every stage $t \geq s+1$, requirement R_i is deactivated if and only if we discover a cycle or a cycle with a tail of length t starting with c_i. If this does not happen at any stage, then the line starting with c_i is becoming longer at every stage and never closes. Hence, $(\mathbb{N}, p_i)$ contains an $\mathbb{N}$-chain with an element c_i. So this structure is not cyclic and R_i is satisfied. ◀

▶ **Lemma 16.** *The domain of $\mathcal{A}$ is $\mathbb{N}$.*

Proof. Whenever we add a new element to $\mathcal{A}$, it is the least natural number which is currently not there. It follows that the domain of $\mathcal{A}$ is either all of $\mathbb{N}$ or some initial segment of it.

It remains to show that the $dom(\mathcal{A})$ is infinite. Suppose not. Let a be the largest (as a number) element in $\mathcal{A}$. Suppose that a was added at some stage s and that at the end of stage s the only active requirements were $R_{i_1}, \dots, R_{i_k}$. We consider stages $s+1, \dots, s+i_k+1$. We observe that there are i_k+1 of them and this is more than the number of active requirements. Since each requirement gets deactivated at most once, it follows that there is some t such that $s+1 \leq t \leq s+i_k+1$ such that none of the requirements is deactivated at stage t. This implies that at stage t we have not discovered any new cycle of length t. Hence at stage t we add a cycle of length t to $\mathcal{A}$ and this cycle consists of new elements larger than a. Hence a is not the largest natural number in $\mathcal{A}$ contrary to our assumption. ◀

▶ **Lemma 17.** *$\mathcal{A}$ is not punctually presentable.*

Proof. Suppose not. Then $\mathcal{A} \cong (\mathbb{N}, p_i)$, for some $i \in \mathbb{N}$. By Lemma 13, $\mathcal{A}$ is a simple cyclic injection structure. By Lemmas 14 and 15, R_i is satisfied. Since $(\mathbb{N}, p_i)$ is also a simple cyclic injection structure, there is some cycle length occurring in p_i but not in f. This contradicts the assumption that $(\mathbb{N}, f) \cong (\mathbb{N}, p_i)$. Hence, $\mathcal{A}$ is not punctually presentable. ◀

5 Functional trees

In this section we prove the main result of the paper:

▶ **Theorem 5.** *The class of functional trees is not punctually robust.*

▶ **Definition 18** (functional tree)**.** *Let $A \neq \emptyset$ be a set and let $T : A \to A$. (A, T) is a* functional tree*, if there is a unique r such that $T(r) = r$, and for every $x \in A$ there exists $i \in \mathbb{N}$ such that $T^i(x) = r$. The unique r is called the root, and is denoted by $r(A, T)$.*

Before we start, we need several technical notions.

First, observe that a functional tree (P, T) may be viewed as a partial order $(P, \leq)$ defined as follows: $x \leq y \Leftrightarrow \exists i \in \mathbb{N}\, T^i(x) = y$. This allows us to use a convenient order-theoretic notation when speaking about trees. However, we should keep in mind that this is just a manner of speaking and that in this section we deal with functional trees. Given a partial order $(P, \leq)$, we define $P_{\leq x} = \{y \in P : y \leq x\}$ and $P_{\geq x} = \{y \in P : y \geq x\}$. The corresponding strict partial order is denoted by $<$. Elements $x, y \in P$ are adjacent, $Adj(x, y)$, if and only if $x < y \wedge \neg \exists z \in P\, x < z < y$. To avoid confusion, we sometimes write $\leq_T$ or Adj_T to indicate that the ordering or adjacency relation is induced by T.

▶ **Definition 19** (branching node, branching, binary branching). *$x \in T$ is a* branching node *of T (or x branches in T) if it has at least two children in T. Such an x induces a unique subtree of T, called a branching and defined as $br(x, T) = \{y \in T : Adj(y, x)\} \cup T_{\geq x}$. If x is a branching node, we define $|br(x, t)|$, the length of $br(x, t)$, as the length of $T_{\geq x}$. By a* binary branching *we mean a tree with exacly two leaves sharing a parent.*

▶ **Definition 20** (uniquely branching tree). *We say that a tree T is uniquely branching if for every $n \in \mathbb{N}$, there exists at most one branching node $x \in T$ such that $|T_{\geq x}| = n$.*

▶ **Definition 21** (level). *We say that a* branching *node $x \in T$ belongs to the level n of T if the set $T_{>x}$ contains precisely n branching nodes. We denote the level n of T by $T[n]$. We sometimes refer to the members of $T[n]$ as n-level nodes.*

Keep in mind that we number levels $0, 1, \dots$. Therefore, the first level is level 0. Level $T[n]$ may be empty but if $T[n] \neq \emptyset$ then $T[k] \neq \emptyset$, for $k < n$.

▶ **Definition 22** (i-level subtree). *Let T be a tree such that $T[i] \neq \emptyset$. We define $T[\leq i]$ as the least subtree of T containing all nodes at levels $\leq i$ together with their children.*

Notice that $T[\leq i]$ is the sum of the branchings $br(x, T)$ for all $x \in T[j]$ such that $j \leq i$.

Recall that a binary tree is a tree in which every internal node has at most two children. In a proper binary tree, every internal node has exactly two children.

▶ **Lemma 23.** *Let $(T, \leq)$ be a finite proper binary tree and let $F \subseteq T$ be such that, at every level of T except the first, at most one node is in F. Then there exists a leaf $x \in T$ such that $T_{\geq x} \cap F = \emptyset$.*

Proof. By assumption, $r(T) \notin F$. Suppose we have a path $x_n, x_{n-1}, \dots, x_0 = r(T)$ such that $x_i \notin F$, for $i = 0, 1, \dots, n$. If x_n is a leaf, we are done. If not, x_n has two children. These two children are at the same level and one of them is outside F. Let x_{n+1} to be a child outside F. ◁

▶ **Definition 24** (attaching a tree to a leaf). *Let $T, \hat{T}$ be disjoint finite trees and let $z \in T$ be a leaf. T' is obtained from T by attaching $\hat{T}$ to z in T if $dom(T') = dom(T) \cup (dom(\hat{T}) \setminus \{r(\hat{T})\})$ and $x, y \in dom(T')$ satisfy $Adj_{T'}(x, y)$ iff $Adj_T(x, y) \vee Adj_{\hat{T}}(x, y) \vee Adj_{\hat{T}}(x, r(\hat{T})) \wedge y = z$.*

▶ **Definition 25** (functional semitree). *Let A be a finite set and let $T : A \to A$ be a partial function. We say that (A, T) is a* functional semitree *if there is a unique r such that $T(r) = r$, and $(A, \chi_T \setminus \{(r, r)\})$ is an acyclic directed graph. The unique r is called the root, and is denoted by $r(A, T)$.*

The difference between a semitree and a tree is that the former may contain nodes that are not connected to the root via any path. We will use the letters t and q, possibly with decorations, to refer to *finite* trees and to semitrees, respectively.

▶ **Definition 26** (rooted part of T). *$R(T)$ denotes the largest subtree of a semitree T.*

At every stage of the construction, the main tree T that we build is approximated by a finite tree. As we will see, the growth of T is modulated by a set of nodes F.

▶ **Definition 27** (closed node, open node). *A node $y \in T$ is closed at a given stage if $T_{\geq y} \cap F \neq \emptyset$ at that stage. A node y is open if y is not closed, that is $T_{\geq y} \cap F = \emptyset$.*

▶ **Definition 28** (leaf extension). *Let t be a tree with a distinguished set of nodes F. We say that t' is a* leaf extension *of a tree t (in symbols: $t' \sqsupseteq t$) if, for some $k > 0$, there exist disjoint (from t and from each other) finite trees $\tilde{t}_1, \ldots, \tilde{t}_k$, and pairwise distinct open leaves $x_1, \ldots, x_k \in t$, such that t' is obtained from t by simultaneously attaching each $\tilde{t}_i$ to x_i in t. We say that t' is a* proper leaf extension *of t (in symbols: $t' \sqsupset t$) if $t' \sqsupseteq$ and $t' \neq t$.*

▶ **Definition 29** (matching). *(h, t') is a* matching of q into t *(in symbols: $(h, t') : p \hookrightarrow t$), if $t' \sqsupseteq t$ and $h : R(q) \hookrightarrow t'$ is an embedding such that $img(h) \supseteq dom(t') \setminus dom(t)$. A matching (h, t') of q into t is proper, if $t' \sqsupset t$. We say that q is* (properly) matchable with t *if there exists a (proper) matching (h, t') of q into t.*

▶ **Lemma 30.** *Let P be an infinite tree and let t be a finite tree whose level n is the maximal one (that is, $t[n] \neq \emptyset$ and $t[n+1] = \emptyset$) and $t[\leq n] = t$. Let q be a finite subtree of P. If q is not matchable with t, then $P \ncong T$, for every infinite tree $T \supset t$ such that $T[\leq n] = t$.*

Proof. Suppose there is an infinite tree $T \supset t$ such that $T[\leq n] = t$ and $P \cong T$ via $h : P \to T$. Let $h(q)$ be the isomorphic image of q (hence, a subtree of T). Let $t' = T \upharpoonright dom(t) \cup dom(h(q))$. t' is a leaf extension of t. Since q is a tree, $R(q) = q$. We observe that $(h \upharpoonright q, t')$ is a matching of q into t. ◀

▶ **Definition 31** (outside branching). *Suppose q is matchable with t. We say that q* branches outside *t at x if x branches in q and $|q_{\geq x}|$ is greater than the length of every branching in t. We say that q branches outside t if it branches outside t for some x.*

▶ **Definition 32** (inside branching). *Suppose q is matchable with t. We say that q* branches inside *t at x if x branches in $R(q)$, $br(x, q)$ embeds in t and for every matching $(h, t') : q \hookrightarrow t$, $h(q_{\leq x}) \cap t' \setminus t \neq \emptyset$ (i.e., h maps some descendants of x to $t' \setminus t$).*

We are ready to start the proof of Theorem 5.

We build an infinite computable functional tree T with domain $\mathbb{N}$ such that, for all $i \in \mathbb{N}$, the following requirements R_i are satisfied: $\mathcal{T} \ncong \mathcal{P}_i$, where $\mathcal{P}_i = (\mathbb{N}, p_i)$. T will be binary, uniquely branching and it will grow only through its leaves. T will be approximated by a sequence of finite trees $T_0 \subseteq T_1 \subseteq \ldots$, with $T = \bigcup_{s \in \mathbb{N}} T_s$. Occasionally, when it does not lead to confusion, we take the liberty to use the symbol T to refer to T at a given stage s, i.e. to T_s. During the construction, we approximate $\mathcal{P}_i$ by looking at certain specific finite approximations of $\mathcal{P}_i$, which we call anticipations. We make this notion precise in Definition 34. For now, it sufficient to know that an anticipation of $\mathcal{P}_i$ simply looks at portions of $\mathcal{P}_i$ that are large compared with the current approximation of $\mathcal{T}$. We simultaneously build a dynamic set $F \subset T$. We will put elements into F but will never withdraw them.

▶ Remark 33. An approximation $\mathcal{P}_{i,s} = (A, p_i \upharpoonright A)$ of a functional tree $\mathcal{P}_i$ may actually be a semi-tree. This is because A may contain nodes which are connected to the root via nodes from $\mathbb{N} \setminus A$.

Satisfaction of R_i will be based on two strategies that we describe below. In the description of these strategies, we mention a tree t. The role of this tree will become clear when we describe the *StrategySelection* procedure. When a strategy is called, t is given as one of the inputs and used t to compute anticipations of $\mathcal{P}_i$. These anticipations depend on the number of stage s and t, hence their name: (s, t)-anticipations.

Outside-branch Strategy

We say that the outside-branch strategy for p_i is ready at stage s for a tree t if the (s, t)-anticipation q of p_i is a functional semitree and q branches outside T_{s-1}. The strategy is called only when it is ready in the specified sense. The outside-branch strategy is called with arguments q, T_{s-1}, where q is some (s, t)-anticipation of p_i that branches outside T_{s-1}.

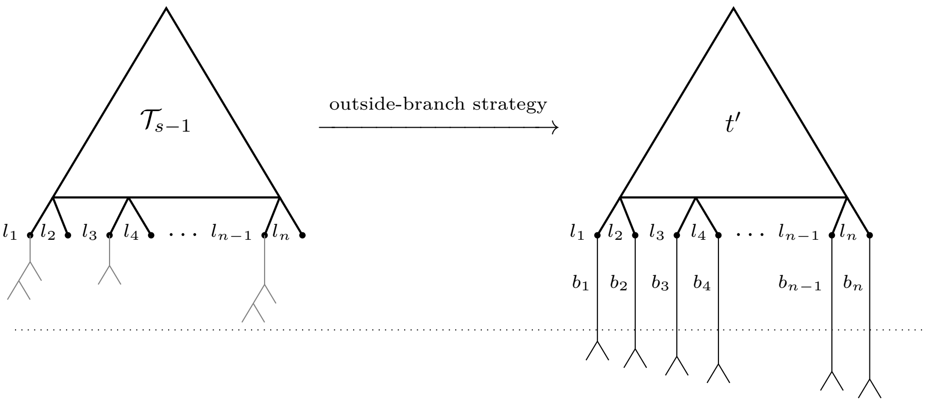

Figure 1 Outside-branch strategy.

The idea of the strategy is as follows (see, also, Figure 1). By the definition of the outside-branching, q contains a branching b that is longer than every branching in T_{s-1} (hence the word "outside-branching"). If we wanted to embed b into T, we would have to extend T_{s-1} to include the branching length of b in the extension of T_{s-1}. We purposely extend T_{s-1} to a leaf extension $t' \sqsupset T_{s-1}$ that omits the branching length of b. Recall that the construction is arranged in such a way that T grows only through its leaves and whenever we add new branchings into T, their length is greater than any branching that was in T so far. Hence, once we omit a given branching length in T, T will not have any branching of this length at all. Therefore, if we set $T_s = t'$, we would kill the potential isomorphism $\mathcal{T} \cong \mathcal{P}_i$ permanently.

More precisely, we produce t' in the following way. Let $d = max\{|q_{\geq x}| : x \text{ branches in } q\}$. Let $\{l_1, \dots, l_n\}$ be the set of all open leaves of T_{s-1}. We make binary branchings $b_1, \dots, b_n$ such that for all i, j, $|(T_{s-1})_{\geq l_i}| + |b_i| > d$ and $i \neq j \Rightarrow |(T_{s-1})_{\geq l_i}| + |b_i| \neq |(T_{s-1})_{\geq l_j}| + |b_j|$. The strategy outputs t' obtained from T_{s-1} by simultaneous attachment of each b_i to l_i. We make sure t' is extended by the least fresh numbers not occurring in T_{s-1}.

The outside-branch strategy is illustrated in Figure 1. T_{s-1} is shown on the left in black. The tree $R(q)$ (or rather a leaf extension of T_{s-1} into which $R(q)$ embeds) is shown explicitly only in part using gray subtrees on the left. The output of the outside-branch strategy is t' shown on the right which has very long branchings attached to $l_1, \dots, l_n$, the open leaves of T_{s-1}, so that t' omits some branching lengths of $R(q)$. The horizontal dotted line indicates that the lengths of the branchings below it are greater than the lengths of all the branchings in the tree on the left.

Inside-branch Strategy

We say that the inside-branch strategy for p_i is ready at stage s for a tree t if the (s, t)-anticipation q of p_i and T_{s-1} satisfy the following conditions:

$$q \text{ is a functional semitree,} \tag{1}$$

$$T_{s-1} \text{ and } R(q) \text{ have level } i+1, \tag{2}$$

$$R(q)[\leq i+1] \cong T[\leq i+1], \tag{3}$$

$$q \text{ branches inside } T_{s-1}. \tag{4}$$

The strategy is called only when it is ready in the specified sense. We call it with arguments q, T_{s-1}, where q is some (s, t)-anticipation of p_i that branches inside T_{s-1}.

The idea of the inside-branch strategy is as follows. By the definition of the inside-branching, q contains a branching node x such that $br(x, q)$ embeds into T_{s-1} (hence the word "inside-branching"). Since T_{s-1} is uniquely branching, there is only one way of embedding this branching to T_{s-1}. Suppose this unique embedding maps x to $y \in T_{s-1}$. By the definition of the inside-branching, there is no way of embedding the subtree $q_{\leq x}$ into the subtree $(T_{s-1})_{\leq y}$ without prolonging some paths in the subtree $(T_{s-1})_{\leq y}$. Hence, if we decide to put y (or some of its ancestors) into F, we would stop growing $(T_{s-1})_{\leq y}$, that is, we would have (in the limit) $T_{\leq y} = (T_{s-1})_{\leq y}$, thus killing the isomorphism $\mathcal{T} \cong \mathcal{P}_i$ permanently.

The details of the strategy follow. Suppose that the inside-branch strategy for p_i is ready and thus (1)-(4) hold. The strategy will stop the growth of T from exactly one node at level $i+1$ of T. Since q branches inside T_{s-1}, let x be a node of T_{s-1} at which q branches inside T_{s-1}. If x belongs to level $j > i+1$, then the path connecting x to the root must intersect level $i+1$ and the point of intersection is the branching node that we put into F; note that this point is unique because T is uniquely branching and (2) and (3) hold. If x belongs to level $i+1$, we simply put x to F; again, this x is unique by the same reasoning. If x belongs to level $\leq i$ but not to level $i+1$, it means that T_{s-1} did not have chance to grow up to level $i+1$ from x (and will not have such a chance anymore, because we never withdraw elements from F) and therefore we do not have to take any action.

Construction

The construction is arranged in stages $s = 0, 1, \ldots$. For $s = 0$, we set $T_0(0) = 0$ with domain $\{0\}$ and $F = \emptyset$. No R_i is satisfied at stage 0. At each subsequent stage $s > 0$, we start with a finite tree T_{s-1}. We make a call to $StrategySelection(s, T_{s-1})$ and after it finishes working, we go to the next stage. This ends the construction.

StrategySelection is a recursive procedure that selects which strategy to perform and with which arguments. It uses a specific way of growing our approximations.

▶ **Definition 34** (anticipation). *Let $p : \mathbb{N} \to \mathbb{N}$, $s \in \mathbb{N}$ and let T be a finite tree. Let $C = [0, s) \cup [0, |T| + 1)$ and $D = \bigcup_{l=0}^{H(T)+s} p^l(C)$. We say that $p \restriction D$ is the (s, T)-anticipation of p.*

We say that p_i is ready at stage s for a tree t if either the outside-branch or the inside-branch strategy for p_i is ready at stage s for t.

StrategySelection(n, t). Check whether there exists an unsatisfied R_i with $i < n$ such that p_i is ready at stage s for t. If there is no such i, return from the current call to *StrategySelection* with permission. Otherwise, let $k < n$ be the least such i.

If the (s, t)-anticipation of p_k branches inside T_{s-1}, perform the inside-branch strategy with the (s, t)-anticipation of p_k, T_{s-1} as arguments (we say that p_k triggers the inside-branch strategy). Declare R_i as satisfied and return from the current call to *StrategySelection* without permission.

If it is not the case that the (s, t)-anticipation of p_k branches inside T_{s-1}, then the (s, t)-anticipation of p_k branches outside T_{s-1}. In that case we let t' be the output of the outside-branch strategy with the (s, t)-anticipation of p_k and T_{s-1} as arguments, and we call $StrategySelection(k, t')$ (we say that p_k asks for permission). If the call returns with permission, we set $T_s = t'$ (we say that p_k triggers the outside-branch strategy), declare that R_k is satisfied, and we return without permission.

Verification

It is clear that T is computable and that if it is infinite then its domain is equal to $\mathbb{N}$.

▶ **Lemma 35.** *T is infinite and has infinitely many branchings of distinct length.*

Proof. We show by induction on the number of levels that T has infinitely many levels.

Suppose the current T has no levels at all, i.e. the domain of T is $\{0\}$. 0 is not a branching node of T and therefore it cannot trigger the inside-branch strategy. So $0 \notin F$ forever. However, at some stage $u \geq s$, we will see p_i, with $i < u$, such that the anticipation of p_i will branch outside T and since 0 will be an open leaf of T at that stage, it will trigger the outside-branch strategy and add level 0 to T. If T has only one level, i.e., level 0, the unique branching node in T will never be put into F (because the inside-branch strategy may affect only levels ≥ 1). As above, we can show that T will grow up to level 1.

Now, let us suppose that T has exactly n levels, where $n > 1$ (that is, levels $0, 1, \dots, n-1$). The construction may put into F at most one node from each of the levels $1, 2, \dots, n-1$. Once it does, it never withdraws them from F. Suppose we are at a stage s_0 after which the construction do not add any new nodes from levels $1, 2, \dots, n-1$ into F. This means that it will never be the case that, for some $0 \leq i \leq n-2$, R_i is unsatisfied and the inside-branch strategy for p_i is ready (if we later encountered such an i, the inside-branch strategy would put some element from levels $1, 2, \dots, n-1$ into F, contradicting our choice of s_0). If T has grown by the time we reached stage s_0, we are done. So suppose otherwise. Clearly, at some later stage s, some p_j, $j < s$, with unsatisfied R_j will show us an anticipation q such that q is a functional semitree and q branches outside T. Choose the least such j at stage s. Clearly, the outside-branch strategy for p_j is ready at stage s (and R_j is unsatisfied). Moreover, no outside-branch strategy for p_k with $k < j$ is ready because of the choice of j. As for the inside-branch strategy for p_k with $k < j$, either R_k is satisfied or the inside-branch strategy for p_k not ready – this follows from the choice of s_0. Therefore, p_k will be granted permission. By the arrangement of the inside-branch strategy and by Lemma 23, T has open leaves. Therefore, the outside-branch strategy for p_k will extend T by another level.

We have already shown that the outside-branch strategy acts infinitely often. Since it always adds new branchings, there must be infinitely many branchings in T. Clearly, the strategy also guarantees that any two different branchings do not have the same length. ◀

▶ **Lemma 36.** *For every $i \in \mathbb{N}$, if $\mathcal{P}_i$ is a functional tree, then R_i is eventually satisfied.*

Proof. Fix a punctual structure $\mathcal{P}_i$ and assume that there exists a stage s_0 after which for every $j < i$, either R_i is satisfied or p_j is not ready (this holds vacuously for $i = 0$). Suppose that $\mathcal{P}_i$ is a uniquely branching functional tree (if not, $\mathcal{T} \not\cong \mathcal{P}_i$). We will show that R_i will be eventually satisfied.

Choose a stage s_0 as above and assume that $i < s_0$. Suppose that at the beginning of s_0 the requirement R_i has not yet been declared as satisfied (that is, neither of the two strategies has been triggered before s_0).

If at some stage $u \geq s_0$, we see that an anticipation q of p_i is not matchable with T_{u-1}, then R_i is satisfied by Lemma 30. In the lemma, we take $P = p_i$, $t = T_{u-1}$ and q. Let n be the maximal level of t. By the construction $t[\leq n] = t$. The infinite tree T that we are building will be such that $T \supset T_{u-1} = t$ and $T[\leq n] = t$. Hence, the premises of the lemma are satisfied. It means that $\mathcal{T} \not\cong \mathcal{P}_i$ and thus R_i is satisfied. We can therefore assume that, for $u \geq s_0$, any considered anticipation of p_i is matchable with T_{u-1}.

Now, if at some stage $u \geq s_0$ the requirement R_i is still not satisfied but p_i is ready at stage u for T_{u-1}, i will be the least j with that property. So, according to *StrategySelection*, either it will trigger an inside-branch strategy, or it will ask for permission and receive it, thus triggering an outside-branch strategy. Now, it may happen that p_i becomes ready because the outside-branch strategy for p_i is ready but the inside-branch strategy is not. In that case, according to the *StrategySelection*, p_i will receive permission and thus R_i will become satisfied.

So assume p_i never becomes ready for this reason after stage s_0. Observe that if anticipations of p_i and T_s always fail to satisfy (1), (2) or (3), then $\mathcal{T} \not\cong \mathcal{P}_i$. So assume that after stage s_0 these conditions are always satisfied. Therefore, it remains to prove that at some stage $u \geq s_0$, the inside-branch strategy is triggered.

It is important to note that once the level $i+1$ of T is done, T does not change up to level $i+1$ at any later stage (it may only add some nodes from levels $\leq i+1$ to F but this will not change the structure of T up to level $i+1$).

Consider stage $u \geq s_0$. The construction calls $\mathit{StrategySelection}(u, T_{u-1})$. Let q be the initial anticipation of p_i at stage u, namely the (u, T_{u-1})-anticipation of p_i. By the definition of anticipation, q contains more nodes than T_{u-1}. Therefore, the situation in which $R(q) = q$ and $R(q) \hookrightarrow T_{u-1}$ is not possible. So we have two remaining cases:

(a) $R(q) \hookrightarrow T_{u-1}$ and $R(q) \neq q$. In this case, there are nodes $z \in q \setminus R(q)$ that are disconnected from the root. Moreover, by the definition of anticipation, if $z \in q \setminus R(q)$ and z does not have children in q, then z gives rise to a chain of length $H(T_{u-1}) + u$ in q.

(b) $R(q) \not\hookrightarrow T_{u-1}$. In this case, q must be properly matchable with T_{u-1}. To see why, recall that q is matchable with T_{u-1}. So $R(q)$ embeds in a leaf extension T' of T_{u-1}. But any such leaf extension must be proper – otherwise $R(q) \hookrightarrow T_{u-1}$. From this it follows that q branches inside T_{u-1}. For take a proper matching of q into T_{u-1} that embeds q into $T' \sqsupset T_{u-1}$. Take the least $z \in T' \setminus T_{u-1}$. This z is connected to the root of T_{u-1} via a path that overlaps with initial $i+1$ levels of T_{u-1}. But every such path (the one in T_{u-1} or its preimage in q) contains branching nodes because q contains a copy of initial $i+1$ levels of T_{u-1}. Therefore, q branches inside T_{u-1}, and thus q is ready at stage u for T_{u-1}. Hence the inside branch strategy will handle R_i.

Assume that (b) holds. Therefore, the inside-branch strategy for p_i is ready at stage u for T_{u-1}. Hence, R_i becomes satisfied immediately after *StrategySelection* is called.

Assume that we are in case (a). Then p_i is not ready at stage u for T_{u-1}. But other p_j, with $j > i$ will become ready later on, say at stage v. If such p_j triggers an inside-branch strategy to satisfy R_j, our tree does not grow and we therefore do not miss an opportunity to satisfy R_i. However, if p_j, with $j > i$ wants to trigger an outside-branch strategy (which must happen eventually), it will produce $T' \supset T_{u-1}$ and ask for permission. So before p_j is allowed to act by extending the current tree from T_{u-1} to $T' \supset T_{u-1}$, we first check whether p_i is ready at stage v for the (bigger) tree T' that we would grow if we allowed p_j to act first. If it is not ready, it means that we can permit p_j to trigger an outside-branch strategy and set $T_v = T'$. For it means that all the long disconnected chains that we had in q remain disconnected, even after prolonging them up to length $H(T') + v$ in the (v, T')-anticipation of p_i. Notice that if we did not insist on asking for permission, we would set $T_v := T' \supset T_{u-1}$ and it could happen that prolonging a bit the disconnected chains in q would change q into a tree that embeds into T_v and we would miss the opportunity to satisfy R_i. Asking for permission prevents this.

Finally, it suffices to observe that, since p_i is a tree, at some point these disconnected chains will connect to the root, either at the beginning of *StrategySelection* or after being asked for permission by some other p_j, with $j > i$. Since these chains are kept very long (longer than any path in the current T), once they become connected, they necessarily stick out of T and thus branch inside it. At this point the inside-branch strategy is triggered and R_i is satisfied. ◀

Abstract

Twin-width is a width parameter introduced by Bonnet, Kim, Thomassé and Watrigant [FOCS'20, JACM'22], which has many structural and algorithmic applications. Hliněný and Jedelský [ICALP'23] showed that every planar graph has twin-width at most 8. We prove that the twin-width of every graph embeddable in a surface of Euler genus g is at most $18\sqrt{47g} + O(1)$, which is asymptotically best possible as it asymptotically differs from the lower bound by a constant multiplicative factor. Our proof also yields a quadratic time algorithm to find a corresponding contraction sequence. To prove the upper bound on twin-width of graphs embeddable in surfaces, we provide a stronger version of the Product Structure Theorem for graphs of Euler genus g that asserts that every such graph is a subgraph of the strong product of a path and a graph with a tree-decomposition with all bags of size at most eight with a single exceptional bag of size $\max\{6, 32g - 37\}$.

1 Introduction

Twin-width is a graph parameter, which has recently been introduced by Bonnet, Kim, Thomassé and Watrigant [16, 17]. It has quickly become one of the most intensively studied graph width parameters due to its many connections to algorithmic and structural questions in both computer science and mathematics. In particular, classes of graphs with bounded twin-width (we refer to Section 2 for the definition of the parameter) include at the same time well-structured classes of sparse graphs and well-structured classes of dense graphs. Particular examples are classes of graphs with bounded tree-width, with bounded rank-width (or equivalently with bounded clique-width), and classes excluding a fixed graph as a minor. As the first order model checking is fixed parameter tractable for classes of graphs with bounded twin-width [16, 17], the notion led to a unified view of various earlier results on fixed parameter tractability of first order model checking of graph properties [21, 22, 30–33, 49], and more generally first order model checking properties of other combinatorial structures such as matrices, permutations and posets [4, 12, 19, 20].

The foundation of the theory concerning twin-width has been laid by Bonnet, Kim, Thomassé and their collaborators in a series of papers [8–14,16,17], also see [51]. The amount of literature on twin-width is rapidly growing and includes exploring algorithmic aspects of twin-width [6,10,12,15,48], its combinatorial properties [2,4,7,10,14,24,47], and connections to logic and model theory [12,16,17,19,20,34]. While many important graph classes have bounded twin-width, good bounds are known only in a small number of specific cases. One of the examples is the class of graphs of bounded tree-width where an asymptotically optimal bound, exponential in tree-width, was proven by Jacob and Pilipczuk [40]. Another example is the class of planar graphs. The first explicit bound of 583 by Bonnet, Kwon and Wood [18] was gradually improved [5,35,40] culminating with a bound of 8 obtained by Hliněný and Jedelský [38]; also see [36,37] for a simpler proof and [41] for a promising approach of obtaining the upper bound of 7, which would be tight since Lamaison and the first author [42] constructed a planar graph with twin-width 7. In this paper, we extend this list by providing an asymptotically optimal upper bound on the twin-width of graphs embeddable in surfaces of higher genera. We prove the following two results (the latter is used to prove the former):

- We show that the twin-width of a graph embeddable in a surface of Euler genus g is at most $18\sqrt{47g}+O(1)$, which is asymptotically best possible; our proof also yields a quadratic time algorithm to find a witnessing sequence of vertex contractions.
- We provide a strengthening of the Product Structure Theorem for graphs embeddable in a surface of Euler genus g by showing that such graphs are subgraphs of a strong product of a path and a graph that almost has a bounded tree-width.

We next present the two results in more detail while also presenting the related existing results. While we prove both results in purely structural way, their proofs are algorithmic and yield a quadratic time algorithm (when the genus $g>0$ is fixed) that given a graph G embeddable in a surface of genus g, constructs a sequence of contractions witnessing that the twin-width of G is at most $18\sqrt{47g}+O(1)$. Further details are discussed in Section 5.

1.1 Twin-width of graphs embeddable in surfaces

Graphs that can be embedded in surfaces of higher genera, such as the projective plane, the torus and the Klein bottle, form important minor-closed classes of graphs with many applications and connections [45]. While the general theory concerning minor-closed classes of graphs yields that graphs embeddable in a fixed surface have bounded twin-width, the bounds are quite enormous: the results from [14, Section 4] on d-contractible graphs (graphs embeddable in a surface of Euler genus g are $O(g)$-contractible [39]) yields a bound double exponential in g, and the Product Structure Theorem for graphs embeddable in surfaces [26,28] together with results on the twin-width of graphs with bounded tree-width [40], of the strong product of graphs [46] and their subgraph closure [9] yields an exponential bound.

Bonnet, Kwon and Wood [18] showed that every graph embeddable in a surface of Euler genus g has twin-width at most $205g+583$. Our main result asserts that twin-width of every graph embeddable in a surface of Euler genus g is at most $18\sqrt{47g}+O(1)\approx 123.4\sqrt{g}+O(1)$. This bound is asymptotically optimal as any graph with $\sqrt{6g}-O(1)$ vertices can be embedded in a surface of Euler genus g and the n-vertex Erdős-Rényi random graph $G_{n,1/2}$ has twin-width at least $n/2-O(\sqrt{n\log n})$ [1], i.e., there exists a graph with twin-width $\sqrt{3g/2}-o(\sqrt{g})$ embeddable in a surface of Euler genus g. In particular, our upper bound asymptotically differs from the lower bound by a multiplicative factor $6\sqrt{282}\approx 100.76$. While several parts of our argument can be refined to decrease the multiplicative constant (to around 20), we have decided not to do so due to the technical nature of such refinements and the absence of additional structural insights gained by doing so.

1.2 Product Structure Theorem

On the way to our main result, we prove a modification of the Product Structure Theorem that applies to graphs embeddable in surfaces. The Product Structure Theorem is a recent significant structural result obtained by Dujmović, Joret, Micek, Morin, Ueckerdt and Wood [26, 28], which brought new substantial insights into the structure of planar graphs and led to breakthroughs on several long standing open problems concerning planar graphs, see, e.g. [25]. We also refer to the survey by Dvořák et al. [29] on the topic. The statement of the Product Structure Theorem originally proven by Dujmović et al. [26, 28] reads as follows (we remark that the statement in [26, 28] does not include the condition on planarity of the graph of bounded tree-width, however, an easy inspection of the proof yields this).

▶ **Theorem 1.** *Every planar graph is a subgraph of the strong product of a path and a planar graph with tree-width at most* 8*.*

Ueckerdt et al. [52] improved this as follows (we state a corollary of their main result to avoid defining the notion of simple tree-width, which is not needed in our further presentation).

▶ **Theorem 2.** *Every planar graph is a subgraph of the strong product of a path and a planar graph with tree-width at most* 6*.*

Dujmović et al. [26, 28] also proved two extensions of the Product Structure Theorem to graphs embeddable in surfaces.

▶ **Theorem 3.** *Every graph embeddable in a surface of Euler genus $g > 0$ is a subgraph of the strong product of a path, the complete graph K_{2g} and a planar graph with tree-width at most* 9*.*

▶ **Theorem 4.** *Every graph embeddable in a surface of Euler genus $g > 0$ is a subgraph of the strong product of a path, the complete graph $K_{\max\{2g,3\}}$ and a planar graph with tree-width at most* 4*.*

A stronger version was proven by Distel at el. [23]; the discussion of the even stronger statement implied by the proof of the next theorem given in [23] can be found after Theorem 6.

▶ **Theorem 5.** *Every graph embeddable in a surface of Euler genus $g > 0$ is a subgraph of the strong product of a path, the complete graph $K_{\max\{2g,3\}}$ and a planar graph with tree-width at most* 3*.*

We remark that it is not possible to replace K_{2g} in the statement of Theorems 3, 4 and 5 with a complete graph with $o(g)$ vertices as long as the bound on the tree-width stays constant since the layered tree-width of graphs embeddable in a surface of Euler genus g is linear in g [27] (the definition of layered tree-width is given in Section 2). To prove our upper bound on the twin-width of graphs embeddable in surfaces, we strengthen the statement of the Product Structure Theorem for graphs embeddable in surfaces as follows. Theorems 3, 4 and 5 imply that every graph embeddable in a surface of Euler genus $g > 0$ is a subgraph of the strong product of a path and a graph with tree-width at most $20g - 1$, $\max\{10g - 1, 14\}$ and $\max\{8g - 1, 11\}$, respectively. The next theorem, which we prove in Section 3, asserts that it is possible to assume that the tree-width of the graph in the product is almost at most 7 in the sense that all bags except possibly for a single bag have size at most 8.

▶ **Theorem 6.** *Every graph embeddable in a surface of Euler genus $g > 0$ is a subgraph of the strong product of a path and a graph H that has a rooted tree-decomposition such that*

- *the root bag has size at most $\max\{6, 32g - 37\}$, and*
- *every bag except the root bag has size at most* 8*.*

Similarly as it is not possible to replace K_{2g} with a complete graph with $o(g)$ vertices in Theorem 3, it is necessary to permit at least one of the bags to have a size linear in g in Theorem 6. Hence, the statement of Theorem 6 is the best possible asymptotically.

We remark that the proof of Theorem 5 given in [23] implies that every graph embeddable in a surface of Euler genus $g > 0$ is a subgraph of the strong product of a path and a graph that can be obtained from a planar graph with tree-width at most 3 by replacing one vertex of this planar graph with K_{2g} and the remaining vertices with K_3 (and replacing each edge of the planar graph with a complete bipartite graph between the corresponding sets of vertices). However, the vertex of the planar graph that is replaced with K_{2g} can be contained in many bags of the tree-decomposition and so the proof given in [23] does not yield a statement similar to that of Theorem 6 since the number of bags in the tree-decomposition with size linear in g can be arbitrary (although each such bag contains the same $2g$ vertices of K_{2g} in addition to 9 other vertices). The main new component in the proof of Theorem 6 (compared to the proofs given in [23, 26, 28]) is Lemma 12 given in Section 3, which is crucial so that we are able to restrict the sizes of all but one bag in a tree-decomposition to a constant size.

We also note the following corollary of Theorem 6 for projective planar graphs.

▶ **Corollary 7.** *Every graph embeddable in the projective plane is a subgraph of the strong product of a path and a graph with tree-width at most* 7*.*

2 Preliminaries

In this section, we introduce notation used throughout the paper. We use $[n]$ to denote the set of the first n positive integers, i.e., $\{1, \ldots, n\}$. All graphs considered in this paper are simple and have no parallel edges unless stated otherwise; if G is a graph, we use $V(G)$ to denote the vertex set of G. A *triangulation* of the plane or a surface of Euler genus $g > 0$ is a graph embedded in such a surface such that every face is a 2-cell, i.e., homeomorphic to a disk, and bounded by a triangle. A *near-triangulation* is a 2-connected graph G embedded in the plane such that each inner face of G is bounded by a triangle.

We next give a formal definition of twin-width. A *trigraph* is a graph with some of its edges being red; the *red degree* of a vertex v is the number of red edges incident with v. If G is a trigraph and v and v' form a pair of its (not necessarily adjacent) vertices, then the trigraph obtained from G by *contracting* the vertices v and v' is the trigraph obtained from G by removing the vertices v and v' and introducing a new vertex w such that w is adjacent to every vertex u that is adjacent to at least one of the vertices v and v' in G and the edge wu is red if u is not adjacent to both v and v' or at least one of the edges vu and $v'u$ is red. The *twin-width* of a graph G is the smallest integer k such that there exists a sequence of contractions that reduces the graph G, i.e., the trigraph with the same vertices and edges as G and no red edges, to a single vertex, and none of the intermediate graphs contains a vertex of red degree more than k.

A *rooted tree-decomposition* $\mathcal{T}$ of a graph G is a rooted tree such that each vertex of $\mathcal{T}$ is a subset of $V(G)$, which we refer to as a *bag*, and that satisfies the following:

- for every vertex v of G, there exists a bag containing v,
- for every vertex v of G, the bags containing v form a connected subgraph (subtree) of $\mathcal{T}$, and
- for every edge e of G, there exists a bag containing both end vertices of e.

If the choice of the root is not important, we just speak about a *tree-decomposition* of a graph G. The *width* of a tree-decomposition $\mathcal{T}$ is the maximum size of a bag of $\mathcal{T}$ decreased by one, and the *tree-width* of a graph G is the minimum width of a tree-decomposition of G.

A *k-tree* is defined recursively as follows: the complete graph K_k is a k-tree and if G is a k-tree, then any graph obtained from G by introducing a new vertex and making it adjacent to any k vertices of G that form a complete subgraph in G is also a k-tree. Note that a graph G is a 1-tree if and only if G is a tree. More generally, a graph G has tree-width at most k if and only if G is a subgraph of a k-tree, and if G has at least k vertices, then G is a spanning subgraph of a k-tree. Note that k-trees have a tree-like structure given by their recursive definition, which also gives a rooted tree-decomposition of G with width k: the rooted tree-decomposition of K_k consists of a single bag containing all k vertices, and the rooted tree-decomposition of the graph obtained from a k-tree G by introducing a vertex w can be obtained from the rooted tree-decomposition $\mathcal{T}_G$ of G by introducing a new bag containing w and its k neighbors and making this bag adjacent to the bag of $\mathcal{T}_G$ that contains all k neighbors of w (such a bag exists since the subtrees of a tree have the Helly property).

A *BFS spanning tree* T of a (connected) graph G is a rooted spanning tree such that the path from the root to any vertex v in T is the shortest path from the root to v in G; in particular, a BFS spanning tree can be obtained by the breadth-first search (BFS). A *layering* is a partition of a vertex set of a graph G into sets $V_1, \dots, V_k$, which are called *layers*, such that every edge of G connects two vertices of the same or adjacent layers. i.e., layers whose indices differ by one. If T is a BFS spanning tree of G, then the partition of $V(G)$ into sets based on the distance from the root of T is a layering. A *BFS spanning forest* F of a (not necessarily connected) graph G is a rooted spanning forest, i.e., a forest consisting of rooted trees, such that there exists a layering $V_1, \dots, V_k$ compatible with F, i.e., for every tree of F, there exists d such that the vertices at distance ℓ from the root are contained in $V_{d+\ell}$. Note that if G is a graph and T a BFS spanning tree of G, then removing the same vertices in G and T results in a graph G' and a BFS spanning forest of G'. Finally, the *layered tree-width* of a graph G is the minimum k for which there exists a tree-decomposition $\mathcal{T}$ of G and a layering such that every bag of $\mathcal{T}$ contains at most k vertices from the same layer.

Consider a graph G and a BFS spanning tree T of G. A *vertical* path is a path contained in T with no two vertices from the same layer, i.e., a subpath of a path from a leaf to the root of T. The vertex of a vertical path closest to the root is its *top* vertex and the vertex farthest is its *bottom* vertex. Vertical paths with respect to a BFS spanning forest are defined analogously. If $\mathcal{P}$ is a partition of the vertex set of G to vertical paths, the graph $G/\mathcal{P}$ is the graph obtained by contracting each of the paths contained in $\mathcal{P}$ to a single vertex; note that the vertices of $G/\mathcal{P}$ can be viewed as the vertical paths contained in $\mathcal{P}$ and two vertical paths P and P' are adjacent in $G/\mathcal{P}$ if the graph G has an edge between $V(P)$ and $V(P')$.

3 Product Structure Theorem for graphs on surfaces

In this section, we provide the version of the Product Structure Theorem for graphs on surfaces, which we need to prove our upper bound on the twin-width. We start with recalling the following lemma proven by Dujmović et al. [26, 28]; note that the fundamental cycles determined by the edges $a_1b_1, \dots, a_gb_g$ generate the fundamental group of the surface Σ.

▶ **Lemma 8.** *Let G be a triangulation of a surface Σ of Euler genus $g > 0$ and let T be a BFS spanning tree of G. There exist edges $a_1b_1, \dots, a_gb_g$ not contained in the tree T with the following property. Let F_0 be the subset of edges of G comprised of the g edges $a_1b_1, \dots, a_gb_g$ and the edges of the $2g$ paths in T from the root of T to the vertices $a_1, \dots, a_g$ and $b_1, \dots, b_g$. The surface Σ after the removal of the edges contained in F_0 is homeomorphic to a disk and its boundary is formed by a closed walk comprised of the edges contained in F_0.*

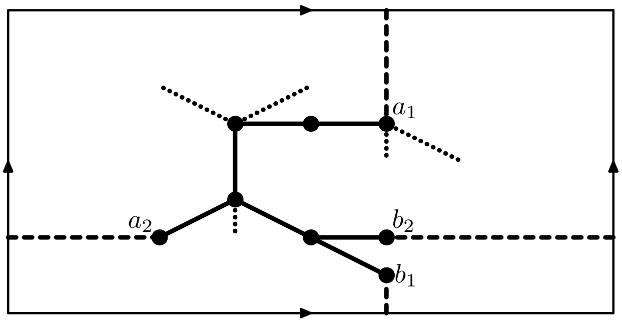

Figure 1 A rooted tree T_0 and edges a_1b_1 and a_2b_2, which are drawn dashed, bounding a part of the torus that is homeomorphic to a disk as in Lemma 9. Possible additional edges of the BFS spanning tree T are drawn dotted.

Using Lemma 8, one can prove the following; we refer to Figure 1 for the illustration of the notation in the case of the torus. The proof of the lemma is omitted due to space constraints.

▶ **Lemma 9.** *Let G be a triangulation of a surface of Euler genus $g > 0$ and let T be a BFS spanning tree of G. There exist a closed walk W in G, a subtree T_0 of T that contains the root of T, and k vertex-disjoint vertical paths $P_1, \ldots, P_k$, $k \leq 2g$, such that*

- *the closed walk W bounds a part of the surface homeomorphic to a disk,*
- *the sets $V(P_1), \ldots, V(P_k)$ form a partition of $V(T_0)$, i.e., $V(T_0) = V(P_1) \cup \cdots \cup V(P_k)$, and*
- *the sequence of vertices given by traversing the closed walk W can be split into at most $6g - 1$ segments such that all vertices of each segment belong to the same vertical path.*

Lemma 9 is one of two key ingredients for the proof of Theorem 13. The second, which is Lemma 12, relates to partitioning disk regions bounded by vertical paths. Similarly to [26, 28, 52], we make use of Sperner's Lemma, see e.g. [3, 50].

▶ **Lemma 10.** *Let G be a near-triangulation. Suppose that the vertices of G are colored with three colors in such a way that the vertices of each of the three colors on the outer face are consecutive, i.e., they form a non-empty path. There exists an inner face that contains one vertex of each of the three colors.*

The proof of the next lemma follows the lines of the proof of [52, Lemma 8] and is omitted due to space constraints. We say that a cycle is *covered* by paths $P_1, \ldots, P_k$ if each path is a subpath of the cycle and each vertex of the cycle belongs to one of the paths $P_1, \ldots, P_k$.

▶ **Lemma 11.** *Let G be a near-triangulation and let T be a BFS rooted spanning forest such that all roots of T are on the outer face. If the boundary cycle of the outer face can be covered by at most 6 vertex-disjoint vertical paths, say $P_1, \ldots, P_k$, $k \leq 6$, then there exists a collection $\mathcal{P}$ of vertex-disjoint vertical paths such that*

- *the collection $\mathcal{P}$ contains the paths $P_1, \ldots, P_k$,*
- *every vertex of G is contained in one of the paths in $\mathcal{P}$, and*
- *$G/\mathcal{P}$ has a rooted tree-decomposition of width at most seven such that the root bag contains the k vertices corresponding to the paths $P_1, \ldots, P_k$.*

To state the next lemma, which is the second ingredient to prove the main result of this section, we need the following definition: if G' is a subgraph of a graph G embedded in a surface, a face of G' is a *region* if its interior contains a vertex or an edge of G; an *inner region* is an inner face that is a region. The proof of the lemma is omitted due to space constraints.

▶ **Lemma 12.** *Let G be a near-triangulation and let T be a BFS rooted spanning forest such that all roots of T are on the outer face. If the boundary cycle of the outer face can be covered by $k \geq 6$ vertex-disjoint vertical paths $P_1, \ldots, P_k$, then there exist a 2-connected subgraph G' of G and a collection $\mathcal{P}$ of vertex-disjoint vertical paths such that*

- *$\mathcal{P}$ contains the vertical paths $P_1, \ldots, P_k$,*
- *$\mathcal{P}$ contains at most $\max\{6, 6k - 32\}$ vertical paths,*
- *the vertex set of G' is the union of the vertex sets of the vertical paths contained in $\mathcal{P}$,*
- *the graph G' contains the boundary of the outer face,*
- *the graph G' has at most $\max\{1, 3k - 18\}$ inner regions, and*
- *the boundary cycle of each inner region of G' can be covered by at most six paths such that each is a subpath of a path from $\mathcal{P}$.*

We can now prove the main result of this section. Since a triangulation G in Theorem 13 is a subgraph of the strong product of a path and the graph $G/\mathcal{P}$, Theorem 13 readily implies Theorem 6. We remind that a tree-decomposition of $G/\mathcal{P}$ is a tree whose vertices are bags containing paths from the set $\mathcal{P}$ (the vertices of $G/\mathcal{P}$ can be viewed as these paths).

▶ **Theorem 13.** *Let G be a triangulation of a surface of Euler genus $g > 0$ and let T be a BFS spanning tree of G. There exists a collection $\mathcal{P}$ of vertical paths that partition the vertex set of G and the graph $G/\mathcal{P}$ has a rooted tree-decomposition such that*

- *the root bag has size at most $\max\{6, 32g - 37\}$,*
- *the root bag has at most $6 \cdot \max\{1, 18g - 21\}$ children, and*
- *every bag except the root bag has size at most 8.*

Moreover, every subtree $\mathcal{T}'$ of the tree-decomposition formed by a child of the root and all its descendants satisfies the following:

- *the bags of $\mathcal{T}'$ contain at most six paths that are contained in the root bag, and*
- *if $P_1, \ldots, P_k$ are all paths from $\mathcal{P}$ that are contained in the bags of $\mathcal{T}'$ but not in the root bag, the subgraph induced by $V(P_1) \cup \cdots \cup V(P_k)$ has a component joined by an edge to each of the paths that are contained both in the root bag and in $\mathcal{T}'$.*

Proof. Fix a triangulation G of a surface of Euler genus $g > 0$ and a BFS spanning tree T of G. We apply Lemma 9 to obtain a closed walk W, a subtree T_0 of T and k vertex-disjoint vertical paths $P_1, \ldots, P_k$, $k \leq 2g$, with the properties given in Lemma 9. Let $\ell \leq 6g - 1$ be the number of segments that cover the closed walk W as in the statement of the lemma.

We first deal with the general case $\ell \geq 7$ (note that if $\ell \geq 7$, then $g \geq 2$). We apply Lemma 12 to the near-triangulation obtained by cutting along the closed walk W, the BFS spanning forest obtained from T_0 by duplicating the vertices contained in W as needed, and the ℓ vertical paths that corresponds to the segments that cover the closed walk W. We obtain a collection $\mathcal{P}_0$ of vertex-disjoint vertical paths that contains at most $5\ell - 32$ additional vertical paths and a 2-connected subgraph G' such that the boundary of each inner region of G' can be covered by at most six paths contained in $\mathcal{P}_0$. In addition, the number of inner regions of G', further denoted by f, is at most $3\ell - 18$. Since $\ell \leq 6g - 1$, we obtain that $\mathcal{P}_0$ contains at most $30g - 37$ additional vertical paths and that $f \leq 18g - 21$. We now identify the duplicated vertices of T_0, i.e., G' has been modified to a subgraph of G, and we replace in the collection $\mathcal{P}_0$ the ℓ paths that cover the closed walk W with the paths $P_1, \dots, P_k$. Hence, the size of the collection $\mathcal{P}_0$ is at most $32g - 37$ (note that $k \le 2g$) and the boundary of each region of G' is still covered by at most six paths such that each is a subpath of the vertical paths contained in $\mathcal{P}_0$ (two different paths can be subpaths of the same vertical path).

If $\ell \le 6$ (and so $k \le 6$), we set $\mathcal{P}_0$ to be the collection $\{P_1, \dots, P_k\}$ and G' the graph consisting of the vertices and the edges of the closed walk W; note that the only face of G' bounds a near-triangulation in G and $f = 1$.

We now proceed jointly for all values of ℓ. Suppose there is a region of G' such that the subgraph of G induced by the vertices of G inside this region does not have a component joined by an edge to each of the (at most six) paths that cover the boundary of the region and that are subpaths of paths from $\mathcal{P}_0$. Then, because G is a triangulation, there are two vertices on the boundary of this region joined by an edge not contained in G' and we add this edge to G'. We proceed as long as such a region exists and eventually obtain a graph G'' with $f' \le 6f$ regions such that the boundary of each region can be covered by at most six paths, each subpath of a path contained in $\mathcal{P}_0$, and each region contains a component that is joined by an edge to each of the (at most six) paths that cover its boundary. We now apply Lemma 11 to each of the f' near-triangulations bounded by the regions of G'' and obtain rooted tree-decompositions $\mathcal{T}_1, \dots, \mathcal{T}_{f'}$ with width at most seven of each them. Let $\mathcal{P}$ be the collection of vertical paths obtained from $\mathcal{P}_0$ by including all additional vertical paths obtained by these f' applications of Lemma 11.

We now construct a rooted tree-decomposition of $G/\mathcal{P}$. The root bag contains the vertices corresponding to the paths in $\mathcal{P}_0$ and the subtrees rooted at its children are $\mathcal{T}_1, \dots, \mathcal{T}_{f'}$. So, the root bag has size $|\mathcal{P}_0| \le \max\{6, 32g - 37\}$, it has $f' \le 6f \le 6\max\{1, 18g - 21\}$ children, and all bags except the root bag has size at most 8. Consider now a subtree $\mathcal{T}_i$, $i \in [f']$. The only paths from $\mathcal{P}_0$ contained in the bags of $\mathcal{T}_i$ are the at most six paths whose subpaths cover the boundary of the corresponding region of G'' and the vertices contained in the paths of the bags of $\mathcal{T}_i$ but not in the paths of $\mathcal{P}_0$ are exactly the vertices of G contained inside the region. Hence, the subgraph of G induced by such vertices has a component joined by an edge to each of the paths from $\mathcal{P}_0$ contained in the root bag of $\mathcal{T}_i$. We conclude that the obtained rooted tree-decomposition of $G/\mathcal{P}$ has the properties given in the statement. ◀

4 Bound on twin-width

We now present the asymptotically optimal upper bound on the twin-width of graphs embeddable in surfaces.

▶ **Theorem 14.** *The twin-width of every graph G of Euler genus $g \ge 1$ is at most*

$$6 \cdot \max\left\{3\sqrt{47g} + 1, 2^{24}\right\} = 18\sqrt{47g} + O(1).$$

Proof. Fix a graph G of Euler genus $g > 0$ and let G_0 be any triangulation of the surface with Euler genus g that G is a spanning subgraph of G_0, i.e., $V(G_0) = V(G)$ (to avoid unnecessary technical issues related to adding new vertices, G_0 may contain parallel edges).

We apply Theorem 13 to G_0 and an arbitrary BFS spanning tree T_0; let $\mathcal{P}$ be a collection of vertical paths and $\mathcal{T}$ a rooted tree-decomposition as in Theorem 13. Let $P_1, \dots, P_k$ be the vertical paths contained in the root bag and let $\mathcal{T}_1, \dots, \mathcal{T}_\ell$ be the subtrees rooted at the children of the root bag (note that $k \le 32g$ and $\ell \le 108g$). Further, let V_i, $i \in [\ell]$, be the vertices contained in the vertical paths in the bags of $\mathcal{T}_i$ that are not contained in the root bag. Note that for every $i = 1, \dots, \ell$, the subgraph induced by a set V_i has a component that is joined by an edge to each path P_j, $j \in [k]$, that is contained in a bag of the subtree $\mathcal{T}_i$.

Let H_0 be the graph obtained from G_0 by contracting each of the $k+\ell$ sets $V(P_1),\dots,V(P_k)$ and $V_1,\dots,V_\ell$ to a single vertex. Let $a_1,\dots,a_k$ and $b_1,\dots,b_\ell$ be the resulting vertices. Observe that H_0 can be obtained from G_0 by contracting edges and deleting vertices. Indeed, the vertices $a_1,\dots,a_k$ are obtained by contracting paths $P_1,\dots,P_k$ and each vertex b_i, $i=1,\dots,\ell$, can be obtained as follows: first contract the component of the subgraph induced by the set V_i that is joined by an edge to each of the paths $P_1,\dots,P_k$ contained in the subtree $\mathcal{T}_i$ to a single vertex, and then delete all the vertices of V_i not contained in this component. Since H_0 can be obtained from G_0 by contracting edges and deleting vertices, the graph H_0 can be embedded in the same surface as G_0. Hence, the number of the edges of H_0 is at most $3(k+\ell)-6+3g \le 3(k+\ell+g)$; the latter bound applies even if $k+\ell=2$. Since each subtree $\mathcal{T}_i$ contains at most six of the paths $P_1,\dots,P_k$, each of the vertices $b_1,\dots,b_\ell$ has degree at most six and all its (at most six) neighbors are among the vertices $a_1,\dots,a_k$.

Let $s=3\sqrt{47g}$; note that $s\ge 6$. We next split the vertices $a_1,\dots,a_k$ into sets $A_1,\dots,A_{k'}$ and the vertices $b_1,\dots,b_\ell$ into sets $B_1,\dots,B_{\ell'}$ as follows; a similar argument has also been used in [2]. Keep adding the vertices $b_1,\dots,b_\ell$ to the set B_1 until the sum of their degrees just exceeds s, then keep adding the remaining vertices to the set B_2 until the sum of their degrees just exceeds s, etc. Observe that the sum of the degrees of the vertices in each of the sets $B_1,\dots,B_{\ell'}$ is at most $s+6\le 2s$ and the sum of the degrees of the vertices in each of the sets $B_1,\dots,B_{\ell'-1}$ is at least s. Each of the vertices $a_1,\dots,a_k$ with degree larger than s forms a set of size one, and the remaining vertices are split in the same way as the vertices $b_1,\dots,b_k$. Each of the sets $A_1,\dots,A_{k'}$ has either size one or the sum of the degrees of its vertices is at most $2s$, and the sum of the degrees of the vertices in each of the sets $A_1,\dots,A_{k'-1}$ is at least s. Let H_0' be the graph obtained from H_0 by contracting the vertices in each of the sets $A_1,\dots,A_{k'}$ and each of the sets $B_1,\dots,B_{\ell'}$ to a single vertex; note that the graph H_0' does not need to be embeddable in the same surface as H_0. Since the sum of the degrees of the vertices $a_1,\dots,a_k$ and $b_1,\dots,b_\ell$ is at most $6(k+\ell+g)\le 846g$ (as H_0 has at most $3(k+\ell+g)$ edges), we obtain that $k'+\ell'\le \frac{846g}{s}+2=2s+2$, i.e., H_0' has at most $2s+2$ vertices.

We now describe the order in which we contract the vertices of G, and we analyze the described order later. In what follows, when we say a *layer*, we always refer to the layers given by the BFS spanning tree T_0 from the application of Theorem 13. In particular, each vertex of G is adjacent only to the vertices in its own layer and the two neighboring layers. To make the presentation clearer, we split contracting vertices into three phases.

Phase I. This phase consists of ℓ subphases. In the i-th subphase, $i\in[\ell]$, we contract all the vertices of the set V_i that are contained in the same layer to a single vertex in the way that we now describe. Then, we possibly contract them to some of the vertices created in the preceding subphases, i.e., those obtained by contracting vertices in $V_1\cup\dots\cup V_{i-1}$. In this phase, *we never contract two vertices contained in different layers* and no contraction involves any vertex from $V(P_1)\cup\dots\cup V(P_k)$.

Subphase. Fix $i\in[\ell]$. Let G_i be the subgraph of $G_0/\mathcal{P}$ induced by the vertices contained in the bags of the subtree $\mathcal{T}_i$ and let n' be the number of the paths $P_1,\dots,P_k$ that are contained in the bags of the subtree $\mathcal{T}_i$; note that $n'\le 6$. If the graph G_i has less than 8 vertices, we proceed directly to the conclusion of the subphase, which is described below. If the graph G_i has at least 8 vertices, G_i is a subgraph of a spanning subgraph of a 7-tree G_i' such that the n' vertices corresponding to the paths from the set $\{P_1,\dots,P_k\}$ are contained in the initial complete graph of G_i'.

Fix any order $Q_1,\dots,Q_n$ of the vertical paths corresponding to the vertices of G_i' such that the neighbors of Q_j, $j\in[n]$, among $Q_1,\dots,Q_{j-1}$ form a complete graph of order at most 7 in G_i' and the n' paths from the set $\{P_1,\dots,P_k\}$ are the paths $Q_1,\dots,Q_{n'}$. Let C_j be the complete subgraph of G_i formed by Q_j and its (at most 7) neighbors among $Q_1, \ldots, Q_{j-1}$. Note that the neighbors in G of each vertex of a path Q_j, $j \in [n]$, are contained in at most seven of the paths $Q_1, \ldots, Q_{j-1}$, which are exactly the paths forming the complete graph C_j. We define the *j-shadow* of a vertex $v \in V_i$ to be the set of its neighbors contained in the paths $Q_1, \ldots, Q_{j-1}$. Since every vertex of Q_j has at most 21 neighbors on the paths $Q_1, \ldots, Q_{j-1}$ (as its neighbors must be in the same or adjacent layers), the j-shadow of a vertex contained in the path Q_j has at most 21 vertices.

We now use the tree-like structure of the 7-tree G'_i to define the order of contractions of the vertices contained in V_i; this part of our argument is analogous to that used in [40] in relation to twin-width of graphs with bounded tree-width. We proceed iteratively for $j = n-1, \ldots, n'$. Before we describe the order of contractions, we present the properties satifised at the end of the iterations. At the end of the iteration for $j = n-1, \ldots, n'+1$, all vertices of V_i that

- are contained in paths of the same component of $G'_i \setminus \{Q_1, \ldots, Q_{j-1}\}$,
- have the same j-shadow, and
- are in the same layer

will have been contracted to a single vertex. At the end of the iteration for $j = n'$, all vertices of V_i with the same $(n'+1)$-shadow that are contained in the same layer will have been contracted to a single vertex. In particular, at the end of the iteration for $j = n'$, all vertices of V_i contained in the same layer will have been contracted to at most $2^{3n'}$ vertices (a vertex can have at most three neighbors on each path Q_j, $j \in [n']$, which are the vertex on the same layer and the two vertices on the adjacent layers, and the $(n'+1)$-shadow is a subset of these $3n'$ vertices).

For $j \in \{n-1, \ldots, n'\}$, we now describe the order of contractions of the vertices in the iteration for j. Let m be the number of components of $G'_i \setminus \{Q_1, \ldots, Q_j\}$ that are included in the component of $G'_i \setminus \{Q_1, \ldots, Q_{j-1}\}$ that contains Q_j, and let $W_1, \ldots, W_m$ be the sets of vertices obtained by contracting (in the previous iterations) vertices on the paths of these m components; note that the vertices in $W_1, \ldots, W_m$ are obtained by contracting some vertices contained in $V(Q_{j+1}) \cup \cdots \cup V(Q_n) \subseteq V_i$. Observe that each of the sets $W_1, \ldots, W_m$ has at most 2^{21} vertices in each layer (as the $(j+1)$-shadow of vertices on the same layer are subsets of the same set of $3 \cdot 7 = 21$ vertices). We first contract each vertex of W_2 to the vertex W_1 with the same $(j+1)$-shadow on the same layer if such vertex exists. Next, we contract each vertices of W_3 to the vertex of $W_1 \cup W_2$ with the same $(j+1)$-shadow on the same layer if such vertex exists, etc. At the end of this process, all vertices of $W_1 \cup \cdots \cup W_m$ with the same $(j+1)$-shadow that are on the same layer have been contracted to a single vertex (note that there are at most 2^{24} such vertices in each layer as the $(j+1)$-shadows are subsets of the same set of $3 \cdot 8 = 24$ vertices). If $j > n'$, we contract all resulting vertices with the same j-shadow that are on the same layer to a single vertex, and subsequently, we contract the vertex contained on the path Q_j to the vertex with the same j-shadow on the same layer (if such vertex exists). The description of the iteration for j is now finished.

Conclusion of subphase. The i-th subphase concludes by contracting all the vertices of V_i in the same layer to a single vertex, and if the vertex b_i is not the vertex with the smallest index in the set $B_{i'}$ such that $b_i \in B_{i'}$, i.e., $b_{i-1} \in B_{i'}$, then we contract each resulting vertex w to the vertex obtained in the $(i'-1)$-th subphase that is in the same layer as w (if such vertex exists).

Phase II. The graph obtained after Phase I has at most $k + \ell'$ vertices in each layer: k correspond to the vertices $a_1, \ldots, a_k$ of the graph H_0, i.e., they are contained on the paths $P_1, \ldots, P_k$, and the remaining ℓ' to the sets $B_1, \ldots, B_{\ell'}$ (see Figure 2). For every $i = 1, \ldots, k'$,

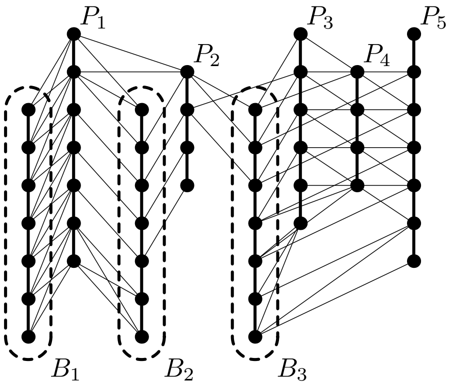

Figure 2 An example of a graph obtained after Phase I in the proof of Theorem 14 ($k = 5$ and $\ell' = 3$). The edges of vertical paths are drawn in bold. Note that there are no edges between paths corresponding to the set B_1, B_2 and B_3.

we contract all the vertices on the paths of A_i that are in the same layer to a single vertex as follows. Let $P_{i_1}, \dots, P_{i_n}$ be the paths corresponding to the vertices of A_i. We first contract the vertices of P_{i_1} and P_{i_2} that are in the same layer, proceeding from top to bottom (starting with the layer that contains both such vertices). We then contract the vertices of P_{i_3} to the vertices created previously, again in each layer proceeding from top to bottom, then the vertices of P_{i_4}, etc. At the end of this phase, we obtain a graph that is a subgraph of the strong product of a path and the graph H'_0. Since H'_0 has $k' + \ell' \leq 2s + 2$ vertices, each layer now contains at most $2s + 2$ vertices.

Phase III. We now contract all the vertices contained in the top layer to a single vertex, then all the vertices of the next layer to a single vertex, etc. Finally, we contract the vertices one after another to eventually obtain a single vertex, starting with the two vertices of the top two layers, then contracting the vertex in the third layer, etc.

Analysis of red degrees. We now establish an upper bound on the maximum possible red degree of the vertices of the graphs obtained throughout the described sequence of contractions. We start with Phase I. During the i-th subphase and the iteration for j, the only new red edges ever created are among the vertices of $W_1, \dots, W_m$ and the path Q_j. Since the vertices of $W_1 \cup \dots \cup W_m$ have at most 2^{24} different $(j+1)$-shadows (the neighbors in their shadows are only on the paths contained in C_j), each vertex has neighbors in its and the two neighboring layers, and we first contract all vertices of $W_1 \cup W_2$ with the same $(j+1)$-shadow, then all vertices of $W_1 \cup W_2 \cup W_3$, etc., the red degree of any vertex does not exceed $2 \cdot 3 \cdot 2^{24} = 3 \cdot 2^{25}$. We eventually arrive at having at most 2^{24} vertices in each layer and so their red degrees do not exceed $3 \cdot 2^{24}$. Then, the vertices with the same j-shadow that are on the same layer are contracted, which can result in the vertices of Q_j (temporarily) having the red degree up to $3 \cdot 2^{24}$. At the end of iteration for $j > n'$, there are at most 2^{21} vertices in each layer that have been obtained from $W_1 \cup \dots \cup W_m$ and so the red degree of each of them is at most $3 \cdot 2^{21}$. Also note that there is no red edge between the vertices on the paths $Q_1, \dots, Q_{j-1}$ and the remaining vertices of V_i.

At the beginning of the conclusion of the subphase, each layer has at most 2^{18} vertices obtained from contracting the vertices of V_i (note that this bound also holds when G_i has less than eight vertices, i.e., when we proceeded directly to the conclusion of the subphase). The conclusion of the subphase starts with contracting these vertices to a single vertex per layer: this can increase the red degree of vertices on at most six paths $P_1, \dots, P_k$ and the red degree of each vertex on these paths can increase by at most three. When the subphase finishes, each of the vertices contained in the paths $P_1, \dots, P_k$ has at most $3\ell'$ red neighbors (although during the subphase it can have upto three additional red neighbors), and each of the vertices obtained by contracting the vertices of $V_1, \dots, V_i$ has red degree at most $6s$ (since the sum of the degrees of the vertices in each set $B_1, \dots, B_{\ell'}$ is at most $2s$). In particular, the red degree of each vertex on the paths $P_1, \dots, P_k$ never exceeds $3(\ell' + 1)$. We conclude that the red degree of none of the vertices exceeds the largest of the following three bounds: $3 \cdot 2^{25}$, $3(\ell' + 1)$ and $6s$. Moreover, the red degree of no vertex exceeds $\max\{3\ell', 6s\} \leq 6s + 3$ (recall that $\ell' \leq 2s + 1$) at the end of each subphase (and so also at the end of Phase I).

During Phase II, each vertex has at most $\max\{k' + \ell', 2s\}$ red neighbors in its layer and in each of the neighboring layers. Indeed, the vertices obtained from those on the paths $P_1, \dots, P_k$ have at most $k' + \ell'$ red neighbors in each layer (at most k' neighbors among vertices obtained from contracting vertices on the paths $P_1, \dots, P_k$, and there are at most ℓ' vertices in each layer obtained by contracting vertices not on the paths $P_1, \dots, P_k$) and the vertices obtained from those not on the paths $P_1, \dots, P_k$ have at most $2s$ red neighbors in each layer as this is simply the upper bound on the number of their neighbors on the paths $P_1, \dots, P_k$. Hence, during the entire Phase II, the red degree of any vertex never exceeds

$$3 \max\{k' + \ell', 2s\} \leq 3 \max\{2(s + 1), 2s\} = 6(s + 1).$$

Finally, since the number of vertices contained in each layer at the end of Phase II is at most $k' + \ell'$, during the entire Phase III, the red degree of no vertex exceeds $3(k' + \ell') - 1$.

Hence, we have established that the red degree of no vertex exceeds $\max\left\{6(s + 1), 3 \cdot 2^{25}\right\}$ during the whole process, which implies the bound claimed in the statement. ◀

5 Algorithmic aspects

We now overview the main steps of the algorithm based on the proof of Theorem 14 that computes a witnessing sequence of vertex contractions of a graph embeddable in a fixed surface. We remark that we measure the time complexity in terms of the number of vertices, and we recall the number of edges of an n-vertex graph embeddable in a surface of Euler genus g is at most $3n + 3g - 6$, i.e., linear in the number of vertices when g is fixed.

Since it is possible to find an embedding of a graph in a fixed surface in linear time [43, 44], we can assume that the input graph G is given together with its embedding in the surface. When the embedding of G in the surface is fixed, we complete it to a triangulation G' (we permit adding parallel edges if needed). We next choose an arbitrary BFS spanning tree T of G' and identify g edges $a_1b_1, \dots, a_gb_g$ as described in Lemma 8, which was proven in [26, 28]. The proof of Lemma 8 in [26, 28] proceeds by constructing a spanning tree in the dual graph that avoids the edges of T and choosing the edges contained in neither T nor the spanning tree of the dual graph as the edges $a_1b_1, \dots, a_gb_g$; this can be implemented in linear time. When the edges $a_1b_1, \dots, a_gb_g$ are fixed, the construction of the walk W and the vertical paths described in Lemma 9 requires linear time.

We next compute the vertical paths described in Lemma 12 such that the boundary of each region of the graph G' obtained from the near-triangulation bounded by W can be covered by subpaths of at most six vertical paths. This requires processing the near-triangulation repeatedly following the steps of the inductive proof of Lemma 12: each step can be implemented in linear time and the number of steps is also at most linear. We then apply the recursive procedure described in the proof of Lemma 11 to each graph contained in one of the regions of G'; again, the number of steps in the recursive procedure is linear and each can be implemented in linear time. In this way, we obtain the collection $\mathcal{P}$ of vertical paths and the tree-decomposition $\mathcal{T}$ of $G'/\mathcal{P}$ described in Theorem 13. Note that the paths $\mathcal{P}$ and the tree-decomposition $\mathcal{T}$ fully determine the order of the contraction of the vertices and the order can be easily determined in linear time following the proof of Theorem 14.

We conclude that there is a quadratic time algorithm that constructs a sequence of contractions such that the red degree of trigraphs obtained during contractions does not exceed the bound given in Theorem 14. We remark that we have not attempted to optimize the running time of the algorithm, which would particularly require to implement the recursive steps of the proofs of Lemmas 11 and 12 more efficiently.

Agafonov's Theorem for Probabilistic Selectors

Jakob Grue Simonsen
University of Copenhagen, Denmark

Abstract

A normal sequence over $\{0,1\}$ is an infinite sequence for which every word of length k appears with frequency 2^{-k}. Agafonov's eponymous theorem states that selection by a finite state selector preserves normality, i.e. if α is a normal sequence and A is a finite state selector, then the subsequence $A(\alpha)$ is either finite or a normal sequence.

In this work, we address the following question: does this result hold when considering probabilistic selectors? We provide a partial positive answer, in the case where the probabilities involved are rational. More formally, we prove that given a normal sequence α and a rational probabilistic selector P, the selected subsequence $P(\alpha)$ will be a normal sequence with probability 1.

1 Introduction

Let $\alpha = x_1 x_2 \cdots$ be an infinite sequence over $\{0,1\}$; α is said to be *normal* if every finite string of length n over Σ occurs with limiting frequency 2^{-n} in α [5]. By standard reasoning, almost all infinite sequences are normal when the set $\{0,1\}^\omega$ of infinite sequences is equipped with the usual Borel measure. Concrete examples of normal sequences include Champernowne's binary sequence $0100011011000001\cdots$ [11], and many more examples exist [7].

A *finite-state selector* is a deterministic finite automaton (DFA) that selects the nth symbol from α if the length $n-1$ prefix of α is accepted by the DFA. *Agafonov's Theorem* [15, 1] is the celebrated result that a sequence α is normal iff any DFA that selects an infinite sequence from α, selects a normal sequence. While alternative proofs, generalizations [20] – and counter-examples to generalizations [13] – abound, all results in the literature consider deterministic or non-deterministic DFAs, but none consider probabilistic computation.

The extension to probabilistic selection is quite natural – not only are the underlying notions probabilistic in nature (i.e., normality of the transformed sequence), but the machinery of finite automata and similar computational devices itself has a 60-year history [18] of being extended to probabilistic devices.

In the present paper we study finite-state selectors equipped with probabilistic transitions from each state. As finite-state selectors can be viewed as devices sequentially processing successively larger prefixes of infinite sequences, we eschew the machinery of stochastic languages (where the initial state is a probability distribution on the states, and a string is accepted according to thresholding rules) – instead initial and accepting states are kept "as usual" in finite-state selectors. Probabilistic selection entails that normality may not be

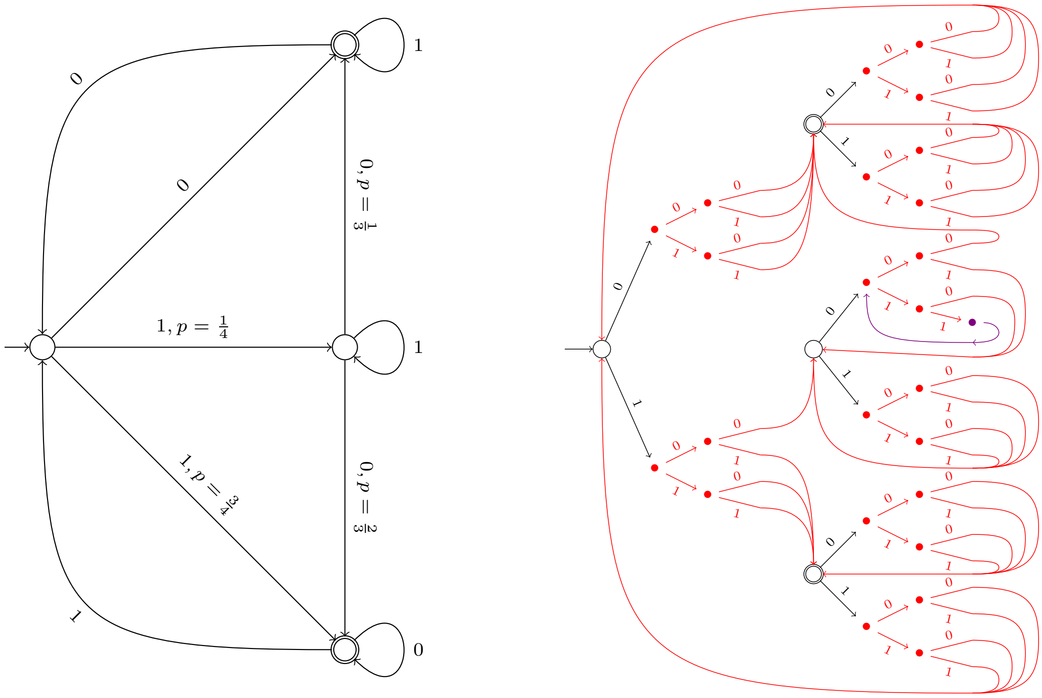
preserved in all runs of an automaton: For example, consider an automaton with two states S_1 and S_2, only one of which is accepting, and transitions on 0 and 1 from S_i to S_i ($i \in \{1,2\}$) with probability $1/2$ and from S_i to $S_{i+1 \mod 2}$ with probability $1/2$; then for any normal sequence α, there is a run of the automaton on α that will select the sequence $0^\omega = 000\cdots$. The main result of the present paper is to show that the probability of having such runs is zero – in fact that for any probabilistic finite-state selector A with rational probabilities and any normal sequence α, *the probability that a run of A on α will select a normal sequence is 1.* The proof progresses by treating the relatively tame case of *dyadic* probabilities (i.e., of the form $a/2^k$ with a and k non-negative integers) first, and subsequently "simulating" finite-state selectors with arbitrary rational probabilities by "determinized" selectors with dyadic probabilities.

Figure 1 shows a probabilistic finite-state selector (Figure 1a) with two probabilistic transitions: one involves dyadic probabilities, the second one involves rational but non-dyadic probabilities. On the right-hand side (Figure 1b) is the determinization of this selector[1]. All unlabelled edges correspond to transitions valid for both 0 and 1. Determinizing the selector is done by introducing *gadgets* (shown in red) that simulate the probabilistic choices by drawing bits from a random advice sequence.



(a) A probabilistic selector.

(b) Determinization.

Figure 1 A probabilistic finite state selector and its determinization.
Unlabelled edges correspond to blind transitions, i.e. transitions valid for both 0 and 1.

[1] In fact, the determinisation as defined below would impose that all transition are represented as rationals of denominator 6 to ensure some regularity (this is discussed in Remark 20). For pedagogical purposes we however decided to show both a gadget for a dyadic transition and one for a rational but non-dyadic one.

Contributions. We prove that (the pertinent analogue of) Agafonov's Theorem holds in the setting of probabilistic selection, namely that a probabilistic finite state selector with rational probabilities preserves normality with probability 1. An added contribution is that the proof methods involved are novel, and may be of independent interest. As in Agafonov's original paper, and to keep complexity simple, all results are stated for binary alphabets. We fully expect all results to hold for arbitrary finite alphabets, *mutatis mutandis.*

Related work. Agafonov's Theorem has been generalized in multiple ways beyond finite automata (see, e.g.,[3, 2, 4, 10, 12, 20]). Conversely, it is known that when adding trifling computational expressivity to finite-state selectors, counterexamples to Agafonov's Theorem for the resulting selectors can be constructed [13]. While some existing work considers preservation of more general measures by finite automata, or similar selectors [9], and substantial work exists relating equidistribution to various types of automata [19, 4] no extant work considers stochastic *selection.* Agafonov's Theorem itself has been proved by a multitude of different techniques, e.g. [6, 8, 4]; it is conceivable that some of these can be adapted to alternative proofs, or extensions, of the results reported in the present paper.

2 Preliminaries and notation

Elements of $\{0,1\}^\omega$ are denoted by α, β, etc. Finite sequences (elements of $\{0,1\}^*$), or *words* are denoted by u, v, w, etc.

If $v, w \in \{0,1\}^*$, $v \cdot w$ denotes the concatenation of v and w; the definition extends to $v \cdot \alpha$ for $\alpha \in \{0,1\}^\omega$ *mutatis mutandis.*

The non-negative integers are denoted by $\mathbf{N}$, and the positive integers by $\mathbf{N}_{>0}$. If $N \in \mathbf{N}$ and $\alpha = a_1 a_2 \cdots \in \{0,1\}^\omega$, we denote by $\alpha|_{\leq N}$ the finite sequence $a_1 a_2 \cdots a_n$.

Given a set S we write $\mathrm{Dist}(S)$ the space of probability distributions on S. Given a probability distribution $\delta \in \mathrm{Dist}(S)$, we say that δ is *dyadic* (resp. *rational*) when for all $s \in S$, $\delta(s)$ is a dyadic number (resp. a rational number), that is a number of the form $\frac{p}{2^k}$ for integers p, k.

We consider the standard probability *measure* $\mathrm{Prob}_{\rho \in \{0,1\}^\omega}$ on $\{0,1\}^\omega$ equipped with the least Σ-algebra induced by the cylinder sets $C_w = \{\alpha \mid \exists \alpha' \in \{0,1\}^\omega, \alpha = w \cdot \alpha'\}$ and such that $\mathrm{Prob}_{\rho \in \{0,1\}^\omega} C_w = 2^{-|w|}$ for $w \in \{0,1\}^*$. Elements of $\{0,1\}^\omega$ drawn according to this measure are called *fair random infinite sequence.*

▶ **Definition 1.** *Let $a = a_1 \cdots a_m$ and $b = b_1 \cdots b_n$ be finite sequences such that $n < m$. An* occurrence *of b in a is an integer i with $1 \leq i \leq m$ such that $a_i = b_1, a_{i+1} = b_2, \dots a_{i+n-1} = b_n$. If $\alpha = a_1 a_2 \cdots$ is an infinite sequence and $w = w_1 \cdots w_n$ is a word, we denote by $\sharp_N\{w\}(\alpha)$ the number of occurrences of w in $a_1 a_2 \cdots a_N$.*

A sequence $\alpha \in \{0,1\}^\omega$ is said to be normal *if, for any $m \in \mathbf{N}$ and any $w = w_1 \cdots w_m \in \{0,1\}^m$, the limit $\lim_{N\to\infty} \sharp_N\{w\}(\alpha)/N$ exists and equals 2^{-m}.*

▶ **Definition 2.** *Let $\alpha = a_1 a_2 \cdots$ be an infinite sequence, and i and n be positive integers. The ith* block of size n in α, *denoted $B^i_n(\alpha)$, is the finite sequence $a_{(i-1)n+1} a_{(i-1)n+2} \cdots a_{in}$. If w is a finite sequence of length k with $k = jn + r$ for appropriate j and $r < n$, the ith block of size n in a finite sequence of length $k \geq n$ is defined* mutatis mutandis *for any $i \leq j$.*

Given a word $w \in \{0,1\}^n$, we write $\sharp^{(n)}_N\{w\}(\alpha)$ for the number of blocks of size n that are equal to w in the prefix of size $N \times n$:

$$\sharp^{(n)}_N\{w\}(\alpha) = \mathrm{Card}\{i \in [0, N-1] \mid B^i_n(\alpha) = w\},$$

for $k \in \mathbf{N}$ and $w \in \{0,1\}^k$. We define $\mathrm{freq}(\alpha, w)$ *as the following limit, when it exists:*

$$\mathrm{freq}(\alpha, w) = \lim_{N \to \infty} \frac{\sharp_N^{(n)}\{w\}(\alpha)}{N}.$$

Let $k \in \mathbf{N}$, the sequence is length-k*-normal if for all words $w \in \Sigma^k$,* $\mathrm{freq}(\alpha, w)$ *is well defined and equal to 2^{-k}.*

The sequence α is said to be block normal *if it is* length-k*-normal for all k.*

By standard results, an infinite sequence α is normal iff it is block-normal [14, 16, 17].

We now define the crucial notion of *probabilistic finite state selector*. The usual notion of deterministic finite state selectors is a special case of this definition.

▶ **Definition 3.** *A probabilistic finite state selector $\mathcal{S}$ is a tuple (Q, t, ι, A) where Q is a finite set of states, $\iota \in Q$ is the initial state, $A \subset Q$ is the subset of accepting states, and $t : Q \times \{0,1\} \to \mathrm{Dist}(Q)$ is a probabilistic transition function.*

A rational (resp. dyadic, resp. deterministic) finite selector is a probabilistic finite state selector in which all distributions $t(q, a)$ (for $q \in Q$ and $a \in \{0,1\}$) are rational (resp. dyadic, resp. deterministic).

Given a probabilistic selector $\mathcal{S}$ and a sequence $\alpha \in \{0,1\}^\omega$, one can define a probability distribution over $\{0,1\}^\omega$ defined through *selection* of elements of α by $\mathcal{S}$.

Observe that if $\mathcal{S}$ is deterministic, the induced probability distribution assigns probability 1 to *the unique* selected subsequence $\mathcal{S}(\alpha)$ of α considered in the standard Agafonov theorem, i.e. the sequence of bits α_i in α such that $\mathcal{S}$ reaches an accepting state when given the prefix $\alpha_0 \dots \alpha_{i-1}$.

▶ **Definition 4.** *Given a probabilistic finite state selector $\mathcal{S}$ and an infinite sequence α, the* selection random variable *$S(\alpha)$ is the random variable over $\{0,1\}^\omega$ defined as follows on cylindrical sets C_w:*

$$S(\alpha)(C_w) = \sum_{i_1 < \dots < i_{|w|} \in \mathbf{N}, \alpha_{i_1}\alpha_{i_2}\dots\alpha_{i_{|w|}} = w} \mathrm{Prob}(\mathcal{S}, i_1 < \dots < i_{|w|})$$

where $\mathrm{Prob}(\mathcal{S}, i_1 < \dots < i_{|w|})$ denotes the probability that the first $|w|$ times the selector $\mathcal{S}$ reaches an accepting state on input α correspond to the indices $i_1 - 1, i_2 - 1, \dots, i_{|w|} - 1$.

We finally recall the standard Agafonov theorem.

▶ **Theorem 5.** *Let $\alpha \in \{0,1\}^\omega$ be a sequence, and $\mathcal{S}$ a deterministic finite selector. Then α is normal if and only if for all deterministic finite selector $\mathcal{S}$, the subsequence $\mathcal{S}(\alpha)$ is either finite or normal.*

2.1 Technical lemmas about normality

We will establish a few results on normal sequences that will be useful in later proofs. We first define notions that will be used in the proofs.

▶ **Definition 6.** *Let $\alpha \in \{0,1\}^\omega$ be a sequence, and $w \in \{0,1\}^*$ a word. We say that α is* w-normal *if $\lim_{N \to \infty} \frac{\sharp_N\{w\}(\alpha)}{N} = 2^{-|w|}$.*

Given $\epsilon \in \mathbf{R}$, we say that α is w-normal up to ϵ *if $\exists N_0, \forall N > N_0, \left| \frac{\sharp_N\{w\}(\alpha)}{N} - 2^{-|w|} \right| < \epsilon$.*

We now restate a weaker property for sequences than normality: being normal for words of a fixed length k. The main lemma associated to that notion will be that if a sequence is normal for words of length mk for a fixed integer k and all integers m, then it is normal (i.e. normal for words of arbitrary length).

▶ **Definition 7.** *Let $k \in \mathbf{N}$, the sequence is* length-k-normal *if for all words $w \in \{0,1\}^k$, $\mathrm{freq}(\alpha, w)$ is well defined and equal to 2^{-k}.*

▶ **Lemma 8.** *Let α be a sequence in $\{0,1\}^\omega$. The following are equivalent:*

- *α is normal*
- *there exists $m \in \mathbf{N}_{>0}$ such that α is* length-km *normal for all $k \in \mathbf{N}$.*

Proof. Consider a sequence α which is length-km normal for all $k \in \mathbf{N}$, and fix a word $w \in \{0,1\}^n$. We will use the length-mn normality of α. For this, we note that we can write:

$$\begin{aligned}
\sharp^{(n)}_N\{w\}(\alpha) &= \sum_{w_1,\dots,w_m\in\{0,1\}^n} \mathrm{Card}\{i \in \{1,\dots,m\} \mid w_i = w\}.\sharp^{(mn)}_{N/m}\{w_1\cdot\dots\cdot w_m\}(\alpha)\\
&= \sum_{w_1,\dots,w_{m-1}\in\{0,1\}^n} \sum_{j=1}^{m} \sharp^{(mn)}_{N/m}\{w_1\cdot\dots\cdot w_{j-1}\cdot w\cdot w_j\cdot w_{m-1}\}(\alpha)\\
&= \sum_{w_1,\dots,w_{m-1}\in\{0,1\}^n} m\sharp^{(mn)}_{N/m}\{w\cdot w_1\cdot\dots\cdot w_{m-1}\}(\alpha)
\end{aligned}$$

As a consequence:

$$\begin{aligned}
\mathrm{freq}(\alpha, w) &= \lim_{N\to\infty} \frac{\sharp^{(n)}_N\{w\}(\alpha)}{N}\\
&= \lim_{N\to\infty} \sum_{w_1,\dots,w_m\in\{0,1\}^n} \frac{\mathrm{Card}\{i \in \{1,\dots,m\} \mid w_i = w\}.\sharp^{(mn)}_{N/m}\{w_1\cdot\dots\cdot w_m\}(\alpha)}{N}\\
&= \lim_{N\to\infty} \sum_{w_1,\dots,w_{m-1}\in\{0,1\}^n} \frac{m.\sharp^{(mn)}_{N/m}\{w\cdot w_1\cdot\dots\cdot w_{m-1}\}(\alpha)}{N}\\
&= \sum_{w_1,\dots,w_{m-1}\in\{0,1\}^n} \lim_{N\to\infty} \frac{\sharp^{(mn)}_{N/m}\{w\cdot w_1\cdot\dots\cdot w_{m-1}\}(\alpha)}{N/m}\\
&= \sum_{w_1,\dots,w_{m-1}\in\{0,1\}^n} \mathrm{freq}(\alpha, w\cdot w_1\cdot\dots\cdot w_{m-1})\\
&= \sum_{w_1,\dots,w_{m-1}\in\{0,1\}^n} 2^{-mn} = 2^{n(m-1)}2^{-mn} = 2^{-n}
\end{aligned}$$ ◀

Now the following lemma states that the proportion of blocks equal to a fixed word w in a prefix of size N of a normal sequence asymptotically behaves as a linear function. The proof is quite straightforward.

▶ **Lemma 9.** *Let α be a normal sequence and $w \in \{0,1\}^n$. Then $\sharp^{(n)}_N\{w\}(\alpha) = 2^{-n}N + o(N)$.*

Proof. If it were not true, we would have that there exists some $\epsilon > 0$ and a sequence $(N_i)_{i\in\mathbf{N}}$ such that $\left|\sharp^{(n)}_{N_i}\{w\}(\alpha) - 2^{-n}N_i\right| > \epsilon N_i$ for all $i \in \mathbf{N}$. In other words,

$$\left|\frac{\sharp^{(n)}_{N_i}\{w\}(\alpha)}{N_i} - 2^{-n}\right| > \epsilon.$$

This contradicts the normality of α since it implies that $\lim_{i\to\infty}\left|\frac{\sharp^{(n)}_{N_i}\{w\}(\alpha)}{N_i} - 2^{-n}\right| = 0$. ◀

We will now define a partition of the set of blocks $(B^j_K(\alpha))_{j\in\mathbf{N}}$ into groups $(E_i)_{i\in\mathbf{N}}$ such that each $r \in \{0,1\}^K$ appears exactly once in each E_i. Those will be defined from a partition $(V_i^K(\alpha))_{i\in\mathbf{N}}$ of $\mathbf{N}$ such that the set $V_i^K(\alpha)$ contains the indices of the blocks of size K of α contained in E_i.

▶ **Definition 10.** *Let $\alpha \in \{0,1\}^\omega$ be a normal sequence, and $K \in \mathbf{N}$. We define $\theta_i(\alpha) : \{0,1\}^K \to \mathbf{N}$ as mapping a word w to the value j such that $B^j_K(\alpha)$ is exactly the i-th block of size K of α equal to w. (i.e. there are exactly $i-1$ indices $j_1 < j_2 < j_3 < \ldots < j_{i-1} < j$ such that $\forall k$, $B^{j_k}_K(\alpha) = w \wedge B^j_K(\alpha) = w$)*

The sets of indices $(V_i^K(\alpha))_{i\in\mathbf{N}} \subset \mathbf{N}$ are then defined as the image $\operatorname{Im}(\theta_i(\alpha))$.

The next lemma gives useful bounds on the V_i^K.

▶ **Lemma 11.** *Let α be a normal sequence, $K \in \mathbf{N}$. Consider the sets $V_i^K(\alpha)$ from Definition 10. We have that $\max_{i=1}^N \max V_i^K(\alpha) = N2^K + o(N)$, and $|[N] \setminus \bigcup_{i=1}^{N/2^K} V_i| = o(N)$.*

Proof. This comes from the fact that for any $w \in \{0,1\}^n$, $\sharp_N^{(n)}\{w\}(\alpha) = 2^{-|w|}N + o(N)$. ◀

The following probabilistic lemma is needed for the proof of Lemma 30.

▶ **Lemma 12.** *Let Ω_1 and Ω_2 be two sample spaces. Let $(X_i)_{i\in\mathbf{N}}$ be an iid family of r.v. which take value in $\Omega_1^{\mathbf{N}}$, $(Y_i)_{i\in\mathbf{N}}$ another iid family of r.v. which take value in $\Omega_2^{\mathbf{N}}$. Let $f(X,Y)$ be a function in $\Omega_1 \times \Omega_2 \mapsto \mathbf{R}$. Suppose $\forall x \in \Omega_1, \forall y \in \Omega_2, f(X_0, y)$ and $f(x, Y_0)$ have finite expected value and variance then*

$$\mathbb{P}_{Y_i}\left(\sum_x \left[\mathbb{P}(X = x)\sum_{i=1}^N f(x, Y_i)\right] = N \times \mathbb{E}_{X_0,Y_0}(f(X_0,Y_0)) + o(N)\right) = 1.$$

Proof. This is a direct application of the law of large numbers . ◀

3 Dyadic case

We first restrict to dyadic selectors. Given a dyadic selector $S = (Q, t, \iota, A)$, we define its dyadicity degree as the smallest integer D such that for all states $q, q' \in Q$ and element $a \in \{0,1\}$, the probability $t(q,a)(q')$ can be written as $\frac{m}{2^D}$.

We first define the determinisation of a dyadic selector.

▶ **Definition 13.** *Given a dyadic selector $\mathcal{S} = (Q, t, \iota, A)$ of dyadicity degree D, we define a* determinisation $\operatorname{Det}(\mathcal{S})$ *of S as the deterministic selector (Q', t', ι', A') where:*

- *$Q' = Q \cup Q \times \{0,1\} \times \{0,1\}^{\leq D-1}$;*
- *$\iota' = \iota$ and $A' = A$;*
- *the transition function t is defined as follows:*
  - *for all $q \in Q$, $t'(q,a) = (q, a, \epsilon)$ where ϵ is the empty word;*
  - *for all $((q,b,w)$ with $w \in \{0,1\}^{\leq D-2}$, $t'((q,b,w),a) = (q,b,w\cdot a)$;*
  - *for all (q,b,w) with $w \in \{0,1\}^{D-1}$, $t'((q,b,w),a) = q'$ where $q' = \phi(w\cdot a)$ for a chosen $\phi_{q,b} : 2^D \to Q$ such that the preimage of any $s \in Q$ has cardinality m_s where m_s is defined by $t(q,b)(s) = \frac{m_s}{2^D}$.*

Now, the principle is that the behaviour of a dyadic selector S on the sequence α can be simulated by the behaviour of a determinisation $\operatorname{Det}^D(\mathcal{S})$ computing on an interleaving of α and a random *advice* string ρ.

▶ **Definition 14.** *Let α, ρ be sequences in $\{0,1\}^\omega$, and $D \in \mathbf{N}$. The interwoven sequence $I^D(\alpha,\rho)$ is defined as the sequence:*

$$\alpha_0\rho_0 \dots \rho_{D-1}\alpha_1\rho_D \dots \rho_{2D-1} \dots .$$

Note that the interweaving of two normal sequences can be a non-normal sequence, e.g. the interweaving of α with itself $I^1(\alpha,\alpha)$ is not normal.

▶ **Lemma 15.** *Let $\mathcal{S}$ be a dyadic selector of dyadicity degree D. Then for all sequences $\alpha \in \{0,1\}^\omega$ the random variables $\mathcal{S}(\alpha)$ and $\mathrm{Det}(\mathcal{S})(I^D(\alpha,\rho))$ where ρ is drawn uniformly at random in $\{0,1\}^\omega$ have the same distribution.*

Proof. This is a special case of Lemma 23. ◀

Consider given a normal sequence α. We now prove that for almost all random advice sequence $\rho \in \{0,1\}^\omega$, the interwoven sequence $I^D(\alpha,\rho)$ is normal. This is the key lemma in the proof of Theorem 17.

▶ **Lemma 16.** *Let $\alpha \in \{0,1\}^\omega$ be a normal sequence. Then for all $D \in \mathbf{N}$,*

$$\mathrm{Prob}_{\rho\in\{0,1\}^\omega}[I^D(\alpha,\rho) \textit{is normal}] = 1.$$

Proof. In case $D = 0$, the interwoven sequence $I^D(\alpha,\rho)$ is equal to α. As a consequence, $\mathrm{Prob}_{\rho\in\{0,1\}^\omega}[I^D(\alpha,\rho)$ is normal$]$ is equal to 1.

We now suppose that $D \neq 0$. Given $m \in \mathbf{N}_{>0}$, we will show that $I^D(\alpha,\rho)$ is length-$(D+1)m$ normal with probability 1. This implies that for almost all $\rho \in \{0,1\}^\omega$, the sequence $I^D(\alpha,\rho)$ is length-$(D+1)m$ normal for every $m \in \mathbf{N}_{>0}$. By Lemma 8, this implies that for almost all $\rho \in \{0,1\}^\omega$, the sequence $I^D(\alpha,\rho)$ is normal.

We now fix $m \in \mathbf{N}_{>0}$, and $w \in \{0,1\}^{(D+1)m}$. We will consider the block decomposition of $I^D(\alpha,\rho)$ into blocks of size $(D+1)m$ and prove that:

$$\mathrm{Prob}_{\rho\in\{0,1\}^\omega}\left(\lim_{N\to\infty}\frac{\sharp_N^{((D+1)m)}\{w\}(I^D(\alpha,\rho))}{N} = 2^{-(D+1)m}\right) = 1.$$

We note that blocks of size $(D+1)m$ follow the pattern:

$$\alpha_i r_j \dots r_{j+D}\alpha_{i+1}r_{j+D}\dots r_{j+2D}\dots\alpha_{i+m-1}r_{j+(m-1)D}\dots r_{j+mD}.$$

We will consider $\lfloor w \rfloor_D = w_0 w_{D+1} w_{2(D+1)} \dots w_{(m-1)(D+1)}$ the subword of w corresponding to the positions of bits from α in this pattern.

We will consider the block decomposition of α into blocks of size m. Let $\mathrm{idx}(i) = j$ where j is the i-th block such that $B_j^m(\alpha) = \lfloor w \rfloor_D$. Note that this function is well defined because α is a normal sequence. Note that if a given block $B_i^{(D+1)m}(I^D(\alpha,\rho))$ is equal to w, then $\lfloor B_i^{(D+1)m}(I^D(\alpha,\rho))\rfloor_D$ should be equal to $\lfloor w \rfloor_D$. We write $\tilde{N} = \sharp_N^{(m)}\{\lfloor w \rfloor_D\}(\alpha)$, note that it is the maximal i such that $\mathrm{idx}(i) < N$. We also define $\bar{w}$ as the complementary subsequence of w:

$$\bar{w} = w_1 \dots w_D w_{D+2} \dots w_{2(D+1)-1} w_{2(D+1)+1} \dots w_{m(D+1)-1}.$$

We introduce a new notation: we will write $\sharp_{\mathrm{Im(idx)}<N}^{((D+1)m)}\{w\}(I^D(\alpha,\rho))$ to denote the number of blocks of size $(D+1)m$ equal to w within the blocks indexed by some $j < N$ in Im(idx).

$$P = \mathrm{Prob}_{\rho\in\{0,1\}^\omega}\left(\lim_{N\to\infty}\frac{\sharp_N^{((D+1)m)}\{w\}(I^D(\alpha,\rho))}{N} = 2^{-(D+1)m}\right)$$
$$= \mathrm{Prob}_{\rho\in\{0,1\}^\omega}\left(\lim_{N\to\infty}\frac{\sharp_{\mathrm{Im(idx)}<N}^{((D+1)m)}\{w\}(I^D(\alpha,\rho))}{N} = 2^{-(D+1)m}\right)$$

Now by Lemma 9 we have that $\lim_{N\to\infty}\tilde{N} = N.2^{-m}$. Hence:

$$P = \mathrm{Prob}_{\rho\in\{0,1\}^\omega}\left(\lim_{\tilde{N}\to\infty}\frac{\sharp_{\mathrm{Im(idx)}<N}^{((D+1)m)}\{w\}(I^D(\alpha,\rho))}{\tilde{N}.2^{-m}} = 2^{-(D+1)m}\right)$$
$$= \mathrm{Prob}_{\rho\in\{0,1\}^\omega}\left(\lim_{\tilde{N}\to\infty}\frac{\sharp_{\mathrm{Im(idx)}<N}^{((D+1)m)}\{w\}(I^D(\alpha,\rho))}{\tilde{N}} = 2^{-Dm}\right)$$
$$= \mathrm{Prob}_{\rho\in\{0,1\}^\omega}\left(\lim_{\tilde{N}\to\infty}\frac{\sharp_{\mathrm{Im(idx)}<N}^{(Dm)}\{\bar{w}\}(\rho)}{\tilde{N}} = 2^{-Dm}\right)$$

By the law of large numbers, we have that

$$\mathrm{Prob}_{\rho\in\{0,1\}^\omega}\left(\lim_{\tilde{N}\to\infty}\frac{\sharp_{\mathrm{Im(idx)}<N}^{(Dm)}\{\bar{w}\}(\rho)}{\tilde{N}} = 2^{-Dm}\right) = 1,$$

which concludes the proof. ◀

This lemma then leads to the following theorem.

▶ **Theorem 17.** *Let $\alpha \in \{0,1\}^\omega$ be a sequence. Then α is normal if and only if for all dyadic finite selector $\mathcal{S}$ the probability that $\mathcal{S}(\alpha)$ is either finite or normal is equal to 1.*

Proof. The right to left implication is simply a consequence of Agafonov's theorem (Theorem 5) since if for all dyadic finite selector $\mathcal{S}$ the probability that $\mathcal{S}(\alpha)$ is either finite or normal is equal to 1, then for all deterministic finite selector $\mathcal{S}$ the selected subsequence $\mathcal{S}(\alpha)$ is either finite or normal.

Now, suppose that the above implication from left to right is false. Then by Lemma 15 there exists a subset $R \subset \{0,1\}^\omega$ of strictly positive measure such that $\mathrm{Det}(\mathcal{S})(I^D(\alpha,\rho))$ is infinite and not normal for all $\rho \in R$. Since almost for almost all $\rho \in \{0,1\}^\omega$ the interwoven sequence $I^D(\alpha,\rho)$ is normal, this implies that there exists a ρ such that $I^D(\alpha,\rho)$ is normal and $\mathrm{Det}(\mathcal{S})(I^D(\alpha,\rho))$ is infinite and not normal. But this contradict Agafonov's theorem (Theorem 5). ◀

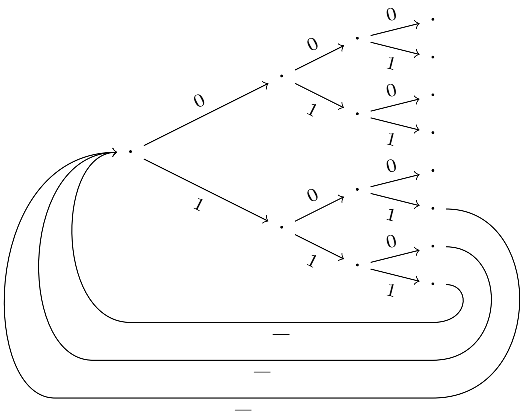
We will now consider the case of rational selectors. The difficulty in adapting the proof lies in the fact that the interwoven sequence has a less regular structure. In the above proof, each block of size $(D+1)m$ followed the same pattern. But in the case of rational selectors, the presence of feedback loops renders those pattern random, this makes the proof significantly harder. Indeed in the dyadic case the value of a block of size $(D+1)m$ was independent of the value of other blocks of size $(D+1)m$, in the rational case this is no longer true, thus we cannot apply the law of large numbers. Informally to make our proof work we divide $\mathcal{S}(\alpha)$ into non adjacent blocks whose values are independent, some bits are not contained in any blocks but we argue they are few of them and thus they don't prevent $\mathcal{S}(\alpha)$ from being normal.

4 Rational selector

4.1 Determinisation

The first step in extending the results to the rational case is to define the determinization. This will follow the same principle as for the dyadic case, but the parts of the determinized automaton that simulates probabilistic choices will contain feedback loops. Nonetheless, incorporating feedback loops is enough to represent any rational distribution, as shown in the next lemma.

▶ **Definition 18.** *A (k, f)-gadget is a regular binary tree of depth k, extended with blind transitions from the last F leaves to the root.*



▶ **Lemma 19.** *Any rational distribution* $\mathrm{Dist}(S)$ *is simulated by a gadget.*

Proof. Let $p_1, \dots, p_k$ be rationals with $\sum_i p_i = 1$, and suppose $p_i \leq p_{i+1}$ for all i. Consider M the smallest common multiple of all denominators of the elements p_i, and write $p_i = \frac{\tilde{p}_i}{M}$. We will denote by $q_i = \sum_{j=1}^{i} \tilde{p}_i$. Note that $q_0 = 0$ and $q_k = \sum_i \tilde{p}_i = M$. Now consider P the smallest natural number such that $2^P \geq M$. We build the regular automaton of depth P with feedback loops on $2^P - M$ leaves. We will show that the probability p of reaching a leaf within $[q_i + 1, q_{i+1}]$ is equal to p_i. One only need to compute:

$$p = \frac{\tilde{p}_i}{2^P} \sum_{m \geq 0} \left(\frac{2^P - M}{2^P} \right)^m = \frac{\tilde{p}_i}{2^P} \frac{1}{1 - \frac{2^P - M}{2^P}} = \frac{\tilde{p}_i}{2^P} \frac{2^P}{2^P - (2^P - M)} = \frac{\tilde{p}_i}{2^P} \frac{2^P}{M} = \frac{\tilde{p}_i}{M} = p_i \quad ◀$$

We will now define the determinisation of a rational selector in a similar way as for the dyadic case. First, since the selector is finite, one can write all rational numbers involved with a common denominator, say k. Given a rational selector $\mathcal{S}$, we will call k the *rationality degree* of $\mathcal{S}$. Then each transition will be simulated by a gadget as defined above.

▶ Remark 20. Note that since all rational distribution are represented with the same denominator, then all gadgets will have the same size. Indeed, let us define the *dyadicity degree* D of a rational selector $\mathcal{S}$ as the smallest integer such that $2^D \geq k$, where k is its rationality degree. Then the feedback edges of all gadgets corresponding to rational transitions correspond to the $2^D - k$ last edges in the gadget, and this does not depend on the specific transition considered.

The determinisation therefore has a quite *regular* structure which will be mirrored in the corresponding interwoven sequences.

▶ **Definition 21.** *Let $\mathcal{S} = (Q, \iota, t, A)$ be a rational selector of rationality degree k and dyadicity degree D. We define its* determinisation $\mathrm{Det}(\mathcal{S})$ *as the deterministic selector (Q', ι, t, A) where:*

- *$Q' = Q \cup Q \times \{0,1\} \times \big(\{0,1\}^{\leq k-1} \cup \{\text{return}\}\big)$;*
- *$\iota' = \iota$ and $A' = A$;*
- *the transition function t is defined as follows:*
  - *for all $q \in Q$, $t'(q, a) = (q, a, \epsilon)$ where ϵ is the empty list;*
  - *for all $((q, b, w)$ with $w \in \{0,1\}^{\leq k-2}$, $t'((q, b, w), a) = (q, b, w \cdot a)$;*
  - *for all (q, b, w) with $w \in \{0,1\}^{k-1}$ and $a \in \{0,1\}$:*
    - *if $w \cdot a$ belongs to the $2^D - k$ last leaves (i.e. the $2^D - k$ largest elements of $\{0,1\}^D$ for the natural order), then $t'((q, b, w), a) = (q, b, \text{return})$;*
    - *otherwise, $t'((q, b, w), a) = q'$ where $q' = \phi(w \cdot a)$ for a chosen $\phi_{q,b} : k \to Q$ such that the preimage of any $s \in Q$ has cardinality m_s where m_s is defined by $t(q, b)(s) = \frac{m_s}{k}$;*
  - *for all (q, b, return) and any $a \in \{0,1\}$, $t'(q, b, \text{return}) = (q, b, \epsilon)$.*

▶ **Definition 22.** *Let $\mathcal{S}$ be a rational selector of rationality degree k and dyadicity degree D, $\alpha \in \{0,1\}^\omega$ an input sequence, and $\rho \in \{0,1\}^\omega$ an* advice *sequence. We define the interwoven sequence $I_k^D(\alpha, \rho)$ as:*

$$\alpha_1 \rho_1 \dots \rho_{i_1} \alpha_2 \rho_{i_1+1} \dots \rho_{i_2} \alpha_3 \dots,$$

where $i_1 < i_2 < \dots$ is the sequence of indices i_j such that $\rho_{i_j+1} \dots \rho_{i_{j+1}}$ is equal to $w_1 r_1 w_2 r_2 \dots r_m w_{m+1}$ where:

- *$w_1, w_2, \dots, w_m$ are among the $2^D - k$ greatest elements in $\{0,1\}^D$ (considered with the natural alphabetical order);*
- *w_{m+1} belongs to the k smallest elements in $\{0,1\}^D$;*
- *r_i are bits in $\{0,1\}$ which we will call* return bits*, corresponding to feedback loops.*

We note that this is a direct generalisation of the dyadic case, i.e. if the considered selector is dyadic, then the interwoven sequence $I_{2^D}^D$ just defined coincides with the definition from the previous section. Similarly, the determinisation of a dyadic selector is a special case of the determinisation of a rational selector. We can see here the difficulty in adapting the proof to the rational case arising: instead of interweaving one block of ρ of size D between each bit of α, we interweave a block of bits from ρ of variable length.

Note however that we carefully defined the determinisation so that the size of these blocks does not depend on the values α_i. Moreover, feedback loops introduce random *return* bits, allowing us to write the interwoven sequence as a sequence of blocks of the form $a r_1 \dots r_D$ where a is either a bit from α or a return bit from ρ and $r_1 \dots r_D$ are bits from ρ.

First, we check that the determinisation simulates the rational selector when given random advice strings.

▶ **Lemma 23.** *Let $\mathcal{S}$ be a rational selector of rationality degree k and dyadicity degree D. Then for all sequence $\alpha \in \{0,1\}^\omega$ the random variables $\mathcal{S}(\alpha)$ and $\mathrm{Det}(\mathcal{S})(I_k^D(\alpha, \rho))$ where ρ is an infinite fair random sequence, have the same distribution.*

Proof. Let ρ be an infinite fair random sequence. By construction of $\mathrm{Det}(\mathcal{S})(I_k^D(\alpha, \rho))$, for a any two state q and q' the probability of going from q to q' in $\mathrm{Det}(\mathcal{S})(I_k^D(\alpha, \rho))$ (ignoring the gadget states in between) is equal to the probability of going from q to q' in $\mathcal{S}(\alpha)$. ◀

4.2 Rational selectors preserve normality

In the following, α will be a infinite sequence, not considered normal unless explicitly stated. We will write w to denote a finite word. We denote by ρ and τ fair infinite random sequences, and by r a finite random sequence. Lastly, q will be the probability to loop back at the end of a gadget, equal to $1 - \frac{k}{2^D}$. We will denote by $A(N) \xrightarrow{N} B(N)(1 \pm \epsilon)$ the fact that

$$\exists N_0, \forall N > N_0, B(N)(1-\epsilon) < A(N) < B(N)(1+\epsilon).$$

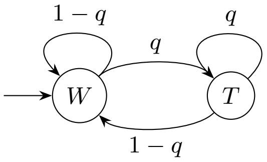
To prove that rational selectors preserve normality, we will prove in this section that $\mathbb{P}_\rho(I_k^D(\alpha,\rho)\text{is normal}) = 1$, that is the generalised version of Lemma 16. As in the dyadic case, this is the crux of the problem, and the proof of the main theorem will easily follow. In order to prove this technical lemma, we analyze a process we call $\mathcal{F}$ which takes a sequence α and inserts in between every bit of α a random amount of random bits. We will then show that if α is normal the sequence $\mathcal{F}(\alpha)$ obtained in this way is normal. Finally we will argue that normality of $I_k^D(\alpha,\rho)$ amounts to the normality of $\mathcal{F}(\alpha)$.

▶ **Definition 24** (Random process $\mathcal{F}_q$)**.** *Suppose given $K \in \mathbf{N}$, $w \in \{0,1\}^K$, $q \in [0;1[$, and $\tau \in \{0,1\}^\omega$. We define $\mathcal{F}_q(w,\tau) \in \{0,1\}^*$ as the random variable described in Figure 2 where we consume a bit of w when we get to state W and a bit of τ when we get to state T. The process stops when the state W is reached and there are no more bits of w to be consumed. The output is all the consumed bit in timely order.*

We denote by $\mathcal{F}_q(w)$ the random variable $\mathcal{F}_q(w,\tau)$ where τ is a fair random infinite sequence.

In the following, we may not specify q and just write $\mathcal{F}(w,\tau)$ when the context is clear.

▶ Remark 25. Note that τ needs to be infinite because we have no bound on how many bits of it we may consume.



Example: if $w = 0110$, $\tau = 10010...$, then

$$\mathcal{F}(w) = 010110010,$$

with the sequence of states

$$WTTWWTWTTW.$$

Figure 2 The random process $\mathcal{F}$.

For now $\mathcal{F}$ has only been defined on finite strings. We extend it to infinite strings in an intuitive way.

▶ **Definition 26.** *Suppose given $\alpha \in \{0,1\}^\omega$, $K \in \mathbf{N}$, and $q \in \mathbf{R}$. Let $(\mathcal{F}_i)_{i\in\mathbf{N}}$ be an iid family of random variables of law $\mathcal{F}$. The random variable $\mathcal{F}_q(\alpha)$ is the infinite sequence distributed as the concatenation of the $\mathcal{F}_i$ applied to the blocks $B_K^i(\alpha)$:*

$$\mathcal{F}_0(B_K^0(\alpha))\mathcal{F}_1(B_K^1(\alpha))\mathcal{F}_2(B_K^2(\alpha))\ldots.$$

Note that the value of K does not change the distribution of the random variable $\mathcal{F}(\alpha)$, hence the definition is unambiguous.

In the next lemma we analyze the length of $\mathcal{F}(w)$.

▶ **Lemma 27.** *Let $q \in [0;1[$ and $(\mathcal{F}_i)$ be an iid family of random variables of law $\mathcal{F}_q$. Then for all $K \in \mathbf{N}$ and for any family $(w_i)_{i\in\mathbf{N}} \in (\{0,1\}^K)^{\mathbf{N}}$,*

$$\mathbb{P}\left(\sum_{i\leq N} |\mathcal{F}_i(w_i)| = NKq^{-1} + o(NKq)\right) = 1.$$

Proof. By standard Markov chain analysis, the expected value of $|\mathcal{F}_i(w_i)|$ is Kq^{-1} and its variance is finite, furthermore the $\mathcal{F}_i(w_i)$ are independent the strong law of large number therefore applies and we get the desired result. ◀

In the next lemma we show that for any w we can approximate the number of w in $\mathcal{F}(\alpha) = \mathcal{F}_0(B^0_K(\alpha))\mathcal{F}_1(B^1_K(\alpha))\mathcal{F}_2(B^2_K(\alpha))\dots$ by adding up the number of w in each $\mathcal{F}_i(B^i_K(\alpha))$ separately. The larger K the more precise the approximation. What we gain from this separation is that the random variable $\sharp_{s_i-|w|}\{w\}(\mathcal{F}_i(B^i_K(\alpha)))$ are independent and we can apply the law of large numbers. In contrast in $\mathcal{F}(\alpha)$ where we concatenate the $\mathcal{F}_i(B^i_K(\alpha))$ we do not have independence because knowing that w appears at the end of $\mathcal{F}_1(B^1_K(\alpha))$ may influence that it appears at the beginning of $\mathcal{F}_2(B^2_K(\alpha))$.

▶ **Lemma 28.** *Let $\alpha \in \{0,1\}^\omega$ be a normal sequence, $w \in \{0,1\}^M$ be a word, and $(\mathcal{F}_i)_{i\in\mathbf{N}}$ be an iid family of random variables of law $\mathcal{F}$. For all $K \in \mathbf{N}$, we write $\beta = \mathcal{F}_0(B^0_K(\alpha))\mathcal{F}_1(B^1_K(\alpha))\mathcal{F}_2(B^2_K(\alpha))\dots$ and for all i we define $s_i = |\mathcal{F}_i(B^i_K(\alpha))|$ and $S_N = \sum_{i=0}^N s_i$. Then we have that*

$$\left[\sum_{i=0}^N \sharp_{s_i-|w|}\{w\}(\mathcal{F}_i(B^i_K(\alpha)))\right] - \sharp_{S_N}\{w\}(\beta) < MN.$$

Proof. First note that we count indices up to $s_i - |w|$ in $\sharp_{s_i-|w|}\{w\}(\mathcal{F}_i(B^i_K(\alpha)))$ because if w appears in $\mathcal{F}_i(B^i_K(\alpha))$ it must appear before the last $|w|$ bits. For this reason we also mention that $\sharp_{s_i-|w|}\{w\}(\mathcal{F}_i(B^i_K(\alpha))) = \sharp_{|w|}\{w\}(\mathcal{F}_i(B^i_K(\alpha)))$.

Then note that $\sharp_{S_N}\{w\}(\beta) \geq \left[\sum_{i=0}^N \sharp_{s_i-|w|}\{w\}(\mathcal{F}_i(B^i_K(\alpha)))\right]$ indeed if w appears somewhere in one of the $\mathcal{F}_i(B^i_K(\alpha))$ then it also appears in β.

Therefore every w is counted in $\sharp_{S_N}\{w\}(\beta)$ and not in $\left[\sum_{i=0}^N \sharp_{s_i-|w|}\{w\}(\mathcal{F}_i(B^i_K(\alpha)))\right]$ appears at an index in the $|w|$ last bits of an $F_i(B^i_K(\alpha))$. There are at most $|w| \times N = MN$ of those. ◀

We have that $\sum_{i=0}^N |\mathcal{F}_i(B^i_K(\alpha))|$ tends to NKq^{-1}, thus by taking large values of K the discrepancy MN of the number of w noticed in the previous theorem can be made negligible when compared to the size of the string.

In the next theorem we just prove that for a random ρ the proportion of w in $\mathcal{F}_i(B^i_K(\rho))$ is approximately $2^{-|w|}|\mathcal{F}_i(B^i_K(\rho))|$ on average.

▶ **Lemma 29.** *Suppose given $\rho \in \{0,1\}^\omega$ a fair random infinite sequence, $q \in [0;1[$, and $w \in \{0,1\}^M$. Let $(\mathcal{F}_i)_{i\in\mathbf{N}}$ be an iid family of random variables of law $\mathcal{F}_q$. For all i, we write $s_i = |\mathcal{F}_i(B^i_K(\rho))|$ and for all N, $S_N = \sum_{i=0}^N s_i$. Then for any $\epsilon > 0$, there exists $K \in \mathbf{N}$ such that:*

$$\left|\mathbb{E}(\sharp_{s_i-|w|}\{K\}(\mathcal{F}_i(B^i_w(\rho)))) - 2^{-|w|}Kq^{-1}\right| < \epsilon.$$

Proof. This result can be shown by standard analysis of fair random sequences of size Kq^{-1}. Indeed for a random ρ, $\mathcal{F}_i(B^i_K(\rho))$ is just a random sequence of expected size Kq^{-1}. Let $\epsilon \in \mathbf{R}$. If K is large enough, there exists some $\epsilon' \in \mathbf{R}$ such that a random sequence of size Kq^{-1} contains on average $2^{-|w|}Kq^{-1} + \epsilon'$ occurrences of w where $|\epsilon'| < \epsilon$. ◀

▶ **Lemma 30.** *Let α be a normal sequence, for any $w \in \{0,1\}^*$ and $q \in [0,1[$, $\mathcal{F}_q(\alpha)$ is w-normal with probability 1.*

Proof of Lemma 30. Let $(\mathcal{F}_i)_{i\in\mathbf{N}}$ be random independent processes $\mathcal{F}$. Let α be a normal sequence. Let $w \in \{0,1\}^*$, $\epsilon' \in \mathbf{R}$, and $q \in [0;1[$. Then

$$\mathbb{P}\left(\mathcal{F}_q(\alpha)\text{is } w\text{-normal up to } \epsilon'\right) = 1 \Leftrightarrow \mathbb{P}\left(\lim_N \frac{\sharp_N\{w\}(\mathcal{F}_q(\alpha))}{N} = 2^{-|w|} \pm \epsilon\right) = 1.$$

Using Lemma 28 by introducing independent random variables $\mathcal{F}_i$ of law $\mathcal{F}_q$, and writing $s_i = |\mathcal{F}_i(B^i_K(\alpha))|$, the above result is implied by:

$$\forall\epsilon, \exists K, \mathbb{P}\left(\sum_{i\leq N} \sharp_{s_i-|w|}\{w\}(\mathcal{F}_i(B^i_K(\alpha))) \xrightarrow{N} 2^{-|w|}KNq^{-1}(1\pm\epsilon)\right) = 1.$$

Take $V_i(\alpha)$ as defined in definition 10. Call $B_N = \{i \in [1; \frac{N}{2^K}] \mid \max(V_i(\alpha)) < N\}$. We group the indices of blocks $B^j_K(\alpha)$ into sets V_i of size 2^K and such that $|V_i| = 2^K$. We may also change $s_j - |w|$ to s_j as explained in the proof of Lemma 28. Then the above is equivalent to

$$\forall\epsilon, \exists K, \mathbb{P}\left(S_1 + S_2 \xrightarrow{N} 2^{-|w|}KNq^{-1}(1\pm\epsilon)\right) = 1,$$

where

$$S_1 = \sum_{i\in B_N}\sum_{j\in V_i(\alpha)} \sharp_{s_j}\{w\}(\mathcal{F}_j(B^j_K(\alpha))), \qquad S_2 = \sum_{j\in[N]\setminus\bigcup_{i\in B_N} V_i} \sharp_{s_j}\{w\}(\mathcal{F}_j(B^j_K(\alpha))).$$

By Lemma 11, we have that $|B_N| = \frac{N}{2^K} + g(N)$, where $g(N) = o(N)$. The equation can thus be further rewritten as:

$$\mathbb{P}\left(T_1 + T_2 + T_3 \xrightarrow{N} 2^{-|w|}KNq(1\pm\epsilon)\right) = 1,$$

where:

$$T_1 = \sum_{i\in[N/2^K]}\sum_{j\in V_i(\alpha)} \sharp_{s_j}\{w\}(\mathcal{F}_j(B^j_K(\alpha))),$$

$$T_2 = \sum_{i=1+N/2^K}^{\frac{N}{2^K}+g(N)}\sum_{j\in V_i(\alpha)} \sharp_{s_j}\{w\}(\mathcal{F}_j(B^j_K(\alpha))),$$

$$T_3 = \sum_{j\in[N]\setminus\bigcup_{i\in B_N} V_i} \sharp_{s_j}\{w\}(\mathcal{F}_j(B^j_K(\alpha))).$$

We now consider each term separately.

The term T_1. By construction of the V_i, as j ranges across all values in V_i, $B^j_K(\alpha)$ takes all values in $\{0,1\}^K$. By creating an appropriate bijection between j and (i,r), we can write

$$\sum_{i\in[\frac{N}{2^K}]}\sum_{j\in V_i(\alpha)} \sharp_{s_j}\{w\}(\mathcal{F}_j(B^j_K(\alpha))) = \sum_{i\in[\frac{N}{2^K}]}\sum_{r\in\{0,1\}^K} \sharp_{s_{i,r}}\{w\}(\mathcal{F}_{i,r}(r)).$$

We recognize a sum over expectations as in Lemma 12. By Lemma 29, we can take K big enough such that the expected value of $\sharp_{s_{i,r}}\{w\}(\mathcal{F}_{i,r}(r))$ is $Kq^{-1}2^{-|w|}(1\pm\epsilon)$. Thus:

$$\forall\epsilon, \exists K, \mathbb{P}\left(\sum_{i\in[\frac{N}{2^K}]}\sum_{j\in V_i(\alpha)} \sharp_{s_j}\{w\}(\mathcal{F}_j(B^j_K(\alpha))) \xrightarrow{N} 2^{-|w|}KNq^{-1}(1\pm\epsilon)\right) = 1.$$

The term T_2. We have that

$$\forall \epsilon, \forall K, \mathbb{P}\left(\left[\sum_{i=1+N/2^K}^{\frac{N}{2^K}+g(N)} \sum_{j \in V_i(\alpha)} \sharp_{s_j}\{w\}(\mathcal{F}_j(B_K^j(\alpha)))\right] = o(N)\right) = 1,$$

because $g(N) = o(N)$ and the random variable $\sharp_{s_j}\{w\}(\mathcal{F}_j(B_K^j(\alpha)))$ has finite expected value and variance (in particular constant in N).

The term T_3. We have that

$$\mathbb{P}\left(\sum_{j \in [N] \setminus \bigcup_{i \in B_N} V_i} \sharp_{s_j}\{w\}(\mathcal{F}_j(B_K^j(\alpha))) = o(n)\right) = 1.$$

The sum is over $o(N)$ terms by Lemma 11 and the random variable $\sharp_{s_j}\{w\}(\mathcal{F}_j(B_K^j(\alpha)))$ is of finite expected value and variance.
By combining the three results we can get that

$$\forall \epsilon' \in \mathbf{R}, \mathbb{P}(\mathcal{F}(\alpha)\text{is } w\text{-normal up to } \epsilon') = 1.$$

We define the sequence $(\epsilon_n)_{n \in \mathbf{N}} \in \mathbf{R}^{\mathbf{N}}$ as $\epsilon_n = 1/(n+1)$. We have that

$$\mathbb{P}(\forall n, \mathcal{F}(\alpha)\text{is } w\text{-normal up to } \epsilon_n) = 1$$

as an intersection of countably many events of probability 1. We then get, using the fact that all Cauchy sequences converge on $\mathbf{R}$, that $\mathbb{P}(\mathcal{F}(\alpha)\text{is } w\text{-normal}) = 1$. ◀

▶ **Lemma 31.** *Let α be a normal number then $\mathcal{F}(\alpha)$ is normal with probability 1.*

Proof. By lemma 30 $\forall w \in \{0,1\}^*$, $\mathcal{F}(\alpha)$ is w-normal with probability 1. $\mathbb{P}(\mathcal{F}(\alpha)\text{is normal}) = \mathbb{P}(\forall w \in \{0,1\}^*, \mathcal{F}(\alpha)\text{is } w\text{-normal})$, since this is an intersection of countably many event of probability 1, we have that $\mathcal{F}(\alpha)$ is normal with probability 1. ◀

▶ **Lemma 32.** *For any positive integer D, any $k \in [2^{D-1}; 2^D]$*

$$\mathbb{P}_\rho(I_k^D(\alpha, \rho)\textit{is normal}) = 1.$$

Proof. Let D be a positive integer, $k \in [2^{D-1}; 2^D]$. There are 3 kinds of bits in $I_k^D(\alpha, \rho)$: bits from α, bits from ρ appearing inside the gadgets (we call this sequence γ) and bits from ρ corresponding to return bits (we call this infinite sequence of bits τ). Note that γ and τ are both independent fair random infinite sequences.

Note that in $I_k^D(\alpha, \rho)$, we find every bit from α and τ at indices multiple of $D+1$. We define the infinite sequence y as such: $\forall i \in \mathbf{N}, y_i = I_k^D(\alpha, \rho)_{i(D+1)}$.

Notice that $I_k^D(\alpha, \rho) = I^D(y, \gamma)$ (where the second I is from defintion 14). Since γ is a fair infinite random sequence then by using theorem 16 if y is normal then so is $I_k^D(\alpha, \rho)$ with probability 1 over γ.

Thus now we only need to show that y is normal with probability 1. Notice that the distribution of y is the same as $\mathcal{F}_q(\alpha)$ with $q = 1 - \frac{k}{2^D}$. Therefore by theorem 31 y is normal with probability 1. ◀

This gives the main theorem. The proof follows the proof of Theorem 17, using Lemma 32 and and Lemma 23.

▶ **Theorem 33.** *Let $\alpha \in \{0,1\}^\omega$ be a sequence. Then α is normal if and only if for all rational selector $\mathcal{S}$ the probability that $\mathcal{S}(\alpha)$ is either finite or normal is equal to 1.*

While we think the equivalent statement to hold for general probabilistic selectors, we believe that establishing such a result would require a different proof method.

Unweighted Geometric Hitting Set for Line-Constrained Disks and Related Problems

Abstract

Given a set P of n points and a set S of m disks in the plane, the disk hitting set problem asks for a smallest subset of P such that every disk of S contains at least one point in the subset. The problem is NP-hard. This paper considers a line-constrained version in which all disks have their centers on a line. We present an $O(m\log^2 n+(n+m)\log(n+m))$ time algorithm for the problem. This improves the previous result of $O(m^2\log m+(n+m)\log(n+m))$ time for the weighted case of the problem where every point of P has a weight and the objective is to minimize the total weight of the hitting set. Our algorithm also solves a more general line-separable problem with a single intersection property: The points of P and the disk centers are separated by a line ℓ and the boundary of every two disks intersect at most once on the side of ℓ containing P.

1 Introduction

Let P be a set of n points and S a set of m disks in the plane. The *hitting set* problem is to compute a smallest subset of P such that every disk in S contains at least one point in the subset (i.e., every disk is *hit* by a point in the subset, and the subset is called a *hitting set*). The problem is NP-hard, even if all disks have the same radius [18, 25]. Polynomial-time approximation algorithms are known for the problem, e.g., [3, 15, 16, 21, 24, 25].

In this paper, we consider the *line-constrained* version of the problem, where centers of all disks are on a line while the points of P can be anywhere in the plane. The weighted case of the problem was studied by Liu and Wang [22], where each point of P has a weight and the objective is to minimize the total weight of the hitting set. Their algorithm runs in $O((m+n)\log(m+n)+\kappa\log m)$ time, where κ is the number of pairs of disks that intersect and $\kappa=O(m^2)$ in the worst case. They reduced the runtime to $O((m+n)\log(m+n))$ for the *unit-disk case*, where all disks have the same radius [22]. Our problem in this paper is for the unweighted case. To the best of our knowledge, we are not aware of any previous work that particularly studied the unweighted hitting set problem for line-constrained disks. We propose an algorithm of $O(m\log^2 n+(n+m)\log(n+m))$ time, which improves the weighted case algorithm of $O(m^2\log m+(n+m)\log(n+m))$ worst-case time [22]. Perhaps theoretically more interesting is that the worst-case runtime of our algorithm is near linear.

1.1 Related work

A closely related problem is the disk coverage problem, which is to compute a smallest subset of S that together cover all the points of P. This problem is also NP-hard because it is dual to the hitting set problem in the unit-disk case (i.e., all disks have the same radius). Polynomial-time algorithms are known for certain special cases, e.g., [1,4,9,10]. In particular, the line-constrained problem (in which all disks are centered on a line) was studied by Pedersen and Wang [26]. Their algorithm runs in $O((m+n)\log(m+n)+\kappa\log m)$ time, where κ is the number of pairs of disks that intersect and $\kappa=O(m^2)$ in the worst case; they also solved the unit-disk case in $O((m+n)\log(m+n))$ time. As noted above, in the unit-disk case, the coverage and hitting set problems are dual to each other and therefore the two problems can essentially be solved by the same algorithm. However, this is not the case if the radii of the disks are different.[1]

In addition, the $O((m+n)\log(m+n)+\kappa\log m)$ time algorithm of Pedersen and Wang [26] also works for the weighted *line-separable unit-disk* version, where all disks have the same radius and the disk centers are separated from the points of P by a line.

All the above results are for the weighted case. The unweighted disk coverage case was also particularly studied before. Liu and Wang [23][2] considered the line-constrained problem and gave an $O(m\log n\log m+(n+m)\log(n+m))$ time algorithm. For the line-separable unit-disk case, Ambühl et al. [1] derived an algorithm of $O(m^2n)$ time, which was used as a subroutine in their algorithm for the general coverage problem in the plane (without any constraints). An improved $O(nm+n\log n)$ time algorithm is presented in [8]. Liu and Wang's approach [23] solves this case in $O((n+m)\log(n+m))$ time.

If disks of S are half-planes, the problem becomes the half-plane coverage problem. For the weighted case, Chan and Grant [4] proposed an algorithm for the *lower-only case* where all half-planes are lower ones; their algorithm runs in $O(n^4)$ time when $m=n$. With the observation that a half-plane may be considered as a unit disk of infinite radius, the lower-only half-plane coverage problem is essentially a special case of the line-separable unit-disk coverage problem [26]. Consequently, applying the algorithm of [26] can solve the weighted lower-only case in $O(n^2\log n)$ time (when $m=n$) and applying the algorithm of [23] can solve the unweighted lower-only case in $O(n\log n)$ time. Wang and Xue [28] derived another $O(n\log n)$ time algorithm for the unweighted lower-only case with a different approach and also proved an $\Omega(n\log n)$ lower bound under the algebraic decision tree model by a reduction from the set equality problem [2] (note that this leads to the same lower bound for the line-separable unit-disk coverage problem). For the general case where both upper and lower half-planes are present, Har-Peled and Lee [17] solved the weighted problem in $O(n^5)$ time. Pedersen and Wang [26] showed that the problem can be reduced to $O(n^2)$ instances of the lower-only case problem. Consequently, applying the algorithms of [26] and [23] can solve the weighted and unweighted cases in $O(n^4\log n)$ and $O(n^3\log n)$ time, respectively. Wang and Xue [28] gave a more efficient algorithm of $O(n^{4/3}\log^{5/3}n\log^{O(1)}\log n)$ time for the unweighted case.

[1] Note that [12] provides a method to reduce certain coverage problems to instances of the hitting set problem; however, the reduction algorithm, which takes more than $O(n^5)$ time, is not efficient.

[2] See the arXiv version of [23], which improves the result in the original conference paper. The algorithms follow the same idea, but the arXiv version provides more efficient implementations.

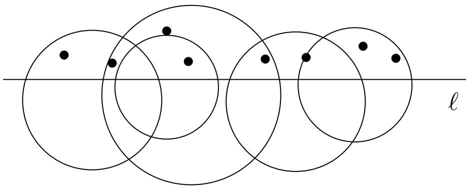

Figure 1 Illustrating the line-separable single-intersection case: Centers of all disks are below ℓ.

1.2 Our result

Instead of solving the line-constrained problem directly, we tackle a more general problem in which the points of P and the centers of the disks of S are separated by a line ℓ such that the boundaries of every two disks intersect at most once on the side of ℓ containing P (see Fig. 1). We refer to it as the *line-separable single-intersection* hitting set problem (we will explain it later why this problem is more general than the line-constrained problem). We present an algorithm of $O(m \log^2 n + (n+m)\log(n+m))$ time for the problem. To this end, we find that some points in P are "useless" and thus can be pruned from P. More importantly, the remaining points have certain properties so that the problem can be reduced to the 1D hitting set problem, which can then be easily solved. The algorithm itself is relatively simple and quite elegant. However, one challenge is to show its correctness, and specifically, to prove why the "useless" points are indeed useless. The proof is lengthy and fairly technical, which is one of our main contributions.

The line-constrained problem. To solve the line-constrained problem, where all disks of S are centered on a line ℓ, the problem can be reduced to the line-separable single-intersection case. Indeed, without loss of generality, we assume that ℓ is the x-axis. For each point p of P below ℓ, we replace p by its symmetric point with respect to ℓ. As such, we obtain a set of points that are all above ℓ. Since all disks are centered on ℓ, it is not difficult to see that an optimal solution using this new set of points corresponds to an optimal solution using P. Furthermore, since disks are centered on ℓ, although their radii may not be equal, the boundaries of any two disks intersect at most once above ℓ. Therefore, the problem becomes an instance of the line-separable single-intersection case. As such, applying the algorithm for line-separable single-intersection problem solves the line-constrained problem in $O(m \log^2 n + (n+m)\log(n+m))$ time. Therefore, in the rest of the paper, we will focus on solving the line-separable single-intersection problem.

The unit-disk case. As mentioned earlier, the unit-disk case problem where all disks have the same radius can be reduced to the coverage problem (and vice versa). More specifically, if we consider the set of unit disks centered at the points of P as a set of "dual disks" and consider the centers of the disks of S a set of "dual points", then the hitting set problem is equivalent to finding a smallest subset of dual disks whose union covers all dual points. Consequently, applying the line-separable unit-disk coverage algorithm in [23] solves the hitting set problem in $O((n+m)\log(n+m))$ time. Nevertheless, we show that our technique can directly solve the hitting set problem in this case in the same time complexity.

The half-plane hitting set problem. As in the coverage problem discussed above, if disks of S are half-planes, the problem becomes the half-plane hitting set problem. For the weighted case, the approach of Chan and Grant [4] solves the lower-only case in $O(n^4)$ time when

$m = n$. Again, with the observation that a half-plane may be viewed as a unit disk of infinite radius, the lower-only half-plane hitting set problem is a special case of the line-separable unit-disk hitting set problem. As such, applying the algorithm of [22] can solve the weighted lower-only case in $O(n^2 \log n)$ time (when $m = n$) and applying the unit-disk case algorithm discussed above can solve the unweighted lower-only case in $O(n \log n)$ time. For the general case where both upper and lower half-planes are present, Har-Peled and Lee [17] solved the weighted problem in $O(n^6)$ time. Liu and Wang [22] showed that the problem (for both the weighted and unweighted cases) can be reduced to $O(n^2)$ instances of the lower-only case problem. Consequently, applying the above algorithms for the weighted and unweighted lower-only case problems can solve the weighted and unweighted general case problems in $O(n^4 \log n)$ and $O(n^3 \log n)$ time, respectively.

Lower bound. As discussed above, the $\Omega(n \log n)$ lower bound in [28] for the lower-only half-plane coverage problem leads to the $\Omega(n \log n)$ lower bound for the line-separable unit-disk coverage problem when $m = n$. As the unit-disk hitting set problem is dual to the unit-disk coverage problem, it also has $\Omega(n \log n)$ as a lower bound. Since the unit-disk hitting set problem is a special case of the line-separable single-intersection hitting set problem, $\Omega(n \log n)$ is also a lower bound of the latter problem. Similarly, since the lower-only half-plane hitting set is dual to the lower-only half-plane coverage, $\Omega(n \log n)$ is also a lower bound of the former problem.

An algorithm in the algebraic decision tree model. In the algebraic decision tree model, where the time complexity is measured only by the number of comparisons, our method, combining with a technique recently developed by Chan and Zheng [6], shows that the line-separable single-intersection problem (and thus the line-constrained problem) can be solved using $O((n+m)\log(n+m))$ comparisons, matching the above lower bound. To ensure clarity in the following discussion, unless otherwise stated, all time complexities are based on the standard real RAM model.

Outline. The rest of the paper is organized as follows. After introducing the notation in Section 2, we describe our algorithm in Section 3. The algorithm correctness is proved in Section 4. We show how to implement the algorithm efficiently in Section 5. The algebraic decision tree algorithm and the unit-disk case algorithm are also discussed in Section 5.

2 Preliminaries

This section introduces some notation and concepts that will be used throughout the paper.

As discussed above, we focus on the line-separable single-intersection case. Let P be a set of n points and S a set of m disks in the plane such that the points of P and the centers of the disks of S are separated by a line ℓ and the boundaries of every two disks intersect at most once on the side of ℓ which contains P. Note that the points of P and the disk centers may be on ℓ. Without loss of generality, we assume that ℓ is the x-axis and the points of P are above (or on) ℓ while the disk centers are below (or on) ℓ (see Fig. 1). As such, the boundaries of every two disks intersect at most once above ℓ. Our goal is to compute a smallest subset of P such that each disk of S is hit by at least one point in the subset.

Under this setting, for each disk $s \in S$, only its portion above ℓ matters for our problem. Hence, unless otherwise stated, a disk s refers only to its portion above (and on) ℓ. As such, the boundary of s consists of an *upper arc*, i.e., the boundary arc of the original disk above ℓ, and a *lower segment*, i.e., the intersection of s with ℓ. Note that s has a single leftmost (resp., rightmost) point, which is the left (resp., right) endpoint of the lower segment of s.

If P' is a subset of P that form a hitting set for S, we call P' a *feasible solution*. If P' is a feasible solution of minimum size, then P' is an *optimal solution*.

We assume that each disk of S is hit by at least one point of P since otherwise there would be no feasible solution. Our algorithm is able to check whether the assumption is met.

We make a general position assumption that no two points of A have the same x-coordinate, where A is the union of P and the set of the leftmost and rightmost points of the upper arcs of all disks. Degenerate cases can be handled by standard perturbation techniques, e.g., [14].

For any point p in the plane, we denote its x-coordinate by $x(p)$. We sort all points in P in ascending order of their x-coordinates, resulting in a sorted list $\{p_1, p_2, \cdots, p_n\}$. We use $P[i, j]$ to denote the subset $\{p_i, p_{i+1}, \cdots, p_j\}$, for any $1 \leq i \leq j \leq n$. We sort all disks in ascending order of the x-coordinates of the leftmost points of their upper arcs; let $\{s_1, s_2, \cdots, s_m\}$ be the sorted list. We use $S[i, j]$ to denote the subset $\{s_i, s_{i+1}, \cdots, s_j\}$, for $1 \leq i \leq j \leq m$. For convenience, let $P[i, j] = \emptyset$ and $S[i, j] = \emptyset$ if $i > j$. For each disk s_i, let l_i and r_i denote the leftmost and rightmost points of its upper arc, respectively.

For any disk $s \in S$, we use $S_l(s)$ (resp., $S_r(s)$) to denote the subset of disks S whose leftmost points are to the left (resp., right) of that of s, that is, if the index of s is i, then $S_l(s) = S[1, i-1]$ and $S_r(s) = S[i+1, m]$. For any disk $s' \in S_l(s)$, we also say that s' is *to the left* of s; similarly, if $s' \in S_r(s)$, then s' is *to the right* of s. For convenience, if s' is to the left of s, we use $s' \prec s$ to denote it.

For a point $p_i \in P$ and a disk $s_k \in S$, we say that p_i is *vertically above* s_k (or s_k is *vertically below* p_i) if p_i is outside s_k and $x(l_k) < x(p_i) < x(r_k)$.

The non-containment property. If a disk s_i contains another disk s_j completely, then s_i is redundant for our problem since any point hitting s_j also hits s_i. It is easy to find those redundant disks in $O(m \log m)$ time (indeed, this is a 1D problem since s_i contains s_j if and only if the lower segment of s_i contains that of s_j). Therefore, to solve our problem, we first remove such redundant disks from S and then work on the remaining disks. For simplicity, from now on we assume that no disk of S contains another. Therefore, S has the following *non-containment* property, which is critical to our algorithm.

▶ **Observation 1.** (Non-Containment Property) *For any two disks $s_i, s_j \in S$, $x(l_i) < x(l_j)$ if and only if $x(r_i) < x(r_j)$.*

3 The algorithm description

In this section, we describe our algorithm. We follow the notation defined in Section 2.

We begin with the following definition, which is critical for our algorithm.

▶ **Definition 2.** *For each disk $s_i \in S$, among all the points of P covered by s_i, define $a(i)$ as the smallest index of these points and $b(i)$ the largest index of them.*

Since each disk s_i contains at least one point of P, both $a(i)$ and $b(i)$ are well defined.

▶ **Definition 3.** *For any point $p_k \in P$, we say that p_k is* prunable *if there is a disk $s_i \in S$ such that $p_k \notin s_i$ and $a(i) < k < b(i)$.*

We now describe our algorithm. Although the description seems simple, establishing its correctness is by no means an easy task. We devote Section 4 to the correctness proof. The implementation of the algorithm, which is also not straightforward, is presented in Section 5.

Algorithm description. The algorithm has three main steps.

1. Compute $a(i)$ and $b(i)$ for all disks $s_i \in S$. We will show in Section 5 that this can be done in $O(m \log^2 n + (n+m)\log(n+m))$ time.
2. Find all prunable points; let Q be the set of all prunable points. We will show in Section 5 that Q can be computed in $O((n+m)\log(n+m))$ time.
   Let $P^* = P \setminus Q$. We will prove in Section 4 that P^* contains an optimal solution to the hitting problem on P and S. This means that it suffices to work on P^* and S.
3. Reduce the hitting set problem on P^* and S to a 1D hitting set problem, as follows. For each point of P^*, we project it perpendicularly onto ℓ. Let $\tilde{P}$ be the set of all projected points. For each disk $s_i \in S$, we create a segment on ℓ whose left endpoint has x-coordinate equal to $x(p_{a(i)})$ and whose right endpoint has x-coordinate equal to $x(p_{b(i)})$. Let $\tilde{S}$ be the set of all segments thus created.
   We solve the following 1D hitting set problem: Find a smallest subset of points of $\tilde{P}$ such that every segment of $\tilde{S}$ is hit by a point of the subset. This 1D problem can be easily solved in $O((|\tilde{S}|+|\tilde{P}|)\log(|\tilde{S}|+|\tilde{P}|))$ time [22],[3] which is $O((m+n)\log(m+n))$ since $|\tilde{P}| \leq n$ and $|\tilde{S}| = m$.
   Suppose that $\tilde{P}_{\text{opt}}$ is any optimal solution for the 1D problem. We create a subset P^*_{opt} of P^* as follows. For each point of $\tilde{P}_{\text{opt}}$, suppose that it is the projection of a point $p_i \in P^*$; then we add p_i to P^*_{opt}. We will prove in Section 4 that P^*_{opt} is an optimal solution to the hitting set problem on P^* and S.

   We summarize the result in the following theorem.

▶ **Theorem 4.** *Given a set P of n points and a set S of m disks in the plane such that the disk centers are separated from the points of P by a line and the single-intersection condition is satisfied, the hitting set problem is solvable in $O(m\log^2 n + (n+m)\log(n+m))$ time.*

4 Algorithm correctness

In this section, we prove the correctness of our algorithm. More specifically, we will argue the correctness of the second and the third main steps of the algorithm. We start with the third main step, as it is relatively straightforward. In fact, arguing the correctness of the second main step is quite challenging and is a main contribution of our paper.

Correctness of the third main step. For each disk $s_i \in S$, let s'_i refer to the segment of $\tilde{S}$ created from s_i. For each point $p_j \in P$, let p'_j refer to the point of $\tilde{P}$ which is the projection of p_j. Lemma 5 justifies the correctness of the third main step of the algorithm.

▶ **Lemma 5.** *A point $p_j \in P^*$ hits a disk $s_i \in S$ if and only if p'_j hits s'_i.*

Proof. Suppose p_j hits s_i. Then, $p_j \in s_i$. By definition, we have $a(i) \leq j \leq b(i)$. Hence, $x(p_{a(i)}) \leq x(p_j) \leq x(p_{b(i)})$, and thus p'_j hits s'_i by the definitions of p'_j and s'_i.

On the other hand, suppose that p'_j hits s'_i. Then, according to the definitions of p'_j and s'_i, $x(p_{a(i)}) \leq x(p_j) \leq x(p_{b(i)})$ holds. If $j = a(i)$ or $j = b(i)$, then p_j must hit s_i following the definitions of $a(i)$ and $b(i)$. Otherwise, we have $a(i) < j < b(i)$. Observe that p_j must be inside s_i since otherwise p_j would be a prunable point and therefore could not be in P^*. As such, p_j must hit s_i. ◀

[3] The algorithm in [22], which uses dynamic programming, is for the weighted case where each point has a weight. Our problem is simpler because it is the unweighted case. We can use a simple greedy algorithm to solve it.

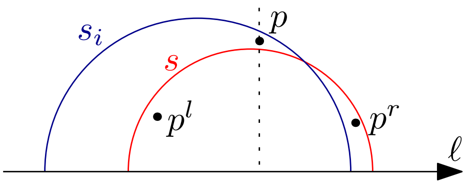

Figure 2 Illustrating the proof of Observation 6.

4.1 Correctness of the second main step

In what follows, we focus on the correctness of the second main step.

For any disk s, let $P(s)$ denote the subset of points of P inside s. For any point p, let $S(p)$ denote the subset of disks of S hit by p. For any subset $P' \subseteq P$, by slightly abusing notation, let $S(P')$ denote the subset of disks of S hit by at least one point of P', i.e., $S(P') = \bigcup_{p \in P'} S(p)$.

The following observation follows directly from the definition of prunable points.

▶ **Observation 6.** *Suppose a point p is a prunable point in P. Then, there is a disk $s \in S$ vertically below p such that the following are true.*

1. *$P(s)$ has both a point left of p and a point right of p.*
2. *For any two points $p^l, p^r \in P(s)$ with one left of p and the other right of p, we have $S(p) \subseteq S(p^l) \cup S(p^r)$.*

Proof. The first statement directly follows the definition of prunable points. For the second statement, without loss of generality, assume that p^l is left of p while p^r is right of p (see Fig. 2). Consider any disk $s_i \in S(p)$. By definition, $p \in s_i$. As $p \notin s$, $s_i \neq s$. Hence, s_i is either in $S_l(s)$ or in $S_r(s)$. If $s_i \in S_l(s)$, then due to the non-containment property, s_i must contain the area of s to the left of p and therefore must contain p^l, which implies $s_i \in S(p^l)$. Similarly, if $s_i \in S_r(s)$, then s_i must be in $S(p^r)$. ◀

The following lemma establishes the correctness of the second main step of the algorithm.

▶ **Lemma 7.** *P^* contains an optimal solution for the hitting set problem on S and P.*

Proof. Let P_{opt} be an optimal solution for S and P. Let Q be the set of all prunable points. Recall that $P^* = P \setminus Q$. If $P_{\text{opt}} \cap Q = \emptyset$, then $P_{\text{opt}} \subseteq P^*$ and thus the lemma is vacuously true. In what follows, we assume that $|P_{\text{opt}} \cap Q| \geq 1$.

Pick an arbitrary point from $P_{\text{opt}} \cap Q$, denoted by $\hat{p}_1$. Below, we give a process that can find a point p^* from P^* to replace $\hat{p}_1$ in P_{opt} such that the new set $P^1_{\text{opt}} = \{p^*\} \cup P_{\text{opt}} \setminus \{\hat{p}_1\}$ is a feasible solution, implying that P^1_{opt} is still an optimal solution since $|P^1_{\text{opt}}| = |P_{\text{opt}}|$. As $p^* \in P^*$, we have $|P^1_{\text{opt}} \cap Q| = |P_{\text{opt}} \cap Q| - 1$. Therefore, if $P^1_{\text{opt}} \cap Q$ is still nonempty, then we can repeat the process for other points in $P^1_{\text{opt}} \cap Q$ until we obtain an optimal solution P^*_{opt} with $P^*_{\text{opt}} \cap Q = \emptyset$, which will prove the lemma. The process involves induction. To help the reader understand it better, we first provide the details for the first two iterations of the process (we will introduce some notation that appears unnecessary for the first two iterations, but these will be needed for explaining the inductive hypothesis later).

The first iteration. Let $P'_{\text{opt}} = P_{\text{opt}} \setminus \{\hat{p}_1\}$. Since $\hat{p}_1 \in Q$, by Observation 6, S has a disk $\hat{s}_1$ vertically below $\hat{p}_1$ such that $P(\hat{s}_1)$ contains both a point left of $\hat{p}_1$, denoted by $\hat{p}^l_1$, and a point right of $\hat{p}_1$, denoted by $\hat{p}^r_1$. Furthermore, $S(\hat{p}_1) \subseteq S(\hat{p}^l_1) \cup S(\hat{p}^r_1)$. Since $\hat{p}_1 \notin \hat{s}_1$ and $P_{\text{opt}} = P'_{\text{opt}} \cup \{\hat{p}_1\}$ forms a hitting set of P, P'_{opt} must have a point p that hits $\hat{s}_1$. Clearly, p

is left or right of $\hat{p}_1$. Without loss of generality, we assume that p is right of $\hat{p}_1$. Since $\hat{p}_1^r$ refers to an arbitrary point to the right of $\hat{p}_1$ that hits $\hat{s}_1$ and p is also a point to right of $\hat{p}_1$ that hits $\hat{s}_1$, for notational convenience, we let $\hat{p}_1^r$ refer to p. As such, $\hat{p}_1^r$ is in P'_{opt}.

Consider the point $\hat{p}_1^l$. Since $S(\hat{p}_1) \subseteq S(\hat{p}_1^l) \cup S(\hat{p}_1^r)$ and $\hat{p}_1^r$ is in P'_{opt}, it is not difficult to see that $S(P_{\text{opt}}) \subseteq S(P'_{\text{opt}}) \cup S(\hat{p}_1^l)$ and thus $P'_{\text{opt}} \cup \{\hat{p}_1^l\}$ is a feasible solution. As such, if $\hat{p}_1^l \notin Q$, then we can use $\hat{p}_1^l$ as our target point p^* and our process (to find p^*) is performed. In what follows, we assume $\hat{p}_1^l \in Q$.

We let $\hat{p}_2 = \hat{p}_1^l$. Define $A_1 = \{\hat{p}_1^r\}$. According to the above discussion, $A_1 \subseteq P'_{\text{opt}}$, $S(\hat{p}_1) \subseteq S(A_1) \cup S(\hat{p}_2)$, $P'_{\text{opt}} \cup \{\hat{p}_2\}$ is a feasible solution, $\hat{p}_1$ is vertically above $\hat{s}_1$, and $\hat{p}_2 \in \hat{s}_1$.

The second iteration. We are now entering the second iteration of our process. First, notice that $\hat{p}_2$ cannot be $\hat{p}_1$ since $\hat{p}_2 = \hat{p}_1^l$, which cannot be $\hat{p}_1$. Our goal in this iteration is to find a *candidate point* p' to replace $\hat{p}_2$ so that $P'_{\text{opt}} \cup \{p'\}$ also forms a hitting set of S. Consequently, if $p' \notin Q$, then we can use p' as our target p^*; otherwise, we need to guarantee $p' \neq \hat{p}_1$ so that our process will not enter a loop. The discussion here is more involved than in the first iteration.

Since $\hat{p}_2 \in Q$, by Observation 6, S has a disk $\hat{s}_2$ vertically below $\hat{p}_2$ such that $P(\hat{s}_2)$ contains both a point left of $\hat{p}_2$, denoted by $\hat{p}_2^l$, and a point right of $\hat{p}_2$, denoted by $\hat{p}_2^r$. Further, $S(\hat{p}_2) \subseteq S(\hat{p}_2^l) \cup S(\hat{p}_2^r)$. Depending on whether $\hat{s}_2$ is in $S(A_1)$, there are two cases.

- If $\hat{s}_2 \notin S(A_1)$, since $\hat{p}_2$ does not hit $\hat{s}_2$ and $S(\hat{p}_1) \subseteq S(A_1) \cup S(\hat{p}_2)$, we obtain $\hat{s}_2 \notin S(\hat{p}_1)$. Now we can basically repeat our argument from the first iteration. Since $\hat{p}_2$ does not hit $\hat{s}_2$ and $P'_{\text{opt}} \cup \{\hat{p}_2\}$ is a feasible solution, P'_{opt} must have a point p that hits $\hat{s}_2$. Clearly, p is either left or right of $\hat{p}_2$.
  We first assume that p is right of $\hat{p}_2$. Since $\hat{p}_2^r$ refers to an arbitrary point to the right of $\hat{p}_2$ that hits $\hat{s}_2$ and p is also a point to right of $\hat{p}_2$ that hits $\hat{s}_2$, for notational convenience, we let $\hat{p}_2^r$ refer to p. As such, $\hat{p}_2^r$ is in P'_{opt}.
  We let $\hat{p}_2^l$ be our candidate point, which satisfies our need as discussed above for p'. Indeed, since $P'_{\text{opt}} \cup \{\hat{p}_2\}$ is an optimal solution, $S(\hat{p}_2) \subseteq S(\hat{p}_2^l) \cup S(\hat{p}_2^r)$, and $\hat{p}_2^r \in P'_{\text{opt}}$, we obtain that $P'_{\text{opt}} \cup \{\hat{p}_2^l\}$ also forms a hitting set of S. Furthermore, since $\hat{p}_2^l$ hits $\hat{s}_2$ while $\hat{p}_1$ does not, we know that $\hat{p}_2^l \neq \hat{p}_1$. Therefore, if $\hat{p}_2^l \notin Q$, then we can use $\hat{p}_2^l$ as our target p^* and we are done with the process. Otherwise, we let $\hat{p}_3 = \hat{p}_2^l$ and then enter the third iteration. In this case, we let $A_2 = A_1 \cup \{\hat{p}_2^r\}$. According to our above discussion, $A_2 \subseteq P'_{\text{opt}}$, $S(\hat{p}_2) \subseteq S(A_2) \cup S(\hat{p}_3)$, $\{\hat{p}_3\} \cup P'_{\text{opt}}$ is a feasible solution, $\hat{p}_2$ is vertically above $\hat{s}_2$, and $\hat{p}_3 \in \hat{s}_2$.
  The above discussed the case where p is right of $\hat{p}_2$. If p is left of $\hat{p}_2$, then the analysis is symmetric.[4]
- If $\hat{s}_2 \in S(A_1)$, we let $\hat{p}_2^l$ be our candidate point. We show below that it satisfies our need as discussed above for p', i.e., $\{\hat{p}_2^l\} \cup P'_{\text{opt}}$ forms a hitting set of S and $\hat{p}_2^l \neq \hat{p}_1$.
  Indeed, since $A_1 = \{\hat{p}_1^r\}$ and $\hat{s}_2 \in S(A_1)$, $\hat{s}_2$ is hit by $\hat{p}_1^r$. Since $\hat{p}_1^r$ is to the right of $\hat{p}_1$, and $\hat{p}_2$, which is $\hat{p}_1^l$, is to the left of $\hat{p}_1$, we obtain that $\hat{p}_1^r$ is to the right of $\hat{p}_2$. Since $\hat{p}_2^l$ hits $\hat{s}_2$, $\hat{p}_2^l$ is to the left of $\hat{p}_2$, $\hat{p}_1^r$ hits $\hat{s}_2$, and $\hat{p}_1^r$ is to the right of $\hat{p}_2$, by Observation 6, $S(\hat{p}_2) \subseteq S(\hat{p}_2^l) \cup S(\hat{p}_1^r)$, i.e., $S(\hat{p}_2) \subseteq S(\hat{p}_2^l) \cup S(A_1)$. Since $P'_{\text{opt}} \cup \{\hat{p}_2\}$ is a feasible solution and $A_1 \subseteq P'_{\text{opt}}$, it follows that $\{\hat{p}_2^l\} \cup P'_{\text{opt}}$ is also a feasible solution. On the other hand, since $\hat{p}_2^l$ is to the left of $\hat{p}_2$ while $\hat{p}_2$ (which is $\hat{p}_1^l$) is to the left of $\hat{p}_1$, we know that $\hat{p}_2^l$ is to the left of $\hat{p}_1$ and thus $\hat{p}_2^l \neq \hat{p}_1$.

[4] More specifically, if $\hat{p}_2^r \notin Q$, then we can use $\hat{p}_2^r$ as our target p^* and the process is complete. Otherwise, we let $\hat{p}_3 = \hat{p}_2^r$ and enter the third iteration; in this case, we let $A_2 = A_1 \cup \{\hat{p}_2^l\}$.

As such, if $\hat{p}_2^l \notin Q$, we can use $\hat{p}_2^l$ as our target p^* and we are done with the process. Otherwise, we let $\hat{p}_3 = \hat{p}_2^l$ and continue with the third iteration. In this case, we let $A_2 = A_1$. According to our above discussion, $A_2 \subseteq P'_{\text{opt}}$, $S(\hat{p}_2) \subseteq S(A_2) \cup S(\hat{p}_3)$, $P'_{\text{opt}} \cup \{\hat{p}_3\}$ is a feasible solution, $\hat{p}_2$ is vertically above $\hat{s}_2$, and $\hat{p}_3 \in \hat{s}_2$.

This finishes the second iteration of the process.

Inductive step. In general, suppose that we are entering the i-th iteration of the process with the point $\hat{p}_i \in Q$, $i \geq 2$. We make the following inductive hypothesis for i.

1. We have points $\hat{p}_k \in Q$ for all $k = 1, 2, \ldots, i-1$ in the previous $i-1$ iterations such that $\hat{p}_i \neq \hat{p}_k$ for any $1 \leq k \leq i-1$
2. We have subsets A_k for all $k = 1, 2, \ldots, i-1$ such that $A_1 \subseteq A_2 \subseteq \cdots \subseteq A_{i-1} \subseteq P'_{\text{opt}}$, and $S(\hat{p}_k) \subseteq S(A_k) \cup S(\hat{p}_{k+1})$ holds for each $1 \leq k \leq i-1$.
3. For any $1 \leq k \leq i$, $\{\hat{p}_k\} \cup P'_{\text{opt}}$ is a feasible solution.
4. We have disks $\hat{s}_k \in S$ for $k = 1, 2, \ldots, i-1$ such that $\hat{s}_k$ is vertically below $\hat{p}_k$ and $\hat{p}_{k+1} \in \hat{s}_k$.

Our previous discussion already established the hypothesis for $i = 2$ and $i = 3$. Next, we proceed with the i-th iteration argument for any general $i \geq 4$. Our goal is to find a candidate point $\hat{p}_{i+1}$ such that $P'_{\text{opt}} \cup \{\hat{p}_{i+1}\}$ is a feasible solution and the inductive hypothesis still holds for $i+1$.

Since $\hat{p}_i \in Q$, by Observation 6, there is a disk $\hat{s}_i$ vertically below $\hat{p}_i$ such that $P(\hat{s}_i)$ has a point left of $\hat{p}_i$, denoted by $\hat{p}_i^l$, and a point right of $\hat{p}_i$, denoted by $\hat{p}_i^r$. Furthermore, $S(\hat{p}_i) \subseteq S(\hat{p}_i^l) \cup S(\hat{p}_i^r)$. Depending on whether $\hat{s}_i$ is in $S(A_{i-1})$, there are two cases.

1. If $\hat{s}_i \notin S(A_{i-1})$, then since $\hat{s}_i$ does not contain $\hat{p}_i$ and $P'_{\text{opt}} \cup \{\hat{p}_i\}$ is a feasible solution, P'_{opt} must have a point p that hits $\hat{s}_i$. Clearly, p is to the left or right of $\hat{p}_i$. Without loss of generality, we assume that p is to the right of $\hat{p}_i$. Since $\hat{p}_i^r$ refers to an arbitrary point to the right of $\hat{p}_i$ that hits $\hat{s}_i$ and p is also a point to the right of $\hat{p}_i$ that hits $\hat{p}_i$, for notational convenience, we let $\hat{p}_i^r$ refer to p. As such, $\hat{p}_i^r$ is in P'_{opt}.
   We let $\hat{p}_{i+1}$ be $\hat{p}_i^l$ and define $A_i = A_{i-1} \cup \{\hat{p}_i^r\}$. In the following, we argue that the inductive hypothesis holds.
   - First of all, by definition, $\hat{p}_i$ is vertically above $\hat{s}_i$ and $\hat{p}_{i+1} \in \hat{s}_i$. Hence, the fourth statement of the hypothesis holds.
   - Since $\{\hat{p}_i\} \cup P'_{\text{opt}}$ is a feasible solution, $S(\hat{p}_i) \subseteq S(\hat{p}_i^l) \cup S(\hat{p}_i^r)$, $\hat{p}_i^r \in P'_{\text{opt}}$, and $\hat{p}_{i+1} = \hat{p}_i^l$, we obtain that $\{\hat{p}_{i+1}\} \cup P'_{\text{opt}}$ is a feasible solution. This proves the third statement of the hypothesis.
   - Since $A_i = A_{i-1} \cup \{\hat{p}_i^r\}$, $A_{i-1} \subseteq P'_{\text{opt}}$ by inductive hypothesis, and $\hat{p}_i^r \in P'_{\text{opt}}$, we obtain $A_i \subseteq P'_{\text{opt}}$. Furthermore, since $S(\hat{p}_i) \subseteq S(\hat{p}_i^l) \cup S(\hat{p}_i^r)$, $\hat{p}_i^r \in A_i$, and $\hat{p}_{i+1} = \hat{p}_i^l$, we have $S(\hat{p}_i) \subseteq S(A_i) \cup S(\hat{p}_{i+1})$. This proves the second statement of the hypothesis.
   - For any point $\hat{p}_k$ with $1 \leq k \leq i-1$, to prove the first statement of the hypothesis, we need to show that $\hat{p}_k \neq \hat{p}_{i+1}$. To this end, since $\hat{s}_i$ is hit by $\hat{p}_{i+1}$, it suffices to show that $\hat{s}_i$ is not hit by $\hat{p}_k$. Indeed, by the inductive hypothesis, $S(\hat{p}_k) \subseteq S(A_k) \cup S(\hat{p}_{k+1})$ and $S(\hat{p}_{k+1}) \subseteq S(A_{k+1}) \cup S(\hat{p}_{k+2})$. Hence, $S(\hat{p}_k) \subseteq S(A_k) \cup S(A_{k+1}) \cup S(\hat{p}_{k+2})$. As $S(A_k) \subseteq S(A_{k+1})$, we obtain $S(\hat{p}_k) \subseteq S(A_{k+1}) \cup S(\hat{p}_{k+2})$. Following the same argument, we can derive $S(\hat{p}_k) \subseteq S(A_{i-1}) \cup S(\hat{p}_i)$. Now that $\hat{s}_i \notin S(A_{i-1})$ and $\hat{s}_i$ is not hit by $\hat{p}_i$, we obtain that $\hat{s}_i$ is not hit by $\hat{p}_k$.

2. If $\hat{s}_i \in S(A_{i-1})$, then $\hat{s}_i$ is hit by a point of A_{i-1}, say p. As $\hat{p}_i \notin \hat{s}_i$, p is left or right of $\hat{p}_i$. Without loss of generality, we assume that p is to the right of $\hat{p}_i$.
   We let $\hat{p}_{i+1}$ be $\hat{p}_i^l$ and define $A_i = A_{i-1}$. We show in the following that the inductive hypothesis holds.
   - By definition, $\hat{p}_i$ is vertically above $\hat{s}_i$ and $\hat{p}_{i+1} \in \hat{s}_i$. Hence, the fourth statement of the hypothesis holds.
   - Since $\hat{s}_i$ is hit by both p and $\hat{p}_i^l$, $\hat{p}_i^l$ is to the left of $\hat{p}_i$, and p is to the right of $\hat{p}_i$, by Observation 6, $S(\hat{p}_i) \subseteq S(\hat{p}_i^l) \cup S(p)$. Further, since $\{\hat{p}_i\} \cup P'_{\text{opt}}$ is a feasible solution, $p \in A_{i-1} \subseteq P'_{\text{opt}}$, and $\hat{p}_{i+1} = \hat{p}_i^l$, we obtain that $\{\hat{p}_{i+1}\} \cup P'_{\text{opt}}$ is also a feasible solution. This proves the third statement of the hypothesis.
   - Since $A_{i-1} \subseteq P'_{\text{opt}}$ by the inductive hypothesis and $A_i = A_{i-1}$, we have $A_i \subseteq P'_{\text{opt}}$. As discussed above, $S(\hat{p}_i) \subseteq S(\hat{p}_i^l) \cup S(p)$. Since $p \in A_{i-1} = A_i$ and $\hat{p}_{i+1} = \hat{p}_i^l$, we obtain $S(\hat{p}_i) \subseteq S(A_i) \cup S(\hat{p}_{i+1})$. This proves the second statement of the hypothesis.
   - For any point $\hat{p}_k$ with $1 \leq k \leq i-1$, to prove the first statement of the hypothesis, we need to show that $\hat{p}_k \neq \hat{p}_{i+1}$. Depending on whether $x(\hat{p}_i) < x(\hat{p}_k)$, there are two cases (note that $\hat{p}_i \neq \hat{p}_k$ by our hypothesis and thus $x(\hat{p}_i) \neq x(\hat{p}_k)$ due to our general position assumption).
     - If $x(\hat{p}_i) < x(\hat{p}_k)$, then since $\hat{p}_{i+1} = \hat{p}_i^l$, we have $x(\hat{p}_{i+1}) < x(\hat{p}_i) < x(\hat{p}_k)$. Hence, $\hat{p}_k \neq \hat{p}_{i+1}$.
     - If $x(\hat{p}_k) < x(\hat{p}_i)$, then we can prove $\hat{p}_k \notin \hat{s}_i$. This implies that $\hat{p}_k \neq \hat{p}_{i+1}$ as $\hat{p}_{i+1} \in \hat{s}_i$. The proof of $\hat{p}_k \notin \hat{s}_i$, which is quite technical and lengthy, is omitted due to the space limit.

     This proves the first statement of the hypothesis.

   This proves that the inductive hypothesis still holds for $i+1$.

According to the inductive hypothesis, each iteration of the process finds a new candidate point $\hat{p}_i$ such that $P'_{\text{opt}} \cup \{\hat{p}_i\}$ is a feasible solution. If $\hat{p}_i \notin Q$, then we can use $\hat{p}_i$ as our target point p^* and we are done with the process. Otherwise, we continue with the next iteration. Since each iteration finds a new candidate point (that was never used before) and $|Q|$ is finite, eventually we will find a candidate point $\hat{p}_i$ that is not in Q.

This completes the proof of the lemma. ◀

5 Algorithm implementation

In this section, we present the implementation of our algorithm. In particular, we describe how to implement the first two steps of the algorithm: (1) Compute $a(i)$ and $b(i)$ for all disks $s_i \in S$; (2) find the subset Q of all prunable points from P.

The following lemma gives the implementation for the first step of the algorithm.

▶ **Lemma 8.** *Computing $a(i)$ and $b(i)$ for all disks $s_i \in S$ can be done in $O(m \log^2 n + (m+n)\log(m+n))$ time.*

Proof. We only discuss how to compute $a(i)$ since computing $b(i)$ can be done analogously.

Recall that points of P are indexed in ascending order of their x-coordinates as $p_1, \ldots, p_n$. Let T be a complete binary search tree whose leaves from left to right correspond to points of P in their index order. Since $n = |P|$, the height of T is $O(\log n)$. For each node $v \in T$, let P_v denote the subset of points of P in the leaves of the subtree rooted at v. Our algorithm is based on the following observation: a disk $s_i \in S$ contains a point of P_v if and only if s_i contains the closest point of P_v to c_i, where c_i is the center of s_i. In light of this observation, we construct the Voronoi diagram for P_v, denoted by VD_v, and build a point location data structure on VD_v so that each point location query can be answered in $O(\log n)$ time [13, 20]. For time analysis, after VD_v is computed, building the point location data structure on VD_v takes $O(|P_v|)$ time [13, 20]. To compute VD_v, if we do so from scratch, then it takes $O(|P_v| \log |P_v|)$ time. However, using Kirkpatrick's algorithm [19], we can compute VD_v in $O(|P_v|)$ time by merging the Voronoi diagrams VD_u and VD_w for the two children u and w of v, since $P_v = P_u \cup P_w$. As such, if we construct the Voronoi diagrams for all nodes of T in a bottom-up manner, the total time is linear in $\sum_{v\in T} |P_v|$, which is $O(n \log n)$.

For each disk $s_i \in S$, we can compute $a(i)$ using T, as follows. Starting from the root of T, for each node v, we do the following. Let u and w be the left and right children of v, respectively. First, we determine whether s_i contains a point of P_u. To this end, using a point location query on VD_u, we find the point p of P_v closest to c_i. As discussed above, s_i contains a point of P_u if and only if $p \in s_i$. If $p \in s_i$, then we proceed with $v = u$; otherwise, we proceed with $v = w$. In this way, $a(i)$ can be computed after searching a root-to-leaf path of T, which has $O(\log n)$ nodes as the height of T is $O(\log n)$. Because we spend $O(\log n)$ time on each node, the total time to compute $a(i)$ is $O(\log^2 n)$. The time for computing $a(i)$ for all disks $s_i \in S$ is thus $O(m \log^2 n)$.

In summary, the overall time to compute $a(i)$ for all disks $s_i \in S$ is bounded by $O(m \log^2 n + (n + m) \log(n + m))$. ◀

With $a(i)$ and $b(i)$ computed in Lemma 8, Lemma 10 finds all prunable points of P. The algorithm of Lemma 10 relies on the following observation.

▶ **Observation 9.** *For any point $p_k \in P$, p_k is prunable if and only if there is a disk $s_i \in S$ such that $p_k \notin s_i$ and $a(i) \le k \le b(i)$.*

Proof. If p_k is prunable, then by definition there is a disk $s_i \in S$ such that $p_k \notin s_i$ and $a(i) < k < b(i)$.

On the other hand, suppose that there is a disk $s_i \in S$ such that $p_k \notin s_i$ and $a(i) \le k \le b(i)$. By the definition of a_i, s_i contains the point $p_{a(i)}$. Since $p_k \notin s_i$, we obtain $k \neq a(i)$. By a similar argument, we have $k \neq b(i)$. As such, since $a(i) \le k \le b(i)$, we can derive $a(i) < k < b(i)$. Therefore, p_k is prunable. ◀

▶ **Lemma 10.** *All prunable points of P can be found in $O((n + m) \log(n + m))$ time.*

Proof. Recall that ℓ denotes the x-axis. We define T as the standard segment tree [11, Section 10.3] on the n points of ℓ whose x-coordinates are equal to $1, 2, \ldots, n$, respectively. The height of T is $O(\log n)$. For each disk $s_i \in S$, let I_i denote the interval $[a(i), b(i)]$ of ℓ. Following the definition of the standard segment tree [11, Section 10.3], we store I_i in $O(\log n)$ nodes of T. For each node $v \in T$, let S_v denote the subset of disks s_i of S whose interval I_i is stored at v. As such, $\sum_{v\in T} |S_v| = O(m \log n)$.

Consider a point $p_k \in P$. The tree T has a leaf corresponding to a point of ℓ whose x-coordinate is equal to k, called *leaf-k*. Let π_k denote the path of T from the root to leaf-k. Following the definition of the segment tree, we have the following observation: $\bigcup_{v\in\pi_k} S_v = \{s_i \mid s_i \in S, a(i) \le k \le b(i)\}$. By Observation 9, to determine whether p_k is prunable, it suffices to determine whether there is a node $v \in \pi_k$ such that S_v has a disk s_i that does not contain p_k. Recall that all points of P are above ℓ while the centers of all disks of S are below ℓ. Let C_v denote the common intersection of all disks of S_v in the halfplane above ℓ. Observe that S_v has a disk s_i that does not contain p_k if and only if p_k is outside C_v. Based on this observation, for each node $v \in T$, we compute C_v and store it at v. Due to the single-intersection property that the upper arcs of every two disks of S intersect at most once, C_v has $O(|S_v|)$ vertices; in addition, by adapting Graham's scan, C_v can be computed in $O(|S_v|)$ time if the centers of all the disks of S_v are sorted by x-coordinate (due to the non-containment property, this is also the order of the disks sorted by the left or right endpoints of their upper arcs). Assuming that the sorted lists of S_v as above are available for all nodes $v \in T$, the total time for constructing C_v for all nodes $v \in T$ is linear in $\sum_{v \in T} |S_v|$, which is $O(m \log n)$. We show that the sorted lists of S_v for all nodes $v \in T$ can be computed in $O(m \log m + m \log n)$ time, as follows. At the start of the algorithm, we sort all disks of S by the x-coordinates of their centers in $O(m \log m)$ time. Then, for each disk s_i of S following this sorted order, we find the nodes v of T where the interval I_i should be stored, and add s_i to S_v, which can be done in $O(\log n)$ time [11, Section 7.4]. In this way, after all disks of S are processed as above, S_v for every node $v \in T$ is automatically sorted. As such, all processing work on T together takes $O((m+n)\log(m+n))$ time.

For each point $p_k \in P$, to determine whether p_k is prunable, following the above discussion, we determine whether p_k is outside C_v for each node $v \in \pi_k$. Deciding whether p_k is outside C_v can be done in $O(\log m)$ time. Indeed, since the centers of all disks are below ℓ, the boundary of C_v consists of a segment on ℓ bounding C_v from below and an x-monotone curve bounding C_v from above. The projections of the vertices of C_v onto ℓ partition ℓ into a set $\mathcal{I}_v$ of $O(|S_v|)$ intervals. If we know the interval of $\mathcal{I}_v$ that contains $x(p_k)$, the x-coordinate of p_k, then whether p_k is outside C_v can be determined in $O(1)$ time. Clearly, we can find the interval of $\mathcal{I}_v$ that contains $x(p_k)$ in $O(\log m)$ time by binary search. In this way, whether p_k is prunable can be determined in $O(\log m \log n)$ time as π_k has $O(\log n)$ nodes. The time can be improved to $O(\log m + \log n)$ using fractional cascading [7], as follows.

We construct a fractional cascading data structure on the intervals of $\mathcal{I}_v$ of all nodes $v \in T$, which takes $O(m \log n)$ time [7] since the total number of such intervals is $O(m \log n)$. With the fractional cascading data structure, for each point $p_k \in P$, we only need to do binary search on the set of the intervals stored at the root of T to find the interval containing $x(p_k)$, which takes $O(\log(m \log n))$ time. Subsequently, following the path π_k in a top-down manner, the interval of $\mathcal{I}_v$ containing $x(p_k)$ for each node $v \in \pi_k$ can be determined in $O(1)$ time [7]. As such, whether p_k is prunable can be determined in $O(\log n + \log m)$ time. Hence, the total time for checking all the points $p_k \in P$ is $O(n \log(m+n))$.

In summary, the time complexity of the overall algorithm for finding all prunable disks of S is bounded by $O((n+m)\log(n+m))$. ◀

With Lemmas 8 and 10, Theorem 4 is proved.

An algebraic decision tree algorithm. In the algebraic decision tree model, where only comparisons are counted towards time complexities, the problem can be solved in $O((n+m)\log(n+m))$ time, i.e., using $O((n+m)\log(n+m))$ comparisons. To this end, observe that the entire algorithm, with the exception of Lemma 8, takes $O((n+m)\log(n+m))$ time. As such, we only need to show that Lemma 8 can be solved using $O((n+m)\log(n+m))$ comparisons. For this, notice that the factor $O(m \log^2 n)$ in the algorithm of Lemma 8 is caused by the point location queries on the Voronoi diagrams VD_v. The number of point location queries is $O(m \log n)$. The total combinatorial complexity of the Voronoi diagrams VD_v of all nodes $v \in T$ is $O(n \log n)$. To answer these point location queries, we employ a method recently introduced by Chan and Zheng [6]. In particular, by applying [6, Theorem 7.2], all point location queries can be solved using $O((n+m)\log(n+m))$ comparisons (specifically, following the notation in [6, Theorem 7.2], we have $t = O(n)$, $L = O(n \log n)$, $M = O(m \log n)$, and $N = O(n+m)$ in our problem; according to the theorem, all point location queries can be answered using $O(L + M + N \log N)$ comparisons, which is $O((n+m)\log(n+m))$).

The unit-disk case. If all disks of S have the same radius (and the points of P are separated from the centers of all disks of S by the x-axis ℓ), then as discussed in Section 1 this problem can be solved in $O((n+m)\log(n+m))$ time by reducing it to a line-separable unit-disk coverage problem and then applying the algorithm in [23]. Here, we show that our approach can provide an alternative algorithm with the same runtime.

We apply the same algorithm as above. Observe that the algorithm, except for Lemma 8, runs in $O((n+m)\log(n+m))$ time. Hence, it suffices to show that Lemma 8 can be implemented in $O((n+m)\log(n+m))$ time for the unit-disk case, which is done in the following lemma.

▶ **Lemma 11.** *If all disks of S have the same radius, then $a(i)$ and $b(i)$ for all disks $s_i \in S$ can be computed in $O((n+m)\log(n+m))$ time.*

Proof. We only discuss how to compute $a(i)$ since the algorithm for $b(i)$ is similar. We modify the algorithm in the proof of Lemma 8 and follow the notation there.

For any disk $s_i \in S$, to compute $a(i)$, recall that a key subproblem is to determine whether s_i contains a point of P_v for a node $v \in T$. To solve the subproblem, the algorithm of Lemma 8 uses Voronoi diagrams. Here, we use a different approach by exploring the property that all disks of S have the same radius, say r. For any point $p \in P$, let D_p denote the disk of radius r and centered at p. Define $\mathcal{D}_v = \{D_p \mid p \in P_v\}$. For each point $p \in P$, since p is above the axis ℓ, the portion of the boundary of D_p below ℓ is an arc on the lower half circle of the boundary of D_p, and we call it the *lower arc* of D_p. Let $\mathcal{L}_v$ denote the lower envelope of ℓ and the lower arcs of all disks of $\mathcal{D}_v$. Our method is based on the observation that s_i contains a point of P_v if and only if c_i is above $\mathcal{L}_v$, where c_i is the center of s_i.

In light of the above discussion, we construct $\mathcal{L}_v$ for every node $v \in T$. Since all disks of $\mathcal{D}_v$ have the same radius and all their centers are above ℓ, the lower arcs of every two disks of $\mathcal{D}_v$ intersect at most once. Due to this single-intersection property, $\mathcal{L}_v$ has at most $O(|P_v|)$ vertices. To see this, we can view the lower envelope of each lower arc of $\mathcal{D}_v$ and ℓ as an extended arc. Every two such extended arcs still cross each other at most once and therefore their lower envelope has $O(|P_v|)$ vertices following the standard Davenport-Schinzel sequence argument [27] (see also [5, Lemma 3] for a similar problem). Notice that $\mathcal{L}_v$ is exactly the lower envelope of these extended arcs and thus $\mathcal{L}_v$ has $O(|P_v|)$ vertices. Note also that $\mathcal{L}_v$ is x-monotone. In addition, given $\mathcal{L}_u$ and $\mathcal{L}_w$, where u and w are the two children of v, $\mathcal{L}_v$ can be computed in $O(|P_v|)$ time by a straightforward line sweeping algorithm. As such, if we compute $\mathcal{L}_v$ for all nodes $v \in T$ in a bottom-up manner, the total time is linear in $\sum_{v\in T}|P_v|$, which is $O(n\log n)$.

For each disk $s_i \in S$, we now compute $a(i)$ using T, as follows. Starting from the root of T, for each node v, we do the following. Let u and w be the left and right children of v, respectively. We first determine whether c_i is above $\mathcal{L}_u$; since $|P_u| \leq n$, this can be done in $O(\log n)$ time by binary search. More specifically, the projections of the vertices of $\mathcal{L}_u$ onto ℓ partition ℓ into a set $\mathcal{I}_u$ of $O(P_u)$ intervals. If we know the interval of $\mathcal{I}_u$ that contains $x(c_i)$, the x-coordinate of c_i, then whether c_i is above $\mathcal{L}_u$ can be determined in $O(1)$ time. Clearly, finding the interval of $\mathcal{I}_u$ containing $x(c_i)$ can be done by binary search in $O(\log n)$ time. If c_i is above $\mathcal{L}_u$, then s_i must contain a point of P_u; in this case, we proceed with $v = u$. Otherwise, we proceed with $v = w$. In this way, $a(i)$ can be computed after searching a root-to-leaf path of T, which has $O(\log n)$ nodes as the height of T is $O(\log n)$. Because we spend $O(\log n)$ time on each node, the total time for computing $a(i)$ is $O(\log^2 n)$. As in Lemma 10, the time can be improved to $O(\log n)$ using fractional cascading [7], as follows.

We construct a fractional cascading data structure on the intervals of $\mathcal{I}_v$ of all nodes $v \in T$, which takes $O(n\log n)$ time [7] since the total number of such intervals is $O(n\log n)$. With the fractional cascading data structure, for each disk $s_i \in S$, we only need to do binary search on the set of the intervals stored at the root of T to find the interval containing $x(c_i)$, which takes $O(\log n)$ time. After that, the interval of $\mathcal{I}_u$ containing $x(c_i)$ for each node u in the algorithm as discussed above can be determined in $O(1)$ time [7]. As such, $a(i)$ can be computed in $O(\log n)$ time. Hence, computing $a(i)$ for all disks $s_i \in S$ takes $O(m \log n)$ time.

In summary, the total time to compute $a(i)$ for all disks $s_i \in S$ is bounded by $O((n + m)\log(n + m))$ time. ◀

Scheduling with Locality by Routing

Abstract

This work examines a strongly NP-hard routing problem on trees, in which multiple servers need to serve a given set of requests (on vertices), where the routes of the servers start from a common source and end at their respective terminals. Each server can travel free of cost on its source-to-terminal path but has to pay for travel on other edges. The objective is to minimize the maximum cost over all servers. As the servers may pay different costs for traveling through a common edge, balancing the loads of the servers can be difficult. We propose a polynomial-time 4-approximation algorithm that applies the parametric pruning framework but consists of two phases. The first phase of the algorithm partitions the requests into packets, and the second phase of the algorithm assigns the packets to the servers. Unlike the standard parametric pruning techniques, the challenge of our algorithm design and analysis is to harmoniously relate the quality of the partition in the first phase, the balances of the servers' loads in the second phase, and the hypothetical optimal values of the framework. For the problem in general graphs, we show that there is no algorithm better than 2-approximate unless $P = NP$. The problem is a generalization of unrelated machine scheduling and other classic scheduling problems. It also models scheduling problems where the job processing times depend on the machine serving the job and the other jobs served by that machine. This modeling provides a framework that physicalizes scheduling problems through the graph's point of view.

1 Introduction

We propose a generalization of the makespan minimization problem that concerns jobs with *locality* and machines with *preferences*. Consider two jobs sharing some common preprocessing subroutines. The time for serving these jobs is reduced if they are assigned to the same machine since the outcome of the preprocessing can be shared (instead of executing the preprocessing step from scratch again). Jobs are considered to be "close" to each other if they share more preprocessing. In other words, the *locality* of jobs indicates how much acceleration a schedule can achieve when these jobs are assigned to one machine.

On the other hand, the machines have *preferences* on jobs. That is, a machine may be better at serving some of the jobs. If the jobs have common preprocessing routines, the machine that has a preference for the routine can further accelerate the total processing time of the batch of jobs.

For example, consider assigning teaching tasks to faculty members in a department. The teaching tasks can be classified systematically as a rooted tree structure. For instance, an internal node representing Algorithm Design And Analysis course may have two children, Approximation Algorithms and Randomized Algorithms courses. Every faculty member has

their own research area and prefers teaching the courses that match their expertise, where each expertise is a path in the tree starting from the root. A course in an area further away from a teacher's research direction takes this teacher more time to prepare and also makes them less happy. The department's goal is to balance the workload people take to prepare for courses. That is, the objective of the assignment is to make the most unhappy colleague as happy as possible.

In a typical routing problem, there are servers that are able to move along paths on a given graph. A server may be required to stop at a terminal, which is a vertex that is associated with the server. Additionally, a server may also need to travel to some vertices to serve some requests or collect some packets located at the vertices.

To model the job localities and the machine preferences, we propose the *scheduling with locality* problem (Scheduling-with-Locality) and describe it as a routing problem on a graph with server-sensitive edge weights. Given a weighted graph, the jobs are represented by *requests* located at (some of) the vertices, and the distance between requests indicates how close the corresponding jobs are. The machines are represented by *servers* initially at a *source vertex* and aim to travel to their *terminals*. Serving a request by a server is analogous to assigning the corresponding job (of the request) to the corresponding machine (of the server). The traveling distance for a server to serve a request is analogous to the time for processing the corresponding job on the corresponding machine. A server may have some *discount* on the weights of some particular edges. That is, it pays a smaller traveling cost when traveling through these edges. The discount of servers on those edges indicates the *preference* of the corresponding machines serving particular types of jobs. The goal is to compute a schedule for all servers, which is a set of walks (where vertices/edges may repeat), each for one server. A walk corresponding to a server starts from the common source vertex and ends at the terminal of the server. To feasibly serve all requests, the walks should cover all of them. The traveling cost of a server on its walk is the total load (that is, the total processing time) of the corresponding machine. To minimize the makespan of a schedule, we want to find the walks where the maximum traveling cost (with regard to the corresponding server) is minimized. The modeling aims to provide a framework that is capable of transforming scheduling problems into a routing problem that has the potential to capture more properties of the scheduling problems from the graph's point of view.

Formal problem definition. An instance of Scheduling-with-Locality is given by an undirected graph $G = (V, E)$, a set of *servers* $\mathcal{S}$, a set of *requests* $\mathcal{R} \subseteq V$, and a *source* $\rho \in V$. Each server $s \in \mathcal{S}$ is associated with its *terminal* $\tau(s) \in V$. Each edge $e \in E$ is associated with server-sensitive weights $weight(e, s) \geq 0$ for $s \in \mathcal{S}$, where $weight(e, s)$ is the cost for server s traveling through edge e. In a feasible schedule, each server $s \in \mathcal{S}$ is assigned a walk[1] that starts from ρ and ends at $\tau(s)$, and the walks of all servers in $\mathcal{S}$ all together visit all requests $\mathcal{R}$. Let Z_s be the walk assigned to server s by schedule Z, the cost of a server s in this schedule, $cost(Z_s, s)$, is $\sum_{e \in Z_s} weight(e, s)$ by definition. The cost of a schedule Z is defined as the maximum cost of servers on their corresponding walk, $\max_{s \in \mathcal{S}}\{cost(Z_s, s)\}$. The objective is to find a schedule that minimizes the cost, i.e., the maximum traveling cost of server walks.

We consider a special case **Multi-server Routing with Free-paths (MRF) problem**, where the given graph is a weighted tree $\mathcal{T} = (V, E)$ rooted at the source vertex ρ. There is an integral weight function on edges $weight : E \to \mathbb{N}$. We call the path from ρ to $\tau(s)$ the

[1] A *walk* is defined by a sequence of vertices $W = \{v_0, v_1, v_2, \cdots, v_\ell\}$ where v_{i-1} and v_i are adjacent for any $1 \leq i \leq \ell$. It is possible that a vertex or an edge appears multiple times in a walk.

home path of server s, denoted as $P_H(s)$. A server can travel on the edges of its home path free of cost. Formally, $weight(e, s) = 0$ if $e \in P_H(s)$ and $weight(e, s) = weight(e)$ otherwise. We will generalize the edge weights from integers to real numbers later in the paper.

Scheduling-with-Locality can model many scheduling problems, such as Unrelated machine scheduling [21], Machine scheduling with setup times [22], etc. (see the full version for details). On the other hand, although the preferences of servers are limited in the MRF problem, the problem captures the locality-aware properties of scheduling problems, i.e., the cost of a server serving a set of requests depends on the locality of the requests and the server. The problem still preserves servers' preferences for serving batches of requests and accommodates complicated inter-request localities by the tree structure. On the other hand, the routing is tricky due to different edge costs for different servers. In fact, one can show that without wisely partitioning the requests, any algorithm is at least r-approximate, where r is the number of requests.

Our results

For positive results, We propose a two-phase Partition-and-Balancing (PnB) algorithm that first partitions the requests into packets properly and then assigns the packets to the servers while balancing the serving costs of servers. More specifically, we apply the classic *parametric pruning* framework that has been exploited to solve the k-center problem [23]. Intuitively, the framework keeps guessing the optimal value. Given a parameter ϑ as the guessed optimal value, if an algorithm ALG guarantees to return a solution with a cost of $\alpha \cdot \vartheta$ as long as ϑ is a correct guess of the optimal cost, then ALG is α-approximate. Afterward, the framework concentrates on finding a correct guess.

In the two-phase PnB algorithm, we use the parameter ϑ as a hypothesized value of the optimal cost. In the first phase, we partition the requests into packets according to the value of ϑ. The partition ensures that for each packet, the cost of traveling to the packet and the cost of traveling within the packet (to serve the requests) are balanced for any server. Eventually, the cost of serving each packet falls between ϑ and 2ϑ, with a bounded number of packets with serving costs less than ϑ (Lemma 3). The second phase delicately assigns the packets, consulting the value of ϑ and the topology of the server terminals. In the end, with a large enough ϑ, the algorithm guarantees that a server only reaches packets within a distance bounded by a constant factor of ϑ, and the cost of any server is at most 4ϑ (Theorem 5). To make sure that if the algorithm fails to generate an assignment with the cost at most 4ϑ, then the value ϑ must be strictly smaller than the optimal cost, the algorithm is designed such that the information of the instance (that will be used in the second phase) when packing the requests into packets in the first phase is preserved (Theorem 8). Finally, the algorithm is adjusted to solve the problem with real number edge weights via runtime trade-off.

For negative results, we provide the 2-inapproximability for the general scheduling with locality problem (Scheduling-with-Locality) to complete the study (Theorem 15).

Related work

Makespan minimization has been studied in various settings where machines have different speeds with respect to different jobs [7, 12, 13, 15, 17, 20, 21], machines with status and setup costs [1, 10, 18], machines with reconfiguration overheads [19, 25], etc. On the other hand, the scheduling of jobs with locality has raised attention recently [14, 16, 25]. That is, reusing configurations among different jobs increases warm-starts and reduces cold-start overheads.

Jobs scheduling and load balancing. The closest related problem is the jobs scheduling problem with the objective of minimizing the makespan. Lenstra et al. proposed a classic LP-based polynomial time 2-approximation algorithm [21]. In contrast, Gairing et al. provided a combinatorial 2-approximation algorithm [15]. Later, Arad et al. used a parametric pruning style technique [2]. They showed that given values L and T, either there exists no schedule of mean machine completion time L and makespan T, or a schedule of makespan at most $T + L/h < 2T$ can be found in polynomial time, where $h \in (0, 1]$ is the feasibility factor of a given instance. An important special case of job scheduling problem is the restricted assignment problem, where processing times are of the form $p_{i,j} \in \{p_j, \infty\}$. The best known result of the problem to date is a $(\frac{33}{17} + \varepsilon)$-approximation by Svensson [26].

Multiple traveling salespeople problem. Another related problem is the *multiple traveling salespeople problem* [24]. Given a set C of n cities, k salespeople, and a depot $d \in C$, the multiple TSP problem aims to find k tours that start and end at the depot such that all of the cities in C must be visited by at least one salesperson. The objective is to minimize the maximum tour length over the k tours. In Euclidean metric, Monroe and Mount [24] showed that there exists a randomized algorithm for the multiple TSP problem that runs in the expected time $O(n((\frac{1}{\varepsilon})\log(\frac{n}{\varepsilon}))^{O(1/\varepsilon)})$, where $\varepsilon > 0$ is an approximation parameter. For the multiple distinct depots case, Xu and Rodrigues proposed a $\frac{3}{2}$-approximation algorithm [27]. For more approximation algorithms for a variety of vehicle routing problems within graphs, please see [3]. Note that the MRF problem should not be confused with the *k-delivery traveling salesman problem* [4, 6], which is a routing problem of limited-capacity vehicles with pickup and delivery locations.

Note that in these previous works, the number of servers is considered to be constant, while in the MRF problem, the number of servers is part of the input since each server has its own terminal. Moreover, in the MRF problem, the servers are allowed to travel through one edge multiple times. To decrease the overall cost, an optimal solution may send multiple servers through one edge. If the metric space in the multiple TSP problem is a tree, and the servers are allowed to travel through an edge more than once, the multiple TSP problem can be seen as a special case of our problem.

Other related work. MRF is similar to the *school bus problem* with regret minimization [8], in which an algorithm is additionally able to determine the locations of terminals. Bock et al. [8] provide a 13.5-approximation algorithm for the school bus problem. For more similar problems in vehicle routing, readers may refer to the survey [9]. On the other hand, the min-max objective considered in this paper also has a significant impact on other combinatorial optimization problems in vehicle routing [5] and efficiency of allocations [11].

Paper organization. In Section 2, we propose our algorithm PnB. In Section 3, we analyze the correctness and approximation ratio of the PnB algorithm. Finally, in Section 4, we provide complexity results of the SCHEDULING-WITH-LOCALITY problem. Due to the page limit, we skip most of the proofs. The complete version with proofs and pseudocodes is attached in the appendix.

2 Partition-and-Balancing Algorithm

We propose the Partition-and-Balancing (PnB) algorithm for the MRF problem, where the input graph is a weighted tree $\mathcal{T}$ rooted at the source vertex ρ, and $weight(e, s) = 0$ if the edge $e \in P_H(s)$ (that is, e is on the home path of s, from ρ to $\tau(s)$) and $weight(e, s) = weight(e)$ otherwise. We first specify the terminologies that will be used in the algorithm and analysis.

The input tree $\mathcal{T}$ can be partitioned into two components, *skeleton* (denoted by $\mathcal{T}_s$) and *request forest* (denoted by $\mathcal{F}_{\mathcal{R}}$) according to the servers' terminals and the set of requests $\mathcal{R}$. The skeleton is the union of the home paths of all servers, and the request forest is defined by $E(\mathcal{T}) \setminus \mathcal{T}_s$. Each connected component in $\mathcal{F}_{\mathcal{R}}$ is a tree rooted at some vertex on the skeleton. We call the trees *request trees* In other words, the request forest is a set of request trees (see Figure 1). We say that a server s is *based* at a (sub)tree T if $\tau(s) \in T$. We also say that an edge e is a *detour* of server s if $e \in P_H(s') \setminus P_H(s)$, where $s' \neq s$. Conceptually, a detour of server s is an edge that s travels at a non-free cost while there is another server that can travel through it free of cost. Note that the edges in request forest are not detours of any server, as all servers have to pay for travel in request forest.

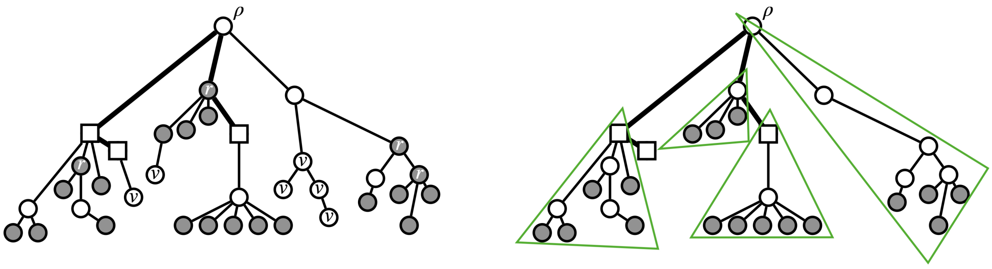
Given an edge-weighted graph, a *walk* is a sequence of vertices $W = \{v_0, v_1, v_2, \cdots, v_\ell\}$ such that v_{i-1} and v_i are adjacent for any $1 \leq i \leq \ell$. The walk W is called a *closed walk* if $v_0 = v_\ell$. The *cost* of walk W is the total weight of the edges and formally $\sum_{i=1}^{\ell} weight((v_{i-1}, v_i))$. Note that in a walk, the vertices or edges may be repeated, and a repeated edge contributes its weight multiple times in the cost of the walk. Given a weighted rooted tree $T = (V, E)$ with weight function $weight : E \to \mathbb{N}$, we denote the subtree rooted on vertex $v \in V$ by T_v. In T, the unique path between a pair of vertices u and v is called (u, v)*-path* and denoted by $P_{u,v}$. We further denote the distance between two vertices u and v by $dist(u, v)$, which is the sum of weights of the edges on $P_{u,v}$. For any connected component $C \subseteq E$, which can be a walk, a path, or even a subtree, we denote $weight(C)$ as the total weight of the edges in C.

For convenience, we define two operations, $\texttt{Walk}(P)$ and $\texttt{Merge}(C, W)$. The $\texttt{Walk}(P)$ operation makes the path P into a walk by going back and forth on the path. Formally, given that $P = [v_1, v_2, \cdots, v_\ell]$, $\texttt{Walk}(P)$ returns a walk $W = \{v_1, v_2, \cdots, v_{\ell-1}, v_\ell, v_{\ell-1}, v_{\ell-2}, \cdots, v_2, v_1\}$. The function $\texttt{Merge}(C, W)$ is to merge the closed walk W to the component C, which can be a path or a walk, by concatenating the two components properly. Note that the $\texttt{Merge}(C, W)$ function is feasible only when W is a closed walk, and there is at least a vertex that is in W and in C at the same time. More formally, assume that $C = \{v_1, v_2, \cdots, v_\ell\}$ is a walk and $W = \{u_1, u_2, \cdots, u_k, u_1\}$, where $v_x = u_y$ for some x and y, $\texttt{Merge}(C, W)$ returns a walk $\{v_1, v_2, \cdots, v_x = u_y, u_{y+1}, \cdots, u_k, u_1, \cdots, u_y = v_x, v_{x+1}, \cdots, v_\ell\}$. If there are multiple vertices that are in both C and W, we break ties arbitrarily.

Instance transformation. We first transform any input tree into a special form, where all requests are at the leaves, and the PnB algorithm works on the transformed instance. Formally, given the input tree $\mathcal{T}$, we first remove all vertices v such that there are no terminals or requests in T_v. Then, we remove the requests on any internal node of the resulting tree. (See Figure 1.)

One can prove by contradiction that in an optimal schedule, no server travels to any of the removed vertices. Moreover, since we only remove requests at the vertices with descendants that also contain requests or terminals, an optimal solution on the original input tree is a feasible schedule of the modified input tree. By a similar reasoning, we can argue that PnB($\mathcal{T}''$) is a feasible schedule of $\mathcal{T}$, where $\mathcal{T}''$ is the modified input tree. Therefore, we have the following lemma, and it is legal to restrict our discussion to the instance where all requests are at the leaves:

▶ **Lemma 1.** *If the PnB algorithm is α-approximate on the modified input $\mathcal{T}''$, PnB algorithm is α-approximate on input $\mathcal{T}$.*



(a) Original instance.

(b) Instance after transformation.

Figure 1 Instance transformation. The squares are terminals, and the gray circles are requests. The thick edges indicate the skeleton $\mathcal{T}_s$. The vertices labeled by v and requests at the vertices labeled by r in 1a are removed in 1b. In 1b, each of the green triangles indicates a request tree.

2.1 PnB algorithm

The PnB algorithm follows the parametric pruning framework and has two phases: `Partition` and `Assignment`. Taking parameter $\vartheta = 1, 2, 3, \cdots$, the algorithm PnB$(\mathcal{T}, \vartheta)$ first calls `Partition`$(\mathcal{T}, \vartheta)$. If `Partition`$(\mathcal{T}, \vartheta)$ does not fail, it returns an updated tree $\mathcal{T}'$ that only consists of the skeleton while each request tree T_w rooted at w is packed into packets stored at the vertex w. Next, the algorithm calls `Assignment`$(\mathcal{T}', \vartheta)$. If `Assignment`$(\mathcal{T}', \vartheta)$ does not fail, it returns a set of $|\mathcal{S}|$ walks, which is an assignment of the packets to the servers. Whenever a phase fails, we terminate the process of PnB$(\mathcal{T}, \vartheta)$ and move on to the next ϑ value.

2.1.1 `Partition`: Packing requests (Phase 1)

Given a value of ϑ, `Partition` deals with the request trees one by one and returns `fail` if there is a request tree with a depth (that is, the length of the longest path from w) larger than $\vartheta/2$. In a request tree T_w, the procedure keeps formulating packets of requests in a bottom-up manner, removing the walk that travels through the packed requests from the request tree, and finally, storing the formulated packets at the root of the request tree. After the `Partition` procedure, if it does not return `fail`, the updated tree $\mathcal{T}'$ has a special form, where the vertices in the request trees except the root are all deleted, and the vertices that were the roots of request trees now store packets. Moreover, each leaf is a terminal of some server in the updated tree $\mathcal{T}'$.

Checking the vertices in the request tree from bottom-top. For each request tree T_w rooted at w, the `Partition` procedure checks the vertices $v_1, v_2, \cdots, v_k$ in T_w in post order. If the subtree T_{v_i} has a weight of less than $\frac{\vartheta - dist(w, v_i)}{2}$, we finish checking v_i and move on to the next vertex v_{i+1} in T_w in the post order. Otherwise, T_{v_i} is "heavy" enough, and we proceed to the next step for partitioning the requests in T_{v_i}.

Partition the requests in a heavy-enough subtree T_{v_i} of request tree T_w. We travel T_{v_i} in the depth-first-search traversal, which is a walk $W_{v_i} = \{v_i, u_1, u_2, \cdots, u_{k_1}, v_i, u_{k_1+1}, u_{k_1+2}, \cdots, u_{k_2}, v_i, \cdots, v_i\}$. Let $\beta_{v_i} = \vartheta - 2 \cdot dist(w, v_i)$. We partition W_{v_i} into sub-walks, $B_1, B_2, \cdots, B_m$, such that each B_j starts and ends at v_i and is the walk with smallest total weight such that $weight(B_j) \geq \beta_{v_i}/2$. Then, each sub-walk B_j is merged to the walk `Walk`(P_{w,v_i}) and forms a packet. The involved vertices in B_j are then trimmed

(f) The five corresponding packets stored at vertex w.

Figure 2 An illustration of `Partition`(ϑ) on T_w. In 2a–2e, the blue trajectories show the walks paid by the "budget" $\beta_{\cdot} = \vartheta - 2 \cdot dist(w, \cdot)$ (where $\cdot$ is the vertex the corresponding DFS starts at), and the red trajectories show the remaining walks back to the vertex $\cdot$. Figure 2f shows the five corresponding packets stored at the vertex w. The green trajectories are the walks `Walk`($P_{w,\cdot}$).

from T_w (except v_i, which is trimmed only when all requests in T_{v_i} are packed, and w, which is never trimmed). Note that the last partition of W_{v_i} may have a weight of less than $\beta_{v_i}/2$. In this case, this sub-walk will be pended and dealt with again when the next vertex v_{i+1} in T_w (in the post-order) is checked. Finally, if at the end of packing on T_w, there are still vertices left in the (trimmed) T_w, these left-over vertices are packed into one packet and stored at w. (See Figure 2.)

2.1.2 `Assignment`: Assigning packets (Phase 2)

After the procedure `Partition` in Section 2.1.1, the modified input tree $\mathcal{T}'$ is exactly the skeleton $\mathcal{T}_s$ with each request tree T_w rooted at the vertex $w \in \mathcal{T}_s$ packed into packets and stored at w. Moreover, every leaf in $\mathcal{T}'$ is a terminal of some server. Let $\mathcal{B}$ denote the set of all packets returned by `Partition`, and $\mathcal{B}_w$ denotes the set of packets stored at vertex

w ($\mathcal{B}_v$ is *empty* if there is no request tree rooted at v). By the process of `Partition`, the packets in $\mathcal{B}_w$ cover all requests in the request tree T_w. In the second phase of our algorithm, `Assignment`, we visit the vertices in $\mathcal{T}'$ in a post-order. When a vertex v is visited, we assign the packets stored in the subtree T_v but "far" enough from v to a server, which has its terminal nearby, and balance the load among the servers. The algorithm returns `fail` if it fails to balance the load of the servers.

Initial assignment. In the round of visiting v, we check its children $c_1, c_2, \cdots, c_k$ one by one. When the child c_i is checked, for any vertex w that is in the subtree T_{c_i} and $dist(w, v) > \frac{\vartheta}{2}$, we *release* the packets in $\mathcal{B}_w$ and assign the packets to a server s based at w (that is, $\tau(s) \in T_w$)[2]. Ties are broken arbitrarily. Note that some servers may have already been assigned packets in previous rounds as we visit the vertices in $\mathcal{T}'$ in a post-order.

To describe how to reassign the packets among servers, we first define the terminologies. We call the total weight of the packets assigned to server s the *work* of s. A server is *heavy*, *light*, or *normal* if its work is strictly greater than 3ϑ, strictly smaller than ϑ, or otherwise, respectively. If a server s' is assigned to serve packets that are initially assigned to another server s, s' is called *helping* for s. Otherwise, a server that helps no other servers is *free*.

Re-assignment for load-balancing. After the initial assignment when checking a child c_i of v, the servers with terminals in T_{c_i} may be light, normal, or heavy. For a server s that becomes heavy in this round, we find some light servers based at T_{c_i} to help it with some of the packets as follows. We first check if there is a light server s' that is based at T_{c_i} and already helped s with some packets. If so, we re-assign some packets released in this round to s'. The re-assignment stops once s or s' becomes normal. If at this moment, s is still heavy, then we search for another light helping server for s based at T_{c_i} and repeat the re-assignment. If there is no light server that helped s before, we find a light free server with its terminal in T_{c_i} that has not helped any other server. If all light servers based at T_{c_i} are helping other servers, and s is still heavy, the procedure `Assignment` returns `fail`.

Wrap the packets into walks. Finally, let $W_s \subseteq V(\mathcal{T}')$ be the set of vertices that store packets assigned to server s and L_s be the set of vertices on the $(\rho, \tau(s))$-path. The packets assigned to s can be wrapped up into a walk from ρ to $\tau(s)$ by traversing the subtree induced by $W_s \cup L_s$.

Figure 3 is an example of the released packets when checking c and the servers' status after the initial assignment. The pseudocode of `Assignment` can be found in the full version.

3 Analysis of PnB algorithm

Throughout the analysis, we use OPT to denote the optimal schedule. We also use OPT to denote the value of the optimal schedule when the context is clear.

Sizes of the packets successfully returned by `Partition` are bounded

Recall that the PnB algorithm is run on a modified input tree $\mathcal{T}$, where each leaf is a terminal of some server. With parameter ϑ, the procedure `Partition` either returns `fail` or modifies the input tree $\mathcal{T}$ into $\mathcal{T}'$ that contains the same vertices as $\mathcal{T}'$, and the packets are stored at

[2] Note that all these vertices on the path from v to c_i to w are all in $\mathcal{T}'$.

(c) After re-assignment.

Figure 3 Illustration of `Assignment`(ϑ) when v is visited and in the round of checking c. Each bean-shaped object is a packet from `Partition`(ϑ). The solid bean-shaped green objects are released when c is checked, as they are outside the range of $\frac{\vartheta}{2}$ from v. The hollow and dashed-lined ones are packets released in previous rounds, and the hollow and solid-lined ones have not been released. The squares indicate the servers' terminals. The square is white/black/gray if its corresponding server is light/heavy/normal. When a terminal is a double-layered square, its corresponding server is helping. The gray arrows from $\tau(s')$ to $\tau(s)$ indicate that s' is helping s with some packets. Note that in this example, after checking c, `Assignment`(ϑ) must return `fail` as the servers with the terminals at u_1, u_2 and u_3 are heavy, but there are no free light servers in T_c.

some of these vertices. Consider any request tree T_w rooted at $w \in \mathcal{T}'$. By construction, the procedure `Partition` packed each request in T_w into exactly one packet that is stored at the vertex w, as long as `Partition`(ϑ) does not return `fail`.

`Partition` fails when there is a path $P_{w,\ell}$, where $w \in \mathcal{T}'$ and ℓ is a leaf in T_w, such that $dist(w, \ell) > \frac{\vartheta}{2}$. Since we work on the modified input tree, the only vertex that can be a terminal in T_w is 2. Thus, any server that serves the request on ℓ has cost at least $2 \cdot dist(w, \ell)$. Therefore, we have the following lemma:

▶ **Lemma 2.** *If* `Partition`(ϑ) *returns* `fail`*, then* $OPT > \vartheta$*.*

On the other hand, if `Partition` returns a partition regarding ϑ, each packet B stored at vertex $w \in \mathcal{T}'$ is a closed walk containing w. For any packet B packed when $v_i \in T_w$ is visited, it was packed using a budget of $\vartheta - 2 \cdot dist(w, v_i)$. Since we only pack heavy enough request trees, and the vertices in the request tree are packed from the bottom up, the trip back to v_i after the budget is off is bounded by a function of ϑ and the distance between w and v_i. By careful calculations, we have the following lemma:

▶ **Lemma 3.** *If* `Partition`(ϑ) *does not return* `fail`*, for any packet* B*,* $weight(B) \leq 2\vartheta$*.*

`Assignment` feasibly returns a schedule with a cost of 4ϑ

After `Assignment`(ϑ), if it does not return `fail`, each server is assigned a set of packets, where each packet is a closed walk by the construction. Recall that a packet $B \in \mathcal{B}_w$ is assigned to a server s' either because B is assigned to s initially or s' is helping another server s with B. In the prior case, w is on $P_H(s') = P_{\rho,\tau(s')}$ and can be merged with $P_H(s')$ without incurring any detour edges. In the latter case, w is on $P_H(s) = P_{\rho,\tau(s)}$, and B was released when the algorithm visited some vertex $c \in P_{\rho,w}$, which is a common ancestor of $\tau(s')$ and $\tau(s)$. Thus, B can be merged with the walk `Walk`($P_{a,\tau(s)}$), and the merged walk can be merged with the path $P_H(s')$. Therefore, the packets assigned to server s' can be merged with $P_H(s')$ into a walk from the root to $\tau(s')$, and we have the following feasibility of the PnB algorithm (see the full version for a complete proof):

▶ **Theorem 4.** *Given instance $\mathcal{T}$, the transformed instance $\mathcal{T}'$, and a parameter of value ϑ, if* `Assignment`($\mathcal{T}', \vartheta$) *does not return* `fail`*,* PnB($\mathcal{T}, \vartheta$) *is feasible. Moreover, the cost of* PnB($\mathcal{T}, \vartheta$) *equals to the cost of* PnB($\mathcal{T}', \vartheta$)*.*

To bound the cost of any server, we first bound the cost spent on the server's detours. By the selection of helping servers, any server s' that helps another server s with packet $B \in \mathcal{B}_w$ is taking detours with a total distance of at most $2 \cdot dist(w, a)$, where a is the lowest common ancestor of $\tau(s')$ and $\tau(s)$. Since in each round, we only release "far-away" packets in terms of ϑ, $2 \cdot dist(w, a) \leq \vartheta$. Hence, the total detour length of s' is at most ϑ. Therefore, we have the following theorem:

▶ **Theorem 5.** *Given that* `Assignment`(ϑ) *does not return* `fail`*, the cost of any server on serving all packets assigned to it is at most 4ϑ.*

The lower bound of the optimal cost

There are two occasions that PnB returns `fail`; one is in the procedure `Partition`, and another one is in the procedure `Assignment`. In Lemma 2, we have shown that if `Partition` returns `fail`, the optimal cost must be larger than ϑ. Next, we consider the case when `Partition` successfully returns a partition of requests while `Assignment` returns `fail`.

We first argue that the partition returned by `Partition`(ϑ) is *sufficiently cost-efficient.* More specifically, if `Partition`(ϑ) does not return `fail`, and the optimal cost is at most ϑ, then total cost the optimal schedule has to pay is comparable to the total work of all packets.

▶ **Lemma 6.** *Given that* `Partition`(ϑ) *does not return* `fail`*, if $OPT \leq \vartheta$, then the sum of the cost of servers in the optimal schedule is at least $\sum_{packets\ B} weight(B)$. That is, $\sum_{s \in \mathcal{S}} cost^{OPT}(s) \geq \sum_{B \in \mathcal{B}} weight(B)$.*

Proof (Sketch). We denote n_e^* as the number of servers OPT sends over the edge e, and b_e as the number of packets constructed by `Partition`($\vartheta, \mathcal{T}$) that contain e. It is equivalent to prove that if $\text{OPT} \leq \vartheta$, $n_e^* \geq b_e$ for any edge $e \in \mathcal{F}_{\mathcal{R}}$. We prove this claim by induction on the edges with depths from the bottom up. Consider an edge $e = (u, v)$ in a request tree T_w, where u is v's parent. Denote $weight_{T_v}(B)$ the total weight of edges in packet B that are also in T_v. The total cost of servers in the optimal solution spent in the subtree T_v is $\sum_{e' \in T_v} n_{e'}^* \cdot weight(e') \geq \sum_{e' \in T_v} b_{e'} \cdot weight(e')$ by the inductive hypothesis. By construction, any packet that contains $e' \in T_v$ must contain the edge $e = (u, v)$. Therefore, the total weight $\sum_{e' \in T_v} b_{e'} \cdot weight(e') = \sum_{B: e \in B} weight_{T_v}(B)$.

Next, we bound $\sum_{B: e \in B} weight_{T_v}(B)$. By case distinction, any packet B containing the edge e that was packed when v or some descendent of v is visited has $weight_{T_v}(B) \geq \vartheta - 2 \cdot dist(w, v)$. Moreover, there is at most another packet containing the edge e that was packed when some ancestor of v is visited. Therefore, the total weight of the packets that contain e is at least $m \cdot (\vartheta - 2 \cdot dist(w, v)) + weight(\hat{B})$, where m is the total number of packets formed by visiting v or some descendent of v, and $\hat{B}$ is the packets packed when an ancestor of v is visited. Meanwhile, $b_e = m + \mathbb{1}[\text{there is at least one packet in } \hat{B}]$[3].

Finally, since $\text{OPT} \le \vartheta$, and v is in the request tree T_w, any server that travels to v has to finish its route in T_v with a cost of at most $\vartheta - 2 \cdot dist(w, v)$. Therefore, an optimal solution has to send at least $\frac{\sum_{B:e\in B} weight_{T_v}(B)}{\vartheta - 2\cdot dist(w,v)}$ servers over the edge e to serve all requests in T_v. Hence, $n_e^* \ge m + \mathbb{1}[\text{there is at least one packet in } \hat{B}] = b_e$, since n_e^* is integral. ◀

Next, we show that if `Assignment`(ϑ) returns `fail`, the average cost of the servers in the (failed) `Assignment`(ϑ) assignment on serving the packets must be strictly larger than ϑ.

▶ **Lemma 7.** *Given that* `Assignment`(ϑ) *returns* `fail`*, on average, each server in the PnB assignment is assigned by packets with total work strictly larger than* ϑ*.*

Proof (Sketch). Assume that `Assignment`(ϑ) returns `fail` when visiting v and checking the child c. Consider the set $\mathcal{S}'$ of servers that an optimal solution uses to serve the requests in T_c. There are two cases of the optimal solution: 1) there exists at least one server in $\mathcal{S}'$ who has its terminal outside T_c, or 2) all servers in $\mathcal{S}'$ have their terminals in T_c. It is easy to see in case 1, the optimal cost is at least ϑ due to any packets inside T_c are at least $\vartheta/2$ away from c.

For Case 2, we use a *helping forest* argument described below. Consider the servers' packets with their terminals in T_c at the moment when `Assignment`(ϑ) returns `fail`. We construct helping trees, which are rooted trees, where each node corresponds to a server by making s' a child of s if s' helps s with some packets.[4] In each helping tree, the root and the internal nodes are normal (or heavy if it is the server that triggers `Assignment`(ϑ) to return `fail`). Consider any internal node s and its children, which are sorted by the order that they help s. The servers s and all its children but the last one must be all normal. On the other hand, the last child can be normal or light. Furthermore, if the last child is light, it is a leaf, as it needs no one to help it. Hence, any internal node has at most one light leaf. The total work of an internal node s and its light leaf s_ℓ is at least 3ϑ, since $work(s) > 3\vartheta$ right before s_ℓ helps s. Therefore, the theorem is proven by the fact that the average work of the servers with terminals in T_c is strictly greater than $\frac{n\cdot\vartheta + \ell\cdot 3\vartheta}{n+2\ell} > \vartheta$, where ℓ is the number of internal node-light leaf pairs, and n is the number of other nodes in the helping forest. ◀

Now, we are ready to prove our main theorem.

▶ **Theorem 8.** *Given that* $\text{PnB}(\mathcal{T}, \vartheta)$ *returns* `fail`*,* $OPT > \vartheta$*.*

Proof. By the construction, `Partition`(ϑ) returns `fail`, the optimal cost must be strictly larger than ϑ. When `Assignment`(ϑ) returns `fail`, there are two cases of the optimal cost: 1) $\text{OPT} > \vartheta$, and 2) $\text{OPT} \le \vartheta$. Suppose on contrary that `Assignment`(ϑ) returns `fail` and $\text{OPT} \le \vartheta$. Then, $\text{OPT} \ge$ average cost of all servers $= \frac{\sum_{s\in\mathcal{S}} cost^{\text{OPT}}(s)}{|\mathcal{S}|} \ge \frac{\sum_{B\in\mathcal{B}} weight(B)}{|\mathcal{S}|}$, where the inequality is by Lemma 6. By Lemma 7, $\frac{\sum_{B\in\mathcal{B}} weight(B)}{|\mathcal{S}|} > \vartheta$. In result, $\text{OPT} > \vartheta$, which contradicts to the assumption that $\text{OPT} \le \vartheta$. ◀

By Theorem 5, Theorem 8, and the parametric pruning framework, we get the approximation ratio:

▶ **Theorem 9.** *PnB is a* 4*-approximation.*

[3] The function $\mathbb{1}[X]$ is 1 if statement X is true and is 0 otherwise.

[4] By the construction, a server s helped by another server will not help other servers, while a helping server s' may be helped by other servers later.

4 Runtime and complexity

4.1 Runtime

Based on the pseudocode, the runtime of PnB depends on a polynomial function of the number of vertices, the number of requests, the number of servers and the value of the optimal schedule. We can slightly improve it as follows. Previously, we search for ϑ^* through a linear scan of ϑ starting from 1, 2, and so on. The scan can be accelerated by binary search.

More specifically, we make ϑ starting from 1, double its value until PnB outputs a feasible schedule, and then binary search within the range up to the ϑ of the feasible schedule. Therefore, for the part of the value of optimal schedule, the runtime reduces to a logarithmic function of the value.

▶ **Theorem 10.** *PnB runs in $O(|V|^3 \log OPT(\mathcal{T}))$ time where $|V|$ is the number of vertices in the input tree $\mathcal{T}$.*

▶ **Corollary 11.** *PnB runs in polynomial time.*

By the binary search method, we can generalize the edge weights from integers to real numbers.

▶ **Theorem 12.** *For real number edge weights, PnB is $(4+\epsilon)$-approximation with runtime $O(|V|^3(4/\epsilon - 1 + \log\lceil OPT(\mathcal{T})\rceil))$ where $|V|$ is the number of vertices in the input tree $\mathcal{T}$.*

4.2 Complexity results

First, by reducing from 3-Partition, we have the following theorem for MRF:

▶ **Theorem 13.** *MRF is strongly NP-hard even if the input is a star.*

Then, we move on to the complexity of Scheduling-with-Locality. We show that the unrelated machine scheduling problem can be reduced to a special case of the scheduling with locality problem. Thus, the problem is more general than the unrelated machine scheduling problem in the sense of approximation ratios.

▶ **Theorem 14.** *For $\alpha < 1.5$, there does not exist a polynomial-time α-approximation algorithm for Scheduling-with-Locality even if we restrict that a server only gets discounts on the edges of the path from the source vertex to its terminal, unless $P = NP$.*

For the rest of the section, we show the following theorem by a reduction from 3-dimensional matching.

▶ **Theorem 15.** *For $\alpha < 2$, there does not exist a polynomial-time α-approximation algorithm for Scheduling-with-Locality even if the edge weights consist of only 0 and 1, unless $P = NP$.*

3-Dimensional matching. In the problem, there are disjoint vertex sets A, B and C with $|A| = |B| = |C| = n$. There is also a set of triples T. Each $t \in T$ is (a_t, b_t, c_t) for some $a_t \in A$, $b_t \in B$ and $c_t \in C$. There is a matching if we can find n triples that cover $A \cup B \cup C$. It is known that 3-dimensional matching is NP-hard.

Construction of the reduction. If $|T| < n$, we construct a trivial no-instance. Thus in the following, we assume $|T| \geq n$. For ease of the description, there is no discounts on any edge for each server by default. For each vertex $x \in A \cup B \cup C$, there is a corresponding request vertex r_x. There are additionally $|T| - n$ dummy request vertices D. For each triple $t = (a, b, c) \in T$, there are four vertices v_t, x_t, y_t and z_t. Each triple has a corresponding server. Let s be the corresponding server of t. Vertex v_t is the terminal of s. There are edges (v_t, x_t), (x_t, y_t) and (y_t, z_t). The weights of the three edges is 1 and the discounts of (x_t, y_t) and (y_t, z_t) for server s are 0. There are additionally edges (x_t, r_a), (y_t, r_b) and (z_t, r_c) all with weight 0. In addition, v_t is adjacent to all the dummy requests D, and these edges all have weight 1. Finally, v_t is also adjacent to the source vertex. The edge has weight 1, but the corresponding server s has a discount 0.

The construction has the following properties.

▶ **Observation 16.** *Consider two different servers s and s', and their corresponding triples $t = (a, b, c) \in T$ and $t' = (a', b', c') \in T$ respectively. Any walk starting from the terminal of s and ending at x'_t incurs a cost of at least 2 for server s if $a \neq a'$. The reversed walk (from x'_t to the terminal of s) also incurs a cost of at least 2 for server s if $a \neq a'$. Both statements are also true if we replace the vertices (a, a', x'_t) by (b, b', y'_t) or replace (a, a', x'_t) by (c, c', z'_t).*

▶ **Lemma 17.** *For Scheduling-with-Locality, the question of deciding if there exists a feasible schedule with makespan at most 2 is NP-hard.*

Proof of Theorem 15. By the construction and Observation 16, it is easy to see that any feasible schedule with a makespan strictly larger than 2 has a makespan larger than 4. Thus, the theorem follows. ◀

Abstract

Given a set P of n points and a set S of n weighted disks in the plane, the disk coverage problem is to compute a subset of disks of smallest total weight such that the union of the disks in the subset covers all points of P. The problem is NP-hard. In this paper, we consider a line-separable unit-disk version of the problem where all disks have the same radius and their centers are separated from the points of P by a line ℓ. We present an $O(n^{3/2}\log^2 n)$ time algorithm for the problem. This improves the previously best work of $O(n^2\log n)$ time. Our result leads to an algorithm of $O(n^{7/2}\log^2 n)$ time for the halfplane coverage problem (i.e., using n weighted halfplanes to cover n points), an improvement over the previous $O(n^4\log n)$ time solution. If all halfplanes are lower ones, our algorithm runs in $O(n^{3/2}\log^2 n)$ time, while the previous best algorithm takes $O(n^2\log n)$ time. Using duality, the hitting set problems under the same settings can be solved with similar time complexities.

1 Introduction

Let P be a set of points, and S a set of disks in the plane such that each disk has a positive weight. The *disk coverage* problem asks for a subset of disks whose union covers all points and the total weight of the disks in the subset is minimized. The problem is NP-hard, even if all disks have the same radius and all disks have the same weight [12, 20]. Polynomial-time approximation algorithms have been proposed for the problem and many of its variants, e.g., [1, 7–9, 13, 17].

In this paper, we consider a *line-separable unit-disk* version of the problem where all disks have the same radius and their centers are separated from the points of P by a line ℓ (see Fig. 1). This version of the problem has been studied before. For the *unweighted case*, that is, all disks have the same weight, Ambühl, Erlebach, Mihalák, and Nunkesser [3] first solved the problem in $O(m^2n)$ time, where $n = |P|$ and $m = |S|$. An improved $O(nm + n\log n)$ time algorithm was later given in [11]. Liu and Wang [19] recently presented an $O((n + m)\log(n + m))$ time algorithm.[1] For the weighted case, Pederson and Wang [22] derived an algorithm of $O(nm\log(m + n))$ time or $O((m + n)\log(m + n) + \kappa\log m)$ time,

[1] The runtime of the algorithm in the conference paper of [19] was $m^{2/3}n^{2/3}2^{O(\log^*(m+n))} + O((n + m)\log(n + m))$, which has been improved to $O((n + m)\log(n + m))$ time in the latest arXiv version.

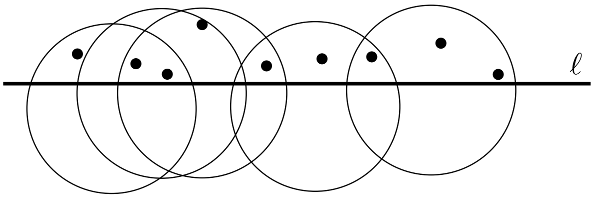

Figure 1 Illustrating the line-separable unit-disk case: All points of P are above ℓ while the centers of all disks are below ℓ.

where κ is the number of pairs of disks that intersect and $\kappa = O(m^2)$ in the worst case. In this paper, we propose an algorithm of $O(n\sqrt{m}\log^2 m + (m+n)\log(m+n))$ time for the weighted case. In addition to the improvement over the previous work, perhaps theoretically more interesting is that the runtime of our algorithm is subquadratic.

The halfplane coverage problem. If every disk of S is a halfplane, then the problem becomes the *halfplane coverage problem*. To solve the problem, Pedersen and Wang [22] showed that the problem can be reduced to $O(n^2)$ instances of the *lower-only halfplane coverage problem* in which all halfplanes are lower halfplanes; this reduction works for both the unweighted and the weighted cases. Consequently, if the lower-only problem can be solved in $O(T)$ time, then the general problem (i.e., S has both lower and upper halfplanes) is solvable in $O(n^2 \cdot T)$ time.

For the weighted lower-only problem, Chan and Grant [8] first gave an algorithm that runs in $O((m+n)^4)$ time. As observed in [22], the lower-only halfplane coverage problem is actually a special case of the line-separable unit-disk coverage problem. Indeed, let ℓ be a horizontal line below all the points of P. Then, since each halfplane of S is a lower halfplane, it can be considered a disk of infinite radius with center below ℓ. In this way, the lower-only halfplane coverage problem becomes an instance of the line-separable unit-disk coverage problem. As such, with their algorithm for the weighted line-separable unit-disk coverage problem, Pederson and Wang [22] solved the weighted lower-only halfplane coverage problem in $O(nm + n\log n)$ time or $O((m+n)\log(m+n) + m^2\log m)$ time. Using our new algorithm for the weighted line-separable unit-disk coverage problem, the weighted lower-only halfplane coverage problem can now be solved in $O(n\sqrt{m}\log^2 m + (m+n)\log(m+n))$ time.

The unweighted lower-only halfplane coverage problem can be solved faster. Indeed, since the problem is a special case of the unweighted line-separable unit-disk coverage problem, with the $O((n+m)\log(n+m))$ time algorithm of Liu and Wang [19] for the latter problem, the unweighted lower-only halfplane coverage problem is solvable in $O((n+m)\log(n+m))$ time. Wang and Xue [24] derived another $O((n+m)\log(n+m))$ time algorithm for the unweighted lower-only halfplane coverage problem with a different approach (which does not work for the unit-disk problem); they also solved the general unweighted halfplane coverage problem in $O(n^{4/3}\log^{5/3} n \log^{O(1)} \log n)$ time. In addition, by a reduction from the set equality problem [4], a lower bound of $\Omega((n+m)\log(n+m))$ is proved in [24] for the lower-only halfplane coverage problem under the algebraic decision tree model.

The hitting set problem. A related problem is the hitting set problem in which each point of P has a positive weight and we seek to find a subset of points with minimum total weight so that each disk of S contains at least one point of the subset. Since the disks of S have the same radius, the problem is actually "dual" to the disk coverage problem. More specifically, if we consider the set of unit disks centered at the points of P as a set of "dual disks" and consider the centers of the disks of S as a set of “dual points”, then the hitting set problem on P and S is equivalent to finding a minimum weight subset of dual disks whose union covers all dual points. Consequently, applying our new weighted case line-separable unit-disk coverage algorithm in this paper solves the weighted line-separable unit-disk hitting set problem in $O(m\sqrt{n}\log^2 n + (m+n)\log(m+n))$ time; applying the $O((m+n)\log(m+n))$ time algorithm in [19] for the unweighted line-separable unit-disk coverage algorithm solves the unweighted line-separable unit-disk hitting set problem in $O((m+n)\log(m+n))$ time.

If every disk of S is a halfplane, then the problem becomes the *halfplane hitting set* problem. Har-Peled and Lee [14] first solved the weighted problem in $O((m+n)^6)$ time. Liu and Wang [18] showed that the problem can be reduced to $O(n^2)$ instances of the *lower-only halfplane hitting set problem* in which all halfplanes are lower halfplanes; this reduction works for both the unweighted and the weighted cases. Consequently, if the lower-only problem can be solved in $O(T)$ time, then the general problem can be solved in $O(n^2 \cdot T)$ time. For the lower-only problem, as in the coverage problem, it is a special case of the line-separable unit-disk hitting set problem; consequently, the weighted and unweighted cases can be solved in $O(m\sqrt{n}\log^2 n + (m+n)\log(m+n))$ time using our new algorithm in this paper and $O((m+n)\log(m+n))$ time using the algorithm in [19], respectively.

Other related work. Pedersen and Wang [22] actually considered a *line-constrained* disk coverage problem, where disk centers are on the x -axis while the points of P can be anywhere in the plane, but the disks may have different radii. They solved the weighted case in $O(nm + n\log n)$ time or $O((m+n)\log(m+n) + \kappa\log m)$ time, where κ is the number of pairs of disks that intersect. For the unweighted case, Liu and Wang [19] gave an algorithm of $O((n+m)\log(m+n) + m\log m\log n)$ time. The line-constrained disk hitting set problem was also studied by Liu and Wang [18], where an $O((m+n)\log(m+n) + \kappa\log m)$ time algorithm was derived for the weighted case, matching the time complexity of the above line-constrained disk coverage problem. Other types of line-constrained problems have also been considered in the literature, e.g., [2,5,6,15,16,21,25].

Our approach. Our algorithm for the weighted line-separable unit-disk coverage problem is essentially a dynamic program. The algorithm description is quite simple and elegant. However, it is not straightforward to prove its correctness. To this end, we show that our algorithm is consistent with the algorithm in [22] for the same problem; one may view our algorithm as a different implementation of the algorithm in [22]. Another challenge of our approach lies in its implementation. More specifically, our algorithm has two key operations, and the efficiency of the algorithm hinges on how to perform these operations efficiently. For this, we construct a data structure based on building a cutting on the disks of S [10]. Although we do not have a good upper bound on the runtime of each individual operation of the algorithm, we manage to bound the total time of all operations in the algorithm by $O(n\sqrt{m}\log^2 m + (m+n)\log(m+n))$.

Outlines. The rest of the paper is structured as follows. After introducing some notation in Section 2, we describe our algorithm and prove its correctness in Section 3. The implementation of the algorithm is presented in Section 4.

2 Preliminaries

We follow the notation defined in Section 1, e.g., P, S, m, n, ℓ. All disks of S have the same radius, which we call *unit disks*. Without loss of generality, we assume that ℓ is the x-axis and all points of P are above ℓ while all centers of disks of S are below ℓ. Note that when we say that a point is above (or below) ℓ, we allow the case where the point is on ℓ.

We assume that each point of P is covered by at least one disk since otherwise there would be no solution. Our algorithm can check whether this assumption is met. For ease of discussion, we make a general position assumption that no point of P lies on the boundary of a disk and no two points of P have the same x-coordinate.

We call a subset S' of S a *feasible subset* if the union of all disks of S' covers all points of P. If S' is a feasible subset of minimum total weight, then S' is called an *optimal subset*. Let δ_{opt} denote the total weight of all disks in an optimal subset; we call δ_{opt} the *optimal objective value*.

For any point q in the plane, let $S_q \subseteq S$ denote the subset of disks containing q; define $\overline{S_q} = S \setminus S_q$. For each disk $s \in S$, let $w(s)$ denote its weight.

3 Algorithm description and correctness

We now present our algorithm. As mentioned above, the algorithm description is quite simple. The challenging part is to prove its correctness and implement it efficiently. In the following, we first describe the algorithm in Section 3.1, and then establish its correctness in Section 3.2. The algorithm implementation will be elaborated in Section 4.

3.1 Algorithm description

We first sort the points of P from left to right as $p_1, p_2, \ldots, p_n$. Our algorithm then processes the points of P in this order. For each point $p_i \in P$, the algorithm computes a value δ_i. The algorithm also maintains a value $cost(s)$ for each disk $s \in S$, which is initialized to its weight $w(s)$. The pseudocode of the algorithm is given in Algorithm 1.

Algorithm 1 The primal algorithm.

```
Input: The points of $P$ are sorted from left to right as $p_1, p_2, \ldots, p_n$
Output: The optimal objective value $\delta_{\text{opt}}$
$cost(s) \leftarrow w(s)$, for all disks $s \in S$;
for $i \leftarrow 1$ to $n$ do
    $\delta_i \leftarrow \min_{s \in S_{p_i}} cost(s)$;                  // FindMinCost Operation
    $cost(s) \leftarrow w(s) + \delta_i$ for all disks $s \in \overline{S_{p_i}}$;     // ResetCost Operation
end
return $\delta_n$;
```

The algorithm is essentially a dynamic program. We prove in Section 3.2 that the value δ_n returned by the algorithm is equal to δ_{opt}, the optimal objective value. To find an optimal subset, one could slightly modify the algorithm following the standard dynamic programming backtracking technique. More specifically, if δ_n is equal to $cost(s)$ for some disk $s \in S_{p_n}$, then s should be reported as a disk in the optimal subset. Suppose that $cost(s)$ is equal to $w(s) + \delta_i$ for some point p_i. Then δ_i is equal to $cost(s')$ for some disk $s' \in S_{p_i}$ and s' should be reported as a disk in the optimal subset. We continue this backtracking process until a disk whose cost is equal to its own weight is reported (in which case all points of P are covered by the reported disks).

For reference purposes, we use FindMinCost to refer to the operation in Line 3 and use ResetCost to refer to the operation in Line 4 of Algorithm 1. The efficiency of the algorithm hinges on how to implement these two *key operations*, which will be discussed in Section 4.

3.2 Correctness of Algorithm 1

We prove that Algorithm 1 is correct, i.e., prove $\delta_n = \delta_{\mathrm{opt}}$. To this end, we show that our algorithm is consistent with the algorithm of Pederson and Wang [22] for the same problem, or alternatively, our algorithm provides a different implementation of their algorithm. Their algorithm first reduces the problem to a 1D interval coverage problem and then solves the interval coverage problem by a dynamic programming algorithm. In the following, we first review their problem reduction in Section 3.2.1 and then explain their dynamic programming algorithm in Section 3.2.2. Finally, we show that our algorithm is essentially an implementation of their dynamic programming algorithm in Section 3.2.3.

3.2.1 Reducing the problem to an interval coverage problem

For convenience, let p_0 (resp., p_{n+1}) be a point to the left (resp., right) all the points of P and is not contained in any disk of S.

Consider a disk $s \in S$. We say that a subsequence $P[i,j]$ of P with $1 \leq i \leq j \leq n$ is a *maximal subsequence covered* by s if all points of $P[i,j]$ are covered by s but neither p_{i-1} nor p_{j+1} is (it is well defined due to p_0 and p_{n+1}). Define $F(s)$ as the set of all maximal subsequences covered by s. It is easy to see that the subsequences of $F(s)$ are pairwise disjoint.

For each point p_i of P, we vertically project it on the x-axis ℓ; let p_i^* denote the projection point. Let P^* denote the set of all such projection points. Due to our general position assumption that no two points of P have the same x-coordinate, all points of P^* are distinct. For any $1 \leq i \leq j \leq n$, we use $P^*[i,j]$ to denote the subsequence $p_i^*, p_{i+1}^*, \ldots, p_j^*$.

Next, we define a set S^* of line segments on ℓ as follows. For each disk $s \in S$ and each subsequence $P[i,j] \in F(s)$, we create a segment for S^*, denoted by $s^*[i,j]$, with the left endpoint at p_i^* and the right endpoint at p_j^*. As such, $s^*[i,j]$ covers all points of $P^*[i,j]$ and does not cover any point of $P^* \setminus P^*[i,j]$. We let the weight of $s^*[i,j]$ be equal to $w(s)$. We say that $s^*[i,j]$ is *defined* by the disk s.

Consider the following *interval coverage* problem (i.e., each segment of S^* can also be considered an interval of ℓ): Find a subset of segments of S^* of minimum total weight such that the union of the segments in the subset covers all points of P^*. Pederson and Wang [22] proved that an optimal solution to this interval coverage problem corresponds to an optimal solution to the original disk coverage problem on P and S. More specifically, suppose that S^*_{opt} is an optimal subset of the interval coverage problem. Then, we can obtain an optimal subset S_{opt} for the disk coverage problem as follows: For each segment $s^*[i,j] \in S^*_{\mathrm{opt}}$, we add the disk that defines $s^*[i,j]$ to S_{opt}. It is proved in [22] that S_{opt} thus obtained is an optimal subset of the disk coverage problem. Note that since a disk of S may define multiple segments of S^*, a potential issue with S_{opt} is that a disk may be included in S_{opt} multiple times (i.e., if multiple segments defined by the disk are in S^*_{opt}); but this is proved impossible [22].

3.2.2 Solving the interval coverage problem

We now explain the dynamic programming algorithm in [22] for the interval coverage problem.

Let p_0^* be the vertical projection of p_0 on ℓ. Note that $p_0^*, p_1^*, \ldots, p_n^*$ are sorted on ℓ from left to right. For each segment $s^* \in S^*$, let $w(s^*)$ denote the weight of s^*.

For each segment $s^* \in S^*$, define f_{s^*} as the index of the rightmost point of $P^* \cup \{p_0^*\}$ strictly to the left of the left endpoint of s^*. Note that f_{s^*} is well defined due to p_0^*.

For each $i \in [1, n]$, define δ_i^* as the minimum total weight of a subset of segments of S^* whose union covers all points of $P^*[1, i]$. The goal of the interval coverage problem is to compute δ_n^*, which is equal to δ_{opt} [22]. For convenience, we let $\delta_0^* = 0$. For each segment $s^* \in S^*$, define $cost(s^*) = w(s^*) + \delta^*_{f_{s^*}}$. One can verify that $\delta_i^* = \min_{s^* \in S^*_{p_i^*}} cost(s^*)$, where $S^*_{p_i^*} \subseteq S^*$ is the subset of segments that cover p_i^*. This is the recursive relation of the dynamic programming algorithm.

Assuming that the indices f_{s^*} for all disks $s^* \in S^*$ have been computed, the algorithm works as follows. We sweep a point q on ℓ from left to right. Initially, q is at p_0^*. During the sweeping, we maintain the subset $S_q^* \subseteq S^*$ of segments that cover q. The algorithm maintains the invariant that the cost of each segment of S_q^* is already known and the values δ_i^* for all points $p_i^* \in P^*$ to the left of q have been computed. An event happens when q encounters an endpoint of a segment of S^* or a point of P^*. If q encounters a point $p_i^* \in P^*$, then we find the segment of S_q^* with the minimum cost and assign the cost value to δ_i^*. If q encounters the left endpoint of a segment s^*, we set $cost(s^*) = w(s^*) + \delta^*_{f_{s^*}}$ and then insert s^* into S_q^*. If q encounters the right endpoint of a segment, we remove the segment from S_q^*. The algorithm finishes once q meets p_n^*, at which event δ_n^* is computed.

Remark. It was shown in [22] that the above dynamic programming algorithm for the interval coverage problem can be implemented in $O((|P^*| + |S^*|) \log(|P^*| + |S^*|))$. While $|P^*| = n$, $|S^*|$ may be relatively large. A straightforward upper bound for $|S^*|$ is $O(nm)$. Pederson and Wang [22] proved another bound $|S^*| = O(n + m + \kappa)$, where κ is the number of pairs of disks that intersect. This leads to their algorithm of $O(nm \log(m + n) + n \log n)$ time or $O((m + n) \log(m + n) + \kappa \log m)$ time for the original disk coverage problem on P and S.

3.2.3 Correctness of our algorithm

Next, we argue that $\delta_n = \delta_n^*$, which will establish the correctness of Algorithm 1 since $\delta_n^* = \delta_{\text{opt}}$. In fact, we will show that $\delta_i = \delta_i^*$ for all $1 \le i \le n$. We prove it by induction.

As the base case, we first argue $\delta_1 = \delta_1^*$. To see this, by definition, $\delta_1 = \min_{s \in S_{p_1}} w(s)$ because $cost(s) = w(s)$ initially for all disks $s \in S$. For δ_1^*, notice that $f_{s^*} = 0$ for every segment $s^* \in S^*_{p_1^*}$. Since $\delta_0^* = 0$, we have $\delta_1^* = \min_{s^* \in S^*_{p_1^*}} w(s^*)$. By definition, a segment $s^* \in S^*$ covers p_1^* only if the disk of S defining s^* covers p_1, and the segment has the same weight as the disk. Therefore, s^* is in $S^*_{p_1^*}$ only if the disk of S defining s^* is in S_{p_1}. On the other hand, if a disk s covers p_1, then s must define exactly one segment in S^* covering p_1^*. Hence, for each disk $s \in S_{p_1}$, it defines exactly one segment in $S^*_{p_1^*}$ with the same weight. This implies that δ_1^* is equal to the minimum weight of all disks of S covering p_1, and therefore, $\delta_1^* = \delta_1$ must hold.

Consider any i with $2 \le i \le n$. Assuming that $\delta_j = \delta_j^*$ for all $1 \le j < i$, we now prove $\delta_i = \delta_i^*$. Recall that $\delta_i = \min_{s \in S_{p_i}} cost(s)$ and $\delta_i^* = \min_{s^* \in S^*_{p_i^*}} cost(s^*)$. As argued above, each disk $s \in S_{p_i}$ defines a segment in $S^*_{p_i^*}$ with the same weight and each segment $s^* \in S^*_{p_i^*}$ is defined by a disk in S_{p_i} with the same weight. Let s^* be the segment of $S^*_{p_i^*}$ defined by a disk $s \in S_{p_i}$. To prove $\delta_i = \delta_i^*$, it suffices to show that $cost(s)$ of s is equal to $cost(s^*)$ of s^*. To see this, first note that $w(s) = w(s^*)$. By definition, $cost(s^*) = w(s^*) + \delta^*_{f_{s^*}}$. For notational convenience, let $j = f_{s^*}$. By definition, all points of $P^*[j + 1, i]$ are covered by the segment s^* but the point p_j^* is not. Therefore, all points of $P[j + 1, i]$ are covered by the disk s but p_j is not. As such, during the ResetCost operation of the j-th iteration of the for loop in Algorithm 1, $cost(s)$ will be set to $w(s) + \delta_j$; furthermore, $cost(s)$ will not be reset again during the i'-th iteration for all $j + 1 \leq i' \leq i$. Therefore, we have $cost(s) = w(s) + \delta_j$ at the beginning of the i-th iteration of the algorithm. Since $\delta_j = \delta_j^*$ holds by induction hypothesis and $w(s) = w(s^*)$, we obtain $cost(s) = cost(s^*)$. This proves $\delta_i = \delta_i^*$.

The correctness of Algorithm 1 is thus established.

Remark. The above proof for $\delta_n = \delta_{\text{opt}}$ also implies that $\delta_i = \delta_{\text{opt}}^i$ for all $1 \leq i \leq n-1$, where δ_{opt}^i is the minimum total weight of a subset of disks whose union covers all points of $P[1, i]$. Indeed, we can apply the same proof to the points of $P[1, i]$ only. Observe that δ_i will never change after the i-th iteration of Algorithm 1.

4 Algorithm implementation

In this section, we discuss the implementation of Algorithm 1. Specifically, we describe how to implement the two key operations FindMinCost and ResetCost. A straightforward method can implement each operation in $O(m)$ time, resulting in a total $O(mn + n \log n)$ time of the algorithm. Note that this is already a logarithmic factor improvement over the previous work of Pederson and Wang [22]. In the following, we present a faster approach of $O(n\sqrt{m} \log^2 m + (m + n) \log(m + n))$ time.

Duality. Recall that the points of P are sorted from left to right as $p_1, p_2, \ldots, p_n$. In fact, we consider the problem in the "dual" setting. For each point $p_i \in P$, let d_i denote the unit disk centered at p_i, and we call d_i the *dual disk* of p_i. For each disk $s \in S$, let q_s denote the center of s, and we call q_s the *dual point* of s. We define the weight of q_s to be equal to $w(s)$. We use D to denote the set of all dual disks and Q the set of all dual points. For each dual point $q \in Q$, let $w(q)$ denote its weight. Because all disks of S are unit disks, we have the following observation.

▶ **Observation 1.** *A disk $s \in S$ covers a point $p_i \in P$ if and only if the dual point q_s is covered by the dual disk d_i.*

For any disk $d_i \in D$, let Q_{d_i} denote the subset of dual points of Q that are covered by d_i, i.e., $Q_{d_i} = Q \cap d_i$. Define $\overline{Q_{d_i}} = Q \setminus Q_{d_i}$. In light of Observation 1, Algorithm 1 is equivalent to the following Algorithm 2.

Algorithm 2 An algorithm "dual" to Algorithm 1.

```
$cost(q) \leftarrow w(q)$, for all dual points $q \in Q$;
for $i \leftarrow 1$ to $n$ do
    $\delta_i \leftarrow \min_{q \in Q_{d_i}} cost(q)$;                        // FindMinCost Operation
    $cost(q) \leftarrow w(q) + \delta_i$ for all dual points $q \in \overline{Q_{d_i}}$;     // ResetCost Operation
end
return $\delta_n$;
```

In the following, we will present an implementation for Algorithm 2, and in particular, for the two operations FindMinCost and ResetCost.

For each disk $d_i \in D$, since its center is above the x-axis ℓ and all points of Q are below ℓ, only the portion of d_i below ℓ matters to Algorithm 2. We call the boundary portion of d_i below ℓ the *lower arc* of d_i. Let H denote the set of the lower arcs of all disks of D.

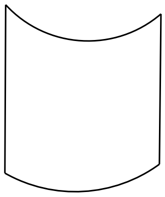

Figure 2 Illustrating a pseudo-trapezoid.

Cuttings. Our algorithm will need to construct a cutting on the arcs of H [10]. We explain this concept first. Note that $|H| = n$. For a parameter r with $1 \leq r \leq n$, a $(1/r)$-*cutting* Ξ of size $O(r^2)$ for H is a collection of $O(r^2)$ constant-complexity cells whose union covers the entire plane and whose interiors are pairwise disjoint such that the interior of each cell $\sigma \in \Xi$ is crossed by at most n/r arcs of H, i.e., $|H_\sigma| \leq n/r$, where H_σ is the subset of arcs of H that cross the interior of σ (H_σ is often called the *conflict list* in the literature). Let D_σ be the subset of disks of D whose lower arcs are in H_σ. Hence, we also have $|D_\sigma| \leq n/r$.

We actually need to construct a *hierarchical cutting* for H [10]. We say that a cutting Ξ' *c-refines* another cutting Ξ if each cell of Ξ' is completely inside a single cell of Ξ and each cell of Ξ contains at most c cells of Ξ'. Let Ξ_0 denote the cutting with a single cell that is the entire plane. We define cuttings $\{\Xi_0, \Xi_1, ..., \Xi_k\}$, in which each Ξ_i, $1 \leq i \leq k$, is a $(1/\rho^i)$-cutting of size $O(\rho^{2i})$ that c-refines Ξ_{i-1}, for two constants ρ and c. By setting $k = \lceil \log_\rho r \rceil$, the last cutting Ξ_k is a $(1/r)$-cutting. The sequence $\{\Xi_0, \Xi_1, ..., \Xi_k\}$ is called a *hierarchical* $(1/r)$-*cutting* for H. If a cell σ' of Ξ_{i-1}, $1 \leq i \leq k$, contains cell σ of Ξ_i, we say that σ' is the *parent* of σ and σ is a *child* of σ'. We can also define *ancestors* and *descendants* correspondingly. As such, the hierarchical $(1/r)$-cutting can be viewed as a tree structure with the single cell of Ξ_0 as the root. We often use Ξ to denote the set of all cells in all cuttings Ξ_i, $0 \leq i \leq k$. The total number of cells of Ξ is $O(r^2)$ [10].

A hierarchical $(1/r)$-cutting of H can be computed in $O(nr)$ time, e.g., by the algorithm in [23], which adapts Chazelle's algorithm [10] for hyperplanes. The algorithm also produces the conflict lists H_σ (and thus D_σ) for all cells $\sigma \in \Xi$, implying that the total size of these conflict lists is bounded by $O(nr)$. In particular, each cell of the cutting produced by the algorithm of [23] is a (possibly unbounded) *pseudo-trapezoid* that typically has two vertical line segments as left and right sides, a sub-arc of an arc of H as a top side (resp., bottom side) (see Fig. 2).

In what follows, we first discuss a preprocessing step in Section 4.1. The algorithms for handling the two key operations are described in the subsequent two subsections, respectively. Section 4.4 finally summarizes everything.

4.1 Preprocessing

In order to handle the two key operations, we first perform some preprocessing work before we run Algorithm 2. As discussed above, we first sort all points of P from left to right. In the following, we describe a data structure which will be used to support the two key operations.

We start by computing a hierarchical $(1/r)$-cutting $\{\Xi_0, \Xi_1, ..., \Xi_k\}$ for H in $O(nr)$ time [10,23], for a parameter $1 \leq r \leq n$ to be determined later. We follow the above notation, e.g., σ, H_σ, D_σ, Ξ. As discussed above, the cutting algorithm also produces the conflict lists H_σ (and thus D_σ) for all cells $\sigma \in \Xi$. Using the conflict lists, we compute a list $L(d_i)$ for each disk $d_i \in D$, where $L(d_i)$ comprises all cells $\sigma \in \Xi$ such that $d_i \in D_\sigma$. Computing $L(d_i)$ for all disks $d_i \in D$ can be done in $O(\sum_{\sigma \in \Xi} |H_\sigma|)$ time by simply traversing the conflict lists H_σ of all cells $\sigma \in \Xi$, which takes $O(nr)$ time as $\sum_{\sigma \in \Xi} |H_\sigma| = O(nr)$. Note that this also implies $\sum_{d_i \in D} |L(d_i)| = O(nr)$.

For any region R in the plane, let $Q(R)$ denote the subset of points of Q that are inside R, i.e., $Q(R) = Q \cap R$.

For simplicity, we assume that no point of Q is on the boundary of any cell of Ξ. This implies that each point of Q is in the interior of a single cell of Ξ_i, for all $0 \leq i \leq k$. We compute the subset $Q(\sigma)$ of all cells σ in the last cutting Ξ_k. This can be done by a point location procedure as follows. For each point $q \in Q$, starting from the only cell of Ξ_0, we find the cell σ_i of Ξ_i containing q, for each $0 \leq i \leq k$. More precisely, suppose that σ_i is known. To find σ_{i+1}, we simply check all $O(1)$ children of σ_i and find the one that contains q, which takes $O(1)$ time. As such, processing all points of Q takes $O(m \log r)$ time as $k = O(\log r)$, after which $Q(\sigma)$ for all cells $\sigma \in \Xi_k$ are computed. We explicitly store $Q(\sigma)$ for all cells $\sigma \in \Xi_k$. Note that the subsets $Q(\sigma)$ for all cells $\sigma \in \Xi_k$ form a partition of Q. Therefore, we have the following observation.

▶ **Observation 2.** $\sum_{\sigma \in \Xi_k} |Q(\sigma)| = m$.

Note that a cell $\sigma \in \Xi$ is the ancestor of another cell $\sigma' \in \Xi$ (alternatively, σ' is a descendant of σ) if and only if σ fully contains σ'. For convenience, we consider σ an ancestor of itself but not a descendant of itself. Let $A(\sigma)$ denote the set of all ancestors of σ and $B(\sigma)$ the set of all descendants of σ. Hence, σ is in $A(\sigma)$ but not in $B(\sigma)$. Let $C(\sigma)$ denote the set of all children of σ Clealy, $|A(\sigma)| = O(\log r)$ and $|C(\sigma)| = O(1)$.

Variables and algorithm invariants. For each point $q \in Q$, we associate with it a variable $\lambda(q)$. For each cell $\sigma \in \Xi$, we associate with it two variables: $minCost(\sigma)$ and $\lambda(\sigma)$. If $|Q(\sigma)| = \emptyset$, then $minCost(\sigma) = \infty$ and $\lambda(\sigma) = 0$ always hold during the algorithm. Our algorithm for handling the two key operations will maintain the following two invariants.

▶ **Algorithm Invariant 1.** *For any point $q \in Q$, $cost(q) = w(q) + \lambda(q) + \sum_{\sigma' \in A(\sigma)} \lambda(\sigma')$, where σ is the cell of Ξ_k that contains q.*

▶ **Algorithm Invariant 2.** *For each cell $\sigma \in \Xi$ with $Q(\sigma) \neq \emptyset$, if σ is a cell of Ξ_k, then $minCost(\sigma) = \min_{q \in Q(\sigma)}(w(q) + \lambda(q))$; otherwise, $minCost(\sigma) = \min_{\sigma' \in C(\sigma)}(minCost(\sigma') + \lambda(\sigma'))$.*

The above algorithm invariants further imply the following observation.

▶ **Observation 3.** *For each cell $\sigma \in \Xi$ with $Q(\sigma) \neq \emptyset$, $\min_{q \in Q(\sigma)} cost(q) = minCost(\sigma) + \sum_{\sigma' \in A(\sigma)} \lambda(\sigma')$.*

Proof. We prove the observation by induction. For the base case, consider a cell σ of the last cutting Ξ_k. By the two algorithm invariants, we have

$$\begin{aligned}
\min_{q \in Q(\sigma)} cost(q) &= \min_{q \in Q(\sigma)} \Big(w(q) + \lambda(q) + \sum_{\sigma' \in A(\sigma)} \lambda(\sigma') \Big) && \text{by Algorithm Invariant 1} \\
&= \min_{q \in Q(\sigma)} \Big(w(q) + \lambda(q) \Big) + \sum_{\sigma' \in A(\sigma)} \lambda(\sigma') \\
&= minCost(\sigma) + \sum_{\sigma' \in A(\sigma)} \lambda(\sigma'). && \text{by Algorithm Invariant 2}
\end{aligned}$$

This proves the observation for σ.

Now consider a cell $\sigma \in \Xi \setminus \Xi_k$. We assume that the observation holds for all children σ' of σ, i.e., $\min_{q \in Q(\sigma')} cost(q) = minCost(\sigma') + \sum_{\sigma'' \in A(\sigma')} \lambda(\sigma'')$. Then, we have

$$\begin{aligned}
\min_{q \in Q(\sigma)} cost(q) &= \min_{\sigma' \in C(\sigma)} \min_{q \in Q(\sigma')} cost(q) \\
&= \min_{\sigma' \in C(\sigma)} \Big(minCost(\sigma') + \sum_{\sigma'' \in A(\sigma')} \lambda(\sigma'') \Big) && \text{by induction hypothesis} \\
&= \min_{\sigma' \in C(\sigma)} \Big(minCost(\sigma') + \lambda(\sigma') \Big) + \sum_{\sigma'' \in A(\sigma)} \lambda(\sigma'') \\
&= minCost(\sigma) + \sum_{\sigma'' \in A(\sigma)} \lambda(\sigma''). && \text{by Algorithm Invariant 2}
\end{aligned}$$

This proves the observation. ◀

For each cell $\sigma \in \Xi$, we also maintain $\mathcal{L}(\sigma)$, a list comprising all descendant cells σ' of σ whose values $\lambda(\sigma')$ are not zero and all points $q \in Q(\sigma)$ whose values $\lambda(q)$ are not zero. As $\mathcal{L}(\sigma)$ has both cells of $B(\sigma)$ and points of $Q(\sigma)$, for convenience, we use an “element” to refer to either a cell or a point of $\mathcal{L}(\sigma)$. As such, for any element $e \in B(\sigma) \cup Q(\sigma)$ with $e \notin \mathcal{L}(\sigma)$, $\lambda(e) = 0$ must hold. As will be seen later, whenever the algorithm sets $\lambda(\sigma)$ to a nonzero value for a cell $\sigma \in \Xi$, σ will be added to $\mathcal{L}(\sigma')$ for every ancestor σ' of σ with $\sigma' \neq \sigma$. Similarly, whenever the algorithm sets $\lambda(q)$ to a nonzero value for a point q, then q will be added to $\mathcal{L}(\sigma')$ for every cell $\sigma' \in A(\sigma)$, where σ is the cell of Ξ_k containing q.

Initialization. The above describes the data structure. We now initialize the data structure, and in particular, initialize the variables $\mathcal{L}(\cdot)$, $\lambda(\cdot)$, $minCost(\cdot)$ so that the algorithm invariants hold.

First of all, for each cell $\sigma \in \Xi$, we set $\mathcal{L}(\sigma) = \emptyset$ and $\lambda(\sigma) = 0$. For each point $q \in Q$, we set $\lambda(q) = 0$. Since $cost(q) = w(q)$ initially, it is not difficult to see that Algorithm Invariant 1 holds.

We next set $minCost(\sigma)$ for all cells of $\sigma \in \Xi$ in a bottom-up manner following the tree structure of Ξ. Specifically, for each cell σ in the last cutting Ξ_k, we set $minCost(\sigma) = \min_{q \in Q(\sigma)} w(q)$ by simply checking every point of $Q(\sigma)$. If $Q(\sigma) = \emptyset$, we set $minCost(\sigma) = \infty$. This establishes the second algorithm invariant for all cells $\sigma \in \Xi_k$. Then, we set $minCost(\sigma)$ for all cells of $\sigma \in \Xi_{k-1}$ with $minCost(\sigma) = \min_{\sigma' \in C(\sigma)}(minCost(\sigma') + \lambda(\sigma'))$, after which the second algorithm invariant holds for all cells $\sigma \in \Xi_{k-1}$. We continue this process to set $minCost(\sigma)$ for cells in $\Xi_{k-2}, \Xi_{k-3}, \ldots, \Xi_0$. After that, the second algorithm invariant is established for all cells $\sigma \in \Xi$.

In addition, for each cell σ in the last cutting Ξ_k, in order to efficiently update $minCost(\sigma)$ once $\lambda(q)$ changes for a point $q \in Q(\sigma)$, we construct a min-heap $\mathcal{H}(\sigma)$ on all points q of $Q(\sigma)$ with the values $w(q) + \lambda(q)$ as “keys”. Using the heap, if $\lambda(q)$ changes for a point $q \in Q(\sigma)$, $minCost(\sigma)$ can be updated in $O(\log m)$ time as $|Q(\sigma)| \leq m$.

This finishes our preprocessing step for Algorithm 2. The following lemma analyzes the time complexity of the preprocessing.

▶ **Lemma 4.** *The preprocessing takes $O(n \log n + nr + m \log r)$ time.*

Proof. First of all, sorting P takes $O(n \log n)$ time. Constructing the hierarchical cutting Ξ takes $O(nr)$ time. Computing the lists $L(d_i)$ for all disks $d_i \in D$ also takes $O(nr)$ time. The point location procedure for computing the subsets $Q(\sigma)$ for all cells $\sigma \in \Xi_k$ runs in $O(m \log r)$ time. For the initialization step, setting $\mathcal{L}(Q) = \emptyset$ and $\lambda(\sigma) = 0$ for all cells $\sigma \in \Xi$

takes $O(r^2)$ time as $|\Xi| = O(r^2)$. Since Ξ_k has $O(r^2)$ cells, computing $minCost(\sigma)$ for all cells $\sigma \in \Xi_k$ can be done in $O(r^2 + \sum_{\sigma \in \Xi_k} |Q(\sigma)|)$ time, which is $O(r^2 + m)$ by Observation 2. Initializing $minCost(\sigma)$ for all other cells $\sigma \in \Xi \setminus \Xi_k$ takes $O(r^2)$ time since each cell has $O(1)$ children (and thus computing $minCost(\sigma)$ for each such cell σ takes $O(1)$ time). Finally, constructing a heap $\mathcal{H}(\sigma)$ for all cells $\sigma \in \Xi_k$ takes $O(\sum_{\sigma \in \Xi_k} |Q(\sigma)|)$ time, which is $O(m)$ by Observation 2. Since $r \leq n$, $r^2 \leq nr$. Therefore, the total time of the preprocessing is $O(n \log n + nr + m \log r)$. ◀

4.2 The FindMinCost operation

We now discuss how to perform the FindMinCost operation.

Consider a disk d_i in FindMinCost operation of the i-th iteration of Algorithm 2. The goal is to compute $\min_{q \in Q_{d_i}} cost(q)$, i.e., the minimum cost of all points of Q inside the disk d_i.

Recall that $L(d_i)$ is the list of all cells $\sigma \in \Xi$ such that $d_i \in D_\sigma$. Define $L_1(d_i)$ to be the set of all cells of $L(d_i)$ that are from Ξ_k and let $L_2(d_i) = L(d_i) \setminus L_1(d_i)$. Define $L_3(d_i)$ as the set of cells $\sigma \in \Xi$ such that σ's parent is in $L_2(d_i)$ and σ is completely contained in d_i. We first have the following observation following the definition of the hierarchical cutting.

▶ **Observation 5.** *Q_{d_i} is the union of $\bigcup_{\sigma \in L_1(d_i)} (Q(\sigma) \cap d_i)$ and $\bigcup_{\sigma \in L_3(d_i)} Q(\sigma)$.*

Proof. Consider a point $q \in \bigcup_{\sigma \in L_1(d_i)} (Q(\sigma) \cap d_i)$. Suppose that q is in $Q(\sigma) \cap d_i$ for some cell $\sigma \in L_1(d_i)$. Then, since $q \in d_i$, it is obvious true that $q \in Q_{d_i}$.

Consider a point $q \in \bigcup_{\sigma \in L_3(d_i)} Q(\sigma)$. Suppose that $q \in Q(\sigma)$ for some cell $\sigma \in L_3(d_i)$. By the definition of $L_3(d)$, σ is fully contained in d_i. Therefore, $q \in d_i$ holds. Hence, $q \in Q_{d_i}$.

On the other hand, consider a point $q \in Q_{d_i}$. By definition, d_i contains q. Let σ be the cell of Ξ_k containing q. Since both d_i and σ contain q, $d_i \cap \sigma \neq \emptyset$. Therefore, either $\sigma \subseteq d_i$ or the boundary of d_i crosses σ. In the latter case, we have $\sigma \in L_1(d_i)$ and thus $q \in \bigcup_{\sigma \in L_1(d_i)} (Q(\sigma) \cap d_i)$. In the former case, σ must have two ancestors σ_1 and σ_2 such that (1) σ_1 is the parent of σ_2; (2) σ_2 is fully contained in d_i; (3) the boundary of d_i crosses σ_1. This is true because σ is fully contained in d_i while the boundary of d_i crosses the only cell of Ξ_0, which is the entire plane and is an ancestor of σ. As such, σ_1 must be in $L_2(d_i)$ and σ_2 must be in $L_3(d_i)$. Therefore, q must be in $\bigcup_{\sigma \in L_3(d_i)} Q(\sigma)$.

This proves the observation. ◀

With Observation 5, we now describe our algorithm for FindMinCost. Let α be a variable, which is initialized to ∞. At the end of the algorithm, we will have $\alpha = \min_{q \in Q_{d_i}} cost(q)$. For each cell σ in the list $L(d_i)$, if it is from $\sigma \in \Xi_k$, i.e., $\sigma \in L_1(d_i)$, then we process σ as follows. For each point $q \in Q(\sigma)$, by Algorithm Invariant 1, we have $cost(q) = w(q) + \lambda(q) + \sum_{\sigma' \in A(\sigma)} \lambda(\sigma')$. If $q \in d_i$, we compute $cost(q)$ by visiting all cells of $A(\sigma)$, which takes $O(\log r)$ time, and then we update $\alpha = \min\{\alpha, cost(q)\}$.

If $\sigma \in L_2(d_i)$, then we process it as follows. For each child σ' of σ that is fully contained in d_i (i.e., $\sigma \in L_3(d_i)$), we compute $\alpha_{\sigma'} = minCost(\sigma') + \sum_{\sigma'' \in A(\sigma')} \lambda(\sigma'')$ by visiting all cells of $A(\sigma')$, which takes $O(\log r)$ time. By Observation 3, we have $\alpha_{\sigma'} = \min_{q \in Q(\sigma)} cost(q)$. Then we update $\alpha = \min\{\alpha, \alpha_{\sigma'}\}$. After processing every cell $\sigma \in L(d_i)$ as above, we return α, which is equal to $\min_{q \in Q_{d_i}} cost(q)$ according to our algorithm invariants as well as Observation 5. This finishes the FindMinCost operation. The following lemma analyzes the runtime of the operation.

▶ **Lemma 6.** *The total time of the FindMinCost operations in the entire Algorithm 2 is bounded by $O((nr + mn/r) \log r)$.*

Proof. Recall that in each operation we processes cells of $L_1(d_i)$ and cells of $L_2(d_i)$ in different ways. The total time of the operation is the sum of the time for processing $L_1(d_i)$ and the time for processing $L_2(d_i)$.

For the time for processing $L_1(d_i)$, for each cell $\sigma \in L_1(d_i)$, for each point $q \in Q(\sigma) \cap d_i$, we spend $O(\log r)$ time computing $cost(q)$. Hence, the time for processing cells of $L_1(d_i)$ for each d_i is bounded by $O(\sum_{\sigma \in L_1(d_i)} |Q(\sigma)| \log r)$. The total time of processing $L_1(d_i)$ in the entire algorithm is on the order of $\sum_{i=1}^{n} \sum_{\sigma \in L_1(d_i)} |Q(\sigma)| \cdot \log r = \sum_{\sigma \in \Xi_k} (|D_\sigma| \cdot |Q(\sigma)|) \cdot \log r$. Recall that $|D_\sigma| \leq n/r$ for each cell $\sigma \in \Xi_k$. Hence, $\sum_{\sigma \in \Xi_k} (|D_\sigma| \cdot |Q(\sigma)|) \leq n/r \cdot \sum_{\sigma \in \Xi_k} |Q(\sigma)|$, which is $O(mn/r)$ by Observation 2. Therefore, the total time for processing cells of $L_1(d_i)$ in the entire Algorithm 2 is $O(mn/r \cdot \log r)$.

For the time for processing $L_2(d_i)$, for each cell $\sigma \in L_2(d_i)$, for each child σ' of σ, it takes $O(\log r)$ time to compute $\alpha_{\sigma'}$. Since σ has $O(1)$ cells, the total time for processing all cells of $L_2(d_i)$ is $O(|L_2(d_i)| \cdot \log r)$. The total time of processing $L_2(d_i)$ in the entire algorithm is on the order of $\sum_{i=1}^{n} |L_2(d_i)| \cdot \log r$. Note that $\sum_{i=1}^{n} |L_2(d_i)| \leq \sum_{i=1}^{n} |L(d_i)| = O(nr)$. Therefore, the total time for processing cells of $L_2(d_i)$ in the entire Algorithm 2 is $O(nr \log r)$.

Summing up the time for processing $L_1(d_i)$ and $L_2(d_i)$ leads to the lemma. ◀

4.3 The ResetCost operation

We now discuss the ResetCost operation. Consider the ResetCost operation in the i-th iteration of Algorithm 2. The goal is to reset $cost(q) = w(q) + \delta_i$ for all points $q \in Q$ that are outside the disk d_i. To this end, we will update our data structure, and more specifically, update the $\lambda(\cdot)$ and $minCost(\cdot)$ values for certain cells of Ξ and points of Q so that the algorithm invariants still hold.

Define $L_4(d_i)$ as the set of cells $\sigma \in \Xi$ such that σ's parent is in $L_2(d_i)$ and σ is completely outside d_i. Let $\overline{d_i}$ denote the region of the plane outside the disk d_i. We have the following observation, which is analogous to Observation 5.

▶ **Observation 7.** *$\overline{Q_{d_i}}$ is the union of $\bigcup_{\sigma \in L_1(d_i)} (Q(\sigma) \cap \overline{d_i})$ and $\bigcup_{\sigma \in L_4(d_i)} Q(\sigma)$.*

Proof. The proof is the same as that of Observation 5 except that we use $\overline{d_i}$ to replace d_i and use $L_4(d_i)$ to replace $L_3(d_i)$. We omit the details. ◀

Our algorithm for ResetCost works as follows. Consider a cell $\sigma \in L(d_i)$. As for the FindMinCost operation, depending on whether σ is from $L_1(d_i)$ or $L_2(d_i)$, we process it in different ways.

If σ is from $L_1(d_i)$, we process σ as follows. For each point $q \in Q(\sigma)$, if $q \in \overline{d_j}$, then we are supposed to reset $cost(q)$ to $w(q) + \delta_i$. To achieve the effect and also maintain the algorithm invariants, we do the following. First, we set $\lambda(q) = \delta_i - \sum_{\sigma' \in A(\sigma)} \lambda(\sigma')$, which can be done in $O(\log r)$ time by visiting the ancestors of σ. As such, we have $w(q) + \lambda(q) + \sum_{\sigma' \in A(\sigma)} \lambda(\sigma') = w(q) + \delta_i$, which establishes the first algorithm invariant for q. For the second algorithm invariant, we first update $minCost(\sigma)$ using the heap $\mathcal{H}(\sigma)$, i.e., by updating the key of q to the new value $w(q) + \lambda(q)$. The heap operation takes $O(\log m)$ time. Next, we update $minCost(\sigma')$ for all ancestors σ' of σ in a bottom-up manner using the formula $minCost(\sigma') = \min_{\sigma'' \in C(\sigma')}(minCost(\sigma'') + \lambda(\sigma''))$. Since each cell has $O(1)$ children, updating all ancestors of σ takes $O(\log r)$ time. This establishes the second algorithm invariant. Finally, since $\lambda(q)$ has just been changed, if $\lambda(q) \neq 0$, then we add q to the list $\mathcal{L}(\sigma')$ for all cells $\sigma' \in A(\sigma)$. Note that for each such $\mathcal{L}(\sigma')$ it is possible that q was already in the list before; but we do not check this and simply add q to the end of the list (and thus the list may contain multiple copies of q). This finishes the processing of q, which takes $O(\log r + \log m)$ time. Processing all points of $q \in Q(\sigma)$ as above takes $O(|Q(\sigma)| \cdot (\log r + \log m))$ time.

If σ is from $L_2(d_i)$, then we process σ as follows. For each child σ' of σ, if σ' is completely outside d_i, then we process σ' as follows. We are supposed to reset $cost(q)$ to $w(q) + \delta_i$ for all points $q \in Q(\sigma')$. In other words, the first algorithm invariant does not hold any more and we need to update our data structure to restore it. Note that the second algorithm invariant still holds. To achieve the effect and also maintain the algorithm invariants, we do the following. For each element e in the list $\mathcal{L}(\sigma')$ (recall that e is either a cell of $B(\sigma')$ or a point of $Q(\sigma')$), we process e as follows. First, we remove e from $\mathcal{L}(\sigma')$. Then we reset $\lambda(e) = 0$. If e is a point of $Q(\sigma')$, then let σ_e be the cell of Ξ_k that contains e; otherwise, e is a cell of $B(\sigma')$ and let σ_e be the parent of e. Since $\lambda(e)$ is changed, we update $minCost(\sigma'')$ for all cells $\sigma'' \in A(\sigma_e)$ in the same way as above in the first case for processing $L_1(d_i)$, which takes $O(\log r + \log m)$ time. This finishes processing e, after which the second algorithm invariant still holds. After all elements of $\mathcal{L}(\sigma')$ are processed as above, $\mathcal{L}(\sigma')$ becomes $\emptyset$ and we reset $\lambda(\sigma') = \delta_i - \sum_{\sigma'' \in A(\sigma') \setminus \{\sigma'\}} \lambda(\sigma'')$. Since $\lambda(\sigma')$ has been changed, we update $minCost(\sigma'')$ for all cells $\sigma'' \in A(\sigma)$ in the same way as before (which takes $O(\log r)$ time), after which the second algorithm invariant still holds. In addition, if $\lambda(\sigma') \neq 0$, then we add σ' to the list $\mathcal{L}(\sigma'')$ for all cells $\sigma'' \in A(\sigma)$, which again takes $O(\log r)$ time. This finishes processing σ', which takes $O(|\mathcal{L}(\sigma')| \cdot (\log r + \log m))$ time. It remains to restore the first algorithm invariant, for which we have the following observation.

▶ **Observation 8.** *After σ' is processed, the first algorithm invariant is established for all points $q \in Q(\sigma')$.*

Proof. Consider a point $q \in Q(\sigma')$. It suffices to show $w(q) + \delta_i = w(q) + \lambda(q) + \sum_{\sigma'' \in A(\sigma_q)} \lambda(\sigma'')$, where σ_q is the cell of Ξ_k that contains q. After the elements of the list $\mathcal{L}(\sigma')$ are processed as above, we have $\lambda(q) = 0$ for all points $q \in Q(\sigma')$ and $\lambda(\sigma'') = 0$ for all descendants σ'' of σ'. Therefore, $w(q) + \lambda(q) + \sum_{\sigma'' \in A(\sigma_1)} \lambda(\sigma_1) = w(q) + \sum_{\sigma'' \in A(\sigma')} \lambda(\sigma'') = w(q) + \lambda(\sigma') + \sum_{\sigma'' \in A(\sigma') \setminus \{\sigma'\}} \lambda(\sigma'')$. Recall that $\lambda(\sigma') = \delta_i - \sum_{\sigma'' \in A(\sigma') \setminus \{\sigma'\}} \lambda(\sigma'')$. We thus obtain $w(q) + \lambda(q) + \sum_{\sigma'' \in A(\sigma_q)} \lambda(\sigma'') = w(q) + \delta_i$. ◀

This finishes the ResetCost operation. According to Observation 7, $cost(q)$ has been reset for all points $q \in Q$ that are outside d_i. The following lemma analyzes the runtime of the operation.

▶ **Lemma 9.** *The total time of the ResetCost operations in the entire Algorithm 2 is bounded by $O((nr + mn/r) \cdot \log r \cdot (\log r + \log m))$.*

Proof. Recall that we processes cells of $L_1(d_i)$ and cells of $L_2(d_i)$ in different ways. The total time of the operation is the sum of the time for processing $L_1(d_i)$ and the time for processing $L_2(d_i)$.

For the time for processing $L_1(d_i)$, for each cell $\sigma \in L_1(d_i)$, recall that processing all points of $Q(\sigma)$ takes $O(|Q(\sigma)| \cdot (\log r + \log m))$ time. Hence, the total time for processing cells of $L_1(d_i)$ is on the order of $\sum_{\sigma \in L_1(d_i)} |Q(\sigma)| \cdot (\log r + \log m)$. The total time for processing cells of $L_1(d_i)$ in the entire Algorithm 2 is thus on the order of $\sum_{i=1}^{n} \sum_{\sigma \in L_1(d_i)} |Q(\sigma)| \cdot (\log r + \log m)$. As analyzed in the proof of Lemma 6, $\sum_{i=1}^{n} \sum_{\sigma \in L_1(d_i)} |Q(\sigma)| = O(mn/r)$. Therefore, the total time for processing cells of $L_1(d_i)$ in the entire Algorithm 2 is $O(mn/r \cdot (\log r + \log m))$.

For the time for processing $L_2(d_i)$, for each cell $\sigma \in L_2(d_i)$, for each child σ' of σ, processing σ' takes $O(|\mathcal{L}(\sigma')| \cdot (\log r + \log m))$ time. Next, we give an upper bound for $|\mathcal{L}(\sigma')|$ for all such cells σ' in the entire algorithm. Recall that each element e of $\mathcal{L}(\sigma')$ is either a point $q \in Q(\sigma')$ or a descendant cell $\sigma'' \in B(\sigma')$. Let $\mathcal{L}_1(\sigma')$ denote the subset of elements of $\mathcal{L}(\sigma')$ in the former case and $\mathcal{L}_2(\sigma')$ the subset of elements in the latter case. In the following we provide an upper bound for each subset.

1. For $\mathcal{L}_1(\sigma')$, notice that a point q is in the list only if σ_q is crossed by the lower arc of a disk d_i, where σ_q is the cell of Ξ_k containing q. If q is outside d_i, then a copy of q will be added to $\mathcal{L}(\sigma'')$ for all $O(\log r)$ cells σ'' of $A(\sigma_q)$. As $|D_{\sigma_q}| \leq n/r$, the number of elements in $\mathcal{L}_1(\sigma')$ contributed by the points of $Q(\sigma_q)$ for all such cells σ' in the entire algorithm is bounded by $O(|Q(\sigma_q)| \cdot n/r \cdot \log r)$. In light of Observation 2, the total size of $\mathcal{L}_1(\sigma')$ of all such cells σ' in the entire Algorithm 2 is $O(mn/r \cdot \log r)$.
2. For $\mathcal{L}_2(\sigma')$, observe that a cell σ_1 is in the list only if σ_2 is crossed by the lower arc of a disk d_i, where σ_2 is the parent of σ_1. If σ_1 is completely outside d_i, then a copy of σ_1 is added to $\mathcal{L}(\sigma'')$ for all $O(\log r)$ cells σ'' of $A(\sigma_2)$. As such, the number of elements in $\mathcal{L}_2(\sigma')$ for all such cells σ' in the entire algorithm contributed by each cell $\sigma_1 \in \Xi$ is bounded by $O(|D_{\sigma_2}| \cdot \log r)$. Since every cell of Ξ has $O(1)$ children and $\sum_{\sigma_2 \in \Xi} |D_{\sigma_2}| = O(nr)$, the total size of $\mathcal{L}_2(\sigma')$ of all such cells σ' in the entire Algorithm 2 is $O(nr \cdot \log r)$.

Therefore, the total time for processing cells of $L_2(d_i)$ in the entire Algorithm 2 is $O((nr + mn/r) \cdot \log r \cdot (\log r + \log m))$.

Summing up the time for processing $L_1(d_i)$ and $L_2(d_i)$ leads to the lemma. ◀

4.4 Putting it all together

We summarize the time complexity of the overall algorithm. By Lemma 4, the preprocessing step takes $O(n \log n + nr + m \log r)$ time. By Lemma 6, the total time for performing the FindMinCost operations in the entire algorithm is $O((nr + mn/r) \cdot \log r)$. By Lemma 9, the total time for performing the ResetCost operations in the entire algorithm is $O((nr + mn/r) \cdot \log r \cdot (\log m + \log r))$. Therefore, the total time of the overall algorithm is $O(n \log n + m \log r + (nr + mn/r) \cdot \log r \cdot (\log m + \log r))$. Recall that $1 \leq r \leq n$. Setting $r = \min\{\sqrt{m}, n\}$ gives the upper bound $O(n\sqrt{m} \log^2 m + (n + m) \log(n + m))$ for the time complexity of the overall algorithm.

Note that we have assumed that each point of P is covered by at least one disk of S. In this is not the case, then no feasible subset exists (alternatively, one may consider the optimal objective value ∞); if we run our algorithm in this case, then one can check that the value δ_n returned by our algorithm is ∞. Hence, our algorithm can automatically determine whether a feasible subset exists.[2]

▶ **Theorem 10.** *Given a set of n points and a set of m weighted unit disks in the plane such that the points and the disk centers are separated by a line, there is an $O(n\sqrt{m} \log^2 m + (n + m) \log(n + m))$ time algorithm to compute a subset of disks of minimum total weight whose union covers all points.*

Streaming in Graph Products

Markus Lohrey
Universität Siegen, Germany

Julio Xochitemol
Universität Siegen, Germany

Abstract

We investigate the streaming space complexity of word problems for groups. Using so-called distinguishers, we prove a transfer theorem for graph products of groups. Moreover, we use distinguishers to obtain a logspace streaming algorithm for the membership problem in a finitely generated subgroup of a free group.

1 Introduction

The word problem for a fixed finitely generated (f.g. for short) group G is the following computational problem: Fix a finite set of generators Σ for G, which means that every element of G can be written as a finite product of elements from Σ. The input for the word problem is a finite word $a_1 a_2 \cdots a_n$ over the alphabet Σ and the question is whether this word evaluates to the group identity of G. The word problem was introduced by Dehn in 1911 [5]. It is arguably the most important computational problem in group theory and has been studied by group theorists as well as computer scientists. In general, the word problem is undecidable [4, 20], but for many classes of groups (e.g. linear groups, metabelian groups, hyperbolic groups) efficient algorithms exist; see e.g. [15] for an overview.

In [16, 17] we started to investigate streaming algorithms for the word problem of a group G. The input stream is a word $w \in \Sigma^*$ over the generators and the algorithm has to decide whether $w = 1$ holds in the group G. This can be viewed as a streaming algorithm for the formal language $\{w \in \Sigma^* : w = 1 \text{ in } G\}$. Streaming algorithms for formal languages (mainly subclasses of context-free languages) have been studied in [1, 2, 7, 18]. In [16, 17] we consider the space complexity of streaming algorithms. For deterministic streaming algorithms it turnes out that the space complexity of the word problem for a f.g. group G is tightly related to the growth of G: if $\gamma(n)$ is the growth function of G (which is the number of different group elements that can be represented by words of length at most n over the generating set), then the space complexity of the best deterministic streaming algorithm for the word problem of G is roughly $\log \gamma(n/2)$. This result basically reduces the study of deterministic streaming algorithms for word problems to the study of growth in groups, which is an important research area in geometric group theory with many deep results.

In [16, 17] we therefore mainly focus on randomized streaming algorithms for word problems. For this it turns out to be useful to consider so called distinguishers for groups. Roughly speaking, a distinguisher for a f.g. group G with finite generating set Σ is a randomized streaming algorithm $\mathcal{A}$ such that for all words $u, v \in \Sigma^*$ of length at most n we have that: (i) if u and v evaluate to the same element of G then with high probability, u and

v lead to the same memory state of $\mathcal{A}$, and (ii) if u and v evaluate to different elements of G then with high probability, u and v lead to different memory states of $\mathcal{A}$; see Section 4. It is easy to obtain from a distinguisher $\mathcal{R}$ for the group G a randomized streaming algorithm $\mathcal{S}$ for the word problem of G (with low error probability). Moreover, the space complexity of $\mathcal{S}$ is only twice the space complexity of $\mathcal{R}$; see Lemma 3.

We showed in [16, 17] that for many important f.g. groups G there exist logspace distinguishers with error probability $1/n^c$ for any constant $c > 1$, where n is the input length. This is in particular the case for f.g. linear groups (matrix groups). In general, the growth of a linear group can be $2^{\Theta(n)}$ (take for instance a free group of rank 2), and therefore its deterministic streaming space complexity can be $\Theta(n)$, which is the worst case (the streaming algorithms can always store the whole prefix of the input stream). We proved in [17] also the following transfer theorem for wreath products: If G is a f.g. group having a distinguisher with space complexity $s(n)$ and error probability $\epsilon(n)$ and A is a f.g. abelian group then there is a distinguisher for the wreath product $A \wr G$ having space complexity $\mathcal{O}(s(n) + \log n)$ and error probability roughly $n^2\epsilon(n)$. Interestingly, if H is any non-abelian group then any randomized streaming algorithm with error at most $1/2 - \epsilon$ for the word problem of $H \wr G$ must have the worst-case space complexity $\Theta(n)$; see [16, Theorem 21].

The first main result of the paper states a similar transfer theorem for *graph products*. This is an important construction in group theory that generalizes the direct product as well as the free product. It can be seen as a partially commutative version of the free product, where some of the factors G_i in a free product $G_1 * G_2 * \cdots * G_k$ are allowed to commute. Which of G_i commute is specified by a graph on the index set $\{1, \dots, k\}$. We show that if every group G_i ($1 \leq i \leq k$) has a distinguisher with space complexity at most $s(n)$ and error probability $\epsilon(n)$, then every graph product of the groups G_i has a distinguisher with space complexity $\mathcal{O}(s(n) + \log n)$ and error probability roughly $n^2\epsilon(n)$ (Theorem 9). As a corollary we obtain for instance a randomized streaming algorithm with logarithmic space complexity for the word problem of a graph product of linear groups. Theorem 9 is similar to the following result from [6]: If the word problem for every group G_i can be solved in deterministic logspace on a Turing machine then the same is true for every graph product of the G_i. Kausch in his thesis [13] strengthened this result by showing that the word problem of the graph product is AC_0-Turing-reducible to the word problems of the G_i ($1 \leq i \leq k$) and the free group of rank two.

Our second main contribution deals with randomized streaming algorithms for subgroup membership problems. In a subgroup membership problem one has a subgroup H of a f.g. group G. For an input word $w \in \Sigma^*$ (Σ is again a finite set of generators for G) one has to determine whether w represents an element of H. The word problem is the special case where $H = 1$. We present a randomized streaming algorithm with logarithmic space complexity for the case where G is a f.g. free group and H is a f.g. subgroup of G (Theorem 14). Moreover, we show that this result extends neither to the case where H is not finitely generated (Theorem 15) nor the case where H is a finitely generated subgroup of a direct product of two free groups of rank two (Theorem 16).

2 Preliminaries

For integers $a < b$ let $[a, b]$ be the integer interval $\{a, a + 1, \dots, b\}$. We write $[0, 1]_{\mathbb{R}}$ for the set $\{r \in \mathbb{R} \colon 0 \leq r \leq 1\}$ of all probabilities.

Let Σ be a finite alphabet. As usual we write Σ^* for the set of all finite words over the alphabet w. The empty word is denoted with ε. For a word $w = a_1 a_2 \cdots a_n$ ($a_1, a_2, \dots, a_n \in \Sigma$) let $|w| = n$ be its length and $w[i] = a_i$ (for $1 \leq i \leq n$) the symbol at position i.

A prefix of a word w is a word u such that $w = uv$ for some word v. We denote with $\mathcal{P}(w)$ the set of all prefixes of w. Let $\Sigma^+ = \Sigma^* \setminus \{\varepsilon\}$ be the set of non-empty words and $\Sigma^{\leq n} = \{w \in \Sigma^* \colon |w| \leq n\}$ be the set of all words of length at most n. For a subalphabet $\Theta \subseteq \Sigma$ we denote with $\pi_\Theta : \Sigma^* \to \Theta^*$ the projection homomorphism that deletes all symbols from $\Sigma \setminus \Theta$ in a word: $\pi_\Theta(a) = a$ for $a \in \Theta$ and $\pi_\Theta(a) = \varepsilon$ for $a \in \Sigma \setminus \Theta$.

2.1 Sequential transducer

In Section 5 we make use of (left-)sequential transducers, see e.g. [3] for more details. A sequential transducer is a tuple $\mathcal{T} = (Q, \Sigma, \Gamma, q_0, \delta)$, where Q is a finite set of states, Σ is the input alphabet, Γ is the output alphabet, $q_0 \in Q$ is the initial state, and $\delta : Q \times \Sigma \to Q \times \Gamma^*$ is the transition function. The meaning of $\delta(q, a) = (p, u)$ is that if $\mathcal{T}$ is in state q and the next input symbol is a then it moves to state p and outputs the word u. We extend δ to a mapping $\delta : Q \times \Sigma^* \to Q \times \Gamma^*$ as follows, where $q \in Q$, $a \in \Sigma$ and $w \in \Sigma^*$:

- $\delta(q, \varepsilon) = (q, \varepsilon)$ for all $q \in Q$, and
- if $\delta(q, a) = (p, u)$ and $\delta(p, w) = (r, v)$ then $\delta(q, aw) = (r, uv)$.

We define the function $f_\mathcal{T} : \Sigma^* \to \Gamma^*$ computed by $\mathcal{T}$ by $f_\mathcal{T}(w) = x$ if and only if $\delta(q_0, w) = (q, x)$ for some $q \in Q$. Intuitively, in order compute $f_\mathcal{T}(w)$, $\mathcal{T}$ reads the word w starting in the initial state q_0 and thereby concatenates all the outputs produced in the transitions.

2.2 Probabilistic finite automata

In the following we introduce probabilistic finite automata [21, 22] as a model for randomized streaming algorithms. A *probabilistic finite automaton* (PFA) $\mathcal{A} = (Q, \Sigma, \iota, \rho, F)$ consists of a finite set of states Q, a finite alphabet Σ, an *initial state distribution* $\iota\colon Q \to [0,1]_\mathbb{R}$, a *transition probability function* $\rho\colon Q \times \Sigma \times Q \to [0,1]_\mathbb{R}$ and a set of final states $F \subseteq Q$ such that $\sum_{q \in Q} \iota(q) = 1$ and $\sum_{q \in Q} \rho(p, a, q) = 1$ for all $p \in Q$, $a \in \Sigma$. If ρ is required to map into $\{0, 1\}$, then $\mathcal{A}$ is a *semi-probabilitistic finite automaton* (semiPFA). This means that after choosing the initial state according to the distribution ι, $\mathcal{A}$ proceeds deterministically.

Let $\mathcal{A} = (Q, \Sigma, \iota, \rho, F)$ be a PFA. For a random variable X with values from Q and $a \in \Sigma$ we define the random variable $X \cdot a$ (which also takes values from Q) by

$$\mathsf{Prob}[X \cdot a = q] = \sum_{p \in Q} \mathsf{Prob}[X = p] \cdot \rho(p, a, q).$$

For a word $w \in \Sigma^*$ we define a random variable $\mathcal{A}(w)$ with values from Q inductively as follows: the random variable $\mathcal{A}(\varepsilon)$ is defined such that $\mathsf{Prob}[\mathcal{A}(\varepsilon) = q] = \iota(q)$ for all $q \in Q$. Moreover, $\mathcal{A}(wa) = \mathcal{A}(w) \cdot a$ for all $w \in \Sigma^*$ and $a \in \Sigma$. Thus, $\mathsf{Prob}[\mathcal{A}(w) = q]$ is the probability that $\mathcal{A}$ is in state q after reading w. For a language $L \subseteq \Sigma^*$, the *error probability* of $\mathcal{A}$ on $w \in \Sigma^*$ for L is

$$\epsilon(\mathcal{A}, w, L) = \begin{cases} \mathsf{Prob}[\mathcal{A}(w) \notin F] & \text{if } w \in L, \\ \mathsf{Prob}[\mathcal{A}(w) \in F] & \text{if } w \notin L. \end{cases}$$

If $\mathcal{A}$ is a semiPFA then we can identify ρ with a mapping $\rho : Q \times \Sigma \to Q$, where $\rho(p, a)$ is the unique state q with $\rho(p, a, q) = 1$. This mapping ρ is extended to a mapping $\rho : Q \times \Sigma^* \to Q$ in the usual way: $\rho(p, \varepsilon) = p$ and $\rho(p, aw) = \rho(\rho(p, a), w)$. We then obtain

$$\mathsf{Prob}[\mathcal{A}(w) = q] = \sum \{\iota(p) : p \in Q, \rho(p, w) = q\}.$$

For a semiPFA $\mathcal{A} = (Q, \Sigma, \iota, \rho, F)$ and a boolean condition $\mathcal{E} : Q \to \{0, 1\}$ we define the probability $\mathsf{Prob}_{q \in Q}[\mathcal{E}(q)] = \sum\{\iota(q) : q \in Q, \mathcal{E}(q) = 1\}$. SemiPFAs are needed in Section 4 for the notion of a distinguisher.

2.3 Randomized streaming algorithms

In this section we define our model of randomized streaming algorithms. It is a non-uniform model in the sense that for every input length n we have a separate algorithm that handles inputs of length at most n. Formally, a (non-uniform) *randomized streaming algorithm* is a sequence $\mathcal{R} = (\mathcal{A}_n)_{n \geq 0}$ of PFA $\mathcal{A}_n$ over the same alphabet Σ. If every $\mathcal{A}_n$ is a semiPFA, we speak of a *semi-randomized streaming algorithm.*

Let $\epsilon_0, \epsilon_1 : \mathbb{N} \to [0,1]_{\mathbb{R}}$ be monotonically decreasing functions. A randomized streaming algorithm $\mathcal{R} = (\mathcal{A}_n)_{n \geq 0}$ is (ϵ_0, ϵ_1)*-correct* for a language $L \subseteq \Sigma^*$ if for every large enough $n \geq 0$ and every word $w \in \Sigma^{\leq n}$ we have the following:

- if $w \in L$ then $\epsilon(\mathcal{A}_n, w, L) \leq \epsilon_1(n)$, and
- if $w \notin L$ then $\epsilon(\mathcal{A}_n, w, L) \leq \epsilon_0(n)$.

If $\epsilon_0 = \epsilon_1 =: \epsilon$ then we also say that $\mathcal{R}$ is ϵ-correct for L. We say that $\mathcal{R}$ is a randomized streaming algorithm for L if it is $1/3$-correct for L. The choice of $1/3$ for the error probability is not important. Using a standard application of the Chernoff bound, one can make the error probability an arbitrarily small constant; see [17, Theorem 4.1].

The *space complexity* of the randomized streaming algorithm $\mathcal{R} = (\mathcal{A}_n)_{n \geq 0}$ is the function $s(\mathcal{R}, n) = \lceil \log_2 |Q_n| \rceil$, where Q_n is the state set of $\mathcal{A}_n$. The motivation for this definition is that states of Q_n can be encoded by bit strings of length at most $\lceil \log_2 |Q_n| \rceil$. The *randomized streaming space complexity of the language* L is the smallest possible function $s(\mathcal{R}, n)$, where $\mathcal{R}$ is a randomized streaming algorithm for L. It is always bounded by $\mathcal{O}(n)$ since even a deterministic streaming algorithm can store the whole input word $w \in \Sigma^{\leq n}$ using $\mathcal{O}(n)$ bits.

As remarked before, our model of randomized streaming algorithms is non-uniform in the sense that for every input length n we have a separate streaming algorithm $\mathcal{A}_n$. This makes lower bounds of course stronger. On the other hand, the randomized streaming algorithms that we construct for concrete groups will be mostly uniform in the sense that there is an efficient algorithm that constructs from a given n the PFA $\mathcal{A}_n$. An exception is the following theorem (see [17, Theorem 4.3]), which uses non-uniformity in a crucial way.

▶ **Theorem 1.** *Let $\mathcal{R}$ be a randomized streaming algorithm such that $s(\mathcal{R}, n) \geq \Omega(\log n)$ and $\mathcal{R}$ is ϵ-correct for a language L. Then there exists a semi-randomized streaming algorithm $\mathcal{S}$ such that $s(\mathcal{S}, n) = \Theta(s(\mathcal{R}, n))$ and $\mathcal{S}$ is 2ϵ-correct for the language L.*

3 Groups and word problems

Let G be a group. The identity element will be always denoted with 1. For a subset $\Sigma \subseteq G$, we denote with $\langle \Sigma \rangle$ the subgroup of G generated by Σ. It is the set of all products of elements from $\Sigma \cup \Sigma^{-1}$. It can be also defined as the smallest (w.r.t. inclusion) subgroup of G that contains Σ. Similarly, the *normal closure* $N(\Sigma)$ of Σ is smallest normal subgroup of G that contains Σ. In this case, one gets the quotient group $G/N(\Sigma)$.

We only consider *finitely generated* (f.g.) groups G, for which there is a finite set $\Sigma \subseteq G$ with $G = \langle \Sigma \rangle$; such a set Σ is called a *finite generating set* for G. If $\Sigma = \Sigma^{-1}$ then we say that Σ is a *finite symmetric generating set* for G. In the following we assume that all finite generating sets are symmetric. Every word $w \in \Sigma^*$ evaluates to a group element $\pi_G(w)$ in the natural way; here $\pi_G : \Sigma^* \to G$ is the canonical morphism from the free monoid Σ^* to G that is the identity on Σ. Instead of $\pi_G(u) = \pi_G(v)$ we also write $u \equiv_G v$. Let $\mathsf{WP}(G, \Sigma) = \{w \in \Sigma^* \mid \pi_G(w) = 1\}$ be the *word problem for* G with respect to the generating set Σ.

We are interested in streaming algorithms for words problems $\mathsf{WP}(G, \Sigma)$. By the following lemma (see [17, Lemma 5.1]) the randomized streaming space complexity for a word problem only changes by a constant when the generating set is changed.

▶ **Lemma 2.** *Let Σ_1 and Σ_2 be finite symmetric generating sets for the group G and let $s_i(n)$ be the randomized streaming space complexity of $\mathsf{WP}(G, \Sigma_i)$. Then there exists a constant c that depends on G, Σ_1 and Σ_2 such that $s_1(n) \leq s_2(c \cdot n)$.*

4 Distinguishers for groups

Let G be a f.g. group G with the finite generating set Σ. Moreover, let $\epsilon_0, \epsilon_1 : \mathbb{N} \to [0,1]_{\mathbb{R}}$ be monotonically decreasing functions. A *semi-randomized* streaming algorithm $(\mathcal{A}_n)_{n\geq 0}$ with $\mathcal{A}_n = (Q_n, \Sigma, \iota_n, \rho_n, F_n)$ is called an (ϵ_0, ϵ_1)*-distinguisher* for G (with respect to Σ), if the following properties hold for all large enough $n \geq 0$ and all words $u, v \in \Sigma^{\leq n}$:

- If $u \equiv_G v$ then $\mathsf{Prob}_{q\in Q_n}[\rho_n(q,u) = \rho_n(q,v)] \geq 1 - \epsilon_1(n)$. In other words: for a randomly chosen initial state, the semiPFA $\mathcal{A}_n$ arrives with probability at least $1 - \epsilon_1(n)$ in the same state after reading u and v.
- If $u \not\equiv_G v$ then $\mathsf{Prob}_{q\in Q_n}[\rho_n(q,u) \neq \rho_n(q,v)] \geq 1 - \epsilon_0(n)$. In other words: for a randomly chosen initial state, the semiPFA $\mathcal{A}_n$ arrives with probability at least $1 - \epsilon_0(n)$ in different states after reading u and v.

Note that the set F_n of final states of $\mathcal{A}_n$ is not important for a distinguisher and we will just write $\mathcal{A}_n = (Q_n, \Sigma, \iota_n, \rho_n)$ in the following if we talk about an (ϵ_0, ϵ_1)-distinguisher $(\mathcal{A}_n)_{n\geq 0}$. The following result is shown in [17].

▶ **Lemma 3.** *Let $\mathcal{R}$ be an (ϵ_0, ϵ_1)-distinguisher for G with respect to Σ. Then $\mathsf{WP}(G, \Sigma)$ has an (ϵ_0, ϵ_1)-correct semi-randomized streaming algorithm with space complexity $2 \cdot s(\mathcal{R}, n)$.*

Due to Lemma 3, our goal in the rest of the paper will be the construction of space efficient (ϵ_0, ϵ_1)-distinguishers for groups. In the next section we will need some further observations on (ϵ_0, ϵ_1)-distinguishers that we introduce in the rest of this section.

For equivalence relations $\equiv_1$ and $\equiv_2$ on a set A and a subset $S \subseteq A$ we say that:

- $\equiv_1$ refines $\equiv_2$ on S if for all $a, b \in S$ we have: if $a \equiv_1 b$ then $a \equiv_2 b$;
- $\equiv_1$ equals $\equiv_2$ on S if for all $a, b \in S$ we have: $a \equiv_1 b$ if and only if $a \equiv_2 b$.

For a semiPFA $\mathcal{A} = (Q, \Sigma, \iota, \rho)$ and a state $q \in Q$ we define the equivalence relation $\equiv_{\mathcal{A},q}$ on Σ^* as follows: $u \equiv_{\mathcal{A},q} v$ if and only if $\rho(q,u) = \rho(q,v)$. Whenever $\mathcal{A}$ is clear from the context, we just write $\equiv_q$ instead of $\equiv_{\mathcal{A},q}$. The statements from the following lemma can be shown by straightforward applications of the union bound; see [17].

▶ **Lemma 4.** *Let $(\mathcal{A}_n)_{n\geq 0}$ be an (ϵ_0, ϵ_1)-distinguisher for the f.g. group G with respect to the generating set Σ. Let $\mathcal{A}_n = (Q_n, \Sigma, \iota, \rho)$. Consider a set $S \subseteq \Sigma^{\leq n}$. Then, the following statements hold, where $\equiv_q$ refers to $\mathcal{A}_n$:*

- $\mathsf{Prob}_{q\in Q_n}[\equiv_G$ *equals* $\equiv_q$ *on* $S] \geq 1 - \max\{\epsilon_0(n), \epsilon_1(n)\}\binom{|S|}{2}$,
- $\mathsf{Prob}_{q\in Q_n}[\equiv_G$ *refines* $\equiv_q$ *on* $S] \geq 1 - \epsilon_1(n)\binom{|S|}{2}$,
- $\mathsf{Prob}_{q\in Q_n}[\equiv_q$ *refines* $\equiv_G$ *on* $S] \geq 1 - \epsilon_0(n)\binom{|S|}{2}$.

The following two simple lemmas are needed in Section 5; their proofs can be found in [17]. Recall that for a word w we write $\mathcal{P}(w)$ for the set of all prefixes of w.

▶ **Lemma 5.** *Let G be a f.g. group with the finite generating set Σ and let $\mathcal{A} = (Q, \Sigma, \iota, \rho)$ be a semiPFA with $q \in Q$. Consider $u, v \in \Sigma^*$ such that $\equiv_G$ refines $\equiv_q$ on $\mathcal{P}(u) \cup \mathcal{P}(v)$ and let $u = xyz$ with $y \equiv_G 1$. Then $\equiv_G$ refines $\equiv_q$ on $\mathcal{P}(xz) \cup \mathcal{P}(v)$.*

▶ **Lemma 6.** *Let G, $\mathcal{A}$, and q be as in Lemma 5. Consider $u, v \in \Sigma^*$ such that $\equiv_q$ refines $\equiv_G$ on $\mathcal{P}(u) \cup \mathcal{P}(v)$ and let $u = xyz$ with $\rho(q, x) = \rho(q, xy)$. Then $\equiv_q$ refines $\equiv_G$ on $\mathcal{P}(xz) \cup \mathcal{P}(v)$.*

Finally we state the following result from [17, Theorem 9.1]. Recall that a linear group is a group of matrices over some field.

▶ **Theorem 7.** *For every f.g. linear group G and every $c > 0$ there exists a $(1/n^c, 0)$-distinguisher with space complexity $\mathcal{O}(\log n)$.*

Theorem 7 can serve as a basis for the construction of further distinguishers. Note that in the positive case (where $u \equiv_G v$) the error probability is zero.

5 Randomized streaming algorithms for graph products

In this section we investigate a common generalization of the free product and direct product, which is known as the graph product of groups.

Let us first define the free product of two groups G and H. Let $A = G \setminus \{1\}$ and $B = H \setminus \{1\}$. W.l.o.g. we assume that $A \cap B = \emptyset$. The *free product* $G * H$ consists of all alternating sequences $a_1 a_2 \cdots a_n$ where $n \geq 0$, $a_i \in A \cup B$ for all $i \in [1, n]$ and $a_i \in A \Leftrightarrow a_{i+1} \in B$ for all $i \in [1, n-1]$. The identity element is of course the empty sequence ε. The product $u \cdot v$ of two elements $u, v \in G * H$ is obtained by concatenating u and v and then making the obvious simplifications according to the multiplication tables of G and H. More precisely, let $u = a_n a_{n-1} \cdots a_1$ and $v = b_1 b_2 \cdots b_m$. If $n = 0$ then $u \cdot v = v$ and if $m = 0$ then $u \cdot v = u$. Now assume that $n > 0$ and $m > 0$. If $a_1 \in A \Leftrightarrow b_1 \in B$ then $u \cdot v = a_n a_{n-1} \cdots a_1 b_1 b_2 \cdots b_m$. Otherwise choose $k \geq 0$ maximal such that $a_i = b_i^{-1}$ (in either G or H) holds for all $i \in [1, k]$. If $k = n$ then $u \cdot v = b_{k+1} \cdots b_m$ and if $k = m$ then $u \cdot v = a_n \cdots a_{k+1}$. Finally, if $k < n$ and $k < m$ then $u \cdot v = a_n \cdots a_{k+2} (a_{k+1} \cdot b_{k+1}) b_{k+2} \cdots b_m$. Note that $a_{k+1} \cdot b_{k+1}$ is a nontrivial element (either in G or H) by the choice of k. The free product of several groups $G_1, \ldots, G_c$ can be simply defined as $\ast_{i \in [1,c]} G_i = (\cdots((G_1 * G_2) * G_3) * \cdots * G_c)$.

A graph product is specified by a list of groups $G_1, \ldots, G_c$ and a symmetric and irreflexive relation $I \subseteq [1, c] \times [1, c]$. The corresponding *graph product* $G = \mathsf{GP}(G_1, \ldots, G_c, I)$ is the quotient $(\ast_{i \in [1,c]} G_i)/N$ of the free product $\ast_{i \in [1,c]} G_i$ modulo the normal closure N of all commutators $aba^{-1}b^{-1}$, where $a \in G_i$, $b \in G_j$ and $(i, j) \in I$. In other words, we take the free product $\ast_{i \in [1,c]} G_i$ but allow elements from groups G_i and G_j with $(i, j) \in I$ to commute. Graph products interpolate in a natural way between free products ($I = \emptyset$) and direct products ($I = \{(i, j) : i, j \in [1, c], i \neq j\}$). Graph products were introduced by Green in her thesis [8]. Graph products $\mathsf{GP}(G_1, \ldots, G_c, I)$, where every G_i is isomorphic to $\mathbb{Z}$, are also known as *graph groups* (or right-angled Artin groups). We will make use of the fact that every graph group is linear [11].

Let Σ_i be a finite symmetric generating set for G_i, where w.l.o.g. $1 \notin \Sigma_i$ and $\Sigma_i \cap \Sigma_j = \emptyset$ for $i \neq j$. Then, $\Sigma = \bigcup_{i=1}^{c} \Sigma_i$ generates G. For a word $u \in \Sigma^*$, the *block factorization* of u is the unique factorization $u = u_1 u_2 \cdots u_l$ such that $l \geq 0$, $u_1, \ldots, u_l \in \bigcup_{i \in [1,c]} \Sigma_i^+$ and $u_j u_{j+1} \notin \bigcup_{i \in [1,c]} \Sigma_i^+$ for all $j \in [1, l-1]$. The factors $u_1, u_2, \ldots, u_l$ are called the *blocks* of u.

We define several rewrite relations on words from Σ^* as follows: take $u, v \in \Sigma^*$ and let $u = u_1 u_2 \cdots u_l$ be the block factorization of u.

- We write $u \leftrightarrow_s v$ (s for swap) if there is $i \in [1, l-1]$ and $(j, k) \in I$ such that $u_i \in \Sigma_j^+$, $u_{i+1} \in \Sigma_k^+$ and $v = u_1 u_2 \cdots u_{i-1} u_{i+1} u_i u_{i+2} \cdots u_l$. In other words, we swap consecutive commuting blocks. Note that $\leftrightarrow_s$ is a symmetric relation.

- We write $u \to_d v$ (d for delete) if there is $i \in [1,l]$ and $j \in [1,c]$ such that $u_i \in \Sigma_j^+$, $u_i \equiv_{G_j} 1$ and $v = u_1 u_2 \cdots u_{i-1} u_{i+1} u_{i+2} \cdots u_l$. In other words, we delete a block that is trivial in its group.
- We write $u \leftrightarrow_r v$ (r for replace) if there is $i \in [1,l]$ and $j \in [1,c]$ such that $u_i, u_i' \in \Sigma_j^+$, $u_i \equiv_{G_j} u_i'$ and $v = u_1 u_2 \cdots u_{i-1} u_i' u_{i+1} u_{i+2} \cdots u_l$. In other words, we replace a block by an equivalent non-empty word. Note that $\leftrightarrow_r$ is a symmetric relation.

Clearly, in all three cases we have $u \equiv_G v$. If $u \to_d v$, then the number of blocks of v is smaller than the number of blocks of u and if $u \leftrightarrow_s v$ then the number of blocks of v can be smaller than the number of blocks of u (since two blocks can be merged into a single block). We write $u \leftrightarrow_{sr} v$ if $u \leftrightarrow_s v$ or $u \leftrightarrow_r v$ and we write $u \to_{sd} v$ if $u \leftrightarrow_s v$ or $u \to_d v$.

Let us say that a word $u \in \Sigma^*$ with l blocks is *reduced*, if there is no $v \in \Sigma^*$ such that $u \to_{sd}^* v$ and v has at most $l-1$ blocks. Clearly, for every word $u \in \Sigma^*$ there is a reduced word $u' \in \Sigma^*$ such that $u \to_{sd}^* u'$. The following result can be found in [8, Theorem 3.9] and [10] in slightly different notations.

▶ **Lemma 8.** *Let G be a graph product as above and $u, v \in \Sigma^*$. The following are equivalent:*

- $u \equiv_G v$
- *There are reduced words u', v' such that $u \to_{sd}^* u'$, $v \to_{sd}^* v'$, and $u' \leftrightarrow_r^* v'$.*

Consider a word $u \in \Sigma^*$ and its block factorization $u = u_1 u_2 \ldots u_l$. A *pure prefix* of u is a word $u_{k_1} u_{k_2} \cdots u_{k_m}$ such that for some $i \in [1,c]$ we have

- $1 \le k_1 < k_2 < \cdots < k_m \le l$,
- $u_{k_1}, u_{k_2}, \ldots, u_{k_m} \in \Sigma_i^+$ and
- if $k_j < p < k_{j+1}$ for some $j \in [1, m-1]$ or $1 \le p < k_1$ then $u_p \notin \Sigma_i^+$.

▶ **Theorem 9.** *Let $G = \mathsf{GP}(G_1, \ldots, G_c, I)$ be a graph product as above and let $\mathcal{R}_i = (\mathcal{A}_{i,n})_{n \ge 0}$ be an (ϵ_0, ϵ_1)-distinguisher for G_i. Let $d \ge 1$ and define $\zeta_0(n) = 2\epsilon_0(n) c n^2 + 1/n^d$ and $\zeta_1(n) = 2\epsilon_1(n) c n^2$. Then, there exists a (ζ_0, ζ_1)-distinguisher for G with space complexity $\mathcal{O}(\sum_{i=1}^c s(\mathcal{R}_i, n) + \log n)$.*

Proof. Let us fix an input length n and let $\mathcal{A}_{i,n} = (Q_{i,n}, \Sigma_i, \iota_{i,n}, \rho_{i,n})$, where w.l.o.g. $Q_{i,n} = [0, |Q_{i,n}| - 1]$. To simplify the notation, we will omit the second subscript n in the following, i.e., we write $\mathcal{A}_i = (Q_i, \Sigma_i, \iota_i, \rho_i)$ with $Q_i = [0, |Q_i| - 1]$ for the semiPFA $\mathcal{A}_{i,n}$. For a state $q \in Q_i$, we will use the equivalence relation $\equiv_q \; = \; \equiv_{\mathcal{A}_i, q}$ defined in Section 4. For a word $w \in \Sigma^*$, we write $\pi_i(w)$ for the projection $\pi_{\Sigma_i}(w)$.

For every $i \in [1,c]$ we choose a new symbol a_i and consider the infinite cyclic group $\langle a_i \rangle \cong \mathbb{Z}$. Let $\Gamma = \{a_1, a_1^{-1}, \ldots, a_c, a_c^{-1}\}$ and consider the graph group $H = \mathsf{GP}(\langle a_1 \rangle, \ldots, \langle a_c \rangle, I)$. Since every graph group is linear, there is a $(1/m^d, 0)$-distinguisher $(\mathcal{B}_m)_{m \ge 0}$ with space complexity $\mathcal{O}(\log m)$ for H by Theorem 7. Let $\mathcal{B}_m = (R_m, \Gamma, \lambda_m, \sigma_m)$.

We build from the semiPFA $\mathcal{A}_i$ and a state $q \in Q_i$ a sequential transducer $\mathcal{T}_{i,q} = (Q_i, \Sigma_i, \{a_i, a_i^{-1}\}, q, \delta_i)$, where for all $a \in \Sigma_i$ and $p \in Q_i$ we define (recall that $Q_i \subseteq \mathbb{N}$):

$$\delta_i(p, a) = (\rho_i(p, a), a_i^{-p} a_i^{\rho_i(p,a)}).$$

Let $f_{i,q} := f_{\mathcal{T}_{i,q}} : \Sigma_i^* \to \{a_i, a_i^{-1}\}^*$ be the function computed by $\mathcal{T}_{i,q}$. For a tuple $\bar{q} = (q_1, \ldots, q_c) \in \prod_{i \in [1,c]} Q_i$ of states from the semiPFAs $\mathcal{A}_i$ we define the sequential transducer $\mathcal{T}_{\bar{q}}$ by taking the direct product of the $\mathcal{T}_{i,q_i}$ ($i \in [1,c]$). Formally, it is defined as follows:

$$\mathcal{T}_{\bar{q}} = (\prod_{i \in [1,c]} Q_i, \Sigma, \Gamma, \bar{q}, \delta)$$

Algorithm 1 (ζ_0,ζ_1)-distinguisher for $\mathsf{GP}(G_1,\dots,G_c,I)$.

```
global variables: $q_i \in Q_i$ for all $i \in [1,c]$, $r \in R_m$
initialization:
guess $q_i \in Q_i = [0, |Q_i|-1]$ according to the input distribution $\iota_i$ of $\mathcal{A}_i$ ;
guess $r \in R_m$ according to the input distribution $\lambda_m$ of $\mathcal{B}_m$ ;
next input letter: $a \in \Sigma$
let $i \in [1,c]$ such that $a \in \Sigma_i$ ;
$r := \sigma_m(r, a_i^{-q_i} a_i^{\rho_i(q_i,a)})$ ; $q_i := \rho_i(q_i,a)$ ;
```

where for every $i \in [1,c]$, $a \in \Sigma_i$, and $(p_1,\dots,p_c) \in \prod_{i\in[1,c]} Q_i$ we have

$$\delta((p_1,\dots,p_c),a) = \big((p_1,\dots,p_{i-1},\rho_i(p_i,a),p_{i+1},\dots,p_c), a_i^{-p_i} a_i^{\rho_i(p_i,a)}\big).$$

Let $f_{\bar q} := f_{\mathcal{T}_{\bar q}} : \Sigma^* \to \Gamma^*$ be the function computed by $\mathcal{T}_{\bar q}$. Moreover, define

$$m = 2 \cdot n \cdot \max\{|Q_i| \colon i \in [1,c]\} \le n \cdot 2^{1+\max\{s(\mathcal{R}_i,n)\colon i\in[1,c]\}}.$$

Note that $|f_{\bar q}(w)| \le m$ if $|w| \le n$.

Our randomized streaming algorithm for G and input length n uses the semiPFA $\mathcal{B}_m$. States of $\mathcal{B}_m$ can be stored with $\mathcal{O}(\log m) \le \mathcal{O}(\max\{s(\mathcal{R}_i,n)\colon i \in [1,c]\} + \log n)$ bits. Basically, for an input word $w \in \Sigma^{\le n}$ the algorithm simulates $\mathcal{A}_i$ ($i \in [1,c]$) on the projections $w_i = \pi_i(w)$ and feeds the word $f_{\bar q}(w)$ into the semiPFA $\mathcal{B}_m$. Here, the state tuple $\bar q$ is randomly guessed in the beginning according to the distributions ι_i. The complete streaming algorithm is Algorithm 1. It stores at most $\sum_{i=1}^{c} s(\mathcal{R}_i,n) + \mathcal{O}(\max\{s(\mathcal{R}_i,n)\colon i \in [1,c]\} + \log n)$ bits.

Before we analyze the error probability of the algorithm we need some preparations. For $i \in [1,c]$ and a word $w \in \Sigma^*$ let $\mathcal{P}_i(w) = \mathcal{P}(\pi_i(w))$ be the set of all prefixes of the projection $\pi_i(w)$. Assume that $y \in \Sigma_i^+$ is a block of w and write $w = xyz$. We then have $f_{\bar q} = f_{\bar q}(x) f_{\bar r}(y) f_{\bar s}(z)$, where $\delta(\bar q, x) = (\bar r, f_{\bar q}(x))$ and $\delta(\bar r, y) = (\bar s, f_{\bar r}(y))$. The word $f_{\bar r}(y)$ is also a block of $f_{\bar q}$ (for this it is important that the transducers $\mathcal{T}_{j,q}$ translate non-empty words into non-empty words). Since $y \in \Sigma_i^+$ we have $r_j = s_j$ for all $j \in [1,c] \setminus \{i\}$ and $f_{\bar r}(y) = f_{i,r_i}(y)$. In addition, the definition of the transducer $\mathcal{T}_{i,r_i}$ implies that $f_{\bar r}(y) \equiv_{\langle a_i \rangle} a_i^{-r_i} a_i^{s_i}$.

Consider now two input words $u, v \in \Sigma^{\le n}$ and let $\mathcal{S}_i = \mathcal{P}_i(u) \cup \mathcal{P}_i(v)$ for $i \in [1,c]$, so that $|\mathcal{S}_i| \le 2n$. By Lemma 4 we have for all $i \in [1,c]$:

- $\mathsf{Prob}_{q\in Q_i}[\equiv_q \text{ refines } \equiv_{G_i} \text{ on } \mathcal{S}_i] \ge 1 - \epsilon_0(n)\binom{|\mathcal{S}_i|}{2} \ge 1 - 2\epsilon_0(n)n^2$,
- $\mathsf{Prob}_{q\in Q_i}[\equiv_{G_i} \text{ refines } \equiv_q \text{ on } \mathcal{S}_i] \ge 1 - \epsilon_1(n)\binom{|\mathcal{S}_i|}{2} \ge 1 - 2\epsilon_1(n)n^2$.

Our error analysis of Algorithm 1 is based on the following two claims.

▷ Claim 10. Assume that $\bar q = (q_1,\dots,q_c)$ is such that $\equiv_{G_i}$ refines $\equiv_{q_i}$ on $\mathcal{S}_i$ for every $i \in [1,c]$. If $u \to_{sd}^* u'$ and $v \to_{sd}^* v'$, then $f_{\bar q}(u) \to_{sd}^* f_{\bar q}(u')$, $f_{\bar q}(v) \to_{sd}^* f_{\bar q}(v')$ and $\equiv_{G_i}$ refines $\equiv_{q_i}$ on $\mathcal{P}_i(u') \cup \mathcal{P}_i(v')$ for every $i \in [1,c]$.

Proof. It suffices to show the following: If $u \to_{sd} u'$ holds, then $f_{\bar q}(u) \to_{sd} f_{\bar q}(u')$ and $\equiv_{G_i}$ refines $\equiv_{q_i}$ on $\mathcal{P}_i(u') \cup \mathcal{P}_i(v)$ for every $i \in [1,c]$. From this (and the symmetric statement where $v \to_{sd} v'$ and $u = u'$) we obtain the general statement by induction on the number of $\to_{sd}$-steps. We distinguish two cases.

Case 1. $u \leftrightarrow_s u'$. We must have $u = xy_1y_2z$ and $u' = xy_2y_1z$ for blocks y_1, y_2 such that $y_1 \in \Sigma_i^+$, $y_2 \in \Sigma_j^+$ and $(i,j) \in I$ (in particular $i \neq j$). We obtain

$$\begin{aligned} f_{\bar{q}}(u) &= f_{\bar{q}}(x) f_{\bar{p}}(y_1) f_{\bar{r}}(y_2) f_{\bar{s}}(z) \text{ and} \\ f_{\bar{q}}(u') &= f_{\bar{q}}(x) f_{\bar{p}}(y_2) f_{\bar{r}'}(y_1) f_{\bar{s}}(z), \end{aligned}$$

where $\delta(\bar{q}, x) = (\bar{p}, f_{\bar{q}}(x))$, $\delta(\bar{p}, y_1) = (\bar{r}, f_{\bar{p}}(y_1))$, $\delta(\bar{r}, y_2) = (\bar{s}, f_{\bar{r}}(y_2))$, $\delta(\bar{p}, y_2) = (\bar{r}', f_{\bar{p}}(y_2))$, and $\delta(\bar{r}', y_1) = (\bar{s}, f_{\bar{r}'}(y_1))$. If we write $\bar{p} = (p_1, \ldots, p_c)$, then there are states $r_i \in Q_i$ and $r_j \in Q_j$ such that

$$\begin{aligned} \bar{r} &= (p_1, \ldots, p_{i-1}, r_i, p_{i+1}, \ldots, p_c), && (1) \\ \bar{r}' &= (p_1, \ldots, p_{j-1}, r_j, p_{j+1}, \ldots, p_c), \text{ and} && (2) \\ \bar{s} &= (p_1, \ldots, p_{i-1}, r_i, p_{i+1}, \ldots, p_{j-1}, r_j, p_{j+1}, \ldots, p_c) && (3) \end{aligned}$$

(we assume w.l.o.g. that $i < j$). Moreover, $f_{\bar{p}}(y_1) = f_{i,p_i}(y_1) = f_{\bar{r}'}(y_1) \in \{a_i, a_i^{-1}\}^+$ and $f_{\bar{r}}(y_2) = f_{j,p_j}(y_2) = f_{\bar{p}}(y_2) \in \{a_j, a_j^{-1}\}^+$. Thus, we have

$$\begin{aligned} f_{\bar{q}}(u) &= f_{\bar{q}}(x) f_{\bar{p}}(y_1) f_{\bar{r}}(y_2) f_{\bar{s}}(z) \\ &= f_{\bar{q}}(x) f_{i,p_i}(y_1) f_{j,p_j}(y_2) f_{\bar{s}}(z) \\ &\leftrightarrow_s f_{\bar{q}}(x) f_{j,p_j}(y_2) f_{i,p_i}(y_1) f_{\bar{s}}(z) \\ &= f_{\bar{q}}(x) f_{\bar{p}}(y_2) f_{\bar{r}'}(y_1) f_{\bar{s}}(z) \\ &= f_{\bar{q}}(u'). \end{aligned}$$

Moreover, since $\mathcal{P}_i(u') = \mathcal{P}_i(u)$ and $\equiv_{G_i}$ refines $\equiv_{q_i}$ on $\mathcal{S}_i$ for all $i \in [1,c]$, it follows that $\equiv_{G_i}$ refines $\equiv_{q_i}$ on $\mathcal{P}_i(u') \cup \mathcal{P}_i(v)$ for all $i \in [1,c]$.

Case 2. $u \to_d u'$. Then we obtain a factorization $u = xyz$, where $y \in \Sigma_i^+$ is a block, $y \equiv_{G_i} 1$, and $u' = xz$. We obtain a factorization

$$f_{\bar{q}}(u) = f_{\bar{q}}(x) f_{\bar{r}}(y) f_{\bar{s}}(z),$$

where $\delta(\bar{q}, x) = (\bar{r}, f_{\bar{q}}(x))$ and $\delta(\bar{r}, y) = (\bar{s}, f_{\bar{r}}(y))$. The word $f_{\bar{r}}(y)$ is a block of $f_{\bar{q}}(u)$. For the projection $\pi_i(u)$ we have $\pi_i(u) = \pi_i(x) y \pi_i(z)$. Since $\equiv_{G_i}$ refines $\equiv_{q_i}$ on $\mathcal{S}_i$ and $\pi_i(x) \equiv_{G_i} \pi_i(x)y$, we obtain $\pi_i(x) \equiv_{q_i} \pi_i(x)y$. Since r_i (resp., s_i) is the state reached from q_i by the automaton $\mathcal{A}_i$ after reading $\pi_i(x)$ (resp., $\pi_i(x)y$), we obtain $r_i = s_i$ and hence $\bar{r} = \bar{s}$. This implies

$$f_{\bar{r}}(y) \equiv_{\langle a_i \rangle} a_i^{-r_i} a_i^{s_i} \equiv_{\langle a_i \rangle} 1.$$

Moreover, we have

$$f_{\bar{q}}(u') = f_{\bar{q}}(xz) = f_{\bar{q}}(x) f_{\bar{r}}(z) = f_{\bar{q}}(x) f_{\bar{s}}(z).$$

We therefore get $f_{\bar{q}}(u) \to_d f_{\bar{q}}(u')$.

It remains to show that $\equiv_{G_j}$ refines $\equiv_{q_j}$ on $\mathcal{P}_j(u') \cup \mathcal{P}_j(v)$ for every $j \in [1,c]$. For $j \neq i$ this is clear since $\mathcal{P}_j(u') \cup \mathcal{P}_j(v) = \mathcal{S}_j$. For $j = i$ we can use Lemma 5 for the words $\pi_i(u) = \pi_i(x) y \pi_i(z)$ and $\pi_i(v)$. ◁

▷ Claim 11. Assume that $\bar{q} = (q_1, \ldots, q_c)$ is such that $\equiv_{q_i}$ refines $\equiv_{G_i}$ on $\mathcal{S}_i$ for every $i \in [1,c]$. If $f_{\bar{q}}(u) \to_{sd}^* \tilde{u}$ and $f_{\bar{q}}(v) \to_{sd}^* \tilde{v}$, then there are $u', v' \in \Sigma^*$ such that $u \to_{sd}^* u'$, $v \to_{sd}^* v'$, $f_{\bar{q}}(u') = \tilde{u}$, $f_{\bar{q}}(v') = \tilde{v}$ and $\equiv_{q_i}$ refines $\equiv_{G_i}$ on $\mathcal{P}_i(u') \cup \mathcal{P}_i(v')$ for every $i \in [1,c]$.

Proof. The proof is very similar to the above proof of Claim 10. As in the above proof of Claim 10, it suffices to consider the case where $f_{\bar{q}}(u) \to_{sd} \tilde{u}$ and $\tilde{v} = f_{\bar{q}}(v)$.

Case 1. $f_{\bar{q}}(u) \leftrightarrow_s \tilde{u}$. Since the blocks of u are translated into the blocks of $f_{\bar{q}}(u)$ by the transducer $\mathcal{T}_{\bar{q}}$, we obtain a factorization $u = xy_1y_2z$ for blocks $y_1 \in \Sigma_i^+, y_2 \in \Sigma_j^+$ of u such that $(i,j) \in I$ (in particular $i \neq j$) and

$$\begin{aligned} f_{\bar{q}}(u) &= f_{\bar{q}}(x)f_{\bar{p}}(y_1)f_{\bar{r}}(y_2)f_{\bar{s}}(z), \\ \tilde{u} &= f_{\bar{q}}(x)f_{\bar{r}}(y_2)f_{\bar{p}}(y_1)f_{\bar{s}}(z). \end{aligned}$$

Here, the state tuples $\bar{p} = (p_1, \ldots, p_c)$, $\bar{r}$, and $\bar{s}$ are as in the above proof of Claim 10, see in particular (1) and (3). We can then define the tuple $\bar{r}'$ as in (2) and get $f_{\bar{p}}(y_1) = f_{i,p_i}(y_1) = f_{\bar{r}'}(y_1) \in \{a_i, a_i^{-1}\}^+$ and $f_{\bar{r}}(y_2) = f_{j,p_j}(y_2) = f_{\bar{p}}(y_2) \in \{a_j, a_j^{-1}\}^+$. We thus have

$$\tilde{u} = f_{\bar{q}}(x)f_{\bar{r}}(y_2)f_{\bar{p}}(y_1)f_{\bar{s}}(z) = f_{\bar{q}}(x)f_{\bar{p}}(y_2)f_{\bar{r}'}(y_1)f_{\bar{s}}(z) = f_{\bar{q}}(xy_2y_1z).$$

Clearly, we also have $u = xy_1y_2z \rightarrow_s xy_2y_1z$. So, we can set $u' = xy_2y_1z$. Since $\mathcal{P}_i(u') = \mathcal{P}_i(u)$ for all $i \in [1,c]$, it follows that $\equiv_{q_i}$ refines $\equiv_{G_i}$ on $\mathcal{P}_i(u') \cup \mathcal{P}_i(v)$ for all $i \in [1,c]$.

Case 2. $f_{\bar{q}}(u) \rightarrow_d \tilde{u}$. Then we obtain a factorization $u = xyz$, where $y \in \Sigma_i^+$ is a block of u,

$$\begin{aligned} f_{\bar{q}}(u) &= f_{\bar{q}}(x)f_{\bar{r}}(y)f_{\bar{s}}(z), \text{ and} \\ \tilde{u} &= f_{\bar{q}}(x)f_{\bar{s}}(z). \end{aligned}$$

The state tuples $\bar{r}$ and $\bar{s}$ are such that $\delta(\bar{q}, x) = (\bar{r}, f_{\bar{q}}(x))$ and $\delta(\bar{r}, y) = (\bar{s}, f_{\bar{r}}(y))$. Moreover, the word $f_{\bar{r}}(y)$ is a block of $f_{\bar{q}}(u)$ with

$$a_i^{-r_i}a_i^{s_i} \equiv_{\langle a_i \rangle} f_{\bar{r}}(y) \equiv_{\langle a_i \rangle} 1.$$

This implies that $r_i = s_i$ and hence $\bar{r} = \bar{s}$. We therefore have

$$\rho_i(q_i, \pi_i(x)) = r_i = s_i = \rho_i(q_i, \pi_i(x)y).$$

Since $\equiv_{q_i}$ refines $\equiv_{G_i}$ on $\mathcal{S}_i$ and $\pi_i(x), \pi_i(x)y \in \mathcal{S}_i$, we get $\pi_i(x) \equiv_{G_i} \pi_i(x)y$, i.e., $y \equiv_{G_i} 1$. If we set $u' = xz$ we get $u \rightarrow_d u'$ and

$$\tilde{u} = f_{\bar{q}}(x)f_{\bar{s}}(z) = f_{\bar{q}}(x)f_{\bar{r}}(z) = f_{\bar{q}}(xz) = f_{\bar{q}}(u').$$

It remains to show that $\equiv_{q_j}$ refines $\equiv_{G_j}$ on $\mathcal{P}_j(u') \cup \mathcal{P}_j(v)$ for every $j \in [1,c]$. For $j \neq i$ this is clear since $\mathcal{P}_j(u') \cup \mathcal{P}_j(v) = \mathcal{S}_j$. For $j = i$ we can use Lemma 6 for the words $\pi_i(u) = \pi_i(x)y\pi_i(z)$ and $\pi_i(v)$. ◁

We now estimate the error for the input words u and v. There are two cases to consider:

Case 1. $u \equiv_G v$. We will show that Algorithm 1 reaches with probability at least $1 - 2\epsilon_1(n)cn^2$ the same state when running on u and v, respectively. For this, assume that the randomly selected initial states $q_i \in Q_i$ are such that $\equiv_{G_i}$ refines $\equiv_{q_i}$ on $\mathcal{S}_i$ for all $i \in [1,c]$. This happens with probability at least $1 - 2\epsilon_1(n)cn^2$.

First note that $u \equiv_G v$ implies $\pi_i(u) \equiv_{G_i} \pi_i(v)$ for all $i \in [1,c]$. Since $\equiv_{G_i}$ refines $\equiv_{q_i}$ on $\mathcal{S}_i$, we obtain $\rho_i(q_i, \pi_i(u)) = \rho_i(q_i, \pi_i(v))$. It remains to show that after reading u and v, also the states of $\mathcal{B}_m$ are the same. For this we show that $f_{\bar{q}}(u) \equiv_H f_{\bar{q}}(v)$ in the graph group H.

From Lemma 8 it follows that there are reduced words $u', v' \in \Sigma^*$ such that $u \rightarrow_{sd}^* u'$, $v \rightarrow_{sd}^* v'$, and $u' \leftrightarrow_r^* v'$. Claim 10 implies $f_{\bar{q}}(u) \rightarrow_{sd}^* f_{\bar{q}}(u')$, $f_{\bar{q}}(v) \rightarrow_{sd}^* f_{\bar{q}}(v')$, and $\equiv_{G_i}$ refines $\equiv_{q_i}$ on $\mathcal{P}_i(u') \cup \mathcal{P}_i(v')$ for every $i \in [1,c]$. Since $u' \leftrightarrow_r^* v'$ we can write the block factorizations of u' and v' as $u' = u_1u_2 \cdots u_l$ and $v' = v_1v_2 \cdots v_l$ with $u_i, v_i \in \Sigma_{j_i}^+$ for some $j_i \in [1,c]$ and $u_i \equiv_{G_{j_i}} v_i$ for all $i \in [1,l]$. The block factorizations of $f_{\bar{q}}(u')$ and $f_{\bar{q}}(v')$ can be written as $f_{\bar{q}}(u') = \tilde{u}_1\tilde{u}_2 \cdots \tilde{u}_l$ and $f_{\bar{q}}(v') = \tilde{v}_1\tilde{v}_2 \cdots \tilde{v}_l$ with $\tilde{u}_i, \tilde{v}_i \in \{a_{j_i}, a_{j_i}^{-1}\}^+$.

We claim that $\tilde{u}_i \equiv_{\langle a_{j_i} \rangle} \tilde{v}_i$ for all $i \in [1,l]$, which implies $f_{\bar{q}}(u') \equiv_H f_{\bar{q}}(v')$. Since $u_i \equiv_{G_{j_i}} v_i$ for all $i \in [1,l]$, we get the following: if $u'' = u_{k_1} u_{k_2} \cdots u_{k_e} \in \Sigma_j^*$ is a pure prefix of u' for some $j \in [1,c]$ then $v'' = v_{k_1} v_{k_2} \cdots v_{k_e} \in \Sigma_j^*$ is a pure prefix of v' such that $u'' \equiv_{G_j} v''$. Since $\equiv_{G_j}$ refines $\equiv_{q_j}$ on $\mathcal{P}_j(u') \cup \mathcal{P}_j(v')$ and $u'', v'' \in \mathcal{P}_j(u') \cup \mathcal{P}_j(v')$, we obtain $\rho_j(q_j, u'') = \rho_j(q_j, v'')$. This implies $\tilde{u}_i \equiv_{\langle a_{j_i} \rangle} \tilde{v}_i$ for all $i \in [1,l]$ and hence $f_{\bar{q}}(u') \equiv_H f_{\bar{q}}(v')$. From this, we finally get $f_{\bar{q}}(u) \equiv_H f_{\bar{q}}(u') \equiv_H f_{\bar{q}}(v') \equiv_H f_{\bar{q}}(v)$.

Recall that $f_{\bar{q}}(u)$ (resp., $f_{\bar{q}}(v)$ is the word fed into the semiPFA $\mathcal{B}_m$ on input u (resp., v). Since $(\mathcal{B}_n)_{n \geq 0}$ is a $(1/n^d, 0)$-distinguisher for H, it follows that $f_{\bar{q}}(u)$ and $f_{\bar{q}}(v)$ lead in $\mathcal{B}_m$ with probability one to the same state. Hence, Algorithm 1 reaches with probability at least $1 - 2\epsilon_1(n)cn^2$ the same state when running on u and v, respectively.

Case 2. $u \not\equiv_G v$. We will show that Algorithm 1 reaches with probability at least $1 - (2\epsilon_0(n)cn^2 + 1/n^d)$ different states when running on u and v, respectively. To show this, assume that the randomly selected initial states $q_i \in Q_i$ are such that $\equiv_{q_i}$ refines $\equiv_{G_i}$ on $\mathcal{S}_i$ for all $i \in [1,c]$. This happens with probability at least $1 - 2\epsilon_0(n)cn^2$.

We claim that $f_{\bar{q}}(u) \not\equiv_H f_{\bar{q}}(v)$. In order to get a contradiction, assume that $f_{\bar{q}}(u) \equiv_H f_{\bar{q}}(v)$. From Lemma 8 it follows that there are reduced words $\tilde{u}, \tilde{v} \in \Gamma^*$ such that $f_{\bar{q}}(u) \to_{sd}^* \tilde{u}$, $f_{\bar{q}}(v) \to_{sd} \tilde{v}$ and $\tilde{u} \leftrightarrow_r^* \tilde{v}$. By Claim 11 there are $u', v' \in \Sigma^*$ such that $u \to_{sd}^* u'$, $v \to_{sd}^* v'$, $f_{\bar{q}}(u') = \tilde{u}$, $f_{\bar{q}}(v') = \tilde{v}$ and $\equiv_{q_i}$ refines $\equiv_{G_i}$ on $\mathcal{P}_i(u') \cup \mathcal{P}_i(v')$ for every $i \in [1,c]$.

Since $f_{\bar{q}}(u') \leftrightarrow_r^* f_{\bar{q}}(v')$ we can write the block factorizations of $f_{\bar{q}}(u')$ and $f_{\bar{q}}(v')$ as $f_{\bar{q}}(u') = \tilde{u}_1 \tilde{u}_2 \cdots \tilde{u}_l$ and $f_{\bar{q}}(v') = \tilde{v}_1 \tilde{v}_2 \cdots \tilde{v}_l$ with $\tilde{u}_i, \tilde{v}_i \in \{a_{j_i}, a_{j_i}^{-1}\}^+$ for some $j_i \in [1,c]$ and $\tilde{u}_i \equiv_{\langle a_{j_i} \rangle} \tilde{v}_i$ for all $i \in [1,l]$. Clearly, the block factorizations of u' and v' can then be written as $u' = u_1 u_2 \cdots u_l$ and $v' = v_1 v_2 \cdots v_l$, where the block $u_i \in \Sigma_{j_i}^+$ (resp., $v_i \in \Sigma_{j_i}^+$) is translated into the block $\tilde{u}_i$ (resp., $\tilde{v}_i$) by the sequential transducer $\mathcal{T}_{\bar{q}}$.

We claim that $u_i \equiv_{G_{j_i}} v_i$ for all $i \in [1,l]$. Since $\tilde{u}_i \equiv_{\langle a_{j_i} \rangle} \tilde{v}_i$ for all $i \in [1,l]$ we have the following: if $\tilde{u}'' = \tilde{u}_{k_1} \tilde{u}_{k_2} \cdots \tilde{u}_{k_e} \in \{a_j, a_j^{-1}\}^*$ is a pure prefix of $f_{\bar{q}}(u')$ for some $j \in [1,c]$ then $\tilde{v}'' = \tilde{v}_{k_1} \tilde{v}_{k_2} \cdots \tilde{v}_{k_e} \in \{a_j, a_j^{-1}\}^*$ is a pure prefix of $f_{\bar{q}}(v')$ and $\tilde{u}'' \equiv_{\langle a_j \rangle} \tilde{v}''$. Let $p_j = \rho_j(q_j, u_{k_1} u_{k_2} \cdots u_{k_e})$ and $r_j = \rho_j(q_j, v_{k_1} v_{k_2} \cdots v_{k_e})$. We therefore have

$$a_j^{-q_j} a_j^{p_j} \equiv_{\langle a_j \rangle} \tilde{u}'' \equiv_{\langle a_j \rangle} \tilde{v}'' \equiv_{\langle a_j \rangle} a_j^{-q_j} a_j^{r_j},$$

i.e., $p_j = r_j$. Since $\equiv_{q_j}$ refines $\equiv_{G_j}$ on $\mathcal{P}_j(u') \cup \mathcal{P}_j(v')$ and $u_{k_1} u_{k_2} \cdots u_{k_e}$ as well as $v_{k_1} v_{k_2} \cdots v_{k_e}$ belong to $\mathcal{P}_j(u') \cup \mathcal{P}_j(v')$, we obtain $u_{k_1} u_{k_2} \cdots u_{k_e} \equiv_{G_j} v_{k_1} v_{k_2} \cdots v_{k_e}$. This holds for all pure prefixes of u'. We therefore have $u_i \equiv_{G_{j_i}} v_i$ for all $i \in [1,l]$, which implies $u' \equiv_G v'$. Finally, we get $u \equiv_G u' \equiv_G v' \equiv_G v$, which is a contradiction. Hence, we must have $f_{\bar{q}}(u) \not\equiv_H f_{\bar{q}}(v)$.

Since the algorithm feeds $f_{\bar{q}}(u)$ (resp., $f_{\bar{q}}(v)$) into the semiPFA $\mathcal{B}_m$, the latter reaches different states with probability at least $1 - 1/m^d \geq 1 - 1/n^d$ (under the assumption that $\equiv_{q_i}$ refines $\equiv_{G_i}$ on $\mathcal{S}_i$ for all $i \in [1,c]$). Hence, the probability that Algorithm 1 reaches different states when running on u and v is at least $(1 - 2\epsilon_0(n)cn^2)(1 - 1/n^d) \geq 1 - (2\epsilon_0(n)cn^2 + 1/n^d)$. ◀

Theorem 9 only makes sense if $\epsilon_0(n), \epsilon_1(n) < 1/2cn^2$. Most of the distinguishers from [17] have an error probability of $1/n^c$ for any chosen $c > 0$; see Theorem 7 for the case of f.g. linear groups. Moreover, notice that if $\epsilon_1 = 0$ then also $\zeta_1 = 0$ in Theorem 9. Combined with Theorem 7, Lemma 3, and the transfer theorems from [17] mentioned in Section 1, we get a logspace randomized streaming algorithm with a one-sided error (no error if $w \equiv_G 1$) for the word problem of any f.g. group G that can be constructed from f.g. linear groups using finite extensions, wreath products with a f.g. abelian left factor, and graph products. These groups are in general not linear; see the characterization of linear wreath products in [23].

6 Randomized streaming algorithms for subgroup membership

Let G be a f.g. group with a finite symmetric generating set Σ and let H be a subgroup of G. As before, $\pi_G : \Sigma^* \to G$ is the morphism that maps a word $w \in \Sigma^*$ to the group element represented by w. We define the language $\mathsf{GWP}(G, H, \Sigma) = \{w \in \Sigma^* : \pi_G(w) \in H\}$. GWP stands for generalized word problem which is another common name for the subgroup membership problem. Note that $\mathsf{GWP}(G, 1, \Sigma) = \mathsf{WP}(G, \Sigma)$. In the following we are interested in randomized streaming algorithms for $\mathsf{GWP}(G, H, \Sigma)$. One can easily show a statement for $\mathsf{GWP}(G, H, \Sigma)$ analogously to Lemma 2, which allows us to skip the generating set Σ in combination with the $\mathcal{O}$-notation and just write $\mathsf{GWP}(G, H)$ in the following.

For this section we fix a finite alphabet Σ and take a copy $\Sigma^{-1} = \{a^{-1} : a \in \Sigma\}$ of formal inverses. Let $\Gamma = \Sigma \cup \Sigma^{-1}$. We extend the mapping $a \mapsto a^{-1}$ $(a \in \Sigma)$ to the whole alphabet Γ by setting $(a^{-1})^{-1} = a$. Moreover, for a word $w = a_1 a_2 \cdots a_n$ with $a_i \in \Gamma$ we define $w^{-1} = a_n^{-1} \cdots a_2^{-1} a_1^{-1}$. A word $w \in \Gamma^*$ is called reduced if it contains no factor of the form aa^{-1} for $a \in \Gamma$. Let $\mathsf{Red}(\Gamma) \subseteq \Gamma^*$ be the set of reduced words. It is convenient to identify the free group $F(\Sigma)$ with the set $\mathsf{Red}(\Gamma)$ of reduced words and the following multiplication operation: Let $u, v \in \mathsf{Red}(\Gamma)$. Then one can uniquely write u and v as $u = xy$ and $v = y^{-1}z$ such that $xz \in \mathsf{Red}(\Gamma)$ and define the product of u and v in the free group $F(\Sigma)$ as xz. For every word $w \in \Gamma^*$ we can define a unique reduced word $\mathsf{red}(w)$ as follows: if $w \in \mathsf{Red}(\Gamma)$ then $\mathsf{red}(w) = w$ and if $w = uaa^{-1}v$ for $u, v \in \Gamma^*$ and $a \in \Gamma$ then $\mathsf{red}(w) = \mathsf{red}(uv)$. It is important that this definition does not depend on which factor aa^{-1} is deleted in w. The reduction relation $uaa^{-1}v \to uv$ for all $u, v \in \Gamma^*$ and $a \in \Gamma$ is a so-called confluent relation. The reduction mapping $w \mapsto \mathsf{red}(w)$ then becomes the canonical morphism mapping a word $w \in \Gamma^*$ to the element of the free group represented by w.

In the following we have to deal with a special class of finite automata over the alphabet Γ. A partial deterministic finite automaton (partial DFA) is defined as an ordinary DFA except that the transition function $\delta : Q \times \Gamma \to Q$ is only partially defined. As for (total) DFAs we extend the partial transition function $\delta : Q \times \Gamma \to Q$ to a partial function $\delta : Q \times \Gamma^* \to Q$. For $q \in Q$ and $w \in \Gamma^*$ we write $\delta(q, w) = \perp$ if $\delta(q, w)$ is undefined, which means that one cannot read the word w into the automaton $\mathcal{A}$ starting from state q. A *partial inverse automaton* $\mathcal{A} = (Q, \Gamma, q_0, \delta, q_f)$ over the alphabet Γ is a partial DFA with a single final state q_f and such that for all $p, q \in Q$ and $a \in \Gamma$, $\delta(p, a) = q$ implies $\delta(q, a^{-1}) = p$.

The main technique to deal with f.g. subgroups of a free group is Stallings folding [12]. For our purpose it suffices to know that for every f.g. subgroup $G \leq F(\Sigma)$ there exists a partial inverse automaton $\mathcal{A}_G$ over the alphabet Γ such that for every $w \in \mathsf{Red}(\Gamma)$, $w \in G$ if and only if $w \in L(\mathcal{A}_G)$. We call $\mathcal{A}_G$ the Stallings automaton for G. It has the additional property that the unique final state is the initial state. The Stallings automaton for G can be constructed quite efficiently from a given set of generators for G, but we do not need this fact since G will be fixed and not considered to be part of the input in our main result, Theorem 14 below.

Let G be a fixed f.g. subgroup of $F(\Sigma)$ and let $\mathcal{A}_G = (Q, \Gamma, q_0, \delta, q_0)$ be its Stallings automaton in the following. An important property of $\mathcal{A}_G$ is the following: If $q, q' \in Q$ and $u \in \Gamma^*$ (u is not necessarily reduced) are such that $\delta(q, u) = q'$ then also $\delta(q, \mathsf{red}(u)) = q'$. This follows from the fact that $\delta(q, aa^{-1}) = q$ for every $q \in Q$ and $a \in \Gamma$. In particular, if $\delta(q_0, u) \neq \perp$, then $u \in L(\mathcal{A}_G)$ if and only if $\mathsf{red}(u) \in L(\mathcal{A}_G)$ if and only if $\mathsf{red}(u) \in G$.

▶ **Definition 12.** *For a word $w \in \Gamma^*$ we define the $\mathcal{A}_G$-factorization of w uniquely as either*

(i) $w = w_0 a_1 u_1 \; w_1 a_2 u_2 \cdots w_{k-1} a_k u_k \; w_k$ *or*

(ii) $w = w_0 a_1 u_1 \; w_1 a_2 u_2 \cdots w_{k-1} a_k u_k \; w_k a_{k+1} v$

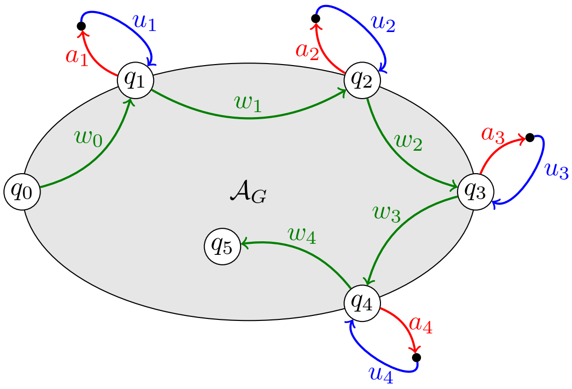

Figure 1 An $\mathcal{A}_G$-factorization of type (i) for $k = 4$. The red-blue loops outside of $\mathcal{A}_G$ are loops in the Cayley-graph of the free group $F(\Sigma)$.

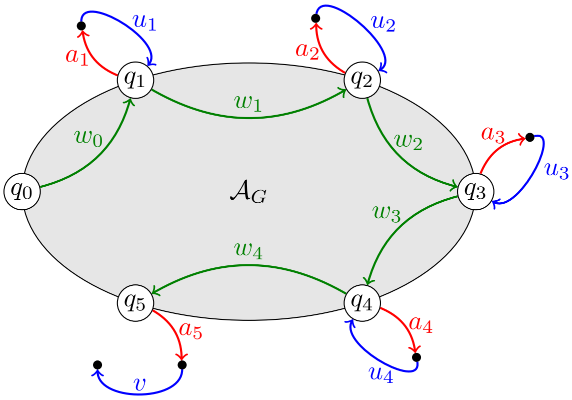

Figure 2 An $\mathcal{A}_G$-factorization of type (ii) for $k = 4$. The red-blue loops outside of $\mathcal{A}_G$ are loops in the Cayley-graph of the free group $F(\Sigma)$.

such that the following properties hold, where $\ell = k$ in case (i) and $\ell = k+1$ in case (ii):

- $w_0, \ldots, w_k, u_1, \ldots, u_k, v \in \Gamma^*$, $a_1, \ldots, a_\ell \in \Gamma$,
- *there are states $q_1, \ldots, q_{k+1} \in Q$ such that $\delta(q_i, w_i) = q_{i+1}$ for all $i \in [0, k]$ (recall that q_0 is the initial state of $\mathcal{A}_G$),*
- *$\delta(q_i, a_i) = \bot$ for all $i \in [1, \ell]$,*
- *for all $i \in [1, k]$, $\mathsf{red}(a_i u_i) = \varepsilon$ but there is no prefix $u \neq u_i$ of u_i with $\mathsf{red}(a_i u) = \varepsilon$, and*
- *in case (ii), v has no prefix x with $\mathsf{red}(a_{k+1} x) = \varepsilon$.*

Depending on which of the two cases (i) and (ii) in Definition 12 holds, we say that w has an $\mathcal{A}_G$-factorization of type (i) or type (ii).

Let us explain the intuition of the $\mathcal{A}_G$-factorization of w; see also Figures 1 and 2. We start reading the word w into the automaton $\mathcal{A}_G$, beginning at q_0, as long as possible. If it turns out that $\delta(q_0, w)$ is defined, then the $\mathcal{A}_G$-factorization of w consists of the single factor $w_0 = w$ and we obtain type (i). Otherwise, there is a shortest prefix w_0 of w (the first factor of the $\mathcal{A}_G$-factorization) such that after reading w_0 we reach the state $\delta(q_0, w_0) = q_1$ of $\mathcal{A}_G$ and $\delta(q_1, a_1) = \bot$, where a_1 is the symbol following w_0 in w. In other words, when trying to read a_1, we escape the automaton $\mathcal{A}_G$ for the first time. At this point let $w = w_0 a_1 x$.

Algorithm 2 $1/n^c$-correct randomized streaming algorithm for $\mathsf{GWP}(F(\Sigma), G)$.

```
   global variables: $q \in Q$, $p, r \in R_n$, $\beta \in \{0,1\}$
   initialization:
1  $q := q_0$ ; $\beta := 1$ ;
2  guess $r \in R_n$ according to the initial state distribution $\lambda_n$ of $\mathcal{B}_n$ ;
   next input letter: $a \in \Gamma$
3  if $\beta = 1$ and $\delta(q,a) = \bot$ then
4      $\beta := 0$ ; $p := r$
5  end
6  if $\beta = 1$ and $\delta(q,a) \neq \bot$ then
7      $q := \delta(q,a)$
8  end
9  $r := \sigma_n(r,a)$ ;
10 if $\beta = 0$ and $r = p$ then
11     $\beta := 1$
12 end
13 accept if $\beta = 1$ and $q = q_0$
```

We then take the shortest prefix u_1 of x such that $a_1 u_1 = 1$ in $F(\Sigma)$ (if such a prefix does not exist, we terminate in case (ii)). This yields a new factorization $w = w_0 a_1 u_1 y$. We then repeat this process with the word y starting from the state q_1 as long as possible. There are two possible terminations of the process: starting from state q_k we can read the whole remaining suffix into $\mathcal{A}_G$ (and arrive in state q_{k+1}). This suffix then yields the last factor w_k and we obtain (i). In the other case, we leave the automaton $\mathcal{A}_G$ with the symbol a_{k+1} from state q_{k+1} ($\delta(q_{k+1}, a_{k+1}) = \bot$) and the remaining suffix has no prefix x such that $a_{k+1}x$ evaluates to the identity in $F(\Sigma)$. The remaining suffix then yields the last factor v and we obtain (ii). The following lemma is shown in [17].

▶ **Lemma 13.** *Let $w \in \Gamma^*$ and assume that the $\mathcal{A}_G$-factorization of w and the states $q_1, \ldots, q_{k+1}$ are as in Definition 12.*

- *If the $\mathcal{A}_G$-factorization of w is of type (i) then $\mathsf{red}(w) \in G$ if and only if $q_{k+1} = q_0$.*
- *If the $\mathcal{A}_G$-factorization of w is of type (ii) then $\mathsf{red}(w) \notin G$.*

▶ **Theorem 14.** *Let G a fixed f.g. subgroup of $F(\Sigma)$. For every $c > 0$ there is a $1/n^c$-correct randomized streaming algorithm for $\mathsf{GWP}(F(\Sigma), G)$ with space complexity $\mathcal{O}(\log n)$.*

Proof. We would like to use the Stallings automaton $\mathcal{A}_G = (Q, \Gamma, q_0, \delta, q_0)$ as a streaming algorithm for $\mathsf{GWP}(F(\Sigma), G)$ (note that $|Q|$ is a constant since G is fixed). The problem is that the input word is not necessarily reduced. We solve this problem by using a $(1/n^{c+2}, 0)$-distinguisher $(\mathcal{B}_n)_{n \geq 0}$ for $F(\Sigma)$ with space complexity $\mathcal{O}(\log n)$. It exists by Theorem 7 since f.g. free groups are linear. Fix an input length n and let $\mathcal{B}_n = (R_n, \Gamma, \lambda_n, \sigma_n)$. Consider an input word $w \in \Gamma^{\leq n}$. Our randomized streaming algorithm for $\mathsf{GWP}(F(\Sigma), G)$ is Algorithm 2.

The space needed by Algorithm 2 is $\mathcal{O}(\log n)$: The variables q and β need constant space and p and r both need $\mathcal{O}(\log n)$ bits. Let us now show that the error probability of Algorithm 2 is bounded by $1/n^c$. For this let $S = \mathcal{P}(w)$ be the set of all prefixes of w. For the initially guessed state $r_0 \in R_n$ (line 3) we have by Lemma 4:

$$\mathop{\mathsf{Prob}}_{r_0 \in R_n}[\equiv_{F(\Sigma)} \text{ equals } \equiv_{r_0} \text{ on } S] \geq 1 - 1/n^{c+2}\binom{|S|}{2} \geq 1 - 1/n^c.$$

Assume for the further consideration that the guessed state r_0 is such that $\equiv_{F(\Sigma)}$ and $\equiv_{r_0}$ are equal on S. We claim that under this assumption, Algorithm 2 accepts in line 13 after reading w if and only if $\mathsf{red}(w) \in G$. For this, assume that the $\mathcal{A}_G$-factorization of w and the states $q_1, \ldots, q_{k+1} \in Q$ are as in Definition 12. By Lemma 13 it suffices to show the following:

(a) If the $\mathcal{A}_G$-factorization of w is of type (i) then after reading w we have $\beta = 1$ and $q = q_{k+1}$ in Algorithm 2.

(b) If the $\mathcal{A}_G$-factorization of w is of type (ii) then $\beta = 0$ after reading w in Algorithm 2.

To see this, observe that Algorithm 2 simulates $\mathcal{B}_n$ on w starting from r_0 (line 9). Moreover, initially we have $\beta = 1$ (line 1). This implies that Algorithm 2 simulates the Stallings automaton $\mathcal{A}_G$ on w as long as possible (line 7). If this possible for the whole input w (i.e., $\delta(q_0, w) \neq \bot$) then w has an $\mathcal{A}_G$-factorization of type (i) consisting of the single factor w (i.e., $k = 0$). Moreover, after processing w by Algorithm 2, we have $\beta = 1$ and the program variable q holds $\delta(q_0, w) = q_1 = q_{k+1}$. We obtain the above case (a).

Assume now that $k > 0$. The $\mathcal{A}_G$-factorization of w starts with $w_0 a_1$, where $\delta(q_0, w_0) = q_1$ and $\delta(q_1, a_1) = \bot$. After processing w_0 by Algorithm 2 we have $q = q_1$ and $r = \sigma_n(r_0, w_0)$. While processing the next letter a_1, Algorithm 2 sets β to 0 and saves the current state $r = \sigma_n(r_0, w_0)$ of $\mathcal{B}_n$ in the variable p (line 4). Let us write $w = w_0 a_1 v$. Since the flag β was set to 0, Algorithm 2 only continues the simulation of $\mathcal{B}_n$ on input $a_1 v$ starting from state $\sigma_n(r_0, w_0) = p$. Our assumption that $\equiv_{F(\Sigma)}$ and $\equiv_{r_0}$ are equal on the set S implies that for every prefix x of v we have: $\mathsf{red}(a_1 x) = \varepsilon$ if and only if $p = \sigma_n(r_0, w_0) = \sigma_n(r_0, w_0 a_1 x)$. In line 10, the algorithm checks the latter equality in each step (as long as $\beta = 0$). If there is no prefix x of v with $\mathsf{red}(a_1 x) = \varepsilon$ then the $\mathcal{A}_G$-factorization of w is of type (ii) (it is $w_0 a_1 v$) and the flag β is 0 after reading w. We then obtain the above case (b). Otherwise, u_1 is the shortest prefix of v with $\mathsf{red}(a_1 u_1) = \varepsilon$. Moreover, after processing u_1, the if-condition in line 10 is true for the first time. The algorithm then sets the flag β back to 1 (line 11) and resumes the simulation of the automaton $\mathcal{A}_G$ in state q_1 (which is still stored in the program variable q). This process now repeats and we see that the algorithm correctly locates the factors of the $\mathcal{A}_G$-factorization of w. This shows the above points (a) and (b). ◀

It is not possible to generalize Theorem 14 to subgroups of $F(\Sigma)$ that are not finitely generated. The proof of the following theorem (see [17]) uses the fact there is a finitely presented group whose word problem has randomized streaming space complexity $\Omega(n)$. A concrete example is Thompson's group F; see [16, Corollary 22].

▶ **Theorem 15.** *The free group F_2 of rank two has a normal subgroup N such that the randomized streaming space complexity of the language* $\mathsf{GWP}(F_2, N)$ *is in $\Theta(n)$.*

Applying Mihaĭlova's construction [19] to the normal subgroup N from Theorem 15 yields:

▶ **Theorem 16.** *There is a f.g. subgroup G of $F_2 \times F_2$ such that the randomized streaming space complexity of* $\mathsf{GWP}(F_2 \times F_2, G)$ *is in $\Theta(n)$.*

7 Open problems

A very important class of groups in geometric group theory is the class of hyperbolic groups; see [9] for background. Free groups are the simplest hyperbolic groups. Hyperbolic groups have some good algorithmic properties. For instance, their word problems can be decided in linear time by Dehn's algorithm. It would be interesting to know whether every hyperbolic group has an ϵ-distinguisher (say for $\epsilon = 1/3$) with space complexity $\mathcal{O}(\log n)$, which would imply that every hyperbolic group has randomized streaming space complexity $\mathcal{O}(\log n)$. One should remark that it is also open whether the word problem for a hyperbolic group belongs to randomized logspace (RL). The best known space upper bound for the word problem of a hyperbolic group is $\mathsf{DPSPACE}(\log^2 n)$. This follows from the fact that the word problem of a hyperbolic group belongs to LogCFL [14].

It would be also interesting to see whether a transfer theorem similar to Theorem 9 can be shown for certain fundamental groups of graphs of groups, e.g. when all edge groups are finite.

Algorithmic Dimensions via Learning Functions

Jack H. Lutz
Department of Computer Science, Iowa State University, Ames, IA, USA

Andrei N. Migunov
Department of Mathematics and Computer Science, Drake University, Des Moines, IA, USA

Abstract

We characterize the algorithmic dimensions (i.e., the lower and upper asymptotic densities of information) of infinite binary sequences in terms of the inability of learning functions having an algorithmic constraint to detect patterns in them. Our pattern detection criterion is a quantitative extension of the criterion that Zaffora Blando used to characterize the algorithmically random (i.e., Martin-Löf random) sequences. Our proof uses Lutz's and Mayordomo's respective characterizations of algorithmic dimension in terms of gales and Kolmogorov complexity.

1 Introduction

Algorithmic dimension was first formulated as a Σ_1^0 effectivization of classical Hausdorff dimension [12, 14].[1] The algorithmic dimension $\mathrm{adim}(\Gamma)$ of a set Γ of infinite binary sequences is, in fact, an upper bound of the Hausdorff dimension $\dim_H(\Gamma)$ of this set. Since algorithmic dimension has the *absolute stability* property that $\mathrm{adim}(\Gamma)$ is always the supremum of all $\mathrm{adim}(\{X\})$ for $X \in \Gamma$, it was natural to define $\dim(X) = \mathrm{adim}(\{X\})$ for all infinite binary sequences X and to investigate algorithmic dimension entirely in terms of the dimensions $\dim(X)$ of individual sequences X. Mayordomo [23] proved that the dimension $\dim(X)$, originally defined in terms of algorithmic betting strategies called *gales*, can also be characterized as the lower asymptotic density of the algorithmic information content of X. The more recent *point-to-set principle* [15] uses relativization to give the characterization

$$\dim_H(\Gamma) = \min_{A \subseteq \mathbb{N}} \sup_{X \in \Gamma} \dim^A(X)$$

of classical Hausdorff dimension. This principle has enabled several recent uses of computability theory to prove new classical theorems about Hausdorff dimension[21, 19, 20, 27, 18, 4, 5, 16, 17].[2]

Algorithmic dimension has the same Σ_1^0 "level of effectivization" as algorithmic randomness (also called "Martin-Löf randomness" [22] or, simply, "randomness"). In fact, every algorithmically random sequence X satisfies $\dim(X) = 1$, although the converse does not hold [14].

[1] Algorithmic dimension has also been called "constructive dimension", "effective Hausdorff dimension", and "effective dimension" by various authors.

[2] A theorem is "classical" here if its statement does not involve computability or related aspects of mathematical logic. Hence "new classical theorem" is not an oxymoron.

Computable learning theory, as initiated by Gold in 1967 [7, 25, 10], has been used to shed new light on randomness notions. Specifically, in 2008, Osherson and Weinstein [24] characterized two randomness notions, called weak 1-randomness and weak 2-randomness, for sequences X in terms of the inability of computable learning functions to detect patterns in X. Even more compellingly, Zaffora Blando [32] recently formulated a clever variant of Osherson and Weinstein's pattern detection criteria, called uniform weak detection, and used this to give an exact characterization of algorithmic (i.e., Martin-Löf) randomness.[3]

In this paper we introduce a quantitative version of Zaffora Blando's uniform weak detection criterion, called *s-learnability*, and we use this to characterize algorithmic dimension in terms of learning functions. Our main theorem says that, for every infinite binary sequence X, $\dim(X)$ is the infimum of all nonnegative real numbers s for which some learning function s-learns X. Our proof of this result uses methods of Osherson, Weinstein, and Zaffora Blando, together with martingale and Kolmogorov complexity techniques of Mayordomo [23]. We also characterize both the classical *packing dimension* $\dim_P$ [29, 30] and the *algorithmic strong dimension* $\mathrm{Dim}(X)$ [1] of a sequence in terms of learning functions. Along the way, we show that algorithmic randomness can also be characterized by specifically *polynomial-time* computable learning functions.

2 Preliminaries

Let $\mathbb{N}$ represent the natural numbers $\{0, 1, 2, ...\}$, $\mathbb{Q}$ the rationals, and $\mathbb{R}$ the reals. We will often use the extended naturals $\mathbb{N} \cup \{\infty\}$ and the extended reals $\mathbb{R} \cup \{\infty\}$. More often, we will refer to the respectively half open and closed intervals, $[0, \infty)$ and $[0, \infty]$.

We denote by $\{0, 1\}^*$ the set of all (finite) binary strings, and by $\{0, 1\}^\infty$ the set of all infinite binary sequences, which we call the *Cantor space* $\mathbf{C}$. We denote the length in bits of a string or sequence w by $|w|$. The *empty string* is the unique string λ with $|\lambda| = 0$. If Z is an element of $\{0, 1\}^\infty$ or of $\{0, 1\}^*$, we write $Z \upharpoonright n$ for the first n bits of Z if $|Z| \geq n$, and the value is undefined otherwise . Note that for all $n \in \mathbb{N}$, and all $Z \in \{0, 1\}^\infty$, $|Z \upharpoonright n| = n$. We write $w \sqsubseteq Z$ if w is a *prefix* of Z, i.e., if $w = Z \upharpoonright |w|$. We write $w \sqsubset Z$ if w is a *proper prefix* of Z, i.e., if w is a prefix of Z and $w \neq Z$.

For any string $w \in \{0, 1\}^*$, the *cylinder* at w is

$$C_w = \{Z \in \mathbf{C} \mid w \sqsubseteq Z\}.$$

If A is a set of strings, we denote the union of cylinders at those strings by $[\![A]\!] = \cup_{w \in A} C_w$. A (Borel) probability measure on $\mathbf{C}$ is a function $\mu : \{0, 1\}^* \to [0, 1]$ such that $\mu(\lambda) = 1$ and $\mu(w) = \mu(w0) + \mu(w1)$ for all $w \in \{0, 1\}^*$. Intuitively, $\mu(w)$ is the probability that $Z \in C_w$ when $Z \in \mathbf{C}$ is "chosen according to μ". In this sense, $\mu(w)$ is an abbreviation for $\mu(C_w)$. Standard methods [2] extend μ from cylinders to a σ-algebra $\mathcal{F}$ on $\mathbf{C}$, so that $(\mathbf{C}, \mathcal{F}, \mu)$ is a probability space in the classical sense.

Most of our attention is on the uniform (Lebesgue) probability measure λ on $\mathbf{C}$ defined by $\lambda(w) = 2^{-|w|}$ for all $w \in \{0, 1\}^*$. We rely on context to distinguish Lebesgue measure from the empty string.

[3] Zaffora Blando's paper also characterized Schnorr randomness in terms of "computably uniform weak detection", but this is not germane to our work here.

▶ **Definition.** *A function $f : \{0,1\}^* \to [0,\infty)$ is lower semicomputable if there exists a computable function $g : \{0,1\}^* \times \mathbb{N} \to \mathbb{Q} \cap [0,\infty)$ such that for all $w \in \{0,1\}^*, t \in \mathbb{N}$,*

$$g(w,t) \leq g(w,t+1) \leq f(w)$$

and

$$\lim_{t\to\infty} g(w,t) = f(w).$$

We will say that a set S of real numbers is *uniformly left computably enumerable (uniformly left c.e.)* if there exists a lower-semicomputable function whose range is S.

3 Algorithmic randomness via learning functions

The algorithmic randomness of a sequence was originally defined in [22] in terms of algorithmic measure theory. In this view, an algorithmically random sequence is one which belongs to every algorithmically definable measure one set. Martin-Löf shows that all algorithmically nonrandom sequences belong to one universal algorithmically measure-zero set.

▶ **Definition** ([22]). *If μ is a probability measure on $\boldsymbol{C}$, then we say a set X has* algorithmic μ-measure zero *if there exists a computable function $g : \mathbb{N} \times \mathbb{N} \to \{0,1\}^*$ such that: for every $k \in \mathbb{N}$,*

$$X \subseteq \bigcup_{n=0}^{\infty} C_{g(k,n)}$$

and

$$\sum_{n=0}^{\infty} \mu(C_{g(k,n)}) \leq 2^{-k}.$$

▶ **Definition** ([22]). *We say a sequence S is* Martin-Löf μ-nonrandom *if $\{S\}$ has algorithmic μ-measure zero, and* Martin-Löf μ-random *otherwise.*

When the probability measure μ is the Lebesgue measure λ defined in section 2, we omit it from the terminology in the preceding two definitions. Randomness can also be characterized using gambling strategies called *gales*.

▶ **Definition** ([14]). *For $s \in [0,\infty)$, a* μ-s-gale *is a function $d : \{0,1\}^* \to [0,\infty)$ that satisfies the condition that*

$$d(w)\mu(w)^s = d(w0)\mu(w0)^s + d(w1)\mu(w1)^s,$$

for every $w \in \{0,1\}^*$.

Sometimes, when the probability distribution μ is clear from context, we will refer simply to s-gales. A *martingale* is a 1-gale. If not stated explicitly otherwise, we assume that the *initial capital* of a gale is $d(\lambda) = 1$.

▶ **Definition.** *A μ-s-gale d* succeeds *on a set Γ of sequences if*

$$\limsup_{n\to\infty} d(X \restriction n) = \infty$$

for every sequence $X \in \Gamma$.

Ville shows the following:

▶ **Theorem 1** ([31]). *Let $\lambda(E)$ denote the Lebesgue measure of a set $E \subseteq \{0,1\}^\infty$. The following are equivalent:*

(1) $\lambda(E) = 0$

(2) *There exists a martingale $d : \{0,1\}^* \to [0,\infty)$ that succeeds on E.*

Schnorr effectivizes Ville's theorem as follows:

▶ **Theorem 2** ([26]). *A set of sequences Γ is Martin-Löf random if and only if there exists no lower-semicomputable martingale that succeeds on Γ.*

We will revisit gales in a later section, when we discuss dimension.

▶ **Definition** ([25]). *A function $l : \{0,1\}^* \to \{\text{YES}, \text{NO}\}$ is called a* learning function.

YES and NO are simply aliases for 1 and 0, respectively.

One can impose resource bounds on learning functions or on properties of these functions such as their average answers "along" a string w. l may be computable (in which case we call it a computable learning function or *CLF*), or l may have lower-semicomputable averages at all points in $\{0,1\}^*$, or any number of other resource restrictions.

▶ **Definition** ([32]). *A learning function l is said to* uniformly weakly detect *that a sequence $X \in \{0,1\}^\infty$ is patterned if and only if*

1. $l(X \upharpoonright m) = \text{YES}$ *for infinitely many $m \in \mathbb{N}$, and*
2. $\lambda(\{Y \in \{0,1\}^\infty \mid \#\{m \in \mathbb{N} \mid l(Y \upharpoonright m) = \text{YES}\} \geq n\}) \leq 2^{-n}$
   for all $n \in \mathbb{N}$.

Zaffora Blando shows that computable learning functions and uniform weak detectability characterise Martin-Löf randomness:

▶ **Theorem 3** ([32]). *A sequence $X \in \{0,1\}^\infty$ is Martin-Löf random if and only if there is no computable learning function that uniformly weakly detects that X is patterned.*

▶ **Theorem 4.** *The following are equivalent:*

1. *There exists a computable learning function that uniformly weakly detects that X is patterned.*
2. *There exists a polynomial-time computable learning function that uniformly weakly detects that X is patterned.*

Proof. (2) $\implies$ (1) is immediate.

To see that (1) $\implies$ (2):

Let l be a computable learning function which uniformly weakly detects that X is patterned. Let $M_l(w)$ be a TM which computes $l(w)$. Algorithm 1 specifies a learning function with the following properties:

$\hat{l} = \text{YES}$ if there exist $w' \sqsubset w$ and $t_{w'} \in \mathbb{N}$ such that all of the following hold:

1. $|w| = |w'| + t_{w'}$
2. $l(w') = \text{YES}$
3. $t_{w'} = \min\{t \mid M_l(w') = \text{YES} \text{ after } t \text{ steps}\}$,

and $\hat{l} = \text{NO}$ otherwise.

If l says YES infinitely often on X, then there are infinitely many $w', t_{w'}$ where $M_l(w') = \text{YES}$ after exactly $t_{w'}$ time steps. Thus there are infinitely many w with $|w| = |w'| + t_{w'}$ where $\hat{l}$ says YES. Thus, $\hat{l}$ says YES infinitely often on X.

For all $Y \in \{0,1\}^\infty$, the number of YES given by $\hat{l}$ along Y remains the same as the number given by l, all such answers being "delayed" until later. Thus, the measure condition is satisfied. Thus, $\hat{l}$ is a learning function which uniformly weakly detects that X is patterned.

Algorithm 1 $M_{\hat{l}}$.

```
Input $w$:
for all $w' \sqsubset w$ do
    Run $M_l(w')$ for exactly $|w| - |w'|$ steps.
    if $M_l(w')$ prints YES for the first time after exactly $|w| - |w'|$ steps then
        return YES
    else
        Continue
    end if
end for
return NO
```

$M_{\hat{l}}$ always halts and terminates in time polynomial in $|w|$. Thus, $\hat{l}$ is polynomial-time computable. ◀

As a result, one can characterize algorithmic randomness in terms of polynomial-time computable learning functions:

▶ **Corollary 5.** *A sequence $X \in \{0,1\}^\infty$ is Martin-Löf random if and only if there is no polynomial-time computable learning function that uniformly weakly detects that X is patterned.*

We also note a useful fact about uniform weak detectability:

▶ **Observation 6.** *If l_1 uniformly weakly detects that Γ_1 is patterned, and l_2 uniformly weakly detects that Γ_2 is patterned, then there exists a learning function l_3 which uniformly weakly detects that $\Gamma_1 \cup \Gamma_2$ is patterned. This transformation preserves computability.*

Proof. Define l_3 by:

$l_3(v) =$ YES if either $l_1(v) =$ YES or $l_2(v) =$ YES, unless for all $v' \sqsubset v$ $l_1(v) =$ NO or for all $v' \sqsubset v$ $l_2(v) =$ NO.

That is, l_3 says YES whenever either l_1 or l_2 would say YES, except for the first time for each.

It is easy to verify that l_3 says YES infinitely often on every $X \in \Gamma_1 \cup \Gamma_2$ and that the measure property is satisfied. It is also easy to show that if l_1 and l_2 are computable, then l_3 is as well. ◀

As a result, uniform weak detectability by computable learning functions is closed under finite unions.

4 Classical and algorithmic dimensions

Next, we review the definitions of classical and algorithmic dimensions.

We say a set A *covers* a set of sequences Γ if for every $X \in \Gamma$ there is some $w \in A$, $w \sqsubseteq X$. Let $k \in \mathbb{N}$, and let $\mathcal{A}_k = \{A \mid A \text{ is a prefix set and } \forall x \in A, |x| \geq k\}$. Let

$$\mathcal{A}_k(\Gamma) = \{A \in \mathcal{A}_k \mid A \text{ covers } \Gamma\},$$

and let

$$H^s_k(\Gamma) = \inf_{A \in \mathcal{A}_k(\Gamma)} \sum_{w \in A} 2^{-s|w|}.$$

Note that this infimum is taken only over sets of cylinders, not over all possible covers. For that reason, the following function is a proxy for - and is within a constant multiplicative factor of - what is know as the *s-dimensional Hausdorff outer measure*, in which all covers are considered.

▶ **Definition** ([8]). $H^s(\Gamma) = \lim_{k\to\infty} H^s_k(\Gamma)$.

For any set Γ, there exists some $s \in [0, \infty)$ such that for every $a < s < b$,

1. $H^a(\Gamma) = \infty$, and
2. $H^b(\Gamma) = 0$.

The real number s is the Hausdorff dimension of Γ:

▶ **Definition** ([8]). *The* Hausdorff dimension *of a set* $\Gamma \subseteq \{0,1\}^\infty$ *is*

$$\dim_H(\Gamma) = \inf\{s \in [0,\infty) \mid H^s(\Gamma) = 0\}.$$

Hausdorff dimension can be characterized in terms of gales:

▶ **Theorem 7** ([13]).

$$\dim_H(\Gamma) = \inf\{s \in [0,\infty)| \textit{ there exists an s-gale that succeeds on } \Gamma\}.$$

Lutz also showed that by effectivizing gales[4] at various levels, one can obtain various *effective* dimension notions, including the *algorithmic dimension*:

▶ **Definition** ([14]). *The* algorithmic dimension *of a set* $\Gamma \subseteq \{0,1\}^\infty$ *is*

$$\text{adim}(\Gamma) = \inf\{s \in [0,\infty)| \textit{ there exists}$$

$$\textit{a lower semicomputable s-gale that succeeds on } \Gamma\}.$$

We also note the following theorem:

▶ **Theorem 8** ([14]). *Let μ be a probability measure on $\{0,1\}^\infty$, let $s, s' \in [0,\infty)$, and let $d, d' : \{0,1\}^* \to [0,\infty)$. Assume that*

$$d(w)\mu(w)^s = d'(w)\mu(w)^{s'}$$

for all $w \in \{0,1\}^*$. Then, d is a μ-s-gale if and only if d' is a μ-s'-gale.

A corollary of this theorem, which we will make use of in the main proof of the next section, is the following:

▶ **Proposition 9.** *If d is an s-gale that succeeds on X then there exists a martingale d' that succeeds on X against order $h(w) = 2^{(1-s)|w|}$. That is,*

$$\limsup_{n\to\infty} \frac{d(X \upharpoonright n)}{h(n)} = \infty.$$

[4] In Lutz' original proof, *supergales* are used. These satisfy the gale definition with $\leq$ in place of equality. [9] shows that gales suffice for the characterization of algorithmic dimension.

Another important classical dimension notion is the packing dimension [30, 29]. As with the Hausdorff dimension, it is easier to define it in terms of gales than in terms of its original conception via coverings. First we define a notion of *strong success* for gales:

▶ **Definition** ([1]). *A μ-s-gale d* succeeds strongly *on a set Γ of sequences if*

$$\liminf_{n\to\infty} d(X \restriction n) = \infty$$

for every sequence $X \in \Gamma$.

▶ **Definition** ([1]). *The* packing dimension *of a set $\Gamma \subseteq \{0,1\}^\infty$ is*

$$\dim_P(\Gamma) = \inf\{s \in [0,\infty) | \text{ there exists an } s\text{-gale that succeeds strongly on } \Gamma\}.$$

The packing dimension can be effectivized as follows:

▶ **Definition** ([1]). *The* algorithmic packing dimension *or* algorithmic strong dimension *of a set $\Gamma \subseteq \{0,1\}^\infty$ is*

$$\mathrm{aDim}(\Gamma) = \inf\{s \in [0,\infty) | \text{ there exists a lower semi-computable } s\text{-gale}$$

$$\text{that succeeds strongly on } \Gamma\}.$$

We use the above notations adim and aDim when describing the algorithmic dimensions of sets in order to distinguish these from their classical counterparts. When applied to individual sequences, we often use dim and Dim, respectively, as there is no ambiguity.

5 Hausdorff dimension via learning functions

Learning functions can be used to characterize the classical (Hausdorff) dimension. Once such a characterization is in place, one can impose further restrictions on the computability of learning functions and thereby use the notion of learning to characterize dimension notions at various levels of effectivity.

We refine the definition of uniform weak detectability, by adding a requirement on the frequency of YES answers, in order to characterize dimension. Recall that we identify YES with 1 and NO with 0, thus the sum in the following definition is well-defined.

▶ **Definition.** *If l is a learning function, the* path average of l up to w *is denoted*

$$\mathrm{AVG}_l(w) = \frac{\sum_{i=0}^{i=|w|} l(w \restriction i)}{|w|}.$$

Let Δ be a computability restriction such as “lower semi-computable”, “computable”, or “all” (the absence of a restriction).

▶ **Definition.** *A sequence X is (Δ)-s-*learnable *if and only if there exists a function l : $\{0,1\}^* \to \{\mathrm{YES}, \mathrm{NO}\}$ such that the following three conditions are satisfied.*

1. *For every $w \in \{0,1\}^*$, the path averages $\mathrm{AVG}_l(w)$ are uniformly Δ-computable (in w).*
2. *For all $n \in \mathbb{N}$,*

$$\lambda(\{Y \in \{0,1\}^\infty \mid \#\{i \mid l(Y \restriction i) = \mathrm{YES}\} \geq n)\}) \leq 2^{-n}.$$

3. $\limsup_{n\to\infty} \mathrm{AVG}_l(X \restriction n) \geq 1 - s.$

We say that a sequence X is *strongly* (Δ)*-s-learnable* if it satisfies (1) and (2) above, and satisfies condition (3) with a $\liminf$ rather than a $\limsup$.

Specifically, we will say that *algorithmic* s-learnability corresponds to $\Delta = \Sigma^0_1$, *computable* s-learnability corresponds to $\Delta = \Delta^0_1$ and s-learnability as such corresponds to no resource restriction (in other words, any learning functions at all can be used). Note that the restriction on computability is not applied to the learning function itself, but to its path averages on the elements of $\{0,1\}^*$.

We often refer to a learning function which satisfies these properties as an *s-learner*, and we say it *s-learns* a sequence or set of sequences.

This definition is in the spirit of [28], emphasizing learnability criteria based on frequencies of YES answers, rather than restrictions on the measure conditions.

A function $l : \{0,1\}^* \to \{\text{NO}, \text{YES}\}$ is associated to a transformation $\hat{l} : \{0,1\}^\infty \to \{\text{NO}, \text{YES}\}^\infty$ defined by $\hat{l}(Y) = X$, where $X[n] = l(Y \restriction n)$. In this sense, each sequence x is transformed into a sequence consisting of YES and NO "bits". For any set S, and function $f : \{0,1\}^\infty \to \{0,1\}^\infty$, $f^{-1}[S]$ is the set of all X with $f(X) \in S$. Define functions $\hat{l}$ on finite strings analogously.

► **Observation 10.** *For every learner l and every $Y \in \{0,1\}^\infty$, either l s-learns every $X \in \hat{l}^{-1}[Y]$ or none of them.*

This is immediate from the success criterion. s-learning a sequence is purely a matter of the asymptotic frequency with which some learner says YES on prefixes of that sequence, assuming the measure condition is satisfied by l.

Closure under finite unions also holds for s-learnability:

► **Observation 11.** *If l_1 s-learns Γ_1 and l_2 s-learns Γ_2, then there exists a learning function l_3 which s-learns $\Gamma_1 \cup \Gamma_2$.*

Proof. The idea is the same as in Observation 6. Define l_3 by:

$l_3(v) = \text{YES}$ if either $l_1(v) = \text{YES}$ or $l_2(v) = \text{YES}$, unless it's the first time that either l_1 or l_2 has said YES on any $v' \sqsubseteq v$.

Note that $\limsup_{n\to\infty} \frac{\sum^n l(X\restriction i)}{n} \geq (1-s)$ implies that $\limsup_{n\to\infty} \frac{\sum^n l(X\restriction i)}{n} - \frac{k}{n} \geq (1-s)$ for any fixed k. ◄

We will now show that s-learning characterizes Hausdorff dimension.

Let $\mathscr{G}(\Gamma) = \{s \in (0,\infty) \mid$ there exists a learning function l which s-learns every $X \in \Gamma\}$. The following theorem is a characterization of Hausdorff dimension in terms of learning functions.

► **Theorem 12.** *For all $\Gamma \subseteq \{0,1\}^\infty$,*

$$\dim_H(X) = \inf \mathscr{G}(\Gamma).$$

Proof. Assume $\dim_H(\Gamma) \leq s$. Then for all $s' > s$ there exists an s'-gale which succeeds on Γ, and by Proposition 9 there exists a martingale d which, for every $X \in \Gamma$ succeeds on X against order $h(w) = 2^{(1-s')|w|}$. That is, d doubles its money asymptotically $1 - s'$ share of the time. Let

$$\gamma_d(w) = \begin{cases} \text{YES} & \text{if there exists } w' \sqsubseteq w \text{ such that } d(w) \geq 2 \cdot d(w') \text{ and} \\ & \forall \hat{w} \text{ satisfying } w' \sqsubset \hat{w} \sqsubset w,\ \gamma_d(\hat{w}) = \text{NO} \\ \text{NO} & \text{otherwise} \end{cases} \tag{5.1}$$

γ_d says YES every time d doubles its money (attains a new 2^k value). The set of sequences on which γ_d says YES infinitely often is the same as the set of sequences on which d wins unbounded money *against* h, thus it has measure zero. Thus for any $X \in \Gamma$ there must be infinitely many $X \upharpoonright n$ such that $\gamma_d(X \upharpoonright n)$ has YES density at least $(1 - s')$ at $X \upharpoonright n$.

Let $n \in \mathbb{N}$ and let $B_n = \{w \mid d(w) \geq 2^n \text{ and } \forall v \sqsubseteq w, d(v) < 2^n\}$. B_n is the (prefix-)set of all w at which d has accumulated 2^n value for "the first time". By the Kolmogorov inequality ([31]), $\lambda(\cup_{w \in B_n} C_w) \leq 2^{-n}$. For all n,

$$\begin{aligned} A_n^{\gamma_d} &= \{Y \mid \#\{m \mid \gamma_d(Y \upharpoonright m) = \text{YES}\} \geq n\} \\ &\subseteq \{Y \mid \exists k \; d(Y \upharpoonright k) \geq 2^n\} \\ &= \cup_{w \in B_n} C_w, \end{aligned}$$

Thus, for all n, $\lambda(A_n^{\gamma_d}) \leq \lambda(\cup_{w \in B_n} C_w) \leq 2^{-n}$. Thus γ_d s'-learns every $X \in \Gamma$.

In the other direction, suppose that for all $s' > s$ there is a learning function which s'-learns every $X \in \Gamma$. Let l be such a learning function. We show $\dim_H(\Gamma) \leq s$. Let k, r be any integers. Let

$$\hat{A}_k = \{w \mid \#\,\text{YES}(w) \geq r + (1 - s')|w| \text{ and } \forall v \sqsubset w, v \notin \hat{A}_k\}.$$

$\hat{A}_k \in \mathcal{A}_k(\Gamma)$ because for all $w \in \hat{A}_k$, $|w| > k$, and $\hat{A}_k$ is a prefix set.

For every n,

$$\lambda(\{Y \mid \#\,\text{YES}(Y) \geq r + (1 - s')n\}) \leq 2^{-r-(1-s')n}.$$

Thus, the number of strings of length exactly k which can have at least $r + (1 - s')k$ YES answers is at most

$$\frac{2^{-r-(1-s')k}}{2^{-k}} = 2^{-r+s'k}.$$

$$H_k^{s'}(\Gamma) \leq \sum_{w \in \hat{A}_k} 2^{-s'|w|} \leq \sum_{n=k}^{\infty} |\hat{A}_k^{=n}| 2^{-s'n} \leq 2^{-r+s'k} 2^{-s'k} = 2^{-r},$$

where the third inequality is due to the Kraft inequality [11, 3], because $\hat{A}_k$ is a prefix set.

Thus

$$\begin{aligned} H^{s'}(\Gamma) &= \lim_{k \to \infty} \inf_{A \in \mathcal{A}_k(\Gamma)} \sum_{w \in A} 2^{-s|w|} \\ &\leq \lim_{k \to \infty} \sum_{w \in \hat{A}_k} 2^{-s|w|} \\ &= 0. \end{aligned}$$

Thus $\dim_H(\Gamma) \leq s$. ◀

6 Algorithmic dimension via learning functions

In this section, we show that algorithmic s-learning characterizes algorithmic dimension.

Recall that a learning function *algorithmically s-learns* a set $\Gamma \subseteq \{0, 1\}^\infty$ if it satisfies the definition of s-learning with $\Delta = \Sigma_1^0$. In other words, we require that the path-averages of l on all strings w are uniformly lower semicomputable real numbers.

Before we discuss the proof that algorithmic s-learnability characterizes algorithmic dimension, we note why it is at least *seemingly difficult* to directly lower semi-compute the learning function described in Theorem 12. For one, a suitable notion of lower semi-computability is hard to establish for functions mapping to $\{0,1\}$. Secondly, the learning function γ_d in the proof of Theorem 12 relies on being able to place a YES answer every time the "underlying" martingale doubles its money for the first time. That is, every time it achieves a new value 2^k for the first time along some sequence. Though checking whether this happens *eventually* is lower semicomputable, checking whether it has happened at a particular w for the *first time* is not. Instead, we can simply require that path-averages be lower semicomputable. Thus, the conditions of algorithmic s-learnability coincide with the existence of lower semi-computable martingales succeeding against exponential orders.

For a given martingale d, we define the learning function γ_d as in Theorem 12. Note that if d is lower semi-computable with computable witness $\hat{d}$, then the path averages of γ_d are lower semi-computable uniformly in w via the computable witness below (Algorithm 2).

Algorithm 2 AVG_l.

```
Input $w, k$:
Compute all the values $\hat{d}(\lambda, k), \dots, \hat{d}(w, k)$.
Compute $m_{w,k} = \max_{w' \sqsubseteq w} \left\{ \log_2 \left( \hat{d}(w', k) \right) \right\}$
return $\frac{m_{w,k}}{|w|}$
```

As a result, the set

$$T = \{w \mid \mathrm{AVG}_{\gamma_d}(w) \geq 1 - s\}$$

is computably enumerable, and so are all of the slices

$$T_m = \{w \mid \mathrm{AVG}_{\gamma_d}(w) \geq 1 - s \text{ and } |w| = m\}.$$

Let $\mathscr{G}_{\text{alg}}(\Gamma) = \{s \in [0, \infty) \mid \text{there exists a learning function } l \text{ which algorithmically } s\text{-learns every } X \in \Gamma\}$.

We now prove our main theorem.

▶ **Theorem 13.** *For all* $\Gamma \subseteq \{0,1\}^\infty$*,*

$$\mathrm{adim}(\Gamma) = \inf \mathscr{G}_{\text{alg}}(\Gamma).$$

Proof. Let $s = \inf \mathscr{G}_{\text{alg}}(\Gamma)$. We will show $\dim(\Gamma) \leq s$.

Let $s' > s$ and let l be a learning function that algorithmically s'-learns every $X \in \Gamma$.

[6] Theorem 13.3.4 ([23], Theorem 3.1) states that $\dim(X) = \liminf_n \frac{C(X \upharpoonright n)}{n}$ where C is the *plain Kolmogorov complexity*.

Let $T = \cup T_n$ where $T_n = \{w \mid |w| = n \text{ and } \mathrm{AVG}_l(w) \geq 1 - s\}$. T is computably enumerable due to the first condition of s'-learnability.

For each n, $\lambda(\cup_{w \in T_n} C_w) \leq 2^{-(1-s')n}$ as a result of the measure condition of s'-learnability, since every sequence Y with at least $n(1-s)$ YES answers at length n is in the set of sequences which have at least $n(1-s)$ YES answers total, and the measure of the latter set is at most $2^{-(1-s')n}$. Thus, since each $w \in T_n$ has measure 2^{-n} and all are disjoint, we have $|T_n| \leq 2^{s'n}$. As a result, in plain Kolmogorov complexity terms, we only need to supply at most $s'n$ bits to identify an element of T living in T_n (we get n "for free" as long as we supply *exactly* $s'n$ bits, and use them to identify the slice T_n of T).

This means that for all $w \in T$, $C(w) \leq s'|w|$. Note that for every $X \in\ \Gamma$, there are infinitely many n so that $X \upharpoonright n \in T$.

It follows, then, that for every $X \in \Gamma$,

$$\dim(X) = \liminf_n \frac{C(X \upharpoonright n)}{n} \leq \frac{s'n}{n} = s',$$

and thus - since $s' > s$ was arbitrary - $\dim(\Gamma) \leq s$.

In the other direction, we show that if $\dim(\Gamma) \leq s$, then for every $s' > s$, Γ is algorithmically s'-learnable.

Again, let $s' > s$ and let d be a martingale which succeeds against order $2^{(1-s')n}$ on every $X \in \Gamma$. Define the learning function γ_d, as in Theorem 12 (Eq. 5.1), to say YES every time d doubles its money (attains a new 2^k value) for the first time along each path.

We have established that the values $\mathrm{AVG}_{\gamma_d}(w)$ are uniformly lower-semicomputable when d is lower-semicomputable. We also know from the proof of Theorem 12 that γ_d satisfies the measure condition and that $\limsup_{n\to\infty} \mathrm{AVG}(l, X \upharpoonright n) \geq 1 - s'$, for every $X \in \Gamma$. ◀

7 Strong algorithmic dimension via learning functions

In this section, we characterize the packing dimension as well as the strong algorithmic dimension of a set of binary sequences in terms of strong s-learning and strong algorithmic s-learning, respectively.

For any $\Gamma \subseteq \{0,1\}^\infty$, let $\Gamma \upharpoonright n = \{w \mid |w| = n$ and w is a prefix of some $v \in \Gamma\}$.

▶ **Definition** ([6]). *For any $\Gamma \subseteq \{0,1\}^\infty$, let the* upper box-counting dimension *of Γ be*

$$\overline{\dim_B(\Gamma)} = \limsup_n \frac{\log |\Gamma \upharpoonright n|}{n}.$$

▶ **Theorem 14** ([1]). *For every $X \in \{0,1\}^\infty$,*

$$\mathrm{Dim}(X) = \limsup_n \frac{C(X \upharpoonright n)}{n}.$$

Let $\mathscr{G}_{str}(\Gamma) = \{s \in [0,\infty) \mid$ there exists a learning function f which strongly s-learns every $X \in \Gamma\}$.

▶ **Theorem 15.** *Let $\Gamma \subseteq \{0,1\}^\infty$. Then,*

$$\dim_P(\Gamma) = \inf \mathscr{G}_{str}(\Gamma).$$

Proof. First, we show that if, for arbitrary $s' > s$, l is a learning function that strongly s'-succeeds on Γ, then $\dim_P(\Gamma) \leq s$.

The proof is much the same as [1] and [4] Theorem 13.11.9, except we start with a learning function instead of a gale. Assume the hypothesis. Let $\hat{s} > s'$ be arbitrary.

Let

$$T_n = \{w \mid \mathrm{AVG}_l(w) \geq 1 - \hat{s} \text{ and } |w| = n\}$$

be the set of strings of length n on which l achieves the requisite density. Then, for all $X \in \Gamma$, and for all but finitely many $n \in \mathbb{N}$, $X \in \cup_{w\in T_n} C_w$, i.e.

$$\Gamma \subseteq \cup_i \cap_{j\geq i} [\![T_j]\!].$$

Let $Z_n = \cap_{m \geq n} [\![T_m]\!]$. Then, $X \in Z_n$ means that after the nth prefix, all remaining prefixes of X have density at least $1 - \hat{s}$.

It suffices - by the countable stability of $\dim_P$ and the fact that $\dim_P \leq \overline{\dim_B}$ (see [6] 13.11.3) - to show that $\overline{\dim_B}(Z_n) \leq \hat{s}$, for all n. While the original proof uses Kolmogorov's inequality, we are not dealing with a gale. We have shown in the proof of Theorem 13 that if l is an $\hat{s}$-learner, then the set T_n satisfies $|T_n| \leq 2^{\hat{s}n}$.

Then,

$$\overline{\dim_B(Z_i)} = \limsup_n \frac{\log |Z_i \restriction n|}{n} \leq \limsup_n \frac{\log |T_n|}{n} \leq \hat{s}.$$

Since $\hat{s} > s' > s$ are arbitrary, $\dim_P(\Gamma) \leq \overline{\dim_B}(\Gamma) = \overline{\dim_B}(\cup Z_i) \leq s$.

In the other direction, simply note that if $\dim_P(\Gamma) \leq s$ then for every $s' > s$ there exists a martingale $d_{s'}$ which strongly s'-succeeds against order $2^{(1-s')n}$ on every $X \in \Gamma$, and the frequency with which the martingale doubles its money is always eventually bounded below. Thus, a learner defined as in Eq. 5.1 will have the desired YES density on the same sequences. ◀

Let $\mathscr{G}^{str}_{\text{alg}}(\Gamma) = \{s \in [0, \infty) \mid$ there exists a learning function l which strongly algorithmically s-learns every $X \in \Gamma\}$.

▶ **Theorem 16.** *Let* $\Gamma \subseteq \{0,1\}^\infty$. *Then,*

$$\text{aDim}(\Gamma) = \inf \mathscr{G}^{str}_{\text{alg}}(\Gamma).$$

Proof. Much like the gale characterization of aDim resembles the gale characterization of adim with minor changes (see [1] and [6], Corollary 13.11.12), this proof closely resembles the proof of Theorem 13.

We replace the lim inf with a lim sup in order to apply Theorem 14, and we replace the observation that infinitely many n satisfy $X \restriction n \in T$ with "all but finitely many."

In the other direction, we assume there exists a lower semi-computable martingale $d_{s'}$ which succeeds strongly against order $2^{(1-s')n}$ on every $X \in \Gamma$. A learning function defined in the same way as before (Eq. 5.1) will have the requisite density of YES answers, and will also have uniformly lower-semicomputable averages at each $w \in \{0,1\}^*$, as established in Section 6. ◀

On the Complexity of the Conditional Independence Implication Problem with Bounded Cardinalities

Michał Makowski
Faculty of Mathematics, Informatics and Mechanics, University of Warsaw, Poland

Abstract

We show that the conditional independence (CI) implication problem with bounded cardinalities, which asks whether a given CI implication holds for all discrete random variables with given cardinalities, is co-NEXPTIME-hard. The problem remains co-NEXPTIME-hard if all variables are binary. The reduction goes from a variant of the tiling problem and is based on a prior construction used by Cheuk Ting Li to show the undecidability of a related problem where the cardinality of some variables remains unbounded. The CI implication problem with bounded cardinalities is known to be in EXPSPACE, as its negation can be stated as an existential first-order logic formula over the reals of size exponential with regard to the size of the input.

1 Introduction

The implication problem for conditional independence statements is one of the major decision problems arising in multivariate statistical modeling and other applications [2]. The problem asks whether a list of conditional independence statements implies another such statement (see the exact formulation below). The problem is a special case of the conditional entropic inequality problem, as the statement *X and Y are independent, given Z* (sometimes denoted $X \perp Y \mid Z$) is equivalent to the equation $I(X;Y|Z) = 0$ in information theory. Here the random variables in consideration are of the form $(X_{i_1}, \dots, X_{i_\ell})$, abbreviated by X_Z with $Z = \{i_1, \dots, i_\ell\}$, selected from a fixed n-tuple of variables $X_1, \dots, X_n$ considered with a joint distribution. As with the general problem, this can be considered over continuous, infinite discrete or finite discrete random variables. Furthermore, the CI implication problem can be refined by imposing certain requirements on the sets A, B, C in $X_A \perp X_B \mid X_C$, e.g., they must be pairwise disjoint for *disjoint CI*, and for *saturated CI* they must additionally satisfy $A \cup B \cup C = \{1, \dots, n\}$. We will focus on discrete random variables with a finite domain and without constraints on the sets, addressing disjoint CI in the full version.

If the domain size is bounded, this problem is decidable since the conditional independence can be expressed as an arithmetic formula in terms of elementary events' probabilities. Considering all possible domain sizes yields a semi-algorithm for finding a counter-example to the implication, showing that the unbounded problem is co-recursively enumerable (as noted by Khamis *et al* [5]). The decidability of the general CI implication problem was unknown for a long time, with only special cases resolved. Finally, Cheuk Ting Li published two papers [8, 9] proving the problem to be undecidable. This was also shown independently

by Kühne and Yashfe [6]. Still unknown is the complexity of the bounded problem – the method of constructing an existential formula of Tarski's arithmetic yields an upper bound of EXPSPACE (cf. [1]), while the other published algorithms appear to be mostly heuristics. Hannula *et al* [4] conjectured that the problem can be actually easier, especially in the case where all variables are binary, as the arithmetic formula in question is of a very special form.

In this paper we show that the problem is in general co-NEXPTIME-hard, and the hardness result continues to hold if all variables are binary. Our reduction is an adaptation of the construction presented by Li [8] to show that the problem is undecidable if the cardinalities of some variables are bounded. While there is still a gap between the lower and upper bound, this shows that the complexity of the CI implication problem is harder than it might have been expected.

2 Problem statement

Denote by $\mathrm{card}(X)$ the cardinality of a random variable X. Formally, the following problem will be considered:

Bounded CI Implication

Input: Integers m, n, given in unary. A list of $m+1$ triples (A_i, B_i, C_i) of subsets of $\{1, \dots, n\}$. A list of n integers K_j, given in binary.

Question: Determine whether the implication

$$\bigwedge_{i \in \{1,\dots,m\}} (I(X_{A_i}; X_{B_i} | X_{C_i}) = 0) \Rightarrow I(X_{A_{m+1}}; X_{B_{m+1}} | X_{C_{m+1}}) = 0$$

holds for all jointly distributed random variables $(X_1, \dots, X_n)$ with $\mathrm{card}(X_j) \leq K_j$ for all $j \in \{1, \dots, n\}$.

We define Constant-bounded CI Implication as a variant of the above problem in which all K_i are fixed to be equal to 2 rather than given as input. We show the following:

▶ **Theorem 1.** *Bounded CI Implication and Constant-bounded CI Implication are co-NEXPTIME-hard. This also holds in the disjoint CI case, i. e. when for each i the sets A_i, B_i, C_i are pairwise disjoint.*

We focus on the first part of the theorem – the proof of the second part differs little from that given by Li [8] and is given in the full version.

In order to state the tiling-based problems utilized in the reduction, we introduce some definitions based on those in [7]. We define a *tiling system* as a triple $\mathcal{D} = (D, H, V)$, where D is a finite set of tiles and $H, V \subseteq D^2$ are the horizontal and vertical constraints, accordingly, which give the pairs of tiles that may be neighbors. This is a generalization of Wang tiles, where a set of colors C is given and tiles (formally quadruples from the set C^4) are represented by squares with colored edges with the requirement that only edges of the same color may touch. As stated in [12], Wang tiles correspond exactly to those tiling systems for which the implication $(a\,R\,b \wedge a\,R\,c \wedge d\,R\,b) \Rightarrow d\,R\,c$ holds for all $a, b, c, d \in D$ and both $R \in \{H, V\}$.

We define a $k \times l$ *tiling* by $\mathcal{D}$ as a function $f : \{0, \dots, k-1\} \times \{0, \dots, l-1\} \to D$ such that:

- $(f(m,n), f(m+1,n)) \in H$ for all $m < k-1, n < l$,
- $(f(m,n), f(m,n+1)) \in V$ for all $m < k, n < l-1$.

A *periodic tiling* is one that also has $(f(k-1,n), f(0,n)) \in H$ and $(f(m,l-1), f(m,0)) \in V$ for all $m < k, n < l$. For a (non-periodic) $k \times l$ tiling f, the *starting tile* and *final tile* are the values of $f(0,0)$ and $f(k-1,l-1)$, respectively.

We will show a polynomial-time many-one reduction from the following problem, which is known to be NEXPTIME-complete [7, exercise 7.2.2.]:

Binary Bounded Tiling
Input: A tiling system $\mathcal{D}$, a starting tile $d_0 \in D$, an integer k given in binary.
Question: Determine whether there exists a $k \times k$ tiling f by $\mathcal{D}$ such that $f(0,0) = d_0$.

The reduction consists of two parts, the first being a purely tiling-based reduction from the above to the following intermediate problem:

Periodic Bounded Tiling
Input: A tiling system $\mathcal{D}$, a designated tile t, integers m, n given in binary.
Question: Determine whether there exists a periodic tiling by $\mathcal{D}$ of size at most $m \times n$ which uses tile t.

The second part is a reduction from Periodic Bounded Tiling to the complement of Bounded CI Implication, based on a construction by Li [8].

3 First part of the reduction

We first show a polynomial-time many-one reduction from Binary Bounded Tiling to Periodic Bounded Tiling. This means that given a tiling system $\mathcal{D}$, starting tile d_0 and integer k, we will construct in polynomial time a tiling system $\mathcal{D}''$, designated tile t and integers m, n such that Binary Bounded Tiling gives a positive answer for input $(\mathcal{D}, d_0, k)$ iff Periodic Bounded Tiling gives a positive answer for input $(\mathcal{D}'', t, m, n)$. This consists of two steps:

1. Modify $\mathcal{D}$ into system $\mathcal{D}'$ such that valid tilings by $\mathcal{D}$ of size $k \times k$ correspond to valid tilings by $\mathcal{D}'$ with certain corner constraints.
2. Modify $\mathcal{D}'$ into system $\mathcal{D}''$ and tile t such that valid tilings by $\mathcal{D}'$ with the above corner constraints correspond to periodic tilings by $\mathcal{D}''$ of size $(k+1) \times (k+1)$ that use tile t.

This is a fairly typical reduction between tilings, similar to problems considered for instance in [3].

Limiting tiling size

For the first step, we create a tiling system $\mathcal{C}$ (of polynomial size with regard to the length of k), along with starting tile c_0 and final tile c_1, implementing a binary counter that counts down from an appropriately chosen $k' \leq k$ (close to k) and whose position shifts by 1 with each decrement. The tile c_1 occurs when the counter reaches 0. Similar constructions have been shown [11], our example is given in Figure 1. Thus, any tiling by $\mathcal{C}$ with c_0 in the top-right corner and c_1 in the bottom-left must be of size exactly $k \times k$.

Consider a "layering" of $\mathcal{D}$ and $\mathcal{C}$ into system $\mathcal{D} \times \mathcal{C} = (D \times C, H_{D \times C}, V_{D \times C})$, where the relations are defined as $R_{D \times C} = \{((d,c),(d',c')) : (d,d') \in R_D \wedge (c,c') \in R_C\}$ for both $R \in \{H, V\}$. This way, any tiling by $\mathcal{D} \times \mathcal{C}$ corresponds to a pair of tilings by $\mathcal{D}$ and $\mathcal{C}$. We let $\mathcal{D}' = \mathcal{D} \times \mathcal{C}$ and define the corner constraints mentioned in point 2 by restricting the possible starting and final tiles to $S = \{(d_0, c_0)\}, F = \{(d, c_1) : d \in D\}$ respectively. This yields tilings by $\mathcal{D}'$ which consist of a tiling by $\mathcal{D}$ with starting tile d_0 and a tiling by $\mathcal{C}$ with starting tile c_0 and final tile c_1.

Periodic tilings

The second step realizes the above constraint while also converting between periodic and non-periodic tilings. It consists of adding 5 new tiles to $\mathcal{D}'$ – ⊞, ⊟, ◫, ▲, ▼ – yielding $\mathcal{D}''$. The added constraints are shown in Figure 2 and an example tiling in Figure 3. The distinguished tile t is ⊞ – the idea is that its usage forces a "border" of ⊟ and ◫ tiles. Within each of these borders (there can be multiple if ⊞ is used more than once) there is a valid tiling by the system $\mathcal{D}'$ additionally satisfying the starting and final constraints S, F.

Final conversion

Combining the above steps, a tiling by $\mathcal{D}$ of size $k \times k$ is represented by a periodic $(k+1) \times (k+1)$ tiling by $\mathcal{D}''$ and thus we let $m = n = k + 1$. The designated tile is set to ⊞, completing the reduction from Binary Bounded Tiling to Periodic Bounded Tiling.

Variant with only powers of two

Consider the following variant of the tiling problem:

Power-of-two Periodic Bounded Tiling
Input: Integers m, n given in unary, a tiling system $\mathcal{D}$, a designated tile t.
Question: Determine whether there exists a periodic tiling by $\mathcal{D}$ of size at most $2^m \times 2^n$ which uses tile t.

Note that this is the same as taking the input in binary while restricting it only to powers of two. This variant is also NEXPTIME-hard because in the above reduction, the only possible sizes of tiling by the constructed tiling system are multiples of $k + 1$, both in width and height. Letting $m = n = \lceil \log_2(k + 1) \rceil$, we have $k + 1 \leq 2^m < 2(k + 1)$ and the same for 2^n. Therefore, the possible tilings are the same for size bound $(k + 1) \times (k + 1)$ and $2^{\lceil \log_2(k+1) \rceil} \times 2^{\lceil \log_2(k+1) \rceil}$.

4 Second part of the reduction

Given a tiling system $\mathcal{D}$, a designated tile t and integers m, n given in binary, we will construct (in polynomial time) a CI implication with bounded cardinalities which does not hold iff Periodic Bounded Tiling has a solution for input $(\mathcal{D}, t, m, n)$. This is based on the construction of Li [8]. Proofs which differ from the original only by specifying cardinality bounds are deferred to the full version. The main changes to Li's construction are as follows:

- provide bounds for the random variables used in the construction – this is done as the implication is being constructed;
- reduce the size of the implication from exponential to polynomial with regard to the input – only one part (the predicate COL) needs to be replaced by a polynomial-size equivalent;
- modify the representation of tiles to better suit bounded size and non-Wang tiles;
- add the requirement of the usage of a given tile – this is done by modifying the consequent of the implication.

4.1 Preliminaries

We denote by $\mathrm{Unif}(S)$ a uniform distribution over set S and by $\mathrm{Bern}(p)$ a Bernoulli distribution with parameter p. We use the shorthand X^k to represent a tuple of random variables $(X_1, \ldots, X_k)$, which is in itself also a random variable.

						$_1$	1_0	0_1	1
					$_1$	1_0	0_0	0	
				$_0$	0_1	1^*_1	1^*		
			$_0$	0_1	1_0	0			
		$_0$	0_0	0_1	1^*				
	$_0$	0_0	0_0	0					
$\star$	1^*_1	1^*_1	1^*						

Figure 1 A tiling implementation of a binary counter which shifts its position on every decrement, with the starting and final tile in the top-right and bottom-left corners respectively. This example counts down from 5 (101 in binary). Every tile except for the final $\star$ is of the form a^c_b, where a is the bit value (possibly blank), b is the value of the bit directly to the right (or blank if there is none), and c is optionally $*$ if a borrow operation is required. The shaded tiles of the top row function in the same manner, but they are "memorized" within the tiling system such that the placement of the top-right tile forces the top row to write out the binary initial value. The tiles in the lower rows are chosen deterministically based on their right and top neighbor. Finally, the $\star$ tile only occurs when the tile above is blank and the one to the right requires a borrow, which indicates that the counter has just gone below zero. In order to be unable to further count down, we disallow any tiles being below or to the left of tile $\star$. The size of the tiling is $(k' + b + 2) \times (k' + 2)$, where b is the number of bits and k' is the initial value; however, this could be modified such that the final tiling has size $(k' + b + 2) \times (k' + b + 2)$ by padding with b dummy rows at the top. For sufficiently large k, we can always efficiently find b, k' such that $k' + b + 2 = k$.

Figure 2 Modified adjacency relation for the system $\mathcal{D}''$ – only adjacencies marked by ● are permitted, as well as all adjacencies from the original tiling system. The asterisk denotes any tiles from the system $\mathcal{D}'$, while s, f represent any tile from the initial and final subset of tiles, respectively (S and F defined above).

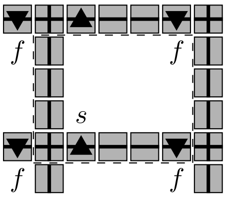

Figure 3 An example "border" created by the above tiling, with tiles from the original set not shown and s, f representing tiles from S, F respectively. The dashed rectangle represents the actual rectangle being tiled, while the tiles outside are periodic copies added to better illustrate the construction.

The *entropy* of a finite discrete random variable X with domain $\mathcal{X}$ is defined as

$$H(X) = -\sum_{x\in\mathcal{X}} \mathbf{P}(X = x)\log \mathbf{P}(X = x).$$

The *entropy of X conditioned on Y*, with X, Y finite discrete random variables with domains $\mathcal{X}, \mathcal{Y}$ respectively, is defined as

$$H(X|Y) = -\sum_{x\in\mathcal{X},y\in\mathcal{Y}} \mathbf{P}(X = x \wedge Y = y)\log \frac{\mathbf{P}(X = x \wedge Y = y)}{\mathbf{P}(X = x)}.$$

Finally, the *conditional mutual information of X and Y given Z* can be defined as

$$I(X;Y|Z) = H(X|Z) - H(X|Y,Z).$$

Similarly, the *mutual information* of X and Y is defined as

$$I(X;Y) = H(X) - H(X|Y).$$

Note that the conditional independence (CI) statement $I(X;Y|Z) = 0$ is equivalent to the fact that X and Y are independent given Z, and thus can be expressed without the usage of logarithms as

$$\mathbf{P}(X = x \wedge Y = y \wedge Z = z)\mathbf{P}(Z = z) = \mathbf{P}(X = x \wedge Z = z)\mathbf{P}(Y = y \wedge Z = z)$$

for all $x \in \mathcal{X}, y \in \mathcal{Y}, z \in \mathcal{Z}$. Further, the functional dependence statement $H(X|Y) = 0$, which states that for any $y \in \mathcal{Y}$, there exists exactly one $x \in \mathcal{X}$ such that $\mathbf{P}(X = x \wedge Y = y) \neq 0$ can be expressed equivalently as a (non-disjoint) CI statement $I(X;X|Y) = 0$.

We will follow Li's construction [8], providing cardinality bounds and modifications where necessary. While the final goal is a CI implication, we will mostly construct *affine existential information predicates* (AEIP) [8], converting to a CI implication at the end. We will only consider a special form of AEIP which consists of an existentially quantified conjunction of CI statements. This family of predicates is closed under conjunction, in particular we can use a predicate within the definition of another predicate (implicitly renaming variables in the case of a naming conflict).

Since our goal is to construct a bounded CI implication, every quantified variable will be given a *cardinality bound* – the maximum allowed size of its domain. We denote the existential quantification of a variable X with $\mathrm{card}(X) \leq k$ by the shorter notation $\exists X \leq k$, similarly for tuple variables $\exists X^2 \leq k$ represents the existence of variables X_1, X_2 with $\mathrm{card}(X_1), \mathrm{card}(X_2) \leq k$. Whenever a predicate takes arguments, their cardinalities are already bounded since they have been quantified. We may need to refer to these bounds when quantifying new variables, denoting by K_X the bound already given to variable X. Finally, whenever $\leq$ is replaced by $\leq_i$, this indicates an "implicit" bound, that is one which does not change the meaning of the predicate because it is already satisfied by any such quantified variable even without the explicit bound. An example of this is that whenever $H(X|Y) = 0$, X is functionally dependent on Y and so $X \leq_i K_Y$.

The first defined predicate is TRIPLE:

$$\begin{aligned}\mathrm{TRIPLE}(Y_1, Y_2, Y_3) : {}& H(Y_1|Y_2, Y_3) = H(Y_2|Y_1, Y_3) = H(Y_3|Y_1, Y_2) = 0\\ &\wedge I(Y_1; Y_2) = I(Y_1; Y_3) = I(Y_2; Y_3) = 0.\end{aligned}$$

By definition, predicate TRIPLE of three variables Y_1, Y_2, Y_3 is satisfied iff Y_1, Y_2, Y_3 are pairwise independent and each variable is functionally dependent on the other two. Functional dependency is a special case of conditional independence, since $H(X|Y) = I(X;X|Y)$. The following is shown in [13]:

▶ **Lemma 1.** *If* $\mathrm{TRIPLE}(X,Y,Z)$ *is satisfied, then* X,Y,Z *are all uniformly distributed and have the same cardinality.*

This is used in the next predicate, UNIF:

$$\mathrm{UNIF}(X) : \exists U_1 \leq_i K_X, U_2 \leq_i K_X : \mathrm{TRIPLE}(X,U_1,U_2).$$

By definition, predicate UNIF of one variable X is satisfied iff there exist discrete random variables U_1, U_2 jointly distributed with X such that $\mathrm{TRIPLE}(X,U_1,U_2)$ holds, which in turn is equivalent to X being uniformly distributed over its support. Lemma 1 immediately shows that the implicit cardinality bounds for U_1, U_2 are correct.

For any constant k, predicate $\mathrm{UNIF}_k(X)$ is defined to imply X being uniformly distributed over a domain of size k:

$$\mathrm{UNIF}_k(X) : \mathrm{UNIF}(X) \wedge \alpha_k \leq H(X) \leq \alpha_{k+1},$$

where $\alpha_k \in \mathbb{Q}$ is some rational with $\log(k-1) < \alpha_k < \log k$ (because the entropy of a uniform variable is the logarithm of the cardinality of its support). While this is still a valid AEIP, it is not a conjunction of CI statements. However, in the bounded cardinality setting UNIF_k can be restated in this form [8, 10]. Note that this predicate imposes an exact domain size constraint, while the cardinality bounds given as input provide only an upper bound. Finally, note that the predicates UNIF, UNIF_k are satisfiable – for any $k > 0$, there exists a variable X which satisfies $\mathrm{UNIF}_k(X)$ and so $\mathrm{UNIF}(X)$.

Define the *characteristic bipartite graph* of random variables X_1, X_2 with (disjoint) supports $\mathcal{X}_1, \mathcal{X}_2$ as the undirected graph with set of vertices $V = \mathcal{X}_1 \cup \mathcal{X}_2$ and set of edges $E = \{(x_1,x_2) : x_1 \in \mathcal{X}_1, x_2 \in \mathcal{X}_2, \mathbf{P}(X_1 = x_1 \wedge X_2 = x_2) > 0\}$.

Li constructs the predicate

$$\begin{aligned}\mathrm{CYCS}(X_1,X_2) : \exists U \leq_i 2 : &\ \mathrm{UNIF}(X_1) \wedge \mathrm{UNIF}(X_2) \wedge \mathrm{UNIF}_2(U)\\ &\wedge I(X_1;U) = I(X_2;U) = 0\\ &\wedge H(X_1|X_2,U) = H(X_2|X_1,U) = 0\\ &\wedge H(U|X_1,X_2) = 0\end{aligned}$$

and shows the following (without cardinality bounds):

▶ **Lemma 2.** $\mathrm{CYCS}(X_1,X_2)$ *is satisfied iff* X_1, X_2 *are uniform and the characteristic bipartite graph of* X_1, X_2 *consists only of vertex-disjoint simple cycles.*

Furthermore, this predicate is satisfiable – for any finite collection of even-length cycles, we can clearly find X_1, X_2 such that their characteristic bipartite graph consists exactly of this collection of cycles.

4.2 Overview of the construction

We now give an overview of the following steps of the construction. Section 4.3 defines the predicate $\mathrm{TORI}'(X^2,Y^2,Z)$, which enforces that the characteristic bipartite graph of X_1 and X_2 is a collection of cycles, similarly for Y_1 and Y_2. Finally, we require that Z be distributed uniformly over two values and that the three variables X^2, Y^2, Z be independent. The distribution of (X^2,Y^2) then represents a collection of tori, with each quadruple of values of (X_1,X_2,Y_1,Y_2) representing a vertex in some torus. The addition of variable Z effectively creates a corresponding copy of this collection.

With the goal of creating meaningful labels to be applied to the vertices of the aforementioned graph, which are represented by k-tuple of binary variables W^k, Section 4.4 defines the predicates $\mathrm{SW}'(W^k, V^k, \bar{V}^k, F)$ and $\mathrm{COL}'(W^k, V^k, \bar{V}^k, F)$. The former ensures that $V_i = (1 - W_i)F, \bar{V}_i = W_i F$ (up to relabeling) with the side-effect of requiring each $W_i \sim \mathrm{Bern}(\frac{1}{2})$. The latter predicate restricts W^k such that the only values that are possible have either $W_k = 1$ and exactly one $W_i = 0$, or $W_k = 0$ and exactly one $W_i = 1$, for some $i \in \{1, \ldots, k-1\}$.

Section 4.5 combines the prior predicates in predicate $\mathrm{CTORI}'(X^2, Y^2, Z, W^k, V^k, \bar{V}^k, F)$ in such a way that each vertex is assigned exactly one label, i. e. W^k depends functionally on (X^2, Y^2, Z). This is extended in predicate $\mathrm{OTORI}'(X^2, Y^2, Z, W^k, V^k, \bar{V}^k, F)$, which assigns four possible *groups* to vertex labels and enforces a structure as shown in Figure 4.

Finally, the predicate $\mathrm{TTORI}'(X^2, Y^2, Z, W^k, V^k, \bar{V}^k, F)$ defined in Section 4.7 restricts the possible labels of vertices connected by edges so as to enforce the given vertical and horizontal constraints of the given tile system.

4.3 Grid

A collection of tori is constructed by Li using the following predicate (where X^2 represents a pair of variables (X_1, X_2), similarly for Y^2):

$$\mathrm{TORI}(X^2, Y^2) : \mathrm{CYCS}(X^2) \wedge \mathrm{CYCS}(Y^2) \wedge I(X^2; Y^2) = 0,$$

When the above holds, fixing any three of the variables X_1, X_2, Y_1, Y_2 leaves two possible values of the fourth. Similarly, fixing one variable from X_1, X_2 and one from Y_1, Y_2 gives the remaining two variables a distribution over four values. This is visualized by a graph similar in idea to the bipartite characteristic graph: its vertices are quadruples of values (x_1, x_2, y_1, y_2) which satisfy $\mathbf{P}(X_1 = x_1 \wedge X_2 = x_2 \wedge Y_1 = y_1 \wedge Y_2 = y_2) > 0$, with edges connecting any two quadruples which differ in exactly one out of these four values. When arranged in a grid with possible pairs (X_1, X_2) on one axis and (Y_1, Y_2) on the other, as in Figure 4, the torus structure becomes apparent. Again, this predicate is satisfiable in the sense that any collection of tori which is a product of two collections of even-length cycles has a representation by random variables X^2, Y^2.

Our construction departs slightly from the construction of Li, adding another coordinate Z, corresponding to taking two copies of the collection of tori, with the edges and faces described above preserved when Z is fixed. Additionally, fixing X^2 and Y^2 but not Z "connects" two corresponding vertices in the two copies. The predicate for this is as follows:

$$\begin{aligned}\mathrm{TORI}'(X^2, Y^2, Z) : {} & \mathrm{CYCS}(X^2) \wedge \mathrm{CYCS}(Y^2) \wedge \mathrm{UNIF}_2(Z) \\ & \wedge I(X^2, Y^2; Z) = 0 \wedge I(X^2, Z; Y^2) = 0 \wedge I(Y^2, Z; X^2) = 0.\end{aligned}$$

4.4 Vertex labels

The basis for constructing labels which will later on be assigned to vertices is the following predicate defined by Li:

$$\begin{aligned}\mathrm{FLIP}(F, G_1, G_2) : \exists U \leq_i 4, Z^2 \leq_i 3 : {} & \mathrm{UNIF}_4(U) \wedge \mathrm{UNIF}_2(F) \\ & \wedge H(F, G_1, G_2 | U) = I(G_1; G_2 | F) = 0 \\ & \wedge \mathrm{UNIF}_3(Z_1) \wedge I(Z_1; G_1) = H(U | G_1, Z_1) = 0 \\ & \wedge \mathrm{UNIF}_3(Z_2) \wedge I(Z_2; G_2) = H(U | G_2, Z_2) = 0.\end{aligned}$$

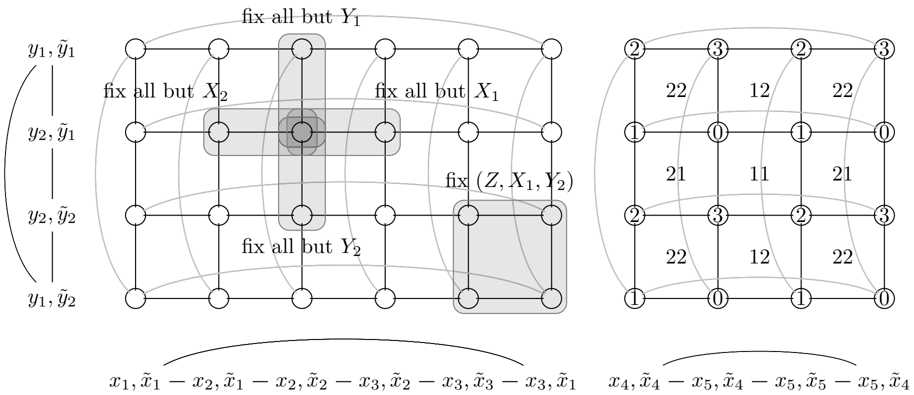

Figure 4 Visualization of the tori which are a product of the cycles created by (X_1, X_2) and (Y_1, Y_2), with each vertex corresponding to a quadruple of the values of (X_1, X_2, Y_1, Y_2). The axes show these cycles – a quadruple's (X_1, X_2) (resp. (Y_1, Y_2)) values are determined by projecting onto the horizontal (resp. vertical) axis. Additionally, the left torus shows highlighted edges which arise when all but one variable (of X_1, X_2, Y_1, Y_2, Z) are fixed as well as an example face which arises when Z and two other variables are fixed. The right torus has each face labeled with its type and each vertex labeled with its group – these are used in Section 4.6 in order to restrict allowed labelings of the vertices. The second "corresponding" torus and the Z axis are omitted for clarity.

Recalling that $\mathrm{Unif}(S)$ denotes a uniform distribution over set S, the following is shown:

▶ **Lemma 3.** $\mathrm{FLIP}(F, G_1, G_2)$ *is satisfied iff, up to relabeling,* (F, G_1, G_2) *has the distribution Unif*$(\{(0,0,0), (0,1,0), (1,0,0), (1,0,1)\})$.

For any $k \geq 4$, Li defines the predicate SW which allows us to represent strings of k bits. Here, W^k represents a tuple of variables $(W_1, \ldots, W_k)$, same for $V^k, \bar{V}^k$: Intuitively, the value of W_i determines whether F is copied into V_i or $\bar{V}_i$, hence the name SW for *switch*.

$$\begin{aligned}\mathrm{SW}(W^k, V^k, \bar{V}^k, F) : \exists G \leq_i 2 : I(W^k; F, G) = 0 \\ \wedge \bigwedge_{i \in \{1,\ldots,k\}} \big(\mathrm{UNIF}_2(W_i) \wedge H(V_i, \bar{V}_i | W_i, F) = I(V_i; \bar{V}_i | W_i) = 0 \\ \wedge \mathrm{FLIP}(F, G, V_i) \wedge \mathrm{FLIP}(F, G, \bar{V}_i)\big)\end{aligned}$$

▶ **Lemma 4.** *If* $\mathrm{SW}(W^k, V^k, \bar{V}^k, F)$ *is satisfied, then we have (without loss of generality)* $V_i = (1 - W_i)F, \bar{V}_i = W_i F$ *for all* i.

The predicate SW is satisfiable: we let (F, G) take each of the values $(0,0)$, $(0,1)$ with probability $\frac{1}{4}$, in which case we let $V_i = \bar{V}_i = 0$, and the value $(1,0)$ with probability $\frac{1}{2}$, in which case $V_i = 1 - W_i, \bar{V}_i = W_i$. As long as each $W_i \sim \mathrm{Bern}(\frac{1}{2})$ (recall that $\mathrm{Bern}(p)$ denotes a Bernoulli distribution with parameter p), we can satisfy the predicate for any distribution of W^k. This predicate additionally has the following property:

▶ **Lemma 5.** *If* $\mathrm{SW}(W^k, V^k, \bar{V}^k, F)$ *is satisfied, then for any* $S, \bar{S} \subseteq \{1, \ldots, k\}$ *we have*

$$H(F | V_S, \bar{V}_{\bar{S}}, W^k) = \mathbf{P}(sat(W^k, S, \bar{S}) = 1),$$

where

$$sat(w^k, S, \bar{S}) = \Big(\prod_{i \in S} w_i\Big)\Big(\prod_{i \in \bar{S}} (1 - w_i)\Big),$$

i.e. if $w_i = 1$ *for all* $i \in S$ *and* $w_i = 0$ *for* $i \in \bar{S}$ *then* $sat(w^k, S, \bar{S})$ *equals 1 and otherwise it equals 0.*

This immediately yields the following:

▶ **Lemma 6.** *The equality* $H(F|V_{\{i\in\{1,\dots,k\}\,:\,w_i=1\}}, \bar{V}_{\{i\in\{1,\dots,k\}\,:\,w_i=0\}}, W^k) = \mathbf{P}(W^k = w^k)$ *holds for any* $w^k \in \{0,1\}^k$. ⌟

Using these properties, we can disallow certain values of W^k from occurring using a CI statement. This is used by Li to limit the possible values of W^k to the set $T_k \subseteq \{0,1\}^k$, which consists of $2(k-1)$ *labels* (referred to as *colors* by Li), each one with a *value* and *sign*. The set consists of strings in which exactly one bit differs from the last bit, that is for any $w^k \in T_k$ we have $w_j \neq w_k$ for exactly one $j \neq k$. The sign of the label is determined by w_k – negative when $w_k = 1$, positive when $w_k = 0$ – and j is the value of the label. For example, the elements of $T_4 = \{0111, 1011, 1101, 1000, 0100, 0010\}$ correspond in order to labels $\{-1, -2, -3, +1, +2, +3\}$.

Li's predicate for enforcing this is simple:

$$\begin{aligned}\mathrm{COL}(W^k, V^k, \bar{V}^k, F):\ & \mathrm{SW}(W^k, V^k, \bar{V}^k, F)\\ \wedge & \bigwedge_{w^k\in\{0,1\}^k\setminus T_k} \big(H(F|V_{\{i:w_i=1\}}, \bar{V}_{\{i:w_i=0\}}, W^k) = 0\big),\end{aligned}$$

This predicate simply disallows the occurrence of any $w^k \notin T_k$, hence we have

▶ **Lemma 7.** *If* $\mathrm{COL}(W^k, V^k, \bar{V}^k, F)$ *is satisfied, then* $\mathbf{P}(W^k \notin T_k) = 0$. ⌟

While sufficient for showing undecidability, this predicate cannot be used in a polynomial-time reduction due to its size being exponential with regard to k. However, an equivalent polynomial-size predicate can be easily constructed: with

$$\bigwedge_{\substack{i,j\in\{1,\dots,k-1\},\\ i<j}} (H(F|V_{\{i,j\}}, \bar{V}_{\{k\}}, W^k) = 0),$$

we disallow all w^k such that $w_k = 0$ and $w_i = w_j = 1$ for some $1 \leq i < j < k$. Similarly,

$$\bigwedge_{\substack{i,j\in\{1,\dots,k-1\},\\ i<j}} (H(F|V_{\{k\}}, \bar{V}_{\{i,j\}}, W^k) = 0)$$

disallows all w^k such that $w_k = 1$ and $w_i = w_j = 0$ for some $1 \leq i < j < k$. The only remaining w^k have either $w_k = 0$ and at most one 1 in $\{1,\dots,k-1\}$ or have $w_k = 1$ and at most one 0 in $\{1,\dots,k-1\}$. The strings 0^k and 1^k are disallowed by $H(F|V_{\{1,\dots,k\}}, \bar{V}_\varnothing, W^k) = 0$ and $H(F|V_\varnothing, \bar{V}_{\{1,\dots,k\}}, W^k) = 0$. Combined, these yield the polynomial-size predicate

$$\begin{aligned}\mathrm{COL}'(W^k, V^k, \bar{V}^k, F) :\ & \mathrm{SW}(W^k, V^k, \bar{V}^k, F)\\ \wedge & \bigwedge_{\substack{i,j\in\{1,\dots,k-1\},\\ i<j}} (H(F|V_{\{i,j\}}, \bar{V}_{\{k\}}, W^k) = 0)\\ \wedge & \bigwedge_{\substack{i,j\in\{1,\dots,k-1\},\\ i<j}} (H(F|V_{\{k\}}, \bar{V}_{\{i,j\}}, W^k) = 0)\\ \wedge\ & H(F|V_{\{1,\dots,k\}}, \bar{V}_\varnothing, W^k) = 0\\ \wedge\ & H(F|V_\varnothing, \bar{V}_{\{1,\dots,k\}}, W^k) = 0\end{aligned}$$

equivalent to the exponential-size COL.

4.5 Edge constraints

The next predicate is the following, with COL used in place of COL′ in Li's original construction:

$$\begin{aligned}\mathrm{COLD}(X, W^k, V^k, \bar{V}^k, F) : &\ \mathrm{COL}'(W^k, V^k, \bar{V}^k, F)\\ &\wedge H(W^k|X) = I(V^k, \bar{V}^k, F; X|W^k) = 0.\end{aligned}$$

This predicate will represent the labeling of vertices, with X representing the coordinate and W^k (which depends functionally on X) representing its label. For any $x \in \mathcal{X}$, denote by $w^k(x)$ the unique value of w^k which satisfies $\mathbf{P}(W^k = w^k|X = x) > 0$.

Suppose that $\mathrm{COLD}(X, W^k, V^k, \bar{V}^k, F)$ is satisfied and let E be any random variable which *splits X into sets of (a constant) size l* – we say this is the case when $H(E|X) = 0$ and $X|E = e$ is uniform over l values for all $e \in \mathcal{E}$. This is not verified by a predicate; rather, we will only choose E which have this property by definition. Fixing subsets of indices $S, \bar{S} \subseteq \{1, \dots, k\}$, we define for any $e \in \mathcal{E}$ the value a_e:

$$a_e = |\{x : \mathbf{P}(X = x|E = e) > 0 \wedge \mathrm{sat}(w^k(x), S, \bar{S}) = 1\}|$$

In order to impose restrictions on the possible values of a_e, Li defines the following predicates:

$$\begin{aligned}\mathrm{SAT}_{\neq 1/2,S,\bar{S}}(E, W^k, V^k, \bar{V}^k, F) : &\ \exists U \leq_i 2 : \mathrm{UNIF}_2(U) \wedge I(U; E, V_S, \bar{V}_{\bar{S}}) = 0\\ &\wedge H(F|V_S, \bar{V}_{\bar{S}}, E, U) = 0,\\ \mathrm{SAT}_{\leq 1/2,S,\bar{S}}(E, W^k, V^k, \bar{V}^k, F) : &\exists U \leq_i 3 : \mathrm{UNIF}_3(U) \wedge I(U; E, V_S, \bar{V}_{\bar{S}}) = 0\\ &\wedge H(F|V_S, \bar{V}_{\bar{S}}, E, U) = 0,\\ \mathrm{SAT}_{\leq 3/4,S,\bar{S}}(E, W^k, V^k, \bar{V}^k, F) : &\exists U \leq_i 105 : \mathrm{UNIF}_{105}(U) \wedge I(U; E, V_S, \bar{V}_{\bar{S}}) = 0\\ &\wedge H(F|V_S, \bar{V}_{\bar{S}}, E, U) = 0.\end{aligned}$$

The predicates satisfy the following properties.

▶ **Lemma 8.** *If* $\mathrm{COLD}(X, W^k, V^k, \bar{V}^k, F)$ *is satisfied and E splits X into sets of size 2, then* $\mathrm{SAT}_{\neq 1/2,S,\bar{S}}(E, W^k, V^k, \bar{V}^k, F)$ *is satisfied iff $a_e \neq 1$ for all $e \in \mathcal{E}$.*

▶ **Lemma 9.** *If* $\mathrm{COLD}(X, W^k, V^k, \bar{V}^k, F)$ *is satisfied and E splits X into sets of size 2, then* $\mathrm{SAT}_{\leq 1/2,S,\bar{S}}(E, W^k, V^k, \bar{V}^k, F)$ *is satisfied iff $a_e \leq 1$ for all $e \in \mathcal{E}$.*

▶ **Lemma 10.** *If* $\mathrm{COLD}(X, W^k, V^k, \bar{V}^k, F)$ *is satisfied and E splits X into sets of size 4, then* $\mathrm{SAT}_{\leq 3/4,S,\bar{S}}(E, W^k, V^k, \bar{V}^k, F)$ *is satisfied iff $a_e \leq 3$ for all $e \in \mathcal{E}$.*

The next defined predicate is the following:

$$\begin{aligned}\mathrm{CTORI}'(X^2, Y^2, Z, W^k, V^k, \bar{V}^k, F) &: \mathrm{TORI}'(X^2, Y^2, Z)\\ &\wedge \mathrm{COLD}((X^2, Y^2, Z), W^k, V^k, \bar{V}^k, F),\end{aligned}$$

which simply implies applying labels (without any constraints) to the vertices of the tori. In the original predicate, which uses TORI instead of TORI′, there is no coordinate Z. Clearly, this predicate is satisfiable in the sense that any collection of pairs of tori of even size which is labeled in a manner that satisfies the requirement $W_i \sim \mathrm{Bern}(\frac{1}{2})$ has a corresponding representation by $X^2, Y^2, Z, W^k, V^k, \bar{V}^k, F$. In particular, this W_i requirement is satisfied by any labeling in which any pair of corresponding vertices (those which differ only in the Z

coordinate) has labels of the same value but opposite sign. This is because negating the sign of a label corresponds to negating all of its bits. For a set of labels $\mathcal{L} = \{0, \dots, l-1\}$, we now label the vertices with labels from the set $\{0, \dots, 4l-1\}$ and so we set $k = 4l+1$. For any $i \in \{0, \dots, l\}$, $j \in \{0, \dots, 3\}$, we identify all four labels $4i+j$ with the original label i, referring to any vertex whose label is $4i+j$ as a *group j vertex*. The group of a vertex is used to orient it relative to its neighbors – this is achieved by the following predicate:

$$\begin{aligned}
&\mathrm{OTORI}'(X^2, Y^2, Z, W^k, V^k, \bar{V}^k, F):\\
&\ \mathrm{CTORI}'(X^2, Y^2, Z, W^k, V^k, \bar{V}^k, F)\\
&\wedge\ \mathrm{SAT}_{\neq 1/2,\{k\},\varnothing}((X_1, X_2, Y_1, Z), W^k, V^k, \bar{V}^k, F)\\
&\wedge\ \mathrm{SAT}_{\neq 1/2,\{k\},\varnothing}((X_1, X_2, Y_2, Z), W^k, V^k, \bar{V}^k, F)\\
&\wedge\ \mathrm{SAT}_{\neq 1/2,\{k\},\varnothing}((X_1, Y_1, Y_2, Z), W^k, V^k, \bar{V}^k, F)\\
&\wedge\ \mathrm{SAT}_{\neq 1/2,\{k\},\varnothing}((X_2, Y_1, Y_2, Z), W^k, V^k, \bar{V}^k, F)\\
&\wedge \bigwedge_{j_1, j_2 \in J_1} \big(\mathrm{SAT}_{\leq 1/2,\varnothing,\{1,\dots,k\}\setminus\{j_1,j_2\}}((X_1, X_2, Y_1, Z), W^k, V^k, \bar{V}^k, F)\\
&\qquad\qquad \wedge \mathrm{SAT}_{\leq 1/2,\varnothing,\{1,\dots,k\}\setminus\{j_1,j_2\}}((X_1, X_2, Y_2, Z), W^k, V^k, \bar{V}^k, F)\\
&\qquad\qquad \wedge \mathrm{SAT}_{\leq 1/2,\{1,\dots,k\}\setminus\{j_1,j_2\},\varnothing}((X_1, X_2, Y_1, Z), W^k, V^k, \bar{V}^k, F)\\
&\qquad\qquad \wedge \mathrm{SAT}_{\leq 1/2,\{1,\dots,k\}\setminus\{j_1,j_2\},\varnothing}((X_1, X_2, Y_2, Z), W^k, V^k, \bar{V}^k, F)\big)\\
&\wedge \bigwedge_{j_1, j_2 \in J_2} \big(\mathrm{SAT}_{\leq 1/2,\varnothing,\{1,\dots,k\}\setminus\{j_1,j_2\}}((X_1, Y_1, Y_2, Z), W^k, V^k, \bar{V}^k, F)\\
&\qquad\qquad \wedge\ \mathrm{SAT}_{\leq 1/2,\varnothing,\{1,\dots,k\}\setminus\{j_1,j_2\}}((X_2, Y_1, Y_2, Z), W^k, V^k, \bar{V}^k, F)\\
&\qquad\qquad \wedge\ \mathrm{SAT}_{\leq 1/2,\{1,\dots,k\}\setminus\{j_1,j_2\},\varnothing}((X_1, Y_1, Y_2, Z), W^k, V^k, \bar{V}^k, F)\\
&\qquad\qquad \wedge\ \mathrm{SAT}_{\leq 1/2,\{1,\dots,k\}\setminus\{j_1,j_2\},\varnothing}((X_2, Y_1, Y_2, Z), W^k, V^k, \bar{V}^k, F)\big)\\
&\wedge\ \mathrm{SAT}_{\leq 1/2,\{k\},\varnothing}((X_1, X_2, Y_1, Y_2), W^k, V^k, \bar{V}^k, F)\\
&\wedge\ \mathrm{SAT}_{\leq 1/2,\varnothing,\{k\}}((X_1, X_2, Y_1, Y_2), W^k, V^k, \bar{V}^k, F),
\end{aligned}$$

where

$$\begin{aligned}
J_1 &= \{(j_1, j_2) \in \{1, \dots, k-1\} : \{j_1 \bmod 4, j_2 \bmod 4\} \notin \{\{0,1\},\{2,3\}\}\},\\
J_2 &= \{(j_1, j_2) \in \{1, \dots, k-1\} : \{j_1 \bmod 4, j_2 \bmod 4\} \notin \{\{1,2\},\{0,3\}\}\}.
\end{aligned}$$

The only difference between OTORI' and Li's original OTORI is the added variable Z and the final two $\mathrm{SAT}_{\leq 1/2}$ predicates. We have the following fact:

▶ **Lemma 11.** *If* $\mathrm{OTORI}\,'(X^2, Y^2, Z, W^k, V^k, \bar{V}^k, F)$ *is satisfied, then the following statements hold:*

1. *within each torus, all vertices' labels have the same sign;*
2. *any two vertices differing only in the Z coordinate have opposite sign;*
3. *any pair of vertices connected by a vertical edge either has groups 1 and 0 or 2 and 3;*
4. *any pair of vertices connected by a horizontal edge either has groups 1 and 2 or 3 and 0.*

Proof. Recall that fixing the variable Z along with any three of the variables X_1, X_2, Y_1, Y_2 leaves two possible values for the remaining variable. These correspond to two vertices of an edge, as illustrated in Figure 4. Therefore, the first four $\mathrm{SAT}_{\neq 1/2,\{k\},\varnothing}$ predicates state that for any edge (u, v), the value of w_k for u and v cannot differ, which implies exactly Point 1 above. Point 2 follows directly from the last two $\mathrm{SAT}_{\leq 1/2}$ predicates – of the two vertices which differ only in the Z coordinate, at most one can have $w_k = 0$ and at most one can have $w_k = 1$.

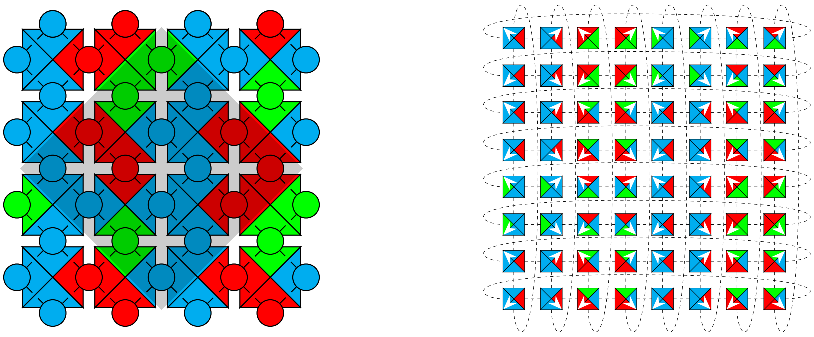

Figure 5 Left: Li's representation of a 4 × 4 torus coloring and the 4 × 4 tiling that it yields. The conversion from 16 vertices to 32 gives the tiling an additional diagonal periodicity. Combined with the fact that this does not work for non-square $n \times m$ tilings (without arranging them into a $\operatorname{lcm}(n, m) \times \operatorname{lcm}(n, m)$ square), this proves problematic for restricting the size of a periodic tiling. Right: the corresponding 8 × 8 torus labeling in our representation. Each tile has 4 labels, one for each corner of the tile (indicated by the arrow in this case). The tiles do not need to be Wang tiles.

For the next two points, note that for $j_1, j_2 \neq k$, we have $\operatorname{sat}(w^k, \{1, \dots, k\} \setminus \{j_1, j_2\}, \varnothing) = 1$ iff w^k represents one of the labels $\{-j_1, -j_2\}$ – for positive labels, we have $w_k = 0$ and for negative labels other than $-j_1, -j_2$, we have $w_i = 0$ for some $i \notin \{j_1, j_2\}$. Analogously, $\operatorname{sat}(w^k, \varnothing, \{1, \dots, k\} \setminus \{j_1, j_2\}) = 1$ iff w^k represents one of $\{+j_1, +j_2\}$. Thus, the four $\mathrm{SAT}_{\leq 1/2, \varnothing, \{1,\dots,k\} \setminus \{j_1, j_2\}}$ predicates within the conjunction over $j_1, j_2 \in J_1$ imply exactly Point 3, with the conjunction over $j_1, j_2 \in J_2$ implying Point 4 analogously. Clearly, OTORI$'$ is satisfiable – an example torus (with coordinate Z omitted) is shown in Figure 4. ◀

4.6 Tiles

Li denotes the set of four possible vertices when (Z, X_i, Y_j) is fixed as a *type ij face* for any $i, j \in \{1, 2\}$ – e. g. fixing (Z, X_1, Y_2) yields a type 12 face. The relation between face types and vertex groups is illustrated in Figure 4.

Li's construction utilizes the fact that the four corner-neighbors of any type 11 face are type 22 faces and vice versa. Because the original construction makes use of a Wang tiling system, these connecting corner vertices can represent the edge colors of the touching tiles. An example is shown in Figure 5. The diagonal nature of this tiling proves problematic when we wish to restrict its size, thus we simply use faces (of type 11) to directly represent tiles, which also allows us to use the general form of tiling systems. Figure 5 illustrates a torus labeling in our representation. For given tiling system $\mathcal{D} = (D, H, V)$, we define the following sets:

$$\begin{aligned}
\mathcal{D}_{11} &= \{(4t+1, 4t+2, 4t+3, 4t) : t \in D\},\\
\mathcal{D}_{12} &= \{(4v, 4v+3, 4u+2, 4u+1) : (u, v) \in V\},\\
\mathcal{D}_{21} &= \{(4u+2, 4u+1, 4v, 4v+3) : (u, v) \in H\},
\end{aligned}$$

and for each $i \in \{11, 12, 21\}$,

$$I_i = \{j_1, \dots, j_4 \in \{1, \dots, k-1\} : j_i \bmod 4 \text{ distinct}, \{j_1, \dots, j_4\} \notin \mathcal{D}_i\}.$$

The final predicate to enforce that the coloring represents a valid tiling (of size at most $m \times n$) is defined as follows:

$$\begin{aligned}
\mathrm{TTORI}'_{\mathcal{D}} \ : \ & \exists X^2 \le m, Y^2 \le n, Z \le_i 2, W^k \le_i 2, V^k \le_i 2, \bar{V}^k \le_i 2, F \le_i 2 : \\
& \mathrm{OTORI}'(X^2, Y^2, Z, W^k, V^k, \bar{V}^k, F) \\
& \wedge \bigwedge_{j_1,\dots,j_4 \in I_{11}} \Big(\mathrm{SAT}_{\le 3/4, \varnothing, \{1,\dots,k\} \setminus \{j_1,\dots,j_4\}}((X_1, Y_1, Z), W^k, V^k, \bar{V}^k, F) \\
& \qquad \wedge \mathrm{SAT}_{\le 3/4, \{1,\dots,k\} \setminus \{j_1,\dots,j_4\}, \varnothing}((X_1, Y_1, Z), W^k, V^k, \bar{V}^k, F)\Big) \\
& \wedge \bigwedge_{j_1,\dots,j_4 \in I_{12}} \Big(\mathrm{SAT}_{\le 3/4, \varnothing, \{1,\dots,k\} \setminus \{j_1,\dots,j_4\}}((X_1, Y_2, Z), W^k, V^k, \bar{V}^k, F) \\
& \qquad \wedge \mathrm{SAT}_{\le 3/4, \{1,\dots,k\} \setminus \{j_1,\dots,j_4\}, \varnothing}((X_1, Y_2, Z), W^k, V^k, \bar{V}^k, F)\Big) \\
& \wedge \bigwedge_{j_1,\dots,j_4 \in I_{21}} \Big(\mathrm{SAT}_{\le 3/4, \varnothing, \{1,\dots,k\} \setminus \{j_1,\dots,j_4\}}((X_2, Y_1, Z), W^k, V^k, \bar{V}^k, F) \\
& \qquad \wedge \mathrm{SAT}_{\le 3/4, \{1,\dots,k\} \setminus \{j_1,\dots,j_4\}, \varnothing}((X_2, Y_1, Z), W^k, V^k, \bar{V}^k, F)\Big).
\end{aligned}$$

▶ **Lemma 12.** $\mathrm{TTORI}'_{\mathcal{D}}$ *is satisfied iff $\mathcal{D}$ admits a periodic tiling of size at most $m \times n$.*

Proof. All implicit bounds follow from previously defined predicates used within $\mathrm{TTORI}'_{\mathcal{D}}$: TORI′ for Z, SW for W^k, and FLIP for V^k, $\bar{V}^k$, F. The bounds of m, n for X^2, Y^2 imply that the tori can take any even size up to $2m \times 2n$.

For the "only if" direction, note that the three conjunctions, similarly as in the predicate OTORI, forbid faces of type 11, 12, 21 from being not of the form in $\mathcal{D}_{11}, \mathcal{D}_{12}, \mathcal{D}_{21}$, respectively. Clearly, the set $\mathcal{D}_{11}$ consists of exactly those tiles (represented as type 11 faces) which are in D. Similarly, $\mathcal{D}_{12}, \mathcal{D}_{21}$ consist of all those "glue" type 12 and 21 faces which are allowed by H, V respectively. Therefore, in a distribution satisfying $\mathrm{TTORI}'_{\mathcal{D}}$, the type 11 faces represent tiles and neighboring tiles respect the constraints H and V. Therefore, each torus corresponds to a periodic tiling by $\mathcal{D}$. Since the tori are of size at most $2m \times 2n$, the tiling is of size at most $m \times n$.

For the "if" direction, for any given tiling by $\mathcal{D}$ of size at most $m \times n$, we create a pair of corresponding tori, labeled such that one represents the positive version of this tiling and the other the negative version. The satisfiability arguments show that this can be done for any given tiling. ◀

4.7 Final construction

Once fully expanded, the $\mathrm{TTORI}'_{\mathcal{D}}$ predicate is of the form (omitting the bounds for clarity)

$$\exists B, X^2, Y^2, W^k, V^k, \bar{V}^k, F, \dots : \Big(B \sim \mathrm{Bern}(1/2) \wedge \bigwedge\nolimits_i (I(A_i; B_i | C_i) = 0)\Big),$$

where A_i, B_i, C_i are tuples of the quantified variables. Its negation can be equivalently rewritten:

$$\begin{aligned}
& \neg\exists B, \dots : \big(B \sim \mathrm{Bern}(1/2) \wedge \bigwedge\nolimits_i (I(A_i; B_i | C_i) = 0)\big) \\
\Leftrightarrow\ & \forall B, \dots : \big(B \not\sim \mathrm{Bern}(1/2) \vee \neg \bigwedge\nolimits_i (I(A_i; B_i | C_i) = 0)\big) \\
\Leftrightarrow\ & \forall B, \dots : \big(\big(\bigwedge\nolimits_i (I(A_i; B_i | C_i) = 0)\big) \Rightarrow B \not\sim \mathrm{Bern}(1/2)\big) \\
\Leftrightarrow\ & \forall B, \dots : \big(\big(\mathrm{UNIF}(B) \wedge |B| \le 2 \wedge \bigwedge\nolimits_i (I(A_i; B_i | C_i) = 0)\big) \Rightarrow H(B) = 0\big).
\end{aligned}$$

The last equivalence holds because a variable B with $|B| \le 2$ and $\mathrm{UNIF}(B)$ can either be uniform over one value and have entropy 0 or uniform over two values and have entropy 1. This final form is a valid CI implication with (partial) cardinality bounds. In the bounded case, the established cardinality bounds are preserved.

Enforcing the usage of a designated tile

We extend Li's above construction to enforce that a given tile t be used in the tiling. Recall from Lemma 6 that for any $w^k \in \{0,1\}^k$,

$$H(F|V_{\{i:w_i=1\}}, \bar{V}_{\{i:w_i=0\}}, W^k) = \mathbf{P}(W^k = w^k).$$

Furthermore, variable F is constrained by the predicate $\mathrm{UNIF}_2(F)$. It can be equivalently restated as $\mathrm{UNIF}_=(F,B)$, where $\mathrm{UNIF}_=$ is defined by Li as follows:

$$\mathrm{UNIF}_=(Y,Z) : \exists U^3 \leq_i K_Y : \mathrm{TRIPLE}(Y,U_1,U_2) \wedge \mathrm{TRIPLE}(Z,U_1,U_3).$$

Clearly, $\mathrm{UNIF}_=(F,B)$ holds iff F and B are both uniform with the same cardinality and hence $\mathrm{UNIF}_2(F)$ can be replaced by $\mathrm{UNIF}_=(F,B)$. Therefore, if the (conditional) entropy of F is nonzero, then the entropy of B must also be nonzero and so we must have $B \sim \mathrm{Bern}(\frac{1}{2})$.

Given a designated tile t, let $w^k \in T_k$ be the value of W^k corresponding to label t (without loss of generality, of vertex group 0 and positive sign) and $S = \{i : w_i = 1\}, \bar{S} = \{i : w_i = 0\}$. The modified implication is as follows:

$$\forall B, \ldots : \big(\big(\mathrm{UNIF}(B) \wedge |B| \leq 2 \wedge \bigwedge\nolimits_i (I(A_i;B_i|C_i) = 0)\big) \Rightarrow H(F|V_S, \bar{V}_{\bar{S}}, W^k) = 0\big).$$

The counterexamples of this implication are exactly those labelings which use the tile t. Altogether, this chapter has shown the following theorem:

▶ **Theorem 2.** *For any given tiling system $\mathcal{D}$ along with tile t and natural numbers m, n, there exists a bounded CI implication which holds iff $\mathcal{D}$ does not admit a periodic tiling of size at most $m \times n$ which makes use of tile t. Moreover, the implication can be computed in time polynomial with regard to the size of the tiling system, while the bounds can be computed in time polynomial w.r.t. to the size of m, n.*

Theorem 2 gives exactly a polynomial-time many-one reduction from PERIODIC BOUNDED TILING to the complement of BOUNDED CI IMPLICATION, in particular because m, n and K are encoded in the same manner. In the case of CONSTANT-BOUNDED CI IMPLICATION, the above argument does not work since we have constant bounds larger than 2 as well as bounds whose value depends on the input. However, any variable X with cardinality bound 2^j can be replaced by the tuple $(X_1, \ldots, X_j)$, where X_i has cardinality bound 2 for each $i \in \{1, \ldots, j\}$. These are clearly equivalent, since each X_i can correspond to the i-th bit of X. More generally, a variable with cardinality bound l can be replaced by $(X_1, \ldots, X_{\lceil \log l \rceil})$, with each X_i's cardinality bounded by 2 and the additional requirement $\mathrm{UNIF}'_k((X_1, \ldots, X_{\lceil \log l \rceil}))$. Here $\mathrm{UNIF}'_k(Y)$ is a modification of the UNIF_k predicate such that it enforces Y being uniform with $|Y| \leq k$. The construction of both of these follows closely that of Li and is given in detail in the full version. Note that the resulting predicate can be large, but this is only important when the bound is not constant – in our case these are only the two bounds $X^2 \leq m, Y^2 \leq n$. To avoid this issue, we reduce from POWER-OF-TWO PERIODIC BOUNDED TILING – then X_i, Y_i (for $i \in \{1,2\}$) have bounds $2^m, 2^n$ respectively, while the remaining variables have constant bounds. Replacing X_1, X_2, Y_1, Y_2 by tuples of binary variables as shown above, we obtain a CI implication of size $N \cdot O(m+n)$, where N is the size of the original implication. The number of random variables grows similarly. The newly created bounds are all constant, and the reduction takes time polynomial with regard to the input size. The values of the remaining constant bounds are known and therefore each such variable can be converted in constant time. Together, these two results yield Theorem 1.

Abstract

Weighted Timed Games (WTGs for short) are widely used to describe real-time controller synthesis problems, but they rely on an unrealistic perfect measure of time elapse. In order to produce strategies tolerant to timing imprecisions, we consider a notion of robustness, expressed as a parametric semantics, first introduced for timed automata. WTGs are two-player zero-sum games played in a weighted timed automaton in which one of the players, that we call Min, wants to reach a target location while minimising the cumulated weight. The opponent player, in addition to controlling some of the locations, can perturb delays chosen by Min. The robust value problem asks, given some threshold, whether there exists a positive perturbation and a strategy for Min ensuring to reach the target, with an accumulated weight below the threshold, whatever the opponent does.

We provide in this article the first decidability result for this robust value problem. More precisely, we show that we can compute the robust value function, in a parametric way, for the class of divergent WTGs (this class has been introduced previously to obtain decidability of the (classical) value problem in WTGs without bounding the number of clocks). To this end, we show that the robust value is the fixpoint of some operators, as is classically done for value iteration algorithms. We then combine in a very careful way two representations: piecewise affine functions introduced in [1] to analyse WTGs, and shrunk Difference Bound Matrices (shrunk DBMs for short) considered in [29] to analyse robustness in timed automata. The crux of our result consists in showing that using this representation, the operator of value iteration can be computed for infinitesimally small perturbations. Last, we also study qualitative decision problems and close an open problem on robust reachability, showing it is EXPTIME-complete for general WTGs.

1 Introduction

The design and synthesis of real-time systems have long been paramount challenges, given the critical need for dependable and efficient systems in a variety of applications. In particular, the pursuit of robustness and reliability in these systems has led researchers to explore innovative methods and formalisms to address the complexities inherent in real-time environments. In this work, we focus on game-based models, and more precisely on the game extension of timed automata [2], a.k.a. timed games, which provide an elegant framework for capturing the interplay between system components, environment dynamics, and strategic decision-making. More precisely, in this model, locations of a timed automaton are split amongst the two players, which play in turn in the infinite-state space of the automaton.

Regarding robustness, prior studies have primarily focused on areas such as fault tolerance, adaptive control, and formal methods. In this work, we follow a series of works based on game theory. The objective is to fill the gap between mathematical models such as timed automata, often used for model-checking purposes, and implementation constraints, in which clocks only have finite precision, and actions are not instantaneous. To that end, a parametric semantics has been considered in [27], which consists in allowing the delays to be perturbed by some limited amount. The uncertainty of the system, i.e. the perturbation of the delays, is modelled by an adversarial environment. Two kinds of problems can then be considered: first, the analysis may be done for a fixed perturbation bound (we call it a *fixed-perturbation robustness problem*); second, in order to abstract the precise settings of the implementation, and as the exact value of the perturbation bound may be unknown, one can try to determine whether there exists a perturbation bound under which the system is reliable (we call it an *existential robustness problem*). By monotonicity of the semantics w.r.t. the perturbation bound, if one manages to prove the reliability against some perturbation bound, then it still holds for smaller perturbations. Initially introduced for model-checking purposes [20, 8], this approach has been lifted to automatic synthesis, yielding the so-called *conservative semantics*, studied for instance in [30, 26, 19]. In these works, a player named Controller aims at satisfying a liveness objective while its opponent may perturb the delays.

In the present work, we aim to go beyond qualitative objectives, and tackle quantitative aspects. In real-time systems and critical applications, quantitative aspects such as resource utilization and performance metrics hold important significance. This has led to the model of *weighted timed games* (WTG for short), which has been widely studied during the last two decades. When considering a reachability objective, Controller (a.k.a. player Min) aims at reaching a set of target locations while minimizing the accumulated weight. One is then interested in the *value problem*, which consists in deciding, given some threshold, whether a strategy for Min exists to reach some target location while keeping the accumulated cost below this threshold. While this problem is undecidable in general [11, 5, 14], several subclasses have been identified that allow one to regain decidability. Amongst recent works, we can cite the class of divergent WTGs [18] which generalize to arbitrary costs the class of strictly non-Zeno costs introduced in [6], or the class of one-clock WTGs [24].

The core objective of this research is to explore the synthesis of real-time systems that not only meet timing constraints but also optimize performance with respect to specified weight objectives and are robust against timing imprecisions. To that end, we aim to study the setting of timed games extended with both robustness issues and quantitative aspects. We focus on the conservative semantics and on reachability objectives. In this setting, under a fixed perturbation, the player Min aims at reaching a set of target locations while minimizing the accumulated weight, and resisting delay perturbations. This leads to a notion of *robust value under a fixed perturbation*: this is simply the best value Min can achieve. The associated fixed perturbation robust value problem aims at comparing this value with a given threshold. When turning to the existential robustness decision problem, one considers the notion of *robust value*, defined as the limit of robust values for arbitrarily small perturbation values. We prove that this limit exists, and study the associated decision problem, which we simply call *robust value problem*, and which can be defined as follows: given a threshold, determine whether there exists a positive perturbation, and a winning strategy for Min ensuring that the accumulated weight until the target is below the threshold.

This problem is highly challenging as it combines difficulties coming from the introduction of weights, with those due to the analysis of an existential problem for the parametric semantics of robustness. Unsurprisingly, it has been shown to be undecidable [28]. To highlight the challenges we face, already in the qualitative setting (w/o weights), the setting of two-player has not been addressed yet for the conservative semantics, hence the existential robust reachability problem was left open in [28]. Indeed, in [19, 30], only the one-player case is handled (a partial extension is considered in [26]) and the existential robustness reachability problem for the two-player setting has only been solved for the excessive semantics (an alternative to the conservative semantics) in [10]. Regarding the quantitative setting, very few works have addressed robustness issues. The fixed-perturbation robust value problem is shown to be decidable for one-clock weighted timed games in [21], with non-negative weights only, and for the excessive semantics. In [9], the authors consider the one-player case and prove that the robust value problem is PSPACE-complete.

Our contributions are as follows: first, regarding the qualitative setting, we close the case of existential robust reachability in two-player timed games for the conservative semantics, and show that this problem is EXPTIME-complete. To do so, we introduce a construction which allows us to reduce the problem to the excessive semantics solved in [10]. As a corollary, we deduce an upper bound on the length of paths to the target.

Then, we turn to the quantitative setting and show that for the class of divergent WTGs (one of the largest classes of WTGs for which the decidability of the value problem is known), the robust value problem is decidable. We proceed as follows:

1. We characterize the robust value for a fixed perturbation as the fixpoint of some operator.
2. We show that for acyclic WTGs, this fixpoint can be obtained as a finite iteration of this operator, which we decompose using four simpler operators.
3. We introduce a symbolic parametric approach for the computation of this operator, for arbitrarily small values of the perturbation. This requires carefully combining the representation of value functions using piecewise affine functions introduced in [1] with the notion of shrunk DBMs, used in [29] to analyse robustness issues in timed automata. This yields the decidability of the robust value problem for the class of acyclic WTGs.
4. By combining this with the upper bound deduced from the qualitative analysis, we show the decidability of the robust value problem for the whole class of divergent WTGs.

In Section 2, we introduce WTGs, under the prism of robustness. We describe in Section 3 the robustness problems we consider, present our contributions for qualitative ones, and state that we can solve the quantitative one for acyclic WTGs. Sections 4 and 5 detail how to prove this result, following steps 1.-3. described above. Last, Section 6 extends this positive result to the class of divergent WTGs. Omitted proofs can be found in a long version of this article [25].

2 Robustness in weighted timed games

We let $\mathcal{X}$ be a finite set of variables called clocks. A valuation is a mapping $\nu\colon \mathcal{X} \to \mathbb{R}_{\geq 0}$. For a valuation ν, a delay $t \in \mathbb{R}_{\geq 0}$ and a subset $Y \subseteq \mathcal{X}$ of clocks, we define the valuation $\nu + t$ as $(\nu+t)(x) = \nu(x) + t$, for all $x \in \mathcal{X}$, and the valuation $\nu[Y := 0]$ as $(\nu[Y := 0])(x) = 0$ if $x \in Y$, and $(\nu[Y := 0])(x) = \nu(x)$ otherwise. A (non-diagonal) guard on clocks of $\mathcal{X}$ is a conjunction of atomic constraints of the form $x \bowtie c$, where $\bowtie \in \{\leq, <, =, >, \geq\}$ and $c \in \mathbb{N}$. A valuation $\nu\colon \mathcal{X} \to \mathbb{R}_{\geq 0}$ satisfies an atomic constraint $x \bowtie c$ if $\nu(x) \bowtie c$. The satisfaction relation is extended to all guards g naturally, and denoted by $\nu \models g$. We let $\mathsf{Guards}(\mathcal{X})$ denote the set of guards over $\mathcal{X}$.

▶ **Definition 1.** *A* weighted timed game *(WTG) is a tuple* $\mathcal{G} = \langle L_{\mathsf{Min}}, L_{\mathsf{Max}}, L_T, \mathcal{X}, \Delta, \mathsf{wt}\rangle$ *where* L_{Min}, L_{Max}, L_T *are finite disjoint subsets of* Min *locations,* Max *locations, and target locations, respectively (we let* $L = L_{\mathsf{Min}} \uplus L_{\mathsf{Max}} \uplus L_T$*),* $\mathcal{X}$ *is a finite set of clocks,* $\Delta \subseteq L \times \mathsf{Guards}(\mathcal{X}) \times 2^{\mathcal{X}} \times L$ *is a finite set of transitions, and* $\mathsf{wt}\colon \Delta \uplus L \to \mathbb{Z}$ *is the weight function.*

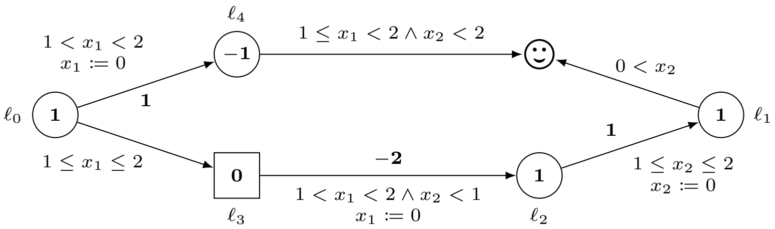

Figure 1 An acyclic WTG with two clocks.

The usual semantics, called *exact semantics*, of a WTG $\mathcal{G}$ is defined in terms of a game played on an infinite transition system whose vertices are configurations of the WTG denoted by $\mathsf{Conf} = \mathsf{Conf}_{\mathsf{Min}} \uplus \mathsf{Conf}_{\mathsf{Max}} \uplus \mathsf{Conf}_T$. A configuration is a pair (ℓ, ν) with a location and a valuation of the clocks. A configuration is final (resp. belongs to Min, or Max), and belongs to Conf_T (resp. to $\mathsf{Conf}_{\mathsf{Min}}$, or $\mathsf{Conf}_{\mathsf{Max}}$) if its location is a target location of L_T (resp. of L_{Min}, or L_{Max}). The alphabet of the transition system is given by $\Delta \times \mathbb{R}_{\geq 0}$: a pair (δ, t) encodes the delay t that a player wants to spend in the current location, before firing transition δ. An example of WTG is depicted in Figure 1.

In this article, we consider an alternative semantics to model the robustness, traditionnally called the *conservative semantics*. It is defined in a WTG $\mathcal{G}$ according to a fixed parameter $p > 0$. This semantics allows Max to slightly perturb the delays chosen by Min with an amplitude bounded by p. From the modelling perspective, the perturbations model the small errors of physical systems on the real value of clocks. Conservative means that the delays proposed by Min must remain feasible after applying all possible perturbations. In particular, the conservative semantics does not add new edges with respect to the exact one.

▶ **Definition 2.** *Let $\mathcal{G} = \langle L_{\mathsf{Min}}, L_{\mathsf{Max}}, L_T, \mathcal{X}, \Delta, \mathsf{wt}\rangle$ be a WTG. For $p \geq 0$, we let $[\![\mathcal{G}]\!]^p = \langle S, E, \mathsf{wt}\rangle$ with $S = S_{\mathsf{Min}} \uplus S_{\mathsf{Max}} \uplus S_T$ the set of* states *with $S_{\mathsf{Min}} = \mathsf{Conf}_{\mathsf{Min}}$, $S_T = \mathsf{Conf}_T$ and $S_{\mathsf{Max}} = \mathsf{Conf}_{\mathsf{Max}} \cup (\mathsf{Conf}_{\mathsf{Min}} \times \mathbb{R}_{\geq 0} \times \Delta)$; $E = E_{\mathsf{Min}} \uplus E_{\mathsf{Max}} \uplus E_{\mathit{rob}}$ the set of* edges *with*

$$E_{\mathsf{Max}} = \big\{\big((\ell,\nu) \xrightarrow{\delta,t} (\ell',\nu')\big) \mid \ell \in L_{\mathsf{Max}}, \nu + t \models g \text{ and } \nu' = (\nu + t)[Y := 0]\big\}$$
$$E_{\mathsf{Min}} = \big\{\big((\ell,\nu) \xrightarrow{\delta,t} (\ell,\nu,\delta,t)\big) \mid \ell \in L_{\mathsf{Min}}, \nu + t \models g \text{ and } \nu + t + 2p \models g\big\}$$
$$E_{\mathit{rob}} = \big\{\big((\ell,\nu,\delta,t) \xrightarrow{\delta,\varepsilon} (\ell',\nu')\big) \mid \varepsilon \in [0,2p] \text{ and } \nu' = (\nu + t + \varepsilon)[Y := 0]\big\}$$

where $\delta = (\ell, g, Y, \ell') \in \Delta$; and $\mathsf{wt}\colon S \cup E \to \mathbb{Z}$ the weight function such that for all states $s \in S$ with $s = (\ell, \nu)$ or $s = (\ell, \nu, \delta, t)$, $\mathsf{wt}(s) = \mathsf{wt}(\ell)$, and all edges $e \in E$, $\mathsf{wt}(e) = \mathsf{wt}(\delta)$ if $e = (s \xrightarrow{\delta,t} s')$ with $s \in \mathsf{Conf}$, or $\mathsf{wt}(e) = 0$ otherwise.

When $p = 0$, the infinite transition system $[\![\mathcal{G}]\!]^0$ describes the exact semantics of the game, the usual semantics where each step of the player Min is cut into the true step, followed by a useless edge $(\ell, \nu, \delta, t) \xrightarrow{\delta,0} (\ell', \nu')$ where Max has no choice. When $p > 0$, the infinite transition system $[\![\mathcal{G}]\!]^p$ describes the conservative semantics of the game: states $(\ell, \nu, \delta, t) \in \mathsf{Conf}_{\mathsf{Min}} \times \mathbb{R}_{\geq 0} \times \Delta$ where Max must choose the perturbation in the interval $[0, 2p]$ are called *perturbed states*.

Let s be a state of $[\![\mathcal{G}]\!]^p$, we denote by $E(s)$ the set of possible outgoing edges of $[\![\mathcal{G}]\!]^p$ from s. We extend this notation to locations to denote the set of outgoing transitions in $\mathcal{G}$. A state (resp. location) s is a *deadlock* when $E(s) = \emptyset$. We note that the conservative semantics may introduce deadlock in configurations of Min (even if an outgoing edge exists in the exact semantics). Thus, unlike in the literature [1, 18], we allow state *and* location deadlocks.

A *finite play* of $\mathcal{G}$ w.r.t. the conservative semantics with parameter p is a sequence of edges in the transition system $[\![\mathcal{G}]\!]^p$ starting in a configuration of $\mathcal{G}$. We denote by $|\rho|$ the number of edges of ρ, and by $\mathsf{last}(\rho)$ its last state. The concatenation of two finite plays ρ_1 and ρ_2, such that ρ_1 ends in the same state as ρ_2 starts, is denoted by $\rho_1\rho_2$. Moreover, for modelling reasons, we only consider finite plays (starting and) ending in a configuration of $\mathcal{G}$. Since a finite play is always defined regarding a parameter p for the conservative semantics, we denote by FPlays^p this set of finite plays. Moreover, we denote by $\mathsf{FPlays}^p_{\mathsf{Min}}$ (resp. $\mathsf{FPlays}^p_{\mathsf{Max}}$) the subset of these finite plays ending in a state of Min (resp. Max). A *maximal play* is then a maximal sequence of consecutive edges: it is either a finite play reaching a deadlock (not necessary in L_T), or an infinite sequence such that all its prefixes are finite plays.

The objective of Min is to reach a target configuration, while minimising the cumulated weight up to the target. Hence, we associate to every finite play $\rho = s_0 \xrightarrow{\delta_0,t_0} s_1 \xrightarrow{\delta_1,t_1} \cdots s_k$ (some edges are in E_{rob}, others are not) its cumulated weight, taking into account both discrete and continuous costs: $\mathsf{wt}_\Sigma(\rho) = \sum_{i=0}^{k-1}[t_i \times \mathsf{wt}(s_i) + \mathsf{wt}(\delta_i)]$. Then, the weight of a maximal play ρ, denoted by $\mathsf{wt}(\rho)$, is defined by $+\infty$ if ρ does not reach L_T (because it is infinite or reaches another deadlock), and $\mathsf{wt}_\Sigma(\rho)$ if it ends in (ℓ,ν) with $\ell \in L_T$.

A strategy for Min (resp. Max) is a mapping from finite plays ending in a state of Min (resp. Max) to a decision in (δ,t) labelling an edge of $[\![\mathcal{G}]\!]^p$ from the last state of the play. Since plays could reach a deadlock state of Min, we consider strategies of Min to be partial mappings. For instance, in the WTG depicted in Figure 1 and a perturbation p, a strategy for Min in all plays ending in (ℓ_2,ν) can be defined only when $\nu(x_2) \leq 2-2p$ since, otherwise, there are no outgoing edges in $[\![\mathcal{G}]\!]^p$ from this state. Symmetrically, we ask for Max to always propose a move if we are not in a deadlock state. More formally, a strategy for Min, denoted χ, is a (possibly partial) mapping $\chi\colon \mathsf{FPlays}^p_{\mathsf{Min}} \to E$ such that $\chi(\rho) \in E(\mathsf{last}(\rho))$. A strategy for Max, denoted ζ, is a (possibly partial) mapping $\zeta\colon \mathsf{FPlays}^p_{\mathsf{Max}} \to E$ such that for all ρ, if $E(\mathsf{last}(\rho)) \neq \emptyset$, then $\chi(\rho)$ is defined, and in this case belongs to $E(\mathsf{last}(\rho))$. The set of strategies of Min (resp. Max) with the perturbation p is denoted by $\mathsf{Strat}^p_{\mathsf{Min}}$ (resp. $\mathsf{Strat}^p_{\mathsf{Max}}$).

A play or finite play $\rho = s_0 \xrightarrow{\delta_0,t_0} s_1 \xrightarrow{\delta_1,t_1} \cdots$ *conforms* to a strategy χ of Min (resp. Max) if for all k such that s_k belongs to Min (resp. Max), we have that $(\delta_k,t_k) = \chi(s_0 \xrightarrow{\delta_0,t_0} \cdots s_k)$. For all strategies χ and ζ of players Min and Max, respectively, and for all configurations (ℓ_0,ν_0), we let $\mathsf{Play}((\ell_0,\nu_0),\chi,\zeta)$ be the outcome of χ and ζ, defined as the unique maximal play conforming to χ and ζ and starting in (ℓ_0,ν_0).

The semantics $[\![\mathcal{G}]\!]^p$ is monotonic with respect to the perturbation p in the sense that Min has more strategies when p decreases, while Max can obtain, against a fixed strategy of Min, a smaller weight when p decreases. Formally, we have:

▶ **Lemma 3.** *Let $\mathcal{G}$ be a WTG, and $p > p' \geq 0$ be two perturbations. Then*

1. $\mathsf{Strat}^p_{\mathsf{Min}} \subseteq \mathsf{Strat}^{p'}_{\mathsf{Min}}$;
2. *for all* $\chi \in \mathsf{Strat}^p_{\mathsf{Min}}$, $\sup_{\zeta\in\mathsf{Strat}^p_{\mathsf{Max}}} \mathsf{wt}(\mathsf{Play}((\ell,\nu),\chi,\zeta)) \geq \sup_{\zeta\in\mathsf{Strat}^{p'}_{\mathsf{Max}}} \mathsf{wt}(\mathsf{Play}((\ell,\nu),\chi,\zeta))$.

3 Deciding the robustness in weighted timed games

We aim to study what Min can guarantee, qualitatively and then quantitatively, in the conservative semantics of weighted timed games whatever Max does.

Qualitative robustness problems. Formally, given a WTG $\mathcal{G}$ and a perturbation p, we say a strategy χ of Min is *winning* in $[\![\mathcal{G}]\!]^p$ from configuration (ℓ,ν) if for all strategies ζ of Max, $\mathsf{Play}((\ell,\nu),\chi,\zeta)$ is a finite play ending in a location of L_T.

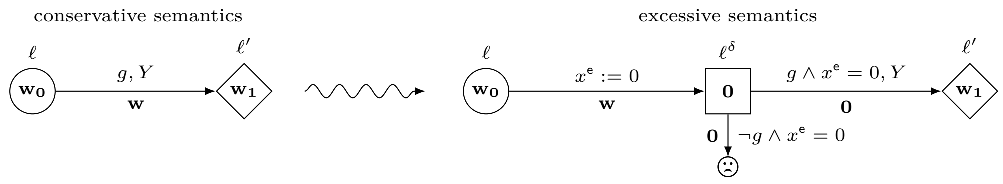

Figure 2 Gadget used to encode the conservative semantics into the excessive one. Each transition $\delta = (\ell, g, Y, \ell')$ with $\ell \in L_{\mathsf{Min}}$ is replaced by the gadget. Symbols w, w_0, w_1 denote weights from $\mathcal{G}$. The new location ℓ^δ of Max uses a fresh clock x^{e} to test the guard after the perturbation (as in the conservative semantics). The new location ☹ is a deadlock (thus winning for Max).

There are two possible questions, whether the perturbation p is fixed, or if we should consider it to be infinitesimally small:

- *fixed-perturbation robust reachability problem*: given a WTG $\mathcal{G}$, a configuration (ℓ, ν) and a perturbation $p > 0$, decide whether Min has a winning strategy χ from (ℓ, ν) in $[\![\mathcal{G}]\!]^p$;
- *existential robust reachability problem*: given a WTG $\mathcal{G}$ and a configuration (ℓ, ν), decide whether there exists $p > 0$ such that Min has a winning strategy χ from (ℓ, ν) in $[\![\mathcal{G}]\!]^p$. Notice that by Lemma 3, if Min has a winning strategy χ from (ℓ, ν) in $[\![\mathcal{G}]\!]^p$, then he has one in $[\![\mathcal{G}]\!]^{p'}$ for all $p' \leq p$.

When the perturbation p is fixed, we can encode in a WTG the conservative semantics described in $[\![\mathcal{G}]\!]^p$, by adding new locations for Max to choose a perturbation, and by modifying the guards that will now use the perturbation p. Solving the fixed-perturbation robust reachability problem then amounts to solving a reachability problem in the modified WTG[1] which can be performed in EXPTIME [3] (here weights are useless). Since the reachability problem in timed games is already EXPTIME-complete [22], we obtain:

▶ **Proposition 4.** *The fixed-perturbation robust reachability problem is* EXPTIME*-complete.*

We now turn our attention to the existential robust reachability problem. This problem was left open for the conservative semantics (see [28], Table 1.2 page 17), while it has been solved in [10] for an alternative semantics of robustness, known as the *excessive semantics*. Intuitively, while the conservative semantics requires that the delay, after perturbation, satisfies the guard, the excessive semantics only requires that the delay, *without perturbation*, satisfies the guard. We present a reduction from the conservative semantics to the excessive one, allowing us to solve the existential robust reachability problem for the conservative semantics. Intuitively, the construction (depicted on Figure 2) adds a new location (for Max) for each transitions of Min to test the delay chosen by Min after the perturbation:

▶ **Proposition 5.** *The existential robust reachability problem is* EXPTIME*-complete.*

Quantitative fixed-perturbation robustness problem. We are also interested in the minimal weight that Min can guarantee while reaching the target whatever Max does: to do that we define *robust values*. First, we define the *fixed-perturbation robust value*: for all configurations (ℓ, ν) of $\mathcal{G}$ (and not for all states of the semantics), we let $\overline{\mathsf{rVal}}^p(\ell, \nu) = \inf_{\chi \in \mathsf{Strat}^p_{\mathsf{Min}}} \sup_{\zeta \in \mathsf{Strat}^p_{\mathsf{Max}}} \mathsf{wt}(\mathsf{Play}((\ell, \nu), \chi, \zeta))$.

[1] By transforming the WTG, its guards use rational instead of natural numbers (due to p). To fit the classical definition of WTG, we can apply a scaling factor (i.e. $1/p$) to all constants appearing in this WTG. We note that this operation preserves the set of winning strategies for the reachability objective (here weights are irrelevant) by applying the scaling operations on strategies too.

Since a fixed-perturbation conservative semantics defines a *quantitative reachability game*[2], where configurations of Max also contain the robust states, we obtain that the fixed-perturbation robust value is determined, by applying [13, Theorem 2.2], i.e. that $\overline{\mathsf{rVal}}^p(\ell,\nu) = \sup_{\zeta\in\mathsf{Strat}^p_{\mathsf{Max}}} \inf_{\chi\in\mathsf{Strat}^p_{\mathsf{Min}}} \mathsf{wt}(\mathsf{Play}((\ell,\nu),\chi,\zeta))$. We therefore denote rVal^p this value.

▶ Remark 6. In [9, 10, 21], the set of possible perturbations for Max is $[-p,p]$. For technical reasons, we use a (equivalent) perturbation with a shift of the delay proposed by Min by p.

When $p=0$, rVal^0 defines the *(exact) value* that is used to study the value problem in WTGs. By Lemma 3, we can deduce that the fixed-perturbation robust value is monotonic with respect to the perturbation p and is always an upper-bound for the (exact) value.

▶ **Lemma 7.** *Let $\mathcal{G}$ be a WTG, and $p > p' \geq 0$ be two perturbations. Then, for all configurations (ℓ,ν), $\mathsf{rVal}^p(\ell,\nu) \geq \mathsf{rVal}^{p'}(\ell,\nu)$.*

As in the qualitative case, when the perturbation p is fixed, we can encode in polynomial time in a WTG the conservative semantics described in $[\![\mathcal{G}]\!]^p$. Unfortunately, the value of WTGs is not always computable since the associated decision problems (in particular the *value problem* that requires to decide if the value of a given configuration is below a given threshold) are undecidable [11, 4, 14]. However, in subclasses of WTGs where the value function can be computed, like acyclic WTGs (where every path in the graph of the WTGs is acyclic, decidable in 2-EXPTIME [15]) or divergent WTGs (that we recall in Section 6, in 3-EXPTIME [6, 16]), the fixed-perturbation robust value is also computable (if the modified game falls in the subclass). In particular, we obtain:

▶ **Proposition 8.** *We can compute the fixed-perturbation robust value of a WTG that is acyclic (in 2-*EXPTIME*) or divergent (in 3-*EXPTIME*), for all possible initial configurations.*

On top of computing the robust values, the previous works also allow one to synthesize almost-optimal (*i.e.* arbitrarily close from the value) strategies for both players.

Quantitative robustness problem. Now, we consider the existential version of this problem by considering an infinitesimal perturbation. We thus want to know what Min can guarantee as a value if Max plays infinitesimally small perturbations. To define properly the problem, we introduce a new value: given a WTG $\mathcal{G}$, the *robust value* is defined, for all configurations (ℓ,ν) of $\mathcal{G}$, by $\overline{\mathsf{rVal}}(\ell,\nu) = \lim_{p\to 0, p>0} \mathsf{rVal}^p(\ell,\nu)$. This value is defined as a limit of functions (the fixed-perturbation robust values), which can be proved to always exist as the limit of a non-increasing sequence of functions (see Lemma 7). The decision problem associated to this robust value is: given a WTG $\mathcal{G}$, an initial configuration (ℓ,ν), and a threshold $\lambda \in \mathbb{Q}\cup\{-\infty,+\infty\}$, decide if $\overline{\mathsf{rVal}}(\ell,\nu) \leq \lambda$. We call it the *robust value problem.*

Unsurprisingly, this problem is undecidable [9, Theorem 4]. We will thus consider some restrictions over WTGs. In particular, we consider classes of WTGs where the (non robust) value problem is known as decidable for the exact semantics: acyclic WTGs [1], and divergent WTGs [6, 16]. Our first main contribution concerns the acyclic case:

▶ **Theorem 9.** *The robust value problem is decidable over the subclass of acyclic WTGs.*

The next two sections sketch the proof of this theorem via an adaptation of the value iteration algorithm [1] used to compute the value function in (non-robust) acyclic WTGs: it consists in computing iteratively the best thing that both players can guarantee in a bounded

[2] A quantitative reachability game introduced in [12] is an abstract model to formally define the semantics of quantitative (infinite) games.

number of steps, that increases step by step. It is best described by a mapping $\mathcal{F}$ that explains how a value function gets modified by allowing one more step for the players to play. The adaptation we propose consists in taking the robustness into account by using shrunk DBM techniques introduced in [29]: instead of inequalities on the difference of two clock values of the form $x - y \leq c$ involving rational constants c, the constants c will now be of the form $a - bp$, with a a rational and b a positive integer, p being an infinitesimal perturbation. This will allow us to compute a description of the fixed-perturbation values for all initial configurations, for all perturbations p smaller than an upperbound that we will compute. The robust value will then be obtained by taking the limit of this parametric representation of the fixed-perturbation values when p tends to 0. Our algorithm will also compute an upperbound on the biggest allowed perturbation p. As in previous works, once the value is computed, we can also synthesize almost-optimal strategies.

Section 4 will describe the mapping $\mathcal{F}_p$, with a known perturbation p: the iteration of this operator will be shown to converge towards the fixed-perturbation value rVal^p. The robust value functions will be shown to always be piecewise affine functions with polytope pieces. Section 5 describes the parametric representation of these functions, where the perturbation is no longer fixed but is a formal parameter $\mathfrak{p}$. We then explain how the mapping $\mathcal{F}_p$ can be computed for all small enough values of p at once, allowing us to conclude.

4 Operator $\mathcal{F}_p$ to compute the fixed-perturbation value

The first step of the proof is the definition of the new operator adapted from the operator $\mathcal{F}$ of [1]. We thus fix a perturbation $p > 0$, and we define an operator $\mathcal{F}_p$ taking as input a mapping $X \colon L \times \mathbb{R}_{\geq 0}^{\mathcal{X}} \to \mathbb{R}_\infty$, computing a mapping $\mathcal{F}_p(X) \colon L \times \mathbb{R}_{\geq 0}^{\mathcal{X}} \to \mathbb{R}_\infty$ defined for all configurations (ℓ, ν) by $\mathcal{F}_p(X)(\ell, \nu)$ equal to

$$\begin{cases} 0 & \text{if } \ell \in L_T \\ +\infty & \text{if } \ell \in L_{\mathsf{Max}} \text{ and } E(\ell,\nu) = \emptyset \quad (\text{if } \mathsf{Max} \text{ reaches a deadlock, he wins}) \\ \sup_{(\ell,\nu) \xrightarrow{\delta,t} (\ell',\nu') \in [\![\mathcal{G}]\!]^p} \big[t\,\mathsf{wt}(\ell) + \mathsf{wt}(\delta) + X(\ell',\nu')\big] & \text{if } \ell \in L_{\mathsf{Max}} \text{ and } E(\ell,\nu) \neq \emptyset \\ \inf_{(\ell,\nu) \xrightarrow{\delta,t} (\ell,\nu,\delta,t) \in [\![\mathcal{G}]\!]^p} \sup_{(\ell,\nu,\delta,t) \xrightarrow{\delta,\varepsilon} (\ell,\nu') \in [\![\mathcal{G}]\!]^p} \big[(t{+}\varepsilon)\,\mathsf{wt}(\ell){+}\mathsf{wt}(\delta){+}X(\ell',\nu')\big] & \text{if } \ell \in L_{\mathsf{Min}} \end{cases}$$

In the following, we let $\mathbb{V}^0$ be the mapping $L \times \mathbb{R}_{\geq 0}^{\mathcal{X}} \to \mathbb{R}_\infty$ defined by $\mathbb{V}^0(\ell,\nu) = 0$ if $\ell \in L_T$ and $\mathbb{V}^0(\ell,\nu) = +\infty$ otherwise. By adapting the proof of the non-robust setting, we show:

▶ **Lemma 10.** *Let $\mathcal{G}$ be an acyclic WTG, $p > 0$, D is the depth of $\mathcal{G}$, i.e. the length of a longest path in $\mathcal{G}$. Then,* rVal^p *is a fixpoint of $\mathcal{F}_p$, and* $\mathsf{rVal}^p = \mathcal{F}_p^D(\mathbb{V}^0)$.

We can thus compute the fixed-perturbation robust value of an acyclic WTG by repeatedly computing $\mathcal{F}_p$. We will see in the next section that this computation can be made for all small enough p by using a parametric representation of the mappings. It will be easier to split the computation of $\mathcal{F}_p$ in several steps (as done in the non robust case [1, 18]). Each of the four operators takes as input a mapping $V \colon \mathbb{R}_{\geq 0}^{\mathcal{X}} \to \mathbb{R}_\infty$ (where the location ℓ has been fixed, with respect to mappings $L \times \mathbb{R}_{\geq 0}^{\mathcal{X}} \to \mathbb{R}_\infty$), and computes a mapping of the same type.

- The operator $\mathsf{Unreset}_Y$, with $Y \subseteq \mathcal{X}$ a subset of clocks, is such that for all $\nu \in \mathbb{R}_{\geq 0}^{\mathcal{X}}$, $\mathsf{Unreset}_Y(V)(\nu) = V(\nu[Y := 0])$.
- The operator Guard_δ, with $\delta = (\ell, g, Y, \ell')$ a transition of Δ, is such that for all $\nu \in \mathbb{R}_{\geq 0}^{\mathcal{X}}$, if $\nu \models g$, then $\mathsf{Guard}_\delta(V)(\nu) = V(\nu)$; otherwise, $\mathsf{Guard}_\delta(V)(\nu)$ is equal to $-\infty$ if $\ell \in L_{\mathsf{Max}}$, and $+\infty$ if $\ell \in L_{\mathsf{Min}}$.

- The operator Pre_ℓ, with $\ell \in L$, is such that for all $\nu \in \mathbb{R}^{\mathcal{X}}_{\geq 0}$, $\mathsf{Pre}_\ell(V)(\nu)$ is equal to $\sup_{t\geq 0}[t\,\mathsf{wt}(\ell) + V(\nu+t)]$ if $\ell \in L_{\mathsf{Max}}$, and $\inf_{t\geq 0}[t\,\mathsf{wt}(\ell) + V(\nu+t)]$ if $\ell \in L_{\mathsf{Min}}$.
- The operator $\mathsf{Perturb}^p_\ell$, with perturbation $p > 0$ and $\ell \in L_{\mathsf{Min}}$, is such that for all $\nu \in \mathbb{R}^{\mathcal{X}}_{\geq 0}$, $\mathsf{Perturb}^p_\ell(V)(\nu) = \sup_{\varepsilon\in[0,2p]}[\varepsilon\,\mathsf{wt}(\ell) + V(\nu+\varepsilon)]$.

Though the situation is not symmetrical for Min and Max in $\mathcal{F}_p$, in particular for the choice of delay t, the definition of Pre_ℓ does not differentiate the two players with respect to their choice of delay. However, the correctness of the decomposition comes from the combination of this operator with Guard_δ (that clearly penalises Min if he chooses a delay such that the translated valuation does not satisfy the guard) and $\mathsf{Perturb}^p_\ell$ that allows Max to select a legal perturbation not satisfying the guard, leading to a value $+\infty$ afterwards.

For a mapping $\mathbb{V}\colon L \times \mathbb{R}^{\mathcal{X}}_{\geq 0} \to \mathbb{R}_\infty$ and a location ℓ, we can extract the submapping for the location ℓ, that we denote by $\mathbb{V}_\ell\colon \mathbb{R}^{\mathcal{X}}_{\geq 0} \to \mathbb{R}_\infty$, defined for all $\nu \in \mathbb{R}^{\mathcal{X}}_{\geq 0}$ by $\mathbb{V}_\ell(\nu) = \mathbb{V}(\ell,\nu)$. Mappings $\mathbb{R}^{\mathcal{X}}_{\geq 0} \to \mathbb{R}_\infty$ can be compared, by using a pointwise comparison: in particular the maximum or minimum of two such mappings is defined pointwisely. The previous operators indeed allow us to split the computation of $\mathcal{F}_p$. We also rely on the classical notion of *regions*, as introduced in the seminal work on timed automata [2]. Indeed, for a given location ℓ, the set of deadlock valuations ν where $E(\ell,\nu) = \emptyset$ is a union of regions that we denote R_ℓ in the following, and that can easily be computed.

▶ **Lemma 11.** *For all $\mathbb{V}\colon L \times \mathbb{R}^{\mathcal{X}}_{\geq 0} \to \mathbb{R}_\infty$, $\ell \in L$, and $p > 0$, $\mathcal{F}_p(\mathbb{V})(\ell)$ equals*

$$\begin{cases} \nu \mapsto 0 & \text{if } \ell \in L_T \\ \left(\nu \mapsto \begin{cases} +\infty & \text{if } \nu \in R_\ell \\ \Big(\max\limits_{\delta=(\ell,g,Y,\ell')\in\Delta}\big[\mathsf{wt}(\delta) + \mathsf{Pre}_\ell(\mathsf{Guard}_\delta(\mathsf{Unreset}_Y(\mathbb{V}_{\ell'})))\big]\Big)(\nu) & \text{if } \nu \notin R_\ell \end{cases}\right) & \text{if } \ell \in L_{\mathsf{Max}} \\ \min\limits_{\delta=(\ell,g,Y,\ell')\in\Delta}\big[\mathsf{wt}(\delta) + \mathsf{Pre}_\ell(\mathsf{Perturb}^p_\ell(\mathsf{Guard}_\delta(\mathsf{Unreset}_Y(\mathbb{V}_{\ell'}))))\big] & \text{if } \ell \in L_{\mathsf{Min}} \end{cases}$$

5 Encoding parametric piecewise affine functions

We now explain how to encode the mappings that the operators defined in the previous section take as input, to compute $\mathcal{F}_p$ for all perturbation bounds $p > 0$ at once. We adapt the formalism used in [1, 18] to incorporate the perturbation p. This formalism relies on the remark that $\mathbb{V}^0$ is a piecewise affine function, and that if $\mathbb{V}$ is piecewise affine, so is $\mathcal{F}_p(\mathbb{V})$: thus we only have to manipulate such piecewise affine functions.

To model the robustness, that depends on the perturbation bound p, and maintain a parametric description of all the value functions for infinitesimally small values of p, we consider piecewise affine functions that depend on a formal parameter $\mathfrak{p}$ describing the perturbation. The pieces over which the function is affine, that we call cells in the following, are polytopes described by a conjunction of affine equalities and inequalities involving $\mathfrak{p}$. Some of our computations will only hold for small enough values of the parameter $\mathfrak{p}$ and we will thus also maintain an upperbound for this parameter.

▶ **Definition 12.** *We call* parametric affine expression *an expression E of the form $\sum_{x\in\mathcal{X}} \alpha_x\, x + \beta + \gamma\mathfrak{p}$ with $\alpha_x \in \mathbb{Q}$ for all $x \in \mathcal{X}$, $\beta \in \mathbb{Q} \cup \{-\infty, +\infty\}$, and $\gamma \in \mathbb{Q}$. The semantics of such an expression is given for a particular perturbation p as a mapping $[\![E]\!]_p\colon \mathbb{R}^{\mathcal{X}}_{\geq 0} \to \mathbb{R}_\infty$ defined for all $\nu \in \mathbb{R}^{\mathcal{X}}_{\geq 0}$ by $[\![E]\!]_p(\nu) = \sum_{x\in\mathcal{X}} \alpha_x\, \nu(x) + \beta + \gamma p$.*

A partition of $\mathbb{R}^{\mathcal{X}}_{\geq 0}$ into cells is described by a set $\mathcal{E} = \{E_1, \dots, E_m\}$ of parametric affine expressions. Every expression can be turned into an equation or inequation by comparing it to 0 with the symbol $=$, $<$ or $>$. The partition of $\mathbb{R}^{\mathcal{X}}_{\geq 0}$ is obtained by considering all

$x_1 - x_2 + 1/2$
$x_1 - x_2 + 2\mathfrak{p}$
$x_1 - x_2 - 1 + 7\mathfrak{p}/2$

Figure 3 On the left, we depict the partition defined from $\mathcal{E} = \{x_2 - 2\mathfrak{p}, 2x_1 + x_2 - 2 + \mathfrak{p}, 2x_1 - x_2 + 1/2\}$, for a small enough value of $\mathfrak{p}$. On the right, we depict the atomic partition induced by $\mathcal{E}$, and draw in red the added parametric affine expressions.

the combinations of equations and inequations for each $1 \leq i \leq m$: such a combination is described by a tuple $(\bowtie_i)_{1\leq i\leq m}$ of symbols in $\{=,<,>\}$. For a given perturbation p, we let $\llbracket \mathcal{E}, (\bowtie_i)_{1\leq i\leq m}\rrbracket_p$ be the set of valuations ν such that for all $i \in \{1,\dots,m\}$, $\llbracket E_i\rrbracket_p \bowtie_i 0$.

We call *cell* every such combination such that for p that tends to 0, while being positive, the set $\llbracket \mathcal{E}, (\bowtie_i)_{1\leq i\leq m}\rrbracket_p$ is non empty. We let $\mathcal{C}(\mathcal{E})$ be the set of cells of $\mathcal{E}$. Notice that it can be decided (in at most exponential time) if a combination $(\bowtie_i)_{1\leq i\leq m}$ is a cell, by encoding the semantics in the first order theory of the reals, and deciding if there exists an upperbound $\eta > 0$ such that for all $0 < p \leq \eta$, $\llbracket \mathcal{E}, (\bowtie_i)_{1\leq i\leq m}\rrbracket_p$ is non empty. Moreover, we can compute the biggest such upperbound η if it exists. The upperbound of the partition $\mathcal{E} = \{E_1,\dots,E_m\}$ is then defined as the minimum such upperbound over all cells (there are at most 3^m cells), and denoted by $\eta(\mathcal{E})$ in the following. On the left of Figure 3, we depict the partition of $\mathbb{R}^{\mathcal{X}}_{\geq 0}$ defined from $\mathcal{E} = \{x_2 - 2\mathfrak{p}, 2x_1 + x_2 - 2 + \mathfrak{p}, 2x_1 - x_2 + 1/2\}$, with a fixed value of the perturbation. In blue, we color the cell defined by $(>,<,>)$. We note that this cell is non-empty when $p \leq 1/2$. By considering other cells, we obtain that $\eta(\mathcal{E}) = 1/2$.

In the following, we may need to record a smaller upperbound than $\eta(\mathcal{E})$, in order to keep the tightest constraint seen so far in the computation. We thus call *parametric partition* a pair $\langle \mathcal{E}, \eta\rangle$ given by a set of equations and a perturbation $\eta > 0$ that is at most $\eta(\mathcal{E})$.

For a cell $c \in \mathcal{C}(\mathcal{E})$, an expression E of $\mathcal{E}$ is said to be on the *border* of c if the removal of E from the set $\mathcal{E}$ of expressions forbids one to obtain the set of valuations $\llbracket c\rrbracket_p$ with the resulting cells for all small enough values of $p > 0$: more precisely, we require that no cell $c' \in \mathcal{C}(\mathcal{E} \setminus \{E\})$ is such that for some $p \leq \eta(\mathcal{E})$, $\llbracket c\rrbracket_p = \llbracket c'\rrbracket_p$. Because of the definition of $\eta(\mathcal{E})$, this definition does not depend on the actual value of p that we consider (and we could thus replace "for some" by "for all" above). On the left of Figure 3, all expressions are on the border for the blue cell, but only two of them are on the border of the orange cell.

The proofs that follow (in particular time delaying that requires to move along diagonal lines) requires to adapt the notion of *atomicity* of a parametric partition, originally introduced in the non-robust setting [1, 18]. A parametric affine expression $E = \sum_{x\in\mathcal{X}} \alpha_x\, x + \beta + \gamma p$ is said to be *diagonal* if $\sum_{x\in\mathcal{X}} \alpha_x = 0$: indeed, for all $p > 0$, $\llbracket E\rrbracket_p(\nu) = \llbracket E\rrbracket_p(\nu + t)$ for all $t \in \mathbb{R}$. A parametric partition is said to be *atomic* if for all cells $c \in \mathcal{C}(\mathcal{E})$, there are at most two non-diagonal parametric affine expressions on the border of c: intuitively, one border is reachable from every valuation by letting time elapse, and the other border is such that by letting time elapse from it we can reach all valuations of the cell. An atomic partition decomposes the space into tubes whose borders are only diagonal, each tube being then sliced by using only non-diagonal expressions. In particular, each cell c of an atomic partition has a finite set of cells that it can reach by time elapsing (and dually a set of cells that can reach c by time elapsing), and this set does not depend on the value of the parameter p, nor the starting valuation in $[\![c]\!]_p$. On the right of Figure 3, we depict the atomic partition associated with the same set of expressions used on the left. The diagonal expressions are depicted in red. We note that the cell colored in blue on the left is split into five cells that are non-empty when $p \leq 3/7$. We can describe the new parametric partition as $(\{x_2 - 2\mathfrak{p}, 2x_1 + x_2 - 2 + \mathfrak{p}, 2x_1 - x_2 + 1/2, x_1 - x_2 - 1 + 7\mathfrak{p}/2, x_1 - x_2 + 2\mathfrak{p}, x_1 - x_2 + 1/2, x_1 - x_2 + 7/8 - \mathfrak{p}/4\}, 3/7)$. As we will see below, a parametric partition can always be made atomic, by adding some diagonal parametric affine expressions.

A *parametric value function* (PVF for short) is a tuple $F = \langle \mathcal{E}, \eta, (f_c)_{c \in \mathcal{C}(\mathcal{E})} \rangle$ where $\langle \mathcal{E}, \eta \rangle$ is a partition and, for all cells $c \in \mathcal{C}(\mathcal{E})$, f_c is a parametric affine expression. For a perturbation $0 < p \leq \eta$, the semantics $[\![F]\!]_p$ of this tuple is a mapping $\mathbb{R}^{\mathcal{X}}_{\geq 0} \to \mathbb{R}_\infty$ defined for all valuations ν by $[\![F]\!]_p(\nu) = [\![f_c]\!]_p(\nu)$ where c is the unique cell such that $\nu \in [\![c]\!]_p$. A PVF is said to be *atomic* if its parametric partition is atomic. As announced above, we can always refine a PVF so that it becomes atomic.

▶ **Lemma 13.** *If $F = \langle \mathcal{E}, \eta, (f_c)_{c \in \mathcal{C}(\mathcal{E})} \rangle$ is a PVF, we can compute an atomic PVF $F' = \langle \mathcal{E}', \eta', (f'_c)_{c \in \mathcal{C}(\mathcal{E}')} \rangle$ such that $\eta' \leq \eta$, and $[\![F]\!]_p = [\![F']\!]_p$ for all $p \leq \eta'$.*

To conclude the proof of Theorem 9, we need to compute one application of $\mathcal{F}_p$ over a mapping $X \colon L \times \mathbb{R}^{\mathcal{X}}_{\geq 0} \to \mathbb{R}_\infty$ that is stored by a PVF for each location. Moreover, our computations must be done for all small enough values of p simultaneously.

▶ **Proposition 14.** *Let $F = \langle \mathcal{E}, \eta, (f_c)_{c \in \mathcal{C}(\mathcal{E})} \rangle$ be a PVF. We can compute a PVF $F' = \langle \mathcal{E}', \eta', (f'_c)_{c \in \mathcal{C}(\mathcal{E}')} \rangle$ with $\eta' \leq \eta$, and $[\![F']\!]_p = \mathcal{F}_p([\![F]\!]_p)$ for all $p \leq \eta'$.*

Sketch of the proof. By using Lemma 11, it suffices to perform the proof independently for the four operators, as well as maximum or minimum operations. Proofs from [1, 18] can be adapted for the maximum/minimum operations as well as the operators Guard_δ and $\mathsf{Unreset}_Y$ that exist also in the non-robust setting. In the case of Max, the two cases depend only on the regions and we thus only apply the various operators for starting valuations not in R_ℓ.

For the operator Pre_ℓ (and similarly $\mathsf{Perturb}^p_\ell$), the adaptation is more subtle. The key ingredient, for instance to compute it over an atomic partition for a location ℓ of Max, is to transform the computation of $([\![F]\!]_p)(\nu) = \sup_{t \geq 0}[t\,\mathsf{wt}(\ell) + [\![F]\!]_p(\nu + t)]$ involving a supremum (for a fixed valuation ν, and a fixed perturbation $p \leq \eta$), by using a maximum over a finite set of interesting delays. First, we remark that for every delay $t > 0$, the valuation $\nu + t$ belongs to the open diagonal half-line from ν, which crosses some of the semantics $[\![c']\!]_p$ for certain cells c'. Moreover, this finite (since there are anyway only a finite number of cells in the partition) subset of crossing cells neither depends on the choice of ν in a given starting cell c, nor on the perturbation p as long as it is at most η (by atomicity of the partition). Since the function $[\![F]\!]_p$ is affine in each cell, the above supremum over the possible delays is obtained for a value t that is either 0, or tending to $+\infty$, or on one of the two non-diagonal borders of the previous crossing cells, and we thus only have to consider those borders (that do not depend on the choice of ν in a given starting cell c, nor on the perturbation p). ◀

6 Divergent weighted timed games

From our algorithm to solve acyclic WTGs, we naturally want to extend the computation of the robust value to other classes of WTGs by using an unfolding of the WTG. In particular, we consider the natural extension of *divergent WTGs* (like in [16, 18]) that define a large class of decidable WTGs for the exact semantics, with no limitations on the number of clocks.

As usual in related work [1, 6, 7, 18], we now assume that all clocks are *bounded* by a constant $\mathsf{M} \in \mathbb{N}$, i.e. every transition of the WTG is equipped with a guard g such that $\nu \models g$ implies $\nu(x) \leq \mathsf{M}$ for all clocks $x \in \mathcal{X}$. We denote by W_{loc} (resp. W_{tr}, W_{e}) the maximal weight in absolute values of locations (resp. of transitions, edges) of $\mathcal{G}$, i.e. $W_{\mathsf{loc}} = \max_{\ell \in L} |\mathsf{wt}(\ell)|$ (resp. $W_{\mathsf{tr}} = \max_{\delta \in \Delta} |\mathsf{wt}(\delta)|$, $W_{\mathsf{e}} = \mathsf{M} W_{\mathsf{loc}} + W_{\mathsf{tr}}$).

We use the exact semantics to define the divergence property by relying once again on the regions [2]. We let $\mathsf{Reg}(\mathcal{X}, \mathsf{M})$ be the set of regions when clocks are bounded by M. A game $\mathcal{G}$ (w.r.t. the exact semantics) can be populated with the region information as described formally in [18]: we obtain the *region game* $\mathcal{R}(\mathcal{G})$. We call *region path* a finite or infinite sequence of transitions in this game, and we denote by π such paths. A play ρ in $\mathcal{G}$ can be projected on a region path π: we say that ρ *follows* the region path π. It is important to notice that, even if π is a *cycle* (i.e. starts and ends in the same location of the region game), there may exist plays following it in $\mathcal{G}$ that are not cycles, due to the fact that regions are sets of valuations.

Divergent WTGs are obtained by enforcing a semantical property of divergence (originally called *strictly non-Zeno cost* when only dealing with non-negative weights [6]): it asks that every play (w.r.t. the exact semantics) following a cyclic region path has weight far from 0. Formally, a cyclic region path π of $\mathcal{R}(\mathcal{G})$ is said to be a positive (resp. negative) if every finite play ρ following π satisfies $\mathsf{wt}_\Sigma(\rho) \geq 1$ (resp. $\mathsf{wt}_\Sigma(\rho) \leq -1$).

▶ **Definition 15.** *A WTG is divergent if every cyclic region path is positive or negative.*

Finally, with loss of generality, we only consider divergent WTGs containing no configurations with a value equal to $-\infty$. Intuitively, guaranteeing a value $-\infty$ resembles a Büchi condition for Min, since this means that Max cannot avoid the iteration of negative cycles with his delays. In the robust settings, testing Büchi condition for automata is already non-trivial [19], thus we remove this behaviour in our games in this article. Since the value is a lower bound of the robust value (by Lemma 7), we obtain that all locations have a robust value distinct from $-\infty$. Moreover, testing if such a location exists in a divergent WTG can be done in EXPTIME [18]. Our second contribution is to extend the symbolic algorithm used in the case of acyclic WTGs to compute the robust value in this subclass of divergent WTGs.

▶ **Theorem 16.** *The robust value problem is decidable over the subclass of divergent WTGs without configurations of value $-\infty$.*

Sketch of the proof. We compute the robust value by using an adaptation of the algorithm of [18] used to compute the (exact) value function in divergent WTGs. In particular, its termination is guaranteed by the use of an equivalent definition of divergent WTG requiring that for all strongly connected components (SCC) S of the graph of the region game, either every cyclic region path π inside S is positive (we say that the SCC is positive) or every cyclic region path π inside S is negative (we say that the SCC is negative).

We adapt this argument in the case of the computation of the robust value of a divergent WTG (without configurations with a value equal to $-\infty$). In particular, we observe that if a cyclic region path is positive (resp. negative) w.r.t. the exact semantics, then it is also positive (resp. negative) w.r.t. the conservative semantics, as the latter only filters some plays. Thus, the finite convergence of the value iteration algorithm (defined by $\mathcal{F}_p$ as for acyclic WTG, i.e. initialised by the function $\mathbb{V}^0$ defined such that $\mathbb{V}^0(\ell) = 0$ for all target locations, and $\mathbb{V}^0(\ell) = +\infty$ otherwise) is guaranteed by its finite convergence in finite time in each positive (resp. negative) SCC. Intuitively, in a positive (resp. negative) SCC, the interest of Min (resp. Max) is to quickly reach a target location of $\mathcal{G}$ to minimise the number of positive (resp. negative) cyclic region paths followed along the play that allow us to upperbound the number of iterations needed to obtain the robust value of all locations. Thus, the number of iterations needed to compute the robust value in a divergent WTG is defined by the sum of the number of iterations for each SCC along the longest path of the SCC decomposition. ◀

On top of computing the value, the modified algorithm allows one to synthesize almost-optimal strategies (we can adapt recent works [23] showing that those strategies can be taken among switching strategies for Min and memoryless strategies for Max).

7 Conclusion

This article allows one to compute (finite) robust values of weighted timed games in classes of games (acyclic and divergent) where the non-robust values are indeed computable.

As future works, we would like to carefully explore the exact complexity of our algorithms. Intuitively, each operator used to describe $\mathcal{F}_p$ can be computed in exponential time with respect to the set of cells and the size of η. By [18], the number of cells exponentially grows at each application of $\mathcal{F}_p$ (so it is doubly exponential for the whole computation) and the constants in affine expressions polynomially grow, in the non-robust setting. We hope that such upperbounds remain in the robust setting. This would imply that, for divergent WTGs, our algorithm requires a triply-exponential time, since the unfolding is exponential in the size of $\mathcal{G}$.

We also suggest to extend the setting to incorporate divergent WTGs that contain location with a value equal to $-\infty$. However, fixing it for all divergent WTGs seems to be difficult since, intuitively, the condition to guarantee $-\infty$ looks like a Büchi condition where Max can avoid the iteration of cycles with his delays. Moreover, we would like to study almost-divergent weighted timed games (studied in [17, 18]), a class of games undecidable, but with approximable value functions. We wonder if the robust values could also be approximated by similar techniques. Another direction of research would be to consider the fragment of one-clock weighted timed games, another class of games where the value function is known to be computable (for a long time in the non-negative case [5], very recently in the general case [24]). The difficulty here would be that encoding the conservative semantics in an exact semantics, even with fixed-perturbation, requires the addition of a clock, thus exiting the decidable fragment. The question thus becomes a possible adaptation of techniques used previously to solve non robust one-clock WTGs to incorporate directly the robustness.

Abstract

We investigate the compression sensitivity [Akagi et al., 2023] of lex-parse [Navarro et al., 2021] for two operations: (1) single character edit and (2) modification of the alphabet ordering, and give tight upper and lower bounds for both operations (i.e., we show $\Theta(\log n)$ bounds for strings of length n). For both lower bounds, we use the family of Fibonacci words. For the bounds on edit operations, our analysis makes heavy use of properties of the Lyndon factorization of Fibonacci words to characterize the structure of lex-parse.

1 Introduction

Dictionary compression is a scheme of lossless data compression that is very effective, especially for highly repetitive text collections. Recently, various studies on dictionary compressors and repetitiveness measures have attracted much attention in the field of stringology (see [25, 26] for a detailed survey).

The *sensitivity* [1] of a string compressor/repetitiveness measure c is defined as the maximum difference in the sizes of c for a text T and for a single-character edited string T', which can represent the robustness of the compressor/measure w.r.t. small changes/errors of the input string. Akagi et al. [1] gave upper and lower bounds on the worst-case multiplicative sensitivity of various compressors and measures including the Lempel–Ziv parse family [29, 30], the run-length encoded Burrows-Wheeler transform (RLBWT) [4], and the smallest string attractors [17].

On the other hand, some structures built on strings, including the output of text compressors, can also depend on the order of the alphabet, meaning that a different alphabet ordering can result in a different structure for the same string. Optimization problems of these kinds of structures have recently been studied, e.g., for the RLBWT [2], the RLBWT based on general orderings [12], or the Lyndon factorization [13]. Due to their hardness, efficient exact algorithms/heuristics for minimization have been considered [5, 7, 8, 22, 23].

This paper is devoted to the analysis of the sensitivity of lex-parse. Lex-parse [27] is a greedy left-to-right partitioning of an input text T into phrases, where each phrase starting at position i is $T[i..i + \max\{1, \ell\})$ and ℓ is the longest common prefix between $T[i..n]$ and its lexicographic predecessor $T[i'..n]$ in the set of suffixes of T. Each phrase can be encoded by a pair $(0, T[i])$ if $\ell = 0$, or (ℓ, i') otherwise. By using the lex-parse of size v of a string, we can represent the string with v derivation rules.[1] Lex-parse was proposed as a new variant in a family of ordered parsings that is considered as a generalization of the Lempel–Ziv parsing and a subset of bidirectional macro schemes [28]. We stress that lex-parse can have much fewer factors than the Lempel–Ziv parsing; for instance the number of Lempel–Ziv factors of the k-th Fibonacci word is k while we have only four factors for lex-parse regardless of k (assuming that k is large enough) [27]. Besides having potential for lossless data compression, it helped to gain new insights into string repetitiveness: For instance, a direct relation $v \in O(r)$ between v and the size r of the RLBWT, one of the most important dictionary compressors, holds [27]. Hence, combinatorial studies on lex-parse can lead us to further understanding in string repetitiveness measures and compressors.

The contribution of this paper is twofold. We first consider the sensitivity of lex-parse w.r.t. edit operations, and give tight upper and lower bounds which are logarithmic in the length of the input text. Interestingly, lex-parse is the third measure with super-constant bounds out of (about) 20 measures [1]. Second, we consider a new variant of sensitivity, the alphabet ordering sensitivity (AO-sensitivity) of lex-parse, defined as the maximum difference in the number of phrases of lex-parse between any two alphabet orderings, and give tight upper and lower bounds. For both lower bounds, we use the Fibonacci word. Moreover, we also use properties of the Lyndon factorization [6] for the edit sensitivity to characterize the structure of lex-parse. These insights may be of independent interest. Properties of the Fibonacci word can contribute to the analysis of algorithm complexity. In fact, there are several results regarding lower bounds based on the Fibonacci word (i.e., [9, 14, 16, 27]).

Related work. Inspired by the results of Lagarde and Perifel [19], Akagi et al. [1] pioneered the systematic study of compression sensitivity of various measures w.r.t. edit operations. Giuliani et al. [14] showed an improved lower bound for the additive sensitivity of the run-length BWT. They also use the family of Fibonacci words to obtain their lower bound. Fujimaru et al. [11] presented tight upper and lower bounds for the additive and multiplicative sensitivity of the size of the compact directed acyclic word graph (CDAWG) [3, 10], when edit operations are restricted to the beginning of the text.

2 Preliminaries

Strings

Let Σ be an *alphabet*. An element of Σ^* is called a *string*. The length of a string w is denoted by $|w|$. The empty string ε is the string of length 0. Let Σ^+ be the set of non-empty strings, i.e., $\Sigma^+ = \Sigma^* \setminus \{\varepsilon\}$. For any strings x and y, let $x \cdot y$ (or sometimes xy) denote

[1] We stick to the convention to denote the size of lex-parse by v as done in literature such as [27, 26].

the concatenation of the two strings. For a string $w = xyz$, x, y and z are called a *prefix*, *substring*, and *suffix* of w, respectively. They are called a *proper prefix*, a *proper substring*, and a *proper suffix* of w if $x \neq w$, $y \neq w$, and $z \neq w$, respectively. A proper substring that is both a prefix and a suffix of w is also called a *border* of w. The i-th symbol of a string w is denoted by $w[i]$, where $1 \leq i \leq |w|$. For a string w and two integers $1 \leq i \leq j \leq |w|$, let $w[i..j]$ denote the substring of w that begins at position i and ends at position j. For convenience, let $w[i..j] = \varepsilon$ when $i > j$. Also, let $w[..i] = w[1..i]$ and $w[i..] = w[i..|w|]$. For a string w, let $w^1 = w$ and let $w^k = ww^{k-1}$ for any integer $k \geq 2$. A string w is said to be *primitive* if w cannot be written as x^k for any $x \in \Sigma^+$ and integer $k \geq 2$. The following property is well known.

▶ **Lemma 1** ([20]). *w is primitive if and only if w occurs exactly twice in w^2.*

For a string w, let $w' = w[1..|w|-1]$, $w'' = w[1..|w|-2]$. A sequence of k strings $w_1, \ldots, w_k$ is called a *parsing* or a *factorization* of a string w if $w = w_1 \cdots w_k$. For a binary string w, $\overline{w}$ denotes the bitwise reversed string of w (e.g., $\overline{aab} = baa$ over $\{a, b\}$). Let $\prec$ denote a (strict) total order on an alphabet Σ. A total order $\prec$ on the alphabet induces a total order on the set of strings called the *lexicographic order* w.r.t. $\prec$, also denoted as $\prec$, i.e., for any two strings $x, y \in \Sigma^*$, $x \prec y$ if and only if x is a proper prefix of y, or, there exists $1 \leq i \leq \min\{|x|, |y|\}$ s.t. $x[1..i-1] = y[1..i-1]$ and $x[i] \prec y[i]$. For a string w, let SA_w denote the *suffix array* of w, where the i-th entry $SA_w[i]$ stores the index j of the lexicographically i-th suffix $w[j..]$ of w.

Lex-parse

The lex-parse of a string w is a parsing $w = w_1, \ldots, w_v$, such that each phrase w_j starting at position $i = 1 + \sum_{k<j} |w_k|$ is $w[i..i + \max\{1, \ell\})$, where ℓ is the length of the longest common prefix between $w[i..]$ and its lexicographic predecessor $w[i'..]$ in the set of suffixes of w. Each phrase can be encoded by a pair $(0, w[i])$ if $\ell = 0$ (called an *explicit phrase*), or (ℓ, i') otherwise. We will call $w[i'..]$ the *previous suffix* of $w[i..]$. The size (the number of phrases) of the lex-parse of a string w will be denoted by $v(w)$. Note that a phrase starting at position i is explicit if and only if $w[i..]$ is the lexicographically smallest suffix starting with $w[i]$ and thus there are $|\Sigma|$ of them. Let $w = ababbaaba$. The lex-parse of w is aba, b, ba, a, b, a. Since the previous suffix of $w[1..]$ is $w[7..]$ and the longest common prefix between them is aba, the first phrase is aba. In this example, the last two phrases are explicit phrases.

Lyndon factorizations

A string w is a *Lyndon word* [21] w.r.t. a lexicographic order $\prec$, if and only if $w \prec w[i..]$ for all $1 < i \leq |w|$, i.e., w is lexicographically smaller than all its proper suffixes with respect to $\prec$. The *Lyndon factorization* [6] of a string w, denoted $LF(w)$, is a unique factorization $\lambda_1^{p_1}, \ldots, \lambda_m^{p_m}$ of w, such that each $\lambda_i \in \Sigma^+$ is a Lyndon word, $p_i \geq 1$, and $\lambda_i \succ \lambda_{i+1}$ for all $1 \leq i < m$. A suffix x of w is said to be *significant* if there exists an integer i such that $x = \lambda_i^{p_i} \cdots \lambda_m^{p_m}$ and, for every j satisfying $i \leq j < m$, $\lambda_{j+1}^{p_{j+1}} \cdots \lambda_m^{p_m}$ is a prefix of $\lambda_j^{p_j}$ (cf. [15]). Let $w = bbabbaabaabbaabaabbaabaa$. The Lyndon factorization of w is b^2, abb, $(aabaabb)^2$, aab, a^2. The suffix a^2 that is the last Lyndon factor is always significant. Since a^2 is a prefix of $(aab)a^2$, $(aab)a^2$ is also significant. Since a^2 and $(aab)a^2$ is a prefix of $(aabaabb)^2(aab)a^2$, $(aabaabb)^2(aab)a^2$ is also significant.

Table 1 Fibonacci words F_k up to $k = 8$.

k	F_k	k	F_k
1	b	2	a
3	ab	4	aba
5	$abaab$	6	$abaababa$
7	$abaababaabaab$	8	$abaababaabaababaababa$

Fibonacci words

The k-th (finite) Fibonacci word F_k over a binary alphabet $\{a, b\}$ is defined as follows: $F_1 = b$, $F_2 = a$, $F_k = F_{k-1} \cdot F_{k-2}$ for any $k \geq 3$ (see also an example in Table 1). Let f_k be the length of the k-th Fibonacci word (i.e., $f_k = |F_k|$).

We also use the infinite Fibonacci word $\mathcal{F} = \lim_{k\to\infty} F_k$ over an alphabet $\{a, b\}$. We also use $G_k = F_{k-2}F_{k-1}$ which will be useful for representing relations between even and odd Fibonacci words.

▶ **Lemma 2** (Useful properties of Fibonacci words (cf. [27])). *The following properties hold for every Fibonacci word F_k.*

1. *The length of the longest border of F_k is f_{k-2}.*
2. *F_k has exactly three occurrences of F_{k-2} at position 1, $f_{k-2} + 1$, and $f_{k-1} + 1$ (suffix) for every $k \geq 6$.*
3. $F_k = G_k[1..f_k - 2] \cdot \overline{G_k[f_k - 1..f_k]}$.
4. $G_k = F_k[1..f_k - 2] \cdot \overline{F_k[f_k - 1..f_k]}$.
5. *For every k, aaa and bb do not occur as substrings in F_k [27, Lemma 36].*
6. *F_k is primitive for every k (we can easily obtain the fact from Property 1).*

The next lemma is also useful for our proof which can be obtained from the above properties.

▶ **Lemma 3.** *For any $k \geq 8$, F_{k-4} occurs exactly eight times in F_k.*

Proof. From property 2 of Lemma 2, F_k has at least eight occurrences of F_{k-4} (since the suffix occurrence of F_{k-4} in the second F_{k-2} and the prefix occurrence of F_{k-4} in the third F_{k-2} are the same position). Suppose to the contrary that there exists an occurrence of F_{k-4} in F_k that is different from the eight occurrences. From property 2 of Lemma 2, the occurrence crosses the boundary of the first and the second F_{k-2}. Since F_{k-4} is both a prefix and a suffix of F_{k-2}, the occurrence implies that F^2_{k-4} has F_{k-4} as a substring that is neither a prefix nor a suffix. This contradicts Lemma 1. ◀

Sensitivity of lex-parse

In this paper, we consider two compression sensitivity variants of lex-parse. The first variant is the sensitivity by (single character) edit operations (cf. [1]). For any two strings w_1 and w_2, let $\mathsf{ed}(w_1, w_2)$ denote the edit distance between w_1 and w_2. The worst-case multiplicative sensitivity of lex-parse w.r.t. a substitution is defined as follows:

$$\mathsf{MS}_{\mathtt{sub}}(v, n) = \max_{w_1 \in \Sigma^n} MS_{\mathtt{sub}}(v, w_1),$$

where $MS_{\mathtt{sub}}(v, w_1) = \max\{v(w_2)/v(w_1) \mid w_2 \in \Sigma^n, \mathsf{ed}(w_1, w_2) = 1\}$. $\mathsf{MS}_{\mathtt{ins}}(v, n)$ (resp. $\mathsf{MS}_{\mathtt{del}}(v, n)$) is defined by replacing the condition $w_2 \in \Sigma^n$ with $w_2 \in \Sigma^{n+1}$ (resp. $w_2 \in \Sigma^{n-1}$). The second variant is the sensitivity by alphabet orderings. For any string w and a lexicographic order $\prec$, let $v(w, \prec)$ be the size of the lex-parse of w under $\prec$. We define the alphabet-ordering sensitivity of lex-parse as follows:

$$\mathsf{AOS}(v, n) = \max_{w \in \Sigma^n} AOS(v, w),$$

where $AOS(v, w) = \max_{\prec_1, \prec_2 \in A}\{v(w, \prec_2)/v(w, \prec_1)\}$ and A is the set of orderings over Σ.

3 Upper bounds

We first give upper bounds for both operations. We can obtain the following result by using known connections regarding the bidirectional macro scheme and lex-parse.

▶ **Theorem 4.** $\mathsf{MS}_{\mathtt{sub}}(v, n), \mathsf{MS}_{\mathtt{ins}}(v, n), \mathsf{MS}_{\mathtt{del}}(v, n), \mathsf{AOS}(v, n) \in O(\log n)$.

Proof. For any string w, let $b(w)$ be the size of the smallest bidirectional macro scheme [28]. Then, $v(w) \geq b(w)$ holds [27, Lemma 25]. For any two strings w_1 and w_2 with $\mathsf{ed}(w_1, w_2) = 1$, $v(w_2) \in O(b(w_2) \log(n/b(w_2)))$ [27, Theorem 26] and $b(w_2) \leq 2b(w_1)$ [1, Theorem 11] hold. Hence, for $|w_2| \in \Theta(n)$,

$$\frac{v(w_2)}{v(w_1)} \leq \frac{v(w_2)}{b(w_1)} \in O\left(\frac{b(w_2)\log(n/b(w_2))}{b(w_1)}\right) \subseteq O\left(\frac{b(w_1)\log(n/b(w_1))}{b(w_1)}\right) = O(\log(n/b(w_1))).$$

For any alphabet order $\prec$ on Σ, $v(w, \prec) \in O(b(w) \log(n/b(w)))$ and $v(w, \prec) \geq b(w)$ holds. Hence, for any two alphabet orders $\prec_1$ and $\prec_2$,

$$\frac{v(w, \prec_2)}{v(w, \prec_1)} \leq \frac{v(w, \prec_2)}{b(w)} \in O\left(\frac{b(w)\log(n/b(w))}{b(w)}\right) = O(\log(n/b(w))).$$

These facts imply this theorem. ◀

4 Lower bounds for edit operations

In this section, we give tight lower bounds for edit operations with the family of Fibonacci words.

▶ **Theorem 5.** $\mathsf{MS}_{\mathtt{sub}}(v, n), \mathsf{MS}_{\mathtt{ins}}(v, n), \mathsf{MS}_{\mathtt{del}}(v, n) \in \Omega(\log n)$.

We devote this section to show $\mathsf{MS}_{\mathtt{sub}}(v, n) \in \Omega(\log n)$ since a similar argument can obtain the others. We obtain the claimed lower bound by combining the result of [27] (also in Lemma 20 in Section 5) stating that $v(F_{2k}) = 4$, and the following Theorem 6.

▶ **Theorem 6.** *For every integer $k \geq 6$, there exists a string w of length f_{2k} such that* $\mathsf{ed}(F_{2k}, w) = 1$ *and $v(w) = 2k - 2$.*

Let T_{2k} denote the string obtained from F_{2k} by substituting the rightmost b of F_{2k} with a, i.e., $T_{2k} = F''_{2k} \cdot aa$. We show that the lex-parse of T_{2k} has $2k - 2$ phrases. More specifically, we show that the lengths of the phrases are

$$f_{2k-1} - 1, f_{2k-4} - 1, f_{2k-5} + 1, ..., f_4 - 1, f_3 + 1, 1, 2, 1.$$

There are three types of phrases as follows: (1) first phrase, (2) inductive phrases, (3) last three short phrases. Phrases of Type (1) or Type (3) can be obtained by simple properties of Fibonacci words. However, phrases of Type (2) need a more complicated discussion. We use the Lyndon factorizations of the strings to characterize the inductive phrases. Intuitively, we show that every suffix of T_{2k} that has an odd inductive phrase as a prefix can be written as the concatenation of the odd inductive phrase and a significant suffix.

(1) First phrase and (3) Short phrases

We start from Type (1). From the third property of Lemma 2 and the edit operation, $T_{2k}[1..]$ and $T_{2k}[f_{2k-2}+1..]$ have a (longest) common prefix $x = F'_{2k-1}$ of length $f_{2k-1}-1$ and $T_{2k}[1..] \succ T_{2k}[f_{2k-2}+1..]$ holds. $T_{2k}[f_{2k-2}+1..]$ can be written as $T_{2k}[f_{2k-2}+1..] = x \cdot a$. We show that the previous suffix of $T_{2k}[1..]$ is $T_{2k}[f_{2k-2}+1..]$. Suppose to the contrary that there exists a suffix y of F_{2k} that satisfies $T_{2k}[1..] \succ y \succ T_{2k}[f_{2k-2}+1..]$. Since both $T_{2k}[f_{2k-2}+1..]$ and $T_{2k}[1..]$ have x as a prefix, y can be written as $y = x \cdot a \cdot z_1$ or $y = x \cdot b \cdot z_2$ for some strings z_1, z_2. Since F_{2k-1} ends with aab and thus aa is a suffix of x, the existence of $y = x \cdot a \cdot z_1$ contradicts the fact that a^3 only occurs at the edit position. On the other hand, the existence of $y = x \cdot b \cdot z_2$ contradicts the fact that $x \cdot b = F_{2k-1}$ only occurs as a prefix of T_{2k}, since otherwise it would violate the second property of Lemma 2. Thus $T_{2k}[f_{2k-2}+1..]$ is the previous suffix of $T_{2k}[1..]$, and the length of the first phrase is $|x| = f_{2k-1}-1$.

Next, we consider Type (3) phrases. Since T_{2k} ends with $baaa$ and no Fibonacci word has aaa as a substring, we conclude that $SA_{T_{2k}}[1] = f_{2k}$, $SA_{T_{2k}}[2] = f_{2k}-1$, and $SA_{T_{2k}}[3] = f_{2k}-2$. In particular, ba^3 is the smallest suffix of T_{2k} that begins with b. These facts imply that $T_{2k}[f_{2k}] = a$ and $T_{2k}[f_{2k}-3] = b$ are the explicit phrases, and $T_{2k}[f_{2k}-2..f_{2k}-1] = a^2$ between the explicit phrases is a phrase. Thus the last three phrases are b, a^2, a.

(2) Inductive phrases

In the rest of this section, we explain Type (2) phrases. Firstly, we study the Lyndon factorization $LF(\mathcal{F}) = \ell_1, \ell_2, \dots$ of the (infinite) Fibonacci word. To characterize these Lyndon factors ℓ_i, we use the string morphism ϕ with $\phi(a) = aab, \phi(b) = ab$ as defined in [24, Proposition 3.2].

▶ **Lemma 7** ([24]). *$\ell_1 = ab, \ell_{k+1} = \phi(\ell_k)$, and $|\ell_k| = f_{2k+1}$ holds.*

In order to show our result, we consider the Lyndon factorization of $F''_{2k} (= T''_{2k})$ (Lemma 10). Lemmas 8 and 9 explain the Lyndon factorization of a finite prefix of the (infinite) Fibonacci word by using properties of the morphism ϕ.

▶ **Lemma 8.** *Given a string $w \in \{a,b\}^+$, let $LF(w) = \lambda_1^{p_1}, \dots, \lambda_m^{p_m}$. Then $LF(\phi(w)) = \phi(\lambda_1^{p_1}), \dots, \phi(\lambda_m^{p_m})$.*

Proof. For any two binary strings x and y, it is clear that $\phi(x) \succ \phi(y)$ if $x \succ y$. In the rest of this proof, we show that $\phi(x)$ is a Lyndon word for a Lyndon word x over $\{a,b\}$. If $|x| = 1$, then the statement clearly holds. Suppose that $|x| \geq 2$. Let $\tilde{x}$ be a non-empty proper suffix of $\phi(x)$. Then $\tilde{x}$ can be represented as $\tilde{x} = \phi(y)$ for some suffix y of x, or $\tilde{x} = \alpha \cdot \phi(y)$ for some suffix y of x and $\alpha \in \{ab, b\}$. Since $x \prec y$, $\phi(x) \prec \tilde{x}$ if $\tilde{x} = \phi(y)$ for some suffix y of x. Also in the case of $\tilde{x} = \alpha \cdot \phi(y)$, $\phi(x) \prec \tilde{x}$ holds since $x[1] = a$ (from x is a Lyndon word) and $\phi(x)[1..3] = aab$. Thus, $\phi(x) \prec \tilde{x}$ holds for all non-empty proper suffixes $\tilde{x}$ of x. This implies that $\phi(x)$ is a Lyndon word. Therefore, the statement holds. ◀

▶ **Lemma 9.** *For every integer $i \geq 1$, $LF(\ell'_i) = \phi^{i-1}(a), \ldots, \phi^0(a)$, where $\ell'_i = \ell_i[..|\ell_i| - 1]$.*

Proof. We prove the statement by induction on i. For the base case $i = 1$, $LF(\ell'_1) = a = \phi^0(a)$. Assume that the lemma holds for all $i \leq j$ for some $j \geq 1$. By the definition of the morphism ϕ, $\ell'_{j+1} = \phi(\ell_j)' = \phi(\ell'_j) \cdot a$ holds because ℓ_j ends with b. Also, by using Lemma 8 and the induction hypothesis,

$$LF(\ell'_{j+1}) = LF(\phi(\ell'_j) \cdot a) = LF(\phi(\ell'_j)), a = \phi(LF(\ell'_j)), a = \phi^j(a), \ldots, \phi^1(a), \phi^0(a).$$

Therefore, the lemma holds. ◀

▶ **Lemma 10.** *Let L_i be the i-th Lyndon factor of F''_{2k}. For every $k \geq 2$,*

$$L_i = \begin{cases} \phi^{i-1}(ab) & \text{if } 1 \leq i < k-1, \\ \phi^{2k-i-3}(a) & \text{if } k-1 \leq i \leq 2k-3. \end{cases}$$

Proof. From Lemma 7,

$$\sum_{i=1}^{k-1} |\ell_i| = \sum_{i=1}^{k-1} f_{2i+1} = f_3 + f_5 + \cdots + f_{2k-1} = f_2 + (f_3 + f_5 + \cdots + f_{2k-1}) - 1 = f_{2k} - 1.$$

Thus $LF(F_{2k}) = \ell_1, \ldots, \ell_{k-1}, a$ holds. Also, $L_i = \ell_i$ holds for all $i < k-1$ since ℓ_i is not a prefix of ℓ_{i-1}. In other words, $LF(F''_{2k}) = \ell_1, \ldots, \ell_{k-2}, LF(\ell'_{k-1})$. From Lemma 9,

$$LF(F''_{2k}) = \ell_1, \ldots, \ell_{k-2}, \phi^{k-2}(a), \ldots, \phi^0(a).$$

Then the statement also holds. ◀

Moreover, we can find the specific form of suffixes characterized by the Lyndon factorization of F''_{2k} as described in the next lemma.

▶ **Lemma 11.** *For every integer $i \geq 1$, $\phi^{i-1}(a) \cdots \phi^0(a)$ is a prefix of $\phi^i(a)$.*

Proof. We prove the lemma by induction on i. For the base case $i = 1$, $\phi^0(a) = a$ is a prefix of $\phi^1(a) = aab$. Assume that the statement holds for all $i \leq j$ for some $j \geq 1$. For $i = j+1$,

$$\phi^{j+1}(a) = \phi^j(\phi(a)) = \phi^j(aab) = \phi^j(a)\phi^j(a)\phi^j(b).$$

By induction hypothesis, $\phi^j(a) = \phi^{j-1}(a) \cdots \phi^0(a) \cdot x$ for some string x. Then $\phi^{j+1}(a) = \phi^j(a) \cdot \phi^{j-1}(a) \cdots \phi^0(a) \cdot x \cdot \phi^j(b)$. This implies that the statement also holds for $i = j+1$. Therefore, the lemma holds. ◀

With the Lemmas 10 and 11, we obtain the following lemma, which characterizes the first $k+1$ entries of the suffix array $SA_{T_{2k}}$ of T_{2k}.

Firstly, we consider the order of the significant suffixes of F''_{2k}.

▶ **Lemma 12.** *$SA_{F''_{2k}}[i] = f_{2k} - 1 - \sum_{j=0}^{i-1} |\phi^j(a)|$ for every $i \in [1..k-1]$.*

Proof. We can see that $\phi^{k-2}(a) \cdots \phi^0(a)$ is a suffix of F''_{2k} by Lemma 10. Our claim is that $\phi^{i-1}(a) \cdots \phi^0(a)$ is the i-th lexicographically smallest suffix of F''_{2k} for every $0 \leq i \leq k-1$. We prove the statement by induction on i. For the base case $i = 1$, $\phi^0(a) = a$ is the lexicographically smallest suffix of F''_{2k}. Assume that the statement holds for all $i \leq i'$ for some $i' \geq 1$. Let α be a suffix of $\phi^{i'+1}(a) \cdots \phi^0(a)$ such that there is no d with $\alpha = \phi^d(a) \cdots \phi^0(a)$. (Otherwise we already know that α is a prefix of $\phi^{i'+1}(a)$, which we already processed for a

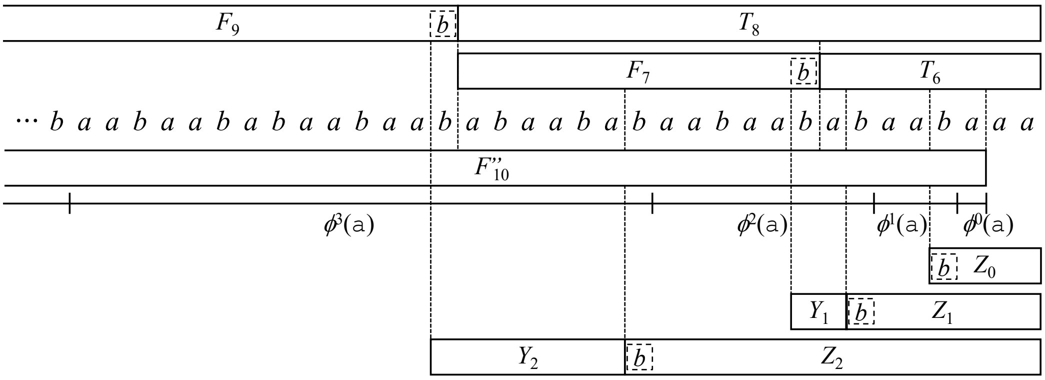

Figure 1 Illustration of the edited string T_{2k} and the Lyndon factorization of F''_{2k} (when $k = 5$).

former suffix array entry.) Then α can be written as $\alpha = \beta \cdot \phi^d(a) \cdots \phi^0(a)$ for some proper suffix β of $\phi^{d+1}(a)$ and $d \in [0..i']$. Since $\phi^{i'+1}(a)$ has $\phi^{d+1}(a)$ as a prefix and there is a mismatching character between $\phi^{d+1}(a)$ and β (from β is a suffix of Lyndon word $\phi^{d+1}(a)$), then $\phi^{i'+1}(a) \prec \beta$ holds. Therefore, the lemma holds. ◀

Because appending a's to the end does not affect suffix orders, we can easily obtain the following lemma from Lemma 12.

▶ **Lemma 13.** *For every $k \geq 2$, $SA_{T_{2k}}[1] = f_{2k}$, $SA_{T_{2k}}[2] = f_{2k} - 1$, and $SA_{T_{2k}}[i] = f_{2k} - 1 - \sum_{j=0}^{i-3} |\phi^j(a)|$ for any i that satisfying $3 \leq i \leq k + 1$.*

Proof. T_{2k} ends with the suffix aa such that $T[f_{2k}..] = a$ is the smallest, and $T[f_{2k} - 1..]$ is the second smallest suffix of T_{2k}. All other suffixes inherit their order from F''_{2k}, and thus $SA_{T_{2k}}[i] = SA_{F''_{2k}}[i - 2]$ for $i \geq 3$. ◀

We define a substring Y_i and suffixes X_i and Z_i of T_{2k} as follows:

$$X_i = T_{2k}[f_{2k} - f_{2i+4}..] \ (1 \leq i \leq k - 3),$$
$$Y_i = T_{2k}[f_{2k} - f_{2i+4}..f_{2k} - f_{2i+3} - 2] \ (1 \leq i \leq k - 3),$$
$$Z_i = T_{2k}[f_{2k} - f_{2i+3} - 1..] \ (0 \leq i \leq k - 3).$$

▶ **Observation 14.** *The following properties hold:*

$$X_i = Y_i \cdot Z_i = b \cdot T_{2i+4},$$
$$Y_i = b \cdot T''_{2i+2},$$
$$Z_i = b \cdot \phi^i(a) \cdots \phi^0(a) \cdot aa.$$

Notice that $|\phi^i(a) \cdots \phi^0(a)| = |\ell'_{i+1}| = f_{2i+3} - 1$ holds. See also Fig. 1 for an illustration of the specific substrings. Then Lemma 13 implies the following corollary.

▶ **Corollary 15.** *For every integer $k \geq 2$ and i satisfying $1 \leq i \leq k - 2$, the previous suffix of Z_i w.r.t. T_{2k} is Z_{i-1}.*

The largest suffix of T_{2k}, denoted by maxsuf, is characterized in the following lemma. We also use this suffix in the main lemma. Intuitively, we show that every suffix of T_{2k} that has an even inductive phrase as a prefix references a suffix that is the concatenation of a string and the maximum suffix (Lemma 18).

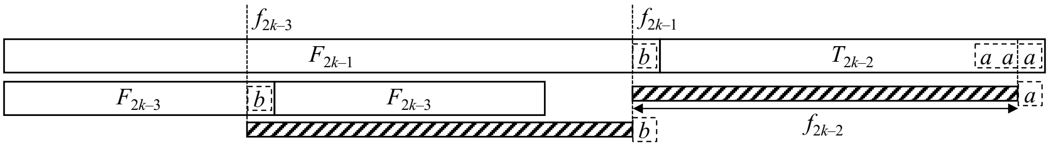

Figure 2 Illustration of T_{2k} for proof of Lemma 16.

▶ **Lemma 16.** *The lexicographically largest suffix* maxsuf *of* T_{2k} *is* $T_{2k}[f_{2k-3}..]$.

Proof. It is known that the lexicographically largest suffix of F_{2k} is $F_{2k}[f_{2k-1}..]$ and the lexicographically second largest suffix of F_{2k} is $F_{2k}[f_{2k-3}..]$ (shown in [18]). Namely, $SA_{F_{2k}}[f_{2k}] = f_{2k-1}, SA_{F_{2k}}[f_{2k} - 1] = f_{2k-3}$. Due to the edit operation, $T_{2k}[f_{2k-3}..] \succ T_{2k}[f_{2k-1}..]$ and the length of the longest prefix of these suffixes is f_{2k-2} (see Fig. 2). Assume on the contrary that there is a suffix $T_{2k}[i..]$ that is lexicographically larger than $T_{2k}[f_{2k-3}..]$. With Property 5 of Lemma 2, the suffix aaa of T_{2k} acts as a unique delimiter such that the suffix $T_{2k}[f_{2k-3}..]$ cannot be a prefix of any other suffixes of T_{2k}. Let j be the smallest positive integer such that $T_{2k}[f_{2k-3}..f_{2k-3} + j] = a$ and $T_{2k}[i..i + j] = b$. If $\max(i + j, f_{2k-3} + j) < f_{2k} - 1$, then $F_{2k}[f_{2k-3}..] \prec F_{2k}[i..]$ holds. This contradicts the fact that the lexicographically second largest suffix of F_{2k} is $F_{2k}[f_{2k-3}..]$. We can observe that there is no j with $\max(i + j, f_{2k-3} + j) \geq f_{2k} - 1$ and $i > f_{2k-3}$ since $T_{2k}[f_{2k} - 1..] = aa$ does not contain b. If $\max(i + j, f_{2k-3} + j) \geq f_{2k} - 1$ and $i < f_{2k-3}$, F_{2k-3} has a beginning position d of an occurrence satisfying $2 \leq d \leq f_{2k-3}$. This contradicts Lemma 2. Therefore, the lemma holds. ◀

To prove Lemma 18, we also introduce the following corollary.

▶ **Corollary 17** (of Lemma 2)**.** *For every i satisfying $i \geq 6$, T_i has exactly two occurrences of F_{i-2}. Moreover, T_i can be written as $T_i = F_{i-2} \cdot F_{i-2} \cdot w$ for some string w.*

▶ **Lemma 18.** *For every $k \geq 2$ and i satisfying $1 \leq i \leq k - 3$, the previous suffix of X_i w.r.t. T_{2k} is $Y_i \cdot a \cdot$* maxsuf*.*

Proof. Firstly, we show that $Y_i \cdot a \cdot \mathsf{maxsuf}$ is a suffix of T_{2k}. It is clear from definitions and properties of Lemma 2 that T_{2k} can be written as $T_{2k} = F'_{2k-3} \cdot \mathsf{maxsuf} = F''_{2k-3} \cdot a \cdot \mathsf{maxsuf} = F_{2k-4} \cdot F''_{2k-5} \cdot a \cdot \mathsf{maxsuf} = F_{2k-5} \cdot F''_{2k-4} \cdot a \cdot \mathsf{maxsuf}$. Since $Y_{k-3} = b \cdot T''_{2k-4} = b \cdot F''_{2k-4}$ and the last character of F_{2k-5} is b (from $2k - 5$ is odd), $Y_{k-3} \cdot a \cdot \mathsf{maxsuf}$ is a suffix of T_{2k}. Moreover, F_{2i+2} is a suffix of F_{2k-4} for every i that satisfying $1 \leq i \leq k - 3$. This implies that $Y_i \cdot a \cdot \mathsf{maxsuf}$ is a suffix of T_{2k} for every i that satisfying $1 \leq i \leq k - 3$.

Now we go back to our main proof of the lemma. Since $X_i = Y_i \cdot b \cdot \phi^i(a) \cdots \phi^0(a) \cdot aa$, $Y_i \cdot a \cdot \mathsf{maxsuf} \prec X_i$ holds. Moreover, $Y_i \cdot a \cdot \mathsf{maxsuf}$ is the lexicographically largest suffix of T_{2k} that has $Y_i \cdot a$ as a prefix. Hence, it is sufficient to prove that X_i is the lexicographically smallest suffix of T_{2k} that has $Y_i \cdot b$ as a prefix. From Property 5 of Lemma 2, no bb occurs in T_{2k}, so every occurrence of $Y_i \cdot b$ is also an occurrence of $Y_i \cdot ba$. We consider occurrences of $Y_i \cdot ba$ in a suffix X_i. From Observation 14 and Corollary 17, $(Y_i \cdot ba)[2..](= F_{2i+2})$ has exactly two occurrences in $X_i(= b \cdot T_{2i+4})$. At the first occurrence, $(Y_i \cdot ba)[2..]$ is preceded by b. At the second occurrence, $(Y_i \cdot ba)[2..]$ is preceded by a. Hence, the rightmost occurrence of $Y_i \cdot ba$ in T_{2k} is at the prefix of X_i. By combining with Lemma 13, we can see that there is no suffix w such that $Y_i \cdot ba \cdot w \prec X_i$ holds. Thus, X_i is the lexicographically smallest suffix of T_{2k} that has $Y_i \cdot b$ as a prefix. Therefore, the lemma holds. ◀

Lex-parse of T_{2k}

Now we can explain the lex-parse of T_{2k}. Recall that the length of the first phrase is $f_{2k-1}-1$ and the last three phrases are b, a^2, a. Hence, from Lemma 18, the second phrase is a prefix Y_{k-3} of $X_{k-3}(= b \cdot T_{2k-2})$. Since the remaining suffix is Z_{k-3}, the next phrase is a prefix $Z_{k-4}[..|Z_{k-4}|-1]$ of Z_{k-3} from Corollary 15. By applying this argument repeatedly, we can finally obtain the lex-parse of size $2k-2$ of T_{2k} as follows:

$$F_{2k}[..f_{2k-1}-1], (Y_{k-3}, Z_{k-4}[..|Z_{k-4}|-1]), \ldots, (Y_1, Z_0[..|Z_0|-1]), b, a^2, a.$$

Furthermore, we can easily obtain $v(F''_{2k} \cdot a) = 2k-2$ for a delete operation. Consider the case for the insertion operation such that \$ (which is the smallest character) is inserted to the preceding position of the last b. We can then show that the lex-parse is of size $2k+1$ by a similar argument as follows:

$$F_{2k}[1..f_{2k-1}-2], (a \cdot Y_{k-3}, Z_{k-4}[..|Z_{k-4}|-2]), \ldots, (a \cdot Y_1, Z_0[..|Z_0|-2]), a, ba, \$, b, a.$$

5 Lower bounds for Alphabet-Ordering

In this section, we give tight lower bound $\mathsf{AOS}(v,n) \in \Omega(\log n)$ with the family of Fibonacci words. Since $b(F_k) \leq 4$ for $k \geq 5$ [27, Lemma 35] also holds, our lower bound is tight for any $n \in \{f_i\}_i$. More precisely, we prove the following theorem that determines the number of lex-parse phrases of the Fibonacci words on any alphabet ordering.

▶ **Theorem 19.** *For any $k \geq 6$,*

$$v(F_k, \prec) = \begin{cases} \lceil \frac{k}{2} \rceil + 1 & \textit{(a) if } k \textit{ is odd and } a \prec b, \quad (\textit{Lemma } 23) \\ 4 & \textit{(b) if } k \textit{ is odd and } b \prec a, \quad (\textit{Lemma } 24) \\ 4 & \textit{(c) if } k \textit{ is even and } a \prec b, \quad (\textit{Lemma } 20) \\ \lceil \frac{k}{2} \rceil + 1 & \textit{(d) if } k \textit{ is even and } b \prec a. \quad (\textit{Lemma } 25) \end{cases}$$

Although the results for a smaller than b have been proven by Navarro et al. [27], we here give alternative proofs for this case that leads us to the proof for the case when b is smaller than a.

5.1 Lex-parse with constant number of phrases

We start with Cases (b) and (c). Since $F_k[f_k-1..f_k] = ba$ for even k and $F_k[f_k-1..f_k] = ab$ for odd k, we already know in the cases (b) and (c) that each of the last two characters forms an explicit phrase. It is left to analyze the non-explicit phrases, where we start with the first phrase. From Property 1 of Lemma 2, F_k has the border F_{k-2} and thus $F_{k-2} = F_k[f_{k-1}..] \prec F_k$ could be used as the reference for the first phrase, given its length is f_{k-2}. To be an eligible reference for lex-parse, we need to check that $F_k[f_{k-1}..]$ is the previous suffix of $F_k[1..]$. However, Property 2 of Lemma 2 states that there is exactly one other occurrence of F_{k-2} in F_k, starting at $f_{k-2}+1$. The proof of the following lemma shows that the suffix starting with that occurrence is lexicographically larger than F_k, and thus indeed the first phrase has length f_{k-2}, and the second phrase starting with that occurrence can make use of F_k as a reference for a phrase that just ends before the two explicit phrases at the end.

▶ **Lemma 20.** *Assume that $k \geq 6$ is even and $a \prec b$ (Case (c) of Thm. 19). Then the lex-parse of F_k is F_{k-2}, $F_k[f_{k-2}+1..f_k-2]$, b, a.*

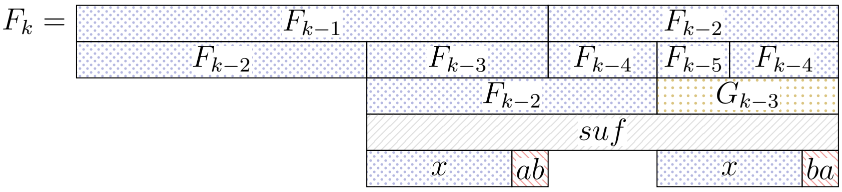

Figure 3 Illustration of the proof of Lemma 20 for k even. If k is odd, the blocks ab and ba are swapped (this gives the setting Lemma 24).

Proof. F_k can be represented as

$$F_k = F_{k-1} \cdot F_{k-2} = F_{k-2} \cdot F_{k-3} \cdot F_{k-4} \cdot F_{k-5} \cdot F_{k-4}.$$

Let $\mathit{suf} = F_{k-2} \cdot G_{k-3}$ (a suffix of F_k) and x be the longest common prefix of F_{k-3} and G_{k-3}. Then $F_k = F_{k-2} \cdot x \cdot ab \cdot F_{k-4} \cdot F_{k-5} \cdot F_{k-4}$ and $\mathit{suf} = F_{k-2} \cdot x \cdot ba$ holds since k is even and $k-3$ is odd. See Fig. 3 for a sketch. This implies that the three suffixes that have F_{k-2} as a prefix satisfy $F_{k-2} \prec F_k \prec \mathit{suf}$. By combining with Property 2 of Lemma 2, the first phrase is F_{k-2} and the second phrase is $F_{k-2} \cdot x$ (which is the longest common prefix of F_k and suf). The third phrase is b which is an explicit phrase of character b since the suffix ba is the lexicographically smallest suffix that has b as a prefix. Finally, the last phrase is an explicit phrase a. ◀

5.2 Lex-parse with logarithmic number of phrases

Next, we discuss the cases that have a logarithmic number of phrases. For any odd $k \geq 7$ and even i satisfying $4 \leq i \leq k-3$, let

$$\mathit{suf}_i = (F_i \cdot F_{i-2} \cdot F_{i-3} \cdots F_4) \cdot ab = F_{i+1},$$
$$\mathit{suf}_i^+ = F_i \cdot \mathit{suf}_i = G_{i+2}.$$

From the definitions, the following properties hold.

▶ **Lemma 21.** *For odd $k \geq 7$, suf_i and suf_i^+ are suffixes of F_k, for every even i with $4 \leq i \leq k-3$. In particular, we have*
(a) *$\mathit{suf}_i = F_{i+1}$ is a prefix of $\mathit{suf}_i^+ = G_{i+2} = F_iF_{i+1}$, and*
(b) *$\mathit{suf}_i^+ = F_iF_{i+1} = F_iF_{i-1}F_{i-2}F_{i-1} = F_{i+1}G_i = \mathit{suf}_i \cdot \mathit{suf}_{i-2}^+$.*

Proof. By definitions, $F_k = F_{k-2}F_{k-3}F_{k-2} = F_{k-2}F_{k-3}\mathit{suf}_{k-3} = F_{k-2}\mathit{suf}_{k-2}^+$. Since suf_{i-2} is a suffix of suf_i, the claim holds for suf_i for every i. Writing $\mathit{suf}_i = F_{i-1} \cdot F_{i-2} \cdot (F_{i-2} \cdot F_{i-3} \cdots F_4) \cdot ab$, we can see that suf_{i-2}^+ is a suffix of suf_i. ◀

We use these suffixes to characterize the lex-parse. The following lemma shows that suf_i is the previous suffix of suf_i^+ w.r.t. F_k for every i, where $f_k - |\mathit{suf}_i^+| + 1$ and $f_k - |\mathit{suf}_i| + 1] - 1$ are the starting positions of suf_i^+ and suf_i in F_k, respectively.

▶ **Lemma 22.** *Assume that $k \geq 7$ is odd and $a \prec b$. The previous suffix of suf_i^+ w.r.t. F_k is suf_i for every even i satisfying $4 \leq i \leq k-3$.*

Proof. Since $\mathit{suf}_i^+ = F_i \cdot F_{i-2} \cdots F_4 \cdot ab \cdot \alpha$ for some string α, suf_i is a prefix of suf_i^+. Thus, $\mathit{suf}_i \prec \mathit{suf}_i^+$. We prove that there is no suffix x of F_k with $\mathit{suf}_i \prec x \prec \mathit{suf}_i^+$ by induction on i.

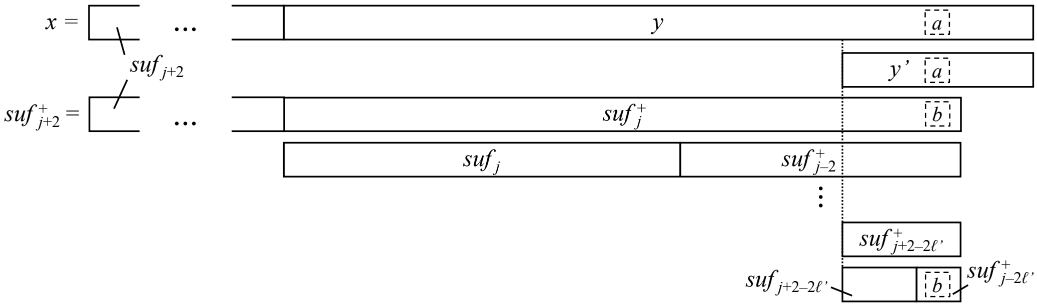

Figure 4 Illustration of the proof of Lemma 22.

Let $i = 4$ for the base case. Assume on the contrary that there exists a suffix x of F_k such that $suf_4 \prec x \prec suf_4^+$. Since $suf_4 = F_5 = F_4 \cdot ab = aba \cdot ab$ and $suf_4^+ = F_4 \cdot F_5 = F_4 \cdot abaab$, x can be written as $x = F_4 \cdot abaaa \cdot y$ for some string y. However, aaa is not a substring of F_k according to Property 5 of Lemma 2, so x cannot exist. Thus, the statement holds for the base case.

Assume that the statement holds for all even $i \leq j$ for some even $j \geq 4$. Suppose on the contrary that there exists a suffix x of F_k such that $suf_{j+2} \prec x \prec suf_{j+2}^+$. Since suf_{j+2} is a prefix of suf_{j+2}^+, we can represent x as $x = suf_{j+2} \cdot y$ for some string y. There are two cases w.r.t. the length of x. (1) Assume that $|suf_{j+2}| < |x| < |suf_{j+2}^+|$. Because of the assumption and the fact that F_{j+2}^2 is a prefix of suf_{j+2}^+ from Lemma 21(a), F_{j+2} occurs as a substring that is neither prefix nor a suffix of F_{j+2}^2. However, F_{j+2}^2 cannot have such occurrence of F_{j+2} since F_{j+2} is primitive (from Property 6 of Lemma 2), a contradiction (from Lemma 1). (2) Assume that $|suf_{j+2}^+| < |x|$. We now use that $suf_i^+ = suf_i \cdot suf_{i-2}^+$ holds from Lemma 21(b). By the assumption, y and suf_j^+ mismatch with a and b, respectively (since x and suf_{j+2}^+ have suf_{j+2} as a prefix). From Lemma 21, suf_{j+2}^+ can be represented as

$$suf_{j+2}^+ = suf_{j+2} \cdot suf_j \cdots suf_{j+2-2\ell} \cdot suf_{j-2\ell}^+ \tag{1}$$

for some integer $\ell \geq 0$. Let ℓ' be the largest integer ℓ such that the mismatch position is in the factor $suf_{i-2\ell}^+$ of the suf_{j+2}^+-factorization in Eq. 1, and y' be the suffix of y that has the factor $suf_{j+2-2\ell'}$ of the factorization in Eq. 1 as a prefix (i.e., $y' = y[|suf_j \cdots suf_{j+2-2(\ell'-1)}| + 1..]$). Since $suf_{j+2-2\ell'}$ is a prefix y', and y' and $suf_{j-2\ell'}^+$ mismatch at the same position, then $suf_{j+2-2\ell'} \prec y' \prec suf_{j+2-2\ell'}^+$ holds. This fact contradicts the induction hypothesis (see also Fig. 4). ◀

Now we can show the following main lemma from the above lemmas.

▶ **Lemma 23.** *Assume that $k \geq 7$ is odd and $a \prec b$. Then the lex-parse of F_k is*

$$F_k[1..f_{k-1} - 2], baF_{k-4}, F_{k-4}, F_{k-6}, \ldots, F_5, a, a, b.$$

Proof. Let x be the longest common prefix of F_{k-3} and G_{k-3}. Due to Property 2 of Lemma 2, there are three suffixes $F_k = F_{k-2} \cdot x \cdot ba \cdot F_{k-4} \cdot F_{k-5} \cdot F_{k-4}$, $suf = F_{k-2} \cdot x \cdot ab$, and F_{k-2} that have F_{k-2} as a prefix. This implies that $F_{k-2} \prec suf \prec F_k$. Thus, the first phrase is $F_{k-2} \cdot x$. Then the remaining suffix is $ba \cdot suf_{k-3} = ba \cdot F_{k-2}$. We show the second phrase is $ba \cdot F_{k-4}$ by proving that the previous suffix of $ba \cdot F_{k-2}$ w.r.t. F_k is $ba \cdot F_{k-4}$. It is clear that $ba \cdot F_{k-4} \prec ba \cdot F_{k-2}$ since $ba \cdot F_{k-4}$ is a prefix of $ba \cdot F_{k-2}$. Suppose on the contrary that there exists a suffix y of F_k that satisfies $ba \cdot F_{k-4} \prec y \prec ba \cdot F_{k-2}$. From the assumption, $ba \cdot F_{k-4}$ is a prefix of y. We can observe that there are three occurrences of $ba \cdot F_{k-4}$ in

F_k from Lemma 3 (i.e., the third, the fourth, and the sixth occurrence of F_{k-4} in F_k). This implies that suffix $ba \cdot F_{k-4} \cdot G_{k-1}$ (regarding the third occurrence of F_{k-4}) of F_k is the only candidate of y. However,

$$y = ba \cdot F_{k-4} \cdot G_{k-1} = ba \cdot F_{k-4} \cdot F_{k-3} \cdot F_{k-2} \succ ba \cdot F_{k-4} \cdot G_{k-3} = ba \cdot F_{k-2}$$

holds. Thus, the previous suffix of $ba \cdot F_{k-2}$ w.r.t. F_k is $ba \cdot F_{k-4}$, and the second phrase is $ba \cdot F_{k-4}$. Then, the remaining suffix is suf^{+}_{k-5}. From Lemma 22, the next phrase is $suf_{k-5} = F_{k-4}$ and the remaining suffix is suf^{+}_{k-7}. This continues until the remaining suffix is aab. It is easy to see that the last three phrases are a, a, b. ◀

We can also prove the following lemmas similarly.

▶ **Lemma 24.** *Assume that $k \geq 7$ is odd and $b \prec a$. Then the lex-parse of F_k is*

$$F_{k-2},\ F_k[f_{k-2}+1..f_k-2],\ a,\ b.$$

▶ **Lemma 25.** *Assume that $k \geq 6$ is even and $b \prec a$. Then the lex-parse of F_k is*

$$F_k[1..f_{k-1}-2], abF_{k-4}, F_{k-4}, F_{k-6}, \ldots, F_6, b, a.$$

Overall, Theorem 19 holds.

6 Conclusion

In this paper, we considered the compression sensitivity of lex-parse for two operations: single character edit and modification of the alphabet ordering, and gave $\Theta(\log n)$ bounds for both operations. A further work in this line of research on the alphabet orderings is the problem of computing optimal alphabet orderings for the lex-parse. The problems for the RLBWT and the Lyndon factorization are known to be NP-hard [2, 13].

Abstract

Hausdorff Φ-dimension is a notion of Hausdorff dimension developed using a restricted class of coverings of a set. We introduce a constructive analogue of Φ-dimension using the notion of constructive Φ-s-supergales. We prove a Point-to-Set Principle for Φ-dimension, through which we get Point-to-Set Principles for Hausdorff dimension, continued-fraction dimension and dimension of Cantor coverings as special cases. We also provide a Kolmogorov complexity characterization of constructive Φ-dimension.

A class of covering sets Φ is said to be "faithful" to Hausdorff dimension if the Φ-dimension and Hausdorff dimension coincide for every set. Similarly, Φ is said to be "faithful" to constructive dimension if the constructive Φ-dimension and constructive dimension coincide for every set. Using the Point-to-Set Principle for Cantor coverings and a new technique for the construction of sequences satisfying a certain Kolmogorov complexity condition, we show that the notions of "faithfulness" of Cantor coverings at the Hausdorff and constructive levels are equivalent.

We adapt the result by Albeverio, Ivanenko, Lebid, and Torbin [1] to derive the necessary and sufficient conditions for the constructive dimension faithfulness of the coverings generated by the Cantor series expansion, based on the terms of the expansion.

1 Introduction

1.1 Faithfulness in dimension

In the study of randomness and information, an important concept is the preservation of randomness across multiple representations of the same object. Martin-Löf randomness, and computable randomness, for example, are preserved among different base-b representations of the same real (see Downey and Hirschfeldt [5], Nies [27], Staiger [31]) and when we convert from the base-b expansion to the continued fraction expansion ([23, 26, 25]).

A quantification of this notion is whether the *rate* of information is preserved across multiple representations. This rate is studied using a constructive analogue of Hausdorff dimension called Constructive dimension [11, 21]. Hitchcock and Mayordomo [8] show that constructive dimension is preserved across base-b representations. However, in a recent work,

49th International Symposium on Mathematical Foundations of Computer Science (MFCS 2024).

Akhil, Nandakumar and Vishnoi [24] show that the rate of information is not preserved across all representations. In particular, they show that constructive dimension is *not* preserved when we convert from base-b representation to continued fraction representation of the same real.

This raises the following question: *Under which settings is the effective rate of information – i.e., constructive dimension – preserved when we change representations of the same real?* Since constructive dimension is a constructive analogue of Hausdorff dimension, this question is a constructive analogue of the concept of "faithfulness" of Hausdorff dimension.

A family of covering sets Φ is "faithful" to Hausdorff dimension if the dimension of every set $\mathcal{F}$ defined using covers constructed using Φ, called the Hausdorff Φ-dimension, coincides with the Hausdorff dimension of $\mathcal{F}$. Faithfulness is well-studied as determining the Hausdorff dimension of a set is often a difficult problem, and faithful coverings help simplify the calculation. This notion is introduced in a work of Besicovitch [3], which shows that the class of dyadic intervals is faithful for Hausdorff dimension. Rogers and Taylor [29] further develop the idea to show that all covering families generated by comparable net measures are faithful for Hausdorff dimension. This implies that the class of covers generated by the base b expansion of reals for any $b \in \mathbb{N} \setminus \{1\}$ is faithful for Hausdorff dimension. However, not all coverings are faithful for Hausdorff dimension. A natural example is the continued fraction representation, which is not faithful for Hausdorff dimension [28]. Faithfulness of Hausdorff dimension has then been studied in various settings [1, 2, 9, 28].

1.2 Constructive Dimension Faithfulness

In this work, we introduce a constructive analogue of Hausdorff Φ-dimension which we call constructive Φ-dimension. A family of covering sets Φ is "faithful" to constructive dimension if the constructive Φ-dimension of every set $\mathcal{F}$ coincides with the constructive dimension of $\mathcal{F}$. Mayordomo and Hitchcock [8] show that all base-b representations of reals, which are faithful for Hausdorff dimension, are also faithful for constructive dimension. On the other hand, Nandakumar, Akhil, and Vishnoi's work shows that the continued fraction expansion, which is not faithful for Hausdorff dimension is also not faithful for constructive dimension [24]. This raises the natural question: *Are faithfulness with respect to Hausdorff dimension and faithfulness with respect to constructive dimension equivalent notions?* A positive answer to this question implies that Hausdorff dimension faithfulness, a geometric notion, can be studied using the tools from information theory. Conversely, the faithfulness results of Hausdorff dimension can help us understand the settings under which constructive dimension is invariant for *every* individual real.

In this work, we show that for the most inclusive generalization of base-b expansions under which faithfulness has been studied classically, namely, for classes of coverings generated by the Cantor series expansions, the notions of Hausdorff faithfulness and constructive faithfulness are indeed equivalent. The Cantor series expansion, introduced by Georg Cantor [4], uses a sequence of natural numbers $Q = \{n_k\}_{k\in\mathbb{N}}$ as the terms of representation. Whereas base-b representation use exponentials with respect to a fixed b, $\{b^n\}_{n\in\mathbb{N}}$, the Cantor series representation $Q = \{n_k\}_{k\in\mathbb{N}}$ uses factorials $\{n_1 \dots n_k\}_{k\in\mathbb{N}}$ as the basis for representation. This class is of additional interest as there are Cantor expansions that are faithful as well as non faithful for Hausdorff dimension, depending on the Cantor series representation $\{n_k\}_{k\in\mathbb{N}}$ in consideration [1]. To establish our result, we use a Φ-dimensional analogue of the Point-to-Set Principle.

1.3 Point-to-Set Principle and Faithfulness

The Point-to-Set principle introduced by J. Lutz and N. Lutz [13] relates the Hausdorff dimension of a set of n-dimensional reals with the constructive dimensions of points in the set, relative to a minimizing oracle. This theorem has been instrumental in answering open questions in classical fractal geometry using the theory of computing (See [14, 20, 19, 18, 13]). Mayordomo, Lutz, and Lutz [15] extend this work to arbitrary separable metric spaces.

In this work, we first prove the Point-to-Set principle for Φ-dimension (Theorem 27) and show that this generalizes the original Point-to-Set principle. We then develop a combinatorial construction of sequences having Kolmogorov complexities that grow at the same rate as a given sequence relative to any given oracle (Theorem 36). This new combinatorial construction may be of independent interest in the study of randomness. Using these new tools, we show that under the setting of covers generated by Cantor series expansions, the notions of constructive faithfulness and Hausdorff dimension faithfulness are equivalent (Theorem 51). We then adapt the result by Albeverio, Ivanenko, Lebid, and Torbin [1] to derive a loglimit condition for the constructive dimension faithfulness of the coverings generated by the Cantor series expansions (Theorem 53).

Our main results include the following.

1. We introduce the notion of constructive Φ-dimension using that subsumes base-b, continued fraction, and Cantor covering dimension. We also give an equivalent Kolmogorov Complexity characterization of constructive Φ-dimension. We prove a Point-to-Set principle for Φ-dimension. This generalizes the original Point-to-Set Principle and yields new Point-to-Set principles for the dimensions of continued fractions and Cantor series representations.
2. Using the point-to-set principle, we characterize constructive faithfulness for Cantor series expansions using a log limit condition of the terms appearing in the series. This generalizes the invariance result of constructive dimension under base b representations to all Cantor series expansions that obey this log limit condition. Moreover, it implies that for any Cantor series expansion that does not obey the log limit condition, there are sequences whose Cantor series dimension is different from its constructive dimension.

The recent works of J. Lutz, N. Lutz, Stull, Mayordomo and others study the "point-to-set principle" of how constructive Hausdorff dimension of points may be used to compute the classical Hausdorff dimension of arbitrary sets. In addition to the generalization of this point-to-set principle to Φ-systems, our final result may be viewed as a new *point-to-set phenomenon* for the notion of "faithfulness": here, equality of the constructive Cantor series dimensions and constructive dimensions of *every point* yield equality for the classical Cantor series and Hausdorff dimensions of *every set*, and conversely.

2 Preliminaries

2.1 Notation

We use Σ to denote the binary alphabet $\{0,1\}$, Σ^* represents the set of finite binary strings, and Σ^∞ represents the set of infinite binary sequences. We use $|x|$ to denote the length of a finite string $x \in \Sigma^*$. For an infinite sequence $X = X_0X_1X_2\ldots$, we use $X \upharpoonright n$ to denote the finite string consisting of the first n symbols of X. When $n \geq m$ we also use the notation $X[m,n]$ to denote the substring $X_mX_{m+1}\ldots X_n$ of $X \in \Sigma^\infty$. We call two sets U and V to be incomparable if $U \not\subseteq V$ and $V \not\subseteq U$. For a set $U \subseteq \mathbb{R}$, we denote $|U|$ to denote the diameter of U, that is $|U| = \sup_{x,y\in U} d(x,y)$, where d is the Euclidean metric.

We use $\emptyset$ to denote the empty set, and we assume $|\emptyset| = 0$. For any finite collection of sets $\{U\}$, we use $\#(U)$ to denote the number of elements in U. Given infinite sequences $X_1, \dots X_n$, we define the *interleaved sequence* $X_1 \oplus X_2 \oplus \dots X_n$ to be the interleaved sequence $X = X_1[0]X_2[0] \dots X_n[0]X_1[1] \dots X_n[1] \dots$. For some fixed $n \in \mathbb{N}$, we use $\mathbb{X} \subseteq \mathbb{R}^n$ to denote the metric space under consideration. We call a set of strings $\mathcal{P} \subset \Sigma^*$ to be prefix free if there are no two strings $\sigma, \tau \in \mathcal{P}$ such that σ is a proper prefix of τ. Given $n \in \mathbb{N}$ we use $[n]$ to denote $\{0, 1, \dots n-1\}$. Kolmogorov Complexity represents the amount of information contained in a finite string. For more details on Kolmogorov Complexity, see [5, 10, 27, 30].

▶ **Definition 1.** *The Kolmogorov complexity of $\sigma \in \Sigma^*$ is defined as $K(\sigma) = \min\limits_{\pi \in \Sigma^*} \{|\pi| \mid U(\pi) = \sigma\}$, where U is a fixed universal prefix free Turing machine.*

2.2 Hausdorff Dimension

The following definitions are originally given by Hausdorff [7]. We take the definitions from Falconer [6].

▶ **Definition 2** (Hausdorff [7])**.** *Given a set $\mathcal{F} \subseteq \mathbb{X}$, a collection of sets $\{U_i\}_{i \in \mathbb{N}}$ where for each $i \in \mathbb{N}$, $U_i \subseteq \mathbb{X}$ is called a δ-*cover of $\mathcal{F}$ *if for all $i \in \mathbb{N}$, $|U_i| \leq \delta$ and $\mathcal{F} \subseteq \bigcup_{i \in \mathbb{N}} U_i$.*

▶ **Definition 3** (Hausdorff [7])**.** *Given an $\mathcal{F} \subseteq \mathbb{X}$, for any $s > 0$, define*

$$\mathcal{H}^s_\delta(\mathcal{F}) = \inf \left\{ \sum_i |U_i|^s : \{U_i\}_{i \in \mathbb{N}} \textit{ is a } \delta\textit{-cover of } \mathcal{F} \right\}.$$

As δ decreases, the set of admissible δ covers decreases. Hence $\mathcal{H}^s_\delta(\mathcal{F})$ increases.

▶ **Definition 4** (Hausdorff [7])**.** *For $s \in (0, \infty)$, the* s-dimensional Hausdorff outer measure *of $\mathcal{F}$ is defined as:*

$$\mathcal{H}^s(\mathcal{F}) = \lim_{\delta \to 0} \mathcal{H}^s_\delta(\mathcal{F}).$$

Observe that for any $t > s$, if $\mathcal{H}^s(\mathcal{F}) < \infty$, then $\mathcal{H}^t(\mathcal{F}) = 0$ (see Section 2.2 in [6]). Finally, we have the following definition of Hausdorff dimension.

▶ **Definition 5** (Hausdorff [7])**.** *For any $\mathcal{F} \subset \mathbb{X}$, the* Hausdorff dimension *of $\mathcal{F}$ is defined as:*

$$\dim(\mathcal{F}) = \inf\{s \geq 0 : \mathcal{H}^s(\mathcal{F}) = 0\}.$$

2.3 Constructive dimension

Lutz [11] defines the notion of effective (equivalently, constructive) dimension of an infinite binary sequence using the notion of lower semicomputable s-gales.

▶ **Definition 6** (Lutz [11])**.** *For $s \in [0, \infty)$, a binary s-gale is a function $d : \Sigma^* \to [0, \infty)$ such that $d(\lambda) < \infty$ and for all $w \in \Sigma^*$, $d(w) = 2^s . \sum_{i \in \{0,1\}} d(wi)$.*

The *success set* of d is $S^\infty(d) = \left\{ X \in \Sigma^\infty \mid \limsup\limits_{n \to \infty} d(X \upharpoonright n) = \infty \right\}$.

For $\mathcal{F} \subseteq [0, 1]$, $\mathcal{G}(\mathcal{F})$ denotes the set of all $s \in [0, \infty)$ such that there exists a lower semicomputable (Definition 24) binary s-gale d with $\mathcal{F} \subseteq S^\infty(d)$.

▶ **Definition 7** (Lutz [11]). *The* constructive dimension *or* effective Hausdorff dimension *of* $\mathcal{F} \subseteq [0,1]$ *is*

$$\operatorname{cdim}(\mathcal{F}) = \inf \mathcal{G}(\mathcal{F}).$$

The constructive dimension of a sequence $X \in \Sigma^\infty$ *is* $\operatorname{cdim}(X) = \operatorname{cdim}(\{X\})$.

Mayordomo [21] extends the result by Lutz [12] to give the following Kolmogorov complexity characterization of constructive dimension of infinite binary sequences.

▶ **Theorem 8** (Lutz [12], Mayordomo [21]). *For any* $X \in \Sigma^\infty$*,*

$$\operatorname{cdim}(X) = \liminf_{n\to\infty} \frac{K(X \upharpoonright n)}{n}.$$

Mayordomo [22] later gave the following Kolmogorov complexity characterization of constructive dimension of points in $\mathbb{R}^n$.

▶ **Definition 9** (Mayordomo [22]). *For any* $x \in \mathbb{R}^n$*,*

$$\operatorname{cdim}(x) = \liminf_{r\to\infty} \frac{K_r(x)}{r}.$$

where $K_r(x) = \min\limits_{q\in\mathbb{Q}^n} \{K(q) : |x-q| < 2^{-r}\}$.

Constructive dimension also works in the Euclidean space. For a real $x = (x_1, ...x_n) \in \mathbb{R}^n$, let binary expansions of the fractional parts of each of the coordinates of x be $S_1 \in \Sigma^\infty, \ldots, S_n \in \Sigma^\infty$ respectively. Then $\operatorname{cdim}(x) = n \cdot \operatorname{cdim}(X)$ where X is the interleaved sequence $X = S_1 \oplus S_2 \cdots \oplus S_n$ [16].

We now state some useful properties of constructive dimension. Lutz [11] shows that the constructive dimension of a set is always greater than or equal to its Hausdorff dimension.

▶ **Lemma 10** (Lutz [11]). *For any* $\mathcal{F} \subseteq \mathbb{X}$, $\dim(\mathcal{F}) \leq \operatorname{cdim}(\mathcal{F})$.

Further, Lutz[11] also shows that the constructive dimension of a set is the supremum of the constructive dimensions of points in the set.

▶ **Lemma 11** (Lutz [11]). *For any* $\mathcal{F} \subseteq \mathbb{X}$, $\operatorname{cdim}(\mathcal{F}) = \sup\limits_{x\in\mathcal{F}} \operatorname{cdim}(x)$.

3 Hausdorff Φ-dimension and Effective Φ-dimension

Hausdorff dimension is defined using the notion of s-dimensional outer measures, where a cover is taken as the of union of a collection of covering sets $\{U_i\}_{i\in\mathbb{N}}$. Here a covering set U_i can be any arbitrary subset of the space (see Section 2.2). We define the general notion of Hausdorff Φ-dimension by restricting the class of admissible covers to Φ-covers, which are the union of sets from a family of covering sets Φ.

3.1 Family of covering sets

In this work, we consider a *family of covering sets* which satisfy the properties given below.

▶ **Definition 12** (Family of covering sets Φ). *We consider the space* $\mathbb{X} \subseteq \mathbb{R}^\eta$ *where* $\eta \in \mathbb{N}$. *A countable family of sets* $\Phi = \bigcup_{n\in\mathbb{Z}} \{U_i^n\}_{i\in\mathbb{N}}$*, where for each* $i \in \mathbb{N}, n \in \mathbb{Z}$, $U_i^n \subseteq \mathbb{X}$*, is called a family of covering sets if it satisfies the following properties:*

- *Increasing Monotonicity: For every $n \in \mathbb{Z}$, $U \in \{U_i^n\}_{i\in\mathbb{N}}$ and $m \leq n$, there is a unique $V \in \{U_i^m\}_{i\in\mathbb{N}}$ such that $U \subseteq V$.*
- *Fineness : Given any $\epsilon > 0$, and $x \in \mathbb{X}$, there exists a $U \in \Phi$ such that $|U| < \epsilon$ and $x \in U$.*

Note that the number of sets $\{U_i^n\}$ in some level $n \in \mathbb{Z}$ can also be finite and bounded by m. The definition still holds because in this case we take $U_j^n = \emptyset$ for $j > m$. Note that from Increasing monotonicity property, it follows that all elements $\{U_i^n\}$ in a particular level $n \in \mathbb{Z}$ are incomparable.

We now define the notion of a Φ-cover of a set.

▶ **Definition 13** (Φ-cover). *Let $\Phi = \bigcup_{n\in\mathbb{Z}}\{U_i^n\}_{i\in\mathbb{N}}$ be a family of covering sets. A Φ - cover of a set $\mathcal{F} \subseteq \mathbb{X}$ is collection of sets $\{V_j\}_{j\in\mathbb{N}} \subseteq \Phi$ such that $\{V_j\}_{j\in\mathbb{N}}$ covers $\mathcal{F}$, that is $\mathcal{F} \subseteq \bigcup\limits_{j\in\mathbb{N}} V_j$*

Note: Mayordomo [22] gives a definition of *Nice covers* of a metric space. They then give the definition of constructive dimension on a metric space with a nice cover. We note here that the notion of Family of covering sets is incomparable with the notion of Nice covers. Our definition does not require the c-cover property and the Decreasing monotonicity property of nice covers. Therefore, our notion includes the setting of continued fraction dimension, which is not captured by Nice covers. Also, the Fineness property required in our definition is not there in the definition of nice covers. The notion of Increasing monotonicity is present in both settings.

3.2 Hausdorff Φ-dimension

Recall from Definition 13 that a Φ-cover of $\mathcal{F}$ is a collection of sets from Φ that covers $\mathcal{F}$. We call this as a δ-cover if the diameter of elements in the cover are less than δ.

▶ **Definition 14.** *Let Φ be a family of covering sets defined over $\mathbb{X}$. Given a set $\mathcal{F} \subseteq \mathbb{X}$, a Φ-cover $\{U_i\}_{i\in\mathbb{N}}$ of $\mathcal{F}$ is called a* δ-cover of $\mathcal{F}$ using Φ *if for all $i \in \mathbb{N}$, $|U_i| \leq \delta$.*

▶ **Definition 15.** *Given an $\mathcal{F} \subseteq \mathbb{X}$, for any $s > 0$, we define*

$$\mathcal{H}_\delta^s(\mathcal{F}, \Phi) = \inf\left\{\sum_i |U_i|^s : \{U_i\}_{i\in\mathbb{N}} \textit{ is a } \delta\textit{-cover of } \mathcal{F} \textit{ using } \Phi\right\}.$$

From the fineness property given in Definition 12, it follows that for any $\mathcal{F} \subseteq \mathbb{X}$, and $\delta > 0$, δ-covers of $\mathcal{F}$ using Φ always exist.

As δ decreases, the set of admissible δ-covers using Φ decreases. Hence $\mathcal{H}_\delta^s(\mathcal{F}, \Phi)$ increases.

▶ **Definition 16.** *For $s \in (0, \infty)$, define the* s-dimensional Φ outer measure *of $\mathcal{F}$ as:*

$$\mathcal{H}^s(\mathcal{F}, \Phi) = \lim_{\delta\to 0} \mathcal{H}_\delta^s(\mathcal{F}, \Phi).$$

Observe that as with the case of classical Hausdorff dimension, for any $t > s$, if $\mathcal{H}^s(\mathcal{F}, \Phi) < \infty$, then $\mathcal{H}^t(\mathcal{F}, \Phi) = 0$ (see Section 2.2 in [6]).

Finally, we have the following definition of Hausdorff Φ-dimension.

▶ **Definition 17.** *For any $\mathcal{F} \subset \mathbb{X}$, the* Hausdorff Φ-dimension *of $\mathcal{F}$ is defined as:*

$$\dim_\Phi(\mathcal{F}) = \inf\{s \geq 0 : \mathcal{H}^s(\mathcal{F}, \Phi) = 0\}.$$

3.3 Effective Φ-dimension

We first formulate the notion of a Φ-s-supergale. A Φ-s-supergale can be seen as a gambling strategy where the bets are placed on the covering sets from Φ. The definitions in this subsection are adaptations from Mayordomo [22].

▶ **Definition 18** (Mayordomo [22]). *Let $\Phi = \bigcup_{n\in\mathbb{Z}}\{U_i^n\}_{i\in\mathbb{N}}$ be a family of covering sets from Definition 12. For $s \in [0,\infty)$, a Φ-s-supergale is a function $d : \Phi \to [0,\infty)$ such that:*

- $\sum\limits_{U\in\{U_i^0\}_{i\in\mathbb{N}}} d(U)|U|^s < \infty$ *and*
- *For all $n \in \mathbb{N}$ and all $U \in \{U_i^n\}_{i\in\mathbb{N}}$, the following condition holds:*

$$d(U).|U|^s \geq \sum_{V\in\{U_i^{n+1}\}_{i\in\mathbb{N}}, V\subseteq U} d(V)|V|^s \ .$$

The following is the generalization of Kraft inequality for s-supergales from Mayordomo [22].

▶ **Lemma 19** (Generalisation of Kraft inequality [22]). *Let d be a Φ-s-supergale. Then for every $\mathcal{E} \subseteq \Phi$ such that the sets in $\mathcal{E}$ are incomparable, we have that*

$$\sum_{V\in\mathcal{E}} d(V)|V|^s \leq \sum_{U\in\{U_i^0\}_{i\in\mathbb{N}}} d(U)|U|^s.$$

▶ **Definition 20** (Mayordomo [22]). *Given $x \in \mathbb{X}$, a Φ-representation of x is a sequence $(U_n)_{n\in\mathbb{Z}}$ such that for each $n \in \mathbb{Z}$, $U_n \in \{U_i^n\}_{i\in\mathbb{N}}$ and $x \in \cap_n U_n$.*

Note that the same x can have multiple Φ-representations. Given $x \in \mathbb{X}$, let $\mathcal{R}(x)$ be the set of Φ-representations of x.

▶ **Definition 21** (Mayordomo [22]). *A Φ-s-supergale d succeeds on $x \in \mathbb{X}$ if there is a $(U_n)_{n\in\mathbb{Z}} \in \mathcal{R}(x)$ such that $\limsup\limits_{n\to\infty} d(U_n) = \infty$.*

Equivalently, a Φ-s-supergale d succeeds on a point $x \in \mathbb{X}$ iff for every $k \in \mathbb{N}$, there exists a $U \in \Phi$ such that $x \in U$ and $d(U) > 2^k$.

▶ **Definition 22.** *The* success set *of d is $S^\infty(d) = \{x \in \mathbb{X} \mid d \text{ succeeds on } x\}$.*

To define constructive Φ-dimension, we require some additional computability restrictions over Φ. It is an adaptation of the definition from [22].

▶ **Definition 23** (Family of computable covering sets Φ). *We consider the space $\mathbb{X} \subseteq \mathbb{R}^\eta$ where $\eta \in \mathbb{N}$ and a family of covering sets $\Phi = \bigcup_{n\in\mathbb{Z}}\{U_i^n\}_{i\in\mathbb{N}}$ from Definition 12. We call Φ to be a family of computable covering sets if it satisfies the following additional properties:*

- *Computable diameter: For every $n \in \mathbb{Z}$ and $i \in \mathbb{N}$, $|U_i^n|$ is computable.*
- *Computable subsets: For every $n \in \mathbb{Z}$, and $i \in \mathbb{N}$, the set $\{j \in \mathbb{N} : U_j^{n+1} \subseteq U_i^n\}$ is uniformly computable.*

In definition 23, when we say $|U_i^n|$ is computable, we mean that there is a turing machine that on input n, i, r outputs a $q \in Q$ such that $||U_i^n| - q| < 2^r$. The set $\{j \in \mathbb{N} : U_j^{n+1} \subseteq U_i^n\}$ is uniformly computable if there is a turing machine which on input i, j, n decides if $U_j^{n+1} \subseteq U_i^n$.

We use constructive Φ-s-gales to define the notion of constructive Φ-dimension. For a Φ-s-gale d to be constructive, we require the gale function d to be lower semicomputable. Note that a lower semicomputable supergale actually takes as input (i, n) where $i \in \mathbb{N}, n \in \mathbb{Z}$ to place bets on U_i^n. We omit this technicality in this paper and keep the domain of the gale as Φ for the sake of simplicity.

▶ **Definition 24.** *A function* $d : \Phi \longrightarrow [0, \infty)$ *is called* lower semicomputable *if there exists a total computable function* $\hat{d} : \Phi \times \mathbb{N} \longrightarrow \mathbb{Q} \cap [0, \infty)$ *such that the following two conditions hold.*

- ***Monotonicity*** *: For all* $U \in \Phi$ *and for all* $n \in \mathbb{N}$*, we have* $\hat{d}(U, n) \leq \hat{d}(U, n + 1) \leq d(U)$*.*
- ***Convergence*** *: For all* $U \in \Phi$*,* $\lim\limits_{n\to\infty} \hat{d}(U, n) = d(U)$*.*

For $\mathcal{F} \subseteq \mathbb{X}$, let $\mathcal{G}_\Phi(\mathcal{F})$ denote the set of all $s \in [0, \infty)$ such that there exists a lower semicomputable Φ-s-supergale d with $\mathcal{F} \subseteq S^\infty(d)$.

▶ **Definition 25.** *The* constructive Φ-dimension *of* $\mathcal{F} \subseteq \mathbb{X}$ *is*

$$\mathrm{cdim}_\Phi(\mathcal{F}) = \inf \mathcal{G}_\Phi(\mathcal{F}).$$

The constructive Φ dimension *of a point* $x \in \mathbb{X}$ *is defined by* $\mathrm{cdim}_\Phi(\{x\})$*, the constructive* Φ*-dimension of the singleton set containing* x*.*

This definition can easily be relativized with respect to an oracle $A \subseteq \mathbb{N}$ by giving the s-supergale an additional oracle access to set $A \subseteq \mathbb{N}$. We denote this using $\mathrm{cdim}^A_\Phi(\mathcal{F})$.

We now show that the constructive Φ-dimension of a set is the supremum of constructive Φ-dimensions of points in the set. The proof is a straightforward adaptation of proof of Theorem 11 by Lutz [11].

▶ **Theorem 26.** *For any family of computable covering sets* Φ *defined over the space* $\mathbb{X}$*, for any* $\mathcal{F} \subseteq \mathbb{X}$*, we have*

$$\mathrm{cdim}_\Phi(\mathcal{F}) = \sup_{x\in\mathcal{F}} \mathrm{cdim}_\Phi(x).$$

4 Point-to-set principle for Φ-dimension

Let $\Phi = \bigcup_{n\in\mathbb{Z}}\{U^n_i\}_{i\in\mathbb{N}}$ be a family of computable covering sets from Definition 23. In this work, we introduce the Point-to-Set principle for Φ-dimension. We show that the Hausdorff Φ-dimension of any set $\mathcal{F} \subseteq \mathbb{X}$ is equal to the relative constructive Φ-dimensions of elements in the set, relative to a minimizing oracle A.

▶ **Theorem 27.** *For a family of computable covering sets* Φ *over the space* $\mathbb{X}$*, for all* $\mathcal{F} \subseteq \mathbb{X}$*,*

$$\dim_\Phi(\mathcal{F}) = \min_{A\subseteq\mathbb{N}} \sup_{x\in\mathcal{F}} \mathrm{cdim}^A_\Phi(x).$$

4.1 Point to Set Principle for constructive dimension

▶ **Definition 28** (Dyadic Family of covers)**.** *Consider the space* $\mathbb{X} = \mathbb{R}^n$*. The dyadic family of covers is the set of coverings* $\Phi_B = \bigcup_{r\in\mathbb{N}}\{[\frac{m_1}{2^r}, \frac{m_1+1}{2^r}] \times \cdots \times [\frac{m_n}{2^r}, \frac{m_n+1}{2^r}]\}_{m_1,m_2\ldots,m_n\in[2^r]}$*.*

It is straightforward to verify that Φ_B is a family of computable covering sets from Definition 23. Besicovitch [3] gave the following Φ-dimension characterization of Hausdorff dimension.

▶ **Lemma 29** (Besicovitch [3])**.** *For all* $\mathcal{F} \subseteq \mathbb{R}^n$*, we have* $\dim(\mathcal{F}) = \dim_{\Phi_B}(\mathcal{F})$*.*

Similarly, we have the following Φ-dimension characterization of Constructive dimension.

▶ **Lemma 30** (Lutz and Mayordomo [16])**.** *For all* $\mathcal{F} \subseteq \mathbb{R}^n$*, we have* $\mathrm{cdim}(\mathcal{F}) = \mathrm{cdim}_{\Phi_B}(\mathcal{F})$*.*

From Theorem 27 for Φ_B and using Lemma 29 and 30, we have the following point-to-set principle from [13] relating Hausdorff and Constructive dimensions.

▶ **Corollary 31** (J.Lutz and N.Lutz [13]). *For all $\mathcal{F} \subseteq \mathbb{X}$,*

$$\dim(\mathcal{F}) = \min_{A \subseteq \mathbb{N}} \sup_{x \in \mathcal{F}} \operatorname{cdim}^A(x).$$

4.2 Point to Set Principle for Continued Fraction dimension

The sequence $Y = [a_1, a_2, \dots]$ where each $a_i \in \mathbb{N}$ is the continued fraction expansion of the number $y = \cfrac{1}{a_1 + \cfrac{1}{a_2 + \cdots}}$. Given $u = [a_1, a_2 \dots a_n] \in \mathbb{N}^*$, the cylinder set of u, C_u is defined as $C_u = [[a_1, a_2, \dots a_n], [a_1, a_2, \dots a_n + 1]]$ when n is even and $C_u = [[a_1, a_2, \dots a_n + 1], [a_1, a_2, \dots a_n]]$ when n is odd.

The notion of constructive continued fraction dimension was introduced by Nandakumar and Vishnoi [26] using continued fraction s-gales. Akhil, Nandakumar and Vishnoi [24] showed that this notion is different from that of constructive dimension.

Consider Φ_{CF} to be the set of covers generated by the continued fraction cylinders, that is $\Phi_{CF} = \bigcup_{n \in \mathbb{Z}} \{C_{[a_1, a_2, \dots a_n]}\}_{a_1 \dots a_n \in \mathbb{N}}$. It is routine to verify that this is a family of computable covering sets from Definition 23. From Theorem 27, we therefore have the following point-to-set principle for Continued fraction dimension.

▶ **Corollary 32.** *For all $\mathcal{F} \subseteq \mathbb{X}$, $\dim_{CF}(\mathcal{F}) = \min_{A \subseteq \mathbb{N}} \sup_{x \in \mathcal{F}} \operatorname{cdim}^A_{CF}(x)$.*

4.3 Effective Φ-dimension using Kolmogorov Complexity

We give an equivalent formulation of constructive Φ-dimension of a point using Kolmogorov complexity. For this, we require some additional properties for the space Φ.

▶ **Definition 33** (Family of finitely intersecting computable covering sets Φ). *We consider the space $\mathbb{X} \subseteq \mathbb{R}^\eta$ where $\eta \in \mathbb{N}$ and a family of computable covering sets $\Phi = \bigcup_{n \in \mathbb{Z}} \{U^n_i\}_{i \in \mathbb{N}}$ from Definition 23. We say that Φ is a family of finitely intersecting computable covering sets if it satisfies the following additional properties:*

- *Density of Rational points: For each $U \in \Phi$, there exists a $q \in \mathbb{Q}^n$ such that $q \in U$.*
- *Finite intersection: There exists a constant $c \in \mathbb{N}$ such that for any collection $\{U_i\} \subseteq \Phi$ satisfying*
  (1) *$U_i \not\subseteq U_j$ for all $i \neq j$, and*
  (2) *$\bigcap_i U_i \neq \emptyset$,*
  we have $\#(\{U_i\}) \leq c$.
- *Membership test: There is a computable function that given $i \in \mathbb{N}$ and $n \in \mathbb{Z}$ and a $q \in \mathbb{Q}^n$ checks if $q \in U^n_i$.*

The Finite intersection property states that the cardinality of any collection of incomparable sets from Φ having non empty intersection is bounded by a constant.

Given family of finitely intersecting computable covering sets Φ over a space $\mathbb{X}$, and an $r \in \mathbb{N}$, we define the notion of Kolmogorov Complexity of a point X at precision r with respect to Φ. We denote this using $K_r(X, \Phi)$.

▶ **Definition 34.** *Given an $r \in \mathbb{N}$, and $x \in \mathbb{X}$, define*

$$K_r(x, \Phi) = \min_{U \in \Phi}\{K(U) \mid x \in U \text{ and } |U| < 2^{-r}\}.$$

where for $U \in \Phi$, $K(U)$ is defined as $K(U) = \min\{K(q) \mid q \in U \cap \mathbb{Q}^n\}$.

For any family of finitely intersecting computable covering sets Φ, we have the following Kolmogorov Complexity characterization of constructive Φ-dimension.

▶ **Theorem 35.** *Given a family of finitely intersecting computable covering sets Φ, over a space $\mathbb{X}$. For any $x \in \mathbb{X}$,*

$$\operatorname{cdim}_\Phi(x) = \liminf_{r \to \infty} \frac{K_r(x, \Phi)}{r}$$

5 Kolmogorov Complexity Construction

In this section we give a technical construction which is crucial in proving the results in section 6. Theorem 36 says that given an infinite sequence X and an oracle A, for any oracle B, there exists a sequence Y whose relativized Kolmogorov complexity (of prefixes) with respect to B is similar to the relativized Kolmogorov complexity (of prefixes) of X with respect to A.

▶ **Theorem 36.** *For all $X \in \Sigma^\infty$ and $A \in \Sigma^\infty$, given a $B \in \Sigma^\infty$, there exists a $Y \in \Sigma^\infty$ such that for all $n \in \mathbb{N}$, $|K^A(X \upharpoonright n) - K^B(Y \upharpoonright n)| = o(n)$ and $\operatorname{cdim}^B(Y) = \operatorname{cdim}(Y)$.*

6 Equivalence of Faithfulness of Cantor Coverings at Constructive and Hausdorff Levels

In this section, we show that when the class of covers Φ is generated by computable Cantor series expansions, the faithfulness at the Hausdorff and constructive levels are equivalent notions.

6.1 Faithfulness of Family of Coverings

We will first see the definition of Hausdorff dimension faithfulness. We then introduce the corresponding notion at the effective level, which we call constructive dimension faithfulness.

A family of covering sets Φ is said to be *faithful* with respect to Hausdorff dimension if the Φ dimension of every set in the space is the same as its Hausdorff dimension.

▶ **Definition 37.** *A family of covering sets Φ over the space $\mathbb{X}$ is said to be* faithful with respect to Hausdorff dimension *if for all $\mathcal{F} \subseteq \mathbb{X}$, $\dim_\Phi(\mathcal{F}) = \dim(\mathcal{F})$.*

We extend the definition to the constructive level as well. A family of computable covering sets Φ is defined to be *faithful* with respect to constructive dimension if the constructive Φ dimension of every set is the same as its constructive dimension.

▶ **Definition 38.** *A family of computable covering sets Φ is said to be* faithful with respect to constructive dimension *if for all $\mathcal{F} \subseteq \mathbb{X}$, $\operatorname{cdim}_\Phi(\mathcal{F}) = \operatorname{cdim}(\mathcal{F})$.*

The following lemma follows from Theorem 26 and Lemma 11. It states that constructive dimension faithfulness can be equivalently stated in terms of preservation of constructive dimensions of points in the set.

▶ **Lemma 39.** *A constructive family of covers Φ is faithful with respect to Constructive dimension if and only if for all $x \in \mathbb{X}$, $\mathrm{cdim}_{\Phi}(x) = \mathrm{cdim}(x)$.*

The following lemma states that the Φ-dimension of a set is always greater than or equal to its Hausdorff dimension. Similarly, the constructive $\Phi-$dimension of a set is always greater than or equal to its constructive dimension.

▶ **Lemma 40.** *For any family of covering sets Φ over $\mathbb{X}$, for all $\mathcal{F} \subseteq \mathbb{X}$, $\dim_{\Phi}(\mathcal{F}) \geq \dim(\mathcal{F})$.*

▶ **Lemma 41.** *For any family of finitely intersecting computable covering sets Φ over $\mathbb{X}$, for all $\mathcal{F} \subseteq \mathbb{X}$, $\mathrm{cdim}_{\Phi}(\mathcal{F}) \geq \mathrm{cdim}(\mathcal{F})$.*

Therefore we have that Φ is not faithful for Hausdorff dimension if and only if there exists an $\mathcal{F} \subset \mathbb{X}$ such that $\dim_{\Phi}(\mathcal{F}) > \dim(\mathcal{F})$. Similarly, Φ is not faithful for Constructive dimension if and only if there exists an $\mathcal{F} \subset \mathbb{X}$ such that $\mathrm{cdim}_{\Phi}(\mathcal{F}) > \mathrm{cdim}(\mathcal{F})$.

6.2 Cantor coverings over unit interval

We consider the faithfulness of family of coverings generated by the computable Cantor series expansion [4]. We call such class of coverings as *Cantor coverings.*

Given a sequence $Q = \{n_k\}_{k\in\mathbb{N}}$ with $n_k \in \mathbb{N} \setminus \{1\}$, the expression

$$x = \sum_{k=1}^{\infty} \frac{\alpha_k}{n_1.n_2 \dots n_k}$$

where $\alpha_k \in [n_k]$ is called the cantor series expansion of the real number $x \in [0, 1]$.

▶ **Definition 42** (Cantor Coverings Φ_Q)**.** *The class of Cantor coverings Φ_Q over the space $\mathbb{X} = [0, 1]$ generated by the Cantor series expansion $Q = \{n_k\}_{k\in\mathbb{N}}$ is the set of intervals*

$$\bigcup_{k\in\mathbb{Z}} \{[\frac{m}{n_0.n_1.n_2 \dots n_k}, \frac{m+1}{n_0.n_1.n_2 \dots n_k}]\}_{m\in[n_0.n_1.n_2 \dots n_k]}$$

with n_0 taken as 1.

▶ **Definition 43** (Computable Cantor Coverings)**.** *The cantor series expansion $Q = \{n_k\}_{k\in\mathbb{N}}$ is said to be computable if there exists a machine that generates n_k given k. We call the class of Cantor coverings Φ_Q generated by a computable Cantor series expansion Q as a class of Computable Cantor Coverings over $\mathbb{X} = [0, 1]$.*

It is routine to verify that for any computable Cantor series expansion $Q = \{n_k\}_{k\in\mathbb{N}}$, the Cantor covering Φ_Q is a family of finitely intersecting computable covering sets from Definition 33. Therefore, from Theorem 27, we have the following Point-to-Set principle for Cantor covering dimension.

▶ **Corollary 44.** *For all $\mathcal{F} \subseteq \mathbb{X}$ and for all computable Cantor coverings Φ_Q,*

$$\dim_{\Phi_Q}(\mathcal{F}) = \min_{A\subseteq\mathbb{N}} \sup_{x\in\mathcal{F}} \mathrm{cdim}^{A}_{\Phi_Q}(x).$$

6.3 Kolmogorov Complexity Characterization of Cantor Series Dimension

We first show a Kolmogorov complexity characterization of constructive Φ-dimension for computable Cantor coverings.

▶ **Theorem 45.** *For any $x \in \mathbb{X}$, and any computable Cantor coverings Φ_Q generated by $Q = \{n_k\}_{k\in\mathbb{N}}$,*

$$\mathrm{cdim}_{\Phi_Q}(x) = \liminf_{k\to\infty} \frac{K(X \upharpoonright m_k)}{m_k}$$

where X is a binary expansion of x and $m_k = \lfloor \log_2(n_1.n_2 \ldots n_k) \rfloor$.

Theorem 8 ensures that when the Kolmogorov complexities of any two $X, Y \in \Sigma^\infty$ align over all finite prefixes, their constructive dimensions become equal. From Theorem 45, we get that when this happens, the constructive Φ-dimensions also become equal.

▶ **Lemma 46.** *For any $x, y \in \mathbb{X}$, $A, B \subseteq \mathbb{N}$ and any class of computable Cantor coverings Φ, if for all n, $|K^A(X \upharpoonright n) - K^B(Y \upharpoonright n)| = o(n)$, then $\mathrm{cdim}^A(x) = \mathrm{cdim}^B(y)$ and $\mathrm{cdim}^A_\Phi(x) = \mathrm{cdim}^B_\Phi(y)$. Here X and Y are the binary expansions of x and y respectively.*

6.4 Faithfulness of Cantor Coverings

Using the Point-to-Set Principle and properties of Kolmogorov complexity, we show that the notions of faithfulness for Cantor coverings at Hausdorff and Constructive levels are equivalent.

We first show that if a class of computable Cantor coverings Φ is faithful with respect to constructive dimension, then Φ is also faithful with respect to Hausdorff dimension.

▶ **Lemma 47.** *For any class of computable Cantor coverings Φ, if for all $\mathcal{F} \subseteq \mathbb{X}$, $\mathrm{cdim}(\mathcal{F}) = \mathrm{cdim}_\Phi(\mathcal{F})$, then for all $\mathcal{F} \subseteq \mathbb{X}$, $\dim(\mathcal{F}) = \dim_\Phi(\mathcal{F})$.*

To prove the converse, we require the construction of set $\mathcal{I}_s$ that contains all points in $\mathbb{X}$ having constructive dimension equal to s.

▶ **Definition 48.** *Given $s \in [0, \infty)$, define $\mathcal{I}_s = \{x \in \mathbb{X} \mid \mathrm{cdim}(x) = s\}$.*

Lutz and Weihrauch [17] showed that the Hausdorff dimension of $\mathcal{I}_s$ is equal to s. We provide a simple alternate proof of this using the point-to-set principle.

▶ **Lemma 49** (Lutz and Weihrauch [17])**.** $\dim(\mathcal{I}_s) = s$.

We now show that if a class of computable Cantor coverings Φ is faithful with respect to Hausdorff dimension, then Φ is also faithful with respect to constructive dimension.

▶ **Lemma 50.** *For any class of computable Cantor coverings Φ, if for all $\mathcal{F} \subseteq \mathbb{X}$, $\dim(\mathcal{F}) = \dim_\Phi(\mathcal{F})$, then for all $\mathcal{F} \subseteq \mathbb{X}$, $\mathrm{cdim}(\mathcal{F}) = \mathrm{cdim}_\Phi(\mathcal{F})$.*

Therefore, we have the following theorem which states that for the classes of Cantor coverings Φ, faithfulness with respect to Hausdorff and Constructive dimensions are equivalent notions.

▶ **Theorem 51.** *For any class of computable Cantor coverings Φ,*

$$\forall \mathcal{F} \subseteq \mathbb{X}\ ;\ \dim(\mathcal{F}) = \dim_\Phi(\mathcal{F}) \iff \forall \mathcal{F} \subseteq \mathbb{X}\ ;\ \mathrm{cdim}(\mathcal{F}) = \mathrm{cdim}_\Phi(\mathcal{F}).$$

6.5 Log limit condition for faithfulness

Albeverio, Ivanenko, Lebid and Torbin [1] showed that the Cantor coverings Φ_Q generated by the Cantor series expansions of $Q = \{n_k\}_{k\in\mathbb{N}}$ can be faithful as well as non faithful with respect to Hausdorff dimension depending on Q. Interestingly, they showed that the Hausdorff dimension faithfulness of Cantor coverings can be determined using the terms n_k in Q.

▶ **Theorem 52** (Albeverio, Ivanenko, Lebid and Torbin [1]). *A family of Cantor coverings Φ_Q generated by $Q = \{n_k\}_{k\in\mathbb{N}}$ is faithful with respect to Hausdorff dimension if and only if* $\lim\limits_{k\to\infty} \frac{\log n_k}{\log n_1 \cdot n_2 \dots n_{k-1}} = 0$.

Using the above result and the result that faithfulness at the constructive level is equivalent to faithfulness with respect to Hausdorff dimension (Theorem 51), we have that the condition stated above provides the necessary and sufficient conditions for Cantor series coverings to be faithful for constructive dimension.

▶ **Theorem 53.** *A family of Cantor coverings Φ_Q generated by $Q = \{n_k\}_{k\in\mathbb{N}}$ is faithful with respect to constructive dimension if and only if*

$$\lim_{k\to\infty} \frac{\log n_k}{\log n_1 . n_2 \dots n_{k-1}} = 0. \tag{1}$$

The Cantor series expansion is a generalization of the base-b representation, which is the special case when $n_k = b$ for all $k \in \mathbb{N}$. That is $Q_b = \{b\}_{n\in\mathbb{N}}$. Since the condition in Theorem 53 is satisfied by Q_b for any $b \in \mathbb{N}$, we have the following result by Hitchcock and Mayordomo about the base invariance of constructive dimension.

▶ **Corollary 54** (Hitchcock and Mayordomo [8]). *For any $x \in [0,1]$ and $k, l \in \mathbb{N} \setminus \{1\}$, $\mathrm{cdim}_{(k)}(x) = \mathrm{cdim}_{(l)}(x)$. where $\mathrm{cdim}_{(k)}(x)$ represents the constructive dimension of x with respect to its base-k representation.*

Note that condition (1) classifies the Cantor series expansions on the basis of constructive dimension faithfulness. As an example, when $n_k = 2^k$, condition (1) holds, and therefore $Q = \{2^k\}_{k\in\mathbb{N}}$ is faithful for constructive dimension. However, when $n_k = 2^{2^k}$, condition (1) does not hold, and therefore $Q = \{2^{2^k}\}_{k\in\mathbb{N}}$ is not faithful for constructive dimension.

7 Conclusion and Open Problems

We develop a constructive analogue of Φ-dimension and prove a Point-to-Set principle for Φ-dimension. Using this, we show that for Cantor series representations, constructive dimension faithfulness and Hausdorff dimension are equivalent notions. We also provide a loglimit condition for faithfulness of Cantor series expansions.

The following are some problems that remain open

1. Are the faithfulness at constructive and Hausdorff levels equivalent for all computable family of covering sets Φ ?
2. What is the packing dimension analogue of faithfulness, is there any relationship between faithfulness of Hausdorff dimension and packing dimension ?
3. Is there any relationship between faithfulness of constructive dimension and constructive strong dimension ?

Toward Grünbaum's Conjecture for 4-Connected Graphs

Christian Ortlieb
Institute of Computer Science, University of Rostock, Germany

Abstract

Given a spanning tree T of a 3-connected planar graph G, the *co-tree* of T is the spanning tree of the dual graph G^* given by the duals of the edges that are not in T. Grünbaum conjectured in 1970 that there is such a spanning tree T such that T and its co-tree both have maximum degree at most 3.

In 2014, Biedl proved that there is a spanning tree T such that T and its co-tree have maximum degree at most 5. Using structural insights into Schnyder woods, Schmidt and the author recently improved this bound on the maximum degree to 4. In this paper, we prove that in a 4-connected planar graph there exists a spanning tree T of maximum degree at most 3 such its co-tree has maximum degree at most 4. This almost solves Grünbaum's conjecture for 4-connected graphs.

1 Introduction

In 1966, Barnette showed that every 3-connected planar graph has a spanning 3-tree [3]. Here and in the following, a k-tree denotes a tree with maximum degree at most k. The dual of a 3-connected planar graph G is also 3-connected and planar. As mentioned in the abstract, for a spanning tree T the duals of the edges $E(G) - E(T)$ form a spanning tree of the dual graph G^*, the so called co-tree $\neg T^*$ of T. Thus, the question of a simultaneous bound on the maximum degree of T and its co-tree naturally arises. In 1970, Grünbaum made the following conjecture.

▶ **Conjecture 1** (Grünbaum [16, p. 1148], 1970). *Every planar 3-connected graph G contains a 3-tree T whose co-tree $\neg T^*$ is also a 3-tree.*

While Grünbaum's conjecture is to the best of our knowledge still unsolved, progress has been made by Biedl [4], who proved the existence of a 5-tree whose co-tree is a 5-tree. Her approach uses structural properties of canonical orderings. Schmidt and the author recently proved that in a 3-connected planar graph there is a spanning tree T such that T and its co-tree have maximum degree at most 4 [20]. In this paper, we prove that in a 4-connected planar graph there is a spanning 3-tree such that its co-tree is a spanning 4-tree of the dual. We use structural properties of minimal Schnyder woods. Schnyder woods are a tool which is widely applied in graph drawing [1,13,15,21,22] and beyond [6,7,10,17].

Our approach divides into two steps. Let G be the graph in question. First, we identify a suitable candidate graph H. This candidate is a spanning and connected subgraph of G of maximum degree at most 3. By the well-known cut-cycle duality [11, Prop. 4.6.1], its co-graph (that is the graph with edge set $E(G^*) - E(H)^*$) is acyclic. We show that the co-graph also has maximum degree 3. Then, we only lack the acyclicity of the primal graph.

Thus, in the second step, we delete edges of the candidate graph H such that it becomes acyclic and the co-graph remains acyclic. Then, we show that the degree of the resulting co-graph does not exceed 4. This then yields the desired 3-tree such that its co-tree is a 4-tree. The first step is far from being trivial. Especially, it is hard to prove the connectivity of the candidate graph. The second step uses parts of the proof of the main theorem of [20]. Hence, we focus on the first step.

We discuss Schnyder woods, their lattice structure and ordered path partitions in Section 2, the candidate graph H in Section 3 and the second and final step in Section 4. Due to space limitations some proofs are omitted or only sketched.

2 Schnyder Woods and Ordered Path Partitions

We only consider simple undirected graphs. A graph is *plane* if it is planar and embedded into the Euclidean plane without intersecting edges. The *neighborhood of a vertex set A* is the union of the neighborhoods of vertices in A. Although parts of this paper use orientation on edges, we will always let vw denote the undirected edge $\{v, w\}$.

2.1 Schnyder Woods

Let $\sigma := \{r_1, r_2, r_3\}$ be a set of three vertices of the outer face boundary of a plane graph G in clockwise order (but not necessarily consecutive). We call r_1, r_2 and r_3 *roots*. The *suspension G^σ* of G is the graph obtained from G by adding at each root of σ a half-edge pointing into the outer face. With a little abuse of notation, we define a *half-edge* as an arc that has a startvertex but no endvertex.

▶ **Definition 2** (Felsner [12]). *Let $\sigma = \{r_1, r_2, r_3\}$ and G^σ be the suspension of a 3-connected plane graph G. A* Schnyder wood *of G^σ is an orientation and coloring of the edges of G^σ (including the half-edges) with the colors 1,2,3 (red, green, blue) such that*

(a) *Every edge e is oriented in one direction (we say e is* unidirected*) or in two opposite directions (we say e is* bidirected*). Every direction of an edge is colored with one of the three colors 1,2,3 (we say an edge is i-*colored *if one of its directions has color i) such that the two colors i and j of every bidirected edge are distinct (we call such an edge i-j-*colored*). Throughout the paper, we assume modular arithmetic on the colors 1,2,3 in such a way that $i+1$ and $i-1$ for a color i are defined as $(i \mod 3)+1$ and $(i+1 \mod 3)+1$, respectively. For a vertex v, a uni- or bidirected edge is* incoming *(i-colored)* in *v if it has a direction (of color i) that is directed toward v, and* outgoing *(i-colored)* of *v if it has a direction (of color i) that is directed away from v.*

(b) *For every color i, the half-edge at r_i is unidirected, outgoing and i-colored.*

(c) *Every vertex v has exactly one outgoing edge of every color. The outgoing 1-, 2-, 3-colored edges e_1, e_2, e_3 of v occur in clockwise order around v. For every color i, every incoming i-colored edge of v is contained in the clockwise sector around v from e_{i+1} to e_{i-1} (see Figure 1).*

(d) *No inner face boundary contains a directed cycle (disregarding possible opposite edge directions) in one color.*

For a Schnyder wood and color i, let T_i be the directed graph that is induced by the directed edges of color i. The following result justifies the name of Schnyder woods.

▶ **Lemma 3** ([13, 21]). *For every color i of a Schnyder wood of G^σ, T_i is a directed spanning tree of G in which all edges are oriented to the root r_i.*

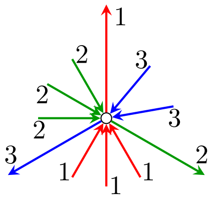

Figure 1 Properties of Schnyder woods. Condition 2c at a vertex.

For a directed graph H, we denote by H^{-1} the graph obtained from H by reversing the direction of all its edges.

▶ **Lemma 4** (Felsner [15]). *For every* $i \in \{1, 2, 3\}$, $T_i^{-1} \cup T_{i+1}^{-1} \cup T_{i+2}$ *is acyclic.*

▶ **Lemma 5** (folklore). *Let* S *be a Schnyder wood of* G^σ. *Then,* G *is internally triangulated, i.e., every face except the outer face is a triangle if and only if every internal edge of* G *is unidirected in* S.

2.2 Dual Schnyder Woods

Let G be a 3-connected plane graph. Any Schnyder wood of G^σ induces a Schnyder wood of a slightly modified planar dual of G^σ in the following way [9, 14] (see [19, p. 30] for an earlier variant of this result given without proof). As common for plane duality, we will use the plane dual operator * to switch between primal and dual objects (also on sets of objects).

Extend the three half-edges of G^σ to non-crossing infinite rays and consider the planar dual of this plane graph. Since the infinite rays partition the outer face f of G into three parts, this dual contains a triangle with vertices b_1, b_2 and b_3 instead of the outer face vertex f^* such that b_i^* is not incident to r_i for every i (see Figure 2). Let the *suspended dual* G^{σ^*} of G^σ be the graph obtained from this dual by adding at each vertex of $\{b_1, b_2, b_3\}$ a half-edge pointing into the outer face.

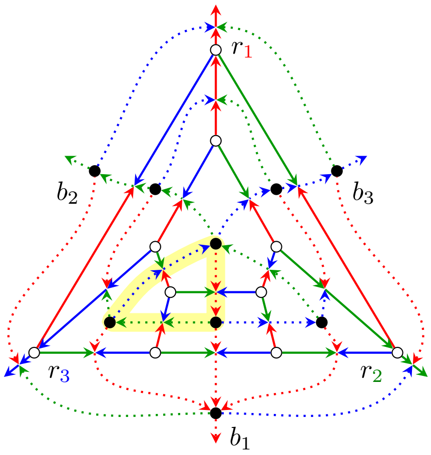

Figure 2 The completion of G obtained by superimposing G^σ and its suspended dual G^{σ^*} (the latter depicted with dotted edges). The primal Schnyder wood is not the minimal element of the lattice of Schnyder woods of G, as this completion contains a clockwise directed cycle (marked in yellow).

Consider the superposition of G^σ and its suspended dual G^{σ^*} such that exactly the primal dual pairs of edges cross (here, for every $1 \leq i \leq 3$, the half-edge at r_i crosses the dual edge $b_{i-1}b_{i+1}$).

▶ **Definition 6.** *For any Schnyder wood S of G^σ, define the orientation and coloring S^* of the suspended dual G^{σ^*} as follows (Figure 2):*

(a) *For every unidirected $(i-1)$-colored edge or half-edge e of G^σ, color e^* with the two colors i and $i+1$ such that e points to the right of the i-colored direction.*

(b) *Vice versa, for every i-$(i+1)$-colored edge e of G^σ, $(i-1)$-color e^* unidirected such that e^* points to the right of the i-colored direction.*

(c) *For every color i, make the half-edge at b_i unidirected, outgoing and i-colored.*

The following lemma states that S^* is indeed a Schnyder wood of the suspended dual. The vertices b_1, b_2 and b_3 are called the *roots* of S^*.

▶ **Lemma 7** ([18], [14, Prop. 3])**.** *For every Schnyder wood S of G^σ, S^* is a Schnyder wood of G^{σ^*}.*

Since $S^{*^*} = S$, Lemma 7 gives a bijection between the Schnyder woods of G^σ and the ones of G^{σ^*}. Let the *completion* $\widetilde{G}$ of G be the plane graph obtained from the superposition of G^σ and G^{σ^*} by subdividing each pair of crossing (half-)edges with a new vertex, which we call a *crossing vertex* (Figure 2). The completion has six half-edges pointing into its outer face.

Any Schnyder wood S of G^σ implies the following natural orientation and coloring $\widetilde{G}_S$ of its completion $\widetilde{G}$: For any edge $vw \in E(G^\sigma) \cup E(G^{\sigma^*})$, let z be the crossing vertex of $\widetilde{G}$ that subdivides vw and consider the coloring of vw in either S or S^*. If vw is outgoing of v and i-colored, we direct $vz \in E(\widetilde{G})$ toward z and i-color it; analogously, if vw is outgoing of w and j-colored, we direct $wz \in E(\widetilde{G})$ toward z and j-color it. In the case that vw is unidirected, say w.l.o.g. incoming at v and i-colored, we direct $zv \in E(\widetilde{G})$ toward v and i-color it. The three half-edges of G^{σ^*} inherit the orientation and coloring of S^* for $\widetilde{G}_S$. By Definition 6, the construction of $\widetilde{G}_S$ implies immediately the following corollary.

▶ **Corollary 8.** *Every crossing vertex of $\widetilde{G}_S$ has one outgoing edge and three incoming edges and the latter are colored 1, 2 and 3 in counterclockwise direction.*

Using results on orientations with prescribed outdegrees on the respective completions, Felsner and Mendez [8, 13] showed that the set of Schnyder woods of a planar suspension G^σ forms a distributive lattice. The order relation of this lattice relates a Schnyder wood of G^σ to a second Schnyder wood if the former can be obtained from the latter by reversing the orientation of a directed clockwise cycle in the completion. This gives the following lemma.

▶ **Lemma 9** ([8, 13])**.** *For the minimal element S of the lattice of all Schnyder woods of G^σ, $\widetilde{G}_S$ contains no clockwise directed cycle.*

We call the minimal element of the lattice of all Schnyder woods of G^σ the *minimal Schnyder wood* of G^σ.

▶ **Lemma 10** (Di Battista et al. [9])**.** *The boundary of every internal face of G can be partitioned into six paths $P_{1,3}$, $p_{2,3}$, $P_{2,1}$, $p_{3,1}$, $P_{3,2}$ and $p_{1,2}$ which appear in that clockwise order. For those paths the following holds (see Figure 3).*

(a) *$P_{i,j}$ consists of one edge which is either unidirected i-colored, unidirected j-colored or i-j-colored. Color i is directed in clockwise direction and color j in counterclockwise direction around f.*

(b) *$p_{i,j}$ consists of a possibly empty sequence of i-j-colored edges such that color i is directed clockwise around f.*

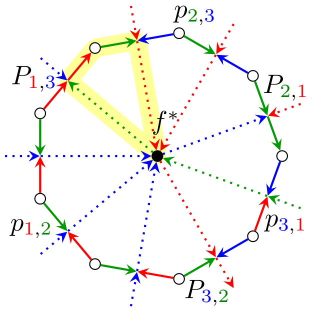

Figure 3 Illustration for Lemma 10. A face f, the paths on its boundary and the dual edges incident to f^*. If $P_{1,3}$ is unidirected 1-colored and $p_{2,3}$ is non-empty, there is a clockwise cycle in $\widetilde{G}_S$, marked in yellow.

2.3 Ordered Path Partitions

We denote paths as tuples of vertices such that consecutive vertices in the tuple are adjacent in the path. If a path P consists of only one vertex x, we might also write $P = x$. The concatenation of two paths P_1 and P_2 we denote by P_1P_2.

▶ **Definition 11.** *For any $j \in \{1,2,3\}$ and any $\{r_1, r_2, r_3\}$-internally 3-connected plane graph G, an* ordered path partition *$\mathcal{P} = (P_0, \dots, P_s)$ of G* with base-pair *(r_j, r_{j+1}) is a tuple of induced paths such that their vertex sets partition $V(G)$ and the following holds for every $i \in \{0, \dots, s-1\}$, where $V_i := \bigcup_{q=0}^{i} V(P_q)$ and the* contour *C_i is the clockwise walk from r_{j+1} to r_j on the outer face of $G[V_i]$.*

(a) *P_0 is the clockwise path from r_j to r_{j+1} on the outer face boundary of G, and $P_s = r_{j+2}$.*
(b) *Every vertex in P_i has a neighbor in $V(G) \setminus V_i$.*
(c) *C_i is a path.*
(d) *Every vertex in C_i has at most one neighbor in P_{i+1}.*

By Definition 11a and 11b, G contains for every i and every vertex $v \in P_i$ a path from v to r_{j+2} that intersects V_i only in v. Since G is plane, we conclude the following.

▶ **Lemma 12.** *Every path P_i of an ordered path partition is embedded into the outer face of $G[V_{i-1}]$ for every $1 \leq i \leq s$.*

2.3.1 Compatible Ordered Path Partitions

We describe a connection between Schnyder woods and ordered path partitions that was first given by Badent et al. [2, Theorem 5] and then revisited by Alam et al. [1, Lemma 1].

▶ **Definition 13.** *Let $j \in \{1,2,3\}$ and S be any Schnyder wood of the suspension G^σ of G. As proven in [1, arXiv version, Section 2.2], the inclusion-wise maximal j-$(j+1)$-colored paths of S then form an ordered path partition of G with base pair (r_j, r_{j+1}), whose order is a linear extension of the partial order given by reachability in the acyclic graph $T_j^{-1} \cup T_{j+1}^{-1} \cup T_{j+2}$; we call this special ordered path partition* compatible *with S and denote it by $\mathcal{P}^{j,j+1}$.*

For example, for the Schnyder wood given in Figure 2, $\mathcal{P}^{2,3}$ consists of the six maximal 2-3-colored paths, of which four are single vertices. We denote each path $P_i \in \mathcal{P}^{j,j+1}$ by $P_i := (v_1^i, \dots, v_k^i)$ such that $v_1^i v_2^i$ is outgoing j-colored at v_1^i.

Let C_i be as in Definition 11. By Definition 11c and Lemma 12, every path $P_i = (v_1^i, \ldots, v_k^i)$ of an ordered path partition satisfying $i \in \{1, \ldots, s\}$ has a neighbor $v_0^i \in C_{i-1}$ that is closest to r_{j+1} and a different neighbor $v_{k+1}^i \in C_{i-1}$ that is closest to r_j. We call v_0^i the *left neighbor* of P_i, v_{k+1}^i the *right neighbor* of P_i and $P_i^e := v_0^i P_i v_{k+1}^i$ the *extension* of P_i; we omit superscripts if these are clear from the context. For $0 < i \leq s$, let the path P_i *cover* an edge e or a vertex x if e or x is contained in C_{i-1}, but not in C_i, respectively.

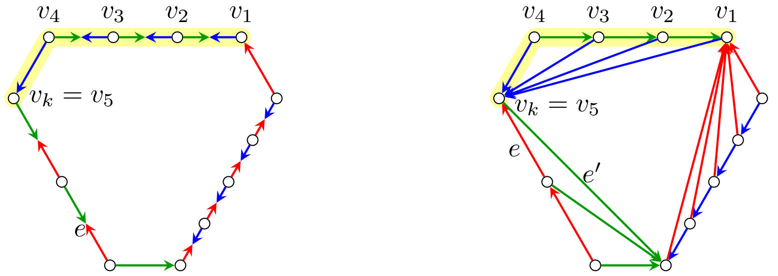
3 The Candidate Graph H

In this section, we define a special triangulation $\tau(G)$ of G. We also give some structural properties of $\tau(G)$. Afterwards, we define our candidate graph H as a subgraph of $\tau(G)$. Then, we are left to show some structural properties of H. First, we show that H is also a subgraph of G. Then, we argue that H and its co-graph have maximum degree at most 3. And finally, we show that if G is 4-connected, then H is connected. The latter will need some technical preparation.

Let P be the counterclockwise 3-colored path on the boundary of some internal face. By Lemma 10, P consists of $p_{2,3}$ (a possibly empty sequence of 2-3-colored edges) and possibly $P_{1,3}$ (an edge which is either unidirected 1-colored, unidirected 3-colored or 1-3-colored). Since S is minimal, we do not have clockwise cycles in $\widetilde{G}_S$. Hence, if $p_{2,3}$ is non-empty, then $P_{1,3}$ is either unidirected 3-colored or 3-1-colored (Figure 3), and we might define $\tau(G)$ as follows. A similar construction, but in the reverse direction, is used by Bonichon et al. [5].

▶ **Definition 14.** *Let G be a 3-connected planar graph and let S be the minimal Schnyder wood of G^σ. Define the internal triangulation $\tau(G)$ of G and the Schnyder wood of the σ-suspension of $\tau(G)$ to be the graph and Schnyder wood obtained by modifying every internal face f of G as follows (Figure 4). Let P be the counterclockwise 3-colored path on the boundary of f and let $v_1, \ldots, v_k$ be its vertices in counterclockwise order around f. If $k \geq 3$, proceed as follows. Add 3-colored edges $v_1v_k, \ldots, v_{k-2}v_k$ directed towards v_k and for $j = 2, \ldots, k-1$ change the color and orientation of v_jv_{j+1} such that v_jv_{j+1} is 2-colored and directed towards v_j. Proceed the same way for the counterclockwise 1-colored path and the counterclockwise 2-colored path on the boundary of f.*

Observe that if G is k-connected, then so is $\tau(G)$.



(a) An internal face of G.

(b) The corresponding subgraph of $\tau(G)$.

Figure 4 Illustration for the definition of $\tau(G)$. The counterclockwise 3-colored path P on the boundary of the face of G is highlighted in yellow.

▶ **Lemma 15.** *For a minimal Schnyder wood of G^σ, Definition 14 yields a minimal Schnyder wood of the σ-suspension of $\tau(G)$.*

▶ **Definition 16.** *Let G be a 3-connected plane graph. Let S be a minimal Schnyder wood of G^σ such that r_1r_3 and r_3r_2 are both edges of G. Define the subgraph H of $\tau(G)$ as follows (Figure 5). Let $V(H) = V(\tau(G))$. The edge set of H is defined in the following. The edges on the outer face of $\tau(G)$ that are either 1-2-colored or 2-3-colored are defined to be in $E(H)$. Now, we define which of the internal edges of $\tau(G)$ are in $E(H)$. For this, we treat the 1-2-colored edges and the 1-3-colored edge like unidirected 1-colored edges. The 2-3-colored edge we treat like a unidirected 2-colored edge. Then, for all $i \in \{1, 2, 3\}$, an internal i-colored edge e of $\tau(G)$ is in $E(H)$ if e and two $(i + 1)$-colored edges form a face. Observe that, by Definition 2c, this face needs to be right of e w.r.t. the orientation of e.*

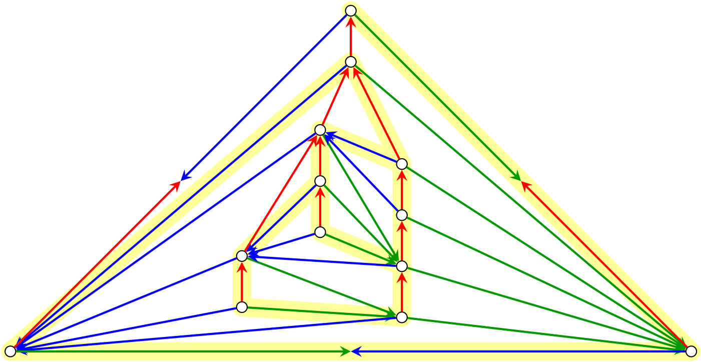


Figure 5 Illustration for the definition of H. H is depicted in yellow.

▶ **Lemma 17.** *As in Definition 16, treat the 1-2-colored edges and the 1-3-colored edge like unidirected 1-colored edges and the 2-3-colored edge like a unidirected 2-colored edge. An edge of $\tau(G)$ with head x is in $E(H)$ if and only if it is the first incoming i-colored edge in clockwise direction at x for some $i \in \{1, 2, 3\}$.*

▶ **Lemma 18.** *H has maximum degree at most 3.*

Sketch of proof. Treat the edges of the outer face of $\tau(G)$ as described in Definition 16. Let $v \in V(H)$ be a vertex that is not a root vertex. It is possible to argue for the root vertices in a similar way. We show that, for every $i \in \{1, 2, 3\}$, of the incoming i-colored and the outgoing $(i + 1)$-colored edges at v there is at most one edge in $E(H)$. Assume that at v there is an incoming edge $e = vy \in E(H)$, and w.l.o.g. e is 2-colored. By Definition 16, e and the outgoing 3-colored edge vx at v form a triangle with another 3-colored edge xy. By Definition 2c, xy is incoming 3-colored at x. Hence, xy precedes vx in clockwise order around x. Thus, by Lemma 17, $vx \notin E(H)$. Furthermore, by Lemma 17, e is the only incoming 2-colored edge at v that is in H.

If at v there is an outgoing edge $vw \in E(H)$, and w.l.o.g. vw is 3-colored. Then, by Definition 16, vw and the at v outgoing 1-colored edge vu are on the boundary of a face together with another 1-colored edge. By Definition 2c, incoming 2-colored edges at v only occur in the clockwise sector between vw and vu. As vw and vu are on the same face, this sector is empty and thus there is no incoming 2-colored edge at v.

Hence, for every $i \in \{1, 2, 3\}$, of the set of the incoming i-colored edges and the outgoing $(i + 1)$-colored edge at v there is at most one edge in $E(H)$. Those three sets cover all edges incident to v and hence $\deg_H(v) \le 3$. Similar arguments show that also the root vertices have degree at most 3. ◀

▶ **Lemma 19.** *H is a subgraph of G.*

Proof. Let $e \in E(\tau(G)) \setminus E(G)$ be w.l.o.g. 3-colored with tail v and head w. In the following, we show that e is no edge of H. This implies that H is a subgraph of G. Let f be the face of $\tau(G)$ that has v and w on the boundary in that clockwise order. Let $e' = wu$ be the edge succeeding e on f in clockwise order. As observed in Definition 14, wu is incoming 3-colored at w (Figure 4). If $w \neq r_3$, then wv is not the in clockwise order first incoming 3-colored edge at w in the sense of Lemma 17. Hence, $wv \notin E(H)$.

So let $w = r_3$. Assume, for the sake of contradiction, that $u = r_1$. The edge $uv = r_1v$ succeeding $wu = r_3r_1$ on f in clockwise order is outgoing 2-colored at u by Definition 14 (Figure 4). The only outgoing 2-colored edge at r_1 is on the clockwise path from r_1 to r_2 on the outer face of $\tau(G)$. And hence, v is on that path. As vr_3 is unidirected, $v \neq r_2$. Hence, $\{v, r_3\}$ is a 2-separator of $\tau(G)$ and thus of G, contradicting the 3-connectivity of G. This implies that $u \neq r_1$ and thus $r_1r_3 \neq wu$. As above, wv is not the in clockwise order first incoming 3-colored edge at w in the sense of Lemma 17, and thus, $wv \notin E(H)$. ◀

▶ **Lemma 20.** *The co-graph $\neg H^*$ of H in G has maximum degree at most 3. All edges in $E(\neg H^*)$ except $(r_1r_3)^*$ are bidirected.*

Sketch of proof. We show that all bidirected edges of G except r_1r_3 are in H. Let $e = xy$ be a bidirected internal edge in G.

Case 1. x and y are both internal vertices of G. Assume that e is w.l.o.g. a 2-3-colored edge in G. By Definition 14, e becomes 2-colored and is on a face with two 3-colored edges e_1 and e_2 in $\tau(G)$. As x and y are both internal vertices, e_1 and e_2 are both internal edges and, by Lemma 5, unidirected. And thus, $e \in E(H)$ by Definition 16.

Case 2. x and y are both on the outer face of G. If they do not appear consecutively, then they form a 2-separator of G, contradicting the 3-connectivity of G. Thus, xy is an edge on the outer face of G. Then, by Definition 16, $e \in E(H)$ if and only if $e \neq r_1r_3$.

Case 3. W.l.o.g. x is on the outer face of G and y is an internal vertex. This case follows with similar arguments as Case 1.

Hence, only $(r_1r_3)^*$ and the dual edges of unidirected edges might be edges of $\neg H^*$. By Corollary 8, the dual edges of unidirected edges in G are bidirected. Also, observe that $(r_1r_3)^*$ is unidirected and points into the outer face of G. Thus, for an internal face f of G only the outgoing edges of f^* might be in $\neg H^*$. Hence, $\deg_{\neg H^*}(f^*) \leq 3$. As, by Definition 16, only one edge on the boundary of the outer face of G is not in H, the dual of the outer face has degree 1 in $\neg H^*$. ◀

The following definition and lemmas are in preparation of the final statement (Proposition 26) of this section. They study the structure of $\tau(G)$ under the assumption that H is not connected. In the end, they allow us to show that if H is not connected, then there is a 3-separator in G (Figure 6). This yields that if G is 4-connected, then H is connected.

▶ **Definition 21.** *For $x \in V(\tau(G))$, define $DFS(x)$ to be the DFS-index of x for a depth first search on T_1 that starts at r_1 and explores the children of each vertex in counterclockwise order.*

For a vertex $x \in V(\tau(G))$ let $p_3(x)$ and $p_1(x)$ be the parent of x in T_3 and T_1, respectively (Figure 6). Let $c_2(x)$ be the vertex such that $c_2(x)x$ is the clockwise first incoming 2-colored edge at x if existent, i.e., $c_2(x)$ is the clockwise first child of x in T_2. Define $ld(x)$ ("leftmost descendant") to be the descendant v of x in T_1 such that v is a leaf of T_1 and $DFS(v)$ is minimal.

For a set of vertices $S \subseteq V(\tau(G))$ denote the set of the descendants of S in T_1 by $desc(S)$. Define $desc^+(S) := desc(S) \cup S$.

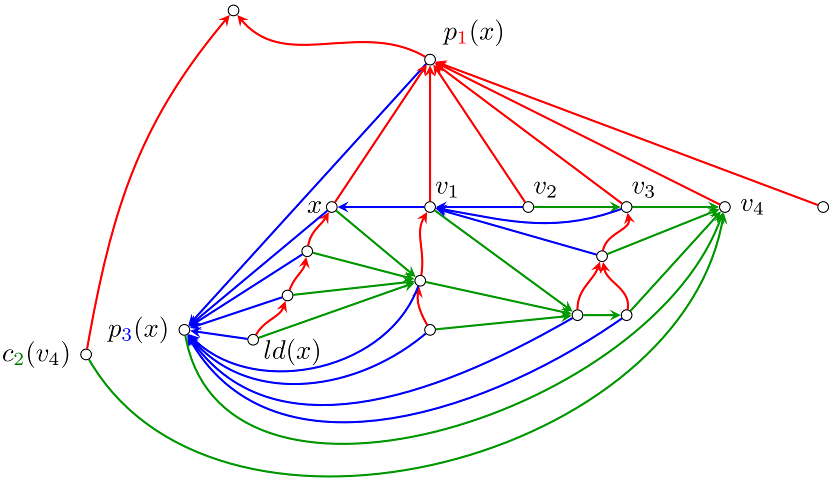

Figure 6 Illustration for Proposition 26. If x is not connected to a vertex with smaller DFS-index in H, then $p_3(x)$, $p_1(x)$ and $v_j = v_4$ form a separating triangle.

▶ Remark 22. Remember that, by Lemma 4, ${T_1}^{-1} \cup T_2 \cup {T_3}^{-1}$ is acyclic. Observe that the DFS-index is a total order of ${T_1}^{-1} \cup T_2 \cup {T_3}^{-1}$. E.g. for an edge xy that is 1-colored incoming at y we have that $DFS(x) > DFS(y)$.

Also, observe that we obtain the path from x to $ld(x)$ in T_1 by descending T_1 starting at x and choosing the counterclockwise first child until we hit a leaf of T_1.

▶ **Lemma 23.** *Assume x is not connected to $p_1(x)$ in H, i.e., there is no path in H that has x and $p_1(x)$ as endpoints. Then, the situation in $\tau(G)$ is as follows. Let $v_0, \dots, v_k$ be the DFS-ordered children of $p_1(x)$ in T_1, i.e., $DFS(v_0) < \dots < DFS(v_k)$, and $x = v_t$ for some $t \in \{0, \dots, k\}$. Then, there exists $j \in \{t+1, \dots, k\}$ such that $c_2(v_j)$ exists and is not in $desc^+(v_t, \dots, v_k)$ (Figure 6). We say that x has property B.*

Proof. Let the *height* of a vertex v in T_1 be the length of a longest oriented path in T_1 from a leaf of T_1 to v. The proof is by induction on the height of $p_1(x)$ in T_1. Assume that this height is one. Then, the vertices $x = v_t, \dots, v_k$ are all leaves in T_1. We now show that if x does not have property B, then x is connected to $p_1(x)$ in H. So assume that for every $i \in \{t+1, \dots, k\}$ either $c_2(v_i)$ does not exist or $c_2(v_i)$ is a vertex of $v_t, \dots, v_k$ in T_1.

If $c_2(v_i)$ does not exist, for some $i \in \{t+1, \dots, k\}$, i.e., v_i does not have an incoming 2-colored edge, then, as $\tau(G)$ is internally 3-connected, v_iv_{i-1} exists and is 3-colored by Definition 2c. As $v_ip_1(x)$ and $v_{i-1}p_1(x)$ are 1-colored, v_iv_{i-1} is in H by Definition 16. Otherwise, $c_2(v_i) = v_j$ for some $j \in \{t, \dots, k\}$. As observed in Definition 21, $DFS(c_2(v_i)) < DFS(v_i)$ and hence $j \in \{t, \dots, i-1\}$. Since $c_2(v_i)v_i$ is in $E(H)$ by Lemma 17, v_j and v_i are connected in H. Hence, in any case v_i is connected in H to a vertex v_j with $j \in \{t, \dots, i-1\}$. This finally yields that $x = v_t$ and v_k are connected in H. As $v_kp_1(x)$ is the clockwise first incoming 1-colored edge at $p_1(x)$, $v_kp_1(x)$ is in $E(H)$ by Lemma 17. And thus, $x = v_t$ and $p_1(x)$ are connected in H.

Assume that the height of $p_1(x)$ is at least two. Again, we show that if x does not have property B, then x and $p_1(x)$ are connected in H. As before, we observe that if $c_2(v_i)$ does not exist for some $i = t+1, \dots, k$, then v_i and v_{i-1} are connected in H. Also, if $c_2(v_i) = v_j$ for some $j \in \{t, \dots, k\}$, then $j < i$ and v_j and v_i are connected in H.

So assume that $c_2(v_i)$ is a descendant of v_j, $j \in \{t, \ldots, k\}$. For the same reason as above, $j \in \{t, \ldots, i-1\}$. Let P be the 1-colored path from $c_2(v_i)$ to v_j in $\tau(G)$. P, $c_2(v_i)v_i$, $v_i p_1(x)$ and $v_j p_1(x)$ form a cycle C. Observe that all vertices of C except for $p_1(x)$ are descendants of $p_1(x)$. Thus, by planarity, for every vertex in the interior of C the outgoing 1-colored path meets $p_1(x)$ or a descendant of $p_1(x)$. And thus, all vertices in the interior of C are descendants of $p_1(v)$ in T_1. Let $y \neq v_j$ be a vertex of P. As $p_1(y)$ is a descendant of $p_1(x)$, it has smaller height in T_1 than $p_1(x)$. We want to apply induction on y. Hence, we need to show that y does not have property B.

Assume, for the sake of contradiction, that y has property B. Then, there is a child z of $p_1(y)$ such that $DFS(y) < DFS(z)$, $c_2(z)$ exists and for every child b of $p_1(y)$ with $DFS(y) \leq DFS(b)$, $c_2(z)$ is neither a descendant nor $c_2(z) = b$. Especially, $DFS(c_2(z)) < DFS(y)$. All vertices of C and all vertices in its interior, except for vertices on the 1-colored path from $p_1(y)$ to $p_1(x)$, have a higher DFS-index than y. By Lemma 4, $c_2(z)$ cannot be on this path from $p_1(y)$ to $p_1(x)$. Thus, $c_2(z)$ cannot occur on C or in its interior. And hence, $c_2(z)$ needs to be in the exterior of C. As all neighbors of y that have a higher DFS-index than y are in the interior of C, we have that z is in the interior of C. Hence, $c_2(z)$ is in the exterior and z is in the interior of C, violating planarity.

This yields that y does not have property B and by induction y and $p_1(y)$ are connected in H. This holds for every vertex on $P \setminus \{v_j\}$. Thus, v_j and $c_2(v_i)$ are connected in H. By Lemma 17, $c_2(v_i)v_i \in E(H)$, and thus v_j and v_i are connected in H. As before, we obtain that x and $p_1(x)$ are connected in H. ◀

▶ **Lemma 24.** *If $x \in V(\tau(G)) \setminus \{r_1\}$ is not connected to a vertex v with $DFS(v) < DFS(x)$ in H, then x is not connected to $p_1(x)$ in H and x is the child of $p_1(x)$ in T_1 with smallest DFS-index. Furthermore, all vertices w on the x-$ld(x)$-path in T_1 are connected to x in H. And we have for all vertices w on the $p_1(x)$-$ld(x)$-path in T_1 that $p_3(w) = p_3(x)$ (Figure 6).*

Proof. Let $x \in V(\tau(G))$ such that x is not connected to a vertex v with $DFS(v) < DFS(x)$. Let $v_0, \ldots, v_k$ be the DFS-ordered children of $p_1(x)$ in T_1. First, we show that $x = v_0$. Assume, for the sake of contradiction, that $x = v_j$ with $j \in \{1, \ldots, k\}$. Then, xv_{j-1} has either color 2 or 3. If it has color 3, then, by Definition 16, xv_{j-1} is in H and $DFS(v_{j-1}) < DFS(x)$, a contradiction. If xv_{j-1} has color 2, then this edge is incoming 2-colored at x, by Definition 2c. This implies that $c_2(x)$ exists. $DFS(c_2(x)) < DFS(x)$ and, by Lemma 17, $c_2(x)x \in E(H)$, a contradiction. And hence, $x = v_0$.

Assume, for the sake of contradiction, that there exists a vertex w on the x-$ld(x)$-path in T_1 such that w is not connected to x in H. Choose w such that $DFS(w)$ is minimal. Then, $p_1(w)$ is connected to x in H, and hence, w is not connected to $p_1(w)$ in H. Thus, by Lemma 23, w has property B. Let $w = w_0, \ldots, w_k$ be the DFS-ordered children of $p_1(w)$ in T_1. Let j be the maximal index such that $c_2(w_j)$ exists and is not a descendant of $p_1(w)$. Since w has property B, j exists. Since j is maximal, w_j does not have property B. Hence, by Lemma 23, it is connected to $p_1(w)$ in H and thus to x. Since $c_2(w_j)w_j \in E(H)$, x is connected to $c_2(w_j)$ in H.

As observed in Definition 21, $DFS(c_2(w_j)) < DFS(w_j)$. The DFS-indices of the vertices $w_0, \ldots, w_{j-1}$ and their descendants are exactly the indices in between $DFS(w_j)$ and $DFS(w_0)$. And the DFS-indices of the vertices on the $p_1(w)$-x-path are exactly the indices in between $DFS(p_1(w))$ and $DFS(x)$. By Lemma 4, $c_2(w_j)$ cannot be on the $p_1(w)$-x-path. Hence, $DFS(c_2(w_j)) < DFS(x)$, a contradiction. Hence, w is connected to x in H.

As all vertices on the x-$ld(x)$-path in T_1 are connected to x in H, they all do not have incoming 2-colored edges. Indeed, incoming 2-colored edges at those vertices would connect x to a vertex with smaller DFS-index. Since every vertex on the x-$ld(x)$-path needs to form a triangle with its parent, the vertex and the parent send their 3-colored outgoing edge to the same vertex $p_3(x)$. ◀

Similar arguments are used to show the following lemma.

▶ **Lemma 25.** *Let $x \in V(\tau(G)) \setminus \{r_1\}$ be not connected to a vertex v with $DFS(v) < DFS(x)$ in H. Let $x = v_0, \dots, v_k$ be the DFS-ordered children of $p_1(x)$ in T_1. Let v_j be the vertex of smallest index such that $c_2(v_j)$ exists and is not in $desc^+(v_0, \dots, v_{j-1})$. Then, the edge $v_j p_3(x)$ is in $E(\tau(G))$.*

▶ **Proposition 26.** *If G is 4-connected, then H is connected.*

Proof. Observe that if G is 4-connected, then so is $\tau(G)$. We show that every vertex $x \neq r_1$ is connected in H to a vertex with lower DFS-index. Assume, for the sake of contradiction, that x is not connected to a vertex with lower DFS-index. With the help of the previous lemmas we show that $p_3(x)$, $p_1(x)$ and v_j (as defined in Lemma 23) form a 3-separator in H. Let $v_0, \dots, v_k$ be the DFS-ordered children of $p_1(x)$ in T_1.

By Lemma 23, there exists a vertex v_j, $j \in \{1, \dots, k\}$ of smallest DFS-index such that $c_2(v_j)$ exists and is not in $desc^+(v_0, \dots, v_{j-1})$. Observe that $p_1(x)v_j$ is an edge of $\tau(G)$.

By Lemma 24, $x = v_0$ and all vertices on the $p_1(x)$-$ld(x)$-path in T_1 send their 3-colored outgoing edge to the same vertex $p_3(x)$. Thus, $p_1(x)p_3(x) \in E(\tau(G))$.

By Lemma 25, the edge $v_j p_3(x)$ exists in $\tau(G)$. Hence, the edges $v_j p_3(x)$, $p_1(x)p_3(x)$ and $p_1(x)v_j$ form a triangle in $\tau(G)$. The vertex x is in the interior of this triangle. Assume, for the sake of contradiction, that r_1 is not in the exterior of this triangle. Then, $r_1 = p_1(x)$ and, by Lemma 24, $x = r_3$. By Definition 16, r_3 is connected to r_1 by the clockwise path on the outer face from r_1 to r_3. As $DFS(r_1) < DFS(r_3)$, we arrive at a contradiction. Hence, r_1 is in the exterior of the triangle of $v_j p_3(x)$, $p_1(x)p_3(x)$, i.e., this triangle is a separating triangle in $\tau(G)$, contradicting the 4-connectivity of $\tau(G)$. This yields that every vertex, except for r_1, is connected to a vertex with lower DFS-index in H, and thus H is connected. ◀

4 A Tree of Maximum Degree 3 and a Co-Tree of Maximum Degree 4

In this section, we give one lemma on the structure of ordered path partitions. Then, we finally prove the main theorem.

We want to remind the reader of the definition of ordered path partitions and the fact that the maximal 2-3-colored paths of a Schnyder wood yield the compatible ordered path partition $\mathcal{P}^{2,3}$.

▶ **Lemma 27** ([20]). *Let G be a 4-connected plane graph, S be the minimal Schnyder wood of G^σ and $\mathcal{P}^{2,3} = (P_0, \dots, P_s)$ be the ordered path partition that is compatible with S. Let $P_i := (v_1, \dots, v_k) \neq P_0$ be a path of $\mathcal{P}^{2,3}$ and v_0 and v_{k+1} be its left and right neighbor. Then, every edge $v_l w \notin \{v_0v_1, v_kv_{k+1}\}$ with $v_l \in P_i$ and $w \in V_{i-1}$ is unidirected, 1-colored and incoming at v_k and $w \notin \{v_0, v_{k+1}\}$.*

▶ **Theorem 28.** *Every 4-connected planar graph G contains a 3-tree such that its co-tree is a 4-tree.*

Sketch of proof. Let S be a minimal Schnyder wood of G such that r_1r_3 and r_3r_2 are both edges of G. By Lemma 9, the completion $\widetilde{G}_S$ of G contains no clockwise directed cycle. By

Proposition 26 and Lemma 19, G has a connected subgraph H as defined in Definition 16. It has maximum degree at most 3 by Lemma 18, and its co-graph has maximum degree at most 3 by Lemma 20. Now, we define a subset D of the edges of H such that $H - D$ becomes acyclic and the degree of its co-graph does not exceed 4.

Let C be a cycle in H. Let $\mathcal{P}^{2,3} = (P_0, \dots, P_s)$ be the compatible ordered path partition of S. Let P be the path of maximal length in C such that $P \subseteq P_M = (v_1, \dots, v_k)$ with $M := \max\{i \mid P_i \cap V(C) \neq \emptyset\}$. P is the *index maximal* subpath of C.

Since $P \subseteq P_M$ is the index maximal subpath of the cycle C, there need to be two edges in H that join a vertex of P with a vertex of V_{M-1}. Say that those edges are the *associated* edges of P. Remember that $V_i := \bigcup_{q=0}^{i} V(P_q)$. The Schnyder wood S is minimal. Hence, by Lemma 27, every edge except for v_0v_1 and v_kv_{k+1} that joins a vertex of P_M with a vertex of V_{M-1} is unidirected, 1-colored and incoming in v_k. Let e_P be the clockwise first incoming 1-colored edge at v_k if existent. Otherwise, let e_P be v_kv_{k+1}. It is possible to show that v_0v_1 and e_P are the only edges in H that join a vertex of P with a vertex of V_{M-1}. This also directly yields that $P = P_M$.

Let $\mathcal{P}_{max}$ be the set of all index maximal subpaths of cycles in H. Now, we need to identify for each $P = (v_1, \dots, v_k) \in \mathcal{P}_{max}$ an edge of the set $E(P) \cup \{v_0v_1, e_P\}$ such that removing those edges leaves H acyclic and connected and does not raise the maximum degree of $\neg H^*$ above 4. Define $D = D_{uni} \cup D_{bi}$ to be this set of edges. Start with $D_{uni} = D_{bi} = \emptyset$.

If e_P is unidirected, add it to D_{uni}. Otherwise, if e_P is bidirected and v_0v_1 is unidirected add v_0v_1 to D_{uni}. By Lemma 20, all edges of $\neg H^*$ except for $(r_1r_3)^*$ are bidirected. As all edges in D_{uni} are unidirected, their duals are bidirected, by Corollary 8. Hence, all edges in $\neg H^* + D^*_{uni}$ except for $(r_1r_3)^*$ are bidirected. By the same reasoning as in the proof of Lemma 20, the maximum degree of $\neg H^* + D^*_{uni}$ is at most 3.

Let $\mathcal{P}^{bi}_{max} \subseteq \mathcal{P}_{max}$ be the paths $P = (v_1, \dots, v_k)$ such that both v_0v_1 and e_P are bidirected. Observe that in this case $e_P = v_kv_{k+1}$. Hence, we now are in the same situation as in the proof of the main theorem of [20]. We are able to apply the exact same arguments in order to obtain the desired set D_{bi} such that $H - D$ becomes acyclic and $\neg H^* + D^*$ remains acyclic and has maximum degree at most 4. Since H has maximum degree at most 3, so does $H - D$. And thus, $H - D$ and $\neg H^* + D^*$ are the desired trees. ◀

C_{2k+1}-Coloring of Bounded-Diameter Graphs

Marta Piecyk
Warsaw University of Technology, Poland

Abstract

For a fixed graph H, in the graph homomorphism problem, denoted by Hom(H), we are given a graph G and we have to determine whether there exists an edge-preserving mapping $\varphi : V(G) \to V(H)$. Note that Hom(C_3), where C_3 is the cycle of length 3, is equivalent to 3-Coloring. The question of whether 3-Coloring is polynomial-time solvable on diameter-2 graphs is a well-known open problem. In this paper we study the Hom(C_{2k+1}) problem on bounded-diameter graphs for $k \geq 2$, so we consider all other odd cycles than C_3. We prove that for $k \geq 2$, the Hom(C_{2k+1}) problem is polynomial-time solvable on diameter-$(k+1)$ graphs – note that such a result for $k = 1$ would be precisely a polynomial-time algorithm for 3-Coloring of diameter-2 graphs. Furthermore, we give subexponential-time algorithms for diameter-$(k+2)$ and -$(k+3)$ graphs.

We complement these results with a lower bound for diameter-$(2k+2)$ graphs – in this class of graphs the Hom(C_{2k+1}) problem is NP-hard and cannot be solved in subexponential-time, unless the ETH fails.

Finally, we consider another direction of generalizing 3-Coloring on diameter-2 graphs. We consider other target graphs H than odd cycles but we restrict ourselves to diameter 2. We show that if H is triangle-free, then Hom(H) is polynomial-time solvable on diameter-2 graphs.

1 Introduction

A natural approach to computationally hard problems is to restrict the class of input graphs, for example by bounding some parameters. One of such parameters is the diameter, i.e., for a graph G, its diameter is the least integer d such that for every pair of vertices u, v of G, there is a u-v path on at most d edges. We say that G is a diameter-d graph, if its diameter is at most d. Recently, bounded-diameter graphs received a lot of attention [23, 20, 25, 3, 2, 24, 9, 6]. It is known that graphs from real life applications often have bounded diameter, for instance social networks tend to have bounded diameter [30]. Furthermore, almost all graphs have diameter 2, i.e., the probability that a random graph on n vertices has diameter 2 tends to 1 when n tends to infinity [21]. Therefore, solving a problem on bounded-diameter graphs captures a wide class of graphs. On the other hand, not all of the standard approaches can be used – note that the class of diameter-d graphs is not closed under vertex deletion.

Even if we consider the class of diameter-2 graphs, its members can contain any graph as an induced subgraph. Indeed, consider any graph G, and let G^+ be the graph obtained from G by adding a universal vertex u, i.e., we add vertex u and make it adjacent to all vertices of G. It is straightforward to observe that the diameter of G^+ is at most 2. This construction

can be used for many graph problems on diameter-2 graphs as a hardness reduction, which proves that they cannot be solved in subexponential time under the Exponential Time Hypothesis (ETH, see [19]), for instance Max Independent Set.

The construction of G^+ also gives us a reduction from $(k-1)$-Coloring to k-Coloring on diameter-2 graphs, and thus for any $k \geq 4$, the k-Coloring problem on diameter-2 graphs is NP-hard and cannot be solved in subexponential time, unless the ETH fails. Note that this argument does not work for $k = 3$ since then we reduce from 2-Coloring, which is polynomial-time solvable. A textbook reduction from NAE-SAT implies that for $d \geq 4$, the 3-Coloring problem is NP-hard and cannot be solved in subexponential-time, unless the ETH fails [28]. Therefore, it is only interesting to study 3-Coloring on diameter-2 and -3 graphs. Mertzios and Spirakis proved that 3-Coloring is NP-hard on diameter-3 graphs [25]. However, the question of whether 3-Coloring can be solved in polynomial time on diameter-2 graphs remains open.

For 3-Coloring on diameter-2 graphs, subexponential-time algorithms were given, first by Mertzios and Spirakis with running time $2^{\mathcal{O}(\sqrt{n \log n})}$ [25]. This was later improved by Dębski, Piecyk, and Rzążewski, who gave an algorithm with running time $2^{\mathcal{O}(n^{1/3} \cdot \log^2 n)}$ [9]. They also provided a subexponential-time algorithm for 3-Coloring for diameter-3 graphs.

The 3-Coloring problem on bounded-diameter graphs was also intensively studied on instances with some additional restrictions, i.e., on graphs with some forbidden induced subgraphs – and on such graph classes polynomial-time algorithms were given [23, 20, 24].

One of the generalizations of graph coloring are homomorphisms. For a fixed graph H, in the graph homomorphism problem, denoted by Hom(H), we are given a graph G, and we have to determine whether there exists an edge-preserving mapping $\varphi : V(G) \to V(H)$, i.e., for every $uv \in E(G)$, it holds that $\varphi(u)\varphi(v) \in E(H)$. Observe that for K_k being a complete graph on k vertices, the Hom(K_k) problem is equivalent to k-Coloring. Observe also that the problem is trivial when H contains a vertex x with a loop since we can map all vertices of G to x. In case when H is bipartite, in fact we have to verify whether G is bipartite and this can be done in polynomial time. Hell and Nešetřil proved that for all other graphs H, i.e., loopless and non-bipartite, the Hom(H) problem is NP-hard [18]. Such a complete dichotomy was provided by Feder, Hell, and Huang also for the list version of the problem [13]. The graph homomorphism problem and its variants in various graph classes and under various parametrizations received recently a lot of attention [26, 15, 14, 4, 5, 7, 8, 14, 27, 17]. We also point out that among all target graphs H, odd cycles received a lot of attention [16, 1, 10, 31, 22]. Note that the cycle on 5 vertices is the smallest graph H such that the Hom(H) problem is not equivalent to graph coloring.

Our contribution. In this paper we consider the Hom(C_{2k+1}) problem on bounded-diameter graphs, where C_{2k+1} denotes the cycle on $2k+1$ vertices. Note that for $k = 1$, we have C_3, so this problem is equivalent to 3-Coloring. In this work we consider all other values of k. Our first result is the following.

▶ **Theorem 1.** *Let $k \geq 2$. Then Hom(C_{2k+1}) can be solved in polynomial time on diameter-$(k+1)$ graphs.*

Note that such a result for $k = 1$ would yield a polynomial-time algorithm for 3-Coloring on diameter-2 graphs. Let us discuss the crucial points where this algorithm cannot be applied directly for $k = 1$. The first property, which holds for every cycle except C_3 and C_6, is that if for some set S of vertices, any two of them have a common neighbor, then there is a vertex that is a common neighbor of all vertices of S. Furthermore, for every cycle of length at least 5 except C_6, for a set S of 3 vertices, every vertex of S has a private neighbor with respect to S, i.e., a neighbor that is non-adjacent to any other vertex of S.

Table 1 Complexity of $\textsc{Hom}(C_{2k+1})$ on bounded-diameter graphs. The symbol in the cell (k, d) denotes that $\textsc{Hom}(C_{2k+1})$ on diameter-d, resp., P – is polynomial-time solvable, NP-h – is NP-hard, S – can be solved in subexponential time, and NS – cannot be solved in subexponential time under the ETH. The rows for $k \geq 2$ are filled due to Theorems 1–3. The first row is based on [25, 9].

k / diam	1	2	3	4	5	6	7	8	9	≥ 10
1	P	S	S, NP-h	NS	NS	NS	NS	NS	NS	NS
2	P	P	P	S	S	NS	NS	NS	NS	NS
3	P	P	P	P	S	S	?	?	NS	NS
4	P	P	P	P	P	S	S	?	?	NS
≥ 5	P	P	P	P	P	P	S	S	?	?

We first show that for an instance of $\textsc{Hom}(C_{2k+1})$, for each vertex v we can deduce the set of vertices it can be mapped to and define a list of v – all lists are of size at most 3. The properties discussed above allow us to encode coloring of a vertex with list of size 3 using its neighbors with lists of size two, and such a reduced instance of a slightly more general problem (we have more constraints than just the edges, but all of them are binary) can be solved in polynomial time by reduction to 2-SAT, similar to the one of Edwards [11].

Furthermore, we give subexponential-time algorithms.

▶ **Theorem 2.** *Let $k \geq 2$. Then $\textsc{Hom}(C_{2k+1})$ can be solved in time:*

(1.) $2^{\mathcal{O}((n \log n)^{\frac{k+1}{k+2}})}$ *on diameter-$(k+2)$ n-vertex graphs,*

(2.) $2^{\mathcal{O}((n \log n)^{\frac{k+2}{k+3}})}$ *on diameter-$(k+3)$ n-vertex graphs.*

Here the branching part of the algorithm is rather standard. The more involved part is to show that after applying braching and reduction rules we are left with an instance that can be solved in polynomial time. Similar to Theorem 1, we first analyze the lists of all vertices, and then reduce to an instance of more general problem where all lists are of size at most 2.

We complement Theorem 1 and Theorem 2 with the following NP-hardness result – since our reduction from 3-SAT is linear, we also prove that the problem cannot be solved in subexponential time under the ETH. The summary of the results is presented in Table 1.

▶ **Theorem 3 (♠).** *Let $k \geq 2$. Then $\textsc{Hom}(C_{2k+1})$ is NP-hard on diameter-$(2k+2)$ graphs (of radius $k+1$) and cannot be solved in subexponential time, i.e., there is no algorithm solving every n-vertex instance G of $\textsc{Hom}(C_{2k+1})$ in time $2^{o(n)} \cdot n^{\mathcal{O}(1)}$, unless the ETH fails.*

The next direction we study in the paper is the following. Instead of considering larger odd cycles and apropriate diameter, we focus on diameter-2 input graphs, but we change the target graph to arbitrary H. Note that it only makes sense to consider graphs H of diameter-2, since the homomorphic image of a diameter-2 graph has to induce a diameter-2 subgraph. We consider triangle-free target graphs. We point out that the class of triangle-free diameter-2 graphs is still very rich, for instance, contains all Mycielski graphs.

▶ **Theorem 4.** *Let H be a triangle-free graph. Then the $\textsc{Hom}(H)$ problem can be solved in polynomial time on diameter-2 graphs.*

Finally, let us point out that we actually prove stronger statements of Theorem 1, Theorem 2, Theorem 4 as we consider more general list version of the problem.

The proofs of statements marked with ♠ can be found in the full version of the paper [29].

2 Preliminaries

For a vertex v, by $N_G(v)$ we denote the neighborhood of v in G, and for a set $U \subseteq V(G)$, we denote $N_G(U) := \bigcup_{u \in U} N_G(u) \setminus U$. By $\text{dist}_G(u,v)$ we denote the length (number of edges) of a shortest u-v path in G. For a positive integer d, by $N_G^{\leq d}(v)$ we denote the set of all vertices $u \in V(G)$ such that $\text{dist}_G(u,v) \leq d$. If G is clear from the contex, we omit the subscript G and simply write $N(v)$, $N(U)$, $N^{\leq d}(v)$, and $\text{dist}(u,v)$. A *diameter* of G, denoted by $\text{diam}(G)$, is the maximum $\text{dist}(u,v)$ over all pairs of vertices $u, v \in V(G)$. We say that G is *diameter-d* graph if $\text{diam}(G) \leq d$. A *radius* of G is the minimum integer r such that there is a vertex $z \in V(G)$ such that for every $v \in V(G)$, it holds that $\text{dist}(v,z) \leq r$. By $[n]$ we denote the set $\{1,2,\ldots,n\}$ and by $[n]_0$ we denote $\{0,1,\ldots,n\}$. Throughout this paper all graphs we consider are simple, i.e., no loops, no multiple edges.

Homomorphisms. For graphs G, H, a homomorphism from G to H is an edge-preserving mapping $\varphi : V(G) \to V(H)$, i.e., for every $uv \in E(G)$, it holds $\varphi(u)\varphi(v) \in E(H)$. For fixed H, called *target*, in the homomorphism problem, denoted by $\text{Hom}(H)$, we are given a graph G, and we have to determine whether there exists a homomorphism from G to H. In the list homomorphism problem, denoted by $\text{LHom}(H)$, G is given along with lists $L : V(G) \to 2^{V(H)}$, and we have to determine if there is a homomorphism φ from G to H which additionally respects lists, i.e., for every $v \in V(G)$ it holds $\varphi(v) \in L(v)$. We will write $\varphi : G \to H$ (resp. $\varphi : (G,L) \to H$) if φ is a (list) homomorphism from G to H, and $G \to H$ (resp. $(G,L) \to H$) to indicate that such a (list) homomorphism exists. Since the graph homomorphism problem generalizes graph coloring we will often refer to homomorphism as coloring and to vertices of H as colors. For an instance (G,L) and an induced subgraph G' of G while refering to a subinstance $(G', L|_{G'})$, we will often simply write (G', L).

Cycles. Whenever C_{2k+1} is the target graph, we will denote its vertex set by $[2k]_0$, unless stated explicitly otherwise. Moreover, whenever we refer to the vertices of the $(2k+1)$-cycle, i.e., cycle on $2k+1$ vertices, by $+$ and $-$ we denote respectively the addition and the subtraction modulo $2k+1$.

Lists. For an instance (G,L) of $\text{LHom}(C_{2k+1})$, by V_i we denote the set of vertices v of G such that $|L(v)| = i$. Sometimes we will refer to vertices of V_1 as *precolored vertices*. We also define $V_{\geq i} = \bigcup_{j \geq i} V_j$. We say that a list $L(v)$ is *of type* $(\ell_1, \ldots, \ell_r)$ if $|L(v)| = r+1$ and its vertices can be ordered $c_0, \ldots, c_r$ so that for every $i \in [r-1]_0$, we have that $c_{i+1} = c_i + \ell_i$. For example, for $k \geq 4$, one of the types of the list $\{1,4,6,7\}$ is $(3,2,1)$.

Binary CSP and 2-SAT. For a given set (domain) D, in the Binary Constraint Satisfaction problem (BCSP) we are given a set V of variables, list function $L : V \to 2^D$, and constraint function $C : V \times V \to 2^{D \times D}$. The task is to determine whether there exists an assignment $f : V \to D$ such that for every $v \in V$, we have $f(v) \in L(v)$ and for every pair $(u,v) \in V \times V$, we have $(f(u), f(v)) \in C(u,v)$. Clearly, any instance of $\text{LHom}(H)$ can be seen as an instance of BCSP, where the domain D is $V(H)$, list function remains the same, and for every edge $uv \in E(G)$ we set $C(u,v) = \{(x,y) \mid xy \in E(H)\}$ and for every $uv \notin E(G)$ we set $C(u,v) = V(H) \times V(H)$. We will denote by $\text{BCSP}(H,G,L)$ the instance of BCSP corresponding to the instance (G,L) of $\text{LHom}(H)$. Standard approach of Edwards [11] with a reduction to 2-SAT implies that in polynomial time we can solve an instance of BCSP with all list of size at most two.

▶ **Theorem 5** (Edwards [11]). *Let (V, L, C) be an instance of BCSP over the domain D. Assume that for every $v \in V$ it holds $|L(v)| \leq 2$. Then we can solve the instance (V, L, C) in polynomial time.*

3 Reduction rules and basic observations

In this section we define reduction rules and show some basic observations.

Reduction rules

Let H be a graph and let (G, L) be an instance of $\text{LHom}(H)$. We define the following reduction rules.

(R1) If $H = C_{2k+1}$ and G contains an odd cycle of length at most $2k-1$, then return NO.
(R2) If $H = C_{2k+1}$ and in G there are two $(2k+1)$-cycles with consecutive vertices respectively $c_0, \ldots, c_{2k}$ and $c'_0, \ldots, c'_{2k}$ and such that $c_0 = c'_0$ and $c_i = c'_j$ for some $i, j \neq 0$, then a) if $i = j$, then identify c_ℓ with c'_ℓ for every $\ell \in [2k]$, b) if $i = -j$, then identify c_ℓ with $c'_{(-\ell)}$ for every $\ell \in [2k]$, c) otherwise return NO.
(R3) For every edge uv, if there is $x \in L(u)$ such that $N_H(x) \cap L(v) = \emptyset$, then remove x from $L(u)$.
(R4) If there is $v \in V(G)$ such that $L(v) = \emptyset$, then return NO.
(R5) For every $v \in V(G)$, if there are $x, y \in L(v)$ such that for every $u \in N_G(v)$, we have $N_H(x) \cap L(u) \subseteq N_H(y) \cap L(u)$, then remove x from $L(v)$.
(R6) For a vertex $x \in V(H)$, and vertices $u, v \in V(G)$ such that $L(u) = L(v) = \{x\}$, if $uv \in E(G)$, then return NO, otherwise contract u with v.

Clearly, each of the above reduction rules can be applied in polynomial time. The following lemma shows that the reduction rules are safe.

▶ **Lemma 6.** *After applying each reduction rule to an instance (G, L) of $\text{LHom}(H)$, we obtain an equivalent instance with diameter at most* $\text{diam}(G)$.

Proof. First, any odd cycle cannot be mapped to a larger odd cycle, so the reduction rule (R1) is safe. Furthermore, for any $(2k+1)$-cycle, in any list homomorphism to C_{2k+1}, its consecutive vertices have to be mapped to consecutive vertices of C_{2k+1}. Let $c_0, \ldots, c_{2k}$ and $c'_0, \ldots, c'_{2k}$ be the vertices of two $(2k+1)$-cycles such that $c_0 = c'_0$ and $c_i = c'_j$ for some $i, j \neq 0$. Suppose we are dealing with a yes-instance and let $\varphi : (G, L) \to C_{2k+1}$. Without loss of generality assume that $\varphi(c_0) = \varphi(c'_0) = 0$ and $\varphi(c_i) = \varphi(c'_j) = i$. Then $\varphi(c_s) = s$ for every $s \in [2k]_0$. Moreover, either $j = i$ or $j = -i$, and $\varphi(c'_s) = s$ for every $s \in [2k]_0$ in the first case, or $\varphi(c'_s) = -s$ for every $s \in [2k]_0$ in the second case. Therefore, the reduction rule (R2) is safe.

Let $uv \in E(G)$ be such that there is $x \in L(u)$ such that $N(x) \cap L(v) = \emptyset$. Suppose that there is a list homomorphism $\varphi : (G, L) \to C_{2k+1}$ such that $\varphi(u) = x$. Then v must be mapped to a vertex from $N(x) \cap L(v) = \emptyset$, a contradiction. Thus we can safely remove x from $L(u)$, and (R3) is safe. Clearly, if any list of a vertex is an empty set, then we are dealing with a no-instance and thus (R4) is safe. Finally, assume there is $v \in V(G)$ and $x, y \in L(v)$ such that for every $u \in N_G(v)$, it holds $N_H(x) \cap L(u) \subseteq N_H(y) \cap L(u)$, and suppose there is a list homomorphism $\varphi : (G, L) \to H$ such that $\varphi(v) = x$. Then φ' defined so that $\varphi'(v) = y$ and $\varphi'(w) = \varphi(w)$ for $w \in V(G) \setminus \{v\}$ is also a list homomorphism $(G, L) \to H$. Therefore, (R5) is safe. If two vertices have the same one-element list, then they must be mapped to the same vertex. Since we only consider loopless graphs H, adjacent vertices of G cannot be mapped to the same vertex. Therefore, if two vertices u, v of G have lists $L(v) = L(u) = \{x\}$ for some $x \in V(H)$, then if $uv \in E(G)$ we are dealing with a no-instance. Otherwise, we can identify u and v and thus (R6) is safe. ◀

In the following lemma we describe the lists of vertices that are at some small distance of a precolored vertex.

▶ **Lemma 7.** *Let $k \geq 2$ and let (G, L) be an instance of* LHOM(C_{2k+1})*. Let $u \in V(G)$ be such that $L(u) = \{i\}$ and let $v \in V(G)$ be such that $\operatorname{dist}(u, v) = d$. If none of the reduction rules can be applied, then*
a) *$L(v) \subseteq \{i-d, i-d+2, \ldots, i-2, i, i+2, \ldots, i+d-2, i+d\}$ if d is even,*
b) *$L(v) \subseteq \{i-d, i-d+2, \ldots, i-1, i+1, \ldots, i+d-2, i+d\}$ if d is odd.*

Proof. Let P be a shortest u-v path such that the consecutive vertices of P are $u = p_0, p_1, \ldots, p_d = v$. We have $L(p_0) = \{i\}$. Since the reduction rule (R3) cannot be applied for p_0p_1, we must have $L(p_1) \subseteq \{i-1, i+1\}$. Applying this reasoning to consecutive vertices of the path, for $j \in [d]$, we must have

$$L(v) \subseteq \{i-j, i-j+2, \ldots, i-2, i, i+2, \ldots, i+j-2, i+j\},$$

if j is even,

$$L(v) \subseteq \{i-j, i-j+2, \ldots, i-1, i+1, \ldots, i+j-2, i+j\},$$

if j is odd, which completes the proof. ◀

The next lemma immediately follows from Lemma 7.

▶ **Lemma 8.** *Let $k \geq 2$ and let (G, L) be an instance of* LHOM(C_{2k+1})*. Let $u, w \in V(G)$ be such that $L(u) = \{i\}$ and $L(w) = \{i+1\}$. Let $v \in V(G)$ be such that $\operatorname{dist}(u, v) = \operatorname{dist}(w, v) = k + \ell$. If none of the reduction rules can be applied, then $L(v) \subseteq \{i+k-\ell+1, i+k-\ell+2, \ldots, i+k+\ell+1\}$.*

In the following lemma we show that for a partial mapping $\varphi : V(G) \to [2k]_0$ for $k \geq 2$, for $v \in V(G)$, if every pair (a, b) of its neighbors is precolored so that $\varphi(a)$ and $\varphi(b)$ have a common neighbor in $L(v)$, then φ can be extended to v so that it preserves the edges containing v.

▶ **Lemma 9.** *Let $k \geq 2$, let (G, L) be an instance of* LHOM(C_{2k+1}) *and let $v \in V(G)$. Let $\varphi : N(v) \to [2k]_0$ be a mapping such that for every $a, b \in N(v)$, we have that $N_{C_{2k+1}}(\varphi(a)) \cap N_{C_{2k+1}}(\varphi(b)) \cap L(v) \neq \emptyset$. Then $\bigcap_{u \in N(v)} N_{C_{2k+1}}(\varphi(u)) \cap L(v) \neq \emptyset$.*

Proof. Define $A = \{\varphi(u) \mid u \in N(v)\}$. If $|A| \leq 2$, then the statement clearly follows. We will show that this is the only case. So suppose that $|A| \geq 3$. If two distinct vertices of C_{2k+1} for $k \geq 2$ have a common neighbor, then they must be at distance exactly two. Without loss of generality, let $0, 2 \in A$ and $1 \in L(v)$. Moreover, let $i \in A \setminus \{0, 2\}$. By assumption $N_{C_{2k+1}}(i) \cap N_{C_{2k+1}}(0) \neq \emptyset$, so $i = 2k-1$. On the other hand, $N_{C_{2k+1}}(i) \cap N_{C_{2k+1}}(2) \neq \emptyset$, so $i = 4$. Thus $2k-1 = 4$, a contradiction. ◀

In the next lemma we show that for an odd cycle C and a vertex v there is at least one pair of consecutive vertices of C with equal distances to v.

▶ **Lemma 10.** *Let G be a connected graph, let C be a cycle in G with consecutive vertices $c_0, \ldots, c_{2k}$, and let $v \in V(G) \setminus V(C)$. Then there is $i \in [2k]_0$ such that $\operatorname{dist}(v, c_i) = \operatorname{dist}(v, c_{i+1})$.*

Proof. First observe, that for all i, we have $|\operatorname{dist}(v, c_i) - \operatorname{dist}(v, c_{i+1})| \leq 1$ since $c_i c_{i+1} \in E(G)$. Therefore, going around the cycle the distance from v to c_i can increase by 1, decrease by 1, or remain the same. Since we have to end up with the same value at the end and the length of the cycle is odd, there is at least one pair of consecutive vertices c_i, c_{i+1} such that $\operatorname{dist}(v, c_i) = \operatorname{dist}(v, c_{i+1})$. ◀

4 Polynomial-time algorithm

In this section we prove Theorem 1. In fact we prove a stronger statement for the list version of the problem.

▶ **Theorem 11.** *Let $k \geq 2$. Then* LHOM(C_{2k+1}) *can be solved in polynomial time on diameter-$(k+1)$ graphs.*

Proof. Let (G, L) be an instance of LHOM(C_{2k+1}) such that G has diameter at most $k+1$. First for every $i \in [2k]_0$ we check whether there is a list homomorphism $\varphi : (G, L) \to C_{2k+1}$ such that no vertex is mapped to i, so we look for a list homomorphism to a path which can be done in polynomial time by [12].

If there is no such a list homomorphism, then we know that all colors have to be used and thus we guess $2k+1$ vertices that will be mapped to distinct vertices of C_{2k+1}. Let $c_0, \ldots, c_{2k}$ be the vertices such that c_i is precolored with i. We check whether such a partial assignment satisfies the edges with both endpoints precolored. Moreover, if c_i, c_{i+1} are non-adjacent, we add the edge $c_i c_{i+1}$ – this operation is safe as c_i, c_{i+1} are precolored with consecutive vertices of C_{2k+1} and adding an edge does not increase the diameter. Finally, we exhaustively apply the reduction rules.

Observe that the vertices $c_0, \ldots, c_{2k}$ induce a $(2k+1)$-cycle C. Suppose there is a vertex v that after the above procedure is not on C. By Lemma 10, there is $i \in [2k]_0$ such that $\operatorname{dist}(v, c_i) = \operatorname{dist}(v, c_{i+1}) =: \ell$.

First we show that we cannot have $\ell \leq k$. Suppose otherwise. Let P_1, P_2 be shortest v-c_i-, and v-c_{i+1}-paths, respectively. Let u be the their last common vertex (it cannot be c_i or c_{i+1} as the distances are the same and c_i, c_{i+1} are adjacent). Note that since P_1, P_2 are shortest, the u-c_i-path P_1' obtained from P_1 and the u-c_{i+1}-path P_2' obtained from P_2 have the same length. Therefore we can construct a cycle by taking P_1', P_2' and the edge $c_i c_{i+1}$. The length of the cycle is odd, and it is at most $2k+1$. This cycle contains at least two vertices from C, so either it should be contracted by (R2) or (R1) would return NO. Therefore we cannot have $\ell \leq k$, and thus, since $\operatorname{diam}(G) \leq k+1$, we have $\ell = k+1$.

By Lemma 8, for $v \in V_{\geq 3}$, we have that $L(v) \subseteq \{i+k, i+k+1, i+k+2\}$. Therefore, all lists of our instance have size at most 3. Moreover, each vertex of V_3 has list of type $(1,1)$. Furthermore, since (R3) cannot be applied, for a vertex with list $\{j, j+1, j+2\}$, the possible lists of its neighbors in $G[V_3]$ are then $\{j-1, j, j+1\}$, $\{j, j+1, j+2\}$, and $\{j+1, j+2, j+3\}$.

For a list $\{i, j, r\}$ of type $(1,1)$, where j is the vertex such that $j = i+1$ and $j = r-1$, we will call j the *middle vertex* of $\{i, j, r\}$. For a homomorphism φ we will say that a vertex $v \in V_3$ is *φ-middle*, if φ maps v to the middle vertex of its list.

Now consider a connected component S of $G[V_3]$, let $v \in V(S)$, and let $L(v) = \{j-1, j, j+1\}$. The following claim is straightforward.

▷ Claim 12. Suppose there is a list homomorphism $\varphi : (S, L) \to C_{2k+1}$. Then

(1.) if v is φ-middle, then any $u \in N_S(v)$ with list $\{j-1, j, j+1\}$ cannot be φ-middle, and every $w \in N_S(v)$ with list $\{j-2, j-1, j\}$ or $\{j, j+1, j+2\}$ has to be φ-middle,

(2.) if v is not φ-middle, then every $u \in N_S(v)$ with list $\{j-1, j, j+1\}$ has to be φ-middle, and any $w \in N_S(v)$ with list $\{j-2, j-1, j\}$ or $\{j, j+1, j+2\}$ cannot be φ-middle.

Thus deciding if one vertex of S is φ-middle, already determines for every vertex of S if it is φ-middle or not. It is described more formally in the following claim, whose proof can be found in the full version of the paper [29].

▷ Claim 13 (♠). In polynomial time we can either (1) construct a partition (U_1, U_2) of $V(S)$ (U_1, U_2 might be empty) such that for every list homomorphism $\varphi : (S, L) \to C_{2k+1}$, either all vertices of U_1 are φ-middle and no vertex of U_2 is φ-middle, or all vertices of U_2 are φ-middle and no vertex of U_1 is φ-middle, or (2) conclude that we are dealing with a no-instance.

Therefore, for every connected component S of $G[V_3]$ we solve two subinstances:

(I1) (S, L_1), where for every $v \in V(S)$ with list $\{i-1, i, i+1\}$ for some $i \in [2k]_0$, $L_1(v) = \{i\}$ if $v \in U_1$ and $L_1(v) = \{i-1, i+1\}$ if $v \in U_2$,

(I2) (S, L_2), where for every $v \in V(S)$ with list $\{i-1, i, i+1\}$ for some $i \in [2k]_0$, $L_2(v) = \{i\}$ if $v \in U_2$ and $L_2(v) = \{i-1, i+1\}$ if $v \in U_1$.

Note that both subinstances have all lists of size at most two and thus can be solved in polynomial time by Theorem 5. If for some component in both cases we obtain NO, then we return NO.

Creating a BCSP instance. Let $(V(G), L, C) = \text{BCSP}(C_{2k+1}, G[V_1 \cup V_2], L)$. We will modify now the instance $(V(G), L, C)$ so it is equivalent to the instance (G, L). For every $v \in V_3$ and for every pair of $a, b \in N(v) \cap V_2$, we leave in $C(a, b)$ only these pairs of vertices that have a common neighbor in $L(v)$ – recall that by Lemma 9 this ensures us that there will be color left for v. Furthermore, for every connected component S of $G[V_3]$, we add constraints according to which of the two possibilities S can be properly colored (possibly S can be colored in both cases) as follows. Let $v \in V(S)$ with $L(v) = \{i-1, i, i+1\}$, and without loss of generality assume that $v \in U_1$. The neighbors of v in V_2 have lists $\{i-1, i\}$ and $\{i, i+1\}$. For each such v:

- if S cannot be properly colored so that vertices of U_1 are middle (v is colored with i), we remove $i-1$ and $i+1$ from the lists of neigbors of v,
- if S cannot be properly colored so that vertices of U_1 are not middle (v is colored with one of $i-1, i+1$), we remove i from the lists of neigbors of v.
- Moreover, for every $u \in V(S)$ with list $\{j-1, j, j+1\}$, for every neighbor $u' \in V_2 \cap N(u)$, and for every $v' \in V_2 \cap N(v)$, if $u \in U_1$, then we remove from $C(u', v')$ pairs $(j, i+1)$, $(j, i-1)$, $(j-1, i)$, $(j+1, i)$, and if $u \in U_2$, then we remove from $C(u', v')$ the pairs (j, i), $(j-1, i-1)$, $(j-1, i+1)$, $(j+1, i-1)$, $(j+1, i+1)$.

This completes the construction of BCSP instance $(V(G), L, C)$. By Theorem 5 we solve $(V(G), L, C)$ in polynomial time.

Correctness. The detailed proof of correctness can be found in the full version of the paper [29].

▷ Claim 14 (♠). $(V(G), L, C)$ is a yes-instance of BCSP iff (G, L) is a yes-instance of LHom(C_{2k+1}).

Let us only mention here the idea behind each of introduced constraints. First, we start with $\text{BCSP}(C_{2k+1}, G[V_1 \cup V_2], L)$, so that the assignment restricted to $V_1 \cup V_2$ can be a list homomorphism φ on $(G[V_1 \cup V_2], L)$. The remaining constraints ensure us that we can extend φ to each connected component S of $G[V_3]$. First, we make sure that for every vertex $v \in V(S)$, there is a color left for v in $L(v)$ – it is a necessary condition. Observe that for a vertex v with list $\{i-1, i, i+1\}$, if the neighbors of v in V_2 are mapped so that there is a color left for v, then either they are colored with $i-1, i+1$ and the color left for v is i, or all such neighbors are colored with i, and both $i-1, i+1$ are left for v (unless one of them is not on $L(v)$). Therefore, we can assume that v has the same list as in one of the instances (I1) and (I2). Moreover, because of the last introduced constraint, all vertices of S have lists corresponding to the same instance, say (I1). Finally, if these lists are still present, then we know that (I1) is a yes-instance, and φ can be extended to S. This completes the proof. ◀

5 Subexponential-time algorithms

In this section we prove the following stronger version of Theorem 2.

▶ **Theorem 15.** *Let $k \geq 3$. Then* LHom(C_{2k+1}) *can be solved in time:*

(1.) $2^{\mathcal{O}((n\log n)^{\frac{k+1}{k+2}})}$ *on n-vertex diameter-$(k+2)$ graphs,*

(2.) $2^{\mathcal{O}((n\log n)^{\frac{k+2}{k+3}})}$ *on n-vertex diameter-$(k+3)$ graphs.*

We start with defining branching rules crucial for our algorithm.

Branching rules. Let $k \geq 2$, let (G, L) be an instance of LHom(C_{2k+1}) and let $d \geq \operatorname{diam}(G)$. Let $\mu = \sum_{\ell=2}^{2k+1} \ell \cdot |V_\ell|$. We define the following branching rules.

(B1) If there is a vertex $v \in V_{\geq 2}$ with at least $(\mu \log \mu)^{1/d}$ neighbors in $V_{\geq 2}$, for some $a \in L(v)$, we branch on coloring v with a or not, i.e., we create two instances $I_a = (G, L_a)$, $I'_a = (G, L'_a)$ such that $L_a(u) = L'_a(u) = L(u)$ for every $u \in V(G) \setminus \{v\}$, and $L_a(v) = \{a\}$ and $L'_a(v) = L(v) \setminus \{a\}$.

(B2) We pick a vertex v and branch on the coloring of $N^{\leq d-1}[v] \cap V_{\geq 2}$, i.e., for every mapping f of $N^{\leq d-1}[v] \cap V_{\geq 2}$ that respects the lists, we create a new instance $I_f = (G, L_f)$ such that $L_f(u) = L(u)$ for $u \notin N^{\leq d-1}[v] \cap V_{\geq 2}$ and $L_f(w) = \{f(w)\}$ for $w \in N^{\leq d-1}[v] \cap V_{\geq 2}$.

Algorithm `Recursion Tree`

Let us describe an algorithm that for fixed d takes an instance (G, L) of LHom(C_{2k+1}) with a fixed precolored $(2k+1)$-cycle C and such that $\operatorname{diam}(G) \leq d$, and returns a rooted tree $\mathcal{R}$ whose nodes are labelled with subinstances of (G, L). We first introduce the root r of $\mathcal{R}$ and we label it with (G, L). Then for every node we proceed recursively as follows. Let s be a node labelled with an instance (G', L') of LHom(C_{2k+1}). We first exhaustively apply to (G', L') reduction rules and if some of the reduction rules returns NO, then s does not have any children. Otherwise, if possible, we apply branching rule (B1). We choose $a \in L(v)$ for (B1) as follows. If on $N_{G'[V_{\geq 2}]}(v)$ there are no lists of type (2), then we take any $a \in L(v)$. Otherwise, let S be the most frequent list of type (2) on $N_{G'[V_{\geq 2}]}(v)$, and let $S = \{j-1, j+1\}$ for some $j \in [2k]_0$. Then we take any $a \in L(v) \setminus \{j\}$. After application of (B1), we exhaustively apply reduction rules to each instance. Furthermore, for each instance created by (B1), we create a child node of s and we label it with that instance.

So suppose that (B1) cannot be applied. We proceed as follows.

Case 1: there is no vertex v such that $\operatorname{dist}(v, c_i) = \operatorname{dist}(v, c_{i+1}) = k+3$ for some $i \in [2k]_0$. Then we apply the branching rule (B2) once, we exhaustively apply reduction rules, and again for each instance created by (B2), we introduce a child node of s. The choice of v is not completely arbitrary. If possible, we choose v so that $\operatorname{dist}(v, C) \geq \lceil \frac{d}{2} \rceil$ – note that the cycle C is present in all instances of $\mathcal{R}$.

Case 2: there exists at least one vertex v such that $\mathrm{dist}(v, c_i) = \mathrm{dist}(v, c_{i+1}) = k + 3$ for some $i \in [2k]_0$. For every $i \in [2k]_0$, we choose (if exists) a vertex v such that $\mathrm{dist}(v, c_i) = \mathrm{dist}(v, c_{i+1}) = k+3$, and again, if possible, we choose v so that $\mathrm{dist}(v, C) \geq \lceil \frac{d}{2} \rceil$. For each such v, we apply the branching rule (B2) and exhaustively reduction rules, and the children of s are those introduced for all instances created in all applications of (B2).

In both cases, we do not recurse on the children of s for which we applied (B2). Let us analyze the running time of `Recursion Tree` and properties of the tree $\mathcal{R}$.

▶ **Lemma 16.** *Given an instance (G, L) of* LHom(C_{2k+1}) *with a fixed precolored $(2k+1)$-cycle C and such that $n = |V(G)|$, $\mathrm{diam}(G) \leq d$, the algorithm `Recursion Tree` in time $2^{\mathcal{O}((n \log n)^{\frac{d-1}{d}})}$ returns a tree $\mathcal{R}$ whose nodes are labelled with instances of* LHom(C_{2k+1}) *and (G, L) is a yes-instance if and only if at least one instance corresponding to a leaf of $\mathcal{R}$ is a yes-instance.*

Proof. First we show that for every node s of $\mathcal{R}$ the corresponding instance is a yes-instance if and only if at least one instance corresponding to a child of s is a yes-instance. Let s be a node of $\mathcal{R}$ and let (G', L') be the corresponding instance. The algorithm `Recursion Tree` applies first reduction rules to (G', L') and by Lemma 6, we obtain equivalent instance. Furthermore, we applied to (G', L') either (B1) or (B2) where the branches correspond to all possible colorings of some set of vertices so indeed (G', L') is a yes-instance if and only if at least one instance corresponding to a child of s is a yes-instance. Since the root of $\mathcal{R}$ is labelled with (G, L), we conclude that (G, L) is a yes-instance if and only if at least one instance corresponding to a leaf of $\mathcal{R}$ is a yes-instance.

It remains to analyze the running time. Let $F(\mu)$ be the upper bound on the running time of `Recursion Tree` applied to an instance (G', L') with $\mu = \sum_{\ell=2}^{2k+1} \ell \cdot |V_\ell|$. Let $p(n)$ be a polynomial such that the reduction rules can be exhaustively applied to an instance on n vertices in time $p(n)$ – note that each reduction rule either decreases the number of vertices/sizes of lists or returns NO, so indeed exhaustive application of reduction rules can be performed in polynomial time. Observe that if we apply (B1) to (G', L'), then

$$F(\mu) \leq F\left(\mu - \frac{(\mu \log \mu)^{1/d}}{2k+1}\right) + F(\mu - 1) + 2 \cdot p(n).$$

Indeed, let v be the vertex to which we apply (B1). If there are no lists of type (2) on $N_{G'[V_{\geq 2}]}(v)$, then in the branch where we set $L(v) = \{a\}$, after application of reduction rules, every neighbor of v must have $L(v) \subseteq \{a-1, a+2\}$. If $|L(v)| \geq 2$ and $L(v) \neq \{a-1, a+1\}$, then $|L(v)| \cap \{a-1, a+1\}| < |L(v)|$. Therefore, in this case we decrease sizes of all lists on $N_{G'[V_{\geq 2}]}(v)$. Otherwise, we chose $a \in L(v) \setminus \{j\}$, where $\{j-1, j+1\}$ is the most frequent list of type (2) on $N_{G'[V_{\geq 2}]}(v)$. Since there are exactly $2k+1$ lists of type (2), at least $\frac{1}{2k+1}$-fraction of $N_{G'[V_{\geq 2}]}(v)$ has list of different type than (2) or has list $\{j-1, j+1\}$. Thus, for the branch where we set $L(v) = \{a\}$, the sizes of lists of at least $\frac{1}{2k+1} \cdot (\mu \log \mu)^{1/d}$ vertices decrease. In the branch where we remove a from $L(v)$, we decrease the size of $L(v)$ at least by one. In both branches we apply the reduction rules, so the desired inequality follows.

If we apply (B2) to (G', L') – recall that we stop recursing in this case – and if we are in Case 1, then we obtain

$$F(\mu) \leq (2k+1)^{(\mu \log \mu)^{\frac{d-1}{d}}} \cdot p(n),$$

since we guess the coloring on $N^{\leq d-1}_{G'[V_{\geq 2}]}(v)$ whose size is bounded by $(\mu \log \mu)^{\frac{d-1}{d}}$ (in this case we could not apply (B1) so the degrees in $G'[V_{\geq 2}]$ are bounded by $(\mu \log \mu)^{1/d}$) and the number of possible colors is at most $2k+1$.

In Case 2, we have:

$$F(\mu) \leq (2k+1)^{(2k+1)\cdot(\mu \log \mu)^{\frac{d-1}{d}}} \cdot p(n),$$

where additional $(2k+1)$ in the exponent comes from the fact that we applied (B2) possibly $(2k+1)$ times.

We can conclude that $F(\mu) \leq 2^{\mathcal{O}((\mu \log \mu)^{\frac{d-1}{d}})}$ (see for example [9], proof of Theorem 7) which combined with the inequality $\mu \leq (2k+1)n = \mathcal{O}(n)$ completes the proof. ◀

The following lemma shows that we can solve every instance corresponding to a leaf of $\mathcal{R}$ in polynomial time. We only sketch the proof here – for the full proof see [29].

▶ **Lemma 17** (♠). *Let (G', L') be an instance of* LHom(C_{2k+1}) *such that* $\operatorname{diam}(G') \leq k+3$ *and let C be a fixed precolored $(2k+1)$-cycle. Assume that we applied algorithm* `Recursion Tree` *to (G', L') and let $\mathcal{R}$ be the resulting recursion tree. Let (G, L) be as instance corresponding to a leaf in $\mathcal{R}$. Then (G, L) can be solved in polynomial time.*

Sketch of proof. By Lemma 10, for every vertex u outside the cycle C, there must be $j \in [2k]_0$ such that $\operatorname{dist}(u, c_j) = \operatorname{dist}(u, c_{j+1})$. Since the reduction rules (R1), (R2) cannot be applied and $\operatorname{diam}(G) \leq k+3$, then that distance is either $k+1$, $k+2$, or $k+3$. In case of $k+1$ or $k+2$ by Lemma 8 have that $L(u) \subseteq \{i-2, i-1, i, i+1, i+2\}$ for some $i \in [2k]_0$, and in case of $k+3$ we have $L(u) \subseteq \{i-3, i-2, i-1, i, i+1, i+2, i+3\}$ for some $i \in [2k]_0$.

Moreover, since for (B2), if we could, we chose vertex v whose distance from C is at least $\lceil \frac{d}{2} \rceil$, each vertex of $V_{\geq 3}$ is at distance $\lfloor \frac{d}{2} \rfloor$ from C. Indeed, every vertex u' that was in $N^{\leq d}_{G[V \geq 2]}(v)$ has list of size at most 2, as we guessed a color either for u' or at least one of its neighbors. So for any vertex u left in $V_{\geq 3}$, the shortest u-v path (whose length is at most the diameter d) should contain a vertex from C and length of that path is at least $\operatorname{dist}(v, C) + \operatorname{dist}(u, C)$. So either all vertices outside C were at distance at most $\lfloor \frac{d}{2} \rfloor$ or v was at distance at least $\lceil \frac{d}{2} \rceil$ and thus u is at distance at most $\lfloor \frac{k+3}{2} \rfloor$ from C. If $k > 3$, then $\lfloor \frac{k+3}{2} \rfloor < k$, which by Lemma 7 implies that $L(u)$ is an independent set. Combining the facts, for $u \in V_{\geq 3}$, diam $\leq k+2$, and $k > 3$, we obtain $L(u) = \{i-2, i, i+2\}$. By careful analysis we can prove that the same holds in the remaining cases (♠).

Furthermore, observe that if v is a neighbor of u with list $\{i-2, i, i+2\}$ and the reduction rule (R3) cannot be applied, then the possible list of v is $\{i-1, i+1\}$, $\{i-3, i+1\}$, $\{i-1, i+3\}$, $\{i-3, i-1, i+1\}$, or $\{i-1, i+1, i+3\}$. If for some vertex u with list $\{i-2, i, i+2\}$, some of possible lists is not present on $N(u)$, then we add v with such a list to G and make it adjacent to u. Note that now the diameter of G might increase, but we will not care about the diameter anymore. Moreover, any list homomorphism on $G - v$ can be extended to v, whose degree is 1. So since now, we can assume that for u with list $\{i-2, i, i+2\}$, all lists $\{i-1, i+1\}$, $\{i-3, i+1\}$, $\{i-1, i+3\}$ are present on $N(u)$ – this will allow us to encode coloring of u on its neighbors with lists of size 2.

BCSP instance. We start with $\operatorname{BCSP}(C_{2k+1}, G - V_3, L)$. Then, for every vertex $v \in V_3$ and for every $v', v'' \in V_2 \cap N(v)$, we leave in $C(v', v'')$ only such pairs that have a common neighbor in $L(v)$. Furthermore, for every edge uv with $u, v \in V_3$ and lists $L(u) = \{i-2, i, i+2\}$, $L(v) = \{i-1, i+1, i+3\}$, and for every pair $u', v' \in V_2$ such that $uu', vv' \in E(G)$, we remove (if they are present) from $C(u', v')$ the following pairs: $(i-3, i+2)$, $(i-1, i+4)$, and $(i+3, i-2)$. This completes the construction of (V, L, C), which is equivalent to (G, L) (♠).

Clearly (V, L, C) is constructed in polynomial time. Moreover, since all the lists have size at most 2, by Theorem 5, (V, L, C) can be solved in polynomial time, which completes the proof. ◀

Now we are ready to prove Theorem 15.

Proof of Theorem 15. Let (G, L) be an instance of LHOM(C_{2k+1}) such that diam(G) is at most $d \in \{k+2, k+3\}$. As in Theorem 1, first for every $i \in [2k]_0$, we check in polynomial time whether there is a list homomorphism $\varphi : (G, L) \to C_{2k+1}$ such that no vertex is mapped to i – this can be done by [12]. If there is no such list homomorphism, we guess $2k+1$ vertices $c_0, \ldots, c_{2k}$ which will be colored so that c_i is mapped to i. We add the edges $c_i c_{i+1}$ and we obtain an induced $(2k+1)$-cycle C (if not, then we are dealing with a no-instance). Note that adding edges cannot increase the diameter and since the edges are added between vertices precolored with consecutive vertices, we obtain an equivalent instance.

Now for (G, L) and C as the fixed precolored $(2k+1)$-cycle we use the algorithm `Recursion Tree`, which by Lemma 16 in time $2^{\mathcal{O}((n \log n)^{\frac{d-1}{d}})}$ returns a tree $\mathcal{R}$. Moreover, in order to solve the instance (G, L) it is enough to solve every instance corresponding to a leaf of $\mathcal{R}$ by Lemma 16, and by Lemma 17, we can solve each such instance in polynomial time. Furthermore, since the size of $\mathcal{R}$ is bounded by the running time, the instance (G, L) can be solved in time $2^{\mathcal{O}((n \log n)^{\frac{d-1}{d}})} \cdot n^{\mathcal{O}(1)} = 2^{\mathcal{O}((n \log n)^{\frac{d-1}{d}})}$, which completes the proof. ◀

6 Beyond odd cycles

In this section we consider target graphs other than odd cycles. Instead, we focus on input graphs with diameter at most 2. Since homomorphisms preserve edges, for graphs G, H, a homomorphism $\varphi : G \to H$ and a sequence of vertices $v_1, \ldots, v_k$ forming a path in G, the sequence $\varphi(v_1), \ldots, \varphi(v_k)$ forms a walk in H. Therefore, if G has diameter at most 2, we can assume that H has also diameter at most 2. The following observation is straightforward.

▶ **Observation 18.** *Let G, H be graphs such that G is connected. If there exists a homomorphism $\varphi : G \to H$, then the image $\varphi(V(G))$ induces in H a subgraph with diameter at most* diam(G)*.*

We prove the following stronger version of Theorem 4.

▶ **Theorem 19.** *Let H be a simple triangle-free graph. Then LHOM(H) is polynomial-time solvable on diameter-2 graphs.*

Proof. Let (G, L) be an instance of LHOM(H). We guess the set of colors that will be used – by Observation 18 they should induce a diameter-2 subgraph H' of H. For each such H', we guess $h' = |H'|$ vertices $v_1, \ldots, v_{h'}$ of G that will be injectively mapped to $V(H') = \{x_1, \ldots, x_{h'}\}$. For each tuple $(H', v_1, \ldots, v_{h'})$, we solve the instance (G, L') of LHOM(H'), where $L'(v) = \{x_i\}$ for $v = v_i$, $i \in [h']$ and $L'(v) = L(v)$ otherwise. Note that (G, L) is a yes-instance if and only if at least one instance (G, L') is a yes-instance.

First for every edge $x_i x_j \in E(H')$, if v_i, v_j are non-adjacent, we add the edge $v_i v_j$ to G – note that this operation is safe, since we cannot increase the diameter by adding edges and we only add edges between vertices that must be mapped to neighbors in H'. Therefore, we can assume that the set $V' = \{v_1, \ldots, v_{h'}\}$ induces a copy of H' in G (if not, then we have an extra edge, which means that we are dealing with a no-instance and we reject immediately). Furthermore, we exhaustively apply reduction rules.

So from now on we assume that the instance (G, L') is reduced. We claim that either (G, L') is a no-instance or $V(G) = \{v_1, \ldots, v_{h'}\}$, i.e., after exhaustive application of the reduction rules the graph G is isomorphic to H'. Note that in the latter case we can return YES as an answer.

Suppose there is $v \in V(G) \setminus V'$. Moreover, we choose such v which is adjacent to some vertex of V' (see Figure 1). Suppose that there exists $\varphi : (G, L') \to H'$ and let $x_i = \varphi(v)$. Then v cannot be adjacent to v_i since there are no loops in H'. Furthermore, the only neighbors of v in V' can be the neighbors of v_i. Suppose that there is $v_j \in N_G(v_i) \cap V'$ which is non-adjacent to v. Since the diameter of G is at most 2, then there must be $u \in N_G(v) \cap N_G(v_j)$. Observe that $u \notin V'$. Indeed, v does not have any neighbors in $V' \setminus N_G(v_i)$ and if $u \in N_G(v)$, then there is a triangle uv_iv_j in a copy of H', a contradiction. Furthermore, it must hold that $\varphi(u)$ is adjacent to x_i in H' as u is adjacent to v and $\varphi(v) = x_i$, and similarly, $\varphi(u)$ must be adjacent to x_j as u is adjacent to v_j. Then $\varphi(u)x_ix_j$ forms a triangle in H', a contradiction. Thus v must be adjacent to all vertices of $N(v_i) \cap V'$.

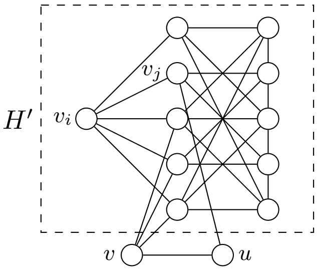

Figure 1 Copy of H' in G and a vertex v such that for some homomorphism φ, it holds $\varphi(v_i) = \varphi(v)$. We show that a vertex u which is a common neighbor of v and some neighbor v_j of v_i in the copy of H' cannot exist.

Since (R3) cannot be applied, each vertex of $L'(v)$ is adjacent to all vertices of $N_H(x_i)$. Moreover, since (R5) cannot be applied, it holds that $L'(v) = \{x_i\}$. Indeed, otherwise there is $x_{i'} \neq x_i$ such that $x_{i'} \in L'(v)$. Recall that $x_{i'}$ is adjacent to all vertices of $N_H(x_i)$. Therefore, $N_H(x_i) \subseteq N_H(x_{i'})$, and thus one of $x_i, x_{i'}$ should have been removed from $L'(v)$ by (R5). Furthermore, since (R6) cannot be applied, we must have $v = v_i \in V'$, a contradiction. This completes the proof. ◀

7 Conclusion

In this paper we studied the computational complexity of Hom(C_{2k+1}) problem on bounded-diameter graphs. We proved that for $k \geq 2$, the Hom(C_{2k+1}) problem can be solved in polynomial-time on diameter-$(k+1)$ graphs and we gave subexponential-time algorithms for diameter-$(k+2)$ and -$(k+3)$ graphs. We also proved that Hom(H) for triangle-free graph H, can be solved in polynomial time on diameter-2 graphs.

The main open problem in this area remains the question whether 3-Coloring on diameter-2 graphs can be solved in polynomial time. However, as more reachable, we propose the following future research directions. (i) Is the Hom(C_{2k+1}) problem NP-hard for the subexponential-time cases, i.e., diameter-$(k+2)$ or -$(k+3)$ graphs? (2) Let H be a diameter-2 graph such that H contains a triangle but $H \not\to K_3$. Is the Hom(H) problem NP-hard?

Demonic Variance and a Non-Determinism Score for Markov Decision Processes

Jakob Piribauer
Technische Universität Dresden, Germany
Universität Leipzig, Germany

Abstract

This paper studies the influence of probabilism and non-determinism on some quantitative aspect X of the execution of a system modeled as a Markov decision process (MDP). To this end, the novel notion of *demonic variance* is introduced: For a random variable X in an MDP $\mathcal{M}$, it is defined as $1/2$ times the maximal expected squared distance of the values of X in two independent execution of $\mathcal{M}$ in which also the non-deterministic choices are resolved independently by two distinct schedulers.

It is shown that the demonic variance is between 1 and 2 times as large as the maximal variance of X in $\mathcal{M}$ that can be achieved by a single scheduler. This allows defining a non-determinism score for $\mathcal{M}$ and X measuring how strongly the difference of X in two executions of $\mathcal{M}$ can be influenced by the non-deterministic choices. Properties of MDPs $\mathcal{M}$ with extremal values of the non-determinism score are established. Further, the algorithmic problems of computing the maximal variance and the demonic variance are investigated for two random variables, namely weighted reachability and accumulated rewards. In the process, also the structure of schedulers maximizing the variance and of scheduler pairs realizing the demonic variance is analyzed.

1 Introduction

In software and hardware systems, uncertainty manifests in two distinct forms: *non-determinism* and *probabilism*. Non-determinism emerges from, e.g., unknown operating environments, user interactions, or concurrent processes. Probabilistic behavior arises through deliberate randomization in algorithms or can be inferred, e.g., from probabilities of component failures. In this paper, we investigate the uncertainty in the value X of some quantitative aspect of a system whose behavior is subject to non-determinism *and* probabilism. On the one hand, we aim to quantify this uncertainty. In the spirit of the variance that quantifies uncertainty in purely probabilistic settings, we introduce the notion of *demonic variance* that generalizes the variance in the presence of non-determinism. On the other hand, we provide a *non-determinism score* (NDS) based on this demonic variance that measures the extent to which the uncertainty of X can be ascribed to the non-determinism.

As formal models, we use Markov decision processes (MDPs, see, e.g., [29]), one of the most prominent models combining non-determinism and probabilism, heavily used in verification, operations research, and artificial intelligence. The non-deterministic choices in an MDP are resolved by a *scheduler*. Once a scheduler is fixed, the system behaves purely probabilistically.

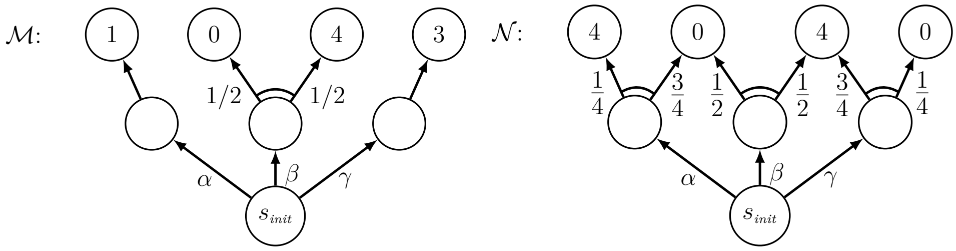

Figure 1 MDPs modeling a communication protocol and the time required to process a message.

Demonic variance. For a random variable Y, the variance is equal to half the expected squared deviation of two independent copies Y_1 and Y_2 of Y:

$$\mathbb{V}(Y) \overset{\text{def}}{=} \mathbb{E}((Y-\mathbb{E}(Y))^2) = \mathbb{E}(Y^2) - \mathbb{E}(Y)^2 = \frac{1}{2}\mathbb{E}(Y_1^2 - 2Y_1Y_2 + Y_2^2) = \frac{1}{2}\mathbb{E}((Y_1-Y_2)^2).$$

For a quantity X in an MDP $\mathcal{M}$, we obtain a random variable $X_{\mathcal{M}}^{\mathfrak{S}}$ for each scheduler $\mathfrak{S}$.[1] The maximal variance $\mathbb{V}_{\mathcal{M}}^{\max}(X) \overset{\text{def}}{=} \sup_{\mathfrak{S}} \mathbb{V}(X_{\mathcal{M}}^{\mathfrak{S}})$ can serve as a measure for the "amount of probabilistic uncertainty" regarding X present in the MDP. However, in the presence of non-determinism, quantifying the spread of outcomes in terms of the squared deviation of two independent executions of a system gives rise to a whole new meaning: We can allow the non-determinism to be resolved independently as well. To this end, we consider two different scheduler $\mathfrak{S}_1$ and $\mathfrak{S}_2$ in two independent copies $\mathcal{M}_1$ and $\mathcal{M}_2$ of $\mathcal{M}$ and define

$$\mathbb{V}_{\mathcal{M}}^{\mathfrak{S}_1,\mathfrak{S}_2}(X) \overset{\text{def}}{=} \frac{1}{2}\mathbb{E}((X_{\mathcal{M}_1}^{\mathfrak{S}_1} - X_{\mathcal{M}_2}^{\mathfrak{S}_2})^2).$$

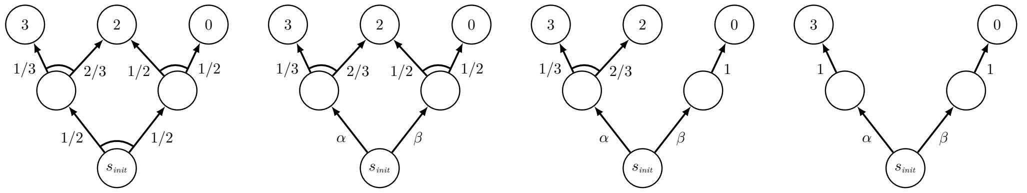
If we now allow for a *demonic* choice of the two schedulers making this uncertainty as large as possible, we arrive at the *demonic variance* $\mathbb{V}_{\mathcal{M}}^{dem}(X) \overset{\text{def}}{=} \sup_{\mathfrak{S}_1,\mathfrak{S}_2} \mathbb{V}_{\mathcal{M}}^{\mathfrak{S}_1,\mathfrak{S}_2}(X)$ of X in $\mathcal{M}$.

▶ **Example 1.1.** To illustrate a potential use case, consider a communication network in which messages are processed according to a randomized protocol employed on different hardware at the different nodes of the network. A low worst-case expected processing time of the protocol is clearly desirable. In addition, however, large differences in the processing time at different nodes make buffering necessary and increase the risk of package losses.

Consider the MDPs $\mathcal{M}$ and $\mathcal{N}$ in Fig. 1 modeling such a communication protocol. Initially, a non-deterministic choice between α, β, and γ is made. Then, a final node containing the processing time X is reached according to the depicted distributions. In both MDPs, the expected value of X lies between 1 and 3 for all schedulers $\mathfrak{S}$ – with the values 1 and 3 being realized by α and γ. Furthermore, as the outcomes lie between 0 and 4, the distribution over outcomes leading to the highest possible variance of 4 is the one that takes value 0 and 4 with probability $\frac{1}{2}$ each, which is realized by a scheduler choosing β. So, $\mathbb{V}_{\mathcal{M}}^{\max}(X) = \mathbb{V}_{\mathcal{N}}^{\max}(X) = 4$.

However, the demonic variances are different: Our results will show that the demonic variance is obtained by a pair of *deterministic* schedulers that do not randomize over the non-deterministic choices. In $\mathcal{M}$, we can easily check that no combination of such schedulers $\mathfrak{S}$ and $\mathfrak{T}$ leads to a value $\mathbb{V}_{\mathcal{M}}^{\mathfrak{S},\mathfrak{T}}(X)$ of more than $4 = \mathbb{V}_{\mathcal{M}}^{\beta,\beta}(X)$ where β denotes the scheduler that chooses β with probability 1. In $\mathcal{N}$, on the other hand, the demonic variance is $\mathbb{V}_{\mathcal{N}}^{dem}(X) = \mathbb{V}_{\mathcal{N}}^{\alpha,\gamma}(X) = \frac{1}{2}\mathbb{E}((X_{\mathcal{N}_1}^{\alpha} - X_{\mathcal{N}_2}^{\gamma})^2) = \frac{1}{2}\left(\frac{10}{16}\cdot 16\right) = 5$.

[1] Note that the notation $X_{\mathcal{M}}^{\mathfrak{S}}$ here differs from the notation used in the technical part of the paper.



(a) NDS $= 0$. **(b)** NDS ≈ 0.32. **(c)** NDS ≈ 0.92. **(d)** NDS $= 1$.

Figure 2 Example MDPs with different non-determinism scores (NDSs).

So, despite the same maximal variance and range of expected values, the worst-case expected squared deviation between two values of X in independent executions is worse in $\mathcal{N}$ than in $\mathcal{M}$. Hence, we argue that the protocol modeled by $\mathcal{M}$ should be preferred.

Non-determinism score (NDS). By the definition of the demonic variance, it is clear that $\mathbb{V}^{dem}_{\mathcal{M}}(X) \geq \mathbb{V}^{\max}_{\mathcal{M}}(X)$. Under mild assumptions ensuring the well-definedness, we will prove that $\mathbb{V}^{dem}_{\mathcal{M}}(X) \leq 2\mathbb{V}^{\max}_{\mathcal{M}}(X)$, too. So, the demonic variance is between 1 and 2 times as large as the maximal variance. We use this to define the *non-determinism score (NDS)*

$$\mathrm{NDS}(\mathcal{M}, X) \overset{\text{def}}{=} \frac{\mathbb{V}^{dem}_{\mathcal{M}}(X) - \mathbb{V}^{\max}_{\mathcal{M}}(X)}{\mathbb{V}^{\max}_{\mathcal{M}}(X)} \in [0,1].$$

The NDS captures how much larger the expected squared deviation of two outcomes can be made by resolving the non-determinism in two executions independently compared to how large it can be solely due to the probabilism under a single resolution of the non-determinism.

▶ **Example 1.2.** For an illustration of the NDS, four simple MDPs and their NDSs are depicted in Figure 2. In all of the MDPs except for the first one, a scheduler has to make a (randomized) choice over actions α and β in the initial state s_{init}. Afterwards one of the terminal states is reached according to the specified probabilities. The terminal states are equipped with a weight that specifies the value of X at the end of the execution. For all of these MDPs, the maximal variance can be computed by expressing the variance in terms of the probability p that α is chosen and maximizing the resulting quadratic function. In the interest of brevity, we do not present these computations. The pair of (deterministic) schedulers realizing the demonic variance always consists of the scheduler choosing α and the scheduler choosing β making it easy to compute the demonic variance in these examples.

Potential applications. First of all, the demonic variance might serve as the basis for refined guarantees on the behavior of systems, in particular, when employed in different environments. As a first result in this direction, we will prove an analogue to Chebyshev's Inequality using the demonic variance. Further, as illustrated in Example 1.1, achieving a low demonic variance or NDS can be desirable when designing systems. Hence, a reasonable synthesis task could be to design a system ensuring a high expected value of a quantity X while keeping the demonic variance of X below a threshold.

Secondly, the demonic variance and the NDS can serve to enhance the explainability of a system's behavior, a topic of growing importance in the area of formal verification (see, e.g., [4] for an overview). More concretely, the NDS can be understood as a measure assigning *responsibility* for the scattering of a quantity X in different executions to the non-determinism and the probabilism present in the system, respectively. Further, considering the NDS for different starting states makes it possible to pinpoint regions of the state space in which the non-determinism has a particularly high influence. Notions of responsibility that quantify to which extent certain facets of the behavior of a system can be ascribed to certain components, states, or events have been studied in various settings [10, 33, 6, 25, 5].

Finally, the NDS can also be understood as a measure for the power of control when non-determinism models controllable aspects of a system. This interpretation could be useful, e.g., when designing exploration strategies in reinforcement learning. Here, the task is to learn good strategies as fast as possible by interacting with a system. One of the main challenges is to decide which regions of the state space to explore (see [21] for a recent survey). Estimations for the NDS starting from different states could be useful here: States from which the NDS is high might be more promising to explore than states from which the NDS is low as the difference in received rewards from such a state is largely subject to randomness.

Contributions. Besides establishing general results for the demonic variance and the NDS, we investigate the two notions for weighted reachability and accumulated rewards. For weighted reachability, terminal states of an MDP are equipped with a weight that is received if an execution ends in this state. For accumulated rewards, all states are assigned rewards that are summed up along an execution. The main contributions of this paper are as follows.

- We introduce the novel notions of demonic variance and non-determinism score. For general random variables X, we prove that the demonic variance is at most twice as large as the maximal variance. Furthermore, we prove an analogue of Chebyshev's inequality. For the non-determinism score, we establish consequences of a score of 0 or 1.
- In the process, we prove a result of independent interest using a topology on the space of schedulers that states that convergence with respect to this topology implies convergence of the corresponding probability measures.
- For weighted reachability, we show that the maximal and the demonic variance can be computed via quadratic programs. For the maximal variance, this results in a polynomial-time algorithm; for the demonic variance, in a separable bilinear program of polynomial size yielding an exponential time upper bound. Further, we establish that there is a memoryless scheduler maximizing the variance and a pair of memoryless deterministic schedulers realizing the demonic variance.
- For accumulated rewards, we prove that the maximal variance and an optimal finite-memory scheduler can be computed in exponential time. Further, we prove that the demonic variance is realized by a pair of deterministic finite-memory schedulers which can be computed via a bilinear program of exponential size.

Related work. We are not aware of investigations of notions similar to the demonic variance for MDPs. Previous work on the variance in MDPs usually focused on the minimization of the variance. In [24], the problem to find schedulers that ensure a certain expected value while keeping the variance below a threshold is investigated for accumulated rewards in the finite horizon setting. It is shown that deciding whether there is a scheduler ensuring variance 0 is NP-hard. In [22], the minimization of the variance of accumulated rewards and of the mean payoff is addressed with a focus on optimality equations and no algorithmic results. The variance of accumulated weights in Markov chains is shown to be computable in polynomial time in [32]. For the mean payoff, algorithms were given to compute schedulers that achieve given bounds on the expectation and notions of variance and variability in [9].

One objective incorporating the variance that has been studied on MDPs is the variance-penalized expectation (VPE) [16, 13, 28]. Here, the goal is to find a scheduler that maximizes the expected reward minus a penalty factor times the variance. In [28], the objective is studied for accumulated rewards. Methodically, our results for the maximal and demonic variance of accumulated rewards share similarities with the techniques of [28] and we make use of some results proved there, such as the result that among expectation-optimal schedulers a variance-optimal memoryless deterministic scheduler can be computed in polynomial time. Nevertheless, the optimization of the VPE inherently requires the minimization of the variance. In particular, it is shown in [28] that deterministic schedulers are optimal for the VPE, while randomization is necessary for the maximization of the variance.

Besides the variance, several other notions that aim to bound the uncertainty of the outcome of some quantitative aspect in MDPs have been studied – in particular, in the context of risk-averse optimization: Given a probability p, quantiles for a quantity X are the best bound B such that X exceeds B with probability at most p in the worst or best case. For accumulated rewards in MDPs, quantiles have been studied in [31, 3, 17, 30]. The *conditional value-at-risk* is a more involved measures that quantifies how far the probability mass of the tail of the probability distribution lies above a quantile. In [20], this notion has been investigated for weighted reachability and mean payoff; in [27] for accumulated rewards. A further measure incentivizing a high expected value while keeping the probability of low outcomes small is the entropic risk measure. For accumulated rewards, this measure has been studied in [2] in stochastic games that extend MDPs with an adversarial player.

Finally, as the demonic variance is a measure that looks at a system across different executions, there is a conceptual similarity to hyperproperties [12, 11]. For probabilistic systems, logics expressing hyperproperties that allow to quantify over different executions or schedulers have been introduced in [1, 15].

2 Preliminaries

Notations for Markov decision processes. A *Markov decision process* (MDP) is a tuple $\mathcal{M} = (S, \mathit{Act}, P, s_{\mathit{init}})$ where S is a finite set of states, Act a finite set of actions, $P\colon S \times \mathit{Act} \times S \to [0,1] \cap \mathbb{Q}$ the transition probability function, and $s_{\mathit{init}} \in S$ the initial state. We require that $\sum_{t\in S} P(s,\alpha,t) \in \{0,1\}$ for all $(s,\alpha) \in S \times \mathit{Act}$. We say that action α is *enabled* in state s iff $\sum_{t\in S} P(s,\alpha,t) = 1$ and denote the set of all actions that are enabled in state s by $\mathit{Act}(s)$. We further require that $\mathit{Act}(s) \neq \emptyset$ for all $s \in S$. If for a state s and all actions $\alpha \in \mathit{Act}(s)$, we have $P(s,\alpha,s) = 1$, we say that s is *absorbing*. The paths of $\mathcal{M}$ are finite or infinite sequences $s_0\,\alpha_0\,s_1\,\alpha_1\dots$ where states and actions alternate such that $P(s_i,\alpha_i,s_{i+1}) > 0$ for all $i \geq 0$. For $\pi = s_0\,\alpha_0\,s_1\,\alpha_1\,\dots\alpha_{k-1}\,s_k$, $P(\pi) = P(s_0,\alpha_0,s_1)\cdot\ldots\cdot P(s_{k-1},\alpha_{k-1},s_k)$ denotes the probability of π and $\mathit{last}(\pi) = s_k$ its last state. Often, we equip MDPs with a reward function $\mathit{rew}\colon S \times \mathit{Act} \to \mathbb{N}$. The *size* of $\mathcal{M}$ is the sum of the number of states plus the total sum of the encoding lengths in binary of the non-zero probability values $P(s,\alpha,s')$ as fractions of co-prime integers as well as the encoding length in binary of the rewards if a reward function is used. A *Markov chain* is an MDP in which the set of actions is a singleton. In this case, we can drop the set of actions and consider a Markov chain as a tuple $\mathcal{M} = (S, P, s_{\mathit{init}}, \mathit{rew})$ where P now is a function from $S \times S$ to $[0,1]$ and rew a function from S to $\mathbb{N}$.

An *end component* of $\mathcal{M}$ is a strongly connected sub-MDP formalized by a subset $S' \subseteq S$ of states and a non-empty subset $\mathfrak{A}(s) \subseteq \mathit{Act}(s)$ for each state $s \in S'$ such that for each $s \in S'$, $t \in S$ and $\alpha \in \mathfrak{A}(s)$ with $P(s,\alpha,t) > 0$, we have $t \in S'$ and such that in the resulting sub-MDP all states are reachable from each other. An end-component is a 0-end-component if it only contains state-action-pairs with reward 0. Given two MDPs $\mathcal{M} = (S, \mathit{Act}, P, s_{\mathit{init}})$ and $\mathcal{N} = (S', \mathit{Act}', P', s'_{\mathit{init}})$, we define the (synchronous) product $\mathcal{M} \otimes \mathcal{N}$ as the tuple $(S \times S', \mathit{Act} \times \mathit{Act}', P^{\otimes}, (s_{\mathit{init}}, s'_{\mathit{init}}))$ where we define $P^{\otimes}((s,s'),(\alpha,\beta),(t,t')) = P(s,\alpha,t)\cdot P(s',\beta,t')$ for all $(s,s'),(t,t') \in S \times S'$ and $(\alpha,\beta) \in \mathit{Act} \times \mathit{Act}'$.

Schedulers. A *scheduler* (also called *policy*) for $\mathcal{M}$ is a function $\mathfrak{S}$ that assigns to each finite path π a probability distribution over $\mathit{Act}(\mathit{last}(\pi))$. If $\mathfrak{S}(\pi) = \mathfrak{S}(\pi')$ for all finite paths π and π' with $\mathit{last}(\pi) = \mathit{last}(\pi')$, we say that $\mathfrak{S}$ is *memoryless.* In this case, we also view schedulers as functions mapping states $s \in S$ to probability distributions over $\mathit{Act}(s)$. A scheduler $\mathfrak{S}$ is called deterministic if $\mathfrak{S}(\pi)$ is a Dirac distribution for each finite path π, in which case we also view the scheduler as a mapping to actions in $\mathit{Act}(\mathit{last}(\pi))$. Given two MDPs $\mathcal{M} = (S, \mathit{Act}, P, s_{\mathit{init}})$ and $\mathcal{N} = (S', \mathit{Act}', P', s'_{\mathit{init}})$ and two schedulers $\mathfrak{S}$ and $\mathfrak{T}$ for $\mathcal{M}$ and $\mathcal{N}$, respectively, we define the product scheduler $\mathfrak{S} \otimes \mathfrak{T}$ for $\mathcal{M} \otimes \mathcal{N}$ by defining for a finite path $\pi = (s_0, t_0)\,(\alpha_0, \beta_0)\,(s_1, t_1)\,\ldots\,(s_k, t_k)$: $\mathfrak{S} \otimes \mathfrak{T}(\pi)(\alpha, \beta) = \mathfrak{S}(s_0\,\alpha_0\,\ldots\,s_k)(\alpha) \cdot \mathfrak{T}(t_0\,\beta_0\,\ldots\,t_k)(\beta)$ for all $(\alpha, \beta) \in \mathit{Act} \times \mathit{Act}'$.

Probability measure. We write $\Pr^{\mathfrak{S}}_{\mathcal{M},s}$ to denote the probability measure induced by a scheduler $\mathfrak{S}$ and a state s of an MDP $\mathcal{M}$. It is defined on the σ-algebra generated by the cylinder sets $\mathit{Cyl}(\pi)$ of all infinite extensions of a finite path $\pi = s_0\,\alpha_0\,s_1\,\alpha_1\,\ldots\alpha_{k-1}\,s_k$ starting in state s, i.e., $s_0 = s$, by assigning to $\mathit{Cyl}(\pi)$ the probability that π is realized under $\mathfrak{S}$, which is $P^{\mathfrak{S}}(\pi) \overset{\text{def}}{=} \prod_{i=0}^{k-1} \mathfrak{S}(s_0\,\alpha_0\ldots\,s_i)(\alpha_i) \cdot P(s_i, \alpha_0, s_{i+1})$. This can be extended to a unique probability measure on the mentioned σ-algebra. For details, see [29]. For a random variable X, i.e., a measurable function defined on infinite paths in $\mathcal{M}$, we denote the expected value of X under a scheduler $\mathfrak{S}$ and state s by $\mathbb{E}^{\mathfrak{S}}_{\mathcal{M},s}(X)$. We define $\mathbb{E}^{\min}_{\mathcal{M},s}(X) \overset{\text{def}}{=} \inf_{\mathfrak{S}} \mathbb{E}^{\mathfrak{S}}_{\mathcal{M},s}(X)$ and $\mathbb{E}^{\max}_{\mathcal{M},s}(X) \overset{\text{def}}{=} \sup_{\mathfrak{S}} \mathbb{E}^{\mathfrak{S}}_{\mathcal{M},s}(X)$. The variance of X under the probability measure determined by $\mathfrak{S}$ and s in $\mathcal{M}$ is denoted by $\mathbb{V}^{\mathfrak{S}}_{\mathcal{M},s}(X)$ and defined by $\mathbb{V}^{\mathfrak{S}}_{\mathcal{M},s}(X) \overset{\text{def}}{=} \mathbb{E}^{\mathfrak{S}}_{\mathcal{M},s}((X - \mathbb{E}^{\mathfrak{S}}_{\mathcal{M},s}(X))^2) = \mathbb{E}^{\mathfrak{S}}_{\mathcal{M},s}(X^2) - \mathbb{E}^{\mathfrak{S}}_{\mathcal{M},s}(X)^2$. We define $\mathbb{V}^{\max}_{\mathcal{M},s}(X) \overset{\text{def}}{=} \sup_{\mathfrak{S}} \mathbb{V}^{\mathfrak{S}}_{\mathcal{M},s}(X)$. If $s = s_{\mathit{init}}$, we sometimes drop the subscript s in $\Pr^{\mathfrak{S}}_{\mathcal{M},s}$, $\mathbb{E}^{\mathfrak{S}}_{\mathcal{M},s}$ and $\mathbb{V}^{\mathfrak{S}}_{\mathcal{M},s}(X)$.

Mixing schedulers. Intuitively, we often want to use a scheduler that initially decides to behave like a scheduler $\mathfrak{S}$ and then to stick to this scheduler with probability p and to behave like a scheduler $\mathfrak{T}$ with probability $1 - p$. As this intuitive description does not match the definition of schedulers as functions from finite paths[2], we provide a formal definition: For two schedulers $\mathfrak{S}$ and $\mathfrak{T}$ and $p \in [0, 1]$, we use $p\mathfrak{S} \oplus (1-p)\mathfrak{T}$ to denote the following scheduler. For a path $\pi = s_0\,\alpha_0\,s_1\,\alpha_1\,\ldots\alpha_{k-1}\,s_k$, we define for an action α enabled in s_k

$$(p\mathfrak{S} \oplus (1-p)\mathfrak{T})(\pi)(\alpha) \overset{\text{def}}{=} \frac{p \cdot P^{\mathfrak{S}}(\pi) \cdot \mathfrak{S}(\pi)(\alpha)}{p \cdot P^{\mathfrak{S}}(\pi) + (1-p) \cdot P^{\mathfrak{T}}(\pi)} + \frac{(1-p) \cdot P^{\mathfrak{T}}(\pi) \cdot \mathfrak{T}(\pi)(\alpha)}{p \cdot P^{\mathfrak{S}}(\pi) + (1-p) \cdot P^{\mathfrak{T}}(\pi)}.$$

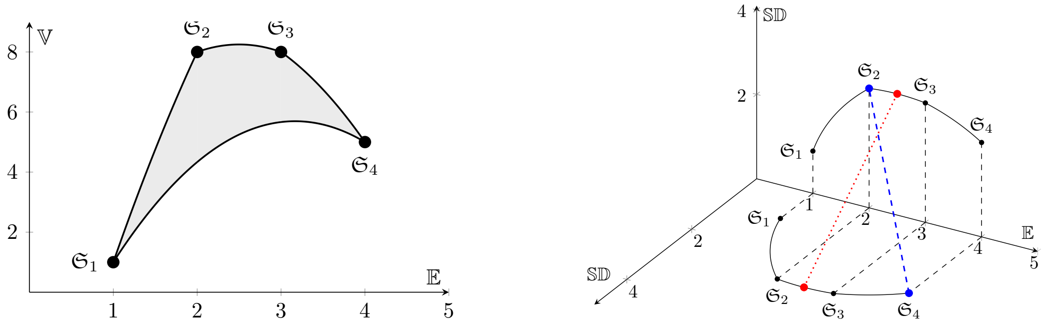
This is well-defined for any path that has positive probability under $\mathfrak{S}$ or $\mathfrak{T}$. The following result is folklore; a proof is included in the full version [26].

▶ **Proposition 2.1.** *Let the schedulers $\mathfrak{S}$ and $\mathfrak{T}$ and the value p be as above. Then, for any path $\pi = s_0\,\alpha_0\,s_1\,\alpha_1\,\ldots\alpha_{k-1}\,s_k$, we have $P^{p\mathfrak{S}\oplus(1-p)\mathfrak{T}(\pi)}(\pi) = pP^{\mathfrak{S}}(\pi) + (1-p)P^{\mathfrak{T}}(\pi)$.*

We conclude $\Pr^{p\mathfrak{S}\oplus(1-p)\mathfrak{T}}_{\mathcal{M},s}(A) = p\Pr^{\mathfrak{S}}_{\mathcal{M},s}(A) + (1-p)\Pr^{\mathfrak{T}}_{\mathcal{M},s}(A)$ for any measurable set of paths A. Hence, we can think of the scheduler $p\mathfrak{S} \oplus (1-p)\mathfrak{T}$ as behaving like $\mathfrak{S}$ with probability p and like $\mathfrak{T}$ with probability $(1-p)$. In particular, we can also conclude that for a random variable X, we have $\mathbb{E}^{p\mathfrak{S}\oplus(1-p)\mathfrak{T}}_{\mathcal{M},s}(X) = p\mathbb{E}^{\mathfrak{S}}_{\mathcal{M},s}(X) + (1-p)\mathbb{E}^{\mathfrak{T}}_{\mathcal{M},s}(X)$. For the variance, we obtain the following as shown in full version [26].

▶ **Lemma 2.2.** *Given $\mathcal{M}$, X, and two schedulers $\mathfrak{S}_1$ and $\mathfrak{S}_2$, as well as $p \in [0, 1]$, let $\mathfrak{T} = p\mathfrak{S}_1 \oplus (1-p)\mathfrak{S}_2$. Then, $\mathbb{V}^{\mathfrak{T}}_{\mathcal{M}}(X) = p\mathbb{V}^{\mathfrak{S}_1}_{\mathcal{M}}(X) + (1-p)\mathbb{V}^{\mathfrak{S}_2}_{\mathcal{M}}(X) + p(1-p)(\mathbb{E}^{\mathfrak{S}_1}_{\mathcal{M}}(X) - \mathbb{E}^{\mathfrak{S}_2}_{\mathcal{M}}(X))^2$.*

[2] This description would be admissible if we allowed stochastic memory updates (see, e.g., [8]).



(a) Possible combinations of variance and expectation in Example 3.2.

(b) Plot of the standard deviation over the expectation on two orthogonal planes.

Figure 3 Graphical illustration of the task to find the demonic variance (see Example 3.2).

Topology and convergence of measures. Given a family of topological spaces $((S_i, \tau_i))_{i\in I}$, the product topology τ on $\prod_{i\in I} S_i$ is the coarsest topology such that the projections $p_i \colon \prod_{i\in I} S_i \to S_i, \quad (s_i)_{i\in I} \mapsto s_i$ are continuous for all $i \in I$. For measures $(\mu_j)_{j\in\mathbb{N}}$ and μ on a measure space (Ω, Σ) where Ω is a metrizable topological space and Σ the Borel σ-algebra on Ω, we say that the sequence $(\mu_j)_{j\in\mathbb{N}}$ *weakly converges* to μ if for all bounded continuous functions $f \colon \Omega \to \mathbb{R}$, we have $\lim_{j\to\infty} \int f \mathrm{d}\mu_j = \int f \mathrm{d}\mu$. The set of infinite paths $\Pi_{\mathcal{M}}$ of an MDP $\mathcal{M}$ with the topology generated by the cylinder sets is metrizable as we can define the metric $d(\pi, \pi') = 2^{-\ell}$ where ℓ is the length of the longest common prefix of π and π'.

3 Demonic variance and non-determinism score

In this section, we formally define the demonic variance. After proving first auxiliary results, we prove an analogue of Chebyshev's Inequality using the demonic variance. Then, we introduce the non-determinism score and investigate necessary and sufficient conditions for this score to be 0 or 1. Proofs omitted here can be found in the full version [26].

Throughout this section, let $\mathcal{M} = (S, Act, P, s_{init})$ be an MDP and let X be a random variable, i.e., a Borel measurable function on the infinite paths of $\mathcal{M}$. We will work under two assumptions that ensure that all notions are well-defined: First, note that $\mathbb{V}^{\max}_{\mathcal{M}}(X) = 0$ implies that there is a constant c such that under all schedulers $\mathfrak{S}$, we have $\Pr^{\mathfrak{S}}_{\mathcal{M}}(X = c) = 1$ – an uninteresting case. Furthermore, for meaningful definitions of demonic variance and non-determinism score, we need that the expected value and the variance of X in $\mathcal{M}$ are finite. Hence, we work under the following assumption:

▶ **Assumption 3.1.** *We assume that* $0 < \mathbb{V}^{\max}_{\mathcal{M}}(X) < \infty$ *and that* $\sup_{\mathfrak{S}} \left|\mathbb{E}^{\mathfrak{S}}_{\mathcal{M}}(X)\right| < \infty$.

3.1 Demonic variance

As described in the introduction, the idea behind the demonic variance is to quantify the expected squared deviation of X in two independent executions of $\mathcal{M}$, in which the non-determinism is resolved independently as well. We use the following notation: Given a path in $\mathcal{M} \otimes \mathcal{M}$ consisting of a sequence of pairs of states and pairs of actions, we denote by X_1 and X_2 the function X applied to the projection of the path on the first component and on the second component, respectively. Given two schedulers $\mathfrak{S}_1$ and $\mathfrak{S}_2$ for $\mathcal{M}$, we define

$$\mathbb{V}^{\mathfrak{S}_1,\mathfrak{S}_2}_{\mathcal{M}}(X) \overset{\text{def}}{=} \frac{1}{2}\mathbb{E}^{\mathfrak{S}_1\otimes\mathfrak{S}_2}_{\mathcal{M}\otimes\mathcal{M}}((X_1 - X_2)^2).$$

Intuitively, in this definition two independent executions of $\mathcal{M}$ are run in parallel while the non-determinism is resolved by $\mathfrak{S}_1$ in the first execution and by $\mathfrak{S}_2$ in the second component. As the two components in the products $\mathcal{M} \otimes \mathcal{M}$ and $\mathfrak{S}_1 \otimes \mathfrak{S}_2$ are independent, the resulting distributions of X in the two components, i.e., X_1 and X_2 are independent as well. The factor $\frac{1}{2}$ is included as for a random variable Y, this factor also appears in the representation $\mathbb{V}(Y) = \frac{1}{2}\mathbb{E}((Y_1 - Y_2)^2)$ for two independent copies Y_1 and Y_2 of Y.

The *demonic variance* is now the worst-case value when ranging over all pairs of schedulers:

$$\mathbb{V}^{dem}_{\mathcal{M}}(X) \overset{\text{def}}{=} \sup_{\mathfrak{S}_1,\mathfrak{S}_2} \frac{1}{2}\mathbb{E}^{\mathfrak{S}_1\otimes\mathfrak{S}_2}_{\mathcal{M}\otimes\mathcal{M}}((X_1 - X_2)^2).$$

A first simple, but useful, result allows us to express $\mathbb{V}^{\mathfrak{S}_1,\mathfrak{S}_2}_{\mathcal{M}}(X)$ in terms of the expected values and variances of X under $\mathfrak{S}_1$ and $\mathfrak{S}_2$.

▶ **Lemma 3.1.** *Given two schedulers $\mathfrak{S}_1$ and $\mathfrak{S}_2$ for $\mathcal{M}$, we have*

$$\mathbb{V}^{\mathfrak{S}_1,\mathfrak{S}_2}_{\mathcal{M}}(X) = \frac{1}{2}\left(\mathbb{V}^{\mathfrak{S}_1}_{\mathcal{M}}(X) + \mathbb{V}^{\mathfrak{S}_2}_{\mathcal{M}}(X) + (\mathbb{E}^{\mathfrak{S}_1}_{\mathcal{M}}(X) - \mathbb{E}^{\mathfrak{S}_2}_{\mathcal{M}}(X))^2\right).$$

This lemma allows us to provide an insightful graphical interpretation of the demonic variance using the standard deviation $\mathbb{SD}(X) \overset{\text{def}}{=} \sqrt{\mathbb{V}(X)}$ of a random variable X:

▶ **Example 3.2.** Suppose in an MDP $\mathcal{M}$, there are four deterministic scheduler $\mathfrak{S}_1, \dots, \mathfrak{S}_4$ with expected values 1, 2, 3, and 4 and variances 1, 8, 8, and 5 for a random variable X. Lemma 2.2 allows us to compute the variances of schedulers obtained by randomization leading to parabolic line segments in the expectation-variance-plane as depicted in Figure 3a (see also [28]). Further randomizations also make it possible to realize any combination of expectation and variance in the interior of the resulting shape. When looking for the maximal variance and the demonic variance, only the upper bound of this shape is relevant.

In Figure 3b, we now depict the standard deviations of schedulers on this upper bound over the expectation twice on two orthogonal planes. Clearly, the highest standard deviation (and consequently variance) is obtained for the expected value 2.5 in this example. The red dotted line of length $\sqrt{2\mathbb{V}^{\max}_{\mathcal{M}}(X)}$ connects the two points corresponding to this maximum on the two planes. Considering $\mathfrak{S}_2$ and $\mathfrak{S}_4$, we can also find the value $\sqrt{2\mathbb{V}^{\mathfrak{S}_2,\mathfrak{S}_4}_{\mathcal{M}}(X)}$: The blue dashed line connects the point corresponding to $\mathfrak{S}_2$ on one of the planes to the point corresponding to $\mathfrak{S}_4$ on the other plane. By the Pythagorean theorem, its length is

$$\sqrt{\sqrt{\mathbb{V}^{\mathfrak{S}_2}_{\mathcal{M}}(X)}^2 + (\mathbb{E}^{\mathfrak{S}_2}_{\mathcal{M}}(X) - (\mathbb{E}^{\mathfrak{S}_4}_{\mathcal{M}}(X))^2 + \sqrt{\mathbb{V}^{\mathfrak{S}_4}_{\mathcal{M}}(X)}^2} = \sqrt{2\mathbb{V}^{\mathfrak{S}_2,\mathfrak{S}_4}_{\mathcal{M}}(X)}.$$

So, finding $\sqrt{2}$ times the "demonic standard deviation" and hence the demonic variance corresponds to finding two points on the two orthogonal graphs with maximal distance.

The relation between maximal and demonic variance is shown in the following proposition.

▶ **Proposition 3.3.** *We have $\mathbb{V}^{\max}_{\mathcal{M}}(X) \leq \mathbb{V}^{dem}_{\mathcal{M}}(X) \leq 2\mathbb{V}^{\max}_{\mathcal{M}}(X)$.*

By means of Chebyshev's Inequality, the variance can be used to bound the probability that a random variable Y lies far from its expected value. Using the demonic variance, we can prove an analogous result providing bounds on the probability that the outcomes of X in two independent executions of the MDP $\mathcal{M}$ lie far apart. This can be seen as a first step in the direction of using the demonic variance to provide guarantees on the behavior of a system.

▶ **Theorem 3.4.** *We have* $\Pr^{\mathfrak{S}\otimes\mathfrak{T}}_{\mathcal{M}\otimes\mathcal{M}}\left(|X_1 - X_2| \geq k \cdot \sqrt{\mathbb{V}^{dem}_{\mathcal{M}}(X)}\right) \leq \frac{2}{k^2}$ *for any* $k \in \mathbb{R}_{>0}$ *and schedulers* $\mathfrak{S}$ *and* $\mathfrak{T}$ *for* $\mathcal{M}$*.*

Using the result that $\mathbb{V}^{dem}_{\mathcal{M}}(X) \leq 2\mathbb{V}^{\max}_{\mathcal{M}}(X)$, we obtain the following variant of the inequality providing a weaker bound in terms of the maximal variance.

▶ **Corollary 3.5.** *We have* $\Pr^{\mathfrak{S}\otimes\mathfrak{T}}_{\mathcal{M}\otimes\mathcal{M}}\left(|X_1 - X_2| \geq k \cdot \sqrt{\mathbb{V}^{\max}_{\mathcal{M}}(X)}\right) \leq \frac{4}{k^2}$ *for any* $k \in \mathbb{R}_{>0}$ *and schedulers* $\mathfrak{S}$ *and* $\mathfrak{T}$ *for* $\mathcal{M}$*.*

3.2 Non-determinism score

We have seen that the demonic variance is larger than the maximal variance by a factor between 1 and 2. As described in the introduction, we use this insight as the basis for a score quantifying how much worse the "uncertainty" of X is when non-determinism can be resolved differently in two executions of an MDP compared to how bad it can be in a single execution. We define the non-determinism score (NDS)

$$\mathrm{NDS}(\mathcal{M}, X) \overset{\text{def}}{=} \frac{\mathbb{V}^{dem}_{\mathcal{M}}(X) - \mathbb{V}^{\max}_{\mathcal{M}}(X)}{\mathbb{V}^{\max}_{\mathcal{M}}(X)}.$$

By Assumption 3.1, the NDS is well-defined. By Proposition 3.3, the NDS always returns a value in $[0, 1]$. Clearly, in Markov chains, the NDS is 0. A bit more general, we can show:

▶ **Proposition 3.6.** *If* $\mathbb{E}^{\mathfrak{S}}_{\mathcal{M}}(X) = \mathbb{E}^{\mathfrak{T}}_{\mathcal{M}}(X)$ *for all schedulers* $\mathfrak{S}$ *and* $\mathfrak{T}$*, then* $\mathrm{NDS}(\mathcal{M}, X) = 0$*.*

In transition systems viewed as MDPs in which all transition probabilities are 0 or 1, the NDS is 1: Under Assumption 3.1 in a transition system the value of X must be bounded, i.e., $X \in [a, b]$ for some $a, b \in \mathbb{R}$ such that $\sup_\pi X(\pi) = b$ and $\inf_\pi X(\pi) = a$ where π ranges over all paths. Any path can be realized by a scheduler with probability 1. So, for any $\varepsilon > 0$, there are schedulers $\mathfrak{S}$ and $\mathfrak{T}$ with $\Pr^{\mathfrak{S}}_{\mathcal{M}}(X < a + \varepsilon) = 1$ and $\Pr^{\mathfrak{T}}_{\mathcal{M}}(X > b - \varepsilon) = 1$. Then, $\mathbb{V}^{\mathfrak{S},\mathfrak{T}}_{\mathcal{M}}(X) \geq \frac{1}{2}(b - a - 2\varepsilon)^2$. For $\varepsilon \to 0$, this converges to $\frac{(a-b)^2}{2}$. It is well-known that the variance of random variables taking values in $[a, b]$ is maximal for the random variable taking values a and b with probability $\frac{1}{2}$ each. The variance in this case is $\frac{(a-b)^2}{4}$. So, the maximal variance is (at most) half the demonic variance in this case. Consequently, the NDS is 1.

Of course, a NDS of 1 does not imply that there are no probabilistic transitions in $\mathcal{M}$. Nevertheless, a NDS of 1 has severe implications showing that the outcome of X can be heavily influenced by the non-determinism in this case as the following theorem shows:

▶ **Theorem 3.7.** *If* $\mathrm{NDS}(\mathcal{M}, X) = 1$*, the following statements hold:*

1. *For every* $\varepsilon > 0$*, there are schedulers* $\mathfrak{Min}_\varepsilon$ *and* $\mathfrak{Max}_\varepsilon$ *with* $\mathbb{E}^{\mathfrak{Min}_\varepsilon}_{\mathcal{M}}(X) \leq \mathbb{E}^{\min}_{\mathcal{M}}(X) + \varepsilon$ *and* $\mathbb{V}^{\mathfrak{Min}_\varepsilon}_{\mathcal{M}}(X) \leq \varepsilon$*, and* $\mathbb{E}^{\mathfrak{Max}_\varepsilon}_{\mathcal{M}}(X) \geq \mathbb{E}^{\max}_{\mathcal{M}}(X) - \varepsilon$ *and* $\mathbb{V}^{\mathfrak{Max}_\varepsilon}_{\mathcal{M}}(X) \leq \varepsilon$*.*
2. *If there are schedulers* $\mathfrak{S}_0$ *and* $\mathfrak{S}_1$*, with* $\mathbb{V}^{dem}_{\mathcal{M}}(X) = \mathbb{V}^{\mathfrak{S}_0,\mathfrak{S}_1}_{\mathcal{M}}(X)$*, then, for* $i = 0$ *or* $i = 1$*,* $\Pr^{\mathfrak{S}_i}_{\mathcal{M}}(X = \mathbb{E}^{\min}_{\mathcal{M}}(X)) = 1$ *and* $\Pr^{\mathfrak{S}_{1-i}}_{\mathcal{M}}(X = \mathbb{E}^{\max}_{\mathcal{M}}(X)) = 1$*.*
3. *If* X *is bounded and continuous wrt the topology generated by the cylinder sets, there are schedulers* $\mathfrak{Min}$ *and* $\mathfrak{Max}$ *with* $\Pr^{\mathfrak{Min}}_{\mathcal{M}}(X = \mathbb{E}^{\min}_{\mathcal{M}}(X)) = 1$ *and* $\Pr^{\mathfrak{Max}}_{\mathcal{M}}(X = \mathbb{E}^{\max}_{\mathcal{M}}(X)) = 1$*.*

The first two statements can be shown by elementary calculations. For the third statement, we use topological arguments. We view schedulers as elements of $\prod_{k=0}^{\infty} \mathrm{Distr}(Act)^{\mathrm{Paths}^k_{\mathcal{M}}}$ where $\mathrm{Paths}^k_{\mathcal{M}}$ is the set of paths of length k in $\mathcal{M}$ and prove the following result:

▶ **Proposition 3.8.** *The space of schedulers* $\mathrm{Sched}(\mathcal{M}) = \prod_{k=0}^{\infty} \mathrm{Distr}(Act)^{\mathrm{Paths}^k_{\mathcal{M}}}$ *with the product topology is compact. So, every sequence of schedulers has a converging subsequence in this space. Further, for a sequence* $(\mathfrak{S}_j)_{j\in\mathbb{N}}$ *converging to a scheduler* $\mathfrak{S}$ *in this space, the sequence of probability measures* $(\Pr^{\mathfrak{S}_j}_{\mathcal{M}})_{j\in\mathbb{N}}$ *weakly converges to the probability measure* $\Pr^{\mathfrak{S}}_{\mathcal{M}}$*.*

An example for a random variable that is bounded and continuous wrt the topology generated by the cylinder sets is the discounted reward: Given a reward function $rew\colon S \to \mathbb{R}$, the discounted reward of a path $\pi = s_0\alpha_0 s_1 \dots$ is defined as $DR_\lambda(\pi) \overset{\text{def}}{=} \sum_{j=0}^{\infty} \lambda^j rew(s_j)$ for some discount factor $\lambda \in (0,1)$. First, $|DR_\lambda|$ is bounded by $\max_{s\in S} |rew(s)| \cdot \frac{1}{1-\lambda}$. Further, for any $\varepsilon > 0$, let N be a natural number such that $\max_{s\in S} |rew(s)| \cdot \frac{\lambda^N}{1-\lambda} < \varepsilon$. Then, $|DR_\lambda(\pi) - DR_\lambda(\rho)| < \varepsilon$ for all paths π and ρ that share a prefix of length more than N.

4 Weighted reachability

We now address the problems to compute the demonic and the maximal variance for weighted reachability where a weight is collected on a run depending on which absorbing state is reached. As the NDS is defined via these two quantities, we do not address it separately here. Throughout this section, let $\mathcal{M} = (S, Act, P, s_{init})$ be an MDP with set of absorbing states $T \subseteq S$ and let $wgt\colon T \to \mathbb{Q}$ be a weight function. We define the random variable WR on infinite paths π by $\mathrm{WR}(\pi) = wgt(t)$ if π reaches the absorbing state $t \in T$, and $\mathrm{WR}(\pi) = 0$ if π does not reach T. The main result we are going to establish is the following:

Main result. *The maximal variance $\mathbb{V}^{\max}_{\mathcal{M}}(\mathrm{WR})$ and an optimal memoryless randomized scheduler can be computed in polynomial time.*

The demonic variance $\mathbb{V}^{dem}_{\mathcal{M}}(\mathrm{WR})$ can be computed as the solution to a bilinear program that can be constructed in polynomial time. Furthermore, there is a pair of memoryless deterministic schedulers realizing the demonic variance.

The following standard model transformation collapsing end components (see [14]) allows us to assume that T is reached almost surely under any scheduler: We add a new absorbing state t^* and set $wgt(t^*) = 0$ and collapse all maximal end components $\mathcal{E}$ in $S \setminus T$ to single states $s_{\mathcal{E}}$. In $s_{\mathcal{E}}$, all actions that were enabled in some state in $\mathcal{E}$ and that did not belong to $\mathcal{E}$ as well as a new action τ leading to t^* with probability 1 are enabled. In the resulting MDP $\mathcal{N}$, the set of absorbing states $T \cup \{t^*\}$ is reached almost surely under any scheduler. Further, for any scheduler $\mathfrak{S}$ for $\mathcal{M}$, there is a scheduler $\mathfrak{T}$ for $\mathcal{N}$ such that the distribution of WR is the same under $\mathfrak{S}$ in $\mathcal{M}$ and under $\mathfrak{T}$ in $\mathcal{N}$, and vice versa. So, w.l.o.g., assume the following:

▶ **Assumption 4.1.** *The set T is reached almost surely under any scheduler $\mathfrak{S}$ for $\mathcal{M}$.*

In the sequel, we first address the computation of the maximal variance and afterwards of the demonic variance of WR in $\mathcal{M}$. Omitted proofs can be found in the full version [26].

Computation of the maximal variance. It is well-known that the set of vectors $(\mathrm{Pr}^{\mathfrak{S}}_{\mathcal{M}}(\Diamond q))_{q\in T}$ of combinations of reachability probabilities for states in T that can be realized by a scheduler $\mathfrak{S}$ can be described by a system of linear inequalities (see, e.g., [18]). We provide such a system of inequalities below in equations (1) – (3). The equations use variables $x_{s.\alpha}$ for all state-action pairs (s, α) encoding the expected number of times action α is taken in state s. Setting $\mathbb{1}_{s=s_{init}} = 1$ if $s = s_{init}$ and $\mathbb{1}_{s=s_{init}} = 0$ otherwise, we require

$$x_{s,\alpha} \geq 0 \qquad \text{for all } (s,\alpha), \tag{1}$$

$$\sum_{\alpha\in Act(s)} x_{s,\alpha} = \sum_{t\in S, \beta\in Act(t)} x_{t,\beta} \cdot P(t,\beta,s) + \mathbb{1}_{s=s_{init}} \qquad \text{for all } s \in S\setminus T, \tag{2}$$

$$y_q = \sum_{t\in S, \beta\in Act(t)} x_{t,\beta} \cdot P(t,\beta,q) \qquad \text{for all } q \in T. \tag{3}$$

The variables y_q for $q \in T$ represent the probabilities that state q is reached. We can now express the expected value of WR and WR^2 via variables e_1 and e_2 via the constraints:

$$e_1 = \sum_{q \in T} y_q \cdot wgt(q) \quad \text{and} \quad e_2 = \sum_{q \in T} y_q \cdot wgt(q)^2. \tag{4}$$

The variance can now be written as a quadratic objective function in e_1 and e_2:

$$\text{maximize} \quad e_2 - e_1^2. \tag{5}$$

▶ **Theorem 4.1.** *The maximal value in objective (5) under constraints (1) – (4) is* $\mathbb{V}^{\max}_{\mathcal{M}}(\mathrm{WR})$.

Due to the concavity of the objective function, we conclude:

▶ **Corollary 4.2.** *The maximal variance* $\mathbb{V}^{\max}_{\mathcal{M}}(\mathrm{WR})$ *can be computed in polynomial time. Furthermore, there is a memoryless randomized scheduler* $\mathfrak{S}$ *with* $\mathbb{V}^{\mathfrak{S}}_{\mathcal{M}}(\mathrm{WR}) = \mathbb{V}^{\max}_{\mathcal{M}}(\mathrm{WR})$, *which can also be computed in polynomial time.*

Computation of the demonic variance. The demonic variance can also be expressed as the solution to a quadratic program. To encode the reachability probabilities for states in T under two distinct schedulers, we use variables $x_{s,\alpha}$ for all state weight pairs (s,α) and y_q for $q \in T$ subject to constraints (1) – (3) as before. Additionally, we use variables $x'_{s,\alpha}$ for all state weight pairs (s,α) and y'_q for $q \in T$ subject to the analogue constraints $(1')$ – $(3')$ using these primed variables. The maximization of the demonic variance can be expressed as

$$\text{maximize} \quad \frac{1}{2} \sum_{q,r \in T} y_q \cdot y'_r \cdot (wgt(q) - wgt(r))^2. \tag{6}$$

▶ **Theorem 4.3.** *The maximum in (6) under constraints (1) – (3), (1′) – (3′) is* $\mathbb{V}^{dem}_{\mathcal{M}}(\mathrm{WR})$.

The quadratic objective function (6) is not concave. However, it is *bilinear* and *separable*. This means that the variables can be split into two sets, the primed and the unprimed variables, such that the quadratic terms only contain products of variables from different sets and each constraint contains only variables from the same set. In general, checking whether the solution to a separable bilinear program exceeds a given threshold is NP-hard [23]. Nevertheless, solution methods tailored for bilinear programs that perform well in practice have been developed (see, e.g., [19]). Further, bilinearity allows us to conclude:

▶ **Corollary 4.4.** *There is a pair of memoryless deterministic schedulers* $\mathfrak{S}$ *and* $\mathfrak{T}$ *for* $\mathcal{M}$ *such that* $\mathbb{V}^{dem}_{\mathcal{M}}(\mathrm{WR}) = \mathbb{V}^{\mathfrak{S},\mathfrak{T}}_{\mathcal{M}}(\mathrm{WR})$.

For the complexity of the threshold problem, we can conclude an NP upper bound. Whether the computation of the demonic variance is possible in polynomial time is left open.

▶ **Corollary 4.5.** *Given* $\mathcal{M}$, *wgt and* $\vartheta \in \mathbb{Q}$, *deciding whether* $\mathbb{V}^{dem}_{\mathcal{M}}(\mathrm{WR}) \geq \vartheta$ *in in NP.*

5 Accumulated rewards

One of the most important random variables studied on MDPs are accumulated rewards: Let $\mathcal{M} = (S, Act, P, s_{init})$ be an MDP and let $rew\colon S \to \mathbb{N}$ be a reward function. We extend the reward function to paths $\pi = s_0\alpha_0 s_1 \ldots$ by $rew(\pi) = \sum_{i=0}^{\infty} rew(s_i)$. For this random variable, we prove the following result:

Main result. *The maximal variance $\mathbb{V}^{\max}_{\mathcal{M}}(rew)$ and an optimal randomized finite-memory scheduler can be computed in exponential time.*

The demonic variance $\mathbb{V}^{dem}_{\mathcal{M}}(rew)$ can be computed as the solution to a bilinear program that can be constructed in exponential time. Furthermore, there is a pair of deterministic finite-memory schedulers realizing the demonic variance.

We provide a sketch outlining the proof strategy. For a detailed exposition, see [26].

Proof sketch for the main result. It can be checked in polynomial time whether $\mathbb{E}^{\max}_{\mathcal{M}}(rew) < \infty$ [14]. If this is the case, this allows us to perform the same preprocessing as in Section 4 that removes all end components without changing the possible distributions of *rew* [14].

Bounding expected values and expectation maximizing actions. After the pre-processing, a terminal state is reached almost surely. As shown in [28], this allows to obtain a bound Q on $\mathbb{E}^{\max}_{\mathcal{M}}(rew^2)$ in polynomial time. Further, the maximal expectation $\mathbb{E}^{\max}_{\mathcal{M},s}(rew)$ from each state s can be computed in polynomial time [7, 14]. From these values, a set of *maximizing actions* $Act^{\max}(s)$ for each state s can be computed. After the preprocessing, a scheduler is expectation optimal iff it only chooses actions from these sets. If a scheduler $\mathfrak{S}$ initially chooses a non-maximizing action in a state s, the expected value $\mathbb{E}^{\mathfrak{S}}_{\mathcal{M},s}(rew)$ is strictly smaller than $\mathbb{E}^{\max}_{\mathcal{M},s}(rew)$. We define δ to be the minimal difference between these values ranging over all starting states and non-maximizing actions. So, δ is the "minimal loss" in expected value of *rew* received by choosing a non-maximizing action.

Switching to expectation maximization. Using the values Q and δ, we provide a bound B such that any scheduler choosing a non-maximizing action with positive probability after a path π with $rew(\pi) \geq B$ cannot realize the maximal variance. Intuitively, the reason is that the influence of accumulating future rewards on the variance grows with the amount of rewards already accumulated due to the quadratic nature of variance. The bound B can be computed in polynomial time and its numerical value is exponential in the size of the input.

It follows that variance maximizing schedulers have to maximize the future expected rewards after a reward of at least B has been accumulated. Furthermore, we can show that among all expectation maximizing schedulers, a variance maximizing scheduler has to be used above the reward bound B. In [28], it is shown that a memoryless deterministic expectation maximizing scheduler $\mathfrak{U}$ that maximizes the variance among all expectation maximizing schedulers can be computed in polynomial time. So, schedulers maximizing the variance of *rew* can be chosen to behave like $\mathfrak{U}$ once a reward of at least B has been accumulated.

Quadratic program. Now, we can unfold the MDP $\mathcal{M}$ by storing in the state space how much reward has been accumulated up to the bound B. This results on an exponentially larger MDP $\mathcal{M}'$. Using the expected values $\mathbb{E}^{\mathfrak{U}}_{\mathcal{M},s}(rew)$ and the variances $\mathbb{V}^{\mathfrak{U}}_{\mathcal{M},s}(rew)$ under $\mathfrak{U}$ from each state s, we can formulate a quadratic program similar to the one for weighted reachability in Section 4 for this unfolded MDP $\mathcal{M}'$. From the solution to this quadratic program, the maximal variance and an optimal memoryless scheduler $\mathfrak{S}$ for $\mathcal{M}'$ can be extracted. Transferred back to $\mathcal{M}$, the scheduler $\mathfrak{S}$ corresponds to a reward-based finite-memory scheduler that keeps track of the accumulated reward up to bound B. As the quadratic program is convex, these computations can be carried out in exponential time.

Demonic variance. For the demonic variance, the overall proof follows the same steps. Similar to the bound B above, a bound B' can be provided such that in any pair of scheduler $\mathfrak{S}$ and $\mathfrak{T}$ realizing the demonic variance, both schedulers can be assumed to switch to the behavior of the memoryless deterministic scheduler $\mathfrak{U}$ above the reward bound B'.

Again by unfolding the state space up to this reward bound, the demonic variance can be computed via a bilinear program of exponential size similar to the one used in Section 4 for weighted reachability. Furthermore, the pair of optimal memoryless deterministic schedulers in the unfolded MDP, which can be extracted from the solution, corresponds to a pair of deterministic reward-based finite-memory schedulers in the original MDP $\mathcal{M}$. ◀

6 Conclusion

We introduced the notion of demonic variance that quantifies the uncertainty under probabilism *and* non-determinism of a random variable X in an MDP $\mathcal{M}$. As this demonic variance is at most twice as big as the maximal variance of X, we used it to define the NDS for MDPs.

The demonic variance can be used to provide new types of guarantees on the behavior of systems. A first step in this direction is the variant of Chebyshev's Inequality using the demonic variance proved in this paper. Furthermore, the demonic variance and the NDS can serve as the basis for notions of responsibility. On the one hand, such notions could ascribe responsibility for the uncertainty to non-determinism and probabilism. On the other hand, comparing the NDS from different starting states can be used to identify regions of the state space in which the non-deterministic choices are of high importance.

For weighted reachability and accumulated rewards, we proved that randomized finite-memory schedulers are sufficient to maximize the variance. For the demonic variance, even pairs of deterministic finite-memory schedulers are sufficient. While we obtained upper bounds via the formulation of the computation problems as quadratic programs, determining the precise complexities is left as future work. In the case of accumulated rewards, we restricted to non-negative rewards. When dropping this restriction, severe difficulties have to be expected as several related problems on MDPs exhibit inherent number-theoretic difficulties rendering the decidability status of the corresponding decision problems open [27].

Of course the investigation of the demonic variance and NDS for further random variables constitutes an interesting direction for future work. For practical purposes, studying also the approximability of the maximal and demonic variance is important.

Finally, In the spirit of the demonic variance, further notions can be defined to quantify the uncertainty in X if the non-determinism in two executions of $\mathcal{M}$ is not resolved independently, but information can be passed between the two executions. This could be useful, e.g., to analyze the potential power of coordinated attacks on a network. Formally, such a notion could be defined as $\sup_{\mathfrak{S}} \mathbb{E}^{\mathfrak{S}}_{\mathcal{M}\otimes\mathcal{M}}((X_1 - X_2)^2)$ where $\mathfrak{S}$ ranges over all schedulers for $\mathcal{M}\otimes\mathcal{M}$. In this context, also using an asynchronous product of $\mathcal{M}$ with $\mathcal{M}$ could be reasonable.

Abstract

We present a computational model for Parsing Expression Grammars (PEGs). The predecessor of PEGs top-down parsing languages (TDPLs) were discovered by A. Birman and J. Ullman in the 1960-s, B. Ford showed in 2004 that both formalisms recognize the same class named Parsing Expression Languages (PELs). A. Birman and J. Ullman established such important properties like TDPLs generate any DCFL and some non-context-free languages like $a^nb^nc^n$, a linear-time parsing algorithm was constructed as well. But since this parsing algorithm was impractical in the 60-s TDPLs were abandoned and then upgraded by B. Ford to PEGs, so the parsing algorithm was improved (from the practical point of view) as well. Now PEGs are actively used in compilers (eg., Python replaced LL(1)-parser with a PEG one) so as for text processing as well. In this paper, we present a computational model for PEG, obtain structural properties of PELs, namely proof that PELs contain Boolean closure of regular closure of DCFLs and PELs are closed over left concatenation with regular closure of DCFLs. We present an extension of the PELs class based on the extension of our computational model. Our model is an upgrade of deterministic pushdown automata (DPDA) such that during the pop of a symbol it is allowed to return the head to the position of the push of the symbol. We provide a linear-time simulation algorithm for the 2-way version of this model, which is similar to the famous S. Cook linear-time simulation algorithm of 2-way DPDA.

1 Introduction

We present a computational model for Parsing Expression Grammars (PEGs) presented by B. Ford in [6]. The predecessor of PEGs top-down parsing languages (TDPLs) was discovered by A. Birman and J. Ullman in the 1960s (so as generalized TDPLs) [4]. While the PEGs formalism has more operations, it has the same power as TDPLs and generalized TDPLs which was shown by B. Ford in [7]. We refer to the class of languages generated by PEGs (and TDPLs, and generalized TDPLs) as *Parsing Expression Languages* (PELs).

Little is known about the structural properties of PELs. From the 60's it is known that PELs contain DCFLs as a subclass and some non-context-free languages like $a^nb^nc^n$ as well. A linear-time parsing algorithm (in RAM) had been constructed for TDPLs, but it was

impractical in the 1960s since it required too much memory for memoization and TDPLs had been abandoned. B. Ford upgraded the TDPLs formalism to PEGs and presented a linear-time practical algorithm in 2002 [6]. Now PEGs are being actively used in compilers (eg., Python replaced an LL(1)-parser with a PEG one [16]) so as for text processing as well. In this paper, we present a computational model for PELs and obtain some interesting properties for this class, analyze (some of) its subclasses, and generalize the PELs class as well.

A computational model for PELs was presented in [12], but this model significantly differs from classical models of computations, so it is hard to clarify the place of PELs among known classes of formal languages, based on this model. So we present a simpler and more convenient model that discovers the place of PEGs in the variety of formal language classes. Namely, the computational model is a modified deterministic pushdown automaton (DPDA) that puts to the stack a symbol with the pointer of the head's position on the tape (from which the push has been performed). During the pop, the automaton has two options: either leave the head in the current position or move the head to the position stored in the pointer (retrieved during the pop of the symbol). We call this model a deterministic pointer pushdown automaton (DPPDA). This description of PELs from the automata point of view helped us to obtain other important results not only for the PELs but for the general area of formal languages as well. Namely, we prove that boolean closure of regular closure of DCFLs is linear-time recognizable (in RAM), what extends the nontrivial result by E. Bertsch and M.-J. Nederhof [3] that regular closure of DCFLs is linear-time recognizable.

To describe our results we shall mention the following important results in the area of formal languages and automata theory. Donald Knuth invented LR(k) grammars that describe DCFLs for $k \geq 1$ and were widely used in practice. It is easier to design an LL(k) grammar for practical purposes, so despite the power of LR, LL grammars are widely used for parsing (and some artificial modification of recursive descent parsing as well). Top-down parsing languages (TDPLs, predecessor of PEGs) cover LL(1) grammars and even contain DCFLs as a subclass, but their linear-time parsing algorithm was impractical in the 1970s, so TDPLs had been abandoned till B. Ford upgraded them to PEGs and presented a practically reasonable linear-time parser (Packrat). So, linear-time recognizable classes of formal languages are used in compilers, and LR (DCFLs) parsers now compete with PEGs which cover a wider class of formal languages that is almost undiscovered. There are no comprehensive results on the structure of PELs, so we make a contribution to this open question. Another wide linear-time recognizable class of formal languages is languages recognizable by two-way deterministic pushdown automata (2DPDA). S. Cook obtained in [5] a famous linear-time simulation algorithm for this model. There also was an amazing story about how D. Knuth used S. Cook's algorithm to discover the Knuth-Morris-Pratt algorithm ([10], Section 7).

We modify 2DPDA in the same way as we did for DPDA: we add symbols to stack with a pointer that allows returning the head to the cell from which the push had been performed. S. Cook's linear-time simulation algorithm applies to this model as well (with a little modification). So we extend the important class of formal languages (recognizable by 2DPDAs) preserving linear-time parsing. This extension can be used to generalize PEGs. Also, this algorithm provides another approach to linear time recognition of languages generated by PEGs described via DPPDAs. Note that there are not many structural results about PELs. Moreover, even equivalence of TDPLs and generalized TDPLs (with PEGs) had been proved by B. Ford [7] decades after these classes had been invented. In our opinion, one of the reasons for that is that TDPL-based formalisms are hard. So even the proof of inclusion DCFLs in PELs [4] is complicated, while it directly follows from the equivalence of PEGs with our model.

So we hope that our model will raise interest in investigations of PELs and will help with these investigations as well. Our results also clarify the place of another interesting result (we also improved it, as described below). It was shown by E. Bertsch and M.-J. Nederhof [3] that regular closure of DCFLs is linear-time recognizable. We show that this class is recognizable by DPPDAs which simplifies the original proof [3] and shows the place of this class in the formal languages classes.

There are many linear-time recognizable classes of formal languages. Recently Rubtsov showed [14] that Hibbard's hierarchy (the subclass of CFLs) is linear-time recognizable. So there are many open questions related to the systematization of linear time recognizable classes of formal languages and particularly the relation of Hibbard's hierarchy with languages recognizable by 1-2 DPPDAs.

1.1 Results

In this paper, we present a new computational model DPPDA which is equivalent to PEGs. We also consider the two-way model 2DPPDA and provide a linear time simulation algorithm for this model following S. Cook's construction. Via DPPDA we show that the PEGs class is closed over left concatenation with regular closure of DCFLs, so PELs contain the regular closure of DCFLs as a subclass. With the linear-time simulation algorithm for 2DPPDA, we obtain another linear-time recognition algorithm for the regular closure of DCFLs and since PELs are closed over Boolean operation we prove that the Boolean closure of regular closure of DCFLs is linear-time recognizable. Note that the last result not only generalizes well known result of linear-time recognizability of regular closure of DCFLs [3], but also our proof is significantly simpler as well.

The full version of this paper is available on arXiv [13]. We put the reference to [13] when the proof is omitted due to the space limitations.

1.2 Basic Notation

We follow the notation from [9] on formal languages, especially on context-free grammars (CFGs) and pushdown automata. We denote the input alphabet as Σ and its elements (letters, terminals) are denoted by small letters $a, b, c, \ldots$, while letters w, x, y, z denote words. The empty word is denoted by ε. We denote nonterminals N by capital letters $A, B, C, \ldots$, and X, Y, Z can be used for both nonterminals and terminals. The axiom is denoted by $S \in N$. Words over the alphabet $N \cup \Sigma$ are called sentential forms and are denoted by small Greek letters.

1.3 Informal Description of PEGs

The formal definition of PEGs is not well intuitive, so we begin with an informal one that clarifies a simple idea behind this formal model. The intuition behind PEGs lies in recursive descent parsing.

One of the parsing methods for CF-grammars is a recursive descent parsing that is a process when the derivation tree is built top-down (starting from the axiom S) and then each nonterminal is substituted according to the associated function. A rollback is possible as well, where by rollback we mean the replacement of one production rule by another or even the replacement of the rule higher above the current node with the deletion of subtrees. This method is very general and we do not go deep into details. For our needs, we describe a recursive descent parsing of LL(1) grammars and its modification that defines PEGs.

For LL(1) grammar, the following assertion holds. Fix a leftmost derivation of a word $w\triangleleft = uav\triangleleft$ and let $uA\alpha\triangleleft$ be a derivation step (here $\triangleleft$ is a right end marker of the input). The next leftmost derivation step is determined by the nonterminal A and the terminal a, so the rule is the function $R(A, a)$. So, the recursive descent algorithm for an LL(1)-parser is as follows. An input $w\triangleleft$ is written in the one-way read-only tape called the *input tape*. The pointer in the (constructing) derivation tree points to the leftmost nonterminal node (without children), initially the axiom S. This node is replaced according to the function R. In the fixed above derivation step $uA\alpha\triangleleft$ the pointer is over the nonterminal A, $R(A, a) = xB\beta$, where $A \to xB\beta$ is a grammar rule. So, $xB\beta$ is glued into A as a subtree, x is a prefix of av and the head of the input tape moves while scanning x. If $R(A, a)$ does not contain a nonterminal, then (after replacement) the tree is traversed via DFS until the next (leftmost!) nonterminal is met. Each terminal during this traversal shifts the head of the input tape. If the symbol under the head differs from the traversed terminal, the input word is rejected. We illustrated the described process in Fig. 1. Note that u, x, α, β are the subtrees and u, v, x, v' in fact occupies several cells of the input tape.

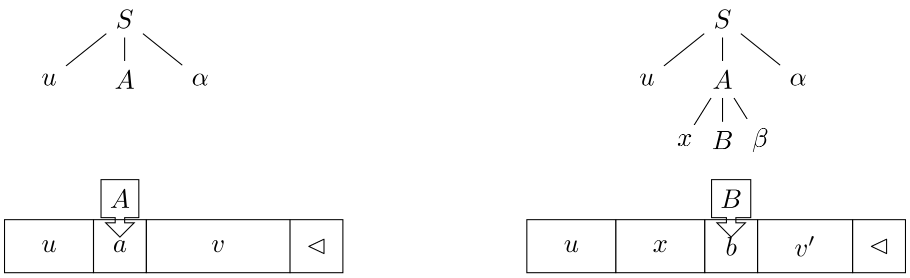

Figure 1 Example of LL(1) recursive descent parsing.

So now we move to the description of PEGs via modification of recursive descent parsing. In the first example, we will provide similar PEG and CFG (Fig. 2) and explain their similarity and differences.

PEG	CFG
$S \leftarrow AB \,/\, BC$	$S \to AB \mid BC$
$A \leftarrow aA \,/\, a$	$A \to aA \mid a$
$B \leftarrow abb \,/\, b$	$B \to abb \mid b$
$C \leftarrow cC \,/\, \varepsilon$	$C \to cC \mid \varepsilon$

Figure 2 PEG and CFG for comparison.

PEGs look similar to context-free grammars, but the meaning of almost all concepts are different, therefore the arrow ← is used to separate the left part of a rule from the right part. The difference comes from the following approach to recursive descent parsing. We describe the PEG via the transformation of the CFG. Let us order all the rules of the CFG for each nonterminal. During recursive descent parsing, we will try each rule according to this order. If a failure happens, let us try the next rule in the order. If the last rule leads us to the failure too, propagate the failure to the parent and try using the next rule in the order on the previous tree level. So, that is the reason why all right-hand sides of the rules in PEG are separated by the delimiter /, but not by |. The order of rules in PEGs matters, unlike CFGs. Consider the parsing (Fig. 3) of the word aab by the PEG defined on Fig. 2.

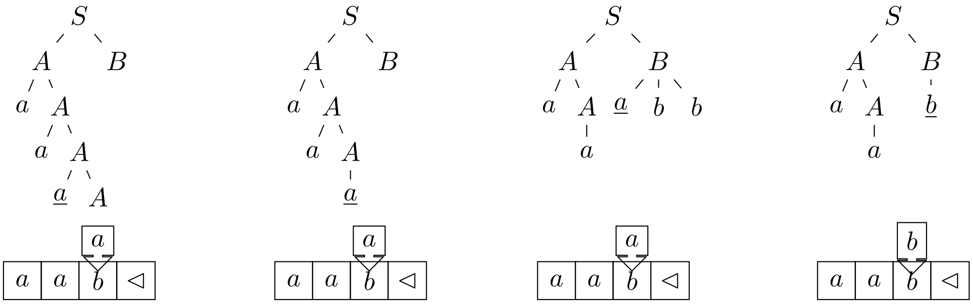

Figure 3 Parsing of aab by PEG.

The rule $A \leftarrow aA$ is applied while the content of the input tape matches the crown (the leafs) of the tree. So, when the last application is unsuccessful, it is replaced by the following rule $A \leftarrow a$ which is unsuccessful too. So failure signal goes to the level above and the second rule $A \leftarrow aA$ is replaced by $A \leftarrow a$. After that, the control goes to the nonterminal B for which firstly the rule $B \leftarrow abb$ is applied, but since it leads to the failure, finally the rule $B \leftarrow b$ is applied and it finishes the parsing since the whole word has been matched.

So PEGs are similar to CFGs since they share the idea of recursive descent parsing. But the difference is significant. Since all the rules for each nonterminal are ordered, the classical notion of concatenation does not apply to PEGs. We cannot say that if a word u is derived from A and v is derived from B, then uv is derived from AB as explained below. In the PEG example above, a word abb is never derived from B because A from AB will always parse all a's from the input. Note that the failure during the parsing occurs only because of a mismatch. So, the input $abbc$ will be parsed by the PEG as following. The prefix ab will be successfully parsed by AB and by S as well, but since the whole word has not been parsed, the input is rejected. Since there was no failure, the rule $S \leftarrow AB$ was not replaced by $S \leftarrow BC$. So the word $abbc$ is not accepted by the PEG while it is derived from the CFG.

▶ Remark 1. It is an open question, whether PELs are closed over concatenation.

Note that the patterns of iteration $A \leftarrow aA\,/\,a$ and $C \leftarrow cC\,/\,\varepsilon$ work in a greedy way. In the case of concatenation Ce (with an expression e), all c's from the prefix of the input would be parsed by C.

In the considered example we have not mentioned an important PEG's operation. There is a unary operator **!** that is applied as follows. In the case **!**e the following happens. Firstly the parsing goes to the expression e. If e parsed the following input successfully (i.e., a subtree for e that matches the prefix of the unprocessed part of the input has been constructed without a failure), then **!**e produces failure. If a failure happens, then **!**e is considered to parse the empty word ε and the parsing process continues. For example, consider the following PEG:

$$S \leftarrow A(\mathbf{!}C)\,/\,B \quad A \leftarrow aAb\,/\,\varepsilon \quad B \leftarrow aBc\,/\,\varepsilon \quad C \leftarrow a\,/\,b$$

($\mathbf{!}C$) guarantees that if $A(\mathbf{!}C)$ finished without failure, then it parsed the whole input. So, in the case of the input a^nb^n for $n \geq 0$, the input will be parsed by $A(\mathbf{!}C)$ and there will be no switch to the rule $S \leftarrow B$. For any other input, the parsing of $A(\mathbf{!}C)$ fails and the rule is switched to $S \leftarrow B$. So, this PEG generates the language $\{a^nb^n \mid n \geq 0\} \cup \{a^nc^n \mid n \geq 0\}$.

Another common use of the operator **!** is its double application that has its name: $\&e = \mathbf{!}(\mathbf{!}e)$. This construction checks whether the prefix of the (unprocessed part of the) input matches e: in the positive case, & parses an empty word and computation continues, in the negative case, it returns failure. So & acts similarly to **!**, but the conditions are flipped. Consider the following example:

$$S \leftarrow (\&(Ac))BC \quad A \leftarrow aAb \,/\, \varepsilon \quad B \leftarrow aB \,/\, a \quad C \leftarrow bCc \,/\, \varepsilon$$

This PEG checks that the input has the prefix $a^n b^n c$ and then parses the input if it has the form $a^+ b^n c^n$, so the PEG generates the language $\{a^n b^n c^n \mid n \geq 1\}$.

So it is known that PEGs generate non CFLs and it is still an open question whether PEGs generate all CFLs. The conditional answer is no: there exists a linear-time parsing algorithm for PEG, while the work of L. Lee [11] and Abboud et al. [1] proves that it is very unlikely for CFLs due to theoretical-complexity assumptions: any CFG parser with time complexity $O(gn^{3-\varepsilon})$, where g is the size of the grammar and n is the length of the input word, can be efficiently converted into an algorithm to multiply $m \times m$ Boolean matrices in time $O(m^{3-\varepsilon/3})$. Note that this conditional result shows that it is unlikely that 2DPPDAs recognize all CFLs as well.

2 Formal Definition of PEGs

Our definition slightly differs from the standard definition of PEG from [7] (Section 3) due to technical reasons. We discuss the difference after the formal definition.

▶ **Definition 2.** *A parsing expression grammar G is defined by a tuple (N, Σ, P, S), where N is a finite set of symbols called* nonterminals*, Σ is a finite input alphabet (a set of* terminals*), $N \cap \Sigma = \varnothing$, $S \in N$ is* the axiom*, and P is a set of* production rules *of the form $A \leftarrow e$ such that each nonterminal $A \in N$ has the only corresponding rule, and e is an expression that is defined recursively as follows. The empty word ε, a terminal $a \in \Sigma$, and a nonterminal $A \in N$ are expressions. If e and e' are expressions, then so are (e) which is equivalent to e, a* sequence ee'*, a* prioritized choice $e \,/\, e'$*, a* not predicate $\mathbf{!}e$*. We assume that **!** has the highest priority, the next priority has the sequence operation and the prioritized choice has the lowest one. We denote the set of all expressions over G by E_G or by E if the grammar is fixed.*

To define the language generated by a PEG G we define recursively a partial function $R : E \times \Sigma^* \to (\Sigma^* \cup \{\mathbf{F}\})$ that takes as input the expression e, the input word w, and if $R(e, w) = s \in \Sigma^*$, then s is the suffix of $w = ps$ such that the prefix p has been parsed by e during the processing of w; if $R(e, w) = \mathbf{F}$ it indicates a failure that happens during the parsing process. So, the function R is defined recursively as follows:

- $R(\varepsilon, w) = w$, $R(a, as) = s$, $R(a, bs) = \mathbf{F}$ (where $a \neq b$)
- $R(e_1 e_2, w) = R(e_2, R(e_1, w))$ if $R(e_1, w) \neq \mathbf{F}$, otherwise $R(e_1 e_2, w) = \mathbf{F}$
- $R(A, w) = R(e, w)$, where $A \leftarrow e \in P$
- $R(e_1 \,/\, e_2, w) = R(e_1, w)$ if $R(e_1, w) \neq \mathbf{F}$, otherwise $R(e_1 \,/\, e_2, w) = R(e_2, w)$
- $R(\mathbf{!}e, w) = w$ if $R(e, w) = \mathbf{F}$, otherwise $R(\mathbf{!}e, w) = \mathbf{F}$

Note that $R(e, w)$ is undefined if during the recursive computation, R comes to an infinite loop. In fact, we will never meet this case because for each PEG there exists an equivalent form for which R is a total function (see Subsection 2.1).

We say that a PEG G *generates* the language $L(G) = \{w \mid R(S, w) = \varepsilon\}$; if $R(S, w) = \varepsilon$ we say that w is *generated* by G.

2.1 Difference with other standard definitions and forms of PEGs

Note that our definition of $L(G)$ differs from [7] (Section 3). The difference is about the operations allowed in PEG and the acceptance condition as well. In this subsection, we explain the difference and provide an overview of different forms of PEGs.

In the case of practical parsing, it is convenient to have more operations in the definition of PEG, but theoretically, it is more convenient to have fewer operations for the sake of the proofs' simplicity. In [7] B. Ford investigated different forms of PEGs and proved their equivalence, so as the equivalence with (generalized) top-down parsing languages. We begin our overview with operations that are so easy to express via operations from our definitions that they can be considered (as programmers say) syntactic sugar:

- **Iterations:** e^* is equivalent to $A \leftarrow eA \,/\, \varepsilon$; $e^+ = ee^*$
- **Option expression:** $e?$ is equivalent to $A \leftarrow e \,/\, \varepsilon$
- **And predicate:** $\&e = \mathbf{!}(\mathbf{!}e)$
- **Any character:** $\bullet = a_1 \,/\, a_2 \,/\, \dots \,/\, a_k$ where $\Sigma = \{a_1, \dots, a_k\}$
- **Failure:** $\mathbf{F} = \mathbf{!}\varepsilon$ (we use the same notation as for the failure result)

We can use these constructions below. In this case, the reader can assume that they are reduced to the operations from Definition 2 as we have described.

So by adding to the definition (or removing) syntactic sugar operations, one obviously obtains an equivalent definition (in terms of recognizable languages' class). Now we move to the nontrivial cases proved in [7].

A PEG G is *complete* if for each $w \in \Sigma^*$ the function $R(S, w)$ is defined. A PEG G is *well-formed* if it does not contain directly or mutually left-recursive rules, such as $A \leftarrow Aa \,/\, a$. It is easy to see that a well-formed grammar is complete. It was proved in [7] that each PEG has an equivalent well-formed one and the algorithm of the transformation had been provided as well. So from now on we assume that each PEG in our constructions is well-formed. Note that most PEGs that are used in practice are well formed by construction.

Another interesting result from [7] is that each PEG has an equivalent one without predicate **!**. Despite this fact, we decided to include **!** in our definition since unlike substitutions for syntactical sugar operations, removing **!** predicate requires significant transformations of the PEG. Since **!** predicate is widely used in practice and it does not affect our constructions, by including **!** in the definition we achieve the constructions that can be used in practice.

As we have already mentioned our condition of the input acceptance also differs from [7]. We used the provided approach since if $R(S, w) = \varepsilon$ we can reconstruct the parsing tree with the root S that generates w. We use this property for the transformation of PEG to the computational model and the inverse transformation as well. Firstly, in [7] there is no axiom in PEG, but there is a starting expression e_S. This difference is insignificant since one can state $e_S = S$ and $S \leftarrow e_S$ for the opposite direction. A PEG from [7] generates the input w if $R(e_S, w) \neq \mathbf{F}$, so $R(e_S, w) = y$, where $w = xy$. So to translate PEG from [7] to ours one needs to set $S \leftarrow e_S(\bullet)^*$. The transformation in the other direction is $e_S = S(\mathbf{!}\bullet)$.

3 Definition of the Computational Model

We call our model *deterministic pointer pushdown automata* (DPPDA). We consider a one-way model (1DPPDA or just DPPDA) as a restricted case of a two-way model (2DPPDA), so we define the two-way model only.

▶ **Definition 3.** *A* 2*-way deterministic pointer pushdown automata M is defined by a tuple*

$$\langle Q, \Sigma_{\triangleright\triangleleft}, \Gamma, F, q_0, z_0, \delta \rangle$$

- Q *is the finite set of automaton states.*
- $\Sigma_{\triangleright\triangleleft} = \Sigma \cup \{\triangleright, \triangleleft\}$*, where* Σ *is the finite input alphabet and* $\triangleright, \triangleleft$ *are the endmarkers. The input has the form* $\triangleright w \triangleleft$, $w \in \Sigma^*$.
- Γ *is the alphabet of the pushdown storage.*
- $F \subseteq Q$ *is the set of the final states.*
- $q_0 \in Q$ *is the initial state.*
- $Z_0 \in \Gamma$ *is the initial symbol in the pushdown storage.*
- δ *is the partial transition function defined as* $\delta : Q \times \Sigma_{\triangleright\triangleleft} \times \Gamma \to Q \times \Gamma_\varepsilon^* \times \{\leftarrow, \downarrow, \uparrow, \to\}$*, where* $\Gamma_\varepsilon = \Gamma \cup \{\varepsilon\}$*. Moreover, if* $\delta(q, a, z) = (q', \alpha, \uparrow)$*, then* $\alpha = \varepsilon$.

To define and operate with configurations of automata we introduce some notation. We denoted by $\alpha \times \vec{i} = (Z_m, i_m), \ldots, (Z_0, i_0)$ the zip of the sequences α and $\vec{i}$, which are of the same length by the definition. A right associative operation $x : \vec{l}$ prepends an element x to the beginning of the vector $\vec{l}$ (we adopt this operator from Haskell programming language). E.g., if $\vec{l} = 1, 2, 3$ and $\vec{r} = 2, 3$, we write $\vec{l} = 1 : \vec{r}$.

A configuration of M on a word w is a quadruple $c \in Q \times (\Gamma \times I)^* \times I$, where $I = \{0, \ldots, |w| + 1\}$; we refer to $w_i, i \in I$ as the i-th input symbol; $w_0 = \triangleright$, $w_{|w|+1} = \triangleleft$. A configuration $c = (q, \alpha \times \vec{i}, j)$ has the following meaning. The head of 2DPPDA M is over the symbol w_j in the state q; the pushdown contains $\alpha = Z_m Z_{m-1} \cdots Z_0$ (the stack grows from right to left) and there is also additional information vector $\vec{i} = i_m, i_{m-1}, \ldots, i_0$, $i_k \in I$ such that Z_k was pushed to the pushdown store when the head was over the i_k-th cell.

The automaton's move is defined via the relation $\vdash$ as follows. Let $\delta(q, a, Z_n) = (q', \beta, d)$. The relation

$$(q, Z_n\alpha \times i_n : \vec{i}, j) \vdash (q', \alpha' \times \vec{i}', j')$$

is defined according to the following case analysis.

- If $d \in \{\leftarrow, \downarrow, \to\}$, then $j' = j - 1$, $j' = j$, $j' = j + 1$ respectively. The cases $a = \triangleright$, $d = \leftarrow$ and $a = \triangleleft$, $d = \to$ are forbidden.
- If $\beta = \varepsilon$ and $d \in \{\leftarrow, \downarrow, \to\}$, then $\alpha' = \alpha$, $\vec{i}' = \vec{i}$
- If $\beta = \varepsilon$ and $d = \uparrow$, then $\alpha' = \alpha$, $\vec{i}' = \vec{i}$, $j' = i_n$
- If $\beta = X_1 \cdots X_k$, $k > 0$, then $\alpha' = \beta Z_n \alpha$, $\vec{i}' = \underbrace{j' : j' : \cdots : j'}_{k} : i_n : \vec{i}$

The initial configuration is $(q_0, Z_0 \times 0, 0)$ and an accepting configuration is $(q_f, \varepsilon \times (), |w| + 1)$, where $q_f \in F$ and by $()$ we have denoted the empty sequence of integers. I.e., M reaches the right end marker $\triangleleft$ empties the stack and finishes the computation in an accepting state. Formally, a word w is accepted by M if there exists a computational path from the initial configuration to an accepting one.

In the case of 1DPPDA (or just DPPDA), the moves $\leftarrow$ are forbidden.

3.1 Properties of DPPDA

Now we discuss the properties of the model and provide some shortcuts for the following needs. Note that each move of a 2DPPDA is either push- or pop-move due to the sake of convenience in the proofs (induction invariants are simpler). At the same time, in constructions, it is convenient to have right, left, and even stay moves that do not change the stack. So we add moves $\hookrightarrow$, $\hookleftarrow$, and $\downarrow$ that are syntactic sugar for such moves. So, when we write $\delta(q, a, z) = (p, \hookrightarrow)$, we mean the sequence of moves:

$$\delta(q, a, z) = (p', Z', \to); \forall \sigma \in \Sigma_{\triangleright\triangleleft} : \delta(p', \sigma, Z') = (p, \varepsilon, \downarrow).$$

The construction for $\hookleftarrow$ and $\downarrow$ are similar.

Due to the definition of δ, a DPPDA can move only if the stack is non-empty and since each move is either push or pop, we have that Z_0 lies at the bottom of the stack till the last move of a computation or even after the last move in the case of unsuccessful computation. In the case of a successful computation, Z_0 is popped at the last move.

4 Equivalence of DPPDAs and PEGs

In this section, we provide an algorithm that transforms a PEG into a DPPDA. The algorithm of the inverse transformation provided in [13] due to space limitations. Our construction is similar to the well-known proof of equivalence between CFGs and DPDA for CFLs, but since both DPPDAs and PEGs are more complicated than DPDAs and CFLs, our constructions are technically harder. We refer the reader to [15] for the detailed explanation of the proof idea, where it was provided for CFLs (so as the proof for CFLs as well).

In this section we assume that PEGs have a special form. We call it Chomsky's normal form since it is similar to such a form for CFGs.

▶ **Definition 4.** *A PEG G has a* Chomsky normal form *if the axiom S never occurs on the right side of the rules and the rules are of the following form:*

$$A \leftarrow B\,/\,C, \quad A \leftarrow BC, \quad A \leftarrow\, !B, \quad A \leftarrow a, \quad A \leftarrow \varepsilon.$$

▶ **Lemma 5** ([13]). *Each PEG G has an equivalent PEG G' in Chomsky's normal form which is complete if so was G.*

▶ **Theorem 6.** *For a PEG G there exists an equivalent DPPDA M.*

Proof. We assume that G is a well-formed PEG in a Chomsky normal form (by Lemma 5). We construct an equivalent DPPDA $M = \langle Q, \Sigma_{\rhd\lhd}, \Gamma, \{q_f\}, q_0, Z_0, \delta\rangle$ by the PEGs description. We formally describe δ on Fig. 4; we do not provide a full list of states Q and pushdown alphabet Γ since most of the states and symbols depend on rules listed in δ's construction and can be easily restored from it. Since the construction is straightforward, we describe here only the main details.

The DPPDA M simulates the parsing process of a PEG G on the input w. Firstly M performs a series of technical moves to come from the initial configuration to the initial simulation configuration:

$$(q_0, Z_0 \times 0, 0) \overset{*}{\vdash} (q, SZ_0 \times (1:0), 1),$$

where q is the *main work state* and S is the axiom of the PEG.

During the simulation the following invariants hold. Below A is a nonterminal of the PEG.

1. If the automaton is in the main work state q and on the top of the stack is the pair $A \times i$, then the head is over the cell i.
2. If the head is over the cell $r+1$ in a state $q_{A_\pm}$ (hereinafter $q_{A_\pm} \in \{q_{A_+}, q_{A_-}\}$) and the topmost symbol had been added at the position l, then it means the following.

   q_{A_+} A subword $s = w_l \cdots w_r$ would be parsed by the PEG from A (starting from the position l); when $r+1 = l$, we have $s = \varepsilon$. In the other direction: if the PEG parses $w_l \cdots w_r$ from A starting from the position l, then the DPPDA that starts computation from the position l in the main work state q with A on the top on the stack finishes at the position $r+1$ with (the same) A on the top of the stack, i.e.,

$$(q, A\alpha \times l : \vec{i}, l) \overset{*}{\vdash} (q_{A_+}, A\alpha \times l : \vec{i}, r+1).$$

q_{A_-} After the PEG started parsing from A from the position l, the computation ended up with a failure at some point in the case of q_{A_-}. In the other direction: if the PEG fails, then for some $r \geq l-1$:

$$(q, A\alpha \times l : \vec{i}, l) \overset{*}{\vdash} (q_{A_-}, A\alpha \times l : \vec{i}, r+1).$$

DPPDA M accepts the input only if the head reaches the symbol $\lhd$ in the state q_{S+} (note that the axiom does not occur on the right side of the rules). Formally, we add the rule

$$\delta(q_{S_+}, \lhd, Z_0) = (q_f, \varepsilon, \downarrow),$$

where q_f is the only final state of the DPPDA. So, from the invariant it follows that the DPPDA accepts the input iff the PEG parses the input.

The rest of the construction is the delta's description in Fig. 4. The proof is a straightforward induction on the recursion depth of the PEGs computation. So we describe the behavior of the automaton corresponding to formal construction in two main cases and check that the invariants hold (the remaining cases are simple).

Construction of δ

We denote by $Z \in \Gamma$ and $\sigma \in \Sigma_{\rhd\lhd}$ arbitrary symbols. The rules are grouped with respect to the PEG's operations. Note that the states q, $q_{A_\pm}$ are the same for all rules, while other states and stack symbols depend on the rule, i.e., stack symbols A_1's from different rules are different even if they correspond to the same nonterminal A. When we use nonterminals (and states) with signs $\pm$ or $\mp$, the signs have corresponding matching, i.e., if in a rule we have $A_\pm$ and $B_\mp$, then when $A_\pm = A_+$, $B_\mp$ equals to B_- and when $A_\pm = A_-$, $B_\mp$ equals to B_+.

0. General rules
- $\delta(q_0, \rhd, Z_0) = (q_0, \hookrightarrow)$; $\forall \sigma' \in \Sigma \cup \{\lhd\} : \delta(q_0, \sigma', Z_0) = (q, S, \downarrow)$;
- $\delta(q_{A_\pm}, \sigma, A) = (q_{A_\pm}, \varepsilon, \downarrow)$; $\delta(q_{S_+}, \lhd, Z_0) = (q_f, \varepsilon, \downarrow)$.

1. $A \leftarrow BC$
- $\delta(q, \sigma, A) = (q, BA_1, \downarrow)$
- $\delta(q_{B_+}, \sigma, A_1) = (q, CA_2, \downarrow)$;
- $\delta(q_{B_-}, \sigma, A_1) = (q_{A_-}, \varepsilon, \uparrow)$;
- $\delta(q_{C_+}, \sigma, A_2) = (q'_{A_2}, \varepsilon, \downarrow)$;
- $\delta(q'_{A_2}, \sigma, A_1) = (q_{A_+}, \varepsilon, \downarrow)$;
- $\delta(q_{C_-}, \sigma, A_2) = (q'_{A_{2-}}, \varepsilon, \uparrow)$;
- $\delta(q'_{A_{2-}}, \sigma, A_1) = (q_{A_-}, \varepsilon, \uparrow)$.

2. $A \leftarrow B \,/\, C$
- $\delta(q, \sigma, A) = (q, BA_1, \downarrow)$
- $\delta(q_{B_+}, \sigma, A_1) = (q_{A_+}, \varepsilon, \downarrow)$
- $\delta(q_{B_-}, \sigma, A_1) = (q_{A_2}, \varepsilon, \uparrow)$
- $\delta(q_{A_2}, \sigma, Z) = (q, CA_2, \downarrow)$
- $\delta(q_{C_+}, \sigma, A_2) = (q_{A_+}, \varepsilon, \downarrow)$
- $\delta(q_{C_-}, \sigma, A_2) = (q_{A_-}, \varepsilon, \uparrow)$;

3. $A \leftarrow \varepsilon$
- $\delta(q, \sigma, A) = (q_{A_+}, \lcurvearrowdown)$

4. $A \leftarrow \mathbf{!}B$
- $\delta(q, \sigma, A) = (q, BA_1, \downarrow)$;
- $\delta(q_{B_\pm}, \sigma, A_1) = (q_{A_\mp}, \varepsilon, \uparrow)$

5. $A \leftarrow a$
- $\delta(q, a, A) = (q_{A_+}, \hookrightarrow)$;
- $\delta(q, b, A) = (q_{A_-}, \lcurvearrowdown)$, here $b \neq a$;

Figure 4 Construction of δ by the PEG G.

Each rule is applied to a configuration of the form $(q, A\alpha \times l : \vec{i}, l)$. In the first case (of concatenation) the automaton pushes the auxiliary symbol A_1 at the same position that A has been pushed (since the invariant 1 holds) and then pushes B. If it reached a configuration of the form $(q_{B_+}, BA_1A\alpha \times l : l : l : \vec{i}, r' + 1)$, then B has successfully parsed the subword $w_l \cdots w_{r'}$ due to invariant 2, then B is popped due to General rules and DPPDA pushes C at the position $r' + 1$ and goes to the main work state q. If then the DPPDA reaches a configuration of the form $(q_{C_+}, CA_2A_1A\alpha \times (r'+1) : (r'+1) : l : l : \vec{i}, r+1)$ we have that the PEG parsed $w_{r'+1} \cdots w_r$ from C and after the sequences of technical pops the automaton comes to the configuration $(q_{A_+}, A\alpha \times l : \vec{i}, r + 1)$ that proves that invariant 2-q_{A_+} holds (the arguments for the other direction are similar).

In the case of reaching the configuration $(q_{C_-}, CA_2A_1A\alpha \times (r'+1) : (r'+1) : l : l : \vec{i}, r+1)$ or $(q_{B_-}, BA_1A\alpha \times l : l : l : \vec{i}, r' + 1)$ earlier, the sequence of pops lead the DPPDA to the configuration $(q_{A_-}, A\alpha \times l : \vec{i}, l)$ that proves that invariant 2-q_{A_-} holds (the arguments for the other direction are similar).

The case of the ordered choice is similar to the case of concatenation. The difference is, that in the case of a configuration $(q_{B_+}, BA_1A\alpha \times l : l : l : \vec{i}, r + 1)$, the automaton reaches the configuration $(q_{A_+}, A\beta \times l : \vec{i}, r + 1)$ via the technical moves, and in the case of $(q_{B_-}, BA_1A\alpha \times l : l : l : \vec{i}, r + 1)$ the automaton reaches the configuration $(q, CA_2A\alpha \times l : l : l : \vec{i}, l)$ after which

$$\text{either } (q, CA_2A\alpha \times l : l : l : \vec{i}, l) \vdash^* (q_{C_+}, CA_2A\alpha \times l : l : l : \vec{i}, r+1) \vdash (q_{A_+}, A\alpha \times l : \vec{i}, r+1),$$

$$\text{or } (q, CA_2A\alpha \times l : l : l : \vec{i}, l) \vdash^* (q_{C_-}, CA_2A\alpha \times l : l : l : \vec{i}, r+1) \vdash^* (q_{A_-}, A\alpha \times l : \vec{i}, l).$$

The analysis of the remaining cases directly follows from the definitions, so we omit it. ◀

5 Linear-Time Simulation of 2DPPDA

Our linear-time simulation algorithm for 2DPPDA is almost the same as S. Cook's algorithm for 2DPDA [5]. One can find the detailed exposition in [2] and [8].

▶ **Theorem 7** ([13]). *Let M be a 2DPPDA. The language $L(M)$ is recognizable in time $O(n)$ in the RAM model. Moreover, there exists an $O(|w|)$ (in RAM) simulation algorithm for M on the input w.*

6 Structural Results

We use the computational model to obtain new structural results about the PELs.

▶ **Lemma 8.** *Let X be a DCFL and Y be a PEL. Then XY is a PEL.*

Proof. We describe a DPPDA M recognizing XY that simulates a DPDA M_X recognizing X and a DPPDA M_Y recognizing Y, constructed by a (well-formed) PEG.

DPPDA M simulates M_X until it reaches an accepting state. Then it pushes the information of the state to the stack, then pushes Z_0 (of M_Y) and simulates M_Y. If M_Y accepts the rest of the input, then the whole input is accepted. Otherwise, M pops symbols from the stack until it reaches the info about the M_X state and continues the simulation until it reaches an accepting state again. This process is continued until either M_Y accepts, or M_X reaches the end of the input (and M_Y rejects ε).

The correctness easily follows from the construction. During the process M tests all the prefixes of the input from X and checks whether the corresponding suffixes belong to Y. ◀

We use the notation PEL, DCFL, and REG for the language classes in formulas (the last one denotes regular languages). Denote by $\Gamma_{\mathsf{REG}}(\mathsf{DCFL})$ the regular closure of DCFLs; this class is defined as follows. $L \in \Gamma_{\mathsf{REG}}(\mathsf{DCFL})$ if there exists a regular expression (RE) R over an alphabet $\Sigma_k = \{a_1, \ldots, a_k\}$ and DCFLs $L_1, \ldots, L_k$ such that if we replace a_i by L_i in R the resulting expression $\psi(R)$ describes L.

▶ **Lemma 9** ([13])**.** $\Gamma_{\mathsf{REG}}(\mathsf{DCFL}) \subseteq \mathsf{PEL}$.

We describe only the proof idea. We provided the proof of Lemma 8 to generalize it as follows. In the case of a single concatenation, we have a kind of linear order for an exhaustive search. In the case of $\Gamma_{\mathsf{REG}}(\mathsf{DCFL})$ we will perform an exhaustive search in the order corresponding to a (graph of) deterministic finite automaton (DFA) recognizing R. If a word w on the input belongs to $L \in \Gamma_{\mathsf{REG}}(\mathsf{DCFL})$, then it can be split into subwords $w_1 \cdots w_k = w$ such that there exists a word $\alpha_1 \cdots \alpha_k \in R$ such that $w_i \in L_{\alpha_i}$, where L_{α_i} is the DCFL from the substitution that maps α_i to L_{α_i}. So, the exhaustive search finds the split of w by considering $\alpha_1 \cdots \alpha_k$ in the length-lexicographic order and considering w's subwords $w_i \in L_{\alpha_i}$ ordered by the length. If a word $w_1 \in L_{\alpha_1}$ is the shortest prefix, the DPPDA tries to find the shortest $w_2 \in L_{\alpha_2}$ and so on. If at some point the DPPDA failed to find $w_{j+1} \in L_{\alpha_{j+1}}$, it rollbacks to α_j and tries to find a longer word $w_j \in L_{\alpha_j}$. If it fails, then it rollbacks to α_{j-1} and so on. During the search of w_j, the DPPDA simulates a DPDA M_j recognizing L_{α_j}.

Denote by $\Gamma_{\mathsf{Bool}}(\mathscr{L})$ the *Boolean closure* of the language's class $\mathscr{L}$, i.e., $\Gamma_{\mathsf{Bool}}(\mathscr{L})$ is a minimal class satisfying the conditions:

- $\mathscr{L} \subseteq \Gamma_{\mathsf{Bool}}(\mathscr{L})$
- $\forall A, B \in \Gamma_{\mathsf{Bool}}(\mathscr{L}) : A \cup B, A \cap B, \overline{A} \in \Gamma_{\mathsf{Bool}}(\mathscr{L})$

▶ **Theorem 10.** *The following assertions hold.*

1. $\Gamma_{\mathsf{Bool}}(\Gamma_{\mathsf{REG}}(\mathsf{DCFL})) \subseteq \mathsf{PEL}$.
2. $\Gamma_{\mathsf{REG}}(\mathsf{DCFL}) \cdot \mathsf{PEL} = \mathsf{PEL}$.

Proof. It was shown in [7] that $\Gamma_{\mathsf{Bool}}(\mathsf{PEL}) = \mathsf{PEL}$. We proved that $\Gamma_{\mathsf{REG}}(\mathsf{DCFL}) \subseteq \mathsf{PEL}$, so $\Gamma_{\mathsf{Bool}}(\Gamma_{\mathsf{REG}}(\mathsf{DCFL})) \subseteq \mathsf{PEL}$.

The inclusion $\Gamma_{\mathsf{REG}}(\mathsf{DCFL}) \cdot \mathsf{PEL} \supseteq \mathsf{PEL}$ is obvious ($\{\varepsilon\} \in \Gamma_{\mathsf{REG}}(\mathsf{DCFL})$). The inclusion $\Gamma_{\mathsf{REG}}(\mathsf{DCFL}) \cdot \mathsf{PEL} \subseteq \mathsf{PEL}$ follows from the modification of the simulation algorithm from the proof of Lemma 9 by the simulation step from the proof of Lemma 8: when M_j reaches an accepting state and the corresponding state of $\mathcal{A}$ is an accepting state, M simulates the DPPDA for the PEG. If it successfully parses the suffix, the input is accepted, otherwise, the simulation continues as in the proof of Lemma 9. Recall that it is not known, whether PELs are closed over concatenation (Remark Remark:ConcatClosure), so we have to use Lemma 9 to for left concatenation with $\Gamma_{\mathsf{REG}}(\mathsf{DCFL})$. ◀

▶ **Corollary 11.** *For each $L \in \Gamma_{\mathsf{Bool}}(\Gamma_{\mathsf{REG}}(\mathsf{DCFL}))$ there exists a RAM-machine M that decides, whether $w \in L$ in time $O(|w|)$. In other words, the class $\Gamma_{\mathsf{Bool}}(\Gamma_{\mathsf{REG}}(\mathsf{DCFL}))$ is linear-time recognizable.*

Monoids of Upper Triangular Matrices over the Boolean Semiring

Andrew Ryzhikov
Department of Computer Science, University of Oxford, UK

Petra Wolf
LaBRI, CNRS, Université de Bordeaux, Bordeaux INP, France

Abstract

Given a finite set $\mathcal{A}$ of square matrices and a square matrix B, all of the same dimension, the membership problem asks if B belongs to the monoid $\mathcal{M}(\mathcal{A})$ generated by $\mathcal{A}$. The rank one problem asks if there is a matrix of rank one in $\mathcal{M}(\mathcal{A})$. We study the membership and the rank one problems in the case where all matrices are upper triangular matrices over the Boolean semiring. We characterize the computational complexity of these problems, and identify their PSPACE-complete and NP-complete special cases.

We then consider, for a set $\mathcal{A}$ of matrices from the same class, the problem of finding in $\mathcal{M}(\mathcal{A})$ a matrix of minimum rank with no zero rows. We show that the minimum rank of such matrix can be computed in linear time.We also characterize the space complexity of this problem depending on the size of $\mathcal{A}$, and apply all these results to the ergodicity problem asking if $\mathcal{M}(\mathcal{A})$ contains a matrix with a column consisting of all ones. Finally, we show that our results give better upper bounds for the case where each row of every matrix in $\mathcal{A}$ contains at most one non-zero entry than for the general case.

1 Introduction

Membership in matrix monoids. Given a finite set $\mathcal{A}$ of $n \times n$ matrices and an $n \times n$ matrix B, *the membership problem* asks if B belongs to the monoid $\mathcal{M}(\mathcal{A})$ generated by $\mathcal{A}$, which is the set of all products of matrices from $\mathcal{A}$. For matrices over rational numbers, membership is solvable in polynomial time if $\mathcal{A}$ consists of one matrix [22]. This result was later extended to the case where $\mathcal{A}$ is a set of commuting matrices [1], and then to a special class of non-commutative matrices [28]. Membership is also decidable for 2×2 non-singular integer matrices [34]. On the other hand, membership is already undecidable for 3×3 integer matrices with determinant equal to 0 [32].

For sets of matrices over the Boolean semiring (the set $\{0, 1\}$ with addition and multiplication defined the same way as for integer numbers, except that $1 + 1 = 1$), many natural problems, including membership, are trivially in PSPACE, and are thus more tractable. However, membership in this case is actually PSPACE-complete [25]. In this paper, we further restrict the setting and study upper triangular matrices over the Boolean semiring. Everywhere below in this paper, we assume all matrices to be square and over the Boolean

semiring, unless specified otherwise. Upper triangular matrices may seem to be a simple and restrictive class, but sets of such matrices and the corresponding automata have been studied extensively, and many problems for them are known to be PSPACE-complete, see e.g. [33, 26, 31, 37, 30]. Nevertheless, we are not aware of any results on the four problems we consider in this paper (membership, rank one, minimum rank of a total word and ergodicity) specifically for the case of upper triangular matrices, except for the results of [43] on the ergodicity problem, which we explain below.

Matrices and sets of matrices over the Boolean semiring play an important role in automata theory [4], discrete-time Markov chains [38], graph theory [2], variable-length codes [12], and symbolic dynamics [27]. They are often used in the theory of nonnegative matrices, since in many problems one is not interested in the actual values of the entries, but only in which values are zero and which are strictly positive [3].

Boolean square matrices can also be viewed as binary relations on a finite set Q. Matrices with at most one non-zero entry in each row thus correspond to partial transformations, and if they have exactly one non-zero entry in every row, to complete transformations. We call such matrices transformation and complete transformation matrices respectively. For monoids of complete transformation matrices, membership is PSPACE-complete [25], and its complexity was studied for several subsclasses [7, 6, 9, 8]. Connections of membership with the automata intersection problem are explored in [13].

The rank one problem. Instead of asking if the monoid $\mathcal{M}(\mathcal{A})$ contains a given matrix, one can ask if it contains a matrix from a certain class. Given a set $\mathcal{A}$ of matrices, *the rank one problem* asks if there is a matrix of rank one in $\mathcal{M}(\mathcal{A})$.

The rank one problem is known to be solvable in polynomial time for monoids of complete transformation matrices (see e.g. [41]), strongly connected monoids of transformation matrices [11] and, more generally, for strongly connected monoids of unambiguous relations and their subclasses [36, 14, 24, 4] (a monoid of $n \times n$ matrices is called *strongly connected* if for each pair (i, j), $1 \leq i, j \leq n$, it contains a matrix whose entry (i, j) is equal to one). The latter case plays an important role in the theory of variable-length codes because of its connections with synchronizing codes [12]. On the other hand, the rank one problem is PSPACE-complete already for monoids of transformation matrices which are not strongly connected [10]. The complexity of deciding if a monoid of complete transformation matrices contains a matrix of given rank is studied in [18].

The rank one problem is related to the Černý conjecture and its generalizations. Indeed, the case of monoids of complete transformations corresponds exactly to the case of complete DFAs, and hence in this case the rank one problem is nothing else than the problem of checking if a complete DFA is synchronizing. We refer to the surveys [41, 42, 23, 5] for the vast literature on synchronizing DFAs.

Careful synchronization and ergodicity. A similar problem is, given a set $\mathcal{A}$ of matrices, to find in $\mathcal{M}(\mathcal{A})$ a minimum rank matrix without zero rows. We call matrices with no zero rows *total*, since they correspond to total relations. For sets of transformation matrices, monoids of matrices containing a total matrix of rank one correspond to carefully synchronizing DFAs [29]. Deciding if $\mathcal{M}(\mathcal{A})$ contains a total matrix of rank one is PSPACE-complete even if $\mathcal{A}$ consists of two matrices [29], and the length of a shortest product of matrices from $\mathcal{A}$ resulting in a total matrix of rank one can be exponential [29]. If $\mathcal{A}$ is a set of upper triangular transformation matrices, deciding if $\mathcal{M}(\mathcal{A})$ contains a total matrix of rank one and finding a product resulting in such a matrix is solvable in polynomial time [43]. We discuss the contributions of [43] and their connection to the results of this paper in more details in the beginning of Section 4.

A closely related notion is that of ergodic matrices (also known as column-primitive [16] or D3-directing [20, 21]). A matrix is called *ergodic* [44] if it has a column consisting of all ones. Note that a transformation matrix is ergodic if and only if it is a total matrix of rank one, that is, this case also coincides with carefully synchronizing DFAs. *The ergodicity problem* asks if a given matrix monoid contains an ergodic matrix. The ergodicity problem is PSPACE-complete [29], but is solvable in polynomial time for monoids of matrices with no zero rows [35, 44]. An application of ergodicity to deciding if a discrete-time multi-agent system can be driven to consensus is presented in [16]. We emphasize that the existing polynomial-time solvability results on ergodicity [44, 16, 15] (except for [43]) consider monoids of matrices with no zero rows, while our results for this problem do not have this requirement.

2 Main definitions and our contributions

Boolean rank. *The Boolean semiring* is the set $\{0, 1\}$ with addition and multiplication defined in the usual way except that $1 + 1 = 1$. All matrices in this paper are over the Boolean semiring. The *Boolean rank* [17] (which we call just *rank* for brevity in this paper) of an $n \times n$ matrix A is the smallest number r such that $A = CR$, where C is an $n \times r$ matrix, and R is an $r \times n$ matrix, with usual matrix multiplication over the Boolean semiring.

For example, the following equality shows that the rank of A is at most two (moreover, it cannot be one since there are two different non-zero rows in A):

$$A = \begin{pmatrix} 1 & 1 & 1 \\ 1 & 1 & 0 \\ 0 & 1 & 1 \end{pmatrix} = \begin{pmatrix} 1 & 1 \\ 1 & 0 \\ 0 & 1 \end{pmatrix} \begin{pmatrix} 1 & 1 & 0 \\ 0 & 1 & 1 \end{pmatrix} = CR.$$

Matrices and automata. Let $\mathcal{A} = \{A_1, \ldots, A_m\}$ be a set of $n \times n$ matrices over the Boolean semiring. The *monoid generated by* $\mathcal{A}$ is the set of all possible products (with respect to the usual matrix multiplication) of matrices from $\mathcal{A}$, including the empty product corresponding to the identity matrix. By assigning to each matrix $A_i \in \mathcal{A}$ a letter a_i from a finite alphabet Σ of size m, the set $\mathcal{A}$ can be equivalently seen as a nondeterministic finite automaton (NFA) with state set $Q = \{1, 2, \ldots, n\}$, alphabet Σ and transition relation $\Delta : Q \times \Sigma \to 2^Q$ defined for each letter a_i by the action of the corresponding matrix A_i. That is, we have $j \in \Delta(i, a_k)$ if and only if the entry (i, j) in A_k is one. If the transition relation is clear from the context, we denote the set $\Delta(q, a)$ as $q \cdot a$. Equivalently, given an NFA (Q, Σ, Δ), we can consider for each $a \in \Sigma$ the matrix such that its entry (p, q), $p, q \in Q$, is non-zero if and only if $q \in \Delta(p, a)$. This allows to consider an NFA as a set of matrices corresponding to its letters. The transition relation can be homomorphically extended to the set Σ^* of words over Σ. Words over Σ thus naturally correspond to products of matrices. In particular, by the matrix of a word we mean the result of this product, and by the rank of a word we mean the rank of its matrix. In this paper we make use of this correspondence between NFAs and matrix monoids and switch between the languages of matrices and automata whenever convenient. We remark that the described construction is nothing more than a homomorphism from the free monoid Σ^* to the monoid of matrices over the Boolean semiring.

In NFA terms, the matrix M of a word w has rank at most r if and only if there exist r subsets $Q_1, \ldots, Q_r$ of Q such that the image of every state of Q under w is a union of some of these subsets. If r is the smallest such number, the rank of M is equal to r. In particular, the rank of a word is one if and only if there is a subset $Q_1 \subseteq Q$ such that the image of every state under w is either Q_1 or the empty set, and not all images are empty.

For a set $S \subseteq Q$ of states and a word $w \in \Sigma^*$, we denote $S \cdot w = \{p \in Q \mid p \in q \cdot w$ for some $q \in S\}$. We say that the action of a word w is *defined* for a state q if $q \cdot w$ is non-empty. A word is called *total* if its action is defined for every state. Equivalently, it means that the matrix of a word does not have zero rows.

An NFA is a *deterministic finite automaton* (DFA) if for every $p \in Q$ and $a \in \Sigma$ we have that $|\Delta(p, a)| \leq 1$. In this case we use δ instead of Δ to emphasize that the transition relation is a (partial) transition function. If moreover $\delta(p, a)$ is defined for every $p \in Q$ and $a \in \Sigma$, the DFA is called *complete*. For DFAs, the rank of a word w is simply the size $|Q \cdot w|$.

Ergodic words. A word w is called *ergodic* for an NFA $\mathcal{A} = (Q, \Sigma, \Delta)$ if there is a state $q \in Q$ such that for every state $p \in Q$ we have $q \in p \cdot w$. Equivalently, a word is ergodic if its matrix contains a column of all ones. Clearly, every ergodic word is total. We call an NFA *ergodic* if it admits an ergodic word.

Partially ordered automata. An NFA $\mathcal{A} = (Q, \Sigma, \Delta)$ is called *partially ordered* (poNFA) if there exists an order $\prec$ on its set of states Q which is preserved by all its transitions. That is, if $p \in \Delta(q, a)$ for $p, q \in Q$ and $a \in \Sigma$, then $q \prec p$ or $q = p$. Such order can be found in time $\mathcal{O}(mn)$ by topological sorting, and in deterministic logarithmic space [40], hence we always assume that a poNFA is provided together with the order $\prec$. Equivalently, an NFA is a poNFA if the underlying digraph of $\mathcal{A}$ does not have any cycles other than self-loops, or, alternatively, if the matrices of all letters of $\mathcal{A}$ are upper triangular. A poNFA $\mathcal{A}$ is called *self-loop deterministic* if for every letter $a \in \Sigma$ such that $q \in q \cdot a$ for a state $q \in Q$ we have $q \cdot a = \{q\}$. Following [26], we denote self-loop deterministic partially ordered NFAs as rpoNFAs. We denote partially ordered DFAs as poDFAs.

Decision problems. An *NFA acceptor* $\mathcal{A} = (Q, \Sigma, \Delta, I, F)$ is an NFA (Q, Σ, Δ) with distinguished sets $I \subseteq Q$ and $F \subseteq Q$ of, respectively, initial and final states. The *language* $L(\mathcal{A})$ of an NFA acceptor is the set of words $w \in \Sigma^*$ such that there exist states $i \in I$, $f \in F$ with $f \in i \cdot w$. Given an NFA acceptor, *the universality problem* asks if it accepts all words over its alphabet. Universality of poNFAs is PSPACE-complete even over a binary alphabet [26], and remains PSPACE-complete for rpoNFAs over polynomial size alphabet [26, 30].

Given an NFA $\mathcal{A}$ and a matrix B, *the membership problem* asks if there exists a word such that its matrix in $\mathcal{A}$ is equal to B. Given an NFA $\mathcal{A}$, the *rank one problem* asks if there is a word whose matrix has rank one in $\mathcal{A}$.

We assume that the reader is familiar with basic notions of automata theory and computational complexity, see e.g. [39].

Our contributions. In the first half of this paper, Section 3, we analyze the computational complexity of the membership and rank one problems for poNFAs (equivalently, for monoids of upper triangular matrices). We show that they are PSPACE-complete for rpoNFAs and ternary poNFAs (Proposition 6). The main results of Section 3 are that for rpoNFAs over a fixed alphabet the membership problem is in NP (Theorem 1), and remains NP-complete even for complete poDFAs over a binary alphabet (Theorem 8). We show containment in NP by proving that for each word there is a short word with the same matrix (Proposition 2). We complement this result with a lower bound on the length of words with a given matrix (Lemma 7).

In the second half of the paper, Section 4, we study the problem of finding the minimum rank of a total word in a poNFA. We show that, depending on the size of the alphabet, this problem lies between L and P-complete, and moreover can be solved in linear time. These results are summarized in Theorem 11. All these results transfer to the problem of ergodicity of a set of upper triangular matrices (Theorem 15), which asks if a matrix monoid contains a matrix with a column consisting of all ones. We then further extend these results to get improved bounds for ergodicity of poDFAs (Theorem 16).

3 Membership and minimum rank

3.1 Upper bounds for rpoNFAs

The goal of this subsection is to prove the following theorem.

▶ **Theorem 1.** *Membership for rpoNFAs over a fixed alphabet is in* NP.

We start with the following key result which, intuitively, shows that if $\mathcal{A}$ is an rpoNFA, a product of matrices from $\mathcal{A}$ cannot contain too many partial products.

▶ **Proposition 2.** *Let $\mathcal{A} = (Q, \Sigma, \Delta)$ be an rpoNFA with n states and m letters. For every word $w \in \Sigma^*$ there exist at most $n(n+1)^{m-1}$ prefixes of w with pairwise different matrices.*

Proof. We prove the statement by induction on m. Clearly, if $m = 1$, the matrix of every word w of length more than n is equal to the matrix of some word v of length at most n, and thus the matrix of every prefix of w is equal to the matrix of some prefix of v, and there are only at most n prefixes.

Assume now that $m \geq 2$ and the statement is true for rpoNFAs over all alphabets $\Sigma' \subset \Sigma$, $|\Sigma'| \leq m - 1$. We can assume that every letter from Σ appears in w, otherwise the statement is proved. Let $Q = Q_1 \cup Q_1'$, where Q_1 is the set of states p such that there exists a letter $a \in \Sigma$ with $p \notin p \cdot a$, and $Q_1' = Q \setminus Q_1$. Let q be a smallest (with respect to $\prec$) state in Q_1, and let $a \in \Sigma$ be a letter such that $q \notin q \cdot a$.

Let w' be the prefix of w before the first appearance of a, that is, w' is the prefix of w such that w' does not contain a, and $w'a$ is also a prefix of w. Clearly, $w' \in (\Sigma \setminus \{a\})^*$. By the induction assumption, there are at most $n(n+1)^{m-2}$ prefixes of w' with pairwise different matrices. After the first application of a, for each state $p \in Q_1 \cdot w'a$ we have that $q \prec p$.

Now we perform the following iterative process. If the suffix of w after the first appearance of a does not contain all letters from Σ, we stop. Otherwise, we consider the smallest state q' in $Q_1 \cdot w'a$ and a letter a' such that $q' \notin q' \cdot a'$, and repeat the argument above with $Q_1 \cdot w'a$ taken as Q_1, q' taken as q, a' taken as a, and w' taken as w. This argument will be repeated at most n times in total, since after n times Q_1 must be empty, and thus the remaining suffix does not change the matrix of the word. Hence we get that there are at most $n \cdot (n(n+1)^{m-2} + 1) \leq n(n+1)^{m-1}$ prefixes of w with pairwise different matrices. ◀

▶ **Lemma 3.** *Let $\mathcal{A}$ be an rpoNFA and w be a word. Let P be the set of matrices of all prefixes of w, and $|P| = k$. Then there exist words $w_1, \ldots, w_k$ such that $w = w_1 w_2 \ldots w_k$, every matrix in P is equal to the matrix of $w_1 \ldots w_i$ for some i, and for each i, $0 \leq i < k$, for every non-empty prefix v of w_{i+1} the matrices of $w_1 w_2 \ldots w_i v$ and $w_1 w_2 \ldots w_i w_{i+1}$ are equal.*

Proof. Represent w as a concatenation $w_1 w_2 \ldots w_k$ of words w_i such that for every i, $0 \leq i < k$, the matrices of $w_1 w_2 \ldots w_i$ and $w_1 w_2 \ldots w_i w_{i+1}$ are different, but the matrix of $w_1 w_2 \ldots w_i v$ is equal to the matrix of $w_1 w_2 \ldots w_i w_{i+1}$ for every non-empty prefix v of w_{i+1}. We only need to show that for $i \neq j$ the matrices of $w_1 w_2 \ldots w_i$ and $w_1 w_2 \ldots w_j$ cannot be equal. This follows from the fact that in rpoNFAs, if for some non-empty words u_1, u_2 the matrices of u_1 and $u_1 u_2$ are different, there is no word u_3 such that the matrices of u_1 and $u_1 u_2 u_3$ are equal. ◀

The following statement implies that membership is in NP for rpoNFAs over a fixed alphabet, thus proving Theorem 1. It also implies that the rank one problem for rpoNFAs over a fixed alphabet is in NP.

▶ **Proposition 4.** *Let $\mathcal{A}$ be an rpoNFA with n states and m letters. Then for every word there exists a word of length at most $n(n+1)^{m-1}$ with the same matrix.*

Proof. Let $w_1, \ldots, w_k$ be the words from the statement of Lemma 3. By Proposition 2, $k \leq n(n+1)^{m-1}$. For each i, $1 \leq i \leq k$, let a_i be the first letter of w_i. Then the matrix of $a_1 a_2 \ldots a_k$ is equal to the matrix of w. ◀

As another consequence of our results, we get an elementary combinatorial proof of a theorem from [26] which originally required some non-trivial formal languages machinery.

▶ **Corollary 5** (Theorem 23 in [26]). *Let $\mathcal{A}$ be an NFA acceptor, and $\mathcal{B}$ be an rpoNFA acceptor, both over the same fixed alphabet. Checking if $L(\mathcal{A}) \subseteq L(\mathcal{B})$ is in* coNP.

Proof. If $L(\mathcal{A}) \not\subseteq L(\mathcal{B})$, there exists a word w accepted by $\mathcal{A}$ and not accepted by $\mathcal{B}$. Let $w_1, \ldots, w_k$ be the words from the statement of Lemma 3. By Proposition 2, $k \leq n(n+1)^{m-1}$. For each i let a_i be the first letter of w_i, and let $w_i = a_i w_i'$. Furthermore, let Σ_i be the set of letters occurring in w_i'. Consider the regular expression $e = a_1 \Sigma_1^* a_2 \Sigma_2^* a_3 \ldots \Sigma_{k-1}^* a_k \Sigma_k^*$. By construction, w is accepted by e, and for every word accepted by e its matrix in $\mathcal{B}$ is equal to the matrix of w in $\mathcal{B}$, and thus every such word is not accepted by $\mathcal{B}$. Moreover, e can be straightforwardly transformed into a poNFA acceptor $\mathcal{E}$ with at most $n(n+1)^{m-1}$ states and m letters. It remains to note that the intersection of $\mathcal{A}$ and $\mathcal{E}$ can be decided in polynomial time, and hence $\mathcal{E}$ can be used as a certificate for coNP. ◀

3.2 Lower bounds for rpoNFAs

We now complement the positive results from the previous subsection with lower bounds. We first show that if the alphabet is not fixed, membership for rpoNFAs is as hard as for general NFAs. The proof of that is done by constructing a reduction from the universality problem for rpoNFA acceptors, which is PSPACE-complete [26]. The same proof works for ternary poNFAs.

▶ **Proposition 6.** *The membership and rank one problems are* PSPACE*-complete for rpoNFAs and ternary poNFAs.*

Proof. To prove both statements, we use the following reduction from the universality problem for poNFA acceptors. Let $\mathcal{A} = (Q, \Sigma, \Delta, I, F)$ be a poNFA acceptor. Construct a poNFA $\mathcal{A}' = (Q \cup \{q_0, p_0, p_1, q_+, q_-\}, \Sigma \cup \{r\}, \Delta')$. The transition relation Δ' includes all transitions in Δ, with the addition of $\Delta'(q_0, r) = I$, $\Delta'(q, r) = \{q_+\}$ if $q \in F$, and $\Delta'(q, r) = \{q_-\}$ if $q \in Q \setminus F$. We also define $\Delta'(p_0, r) = \{p_1\}$, $\Delta'(p_1, r) = \{q_-\}$. Finally, all letters in Σ induce self-loops for q_+, q_-, q_0, p_0, p_1. See Figure 1 for an illustration.

We claim that $\mathcal{A}$ does not accept a word in Σ^* if and only if there exists a word in $\mathcal{A}'$ which maps q_0 and p_0 to $\{q_-\}$, and all other states to the empty set. Indeed, if there exists a word w not accepted by $\mathcal{A}$, then the word rwr has the required action in $\mathcal{A}'$. Conversely, if w' is a word having the required action, then it must contain exactly two occurrences of r, and its factor between the first and the second occurrence of r maps I to a subset of $Q \setminus F$ and is thus not accepted by $\mathcal{A}$. Observe also that every word of rank one must have this action by construction. Furthermore, the described construction preserves the property that the NFA is an rpoNFA. It remains to use the fact that the universality problem is PSPACE-complete for rpoNFA acceptors and binary poNFA acceptors [26]. ◀

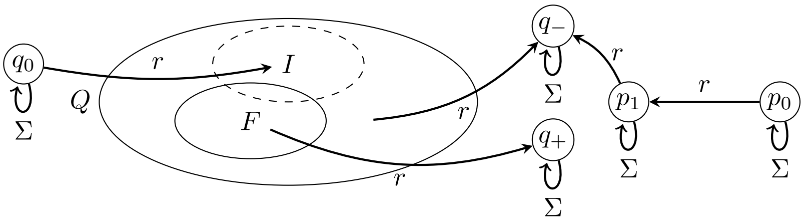

Figure 1 Illustration for the reduction in Proposition 6.

The following lemma provides a lower bound for the value discussed in Proposition 4. We remark that for constant m our lower and upper bounds are asymptotically the same, and if $m = n - 1$ the lower bound is exponential.

▶ **Lemma 7.** *Let n and m be positive natural numbers such that m divides $n - 2$. Then there exists an rpoNFA with n states and m letters such that for some states t and f the length of a shortest word w with $f \cdot w = \{f\}$ and $q \cdot w = \{t\}$ for every state $q \neq f$ is $\frac{n-2}{m}(\frac{n-2}{m} + 1)^{m-1}$.*

Proof. Let $n = ms + 2$. We construct an rpoNFA $\mathcal{A} = (Q, \Sigma, \Delta)$ with the required properties as follows. Let $Q^{(j)} = \{q_1^{(j)}, \ldots, q_s^{(j)}\}$ and $S = \cup_{1 \leq j \leq m} Q^{(j)}$. Take $Q = S \cup \{t, f\}$, where t and f are fresh states, and $\Sigma = \{a_1, a_2, \ldots, a_m\}$. The transition relation Δ is defined for the states in the sets $Q^{(1)}, \ldots, Q^{(m)}$ in such a way that while reading a word w with $S \cdot w = \{t\}$, the states in $Q^{(j)}$ that contain an image of a state from S imitate an m-ary counter counting to zero, with some additional traversal in the process. Formally, for $1 \leq j, k \leq m$, $1 \leq i \leq s$ we set

$$\Delta(q_i^{(k)}, a_j) = \begin{cases} \{f\} & \text{if } j < k; \\ \{q_{i+1}^{(k)}\} & \text{if } j = k \text{ and } i < s; \\ Q^{(k+1)} \cup \ldots \cup Q^{(m)} & \text{if } j = k < m \text{ and } i = s; \\ \{t\} & \text{if } j = k = m \text{ and } i = s; \\ \{q_i^{(k)}\} & \text{if } j > k. \end{cases}$$

See Figure 2 for an illustration.

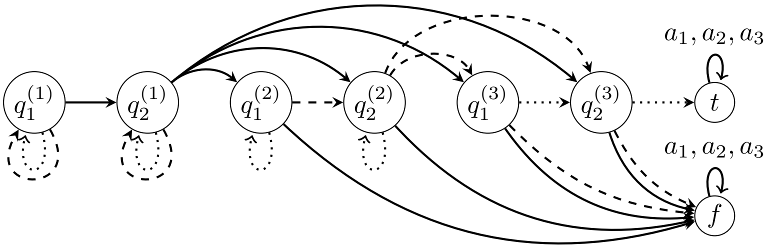

Figure 2 Illustration for the construction in Lemma 7. For unlabeled transitions, solid lines stand for a_1, dashed for a_2, dotted for a_3.

The only way to map a state to $\{t\}$ is to map it first to $\{q_s^{(m)}\}$ and then apply the letter a_m, otherwise the state is mapped to a set containing f. Observe that the shortest word such that $S \cdot w = \{t\}$ is unique. Indeed, at every moment of time there is a unique letter that does not act as the identity and does not map any state of S to f. To estimate the length of this word, we argue inductively. Mapping $Q^{(m)}$ to $\{t\}$ requires a word of length s. Mapping the set $Q^{(j)}$, $j < m$, to $\{t\}$ requires subsequently mapping each of its states to $\cup_{k>j} Q^{(k)}$, and then mapping this union to $\{t\}$ before we can proceed to $Q^{(j-1)}$. Hence we get the bound of $s(s+1)^{m-1}$. ◀

By applying the idea of the reduction in the proof of Proposition 6 to the automaton constructed in the proof of Lemma 7, one can get a slightly weaker lower bound of $\frac{n-4}{m-1}(\frac{n-4}{m-1} + 1)^{m-2} + 1$ for the length of a shortest word of rank one in rpoNFAs with n states and m letters, where $m-1$ divides $n-4$. Recall that a word of rank one is allowed to kill some states.

3.3 Partially ordered DFAs

The following theorem characterizes the complexity of membership and rank one for poDFAs.

▶ **Theorem 8.** *The membership problem is* NP*-complete for complete poDFAs, even over a binary alphabet. The rank one problem is* NP*-complete for poDFAs, even over a binary alphabet.*

The proof of NP-hardness is an adaptation of a construction from [37], and is omitted due to space constraints. Containment in NP follows from the following result.

▶ **Proposition 9.** *Let $\mathcal{A}$ be a poDFA with n states. Then for every word there exists a word of length at most $\frac{1}{2}(n+1)n$ with the same matrix.*

Proof. Let $\mathcal{A} = (Q, \Sigma, \delta)$. Introduce a new state f, and define all undefined transitions of $\mathcal{A}$ to end there. Then for every state $q \in Q \setminus \{f\}$ we have $q \prec f$. Let w be a word such that there is no shorter word with the same matrix. For each prefix $w'a$ of w with $w' \in \Sigma^*, a \in \Sigma$, a must map one of the states in the image $Q \cdot w'$ to a larger state, otherwise this occurrence of a can be removed from w without changing its matrix. Hence the maximal length of w is at most $n + (n-1) + (n-2) + \ldots + 1 = \frac{1}{2}(n+1)n$. ◀

A lower bound on the value from Proposition 9 is provided in Lemma 17 below. Its adaptation provides the following lower bound on shortest words of rank one for poDFAs.

▶ **Lemma 10.** *For every natural numbers n and $m \geq 2$ such that m divides $n-1$, there exists a poDFA with $2n+1$ states and $m+1$ letters such that the length of a shortest word of rank one for it is $\frac{m-1}{2m}(n-1)^2 + (n-1)$.*

We remark that the rank one problem is trivial for poNFAs which do not have a word whose matrix is the zero matrix. Indeed, the minimum rank of a word in such poNFA is just the number of states such that each letter induces a self-loop for them. However, this obviously does not affect the complexity of membership, since adding a fresh state having self-loops by all letters guarantees that the matrix of each word is non-zero, while preserving the actions of all letters on the remaining states. For poDFAs, one can even obtain a complete poDFA by adding a sink state and sending all undefined transitions to it.

4 Total words of minimum rank and ergodic words

As shown above, the rank one problem is NP-complete for poDFAs and PSPACE-complete for rpoNFAs. In this section, we show that computing the minimum rank of a total word in a poNFA can be done in polynomial time. We then consider the case of poDFAs, show a tight quadratic bound on the length of shortest total words of minimum rank, and provide a fast algorithm to compute a total word of minimum rank within this length bound.

In [43], the second author proposed two algorithms for finding a total word of rank one in a poDFA if it exists. The first algorithm is greedy: take a letter mapping a currently active state to a larger one without taking undefined transitions. This algorithm does not seem to generalize to poNFAs, and is inherently sequential even for poDFAs. Moreover, its implementation proposed in [43] has time complexity $\mathcal{O}(mn^3)$. The second algorithm proposed in [43], of time complexity $\mathcal{O}(m^2n^2)$, uses a much less obvious approach. In this section we use a somewhat similar but more involved idea to deal with a more general case of poNFAs, and, in particular, show how to compute the minimum rank of a total word in linear time. For poDFAs, we show that a total word of minimum rank can be found in time $\mathcal{O}(mn^2)$, thus further improving on the results of [43]. We further refine the guarantee on the length of a found total word of minimum rank taking into account the size of the alphabet, and show that our upper bound it tight.

4.1 Total and ergodic words in poNFAs

▶ **Theorem 11.** *Let $\mathcal{A} = (Q, \Sigma, \Delta)$ be a poNFA with n states and m letters.*

(a) *The length of a shortest total word of minimum rank in $\mathcal{A}$ is at most $n(n+1)^m$.*

(b) *Finding the minimum rank of a total word in $\mathcal{A}$ can be done in $\mathcal{O}(m \log m + \log n)$ deterministic space.*
If $m = \mathcal{O}(\frac{\log n}{\log \log n})$, this problem is in L, and if $m = \Theta(n)$, it is P-complete.

(c) *The minimum rank of a total word in $\mathcal{A}$ can be computed in $\mathcal{O}(mn + |\Delta|)$ time, that is, in linear time in the size of the input.*

We first describe an algorithm that, given a poNFA $\mathcal{A} = (Q, \Sigma, \Delta)$ with n states and m letters, constructs an auxiliary sequence of sets $C_0 \supset C_1 \supset \ldots \supset C_k$ and a sequence of distinct letters $a_1, a_2, \ldots, a_k \in \Sigma$ for some $k \leq \min\{m, n-1\}$. Note that we use $\supset$ and $\subset$ to denote proper set inclusion. The value of k is determined by the algorithm and depends on the number of steps it makes. The intuition behind this algorithm (and the reason why it is called “stabilization algorithm”) are provided below in the proof of its correctness.

Stabilization algorithm

We initialize the set of currently considered states $C_0 = Q$ and the currently explored alphabet $\Sigma_0 = \emptyset$. At step i, $i \geq 1$, find a letter $a_i \in \Sigma \setminus \Sigma_{i-1}$ which is defined for every state in C_{i-1} and does not induce a self-loop for at least one of them. That is, for every state $q \in C_{i-1}$, $q \cdot a_i$ must be non-empty, and for at least one state $q \in C_{i-1}$ we must have $q \notin q \cdot a_i$. If no such letter a_i exists, stop and output $|C_{i-1}|$. Define C_i to be the subset of states in C_{i-1} for which a_i induces a self-loop, that is, $C_i = \{q \in C_{i-1} \mid q \in q \cdot a_i\}$. Take $\Sigma_i = \Sigma_{i-1} \cup \{a_i\}$. Go to the step $i + 1$.

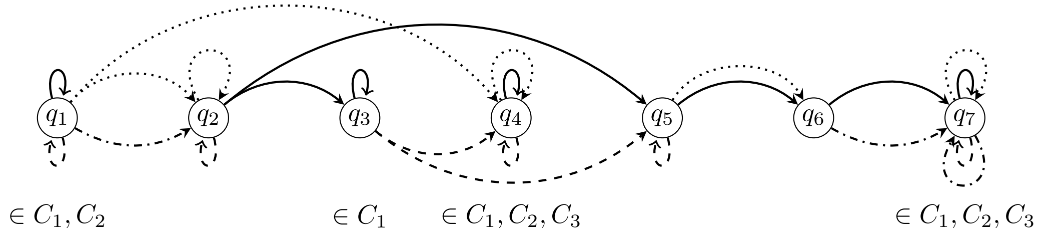

Figure 3 Running example for Section 4.1.

As a running example, we use the rpoNFA in Figure 3. The application of the algorithm gives $C_0 = Q = \{q_1, q_2, q_3, q_4, q_5, q_6, q_7\}$, $C_1 = \{q_1, q_3, q_4, q_7\}$, $C_2 = \{q_1, q_4, q_7\}$, $C_3 = \{q_4, q_7\}$. The letters chosen by the algorithm are as follows: a_1 is solid, a_2 is dashed, a_3 is dotted. The dashdotted letter is not used by the algorithm.

Correctness

We now analyze the output of the algorithm and show that it provides an upper bound on the minimum rank of a total word in $\mathcal{A}$. For rpoNFAs, this upper bound is tight. For general poNFAs, we then extend the algorithm with a second stage using similar ideas.

Assume that the algorithm makes $k + 1 \leq m + 1$ steps and then stops and returns the answer $|C_k|$. Consider the sequence of words defined as $w_0 = \epsilon$, $w_i = w_{i-1}(a_i w_{i-1})^n$ for $1 \leq i \leq k$. In our example, $w_1 = a_1^7$, $w_2 = a_1^7(a_2 a_1^7)^7$, $w_3 = a_1^7(a_2 a_1^7)^7(a_3 a_1^7(a_2 a_1^7)^7)^7$. Table 1 illustrates the images of states under w_i in our example.

The intuition is that with i increasing, the words w_i map every state to larger and larger states with respect to $\prec$, until a fixed point is reached. This can be informally seen as stabilization of the images of states from C_i under the word w_i.

Table 1 The images of states under w_i, $1 \leq i \leq 3$.

q	q_1	q_2	q_3	q_4	q_5	q_6	q_7
$q \cdot w_1$	q_1	q_3, q_7	q_3	q_4	q_7	q_7	q_7
$q \cdot w_2$	q_1	q_4, q_7	q_4, q_7	q_4	q_7	q_7	q_7
$q \cdot w_3$	q_4, q_7	q_4, q_7	q_4, q_7	q_4	q_7	q_7	q_7

▷ Claim 12. For each i, the word w_i is total.

Proof. We show by induction that the image of each state under w_i contains a state from C_i, starting with $i = 1$. By construction, a_1 is defined for every state $q \in C_0 = Q$. Since $\mathcal{A}$ is partially ordered, we get that after n applications of a_1, the image of every state must contain a state q such that $q \in q \cdot a_1$. Every such state is by definition in C_1.

Assume now that the image of every state under w_{i-1} contains a state from C_{i-1}. We thus only need to show that for each state in C_{i-1} its image under w_i contains a state from C_i. By definition, the image of every state from C_{i-1} under a_i is non-empty. Let $q \in C_{i-1}$ be a state. If $q \in C_i$, there is nothing to prove. Otherwise, $q \notin q \cdot a_i$. Thus we have that every state in $q \cdot a_i w_{i-1}$ is larger (with respect to $\prec$) than q. By the induction assumption, there is another state from C_{i-1} in $q \cdot a_i w_{i-1}$. Since $\mathcal{A}$ is partially ordered, by repeating this argument at most n times, we get a state from C_i in the image of q. ◁

▷ Claim 13. For every i, the rank of w_i is at most $|C_i|$.

Proof. For every state $q \in Q$, call *the i-trace of* q the set $q \cdot w_i$. To prove the claim, we show that for every $i \geq 1$ and every state $q \in Q$, the i-trace of q is a union of i-traces of some states from C_i. We prove that by induction on i. For $i = 1$, this is obvious from the construction of w_1 since $\mathcal{A}$ is partially ordered. Assume now that the statement holds true for $i - 1$. Then we need to show that for every $q \in Q$ and $p \in q \cdot w_{i-1}$ we have that $p \cdot (a_i w_{i-1})^n$ is a union of i-traces of some states from C_i. Observe that since $\mathcal{A}$ is partially ordered, for every $p' \in Q$ we have $p' \cdot (a_i w_{i-1})^n = p' \cdot (a_i w_{i-1})^{h(p')}$, where $h(p') = |\{s \in Q \mid p' \prec s \text{ or } p' = s\}|$. Hence, it is enough to prove that $p \cdot (a_i w_{i-1})^{h(p)}$ is a union of i-traces of some states from C_i.

We do that again by induction, now on the order $\prec$. For the largest state t with respect to $\prec$ this is obvious, since its i-trace for every i is $\{t\}$. Assume now that this is true for all states larger than p with respect to $\prec$. If $p \in C_i$, the statement is proved. Assume now that $p \notin C_i$. Then there exists $1 \leq j \leq i$ such that $p \notin p \cdot a_j$, and hence every state in $p \cdot a_i w_{i-1}$ is larger (with respect to $\prec$) than p. For every state p' such that $p \prec p'$, we have that $h(p') < h(p)$, hence we can use the assumption of the induction on $\prec$, which concludes the proof. $\lhd$

Hence we get that w_k is a total word of rank $|C_k|$. If $\mathcal{A}$ is an rpoNFA, the rank of every total word in $\mathcal{A}$ is at least $|C_k|$. Indeed, by the definition of the algorithm, each letter in Σ either induces a self-loop for every state of C_k, or is undefined for at least one state in C_k. Since $\mathcal{A}$ is an rpoNFA, this means that if the action of a word w is defined for every state of $\mathcal{A}$, then for every state $q \in C_k$ we must have $q \cdot w = \{q\}$. Since $\mathcal{A}$ is partially ordered, every set $q \cdot w$ can only contain q and states that are larger with respect to $\prec$ than q, hence the rank of w is at least $|C_k|$. Observe that the length of w_i is $(n+1)^m - 1$, which proves Theorem 11 (a) for rpoNFAs.

To deal with the general case of poNFAs instead of rpoNFAs, we continue our analysis of the stabilization algorithm, and extend it with a very similarly defined second part, which we call moving algorithm. The moving algorithm is executed after the stabilization algorithm. We start with some definitions. Recall that the result of the stabilization algorithm is the set C_k of states and the alphabet Σ_k.

Let $S \subseteq C_k$ be the set of states $q \in C_k$ such that for every letter $a \in \Sigma_k$ we have that $q \cdot a = \{q\}$. Let $\Sigma' \subseteq \Sigma \setminus \Sigma_k$ be the set of letters not from Σ_k which are defined for every state in S. Only letters from $\Sigma_k \cup \Sigma'$ can occur in a total word, since the first occurrence of any other letter will kill at least one state in S. After the stabilization algorithm provides its output, we run the moving algorithm defined as follows.

Moving algorithm

We initialize the set of currently considered states $C'_0 = C_k$ and the currently explored alphabet $\Sigma'_0 = \emptyset$. At step i, $i \geq 1$, find a letter $a'_i \in \Sigma' \setminus \Sigma'_{i-1}$ such that for at least one state $q \in C'_{i-1}$ we have $q \notin q \cdot a'_i$. If no such letter a'_i exists, stop and output $|C'_{i-1}|$. Define C'_i to be the subset of states in C'_{i-1} for which a'_i induces a self-loop, that is, $C'_i = \{q \in C'_{i-1} \mid q \in q \cdot a'_i\}$. Take $\Sigma'_i = \Sigma'_{i-1} \cup \{a'_i\}$. Go to the step $i+1$.

Correctness of the moving algorithm

Assume that the algorithm makes $k'+1$ steps, outputs $|C'_{k'}|$ and stops. Consider the words w'_i defined as follows. We take $w'_0 = (w_k)^n$. This is done to make sure that the image of every state in Q under w'_0 contains at least one state from S. For $1 \leq i \leq k'$, define $w'_i = w'_{i-1}(a'_i w'_{i-1})^n$.

First, we claim that each w'_i is total. This follows inductively from the fact that for every i, the image of every state under w'_i contains at least one state from S, and a'_i is defined for all states in S.

The fact that the rank of w'_i is at most $|C'_i|$ is proved by exactly the same argument as in the proof of Claim 13, since the construction of the words w'_i coincides with the construction of the words w_i. Observe that in the setting of Claim 13, a_i is defined for every state in C_i, but this fact is never used in the proof of this claim.

It remains to show that the rank of every total word in $\mathcal{A}$ is at least $|C'_{k'}|$. Indeed, by the definition of the moving algorithm, for each letter $a \in \Sigma$ which is defined for every state in S, we have that $q \in q \cdot a$ for every state $q \in C'_{k'}$. As argued above, only letters defined for each state in S can occur in a total word, which concludes the proof.

It is easy to see that the length of $w'_{k'}$ is at most $n(n+1)^m$. This concludes the proof of Theorem 11 (a) for general poNFAs.

To simplify the presentation, we assume that if the poNFA is not an rpoNFA, the moving algorithm is the second part of the stabilization algorithm. To comply with the notation of the stabilization algorithm, we define $C_{k+i} = C'_i$ and $\Sigma_{k+i} = \Sigma_k \cup \Sigma'_i$ for $1 \leq i \leq k'$. Observe that by construction, Σ_k and $\Sigma'_{k'}$ do not intersect, every letter in $\Sigma_{k+k'}$ induces a self-loop for every state in $C_{k+k'}$ and $w_{k+k'}$ is a total word of minimum rank. Thus, everywhere below we denote the value $k'+k$ simply by k.

Space complexity

We show how to implement a variant of the stabilization algorithm in $\mathcal{O}(m \log m + \log n)$ deterministic space. To do so, it is enough to note that the sets C_i do not have to be constructed explicitly, and each C_i can be reconstructed on the fly based only on Σ_i. Indeed, assume that the sequence $a_1, \ldots, a_i$ is already constructed and stored in the memory. Then to test if a given state q belongs to C_i, we need to check that all of $a_1, \ldots, a_i$ induce self-loops for it. Testing if a given letter a can be taken as a_i is then straightforward and only requires going through all states of $\mathcal{A}$ in an arbitrary order.

If $m = \mathcal{O}(\frac{\log n}{\log \log n})$, the bit length of the representation of one letter in Σ is $\mathcal{O}(\log \log n)$. Thus storing a sequence $a_1, \ldots, a_d$, $d \leq m$, of letters in Σ requires $\mathcal{O}(\frac{\log n}{\log \log n} \cdot \log \log n) = \mathcal{O}(\log n)$ bits, which provides a deterministic algorithm running in logarithmic space. The described algorithm can obviously also be implemented in polynomial time, and P-hardness is stated in the following lemma. This concludes the proof of Theorem 11 (b).

▶ **Lemma 14.** *Deciding if a poDFA over an alphabet of linear size in the number of its states admits a total word of rank one is* P*-hard under an* AC^0 *reduction.*

Proof. We reduce from the monotone circuit value problem. A *monotone Boolean circuit* is an acyclic digraph $C = (V, E)$ with a labeling function $L : V \to \{\wedge, \vee, \Box\}$. Intuitively, the word "monotone" refers to the fact that negation gates are not allowed. Every vertex labeled by $\{\wedge, \vee\}$ is called *an inner gate* and has indegree two. Each vertex labeled by $\Box$ is called *an input gate* and has outdegree one and indegree zero. Additionally, there is a designated vertex of outdegree zero, which is called *the output gate.* A vertex v with an outgoing edge to a vertex u is called the child of u.

Let k be the number of input gates in C. Then the value of C on the input $x_1, \ldots, x_k$, $x_i \in \{0,1\}$, is defined recursively by computing the value of a gate by applying the corresponding Boolean operation to its children. Given a monotone Boolean circuit C with k input gates and the values $x_1, \ldots, x_k$, $x_i \in \{0,1\}$, of these input gates, the monotone circuit value problem asks if the value of the output gate of C is 1. This problem is P-complete, even if the circuit in the input is topologically ordered [19].

Given $C = (V, E)$ with a labeling function L, and the input values $x_1, \ldots, x_k$, define a poDFA $\mathcal{A} = (Q, \Sigma, \delta)$ as follows. Define $Q = V \cup \{f\}$, where f is a fresh state.

We now define the letters in Σ and their action on the states to force the following behavior of $\mathcal{A}$. We start with the whole set of states active, and then make a state non-active if the corresponding gate can be evaluated to one at the current step. First, we can map every state corresponding to an input gate with value one to f. This is done by a separate letter for each gate, and such a letter leaves every other state in its place. Then we inductively proceed with $\wedge$- and $\vee$-gates, whose corresponding states can be sent to f if and only if all their children in C have value 1 (respectively, at least on child has value 1). This is done by simple gadgets guaranteeing that all the children of a gate (respectively, at least one child of a gate) are non-active by leaving certain transitions for them undefined, see Figure 4 for an illustration of these gadgets. If by some sequence of such letter applications the state corresponding to the output gate can be made non-active, and hence the value of C is 1, then another letter mapping all other states to f can be taken. This letter cannot be taken initially, since it is undefined for the state corresponding to the output gate.

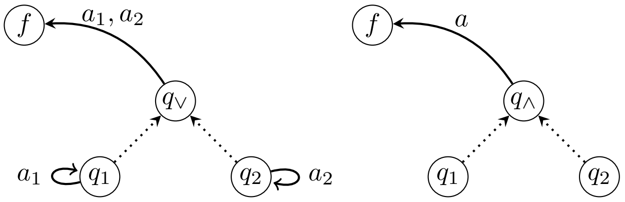

Figure 4 The gadgets for an $\vee$-gate $q_\vee$ with children q_1, q_2 (left) and an $\wedge$-gate $q_\wedge$ with children q_1, q_2 (right). The solid arrows denote transitions of the DFA, and the dotted arrows denote child-parent relations in the circuit.

We now formally define the remaining part of $\mathcal{A}$ to guarantee the described behavior.

- For each input gate v whose value is 1, add a fresh letter mapping v to f and acting as the identity for all states in Q except v.
- For each $\vee$-gate v, add two fresh letters a_1^v, a_2^v acting as follows. Both a_1^v and a_2^v maps v to f. Letter a_1^v induces a self-loop for the first child of v and is undefined for its second child. Symmetrically, a_2^v is undefined for the first child and maps the second child to itself. For all remaining states both a_1^v and a_2^v induce self-loops.
- Similarly, for each $\wedge$-gate v, add a fresh letter a^v to Σ such that a^v maps v to f, is undefined for both children of v and induces self-loops for all other states.
- Finally, add a fresh letter r which is undefined for the state corresponding to the output gate and maps all other states to f.

Applying a total word to $\mathcal{A}$ now resembles sequential evaluation of C: starting from the states corresponding to the input gates, we can make the states corresponding to gates with value one non-active by mapping them to f, and then proceed inductively to their parents. By definition of the action of r, $\mathcal{A}$ has a total word of rank one if and only if the state corresponding to the output gate eventually becomes non-active, which is possible if and only if the value of the output gate in C is one. ◀

Time complexity

To implement the stabilization algorithm with low time complexity, we use a data structure which we simply refer to as a list of states. We implement it as an array of length n that indicates for each state if it appears in the list, and also refers to the previous and next states in the array with respect to $\prec$, if they exist. Hence, testing non-emptiness of such a list can be done in constant time, going through its elements takes time linear in the size of the list (and not in n), and removing an element takes constant time.

We first show how to compute the minimum rank of a total word in time complexity $\mathcal{O}(mn)$. For each letter $a \in \Sigma$ we maintain a list D_a. After step i, this list contains the states in C_i for which a is undefined. We also maintain a list D of letters $a \in \Sigma \setminus \Sigma_i$ for which D_a is currently empty and there is a state $q \in C_i$ which is mapped by a to a different state.

The algorithm makes at most m steps. At step i, we take an arbitrary letter from D as a_i. We then update the set of currently considered states to C_i, which takes $\mathcal{O}(n)$ time, and remove the entry corresponding to each state in $C_{i-1} \setminus C_i$ from all the lists D_a, $a \in \Sigma \setminus \Sigma_i$. Observe that the entry for each state is removed at most once during the execution of the algorithm. Hence, the overall time complexity is $\mathcal{O}(mn + |\Delta|)$, which proves Theorem 11 (c).

Ergodicity

Recall that a word is ergodic if and only if its matrix has a column consisting of all ones. Clearly, in the case of poNFAs, this can only be the last column. We now apply the obtained results to ergodic words for a poNFA $\mathcal{A}$. Let Σ' be the set of letters in Σ which are defined for every state in C_k obtained in the stabilization algorithm. Let $C_k = \{q_1, q_2, \ldots, q_r\}$ such that $q_1 \prec q_2 \prec \ldots \prec q_r$.

Observe that there exists an ergodic word for $\mathcal{A}$ if and only if for every state q_i, $1 \le i \le r-1$, there exists a letter $a'_i \in \Sigma'$ such that there is a state $p \in Q$, $q \prec p$, with $p \in q \cdot a'_i$. If such a letter does not exist for some state in $C_k \setminus \{q_r\}$, an ergodic word for $\mathcal{A}$ obviously does not exist. For the opposite direction, observe that for every state in Q its image under $a'_1 w_k$ contains a state from $C_k \setminus \{q_1\}$. Moreover, $q_r \cdot a'_1 w_k = \{q_r\}$, since q_r must be the largest state in Q with respect to $\prec$. By inductively repeating this argument $r-1$ times in total, we get that for every state in Q its image under the concatenation of the words $(a'_i w_k)$ for $1 \le i \le r-1$ must contain q_k, and hence this word is ergodic. Since $r \le n$, its length is at most $(n-1)n(n+1)^m$. We thus obtain the following theorem.

▶ **Theorem 15.** *Let $\mathcal{A}$ be a poNFA with n states and m letters.*

(a) *The length of its shortest ergodic word is at most $(n-1)n(n+1)^m$.*

(b) *Checking if $\mathcal{A}$ is ergodic can be done in $\mathcal{O}(m \log m + \log n)$ deterministic space. If $m = \mathcal{O}(\frac{\log n}{\log \log n})$, this problem is in L, and if $m = \Theta(n)$, it is P-complete.*

(c) *Checking if $\mathcal{A}$ is ergodic can be done in time $\mathcal{O}(mn + |\Delta|)$.*

4.2 Partially ordered DFAs

For poDFAs, a total word has rank one if and only if it is ergodic. Thus the following theorem, which is the main result of this subsection, applies to ergodic words if one takes $r = 1$.

▶ **Theorem 16.** *Let $\mathcal{A}$ be a poDFA with n states and m letters.*

(a) *The length of a shortest total word of minimum rank r in $\mathcal{A}$ is at most $\frac{k-1}{2k}(n-r)^2 + (n-r)$, where $k = \min\{n-r, m\}$. If m divides $n-r$, the bound is tight.*

(b) *Finding such a word of at most this length can be done in time $\mathcal{O}(mn^2)$.*

We remark on the values that the bound $\frac{k-1}{2k}(n-r)^2 + (n-r)$ takes depending on the size of the alphabet, assuming that $r = 1$. If $m = 2$, the lower bound is $\frac{1}{4}(n-1)(n+3) = \frac{1}{4}n^2 + \mathcal{O}(n)$, while for $m = n-1$ it becomes $\frac{1}{2}n(n-1)$. As we will see later, having more than $n-1$ letters in the alphabet cannot increase the bound.

Proof. We start with proving (a). We continue the analysis of the stabilization algorithm for rpoNFAs from Section 4.1. In the proof of its correctness, we constructed a very long word w_k. However, intuitively, during the application of this word to a poDFA, most letters do not change the image of any state at the moment of their application, and each such letter can thus be removed from the word. For $1 \le i \le k$, denote $|C_i| = c_i$

Put a token onto each state of $\mathcal{A}$ and move them according to the transitions taken during the application of w_k letter by letter. We are going to track the paths of these tokens. First, we claim that for each state, if a token appears on it and then leaves it, it leaves it every time along the transition labeled by the same letter. Indeed, by construction of w_k, each state $q \in Q \setminus C_k$ belongs to a set $C_{i-1} \setminus C_i$ for exactly one value of i, and thus we can show by induction that a_i is the letter labeling such a transition from q. Given a state $q \in Q$, we call such a transition *the moving transition of* q. The number of moving transitions labeled by a_i is $|C_{i-1} \setminus C_i| = c_{i-1} - c_i$. The total number of moving transitions labeled by letters in Σ_i is thus $(c_0 - c_1) + (c_1 - c_2) + \ldots + (c_{i-1} - c_i) = c_0 - c_i$.

Now, consider what happens when w_{i-1} is already applied to $\mathcal{A}$, and we start applying $(a_i w_{i-1})^n$. Observe that at this moment the set of states containing a token is precisely the set C_{i-1}, which can be proved by induction. By the application of $(a_i w_{i-1})^n$, each token on a state in $C_{i-1} \setminus C_i$ is moved to a state in C_i. The number of letters in $(a_i w_{i-1})^n$ whose application moves at least one token is thus upper bounded by the number of moved tokens, which is $|C_{i-1} \setminus C_i|$, multiplied by the number of moving transitions labeled by letters in Σ_{i-1}, plus at most one application of a_i per state in $C_{i-1} \setminus C_i$. Hence we get that the number of useful letters in $(a_i w_{i-1})^n$ is at most $(c_{i-1} - c_i)(c_0 - c_{i-1}) + (c_{i-1} - c_i) = (c_{i-1} - c_i)(c_0 - c_{i-1} + 1)$.

By construction, $c_0 = n$ and $c_k = r$. The overall length of the word consisting only of letters in w_k moving at least one token is upper bounded by

$$\sum_{1 \le i \le k} (c_{i-1} - c_i)(c_0 - c_{i-1} + 1) = (c_0 + 1)(c_0 - c_k) - (\sum_{1 \le i \le k} c_{i-1}^2 - \sum_{1 \le i \le k} c_{i-1} c_i)$$
$$= (c_0 + 1)(c_0 - c_k) - (\frac{1}{2}(c_0^2 - c_k^2) + \frac{1}{2} \sum_{1 \le i \le k} (c_{i-1} - c_i)^2)$$
$$\le (c_0 + 1)(c_0 - c_k) - \frac{1}{2}(c_0^2 - c_k^2) - \frac{1}{2k}(c_0 - c_k)^2 = \frac{k-1}{2k}(n - r)^2 + (n - r).$$

Hence the upper bound is proved. The fact that if m divides $n - r$ the bound is tight follows from the following lemma, concluding the proof of (a).

▶ **Lemma 17.** *For every positive natural numbers n, m and r such that m divides $n - 1$, there exists a poDFA $\mathcal{A}$ with n states and m letters such that the length of its shortest total word of minimum rank r is $\frac{m-1}{2m}(n - r)^2 + (n - r)$.*

Proof. We start with $r = 1$. We construct a poDFA $\mathcal{A} = (Q, \Sigma, \delta)$ as follows. Let $n = ms + 1$ and $Q^{(j)} = \{q_1^{(j)}, \ldots, q_s^{(j)}\}$. Take $Q = \cup_{1 \le j \le m} Q^{(j)} \cup \{q_1^{(m+1)}\}$, and $\Sigma = \{a_1, a_2, \ldots, a_m\}$. For each $1 \le j \le m$, define $\delta(q_i^{(j)}, a_j) = q_{i+1}^{(j)}$ for $1 \le i < s$, $\delta(q_s^{(j)}, a_j) = q_1^{(j+1)}$ and $\delta(q_i^{(j)}, a_\ell) = q_i^{(j)}$ if $j < \ell$ and $1 \le i \le s$. Set each letter in Σ to induce a self-loop for $q_1^{(m+1)}$. Leave all remaining transitions undefined. See Figure 5 for an example.

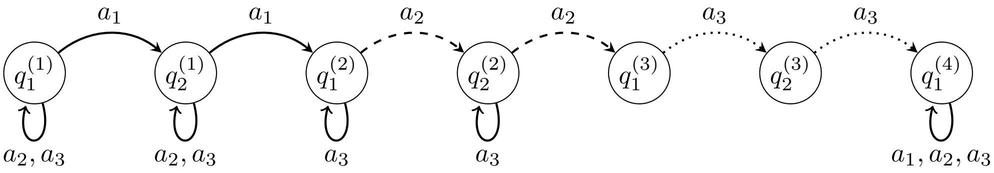

Figure 5 Example of the construction in the proof of Lemma 17 for $m = 3$, $s = 2$ and $r = 1$.

Observe that there exists a unique shortest total word of rank one for $\mathcal{A}$. Indeed, at every moment, only one transition that does not act as the identity can be taken. Namely, if no state in $Q^{(j)}$ is active and some state in $Q^{(j-1)}$ is active, we can take a_j, and as soon as one state in $Q^{(j)}$ becomes active, it has to be sent all the way to $a_1^{(m+1)}$ before any other state can be sent to another state. Hence, the length of a shortest total word of rank one for $\mathcal{A}$ is $s+(s^2+s)+(2s^2+s)+\ldots+((m-1)s^2+s) = s^2(1+2+\ldots+(m-1))+sm = s^2 \cdot \frac{(m-1)m}{2}+ms$. Since $s = \frac{n-1}{m}$, this value is equal to $\frac{m-1}{2m}(n-1)^2 + (n-1)$.

Finally, observe that adding $r-1$ states such that every letter induces a self-loop for each of them provides a required construction for the case of rank r. ◀

We continue with proving item (b) of Theorem 16. To construct a total word of minimum rank within the required length bound, recall the definition of the moving transitions from the length analysis above. For each state $q \in Q$, find the letter labeling its moving transition. Now we follow the tokens. At step i, all tokens on states in C_i are not moved, so we only need to compute a word that maps all tokens on the states in $C_{i-1} \setminus C_i$ to states in C_i. To do so, we need to decide which letters from $(a_i w_i)^n$ move at least one token. Clearly, if a_i does not move anything, we go to the next step. Otherwise, we apply a_i and recursively perform the argument from step $i-1$ for the moved tokens. The total number of moments of time when we do not move anything and thus go to the next step is upper bounded by $\mathcal{O}(mn^2)$ by the construction of w_k, and the number of moves of tokens is upper bounded by $\frac{m-1}{2m}(n-r)^2 + (n-r) = \mathcal{O}(mn^2)$. This concludes the proof of (b). ◀

An Algorithmic Meta Theorem for Homomorphism Indistinguishability

Tim Seppelt
RWTH Aachen University, Germany

Abstract

Two graphs G and H are *homomorphism indistinguishable* over a family of graphs $\mathcal{F}$ if for all graphs $F \in \mathcal{F}$ the number of homomorphisms from F to G is equal to the number of homomorphism from F to H. Many natural equivalence relations comparing graphs such as (quantum) isomorphism, cospectrality, and logical equivalences can be characterised as homomorphism indistinguishability relations over various graph classes.

The wealth of such results motivates a more fundamental study of homomorphism indistinguishability. From a computational perspective, the central object of interest is the decision problem $\textsc{HomInd}(\mathcal{F})$ which asks to determine whether two input graphs G and H are homomorphism indistinguishable over a fixed graph class $\mathcal{F}$. The problem $\textsc{HomInd}(\mathcal{F})$ is known to be decidable only for few graph classes $\mathcal{F}$. Due to a conjecture by Roberson (2022) and results by Seppelt (MFCS 2023), homomorphism indistinguishability relations over minor-closed graph classes are of special interest. We show that $\textsc{HomInd}(\mathcal{F})$ admits a randomised polynomial-time algorithm for every minor-closed graph class $\mathcal{F}$ of bounded treewidth.

This result extends to a version of HomInd where the graph class $\mathcal{F}$ is specified by a sentence in counting monadic second-order logic and a bound k on the treewidth, which are given as input. For fixed k, this problem is randomised fixed-parameter tractable. If k is part of the input, then it is coNP- and coW[1]-hard. Addressing a problem posed by Berkholz (2012), we show coNP-hardness by establishing that deciding indistinguishability under the k-dimensional Weisfeiler–Leman algorithm is coNP-hard when k is part of the input.

1 Introduction

In 1967, Lovász [32] proved that two graphs G and H are isomorphic if and only if they are *homomorphism indistinguishable* over all graphs, i.e. they admit the same number of homomorphisms from every graph F. Subsequently, many graph isomorphism relaxations have been characterised as homomorphism indistinguishability relations. For example, two graphs are quantum isomorphic if and only if they are homomorphism indistinguishable over all planar graphs [34]. Moreover, two graphs satisfy the same sentences in k-variable first-order logic with counting quantifiers if and only if they are homomorphism indistinguishable over all graphs of treewidth less than k [20, 19]. A substantial list of similar results characterises notions from quantum information [34, 5], finite model theory [20, 24, 22], convex optimisation [19, 28, 38], algebraic graph theory [19, 28], machine learning [35, 41, 25], and category theory [18, 1] as homomorphism indistinguishability relations.

The wealth of such examples motivates a more principled study of homomorphism indistinguishability [3, 37, 40]. Notably, all graph classes featured in the results listed above are minor-closed and this is not a mere coincidence [40, Theorem 1]. Therefore, homomorphism indistinguishability relations of minor-closed graph classes are of central interest in light of the emerging theory of homomorphism indistinguishability. In [37], Roberson conjectured that *any two distinct graph classes which are closed under disjoint unions and taking minors have distinct homomorphism indistinguishability relations.* From a computational perspective, the central question on homomorphism indistinguishability concerns the complexity and computability of the following decision problem for a fixed graph class $\mathcal{F}$ [37, Question 9]:

HomInd($\mathcal{F}$)
Input Graphs G and H.
Question Are G and H homomorphism indistinguishable over $\mathcal{F}$?

The graphs G and H may be arbitrary graphs and do not necessarily have to be in $\mathcal{F}$. Typically, the graph class $\mathcal{F}$ is infinite. Thus, the trivial approach to HomInd($\mathcal{F}$) of checking whether G and H have the same number of homomorphisms from every $F \in \mathcal{F}$ does not even render HomInd($\mathcal{F}$) decidable. Beyond this observation, the understanding of the problems HomInd($\mathcal{F}$) is limited to a short list of examples of graph classes $\mathcal{F}$: For the class $\mathcal{G}$ of all graphs, HomInd($\mathcal{G}$) is graph isomorphism [32], a problem representing a long standing complexity-theoretic challenge and currently only known to be in quasi-polynomial time [6]. For the class $\mathcal{P}$ of all planar graphs, HomInd($\mathcal{P}$) is quantum isomorphism and undecidable [34]. Finally, for the class $\mathcal{TW}_k$ of all graphs of treewidth at most k, HomInd($\mathcal{TW}_k$) can be decided in polynomial time with the well-known k-dimensional Weisfeiler–Leman algorithm [20, 19].

These results illustrate that the complexity of HomInd($\mathcal{F}$) is not monotone in the sense that if $\mathcal{F}_1 \subseteq \mathcal{F}_2$, then HomInd($\mathcal{F}_1$) is at most as hard as HomInd($\mathcal{F}_2$). For example, despite that $\mathcal{TW}_2 \subseteq \mathcal{P} \subseteq \mathcal{G}$, deciding homomorphism indistinguishability over $\mathcal{TW}_2$, $\mathcal{P}$, and $\mathcal{G}$ is polynomial-time, undecidable, and quasi-polynomial-time, respectively. Furthermore, although HomInd($\mathcal{TW}_k$) is in polynomial-time for every k, there are infinitely many minor-closed graph classes $\mathcal{F}$ of bounded treewidth, e.g. the classes of k-outerplanar graphs, for which HomInd($\mathcal{F}$) could yet be undecidable. Our main result shows that this is not the case: HomInd($\mathcal{F}$) is in randomised polynomial time for every minor-closed graph class $\mathcal{F}$ of bounded treewidth.

▶ **Theorem 1.** *Let $k \geq 1$. If $\mathcal{F}$ is a k-recognisable class of graphs of treewidth at most $k-1$, then* HomInd($\mathcal{F}$) *is in* coRP*.*

Spelled out, Theorem 1 asserts that there exists a randomised algorithm for HomInd($\mathcal{F}$) which always runs in polynomial time, accepts all YES-instances and incorrectly accepts NO-instances with probability less than one half. Recognisability is a fairly general property that arises in the context of Courcelle's theorem [14], cf. Definition 10. Courcelle showed that every graph class definable in counting monadic second-order logic CMSO_2 is recognisable. This subsumes graph classes defined by finitely many forbidden (induced) subgraphs and minors, and by the Robertson–Seymour Theorem, all minor-closed graph classes.

Thereby, Theorem 1 applies to e.g. the class of graphs of bounded branchwidth, k-outerplanar graphs, and the class of trees of bounded degree. As a concrete application, we resolve an open question from [38] by showing in Theorem 22 that the exact feasibility of the Lasserre semidefinite programming hierarchy for graph isomorphism can be decided in randomised polynomial-time.

The proof of Theorem 1 combines Courcelle's graph algebras [15] with the homomorphism tensors from [34, 28]. Graph algebras comprise labelled graphs and operations on them such as series and parallel composition. Homomorphism tensors keep track of homomorphism counts of labelled graphs. We show that recognisability and bounded treewidth guarantee that homomorphism tensors yield finite-dimensional representations of suitable graph algebras which certify homomorphism indistinguishability and are efficiently computable. The algorithm in Theorem 1 is randomised as it employs arithmetic modulo random primes to deal with integers which would otherwise grow to exponential size. For graph classes of bounded pathwidth, this issue can be avoided:

▶ **Theorem 2.** *Let $k \geq 1$. If $\mathcal{F}$ is a k-recognisable class of graphs of pathwidth at most $k-1$, then* HomInd$(\mathcal{F})$ *is in polynomial time.*

The connection to Courcelle's theorem motivates considering the parametrised problem HomInd. Here, the CMSO_2-sentence φ allows the graph class to be specified as part of the input. Using results by Courcelle [14], we generalise Theorem 1 in Theorem 3.

HomInd
Input Graphs G and H, a CMSO_2-sentence φ, an integer k.
Parameter $|\varphi| + k$.
Question Are G and H homomorphism indistinguishable over the graph class $\mathcal{F}_{\varphi,k}$ of graphs of treewidth at most $k-1$ satisfying φ?

▶ **Theorem 3.** *There exists a computable function $f\colon \mathbb{N} \to \mathbb{N}$ and a randomised algorithm for* HomInd *of runtime $f(|\varphi| + k)n^{O(k)}$ for $n := \max\{|V(G)|, |V(H)|\}$ which accepts all YES-instances and accepts NO-instances with probability less than one half.*

Equipped with the parametrised perspective offered by HomInd, we finally consider lower bounds on the complexity of this problem. Firstly, we show that it is coW[1]-hard and that the runtime in Theorem 3 is optimal under the Exponential Time Hypothesis (ETH).

▶ **Theorem 4.** HomInd *is* coW[1]*-hard under fpt-reductions. Unless* ETH *fails, there is no algorithm for* HomInd *that runs in time $f(|\varphi| + k)n^{o(|\varphi|+k)}$ for any computable function $f\colon \mathbb{N} \to \mathbb{N}$.*

Secondly, we show that, when disregarding the parametrisation, HomInd is coNP-hard. We do so by showing coNP-hardness of deciding indistinguishability under the k-dimensional Weisfeiler–Leman (WL) algorithm (recently, the same result was independently obtained by [31]). WL is an important heuristic in graph isomorphism and tightly related to notions in finite model theory [13] and graph neural networks [41, 35, 25]. The fastest known algorithm for WL runs in time $O(k^2 n^{k+1} \log n)$ [29], which is exponential when regarding k as part of the input. It was shown that when k is fixed, then the problem is PTIME-complete [23]. Establishing lower bounds on the complexity of WL is a challenging problem [7, 8, 26]. Theorem 5 is a first step towards resolving a question posed by Berkholz [7]: Is the decision problem in Theorem 5 EXPTIME-complete?

▶ **Theorem 5.** *The problem of deciding given graphs G and H and an integer $k \in \mathbb{N}$ whether G and H are k-*WL *indistinguishable is* coNP*-hard under polynomial-time many-one reductions.*

2 Preliminaries

All graphs in this work are finite, undirected, and without multiple edges and loops. For a graph G, we write $V(G)$ for its vertex set and $E(G)$ for its edge set. A *homomorphism* $h\colon F \to G$ from a graph F to a graph G is a map $V(F) \to V(G)$ such that $h(u)h(v) \in E(G)$ for all $uv \in E(F)$. Write $\hom(F, G)$ from the number of homomorphisms from F to G.

Two graphs G and H are *homomorphism indistinguishable* over a class of graph $\mathcal{F}$, in symbols $G \equiv_{\mathcal{F}} H$, if $\hom(F, G) = \hom(F, H)$ for all $F \in \mathcal{F}$. For an integer $n \geq 2$, G and H are *homomorphism indistinguishable over $\mathcal{F}$ modulo n*, in symbols $G \equiv_{\mathcal{F}}^{n} H$, if $\hom(F, G) \equiv \hom(F, H) \mod n$ for all $F \in \mathcal{F}$, cf. [21, 30].

2.1 (Bi)labelled Graphs and Homomorphism Tensors

Let $k, \ell \geq 1$. A *distinctly k-labelled graph* is a tuple $\boldsymbol{F} = (F, \boldsymbol{u})$ where F is a graph and $\boldsymbol{u} \in V(F)^k$ is such that $u_i \neq u_j$ for all $1 \leq i < j \leq k$. We say $u_i \in V(F)$, the i-th entry of $\boldsymbol{u}$, *carries the i-th label.* Write $\mathcal{D}(k)$ for the class of distinctly k-labelled graphs.

A *distinctly (k, ℓ)-bilabelled graph* is a tuple $\boldsymbol{F} = (F, \boldsymbol{u}, \boldsymbol{v})$ where F is a graph and $\boldsymbol{u} \in V(F)^k$ and $\boldsymbol{v} \in V(F)^\ell$ are such that $u_i \neq u_j$ for all $1 \leq i < j \leq k$ and $v_i \neq v_j$ for all $1 \leq i < j \leq \ell$. Note that $\boldsymbol{u}$ and $\boldsymbol{v}$ might share entries. We say $u_i \in V(F)$ and $v_i \in V(F)$ *carry the i-th in-label* and *out-label*, respectively. Weite $\mathcal{D}(k, \ell)$ for the class of distinctly (k, ℓ)-bilabelled graphs.

For a graph G, and $\boldsymbol{F} = (F, \boldsymbol{u}) \in \mathcal{D}(k)$ define the *homomorphism tensor* $\boldsymbol{F}_G \in \mathbb{N}^{V(G)^k}$ of $\boldsymbol{F}$ w.r.t. G whose $\boldsymbol{v}$-th entry is equal to the number of homomorphisms $h\colon F \to G$ such that $h(u_i) = v_i$ for all $i \in [k]$. Analogously, for $\boldsymbol{F} \in \mathcal{D}(k, \ell)$, define $\boldsymbol{F}_G \in \mathbb{N}^{V(G)^k \times V(G)^\ell}$. As the entries of homomorphism tensors are integral, we can view them as vectors in vector spaces over $\mathbb{R}$ as in Section 3 or over finite fields $\mathbb{F}_p$ as in Section 4.

As observed in [34, 28], (bi)labelled graphs and their homomorphism tensors are intriguing due to the following correspondences between combinatorial operations on the former and algebraic operations on the latter:

Dropping labels corresponds to sum-of-entries (soe). For $\boldsymbol{F} = (F, \boldsymbol{u}) \in \mathcal{D}(k)$, define the underlying unlabelled graph $\operatorname{soe}(\boldsymbol{F}) := F$ of $\boldsymbol{F}$. Then for all graphs G, $\hom(\operatorname{soe} \boldsymbol{F}, G) = \sum_{\boldsymbol{v} \in V(G)^k} \boldsymbol{F}_G(\boldsymbol{v}) =: \operatorname{soe}(\boldsymbol{F}_G)$.

Gluing corresponds to Schur products. For $\boldsymbol{F} = (F, \boldsymbol{u})$ and $\boldsymbol{F}' = (F', \boldsymbol{u}')$ in $\mathcal{D}(k)$, define $\boldsymbol{F} \odot \boldsymbol{F}' \in \mathcal{D}(k)$ as the k-labelled graph obtained by taking the disjoint union of F and F' and placing the i-th label at the vertex obtained by merging u_i with u'_i for all $i \in [k]$. Then for every graph G and $\boldsymbol{v} \in V(G)^k$, $(\boldsymbol{F} \odot \boldsymbol{F}')_G(\boldsymbol{v}) = \boldsymbol{F}_G(\boldsymbol{v})\boldsymbol{F}'_G(\boldsymbol{v}) =: (\boldsymbol{F}_G \odot \boldsymbol{F}'_G)(\boldsymbol{v})$. One may similarly define the gluing product of two (k, ℓ)-bilabelled graphs.

Series composition corresponds to matrix products. For bilabelled graphs $\boldsymbol{K} = (K, \boldsymbol{u}, \boldsymbol{v})$ and $\boldsymbol{K}' = (K', \boldsymbol{u}', \boldsymbol{v}')$ in $\mathcal{D}(k, k)$, define $\boldsymbol{K} \cdot \boldsymbol{K}' \in \mathcal{D}(k, k)$ as the bilabelled graph obtained by taking the disjoint union of K and K', merging the vertices v_i and u'_i for $i \in [k]$, and placing the i-th in-label (out-label) on u_i (on v'_i) for $i \in [k]$. Then for all graphs G and $\boldsymbol{x}, \boldsymbol{z} \in V(G)^k$, $(\boldsymbol{K} \cdot \boldsymbol{K}')_G(\boldsymbol{x}, \boldsymbol{z}) = \sum_{\boldsymbol{y} \in V(G)^k} \boldsymbol{K}_G(\boldsymbol{x}, \boldsymbol{y})\boldsymbol{K}'_G(\boldsymbol{y}, \boldsymbol{z}) =: (\boldsymbol{K}_G \cdot \boldsymbol{K}'_G)(\boldsymbol{x}, \boldsymbol{z})$. One may similarly compose a graph in $\mathcal{D}(k, k)$ with a graph in $\mathcal{D}(k)$ obtaining one in $\mathcal{D}(k)$. This operation corresponds to the matrix-vector product.

2.2 Labelled Graphs of Bounded Treewidth

Labelled graphs of bounded treewidth represent the technical foundation of most proofs in this article. Several versions of such have been used in previous works [28, 15, 22].

Let F be a graph. A *tree decomposition* of F is a pair (T, β) where T is a tree and $\beta \colon V(T) \to 2^{V(F)}$ is a map such that

1. the union of the $\beta(t)$ for $t \in V(T)$ is equal to $V(F)$,
2. for every edge $uv \in E(F)$ there exists $t \in V(T)$ such that $\{u, v\} \subseteq \beta(t)$,
3. for every vertex $u \in V(F)$ the set of vertices $t \in V(T)$ such that $u \in \beta(t)$ is connected in T.

The *width* of (T, β) is the maximum over all $|\beta(t)| - 1$ for $t \in V(T)$. The *treewidth* $\operatorname{tw} F$ of F is the minimum width of a tree decomposition of F. A *path decomposition* is a tree decomposition (T, β) where T is a path. The *pathwidth* $\operatorname{pw} F$ of F is the minimum width of a path decomposition of F.

Building on [9, Lemma 8], we show in the following Lemma 6 that every tree decomposition can be rearranged such that the depth of the decomposition tree gives a bound on the number of vertices in the decomposed graph.

▶ **Lemma 6.** *Let $k \geq 1$ and F be a graph such that $\operatorname{tw} F \leq k - 1$ and $|V(F)| \geq k$. Then F admits tree decomposition (T, β) such that*

1. *$|\beta(t)| = k$ for all $t \in V(T)$,*
2. *$|\beta(s) \cap \beta(t)| = k - 1$ for all $st \in E(T)$,*
3. *there exists a vertex $r \in V(T)$ such that the out-degree of every vertex in the rooted tree (T, r) is at most k.*

Proof. By [9, Lemma 8], there exists a tree decomposition (T, β) of F satisfying the first two assertions. Pick a root $r \in V(T)$ arbitrarily. To ensure that the last property holds, the tree decomposition is modified recursively as follows:

By merging vertices, it can be ensured that no two children of r carry the same bag, i.e. that there exist no two children $s_1 \neq s_2$ of r such that $\beta(s_1) = \beta(s_2)$.

For every $v \in \beta(r)$, let $C(v)$ denote the set of all children t of r such that $\beta(r) \setminus \beta(t) = \{v\}$, i.e. $C(v)$ is the set of all children of r whose bags do not contain the vertex v. The collection $C(v)$ for $v \in \beta(r)$ is a partition of the children of r in at most k parts. Note that for two distinct children $t_1 \neq t_2$ in the same part $C(v)$ it holds that $|\beta(t_1) \cap \beta(t_2)| = k - 1$. Rewire the children of r as follows: For every $v \in \beta(r)$ with $C(v) \neq \emptyset$, pick $t \in C(v)$, make t a child of r and all other elements of $C(v)$ children of t. The vertex r now has at most k children and the new tree decomposition still satisfies the first two assertions. Proceed by processing the children of r. ◀

Inspired by Lemma 6, we consider the following family of distinctly labelled graphs. The *depth* of a rooted tree (T, r) is the maximal number of vertices on any path from r to a leaf.

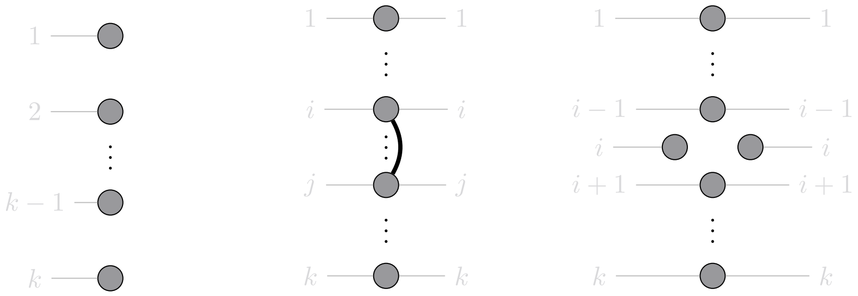
▶ **Definition 7.** *Let $k, d \geq 1$. Define $\mathcal{TW}_d(k)$ as the set of all $\boldsymbol{F} = (F, \boldsymbol{u}) \in \mathcal{D}(k)$ such that F admits a tree decomposition (T, β) of width $\leq k - 1$ satisfying the assertions of Lemma 6 with some $r \in V(T)$ such that $\beta(r) = \{u_1, \dots, u_k\}$ and (T, r) is of depth at most d. Let $\mathcal{TW}(k) \coloneqq \bigcup_{d \geq 1} \mathcal{TW}_d(k)$.*

Every graph in $\mathcal{TW}_d(k)$ has at least k vertices. Conversely, Definition 7 permits the following upper bound on the size of the graphs in $\mathcal{TW}_d(k)$ in terms of d and k.

▶ **Lemma 8.** *Let $k, d \geq 1$. Every $\boldsymbol{F} \in \mathcal{TW}_d(k)$ has at most $\max\{k^d, d\}$ vertices.*

Proof. Let (T, β) and $r \in V(T)$ be as in Definition 7. If $k = 1$, then every vertex in (T, r) has out-degree 1 and F at most d vertices.

Suppose that $k \geq 2$. The proof is by induction on the depth d of the rooted tree (T, r). If $d = 1$, then T contains only a single vertex and $\boldsymbol{F}$ has at most k vertices.



(a) $\boldsymbol{1} \in \mathcal{TW}(k)$. **(b)** $\boldsymbol{A}^{ij} \in \mathcal{D}(k,k)$. **(c)** $\boldsymbol{J}^i \in \mathcal{D}(k,k)$.

Figure 1 The (bi)labelled generators of $\mathcal{TW}(k)$ in wire notion of [34]. A vertex carries in-label (out-label) i if it is connected to the index i on the left (right) by a wire. Actual edges and vertices of the graph are depicted in black.

For the inductive step, let $\boldsymbol{F}$ be of depth d. If r has only a single neighbour s, then $S \coloneqq T - r$ is such that (S, s) is of depth $d-1$. By the inductive hypothesis, $\left|\bigcup_{s\in V(S)} \beta(s)\right| \leq k^d$. Furthermore, $\left|\bigcup_{t\in V(T)} \beta(t) \setminus \bigcup_{s\in V(S)} \beta(s)\right| = 1$. Hence, $\boldsymbol{F}$ has at most $k^{d-1} + 1 \leq k^d$ many vertices.

If r has multiple neighbours, observe that due to Lemma 6 every vertex in $\beta(r)$ is also in $\beta(s)$ for some neighbour s of r. Hence, the number of vertices in $\boldsymbol{F}$ is bounded by the number of vertices covered by the subtrees of $T - r$ rooted in s. Thus, $\boldsymbol{F}$ has at most $k^{d-1} \cdot k \leq k^d$ many vertices. ◀

Clearly, if $\boldsymbol{F} \in \mathcal{TW}(k)$, then $\operatorname{tw}(\operatorname{soe} \boldsymbol{F}) \leq k-1$. Conversely, by Lemma 6, for every F with $\operatorname{tw} F \leq k-1$ and $|V(F)| \geq k$, there exists $\boldsymbol{u} \in V(F)^k$ such that $(F, \boldsymbol{u}) \in \mathcal{TW}(k)$. Thus the underlying unlabelled graphs of the labelled graphs in $\mathcal{TW}(k)$ are exactly the graphs of treewidth $\leq k-1$ on $\geq k$ vertices.

The family $\mathcal{TW}(k)$ is generated by certain small building blocks under series composition and gluing as follows: Let $\boldsymbol{1} \in \mathcal{TW}_1(k)$ be the distinctly k-labelled graph on k vertices without any edges. For $i \in [k]$, let $\boldsymbol{J}^i = (J^i, (1, \dots, k), (1, \dots, i-1, \widehat{i}, i+1, \dots, k))$ the distinctly (k,k)-bilabelled graph with $V(J^i) \coloneqq [k] \cup \{\widehat{i}\}$ and $E(J^i) \coloneqq \emptyset$. Writing $\binom{[k]}{2}$ for the set of pairs of distinct elements in $[k]$, let $\boldsymbol{A}^{ij} = (A^{ij}, (1, \dots, k), (1, \dots, k))$ for $ij \in \binom{[k]}{2}$ be the distinctly (k,k)-bilabelled graph with $V(A^{ij}) \coloneqq [k]$ and $E(A^{ij}) \coloneqq \{ij\}$. These graphs are depicted in Figure 1. Let $\mathcal{B}(k) \coloneqq \{\boldsymbol{J}^i \mid i \in [k]\} \cup \{\boldsymbol{A}^{ij} \mid ij \in \binom{[k]}{2}\}$.

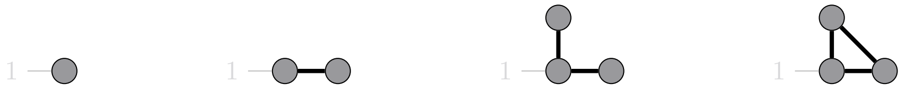
It can be readily verified that if $\boldsymbol{F} \in \mathcal{TW}(k)$ and $\boldsymbol{B} \in \mathcal{B}(k)$, then $\boldsymbol{B} \cdot \boldsymbol{F} \in \mathcal{TW}(k)$. Furthermore, if $\boldsymbol{F}, \boldsymbol{F}' \in \mathcal{TW}(k)$, then $\boldsymbol{F} \odot \boldsymbol{F}' \in \mathcal{TW}(k)$. Conversely, the elements of $\mathcal{B}(k)$ generate $\mathcal{TW}(k)$ in the following sense:

▶ **Lemma 9.** *Let $k \geq 1$. For every $\boldsymbol{F} \in \mathcal{TW}(k)$, one of the following holds:*

1. $\boldsymbol{F} = \boldsymbol{1}$,
2. $\boldsymbol{F} = \prod_{ij \in A} \boldsymbol{A}^{ij} \cdot \boldsymbol{F}'$ *for some* $A \subseteq \binom{[k]}{2}$ *and* $\boldsymbol{F}' \in \mathcal{TW}(k)$ *with less edges than* $\boldsymbol{F}$,
3. $\boldsymbol{F} = \boldsymbol{J}^i \cdot \boldsymbol{F}'$ *for some* $i \in [k]$ *and* $\boldsymbol{F}' \in \mathcal{TW}(k)$ *with less vertices than* $\boldsymbol{F}$,
4. $\boldsymbol{F} = \boldsymbol{F}_1 \odot \boldsymbol{F}_2$ *for* $\boldsymbol{F}_1, \boldsymbol{F}_2 \in \mathcal{TW}(k)$ *on less vertices than* $\boldsymbol{F}$.

2.3 Recognisability and CMSO$_2$

Recognisability is a property of a class of unlabelled graphs which is shared by most named graph classes. It is the assumption of Theorem 1 which rules out esoteric graph classes as constructed in [12, Theorem 1]. We consider the following definition of recognisability.



(a) $\mathbf{1}$. **(b)** $\boldsymbol{P}$. **(c)** $\boldsymbol{Q}$. **(d)** $\boldsymbol{C}$.

Figure 2 Representatives for $\sim^1_{\mathcal{W}}$ and $\mathcal{W}$ the class of paths from Example 11.

▶ **Definition 10** ([11]). *Let $k \geq 1$. For class of unlabelled graphs $\mathcal{F}$, define the equivalence relation $\sim^k_{\mathcal{F}}$ on the class of distinctly k-labelled graphs $\mathcal{D}(k)$ by letting $\boldsymbol{F}_1 \sim^k_{\mathcal{F}} \boldsymbol{F}_2$ if and only if for all $\boldsymbol{K} \in \mathcal{D}(k)$ it holds that*

$$\operatorname{soe}(\boldsymbol{K} \odot \boldsymbol{F}_1) \in \mathcal{F} \iff \operatorname{soe}(\boldsymbol{K} \odot \boldsymbol{F}_2) \in \mathcal{F}.$$

The class $\mathcal{F}$ is k-recognisable *if $\sim^k_{\mathcal{F}}$ has finitely many equivalence classes. The number of classes of $\sim^k_{\mathcal{F}}$ is the* k-recognisability index *of $\mathcal{F}$.*

To parse Definition 10, first recall that $\boldsymbol{K} \odot \boldsymbol{F}_1$ is the k-labelled graph obtained by gluing $\boldsymbol{K}$ and $\boldsymbol{F}_1$ together at their labelled vertices. The soe-operator drops the labels yielding unlabelled graphs. Intuitively, $\boldsymbol{F}_1 \sim^k_{\mathcal{F}} \boldsymbol{F}_2$ iff both or neither of their underlying unlabelled graphs are in $\mathcal{F}$ and the positions of the labels in $\boldsymbol{F}_1$ and $\boldsymbol{F}_2$ is equivalent with respect to membership in $\mathcal{F}$. This intuition is made more concrete in the following example:

▶ **Example 11.** The class $\mathcal{W}$ of all paths is 1-recognisable. Its 1-recognisability index is 4. The equivalence classes are described by the representatives in Figure 2.

Proof. To show that the labelled graphs in Figure 2 cover all equivalence classes, let $\boldsymbol{F} = (F, u)$ be arbitrary. If F is not a path, then $\boldsymbol{F} \sim^1_{\mathcal{W}} \boldsymbol{C}$. Indeed, for every $\boldsymbol{K} \in \mathcal{D}(1)$, F is a subgraph of $\operatorname{soe}(\boldsymbol{K} \odot \boldsymbol{F})$. Hence, regardless of $\boldsymbol{K}$, both $\operatorname{soe}(\boldsymbol{K} \odot \boldsymbol{F})$ and $\operatorname{soe}(\boldsymbol{K} \odot \boldsymbol{C})$ are not paths. If F is a path,, then $\boldsymbol{F}$ and $\mathbf{1}$, $\boldsymbol{P}$, or $\boldsymbol{Q}$ are equivalent depending on whether the degree of u is 0, 1, or 2.

To show that the representatives in Figure 2 are in distinct classes, observe for example that $\operatorname{soe}(\boldsymbol{P} \odot \boldsymbol{P}) \in \mathcal{W}$ while $\operatorname{soe}(\boldsymbol{P} \odot \boldsymbol{Q}) \notin \mathcal{W}$, thus $\boldsymbol{P} \not\sim^1_{\mathcal{W}} \boldsymbol{Q}$. Similarly, $\operatorname{soe}(\mathbf{1} \odot \boldsymbol{Q}) \in \mathcal{W}$ whereas $\operatorname{soe}(\boldsymbol{P} \odot \boldsymbol{Q}) \notin \mathcal{W}$, thus $\mathbf{1} \not\sim^1_{\mathcal{W}} \boldsymbol{P}$. ◀

A more involved example is the following. Analogously, one may argue that every class defined by forbidden minors is recognisable.

▶ **Example 12.** Let $\mathcal{F}$ be the family of H-subgraph-free graphs for some graph H. Then $\mathcal{F}$ is k-recognisable for every $k \geq 1$.

Proof. Suppose H has m vertices. For a distinctly k-labelled graph $\boldsymbol{F} = (F, \boldsymbol{u})$, consider the set $\mathcal{H}(\boldsymbol{F})$ of (isomorphism types of) distinctly k-labelled graphs $\boldsymbol{F}' = (F', \boldsymbol{u})$ where F' is a subgraph of F such that $V(F') \supseteq \{u_1, \dots, u_k\}$ has at most $k + m$ vertices. Clearly, there are only finitely many possible sets $\mathcal{H}(\boldsymbol{F})$. Furthermore, if $\mathcal{H}(\boldsymbol{F}_1) = \mathcal{H}(\boldsymbol{F}_2)$, then $\boldsymbol{F}_1 \sim^k_{\mathcal{F}} \boldsymbol{F}_2$. Indeed, if $\boldsymbol{K} \in \mathcal{D}(k)$ is such that $\operatorname{soe}(\boldsymbol{K} \odot \boldsymbol{F}_1)$ contains H as a subgraph, then so does $\operatorname{soe}(\boldsymbol{K} \odot \boldsymbol{F}_2)$ since $\boldsymbol{F}_1$ and $\boldsymbol{F}_2$ contain the same subgraphs on $k + m$ vertices containing their labelled vertices. ◀

Courcelle [14] proved that every CMSO_2-definable graph class is *recognisable*, i.e. it is k-recognisable for every $k \in \mathbb{N}$. Conversely, Bojańczyk and Pilipczuk [11] proved that if a recognisable class $\mathcal{F}$ has bounded treewidth, then it is CMSO_2-definable. Furthermore, they conjecture that k-recognisability is a sufficient condition for a graph class of treewidth at most $k - 1$ to be CMSO_2-definable.

Here, *counting monadic second-order logic* CMSO_2 is the extension of first-order logic by (1) variables that range over sets of vertices or edges, or over edges, (2) atomic formulas $\operatorname{inc}(x, y)$ which evaluate to true if x is assigned a vertex v and y is assigned an edge e such that v is incident with e, and (3) atomic formulas $\operatorname{card}_{p,q}(X)$ for integers $p, q \in \mathbb{N}$ and set variables X expressing that $|X| \equiv p \mod q$. See [15] for further details.

3 Decidability

As a first step, we show that the problem HomInd($\mathcal{F}$) is decidable for every k-recognisable graph class $\mathcal{F}$ of treewidth at most $k-1$. We do so by establishing a bound on the maximum size of a graph $F \in \mathcal{F}$ for which $\hom(F, G) = \hom(F, H)$ needs to be checked in order to conclude whether $G \equiv_{\mathcal{F}} H$. For a graph class $\mathcal{F}$ and $\ell \in \mathbb{N}$, define the class $\mathcal{F}_{\leq \ell} \coloneqq \{F \in \mathcal{F} \mid |V(F)| \leq \ell\}$.

▶ **Theorem 13.** *Let $k \geq 1$. Let $\mathcal{F}$ be a graph class of treewidth $\leq k-1$ with k-recognisability index C. For graphs G and H on at most n vertices, with $f_{k,C}(n) \coloneqq \max\{k^{2Cn^k}, 2Cn^k\}$,*

$$G \equiv_{\mathcal{F}} H \iff G \equiv_{\mathcal{F}_{\leq f_{k,C}(n)}} H.$$

Fix throughout a graph class $\mathcal{F}$ as in Theorem 13. In reminiscence of Courcelle's theorem, we let Q denote the set of equivalence classes of $\sim^k_{\mathcal{F}}$, as defined in Definition 10, and call them *states*. A state $q \in Q$ is *accepting* if for an (and equivalently, every) $\boldsymbol{F}$ in q it holds that $\operatorname{soe}(\boldsymbol{F}) \in \mathcal{F}$. Write $A \subseteq Q$ for the set of all accepting states.

To every state $q \in Q$, we associate a finite-dimensional vector space spanned by the homomorphism tensors of the k-labelled graphs $\boldsymbol{F}$ that belong to state q. We show that these vector spaces certify homomorphism indistinguishability. Using a dimensionality argument, we show that these vector spaces are spanned by homomorphism tensors of graphs whose size is bounded by the function f from Theorem 13. To that end, we decompose the labelled graphs $\boldsymbol{F} \in \mathcal{TW}(k)$ using the operations considered in Lemma 9.

Formally, we associate to a state $q \in Q$ and an integer $d \geq 1$ the vector space[1]

$$S_d(q) \coloneqq \langle \{\boldsymbol{F}_G \oplus \boldsymbol{F}_H \mid \boldsymbol{F} \in \mathcal{TW}_d(k) \text{ in state } q\} \rangle \subseteq \mathbb{R}^{V(G)^k \cup V(H)^k}.$$

Here, $\boldsymbol{F}$ is a k-labelled graph of bounded treewidth in the state q. The vector $\boldsymbol{F}_G \oplus \boldsymbol{F}_H \coloneqq \binom{\boldsymbol{F}_G}{\boldsymbol{F}_H} \in \mathbb{R}^{V(G)^k \cup V(H)^k}$ is obtained by stacking the homomorphisms vectors of $\boldsymbol{F}$ w.r.t. G and H. Since $\mathcal{TW}_d(k) \subseteq \mathcal{TW}_{d+1}(q)$, the space $S_d(q)$ is a subspace of $S_{d+1}(q)$ for every $d \geq 1$. Ultimately, we are interested in $S(q) \coloneqq \bigcup_{d \geq 1} S_d(q)$, i.e. the vector space spanned by the homomorphism vectors of all labelled graphs of treewidth $\leq k-1$ in state q.

By the following Lemma 14, the vectors in $S(q)$ for $q \in A$ can be used to infer whether G and H are homomorphism indistinguishable over $\mathcal{F}$. For a labelled graph $\boldsymbol{F} \in \mathcal{TW}(k)$, the number $\boldsymbol{1}_G^T(\boldsymbol{F}_G \oplus \boldsymbol{F}_H)$ is equal to the number of homomorphisms from the underlying unlabelled graph of $\boldsymbol{F}$ to G. This observation readily yields the backward implication in Lemma 14. For the forward implication, observe that the space $S(q)$ is spanned by homomorphism tensors $\boldsymbol{F}_G \oplus \boldsymbol{F}_H$, which satisfy the assertion by assumption.

▶ **Lemma 14.** *Two graph G and H are homomorphism indistinguishable over $\mathcal{F}_{\geq k} \coloneqq \{F \in \mathcal{F} \mid |V(F)| \geq k\}$ if and only if $\boldsymbol{1}_G^T v = \boldsymbol{1}_H^T v$ for every $q \in A$ and every $v \in S(q)$.*

[1] Wlog we may suppose that $V(G)$ and $V(H)$ are disjoint.

Proof. For the forward direction, note that $S(q)$ is spanned by the $\boldsymbol{F}_G \oplus \boldsymbol{F}_H$ where $\boldsymbol{F} \in \mathcal{TW}(k)$ is in state q. Let $\boldsymbol{F}$ in $q \in A$ be arbitrary. Then $\operatorname{soe}(\boldsymbol{F}) =: F \in \mathcal{F}_{\geq k}$ and it holds that $\mathbf{1}_G^T(\boldsymbol{F}_G \oplus \boldsymbol{F}_H) = \operatorname{soe}(\boldsymbol{F}_G) = \hom(F, G) = \hom(F, H) = \mathbf{1}_H^T(\boldsymbol{F}_G \oplus \boldsymbol{F}_H)$. Conversely, let $F \in \mathcal{F}_{\geq k}$ be arbitrary. Since $\operatorname{tw} F \leq k-1$, by Lemma 6, there exists $\boldsymbol{u} \in V(F)^k$ such that $\boldsymbol{F} := (F, \boldsymbol{u}) \in \mathcal{TW}(k)$. Furthermore, $\boldsymbol{F}$ belongs to some accepting $q \in Q$. Thus, $\boldsymbol{F}_G \oplus \boldsymbol{F}_H \in S(q)$, and hence $\hom(F, G) = \mathbf{1}_G^T(\boldsymbol{F}_G \oplus \boldsymbol{F}_H) = \mathbf{1}_H^T(\boldsymbol{F}_G \oplus \boldsymbol{F}_H) = \hom(F, H)$. ◀

By Lemma 8, the space $S_d(q)$ for $d \geq 1$ is spanned by homomorphism tensors of graphs of size $\max\{k^d, d\}$. Thus, Theorem 13 follows once we establish that $S_{d'}(q) = S(q)$ for all $q \in Q$ and $d' := 2Cn^k$. This d' arises as an upper bound on the dimension of the space $\bigoplus_{q \in Q} S(q)$. The spaces $\bigoplus_{q \in Q} S_d(q)$ for $d \geq 1$ form a chain of nested subspaces in $\bigoplus_{q \in Q} S(q)$. The following Lemma 15 shows that once this chain becomes stationary, then the maximal subspace is reached.

▶ **Lemma 15.** *If $S_d(q) = S_{d+1}(q)$ for $d \geq 1$ and all $q \in Q$, then $S_d(q) = S(q)$ for all $q \in Q$. In particular, $S_{2Cn^k}(q) = S(q)$ for all $q \in Q$.*

The proof of Lemma 15 relies on the properties of the relation $\sim_{\mathcal{F}}^k$. In particular, it uses the fact that series composition and gluing, the operations under which $\mathcal{TW}(k)$ is generated by Lemma 9, preserve the relation $\sim_{\mathcal{F}}^k$.

▶ **Lemma 16.** *For $\boldsymbol{F}, \boldsymbol{F}', \boldsymbol{F}_1, \boldsymbol{F}_2, \boldsymbol{F}_1', \boldsymbol{F}_2' \in \mathcal{D}(k)$, $\boldsymbol{L} \in \mathcal{D}(k, k)$,*

1. *if $\boldsymbol{F}_1 \sim_{\mathcal{F}}^k \boldsymbol{F}_1'$ and $\boldsymbol{F}_2 \sim_{\mathcal{F}}^k \boldsymbol{F}_2'$, then $\boldsymbol{F}_1 \odot \boldsymbol{F}_2 \sim_{\mathcal{F}}^k \boldsymbol{F}_1' \odot \boldsymbol{F}_2'$,*
2. *if $\boldsymbol{F} \sim_{\mathcal{F}}^k \boldsymbol{F}'$, then $\boldsymbol{L} \cdot \boldsymbol{F} \sim_{\mathcal{F}}^k \boldsymbol{L} \cdot \boldsymbol{F}'$.*

Proof. Let $\boldsymbol{K} = (K, \boldsymbol{u}) \in \mathcal{D}(k)$ be arbitrary. Then $\operatorname{soe}((\boldsymbol{K} \odot \boldsymbol{F}_1) \odot \boldsymbol{F}_2) \in \mathcal{F} \Leftrightarrow \operatorname{soe}((\boldsymbol{K} \odot \boldsymbol{F}_1) \odot \boldsymbol{F}_2') \in \mathcal{F} \Leftrightarrow \operatorname{soe}(\boldsymbol{K} \odot \boldsymbol{F}_1' \odot \boldsymbol{F}_2') \in \mathcal{F}$.

For a (k, k)-bilabelled graph $\boldsymbol{L} = (L, \boldsymbol{u}, \boldsymbol{v})$, write $\boldsymbol{L}^* := (L, \boldsymbol{v}, \boldsymbol{u})$ for the (k, k)-bilabelled graph obtained by swapping the in-labels and out-labels. Then $\operatorname{soe}(\boldsymbol{K} \odot (\boldsymbol{L} \cdot \boldsymbol{F})) = \operatorname{soe}((\boldsymbol{L}^* \cdot \boldsymbol{K}) \odot \boldsymbol{F})$. Thus the second claim follows from the first. ◀

The algebraic operations on homomorphism tensors corresponding to series composition and gluing are the matrix-vector product and Schur product. Crucially, these operations are linear and bilinear, respectively. This allows Lemma 15 to be proven by structural induction along Lemma 9.

Proof of Lemma 15. We argue that $S_d(q) \supseteq S_{d+i}(q)$ for all $i \geq 1$ by induction on i. The base case holds by assumption. The space $S_{d+i+1}(q)$ is spanned by the vectors $\boldsymbol{F}_G \oplus \boldsymbol{F}_H$ where $\boldsymbol{F} \in \mathcal{TW}_{d+i+1}(k)$ is in q. For such $\boldsymbol{F}$, by Lemma 9, there exist $A \subseteq \binom{[k]}{2}$, $L \subseteq [k]$, and $\boldsymbol{F}^\ell \in \mathcal{TW}_{d+i}(k)$ for $\ell \in L$ such that

$$\boldsymbol{F} = \prod_{ij \in A} \boldsymbol{A}^{ij} \cdot \bigodot_{\ell \in L} \boldsymbol{J}^\ell \boldsymbol{F}^\ell.$$

Let q_ℓ denote the state of $\boldsymbol{F}^\ell$. By assumption, there exist $\boldsymbol{K}^{\ell m} \in \mathcal{TW}_d(k)$ in state q_ℓ and $\alpha_m \in \mathbb{R}$ such that $\boldsymbol{F}_G^\ell \oplus \boldsymbol{F}_H^\ell = \sum \alpha_m \boldsymbol{K}_G^{\ell m} \oplus \boldsymbol{K}_H^{\ell m}$. By Lemma 16,

$$\boldsymbol{F} \sim_{\mathcal{F}}^k \prod_{ij \in A} \boldsymbol{A}^{ij} \cdot \bigodot_{\ell \in L} \boldsymbol{J}^\ell \boldsymbol{K}^{\ell m}$$

for all m. Thus, $\boldsymbol{F}_G \oplus \boldsymbol{F}_H$ can be written as linear combination of vectors in $S_{d+i}(q) \subseteq S_d(q)$, by induction. For the final claim, consider the chain of nested subspaces

$$\bigoplus_{q \in Q} S_1(q) \subseteq \bigoplus_{q \in Q} S_2(q) \subseteq \cdots \subseteq \bigoplus_{q \in Q} S(q).$$

By what was just shown, for every $d \geq 1$, either $\bigoplus_{q \in Q} S_d(q)$ is a proper subspace of $\bigoplus_{q \in Q} S_{d+1}(q)$ or $\bigoplus_{q \in Q} S_d(q) = \bigoplus_{q \in Q} S(q)$. Since the dimension of $\bigoplus_{q \in Q} S(q)$ is at most $2Cn^k$, the chain becomes stationary after at most $2Cn^k$ steps. ◀

This concludes the preparations for the proof of Theorem 13.

Proof of Theorem 13. It suffices to prove the backward implication. Since $k \leq k^{2Cn^k}$, it suffices to show that $G \equiv_{\mathcal{F}_{\geq k}} H$ by verifying the condition in Lemma 14. By Lemma 15, $S_d(q) = S(q)$ for $d := 2Cn^k$ and all $q \in Q$. Hence, $S(q)$ is spanned by the $\boldsymbol{F}_G \oplus \boldsymbol{F}_H$ where $\boldsymbol{F} \in \mathcal{TW}_d(k)$ is in state q. By Lemma 8, these graphs have at most $\max\{k^d, d\} = \max\{k^{2Cn^k}, 2Cn^k\}$ vertices. Thus, $\mathbf{1}_G^T(\boldsymbol{F}_G \oplus \boldsymbol{F}_H) = \hom(\operatorname{soe} \boldsymbol{F}, G) = \hom(\operatorname{soe} \boldsymbol{F}, H) = \mathbf{1}_H^T(\boldsymbol{F}_G \oplus \boldsymbol{F}_H)$, as desired. ◀

Finally, we adapt the techniques developed so far to prove the following analogue of Theorem 13 for graph classes of bounded pathwidth. In contrast to Theorem 13, the function in Theorem 17 bounding the size of the graphs which need to be considered is polynomial. The proof is deferred to the full version.

▶ **Theorem 17.** *Let $k \geq 1$. Let $\mathcal{F}$ be a graph class of pathwidth $\leq k-1$ with k-recognisability index C. For graphs G and H on at most n vertices, with $f_{k,C}(n) := 2Cn^k + k - 1$,*

$$G \equiv_{\mathcal{F}} H \iff G \equiv_{\mathcal{F}_{\leq f_{k,C}(n)}} H.$$

4 Modular Homomorphism Indistinguishability in Polynomial Time

The insight that yielded Theorem 13 is that the chain of vector spaces $S_1(q) \subseteq \dots \subseteq S_d(q) \subseteq S_{d+1}(q) \subseteq \dots$ reaches a fixed point after polynomially many steps. In this section, we strengthen this result by showing that bases $B(q)$ for the spaces $S(q)$ can be computed efficiently. A technical difficulty arising here is that the numbers produced in the process can be of doubly exponential magnitude. In order to overcome this problem, we first consider homomorphism indistinguishability modulo primes. See [21, 30], for background on modular homomorphism indistinguishability.

ModHomInd($\mathcal{F}$)
Input Graphs G and H, a prime p in binary.
Question Are G and H homomorphism indistinguishable over $\mathcal{F}$ modulo p?

▶ **Theorem 18.** *Let $k \geq 1$. If $\mathcal{F}$ is a k-recognisable graph class of treewidth $\leq k-1$, then* ModHomInd($\mathcal{F}$) *is in polynomial time.*

The algorithm yielding Theorem 18 is formally stated as Algorithm 1. The idea is to iteratively compute bases $B(q)$ for the spaces

$$S(q) := \langle \{\boldsymbol{F}_G \oplus \boldsymbol{F}_H \mid \boldsymbol{F} \in \mathcal{TW}(k) \text{ in state } q\} \rangle \subseteq \mathbb{F}_p^{V(G)^k \cup V(H)^k}.$$

Initially, all $B(q)$ are empty. Only $B(q_0)$ where q_0 is the state of $\mathbf{1} \in \mathcal{TW}(k)$ from Figure 1a contains the homomorphism vector $\mathbf{1}_G \oplus \mathbf{1}_H$. Subsequently, the operations from Lemma 9 are applied to compute new homomorphism vectors. For every new vector belonging to state q, it is checked whether it is a linear combination of the already computed basis vectors in $B(q)$. If not, it is added to $B(q)$. Analogous to Lemma 15, this process reaches a fixed point after a polynomial number of iterations. At this point, the computed $B(q)$ are bases for the $S(q)$. Finally, Lemma 14 can be invoked to conclude whether the input graphs are homomorphism indistinguishable over $\mathcal{F}$ modulo p.

Algorithm 1 is supplied with a hard-coded description of the graph class $\mathcal{F}$. To that end, consider the following objects. Write $\pi \colon \mathcal{TW}(k) \to Q$ for the map that associates an $\boldsymbol{F} \in \mathcal{TW}(k)$ to its state $q \in Q$. Write q_0 for the state of $\mathbf{1} \in \mathcal{TW}(k)$. Furthermore, write $g \colon Q \times Q \to Q$ and $b_{\boldsymbol{B}} \colon Q \to Q$ for every $\boldsymbol{B} \in \mathcal{B}(k)$ such that

$$g(\pi(\boldsymbol{F}), \pi(\boldsymbol{F}')) = \pi(\boldsymbol{F} \odot \boldsymbol{F}'), \tag{1}$$

$$b_{\boldsymbol{B}}(\pi(\boldsymbol{F})) = \pi(\boldsymbol{B} \cdot \boldsymbol{F}). \tag{2}$$

for every $\boldsymbol{F}, \boldsymbol{F}' \in \mathcal{TW}(k)$ and $\boldsymbol{B} \in \mathcal{B}(k)$. Note that Q, A, g, q_0 and the $b_{\boldsymbol{B}}$, $\boldsymbol{B} \in \mathcal{B}(k)$, are finite objects, which can be hard-coded. The map π does not need to be computable and is only needed for analysing the algorithm.

Algorithm 1 ModHomInd($\mathcal{F}$) for k-recognisable $\mathcal{F}$ of treewidth $\leq k-1$.

```
   Input: graphs $G$ and $H$, a prime $p$ in binary.
   Data: $k$, $Q$, $A$, $q_0$, $g$, $b_{\boldsymbol{B}}$ for $\boldsymbol{B} \in \mathcal{B}(k)$.
   Output: whether $G \equiv^p_{\mathcal{F}} H$.
 1 With brute force check whether $G$ and $H$ are homomorphism indistinguishable over
    the finite graph class $\mathcal{F}_{\leq k}$ modulo $p$ and reject if not;
 2 $B(q_0) \leftarrow \{\mathbf{1}_G \oplus \mathbf{1}_H\} \subseteq \mathbb{F}_p^{V(G)^k \cup V(H)^k}$;
 3 $B(q) \leftarrow \emptyset \subseteq \mathbb{F}_p^{V(G)^k \cup V(H)^k}$ for all $q \neq q_0$;
 4 repeat
 5     foreach $\boldsymbol{B} \in \mathcal{B}(k)$, $q \in Q$, $v \in B(q)$ do
 6         $w \leftarrow (\boldsymbol{B}_G \oplus \boldsymbol{B}_H)v := \begin{pmatrix} \boldsymbol{B}_G & 0 \\ 0 & \boldsymbol{B}_H \end{pmatrix} v$;
 7         if $w \notin \langle B(b_{\boldsymbol{B}}(q)) \rangle$ then
 8             add $w$ to $B(b_{\boldsymbol{B}}(q))$;
 9     foreach $q_1, q_2 \in Q$, $v_1 \in B(q_1)$, $v_2 \in B(q_2)$ do
10         $w \leftarrow v_1 \odot v_2$;

▶ **Lemma 19.** *Write $n := \max\{|V(G)|, |V(H)|\}$ and $C := |Q|$. There exists a computable function f such that Algorithm 1 runs in time $f(k, C) n^{O(k)} (\log p)^{O(1)}$.*

Proof. Consider the following individual runtimes: Counting homomorphisms of a graph on k vertices into a graph on n vertices, can be done in time $O(n^k)$. Hence Line 1 requires time $f(k)n^k$ for some computable function f.

Throughout the execution of Algorithm 1, the vectors in each $B(q)$, $q \in Q$, are linearly independent. Thus, $|B(q)| \leq \dim S(q) \leq 2n^k$ and $\sum_{q \in Q} |B(q)| \leq 2Cn^k$. Hence, the body of the loop in Line 1 is entered at most $2Cn^k$ many times.

The loop in Line 1 iterates over at most $k^2 \cdot C \cdot 2n^k$ many objects. Computing the vector w takes polynomial time in $2n^k \cdot \log p$. The same holds for checking the condition in Line 1, e.g. via Gaussian elimination. The loop in Line 1 iterates over at most $C^2 \cdot (2n^k)^2$ many objects. Finally, checking the condition in Line 1 takes $C \cdot 2n^k \cdot (\log p)^{O(1)}$ many steps. ◀

The following Lemma 20 implies that Algorithm 1 is correct.

▶ **Lemma 20.** *When Algorithm 1 terminates, $B(q)$ spans $S(q)$ for all $q \in Q$.*

Proof. First observe that the invariant $B(q) \subseteq S(q)$ for all $q \in Q$ is preserved throughout Algorithm 1. Indeed, for example in Line 1, since $v \in B(q) \subseteq S(q)$, it can be written as linear combination of $\boldsymbol{F}_G \oplus \boldsymbol{F}_H$ for $\boldsymbol{F} \in \mathcal{TW}(k)$ of state q. Because $\boldsymbol{B} \cdot \boldsymbol{F}$ is in state $b_{\boldsymbol{B}}(q)$ by Equation (2), $(\boldsymbol{B}_G \oplus \boldsymbol{B}_H)v$ is in the span of $\boldsymbol{B}_G\boldsymbol{F}_G \oplus \boldsymbol{B}_H\boldsymbol{F}_H \in S(b_{\boldsymbol{B}}(q))$.

Now consider the converse inclusion. The proof is by induction on the structure in Lemma 9. By initialisation, $\boldsymbol{1}_G \oplus \boldsymbol{1}_H$ is in the span of $B(q_0)$.

For the inductive step, suppose that $\boldsymbol{F} \in \mathcal{TW}(k)$ of state $q \in Q$ is such that $\boldsymbol{F}_G \oplus \boldsymbol{F}_H = \sum_{v \in B(q)} \alpha_v v$ for some coefficients $\alpha_v \in \mathbb{F}_p$. Let $\boldsymbol{B} \in \mathcal{B}(k)$ and $\boldsymbol{F}' := \boldsymbol{B} \cdot \boldsymbol{F}$. Then $(\boldsymbol{B}_G \oplus \boldsymbol{B}_H)v$ is in the span of $B(b_{\boldsymbol{B}}(q))$ for all $v \in B(q)$ by the termination condition. Hence, $\boldsymbol{F}'_G \oplus \boldsymbol{F}'_H = \sum_{v \in B(q)} \alpha_v (\boldsymbol{B}_G \oplus \boldsymbol{B}_H)v$ is in the span of $B(b_{\boldsymbol{B}}(q))$.

Let $\boldsymbol{F}^1, \boldsymbol{F}^2 \in \mathcal{TW}(k)$ of states $q_1, q_2 \in Q$ be such that $\boldsymbol{F}^1_G \oplus \boldsymbol{F}^1_H = \sum_{v \in B(q_1)} \alpha_v v$ and $\boldsymbol{F}^2_G \oplus \boldsymbol{F}^2_H = \sum_{w \in B(q_2)} \beta_w w$ for some coefficients $\alpha_v, \beta_w \in \mathbb{F}_p$. Since the algorithm terminated, all $v \odot w$ for $v \in B(q_1)$ and $w \in B(q_2)$ are in the span of $B(g(q_1, q_2))$. Then $(\boldsymbol{F}^1 \odot \boldsymbol{F}^2)_G \oplus (\boldsymbol{F}^1 \odot \boldsymbol{F}^2)_H = (\boldsymbol{F}^1_G \oplus \boldsymbol{F}^1_H) \odot (\boldsymbol{F}^2_G \oplus \boldsymbol{F}^2_H) = \sum_{v \in B(q_1), w \in B(q_2)} \alpha_v \beta_w (v \odot w)$ is in the span of $B(g(q_1, q_2))$. ◀

This concludes the preparations for the proof of Theorem 18:

Proof of Theorem 18. Lemma 20 implies that the conditions in Lemma 14 and Line 1 are equivalent. Thus, G and H are homomorphism indistinguishable over $\mathcal{F}_{\geq k}$ modulo p if and only if the condition in Line 1 holds. The runtime bound is given in Lemma 19. ◀

5 Randomised Polynomial Time

In this section, we give a randomised polynomial-time reduction from HomInd($\mathcal{F}$) to ModHomInd($\mathcal{F}$). Thereby, we prove Theorems 1 and 2. Theorems 13 and 17 give bounds N on the size of the largest graph in $\mathcal{F}$ which needs to be considered in order to conclude whether two graphs on at most n vertices are homomorphism indistinguishable over $\mathcal{F}$. A graph on at most N vertices may have at most n^N homomorphisms to a graph on n vertices. Thus, for graphs on at most n vertices, homomorphism indistinguishability over $\mathcal{F}$ is the same as homomorphism indistinguishability over $\mathcal{F}$ modulo any number greater than n^N. Equipped with the following Lemma 21, which is derived from the Chinese Remainder Theorem and the Prime Number Theorem, we show Theorems 1 and 2. Let log denote the logarithm to base 2.

▶ **Lemma 21.** *Let $N, n \in \mathbb{N}$ be such that $N \log n \geq e^{2000}$. Let $\mathcal{F}$ be a graph class and G and H be graphs on at most n vertices. If $G \not\equiv_{\mathcal{F}_{\leq N}} H$ then the probability that a random prime $N \log n < p \leq (N \log n)^2$ is such that $G \equiv^p_{\mathcal{F}_{\leq N}} H$ is at most $\frac{2}{N \log n}$.*

For graph classes of bounded pathwidth, the bound on N from Theorem 17 is polynomial in n. Thus, one can enumerate all primes $N \log n < p \leq (N \log n)^2$ in polynomial time and invoke ModHomInd($\mathcal{F}$).

▶ **Theorem 2.** *Let $k \geq 1$. If $\mathcal{F}$ is a k-recognisable class of graphs of pathwidth at most $k - 1$, then* HomInd($\mathcal{F}$) *is in polynomial time.*

For graph classes of bounded treewidth, the bound on N from Theorem 13 is exponential in n. The randomised algorithm yielding Theorem 1 stated in the full version samples primes of polynomial size and invokes $\textsc{ModHomInd}(\mathcal{F})$. Lemma 21 implies that a random prime p of appropriate size certifies that $G \not\equiv_{\mathcal{F}} H$ with high probability. This yields Theorem 1:

▶ **Theorem 1.** *Let $k \geq 1$. If $\mathcal{F}$ is a k-recognisable class of graphs of treewidth at most $k-1$, then $\textsc{HomInd}(\mathcal{F})$ is in* coRP*.*

6 Fixed-Parameter Tractability

In this section, we deduce Theorem 3 from Theorem 1. The challenge is to efficiently compute the data describing the graph class $\mathcal{F}_{\varphi,k}$ for Algorithm 1 from the CMSO_2-sentence φ and k. That this can be done was proven by Courcelle [15]. More precisely, Courcelle proved that for every CMSO_2-sentence φ and integer k one can compute a finite automaton processing expressions which encode (tree decompositions of) graphs of bounded treewidth. It is this automaton from which the data required by Algorithm 1 can be constructed.

▶ **Theorem 3.** *There exists a computable function $f \colon \mathbb{N} \to \mathbb{N}$ and a randomised algorithm for* $\textsc{HomInd}$ *of runtime $f(|\varphi| + k)n^{O(k)}$ for $n := \max\{|V(G)|, |V(H)|\}$ which accepts all* YES*-instances and accepts* NO*-instances with probability less than one half.*

For graph classes of bounded pathwidth, the analogous problem can be decided deterministically in the same time, cf. the full version.

7 Lasserre in Polynomial Time

By phrasing graph isomorphism as an integer program, heuristics from integer programming can be used to attempt to solve graph isomorphism. Prominent heuristics are the Sherali–Adams linear programming hierarchy and the Lasserre semidefinite programming hierarchy. While the (approximate) feasibility of each level of these hierarchies can be decided efficiently, it is known that a linear number of levels is required to decide graph isomorphism for all graphs [4, 27, 38].

In [38], for each $t \geq 1$, feasibility of the t-th level of the Lasserre hierarchy was characterised as homomorphism indistinguishability relation over the graph class $\mathcal{L}_t$ which was constructed in the same paper. Moreover, the authors asked whether there is a polynomial-time algorithm for deciding these relations. In this section, we give a randomised algorithm for this problem which is polynomial-time for every level.

The Lasserre semidefinite program can be solved approximately in polynomial time using e.g. the ellipsoid method. How to decide *exact* feasibility is generally unknown [2]. Since the graph class $\mathcal{L}_t$ is a minor-closed and of treewidth at most $3t-1$, Theorem 1 immediately yields a randomised polynomial-time algorithm for each level of the hierarchy. However, it is not clear how to compute the data describing $\mathcal{L}_t$ given t. The following Theorem 22 overcomes this problem by making the dependence on the parameter t effective:

▶ **Theorem 22.** *There exists a computable function $f \colon \mathbb{N} \to \mathbb{N}$ and a randomised algorithm deciding given graphs G and H on at most n vertices and an integer $t \geq 1$ whether the level-t Lasserre relaxation of the integer program for $G \cong H$ has an exact solution. This algorithm always runs in time $f(t)n^{O(t)}$, accepts all* YES*-instances and accepts* NO*-instances with probability less than one half.*

8 Lower Bounds

In this final section, we establish two hardness results for the problem HomInd. In both cases, we show hardness for families of minor-closed graph classes. The approaches are orthogonal in the sense that the reduction yielding coNP-hardness in Theorem 5 is from a fixed-parameter tractable problem while the reduction yielding coW[1]-hardness in Theorem 4 is not polynomial-time.

coNP-Hardness. The first hardness result concerns deciding whether two graphs are indistinguishable under the k-dimensional Weisfeiler–Leman algorithm when k is part of the input. By [20, 13, 19], k-WL indistinguishability coincides with homomorphism indistinguishability over the class of graphs of treewidth at most k. Hence, the problem in Theorem 5 is clearly a special case of HomInd, i.e. with φ set to true. Thus, when disregarding the parametrisation, HomInd is coNP-hard under polynomial-time many-one reductions. We obtain Theorem 5 by reducing the NP-complete problem of deciding whether a graph of bounded degree has treewidth $\leq k$ [10]. The reduction is based on the ubiquitous CFI construction [13].

▶ **Theorem 5.** *The problem of deciding given graphs G and H and an integer $k \in \mathbb{N}$ whether G and H are k-*WL *indistinguishable is* coNP*-hard under polynomial-time many-one reductions.*

Towards the proof of Theorem 5, we recall the following version of the classical CFI graphs [13] from [37]. Let G be a connected graph and $U \colon V(G) \to \mathbb{Z}_2$ a function from G to the group on two elements $\mathbb{Z}_2$. For a vertex $v \in V(G)$, write $E(v) \subseteq E(G)$ for the set of edges incident to v. The graph G_U has vertices (v, S) for every $v \in V(G)$ and $S \colon E(v) \to \mathbb{Z}_2$ such that $\sum_{e \in E(v)} S(e) = U(v)$. Two vertices (u, S) and (v, T) are adjacent in G_U if $uv \in E(G)$ and $S(uv) + T(uv) = 0$. Note that $|V(G_U)| = \sum_{v \in V(G)} 2^{\deg(v)-1}$. By [37, Lemma 3.2], if $\sum_{v \in V(G)} U(v) = \sum_{v \in V(G)} U'(v)$ for $U, U' \colon V(G) \to \mathbb{Z}_2$, then $G_U \cong G_{U'}$. We may thus write G_0 and G_1 for the *even* and the *odd* CFI graph of G. We recall the following properties:

▶ **Lemma 23** ([37, Corollary 3.7])**.** *Let G be a connected graph and $U \colon V(G) \to \mathbb{Z}_2$. Then the following are equivalent:*

1. $G_0 \cong G_U$,
2. $\sum_{v \in V(G)} U(v) = 0$,
3. $\hom(G, G_0) = \hom(G, G_U)$.

Proof of Theorem 5. For a graph G, write $\Delta(G)$ for its maximum vertex degree. The following problem is NP-complete by [10, Theorem 11]:

BoundedDegreeTreewidth
Input a graph G with $\Delta(G) \leq 9$, an integer k
Question Is $\operatorname{tw} G \leq k$?

By deleting isolated vertices, we may suppose that every connected component of G contains at least two vertices. If G has multiple connected components, take one vertex from each component and connect them in a pathlike fashion. This increases the maximum degree potentially by one but makes the graph connected. The treewidth is invariant under this operation. Thus, we may suppose that G is connected and $\Delta(G) \leq 10$.

Given such an instance, we produce the instance (G_0, G_1, k) of WL, i.e. the decision problem in Theorem 5. Here, G_0 and G_1 are the even and odd CFI graphs of G.

Then G_0 and G_1 are k-WL indistinguishable if and only if $\operatorname{tw} G \geq k+1$. Indeed, by [13, 20] and [36, Lemma 4.4], since G is connected, if $\operatorname{tw} G \geq k+1$, then G_0 and G_1 are k-WL indistinguishable. Conversely, if $\operatorname{tw} G < k+1$, then G_0 and G_1 are distinguished by k-WL since $\hom(G, G_0) \neq \hom(G, G_1)$ by Lemma 23 and [20]. Hence, (G, k) is a YES-instance of BoundedDegreeTreewidth if and only if (G_0, G_1, k) is a NO-instance of WL. The graphs G_0 and G_1 are of size $\sum_{v \in V(G)} 2^{\deg(v)-1} \leq 2^9 n$, which is polynomial in the input. ◀

coW[1]-Hardness. The second hardness result concerns HomInd as a parametrised problem. Write $\mathcal{G}_{\leq k}$ for the class of all graphs on at most k vertices and consider the following problem:

HomIndSize
Input Graphs G and H, an integer $k \geq 1$.
Parameter k.
Question Are G and H homomorphism indistinguishable over the class $\mathcal{G}_{\leq k}$?

The problem HomIndSize fixed-parameter reduces to HomInd. To that end, consider the first-order formula $\varphi_k := \exists x_1 \dots \exists x_k \forall y \bigvee_{i=1}^{k} (y = x_i)$ for $k \in \mathbb{N}$. Then, a graph models φ_k if and only if it has at most k vertices. Furthermore, $|\varphi_k| = O(k)$. Hence, transforming the instance (G, H, k) of HomIndSize to the instance $(G, H, \varphi_k, k-1)$ of HomInd gives the desired reduction. Since $|\varphi_k| + k = O(k)$, Theorem 24 implies Theorem 4.

▶ **Theorem 24.** *HomIndSize is* coW[1]*-hard under fpt-reductions. Unless* ETH *fails, there is no algorithm for* HomIndSize *that runs in time $f(k)n^{o(k)}$ for any computable function $f \colon \mathbb{N} \to \mathbb{N}$.*

Proof. The proof is by reduction from the parametrised clique problem Clique, which is well-known to be W[1]-complete and which does not admit an $f(k)n^{o(k)}$-time algorithm for any computable function f unless ETH fails [16, Theorems 13.25, 14.21].

Let K denote the k-vertex complete graph and K_0 and K_1 the even and odd CFI graphs of K. We first observe that $K_0 \equiv_{\mathcal{G}_{\leq k} \setminus \{K\}} K_1$. Indeed, by [37, Theorem 3.13], for every graph F, $\hom(F, K_0) \neq \hom(F, K_1)$ if and only if there exists a *weak oddomorphism* $h \colon F \to K$ as defined in [37, Definition 3.9]. By definition, a weak oddomorphism is a homomorphism which is surjective on edges and vertices, i.e. for every $uv \in E(K)$ there exists $u'v' \in E(F)$ such that $h(u'v') = uv$. Hence, if $\hom(F, K_0) \neq \hom(F, K_1)$, then F has at least k vertices and $\binom{k}{2}$ edges. The only graph in $\mathcal{G}_{\leq k}$ matching this description is K.

The reduction produces given the instance (G, k) of Clique the instance $(G \times K_0, G \times K_1, k)$ of HomIndSize where K is the k-vertex clique and × denotes the categorical product (also known as tensor product) of two graphs. Producing this instance is fixed-parameter tractable. Furthermore, the parameter k is not affected by this reduction. For correctness, consider the following argument.

If $G \times K_0 \equiv_{\mathcal{G}_{\leq k}} G \times K_1$, then $\hom(K, G) = 0$. Indeed, by assumption and [33, (5.30)], $\hom(K, G) \hom(K, K_0) = \hom(K, G \times K_0) = \hom(K, G \times K_1) = \hom(K, G) \hom(K, K_1)$. However, $\hom(K, K_0) \neq \hom(K, K_1)$ by Lemma 23, and thus $\hom(K, G) = 0$.

Conversely, it holds that $K_0 \equiv_{\mathcal{G}_{\leq k} \setminus \{K\}} K_1$ and hence also $G \times K_0 \equiv_{\mathcal{G}_{\leq k} \setminus \{K\}} G \times K_1$ by the initial observation and [33, (5.30)]. Since $\hom(K, G) = 0$, also $G \times K_0 \equiv_{\mathcal{G}_{\leq k}} G \times K_1$. ◀

9 A Trichotomy for Homomorphism Indistinguishability?

Theorem 1, our central result, asserts that deciding homomorphism indistinguishability is tractable over every recognisable graph class of bounded treewidth. In particular, Theorem 1 shows that $\textsc{HomInd}(\mathcal{F})$ is tractable for every minor-closed graph class of bounded treewidth. Notably, this result does not rely on reformulations of homomorphism indistinguishability relations in terms of logic etc. but operates with the homomorphism counts themselves.

A reasonable next step is to combine Theorem 1 with a hardness result. To that end, we propose the following working hypothesis:

▶ **Conjecture 25.** *Let $\mathcal{F}$ be a minor-closed graph class.*

1. *If $\mathcal{F}$ is the class of all graphs, then $\textsc{HomInd}(\mathcal{F})$ is graph isomorphism.*
2. *If $\mathcal{F}$ has bounded treewidth, then $\textsc{HomInd}(\mathcal{F})$ is in polynomial time.*
3. *If $\mathcal{F}$ is proper and has unbounded treewidth, then $\textsc{HomInd}(\mathcal{F})$ is undecidable.*

The first assertion is implied by [32]. The second assertions amounts to derandomising Theorem 1 and is predicted by the complexity-theoretic hypothesis $\mathrm{P} = \mathrm{BPP}$. The third assertion is wide open: The only minor-closed graph class $\mathcal{F}$ for which $\textsc{HomInd}(\mathcal{F})$ is known to be undecidable, is the class $\mathcal{P}$ of planar graphs, as shown by Mančinska and Roberson [34]. Conjecture 25 is inspired by this example and a result from graph minor theory [39] which asserts that every minor-closed graph class is either of bounded treewidth or contains all planar graphs. Intuitively, $\textsc{HomInd}(\mathcal{P})$ is undecidable since the problem amounts to solving an infinite-dimensional system of equations. Roughly speaking, the dimension corresponds to the number of labels needed to generate all planar graphs under operations like series composition. Theorem 1 makes the other direction of this vague argument precise: We show that if the number of labels is bounded (e.g. the graph class has bounded treewidth), then considering finite-dimensional spaces suffices, rendering the problem tractable. That treewidth might be the right parameter in Conjecture 25 is also suggested by the complexity dichotomy for counting homomorphisms [17].

Conjecture 25 implies a weak version of Roberson's conjecture [37, Conjecture 5] asserting that $\equiv_{\mathcal{F}}$ *is not the isomorphism relation* $\cong$ *for every proper minor-closed graph class* $\mathcal{F}$. Towards Conjecture 25, one could devise reductions between $\textsc{HomInd}(\mathcal{F}_1)$ and $\textsc{HomInd}(\mathcal{F}_2)$ for distinct minor-closed graph classes $\mathcal{F}_1$ and $\mathcal{F}_2$. We are not aware of any such reduction.

Another pathway to Conjecture 25 is suggested by Theorems 13 and 17: Instead of proving hardness of the problem $\textsc{HomInd}(\mathcal{F})$, one may attempt to give lower bounds on any function[2] $f\colon \mathbb{N} \to \mathbb{N}$ such that $G \equiv_{\mathcal{F}} H$ if and only if $G \equiv_{\mathcal{F}_{\leq f(n)}} H$ for all graphs G and H on at most n vertices. This problem is purely combinatorial and avoids the intricacies of computation. Theorems 13 and 17 give such functions for every recognisable graph class of bounded treewidth. By [32], for the class $\mathcal{G}$ of all graphs, f can be taken to be the identity $n \mapsto n$. By [34], there exists no such function for the class $\mathcal{P}$ of all planar graphs which is computable. Conjecture 25 implies that no such function is computable for any minor-closed graph class of unbounded treewidth.

▶ **Question 26.** *For a graph class $\mathcal{F}$, what is the least function $f\colon \mathbb{N} \to \mathbb{N}$ such that*

$$G \equiv_{\mathcal{F}} H \iff G \equiv_{\mathcal{F}_{\leq f(n)}} H$$

for all graphs G and H on at most n vertices?

[2] Such a function always exists since there are only finitely many equivalences classes of $\equiv_{\mathcal{F}}$ on graphs on most n vertices, each pair of which is distinguished by homomorphism counts from a single graph $F \in \mathcal{F}$.

Leakage-Resilient Hardness Equivalence to Logspace Derandomization

Yakov Shalunov[1]

University of Chicago, IL, USA

Abstract

Efficient derandomization has long been a goal in complexity theory, and a major recent result by Yanyi Liu and Rafael Pass identifies a new class of hardness assumption under which it is possible to perform time-bounded derandomization efficiently: that of "leakage-resilient hardness." They identify a specific form of this assumption which is *equivalent* to $\mathsf{prP} = \mathsf{prBPP}$.

In this paper, we pursue an equivalence to derandomization of $\mathsf{prBP}{\cdot}\mathsf{L}$ (logspace promise problems with two-way randomness) through techniques analogous to Liu and Pass.

We are able to obtain an equivalence between a similar "leakage-resilient hardness" assumption and a slightly stronger statement than derandomization of $\mathsf{prBP}{\cdot}\mathsf{L}$, that of finding "non-no" instances of "promise search problems."

1 Introduction

In a time-bounded setting, pseudorandom generators have historically been used to show that certain circuit-complexity lower bounds imply that $\mathsf{P} = \mathsf{BPP}$ (in particular, problems in E which require exponential size circuits [5]). Another key result showed that $\mathsf{P} = \mathsf{BPP}$ (and specifically, a deterministic polynomial-time algorithm for polynomial identity testing) implies that either NEXP requires super-polynomial boolean circuits or computing permanents requires super-polynomial arithmetic circuits [6]. However, historically the lower bounds known to imply $\mathsf{P} = \mathsf{BPP}$ and those implied by $\mathsf{P} = \mathsf{BPP}$ have not matched. Seeing these results, one might hope to find a hardness assumption H such that

"$\mathsf{P} = \mathsf{BPP}$ *if and only if there exists a problem satisfying* H."

A recent exciting paper, "Leakage-Resilient Hardness v.s. Randomness" [8] by Liu and Pass, has done exactly this, building on prior work by Chen and Tell [2]; Nisan and Wigderson [9]; Impagliazzo and Wigderson [5]; Sudan, Trevisan, and Vadhan [13]; and

Goldreich [4]. Liu and Pass found an alternate form of hardness assumption which they were able to formulate as equivalent to prP = prBPP using a cryptographic notion of "leakage-resilient hard functions" [11] – i.e., hard functions which are still uniformly hard even if you have some "leaked" information about the output (formalized as a "leakage function" of bounded output length taking the hard function's output as an input).

In the space-bounded derandomization setting, there's been an enormous effort to prove unconditionally that L = BPL, and while it's believed that there's no obstruction to being able to do so, this goal continues to remain elusive. However, it is also known that it is possible to get a conditional derandomization in logarithmic space with PRG machinery similar to the time-bounded randomization setting [7].

1.1 Overview

In the vein of conditional derandomization, this paper constructs a result similar to Liu and Pass for logarithmic space-bounded computation. We obtain an equivalence utilizing a space-bounded analog to the time-bounded assumption in Liu and Pass's paper.

Liu and Pass's ideas do not carry directly to the space-bounded setting because certain manipulations required by the proof cannot be carried out in logspace. In particular:

Worst-case vs. average-case hardness. A key step in the Liu and Pass proof that "hardness implies derandomization" uses error-correcting codes to convert worst-case hardness to average-case hardness. In the space-bounded setting, we do not have access to error-correcting codes capable of list-decoding the available $\frac{1}{2} + \mathcal{O}\left(\frac{1}{n}\right)$ fraction of correct bits. As a consequence, our version of leakage-resilient hardness is average case instead of worst case. Using a stronger hardness assumption then required additional work in the converse direction.

Average-case hardness. When analyzing the constructed Nisan-Wigderson generator in the standard way, Liu and Pass use rejection sampling to find a prefix fixing for Yao's distingiusher-to-predictor transformation with a sublinear number of trials. However, in the space-bounded setting, we cannot write down a single fixing (since the size of the fixing is superlogarithmic), so our hardness assumption must be strengthened until even a linearly small chance of having the correct fixing contradicts the hardness assumption. This version then allows us to sample once and write it directly to the output tape without verification.

Search problem reduction. When Liu and Pass prove that prP = prBPP implies their hardness assumption, they rely on a prior result by Goldreich to reduce the task of finding a non-no solution for a prBPP search problem to a polynomial number of prBPP decision problems [4], which can then be solved deterministically by assumption. In the space-bounded setting, we've found no equivalent transformation and, as a result, our main theorem works directly with the non-standard derandomization of search problems (which in polynomial time is equivalent to prP = prBPP). Specifically, we use a "one-sided search" which, given a "promise search problem," finds a solution which is not a no-instance (these terms are more precisely defined in the following section).

Nevertheless, we are able to obtain:

▶ **Theorem 1.1** (Main Theorem (informal)). *There is a logspace-computable function which is leakage-resilient hard if and only if it is possible, in logspace, to deterministically solve a one-sided search for any* prBP·L *search problem.*

This shows a meaningful equivalence between a hardness assumption and a derandomization of a search version of prBP·L. Notably, the derandomization necessary follows from the existence of a standard pseudorandom generator construction powerful enough to derandomize prBP·L.

Shortly after the original release of this paper as a preprint, Pass and Renard released their own, independent result "Characterizing the Power of (Persistent) Randomness in Log-space" [10] which presents a theorem very similar to our own – their result is a full derandomization of prBP·L search problems under a roughly equivalent condition. Their techniques in both directions are analogous to ours and their result is fundamentally similar.

In particular, despite presenting their result differently, Pass and Renard's work demonstrates the same one-sided search as ours. While their derandomization direction (claims 5.3, 4.12, 4.9, and 4.10 in [10]) relies on a non-promise version of BP·L search problems (where non-no instances are yes instances), their hardness direction relies on promise search like ours. (Notably, Goldreich's reduction in polynomial time also produces non-no instances rather than yes instances, suggesting this is a more fundamental limit of this formulation of search problems.) Unfortunately, this produces a mismatch that makes their results not quite correct-as-written.

Pass and Renard's paper further contributes a "partial derandomization" analogous to Liu and Pass's low-end regime (i.e. for positive γ, containment of searchBP·L in $\mathsf{searchL}^{1+\gamma}$ is equivalent to existence of $\mathcal{O}(\log^{1+\gamma} n)$ computable hard f). Though we believe it contains the same mismatch of directions, after some simple reformatting into a one-sided derandomization, it will be an elegant extension to the equivalence.

We believe our proof of the key equivalence is more direct, briefer, and clearer as it, in particular, achieves equivalence without the use of Doron and Tell's [3] recent results in logspace PRGs (with no significant increase in complexity) by using a better suited version of leakage resilient hardness. Their result does, however, show that our versions of leakage resilient hardness are equivalent to each other.

Because our result follows a similar path to Liu and Pass's, in Section 2 we provide an accessible summary and informal description of the key ideas in their result.

In Section 3, we provide a formal statement of our result and the definitions necessary for it.

In Sections 4 and 5, we prove the forward and reverse directions of the claim respectively, and in Section 6 we discuss potential further work.

2 Informal description of Liu and Pass's polynomial-time equivalence result

In this section, we provide a high-level summary of Liu and Pass's proof, which also serves as an outline for our own work.

Since it is central to the proof, we start with the definition of "leakage-resilient hardness," which is a uniform hardness assumption coined by Rivest and Shamir in 1985 [11] and modified by Liu and Pass based on Chen and Tell's [2] work with almost-all input hardness.

In the proof, leakage is used to uniformly substitute for non-uniform hard-coded bits in the proof of correctness of the Nisan-Wigderson generator, which we expand on later in the section.

▶ **Definition 2.1** (Almost-all input leakage-resilient hardness [8][11][2]). *Let $f : \{0,1\}^n \to \{0,1\}^n$ be a function. We say that f is* almost-all-input (T,ℓ)-leakage-resilient hard *if for all T-time probabilistic algorithms* (leak, A) *satisfying* $|\mathsf{leak}(x, f(x))| \leqslant \ell(|x|)$*, for all sufficiently long strings x,* $A(x, \mathsf{leak}(x, f(x))) \neq f(x)$ *with probability at least $\frac{2}{3}$.*

To illustrate this property, consider when f is the classical example of a (potentially) hard function used in cryptography: prime factorization of a product, x, of two primes. Given $f(x)$ (a correct factorization of x), a leakage function $\mathsf{leak}(x, f(x))$ which picks the smaller prime number from $f(x)$ and leaks it would make prime factorization "easy" as it would allow the attacker A to simply be a division algorithm. Since both division and identifying the smaller factor can be done in polynomial (say, n^k) time, and the smaller factor must be at most $n/2$ bits, prime factorization is *not* $(n^k, n/2)$-leakage-resilient hard – even if, without leakage, it requires superpolynomial time.

The simplest expression of Liu and Pass's result as relevant to ours is the following:

▶ **Theorem 2.2** (Liu and Pass [8]). *There exists a constant c such that for all $\varepsilon \in (0, 1)$, the following are equivalent:*

- *There exists a function $f : \{0,1\}^n \to \{0,1\}^n$, computable in deterministic polynomial time, which is almost-all input (n^c, n^ε)-leakage-resilient hard; and*
- $\mathsf{prP} = \mathsf{prBPP}$.

2.1 Forward direction (Liu and Pass)

Liu and Pass's forward direction – hardness assumption to $\mathsf{prP} = \mathsf{prBPP}$ – adapts the original proof that the Nisan-Wigderson pseudorandom generator (NW PRG) yields derandomization, with a few key differences. The generator they construct (invented by Goldreich [4]) is "targeted," meaning both it and the distinguishers it beats get access to a "target" string as an input in addition to the seed. When performing derandomization using the generator, the appropriately padded input becomes the target. (The utility of this is explained at the end of this subsection.)

Their construction of a NW-like PRG uses the error-correcting encoded output of the leakage-resilient hard function f on the "target" x instead of the standard hard-coded truth table of a non-uniformly hard function. (In our proof, the error-correcting encoding step is replaced with average-case hardness.)

Recall that in the standard proof of correctness for a Nisan-Wigderson pseudorandom generator, when converting a distinguisher to a predictor, there is a step where a prefix is fixed and a small table of a subset of outputs from the hard truth-table is hard-coded. The key difference here is that, in order to obtain a contradiction, instead of hard-coding this prefix and table non-uniformly, it is instead computed by the leak function, which has access to the hard truth-table (since it is efficiently computed from the output of f, which leak has access to). The prefixes are found by rejection sampling to pick a "good one." (In our proof, we select one randomly.) This output can be made polynomially small compared to n to satisfy the length bound ℓ on leak.

The final step of the proof is to argue that if there is a problem in prBPP that cannot be derandomized by this PRG, we can turn this into a distinguisher by fixing the problem. Observe, however, that for a contradiction, we need derandomization to fail in infinitely many cases (since the hardness assumption is *almost*-all input). Furthermore, we are only fooling *uniform* distinguishers. This is where the targeting of the PRG is necessary.

By using (a padded version of) the input to the decision problem, x, as the target, we ensure that we can uniformly "find" the infinitely many values of x where the distinguisher succeeds. If the PRG were untargeted, we would have no way to uniformly identify which value of x the PRG fails on for a given length, so failing to derandomize some decision problem would not guarantee a distinguisher.

(In our proof, we additionally perform a one-sided search derandomization. The search problem's search algorithm (the "finder") is run a with pseudorandom string generated for each possible seed until one is found which the verifier accepts. We show that such a seed must exist and that this process produces the desired derandomization. In the polynomial time regime, this one-sided search derandomization follows from decision derandomization directly without further access to a PRG and so happens on the converse side.)

2.2 Backward direction (Liu and Pass)

The key idea of the backward direction – prP = prBPP to hardness assumption – is that, if we were able to assign a "random" string to each input, we could build such an f since leaking some information about that random string would not help you reconstruct the rest of the output.

Liu and Pass make use of a result by Goldreich [4] which states that finding non-no solutions to a prBPP search problem can be reduced to a polynomial number of prBPP decision problems. Liu and Pass then formulate finding a "good output" $f(x)$ for any given input x as a prBPP search problem (defined below). They then apply Goldreich's result and then the derandomization assumption to create a hard function whose output is deterministic but behaves sufficiently like a "random string" would.

In Goldreich's formulation, a prBPP search problem is defined as follows:

▶ **Definition 2.3** (prBPP search problems [4])**.** *$R_{\text{YES}}, R_{\text{NO}} \subseteq \{0,1\}^* \times \{0,1\}^*$ where $R_{\text{YES}} \cap R_{\text{NO}} = \varnothing$ represent a* prBPP *search problem if both of the following hold:*

- *R_{YES} and R_{NO} represent a* prBPP *decision problem. I.e., there is a PPT machine V (the "verifier") such that*

$$\forall (x,y) \in R_{\text{YES}},\ \mathbb{P}[V(x,y)=1] \geqslant \frac{2}{3} \quad \textit{and} \quad \forall (x,y) \in R_{\text{NO}},\ \mathbb{P}[V(x,y)=0] \geqslant \frac{2}{3}$$

- *There exists a PPT machine F (the "finder") such that for all x, if $\exists y, (x,y) \in R_{\text{YES}}$, then*

$$\mathbb{P}[(x,F(x)) \in R_{\text{YES}}] \geqslant \frac{2}{3}$$

Let $S_R = \{x : \exists y, (x,y) \in R_{\text{YES}}\}$ be the set of inputs for which a solution exists.

Liu and Pass formulate computing f as finding solutions to a search problem. A given pair (x,y) is a yes-instance of the problem if every pair (A, leak) of attacker and leakage functions whose program descriptions have length at most $\log n$ and which run in the desired time bound has $A(x, \mathsf{leak}(x,y)) = y$ with probability at most $1/6$. Similarly, (x,y) is a no-instance if there exists (A, leak) such that $A(x, \mathsf{leak}(x,y)) = y$ with probability at least $1/3$. (The gap between yes- and no-instance probabilities is allowed by it being a *promise* search problem and is used by the verifier.)

Only attacker pairs bounded to length $2\log n$ need to be considered because this only excludes *any particular* machine from consideration for a finite number of inputs x.

When allowed to use randomness, the finder is simple – as established, simply ignoring x and picking a random string y works with high probability. The verifier can check whether a yes-or-no instance is a yes-instance by simply iterating over all attackers and leakage functions up to length $\log n$ (truncating their run time to the required bound) and checking whether any of them compute y with probability greater than $1/4$. This runs in polynomial time since there are n machines each truncated to a polynomial time bound and each pair only needs to be run polynomially many times to be correct with high probability.

The desired hard function can then be computed by using Goldreich's reduction to reduce the search problem to a polynomial number of prBPP problems. These are then derandomized to deterministically produce a non-no instance. The y-component of the resulting non-no instance is then exactly the desired hard output, by the construction of the search problem.

(In our case, we need access to the PRG rather than merely $\mathsf{prL} = \mathsf{prBP{\cdot}L}$ to perform the one-sided search, so it is performed when proving the forward direction.)

3 Results

▶ **Theorem 3.1** (Main theorem)**.** *There exist parameters $c_1, c_2, \alpha > 0$ (in particular, $\alpha = \frac{1}{3}$ works) such that the following are equivalent:*

1. *There exists a logspace function f which is almost-all-input $(n^{c_1}, c_2 \log n, \ell, \delta)$-leakage-resilient average hard where $\ell = n^{\varepsilon}$ (for $\varepsilon = 2\alpha + \frac{\alpha^3}{5}$) and $\delta = \left(\frac{1}{2} - \frac{1}{m^2}\right)n$ (for $m = n^{\alpha^3/5}$).*
2. *For any prBP·L search problem $R_{\text{YES}}, R_{\text{NO}}$, we can create a deterministic algorithm F' such that for any $x \in S_R$, we have that $(x, F'(x)) \notin R_{\text{NO}}$. (In particular, this implies $\mathsf{prBP{\cdot}L} = \mathsf{prL}$.)*

Proof. The forward direction is theorem 4.1 and the reverse direction is theorem 5.1. ◀

3.1 Preliminaries

Note that we are working with a read-*only* random tape with two-way movement. For decision problems, this definition corresponds to the complexity class BP·L, though we work with its promise and search promise counterparts.

Our result is formulated in terms of "search problems," analogous to the prBPP search problems defined by Goldreich in [4].

▶ **Definition 3.2** (prBP·L search problems)**.** *A pair of sets $R_{\text{YES}}, R_{\text{NO}} \subseteq \{0,1\}^* \times \{0,1\}^*$ where $R_{\text{YES}} \cap R_{\text{NO}} = \varnothing$ represent a prBP·L search problem if both of the following hold*

- *R_{YES} and R_{NO} represent a prBP·L decision problem. I.e., there is a PPT logspace machine V (the "verifier") such that*

$$\forall (x,y) \in R_{\text{YES}},\ \mathbb{P}[V(x,y) = 1] \geqslant \frac{2}{3} \quad \textit{and} \quad \forall (x,y) \in R_{\text{NO}},\ \mathbb{P}[V(x,y) = 0] \geqslant \frac{2}{3}$$

- *There exists a PPT logspace machine F (the "finder") such that for all x, if $\exists y, (x,y) \in R_{\text{YES}}$, then*

$$\mathbb{P}[(x, F(x)) \in R_{\text{YES}}] \geqslant \frac{2}{3}$$

Let $S_R = \{x : \exists y, (x,y) \in R_{\text{YES}}\}$ be the set of inputs for which a solution exists.

This definition is identical to the polynomial variant with the added constraint that the machines are bounded to logarithmic space in addition to the polynomial time bound.

Our hardness assumption is a modification of leakage resilient hardness as defined in definition 2.1 of [8], which in turn builds on [11].

▶ **Definition 3.3** (Almost-all-input leakage resilient average hard)**.** *Let $f : \{0,1\}^n \to \{0,1\}^n$ be a multi-output function. f is* almost-all-input (T, S, ℓ, d)-leakage resilient average hard *if for all S-space T-time probabilistic algorithms (A, leak) satisfying $|\mathsf{leak}(x, f(x))| \leqslant \ell(n)$, we have that for all sufficiently long strings x,*

$$\mathbb{P}[d_H(A(x, \mathsf{leak}(x, f(x))), f(x)) < d(n)] < \frac{1}{n}$$

with probability over the internal randomness of the algorithms, where d_H is Hamming distance.

Note that this is "stronger" than a direct analog to the time-bounded assumption [8] in two ways: first, and most importantly, we've added another parameter which parameterizes how "good of an approximation" is allowed, whereas in the time-bounded setting, forbidding strict equality was sufficient. Second, the allowed probability of "success" is $\frac{1}{n}$ rather than $\frac{1}{3}$.

The first difference converts the worst-case hardness to average-case hardness. It is necessary because in the time-bounded setting, we have access to much more powerful error-correcting codes which are not available in the logspace setting. In the time-bounded setting, error-correcting codes let us convert a small edge in breaking the generator to an exact computation of the hard function. Meanwhile, in the logspace setting, we're limited to just that small edge, so we bake it into the hardness assumption instead.

The second difference exists to handle issues in the distinguisher to predictor transformation. In polynomial time, the attacker functions can "try" $o(1/n)$ strings and figure out which one is the ideal choice, but because the strings are super-logarithmic in length, we cannot verify them in logspace. Thus, the hardness assumption is strengthened to allow simply choosing a random one without verification.

While much of the high-level structure of the following proof is similar to that presented in section 2, we have that:

- in the "hard function implies derandomization" direction, we show the desired derandomization of search problems; and
- in the "derandomization implies hard function" direction, the search problem is constructed such that anything which is not a no-instance is a valid value for the function to take for that x. Then, instead of Goldreich's reduction, we apply the derandomization reduction directly.

4 Existence of hard function implies derandomization

▶ **Theorem 4.1** (Existence implies derandomization). *The forward direction of the main theorem (3.1). I.e., (1) implies (2).*

Proof. Apply lemma 4.4 with $C = 3$ to get the necessary PRG, then apply lemma 4.7 to perform the desired derandomization with the PRG. ◀

The following are fairly standard definitions of a distinguisher and pseudorandom generator with the caveat of the additional "target" string. For brevity, write $D_x^m(\gamma)$ for $D(1^m, x, \gamma)$ and similarly for G.

▶ **Definition 4.2** (Targeted distinguisher). *Given a function $G : \{1\}^m \times \{0,1\}^n \times \{0,1\}^d \to \{0,1\}^m$, a targeted distinguisher for G with advantage $\beta > 0$ is a machine $D : \{1\}^m \times \{0,1\}^n \times \{0,1\}^m$ such that for all sufficiently large m and for all $x \in \{0,1\}^n$, we have that*

$$\left|\mathbb{P}_{s\sim\mathcal{U}_d}\left[D_x^m(G_x^m(s)) = 1\right] - \mathbb{P}_{\gamma\sim\mathcal{U}_m}\left[D_x^m(\gamma) = 1\right]\right| \geqslant \beta \tag{1}$$

where $\mathcal{U}_k$ is the uniform distribution on $\{0,1\}^k$.

Throughout, we will refer to targeted distinguishers as "distinguishers."

This definition becomes useful in the context of the following (modified from [4, 8]):

▶ **Definition 4.3** (Uniform targeted pseudorandom generator). *For parameters S, n, and d dependent on output length m, an S-secure uniform (n, d)-targeted PRG is a deterministic function*

$$G : \{1\}^m \times \{0,1\}^n \times \{0,1\}^d \to \{0,1\}^m$$

which satisfies the property that there does not exist a targeted distinguisher with advantage β running in space S for any $\beta > 0$.

Throughout the rest of this article, "PRG" and "pseudorandom generator" refer to a uniform targeted PRG. n is the "target length" of the generator and d is the "seed length."

We show that our hardness assumption implies an $\mathcal{O}(\log m)$-secure $(\mathsf{poly}(m), \mathcal{O}(\log m))$ PRG and then that the existence of an such a PRG implies the desired derandomization.

4.1 Hard function implies existence of PRG

First, we prove that a hard function with the given parameters implies the existence of a PRG.

Fix a sufficiently small value of $\alpha > 0$. $\alpha = 1/3$ works.

▶ **Lemma 4.4** (Hard function implies existence of PRG). *For any C, there exist constants c_1, c_2 such that if there exists a logspace computable function f such that f is almost-all-input $\left(n^{c_1}, c_2 \log n, n^{\varepsilon}, \left(\frac{1}{2} - \frac{1}{m^2}\right)n\right)$-leakage resilient average hard with $m = n^{\frac{\alpha^3}{5}}$ and $\varepsilon = 2\alpha + \frac{\alpha^3}{5}$, then there exists a $C \log m$-secure $(n, \frac{\log n}{\alpha})$ PRG which is logspace computable.*

As is standard for a Nisan-Wigderson generator, we will require designs for the construction.

▶ **Definition 4.5** (Combinatorial design). *A design is a collection of (potentially large) sets with a bounded pairwise intersection size. More precisely:*

For any natural numbers (d, r, s) such that $d > r > s$, a (d, r, s)-design of size m is a collection $\mathcal{I} = \{I_1, \ldots, I_m\}$ of subsets of $[d]$ such that for each $j \in [m]$, $|I_j| = r$ and for each $k \in [m]$ such that $k \neq j$, $|I_j \cap I_k| \leqslant s$.

Because we're working in logspace, we will need the following lemma:

▶ **Lemma 4.6** (Creating designs). *There is a deterministic algorithm we call $\mathsf{GenDesign}(d, \alpha)$ which produces a $(d, \alpha d, 2\alpha^2 d)$ design of size $2^{\frac{\alpha^4 d}{5}}$ in space $S_{\mathsf{GenDesign}} = \mathcal{O}(d)$.*

Proof. Proven by Klivans and Melkebeek in the appendix of [7]. ◀

Outline of proof of 4.4. As presented in the overview, the construction of the PRG is a fairly standard Nisan-Wigderson generator [9] construction, with the caveats that it is a targeted PRG and that instead of the truth table of a hard-coded non-uniformly hard function, we use the output of our f on the target string. The key change is that the leakage function then replaces the hard-coded tables in the search-to-decision reduction.

We show that this can be done in logspace and that the hard-coded tables fit in the inverse polynomial leakage bound n^{ε}. In order to compute the tables in logspace, the probability of generating "good tables" needs to be low because it's impossible to verify the tables. However, a probability high enough to contradict leakage-resilient hardness, i.e., over $\frac{1}{n}$, is achievable.

Assuming a distinguisher that defeats the PRG, the attacker function is then able to use the tables from the leakage function together with the distinguisher to perform the search-to-decision reduction with enough accuracy to violate the average-case hardness constraint. ◀

Proof of 4.4. With an appropriate choice of c_1, c_2, we can construct a $C \log m$-secure PRG for any constant $C \geqslant 0$.

We construct a targeted PRG $G : \{1\}^m \times \{0,1\}^n \times \{0,1\}^d \to \{0,1\}^m$, where $n = m^{\frac{5}{\alpha^3}}$ and $d = \frac{\log n}{\alpha}$.

The algorithm is similar to that in time-bounded case [8]: it is simply a Nisan Wigderson generator [9], with the hard-coded truth table replaced with one outputted by the hard function.

On input $1^m, x, s$, it proceeds as follows:

1. Compute $z = f(x)$. Define $h(i) = z_i$.
2. Compute $\mathcal{I} = \mathsf{GenDesign}(d, \alpha)$. Note that $r = d\alpha = \log n$ and $2^{\frac{\alpha^4 d}{5}} \geqslant m$ due to our choice of n and d.
3. Output

$$G(1^m, x, s) = h(s_{I_1}) \cdots h(s_{I_m})$$

Suppose there exists a distinguisher D computable in space $C \log m$ with advantage $\beta > 0$. We will use this to approximate f with enough of an advantage to violate the average hardness assumption by a standard hybrid argument (lemma 3.15 in [8], proposition 7.16 in [14], theorem 10.12 in [1]).

We can remove the absolute value from the distinguisher definition (1) by noting that there exists $b \in \{0,1\}$ such that

$$\mathbb{P}_{s \sim \mathcal{U}_d}[D_x^m(G_x^m(s)) = b] - \mathbb{P}_{\gamma \sim \mathcal{U}_m}[D_x^m(\gamma) = b] \geqslant \beta$$

since flipping b flips the sign.

Then, for every $j \in \{0, \dots, m\}$, define

$$H_j = (h(s_{I_1}), \dots, h(s_{I_j}), w_{j+1}, \dots, w_m)$$

(with h defined as in the generator) where $s \sim \mathcal{U}_d$ and each $w_k \sim U_1$ (for $j+1 \leqslant k \leqslant m$). Notice that $H_0 = \mathcal{U}_m$ and $H_m = G(1^m, x, \mathcal{U}_d)$. Therefore it follows that

$$\frac{1}{m} \sum_{j \in 1}^{m} \Big(\mathbb{P}_{y,w}[D_x^m(H_j) = b] - \mathbb{P}_{y,w}[D_x^m(H_{j-1}) = b] \Big)$$
$$= \frac{1}{m} \Big(\mathbb{P}_{y,w}[D_x^m(H_m) = b] - \mathbb{P}_{y,w}[D_x^m(\mathcal{U}_0) = b] \Big) \geqslant \frac{\beta}{m}$$

Considering j as a random variable distributed uniformly over $[m]$, we get that

$$\mathbb{E}_{j \in [m]} \Big[\mathbb{P}_{y,w}[D_x^m(H_j) = b] - \mathbb{P}_{y,w}[D_x^m(H_{j-1}) = b] \Big] \geqslant \frac{\beta}{m}$$

Since $\mathbb{P}_{y,w}[D_x^m(H_j) = b] - \mathbb{P}_{y,w}[D_x^m(H_{j-1}) = b]$ is upper bounded by 1, by an averaging argument, with probability at least $\frac{\beta}{2m}$ over the choice of $j \leftarrow [m]$, $y_{[d] \setminus I_j} \leftarrow \{0,1\}^{d-r}$, and $w_{[m] \setminus [j]} \leftarrow \{0,1\}^{m-j}$, the strings j, $y_{[d] \setminus I_j}$, and $w_{[m] \setminus [j]}$ will satisfy:

$$\mathbb{P}_{y_{I_j} \sim \mathcal{U}_r}[D_x^m(H_j) = b] - \mathbb{P}_{(y_{I_j}, w_j) \sim \mathcal{U}_{r+1}}[D(H_{j-1}) = b] \geqslant \frac{\beta}{2m} \tag{2}$$

Suppose we have a choice j, $y_{[d] \setminus I_j}$, and $w_{[m] \setminus [j]}$ satisfying the above equation. By Yao's prediction vs. indistinguishability theorem [15], it holds that

$$\mathbb{P}_{(y_{I_j}, w_j) \sim \mathcal{U}_{r+1}}\big[D_x^m(H_{j-1}) \oplus b \oplus w_j = h(y_{I_j})\big] \geqslant \frac{1}{2} + \frac{\beta}{2m}$$

There then must exist a choice of w_j such that

$$\mathbb{P}_{y_{I_j} \sim \mathcal{U}_r}\big[D_x^m(H_{j-1}) \oplus b \oplus w_j = h(y_{I_j})\big] \geqslant \frac{1}{2} + \frac{\beta}{2m} \tag{3}$$

Observe that in order to compute H_{j-1} as a function of y_{I_j}, one does not need to know the entire truth table of h. Instead, note that the overlap between I_j and I_i, $i < j$, is at most $2\alpha^2 d = 2\alpha r$. Thus, as a function of y_{I_j}, $h(y_{I_i})$ can only take $2^{2\alpha r}$ possible values. Thus, to compute all of H_{j-1}, one needs $j2^{2\alpha r} \leqslant m2^{2\alpha r}$ bits of the truth table of h.

Then, given a distinguisher D with advantage β, we can approximate f with the functions (A, leak) described below.

On input $x, z = f(x)$, leak proceeds as follows (denote $h(i) = z_i$):

1. Evaluates $\mathcal{I} = \mathsf{GenDesign}(d, \alpha)$, with d chosen the same way as the PRG.
2. Chooses a random $j \in [m]$ and a random $y_{[d]\setminus I_j}$, storing them on its work tape.
3. Writes j and $y_{[d]\setminus I_j}$ to the output tape.
4. For $0 < i < j$ and for each value of y obtained by ranging over possible values of y_{I_j} (since $y_{[d]\setminus I_j}$ is already fixed), leak writes $h(y_{I_i})$ to the output tape.
5. Writes random bits b, w_j and string $w_{[m]-[j]}$ to the output tape.

Then, on input $x, w = \mathsf{leak}(x, f(x))$, A proceeds as follows:

1. A evaluates $\mathcal{I} = \mathsf{GenDesign}(d, \alpha)$, with d chosen the same way as the PRG.
2. Defines b, j, $y_{[d]\setminus I_j}$, w_j, and $w_{[m]\setminus[j]}$ to be those read from its input tape.
3. For each $y_{I_j} = k$ in $[n]$ yielding a full string y,
   a. Computes H_{j-1}, with bit $i < j$ found by looking in position k in the ith table output by leak in step 4 and $i \geqslant j$ found by taking the appropriate bit of w, also output by leak.
   b. Computes $D_x^m(H_{j-1}) \oplus b \oplus w_j$ and writes it to the output tape.

We will show that the result is a pair which runs in the necessary time and space bounds and, with high probability, is a good enough approximation of $f(x)$ to achieve contradiction.

Space-bound. leak step 1 requires space $S_{\mathsf{GenDesign}} = \mathcal{O}(d) = O\left(\frac{\log n}{\alpha}\right)$. Since it is locally computed by future steps, this becomes $\mathcal{O}(S_{\mathsf{GenDesign}})$. The second step requires space $d + \log m$, and uses the local computation of step 1. The third step requires space $\log(\log m + d)$, since it is simply iteration and printing. The fourth step uses space $\log m + d$ again since it iterates over indices i and values of y. For each value, it simply performs a lookup into the input, which requires at most space equal to the size of the index, bounded by $d + 1$. Finally, step 5 requires space $\log m$, since it needs to keep track of the number of bits it needs to write.

Thus, the overall space used by leak is $\mathcal{O}(d) + \mathcal{O}(\log n) + \mathcal{O}(\log m) = \mathcal{O}(\log n + \log \alpha) = \mathcal{O}(\log n)$.

For A, step 1 again requires space $\mathcal{O}(S_{\mathsf{GenDesign}})$. Step 2 is simply a definition and thus requires no space. Step 3 requires $\log n$ bits of iteration overhead plus the space used by 3.(a) and 3.(b). 3.(a) is simply indexing into the input based on k and so requires space $\log n$. This is the locally recomputed by step 3.(b), so 3.(a) requires space $\mathcal{O}(\log n)$. Finally, 3.(b) requires space $C \log m$.

Thus, A and leak run in space $c_2 \log n$ for a constant c_2 dependent only on C.

Time-bound. Due to space constraints, the straightforward time complexity analysis can be found in the full version [12].

Contradiction of hardness. First, note that leak outputs at most $\log m + d - r + m + m2^{2\alpha^2 d}$ bits. The $\log m$ and $d - r$ terms are logarithmic and thus fall within any polynomial bound. The constraints on d and α, chosen such that $d\alpha = \log n$ and $2^{\frac{\alpha^4 d}{5}} = m$ tell us that for the $m2^{2\alpha^2 d}$ term, we have that

$$2\alpha^2 d = \frac{10}{\alpha^2}\log m \quad \text{so} \quad 2^{2\alpha^2 d} = m^{\frac{10}{\alpha^2}}$$

Thus, $m2^{2\alpha^2 d} = m^{\frac{10}{\alpha^2}+1}$, which is

$$m^{\frac{10}{\alpha^2}+1} = \left(n^{\frac{\alpha^3}{5}}\right)^{\frac{10}{\alpha^2}+1} = n^{2\alpha+\frac{\alpha^3}{5}}$$

Thus, if α is small enough (e.g., $\frac{1}{3}$), then for $\varepsilon = 2\alpha + \frac{\alpha^3}{5} < 1$, we have that $|\mathsf{leak}(x, f(x))| \leqslant n^{\varepsilon}$.

Observe that (2) is satisfied with probability $\frac{\beta}{2m}$ by leak's random choice of j, $y_{[d]\setminus I_j}$, and $w_{[m]\setminus[j]}$. Furthermore, with probability 1/4, leak's random choices of b and w_j are the correct choices such that (3) holds. Thus, with probability $\frac{\beta}{8m}$, we have that (3) holds for our choices.

Consider the case where it does. Note that the randomness in (3) is over the argument to h, which is the index into $f(x)$. Then, when A evaluates $D_x^m(H_{j-1}) \oplus b \oplus w_j$ for each index, we conclude that at least a $\frac{1}{2} + \frac{\beta}{2m}$ fraction of bits output by A agree with $f(x)$. We thus have that

$$\mathbb{P}\left[d_H(A(x, \mathsf{leak}(x, f(x))), f(x)) \leqslant \left(\frac{1}{2} - \frac{\beta}{2m}\right)n\right] \geqslant \frac{\beta}{8m}$$

However, note that $\frac{\beta}{8m} > \frac{1}{n}$ for sufficiently large n (since m is polynomially smaller than n) and $\frac{1}{2} - \frac{\beta}{2m} < \frac{1}{2} - \frac{1}{m^2}$ for any constant β and sufficiently large n. This contradicts the hardness assumption of f, so such a distinguisher can't exist and we must have that G is a $C\log m$-secure PRG. ◀

4.2 Derandomization of search problems using the PRG

Now, we prove that the PRG is sufficient. This formulation is similar to work by Goldreich [4] which was seen in Liu and Pass's [8] reproduction.

▶ **Lemma 4.7** (Derandomization of search problems using the PRG). *The existence of a* $3\log m$*-secure* $(\mathsf{poly}(m), \mathcal{O}(\log m))$*, logspace-computable PRG implies (2) of main theorem (3.1).*

As is typical for derandomization using a PRG, we will need the ability to pad strings. We will treat functions $\mathsf{pad}(x, k)$ and $\mathsf{unpad}(x')$ as having "negligible" complexity. The exact definition and proof of this can be seen in the "efficient padding" lemma of the full version [12], but we effectively use an expanded alphabet (encoded as pairs of bits) to add an "pad" character.

We separate our proof of 4.7 into two parts: derandomizing $\mathsf{prBP{\cdot}L}$ using a PRG and then derandomizing $\mathsf{prBP{\cdot}L}$ search problems using both $\mathsf{prBP{\cdot}L} = \mathsf{prL}$ and the PRG.

▶ **Lemma 4.8** (Derandomization of promise problems). *The existence of a* $3\log m$*-secure* $(\mathsf{poly}(m), \mathcal{O}(\log m))$*, logspace-computable PRG implies* $\mathsf{prBP{\cdot}L} = \mathsf{prL}$.

Proof sketch. This is an adaptation of the time-bounded derandomization construction as seen in Goldreich's and Liu and Pass's work. The detailed working is omitted due to space constraints, but can be found in the full version [12] to verify that there are no hiccups related to logarithmic space. (In particular, the unpadded case becomes time $\mathcal{O}(k)$ and space $\log k + \mathcal{O}(1)$, and the padding exponent becomes the maximum of the exponent on time and the multiplier on space.) ◀

Proof of 4.7. Suppose G is an $3\log m$-secure (n, d) PRG with parameters $n = m^\theta$ for some θ and $d = \mathcal{O}(\log m)$. By lemma 4.8, we have that $\mathsf{prBP{\cdot}L} = \mathsf{prL}$.

Suppose $R_{\mathrm{YES}}, R_{\mathrm{NO}}$ is a $\mathsf{prBP{\cdot}L}$ search problem with verifier $V(x, y; \omega)$ and finder $F(x; \gamma)$ where $|\gamma| \leqslant t(|x|)$. Observe that we can derandomize V to $V(x, y)$ (since it is a $\mathsf{prBP{\cdot}L}$ decision problem) such that $(x, y) \in R_{\mathrm{NO}} \implies V(x, y) = 0$ and $(x, y) \in R_{\mathrm{YES}} \implies V(x, y) = 1$.

First we will perform this derandomization for search problems where $F(x; \gamma)$ has time complexity $t(k) = \mathcal{O}(k)$ and the random procedure $M(x; \gamma) = V(x, F(x; \gamma))$ has space complexity $\log k + \mathcal{O}(1)$. Define $m = t(k)$ as the maximum amount of randomness used.

Consider the following deterministic procedure F': On input x,

1. For each seed $s \in \{0, 1\}^d$,
- Compute $b \leftarrow V(x, F(x; G^m_{x'}(s)))$, where $x' = \mathsf{pad}(x, n)$.
- If $b = 1$, output $F(x; G^m_{x'}(s))$.

2. Output the empty string.

Note that this procedure operates in logspace since iterating seeds requires space $d = \mathcal{O}(\log m) = \mathcal{O}(\log k)$ and step 3.(a) and 3.(b) are logspace compositions (a more detailed treatment can be see in the proof of 4.8).

Observe also that if this procedure terminates within the loop, it outputs a string y such that $V(x, y) = 1$ and thus such that $(x, y) \notin R_{\mathrm{NO}}$. It remains to show that this procedure terminates within the loop on all but finitely many inputs (since we can hard-code any finite number of misbehaving cases).

Suppose the contrary. Then there exist infinitely many inputs for which,

$$\forall s \in \{0, 1\}^d \quad V(x, F(x; G^m_{x'}(s))) = 0$$

Further, by definition of a finder, $\mathbb{P}_\gamma[(x, F(x; \gamma)) \in R_{\mathrm{YES}}] \geqslant \frac{2}{3}$. Thus,

$$\mathbb{P}_s[V(x, F(x; G^m_{x'}(s))) = 1] = 0 \quad \text{and} \quad \mathbb{P}_\gamma[(x, F(x; \gamma)) \in R_{\mathrm{YES}}] \geqslant \frac{2}{3}$$

This tells us that $D(1^m, x', r) = M(\mathsf{unpad}(x); r) = M(x; r)$ is a distinguisher with advantage $\beta \geqslant \frac{2}{3}$ which works for infinitely many values of x' and runs in space $2\log m$ (since it is the truncation machine composed with M; again, a more detailed treatment can be seen in the proof of 4.8). This contradicts the security of the generator.

Thus, $(x, F'(x)) \notin R_{\mathrm{NO}}$ for all but finitely many x (which can be hard-coded).

Now consider an arbitrary $\mathsf{prBP{\cdot}L}$ search problem, $(R_{\mathrm{YES}}, R_{\mathrm{NO}})$ with derandomized verifier V and finder $F(x; \gamma)$ such that the time complexity of F is $\mathcal{O}(k^a)$ and the space complexity of $V(x, F(x; \gamma))$ is $b \log k + \mathcal{O}(1)$. Again, let $c = \max(a, b)$ and define $x' = \mathsf{pad}(x, k^c)$. We create $R_{\mathrm{YES}\,\mathsf{pad}} = \{(x', y) : (x, y) \in R_{\mathrm{YES}}\}$ and $R_{\mathrm{NO}\,\mathsf{pad}} = \{(x', y) : (x, y) \in R_{\mathrm{NO}}\}$.

Then $V_{\mathsf{pad}}(x', y) = V(\mathsf{unpad}(x'), y)$, $F_{\mathsf{pad}}(x') = F(\mathsf{unpad}(x'))$ satisfy

$$M_{\mathsf{pad}}(x'; r) = V_{\mathsf{pad}}(x', F_{\mathsf{pad}}(x'; r))$$

being a machine with space complexity $\log k' + \mathcal{O}(1)$ and F_{unpad} having time complexity $\mathcal{O}(k')$. Thus, we have deterministic algorithm $F'_{\mathsf{pad}}(x')$ such that $(x', F'_{\mathsf{pad}}(x')) \notin R_{\mathrm{NO}\,\mathsf{pad}}$.

We can then define F' as the function which on input x computes $F'_{\mathsf{pad}}(\mathsf{pad}(x, k^c))$. Observe that if $(x, F'(x)) \in R_{\mathrm{NO}}$ then $(x', F'_{\mathsf{pad}}(x')) = (x', F'(x)) \in R_{\mathrm{NO}\,\mathsf{pad}}$, which contradicts F'_{pad} being a derandomized finder for $R_{\mathrm{NO}\,\mathsf{pad}}$.

Thus, we have achieved the desired partial derandomization of $\mathsf{prBP{\cdot}L}$ search problems. ◀

5 Derandomization implies existence of hard function

▶ **Theorem 5.1** (Derandomization implies existence). *Suppose that for any* $\mathsf{prBP{\cdot}L}$ *search problem* $(R_{\mathrm{YES}}, R_{\mathrm{NO}})$*, we can create a deterministic algorithm* F' *such that for any* $x \in S_R$*, we have that* $(x, F'(x)) \notin R_{\mathrm{NO}}$*.*

We will show that for any constants c_1, c_2 *there exists a logspace computable function* f *such that* f *is almost-all-input* $(T, S, \ell, d) = \left(n^{c_1}, c_2 \log n, n^{\varepsilon}, \left(\frac{1}{2} - \frac{1}{m^2}\right)n\right)$*-leakage-resilient average hard where* $\varepsilon = 2\alpha + \frac{\alpha^3}{5}$ *and* $m = n^{\frac{\alpha^3}{5}}$ *for* $\alpha = \frac{1}{3}$*.*

The "Random is hard" lemma is similar to claim 1 in section 3.1 of Liu and Pass's paper [8] but needs a much stronger claim than in the time-bounded setting, corresponding to the use of an average-case hardness assumption.

5.1 Random is hard

▶ **Lemma 5.2** (Random is hard). *For* any *probabilistic algorithms* (A, leak) *and for all* $n \in \mathbb{N}$*,* $x \in \{0,1\}^n$*, it holds that*

$$\mathbb{P}[|\mathsf{leak}(x,r)| \leqslant \ell \wedge d_H(A(x, \mathsf{leak}(x,r)), r) < d] \geqslant \frac{1}{2n}$$

with probability at most $n \cdot 2^{n\cdot(H(d/n)-1)+\ell+\mathcal{O}(1)}$ *(where* $H(p)$ *is the binary entropy function* $H(p) = p \log \frac{1}{p} + (1-p) \log \frac{1}{1-p}$*) over* $r \sim \mathcal{U}_n$*.*

Proof. Consider any $n \in \mathbb{N}$, $x \in \{0,1\}^n$, and any probabilistic algorithm A. We will show that for any *deterministic* function leak' that outputs at most ℓ bits,

$$\mathbb{P}_{r\sim\mathcal{U}_n}\left[\mathbb{P}\big[d_H(A(x, \mathsf{leak}'(x,r)), r) < d\big] \geqslant \frac{1}{2n}\right] \leqslant n \cdot 2^{n\cdot(H(d/n)-1)+\ell+\mathcal{O}(1)} \tag{4}$$

The claim for any probabilistic algorithm leak follows immediately by letting leak' be leak with the best random tape fixed. To show (4), consider the set of "bad" r's defined as

$$B = \left\{r \in \{0,1\}^n : \exists w \in \{0,1\}^{\ell} \text{ s.t. } \mathbb{P}[d_H(A(x, \mathsf{leak}(x,r)), r) < d] \geqslant \frac{1}{2n}\right\}$$

For any r, if there exists a leak' such that $|\mathsf{leak}'(x,r)| \leqslant \ell$ and $\mathbb{P}\big[d_H(A(x, \mathsf{leak}'(x,r)), r) < d\big] \geqslant \frac{1}{2n}$, then $r \in B$. Thus, the probability that $A(x, \mathsf{leak}(x,r))$ successfully approximates r is bounded by the probability that $r \in B$.

We now bound B. Observe that for a given choice of $w \in \{0,1\}^{\leqslant \ell}$, there exists $2n$ Hamming balls (which, in the worst case, do not overlap) of radius d contained in B, since there are at most $2n$ Hamming balls which $g(x,w)$ can occupy with probability $\geqslant \frac{1}{2n}$.

Finally, note that a Hamming ball of radius d on strings of length n has volume

$$2^{nH(d/n)-\frac{1}{2}\log n+\mathcal{O}(1)} \leqslant 2^{nH(d/n)+\mathcal{O}(1)}. \quad \text{Thus,} \quad |B| \leqslant 2^{\ell+1} \cdot 2n \cdot 2^{nH(d/n)+\mathcal{O}(1)}$$

We can roll the 2 in $2n$ into the $\mathcal{O}(1)$ in the final exponent, along with the $+1$ in $\ell + 1$.

Thus, the probability that a randomly chosen r satisfies the condition in (4) is at most

$$\frac{|B|}{2^n} \leqslant n \cdot 2^{n(H(d/n)-1)+\ell+\mathcal{O}(1)}$$

◀

5.2 Construction of hard function

Proof of theorem 5.1. We can construct a prBP·L search problem to represent computing our desired hard problem. This search problem is similar to the corresponding search problem from [8] with the changes corresponding directly to the differences between the time-bounded worst-case version of leakage-resilient hardness and the space-bounded average-case version presented in this work.

The search problem. Note that, since we consider only efficiently and uniformly computable (A, leak), a given pair has some constant length. We can thus consider only pairs (A, leak) with descriptions of length at most $\log n$. For any given attacker pair, then, we will only skip it under our search problem in a finite number of cases, which is covered by the almost-all-input hardness.

Let R_{YES} be a binary relation such that $(x, r) \in R_{\mathrm{YES}}$ if both of the following are true:

1. $|x| = |r|$.
2. For all probabilistic (A, leak) such that $|A|, |\mathsf{leak}| \leqslant \log n$ (where $|A|$ (resp. leak) refers to the length of the description of the program A in some arbitrary encoding scheme), it holds that

$$\mathbb{P}\big[|\mathsf{leak}'(x, r)| \leqslant \ell \wedge d_H(A'(x, \mathsf{leak}'(x, r)), r) < d\big] < \frac{1}{2n} \tag{5}$$

where A' and leak' are time-space-truncated versions of A and leak which are only executed until they run for n^{c_1} steps or try to use more than $c_2 \log n$ space (where c_1, c_2 are from theorem 5.1).

Let R_{NO} be a binary relation such that $(x, r) \in R_{\mathrm{NO}}$ if $|x| \neq |r|$ or for *at least one pair* of (A, leak) (within $\log n$ size bound), (5) doesn't hold with a $\frac{1}{n}$ lower bound instead of an $\frac{1}{2n}$ upper bound.

We then show this is a prBP·L search problem by finding a verifier and finder.

Verifier. On input (x, r), the verifier immediately rejects if $|x| \neq |r|$. Otherwise, it enumerates all probabilistic machines (A, leak) such that $|A|, |\mathsf{leak}| \leqslant \log n$. For each one, V estimates the value

$$p_{A,\mathsf{leak}} = \mathbb{P}\big[|\mathsf{leak}'(x, r)| \leqslant \ell \wedge d_H(A'(x, \mathsf{leak}'(x, r)), r) < d\big]$$

by simulating $A'(x, \mathsf{leak}'(x, r))$ polynomially many times and recording whether the Hamming distance is at most d. If during this process, for any (A, leak), we have that the sample estimate $\hat{p}_{A,\mathsf{leak}}$ exceeds $\frac{3}{4n}$, V outputs 0 and terminates. Otherwise, the value $p_{A,\mathsf{leak}}$ is discarded for this attacker pair and estimated for the next attacker pair. If we iterate every attacker pair without terminating, we output 1 and terminate. By the Chernoff bound and the union bound, V will accept with high probability if $(x, r) \in R_{\mathrm{YES}}$ and reject with high probability if $(x, r) \in R_{\mathrm{NO}}$.

This step is exactly where two-way randomness becomes necessary. We can compute $A'(x, \mathsf{leak}'(x, r))$ in logspace since with two-way randomness of BP·L, we can compose functions. The rest is logspace, since computing Hamming distance can be done in a read-once manner by tallying number of agreeing bits, which requires $\log n$ bits, and keeping a tally of successes vs. total count represents the success probability in $\log \mathsf{num\_trials}$ space. Since only a polynomial number of trials is necessary, this is all logspace.

We can compute it in polynomial time, since we only need polynomially many samples and each of A' and leak' is time truncated to a polynomial time-bound.

Finder. On input x, the finder outputs a random string of the same length. Observe that for any fixed $x \in \{0,1\}^n$, by the "random is hard" lemma (5.2), and a union bound over choices of (A, leak), we conclude that $F(x)$ outputs an invalid witness with probability at most

$$n^2 \cdot n \cdot 2^{n(H(d/n)-1)+\ell+\mathcal{O}(1)}$$

When $\ell = n^{\varepsilon} = n^{2\alpha+\frac{\alpha^3}{5}}$ and $\frac{d}{n} = \frac{1}{2} - \frac{1}{m^2}$ with $m = n^{\frac{\alpha^3}{5}}$ and $\alpha = \frac{1}{3}$, this converges to 0, and thus satisfies the search problem requirement of error probability less than $\frac{1}{3}$ (except for perhaps some finite number of small samples where answers can be hard-coded).

Computing the hard function. By the derandomization assumption, there exists a deterministic, logspace function F' such that $(x, F'(x)) \notin R_{\mathrm{NO}}$.

Note that $F'(x) \notin R_{\mathrm{NO}}$, so $|F'(x)| = |x|$ and for all machines (A, leak) which run within the time and space bounds, (5) (with $\frac{1}{2n}$ replaced with $\frac{1}{n}$) holds for all but the finitely many strings too short to include the descriptions of A, leak.

Therefore, by construction, $f = F'$ is a logspace computable $(n^{c_1}, c_2 \log n, \ell, d)$-leakage-resilient average hard function as desired. ◀

6 Discussion

We suspect it is possible to reduce the derandomization part of our assumption to $\mathsf{prBP{\cdot}L} = \mathsf{prL}$, such that we do not explicitly need the separate partial derandomization of $\mathsf{prBP{\cdot}L}$ search problems. However, we were not able to identify such a reduction within the duration of this research.

Abstract

Given a set of n points in $\mathbb{R}^d$ and two positive integers k and m, the Euclidean k-means with outliers problem aims to remove at most m points, referred to as outliers, and minimize the k-means cost function for the remaining points. Developing algorithms for this problem remains an active area of research due to its prevalence in applications involving noisy data. In this paper, we give a $(1+\varepsilon)$-approximation algorithm that runs in $n^2d((k+m)\varepsilon^{-1})^{O(k\varepsilon^{-1})}$ time for the problem. When combined with a coreset construction method, the running time of the algorithm can be improved to be linear in n. For the case where k is a constant, this represents the first polynomial-time approximation scheme for the problem: Existing algorithms with the same approximation guarantee run in polynomial time only when both k and m are constants. Furthermore, our approach generalizes to variants of k-means with outliers incorporating additional constraints on instances, such as those related to capacities and fairness.

1 Introduction

Clustering is a frequently encountered task in many fields related to machine learning, aiming to partition a given set of points into several cohesive clusters. Among the various ways of formalizing the task of clustering, the Euclidean k*-means* problem is perhaps the most commonly studied one. In this problem, we are given a set $\mathcal{P} \subset \mathbb{R}^d$ of points and a positive integer k, and the goal is to identify a set $\mathcal{C} \subset \mathbb{R}^d$ of no more than k centers so that the objective function $\sum_{p\in\mathcal{P}} \min_{c\in\mathcal{C}} ||p-c||^2$ is minimized. Here, the points are partitioned into different clusters according to the disparities in their corresponding centers, namely, the nearest ones. In most applications of the problem, the upper bound on the number of centers (i.e., k) is significantly smaller than the number of points to be clustered. This prompts considerable efforts in developing algorithms for the case where k is fixed. Specifically, it is known that the problem admits *polynomial-time approximation schemes* (PTASs) when k is a constant [14, 18, 11, 37, 33, 34].

Despite extensive study, algorithms developed for the Euclidean k-means problem often exhibit poor performance. The main issue lies in the lack of robustness of the objective function to noisy data: A few *outliers* within the point set can significantly impact the

value of the function. Removing these outliers typically leads to a better clustering result. Motivated thus, we consider the Euclidean *k-means with outliers* (k-MeansOut) problem, which can be defined as follows.

▶ **Definition 1** (Euclidean k-MeansOut). *An instance of Euclidean k-MeansOut is specified by a set $\mathcal{P} \subset \mathbb{R}^d$ of points and two positive integers k and m. A feasible solution to the instance is a set $\mathcal{C} \subset \mathbb{R}^d$ of centers satisfying $|\mathcal{C}| \leq k$ and a set $\mathcal{O} \subseteq \mathcal{P}$ of outliers satisfying $|\mathcal{O}| \leq m$. The cost of such a solution is $\sum_{p\in\mathcal{P}\setminus\mathcal{O}} \min_{c\in\mathcal{C}} ||p-c||^2$. The goal of Euclidean k-MeansOut is to find a feasible solution with minimum cost.*

Solving the Euclidean k-MeansOut problem helps to the removal of more interpretable outliers that can be contextualized by the clusters. This, in turn, results in more cohesive clusters. Notably, it has been observed that adopting this joint perspective on outlier detection and clustering leads to improved performance, even when solely focusing on the task of outlier removal [9, 25]. Given its important role in dealing with noisy data, the Euclidean k-MeansOut problem has received lots of attention from both theoretical and practical points of view. A series of algorithms have been proposed for the problem, including heuristics [9], distributed algorithms [10, 39, 24, 23, 27], approximation algorithms [25, 36, 6, 15, 30, 41], and coreset-construction methods [17, 19, 28, 29].

A commonly used way for relaxing the Euclidean k-MeansOut problem is to assume that the upper bounds on the numbers of centers and outliers (i.e., k and m) are small constants. Under this assumption, several PTASs exist for the problem. Feldman and Schulman [19] showed that a coreset-based approach yields a $(1+\varepsilon)$-approximation algorithm running in $nd(k+m)^{O(k+m)} + (\varepsilon^{-1}k\log n)^{O(1)}$ time, where n denotes the size of the given point set. Bhattacharya et al. [7] later gave an outlier-to-outlier-free reduction, where they mapped an instance of k-MeansOut to an instance of the standard k-means problem. This incurs an arbitrarily small loss in the approximation ratio and a $(k+m)^{m\varepsilon^{-O(1)}}$ multiplicative overhead on the running time of the executed algorithm. Subsequently, Agrawal et al. [1] and Jaiswal and Kumar [32] gave different reductions that impose multiplicative overheads of $n^{O(1)}((k+m)\varepsilon^{-1})^{O(m)}$ and $((k+m)\varepsilon^{-1})^{O(m)}$ on the running time, respectively. When combined with the state-of-the-art approximation scheme running in $O(ndk + d(k\varepsilon^{-1})^{O(1)} + (k\varepsilon^{-1})^{O(k\varepsilon^{-1})})$ time for the Euclidean k-means problem [18], these reductions yield $(1+\varepsilon)$-approximation algorithms with running times exponentially dependent on k and m. When k and m are not fixed, PTASs for Euclidean k-MeansOut exist for the case where d is a constant and the upper-bound constraint on the number of centers can be slightly violated, including the $(d\varepsilon^{-1})^{O(d)}$-swap local-search algorithm given by Friggstad et al. [20] and the algorithm based on split-tree decomposition given by Cohen-Addad et al. [12]. These existing $(1+\varepsilon)$-approximation results are summarized in Table 1.

1.1 Our Results

As described above, there are $(1+\varepsilon)$-approximation algorithms for Euclidean k-MeansOut with running time exponential in both k and m. We cannot hope to achieve a better solution (i.e., an optimal one) in the same time frame: Euclidean k-MeansOut has been shown to be NP-hard, even for the case where $k = 2$ and $m = 0$ [38]. Nevertheless, this negative result does not rule out the possibility of achieving a $(1+\varepsilon)$-approximation solution in a more efficient manner. In particular, given that the outliers often constitute a constant fraction of the entire point set [21, 22, 15], it is interesting to consider whether a $(1+\varepsilon)$-approximation algorithm without exponential dependence on m exists in high-dimensional spaces. The main result in this paper is the first affirmative answer to this question, as described in Theorem 2.

Table 1 $(1+\varepsilon)$-approximation algorithms for Euclidean k-MeansOut. The first two are bi-criteria approximation algorithms that violate the upper-bound constraint on the number of centers by a factor of $1+O(\varepsilon)$. $T(n,d,k,\varepsilon) = O(ndk + d(k\varepsilon^{-1})^{O(1)} + (k\varepsilon^{-1})^{O(k\varepsilon^{-1})})$ denotes the running time of the state-of-the-art approximation scheme for the Euclidean k-means problem.

▶ **Theorem 2.** *Given a constant $\varepsilon \in (0,1)$ and an instance $(\mathcal{P}, k, m)$ of Euclidean k-MeansOut satisfying $\mathcal{P} \subset \mathbb{R}^d$ and $|\mathcal{P}| = n$, there is a $(1+\varepsilon)$-approximation algorithm running in $n^2 d((k+m)\varepsilon^{-1})^{O(k\varepsilon^{-1})}$ time.*

Leveraging a coreset construction method that reduces the point set to a weighted set of size poly(m, k, ε^{-1}) [29], we can improve the running time of the algorithm in Theorem 2 to be linear in n. A detailed analysis is given in Section 4.2.

Awasthi et al. [3] showed that obtaining a PTAS for Euclidean k-MeansOut for arbitrary k and $d = \Omega(\log n)$ is also NP-hard. Given that we avoid the exponential dependence on d, the exponential dependence on k exhibited in Theorem 2 is unavoidable. Existing approximation schemes without exponential dependence on k, like the ones in [20, 12], work only in low-dimensional spaces and select more than k centers.

The optimal solutions to instances of k-MeansOut exhibit a useful property: The center associated with each point is simply the one nearest to the point. This property, called the *locality* property, guides the estimation of the locations of centers selected by an optimal solution. One advantage of our approach is that it no longer relies on the locality property. This enhances the versatility of the approach, allowing us to deal with problems not satisfying the locality property. Indeed, we show that our approach establishes a unified framework for addressing generalizations of Euclidean k-MeansOut that invalidate the locality property, including the Euclidean versions of *capacitated* and *fair* k-MeansOut [32, 13]. As in the unconstrained case, we give the first PTAS for each considered generalization of Euclidean k-MeansOut, assuming k is a constant.

1.2 Our Techniques

Most existing approximation schemes for k-MeansOut are built heavily on the following natural idea: The m outliers can be viewed as m virtual centers, each corresponding to a cluster containing only itself, and solving a $(k+m)$-clustering problem enables the identification of the k centers and m outliers. This provides a clear strategy for constructing the desired approximation solution. However, the complexities of clustering problems increase with the number of centers to be identified, and considering the additional m virtual centers incurs an exponential time-dependence on m, as exhibited in the running times of the approximation schemes given in [19, 7, 1, 32]. To deal with the case where m is super-constant, we employ a different sampling-based method.

Given a small positive constant ε, it is well-known that the centroid of $O(\varepsilon^{-1})$ uniformly sampled points is close to the optimal 1-means clustering center of the entire point set (Lemma 6). Building upon this insight, we uniformly sample from the point set for each cluster defined by an optimal solution, and enumerate the sampled points to find a subset of $O(\varepsilon^{-1})$ points uniformly distributed in the cluster, such that the corresponding center can be approximated by the centroid of the subset. This idea follows the one for the k-means problem outlined in [37], while the case we consider poses more challenges. The first issue we encounter lies in the presence of a non-fixed number of outliers, which reduces the proportion of some small clusters within the point set, and so, the likelihood of obtaining members of these clusters through randomly sampling may not be sufficiently high. To address this issue, we carefully adjust the sampling region for each cluster in a recursive way, ensuring a sufficient proportion of the cluster within the defined region. Another issue emerges as we extend our consideration to the constrained variants of k-MeansOut that do not satisfy the locality property. In these variants, the points are not guaranteed to be close to their corresponding centers. This leads to the lack of a distinct pattern in the distributions of the clusters, making it more difficult to determine appropriate sampling regions. In dealing with this issue, it is essential to address the points that violate the locality property, meaning those far from their corresponding centers. Instead of attempting to find these points through sampling, we regard previously identified approximate centers close to these points as substitutes, enumerating the union of the sampled points and the previously selected centers to construct a small representative set for the considered cluster.

2 Preliminaries

Given a positive integer λ, define $[\lambda] = \{1, \cdots, \lambda\}$. Given a set $\mathcal{X} \subset \mathbb{R}^d$ and a point $y \in \mathbb{R}^d$, let $\Delta(y, \mathcal{X}) = \min_{x \in \mathcal{X}} ||y - x||^2$ denote the squared distance from y to the nearest point in $\mathcal{X}$, and let $\Delta(\mathcal{X}, y) = \sum_{x \in \mathcal{X}} ||x - y||^2$ denote the sum of squared distances from y to the points in $\mathcal{X}$. Additionally, define $c(\mathcal{X}) = |\mathcal{X}|^{-1} \sum_{x \in \mathcal{X}} x$ as the centroid of $\mathcal{X}$, and let $\Delta(\mathcal{X}) = \min_{c \in \mathbb{R}^d} \Delta(\mathcal{X}, c)$ denote the minimum 1-means clustering cost of $\mathcal{X}$.

The following two lemmas provide ways of estimating the squared distances from the points to the centers selected by an approximate solution. As a corollary of the first one, we know that $\Delta(\mathcal{X}) = \Delta(\mathcal{X}, c(\mathcal{X}))$ for each $\mathcal{X} \subset \mathbb{R}^d$.

▶ **Lemma 3** ([35]). *Given a point $x \in \mathbb{R}^d$ and a set $\mathcal{X} \subset \mathbb{R}^d$, we have $\Delta(\mathcal{X}, x) = \Delta(\mathcal{X}) + |\mathcal{X}| \cdot ||c(\mathcal{X}) - x||^2$.*

▶ **Lemma 4** ([16]). *Given a set $\mathcal{X} \subset \mathbb{R}^d$, a real number $\lambda \in (0, 1]$, and a subset $\mathcal{X}' \subseteq \mathcal{X}$ satisfying $|\mathcal{X}'| \geq \lambda|\mathcal{X}|$, we have $||c(\mathcal{X}') - c(\mathcal{X})||^2 \leq (1 - \lambda)(\lambda|\mathcal{X}|)^{-1}\Delta(\mathcal{X})$.*

The following lemma is an extensive version of triangle inequality.

▶ **Lemma 5.** *Given three points x, y, and z in $\mathbb{R}^d$ and a real number $\lambda > 0$, we have $||x - z||^2 \leq (1 + \lambda)||x - y||^2 + (1 + \lambda^{-1})||y - z||^2$.*

Proof. Using triangle inequality, we have$||x - z|| \leq ||x - y|| + ||y - z||$, which implies that

$$\begin{aligned} ||x - z||^2 \leq& (||x - y|| + ||y - z||)^2 \\ =& ||x - y||^2 + ||y - z||^2 + 2\sqrt{\lambda}||x - y||\frac{1}{\sqrt{\lambda}}||y - z|| \\ \leq& ||x - y||^2 + ||y - z||^2 + \lambda||x - y||^2 + \frac{1}{\lambda}||y - z||^2, \end{aligned}$$

as desired. ◀

The following result says that uniform sampling works for the 1-means problem.

▶ **Lemma 6** ([31]). *Given a set $\mathcal{X} \subset \mathbb{R}^d$, a multi-set $\mathcal{S}$ constructed by sampling points from $\mathcal{X}$ independently and uniformly, and a positive real number λ, inequality $||c(\mathcal{S}) - c(\mathcal{X})||^2 \leq (\lambda|\mathcal{S}||\mathcal{X}|)^{-1}\Delta(\mathcal{X})$ holds with probability at least $1 - \lambda$.*

The following result is known as Chernoff bound, which has been widely used in analysis of sampling-based algorithms.

▶ **Lemma 7** ([26]). *Given a set of t independent random variables $a_1, \cdots, a_t$ and a real number $p \in (0,1)$, if $a_i \in \{0,1\}$ and $\mathbf{Pr}[a_i = 1] \geq p$ hold for each $i \in [t]$, then each real number $\lambda \in (0,1)$ satisfies $\mathbf{Pr}\left[\sum_{i=1}^{t} a_i < (1-\lambda)pt\right] < e^{-\frac{1}{2}\lambda^2 pt}$.*

As a corollary of Lemma 7, we have the following result about uniform sampling.

▶ **Lemma 8.** *Given a set $\mathcal{X} \subset \mathbb{R}^d$, a subset $\mathcal{S} \subseteq \mathcal{X}$, a positive integer t, and a real number $\lambda \in (0,1)$, the following event happens with probability more than $1 - e^{-\frac{\lambda^2 t|\mathcal{S}|}{2|\mathcal{X}|}}$: A multi-set of more than t points independently and uniformly sampled from $\mathcal{X}$ contains no less than $(1-\lambda)t|\mathcal{S}||\mathcal{X}|^{-1}$ points in $\mathcal{S}$.*

Proof. We define a set of independent random variables $a_1, \cdots, a_t$ as follows: For each $i \in [t]$, let $a_i = 1$ if the i-th point sampled from $\mathcal{X}$ is in $\mathcal{S}$, and let $a_i = 0$ otherwise. We have $\mathbf{Pr}[a_i = 1] = |\mathcal{S}||\mathcal{X}|^{-1}$ for each $i \in [t]$. Lemma 7 implies that

$$\mathbf{Pr}[\sum_{i=1}^{t} a_i \geq (1-\lambda)t|\mathcal{S}||\mathcal{X}|^{-1}] = 1 - \mathbf{Pr}[\sum_{i=1}^{t} a_i < (1-\lambda)t|\mathcal{S}||\mathcal{X}|^{-1}] > 1 - e^{-\frac{\lambda^2 t|\mathcal{S}|}{2|\mathcal{X}|}}.$$

This completes the proof of Lemma 8. ◀

3 The Sampling Algorithm

In this section we give a sampling-based approach for constructing candidate center sets, as described in Algorithm 1. Taking as inputs three real numbers k, m, and ε, two sets $\mathcal{C}'$ and $\mathcal{P}^\dagger$, and a collection $\mathbb{C}$, the algorithm recursively augments $\mathbb{C}$ with some center sets. Here, k is the upper bound on the size of a center set, m is the upper bound on the number of outliers, ε is the factor trading off the approximation ratio and running time, $\mathcal{C}'$ is a center set that needs to be updated or added to $\mathbb{C}$, $\mathcal{P}^\dagger$ is the sampling region, and $\mathbb{C}$ contains the center sets that have been constructed. The algorithm constructs a multi-set $\mathcal{S}$ as follows: It independently and uniformly samples $O((k+m)\varepsilon^{-3})$ points from $\mathcal{P}^\dagger$ and then adds to the set $O(\varepsilon^{-1})$ copies of each center in $\mathcal{C}'$. After constructing $\mathcal{S}$, the algorithm considers each subset of size $O(\varepsilon^{-1})$ of $\mathcal{S}$, adding the centroid of the subset to $\mathcal{C}'$ and recursively invoking itself with the updated center set. Finally, it throws away half of the points in $\mathcal{P}^\dagger$ that are close to the centers in $\mathcal{C}'$, and invokes itself again with the reduced point set.

By inducting on the sizes of the given sets of centers and points, we obtain the following upper bounds on the running time of our sampling algorithm and the quantity of center sets it generates.

▶ **Lemma 9.** *Given a constant $\varepsilon \in (0,1)$, a collection $\mathbb{C}$, and an instance $(\mathcal{P}, k, m)$ of Euclidean k-MeansOut with $|\mathcal{P}| \leq n$ and $\mathcal{P} \subset \mathbb{R}^d$,* **Sampling**$(k, m, \varepsilon, \emptyset, \mathcal{P}, \mathbb{C})$ *runs in $nd((k+m)\varepsilon^{-1})^{O(k\varepsilon^{-1})}$ time and adds at most $n((k+m)\varepsilon^{-1})^{O(k\varepsilon^{-1})}$ center sets to $\mathbb{C}$.*

Algorithm 1 **Sampling**$(k, m, \varepsilon, \mathcal{C}', \mathcal{P}^\dagger, \mathbb{C})$.

```
   Input: Two positive integers $k$ and $m$, a constant $\varepsilon \in (0,1)$, a set $\mathcal{C}' \subset \mathbb{R}^d$ of no more
          than $k$ centers, a set $\mathcal{P}^\dagger \subset \mathbb{R}^d$ of points, and a collection $\mathbb{C}$ of center sets
1  $N \Leftarrow \lceil (17400k + 60m)\varepsilon^{-3} \rceil$, $M \Leftarrow \lceil 25\varepsilon^{-1} \rceil$;
2  if $|\mathcal{C}'| = k$ then
3      $\mathbb{C} \Leftarrow \mathbb{C} \cup \{\mathcal{C}'\}$;

12         Sampling$(k, m, \varepsilon, \mathcal{C}', \mathcal{P}^\ddagger, \mathbb{C})$.
```

3.1 An Overview of Analysis

We now introduce some notations to be used throughout this section. We consider a constant $\varepsilon \in (0,1)$ and an instance $\mathcal{I} = (\mathcal{P}, k, m)$ of Euclidean k-MeansOut, where $\mathcal{P} \subset \mathbb{R}^d$ and $|\mathcal{P}| = n$. Let $N = \lceil (17400k + 60m)\varepsilon^{-3} \rceil$ and $M = \lceil 25\varepsilon^{-1} \rceil$. Let $\mathcal{P}_1, \cdots, \mathcal{P}_k, \mathcal{O}$ denote $k+1$ arbitrary disjoint subsets of $\mathcal{P}$ satisfying $|\mathcal{O}| = m$, $\bigcup_{i=1}^k \mathcal{P}_i \cup \mathcal{O} = \mathcal{P}$, and $|\mathcal{P}_1| \geq |\mathcal{P}_2| \geq \cdots \geq |\mathcal{P}_k|$. For each $i \in [k]$, let $c_i^* = c(\mathcal{P}_i)$ be the centroid of $\mathcal{P}_i$. Define $\Delta(\mathbb{P}) = \sum_{i=1}^k \Delta(\mathcal{P}_i)$. Let $\mathbb{C}$ denote the collection of center sets constructed by **Sampling**$(k, m, \varepsilon, \emptyset, \mathcal{P}, \emptyset)$. We will show that $\mathbb{C}$ contains a center set approximating $\{c_1^*, \ldots, c_k^*\}$ well with high probability. More formally, we will prove the correctness of the following result.

▶ **Lemma 10.** *The following event happens with probability no less than 15^{-k}: There is a center set $\mathcal{C} \in \mathbb{C}$ satisfying $\sum_{i=1}^k \min_{c \in \mathcal{C}} \Delta(\mathcal{P}_i, c) \leq (1+\varepsilon)\Delta(\mathbb{P})$.*

The proof of Lemma 10, presented in Section 3.2, is based on an inductive method. Specifically, for a given integer $i \in \{2, \cdots, k\}$, we assume that a set $\mathcal{C}_{i-1} = \{c_1, \cdots, c_{i-1}\}$ of centers, where c_j is close to c_j^* for each $j \in [i-1]$, has been constructed, and prove that a center close to c_i^* can be identified and added to $\mathcal{C}_{i-1}$ when invoking Algorithm 1 with $\mathcal{C}_{i-1}$. Define (informally) $\mathcal{B}_{i-1}$ as the set of points close to one of the centers in $\mathcal{C}_{i-1}$. Given a real number λ defined based on the value of ε, we divide the analysis into the following two cases: (1) $|\mathcal{P}_i \backslash \mathcal{B}_{i-1}| \leq \lambda |\mathcal{P}_i|$, and (2) $|\mathcal{P}_i \backslash \mathcal{B}_{i-1}| > \lambda |\mathcal{P}_i|$.

The case of $|\mathcal{P}_i \backslash \mathcal{B}_{i-1}| \leq \lambda |\mathcal{P}_i|$ captures the scenario where most points in $\mathcal{P}_i$ are from $\mathcal{B}_{i-1}$ and in close proximity to one of the centers in $\mathcal{C}_{i-1}$. Conditioned on this, the centers copied in step 6 of Algorithm 1 can be regarded as proxies for the points in $\mathcal{P}_i$. Based on Lemma 4 and Lemma 6, we are able to show that the centroid of a subset of the copies is close to c_i^* and can be added to $\mathcal{C}_{i-1}$ by the algorithm.

For the case where $|\mathcal{P}_i \backslash \mathcal{B}_{i-1}| > \lambda |\mathcal{P}_i|$, we handle the points from $\mathcal{P}_i \cap \mathcal{B}_{i-1}$ similarly to the above approach: We regard the copies of centers in $\mathcal{C}_{i-1}$ as proxies of these points. It remains to consider how to deal with the points from $\mathcal{P}_i \backslash \mathcal{B}_{i-1}$. When formally defining $\mathcal{B}_{i-1}$ in Section 3.2, we carefully establish its range such that the ratio of $|\mathcal{P} \backslash \mathcal{B}_{i-1}|$ to $|\mathcal{P}_i \backslash \mathcal{B}_{i-1}|$ is polynomial in m, k, and ε if $|\mathcal{P}_i \backslash \mathcal{B}_{i-1}| > \lambda|\mathcal{P}_i|$ (as exhibited in Claim 15), which implies that a limited number of points uniformly sampled from $\mathcal{P}\backslash\mathcal{B}_{i-1}$ contains a representative subset of $\mathcal{P}_i\backslash\mathcal{B}_{i-1}$ with a good chance. Furthermore, it is shown that Algorithm 1 can recursively adjust the sampling region to make it close to $\mathcal{P}\backslash\mathcal{B}_{i-1}$, based on the operation in step 12. Putting everything together, we know that a representative subset of $\mathcal{P}_i\backslash\mathcal{B}_{i-1}$ is involved in the points sampled by the algorithm.

3.2 Proof of Lemma 10

It can be seen that the algorithm **Sampling** makes multiple recursive calls to itself. We conceptualize the execution of **Sampling**$(k, m, \varepsilon, \emptyset, \mathcal{P}, \emptyset)$ as a tree denoted by $\mathcal{T}$. Each node within the tree, identified by $(\mathcal{C}', \mathcal{P}^\dagger)$, corresponds to an invocation of the algorithm with center set $\mathcal{C}'$ and sampling region $\mathcal{P}^\dagger$. The children of a node symbolize the recursive calls made in the corresponding invocation of the algorithm, and each leaf of the tree is associated with a set of k centers added to $\mathbb{C}$.

Prior to showing the correctness of Lemma 10, we establish the following invariant for each $i \in [k]$.

$\tau(i)$**:** With probability at least 15^{-i}, there exists a node $(\mathcal{C}_i, \mathcal{P}^\dagger)$ in $\mathcal{T}$ such that (1) $\mathcal{C}_i$ consists of i centers $c_1, \cdots, c_i$ (added in this order), (2) each $j \in [i]$ satisfies $\Delta(\mathcal{P}_j, c_j) \leq (1 + \frac{\varepsilon}{2})\Delta(\mathcal{P}_j) + \frac{\varepsilon}{2k}\Delta(\mathbb{P})$, and (3) $\{p \in \mathcal{P} : \Delta(p, \mathcal{C}_i) > \frac{\varepsilon\Delta(\mathbb{P})}{8k|\mathcal{P}_i|}\} \subseteq \mathcal{P}^\dagger$.

We prove the invariant by induction on i. We first consider the base case of $i = 1$. It can be seen that **Sampling**$(k, m, \varepsilon, \emptyset, \mathcal{P}, \emptyset)$ independently and uniformly samples a multi-set $\mathcal{S}$ of N points from $\mathcal{P}$, and $\mathcal{T}$ has a node $(\{c(\mathcal{S}')\}, \mathcal{P})$ for each $\mathcal{S}' \subset \mathcal{S}$ with $|\mathcal{S}'| = M$. We have $|\mathcal{P}||\mathcal{P}_1|^{-1} = (\sum_{j=1}^{k} |\mathcal{P}_j| + |\mathcal{O}|)|\mathcal{P}_1|^{-1} \leq k + m$ due to the fact that $|\mathcal{P}_1| \geq |\mathcal{P}_2| \geq \cdots \geq |\mathcal{P}_k|$. This inequality and Lemma 8 (with $t = N$ and $\lambda = 1 - M(k + m)N^{-1}$) imply that a node $(\{c(\mathcal{S}')\}, \mathcal{P})$ satisfying $|\mathcal{S}'| = M$ and $\mathcal{S}' \subseteq \mathcal{P}_1$ exists in $\mathcal{T}$ with probability more than $1 - e^{-(1-M(k+m)N^{-1})^2N)/(2(k+m))} > \frac{1}{3}$. Using Lemma 6 (with $\lambda = \frac{4}{5}$), we know that if such a node $(\{c(\mathcal{S}')\}, \mathcal{P})$ exists, then inequality

$$||c(\mathcal{S}') - c_1^*||^2 \leq \frac{5\Delta(\mathcal{P}_1)}{4|\mathcal{P}_1||\mathcal{S}'|} = \frac{\varepsilon\Delta(\mathcal{P}_1)}{20|\mathcal{P}_1|} \tag{1}$$

holds with probability at least $\frac{1}{5}$. Inequality (1) and Lemma 3 imply that

$$\Delta(\mathcal{P}_1, c(\mathcal{S}')) = \Delta(\mathcal{P}_1) + |\mathcal{P}_1| \cdot ||c(\mathcal{S}') - c_1^*||^2 \leq (1 + \frac{\varepsilon}{20})\Delta(\mathcal{P}_1),$$

which in turn implies that $\tau(1)$ is true.

We now assume that $\tau(i - 1)$ holds for an integer $i \in \{2, \cdots, k\}$, and prove that $\tau(i)$ also holds. Let $(\mathcal{C}_{i-1}, \mathcal{P}^\dagger)$ be a node satisfying

$$\Delta(\mathcal{P}_j, c_j) \leq (1 + \frac{\varepsilon}{2})\Delta(\mathcal{P}_j) + \frac{\varepsilon}{2k}\Delta(\mathbb{P}) \tag{2}$$

for each $j \in [i - 1]$ and

$$\{p \in \mathcal{P} : \Delta(p, \mathcal{C}_{i-1}) > \frac{\varepsilon\Delta(\mathbb{P})}{8k|\mathcal{P}_{i-1}|}\} \subseteq \mathcal{P}^\dagger, \tag{3}$$

where $\mathcal{C}_{i-1} = \{c_1, \cdots, c_{i-1}\}$. $\tau(i - 1)$ implies that such a node $(\mathcal{C}_{i-1}, \mathcal{P}^\dagger)$ exists in $\mathcal{T}$ with probability no less than 15^{1-i}. Conditioning on the existence of this node, we define $\mathcal{B}_{i-1} = \{p \in \mathcal{P} : \Delta(p, \mathcal{C}_{i-1}) \leq \frac{\varepsilon\Delta(\mathbb{P})}{8k|\mathcal{P}_i|}\}$. Let $\mathcal{P}_i^n = \mathcal{P}_i \cap \mathcal{B}_{i-1}$ and $\mathcal{P}_i^f = \mathcal{P}_i\backslash\mathcal{B}_{i-1}$ for brevity. As described in Section 3.1, we prove $\tau(i)$ differently based on the size of $\mathcal{P}_i^f$. Specifically, we consider the following two cases: (1) $|\mathcal{P}_i^f| \leq \frac{\varepsilon}{17}|\mathcal{P}_i|$, and (2) $|\mathcal{P}_i^f| > \frac{\varepsilon}{17}|\mathcal{P}_i|$. These two cases are respectively analyzed in the following two subsections.

Case (1): $|\mathcal{P}_i^f| \leq \frac{\varepsilon}{17}|\mathcal{P}_i|$

In this case, most points in $\mathcal{P}_i$ are close to the centers in $\mathcal{C}_{i-1}$, based on which we show that a convex combination of the latter's members effectively approximates c_i^*. We consider a multi-set $\mathcal{P}_i' = \{c(p) : p \in \mathcal{P}_i^n\}$, where $c(p)$ is the center in $\mathcal{C}_{i-1}$ nearest to p. The proximity of each point in $\mathcal{P}_i^n$ to its counterpart in $\mathcal{P}_i'$, combined with the substantial proportion of $\mathcal{P}_i^n$ in $\mathcal{P}_i$, implies that the centroid of $\mathcal{P}_i'$ is close to c_i^*. This is confirmed by the following lemma.

► **Lemma 11.** *If $|\mathcal{P}_i^f| \leq \frac{\varepsilon}{17}|\mathcal{P}_i|$, then we have $||c(\mathcal{P}_i') - c_i^*||^2 \leq \frac{\varepsilon\Delta(\mathcal{P}_i)}{8|\mathcal{P}_i|} + \frac{\varepsilon\Delta(\mathbb{P})}{4k|\mathcal{P}_i|}$.*

Lemma 11 suggests that $c(\mathcal{P}_i')$ is close to c_i^*. Unfortunately, directly approximating c_i^* using $c(\mathcal{P}_i')$ is not feasible, as the members of both $\mathcal{P}_i^n$ and $\mathcal{P}_i'$ are unknown. The idea of Algorithm 1 is to take M copies of each center from $\mathcal{C}_{i-1}$ and simulate $\mathcal{P}_i'$ using a subset of these copies. The following lemma implies that this yields a center approximating c_i^* well with high probability and, furthermore, generates the node claimed in $\tau(i)$.

► **Lemma 12.** *If $|\mathcal{P}_i^f| \leq \frac{\varepsilon}{17}|\mathcal{P}_i|$, then the following event happens with probability at least $\frac{1}{5}$: $(\mathcal{C}_{i-1}, \mathcal{P}^\dagger)$ has a child $(\mathcal{C}_{i-1} \uplus \{c_i\}, \mathcal{P}^\dagger)$ satisfying $\{p \in \mathcal{P} : \Delta(p, \mathcal{C}_{i-1} \uplus \{c_i\}) > \frac{\varepsilon\Delta(\mathbb{P})}{8k|\mathcal{P}_i|}\} \subseteq \mathcal{P}^\dagger$ and $\Delta(\mathcal{P}_i, c_i) < (1 + \frac{\varepsilon}{2})\Delta(\mathcal{P}_i) + \frac{\varepsilon}{2k}\Delta(\mathbb{P})$.*

Proof. The fact that $|\mathcal{P}_1| \geq |\mathcal{P}_2| \geq \cdots \geq |\mathcal{P}_k|$ and $\Delta(p, \mathcal{C}_{i-1}) \geq \Delta(p, \mathcal{C}_{i-1} \uplus \{c\})$ for each $p \in \mathcal{P}$ and $c \in \mathbb{R}^d$ suggests that

$$\{p \in \mathcal{P} : \Delta(p, \mathcal{C}_{i-1} \uplus \{c\}) > \frac{\varepsilon\Delta(\mathbb{P})}{8k|\mathcal{P}_i|}\} \subseteq \{p \in \mathcal{P} : \Delta(p, \mathcal{C}_{i-1}) > \frac{\varepsilon\Delta(\mathbb{P})}{8k|\mathcal{P}_{i-1}|}\} \subseteq \mathcal{P}^\dagger \tag{4}$$

for each $c \in \mathbb{R}^d$, where the last step is due to inequality (3).

In the invocation of Algorithm 1 corresponding to $(\mathcal{C}_{i-1}, \mathcal{P}^\dagger)$, the algorithm takes M copies of each center from $\mathcal{C}_{i-1}$ and calculates the centroid of each subset of the copies with size M. By Lemma 6 (with $\lambda = \frac{4}{5}$) and the fact that $\mathcal{P}_i' \subseteq \mathcal{C}_{i-1}$, we know that a center c_i identified in this way satisfies

$$||c_i - c(\mathcal{P}_i')||^2 \leq \frac{5\Delta(\mathcal{P}_i')}{4M|\mathcal{P}_i'|} \leq \frac{\varepsilon\Delta(\mathcal{P}_i')}{20|\mathcal{P}_i'|} = \frac{\varepsilon\Delta(\mathcal{P}_i')}{20|\mathcal{P}_i^n|} \tag{5}$$

with probability no less than $\frac{1}{5}$.

Denote by c_i a center satisfying inequality (5). Intuitively, inequality (5) and Lemma 11 imply an upper bound on the squared distance from c_i to c_i^*. Combining this insight with Lemma 3, we can derive the following claim.

▷ Claim 13. If $|\mathcal{P}_i^f| \leq \frac{\varepsilon}{17}|\mathcal{P}_i|$, then we have $\Delta(\mathcal{P}_i, c_i) < (1 + \frac{\varepsilon}{2})\Delta(\mathcal{P}_i) + \frac{\varepsilon}{2k}\Delta(\mathbb{P})$.

Using Claim 13 and inequality (4), we complete the proof of Lemma 12. ◄

Case (2): $|\mathcal{P}_i^f| > \frac{\varepsilon}{17}|\mathcal{P}_i|$

As in the previous case, we simulate the points in $\mathcal{P}_i^n$ using the centers in $\mathcal{C}_{i-1}$. The main challenge in the current case is that we cannot ignore the points from $\mathcal{P}_i^f$ as we did previously, since their proportion in $\mathcal{P}_i$ is no longer bounded by a small value. As a remedy, we argue that we can sample sufficient points from $\mathcal{P}_i^f$ in step 5 of Algorithm 1 by recursively adjusting the sampling region. Furthermore, we will show that a combination of these sampled points and the centers in $\mathcal{C}_{i-1}$ approximates c_i^* well.

The following lemma suggests a lower bound on the proportion of $\mathcal{P}_i^f$ within a carefully selected sampling region.

▶ **Lemma 14.** *If $|\mathcal{P}_i^f| > \frac{\varepsilon}{17}|\mathcal{P}_i|$, then there is a node $(\mathcal{C}_{i-1}, \mathcal{P}^\ddagger)$ in the descendants of $(\mathcal{C}_{i-1}, \mathcal{P}^\dagger)$ (including itself) that satisfies $\mathcal{P}\backslash\mathcal{B}_{i-1} \subseteq \mathcal{P}^\ddagger$ and $\varepsilon^{-2}(580k + 2m)|\mathcal{P}_i^f| > |\mathcal{P}^\ddagger|$.*

Proof. Our idea for proving Lemma 14 is to show that $|\mathcal{P}_i^f|$ is not too small compared to $|\mathcal{P}\backslash\mathcal{B}_{i-1}|$, and then argue that the invocation of Algorithm 1 corresponding to $(\mathcal{C}_{i-1}, \mathcal{P}^\dagger)$ can find a sampling region $\mathcal{P}^\ddagger$ close to $\mathcal{P}\backslash\mathcal{B}_{i-1}$.

The following claim establishes a lower bound on the ratio of $|\mathcal{P}_i^f|$ to $|\mathcal{P}\backslash\mathcal{B}_{i-1}|$.

▷ Claim 15. If $|\mathcal{P}_i^f| > \frac{\varepsilon}{17}|\mathcal{P}_i|$, then $\varepsilon^{-2}(290k + m)|\mathcal{P}_i^f| > |\mathcal{P}\backslash\mathcal{B}_{i-1}|$.

The fact that $|\mathcal{P}_1| \geq |\mathcal{P}_2| \geq \cdots \geq |\mathcal{P}_k|$ and inequality (3) imply that

$$\mathcal{P}\backslash\mathcal{B}_{i-1} = \{p \in \mathcal{P} : \Delta(p, \mathcal{C}_{i-1}) > \frac{\varepsilon\Delta(\mathbb{P})}{8k|\mathcal{P}_i|}\} \subseteq \mathcal{P}^\dagger. \tag{6}$$

We sort the points $p \in \mathcal{P}^\dagger$ by decreasing values of $\Delta(p, \mathcal{C}_{i-1})$. Let p_t be the t-th point in this order for each $t \in [|\mathcal{P}^\dagger|]$, and define $\mathcal{P}_s^\dagger = \{p_t : t \in [\lfloor 2^{-s}|\mathcal{P}^\dagger|\rfloor]\}$ for each integer $s \in [0, \lfloor\log|\mathcal{P}^\dagger|\rfloor]$. Equality (6) implies the existence of an integer $\tilde{s} \in [0, \lfloor\log|\mathcal{P}^\dagger|\rfloor]$ satisfying $\mathcal{P}\backslash\mathcal{B}_{i-1} \subseteq \mathcal{P}_{\tilde{s}}^\dagger$ and $2|\mathcal{P}\backslash\mathcal{B}_{i-1}| \geq |\mathcal{P}_{\tilde{s}}^\dagger|$, and we have $\varepsilon^{-2}(580k+2m)|\mathcal{P}_i^f| > |\mathcal{P}_{\tilde{s}}^\dagger|$ due to Claim 15. Moreover, the operations performed in steps 12 and 13 of Algorithm 1 ensure that $(\mathcal{C}_{i-1}, \mathcal{P}_{\tilde{s}}^\dagger)$ is a descendant of $(\mathcal{C}_{i-1}, \mathcal{P}^\dagger)$. This completes the proof of Lemma 14. ◀

Following the approach in Case (1), we consider a multi-set where each $p \in \mathcal{P}_i^n$ is replaced by the nearest center $c(p)$ in $\mathcal{C}_{i-1}$. We define the multi-set as $\mathcal{P}_i' = \{c(p) : p \in \mathcal{P}_i^n\} \cup \mathcal{P}_i^f$. Intuitively, we can closely simulate this multi-set using the union of a subset of $\{c(p) : p \in \mathcal{P}_i^n\}$ and a set of points sampled from $\mathcal{P}_i^f$, and the centroid of the simulated set is close to c_i^*, given that the squared distance from each $p \in \mathcal{P}_i^n$ to $c(p)$ is upper-bounded by a small value and sufficient points from $\mathcal{P}_i^f$ can be sampled. This motivates the following lemma.

▶ **Lemma 16.** *If $|\mathcal{P}_i^f| > \frac{\varepsilon}{17}|\mathcal{P}_i|$, then the following event happens with probability at least $\frac{1}{15}$: $(\mathcal{C}_{i-1}, \mathcal{P}^\dagger)$ has a descendant $(\mathcal{C}_{i-1} \uplus \{c_i\}, \mathcal{P}^\ddagger)$ with $\{p \in \mathcal{P} : \Delta(p, \mathcal{C}_{i-1} \uplus \{c_i\}) > \frac{\varepsilon\Delta(\mathbb{P})}{8k|\mathcal{P}_i|}\} \subseteq \mathcal{P}^\ddagger$ and $\Delta(\mathcal{P}_i, c_i) < (1 + \frac{\varepsilon}{2})\Delta(\mathcal{P}_i) + \frac{\varepsilon}{2k}\Delta(\mathbb{P})$.*

Proof. Denote by $(\mathcal{C}_{i-1}, \mathcal{P}^\ddagger)$ the descendant of $(\mathcal{C}_{i-1}, \mathcal{P}^\dagger)$ claimed in Lemma 14. When calling Algorithm 1 with $(\mathcal{C}_{i-1}, \mathcal{P}^\ddagger)$, we independently and uniformly sample N points from $\mathcal{P}^\ddagger$ and take M copies of each center from $\mathcal{C}_{i-1}$ to construct a multi-set $\mathcal{S}$. $(\mathcal{C}_{i-1}, \mathcal{P}^\ddagger)$ has a child $(\mathcal{C}_{i-1} \uplus \{c(\mathcal{S}')\}, \mathcal{P}^\ddagger)$ for each $\mathcal{S}' \subset \mathcal{S}$ with $|\mathcal{S}'| = M$. By Lemma 8 (with $t = N$ and $\lambda = \frac{1}{6}$) and the fact that $\mathcal{P}_i^f \subseteq \mathcal{P}\backslash\mathcal{B}_{i-1} \subseteq \mathcal{P}^\ddagger$ and $\varepsilon^{-2}(580k + 2m)|\mathcal{P}_i^f| > |\mathcal{P}^\ddagger|$ (due to Lemma 14), we know that $\mathcal{S}$ contains no less than M points uniformly distributed in $\mathcal{P}_i^f$ with probability at least $1 - e^{-\varepsilon^2 N/(72(580k+2m))} > \frac{1}{3}$. Moreover, the probability that $\mathcal{S}$ has a subset $\mathcal{S}'$ consisting of M points uniformly distributed in $\mathcal{P}_i'$ can be lower-bounded by the same constant, given that there are M copies of each distinct member of $\mathcal{P}_i'\backslash\mathcal{P}_i^f$ within $\mathcal{S}$. Under the assumption that such a subset $\mathcal{S}'$ exists, Lemma 4 (with $\lambda = \frac{4}{5}$) implies that inequality

$$||c_i - c(\mathcal{P}_i')||^2 \leq \frac{5\Delta(\mathcal{P}_i')}{4M|\mathcal{P}_i'|} = \frac{\varepsilon\Delta(\mathcal{P}_i')}{20|\mathcal{P}_i|} \tag{7}$$

holds with probability at least $\frac{1}{5}$, where $c_i = c(\mathcal{S}')$ is the centroid of $\mathcal{S}'$. Putting everything together, we know that $(\mathcal{C}_{i-1}, \mathcal{P}^\ddagger)$ has a child $(\mathcal{C}_{i-1} \uplus \{c_i\}, \mathcal{P}^\ddagger)$ satisfying inequality (7) with probability at least $\frac{1}{15}$.

We now show that $(\mathcal{C}_{i-1} \uplus \{c_i\}, \mathcal{P}^\ddagger)$ satisfies the properties claimed in Lemma 16. By a similar argument as in the proof of Claim 13, we can obtain the following upper bound on $\Delta(\mathcal{P}_i, c_i)$.

Algorithm 2 The Algorithm for Euclidean k-MeansOut.

```
Input: A constant $\varepsilon \in (0,1)$ and an instance $(\mathcal{P},k,m)$ of Euclidean $k$-MeansOut
       satisfying $\mathcal{P} \subset \mathbb{R}^d$
Output: A set $\mathcal{C} \subset \mathbb{R}^d$ of no more than $k$ centers and a set $\mathcal{O} \subseteq \mathcal{P}$ of no more than
        $m$ outliers
$\mathbb{C} \Leftarrow \emptyset$;
for $t \Leftarrow 1$ to $15^k$ do
    Sampling$(k, m, \varepsilon, \emptyset, \mathcal{P}, \mathbb{C})$;
for each $\mathcal{C}' \in \mathbb{C}$ do
    cost$(\mathcal{C}') \Leftarrow \min_{\mathcal{O}' \subseteq \mathcal{P} \wedge |\mathcal{O}'| \leq m} \sum_{p \in \mathcal{P} \setminus \mathcal{O}'} \Delta(p, \mathcal{C}')$;
$\mathcal{C} \Leftarrow \arg\min_{\mathcal{C}' \in \mathbb{C}}$ cost$(\mathcal{C}')$;
$\mathcal{O} \Leftarrow \arg\max_{\mathcal{O}' \subseteq \mathcal{P} \wedge |\mathcal{O}'| \leq m} \sum_{p \in \mathcal{O}'} \Delta(p, \mathcal{C})$;
return $\mathcal{C}, \mathcal{O}$.
```

▷ Claim 17. If $|\mathcal{P}_i^f| > \frac{\varepsilon}{17}|\mathcal{P}_i|$, then $\Delta(\mathcal{P}_i, c_i) < (1+\frac{\varepsilon}{5})\Delta(\mathcal{P}_i) + \frac{3\varepsilon}{10k}\Delta(\mathbb{P})$.

Observe that

$$\{p \in \mathcal{P} : \Delta(p, \mathcal{C}_{i-1} \uplus \{c_i\}) > \frac{\varepsilon\Delta(\mathbb{P})}{8k|\mathcal{P}_i|}\} \subseteq \{p \in \mathcal{P} : \Delta(p, \mathcal{C}_{i-1}) > \frac{\varepsilon\Delta(\mathbb{P})}{8k|\mathcal{P}_i|}\} = \mathcal{P} \setminus \mathcal{B}_{i-1} \subseteq \mathcal{P}^{\ddagger},$$

where the last step is due to Lemma 14. Combining this with Claim 17, we know that Lemma 16 is true. ◀

Lemma 12 and Lemma 16 suggest that for each $i \in \{2, \cdots, k\}$, $\tau(i)$ holds if $\tau(i-1)$ is true. Combining this with the initial condition $\tau(1)$ being true, we establish the validity of $\tau(i)$ for each $i \in [k]$. The proof of Lemma 10 effortlessly follows from the statement of $\tau(k)$.

4 Applications

In this section we show the applications of Algorithm 1. We first address the Euclidean k-MeansOut problem, and then show how to extend our approach to constrained cases.

4.1 The Algorithm for Euclidean k-MeansOut

Our approach for solving Euclidean k-MeansOut is presented in Algorithm 2, which takes as inputs a constant $\varepsilon \in (0,1)$ and an instance $\mathcal{I} = (\mathcal{P}, k, m)$ with $\mathcal{P} \subset \mathbb{R}^d$ and $|\mathcal{P}| = n$. The algorithm iteratively invokes Algorithm 1 to construct a collection of center sets and returns the one, along with the corresponding outlier set, that minimizes the cost for $\mathcal{I}$. By analyzing the performance of Algorithm 2, we complete the proof of Theorem 2.

Proof (of Theorem 2). Let $(\mathcal{C}^*, \mathcal{O}^*)$ be an optimal solution to $\mathcal{I}$, which opens a set $\mathcal{C}^* = \{c_1^*, \cdots, c_k^*\}$ of k centers from $\mathbb{R}^d$ and removes a set $\mathcal{O}^*$ of m outliers from $\mathcal{P}$. For each $i \in [k]$, denote by $\mathcal{P}_i^*$ the subset of the points in $\mathcal{P} \setminus \mathcal{O}^*$ whose closest center in $\mathcal{C}^*$ is c_i^*. Define $\Delta(\mathbb{P}) = \sum_{i=1}^{k} \Delta(\mathcal{P}_i^*, c_i^*) = \sum_{p \in \mathcal{P} \setminus \mathcal{O}^*} \Delta(p, \mathcal{C}^*)$ as the cost of $(\mathcal{C}^*, \mathcal{O}^*)$. Moreover, let $\mathbb{C}$ be the collection of center sets constructed by Algorithm 2, and let $(\mathcal{C}, \mathcal{O})$ be the solution to $\mathcal{I}$ returned by the algorithm. Observe that the statement in Lemma 10 holds with probability no less than 15^{-k}. Given that Algorithm 2 invokes **Sampling** 15^k times to construct $\mathbb{C}$, the probability of the statement in Lemma 10 being true in at least one of these invocations can be lower-bounded by $1 - (1 - 15^{-k})^{15^k} > 1 - e^{-1}$. Consequently, inequality

$$\sum_{p\in\mathcal{P}\setminus\mathcal{O}} \Delta(p,\mathcal{C}) \le \sum_{i=1}^{k} \min_{c\in\mathcal{C}} \Delta(\mathcal{P}_i^*, c) \le (1+\varepsilon)\Delta(\mathbb{P}) \tag{8}$$

holds with probability at least $1-e^{-1}$, where the first step is due to the operation in step 9 of Algorithm 2, and the second step follows from Lemma 10. Inequality (8) implies that the approximation ratio of Algorithm 2 is $1+\varepsilon$.

It remains to analyze the running time of Algorithm 2. Lemma 9 implies that invoking **Sampling** 15^k times takes $nd((k+m)\varepsilon^{-1})^{O(k\varepsilon^{-1})}$ time and adds $n((k+m)\varepsilon^{-1})^{O(k\varepsilon^{-1})}$ center sets to $\mathbb{C}$. For each center set from $\mathbb{C}$, the algorithm takes $O(ndk)$ time to compute the corresponding cost for $\mathcal{I}$. Consequently, we know that Algorithm 2 runs in $n^2d((k+m)\varepsilon^{-1})^{O(k\varepsilon^{-1})}$ time. This completes the proof of Theorem 2. ◀

4.2 A Coreset-Based Accelerated Algorithm

In a recent study, Huang et al. [29] showed that a subset of $\text{poly}(m,k,\varepsilon^{-1})$ weighted points, referred to as a coreset, can be identified in linear time for the given instance of Euclidean k-MeansOut, such that the outlier-removal clustering costs, induced by any set of k centers, are similar between the coreset and the entire point set. Such a method for coreset construction can serve as a means to accelerate our algorithm. Specifically, when selecting a well-performing center set from the collection $\mathbb{C}$, we can compare the clustering costs induced by the center sets on the coreset rather than the entire point set. This reduces the running time of the algorithm in Theorem 2 to $nd((k+m)\varepsilon^{-1})^{O(k\varepsilon^{-1})}$, with an arbitrarily small loss in the approximation ratio.

▶ **Lemma 18** ([29]). *Given a constant $\varepsilon\in(0,1)$, an instance $\mathcal{I}=(\mathcal{P},k,m)$ of Euclidean k-MeansOut satisfying $\mathcal{P}\subset\mathbb{R}^d$ and $|\mathcal{P}|=n$, and an algorithm that has the guarantee of yielding a solution $(\mathcal{C},\mathcal{O})$ satisfying $\sum_{p\in\mathcal{P}\setminus\mathcal{O}}\Delta(p,\mathcal{C})\le\alpha\cdot opt$, $|\mathcal{C}|\le\beta k$, and $|\mathcal{O}|\le\gamma m$ for three real numbers $\alpha,\beta,\gamma\ge1$ in $T(n,d,k,m)$ time (opt is the cost of an optimal solution to $\mathcal{I}$), a weighted subset $\mathcal{S}\subseteq\mathcal{P}$ satisfying $|\mathcal{S}|\le\gamma m+\beta(k\varepsilon^{-1})^{O(1)}$ with weight function $w:\mathcal{S}\to[0,+\infty)$ can be constructed in $T(n,d,k,m)+O(ndk)$ time, such that*

$$\min_{\mathcal{O}'\subseteq\mathcal{S}\wedge\sum_{p\in\mathcal{O}'}w(p)\le m}\ \sum_{p\in\mathcal{S}\setminus\mathcal{O}'} w(p)\Delta(p,\mathcal{C}') \in (1\pm\alpha\varepsilon) \min_{\mathcal{O}'\subseteq\mathcal{P}\wedge|\mathcal{O}'|\le m}\ \sum_{p\in\mathcal{P}\setminus\mathcal{O}'} \Delta(p,\mathcal{C}')$$

for each $\mathcal{C}'\subset\mathbb{R}^d$ with $|\mathcal{C}'|=k$.

To leverage Lemma 18, we give a straightforward and fast bi-criteria approximation algorithm for Euclidean k-MeansOut, based on the D^2-sampling method given by Arthur and Vassilvitskii [2].

▶ **Lemma 19.** *Given an instance $\mathcal{I}=(\mathcal{P},k,m)$ of Euclidean k-MeansOut with $\mathcal{P}\subset\mathbb{R}^d$ and $|\mathcal{P}|=n$, a center set $\mathcal{C}\subset\mathbb{R}^d$ satisfying $|\mathcal{C}|=O(k+m)$ and $\sum_{p\in\mathcal{P}}\Delta(p,\mathcal{C})\le O(opt)$ can be identified in $O(nd(k+m))$ time, where opt is the cost of an optimal solution to $\mathcal{I}$.*

Taking as an input the algorithm given in Lemma 19, Lemma 18 yields a coreset of size $((k+m)\varepsilon^{-1})^{O(1)}$ in $O(nd(k+m))$ time. Leveraging this coreset allows us to reduce the running time of our algorithm for Euclidean k-MeansOut to be linear in n, as described in the following theorem.

▶ **Theorem 20.** *Given a constant $\varepsilon \in (0,1)$ and an instance $(\mathcal{P}, k, m)$ of Euclidean k-*MeansOut *satisfying $\mathcal{P} \subset \mathbb{R}^d$ and $|\mathcal{P}| = n$, there is a $(1+O(\varepsilon))$-approximation algorithm running in $nd((k+m)\varepsilon^{-1})^{O(k\varepsilon^{-1})}$ time.*

Proof. Let $\mathcal{S} \subseteq \mathcal{P}$ be the coreset constructed by Lemma 18 when taking as inputs constant ε, instance $(\mathcal{P}, k, m)$, and the algorithm in Lemma 19, and let $w : \mathcal{S} \to [0, +\infty)$ be the corresponding weight function. We have $|\mathcal{S}| \le ((k+m)\varepsilon^{-1})^{O(1)}$ due to Lemma 18 and Lemma 19. Our accelerated algorithm for Euclidean k-MeansOut is identical to Algorithm 2, differing only in steps 6 and 8, where we calculate the outlier-removal clustering costs induced by the candidate center sets and select the one with minimum cost. We now define

$$\texttt{wcost}(\mathcal{C}') = \min_{\mathcal{O}' \subseteq \mathcal{S} \wedge \sum_{p \in \mathcal{O}'} w(p) \le m} \sum_{p \in \mathcal{S} \setminus \mathcal{O}'} w(p) \Delta(p, \mathcal{C}')$$

for each $\mathcal{C}' \in \mathbb{C}$ in step 6 of the algorithm, and select the center set $\mathcal{C} \in \mathbb{C}$ with minimum value of $\texttt{wcost}(\mathcal{C})$ in step 8.

Observe that calculating $\texttt{wcost}(\mathcal{C}')$ for each $\mathcal{C}' \in \mathbb{C}$ takes $O(|\mathcal{S}||\mathcal{C}'|d) \le d((k+m)\varepsilon^{-1})^{O(1)}$ time. Combining this with the fact that we take $nd((k+m)\varepsilon^{-1})^{O(k\varepsilon^{-1})}$ time to construct a collection $\mathbb{C}$ of $n((k+m)\varepsilon^{-1})^{O(k\varepsilon^{-1})}$ candidate center sets (as argued in the proof of Theorem 2), we know that the accelerated algorithm runs in $nd((k+m)\varepsilon^{-1})^{O(k\varepsilon^{-1})}$ time.

The analysis of the approximation ratio of our accelerated algorithm follows that of Algorithm 2 (given in the proof of Theorem 2). Denote by $(\tilde{\mathcal{C}}, \tilde{\mathcal{O}})$ the solution to $\mathcal{I}$ constructed by the accelerated algorithm, and let $(\mathcal{C}, \mathcal{O})$ be a solution to $\mathcal{I}$ satisfying inequality (8). We have

$$\sum_{p \in \mathcal{P} \setminus \tilde{\mathcal{O}}} \Delta(p, \tilde{\mathcal{C}}) \le \frac{\texttt{wcost}(\tilde{\mathcal{C}})}{1 - O(\varepsilon)} \le \frac{\texttt{wcost}(\mathcal{C})}{1 - O(\varepsilon)} \le \frac{1 + O(\varepsilon)}{1 - O(\varepsilon)} \sum_{p \in \mathcal{P} \setminus \mathcal{O}} \Delta(p, \mathcal{C}), \tag{9}$$

where the first and third steps follow from the approximation guarantee of the coreset given by Lemma 18 and Lemma 19, and the second step is due to the fact that the center set $\tilde{\mathcal{C}}$ selected by our accelerated algorithm satisfies $\texttt{wcost}(\tilde{\mathcal{C}}) = \min_{\mathcal{C}' \in \mathbb{C}} \texttt{wcost}(\mathcal{C}')$. Combining inequality (9) with inequality (8), we know that the approximation ratio of the accelerated algorithm is $1 + O(\varepsilon)$. ◀

5 Extensions to Constrained Cases

Constrained k-MeansOut problems generalize k-MeansOut by introducing additional constraints on the feasibilities of solutions. For example, in the capacitated generalization, there is an upper bound on the size of each cluster. Similarly, in the lower-bounded generalization, each cluster must contain at least a specified number of points. There are known frameworks for reducing constrained k-MeansOut problems to their outlier-free counterparts with small losses in the approximation ratios [32, 13]. Combined with the approximation schemes applicable in outlier-free cases, such as the ones given in [8, 16, 4], these frameworks enable the development of $(1+\varepsilon)$-approximation algorithms for constrained k-MeansOut problems. However, similar to the unconstrained case, the reductions given in [32, 13] require time exponentially dependent on m.

An apparent distinction between constrained k-MeansOut problems and the unconstrained counterpart lies in the locality property described in Section 1.1: In the former, clusters in an optimal solution can be quite different from the ones with minimum clustering cost, as additional constraints are imposed on their feasibilities. Fortunately, Lemma 10 implies that a near-optimal set of centers corresponding to any outlier-removal k-clustering result can be found by Algorithm 1, including those imposed with additional constraints. Given k good-enough centers, it is sufficient to remove the outliers and assign each point to a center under the additional constraints. Indeed, combining Algorithm 1 with problem-specific methods for identifying outliers and assigning points, we obtain the first PTASs for constrained k-MeansOut problems in Euclidean spaces for constant k and super-constant m, including capacitated and fair k-MeansOut.

Our algorithms for constrained k-MeansOut problems closely resemble Algorithm 2, with the only difference being in the construction of the solution based on $\mathbb{C}$ (as shown in steps 5-10). Given a set $\mathcal{P} \subset \mathbb{R}^d$ with $|\mathcal{P}| = n$, a real number $\varepsilon \in (0, 1]$, and two positive integers k and m, let $\mathbb{C}$ be the collection of center sets constructed by Algorithm 2. By Lemma 10 and the fact that $\mathbb{C}$ is constructed by invoking **Sampling** 15^k times, we know that the following event happens with probability no less than $1 - (1 - 15^{-k})^{15^k} > 1 - e^{-1}$: For any k disjoint subsets $\mathcal{P}_1, \cdots, \mathcal{P}_k$ of $\mathcal{P}$ with $\sum_{i=1}^{k} |\mathcal{P}_i| = n - m$, there is a center set $\mathcal{C} \in \mathbb{C}$ satisfying

$$\sum_{i=1}^{k} \min_{c \in \mathcal{C}} \Delta(\mathcal{P}_i, c) \leq (1 + \varepsilon) \sum_{i=1}^{k} \Delta(\mathcal{P}_i). \tag{10}$$

This implies a good chance of finding a near-optimal set of centers corresponding to any outlier-removal k-clustering result in $\mathbb{C}$. The next step involves developing problem-specific methods to remove m outliers and partition the remaining points into k clusters based on the given center set, with the objective of minimizing the clustering cost (defined as the sum of the squared distances from the points to the corresponding centers) while satisfying the specified additional constraints. If we can remove the outliers and partition the points in an optimal way, then the guarantee of the center set given in inequality (10) suggests the achievement of a $(1 + \varepsilon)$-approximation solution.

5.1 The Algorithm for Capacitated k-MeansOut

Capacitated clustering is one of the most extensively studied generalizations of the standard clustering formulation, which imposes an upper-bound constraint on the size of each cluster. An Euclidean instance of capacitated k-MeansOut is specified by a set $\mathcal{P} \subset \mathbb{R}^d$ of n points, two positive integers k and m, and a *capacity* $u \geq 1$. A feasible solution to the instance selects a set $\mathcal{C} \subset \mathbb{R}^d$ of centers and a set $\mathcal{O} \subseteq \mathcal{P}$ of outliers, and assigns each point $p \in \mathcal{P} \backslash \mathcal{O}$ to a center $\varphi(p) \in \mathcal{C}$, such that $|\mathcal{C}| \leq k$, $|\mathcal{O}| \leq m$, and $|\varphi^{-1}(c)| \leq u$ for each $c \in \mathcal{C}$. The cost of such a solution is $\sum_{p \in \mathcal{P} \backslash \mathcal{O}} ||p - \varphi(p)||^2$. The goal of the problem is to find a feasible solution with minimum cost.

Motivated by the method for solving outlier-free constrained problems given in [16], we reduce the task of identifying outliers and assigning points for capacitated k-MeansOut to the well-known *minimum-cost circulation* problem [40], which can be defined as follows.

▶ **Definition 21** (minimum-cost circulation). *An instance of the minimum-cost circulation problem is specified by a directed graph $G(\mathcal{V}, \mathcal{A})$ with a set $\mathcal{V}$ of vertices and a set $\mathcal{A}$ of arcs, where each $(v, w) \in \mathcal{A}$ has a cost $\Delta(v, w) \geq 0$, a capacity $u(v, w) \geq 0$, and a demand $l(v, w) \in [0, u(v, w)]$. A feasible solution to the instance associates each $(v, w) \in \mathcal{A}$ with a flow $f(v, w) \in [l(v, w), u(v, w)]$ such that $\sum_{w:(v,w) \in \mathcal{A}} f(v, w) = \sum_{w:(w,v) \in \mathcal{A}} f(w, v)$ for each $v \in \mathcal{V}$. The cost of this solution is $\sum_{(v,w) \in \mathcal{A}} \Delta(v, w) f(v, w)$. The problem aims to find a feasible solution with minimum cost.*

Let $\mathcal{I} = (\mathcal{P}, k, m, u)$ be an Euclidean instance of capacitated k-MeansOut. As previously discussed, Algorithm 2 can construct a collection $\mathbb{C}$ of center sets, including a near-optimal one for $\mathcal{I}$, with high probability. For each $\mathcal{C} \in \mathbb{C}$, we construct an instance of minimum-cost circulation as follows.

- The vertex set $\mathcal{V}$ consists of the points in $\mathcal{P}$, the centers in $\mathcal{C}$, and three additional vertices v_1, v_2, and v_3.
- There is an arc $(v_3, v_1) \in \mathcal{A}$ with $\Delta(v_3, v_1) = 0$ and $u(v_3, v_1) = l(v_3, v_1) = |\mathcal{P}|$.
- For each $p \in \mathcal{P}$ and $c \in \mathcal{C}$, there is an arc $(p, c) \in \mathcal{A}$ with $\Delta(p, c) = ||p - c||^2$, $u(p, c) = 1$, and $l(p, c) = 0$. Here, $f(p, c) = 1$ signifies the assignment of point p to center c (i.e., $\varphi(c) = p$).
- For each $p \in \mathcal{P}$, there is an arc $(p, v_2) \in \mathcal{A}$ with $\Delta(p, v_2) = 0$, $u(p, v_2) = 1$, and $l(p, v_2) = 0$. A point p with $f(p, v_2) = 1$ is identified as an outlier. To ensure that the outliers are no more than m (more formally, $\sum_{p \in \mathcal{P}} f(p, v_2) \leq m$), we add to $\mathcal{A}$ an arc (v_2, v_3) with $\Delta(v_2, v_3) = 0$, $u(v_2, v_3) = m$, and $l(v_2, v_3) = 0$.
- To ensure that each $p \in \mathcal{P}$ is assigned to a center in $\mathcal{C}$ or identified as an outlier (i.e., $\sum_{c \in \mathcal{C} \cup \{v_2\}} f(p, c) = 1$), we add to $\mathcal{A}$ an arc (v_1, p) with $\Delta(v_1, p) = 0$ and $u(v_1, p) = l(v_1, p) = 1$.
- To satisfy the capacity constraint imposed on each $c \in \mathcal{C}$ (i.e., $\sum_{p \in \mathcal{P}} f(p, c) \leq u$), we add to $\mathcal{A}$ an arc (c, v_3) with $\Delta(c, v_3) = 0$, $u(c, v_3) = \lfloor u \rfloor$, and $l(c, v_3) = 0$.

Given that all the capacities and demands in the instance of minimum-cost circulation described above are integers, its optimal integral solutions can be found in $(nk)^{O(1)}$ time [40]. It can be seen that these solutions correspond to optimal ways of identifying outliers and assigning points for the given center set.

Let $(\mathcal{C}^*, \mathcal{O}^*, \varphi^*)$ be an optimal solution to $\mathcal{I}$, where $\mathcal{C}^* = \{c_1^*, \cdots, c_k^*\}$. For each $i \in [k]$, define $\mathcal{P}_i^* = \{p \in \mathcal{P} \backslash \mathcal{O}^* : \varphi^*(p) = c_i^*\}$. Inequality (10) implies that there is a center set $\mathcal{C} \in \mathbb{C}$ satisfying

$$\sum_{i=1}^{k} \min_{c \in \mathcal{C}} \Delta(\mathcal{P}_i^*, c) \leq (1 + \varepsilon) \sum_{i=1}^{k} \Delta(\mathcal{P}_i^*) = (1 + \varepsilon) \sum_{p \in \mathcal{P} \backslash \mathcal{O}^*} ||p - \varphi^*(p)||^2 \tag{11}$$

with constant probability. Based on an optimal integral solution to the instance of minimum-cost circulation corresponding to such a center set $\mathcal{C}$, we can construct a solution $(\mathcal{C}, \mathcal{O}, \varphi)$ to $\mathcal{I}$ satisfying

$$\sum_{p \in \mathcal{P} \backslash \mathcal{O}} ||p - \varphi(p)||^2 \leq \sum_{i=1}^{k} \min_{c \in \mathcal{C}} \Delta(\mathcal{P}_i^*, c). \tag{12}$$

Inequalities (11) and (12) imply that a $(1 + \varepsilon)$-approximation solution to $\mathcal{I}$ has been constructed. Recall that $\mathbb{C}$ is of size $n((k + m)\varepsilon^{-1})^{O(k\varepsilon^{-1})}$ and can be constructed in $nd((k + m)\varepsilon^{-1})^{O(k\varepsilon^{-1})}$ time (due to Lemma 9). Combining this with the fact that the instance of minimum-cost circulation corresponding to each center set in $\mathbb{C}$ can be solved in $(nk)^{O(1)}$ time, we know that constructing the $(1 + \varepsilon)$-approximation solution takes $n^{O(1)} d((k + m)\varepsilon^{-1})^{O(k\varepsilon^{-1})}$ time.

▶ **Theorem 22.** *Given a constant $\varepsilon \in (0, 1)$ and an Euclidean instance $(\mathcal{P}, k, m, u)$ of capacitated k-MeansOut satisfying $\mathcal{P} \subset \mathbb{R}^d$ and $|\mathcal{P}| = n$, there is a $(1 + \varepsilon)$-approximation algorithm running in $n^{O(1)} d((k + m)\varepsilon^{-1})^{O(k\varepsilon^{-1})}$ time.*

5.2 The Algorithm for Fair k-MeansOut

Motivated by applications related to fair data representation [5], fair clustering problems, which impose constraints on the proportions of each type of points within the clusters, have garnered significant attention. We consider the fair k-MeansOut problem defined in [13]. An instance of the problem is specified by a collection $\mathbb{P} = \{\mathcal{P}^1, \cdots, \mathcal{P}^\ell\}$ of ℓ disjoint sets of points in $\mathbb{R}^d$, a positive integer k, two fairness vectors $\vec{\alpha}, \vec{\beta} \in [0,1]^\ell$, and an outlier vector $\vec{m} \in \mathbb{N}^\ell$. A feasible solution to this instance selects a set $\mathcal{C} \subset \mathbb{R}^d$ of no more than k centers and a set $\mathcal{O} \subseteq \bigcup_{i=1}^{\ell} \mathcal{P}^i$ of outliers, and assigns each point $p \in \bigcup_{i=1}^{\ell} \mathcal{P}^i \backslash \mathcal{O}$ to a center $\varphi(p) \in \mathcal{C}$, such that $|\mathcal{P}^i \cap \varphi^{-1}(c)||\varphi^{-1}(c)|^{-1} \in [\alpha_i, \beta_i]$ and $|\mathcal{P}^i \cap \mathcal{O}| \leq m_i$ for each $i \in [\ell]$ and $c \in \mathcal{C}$. The cost of the solution is $\sum_{i=1}^{\ell} \sum_{p \in \mathcal{P}^i} ||p - \varphi(p)||^2$.

Similar to our previous strategy, we address the fair k-MeansOut problem based on a collection of center sets constructed by repeatedly invoking Algorithm 1. Unfortunately, identifying outliers and assigning points for a given set of centers in an optimal way within polynomial time is no longer feasible. Specifically, a reduction from the 3*D-matching* problem suggests that this task is NP-hard [5]. Using the mixed-integer linear programming-based algorithm given in [13], this task can be completed in an exponential time.

▶ **Lemma 23** ([13]). *Given a set $\mathcal{C} \subset \mathbb{R}^d$ of no more than k centers and an instance $\mathcal{I} = (\mathbb{P}, k, \vec{\alpha}, \vec{\beta}, \vec{m})$ of fair k-MeansOut satisfying $|\mathbb{P}| = \ell$, $\sum_{\mathcal{P} \in \mathbb{P}} |\mathcal{P}| = n$, $\sum_{i=1}^{\ell} m_i = m$, and $\mathcal{P} \subset \mathbb{R}^d$ for each $\mathcal{P} \in \mathbb{P}$, a feasible solution to $\mathcal{I}$ with minimum cost among the ones taking $\mathcal{C}$ as the center set can be constructed in $(k\ell)^{O(k\ell)} n^{O(1)} dL$ time, where L is the bit-size of $\mathcal{I}$.*

Using our sampling-based algorithm for constructing center sets (m is replaced with $\sum_{i=1}^{\ell} m_i$) and the algorithm for constructing solutions given in Lemma 23, we obtain the following approximation scheme for fair k-MeansOut.

▶ **Theorem 24.** *Given a constant $\varepsilon \in (0,1)$ and an instance $\mathcal{I} = (\mathbb{P}, k, \vec{\alpha}, \vec{\beta}, \vec{m})$ of fair k-MeansOut satisfying $|\mathbb{P}| = \ell$, $\sum_{\mathcal{P} \in \mathbb{P}} |\mathcal{P}| = n$, $\sum_{i=1}^{\ell} m_i = m$, and $\mathcal{P} \subset \mathbb{R}^d$ for each $\mathcal{P} \in \mathbb{P}$, there is a $(1+\varepsilon)$-approximation algorithm running in $n^{O(1)} d((k+m)\varepsilon^{-1})^{O(k\varepsilon^{-1})} (k\ell)^{O(k\ell)} L$ time, where L is the bit-size of $\mathcal{I}$.*

6 Conclusions

In this paper, we present $(1+\varepsilon)$-approximation algorithms with running times exponential in k for Euclidean k-MeansOut and constrained generalizations of the problem, including capacitated and fair k-MeansOut. For each considered problem, our proposed algorithm stands for the first PTAS for constant k.

Considering the APX-hardness of Euclidean k-MeansOut [3], it is unlikely to design a $(1+\varepsilon)$-approximation algorithm without exponential dependence on k in high dimensions. Nonetheless, exploring ways to improve the running time of our algorithm for Euclidean k-MeansOut remains an interesting direction for future research. Especially, one can see whether it is possible to develop a $(1+\varepsilon)$-approximation algorithm running in $(ndm)^{O(1)} f(k, \varepsilon)$ time for some positive function f.

Abstract

In the *all-pairs suffix-prefix* (APSP) problem [Gusfield et al., *Inf. Process. Lett.* 1992], we are given a dictionary R of r strings, $S_1, \dots, S_r$, of total length n, and we are asked to find the length $\mathsf{SPL}_{i,j}$ of the *longest* string that is both a suffix of S_i and a prefix of S_j, for all $i, j \in [1\mathinner{.\,.} r]$. APSP is a classic problem in string algorithms with applications in bioinformatics, especially in sequence assembly. Since $r = |R|$ is typically very large in real-world applications, considering all r^2 pairs of strings explicitly is prohibitive. This is when the data structure variant of APSP makes sense; in the same spirit as distance oracles computing shortest paths between any two vertices given online.

We show how to quickly locate *k-approximate matches* (under the Hamming or the edit distance) in R using a version of the k-errata tree [Cole et al., STOC 2004] that we introduce. Let $\mathsf{SPL}^k_{i,j}$ be the length of the longest suffix of S_i that is at distance at most k from a prefix of S_j. In particular, for any $k = \mathcal{O}(1)$, we show an $\mathcal{O}(n \log^k n)$-sized data structure to support the following queries:

- $\mathsf{One\text{-}to\text{-}One}^k(i, j)$: output $\mathsf{SPL}^k_{i,j}$ in $\mathcal{O}(\log^k n \log\log n)$ time.
- $\mathsf{Report}^k(i, d)$: output all $j \in [1\mathinner{.\,.} r]$, such that $\mathsf{SPL}^k_{i,j} \geq d$, in $\mathcal{O}(\log^k n(\log n/\log\log n + \mathsf{output}))$ time, where output denotes the size of the output.

In fact, our algorithms work for any value of k not just for $k = \mathcal{O}(1)$, but the formulas bounding the complexities get much more complicated for larger values of k.

1 Introduction

Given a dictionary R of r strings, $S_1, \dots, S_r$, of total length n, the *all-pairs suffix-prefix* (APSP) problem asks us to find, for each string S_i, $i \in [1\mathinner{.\,.} r]$, its longest suffix that is a prefix of string S_j, for all $j \neq i$, $j \in [1\mathinner{.\,.} r]$. APSP is a classic problem in string algorithms [18] with numerous applications in sequence assembly [18, 26, 31, 7, 10]. Gusfield et al. [19] presented

49th International Symposium on Mathematical Foundations of Computer Science (MFCS 2024).
Editors: Rastislav Královič and Antonín Kučera; Article No. 85; pp. 85:1–85:18

an algorithm running in the optimal $\mathcal{O}(n + r^2)$ time for solving APSP, assuming all strings in R are over an integer alphabet of size $\sigma = n^{\mathcal{O}(1)}$. Many other optimal algorithms exist for APSP aiming at a smaller memory footprint [27, 36, 24].

DNA sequences (fragments) read by sequencing machines are typically assembled by first computing the maximal overlap between every pair of sequences. The size r of dictionary R in this case is very large. In particular, r^2 usually dominates n, and thus the r^2 factor is the bottleneck both in the time and the space complexity of assembly applications. For instance, in typical benchmark datasets for genome assembly using short DNA fragments, r is in the order of 10^6 to 10^8 and n is in the order of 10^8 to 10^{10}. Hence r^2 dominates n significantly.

In [25], we initiated a study on several data structure variants of APSP. Let $\mathsf{SPL}_{i,j}$, for any $i, j \in [1\mathinner{.\,.} r]$, denote the length of the *longest* suffix of S_i that is a prefix of S_j. We proposed $\mathcal{O}(n)$-sized data structures to support the following queries:

- One-to-One(i, j): output $\mathsf{SPL}_{i,j}$ in $\mathcal{O}(\log \log r)$ time.
- Report(i, d): output all distinct $j \in [1\mathinner{.\,.} r]$ such that $\mathsf{SPL}_{i,j} \geq d$, for some $d \in \mathbb{N}$, in $\mathcal{O}(\log n/ \log \log n + \mathsf{output})$ time, where output denotes the size of the output.

We also proposed other $\mathcal{O}(n)$-sized data structures for answering One-to-All(i), Count(i, ℓ), and Top(i, K) queries efficiently (see [25] for the precise definitions of these queries).

This framework is interesting both from a practical and from a theoretical perspective. By being able to answer different types of such queries efficiently, practitioners may be able to design alternative algorithms that *avoid the r^2 factor* in their time or space complexity; see the recent work of Talera et al. [33], which investigates practical aspects of our framework. Furthermore, the underlying data structure problems are also appealing from a theoretical perspective: (i) they are analogous to *distance oracles* for networks [35, 28, 14, 13, 11, 17]; and (ii) they are special types of *internal pattern matching* data structures [21, 20, 2, 1, 12, 4].

In this work, we make the next natural yet *challenging* step, that is, extend the framework we introduced in [25] to support *k-approximate suffix-prefix* queries. Indeed, these are the most useful queries in real-world applications. Approximate variants of APSP, under the Hamming or edit distance, have been considered in the literature. Barton et al. [5] showed how to solve the problem for two strings ($r = 2$), under Hamming or edit distance k, in $\mathcal{O}(nk)$ time. Thankachan et al. [34] showed how to solve the problem in $\mathcal{O}((n+r^2) \log^k n)$ time under Hamming or edit distance k, for any r and $k = \mathcal{O}(1)$. Many other proposed methods aimed at practical efficiency and are thus based on filtering strategies [29, 37, 22]. They typically use a two-step approach: candidate regions are identified that potentially correspond to sought matches; and those candidates are checked to actually verify the desired matching condition. These approaches do not yield strong theoretical time bounds but they are very efficient in practice. In any case, none of the proposed methods addresses the data structure variant.

Problems Statements. Let us start with the following basic definition.

▶ **Definition 1.** *For any given set $R = \{S_1, \ldots, S_r\}$ of r strings, we define the* longest suffix-prefix of S_i and S_j with k-errors *as the longest suffix U_i of S_i that is at Hamming/edit distance at most k from some prefix V_j of S_j. We denote the length of U_i by $\mathsf{SPL}^k_{i,j}$.*

By fixing k *apriori*, we want to efficiently compute the values $\mathsf{SPL}^k_{i,j}$ for certain (S_i, S_j) pairs given in an online fashion. In particular, we consider the following queries:

- One-to-One$^k(i, j)$: output $\mathsf{SPL}^k_{i,j}$.
- Report$^k(i, d)$: output all distinct $j \in [1\mathinner{.\,.} r]$ such that $\mathsf{SPL}^k_{i,j} \geq d$, for some $d \in \mathbb{N}$.

The offline version (that is, the k-approximate variant of APSP), which we denote by APSP^k, is defined as follows: output $\mathsf{SPL}^k_{i,j}$, for all $1 \le i, j \le r$. Recall that APSP^k has already been solved by Thankachan et al. [34] in $\mathcal{O}((n + r^2)\log^k n)$ time for any $k = \mathcal{O}(1)$.

▶ **Observation 2.** *For Hamming distance we always have that $|U_i| = SPL^k_{i,j} = |V_i|$. However, for edit distance it does not need to be the case: we cannot always maximize the lengths of both suffix and prefix simultaneously. For $S_i = \mathtt{xx}\cdots\mathtt{xabcd}, S_j = \mathtt{bcdeyy}\cdots\mathtt{y}$, we have $SPL^1_{i,j} = 4$ as $\mathtt{abcd}$ is at edit distance 1 from $\mathtt{bcd}$, but $\mathtt{bcd}$ is at edit distance 1 from $\mathtt{bcde}$, and $\mathtt{abcd}$ is at edit distance 2 from $\mathtt{bcde}$. In this sense, edit distance is a bit more complicated.*

Results and Paper Organization. We assume the standard word-RAM model of computations with word size $w = \Omega(\log n)$, where n is the input size. We present our results below for any $k = \mathcal{O}(1)$; our algorithms work for any arbitrary value of k but the formulas bounding the complexities get much more complicated for larger values of k. For the exact time complexities we defer the reader to the actual theorem statements (Theorems 13 and 14).

Query	Space (words)	Query time	Note
$\mathsf{One\text{-}to\text{-}One}^k(i,j)$	$\mathcal{O}(n\log^k n)$	$\mathcal{O}(\log^k n \log\log n)$	Theorem 13
$\mathsf{Report}^k(i,d)$	$\mathcal{O}(n\log^k n)$	$\mathcal{O}(\log^k n(\log n/\log\log n + \mathsf{output}))$	Theorem 14

Let us introduce the central notion of *extension-prefix pair* for any two strings X and Y.

▶ **Definition 3.** *A pair of strings (Y, X) is an* extension-prefix pair*, if X is a prefix of Y; and hence Y is called an* extension *of X. A pair of strings (Y, X) is a* k-approximate extension-prefix pair*, if X is at (Hamming or edit) distance at most k from some prefix of Y.*

Section 2 introduces the necessary definitions and notation as well as a few observations. In Section 3, we introduce a version of the k-errata tree [15] and show its efficient construction as well as some of its properties that are crucial to arrive at our main results. Specifically in Section 3.1, we show the construction for edit distance, and then also state the changes for the (easier) case of the Hamming distance. In Section 3.2, we show the key combinatorial property of the extension-prefix pairs (Lemma 5) in our k-errata tree. Section 3.3 shows an upper bound on the size of the k-errata tree introduced here for the interesting case where $k = \mathcal{O}(\frac{\log n}{\log\log n})$, which is then used to bound the running time and space of the algorithms – we are not interested in $k = \omega(\frac{\log n}{\log\log n})$ as in this case we have $\text{poly}(n) = \mathcal{O}(\log^k n)$, and hence trivial algorithms become (at least) as efficient as our approach. Section 3.4 refines the combinatorial Lemma 5 to its algorithmic applications (Corollaries 10–12). For the sake of an application, consider that we have two dictionaries D_1 and D_2. We concentrate not only on pairs of strings which are at distance at most k, but globally, for any string $Y \in D_2$, we show how to compute its longest prefix which is at distance at most k from any other string $X \in D_1$, and further show how to compute the set of lengths of all such prefixes.

Finally, in Sections 4.1 and 4.2, we apply our techniques to construct the data structures for answering $\mathsf{One\text{-}to\text{-}One}^k$ and Report^k queries, respectively. Full detailed proofs omitted from the main text are included in Appendix A.

2 Preliminaries

We consider strings over an integer alphabet $\Sigma = [1\mathinner{.\,.}\sigma]$ of size σ. The elements of Σ are called *letters*. A *string* $X = X[1\mathinner{.\,.}n]$ is a sequence of letters from Σ; we denote by $|X| = n$ the *length* of X. The fragment $X[i\mathinner{.\,.}j]$ of X is an *occurrence* of the underlying *substring* $S = X[i]\cdots X[j]$ occurring at *position* i in X. A *prefix* of X is a substring of X of the form

$X[1\,.\,.\,j]$ and a *suffix* of X is a substring of X of the form $X[i\,.\,.\,n]$. The *reverse* of X is the string $X^R = X[n]\cdots X[1]$. By $\mathsf{LCP}(X,Y)$, we denote the length of the longest common prefix of strings X and Y. The *Hamming distance* of two equal-length strings is the number of positions where the strings differ. The *edit distance* (or *Levenshtein distance*) of two strings X and Y is the minimum number of edit operations required to transform X into Y. Here, by *edit operation* we mean an insertion, a substitution, or a deletion of a single letter. A set D of strings is called a *dictionary.*

The following edit-distance property (Lemma 4) underlies most string algorithms on edit distance; e.g., [23]. We provide a proof of this property in Appendix A for completeness.

▶ **Lemma 4.** *For any two strings X and Y, there exists a smallest sequence of edit operations changing X to Y satisfying recursively that the first operation occurs at position $\mathsf{LCP}(X,Y)+1$. By recursively, we mean that after applying the first operation on X to obtain X', the leftmost operation to get from X' to Y occurs at position $\mathsf{LCP}(X',Y)+1 \geq \mathsf{LCP}(X,Y)+1$.*

Let D be a dictionary of $n = |D|$ strings. A node in the trie of D is called *branching* if it has at least two children and *terminal* if it represents a string in D. The *compacted trie* T of D is obtained from the underlying trie by removing all nodes except the root node, the branching and the terminal nodes. The removed nodes are called *implicit* while the remaining ones are called *explicit.* Each terminal node corresponding to a string X from D is labeled with the identifier of X: a pointer to X in D. Edge labels are stored as pointers to fragments of strings in D and so the compacted trie takes $|T| = \mathcal{O}(n)$ extra space.

Our algorithms use a version of the famous k-errata tree of Cole et al. [15]. The tree nodes store information about strings and a representation of edit operations applied on them. In order to efficiently operate on those edit operations we define their representation here as an abstract structure and describe the operations that are performed on such structures later.

For convenience we represent multisets of edit operations by lists sorted non-decreasingly. A Hamming distance list consists of up to k elements, where every element is denoted by l_S, for $l \in [1\,.\,.\,n]$. An edit distance list consists of up to k elements, where every element is denoted by l_E for $l \in [1\,.\,.\,n]$, $E \in \{S, I, D\}$; elements are first sorted by l, then by $D < S < I$, and l_D elements may repeat (denoting that several letter deletions occur at the same position l). A single list does not contain both l_S and l_I, or multiple such elements, for the same l. By $|\ell|$ we denote the number of elements in list ℓ (counting the multiplicities). For any two lists ℓ_1, ℓ_2, by $\ell_1 \subseteq \ell_2$, we denote that every element of ℓ_1 appears in ℓ_2 and the multiplicity of any element in ℓ_1 does not exceed its multiplicity in ℓ_2. By $\ell_1 \cup \ell_2$ we denote the union of the two lists; for each element of ℓ_1 or ℓ_2 its multiplicity is equal to its maximum multiplicity in ℓ_1 and ℓ_2. By $\max^+(\ell)$ we denote the smallest element that can be inserted at the end of list ℓ without breaking the specified condition of the list being non-decreasing; that is, the maximum element of the list if this element may appear multiple times and the smallest larger element if the currently maximal element cannot appear multiple times ($\max^+(\ell) = l_D$ when the last element of ℓ is equal to $l_D, (l-1)_S$ or $(l-1)_I$, $\max^+(\emptyset) = 1_D$). By ℓ^d we denote the prefix of list ℓ containing only the elements l_E such that $l \leq d$, and by $\mathsf{surpl}(\ell)$ we denote the surplus of l_D operations over l_I operations in ℓ, that is $|\{l_D \in \ell\}| - |\{l_I \in \ell\}|$; i.e., by how many letters the length of the string decreases after applying the operations from ℓ.

3 Finding Approximate Extension-Prefix Pairs using the k-Errata Tree

For any dictionary D, extension-prefix pairs can be found by using a trie of D. Every such pair corresponds to a descendant-ancestor node pair in the trie. By using this property, all such pairs can be listed in the optimal time. In this section, we show that for *k-approximate* extension-prefix pairs, a similar property holds for a version of the k-errata tree of the trie of D. We start by showing the tree construction, then we show the counterpart of this property, and we end by showing how to use the tree for finding k-approximate extension-prefix pairs.

The Hamming distance can be treated as a special case of edit distance, where only substitution operations are allowed; we thus focus on the edit distance construction, and then comment on the differences that should be made to obtain the tree for Hamming distance. Let D be a dictionary of $n = |D|$ strings and T be the compacted trie of D. In the complexity analysis of our construction, we assume that $k \leq \frac{\log n}{2 \log \log n}$ [15]. (The construction itself and the combinatorial lemmas *do not assume any bound on* k.)

We compute the *heavy-light decomposition* of T in $\mathcal{O}(n)$ time [32]. Let $s(w)$ denote the number of node labels in the subtree of T rooted at w (these labels identify the full strings from D). We call an edge (u, v) of T *heavy* if $s(v)$ is maximal among every edge originating from u (breaking ties arbitrarily). All other edges are called *light*. We call a node that is reached from its parent through a heavy edge *heavy*; otherwise, it is called *light*. The heavy path of T is the path that starts at the root of T and at each node on the path descends to the heavy child as defined above. The heavy path decomposition is then defined recursively: it is a union of the heavy path of T and the heavy path decompositions of the off-path subtrees of the heavy path. The crucial well-known property of this decomposition is that every root to node path in T passes through $\mathcal{O}(\log n)$ light nodes. Our k-errata tree construction actually refers to the heavy-light decomposition of the uncompacted trie of D – in particular to the direct children of the branching nodes even if those are implicit. The decompositions of both the uncompacted and the compacted versions of T are in a bijection: a child of a branching node of the uncompacted version is light if and only if its closest explicit descendant is light in the compacted version. Therefore we refer to the nodes of the uncompacted version of T, and access all children of the branching nodes in time proportional to the size of its compacted version, obtaining the compacted version of the errata tree in the process.

3.1 The k-Errata Tree Construction

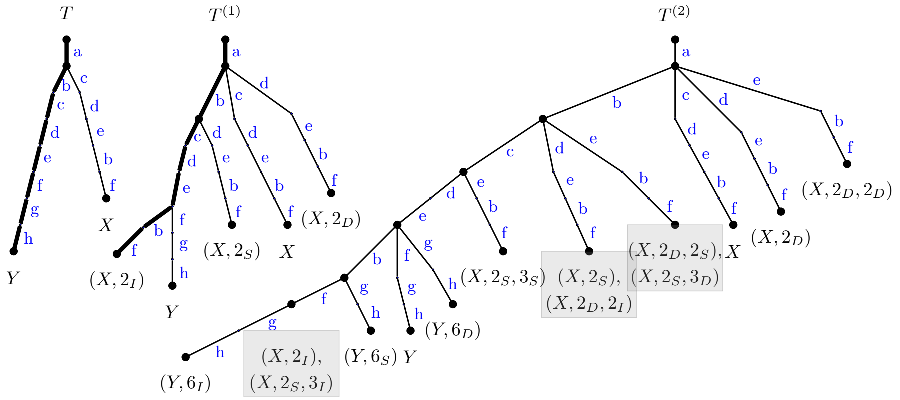

Figure 1 Example of an edit distance 1- and 2-errata tree for trie T of strings $\{Y = \texttt{abcdefgh}, X = \texttt{acdebf}\}$. The rectangles mark the nodes with multiple distinct labels. Notice that a node with label $(Y, 6_I)$ has an ancestor with two labels (X, ℓ), since $|\{2_I\} \cup \{6_I\}| \leq 2$, X is at edit distance at most 2 from some prefix of Y. Label $(X, 2_S, 3_I)$ does not provide such result as $|\{2_S, 3_I\} \cup \{6_I\}| = 3 > 2$.

We denote the k-*errata tree* of T by $T^{(k)}$ and construct it as a 1-errata of $T^{(k-1)}$, where $T^{(0)} = T$. Before constructing the 1-errata tree of T, we compute the heavy-light decomposition of T. For every *light node* v at string depth $l = d(v)$ in T that is reached from its parent through an edge labeled with $a \in \Sigma$, we create three copies of its subtree (inspect Figure 1):

- In one copy, corresponding to a substitution, we change the labels of the subtree nodes from X to (X, l_S) and merge it with the subtree of its heavy sibling.
- In one copy, corresponding to a deletion, we change the labels of the subtree nodes from X to (X, l_D) and merge it with the subtree of its parent.
- In one copy, corresponding to an insertion, we change the labels of the subtree nodes from X to (X, l_I) and merge it with the child of its heavy sibling reached through the edge labeled with letter a (or create such a child if it does not exist).

A node of 1-errata with label: (X, l_S) can be reached by replacing the l-th position of X by the heavy letter (the letter used to reach the heavy child from the node reached by spelling $X[1\mathinner{.\,.} l-1]$ in T); (X, l_D) can be reached by deleting the letter at the l-th position in X; and (X, l_I) can be reached by inserting that heavy letter before the l-th position of X. It should be clear that in the Hamming distance case only the first copy is required.

For convenience, we represent all the added parts of labels collectively with lists of edit operations (see Section 2). To keep the data structure simpler, we avoid introducing redundant labels that would later make proofs and implementations more complicated (in particular an insertion or deletion would change the positions of the edits to the right). Specifically, we produce a copy of a label (X, ℓ) only if the added element l_E is greater or equal to $\max^+(\ell)$. This means that the lists are sorted non-decreasingly. We do not miss any significant sequence of edit operations due to Lemma 4 as shown in the proof of Lemma 5.

Since we may possibly delete a few next letters from the same position (after removing a single letter the next one takes its position) we have to allow elements l_D to appear in a list multiple times. In case of insertions or substitutions this is not needed (and we can prioritize deletions over other operations as there is no reason to first modify a letter and then delete it), hence we do not allow two elements l_I or l_S (or l_I and l_S) for the same $l \in [1\mathinner{.\,.} n]$. As such, the order of elements l_E, $l \in [1\mathinner{.\,.} n], E \in \{S, D, I\}$, is defined by first comparing l, and then $D < S < I$, thus the definition of $\max^+(\ell)$ (see Section 2).

In our construction of trie T, unlike the one used in the classic construction [15] where D is made prefix-free, two terminal nodes can lie on the same heavy path (for an extension-prefix pair (Y, X) for $X, Y \in D$ the node representing X may in fact be an internal labeled node that lies on a heavy path). This does not allow for checking if Y is a k-approximate prefix of X in the same way since it is already an extension of X (in case of edit distance one can always check if the difference of lengths is at most k, and in case of Hamming distance simply respond negatively if $|X| < |Y|$); for example, when $D = \{X = \texttt{abc}, Y = \texttt{abcde}\}$, $T^{(2)} = T$, there is a single heavy path since T has no light nodes. To mitigate this problem and still have the nice properties of our construction (ancestor-descendant relations of the labeled nodes), for a labeled node u with label (X, ℓ) that has (non-trivial) descendants, we also create a copy with label $(X, \ell \cup (d(u)+1)_I)$ and add it to its heavy child (insertion after the last position of X). Substitution and deletion after the end of a string clearly do not make sense, thus an insertion operation is the only one allowed. This change does not influence our bounds on the k-errata tree size as the total size of all such subtrees is the number of the labeled nodes; we change this from $\mathcal{O}(|T| \log^k |T|)$ to $\mathcal{O}(|T|(\log |T| + 1)^k)$.

We remark, that our structure differs substantially from the original k-errata from [15]. In particular, we do not use extra letters outside of the alphabet to mark the edges transitioning from the original tree to a copied part, and instead actually merge the nodes corresponding to the same string. Thanks to this change we do not need to use the extra copies called group trees, which makes the search algorithm simpler in the case of our structure (the first place where the search can diverge from the heavy path is the place where the pattern actually diverges from the heavy path) and running in asymptotically the same time (up to an $f(k)$

factor for some f and $k = \mathcal{O}(\frac{\log n}{\log \log n})$). We do not describe the algorithm in detail however, since in this paper we are only interested in internal queries (the data structure is constructed for the fixed dictionary D and no other string is ever queried). All those simplifications pose the cost of dealing with the lists of edit operations, which are not present in the data structure from [15], but we show how to do that efficiently in the remainder of this section.

3.2 Extension-Prefix Pairs in a k-Errata Tree

We now prove the key combinatorial property of the described k-errata tree of dictionary D.

▶ **Lemma 5.** *For any two elements $X, Y \in D$, X is at edit (resp. Hamming) distance at most k from some prefix of Y if and only if there exist two nodes, u and its descendant v, in $T^{(k)}$ with labels (X, ℓ_1) and (Y, ℓ_2) respectively, such that $|\ell_1 \cup \ell_2| \leq k$, where $T^{(k)}$ is the edit (resp. Hamming) distance k-errata tree of D.*

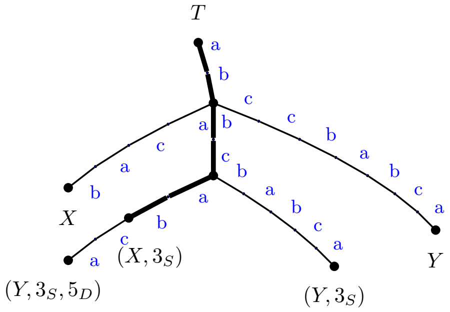

Figure 2 Illustration of a part of the edit distance 2-errata tree T for dictionary D containing $X =$ `abacab` and $Y =$ `abccbabca` with the choice of heavy paths depicted with thicker lines. X is at edit distance 2 from $Y' =$ `abccbab`, which is a prefix of Y; the operations used to transform X into Y' are *substitution* at position 3 and *insertion* at position 5. The lowest common ancestor of nodes with labels X and Y is at string depth 2 (`ab`); as shown in the proof of Lemma 5 there exists a child of this node that is a common ancestor of nodes with labels (X, ℓ'_1) and (Y, ℓ'_2) such that $\ell'_1 \cup \ell'_2 = \{3_S\}$, and a descendant of this child with label (X, ℓ_1) that is an ancestor of a node with label (Y, ℓ_2), such that $|\ell_1 \cup \ell_2| = 2$. Conversely, since there exists such an ancestor-descendant pair of nodes one can compute the list of at most 2 edit operations that transform X into Y'.

Sketch of Proof. The proof of the forward implication follows a path down the k-errata tree – one starts with empty lists ℓ_1 and ℓ_2. Each time an edit operation is applied to X one adds an element to ℓ_1 or ℓ_2 or both (depending on the edit operation and the location of the heavy child) and finds a descendant of the current node that is a common ancestor of nodes with labels (X, ℓ_1) and (Y, ℓ_2). The backward implication can be obtained by reversing that approach and producing a list of at most k edit operations that transform X into a prefix of Y (see Appendix A for the full proof and Figure 2 for an example of the construction). ◀

The full proof shows that, if a prefix Y' of Y is at distance at most k from X, then there exists a pair of nodes u and v with labels (X, ℓ_1) and (Y, ℓ_2), respectively, in an ancestor-descendant relationship, such that $f(d(u)) - k + |\ell_1 \cup \ell_2| \leq |Y'| \leq f(d(u))$, where $f(l) = l + \mathsf{surpl}(\ell_2^l)$ is the actual length of the prefix of Y represented by the ancestor of v at depth l. In particular, the longest prefix is represented by either such a pair for $u = v$ (the whole Y is at edit distance at most k from X), or a pair where $|\ell_1 \cup \ell_2| = k$, and hence $\ell_2 = \ell_2^{d(u)}$.

This property and the monotonicity of $f(l)$ for a single label (Y, ℓ_2) of node v imply that to find the longest prefix of Y at distance at most k from X it is enough to focus on the lowest ancestor u of v with label (X, ℓ_1) such that $|\ell_1 \cup \ell_2| \leq k$. In fact, if $\ell_2 \neq \ell_2^{d(u)}$, then both $u \neq v$ and $|\ell_1 \cup \ell_2^{d(u)}| < |\ell_1 \cup \ell_2| \leq k$, hence there must exist a pair u', v' with labels (X, ℓ'_1) and (Y, ℓ'_2) respectively, for which $d(u') + \mathsf{surpl}(\ell_2'^{d(u')}) > d(u) + \mathsf{surpl}(\ell_2^{d(u)})$ (we can extend the prefix Y' by inserting the next letter of Y after its last position), hence we get the following corollary. (The algorithm can easily use $\ell_2^{d(u)}$ for the comparison between different ℓ_2, but it is neater this way.)

▶ **Corollary 6.** *The length of the longest prefix of Y that is at edit distance at most k from X is equal to the maximum over all node pairs (u, v) of value $d(u) + \mathsf{surpl}(\ell_2)$, where u has label (X, ℓ_1), v has label (Y, ℓ_2), u is a (potentially trivial) ancestor of v, and $|\ell_1 \cup \ell_2| \leq k$.*

This is also the case for the Hamming distance but then $\mathsf{surpl}(\ell_2) = 0$.

When we are interested not only in the longest prefix of Y at edit distance at most k from X, but in the set of all the prefixes with this property, it is enough to compute the union of the intervals $d(u) + \mathsf{surpl}(\ell_2) + [-k + |\ell_1 \cup \ell_2| \mathinner{..} 0]$ over all such pairs u and v.

▶ **Corollary 7.** *The set of lengths of prefixes of Y that are at edit distance at most k from X is equal to the union of intervals $d(u) + \mathsf{surpl}(\ell_2) + [-k + |\ell_1 \cup \ell_2| \mathinner{..} 0]$ over all node pairs (u, v), where u has label (X, ℓ_1), v has label (Y, ℓ_2), u is a (potentially trivial) ancestor of v, and $|\ell_1 \cup \ell_2| \leq k$.*

For Hamming distance the same property is simpler as the intervals are singletons $\{d(u)\}$.

3.3 Size of the k-Errata Tree

For completeness of the k-errata tree construction, we show a bound on the size of the data structure for a compacted trie T with at most n explicit nodes and n distinct node labels. We assume $k \leq \frac{\log n}{2 \log \log n}$ (for all further complexity considerations), but the properties and the correctness of the algorithms shown further do not require this assumption on k. For such a value of k, the size of our data structure is asymptotically the same as of the k-errata tree from [15] up to an $f(k)$ factor (the bound is not necessarily tight – optimizing the $f(k)$ value is not a focus of this paper). The proof of Lemma 8 can be found in Appendix A.

▶ **Lemma 8.** *For any compacted trie T with at most n explicit nodes and n distinct node labels, and for any $k \leq \frac{\log n}{2 \log \log n}$, the k-errata tree $T^{(k)}$ has $\mathcal{O}(nk!(c_\delta \log n)^k)$ explicit nodes and labels, where $c_\delta = 1$ for Hamming distance and $c_\delta = 3$ for edit distance.*

In particular, a single node label of T has $\mathcal{O}(k!(c_\delta \log n)^k)$ copies in $T^{(k)}$.

▶ **Corollary 9.** *For any $k \leq \frac{\log n}{2 \log \log n}$, we have $\log |T^{(k)}| = \mathcal{O}(k \log n)$.*

In what follows, we give the complexity of our algorithms including the proven bound on the $f(k)$ factor, and additionally the formulas in the most interesting case $k = \mathcal{O}(1)$.

3.4 Finding Approximate Prefixes

In Section 3.2, we were interested in a single extension-prefix pair (Y, X), such that $X, Y \in D$. Here, say that we are given two subdictionaries D_1 and D_2 such that $D_1, D_2 \subseteq D$, and want to find for every element of D_2 its longest prefix that is at distance at most k from some element of D_1 using Corollary 6, or the lengths of all such prefixes using Corollary 7. Let $n = |D|, n_1 = |D_1|, n_2 = |D_2|$, and let m be the length of the longest string in D.

By running a DFS on $T^{(k)}$ and storing the labels from all the ancestors of a given node labeled (Y, ℓ_2), $Y \in D_2$, we can find all the pairs where this node is the descendant. We need, however, to take care of the lists of edit operations: for the label (Y, ℓ_2), we have to look for the elements (X, ℓ_1), $X \in D_1$, stored in the set of ancestor labels, such that $|\ell_1 \cup \ell_2| \leq k$. We do not want to check all the elements from this set separately however (potentially there are $\Omega(n)$ such elements). We can group the elements based on their lists ℓ_1; still for a single ℓ_2 there can be $\binom{m}{k}$ such fitting lists ℓ_1 for Hamming distance (and even more for edit distance).

Corollary 6 tells us that as long as $|\ell_1 \cup \ell_2| \leq k$ it does not matter what is the content of ℓ_1, nor what is the X in the label as long as $X \in D_1$. In order to avoid looking for each list ℓ_1 separately, we can store the elements (string depths of nodes with labels (X, ℓ_1) for any $X \in D_1$ and ℓ_1) grouped by the size of ℓ_1 and its intersection with every possible ℓ_2.

More formally we can store the information about the ancestors of the current node of the DFS traversal in stacks indexed with pairs (ℓ, x), where ℓ is a valid list of elements and $x \in [0\,..\,k - |\ell|]$. For a single label (X, ℓ_1) of node u we store $d(u)$ in stacks (ℓ, x), such that $\ell \subseteq \ell_1, |\ell_1| - |\ell| \leq x \leq k - |\ell|$ (ℓ_1 contains all elements of ℓ plus at most x other elements) upon reaching u (and remove it when returning to its parent). Since a list can have up to k elements, every single label (X, ℓ_1) is responsible for $2^{|\ell_1|} \cdot (k - |\ell_1| + 1) \leq 2^k(k+1)$ elements in stacks, hence in total the DFS traversal will perform $\mathcal{O}(2^k(k+1) \cdot |T^{(k)}|) = \mathcal{O}(n(k+1)!(2 \cdot c_\delta \log n)^k)$ operations on stacks. Notice that we use a sparse representation (hash table) to store only the non-empty stacks explicitly – the universe of all possible stacks is of size at least m^k. We can access a stack in $\mathcal{O}(1)$ worst-case time by using perfect hashing [8].

Now, for a single label (Y, ℓ_2) of a node v, $Y \in D_2$, to find the deepest node u with label (X, ℓ_1) over all $X \in D_1$, such that $|\ell_1 \cup \ell_2| \leq k$, one only needs to take the maximum of the top elements over at most $2^{|\ell_2|} = \mathcal{O}(2^k)$ stacks $(\ell, k - |\ell_2|)$ for $\ell \subseteq \ell_2$. Through the whole DFS, we need to perform a total of $\mathcal{O}(n_2 \cdot 2^k k!(c_\delta \log n)^k)$ such operations for all $Y \in D_2$ as there are $\mathcal{O}(k!(c_\delta \log n)^k)$ copies of label Y in $T^{(k)}$ by Lemma 8.

▶ **Corollary 10.** *For any two dictionaries D_1 and D_2 such that $D_1, D_2 \subseteq D$, we can find the longest prefix of Y, for every $Y \in D_2$ at (Hamming or edit) distance at most k from some string $X \in D_1$, in $\mathcal{O}(n(k+1)!(2 \cdot c_\delta \log n)^k)$ total time; for any $k = \mathcal{O}(1)$, this is $\mathcal{O}(n \log^k n)$.*

If we rather want to find the list of *all* the prefixes of Y which are at distance at most k from any $X \in D_1$, we need to look through the whole stacks, not only at the top elements, and also pay attention to the size of $\ell_1 \cup \ell_2$, for labels (Y, ℓ_2).

For a single label (Y, ℓ_2) of a node v, if a node u with label (X, ℓ_1), such that $|\ell_1 \cup \ell_2| = x \leq k$, is an ancestor of v, then upon visiting v, $d(u)$ will be stored on stack (ℓ, y), where $\ell = \ell_1 \cap \ell_2$, and $y = |\ell_1| - |\ell| = |\ell_1 \cup \ell_2| - |\ell_2|$ (as $|\ell_1 \cup \ell_2| = |\ell_1| + |\ell_2| - |\ell|$). For such an element on the stack, we produce an interval $d(u) + \mathsf{surpl}(\ell_2) + [-k + |\ell_1 \cup \ell_2|\,..\,0] = d(u) + \mathsf{surpl}(\ell_2) + [-k + y + |\ell_2|\,..\,0]$ of lengths of prefixes of Y that are at edit distance at most k from X (by Corollary 7), or simply a length $d(u)$ of a prefix of Y at Hamming distance at most k from X.

The element (X, ℓ_1) can be also represented on other stacks (ℓ', y') for $\ell' \subseteq \ell_1 \cap \ell_2$ and $y' \geq |\ell_1| - |\ell'|$, but then $y' + |\ell_2| \geq |\ell_1| + |\ell_2| - |\ell'| \geq |\ell_1| + |\ell_2| - |\ell| = |\ell_1 \cup \ell_2| = y + |\ell_2|$; hence the interval generated this way is a subset of the interval represented by (ℓ, y) and thus does not change the union of such intervals (still we do not know what is the right ℓ or y, so we need to check all valid pairs).

This way we can compute the union of those at most $m \cdot 2^k(k+1)$ elements of stacks for Hamming distance or of at most $(m+k) \cdot 2^k(k+1)$ intervals for edit distance for a single label (Y, ℓ_2) of node v in time proportional to those values (in case of edit distance using the sweep line technique).

▶ **Corollary 11.** *For any two dictionaries D_1 and D_2 such that $D_1, D_2 \subseteq D$, we can find the lengths of all the prefixes of Y at (Hamming or edit) distance at most k from some string $X \in D_1$ for every $Y \in D_2$ in $\mathcal{O}((n + n_2(m+k))(k+1)!(2 \cdot c_\delta \log n)^k)$ total time; for any $k = \mathcal{O}(1)$, this is $\mathcal{O}((n + n_2 m)\log^k n)$, where m is the length of the longest string in D.*

If the focus of the output is oriented towards D_1 instead (we want to know what strings from D_1 are at distance at most k from some prefix of a string in D_2), then we can store in the stacks for each label (X, ℓ_1) the identifier of X instead. In this case if we run a DFS, and for each label (Y, ℓ_2) we collect the union of sets represented by the stacks (ℓ, y), then the union of those results over all $Y \in D_2$ and all ℓ_2 would be equal to exactly the elements of D_1 at distance at most k from some prefix of some $Y \in D_2$.

To avoid handling unnecessary duplicates of strings X for a single (ℓ, y) (with different lists $\ell_1 \supseteq \ell$ and $\ell_1' \supseteq \ell$), or for many different Y, instead of stacks, we store the information in a multiset data structure: a hash table storing as keys the elements of D_1 and as satellite data the multiplicity of every element. When an element $X \in D_1$ is read (and hence also returned), we delete it from every hash table and store it separately, so that it is never added again. The removal of those copies from every multiset is easy since we additionally store pointers to all of them partitioned by the elements of D_1. For the label (Y, ℓ_2), when reading this multiset, we iterate over the elements in the hash table in time proportional to their number (the deleted elements are stored separately). We implement multisets as dynamic perfect hash tables with $\mathcal{O}(1)$-time worst-case operations [8].

▶ **Corollary 12.** *For any two dictionaries D_1 and D_2 such that $D_1, D_2 \subseteq D$, we can find all the elements of D_1 at (Hamming or edit) distance at most k from a prefix of some $Y \in D_2$ in $\mathcal{O}(n(k+1)!(2 \cdot c_\delta \log n)^k)$ total time; for any $k = \mathcal{O}(1)$, this is $\mathcal{O}(n \log^k n)$.*

4 Application to Approximate Suffix-Prefix Dictionary Queries

Recall that we are given a dictionary $R = \{S_1, \ldots, S_r\}$ of r strings whose total length is n, and we want to find, for a given set of pairs i, j, the value $\mathsf{SPL}^k_{i,j}$ equal to the length of the longest suffix of S_i that is at (Hamming or edit) distance at most k from some prefix of S_j.

We focus on finding the longest prefix of S_j that is at distance at most k from some suffix of S_i, as our k-errata structures are more focused on the prefix lengths than suffix lengths; by Observation 2, those values are not necessarily maximized simultaneously in the edit distance case. Still the two problems reduce to one another by reversing all the strings in R. Henceforth, $\mathsf{SPL}^k_{i,j}$ denotes the length of the longest prefix of S_j that is at (Hamming or edit) distance at most k from some suffix of S_i.

In preprocessing, we construct the generalized suffix tree ST_R of R (without the commonly used $\$ \notin \Sigma$ separators) [16]: ST_R is the compacted trie of the suffixes of all strings in R. A node u in ST_R is labeled by i if and only if u represents a suffix of string S_i from R. Provided that we are given an integer $k > 0$, we also construct the k-errata tree $ST_R^{(k)}$ of ST_R. We also distinguish the labels corresponding to the full strings S_i (and not their non-trivial suffixes) – we mark all their copies and store links to them for $\mathcal{O}(1)$-time access.

4.1 Approximate One-to-One Queries

We first describe the full data structure for answering $\mathsf{One\text{-}to\text{-}One}^k$ queries; then we give the querying algorithm; and, finally, we analyze the data structure size and the query time. Recall that $\mathsf{One\text{-}to\text{-}One}^k(i, j)$ returns $\mathsf{SPL}^k_{i,j}$, for two $i, j \in [1\,..\,r]$.

Data Structure. After preprocessing $ST_R^{(k)}$, we construct the data structure for answering $\mathsf{One\text{-}to\text{-}One}^k$ queries. It consists of $\mathcal{O}((k+1)2^k)$ trees, in total, of three types:

- the main tree $ST_R^{(k)}$;
- trees $ST_{i,\ell}$, which contain nodes of $ST_R^{(k)}$ with labels (i,ℓ_1), such that $\ell \subseteq \ell_1$, for $i \in [1\mathinner{.\,.} r]$;
- trees $ST_{i,\ell,x}$, for $x \in [0\mathinner{.\,.} k-|\ell|]$, which contain nodes with labels (i,ℓ_1), such that $\ell \subseteq \ell_1$ and $x \geq |\ell_1| - |\ell|$.

Note that $|\ell| \leq k$ and that we do not actually construct the empty trees (i.e., trees that contain no labels in the instance of the problem). Even though $ST_{i,\emptyset}$ is basically the counterpart of the tree ST_i from the One-to-One without errors solution [25], it is not necessarily equal to the k-errata tree of the suffix tree of S_i, since the heavy-light decomposition of ST_i and of the generalized suffix tree (and hence the errata trees) may differ. That is, to obtain a smaller tree, we make a copy of a larger tree, remove the labels that do not fit, remove the nodes that do not have any labels in their subtree, and finally compactify the tree.

The trees of the first two types are enhanced with rank-select (RS) [6] and lowest common ancestor (LCA) data structures [9]; the trees of the third type are enhanced with a weighted ancestor (WA) data structure [3] plus a pointer from each node to its closest ancestor with a label. (The latter information can be trivially computed by using a DFS tree traversal.)

While the LCA and WA data structures are by default defined on (rooted) trees, we need to specify how the RS data structures are defined on trees (as they are usually defined on arrays). In our case, the RS data structures span over all the node labels (in one of the constructions a single label will actually be given a few next positions). In particular, the positions are first ordered by the position of the node (left to right DFS first visit order), and next its labels (i,ℓ) are ordered lexicographically. In case of $ST_R^{(k)}$, the RS data structure is over the alphabet $[1\mathinner{.\,.} r]$, where the letter representing the node label (i,ℓ) is i. Each label of $ST_R^{(k)}$ is linked with its counterpart from $ST_{i,\emptyset}$. The tree $ST_{i,\ell}$ is connected to trees $ST_{i,\ell\cup\{l_E\}}$, where $l_E \geq \max^+(\ell)$ and trees $ST_{i,\ell,x}$, where $x \leq k-|\ell|$, and hence it contains two separate RS data structures. The first one is over the alphabet of valid elements: $[\max^+(\ell)\mathinner{.\,.} n_S]$ for Hamming distance; $[\max^+(\ell)\mathinner{.\,.}(n+k)_I]$ for edit distance. Each label (i,ℓ_1) is given a position for every element $l_E \in \ell_1$ greater or equal to $\max^+(\ell)$ and this element l_E is its representative. This position in the RS array is linked with the corresponding terminal node of tree $ST_{i,\ell\cup\{l_E\}}$. The second one is over alphabet $[0\mathinner{.\,.} k-|\ell|]$. Each node label (i,ℓ_1) is given $k-|\ell_1|+1$ positions that contain values $x \in [|\ell_1|-|\ell|\mathinner{.\,.} k-|\ell|]$. Each such position is connected to the corresponding node label of the tree $ST_{i,\ell,x}$.

Querying. We want to find $\mathsf{SPL}_{i,j}^k$, i.e., the longest prefix of S_j that is at (Hamming or edit) distance at most k from some suffix of S_i (if we store some additional information with the labels we can also find the length of this suffix). By Lemma 8, S_j corresponds to $\mathcal{O}(k!(c_\delta \log n)^k)$ different node labels (j,ℓ_2) in $ST_R^{(k)}$; we will consider each such label independently, and then choose the optimal result.

For a single node v with label (j,ℓ_2), we want to find its lowest ancestor with label (i,ℓ_1) such that $|\ell_1 \cup \ell_2| \leq k$. We know that the ancestor is contained in one of the trees $ST_{i,\ell,k-|\ell_2|}$ for some $\ell \subseteq \ell_2$. If we know a node v' with a label that is stored in that tree, and is the closest to v in the DFS order of $ST_R^{(k)}$ (they have the deepest LCA among all such nodes v'), then we know that any ancestor of v that belongs to $ST_{i,\ell,k-|\ell_2|}$ is also an ancestor of v', and that every ancestor of v' at depth at most $\mathsf{LCA}(v,v')$ is also an ancestor of v. Thus for knowing the location of v' in $ST_{i,\ell,k-|\ell_2|}$ and the value of $\mathsf{LCA}(v,v')$, it suffices to ask a WA query in $ST_{i,\ell,k-|\ell_2|}$ for node v' and depth $\mathsf{LCA}(v,v')$ and then ask for the lowest ancestor of the node with a label (this information is stored in the node as a pointer) - the answer is

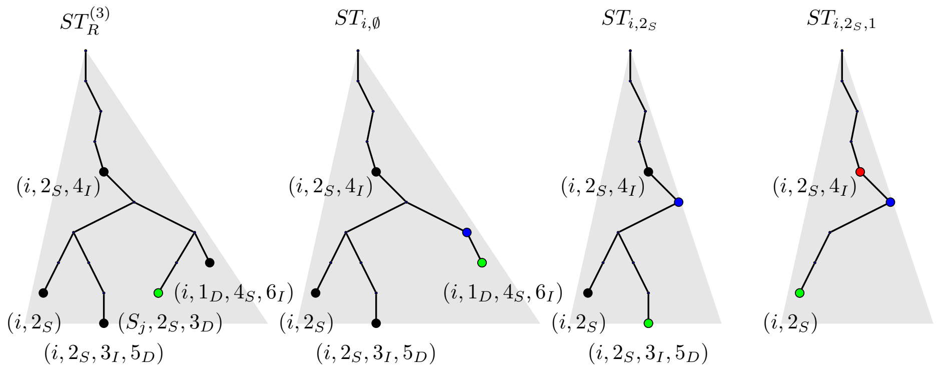

Figure 3 An example traversal through the trees to reach the lowest ancestor (i,ℓ_1) of label $(S_j,2_S,3_D)$, such that $2_S \in \ell_1$ and $|\ell_1 \cup \{2_S,3_D\}| \leq 3$. The green node depicts the label that is closest to $(S_j,2_S,3_D)$ in $ST_R^{(3)}$, out of the ones existing in the tree, while the blue one depicts the lowest common ancestor of the two nodes (equal to green in $ST_R^{(3)}$). The next green node is obtained via a rank-select query, while the blue nodes depth is obtained via an LCA query. After reaching a terminating tree, we ask for the depth of the lowest ancestor of the blue node that contains a label.

the sought ancestor of v. To obtain the location of v' and the value of $\mathsf{LCA}(v,v')$, we jump through the trees in between, always storing the two pieces of information: the labeled node v'' closest to v that appears in the tree; and the value $\mathsf{LCA}(v,v'')$.

In $ST_R^{(k)}$ we want to find the closest label (i,ℓ_1) for any ℓ_1; we simply ask an RS query to find the closest such node to the left and to the right of v. We compare those two nodes by the string depth of their LCA with v, choose the one for which this depth is larger (breaking ties arbitrarily), and then we proceed to the node with this label in $ST_{i,\emptyset}$.

Now, in tree $ST_{i,\ell}$, for $\ell \subseteq \ell_2$, we start with the labeled node v' closest to v in $ST_R^{(r)}$, and the string depth of their LCA. For each element $l_E \in \ell_2$, such that $l_E \geq \max^+(\ell)$, we find the closest node with label (i,ℓ_3) such that $\ell \cup \{l_E\} \subseteq \ell_3$ in $ST_{i,\ell}$ by asking the RS data structure (the one over $[\max^+(\ell)\,..\,(n+k)_I]$) for l_E – both left and right. We compare those two nodes based on the LCA string depth with v' to get the node v'', then compute $\mathsf{LCA}(v,v'') = \min\{\mathsf{LCA}(v,v'),\mathsf{LCA}(v',v'')\}$, and jump to the corresponding terminal node of $ST_{i,\ell\cup\{l_E\}}$ with the new LCA value. Additionally we ask the other RS data structure for the closest label represented by $k-|\ell_2|$, and jump to the labeled node of $ST_{i,\ell,k-|\ell_2|}$. There we find its lowest ancestor at depth at most the value of stored LCA string depth, and ask this ancestor for the string depth of its lowest ancestor storing a label. If this value is larger than the value of the currently stored candidate, we replace the candidate with the new one.

After the whole recursive procedure ends for each labeled node v corresponding to the full string S_j, the stored candidate is the final answer. Inspect Figure 3, for an example.

Data Structure Size. Each node of $ST_R^{(k)}$ belongs to $\mathcal{O}((k+1)\cdot 2^k)$ different trees. In total, the trees have size $N = \mathcal{O}(n(k+1)!(2c_\delta \log n)^k)$. The RS [6], LCA [9], and WA [3] data structures occupy $\mathcal{O}(N)$ space and can be constructed in $\mathcal{O}(N \log\log N)$ time.

Query Time. We have $\mathcal{O}(k!(c_\delta \log n)^k)$ node labels (S_j,ℓ_2) for a full string S_j. For each of those we reach at most 2^k further trees. Each operation of reaching the next tree (from the previous one) costs a constant number of RS, LCA and WA queries – that is, the cost of reaching each tree is $\mathcal{O}(\log\log n)$; hence the total cost is $\mathcal{O}((2c_\delta \log n)^k \log\log n)$. In particular, the RS [6] and WA [3] queries take $\mathcal{O}(\log\log n)$ time when $\mathcal{O}(n)$ space is used.

▶ **Theorem 13.** *For any dictionary of strings of total length n and any $k \leq \frac{\log n}{2\log\log n}$, we can construct a data structure of $\mathcal{O}(n(k+1)!(2c_\delta \log n)^k)$ words of space answering* $\mathsf{One\text{-}to\text{-}One}^k$ *queries in $\mathcal{O}((k+1)!(2c_\delta \log n)^k \log\log n)$ time. The data structure can be constructed in $\mathcal{O}(n(k+1)!(2c_\delta \log n)^k \log\log n)$ time.*

For any $k = \mathcal{O}(1)$, the data structure size is $\mathcal{O}(n \log^k n)$, the query time is $\mathcal{O}(\log^k n \log\log n)$ and the construction time is $\mathcal{O}(n \log^k n \log\log n)$.

4.2 Approximate Report Queries

Once again we use an inverted version of the problem that is equivalent to the original one; i.e., we want to answer $\mathsf{Report}^k(j,d)$ queries that return all the values of $i \in [1\,..\,r]$ such that there exits a prefix of S_j at distance at most k from some suffix of S_i of length at least d. Recall that by Observation 2, for edit distance, this is not necessarily equivalent to finding all j such there exists a prefix of S_j of length at least d at distance at most k from some suffix of S_i – this can be done using the idea of Corollary 12 within the same time complexity.

By Corollary 6, to find whether a prefix of length at least d of S_j is at distance at most k from a suffix of S_i, it suffices to check, for every label (j,ℓ_2) of a node v representing the full string S_j, if it has an ancestor u with label (i,ℓ_1), such that $|\ell_1 \cup \ell_2| \leq k$ and $d(u) \geq d - \mathsf{surpl}(\ell_2)$. We first describe the data structure for answering Report^k queries and analyze its size; then we give the querying algorithm and analyze the query time.

Data Structure. We start by constructing $ST_R^{(k)}$. For each pair (ℓ, x), such that $x \leq k - |\ell|$ and there exists a label with list ℓ in $ST_R^{(k)}$, we create a linear-space 2D rectangle stabbing data structure [30]. For every node u with label (i,ℓ_1), we create a rectangle $[L(u)\,..\,R(u)] \times [0\,..\,d(u)]$ with label i, where $L(u)$ and $R(u)$ are the numbers of the leftmost and the rightmost label in the subtree of u in $ST_R^{(k)}$ when ordered in the left-to-right DFS traversal order, and insert it to data structures (ℓ, x) for each $\ell \subseteq \ell_1$ and $|\ell_1| - |\ell| \leq x \leq k - |\ell|$. Next in every structure we make the rectangles of the same type disjoint.

We have in total $|ST_R^{(k)}| = \mathcal{O}(nk!(c_\delta \log n)^k)$ labels, hence the total number of rectangles in all the data structures is $|ST_R^{(k)}| \cdot (k+1)2^k = \mathcal{O}(n(k+1)!(2c_\delta \log n)^k)$, and the dimensions of the rectangles are in $[0\,..\,|ST_R^{(k)}|] \times [0\,..\,n]$. Hence the total size is $\mathcal{O}(n(k+1)!(2c_\delta \log n)^k)$.

Querying. For each label (j,ℓ_2) of a node v representing the full string S_j, and for each $\ell \subseteq \ell_2$, we ask a query $(L(v), d - \mathsf{surpl}(\ell_2))$ to the 2D rectangle stabbing data structure $(\ell, k - |\ell_2|)$. Over all labels (j,ℓ_2), we have in total $\mathcal{O}(k!(2c_\delta \log n)^k)$ lists of total length $\mathcal{O}(|Q| \cdot k!(2c_\delta \log n)^k)$, where $|Q|$ is the size of the output, and we want to output their union. By using the 2D rectangle stabbing data structure from [30] we obtain the following result.

▶ **Theorem 14.** *For any dictionary of strings of total length n and any $k \leq \frac{\log n}{2\log\log n}$, we can construct a data structure of $\mathcal{O}(nk!(2c_\delta \log n)^k)$ words of space answering* Report^k *queries in $\mathcal{O}((k+1)!(2c_\delta \log n)^k(\log n/\log\log n + |Q|))$ time. For any $k = \mathcal{O}(1)$, the data structure size is $\mathcal{O}(n \log^k n)$ and the query time is $\mathcal{O}(\log^k n(\log n/\log\log n + |Q|))$.*

A Omitted Proofs

Proof of Lemma 4. Say, that the leftmost operation in an optimal sequence of edit operations between strings X and Y happens at position $l_1 \leq \mathsf{LCP}(X, Y)$, that is, in particular $X[l_1] = Y[l_1]$.

The positions $1, \ldots, l_1 - 1$ of strings X and Y are matched respectively, and we need to match the letter $Y[l_1]$ with something in X. Therefore, the leftmost operation (subset of subsequent operations) is either an insertion of letter $Y[l_1]$ or a possibly empty sequence of deletions followed by an identity or a substitution on the first not deleted position (if the first operation after deletions was an insertion, then we can pull this insertion left).

- If the first operation is insertion, then we can instead match letter $Y[l_1]$ with the letter $X[l_1]$, and insert the letter one position further - since the inserted letter and $X[l_1]$ are equal this does not change the number of operations nor the result.
- If a sequence of deletions is followed by an identity, then we can instead match letter $Y[l_1]$ with $X[l_1]$ and delete the matched letter $X[l_2]$ for $l_2 > l_1$ (if the sequence was empty then the position of the first operation was not l_1) shifting the left-most first operation to the right.
- If a sequence of deletions was followed by a substitution of letter $X[l_2]$, then we can instead match letter $Y[l_1]$ with $X[l_1]$ and delete letter $X[l_2]$ obtaining a set of operations of smaller size - a contradiction with the minimality of the set.

For the recursive part the same proof follows the same way after applying the first operation. ◀

Full proof of Lemma 5. (⇒) Let Y' be a prefix of Y at edit distance at most k from X. In particular there exists a sequence of at most k operations that transform X into Y'. Using this sequence of edit operations, we find two nodes u and v in $T^{(k)}$ with labels (X, ℓ_1) and (Y, ℓ_2) respectively, satisfying the conditions of the statement.

Recall that T denotes the compacted trie of D. We start our search at the root of T with two empty lists ℓ_1 and ℓ_2. By Lemma 4 we can safely assume that the position of the first edit operation used to change X into Y' is $l = \mathsf{LCP}(X, Y') + 1 = \mathsf{LCP}(X, Y) + 1$. The letter at position l in X is changed: it is deleted; substituted with the l-th letter of Y'; or the l-th letter of Y' is inserted right before this letter.

Let us first assume that neither X is a prefix of Y nor Y' is a prefix of X (or that we do not have any more edit operations to apply).

We know that in T the nodes with labels X and Y have their lowest common ancestor at depth $l - 1$. Now, assume, that the heavy child of this common ancestor is reached from its parent through an edge labeled with letter a. Now depending on the operation performed:

- If the operation is a substitution, then if $X[l] \neq a$, add l_S to ℓ_1, and if $Y[l] \neq a$, add l_S to ℓ_2 (possibly both lists gain the same element).
- If the operation is a deletion, then if $X[l] \neq a$, add l_D to ℓ_1, otherwise ($Y[l] \neq a$), add l_I to ℓ_2.
- If the operation is an insertion, then, if $Y[l] = a$ ($X[l] \neq a$), add l_I to ℓ_1, otherwise ($Y[l] \neq a$), add l_D to ℓ_2.

Now the nodes with labels (X, ℓ_1) and (Y, ℓ_2) belong to the subtree of a node at depth $l-1$ in $T^{(1)}$ (and hence also in $T^{(k)}$), and actually if the added label was not l_D also of the node at depth l (the heavy child of the one at depth $l-1$), this ensures that the next element will be no smaller than $\max^+(\ell_1 \cup \ell_2)$. Furthermore, we know that the edit distance between X and Y', with the operations in lists ℓ_1 and ℓ_2 applied, is smaller by 1 than the distance between X and Y'.

We iterate this technique at most k times walking down the tree. At step $x \leq k$ we start our work at a node of $T^{(x-1)}$ (a node of $T^{(k)}$ that was there before the x-th step of the k-errata construction) that is an ancestor of nodes with labels (X, ℓ_1) and (Y, ℓ_2). After at most k steps we get to a node in $T^{(k)}$, such that its descendant with label (X, ℓ_1) is an ancestor of the node with label (Y, ℓ_2) as no further edit operations remain. Y' turns out to the prefix of Y with the last $d(v) - d(u)$ letters removed.

Now consider the case where, after applying $x-1$ operations, the nodes with labels (X, ℓ_1) and (Y, ℓ_2), respectively, are already in an ancestor descendant relationship, and there are still operations changing X into Y' not processed yet.

If a node with label (X, ℓ_1) is a (non-trivial) descendant of node with label (Y, ℓ_2) the only possible next operation is deletion (we need to remove the suffix of X). If the first edge used to reach the node with label (X, ℓ_1) from the node with label (Y, ℓ_2) is heavy in $T^{(x-1)}$ we can still add l_I to ℓ_2 (due to the extra copy of labeled nodes), otherwise a node with label $(X, \ell_1 \cup \{l_D\})$ is a descendant of the node with label (Y, ℓ_2) in $T^{(x)}$ of smaller depth. We apply this until we reach a single node with both labels (X, ℓ_1) and (Y, ℓ_2).

If a node with label (X, ℓ_1) is a (non-trivial) ancestor of a node with label (Y, ℓ_2), we already know that the claim is true (for some prefix Y'' of Y, that is at smaller edit distance from X than Y'). We may still want to pair X with a longer (or a shorter) prefix of Y, in particular the longest possible. If the next applied operation is an insertion (we want to make the prefix longer) of letter $Y[l]$, then this is symmetric to the case considered in the previous paragraph. We do not provide any modification that allows applying deletion in this case since, in our main application, we care for the longest prefixes only. Still, we know, that the shortest prefix of Y we could obtain this way would be $k - x + 1$ letters shorter than Y'', and hence every such prefix is actually represented in $T^{(k)}$.

In case of Hamming distance the set of operations consists solely of substitutions, and hence the proof reduces naturally (only elements l_S are inserted to the lists, hence only copies of labels with such lists are considered).

($\Leftarrow$) This is the reversal of the forward ($\Rightarrow$) proof construction, that is, we change ℓ_1 and ℓ_2 into a single list of edit operations.

In the Hamming distance case, the set of mismatches between X and $Y[1\mathinner{.\,.}|X|]$ is contained in the set $\{l : l_S \in \ell_1 \cup \ell_2\}$, hence X and a prefix of Y are at Hamming distance at most $|\ell_1 \cup \ell_2| \leq k$ ($|\ell_1 \cup \ell_2|$ may be greater than the actual Hamming distance if a suboptimal pair of labeled nodes is chosen, but this is not a problem). In the edit distance case, the construction is more complicated due to the shifts made by insertions and deletions.

We have two nodes u and v with labels (X, ℓ_1) and (Y, ℓ_2), respectively, such that u is an ancestor of v. Let Y' be the prefix of Y of length $|Y| - d(v) + d(u) = d(u) + \mathsf{surpl}(\ell_2)$ assuming that $\ell_2 = \ell_2^{d(u)}$ ($l \leq d(u)$ for $l_E \in \ell_2$) – otherwise we can remove those larger elements as those only affect the part of Y that does not play a role in the transformation of X into Y' (there exists a descendant of u with label $(Y, \ell_2^{d(u)})$ which we can choose as our v). We know that after applying operations from ℓ_1 to X and operations from ℓ_2 to Y' we obtain the same string: the one obtained by reading the path from root to u in $T^{(k)}$.

Let $\ell = \ell_1 \cup \ell_2$, and for each element of ℓ we mark whether it comes from ℓ_1, from ℓ_2, or from both. For ℓ it may actually be the case that both l_S and l_I appear (coming from two different lists ℓ_1, ℓ_2); this will not be that much of a problem however since this is counted as two edit operations in $|\ell|$. We continue by showing that in fact ℓ encodes a transformation of X into Y' with the use of at most $|\ell|$ edit operations.

We read ℓ and modify X step by step to reach Y' keeping an invariant that when element l_E is about to be processed the first $l-1+i$ positions of the modified string X are equal to the first $l-1+i$ positions of Y, where the value i represents the imbalance between deletion and insertion operations from ℓ_2 already applied, and hence it starts from 0. We have that $i = \mathsf{surpl}(\ell_2')$, where ℓ_2' is the prefix of ℓ_2 storing operations already applied - $\ell_2' = \ell_2^l$ when we move to the node at depth l for the first time.

- If the element is l_S, we substitute the letter at position $l+i$ of the current version of X with $Y[l+i]$.
- If the element l_D comes from both lists ℓ_1 and ℓ_2 (multiple l_D in both lists are matched into pairs), we replace the letter at position $l+i$ by $Y[l+i]$ and increase i by 1 (deletion of the corresponding letters of both strings is equivalent to a substitution, but the depth of the node decreases by one).
- If the element l_D comes from list ℓ_1 (a surplus in pairing), we remove the letter at position $l+i$ in the current version of X.
- If the element l_D comes from list ℓ_2 (a surplus in pairing), we add letter $Y[l+i]$ between letters at positions $l+i-1$ and $l+i$ in X and increase i by 1.
- If the element l_I comes from both lists we do not modify X, and instead decrease i by 1 (inserting the same letter at corresponding positions in X and Y does not change the edit distance).
- If the element l_I comes from list ℓ_1, we insert letter $Y[l+i]$ between letters at positions $l+i-1$ and $l+i$ in X.
- If the element l_I comes from list ℓ_2, we delete the letter at position $l+i$ in X and decrease i by 1.

Notice that when i decreases, the value l of the next l_E must be strictly greater, hence the sum $l+i$ never decreases between operations; and when $l+i$ increases, $X[l+i]$ and $Y[l+i]$ (for X after the changes applied and the old value of $l+i$) must actually be equal.

Further notice that, as claimed, the prefix Y' obtained from X by applying those edit operations (obtained from ℓ_1 and $\ell_2^{d(u)}$) has length equal to $d(u) + \mathsf{surpl}(\ell_2^{d(u)})$. ◀

Proof of Lemma 8. Let $|T^{(k)}|$ denote the size of the k-errata of T. The proof proceeds by induction. $|T^{(0)}| = |T| \leq 3n$.

Assume, that $|T^{(k-1)}| \leq c_{n,k-1} \cdot n(k-1)!(c_\delta \log n)^{k-1}$, for a constant $3 \leq c_{n,k-1} \leq 16$, depending only on n and k, to be specified later.

A single node or label can be copied at most $c_\delta \log |T^{(k-1)}| + 1$ times, since the heavy-light decomposition of the $(k-1)$-errata tree is weighted by the number of explicit nodes and labels. Note that c_δ comes from the number of copies made, and $+1$ comes from the extra copy of a labeled node that is not a leaf.

Now $c_\delta \log |T^{(k-1)}| + 1 \leq c_\delta \log[c_{n,k-1} \cdot n(k-1)!(c_\delta \log n)^{k-1}] + 1 \leq c_\delta[\log c_{n,k-1} + \log n + (k-1)\log k + (k-1)[\log c_\delta + \log n]] + 1 \leq c_\delta[k(\log n + \log k + 7)] = c_\delta k \log n[1 + \frac{\log k + 7}{\log n}]$.

Hence, $|T^{(k)}| \leq |T^{(k-1)}| \cdot (c_\delta \log |T^{(k-1)}| + 1) \leq c_{n,k-1} \cdot n(k-1)!(c_\delta \log n)^{k-1} \cdot c_\delta k \log n[1 + \frac{\log k + 7}{\log n}] = c_{n,k-1} \cdot [1 + \frac{\log k + 7}{\log n}] \cdot [nk!(c_\delta \log n)^k]$.

Hence for $c_{n,k} = c_{n,k-1} \cdot [1 + \frac{\log k + 7}{\log n}]$ the property $|T^{(k)}| \leq c_{n,k} \cdot nk!(c_\delta \log n)^k$ is satisfied, and it remains to show, that $c_{n,k} \leq 16$ if $k \leq \frac{\log n}{2 \log \log n}$. $c_{n,0} = 3, c_{n,k} \leq 3 \cdot [1 + \frac{\log k + 7}{\log n}]^k$.

Recall, that $(1 + \frac{1}{x})^x \to e$, and that for $k \leq \frac{\log n}{2 \log \log n}$ we have $\frac{\log k + 7}{\log n} \leq \frac{2 \log \log n}{\log n}$ (for large enough n), hence $c_{n,k} \leq 3e < 16$.

The bound on the number of copies of a single label follows analogously. ◀
