We note that a PTAS for CMK can be obtained using ideas of [5]. We outline the main steps. First, item values are discretized into  $O(\log n)$  value classes, where  $n$  is the number of items. Then, enumeration is used to roughly determine the number of items taken from each value class. Clearly, one should take from each value class the items with smallest weights, leading to a reduced problem of packing sufficient items from each value class in the  $m$  given (uniform) bins. Packing these items in  $(1 + \varepsilon) \cdot m + O(1)$  uniform bins can be done using an asymptotic FPTAS for bin packing with cardinality constraint [11] (or more generally, for bin packing with a partition matroid [8]). Finally, the algorithm keeps the  $m$  bins with highest values. We note that the running time of the enumeration step is very high. This leaves open the question whether CMK admits an EPTAS.

## 1.2 Our Results

Our main contribution is in showing that iterative randomized rounding can substantially improve the approximation guarantee of the configuration-LP rounding approach of [12]. The analysis is based on concentration bounds; thus, our iterative algorithm is applied to a slightly restricted subclass of CMK instances in which the value of each configuration is relatively small, and the number of bins is large w.r.t. the given error parameter. Recall that even for two bins the problem does not admit an FPTAS [5]. Hence, we do not expect the iterative approach to work for a small number of bins. More specifically, given an error parameter  $\varepsilon \in (0, 0.1)$  we say that a CMK instance  $\mathcal{I}$  is  $\varepsilon$ -*simple* if (i) every feasible subset of items  $C$  which can be packed in a single bin has value at most  $\varepsilon^{30} \cdot \text{OPT}(\mathcal{I})$ , (ii)  $m > \exp(\exp(\varepsilon^{-30}))$ , and (iii)  $\varepsilon \cdot m \in \mathbb{N}$ , where  $m$  is the number of bins and  $\text{OPT}(\mathcal{I})$  is the optimum value of  $\mathcal{I}$ .<sup>4</sup> For clarity, we first state our algorithmic result for the subclass of  $\varepsilon$ -simple CMK instances (see Section 3 for more details).

► **Theorem 1.** *For every  $\varepsilon \in (0, 0.1)$  and an  $\varepsilon$ -simple CMK instance  $\mathcal{I}$ , iterative randomized rounding (see Algorithm 1) returns a  $(1 - \varepsilon)$ -approximation for  $\mathcal{I}$  in time  $\left(\frac{|\mathcal{I}|}{\varepsilon}\right)^{O(1)}$ , where  $|\mathcal{I}|$  is the encoding size of  $\mathcal{I}$ .*

An in depth look into the algorithm of Fleischer et al. [12] reveals that the approximation ratio of their algorithm on  $\varepsilon$ -simple instance is not better than  $(1 - \frac{1}{e})$ , indicating the improved ratio in Theorem 1 stems from the use of the iterative approach.

<sup>2</sup> We give formal definitions of approximation schemes in Section 2.

<sup>3</sup> The paper [12] shows that the existence of an FPTAS for the single bin subproblem, as in the case of 0/1-knapsack with cardinality constraint, implies a  $(1 - 1/e)$ -approximation for the corresponding variant of SAP.

<sup>4</sup> In our discussion of  $\varepsilon$ -simple instances, we did not attempt to optimize the constants.

We give a simple reduction showing that our algorithm for  $\varepsilon$ -simple instances yields a randomized EPTAS for general CMK instances.

This essentially resolves the complexity status of CMK, since an FPTAS is ruled out [5].

► **Theorem 2.** *There is a randomized EPTAS for CMK.*

For the proof of Theorem 2 see Section 3.

### 1.3 Technical Overview

In the following, we outline our algorithmic approach and its analysis. For clarity, we focus in this section on high-level ideas and omit some technical details to improve clarity. We start with a more formal definition of CMK. An instance of CMK consists of a set of items  $I$ , a weight function  $\mathbf{w} : I \rightarrow [0, 1]$ , a value function  $\mathbf{v} : I \rightarrow \mathbb{R}_{\geq 0}$ , a number of bins  $m \in \mathbb{N}_{>0}$ , and a cardinality constraint  $k \in \mathbb{N}_{>0}$ . A *solution* is a tuple  $(C_1, \dots, C_m)$  such that for all  $j \in \{1, \dots, m\}$  it holds that  $C_j \subseteq I$ ,  $|C_j| \leq k$  and  $\mathbf{w}(C_j) = \sum_{i \in C_j} \mathbf{w}(i) \leq 1$ . The *value* of the solution  $(C_1, \dots, C_m)$  is  $\sum_{i \in S} \mathbf{v}(i)$  where  $S = \bigcup_{j=1}^m C_j$ . The goal is to find a solution of maximum value. Note that we allow the sets  $C_1, \dots, C_m$  to intersect, but if an item appears in multiple sets its value is counted only once.

#### The Algorithm

Our algorithm applies an iterative randomized rounding approach based on a configuration-LP. The use of such linear program dates back to the work of Karmarkar and Karp on bin packing [15], and such linear programs are commonly used in approximation algorithms for resource allocation problems (e.g., [3, 1, 12, 13, 17, 7]).

We use a *configuration polytope*  $P(\ell) \subseteq [0, 1]^I$ , where  $\bar{y} \in P(\ell)$  can be intuitively interpreted as “there is a way to fractionally pack the items into  $\ell$  bins such that each item  $i \in I$  is packed  $\bar{y}_i$  times”. The algorithm takes as an input a value  $\varepsilon > 0$  which serves as a discretization factor and determines the approximation ratio. Our iterative approach uses  $\frac{1}{\varepsilon}$  iterations, and each iteration packs  $\varepsilon \cdot m$  of the remaining bins. Therefore, at the beginning of the  $j$ -th iterations,  $(j-1) \cdot \varepsilon \cdot m$  bins were packed (in previous iterations) and  $(1 - (j-1) \cdot \varepsilon) \cdot m$  bins are still empty. We use  $S_j$  to denote the set of items that were not packed by the end of the  $j$ -th iteration (and thus are still available for packing). The main steps of the algorithm are as follows.

1. Initialize  $S_0 \leftarrow I$  to be all the items.
2. For  $j$  from 1 to  $\frac{1}{\varepsilon}$  do:
  - a. Solve the linear program

$$\begin{aligned}
 \max \quad & \sum_{i \in I} \bar{y}_i \cdot \mathbf{v}(i) \\
 \text{s.t.} \quad & \bar{y} \in P(m \cdot (1 - (j-1) \cdot \varepsilon)) \\
 & \bar{y}_i = 0 \quad \forall i \in I \setminus S_{j-1}
 \end{aligned} \tag{1}$$

That is, we want to obtain a maximum value using  $m \cdot (1 - (j-1) \cdot \varepsilon)$  bins and only items in  $S_{j-1}$ . Let  $\bar{y}^j$  be the solution found.

- b. Sample  $\varepsilon \cdot m$  bins according to the solution  $\bar{y}^j$  (defined more formally in later); update  $S_j$  to be  $S_{j-1}$  minus all the items packed in the current iteration.
3. Return the collection of  $m$  packed bins.

The linear program in (1) can be approximated efficiently, but cannot be solved exactly in polynomial time. For the purpose of this technical overview, we assume it can be solved exactly. In Item 2b we use the randomized rounding technique for configuration LPs of Fleischer et al. [12]. The same randomized rounding technique is commonly used by other algorithms (e.g., [3, 1, 17, 2]). We give the full details on the sampling process in Section 3.

### High Level Analysis

Let  $Q_j$  be the set of items packed in the  $j$ -th iteration (that is,  $Q_j = S_j \setminus S_{j-1}$ ). In the  $j$ -th iteration, the linear program uses  $m \cdot (1 - (j-1) \cdot \varepsilon)$  bins and attains value of  $\sum_{i \in I} \bar{y}_i^j \cdot \mathbf{v}(i)$ , with an average value of  $\frac{\sum_{i \in I} \bar{y}_i^j \cdot \mathbf{v}(i)}{m \cdot (1 - (j-1) \cdot \varepsilon)}$  per bin. As the number of bins sampled in each iteration is *small*, it can be shown that with high probability the average value per bin in the packing generated by the randomized rounding is roughly the same as the average value in the fractional solution. That is,

$$\frac{\sum_{i \in Q_j} \mathbf{v}(i)}{\varepsilon \cdot m} \approx \frac{\sum_{i \in I} \bar{y}_i^j \cdot \mathbf{v}(i)}{m \cdot (1 - (j-1) \cdot \varepsilon)},$$

or equivalently,

$$\sum_{i \in Q_j} \mathbf{v}(i) \approx \varepsilon \cdot \frac{\sum_{i \in I} \bar{y}_i^j \cdot \mathbf{v}(i)}{1 - (j-1) \cdot \varepsilon}.$$

Observe the left hand term is the value attained from items packed in the  $j$ -th iteration. In each iteration of the algorithm the distribution by which the bins are sampled is updated, so the algorithm does not pack items already packed in previous iterations (by the constraints  $\bar{y}_i = 0$  for  $i \in I \setminus S_{j-1}$  in (1)). Thus, we have that  $Q_1, \dots, Q_{\varepsilon-1}$  are disjoint. It follows that the value of the solution returned by the algorithm is

$$\mathbf{v}(I \setminus S_{\varepsilon-1}) = \sum_{j=1}^{\varepsilon-1} \sum_{i \in Q_j} \mathbf{v}(i) \approx \varepsilon \cdot \sum_{j=1}^{\varepsilon-1} \frac{\sum_{i \in I} \bar{y}_i^j \cdot \mathbf{v}(i)}{1 - (j-1) \cdot \varepsilon} \quad (2)$$

Ideally, we would like the average value per bin to be (at least)  $\frac{\text{OPT}}{m}$  in each of the solutions  $\bar{y}^j$ , where OPT is the value of the optimal solution of the instance. That is, the average value per bin in each of the iterations remains the average value per bin in the optimum. As  $\bar{y}^j$  conceptually uses  $m \cdot (1 - (j-1)\varepsilon)$  bins, this implies that

$$\sum_{i \in I} \bar{y}_i^j \cdot \mathbf{v}(i) \gtrsim \frac{\text{OPT}}{m} \cdot m \cdot (1 - (j-1) \cdot \varepsilon) = \text{OPT} \cdot (1 - (j-1) \cdot \varepsilon), \quad (3)$$

for every  $j \in [\varepsilon-1]$ . If we assume (3) holds and plug it into (2), we get that the value of the solution returned by the algorithm is

$$\mathbf{v}(I \setminus S_{\varepsilon-1}) \approx \varepsilon \cdot \sum_{j=1}^{\varepsilon-1} \frac{\sum_{i \in I} \bar{y}_i^j \cdot \mathbf{v}(i)}{1 - (j-1) \cdot \varepsilon} \gtrsim \varepsilon \cdot \sum_{j=1}^{\varepsilon-1} \frac{\text{OPT} \cdot (1 - (j-1) \cdot \varepsilon)}{1 - (j-1) \cdot \varepsilon} = \text{OPT}.$$

That is, the algorithm returns a solution of value close to OPT (not strictly better naturally), assuming (3) holds. This leaves us with the goal of showing that (3) holds with high probability.

### Linear Structures and Equation (3)

To show that (3) holds we define a random vector  $\bar{\gamma}^j \in [0, 1]^I$  for every  $j \in [\varepsilon^{-1}]$ . We use  $\bar{\gamma}^j$  to lower bound the value of the configuration-LP. We show that with high probability (i) the value of  $\bar{\gamma}^j$  (that is,  $\sum_{i \in I} \bar{\gamma}_i^j \cdot \mathbf{v}(i)$ ) is  $\approx (1 - (j - 1)\varepsilon) \cdot \text{OPT}$  and (ii)  $\bar{\gamma}^j \in P((1 + \delta) \cdot m_j)$  where  $m_j = (1 - (j - 1) \cdot \varepsilon) \cdot m$  is the number of remaining bins at the beginning of the  $j$ -th iteration and  $\delta > 0$  is small. Once properties (i) and (ii) are shown, it follows that  $\frac{\bar{\gamma}^j}{1 + \delta}$  is a solution of high value for the linear program in the  $j$ -th iteration, and (3) immediately follows as the algorithm finds an optimal solution in every iteration. Property (i) is shown using a simple calculation of the expected value of the vector  $\bar{\gamma}^j$  followed by an application of a concentration bound which shows that with high probability the value of  $\bar{\gamma}^j$  does not deviate far from its expected value. Showing property (ii) is more challenging.

The polytope  $P(\ell)$  can be represented via a finite set of linear constraints  $\mathcal{S} \subseteq \mathbb{R}_{\geq 0}^I$  by  $P(\ell) = \{\bar{y} \in [0, 1]^I \mid \forall \bar{u} \in \mathcal{S} : \bar{u} \cdot \bar{y} \leq \ell\}$  (the set  $\mathcal{S}$  is the same for every  $\ell$ ). While  $\mathcal{S}$  is finite, its size is non-polynomial in the input instance. A naive approach to show that  $\bar{\gamma}^j \in P((1 + \delta)m_j)$  is to consider each constraint  $\bar{u} \in \mathcal{S}$  separately, and apply concentration bounds to show  $\bar{y} \cdot \bar{u} \lesssim m_j$  with high probability. Subsequently, the union bound can be used to lower bound the probability that  $\bar{y} \cdot \bar{u} \lesssim m_j$  for every  $\bar{u} \in \mathcal{S}$  simultaneously. However, due to the large number of vectors in  $\mathcal{S}$ , a direct application of the union bound does not lead to such useful lower bound.

We use a *linear structure* to overcome the above challenge. The linear structure provides an approximate representation of the configuration polytope using a small number of constraints (that is, the number of constraints only depends on  $\varepsilon$ ). As the number of constraints is reduced, we can now apply the above logic successfully – use a concentration bound to show that each constraint of the linear structure holds independently with high probability, and then use the union bound to show that all the constraints hold simultaneously with high probability. By the properties of the linear structure, once we show that all constraints hold, we are guaranteed that  $\bar{\gamma}^j \in P((1 + \delta) \cdot m_j)$ , as stated in (ii).

The concept of linear structure was introduced in [17]. It is essentially a non-constructive version of the *subset oblivious* algorithms used by the Round&Approx framework of [3]. We construct the linear structure for CMK based on ideas from [17, 1]. The structure leverages the relatively simple structure of the cardinality constraint.

### Technical Contribution

In this paper, we present the first use of an iterative randomized rounding approach of a configuration-LP for a maximization problem. As such, the paper provides the basic foundations required for the analysis of iterative randomized rounding for maximization problems. Iterative randomized rounding of a configuration-LP has been recently used for bin packing problems in [17]. Indeed, in some places the analysis only requires simple adaptations of ideas from [17]. In other parts, the adaptation is more challenging.

These challenges arise mainly due to the fact that while in bin packing all the remaining items must be fully packed by the configuration-LP, in maximization problems the remaining items may be partially selected or not selected at all by the configuration-LP. Thus, the probability of an item to be packed after  $j$  iterations may take different values for different items. In contrast, this probability is the same for all items in the case of bin packing. Similarly, while in the case of bin packing all items must be packed by the configuration-LP in every iteration, in maximization problem there is a degree of freedom in the selection of items to be packed. This, in turn, led to a different approach for the use of the linear structure.

We note that while the paper [7] deals with a generalization of CMK and uses several similar concepts (configuration LP, sampling, subset oblivious algorithms), the algorithm in [7] does not use an iterative approach. It relies on two separate stages: the first uses a randomized rounding of a configuration-LP that is solved once, and the second stage uses a combinatorial algorithm. We believe the analysis of the iterative randomized rounding algorithm presented in this paper will be useful in showing iterative randomized rounding yields an improved approximation for the Uniform 2-dimensional Vector Multiple Knapsack (2d-UMK) problem considered in [7]. The main challenge in applying our analysis to 2d-UMK is that our analysis relies on a robust linear structure, which is unlikely to exist for 2d-UMK (as that would lead to a PTAS, contradicting the hardness results in [7]). This can potentially be bypassed with the use of an analog of the linear structure that holds for 2d-UMK and adaptation of the analysis to this potential structure.

## 1.4 Organization

In Section 2 we give some definitions and notation. Section 3 presents our main algorithm and an outline of its analysis. In Section 4 we give the detailed analysis (proofs of Lemmas 6, 7, 10 and 11). The proofs of Lemma 9 and Lemma 4 are given in the full version of the paper [9].

## 2 Preliminaries

We start with some definitions and notation. Let  $\text{OPT}(I)$  be the value of an optimal solution for an instance  $I$  of a maximization problem  $\Pi$ . For  $\alpha \in (0, 1]$ , a solution  $x$  for the instance  $I$  is an  $\alpha$ -approximate solution if its value is at least  $\alpha \cdot \text{OPT}(I)$ . For  $\alpha \in (0, 1]$ , we say that  $\mathcal{A}$  is an  $\alpha$ -approximation algorithm for  $\Pi$  if for any instance  $I$  of  $\Pi$ ,  $\mathcal{A}$  outputs an  $\alpha$ -approximate solution for  $I$ . An algorithm  $\mathcal{A}$  is a *randomized*  $\alpha$ -approximation for  $\Pi$  if for any instance  $I$  of  $\Pi$  it always returns a solution for  $I$ , and the solution is an  $\alpha$ -approximate solution with probability at least  $\frac{1}{2}$ . A *polynomial-time approximation scheme* (PTAS) for a maximization problem  $\Pi$  is a family of algorithms  $(\mathcal{A}_\varepsilon)_{\varepsilon > 0}$  such that for any  $\varepsilon > 0$ ,  $\mathcal{A}_\varepsilon$  is a polynomial-time  $(1 - \varepsilon)$ -approximation algorithm for  $\Pi$ . As the running time of a PTAS may be impractically high, two restrictive classes of PTAS have been proposed in the literature:  $(\mathcal{A}_\varepsilon)_{\varepsilon > 0}$  is an *efficient* PTAS (EPTAS) if the running time of  $\mathcal{A}_\varepsilon$  is of the form  $f\left(\frac{1}{\varepsilon}\right) \cdot n^{O(1)}$ , where  $f$  is an arbitrary function, and  $n$  is the bit-length encoding size of the input instance;  $(\mathcal{A}_\varepsilon)_{\varepsilon > 0}$  is a *fully* PTAS (FPTAS) if the running time of  $\mathcal{A}_\varepsilon$  is bounded by  $\left(\frac{n}{\varepsilon}\right)^{O(1)}$ . Given a boolean expression  $\mathcal{D}$ , we define  $\mathbb{1}_{\mathcal{D}} \in \{0, 1\}$  such that  $\mathbb{1}_{\mathcal{D}} = 1$  if  $\mathcal{D}$  is true and  $\mathbb{1}_{\mathcal{D}} = 0$  otherwise.

We give an alternative definition of our problem that will be used in the technical sections. An instance of CMK is a tuple  $\mathcal{I} = (I, \mathbf{w}, \mathbf{v}, m, k)$ , where  $I$  is a set of items,  $\mathbf{w} : I \rightarrow [0, 1]$  is the weight function,  $\mathbf{v} : I \rightarrow \mathbb{R}_{\geq 0}$  is the value function,  $m \in \mathbb{N}_{>0}$  is the number of bins, and  $k \in \mathbb{N}_{>0}$  is the cardinality constraint. A *configuration* of the instance  $\mathcal{I}$  is  $C \subseteq I$  such that  $|C| \leq k$  and  $\mathbf{w}(C) = \sum_{i \in C} \mathbf{w}(i) \leq 1$ . Let  $\mathcal{C}_{\mathcal{I}}$  be the set of all configurations of  $\mathcal{I}$ , and  $\mathcal{C}_{\mathcal{I}}(i) = \{C \in \mathcal{C} \mid i \in C\}$  the set of all configurations which contain  $i \in I$ . When clear from the context, we simply use  $\mathcal{C} = \mathcal{C}_{\mathcal{I}}$  and  $\mathcal{C}(i) = \mathcal{C}_{\mathcal{I}}(i)$ .

A *solution* of  $\mathcal{I}$  is a tuple of  $m$  configurations  $S = (C_1, \dots, C_m) \in \mathcal{C}^m$ . The value of the solution  $S = (C_1, \dots, C_m)$  is  $\mathbf{v}(S) = \mathbf{v}\left(\bigcup_{b \in [m]} C_b\right)$  (generally, for any set  $B \subseteq A$  and a function  $f : A \rightarrow \mathbb{R}_{\geq 0}$ , we use  $f(B) = \sum_{b \in B} f(b)$ ). The objective is to find a solution of maximum value. Let  $\text{OPT}(\mathcal{I})$  be the optimal solution value for the instance  $\mathcal{I}$ , and  $|\mathcal{I}|$  the encoding size of  $\mathcal{I}$ . W.l.o.g., we consider a tuple with fewer than  $m$  configurations to be a solution. In this case, for some  $r \leq m$ , the tuple  $(C_1, \dots, C_r) \in \mathcal{C}^r$  is equivalent to the solution  $(C_1, \dots, C_r, \emptyset, \dots, \emptyset) \in \mathcal{C}^m$ .

Our main algorithm, given in Section 3, is applied to a restricted subclass of *simple* instances. We now give a more formal definition for this subclass of instances.

► **Definition 3.** Let  $\varepsilon \in (0, 0.1)$ , We say that a CMK instance  $\mathcal{I} = (I, \mathbf{w}, \mathbf{v}, m, k)$  is  $\varepsilon$ -simple if the following conditions hold.

- For every  $C \in \mathcal{C}$ , we have that  $\mathbf{v}(C) \leq \varepsilon^{30} \cdot \text{OPT}(\mathcal{I})$ .
- $m > \exp(\exp(\varepsilon^{-30}))$
- $\varepsilon \cdot m \in \mathbb{N}$ .

We give a reduction showing that our algorithm for  $\varepsilon$ -simple instances yields a randomized EPTAS for general CMK instances.<sup>5</sup> This is formalized in the next lemma (we give the proof in [9]).

► **Lemma 4.** Given  $\varepsilon \in (0, 0.1)$  such that  $\varepsilon^{-\frac{1}{2}} \in \mathbb{N}$ , let  $\mathcal{A}$  be a randomized algorithm which returns a  $(1 - \varepsilon)$ -approximate solution for any  $\varepsilon$ -simple CMK instance  $\mathcal{I}$  in time  $\left(\frac{|\mathcal{I}|}{\varepsilon}\right)^{O(1)}$ . Then, there is a randomized EPTAS for CMK.

Theorem 2 follows from Theorem 1 and Lemma 4.

### 3 The Algorithm

In this section, we formally present our iterative randomized rounding algorithm for  $\varepsilon$ -simple CMK instances. The algorithm relies on a linear programming (LP) relaxation of CMK that we formalize through the notion of fractional solutions.

A *fractional solution* for an instance  $\mathcal{I} = (I, \mathbf{w}, \mathbf{v}, m, k)$  is a vector  $\bar{x} \in \mathbb{R}_{\geq 0}^{\mathcal{C}}$ ; the value  $\bar{x}_C$  represents a fractional selection of the configuration  $C$  for the solution. The *coverage* of  $\bar{x}$  is the vector  $\text{cover}(\bar{x}) \in \mathbb{R}_{\geq 0}^I$  defined by

$$\forall i \in I: \quad \text{cover}_i(\bar{x}) = (\text{cover}(\bar{x}))_i = \sum_{C \in \mathcal{C}(i)} \bar{x}_C.$$

The vector  $\bar{x}$  is *feasible* if  $\text{cover}(\bar{x}) \in [0, 1]^I$ . The size of  $\bar{x}$  is  $\|\bar{x}\| = \sum_{C \in \mathcal{C}} \bar{x}_C$  (throughout this paper, for every vector  $\bar{z} \in \mathbb{R}^n$  we use  $\|\bar{z}\| = \sum_{i=1}^n |\bar{z}_i|$ ). The *value* of  $\bar{y} \in [0, 1]^I$  is  $\mathbf{v}(\bar{y}) = \sum_{i \in I} \bar{y}_i \cdot \mathbf{v}(i)$ . The *value* of  $\bar{x}$  is the value of the cover of  $\bar{x}$ , that is,  $\mathbf{v}(\bar{x}) = \mathbf{v}(\text{cover}(\bar{x}))$ . For  $\ell \in \mathbb{N}_{>0}$ , let  $[\ell] = \{1, \dots, \ell\}$ .

A solution  $S = (C_1, \dots, C_m)$  for  $\mathcal{I}$ , where  $C_1, \dots, C_m$  are disjoint and non-empty, can be encoded as a feasible fractional solution  $\bar{x} \in \{0, 1\}^{\mathcal{C}}$  defined by  $\bar{x}_{C_b} = 1$  for every  $b \in [m]$ , and  $\bar{x}_C = 0$  for every other configuration. It is easy to verify that  $\|\bar{x}\| = m$ ,  $\text{cover}_i(\bar{x}) = 1$  for every  $i \in S$ ,  $\text{cover}_i(\bar{x}) = 0$  for every  $i \in I \setminus S$ , and  $\mathbf{v}(\bar{x}) = \mathbf{v}(S)$ .

We use fractional solutions to define a linear program (LP). Let  $K$  be a set and  $\bar{\gamma} \in \mathbb{R}^K$ . The *support* of  $\bar{\gamma}$  is  $\text{supp}(\bar{\gamma}) = \{i \in K \mid \bar{\gamma}_i \neq 0\}$ . Let  $\mathcal{I} = (I, \mathbf{w}, \mathbf{v}, m, k)$  be a CMK instance. For every set  $S \subseteq I$  of remaining items and  $\ell \in \mathbb{N}$  remaining bins, we define the configuration LP of  $S$  and  $\ell$  by

$$\begin{aligned} \text{LP}(S, \ell): \quad & \max && \mathbf{v}(\bar{x}) \\ & \text{s.t.} && \bar{x} \text{ is a feasible fractional solution for } \mathcal{I} \\ & && \text{supp}(\bar{x}) \subseteq 2^S \\ & && \|\bar{x}\| = \ell \end{aligned}$$

<sup>5</sup> In our discussion of  $\varepsilon$ -simple instances, we did not attempt to optimize the constants.

That is, in  $\text{LP}(S, \ell)$  exactly  $\ell$  configurations are selected<sup>6</sup>, and these configurations contain only items in  $S$ . We can formally define the configuration polytope  $P(\ell)$  discussed in Section 1.3 via fractional solutions by

$$P(\ell) = \{\text{cover}(\bar{x}) \mid \bar{x} \text{ is a feasible fractional solution for } \mathcal{I} \text{ and } \|\bar{x}\| \leq \ell\}. \quad (4)$$

It can be shown that  $\text{LP}(S_j, (1 - (j - 1) \cdot \varepsilon) \cdot m)$  is equivalent to the linear program in (1).

A generalization of  $\text{LP}(S, \ell)$  for the *separable assignment problem* (SAP) was considered in [12]. Given  $p_i \geq 0$  for every  $i \in I$ , the paper [12] shows that linear programs such as  $\text{LP}(S, \ell)$  admit an FPTAS whenever the *single bin problem* – of finding  $C \in \mathcal{C}$  such that  $\sum_{i \in I} p_i$  is maximized – admits an FPTAS. As the single bin case of CMK has an FPTAS (e.g., [4, 18, 10]), we get the following.

► **Lemma 5.** *There is an algorithm which given a CMK instance  $\mathcal{I} = (I, \mathbf{w}, \mathbf{v}, m, k)$ ,  $S \subseteq I$ ,  $\ell \in \mathbb{N}$  and  $\varepsilon > 0$ , finds a  $(1 - \varepsilon)$ -approximate solution for  $\text{LP}(S, \ell)$  in time  $\left(\frac{|I|}{\varepsilon}\right)^{O(1)}$ .*

Given a fractional solution  $\bar{x}$  such that  $\|\bar{x}\| \neq 0$ , we say that a random configuration  $R \in \mathcal{C}$  is *distributed by  $\bar{x}$* , and write  $R \sim \bar{x}$ , if  $\Pr(R = C) = \frac{\bar{x}_C}{\|\bar{x}\|}$  for all  $C \in \mathcal{C}$ .

The pseudocode of our algorithm for CMK is given in Algorithm 1. In each iteration  $1 \leq j \leq \varepsilon^{-1}$ , the algorithm uses the solution  $\bar{x}^j$  for  $\text{LP}(S_{j-1}, m_j)$  to sample  $\varepsilon \cdot m$  configurations, where  $S_{j-1}$  is the set of items remaining after iteration  $(j - 1)$ , and  $m_j$  is the number of remaining (unassigned) bins.

- 1 Initialize  $S_0 \leftarrow I$
- 2 **for**  $j = 1, \dots, \varepsilon^{-1}$  **do**
- 3     Find a  $(1 - \varepsilon)$ -approximate solution  $\bar{x}^j$  for  $\text{LP}(S_{j-1}, m_j)$ , where  $m_j = m(1 - (j - 1) \cdot \varepsilon)$ .
- 4     Sample independently  $q = \varepsilon \cdot m$  configurations  $R_1^j, \dots, R_q^j \sim \bar{x}^j$ .
- 5     Update  $S_j = S_{j-1} \setminus \left(\bigcup_{b=1}^q R_b^j\right)$ .
- 6 Return as solution  $\left(R_b^j\right)_{1 \leq j \leq \varepsilon^{-1}, 1 \leq b \leq q}$

---

Consider the execution of Algorithm 1 with the input  $\mathcal{I} = (I, \mathbf{w}, \mathbf{v}, m, k)$  and  $\varepsilon \in (0, 0.1)$  such that  $\varepsilon^{-\frac{1}{2}} \in \mathbb{N}$ . The notations we use below, such as  $\bar{x}^j$ ,  $S_j$ , and  $R_b^j$ , refer to the variables used throughout the execution of the algorithm. Clearly, Algorithm 1 returns a solution for  $\mathcal{I}$ . Furthermore, by Lemma 5, the running time of the algorithm is polynomial in  $\mathcal{I}$  and  $\varepsilon^{-1}$ . Let  $V = \mathbf{v} \left(\bigcup_{j=1}^{\varepsilon^{-1}} \bigcup_{b=1}^q R_b^j\right) = \mathbf{v}(I \setminus S_{\varepsilon^{-1}})$  be the value of the returned solution.

## Main Lemmas

In the following, we describe the main lemmas we prove in order to lower bound the value of  $V$ . The proofs of the lemmas are given in Section 4 and the full version of the paper [9].

<sup>6</sup> Note that  $\bar{x}_0$  may be greater than 1.

## 27:10 An EPTAS for Cardinality Constrained Multiple Knapsack

A simple calculation shows that the expected value of  $\mathbf{v}(R_b^j)$ , given all the samples up to (and including) iteration  $(j-1)$ , is  $\frac{\mathbf{v}(\bar{x}^j)}{m \cdot (1 - (j-1)\varepsilon)}$ . To compute the expected value of  $\mathbf{v}\left(\bigcup_{b=1}^q R_b^j\right)$ , we need to take into consideration events in which an item  $i \in I$  appears in several configurations among  $R_1^j, \dots, R_q^j$ . In Section 4.2 we show that, since only a small number of configurations are sampled in each iteration (in comparison to the overall remaining number of bins), such events have small effect on the expected value (with the exception of the last  $\varepsilon^{-\frac{1}{2}}$  iterations). This observation is coupled with a concentration bound to prove the next lemma.

► **Lemma 6.** *With probability at least  $1 - \exp(-\varepsilon^{-8})$ , it holds that*

$$V = \mathbf{v}(I \setminus S_{\varepsilon^{-1}}) \geq \sum_{j=1}^{\varepsilon^{-1} - \varepsilon^{-\frac{1}{2}}} \mathbf{v}(\bar{x}^j) \cdot \frac{(\varepsilon - \varepsilon^{\frac{3}{2}})}{1 - (j-1)\varepsilon} - \varepsilon^9 \cdot \text{OPT}(\mathcal{I}).$$

Lemma 6 is the formal statement of (2). Lemma 6 essentially reduces the problem of deriving a lower bound for  $V$  to obtaining a lower bound on  $\mathbf{v}(\bar{x}^j)$ .

To obtain a lower bound for  $\mathbf{v}(\bar{x}^j)$  we use the following steps. We define random vectors  $\bar{\gamma}^j \in [0, 1]^I$  for every  $j \in [\varepsilon^{-1}]$  such that  $\mathbf{v}(\bar{\gamma}^j)$  is high, and there is  $\bar{z}^j$  such that  $\text{cover}(\bar{z}^j) = \bar{\gamma}^j$  and  $\|\bar{z}^j\| \approx m_j$ . We scale down  $\bar{z}^j$  to obtain a solution for  $\text{LP}(S_{j-1}, m_j)$  of value  $\approx \mathbf{v}(\bar{\gamma}^{j-1})$ , and consequently get a lower bound for  $\mathbf{v}(\bar{x}^j)$ . We use a *linear structure* defined below, to show the existence of  $\bar{z}^j$ . We further use auxiliary random vectors  $\bar{\lambda}^j$  to define  $\bar{\gamma}^j$ .

Let  $(\Omega, \mathcal{F}, \text{Pr})$  be the probability space defined by the execution of the algorithm. Define the  $\sigma$ -algebras  $\mathcal{F}_0 = \{\emptyset, \Omega\}$  and  $\mathcal{F}_j = \sigma(\{R_b^{j'} \mid 1 \leq j' \leq j, 1 \leq b \leq q\})$ . That is,  $\mathcal{F}_j$  describes events which only depend on the outcomes of the random sampling up to (and including) the  $j$ -th iteration of the algorithm. We follow the standard definition of conditional probabilities and expectations given  $\sigma$ -algebras (see, e.g., [6]).

Fix an optimal solution  $(C_1^*, \dots, C_m^*)$  for the instance and let  $S^* = \bigcup_{j=1}^m C_j^*$  be the set of items in this solution. Also, given a set  $S \subseteq I$  denote by  $\mathbb{1}_S$  the vector  $\bar{z} \in \{0, 1\}^I$  satisfying  $\bar{z}_i = 1$  for  $i \in S$ , and  $\bar{z}_i = 0$  otherwise.

We define  $\bar{\gamma}^j$  and  $\bar{\lambda}^j$  inductively using  $S^*$ . Define  $\bar{\gamma}^0 = \mathbb{1}_{S^*}$ , that is  $\bar{\gamma}_i^0 = 1$  for every  $i \in S^*$  and  $\bar{\gamma}_i^0 = 0$  for every  $i \in I \setminus S^*$ . For every  $j \in [\varepsilon^{-1} - 1]$  define  $\bar{\lambda}^j \in \mathbb{R}_{\geq 0}^I$  by

$$\bar{\lambda}_i^j = \frac{1 - j \cdot \varepsilon}{1 - (j-1)\varepsilon} \cdot \frac{1}{\text{Pr}(i \in S_j \mid \mathcal{F}_{j-1})} \cdot \bar{\gamma}_i^{j-1} \quad (5)$$

for all  $i \in S_{j-1}$  and  $\bar{\lambda}_i^j = 0$  for  $i \notin S_{j-1}$ . Intuitively, the expression  $\text{Pr}(i \in S_j \mid \mathcal{F}_{j-1})$  in (5) is the probability that item  $i$  will still be available for packing after the  $j$ -th iteration, where the probability is calculated at the end of the iteration  $j-1$ . Also, for every  $j \in [\varepsilon^{-1} - 1]$  define  $\bar{\gamma}^j \in \mathbb{R}_{\geq 0}^I$  by

$$\bar{\gamma}_i^j = \mathbb{1}_{i \in S_j} \cdot \bar{\lambda}_i^j \quad \forall i \in I. \quad (6)$$

Observe that  $\bar{\lambda}^j$  is  $\mathcal{F}_{j-1}$ -measurable random variable whereas  $\bar{\gamma}^j$  is  $\mathcal{F}_j$ -measurable. Intuitively, this means that the value of  $\bar{\lambda}^j$  is known by the end of the  $(j-1)$ -th iteration, while the value of  $\bar{\gamma}^j$  is only known by the end of the  $j$ -th iteration.

The lower bound on  $\mathbf{v}(\bar{\gamma}^{j-1})$  relies on a simple calculation of expectations followed by a concentration bound. By induction it can be shown that  $\mathbb{E}[\bar{\gamma}_i^{j-1}] = (1 - (j-1)\varepsilon) \cdot \mathbb{1}_{i \in S^*}$ , and therefore,

$$\mathbb{E}[\mathbf{v}(\bar{\gamma}^{j-1})] = (1 - (j-1)\varepsilon) \cdot \mathbf{v}(S^*) = (1 - (j-1)\varepsilon) \cdot \text{OPT}(\mathcal{I}).$$

We use concentration bounds to show that indeed  $\mathbf{v}(\bar{\gamma}^{j-1})$  does not deviate from its expected value.

► **Lemma 7.** *With probability at least  $1 - \exp(-\varepsilon^{-20})$ , it holds that*

$$\forall j \in [\varepsilon^{-1}] : \quad \mathbf{v}(\bar{\gamma}^{j-1}) \geq (1 - \varepsilon(j-1)) \cdot \text{OPT}(\mathcal{I}) - \varepsilon^3 \cdot \text{OPT}(\mathcal{I}).$$

We give the proof of Lemma 7 in the full version of the paper [9].

Our next challenge is to show that there is a solution for  $\text{LP}(S_{j-1}, m_j)$  whose cover is roughly  $\bar{\gamma}^{j-1}$ , which can be alternatively stated as  $\bar{\gamma}^{j-1} \in P(\ell)$  where  $\ell \approx m_j$ , and  $P(\ell)$  is as defined in (4). To this end, we introduce a *linear structure* for CMK. The main idea in linear structures is that they allow us to determine that  $\bar{\gamma}^j \in P(\ell)$  by checking if  $\bar{\gamma}^j$  satisfies a small number of linear inequalities.

Given a vector  $\bar{u} \in \mathbb{R}_{\geq 0}^I$  which defines an inequality in the linear structure, we use concentration bounds to show that  $\bar{\gamma}^j \cdot \bar{u} \leq \mathbb{E}[\bar{\gamma}^j \cdot \bar{u}] + \xi$ , where  $\xi$  is an error term. The concentration bounds we use only provide useful guarantees if the error term  $\xi$  is of order of the maximum sum of entries in  $\bar{u}$  w.r.t. a single configuration, that is,  $\text{tol}(\bar{u}) = \max \{ \sum_{i \in C} \bar{u}_i \mid C \in \mathcal{C} \}$ . We refer to the value  $\text{tol}(\bar{u})$  as the *tolerance* of  $\bar{u}$ . We consequently require the linear structure to be robust to additive errors of order of the tolerance. Also, we say that  $S \subseteq I$  can be *packed into  $\ell \in \mathbb{N}$  bins* if there are  $\ell$  configurations  $C_1, \dots, C_\ell \in \mathcal{C}$  such that  $\bigcup_{b=1}^{\ell} C_b = S$ .

► **Definition 8 (Linear Structure).** *Let  $(I, \mathbf{w}, \mathbf{v}, m, k)$  be a CMK instance and  $\delta > 0$  a parameter. Also, consider a subset  $S \subseteq I$  such that  $S$  can be packed in  $\ell \in \mathbb{N}$  bins. A  $\delta$ -linear structure of  $S$  is a set of vectors  $\mathcal{L} \subseteq \mathbb{R}_{\geq 0}^I$  which satisfy the following property.*

■ *Let  $\bar{y} \in ([0, 1] \cap \mathbb{Q})^I$ ,  $0 < \alpha < 1$  and  $t > 0$ , such that*

1.  $\text{supp}(\bar{y}) \subseteq S$
2.  $\forall \bar{u} \in \mathcal{L} : \quad \bar{u} \cdot \bar{y} \leq \alpha \cdot \bar{u} \cdot \mathbb{1}_S + t \cdot \text{tol}(\bar{u})$

*Then, there is a fractional solution  $\bar{x}$  whose cover is  $\bar{y}$  and  $\|\bar{x}\| \leq \alpha \cdot \ell + 20\delta\ell + (t+1) \cdot \exp(\delta^{-5})$ .*

The size of the structure  $\mathcal{L}$  is  $|\mathcal{L}|$ .

Alternatively, a  $\delta$ -linear structure guarantees for  $S$  that for every  $\bar{y} \in [0, 1]^I$  with rational entries,  $0 < \alpha < 1$  and  $t > 0$ , if  $\text{supp}(\bar{y}) \subseteq S$  and  $\bar{y}$  satisfies  $|\mathcal{L}|$  linear inequalities, then  $\bar{y} \in P(\alpha \cdot \ell + 20\delta\ell + (t+1) \cdot \exp(\delta^{-5}))$ .

In [9] we prove the next result.

► **Lemma 9.** *Given  $\delta > 0$ , let  $I = (I, \mathbf{w}, \mathbf{v}, m, k)$  be a CMK instance, and  $S \subseteq I$  a subset which can be packed into  $\ell > \exp(\delta^{-5})$  bins. Then there is a  $\delta$ -linear structure  $\mathcal{L}$  of  $S$  of size at most  $\exp(\delta^{-4})$ .*

The above lemma is an adaptation of a construction of [17] used to solve the vector bin packing problem, in which there are additional requirements for the packing of  $S$ . Our adaptation leverages the relative simplicity of a cardinality constraint to omit these additional requirements.

We use Lemma 9 to show the existence of an  $\varepsilon^2$ -linear structure of  $S^*$ , where  $S^*$  is the set of items in an optimal solution. We use the linear structure to show the existence of a fractional solution  $\bar{z}^j$  such that  $\text{cover}(\bar{z}^j) = \bar{\gamma}^{j-1}$  and  $\|\bar{z}^j\| \approx (1 - (j-1)\varepsilon)m$  for every  $j \in [\varepsilon^{-1}]$ . A simple scaling is then used to construct a solution for  $\text{LP}(S_{j-1}, m_j)$  and establish the following lower bound on  $\mathbf{v}(\bar{x}^j)$ .

► **Lemma 10.** *With probability at least  $1 - \exp(-\varepsilon^{-20})$ , it holds that*

$$\forall j \in [\varepsilon^{-1}] : \quad \mathbf{v}(\bar{x}^j) \geq (1 - \varepsilon) \cdot \left( 1 - \frac{30 \cdot \varepsilon^2}{1 - (j-1)\varepsilon} \right) \cdot \mathbf{v}(\bar{\gamma}^{j-1}).$$

We give the proof of Lemma 10 in [9]. Together, Lemma 10 and Lemma 7 essentially give the formal proof of (3). Finally, using Lemmas 6, 7, and 10, we obtain the next result, whose proof is given in [9].

► **Lemma 11.** *With probability at least  $1 - \exp(-\varepsilon^{-5})$ , it holds that  $V \geq (1 - 60\sqrt{\varepsilon}) \cdot \text{OPT}(\mathcal{I})$ .*

Theorem 1 follows directly from Lemma 11.

## 4 The Analysis

Consider an execution of Algorithm 1 with the input  $\mathcal{I} = (I, \mathbf{w}, \mathbf{v}, m, k)$  and  $\varepsilon > 0$ . We use the notation and definitions as given in Section 3. Also, let  $\bar{y}^j = \text{cover}(\bar{x}^j)$  be the coverage of  $\bar{x}^j$ . Observe  $\bar{x}^j$  and  $\bar{y}^j$  are  $\mathcal{F}_{j-1}$ -measurable. That is, their values are determined by the outcomes of the samples up to (and including) the  $j - 1$  iteration. As in Section 3 we let  $(C_1^*, \dots, C_m^*)$  be an optimal solution for the instance  $\mathcal{I}$ . We define  $S^* = \bigcup_{b=1}^m C_b^*$  and  $\text{OPT} = \mathbf{v}(S^*) = \text{OPT}(\mathcal{I})$ .

### 4.1 Concentration Bounds

Before we give the proofs of Lemmas 6, 7, 10, and 11, we need to introduce some concentration bounds for *self-bounding functions*.

► **Definition 12.** *A non-negative function  $f : \mathcal{X}^n \rightarrow \mathbb{R}_{\geq 0}$  is called self-bounding if there exist  $n$  functions  $f_1, \dots, f_n : \mathcal{X}^{n-1} \rightarrow \mathcal{R}$  such that for all  $x = (x_1, \dots, x_n) \in \mathcal{X}^n$ ,*

$$0 \leq f(x) - f_t(x^{(t)}) \leq 1, \quad \text{and}$$

$$\sum_{t=1}^n \left( f(x) - f_t(x^{(t)}) \right) \leq f(x),$$

where  $x^{(t)} = (x_1, \dots, x_{t-1}, x_{t+1}, \dots, x_n) \in \mathcal{X}^{n-1}$  is obtained by dropping the  $t$ -th component of  $x$ .

We rely on the following concentration bound due to Boucheron, Lugosi and Massart [3].

► **Lemma 13.** *Let  $f : \mathcal{X}^n \rightarrow \mathbb{R}_{\geq 0}$  be a self-bounding function and let  $X_1, \dots, X_n \in \mathcal{X}$  be independent random variables. Define  $Z = f(X_1, \dots, X_n)$ . Then the following holds:*

1.  $\Pr(Z \geq \mathbb{E}[Z] + t) \leq \exp\left(-\frac{t^2}{2 \cdot \mathbb{E}[Z] + \frac{t}{3}}\right)$ , for every  $t \geq 0$ .
2.  $\Pr(Z \leq \mathbb{E}[Z] - t) \leq \exp\left(-\frac{t^2}{2 \cdot \mathbb{E}[Z]}\right)$ , for every  $t > 0$ .

The setting considered in [3] can be trivially extended to a setting in which the random variable are conditionally independent on a  $\sigma$ -algebra  $\mathcal{G}$  (see [6] for the definition of conditional independence) and the function  $f$  itself is a  $\mathcal{G}$ -measurable random function. This is formally stated in the next lemma.

► **Lemma 14.** *Let  $(\Omega, \mathcal{F}, \Pr)$  be a finite probability space and let  $\mathcal{G} \subseteq \mathcal{F}$  be a  $\sigma$ -algebra. Let  $D$  be a finite set of self-bounding function from  $\mathcal{X}^\ell$  to  $\mathbb{R}_{\geq 0}$  and let  $f \in D$  be a  $\mathcal{G}$ -measurable random function. Also, let  $X_1, \dots, X_\ell \in \mathcal{X}$  be random variables which are conditionally independent given  $\mathcal{G}$ . Define  $Z = f(X_1, \dots, X_n)$ . Then the following holds:*

1.  $\Pr(Z \geq \mathbb{E}[Z | \mathcal{G}] + t | \mathcal{G}) \leq \exp\left(-\frac{t^2}{2 \cdot \mathbb{E}[Z | \mathcal{G}] + \frac{t}{3}}\right)$ , for every  $t \geq 0$ .
2.  $\Pr(Z \leq \mathbb{E}[Z | \mathcal{G}] - t | \mathcal{G}) \leq \exp\left(-\frac{t^2}{2 \cdot \mathbb{E}[Z | \mathcal{G}]}\right)$  for every  $t \geq 0$ .

The generalization in Lemma 14 is required since the variables  $R_1^j, \dots, R_q^j$  are dependent for  $q > 1$  while being conditionally independent given the variables  $R_b^{j'}$  for every  $j' < j$  and  $b \in [q]$ . The following construction for self-bounding function was shown in [7].

► **Lemma 15.** Let  $\mathcal{I} = (I, \mathbf{w}, \mathbf{v}, m, k)$  be a CMK instance, and  $h : I \rightarrow \mathbb{R}_{\geq 0}$ . For some  $\ell \in \mathbb{N}_{>0}$  define  $f : \mathcal{C}^\ell \rightarrow \mathbb{R}_{\geq 0}$  by  $f(C_1, \dots, C_\ell) = \frac{h(\bigcup_{i \in [\ell]} C_i)}{\eta}$  where  $\eta \geq \max_{C \in \mathcal{C}} h(C)$ . Then  $f$  is self-bounding.

## 4.2 The proof of Lemma 6

The first step towards the proof of Lemma 6 is to show a lower bound on the probability of an item to appear in one of the sampled configurations  $R_1^j, \dots, R_q^j$  in terms of  $\bar{y}_i^j$ .

► **Lemma 16.** For every  $i \in I$  and  $j \in [\varepsilon^{-1}]$  it holds that  $\Pr(i \in S_{j-1} \setminus S_j \mid \mathcal{F}_{j-1}) \geq 1 - \exp\left(-\varepsilon \cdot \frac{\bar{y}_i^j}{1-(j-1)\varepsilon}\right)$ .

**Proof.** By a simple calculation,

$$\begin{aligned}
\Pr(i \in S_{j-1} \setminus S_j \mid \mathcal{F}_{j-1}) &= \Pr\left(i \in \bigcup_{b=1}^q R_b^j \mid \mathcal{F}_{j-1}\right) \\
&= 1 - \Pr\left(i \notin \bigcup_{b=1}^q R_b^j \mid \mathcal{F}_{j-1}\right) \\
&= 1 - \prod_{b=1}^q \Pr\left(i \notin R_b^j \mid \mathcal{F}_{j-1}\right) \\
&= 1 - \prod_{b=1}^q \left(1 - \Pr\left(i \in R_b^j \mid \mathcal{F}_{j-1}\right)\right) \\
&= 1 - \prod_{b=1}^q \left(1 - \Pr\left(R_b^j \in \mathcal{C}(i) \mid \mathcal{F}_{j-1}\right)\right).
\end{aligned} \tag{7}$$

The third equality holds as  $R_1^j, \dots, R_q^j$  are conditionally independent given  $\mathcal{F}_{j-1}$ . Therefore, by (7) and since the configurations are distributed by  $\bar{x}^j$  we have

$$\begin{aligned}
\Pr(i \in S_{j-1} \setminus S_j \mid \mathcal{F}_{j-1}) &= 1 - \prod_{b=1}^q \left(1 - \Pr\left(R_b^j \in \mathcal{C}(i) \mid \mathcal{F}_{j-1}\right)\right) \\
&= 1 - \left(1 - \frac{\sum_{C \in \mathcal{C}(i)} \bar{x}_C^j}{\|\bar{x}^j\|}\right)^q \\
&= 1 - \left(1 - \frac{\bar{y}_i^j}{m \cdot (1 - (j-1) \cdot \varepsilon)}\right)^{\varepsilon \cdot m} \\
&= 1 - \left(\left(1 - \frac{\bar{y}_i^j}{m \cdot (1 - (j-1) \cdot \varepsilon)}\right)^{\frac{m \cdot (1 - (j-1) \cdot \varepsilon)}{\bar{y}_i^j}}\right)^{\frac{\varepsilon \cdot \bar{y}_i^j}{(1 - (j-1) \cdot \varepsilon)}} \\
&\geq 1 - (e^{-1})^{\frac{\varepsilon \cdot \bar{y}_i^j}{(1 - (j-1) \cdot \varepsilon)}} \\
&= 1 - \exp\left(-\frac{\varepsilon \cdot \bar{y}_i^j}{(1 - (j-1) \cdot \varepsilon)}\right).
\end{aligned}$$

The inequality holds since  $(1 - \frac{1}{x})^x \leq \frac{1}{e}$  for all  $x \geq 1$ . ◀

## 27:14 An EPTAS for Cardinality Constrained Multiple Knapsack

The next lemma uses Lemma 16 to lower bound the total value of sampled configurations in the  $j$ -th iteration.

► **Lemma 17.** *For all  $j \in [\varepsilon^{-1} - \varepsilon^{-\frac{1}{2}}]$  it holds that*

$$\mathbb{E}[\mathbf{v}(S_{j-1} \setminus S_j) \mid \mathcal{F}_{j-1}] \geq \mathbf{v}(\bar{x}^j) \cdot \left(\varepsilon - \varepsilon^{\frac{3}{2}}\right) \frac{1}{1 - (j-1)\varepsilon}.$$

**Proof.** By Lemma 16 we get

$$\begin{aligned} \mathbb{E}[\mathbf{v}(S_{j-1} \setminus S_j) \mid \mathcal{F}_{j-1}] &= \sum_{i \in I} \mathbf{v}(i) \cdot \Pr(i \in S_{j-1} \setminus S_j \mid \mathcal{F}_{j-1}) \\ &\geq \sum_{i \in I} \mathbf{v}(i) \cdot \left(1 - \exp\left(-\varepsilon \cdot \frac{\bar{y}_i^j}{1 - (j-1)\varepsilon}\right)\right) \\ &\geq \sum_{i \in I} \mathbf{v}(i) \cdot \left(\varepsilon \cdot \frac{\bar{y}_i^j}{1 - (j-1)\varepsilon} - \left(\varepsilon \cdot \frac{\bar{y}_i^j}{1 - (j-1)\varepsilon}\right)^2\right) \tag{8} \\ &= \sum_{i \in I} \mathbf{v}(i) \cdot \left(\varepsilon \cdot \frac{\bar{y}_i^j}{1 - (j-1)\varepsilon} \cdot \left(1 - \varepsilon \cdot \frac{\bar{y}_i^j}{1 - (j-1)\varepsilon}\right)\right). \end{aligned}$$

The second inequality follows from  $1 - \exp(-x) \geq x - x^2$  for all  $x \geq 0$ . By (8) we have

$$\begin{aligned} \mathbb{E}[\mathbf{v}(S_{j-1} \setminus S_j) \mid \mathcal{F}_{j-1}] &\geq \sum_{i \in I} \mathbf{v}(i) \cdot \left(\varepsilon \cdot \frac{\bar{y}_i^j}{1 - (j-1)\varepsilon} \cdot \left(1 - \varepsilon \cdot \frac{1}{1 - (\varepsilon^{-1} - \varepsilon^{-\frac{1}{2}} - 1)\varepsilon}\right)\right) \\ &= \sum_{i \in I} \mathbf{v}(i) \cdot \left(\varepsilon \cdot \frac{\bar{y}_i^j}{1 - (j-1)\varepsilon} \cdot \left(1 - \frac{\varepsilon}{\varepsilon + \varepsilon^{\frac{1}{2}}}\right)\right) \\ &= \frac{1}{1 - (j-1)\varepsilon} \cdot \left(\varepsilon - \frac{\varepsilon^2}{\varepsilon + \varepsilon^{\frac{1}{2}}}\right) \cdot \sum_{i \in I} \mathbf{v}(i) \cdot \bar{y}_i^j \\ &= \frac{1}{1 - (j-1)\varepsilon} \cdot \left(\varepsilon - \frac{1}{\varepsilon^{-1} + \varepsilon^{-\frac{3}{2}}}\right) \cdot \mathbf{v}(\bar{x}^j) \\ &\geq \mathbf{v}(\bar{x}^j) \cdot \left(\varepsilon - \varepsilon^{\frac{3}{2}}\right) \frac{1}{1 - (j-1)\varepsilon}. \end{aligned}$$

The first inequality holds since  $j \leq \varepsilon^{-1} - \varepsilon^{-\frac{1}{2}}$  and since  $\bar{x}^j$  is a feasible solution for  $\text{LP}(S, m_j)$ ; thus,  $\bar{y}^j \in [0, 1]^I$ . ◀

We can also use Lemma 14 to show that the value of the configurations sampled in the  $j$ -th iteration does not deviate significantly from its expected value.

► **Lemma 18.** *For all  $j \in [\varepsilon^{-1}]$  it holds that*

$$\Pr\left(\mathbf{v}(S_{j-1} \setminus S_j) \leq \mathbb{E}[\mathbf{v}(S_{j-1} \setminus S_j) \mid \mathcal{F}_{j-1}] - \varepsilon^{10} \cdot \text{OPT}(\mathcal{I})\right) \leq \exp(-\varepsilon^{-9}).$$

**Proof.** Recall that  $q = \varepsilon \cdot m$ . Define a function  $f : \mathcal{C}^q \rightarrow \mathbb{R}_{\geq 0}$  by  $f(X) = \frac{\mathbf{v}(S)}{\varepsilon^{30} \cdot \text{OPT}(\mathcal{I})}$  for all  $X = (C_1, \dots, C_q) \in \mathcal{C}^q$ . Since  $\mathcal{I}$  is  $\varepsilon$ -simple it holds that  $\mathbf{v}(C) \leq \varepsilon^{30} \cdot \text{OPT}$  for all  $C \in \mathcal{C}$ , thus, by Lemma 15 it follows that  $f$  is a self-bounding function. Therefore,

$$\begin{aligned}
& \Pr \left( \mathbf{v}(S_{j-1} \setminus S_j) \leq \mathbb{E} [\mathbf{v}(S_{j-1} \setminus S_j) \mid \mathcal{F}_{j-1}] - \varepsilon^{10} \cdot \text{OPT}(\mathcal{I}) \mid \mathcal{F}_{j-1} \right) \\
&= \Pr \left( f(R_1^j, \dots, R_q^j) \leq \mathbb{E} \left[ f(R_1^j, \dots, R_q^j) \mid \mathcal{F}_{j-1} \right] - \varepsilon^{-20} \mid \mathcal{F}_{j-1} \right) \\
&\leq \exp \left( - \frac{\varepsilon^{-40}}{2 \cdot \mathbb{E} \left[ f(R_1^j, \dots, R_q^j) \mid \mathcal{F}_{j-1} \right]} \right).
\end{aligned} \tag{9}$$

The inequality holds by Lemma 14. In addition, since  $R_1^j, \dots, R_q^j$  is a solution for  $\mathcal{I}$ , it also holds that

$$\mathbb{E} \left[ f(R_1^j, \dots, R_q^j) \mid \mathcal{F}_{j-1} \right] \leq \frac{\text{OPT}(\mathcal{I})}{\varepsilon^{30} \cdot \text{OPT}(\mathcal{I})} = \varepsilon^{-30}. \tag{10}$$

Hence, by the above

$$\begin{aligned}
& \Pr \left( \mathbf{v}(S_{j-1} \setminus S_j) \leq \mathbb{E} [\mathbf{v}(S_{j-1} \setminus S_j) \mid \mathcal{F}_{j-1}] - \varepsilon^{10} \cdot \text{OPT}(\mathcal{I}) \mid \mathcal{F}_{j-1} \right) \\
&\leq \exp \left( - \frac{\varepsilon^{-40}}{2 \cdot \mathbb{E} \left[ f(R_1^j, \dots, R_q^j) \mid \mathcal{F}_{j-1} \right]} \right) \\
&\leq \exp \left( - \frac{\varepsilon^{-40}}{2 \cdot \varepsilon^{-30}} \right) \\
&= \exp \left( - \frac{\varepsilon^{-10}}{2} \right) \\
&\leq \exp(-\varepsilon^{-9}).
\end{aligned} \tag{11}$$

The first inequality holds by (9). The second inequality follows from (10). For the last inequality, recall that  $\varepsilon < 0.1$ . Therefore, by (11) it holds that (unconditionally on  $\mathcal{F}_{j-1}$ ),

$$\Pr \left( \mathbf{v}(S_{j-1} \setminus S_j) \leq \mathbb{E} [\mathbf{v}(S_{j-1} \setminus S_j) \mid \mathcal{F}_{j-1}] - \varepsilon^{10} \cdot \text{OPT}(\mathcal{I}) \right) \leq \exp(-\varepsilon^{-9}). \quad \blacktriangleleft$$

The proof of Lemma 6 follows from Lemma 17 and Lemma 18.

► **Lemma 6.** *With probability at least  $1 - \exp(-\varepsilon^{-8})$ , it holds that*

$$V = \mathbf{v}(I \setminus S_{\varepsilon^{-1}}) \geq \sum_{j=1}^{\varepsilon^{-1} - \varepsilon^{-\frac{1}{2}}} \mathbf{v}(\bar{x}^j) \cdot \frac{(\varepsilon - \varepsilon^{\frac{3}{2}})}{1 - (j-1)\varepsilon} - \varepsilon^9 \cdot \text{OPT}(\mathcal{I}).$$

**Proof.**

$$\begin{aligned}
 & \Pr \left( \mathbf{v}(I \setminus S_{\varepsilon^{-1}}) \geq \sum_{j=1}^{\varepsilon^{-1} - \varepsilon^{-\frac{1}{2}}} \mathbf{v}(\bar{x}^j) \cdot \frac{(\varepsilon - \varepsilon^{\frac{3}{2}})}{1 - (j-1)\varepsilon} - \varepsilon^9 \cdot \text{OPT}(\mathcal{I}) \right) \\
 & \geq \Pr \left( \bigwedge_{j \in [\varepsilon^{-1} - \varepsilon^{-\frac{1}{2}}]} \left( \mathbf{v}(S_{j-1} \setminus S_j) \geq \mathbf{v}(\bar{x}^j) \cdot \frac{(\varepsilon - \varepsilon^{\frac{3}{2}})}{1 - (j-1)\varepsilon} - \varepsilon^{10} \cdot \text{OPT}(\mathcal{I}) \right) \right) \\
 & \geq \Pr \left( \bigwedge_{j \in [\varepsilon^{-1} - \varepsilon^{-\frac{1}{2}}]} \left( \mathbf{v}(S_{j-1} \setminus S_j) \geq \mathbb{E}[\mathbf{v}(S_{j-1} \setminus S_j) \mid \mathcal{F}_{j-1}] - \varepsilon^{10} \cdot \text{OPT}(\mathcal{I}) \right) \right) \\
 & \geq 1 - \Pr \left( \bigvee_{j \in [\varepsilon^{-1} - \varepsilon^{-\frac{1}{2}}]} \left( \mathbf{v}(S_{j-1} \setminus S_j) < \mathbb{E}[\mathbf{v}(S_{j-1} \setminus S_j) \mid \mathcal{F}_{j-1}] - \varepsilon^{10} \cdot \text{OPT}(\mathcal{I}) \right) \right). \tag{12}
 \end{aligned}$$

The first inequality holds because if all  $\varepsilon^{-1} - \varepsilon^{-\frac{1}{2}}$  events in the second expression occur, then so is the event in the first expression. The second inequality holds by Lemma 17. By (12) and the union bound

$$\begin{aligned}
 & \Pr \left( \mathbf{v}(I \setminus S_{\varepsilon^{-1}}) \geq \sum_{j=1}^{\varepsilon^{-1} - \varepsilon^{-\frac{1}{2}}} \mathbf{v}(\bar{x}^j) \cdot \frac{(\varepsilon - \varepsilon^{\frac{3}{2}})}{1 - (j-1)\varepsilon} - \varepsilon^9 \cdot \text{OPT}(\mathcal{I}) \right) \\
 & \geq 1 - \sum_{j \in [\varepsilon^{-1} - \varepsilon^{-\frac{1}{2}}]} \Pr \left( \mathbf{v}(S_{j-1} \setminus S_j) < \mathbb{E}[\mathbf{v}(S_{j-1} \setminus S_j) \mid \mathcal{F}_{j-1}] - \varepsilon^{10} \cdot \text{OPT}(\mathcal{I}) \right) \\
 & \geq 1 - \varepsilon^{-1} \cdot \exp(-\varepsilon^{-9}) \\
 & \geq 1 - \exp(-\varepsilon^{-8}).
 \end{aligned}$$

The second inequality holds Lemma 18. For the last inequality, recall that  $\varepsilon < 0.1$ .  $\blacktriangleleft$

The remaining proofs are given in the full version of the paper [9].

## Abstract

The problem of rectangle tiling binary arrays is defined as follows. Given an  $n \times n$  array  $A$  of zeros and ones and a natural number  $p$ , our task is to partition  $A$  into at most  $p$  rectangular tiles, so that the maximal weight of a tile is minimized. A tile is any rectangular subarray of  $A$ . The weight of a tile is the sum of elements that fall within it. We present a linear ( $O(n^2)$ ) time  $(\frac{3}{2} + \frac{p^2}{w(A)})$ -approximation algorithm for this problem, where  $w(A)$  denotes the weight of the whole array  $A$ . This improves on the previously known approximation with the ratio 2 when  $\frac{p^2}{w(A)} < 1/2$ .

The result is best possible in the following sense. The algorithm employs the lower bound of  $L = \lceil \frac{w(A)}{p} \rceil$ , which is the only known and used bound on the optimum in all algorithms for rectangle tiling. We prove that a better approximation factor for the binary RTILE cannot be achieved using  $L$ , because there exist arrays, whose every partition contains a tile with weight at least  $(\frac{3}{2} + \frac{p}{w(A)})L$ . We also consider the dual problem of rectangle tiling for binary arrays, where we are given an upper bound on the weight of the tiles, and we have to cover the array  $A$  with the minimum number of non-overlapping tiles. Both problems have natural extensions to  $d$ -dimensional versions, for which we provide analogous results.

## 1 Introduction

In this paper we study several variants of the rectangle tiling problem. These problems belong to a very wide class of discrete optimization tiling problems. As an input, we are given a two-dimensional array  $A[1..n, 1..n]$ , where each cell  $A[i, j]$  has a non-negative weight.

**RTILE.** Given a two-dimensional array  $A$  of size  $n \times n$  and a natural number  $p$ , we partition  $A$  into at most  $p$  rectangular subarrays, called *tiles*, so that the maximum weight of any tile is minimized. In other words, we have to cover  $A$  with tiles such that no two tiles overlap, while minimizing the weight of any tile. The weight of a tile is the sum of the elements that fall within it.

**DRTILE.** A natural variant of RTILE is called the DRTILE problem. The DRTILE problem is a dual of the RTILE problem, where we are given an upper bound  $W$  on the weight of the tiles, and we have to cover the array  $A$  with the minimum number of non-overlapping tiles.

These two problems have a natural extension to  $d$  dimensions. Here the input is a  $d$ -dimensional array  $A$  of size  $n$  in each dimension and we have to partition  $A$  into non-overlapping  $d$ -dimensional tiles so that the optimality criterion of the RTILE/DRTILE problem is satisfied.

In this paper we consider a special case of the RTILE/DRTILE problem, where each cell has a binary weight, i.e., the weight of any cell is either 0 or 1. We extend our approach to solve the  $d$ -dimensional binary RTILE/DRTILE problem.

**Motivation.** The RTILE/ DRTILE problem is a general problem in combinatorial optimization that has a wide variety of applications in real life. These include load balancing in parallel computing environments, video compression, data partitioning, database mining, and building equisum histogram on two or more attributes. A detailed description of the practical applications of RTILE/ DRTILE problem can be found in [1, 7, 11].

**Related Work.** Both the RTILE and DRTILE problems can be solved in polynomial time when the array is one-dimensional. The RTILE problem can be solved using dynamic programming in time  $O(np)$ . For any fixed  $\epsilon < 1$ , the best known algorithm has the running time  $O(\min\{n + p^{1+\epsilon}, n \log n\})$  [8]. An extensive survey on the RTILE problem in one-dimension can be found in [8]. On the other hand, the DRTILE problem in one dimension can be solved using a greedy algorithm in linear time.

Both the RTILE and DRTILE problems have been proven to be NP-hard [7]. Grigni and Manne [6] proved that optimal  $p \times p$  tiling (which is a restricted variant of the RTILE problem) is NP-hard even when the cell weight is binary. Charikar et al. [3] showed this problem to be APX-hard and NP-hard to approximate within a factor of 2. Khanna et al. [7] proved the RTILE problem to be NP-hard to achieve a  $\frac{5}{4}$ -approximation. Recently Głuch and Loryś [5] have improved the lower bound of the RTILE problem to  $\frac{4}{3}$ . It is not known whether the binary RTILE is solvable in polynomial time or NP-hard. Khanna et al. [7] gave the first approximation algorithm for the RTILE problem with the ratio  $\frac{5}{2}$ . The approximation ratio was improved to  $\frac{7}{3}$  independently by Sharp [15] and Loryś and Paluch [9]. Loryś and Paluch [10] gave a  $\frac{9}{4}$ -approximation algorithm for this problem. Berman et al. [1] improved the approximation ratio to  $\frac{11}{5}$ . Finally, Paluch [13] gave a  $\frac{17}{8}$ -approximation for this problem and also proved that the approximation ratio is tight with respect to the used lower bound. As far as the DRTILE problem is concerned, Khanna et al. [7] gave an  $O(n^5)$ -time 4-approximation algorithm using the Hierarchical Binary Tiling (HBT) technique. They improved the approximation ratio to 2 using a modified version of the HBT technique, but the running time of this algorithm is very high making the algorithm less practical. Loryś and Paluch [9] also gave a 4-approximation for the DRTILE problem while improving the running time to linear.

The  $d$ -dimensional version of this problem was introduced by Smith and Suri [16]. They gave a  $\frac{d+3}{2}$ -approximation algorithm that runs in time  $O(n^d + p \log n^d)$ . Sharp [15] improved the approximation ratio to  $\frac{d^2+2d-1}{2d-1}$  that runs in time  $O(n^d + 2^d p \log n^d)$ . Paluch [14] gave a  $\frac{d+2}{2}$ -approximation algorithm while matching the previous running time. She also proved that the ratio is tight with respect to the known lower bound of the problem.

RPACK is an extensively studied variant of rectangle tiling, in which we are given a set of axis-parallel weighted rectangles in a  $n \times n$  grid, and the goal is to find at most  $k$  disjoint rectangles of largest weight. Khanna et al. [7] proved that this problem is NP-hard even when each rectangle intersects at most three other rectangles. They gave an  $O(\log n)$ -approximation algorithm for RPACK that runs in  $O(n^2 p \log n)$  time. In [1] Berman et al.

considered the multi-dimensional version of this problem. The dual of RPACK is known to be NP-hard even when we are interested in finding a sub-set of disjoint rectangles with a total weight equal to at least some given  $w$ . Du et al. [4] considered a min-max version of RTILE, where the weight of each tile cannot be smaller than the given lower bound and the aim is to minimize the maximum weight of a tile. They [4] gave a 5-approximation algorithm for this problem and Berman and Raskhodnikova [2] improved the approximation factor to 4 and the approximation ratio of the binary variant to 3.

**Previous Work.** The binary version of the RTILE problem has also been studied. Khanna et al. [7] gave a  $\frac{9}{4}$ -approximation for the binary RTILE problem. Lorys and Paluch [9] and Berman et al. [1] independently improved the approximation ratio for binary RTILE to 2.

**Our Results.** We improve the approximation ratio of the binary RTILE problem to  $\frac{3}{2} + \frac{p^2}{w(A)}$ , where  $w(A)$  denotes the number of ones in  $A$ . For the arrays  $A$  satisfying  $\frac{p^2}{w(A)} \approx 0$ , it implies that the approximation ratio of the algorithm amounts to  $\frac{3}{2}$ . The running time of our algorithm is linear ( $O(n^2)$ ). The approximation is best possible in the following sense. The algorithm employs the lower bound of  $L = \lceil \frac{w(A)}{p} \rceil$ , which is the only known and used bound on the optimum in all algorithms for rectangle tiling. We prove that a better approximation factor for the binary RTILE cannot be achieved using  $L$ , because there exist arrays, whose every partition contains a tile of weight at least  $(\frac{3}{2} + \frac{p}{w(A)})L$ .

The general approach to solving this problem is to some extent similar to the approach of [13]. The found tiling is also hierarchical and we use the notions of *boundaries* and *types of columns/subarrays* as well as we apply linear programming in a non-standard way. However, in the present paper the types of subarrays are organized in a somewhat different manner. In particular, the idea of *shadows* is new. To compute the desired partition of  $A$  into tiles, we only check a small number of tilings of simply defined subarrays. The subarrays are identified with the help of so called *boundaries* and their *shadows*, which, roughly speaking, designate parts of  $A$  tileable in a certain manner and having a weight greater than  $\frac{3}{2}L$ . To prove the tileability of subarrays composed of multiple simpler subarrays we employ linear programming. Its application here differs from the one in [13] in that each dimension is treated completely symmetrically and thus more “globally” and in the method of showing the feasibility of dual programs. We show that the binary DRTILE problem can be approximated by reducing it to the binary RTILE problem. As for the  $d$ -dimensional binary RTILE problem, the algorithm for the 2-dimensional binary RTILE problem can be extended to obtain an approximation for the  $d$ -dimensional binary RTILE problem. The same approximation ratio for the  $d$ -dimensional binary DRTILE problem can also be found analogously.

**Organization.** In Section 2, we recall the necessary definitions. In Section 3, we revisit the definition of a boundary and introduce shadows of a boundary. In Section 4, we assume that  $w(A) \gg p^2$  and present a  $\frac{3}{2}$ -approximation algorithm for the RTILE problem. The goal of this section is also to introduce the methods needed for the approximation of the binary RTILE more gradually, without obscuring the presentation with many technical aspects. In Section 5 we present a  $(\frac{3}{2} + \frac{p^2}{w(A)})$ -approximation algorithm for the general case (which, in particular, applies also when  $\frac{p^2}{w(A)}$  is not negligible). This approximation is achieved by applying only small modifications to the approach described in Section 4. In Section 6, we show that the approximation factor we obtain for the RTILE problem is tight with respect to the known lower bound. Section 7 contains our result on the DRTILE problem. We conclude by presenting an approximation algorithm for the multi-dimensional RTILE problem in Section 8.

## 2 Preliminaries

Let  $A$  be a two-dimensional array of size  $n \times n$ , where each of its elements belongs to the set  $\{0, 1\}$ . Given  $A$  and a natural number  $p$ , we want to partition  $A$  into  $p$  rectangular subarrays, called *tiles* so that the maximal weight of a tile is minimized. The weight of a tile  $T$ , denoted  $w(T)$ , is the sum of elements within  $T$ .  $w(A)$  denotes the weight of the whole array  $A$ . Since any array element is either equal to 0 or 1,  $w(A)$  amounts to the number of 1s in  $A$ .

First, notice that the problem is trivial when  $p \geq w(A)$ . Assume then that  $p < w(A)$ . Clearly, the maximal weight of a tile cannot be smaller than  $\frac{w(A)}{p}$ . Consequently,  $L = \lceil \frac{w(A)}{p} \rceil$  is a lower bound on the value of the optimal solution to the RTILE problem.

Thus to design an  $\alpha$ -approximation algorithm for the RTILE problem, it suffices to demonstrate the method of partitioning  $A$  into  $p$  tiles such that the weight of each tile does not surpass  $\alpha L$ .

The number  $p$  of allowed tiles is linked to the weight of the array  $A$  in the following manner.

► **Fact 1.** Let  $w(A)$  and  $L$  be as defined above. Then,  $p \geq \lceil \frac{w(A)}{L} \rceil$ .

The proof directly follows from the assumption that  $L = \lceil \frac{w(A)}{p} \rceil$

► **Definition 2.** An array  $A$  is said to be  $f$ -partitioned if it is partitioned into rectangular tiles such that the weight of any tile does not exceed  $f$ .

We denote by  $A[i]$  the  $i$ -th column of  $A$ , by  $A[i..j]$  a subarray of  $A$  consisting of columns  $i, i + 1, \dots, j$ . Thus  $A^T[i]$  denotes the  $i$ -th row of  $A$  and  $A^T[i..j]$  a subarray of  $A$  consisting of rows  $i, i + 1, \dots, j$ .

## 3 The Boundaries and Their Shadows

Let us assume that we want to design an  $\alpha$ -approximation algorithm for the RTILE problem. Hence the weight of any tile must not exceed  $\alpha L$ . In other words, we want to obtain an  $\alpha L$ -partitioning for  $A$ .

To help find such a partitioning we are going to make use of a sequence of (vertical) *boundaries* and their *shadows*. The vertical boundaries and shadows of array  $A$  are defined iteratively below. Each boundary and each shadow is a distinct column of  $A$ . The  $i$ -th boundary of  $A$  is denoted as  $B_i = A[b_i]$ , i.e.,  $B_i$  is the  $b_i$ -th column of  $A$  (or equivalently,  $B_i = A[k]$ , where  $k = b_i$ ). Similarly, the  $i$ -th shadow of  $A$  is denoted as  $B'_i = A[b'_i]$ . The number of boundaries and their shadows depends on the weight and structure of  $A$ . The shadow  $B'_i = A[b'_i]$  is equal to either  $B_i$  or the column succeeding  $B_i$ , i.e. either  $b'_i = b_i$ , or  $b'_i = b_i + 1$ . For each boundary  $B_i$  we define its *type* - we say that boundary  $B_i$  is of type  $j$ , denoted as  $t(B_i) = j$ , if its weight satisfies  $\lfloor \frac{w(B_i)}{\alpha L} \rfloor = j - 1$ .

The ideas behind boundaries and shadows are as follows. The first vertical boundary  $B_1$  indicates simply which part of the array consisting of successive columns starting from the leftmost, exceeds  $\alpha L$ . This means that such a subarray cannot be covered with one tile. However, the subarray  $A[1..b_1 - 1]$  ending on column  $b_1 - 1$  can form one tile, because its weight is not greater than  $\alpha L$ . For  $i > 1$  the  $i$ -th boundary  $B_i = A[b_i]$  is established in the following way. We distinguish two cases: (i)  $B_{i-1} = B'_{i-1}$  and (ii)  $B_{i-1} \neq B'_{i-1}$ . Let us first consider case (i). Suppose that  $t(B_{i-1}) = j$ . Any boundary of type  $j$  can be  $\alpha L$ -partitioned (horizontally) into  $j$  tiles. We check how far to the right we are able to extend one of such partitions. Thus, to identify the  $i$ th boundary  $B_i$ , we find  $b_i$  such that the subarray

■ **Figure 1** An array with column  $A[4]$  as the only boundary.

$A[b'_{i-1}..b_i - 1]$  can be  $\alpha L$ -partitioned horizontally into  $j$  tiles and the subarray  $A[b'_{i-1}..b_i]$  cannot. When (ii)  $B_{i-1} \neq B'_{i-1}$ , to identify the  $i$ th boundary  $B_i$ , we proceed in the same way as with the first boundary  $B_1$ , i.e., we find  $b_i$  such that the subarray  $A[b'_{i-1}..b_i - 1]$  can be  $\alpha L$ -partitioned horizontally into 1 tile and the subarray  $A[b'_{i-1}..b_i]$  cannot.

As for the  $i$ -th shadow  $B'_i$  we put it in the same column as the boundary  $B_i$  if the subarray  $A[b'_{i-1}..b_i]$  cannot be  $\alpha L$ -partitioned into  $t(B_i)$  tiles and otherwise, we put it just behind  $B_i$  - in column  $b_i + 1$ . Notice that in the case of a shadow we check the tileability into  $t(B_i)$  tiles and not  $t(B_{i-1})$ . Also, we observe that  $B_i \neq B'_i$  can happen only when  $t(B_i) > t(B_{i-1})$  or  $B_{i-1} \neq B'_{i-1}$ . If  $B_i \neq B'_i$ , then it means, as we later prove, that the subarray  $A[1..b_i]$  is rather easy to partition and we could in fact tile it with a proper number of tiles and start the process of tiling anew with the subarray  $A[b'_i..n]$ .

We now give a formal definition of a sequence of (vertical) *boundaries* of  $A$  and their *shadows*. For technical reasons we introduce a column  $A[0]$  to array  $A$ .

► **Definition 3.** A boundary  $B_i$  is of type  $j$ , denoted as  $t(B_i) = j$ , if its weight satisfies  $\lfloor \frac{w(B_i)}{\alpha L} \rfloor = j - 1$ . Based on that, the boundaries and their shadows are defined as follows:

1.  $B[0] = A[0], B'_0 = A[1]$ , thus  $b_0 = 0$  and  $b'_0 = 1$ ,
2.  **$i$ -th boundary  $B_i$  :**
  - a. If  $B_{i-1} = B'_{i-1}$ , then  $B_i = A[b_i]$  iff  $A[b_{i-1}..b_i - 1]$  can be  $\alpha L$ -partitioned horizontally into  $t(B_{i-1})$  tiles and  $A[b_{i-1}..b_i]$  cannot.
  - b. If  $B_{i-1} \neq B'_{i-1}$ , then  $B_i = A[b_i]$  iff  $w(A[b_{i-1} + 1..b_i - 1]) \leq \alpha L$  and  $w(A[b_{i-1} + 1..b_i]) > \alpha L$ .
3.  **$i$ -th Shadow  $B'_i$  :** Let  $t(B_i) = j$ .  
 $B'_i = B_i$  iff  $A[b'_{i-1}..b_i]$  cannot be  $\alpha L$ -partitioned horizontally into  $j$  tiles.

The horizontal boundaries are defined analogously. To illustrate the notion of boundaries and shadows let us consider a few examples.

► **Example 4.** Array  $A$  has only one vertical boundary  $B_1 = A[4]$  of type 1.

This means that the total weight of the first 3 columns does not exceed  $\alpha L$ , i.e.,  $w(A[1..3]) \leq \alpha L$ , and the weight of the subarray consisting of columns  $1 \dots 4$  does -  $w(A[1..4]) > \alpha L$ . Since  $t(B_1) = 1$ , by the definition, the weight of  $B_1 = A[4]$  is not greater than  $\alpha L$  and the shadow  $B'_1$  of  $B_1$  coincides with  $B_1$ . Since  $A$  has only one boundary, it means that the weight of the subarray consisting of all columns except for the first 3 is not greater than  $\alpha L$ , i.e.,  $w(A[4..n]) \leq \alpha L$ .

► **Example 5.** Array  $A$  has only one vertical boundary  $B_1 = A[4]$  of type 2 and  $B'_1 = A[4]$ . Exactly as in the example above, we have  $w(A[1..3]) \leq \alpha L$  and  $w(A[1..4]) > \alpha L$ . The weight of  $B_1$  satisfies:  $3L \geq w(A[4]) > \alpha L$ , because  $t(B_1) = 2$ . By the fact that  $B'_1 = B_1$ , we know that the horizontal partition of  $A[1..4]$  into 2 tiles of weight not surpassing  $\alpha L$  is impossible. Since  $A$  has only one boundary, we obtain that  $A[4..n]$  can be partitioned into  $t(B_1) = 2$  tiles.

► **Example 6.** Array  $A$  has only one vertical boundary  $B_1 = A[4]$  of type 2 and  $B'_1 = A[5]$ . Again, we have  $w(A[1..3]) \leq \alpha L$  and  $w(A[1..4]) > \alpha L$ . This time, however,  $B'_1 \neq B_1$ , therefore  $A[1..4]$  can be partitioned into 2 horizontal tiles with weight  $\alpha L$  at most. Since  $A$  has only one boundary and  $B'_1 \neq B_1$ , we have that  $w(A[5..n]) \leq \alpha L$ .

► **Lemma 7.** Let  $k$  denote the number of vertical boundaries of  $A$  and  $T_v = \sum_{i=1}^k t(B_i)$ . Then array  $A$  can be  $\alpha L$ -tilled with  $T_v + 1$  tiles.

**Proof.** Suppose first that for each  $1 \leq i \leq k$  it holds that  $B_i = B'_i$ . Then by Definition 3, each subarray  $A[b_i..b_{i+1} - 1]$  can be tiled horizontally with  $t(B_i)$  tiles and the subarray  $A[1..b_1 - 1]$  can be covered by 1 tile. Therefore we indeed use  $T_v + 1$  tiles.

For the general case, let  $i = \min\{k : B_k \neq B'_k\}$ . It means that the subarray  $A[b_{i-1}..b_i]$  can be tiled horizontally with  $t(B_i)$  tiles. By Definition 3 for each  $j \leq i - 2$  the subarray  $A[b_j..b_{j+1} - 1]$  can be tiled horizontally with  $t(B_j)$  tiles and the subarray  $A[1..b_1 - 1]$  can be covered by a single tile. This way the number of used tiles amounts to  $\sum_{j=1}^{i-2} t(B_j) + t(B_i) + 1 \leq \sum_{j=1}^i t(B_j)$ . We continue in the same manner with the subarray  $A[b'_i..n]$ . ◀

Analogously, we define a horizontal sequence of boundaries of  $A$ , i.e., a vertical sequence of boundaries of  $A^T$ .

Throughout the paper,  $B_1, B_2, \dots, B_k$  and  $C_1, \dots, C_l$  denote, respectively, the vertical and horizontal sequence of boundaries of  $A$ . Let  $T_v = \sum_{i=1}^k t(B_i)$  and  $T_h = \sum_{i=1}^l t(C_i)$  and let  $T = \min\{T_v, T_h\}$ .

► **Fact 8.** Array  $A$  can be  $\alpha L$ -tilled with  $T + 1$  tiles.

Since we can always  $\alpha L$ -partition  $A$  into  $T + 1$  tiles, to prove that there exists an  $\alpha$ -approximation algorithm for the binary RTILE problem, it suffices to show that  $T + 1$  is an allowed number of tiles, i.e., that  $T + 1 \leq p$ . To do so, it is enough to prove that it always holds that  $w(A) > TL$ . This is because since  $w(A) \leq pL$  and  $T$  and  $p$  are integers, the inequality  $w(A) > TL$  implies  $T + 1 \leq p$ .

We state this observation as:

► **Fact 9.** Let  $\alpha$  be such that for any  $A$  it holds that  $w(A) > TL$ . Then  $p \geq T + 1$  and there exists an  $\alpha$ -approximation algorithm for the binary RTILE problem.

Let us first note that it is easy to prove that  $w(A) > \frac{TL}{2}$ .

► **Lemma 10.** The weight of  $A$  satisfies  $w(A) > \frac{TL}{2}$ . Hence,  $p > \frac{T}{2}$ .

**Proof.** We begin by proving that it is always possible to partition the array  $A$  vertically into disjoint subarrays  $A_1, A_2, \dots, A_k$  where each subarray except the first ( $A_1$ ) will contain one of the following boundary types:

1. A single boundary of type  $j$ , where  $j$  is greater than one.
2. Two boundaries of type 1.
3. A boundary of type  $j$  followed by a boundary of type 1, where  $j$  is greater than one.

The first subarray  $A_1$  may have any of the types of boundaries mentioned above or a single boundary of type 1. We will now describe how to construct these subarrays.

Let  $B_1, B_2, \dots, B_l$  be a sequence of vertical boundaries of  $A$ . We construct the subarrays  $A_1, \dots, A_k$  iteratively. If  $t(B_l) > 1$ , then we define  $A[b_l..n]$  as the last vertical subarray, otherwise, the last subarray is represented by  $A[b_{l-1}..n]$ . We then repeat this process on the remaining array  $A[1..b_{x-1}]$ , where  $x \in \{l-1, l\}$  based on our choice of the last vertical subarray. We continue until we cannot construct a vertical subarray with one of the sets of boundaries mentioned in points 1 – 3.

In this case, the remaining subarray either has no boundary or has a boundary of type 1. If it has no boundary, we merge it with the vertical subarray containing the first boundary. If it has a boundary of type 1, we define it as the first vertical subarray and call it  $A_1$ .

Suppose  $T_i$  represents the sum of the types of boundaries that are located within the subarray  $A_i$ . Our goal is to prove that  $w(A_i) \geq \frac{1}{2}T_iL$ . If  $A_i$  contains a boundary  $B_r$  of type  $j > 1$  then,

$$\begin{aligned} w(A_i) &\geq w(B_r) \geq (j-1) \cdot \frac{3}{2}L \geq \frac{1}{3}(j+1) \cdot \frac{3}{2}L \\ &\geq \frac{1}{2}t(B_r)L = \frac{1}{2}T_iL \end{aligned}$$

If  $A_i$  contains two boundaries  $B_r$  and  $B_{r+1}$  of type 1 then,

$$\begin{aligned} w(A_i) &\geq w(A[b_r \dots b_{r+1}]) \geq \frac{3}{2}L \\ &\geq \frac{1}{2}(t(B_r) + t(B_{r+1})) \frac{3}{2}L > \frac{1}{2}T_i \cdot L \end{aligned}$$

If  $B_r$  is a boundary of type  $j > 1$  and  $B_{r+1}$  is a boundary of type 1 in  $A_i$  then,

$$\begin{aligned} w(A_1) &\geq w(B_r) \geq (j-1) \cdot \frac{3}{2}L \geq \frac{1}{3}(j+1) \cdot \frac{3}{2}L \\ &\geq \frac{1}{2}(t(B_r) + t(B_{r+1}))L = \frac{1}{2}T_i \cdot L \end{aligned}$$

If the  $A_1$  contains one of the above sets of boundaries then  $w(A_1) \geq \frac{T_1 \cdot L}{2}$ . Otherwise,  $A_1$  contains a single boundary of type 1. Then,

$$w(A_1) \geq \frac{3}{2}L > \frac{1}{2}t(B_1)L = \frac{1}{2}T_1 \cdot L$$

In conclusion we have proved that for each  $A_i$ ,  $w(A_i) \geq \frac{T_i \cdot L}{2}$ . Therefore  $w(A) \geq \frac{TL}{2}$ . ◀

We now present a lemma that establishes conditions under which a subarray  $A'$  of  $A$  can be partitioned into horizontal tiles.

► **Lemma 11.** *Let  $A' = A[i_1 \dots i_2]$  be a subarray of  $A$  and  $k$  a natural number greater or equal 2.*

*Suppose that  $\frac{w(A[i_1]) + w(A[i_2])}{k} + w(A[i_1 + 1 \dots i_2 - 1]) \leq \alpha L$ . Then  $A'$  can be partitioned into  $k$  horizontal tiles of weight at most: (i)  $\alpha L + 1$  if  $k = 2$ , (ii)  $\alpha L + 2$  if  $k > 2$ .*

**Proof.** We divide the number equal to the sum of the weights of two columns  $A[i_1]$  and  $A[i_2]$  (the columns may be unconnected) by  $k$ . We check where the division lines fall with respect to the subarray. Often they may occur in the middle of a row (consisting of two array elements) and we have to move the division so that the whole row is included or the

■ **Figure 2** An array with one horizontal boundary containing the subarrays  $x_2$  and  $x_1$  and one vertical boundary containing the subarrays  $x_3$ ,  $x_1$  and  $x_4$ .

whole row is excluded. If  $k = 2$ , then we choose one of the two options - moving the division upwards or downwards, hence, in the worst case we may have to increase the weight of one tile by 1. For  $k > 2$ , we may have to shift the division by almost the whole row and thus increase the weight of some tiles by 2. Next we extend this partition to include the subarray  $A'' = A[i_1 + 1 \dots i_2 - 1]$  - we do not change the partition of the two-column subarray, but simply follow the partition lines. In the worst case the whole weight of  $A''$  will fall into only one tile - yielding a tile of weight  $\frac{w(A[i_1]) + w(A[i_2])}{k} + w(A[i_1 + 1 \dots i_2 - 1])$ . ◀

**4** A  $\frac{3}{2}$ -approximation when  $w(A) \gg p^2$

In this section we deal with arrays such that  $\frac{p^2}{w(A)}$  is close to 0, which means that the total weight of any  $p^2$  elements of  $A$  is negligible. We are going to show that under this assumption, for  $\alpha = \frac{3}{2}$ , the weight of  $A$  satisfies  $w(A) > TL$ . Hence, by Fact 9 we get that for this type of arrays there exists a  $\frac{3}{2}$ -approximation for the binary RTILE problem. For the general case the proof that  $\alpha = \frac{3}{2} + \frac{p^2}{w(A)}$ , the weight of  $A$  satisfies  $w(A) > TL$ , presented in the next section will be only a slight modification of the one shown here.

► **Convention 12.** *Throughout this section whenever we speak about tiling and partitioning, we respectively mean “ $\frac{3}{2}L$ -partitioning” and “tiling using tiles of weight at most  $\frac{3}{2}L$ ”.*

► **Remark.** The total number of cells at the intersection of the horizontal and vertical boundaries is  $O(T^2)$ . By Lemma 10 we have that  $O(T^2) = O(p^2)$ . Therefore by the assumption of this section, it implies that the total weight of the cells in the intersections of the boundaries is negligible with respect to the total weight of the array.

► **Observation 13** ([12]). *Assume we have two complexes: one as in Figure 2 and the other with the variables related to the variables of the first one as follows:  $x'_1 = x_1$ ,  $x'_4 = x_4$ ,  $x'_3 = x_3$ ,  $x'_5 = x'_6 = 0$  and  $x'_2 = x_2 + \max\{x_5, x_6\}$ . Then the weight of the second complex is not bigger than the weight of the first one while the inequalities describing the first complex remain true for the second.*

Given an array  $A$  we build a linear program, with the help of which we will be able to relate the total weight of the array to the sum of types of boundaries  $T$ , i.e., we will show that  $w(A) > TL$ .

Using Observation 13, we can assume that the whole weight of the array  $A$  is contained in the boundaries, i.e., each element of  $A$  that does not belong to any boundary has value 0. Each vertical boundary  $B_i$  is crossed by  $l$  horizontal boundaries and thus cut into  $l + 1$  parts. We assign a variable  $x_{j,i}$  to each part, i.e., the  $j$ th part of  $B_i$  consists of elements  $A[c_{j-1} + 1, b_i], A[c_{j-1} + 2, b_i], \dots, A[c_j - 1, b_i]$  and  $x_{j,i}$  denotes the sum of the weights of these elements. Similarly, each horizontal boundary  $C_i$  is crossed by  $k$  vertical boundaries and thus cut into  $k + 1$  parts. We assign a variable  $z_{i,j}$  to each such part. The value of each variable  $x_{j,i}$  or  $z_{i,j}$  denotes the weight of the corresponding part of the boundary.

In the linear program, we minimize the sum of non-negative variables  $x_{j,i}$  and  $z_{i,j}$  subject to a set of constraints associated with the boundaries. For each vertical boundary  $B_i$  we will have either one or two constraints of the following form:

1. If  $t(B_i) > 1$ , then we add the constraint  $\frac{1}{t(B_i)-1} \sum_{j=1}^{l+1} x_{j,i} \geq \frac{3}{2}L$ , which simply describes the total weight of  $B_i$ .
2. a.  $B'_{i-1} \neq B_{i-1}$ .
  - i.  $t(B_i) = 1$ . The added constraint is  $\sum_{j=1}^l z_{j,i} + \sum_{j=1}^{l+1} x_{j,i} > \frac{3}{2}L$ .
  - ii.  $t(B_i) > 1$  and  $B'_i = B_i$  (which means that  $A[b'_{i-1}..b_i]$  cannot be tiled horizontally with  $t(B_i)$  tiles). By Lemma 11 we are justified to add the constraint  $\sum_{j=1}^l z_{j,i} + \frac{1}{t(B_i)} \sum_{j=1}^{l+1} x_{j,i} > \frac{3}{2}L$ .
  - iii.  $t(B_i) > 1$  and  $B'_i \neq B_i$ . In this case we do not add any constraint.
- b.  $B'_{i-1} = B_{i-1}$ .
  - i.  $B'_i \neq B_i$ . The added constraint is  $\sum_{j=1}^l z_{j,i} + \frac{1}{t(B_{i-1})} (\sum_{j=1}^{l+1} x_{j,i} + \sum_{j=1}^{l+1} x_{j,i-1}) > \frac{3}{2}L$ .
  - ii.  $B'_i = B_i$ . Let  $T_i = \max\{t(B_{i-1}), t(B_i)\}$ . The constraint we add is  $\sum_{j=1}^l z_{j,i} + \frac{1}{T_i} (\sum_{j=1}^{l+1} x_{j,i} + \sum_{j=1}^{l+1} x_{j,i-1}) > \frac{3}{2}L$ . The constraint is a consequence of Lemma 11.

Thus, each  $B_i$  defines either one or two constraints. Analogously, each horizontal variable  $C_j$  also defines one or two constraints. The linear program dual to the one we have just described has dual variables  $y'_i, y_i$ . For each  $B_i$  with  $t(B_i) > 1$  let  $y'_i$  denote the dual variable corresponding to the constraint  $\frac{1}{t(B_i)-1} \sum_{j=1}^{l+1} x_{j,i} > \frac{3}{2}L$ . The other type of a constraint (if it exists) defined by  $B_i$  is represented by  $y_i$ . The dual variables corresponding to horizontal boundaries are  $w_i, w'_i$ .

► **Example 14.** In this example array  $A$  has one vertical boundary  $B_1$  of type 1 and one horizontal boundary  $C_1$  of type 1.

|  | 0         | $x_{3,1}$ | 0         | $x_{3,2}$ | 0         |       |
|  |           | $B_1$     |           | $B_2$     |           |       |

■ **Figure 4** An array with two vertical and two horizontal boundaries.

► **Example 15.** In this example array  $A$  has two vertical boundaries and two horizontal ones, each of the four boundaries is of type 1. The array is depicted in Figure 4. The linear program for  $A$  looks as follows. In brackets we give the dual variables corresponding to respective inequalities.

$$\begin{aligned}
 &\text{minimize} && \sum_{i=1}^2 \sum_{j=1}^3 x_{j,i} + \sum_{i=1}^2 \sum_{j=1}^3 z_{i,j} \\
 &\text{subject to} && \sum_{j=1}^3 x_{j,1} + \sum_{i=1}^2 z_{i,1} > \frac{3}{2}L \quad (y_1) \\
 &&& \sum_{i=1}^2 \sum_{j=1}^3 x_{j,i} + \sum_{i=1}^2 z_{i,2} > \frac{3}{2}L \quad (y_2) \\
 &&& \sum_{j=1}^3 z_{1,j} + \sum_{i=1}^2 x_{1,i} > \frac{3}{2}L \quad (w_1) \\
 &&& \sum_{i=1}^2 \sum_{j=1}^3 z_{i,j} + \sum_{i=1}^2 x_{2,i} > \frac{3}{2}L \quad (w_2)
 \end{aligned}$$

► **Example 16.** In this example array  $A$  has two vertical boundaries  $B_1, B_2$  and two horizontal ones  $C_1, C_2$ . Their types are the following:  $t(B_1) = t(C_2) = 2$  and  $t(B_2) = t(C_1) = 1$ . Also  $B'_1 \neq B_1$  and  $C'_2 = C_2$ .

$$\begin{aligned}
 &\text{minimize} && \sum_{i=1}^2 \sum_{j=1}^3 x_{j,i} + \sum_{i=1}^2 \sum_{j=1}^3 z_{i,j} \\
 &\text{subject to} && \frac{1}{2} \sum_{j=1}^3 x_{j,1} + \sum_{i=1}^2 z_{i,1} > \frac{3}{2}L \quad (y_1) \\
 &&& \sum_{j=1}^3 x_{j,1} > \frac{3}{2}L \quad (y'_1) \\
 &&& \sum_{i=1}^2 z_{i,2} + \sum_{j=1}^3 x_{j,2} > \frac{3}{2}L \quad (y_2) \\
 &&& \sum_{j=1}^3 z_{1,j} + \sum_{i=1}^2 x_{1,i} > \frac{3}{2}L \quad (w_1) \\
 &&& \frac{1}{2} \sum_{i=1}^2 \sum_{j=1}^3 z_{i,j} + \sum_{i=1}^2 x_{2,i} > \frac{3}{2}L \quad (w_2) \\
 &&& \sum_{j=1}^3 z_{2,j} > \frac{3}{2}L \quad (w'_2)
 \end{aligned}$$

Let us now build dual linear program for the primal linear program of the Example 16. The dual linear program has the form:

$$\begin{aligned}
 &\text{maximize} && \frac{3}{2}L(y_1 + y_2 + w_1 + w_2) \\
 &\text{subject to} && y'_1 + \frac{1}{2}y_1 + w_1 \leq 1 \quad (x_{1,1}) \\
 &&& y_2 + w_1 \leq 1 \quad (x_{1,2}) \\
 &&& y'_1 + \frac{1}{2}y_1 + w_2 \leq 1 \quad (x_{2,1}) \\
 &&& y_2 + w_2 \leq 1 \quad (x_{2,2}) \\
 &&& y_1 + w_1 + \frac{1}{2}w_2 \leq 1 \quad (z_{1,1}) \\
 &&& y_2 + w_1 + \frac{1}{2}w_2 \leq 1 \quad (z_{1,2}) \\
 &&& y_1 + w'_2 + \frac{1}{2}w_2 \leq 1 \quad (z_{2,1}) \\
 &&& y_2 + w'_2 + \frac{1}{2}w_2 \leq 1 \quad (z_{2,2})
 \end{aligned}$$

To figure out the form of constraints constituting the dual program in general, let us consider a variable  $x_{j,i}$ . Notice that it occurs in at most one constraint defined by a horizontal boundary. It can possibly be contained only in the constraint defined by  $C_j$  represented by  $w_j$ , where its coefficient is 1. If  $t(B_i) = 1$ , then we do not have  $y'_i$  and  $x_{j,i}$  occurs in the constraint represented by  $y_i$  and possibly in the constraint represented by  $y_{i+1}$ . Thus the inequality in the dual program corresponding to  $x_{j,i}$  has the form  $\alpha_{j,i}y_i + \alpha_{j,i+1}y_{i+1} + \beta_{j,i}w_j \leq 1$ , where each of the coefficients belongs to  $[0, 1]$ .

If  $t(B_i) > 1$ , then we do have  $y'_i$  and  $x_{j,i}$  occurs in this constraint with the coefficient  $\frac{1}{t(B_i)-1}$ . If  $B_i \neq B'_i$ , then  $x_{j,i}$  does not occur in any other constraints and the inequality in the dual program has the form  $\frac{1}{t(B_i)-1}y'_i + \beta_{j,i}w_j \leq 1$ , where  $\beta_{j,i} \in [0, 1]$ . Otherwise,  $x_{j,i}$  may also belong to the constraints represented by  $y_i$  and  $y_{i+1}$ . In each one of them it occurs with the coefficient equal to at most  $\frac{1}{t(B_i)}$ . Therefore the inequality has the form  $\frac{1}{t(B_i)-1}y'_i + \alpha_{j,i}y_i + \alpha_{j,i+1}y_{i+1} + \beta_{j,i}w_j \leq 1$ , where each of the coefficients  $\alpha_{j,i+1}, \alpha_{j,i}$  belongs to  $[0, \frac{1}{t(B_i)}]$ .

We are ready to lower bound the weight of the array  $A$  with the aid of its boundaries and their shadows.

► **Lemma 17.**  $w(A) > TL$ .

## 28:12 Rectangle Tiling Binary Arrays

**Proof.** Since the value of any cost function of the dual linear program described above is a lower bound on the minimal value of the cost function of the primal linear program, it suffices to find a feasible assignment of the dual variables such that the cost function will be have value greater than  $TL$ .

▷ **Claim 18.** We can satisfy all constraints of the dual program by assigning the following values to the dual variables. Each  $y_i$  and each  $w_j$  is assigned  $\frac{1}{3}$ . If  $B_i$  defines only one constraint  $y'_i$ , then we assign  $\frac{t(B_i)}{3}$  to  $y'_i$ . Otherwise  $y'_i$  is assigned  $\frac{t(B_i)-1}{3}$ .

The claim follows from the fact that the inequality  $\frac{1}{T-1} \cdot \frac{T}{3} + \frac{1}{3} \leq 1$  is satisfied by each  $T \geq 2$  and that the inequality  $\frac{T-1}{3(T-1)} + \frac{2}{3T} + \frac{1}{3} \leq 1$  is also satisfied by each  $T \geq 2$ .

This means that the total value contributed by the dual variables  $y_i, y'_i$  (corresponding to constraints defined by boundary  $B_i$ ) is at least  $\frac{t(B_i)}{3}$ .

Thus  $w(A) > \frac{3}{2}L(\frac{T_v}{3} + \frac{T_h}{3}) \geq TL$ . ◀

We show a method for finding a tiling of  $A$  with at most  $T + 1$  tiles. By Facts 1, 8, Lemmas 7 and 17, we proved that  $T + 1 \leq p$ , when the approximation factor is  $\frac{3}{2}$ . In other words, we obtain a  $\frac{3}{2}$ -approximation algorithm for binary RTILE.

► **Theorem 19.** For any array  $A$  satisfying  $\frac{p^2}{w(A)} \approx 0$ , there exists a linear time  $\frac{3}{2}$ -approximation algorithm for binary RTILE.

### 5 A $(\frac{3}{2} + \beta)$ -approximation

In this section we examine the general case, arrays such that  $\frac{p^2}{w(A)}$  is not negligible. We will aim for a  $(\frac{3}{2} + \beta)$ -approximation. When  $\beta < \frac{1}{2}$ , the approximation ratio of our algorithm is better than 2. Throughout the section, whenever we refer to tiling and partitioning, we mean  $(\frac{3}{2} + \beta)L$ -partitioning and tiling using tiles of weight at most  $(\frac{3}{2} + \beta)L$ .

We define a sequence of boundaries and shadows analogously as in the previous section, but with respect to  $(\frac{3}{2} + \beta)L$ , i.e., we replace each occurrence of “ $\frac{3}{2}L$ ” with “ $(\frac{3}{2} + \beta)L$ ” and modify the meaning of tiling and partitioning accordingly, i.e., to  $(\frac{3}{2} + \beta)L$ -partitioning.

We want to prove an analogue of Lemma 17. To this end we will consider an analogous linear program, in which we have all the variables occurring in the previous section and additionally we have a variable  $s_{i,j}$  for each pair  $(B_i, C_j)$ , which denotes the element of  $A$  at the intersection of the vertical boundary  $B_i$  and the horizontal boundary  $C_j$ . The function we minimize is  $\sum_{i=1}^k x_{j,i} + \sum_{j=1}^l z_{i,j} + \sum_{i=1}^k \sum_{j=1}^l s_{i,j}$ . For each variable  $s_{i,j}$  we have an additional constraint:  $-s_{i,j} \geq -1$ . The variable  $s_{i,j}$  is also included in all those constraints which refer to the part of  $A$  covering the intersection of  $B_i$  with  $C_j$ .

For instance, the linear program for the array from Example 14 is modified as follows:

$$\begin{aligned} & \text{minimize} && x_{1,1} + x_{2,1} + z_{1,1} + z_{1,2} + s_{1,1} \\ & \text{subject to} && x_{1,1} + x_{2,1} + z_{1,1} + s_{1,1} > (\tfrac{3}{2} + \beta)L & (y_1) \\ & && x_{1,1} + z_{1,1} + z_{1,2} + s_{1,1} > (\tfrac{3}{2} + \beta)L & (w_1) \\ & && -s_{1,1} \geq -1 & (t_{1,1}). \end{aligned}$$

The linear program for the array from Example 15 in the new scenario looks as follows:

$$\begin{aligned} & \text{min} && \sum_{i=1}^2 \sum_{j=1}^3 x_{j,i} + \sum_{i=1}^2 \sum_{j=1}^3 z_{i,j} + \sum_{i=1}^2 \sum_{j=1}^2 s_{i,j} \\ & \text{s.t.} && \sum_{j=1}^3 x_{j,1} + \sum_{i=1}^2 z_{i,1} + \sum_{j=1}^2 s_{1,j} > (\tfrac{3}{2} + \beta)L & (y_1) \\ & && \sum_{i=1}^2 \sum_{j=1}^3 x_{j,i} + \sum_{i=1}^2 z_{i,2} + \sum_{i=1}^2 \sum_{j=1}^2 s_{i,j} > (\tfrac{3}{2} + \beta)L & (y_2) \\ & && \sum_{j=1}^3 z_{1,j} + \sum_{i=1}^2 x_{1,i} + \sum_{i=1}^2 s_{i,1} > (\tfrac{3}{2} + \beta)L & (w_1) \\ & && \sum_{i=1}^2 \sum_{j=1}^3 z_{i,j} + \sum_{i=1}^2 x_{2,i} + \sum_{i=1}^2 \sum_{j=1}^2 s_{i,j} > (\tfrac{3}{2} + \beta)L & (w_2) \\ & && -s_{i,j} \geq -1(t_{i,j}), \text{ for each } 1 \leq i, j \leq 2. \end{aligned}$$

Correspondingly, in the dual program we maximize  $(\frac{3}{2} + \beta)L(\sum y_i + \sum w_j) - \sum t_{i,j}$  and we have an additional constraint for each primal variable  $s_{i,j}$ .

The dual linear program for the array from Example 15 contains the following additional inequalities.

$$\begin{aligned} y_1 + y_2 + w_1 + w_2 - t_{1,1} &\leq 1 && (s_{1,1}) \\ y_1 + y_2 + w_2 - t_{1,2} &\leq 1 && (s_{1,2}) \\ y_2 + w_1 + w_2 - t_{2,1} &\leq 1 && (s_{2,1}) \\ y_2 + w_2 - t_{2,2} &\leq 1 && (s_{2,2}). \end{aligned}$$

We can see that if we want to assign  $\frac{1}{3}$  to each variable  $y_i, w_j$ , then we sometimes also have to assign  $\frac{1}{3}$  to variables  $t_{i,j}$  to ensure the feasibility - compare the first inequality in the set of additional inequalities above. We can notice that we have to assign  $\frac{1}{3}$  to  $t_{i,j}$  only if both  $i < k$  and  $j < l$ , i.e. when  $s_{i,j}$  does not belong to  $B_k$  or  $C_l$ .

► **Lemma 20.** For  $\beta = \frac{p^2}{w(A)}$ , it holds that  $w(A) > TL$ .

**Proof.** We can satisfy all constraints of the dual program by assigning the following values to the dual variables. Each  $y_i$  and each  $w_j$  is assigned  $\frac{1}{3}$ . If  $B_i$  defines only one constraint  $y'_i$ , then we assign  $\frac{t(B_i)}{3}$  to  $y'_i$ . Otherwise  $y'_i$  is assigned  $\frac{t(B_i)-1}{3}$ . Also, each  $t_{i,j}$  such that  $i < k$  and  $j < l$  is assigned  $\frac{1}{3}$ .

Some of the constraints in the primal program have value  $(\frac{3}{2} + \beta)L - 2$  on the right hand side. Such constraints correspond to some borders of type greater than 2, when we use Lemma 11. Let us analyze such cases in more detail. Assume that for a boundary  $B_i$  of type  $k > 2$  we indeed use Lemma 11. Then the primal linear program contains a constraint with value  $(\frac{3}{2} + \beta)L - 2$  on the right hand side. This constraint corresponds to the dual variable  $y_i$ . We notice that  $B_i$  also defines a constraint of type 1, which has  $(\frac{3}{2} + \beta)L$  on the right hand side and corresponds to the dual variable  $y'_i$ . Hence each such boundary contributes at least  $\frac{t(B_i)-1}{3}(\frac{3}{2} + \beta)L + \frac{1}{3}(\frac{3}{2} + \beta)L - 2 \geq (\frac{(\frac{3}{2} + \beta)L - \frac{2}{3}t(B_i)}{3})$  to the cost function of the dual linear program.

Similarly, some of the constraints in the primal program have value  $(\frac{3}{2} + \beta)L - 1$  on the right hand side. Such constraints correspond to some borders of type equal to 2, when we use Lemma 11. Each such boundary contributes at least  $(\frac{(\frac{3}{2} + \beta)L - \frac{1}{2}t(B_i)}{3})$  to the cost function of the dual linear program.

Thus the value of the cost function of the dual linear program is lower bounded by  $((\frac{3}{2} + \beta)L - \frac{2}{3})(\frac{T_v}{3} + \frac{T_h}{3}) - \frac{(T_h-1)(T_v-1)}{3} \geq TL + p\frac{T_v+T_h}{3} - \frac{2}{3}(T_v + T_h) - \frac{(T_h-1)(T_v-1)}{3}$ . Since  $L \geq \frac{w(A)}{p}$ , we get that  $w(A) \geq TL + p\frac{T_v+T_h}{3} + \frac{T_v+T_h}{9} - \frac{T_vT_h}{3} - \frac{1}{3}$ . Because  $p \geq T$ , we obtain that  $\frac{p(T_v+T_h)}{3} + \frac{T_v+T_h}{9} - \frac{T_vT_h}{3} - \frac{1}{3} \geq \frac{T^2}{3} + \frac{T_v+T_h}{9} - \frac{1}{3} > 0$ .

Therefore,  $w(A) > TL$ . ◀

► **Theorem 21.** There exists a  $(\frac{3}{2} + \frac{p^2}{w(A)})$ -approximation algorithm for binary RTILE that has a linear  $(O(n^2))$  running time.

## 6 Tightness of approximation

In this section, we show that the approximation ratio for the RTILE problem is tight with respect to the only known lower bound. Precisely, we prove the following theorem.

► **Theorem 22.** Let  $p = 2k$ , for some  $k \in \mathbb{N}$ . Then, there exists a binary array  $A_k$  such that the maximum weight of a tile in any tiling of  $A_k$  into  $p$  tiles has weight at least  $\frac{3}{2} \cdot \frac{w(A_k)}{p} + 1$ .

(a)

(b)

■ **Figure 5** The empty squares denote a value of 0, while the ones are colored black. (a) On tiling this array with 3 tiles, one tile will always contain 5 ones, giving an approximation factor of  $\frac{5}{3}$ . (b) 4-crosses placed in an array for proving an approximation lower bound of  $\frac{3}{2}$ .

We define an  $L$ -cross to consist of  $2L + 1$  ones, it is obtained by taking a  $(L + 1) \times (L + 1)$  array, and filling the  $(\frac{L}{2} + 1)^{th}$  row as well as the  $(\frac{L}{2} + 1)^{th}$  column with ones, finally the rest of the entries are filled with zeros. The coordinate  $(\frac{L}{2} + 1, \frac{L}{2} + 1)$  is referred to as the center of the  $L$ -cross defined above. An  $L$ -cross centered at  $(x, y)$  is obtained by translating the center of an  $L$ -cross to the coordinate  $(x, y)$ . Note that an  $L$ -cross consists of four contiguous segments of ones, referred to as *arms*, each containing  $\frac{L}{2}$  ones. We define  $A_k$  as shown in Figure 3.

**Proof.** Suppose that  $p$  is even, therefore  $p = 2k$ , for some  $k \in \mathbb{N}$ ; our input binary array  $A_k$  is obtained as follows. We place  $k$  many  $L$ -crosses centered at  $(j \cdot (L + 1) - \frac{L}{2}, j \cdot (L + 1) - \frac{L}{2})$ , for each  $1 \leq j \leq k$ , the rest of the entries of  $A_k$  are zero. Note that the  $L$ -crosses are placed diagonally in a non-overlapping manner, and  $\frac{w(A)}{p} = L$ . The array for  $L = 4$  is illustrated in Figure 5(a).

If  $p = 2$ , then it is obvious that one tile will have to contain 3 arms of the cross and thus have weight  $\frac{3}{2}L + 1$ . We will prove that for every  $k \in \mathbb{N}$ , one of the tiles will have weight at least  $\frac{3}{2}L + 1$ .

Suppose that for  $k$  crosses and  $2k$  tiles the thesis holds by induction. We will now prove it for  $k + 1$  crosses and  $2k + 2$  tiles. Let  $T_1$  be the tile that contains the cell  $A_{k+1}[1, 1]$ . If this tile has weight smaller than  $\frac{3}{2}L$ , then we have the following two cases:

1. If  $T_1$  does not contain the center of the lower left cross  $A_{k+1}[\frac{L}{2} + 1, \frac{L}{2} + 1]$ , then  $T_1$  is formed either by the first  $\frac{L}{2}$  columns or the first  $\frac{L}{2}$  rows. Due to symmetry, it is enough to consider the case when  $T_1$  is formed by the first  $\frac{L}{2}$  columns. Let  $T_2$  be the tile that contains  $A_{k+1}[\frac{L}{2} + 1, 1]$ . If  $T_2$  has weight smaller than  $\frac{3}{2}L$ , then its upper right corner

$A_{k+1}[x, y]$  is such that either  $x < L + 1$  or  $y < L + 1$ . Due to symmetry, it is enough to consider the case when  $x < L + 1$ . In this case, if  $y < n$ , then we can extend  $T_2$  so that  $y = n$  without increasing the weight of  $T_2$  as it would not intersect any new  $L$ -cross.

Thus, we are left with  $2k$  tiles, and an array which has  $A_k$  as a subarray, therefore by the induction hypothesis we get that the weight of maximum weight tile is at least  $\frac{3}{2}L + 1$ .

2. If  $T_1$  contains the center of the cross  $A_{k+1}[\frac{L}{2} + 1, \frac{L}{2} + 1]$ , then its right upper corner  $A_{k+1}[x, y]$  is such that  $x < L + 1$  or  $y < L + 1$ . Notice that we may assume that either one tile will be formed by subarray  $A_{k+1}[x + 1, 1, n, y]$  or by subarray  $A_{k+1}[1, y + 1, x, n]$ . This is because the tile that contains  $A_{k+1}[x + 1, y + 1]$  cannot contain both  $A_{k+1}[1, y + 1]$  and  $A_{k+1}[x + 1, 1]$ . Suppose w.l.o.g. that the tile  $T_2$  that contains  $A_{k+1}[x + 1, 1]$  does not cover any cell of row  $y + 1$ . We may then extend the upper right corner of  $T_2$  till  $A_{k+1}[n, y]$ , without increasing the weight of any tile. We are left with  $2k$  tiles, and the induction hypothesis gives us the result.

In the case when  $p$  is odd, the input binary array  $A'_p$  is obtained from  $A_{k+1}$  by deleting any rows and columns in it with index at least  $k(L + 1) + \frac{L}{2} + 2$ . This, in effect adds an extra half  $L$ -cross near the upper right corner of  $A_k$ . Clearly, for  $p = 3$  it is not possible to tile  $A'_3$  with 3 tiles such that the weight of maximum weight tile is less than  $\frac{3}{2}L$ . The rest of the proof follows from arguments similar to the case when  $p$  is even. ◀

► **Remark.** The approximation factor of our algorithm is  $\frac{3}{2} + \frac{p^2}{w(A)}$  which is equal to  $(\frac{3}{2} + \frac{p}{L})L$ . Since  $\frac{p}{L}$  is equal to  $\frac{p^2}{w(A)}$ , it means that the approximation of our algorithm is tight under the condition that  $w(A) \gg p^2$ .

## 7 DRTILE

In this section, we present an approximation algorithm for the DRTILE problem. We have presented a  $\frac{3}{2} + \beta$ -approximation algorithm for the RTILE problem in Section 3. Now we show how to reduce an instance of the DRTILE problem to an instance of the RTILE problem to achieve an approximation ratio for the DRTILE problem. Before we proceed, let us recall the definition of the DRTILE problem.

### ■ the DRTILE problem

- **Input:** A two-dimensional array  $A$  and a weight upper bound  $w$ .
- **Goal:** Partition  $A$  into a minimum number of non-overlapping tiles, where the weight of each tile must not be larger than  $W$ .

Let us consider an array  $A$  with  $w(A) = n$ . Suppose  $W$ , provided as input, is the maximum allowed weight of any tile. Clearly, the minimal number of tiles we need to use to cover  $A$  is  $\lceil \frac{n}{W} \rceil$ . Consequently,  $\lceil \frac{n}{W} \rceil$  is a lower bound to the optimal solution of the DRTILE problem. Our goal is to obtain a  $\gamma$ -approximation algorithm, where  $\gamma$  depends on  $W$ . Therefore, the number of tiles we are allowed to use to cover  $A$  with this approximation is  $\gamma \times \lceil \frac{n}{W} \rceil$ .

We construct an instance of the the RTILE problem as follows: as an input we have the same array  $A$ , and we are allowed to use at most  $p = \gamma \times \lceil \frac{n}{W} \rceil$  tiles. Hence from Section 2, the lower bound on the maximum weight of a tile is  $\lceil \frac{n}{\gamma \times \lceil \frac{n}{W} \rceil} \rceil$ . Hence the maximum weight of a tile with approximation factor of  $\frac{3}{2} + \beta$  is,

$$\left\lceil \frac{n}{\gamma \times \lceil \frac{n}{W} \rceil} \right\rceil \times \left(\frac{3}{2} + \beta\right) \leq \left\lceil \frac{n}{\gamma \times \frac{n}{W}} \right\rceil \times \left(\frac{3}{2} + \beta\right) = \left\lceil \frac{W}{\gamma} \right\rceil \times \left(\frac{3}{2} + \beta\right).$$

## 28:16 Rectangle Tiling Binary Arrays

For the solution returned by RTILE to be a valid solution of DRTILE, the value of  $\lceil \frac{W}{\gamma} \rceil \times (\frac{3}{2} + \beta)$  must not exceed  $W$ . This allows us to derive a bound on the value of the approximation factor  $\gamma$ , we have,

$$\begin{aligned} \lceil \frac{W}{\gamma} \rceil \times (\frac{3}{2} + \beta) &\leq W \\ \Rightarrow \lceil \frac{W}{\gamma} \rceil &\leq \frac{W}{(\frac{3}{2} + \beta)} \\ \Rightarrow \frac{W}{\gamma} &\leq \frac{W}{(\frac{3}{2} + \beta)} + 1 \\ \Rightarrow \gamma &\geq (\frac{3}{2} + \beta) \cdot \frac{W}{W + (\frac{3}{2} + \beta)}. \end{aligned}$$

This gives us the following theorem.

► **Theorem 23.** *There exists a  $(\frac{3}{2} + \beta) \cdot \frac{W}{W + (\frac{3}{2} + \beta)}$ -approximation algorithm for the DRTILE problem where  $(\frac{3}{2} + \beta)$  is the approximation factor for the RTILE problem. The approximation factor of the DRTILE problem tends to  $\frac{3}{2}$  as the value of  $W$  is increased.*

## 8 The Multidimensional RTILE Problem

In Section 3, the algorithm presented for the RTILE problem was restricted to two dimensions. In this section, we generalize that algorithm for the  $d$ -dimensional RTILE problem, where  $d \geq 2$ . In the  $d$ -dimensional RTILE problem, we are given a  $d$ -dimensional array of size  $n$  in each dimension, containing 0/1 as entries, and we have to partition the array into  $p$  non-overlapping  $d$ -dimensional tiles such that the maximum weight of a tile in a tiling is minimized. Similarly to Section 3, we assume that  $\frac{p^d}{w(A)}$  is close to 0 and give a  $\frac{2d-1}{d}$ -approximation algorithm for the  $d$ -dimensional RTILE problem. Notice that the approximation ratio converges to 2 as we increase the value of  $d$ .

**Boundaries and Shadows.** The definition of the boundaries and their shadows is a generalization of the definitions in Section 3. The *type* of the boundaries in a  $d$ -dimensional array can be defined analogously. By  $[i]$ , we define the set of boundaries of dimension  $n \times n \times \dots \times 1 \times \dots \times n$ , where  $i^{th}$  dimension has size 1.

Let  $B_1, B_2, \dots, B_k \in [i]$ , we define  $T_i = \sum_{i=1}^k t(B_i)$ . Finally  $T$  is defined as  $\min\{T_1, T_2, \dots, T_d\}$ . The following lemma is analogous to Fact 2.

► **Lemma 24.** *Let  $T = \{T_1, T_2, \dots, T_d\}$ , then the array can be  $\frac{2d-1}{d}$ -tiled with  $T + 1$  tiles.*

We can estimate the minimal weight of the array using a linear program. The constraints of the linear program have a similar form as mentioned in Section 3. In two dimensional problem, each constraint is greater than  $1.5L$ . In the  $d$ -dimensional RTILE problem, each constraint is greater than  $\frac{2d-1}{d}L$ , instead of  $1.5L$ .

► **Lemma 25.** *Let  $T = \{T_1, T_2, \dots, T_d\}$ , then  $w(A) > TL$ .*

The proof of this lemma is analogous to Lemma 20.

► **Theorem 26.** *There exists a  $\frac{2d-1}{d}$ -approximation algorithm for the multi-dimensional RTILE problem assuming  $\frac{p^d}{w(A)}$  is negligible.*

## Abstract

---

We consider the *correlated knapsack orienteering* (CorrKO) problem: we are given a travel budget  $B$ , processing-time budget  $W$ , finite metric space  $(V, d)$  with root  $\rho \in V$ , where each vertex is associated with a job with possibly correlated random size and random reward that become known only when the job completes. Random variables are independent across different vertices. The goal is to compute a  $\rho$ -rooted path of length at most  $B$ , in a possibly adaptive fashion, that maximizes the reward collected from jobs that processed by time  $W$ . To our knowledge, CorrKO has not been considered before, though prior work has considered the uncorrelated problem, *stochastic knapsack orienteering*, and *correlated orienteering*, which features only one budget constraint on the *sum* of travel-time and processing-times.

Gupta et al. [19] showed that the *uncorrelated* version of this problem has a constant-factor adaptivity gap. We show that, perhaps surprisingly and in stark contrast to the uncorrelated problem, the *adaptivity gap of CorrKO is at least*  $\Omega(\max\{\sqrt{\log B}, \sqrt{\log \log W}\})$ . Complementing this result, we devise *non-adaptive* algorithms that obtain: (a)  $O(\log \log W)$ -approximation in quasi-polytime; and (b)  $O(\log W)$ -approximation in polytime. This also establishes that the adaptivity gap for CorrKO is at most  $O(\log \log W)$ . We obtain similar guarantees for CorrKO with cancellations, wherein a job can be cancelled before its completion time, foregoing its reward. We show that an  $\alpha$ -approximation for CorrKO implies an  $O(\alpha)$ -approximation for CorrKO with cancellations.

We also consider the special case of CorrKO where job sizes are weighted Bernoulli distributions, and more generally where the distributions are supported on at most two points (2CorrKO). Although weighted Bernoulli distributions suffice to yield an  $\Omega(\sqrt{\log \log B})$  adaptivity-gap lower bound for (uncorrelated) *stochastic orienteering*, we show that they are easy instances for CorrKO. We develop non-adaptive algorithms that achieve  $O(1)$ -approximation, in polytime for weighted Bernoulli distributions, and in  $(n + \log B)^{O(\log W)}$ -time for 2CorrKO. (Thus, our adaptivity-gap lower-bound example, which uses distributions of support-size 3, is tight in terms of support-size of the distributions.)

Finally, we leverage our techniques to provide a quasi-polynomial time  $O(\log \log B)$  approximation algorithm for correlated orienteering improving upon the approximation guarantee in [2].

## 1 Introduction

The *orienteering* problem, first introduced by [16], is a fundamental and widely-studied vehicle-routing problem (VRP). The input to the problem consists of a length/travel bound  $B$ , finite metric space  $(V, d)$  representing travel times, root vertex  $\rho \in V$ , and non-negative rewards

associated with the vertices. The goal is to compute a path rooted at  $\rho$  of length at most  $B$  that collects maximum reward. Orienteering often arises as a subroutine in devising algorithms for other more complex VRPs, both in approximation algorithms [4, 12, 6, 22, 13, 14, 1], as also in computational methods, where it arises as the pricing problem when using a branch-cut-and-price method on a set-covering/configuration LP.

Gupta et al. [19] introduced the following *stochastic* version of orienteering to model settings where one must spend some uncertain amount of time processing a visited node in order to collect its reward. Formally, each vertex corresponds to a job with a random, possibly correlated, processing time and reward, drawn from a given probability distribution. Random variables corresponding to different vertices are independent. The reward and processing time of a job become known only when the job is fully processed. The goal is to devise an algorithm, also called *policy*, that visits a sequence of vertices (starting at  $\rho$ ) in a possibly *adaptive* fashion that maximizes the expected total reward collected, subject to the constraint that the total time expended in traveling and processing jobs is at most  $B$ . Jobs cannot be preempted, and only jobs completed by the time-horizon  $B$  yield reward. This is the *correlated orienteering* (CorrO) problem. We refer to the special case where rewards and sizes are independent, simply as *stochastic orienteering*; due to independence, one can move to deterministic rewards by replacing the random rewards with their expectations.

A related problem, and the focus of this paper, is *correlated knapsack orienteering* (CorrKO), wherein there are two separate budgets:  $B$  for the (deterministic) travel time, and  $W$  for the total time spent in processing jobs. Again, we refer to the uncorrelated problem as *stochastic knapsack orienteering*. Correlated knapsack orienteering can be motivated from a similar perspective as CorrO. Indeed, it is quite natural to decouple the “apples and oranges” entities of travel time and processing time when these may represent disparate resources; e.g., travel time may represent latency of access of jobs in a distributed network, and processing time may present CPU time.

In general, a policy may be *adaptive* and choose the next vertex to visit based on the (size, reward) realizations of the vertices previously visited; unless otherwise stated, the approximation ratio is always measured relative to the maximum reward  $OPT$  that can be achieved by an adaptive policy. On the other hand, a *non-adaptive* policy fixes beforehand the sequence of vertices to visit, and only the stopping-point (when the time-horizon  $B$  is exceeded) depends on the (size, reward) realizations. While adaptive policies may collect much greater reward, non-adaptive policies are usually easier to implement, specify, and analyze, by virtue of the fact that they admit a much-more compact description compared to the decision tree associated with an adaptive policy whose description may require space that is exponential in the input size. Consequently, much work in stochastic optimization has focused on developing good non-adaptive policies and obtaining bounds on the *adaptivity gap*, which is the supremum, over all problem instances, of  $OPT/(\text{maximum reward achieved by a non-adaptive policy})$ ; see e.g., [9, 17, 11, 18, 19, 7, 20].

Prior work has studied stochastic orienteering, CorrO, and stochastic knapsack orienteering, and our current knowledge for these problems can be summarized as follows. (1) The adaptivity gap for stochastic orienteering is  $O(\log \log B)$  [19] and  $\Omega(\sqrt{\log \log B})$  [2], and there is a non-adaptive algorithm that achieves an  $O(1)$ -approximation with respect to the *non-adaptive optimum* [19], and hence obtains an  $O(\log \log B)$ -approximation; the approach leading to the latter result also yields an  $O(1)$ -approximation for *stochastic knapsack orienteering*. (2) The adaptivity gap for CorrO is also  $O(\log \log B)$  [2], but this is established non-constructively; algorithmically, we can obtain  $O(\alpha \log B)$ -approximation in polytime [19] and  $O(\alpha \cdot \frac{\log^2 \log B}{\log \log \log B})$  in quasi-polytime [2], where  $\alpha$  is the approximation ratio for *deadline-TSP*.

To our knowledge, *there is no prior work on CorrKO*. As noted above, (uncorrelated) stochastic knapsack orienteering and CorrO admit quite different guarantees, and this raises the natural question: where does CorrKO stand in terms of difficulty relative to these two problems? Is it more difficult than the uncorrelated problem? How does it compare in difficulty relative to CorrO?

## Our contributions

We initiate a study of correlated knapsack orienteering, and obtain results that, in particular, shed light on these questions. Our chief contributions are as follows.

1. **Adaptivity gap and approximation algorithms.** Somewhat surprisingly, and in stark contrast with (uncorrelated) stochastic knapsack orienteering, we prove that *the adaptivity gap for CorrKO is not a constant*, showing that the correlated problem is strictly harder than the uncorrelated problem.

► **Theorem 1.1** (see Section 3). *The adaptivity gap for CorrKO is  $\Omega(\max\{\sqrt{\log B}, \sqrt{\log \log W}\})$ , where  $B$  is the travel budget and  $W$  is the processing-time budget.*

Complementing this, we develop various *non-adaptive* approximation algorithms for CorrKO. Our main algorithmic result is a *quasi-polytime  $O(\log \log W)$ -approximation algorithm* for CorrKO, which thus shows that the adaptivity gap is  $O(\log \log W)$ .

► **Theorem 1.2.** *There are non-adaptive algorithms for CorrKO with the following guarantees:*

- (a)  $O(\log \log W)$ -approximation in time  $(n + \log B)^{O(\log W \log \log W)}$  (Section 4.1);
- (b)  $O(\log W)$ -approximation in polynomial time (Section 4.2).

By leveraging the approach leading to Theorem 1a, we also obtain the following guarantee for correlated orienteering, which improves upon the approximation guarantee in [2] (that also runs in quasi-polytime) by an  $O(\frac{\log \log B}{\log \log \log B})$ -factor.

► **Theorem 1.3.** *Given an  $\alpha$ -approximation algorithm for deadline TSP with running time  $T$ , we can obtain a non-adaptive  $O(\alpha \log \log B)$ -approximation algorithm for CorrO with running time  $(n + \log B)^{O(\log B \log \log B)} \cdot T$ . Using the algorithm for deadline TSP in [15], we obtain an  $O(\log \log B)$ -approximation in quasi-polytime.*

2. **CorrKO with 2-point distributions.** Our adaptivity-gap lower bound uses distributions of support-size 3, whereas the  $\Omega(\sqrt{\log \log B})$  adaptivity-gap lower-bound example for stochastic orienteering in [2] considers *weighted Bernoulli size distributions*. In Section 5, we investigate CorrKO from a fine-grained-complexity perspective to understand this discrepancy. In contrast with stochastic orienteering, we show that when all distributions are supported on at most 2 points – we call this 2CorrKO – *the adaptivity gap becomes  $O(1)$*  (Theorem 5.3), and we can obtain a *non-adaptive  $O(1)$ -approximation in time  $(n + \log B)^{O(\log W)}$*  (Theorem 5.4). Moreover, for weighted Bernoulli size distributions, we obtain a *polytime non-adaptive  $O(1)$ -approximation* (Theorem 5.5). Our key insight here lies in identifying a novel *deterministic* problem, that we call *orienteering with knapsack deadlines* (OrientKD), which we show is equivalent to 2CorrKO, up constant factors. In OrientKD, in addition to orienteering, each vertex  $v$  has a weight and knapsack deadline, and an orienteering-solution  $P$  is feasible, if for every  $v \in P$ , the total weight of all nodes on  $P$  up to (and including)  $v$  is at most its knapsack deadline. For instance, in a setting where jobs distributed over a network have to be processed on a single machine, travel times could represent the latency involved in accessing a job, and the knapsack deadlines would capture completion-time deadlines on the machine. We obtain

the above approximation guarantee for OrientKD (Theorem 5.1), and hence obtain the same guarantee (up to constant factors) for 2CorrKO.

These results show that our adaptivity-gap example is tight in terms of the support-size: *any* such lower-bound example *must* involve some distribution of support-size at least 3.

3. **CorrKO with cancellations.** In this version (see Section 6), we can *cancel* or discard the current vertex  $v$  at any time-step prior to its completion, foregoing its reward, and we are not allowed to return to  $v$ . We obtain the same approximation guarantees for this problem as for CorrKO: i.e., quasi-polytime  $O(\log \log W)$ -approximation, and polytime  $O(\log W)$ -approximation. En route, we obtain an  $O(1)$ -approximation for the special case where we obtain non-zero rewards only when jobs instantiate to size at most  $W/2$ .

Our results paint a nuanced picture of the complexity of CorrKO vis-a-vis CorrO and stochastic knapsack orienteering. While CorrKO is harder than stochastic knapsack orienteering, our algorithmic results suggest that it is easier than CorrO. We obtain similar approximation factors for both problems in quasi-polytime, but in polytime, we obtain  $O(\log W)$ -approximation for CorrKO, while the current-best polytime factor for CorrO is  $O(\log n \log B)$ ; also, with weighted Bernoulli distributions, CorrKO is provably easier than CorrO.

**Technical overview.** We now highlight the key technical ideas underlying our results. Let  $OPT$  be the optimal reward for CorrKO. Let  $S_v$  denote the random size of vertex  $v$ . For an integer  $j \geq 0$ , let  $X_v^j := \min\{S_v, 2^j\}$  and  $\mu_v^j = \mathbb{E}[X_v^j]$ . The significance of these quantities is that if  $\mu^j(P_{\rho,v} - v) \leq c \cdot 2^j$ , where  $P$  is a rooted path,  $v \in P$ , and  $P_{\rho,v}$  is the  $\rho \rightsquigarrow v$  portion of  $P$ , then a random subpath  $P''$  of  $P$  where we retain each  $u \in P$  independently with probability  $\frac{1}{2c}$  satisfies  $\Pr[v \in P'' \text{ and is processed by time } 2^j] \geq \frac{1}{4c}$ ; this indicates that  $\pi_v(2^j)$ , which is the expected reward of  $v$  if its processing starts by time  $2^j$ , can serve as a good proxy for the expected reward obtained from  $v$ .

**Algorithms for CorrKO and CorrO.** Our quasi-polytime  $O(\log \log W)$ -approximation for CorrKO builds upon a structural result for CorrO shown by [2]. They show that one can extract a suitable rooted path  $Q^*$  from the decision tree representing an optimal adaptive policy and suitable nodes  $\varphi_{-1} = \rho, \varphi_0, \varphi_1, \dots, \varphi_k$  on  $Q^*$ , where  $k \leq \log W$ , such that (roughly speaking): (a) the prefix property  $\mu^j(Q_{\rho, \varphi_j}^* - \varphi_j) \leq O(K) \cdot 2^j$  holds for every  $j = 0, \dots, k$ , and (b)  $\sum_{j=0}^k \sum_{v \in Q_{\varphi_{j-1}, \varphi_j}^*} \pi_v(2^j) = \Omega(OPT)$ , where  $K = O(\log \log W)$  (see Theorem 7.1). So if we could find this path  $Q^*$ , then using the sampling idea described above, one can easily obtain an  $O(K)$ -approximation. For CorrO, Bansal and Nagarajan [2] “guess” the *portal nodes*  $\varphi_0, \dots, \varphi_k$  and write a configuration LP to find suitable paths between every pair of consecutive portal nodes. They use randomized rounding to round a fractional solution, which incurs a  $\frac{\log k}{\log \log k}$ -factor violation of the prefix property due to Chernoff bounds, since for each  $j$ ,  $\mu^j(Q_{\rho, \varphi_j}^* - \varphi_j)$  can be written as a sum of  $O(K) \cdot 2^j$ -bounded independent random variables. When one combines this with the node-sampling step, one therefore incurs an  $O(K \cdot \frac{\log k}{\log \log k})$ -factor loss relative to the value of the LP solution.

For CorrKO (and CorrO), we proceed similarly, but we guess many more portal vertices. We split each  $Q_{\varphi_{j-1}, \varphi_j}^*$  into  $O(K)$  segments having  $\mu^j$ -weight at most  $2^j$ , and guess the end-points of all such segments (see Theorems 4.1, 4.2). We then again set up a configuration LP and use randomized rounding; however, we can now ensure that the prefix property holds with  $O(1)$  violation, since we can decompose  $\mu^j(Q_{\rho, \varphi_j}^* - \varphi_j)$  into a *sum of  $2^j$ -bounded random variables* corresponding to the  $\mu^j$ -weight of each random segment. Thus, an application of Chernoff bounds and the union bound only incurs an  $O(1)$ -factor violation of the prefix property,

since  $K = \Omega(\log k)$ ; therefore, we lose only an  $O(K)$ -factor compared to the value of the LP solution. This idea extends to **CorrO**. The only essential difference between **CorrKO** and **CorrO** comes from how well we can solve the corresponding configuration LP; for **CorrKO**, we can obtain an  $O(1)$ -approximation to the LP-optimum using an  $O(1)$ -approximation algorithm for knapsack orienteering (see below), but for **CorrO**, we obtain an  $O(\alpha)$ -approximate LP solution given an  $\alpha$ -approximation for deadline TSP.

The  $O(\log W)$ -approximation for **CorrKO** proceeds by relating the problem to *knapsack orienteering* (**KnapOrient**), which is orienteering with an additional total-node-weight budget constraint. For each index  $j = 0, 1, \dots, \log W$ , we use the portion of the optimal adaptive-policy tree corresponding to nodes processed at some point in  $[2^j, 2^{j+1})$ , to extract a good *fractional solution to an LP-relaxation* (**KO-LP**) for **KnapOrient**, where we exploit the LP-relaxation for orienteering [14]. This translation is easy because one can naturally interpret the LP variables as corresponding to certain probabilities obtained from an adaptive policy.

We remark that one can combine the LP-relaxations for orienteering [14] and the *correlated knapsack* problem [18], which is the special case where all nodes are co-located, to obtain an LP for **CorrKO**. However, the chief impediment in rounding an LP solution is that the rounding algorithms for orienteering and correlated knapsack may give rise to incompatible orderings. Rounding the orienteering-portion of the LP solution yields a node sequence, and we need to stick with a subsequence of this to satisfy the travel-budget constraint. However, forcing one to consider items in a prescribed order for correlated knapsack can drastically reduce the reward obtained, because jobs that instantiate to large sizes (i.e.,  $> W/2$ ) may need to be processed in a different incompatible order; see Appendix A. This tension is real, as evidenced by our adaptivity-gap lower bound, and seems challenging to deal with.

**2CorrKO.** The chief insight here is that the problematic case where we obtain reward only from large-size instantiations becomes quite structured in two ways. (1) There is no adaptivity gap, since only the path in the adaptive-policy tree corresponding to small-size (i.e.,  $\leq W/2$ ) instantiations can yield non-zero reward. (2) Given (1), one can infer that the reward obtained from a vertex  $v$  is a function of the total small size, and total large-size-instantiation probability of vertices visited up to  $v$ . This allows one to define an instance of *orienteering with knapsack deadlines* (**OrientKD**) to capture the stochastic problem.

**CorrKO with cancellations.** The algorithm for **CorrKO** with cancellations considers two cases. For large-size instantiations, it is not hard to argue that cancellations do not help (as with correlated knapsack [18]). For small-size instantiations, we formulate an LP by combining the LPs for orienteering [14] and *correlated knapsack with cancellations* [18]. We show that from an LP solution, one can define a suitable **KnapOrient**-instance and extract a good LP solution for this **KnapOrient**-instance. The **KnapOrient**-instance is defined in such a way that feasible solutions to this instance can be mapped to fractional solutions to the correlated-knapsack LP. So we can first round the solution to obtain an integral **KnapOrient**-solution  $Q$ , and then utilize the LP-rounding algorithm in [18] for correlated knapsack with cancellations to process vertices, with cancellations, *in the order they appear on  $Q$* . It is crucial here that the algorithm in [18] for small-size instantiations has the flexibility that one can specify a prescribed order for considering vertices (unlike in **CorrKO** with large-size instantiations).

## Related work

As mentioned earlier, *orienteering* is a fundamental problem in combinatorial optimization that finds various applications. Blum et al. [5] devised the first constant-factor approximation algorithm for orienteering, and the current best approximation factor is  $(2 + \epsilon)$  for any

$\epsilon > 0$  [8]. Friggstad and Swamy [14] gave the first LP-based  $O(1)$ -approximation algorithm. Their LP plays an important role for obtaining some of our results. *Deadline TSP*, also known as *deadline orienteering*, is a generalization of orienteering, where nodes now have deadlines, and a path  $P$  is feasible if, for every  $v \in P$ , its travel time along  $P$  is at most its deadline; the goal is again to compute a maximum-reward feasible path. Both orienteering and deadline TSP can be considered in the rooted, or *point-to-point* (P2P) setting, where both the start and end nodes of the path are specified. Deadline TSP admits a polytime  $O(\log n)$ -approximation [1] and an  $O(1)$ -approximation in time  $n^{O(\log(\text{maximum deadline}))}$  [15]. Friggstad and Swamy [15] also consider the more general *monotone-reward TSP*, wherein the reward of a node  $v$  having travel time  $t$  is given by  $\text{rewd}_v(t)$ , where  $\text{rewd}(\cdot)$  is a non-increasing function. They showed that this problem is essentially equivalent to deadline TSP.

The literature on stochastic optimization problems is rich, and we discuss below only the work that is most relevant to our work.

- **Stochastic knapsack problems.** Stochastic orienteering and CorrKO generalize respectively *stochastic knapsack*, which was studied in the seminal work of [9], and *correlated knapsack* [18, 21], which correspond to the special case where all nodes are co-located (i.e., the travel budget is irrelevant). The state-of-the-art for stochastic knapsack is a  $(2 + \epsilon)$ -approximation [3]. Gupta et al. [18] obtained the first constant-factor approximation for correlated knapsack, and the constant was improved to  $(2 + \epsilon)$  by Ma [21].
- **Stochastic VRPs.** We have already mentioned the works of Gupta et al. [19] and [2] that consider (uncorrelated) stochastic orienteering and correlated orienteering. A minimization version of stochastic orienteering, called *stochastic  $k$ -TSP* was considered by [11, 20], where instead of a travel budget, we want to collect a reward of at least  $k$ , and seek to minimize the expected travel time. Ene et al. [11] gave an adaptive  $O(\log k)$ -approximation algorithm for this problem, and Jiang et al. [20] obtained a non-adaptive  $O(1)$ -approximation. The special case where all nodes are co-located is called *stochastic knapsack cover* for which [10] obtained a  $(2 + \epsilon)$ -approximation.
- **Multi-armed bandits with metric switching costs.** A related problem to CorrKO is the *multi-armed bandit* problem with metric switching costs, considered by Guha and Munagala [17], which can be viewed as a setting where each vertex corresponds to a Markov chain (i.e., arm) with known transition probabilities and rewards. Guha and Munagala consider this setting under a crucial *martingale assumption*, which does not hold for CorrO or CorrKO, with separate budgets for the travel-cost and the number of arm-pulls, as in CorrKO. In their setting, one can also abandon a vertex and possibly return to this vertex at a later time. They devise an  $O(1)$ -approximation algorithm for this problem that is a hybrid between adaptive and non-adaptive policies: it non-adaptively specifies the sequence of arms to visit, but adaptively decides when an arm should be abandoned. They use an elegant Lagrangian-relaxation idea to reduce the problem to orienteering; this Lagrangian-relaxation idea was also later used in [19].

## 2 Preliminaries and notation

For an integer  $n \geq 0$ , we use  $[n]$  to denote  $\{1, \dots, n\}$ , where  $[0] := \emptyset$ , and  $\llbracket n \rrbracket$  to denote  $\{0\} \cup [n]$ . For any universe  $U$ , set  $S \subseteq U$  and element  $e \in U$ , we sometimes use  $S - e$  and  $S + e$  to denote  $S \setminus \{e\}$  and  $S \cup \{e\}$  respectively.

The problems we consider involve a metric space  $(V, d)$  and root  $\rho \in V$ . The metric  $d : V \times V \mapsto \mathbb{Z}_{\geq 0}$  is symmetric and captures travel times between vertices; by scaling we may assume that these are integers. Let  $n = |V|$  and  $\Delta$  be the diameter of the metric space. For

a set  $S$  of edges of the underlying complete graph  $(V, E)$ , we use  $d(S)$  to denote  $\sum_{e \in S} d(e)$ . Similarly, for any  $f \in \mathbb{R}^V$  and  $U \subseteq V$ ,  $f(U)$  denotes  $\sum_{v \in U} f_v$ . We say that a path  $P$  in  $G$  is rooted if it begins at  $\rho$ . We always think of the nodes on a rooted path  $P$  as being ordered in increasing order of their distance from  $\rho$  along the path. For any  $u, w \in P$ , we say  $u \prec_P w$  to denote that  $u$  comes before  $w$  on  $P$ , and  $u \preceq_P w$  means that  $u = w$  or  $u \prec_P w$ ; we omit the subscript  $P$  when  $P$  is clear from the context. We will interchangeably think of a path as an edge-set, or a sequence of nodes; the meaning will be clear from the context. For any path  $P$  and nodes  $a, b \in P$ , we use  $P_{a,b}$  to denote the  $a$ - $b$  portion of  $P$ . For a path  $P$  starting at node  $r$ , and a node  $v \in P$ , we define the travel time of  $v$  as  $d(P_{r,v})$ .

**Deterministic max-reward vehicle routing.** The following three vehicle routing problems (VRPs) play a prominent role in the study of stochastic orienteering. All three problems fall in the genre of max-reward VRPs, wherein we have nonnegative node rewards  $\{\pi_v\}_{v \in V}$ , and we need to select some vertices and find a suitable path visiting these vertices, so as to maximize the reward obtained. The differences in the problems lie in which paths are allowed, and the definition of the reward collected by a path. The problems below can be considered in the *rooted* setting, where we have a root  $\rho$  and the feasible paths form a subset of rooted paths, or in the *point-to-point* (P2P) setting, where both a start-node  $a$  and end-node  $b$  are specified, and the feasible paths are a subset of  $a$ - $b$  paths.

- **Orienteering.** We have a budget  $B$ , and feasible paths (in the rooted and P2P versions) are those with length at most  $B$ ; we collect the reward of all nodes on a feasible path.
- **Deadline TSP**, also called **deadline orienteering**. Here nodes have deadlines  $\{D_v\}_{v \in V}$ . A path  $P$  with the appropriate end-points is feasible if the travel time of each node in  $P$  is at most its deadline. So in the rooted case, a rooted path  $P$  is feasible if  $d(P_{\rho,v}) \leq D_v$  for all  $v \in P$ ; in the P2P-case, an  $a$ - $b$  path  $P$  is feasible if  $d(P_{a,v}) \leq D_v$  for all  $v \in P$ . We collect the reward of all nodes on a feasible path. (Equivalently, one can say that the feasible paths are *all* paths with the prescribed end-points, and we collect the reward from all nodes on the path that are visited *by their deadlines*.)

Observe that orienteering is the special case where the deadline of each node is the length bound  $B$ . Also, the rooted and P2P versions of deadline TSP are equivalent [14].

- **Monotone-reward TSP.** This is a generalization of deadline TSP, where each node  $v$  has a non-increasing reward-function  $\pi_v : \mathbb{Z}_+ \mapsto \mathbb{R}_+$ , where  $\pi_v(t)$  gives the reward obtained from  $v$  if  $v$  is visited at time  $t$ . Every path  $P$  with the appropriate end-points is feasible, and the reward of  $P$  is given by  $\sum_{v \in P} \pi_v(\text{travel time of } v) = \sum_{v \in P} \pi_v(d(P_{r,v}))$ , where  $r$  is the start node of  $P$ .

Friggstad and Swamy [14] showed that monotone-reward TSP can be reduced to deadline TSP losing a  $(1 + \epsilon)$ -factor, for an  $\epsilon > 0$ . Monotone-reward TSP will play a key role in the algorithm for correlated orienteering.

**Stochastic orienteering problems.** In the *correlated knapsack orienteering* (CorrKO) problem, each vertex  $v \in V$  is associated with an stochastic job with a random processing time or size  $S_v \in \mathbb{Z}_{\geq 0}$  and a possibly *correlated* random reward  $R_v \in \mathbb{R}_{\geq 0}$ . We use the terms processing time and size interchangeably. These random variables are independent across different vertices, and their distributions are specified in the input. We are given a length or travel-time budget  $B$ , and a processing-time budget  $W$ . A solution, or policy, for CorrKO visits a sequence of (distinct) vertices starting from the root  $\rho$ , in a possibly adaptive fashion, without exceeding the travel-time and processing-time budgets. More precisely, when a vertex  $v$  is visited, it's corresponding job is processed non-preemptively, and we get to know

the processing time and reward of the job only upon its completion; the completion time of job  $v$  is the total processing time of all jobs up to and including  $v$ . So if the adaptive policy visits vertices  $v_0 := \rho, \dots, v_\ell = u$  in that order, then it must be that the total travel-time  $\sum_{i=1}^{\ell} d(v_{i-1}, v_i)$  to get to  $u$  is at most  $B$ , and the total processing time of (the jobs associated with)  $v_1, \dots, v_{\ell-1}$  is at most  $W$ . We collect the rewards of  $v_1, \dots, v_{\ell-1}$ , and we collect  $u$ 's reward if its completion time is at most  $W$ . The goal is to maximize the expected total reward collected. For notational convenience, we also assign a deterministic value of 0 to the reward and processing time of  $\rho$ .

In the *correlated orienteering* (CorrO) problem, the setup is almost the same as in CorrKO, except that there is only one budget  $B$ , which is the budget for the *sum* of the travel times and processing times. (That is, we have one notion of time, which advances due to both travel and the processing of jobs.) So if an adaptive policy for CorrO visits vertices  $v_0 := \rho, \dots, v_\ell = u$  in that order, then we must have  $\sum_{i=1}^{\ell} d(v_{i-1}, v_i) + \sum_{i=1}^{\ell-1} S_{v_i} \leq B$ ; that is, the completion time of each  $v_i$  for  $i = 1, \dots, \ell - 1$ , as also the time when we reach  $v_\ell$ , *taking into account both travel time and processing time*, should be at most  $B$ . We collect rewards from  $v_1 \dots, v_{\ell-1}$ , and we collect  $u$ 's reward if  $\sum_{i=1}^{\ell} d(v_{i-1}, v_i) + \sum_{i=1}^{\ell-1} S_{v_i} \leq B$ .

Any adaptive policy for CorrKO or CorrO can be represented by a decision tree  $\mathcal{T}$  rooted at  $\rho$ , whose nodes are labeled by vertices of  $V$ , and the branches of a node labeled  $v \in V$  correspond to the different size and reward instantiations of  $v$ , with each branch specifying the next node to visit under the corresponding instantiation.

A *nonadaptive policy* (for CorrKO or CorrO) fixes a priori the sequence of vertices to potentially visit, *without looking at the size and reward instantiations*. The *adaptivity gap* for an instance is the ratio (optimal expected reward collected by an adaptive policy)/(optimal reward collected by a nonadaptive policy), and the adaptivity gap for a problem is the supremum over all instances of the adaptivity gap for the instance.

**Deterministic knapsack-constrained vehicle routing.** Algorithms for stochastic orienteering problems frequently utilize knapsack-constrained variants of deterministic VRPs, wherein we seek a feasible solution to the VRP satisfying an additional knapsack constraint on the total vertex-weight of the path. More precisely, suppose we have an underlying “base” max-reward VRP, specified by a collection  $\mathcal{I}$  of feasible paths along with nonnegative vertex-rewards  $\{\pi_v\}_{v \in V}$ , where the goal is to find a maximum-reward path in  $\mathcal{I}$ . In the *knapsack-constrained version of this VRP*, we also have a knapsack constraint specified by nonnegative knapsack weights  $\{\text{wt}_v\}_{v \in V}$  and knapsack budget  $W$ , which restricts the set of feasible solutions to  $\mathcal{I}^{\text{knap}} := \{\tau \in \mathcal{I} : \sum_{v \in \tau} \text{wt}_v \leq W\}$ ; the goal is to find a maximum-reward path in  $\mathcal{I}^{\text{knap}}$ , i.e., a maximum-reward path in  $\mathcal{I}$  satisfying the knapsack constraint. When the base VRP is: (i) orienteering, the knapsack-constrained version is *knapsack orienteering* (KnapOrient); (ii) deadline-TSP, the knapsack-constrained version is *knapsack deadline orienteering* (KnapDO). KnapOrient and KnapDO were considered by [19, 2] in the context of stochastic orienteering. We say that the base-VRP is a rooted-VRP, if all paths in  $\mathcal{I}$  start at the same vertex, and it is a P2P-VRP, if all paths in  $\mathcal{I}$  have the same start and end nodes.

We give a general reduction (Theorem 2.1) showing if the base-VRP is a rooted-VRP or P2P-VRP, and satisfies a certain subpath-closure property, then an  $\alpha$ -approximation for the VRP can be used as a black-box to obtain an  $(\alpha + 2)$ -approximation for the knapsack-constrained VRP. Let  $\tau$  be a path with ends  $a, b \in V$ , which we will view as a sequence of nodes. By a P2P-*subpath* of  $\tau$ , we mean any  $a$ - $b$  path whose node-sequence is a subsequence of  $\tau$ ; by a *rooted-subpath* of  $\tau$ , we mean any path starting at  $a$  whose node-sequence is a subsequence of  $\tau$ . (Note that any subsequence of  $\tau$  yields a path, since we are working with

a complete graph.) The *subpath-closure property* requires that for every path  $\tau \in \mathcal{I}$ : (a) for rooted-VRP, every rooted-subpath  $\tau'$  of  $\tau$  is also in  $\mathcal{I}$ , (b) for P2P-VRP, every P2P-subpath  $\tau'$  of  $\tau$  is also in  $\mathcal{I}$ . Most max-reward VRPs – e.g., orienteering, deadline TSP – satisfy the subpath-closure property. (Also, note that if a VRP satisfies the subpath-closure property, then so does the knapsack-constrained VRP.)

The above reduction is based on a Lagrangian-relaxation idea that was also used by [19], specifically to obtain approximation algorithms for **KnapOrient** and **KnapDO**. However, their approach results in a constant-factor blowup -in the approximation ratio (factor 2 for **KnapOrient**, and factor 4 for **KnapDO**<sup>1</sup> when going from the VRP to the knapsack-constrained VRP; our general reduction yields a better factor, in a somewhat simpler fashion.

► **Theorem 2.1.** *Consider a max-reward rooted-VRP or P2P-VRP, specified by a set  $\mathcal{I}$  of feasible solutions satisfying the subpath-closure property. For any  $\epsilon > 0$ , an  $\alpha$ -approximation algorithm  $\mathcal{A}$  (where  $\alpha \geq 1$ ) for the VRP can be used to obtain an  $(\alpha + 2)(1 + \epsilon)$ -approximation for the knapsack-constrained VRP by making  $O(\frac{\log n}{\epsilon})$  calls to  $\mathcal{A}$ .*

► **Corollary 2.2.** *There are algorithms with the following guarantees.*

- (a)  $(4 + \epsilon)$ -approximation, for any  $\epsilon > 0$ , for rooted- and P2P- knapsack orienteering;
- (b)  $O(\log n)$ -approximation for the rooted and P2P versions of knapsack deadline orienteering, and knapsack monotone-reward TSP;
- (c)  $O(1)$ -approximation in  $O(n^{\log n \Delta})$  time, for the rooted and P2P versions of knapsack deadline orienteering, and knapsack monotone-reward TSP.

**LP-relative guarantee for **KnapOrient**.** For rooted **KnapOrient**, we can utilize Theorem 2.1 to obtain an LP-relative approximation guarantee. This will be useful in devising algorithms for **CorrKO**. Consider the following LP-relaxation for rooted **KnapOrient** along the lines of an LP-relaxation for rooted orienteering in [14]. Let  $\rho$  be the root node for the **KnapOrient** instance. We bidirect the edges of the complete graph on  $V$  to obtain the arc-set  $A$ .

$$\max \quad \sum_{u,v \in V} z_u^v \cdot \pi_u \quad (\text{KO-LP})$$

$$\text{s.t.} \quad x^v(\delta^{\text{in}}(u)) \geq x^v(\delta^{\text{out}}(u)) \quad \forall u \in V - \rho, v \in V \quad (\text{O1})$$

$$x^v(\delta^{\text{in}}(S)) \geq z_u^v \quad \forall v \in V, S \subseteq V - \rho, u \in S \quad (\text{O2})$$

$$z_u^v = 0 \quad \forall u, v \in V : d_{\rho,u} > d_{\rho,v} \quad (\text{O3})$$

$$\sum_{a \in A} d_a \cdot x_a^v \leq Bz_v^v, \quad x^v(\delta^{\text{out}}(\rho)) = z_v^v \quad \forall v \in V \quad (\text{O4})$$

$$x, z \geq 0$$

$$\sum_{v \in V} z_v^v = 1 \quad (\text{O5}) \quad \sum_{u,v \in V} z_u^v \cdot \text{wt}_u \leq W. \quad (\text{KN})$$

The  $x_a^v$  and  $z_u^v$  variables encode the arcs included, and vertices visited, respectively by the **KnapOrient**-path, provided that  $v$  is the node visited that is furthest from  $\rho$ , i.e.,  $v$  maximizes  $d(\rho, u)$  among all nodes  $u$  on the path: constraints (O3) enforce this semantics; in an integer solution, these variables will be 0 if  $v$  is not the furthest visited node from  $\rho$ . Constraints

<sup>1</sup> [19] do not explicitly state a result for **KnapDO**, and instead embed this result within their algorithm for correlated orienteering. We can infer this factor by tracing through their algorithm and analysis.

(O1) and (O2) encode that the  $\rho \rightsquigarrow u$ -connectivity is  $z_u^v$ , and together with (O4) encode that  $\{x_a^v\}$  is a  $\rho$ -preflow of value  $z_v^v$  satisfying the length budget. Constraint (O5) enforces that overall  $x$  is a  $\rho$ -preflow of value 1. Constraints (O1)–(O5) are from the LP for rooted orienteering in [14]; (KN) is the new constraint encoding the knapsack budget.

► **Theorem 2.3.** *We can obtain a KnapOrient-solution that obtains reward at least  $OPT_{KO-LP}/5$ .*

### 3 An adaptivity-gap lower bound for CorrKO

We now show that the adaptivity gap for CorrKO is  $\Omega(\max\{\sqrt{\log B}, \sqrt{\log \log W}\})$ , thereby proving Theorem 1.1. We consider the following instance of correlated knapsack orienteering that has a similar spirit as the adaptivity-gap example in [2] for (uncorrelated) stochastic orienteering. The metric is a tree-metric induced by a complete binary tree  $T$  on a vertex set  $V$ , with root  $r \in V$  and  $H \geq 4$  levels, where the distances decrease geometrically as we move away from  $r$ . To conform to our notation, we include a separate dummy node  $\rho$  that serves as the root for CorrKO, with distance 0 to  $r$ ; but when we say root below, we always mean the root  $r$  of the tree  $T$ . The knapsack budget is  $W := 2^{2^{H+1}}$  and the length/travel budget is  $B := 2^{H-1} - 1$ . For a node  $v \in V$ , we use:  $\text{lev}(v)$  to denote the level of  $v$ ,  $\text{path}(v)$  to denote the unique  $r \rightsquigarrow v$ -path in  $T$ , and  $\text{par}(v)$  to denote the parent of  $v$  if  $v \neq r$ . The root  $r$  is at level  $H$  and each leaf node is at level 1; for a non-leaf node  $v$  at level  $\ell$ , the distance between  $v$  and its children is  $2^{\ell-2}$ . For a rooted path  $P$  in  $T$  we say that a node  $v \in P$  is a right-branching (resp. left-branching) node if the node succeeding  $v$  on  $P$  is its right-child (resp. left-child). We denote by  $\text{rt}(P)$  and  $\text{left}(P)$ , the right-branching nodes and left-branching nodes of  $P$ , respectively. For notational convenience, we assume that the end-node of  $P$  other than  $r$  is a left-branching node; if  $P = r$ , then we say that  $r \in \text{left}(P)$ . The (correlated) (size, reward) distribution of node  $v$  is supported on three points:

$$\begin{aligned} (S_v^{(3)}, R_v^{(3)}) &= (0, 0), & (S_v^{(2)}, R_v^{(2)}) &= \left( 2^{2^{\text{lev}(v)}} \cdot \prod_{w \in \text{rt}(\text{path}(v))} 2^{2^{\text{lev}(w)}}, 0 \right) \\ (S_v^{(1)}, R_v^{(1)}) &= \left( W - \sum_{w \in \text{rt}(\text{path}(v))} S_w^{(2)}, \left( 1 - \frac{1}{\sqrt{H}} \right)^{|\text{rt}(\text{path}(v))|} \right) \end{aligned}$$

and we have  $\Pr[S_v = S_v^{(3)}] = 1 - \frac{1}{\sqrt{H}} - \frac{1}{H}$ ,  $\Pr[S_v = S_v^{(2)}] = \frac{1}{\sqrt{H}}$ ,  $\Pr[S_v = S_v^{(1)}] = \frac{1}{H}$ ; see Fig. 1. Observe that  $S_v^{(2)} \leq (2^{2^{\text{lev}(v)+1}})/2 \leq W/2$ , and  $S_v^{(1)} > W/2$  for every node  $v$ .

Importantly, note that any policy for this instance can obtain positive reward from at most one item. This is because for any  $v \in V$ ,  $S_v^{(1)} > W/2$ . Therefore we can assume that any policy terminates upon observing a size  $S_v^{(1)}$  for any visited vertex  $v$ . The binary tree is built so that a certain adaptive policy (see the proof of Theorem 3.1) can always reach a leaf-node if no positive reward has been collected in previous levels. The construction of the tree prevents any path from going upward from a node to its parent, as this will cause the length budget to run out. But more importantly, the instance is set up to preclude a policy from going to a left child of a node  $v$  if its instantiated size is  $S_v^{(2)}$  in the sense that if this happens then one cannot collect positive reward from this point on (Lemma 3.4).

The adaptivity-gap lower bound immediately follows from Theorems 3.1 and 3.2, since  $H = \Omega(\log B)$  and  $H = \Omega(\log \log W)$  for the above CorrKO instance.

► **Theorem 3.1.** *There is an adaptive policy for the above CorrKO instance that obtains  $\Omega(1)$  expected reward.*

■ **Figure 1** The  $(S_v^{(2)}, R_v^{(2)})$ ,  $(S_v^{(1)}, R_v^{(1)})$  pairs are shown respectively on the left and right of each highlighted vertex in the tree.

► **Theorem 3.2.** *Any nonadaptive policy for the above CorrKO instance obtains expected reward at most  $\frac{2}{\sqrt{H}}$ .*

**Proof of Theorem 3.1.** Consider the following adaptive policy  $\mathcal{A}$ : the policy moves to node  $r$  from  $\rho$ , and then proceeds as follows. Let  $v$  be the current node visited, which is  $r$  initially. If  $v$  is a leaf, then the policy ends after the instantiation of  $v$ . Otherwise, the next node visited by  $\mathcal{A}$  is: the left child of  $v$ , if  $S_v = S_v^{(3)}$ , and the right child of  $v$  if  $S_v = S_v^{(2)}$ ; if  $S_v = S_v^{(1)}$ , then  $\mathcal{A}$  stops and does not visit any other nodes.

Let  $P^*$  denote the (random) path traversed by  $\mathcal{A}$ , which we may view as a rooted path in  $T$ . Let  $v_{\text{last}}$  be the last vertex visited by  $\mathcal{A}$ , i.e.,  $v_{\text{last}}$  is the end-node of  $P^*$  other than  $r$  and  $P^* = \text{path}(v_{\text{last}})$ .

▷ **Claim 3.3.** We have  $d(P^*) \leq B$  and  $S(P^*) := \sum_{v \in P^*} S_v \leq W$  with probability 1.

We argue that the expected reward collected by  $P^*$  is at least  $\frac{1-e^{-1}}{4}$ . Let  $\mathcal{R} = R(P^*) := \sum_{v \in P^*} R_v$  denote the reward obtained by  $P^*$ . Note that  $v_{\text{last}}$  is the only vertex from which  $P^*$  can collect positive reward. So  $\mathbb{E}[\mathcal{R}] = \Pr[S_{v_{\text{last}}} = S_{v_{\text{last}}}^{(1)}] \cdot \mathbb{E}[R_{v_{\text{last}}}^{(1)}]$ . Observe that if  $S_{v_{\text{last}}} \neq S_{v_{\text{last}}}^{(1)}$ , then  $v_{\text{last}}$  is a leaf node, and hence the event  $\{S_{v_{\text{last}}} \neq S_{v_{\text{last}}}^{(1)}\}$  occurs precisely when  $\mathcal{A}$  visits  $H$  vertices, one on each level of  $\mathcal{T}$ , and none of them instantiate to size  $S_v^{(1)}$ . Since vertex sizes are independent across different vertices, we have  $\Pr[S_{v_{\text{last}}} \neq S_{v_{\text{last}}}^{(1)}] = (1 - \frac{1}{H})^H \leq e^{-1}$ , and so  $\mathbb{E}[\mathcal{R}] \geq (1 - e^{-1})\mathbb{E}[R_{v_{\text{last}}}^{(1)}]$ .

We have  $R_{v_{\text{last}}}^{(1)} = (1 - \frac{1}{\sqrt{H}})^{|\text{rt}(P^*)|}$ , and since  $(1 - \frac{1}{\sqrt{H}})^x$  is a convex function, we obtain that  $\mathbb{E}[R_{v_{\text{last}}}^{(1)}] \geq (1 - \frac{1}{\sqrt{H}})^{\mathbb{E}[|\text{rt}(P^*)|]}$ . Observe that  $v \in P^*$  gets included in  $\text{rt}(P^*)$  precisely when  $S_v$  instantiates to  $S_v^{(2)}$ , which happens with probability  $\frac{1}{\sqrt{H}}$ . So we can upper bound  $\mathbb{E}[|\text{rt}(P^*)|]$  by  $H \cdot \frac{1}{\sqrt{H}} = \sqrt{H}$ . It follows that  $\mathbb{E}[R_{v_{\text{last}}}^{(1)}] \geq (1 - \frac{1}{\sqrt{H}})^{\sqrt{H}} \geq \frac{1}{4}$ , where the last inequality uses the fact that  $1 - x \geq 4^{-x}$  for  $x \leq 0.5$ . ◀

**Proof of Theorem 3.2.** Let  $\sigma$  be some non-adaptive policy, which we may again view as a rooted path in  $T$ , since we can always move first to  $r$ . We may assume that  $\sigma$  visits vertices in decreasing order of their levels, since any backtracking from a node  $v$  to its ancestor would cause one to exceed the travel budget. We say that an execution of  $\sigma$  “cheats” if, for some visited node  $v$ ,  $S_v$  instantiates to  $S_v^{(2)}$ , and  $\sigma$  proceeds to visit a vertex in the subtree of  $T$  rooted at the left-child of  $v$ .

► **Lemma 3.4.**  $\sigma$  does not collect any positive reward after cheating.

**Proof.** Suppose  $\sigma$  cheats at some vertex  $u$ . Let  $v$  be any node in the tree rooted at the left-child of  $u$ . The residual knapsack budget after visiting  $u$  is at most  $W - S_u^{(2)}$ . It suffices to show that  $S_v^{(1)} > W - S_u^{(2)}$ . Since  $S_v^{(1)} = W - \sum_{w \in \text{rt}(\text{path}(v))} S_w^{(2)}$ , this amounts to showing that  $S_u^{(2)} > \sum_{w \in A} S_w^{(2)}$ , where  $A = \text{rt}(\text{path}(v))$ . We argue that  $S_w^{(2)} < S_u^{(2)}$  for every  $w \in A$ , and the  $S_w^{(2)}$ 's are distinct for  $w \in A$ . This, coupled with the fact that  $S_u^{(2)}$  and the  $S_w^{(2)}$ 's are all powers of 2, implies the above inequality.

Recall that for a node  $z$ , we have  $S_z^{(2)} = 2^{2^{\text{lev}(z)}} \cdot \prod_{w \in \text{rt}(\text{path}(z))} 2^{2^{\text{lev}(w)}}$ . Let  $A = \{a_1, a_2, \dots, a_{|A|}\}$ , where the nodes are ordered in increasing order of their distance from  $r$ . Then, for any  $i \geq 2$ , we have  $S_{a_i}^{(2)} = 2^{2^{\text{lev}(a_i)}} \cdot S_{a_{i-1}}^{(2)}$ , showing that each  $S_{a_i}^{(2)}$  is a distinct power of 2, and  $S_{a_i}^{(2)}$  increases with  $i$ . Note that  $u \notin \text{rt}(\text{path}(v))$  and  $\text{rt}(\text{path}(u)) \subseteq A$ . So for  $z = a_{|A|}$ , we have  $S_z^{(2)} = \prod_{w \in A - \text{rt}(\text{path}(u))} 2^{2^{\text{lev}(w)}} \cdot \prod_{w \in \text{rt}(\text{path}(u))} 2^{2^{\text{lev}(w)}}$  and  $\prod_{w \in A - \text{rt}(\text{path}(u))} 2^{2^{\text{lev}(w)}} < 2^{2^{\text{lev}(u)}}$ . It follows that  $S_z^{(2)} < S_u^{(2)}$ . ◀

Recall that we view  $\sigma$  also as a rooted path in  $T$ . We can show that the total expected reward obtained from  $\text{rt}(\sigma)$  and  $\text{left}(\sigma)$  are both at most  $\frac{1}{\sqrt{H}}$ , which completes the proof. For the latter bound, we utilize the fact that, due to Lemma 3.4, we can collect positive reward from a node  $v$  only if  $S_w = S_w^{(3)}$  for every  $w \in \text{left}(\text{path}(v)) - v$ . ◀

## 4 Approximation algorithms for CorrKO

We now devise non-adaptive approximation algorithms for CorrKO. In Section 4.1, we develop an  $O(\log \log W)$ -approximation algorithm with  $(n + \log B)^{O(\log W \log \log W)}$  (i.e., quasi-polynomial) running time, which will prove Theorem 1a, and in Section 4.2, we obtain a polytime  $O(\log W)$ -approximation algorithm, thereby proving Theorem 1b.

### 4.1 Quasi-polytime $O(\log \log W)$ -approximation algorithm

There are two chief components underlying our algorithm. First, we isolate a key structural result (Theorems 4.1 and 4.2) showing that from an optimal adaptive policy, one can extract a suitable path  $Q^*$  and certain “portal” vertices on this path, such that the subpaths of  $Q^*$  between these portal vertices satisfy various nice properties. Second, we exploit this structural result algorithmically as follows. The structural result allows us to reduce the problem, at the expense of an  $O(\log \log W)$ -factor loss, to that of finding the portal vertices, and suitable paths between these portal vertices that satisfy certain knapsack constraints on the total expected truncated size  $\mathbb{E}[\min\{S_v, 2^j\}]$  of nodes on these paths. We “guess” (i.e., enumerate over all possible choices of) these portal vertices and some auxiliary information, and set up a configuration LP (CKO-P) to find paths between these portal vertices. This configuration LP can be solved near-optimally, and we show that a fractional solution can be rounded incurring only an  $O(1)$ -factor loss in the objective and in the constraints. Finally, we argue that this leads to an  $O(\log \log W)$ -approximation non-adaptive policy.

Our approach is similar in spirit to the one in [2] for CorrO, and in Section 7, we show that our approach also yields an  $O(\log \log B)$ -approximation for CorrO, which improves upon the guarantee in [2] by an  $O(\frac{\log \log B}{\log \log \log B})$ -factor. While we borrow various ingredients from [2], the key difference between our approach and theirs is that we extract much more information from the adaptive policy in terms of so-called portal vertices, which enables us to round an underlying configuration LP incurring only a *constant-factor* violation in the knapsack constraints; in contrast, this step in [2] incurs an  $O(\frac{\log \log B}{\log \log \log B})$ -factor violation of the constraints, and this savings is the source of our improved guarantee.

**Structural results.** Recall that, for a path  $P$  and nodes  $a, b \in P$ , we use  $P_{a,b}$  to denote the  $a$ - $b$  portion of  $P$ . If  $P$  is a  $u$ - $v$  path, its *regret* is  $d^{\text{reg}}(P) := d(P) - d(u, v)$ , and the *two-point regret* of  $P$  with respect to a node  $a \in P$  is  $d^{\text{reg}}(P, a) := d(P) - d(u, a) - d(a, v) = d^{\text{reg}}(P_{u,a}) + d^{\text{reg}}(P_{a,v})$ . For an index  $j \in \{0, 1, \dots, L := \lceil \log W \rceil\}$ , recall that we define  $X_v^j := \min\{S_v, 2^j\}$  and  $\mu_v^j := \mathbb{E}[X_v^j]$ . For any vertex  $v \in V$ , let  $\pi_v(t) := \mathbb{E}[R_v \cdot \mathbb{1}_{S_v \leq W-t}] = \sum_{t'=0}^{W-t} \Pr[S_v = t'] \cdot \mathbb{E}[R_v | S_v = t']$  denote the expected reward obtained from  $v$  if its processing starts at time  $t$ . Note that  $\pi_v(t) = 0$  for any  $t > W$ . Also, note that  $\pi_\rho(t) = 0$  for all  $t$ . We may assume that  $\pi_v(0) \leq OPT/4$  for every  $v \in V$ , as otherwise, we can obtain  $\Omega(OPT)$  reward by going to a single node.

Throughout, let  $K = 3 \log(6 \log W) + 12$ ,  $L = \lceil \log W \rceil$ ,  $N_1 = 2(K + 1)$ . Define  $\varphi_{-1} := \rho$ .

► **Theorem 4.1.** *There exists a rooted path  $Q^*$  with  $d(Q^*) \leq B$ , vertices  $\varphi_0 \preceq \varphi_1 \preceq \dots \preceq \varphi_k$  on  $Q^*$  for some  $k \leq L$ , and, for each  $j \in \llbracket k \rrbracket$ , a vertex-set  $\text{Por}_j \subseteq Q_{\varphi_{j-1}, \varphi_j}^*$  containing nodes  $\varphi_{j-1}, \varphi_j$ , with  $|\text{Por}_j| \leq N_1$ , whose vertices are ordered by the order they appear on  $Q^*$ , satisfying the following properties.*

- (a)  $\sum_{j=0}^k \sum_{v \in Q_{\varphi_{j-1}, \varphi_j}^* - \varphi_j} \pi_v(2^j - 1) \geq OPT/4$ .
- (b)  $\mu^j(Q_{\rho, \varphi_j}^* - \varphi_j) \leq (K + 1)2^j$  for all  $j \in \llbracket k \rrbracket$ .
- (c) For every  $j \in \llbracket k \rrbracket$  and consecutive nodes  $a, b \in \text{Por}_j$ , we have  $\mu^j(Q_{a,b}^* - b) \leq 2^j$ .

As mentioned earlier, in our quasi-polytime algorithm, we utilize Theorem 4.1 to construct a good rooted path, by using enumeration to guess  $\bigcup_j \text{Por}_j$ , and an LP to then obtain suitable paths between consecutive nodes of  $\bigcup_j \text{Por}_j$ . In order to ensure that the total path length is at most the travel budget  $B$ , we will also need to obtain some information about the lengths  $d(Q_{a,b}^*)$  for consecutive nodes  $a, b$  in  $\bigcup_j \text{Por}_j$ . Naively guessing these lengths would yield incur a large  $B^{O(LN_1)}$ -factor in the running time; to do better, and reduce the dependence to  $(\log B)^{O(LN_1)}$ , we instead guess the two-point regret of each  $Q_{a,b}^*$  with respect to a “mid-point” node, within a factor of 2, which suffices (see Fig. 2). We refine Theorem 4.1 to incorporate these estimates as follows.

► **Theorem 4.2 (Main structural result).** *Let the node-sequence  $\varphi_0, \dots, \varphi_k$ , where  $k \leq L$ , and for each  $j \in \llbracket k \rrbracket$ , the ordered node sequence  $\text{Por}_j$  of at most  $N_1$  nodes, be as given by Theorem 4.1. Define  $\text{Por} := \bigcup_{j=0}^k \text{Por}_j$ , which we call “portal nodes”, where the ordering of nodes in  $\text{Por}$  is  $\text{Por}_0, \text{Por}_1, \dots, \text{Por}_k$ ; for  $a \in \text{Por}$ ,  $a \neq \varphi_k$ , let  $\text{next}(a)$  be the next node in  $\text{Por}$  after  $a$ . For each  $a \in \text{Por} - \varphi_k$ , there exists an  $a$ - $\text{next}(a)$  path  $Q_{a, \text{next}(a)}^*$ , auxiliary node  $m_a$ , and integer  $\gamma_a \geq 0$ , such that the following properties hold.*

- (P1) (Distance)  $d(Q_{a,b}^*) \leq D_a := 2^{\gamma_a} - 1 + d(a, m_a) + d(m_a, b)$  for every pair of consecutive nodes  $a, b \in \text{Por}$ .
- (P2) (Total-length)  $\sum_{a \in \text{Por} - \varphi_k} D_a \leq B$ .
- (P3) (Reward)  $\sum_{j=0}^k \sum_{a \in \text{Por}_j - \varphi_j} \sum_{v \in Q_{a, \text{next}(a)}^* - \text{next}(a)} \pi_v(2^j - 1) \geq OPT/8$ .
- (P4) (Prefix-size)  $\sum_{h=0}^j \sum_{a \in \text{Por}_h - \varphi_h} \mu^j(Q_{a, \text{next}(a)}^* - \text{next}(a)) \leq (K + 1)2^j$  for all  $j \in \llbracket k \rrbracket$ .
- (P5) (Size)  $\mu^j(Q_{a,b}^* - b) \leq 2^j$  for every  $j \in \llbracket k \rrbracket$  and pair of consecutive nodes  $a, b \in \text{Por}_j$ .

**Configuration LP and non-adaptive algorithm.** Now assume that we have found, by enumeration, nodes  $\varphi_0, \dots, \varphi_k$ , where  $k \leq L$ , ordered node-sets  $\text{Por}_j$  for  $j \in \llbracket k \rrbracket$ , and length bounds  $D_a$  for every pair of consecutive nodes  $a, b \in \text{Por} := \bigcup_{j=0}^k \text{Por}_j$ , as stipulated by Theorem 4.2. (We also need to enumerate for  $\{m_a, \gamma_a\}_{a \in \text{Por} - \varphi_k}$ ; we do not use these quantities directly, but these are used to specify the  $D_a$  length bounds.) That is, these objects are compatible with suitable  $Q_{a,b}^*$  paths such that P1–P5 hold. Clearly, this enumeration takes  $(n \log B)^{O(N_1 L)} = (n \log B)^{O(\log W \log \log W)}$  time, which is the source of the running time in Theorem 1a.

■ **Figure 2** Portal nodes  $\text{Por}$  and paths between portal nodes. The solid nodes depict  $\text{Por}_j$ .

We formulate a configuration LP to find  $a$ - $b$  paths, for every pair of consecutive nodes  $a, b \in \text{Por}$ , satisfying properties P1, P3–P5. To this end, fix some  $j \in \llbracket k \rrbracket$  and  $a \in \text{Por}_j - \varphi_j$ , and let  $b = \text{next}(a)$ . The valid  $a$ - $b$  paths (i.e., the configurations) are the solutions to the following (deterministic) *point-to-point knapsack orienteering* ( $\text{KnapOrient}$ ) problem: the end-nodes are  $a, b$ , the length budget is  $D_a$ , the knapsack weights are  $\mu_v^j$  for all  $v \in V - b$  and  $\mu_b^j = 0$ , and the knapsack-budget is  $2^j$ . Let  $\mathcal{I}_a$  denote the set of all feasible solutions to this  $\text{KnapOrient}$  instance.

The configuration LP has variables  $x_\tau^a$ , for every  $a \in \text{Por} - \varphi_k$  and  $\tau \in \mathcal{I}_a$ , indicating the  $a$ - $\text{next}(a)$  paths that are chosen.

$$\max \sum_{j=0}^k \sum_{a \in \text{Por}_j - \varphi_j} \sum_{\tau \in \mathcal{I}_a} x_\tau^a \cdot \left( \sum_{v \in \tau - \text{next}(a)} \pi_v (2^j - 1) \right) \quad (\text{CKO-P})$$

$$\text{s.t.} \quad \sum_{\tau \in \mathcal{I}_a} x_\tau^a = 1 \quad \forall a \in \text{Por} - \varphi_k \quad (1)$$

$$\sum_{a \in \text{Por} - \varphi_k} \sum_{\tau \in \mathcal{I}_a: v \in \tau - \text{next}(a)} x_\tau^a \leq 1 \quad \forall v \in V \quad (2)$$

$$\sum_{h=0}^j \sum_{a \in \text{Por}_h - \varphi_h} \sum_{\tau \in \mathcal{I}_a} x_\tau^a \cdot \mu^j(\tau - \text{next}(a)) \leq (K+1)2^j \quad \forall j \in \llbracket k \rrbracket \quad (3)$$

$$x \geq 0.$$

Constraints (1) encodes that we select an  $a$ - $b$  path for every consecutive pair of nodes  $a, b \in \text{Por}$ , and constraints (2) ensure that each node  $v$  lies on at most one of these  $a$ - $b$  paths; constraint (3) encodes the (Prefix-size) property P4. (Note that if  $\varphi_{h-1} = \varphi_h$ , then  $\text{Por}_h = \{\varphi_h\}$ , so we do not have any term for index  $h$  in the objective function, and on the LHS of (3).)

To gain some intuition, notice that Theorem 4.2 shows that there is a feasible integral solution to (CKO-P) of objective value at least  $OPT/8$ : we set  $x_\tau^a = 1$  for  $\tau = Q_{a, \text{next}(a)}^*$  for every  $a \in \text{Por} - \varphi_k$ . Properties P1 and P5 show that  $Q_{a, \text{next}(a)}^* \in \mathcal{I}_a$ ; property P4 shows that (3) holds, and P3 shows that the objective value is at least  $OPT/8$ .

We can solve (CKO-P) approximately, given an approximation algorithm for  $\text{KnapOrient}$ , since this can be used to obtain an approximate separation oracle for the dual of (CKO-P).

▷ Claim 4.3. The optimal value of (CKO-P),  $OPT_{\text{CKO-P}}$ , is at least  $OPT/8$ .

► **Lemma 4.4.** *Given an  $\alpha$ -approximation algorithm for KnapOrient, we can compute in polytime a solution  $\bar{x}$  to (CKO-P) of objective value at least  $OPT_{\text{CKO-P}}/\alpha$ .*

We use randomized rounding to round the solution  $\bar{x}$  obtained by Lemma 4.4, and Chernoff bounds yield that this only incurs an  $O(1)$ -factor loss in the objective, and in the violation of constraints (3); here is where we crucially exploit property P5. We then obtain an  $O(K)$ -approximate non-adaptive policy for CorrKO from the rounded solution.

■ **Algorithm CSKO-ALG.** // Rounding  $(\bar{x}, \bar{y})$  and obtaining a non-adaptive policy

- 
- 1 Independently, for each  $a \in \text{Por} - \varphi_k$ , letting  $b = \text{next}(a)$ , do the following: pick an  $a$ - $b$  path by choosing  $\tau \in \mathcal{I}_a$  with probability  $\bar{x}_\tau^a/2$ , and choosing the “direct” path  $a, b$  with the remaining probability 0.5; let  $P_{a,b}$  denote the path picked.
  - 2 If for any  $j \in \llbracket k \rrbracket$ , we have  $\sum_{h=0}^j \sum_{a \in \text{Por}_h - \varphi_h} \mu^j (P_{a, \text{next}(a)} - \text{next}(a)) > 5(K+1)2^j$ , then **return** the empty policy that does not visit any node.
  - 3 Consider the concatenated sequence of nodes  $\{P_{a, \text{next}(a)}\}_{a \in \text{Por} - \varphi_k}$  (where  $\text{Por}$  is ordered as in Theorem 4.2). If a non-portal node is repeated in this sequence, then shortcut the  $P_{a, \text{next}(a)}$  paths so as to retain only the first occurrence of each node. Let  $P'_{a, \text{next}(a)}$  denote the shortcut version of  $P_{a, \text{next}(a)}$  (which is still an  $a$ - $\text{next}(a)$  path). Let  $P'$  be the rooted path given by the node-sequence  $\{P'_{a, \text{next}(a)}\}_{a \in \text{Por} - \varphi_k}$ , where we retain only one copy of each portal node.
  - 4 Sample each  $v \in P' - \rho$  independently with probability  $\frac{1}{10(K+1)}$  to obtain the rooted path,  $P''$ . **return** the non-adaptive policy  $P''$ .
- 

**Analysis overview.** The key observation is that since for any  $j \in \llbracket k \rrbracket$ , any  $h \leq j$ , any  $a \in \text{Por}_h - \varphi_h$ , and any  $\tau \in \mathcal{I}_a$ , we have  $\mu^j(\tau - \text{next}(a)) \leq 2^j$ , we obtain that  $\sum_{h=0}^j \sum_{a \in \text{Por}_h - \varphi_h} \mu^j (P_{a, \text{next}(a)} - \text{next}(a))$  is the sum of a collection of independent  $2^j$ -bounded random variables,<sup>2</sup> whose expectation is  $O((K+1) \cdot 2^j)$ , due to constraint (3). It follows from Chernoff bounds that the probability that this sum exceeds  $5(K+1)2^j$ , for any fixed index  $j$ , is  $\exp -\Omega(K)$ , and so by a union bound, step 2 succeeds with high probability (Lemma 4.5).

To bound the reward obtained, consider a node  $v$  and index  $j \in \llbracket k \rrbracket$ , and define  $\bar{y}_v^j := \sum_{a \in \text{Por}_j - \varphi_j} \sum_{\tau \in \mathcal{I}_a: v \in \tau - \text{next}(a)} \bar{x}_\tau^a$ . (Note that  $\sum_{h=0}^k \bar{y}_v^h \leq 1$ .) We say that  $v$  is “visited by segment  $j$ ” if  $v \neq \varphi_j$  and  $v \in \bigcup_{a \in \text{Por}_j - \varphi_j} P_{a, \text{next}(a)}$ ; we say that  $v$  is “retained by segment  $j$ ” if  $v \neq \varphi_j$  and  $v$  remains on  $\bigcup_{a \in \text{Por}_j - \varphi_j} P'_{a, \text{next}(a)}$  after the shortcutting in step 3. Note that the latter events are disjoint, for different  $j$ s. (Note that for a portal node in  $\text{Por}_j - \varphi_j$ , both events happen with probability 1.) Clearly,  $v$  is retained by segment  $j$  only if it is visited by segment  $j$ . For convenience of analysis, we will view step 3 as being executed even if step 2 fails, so we can talk about the event “ $v$  retained by segment  $j$ ” regardless of the outcome of step 2. It is not hard to argue that  $\Pr[v \text{ is retained by segment } j] = \Omega(\bar{y}_v^j)$ , but we need some care to show that this holds even when we condition on the event that step 2 succeeds, as subtle dependencies between events arise here. Nevertheless, we show that this indeed holds (Lemma 4.6).

<sup>2</sup> This is the key difference from [2]. They guess only the  $\varphi_j$  nodes, and so in their case, the corresponding sum gets decomposed into the sum of  $(K+1)2^j$ -bounded random variables, and so an application of Chernoff bounds incurs an additional  $\frac{\log k}{\log \log k} = \frac{\log \log W}{\log \log \log W}$ -factor.

## 29:16 Approximation Algorithms for Correlated Knapsack Orienteering

Finally, given that step 2 succeeds and the rounded path  $P'$  satisfies (3) with  $O((K+1)2^j)$  on the RHS, due to the random sampling in step 4, we can argue that, for any node  $v$  retained by segment  $j$ , the non-adaptive policy processes  $v$  by time  $2^j - 1$  with probability  $\frac{1}{O(K)}$  (Lemma 4.7). Thus, the expected reward of the non-adaptive policy is  $\frac{1}{O(K)} \cdot \sum_{j=0}^k \sum_{v \in V} \bar{y}_j^v \cdot \pi_v(2^j - 1) \geq \frac{OPT}{O(K)}$ .

For an index  $j \in \llbracket k \rrbracket$ , let  $\mathcal{B}_j$  be the event that  $\sum_{h=0}^j \sum_{a \in \text{Por}_h - \varphi_j} \mu^j(P_{a, \text{next}(a)} - \text{next}(a)) > 5(K+1)2^j$ . So  $\mathcal{B} := \bigvee_{j=0}^k \mathcal{B}_j$  is the event that step 2 fails; let  $\mathcal{B}^c$  denote the complement of  $\mathcal{B}$ . Recall that  $K = 3 \log \log(6W) + 12$ .

► **Lemma 4.5.**  $\Pr[\mathcal{B}_j] \leq e^{-(K+1)}$  for all  $j \in \llbracket k \rrbracket$ . Hence,  $\Pr[\mathcal{B}] \leq 1/\text{poly}(\log W)$ .

► **Lemma 4.6.** For any node  $v \in V$  and any  $j \in \llbracket k \rrbracket$ , we have  $\Pr[\{v \text{ is retained by segment } j\} \wedge \mathcal{B}^c] \geq \frac{\bar{y}_j^v}{16}$ .

► **Lemma 4.7.** Consider any node  $v \in V - \varphi_k$ . Suppose that  $v$  is retained by segment  $j$  in step 3. Then  $\Pr[\text{non-adaptive policy } P'' \text{ processes } v \text{ by time } 2^j - 1] \geq \frac{1}{20(K+1)}$ , where the probability is over both the random sampling in step 4 and the random execution of  $P''$ .

**Proof of Theorem 1a.** Combining Lemmas 4.6 and 4.7, and since for any  $v \in V - \varphi_k$ , the events “ $v$  is retained by segment  $j$ ” are disjoint across different  $j$ s, the expected reward obtained from a node  $v$  is at least  $\frac{\sum_{j=0}^k \pi_v(2^j - 1) \bar{y}_j^v}{320(K+1)}$ . So the total expected reward obtained by  $P''$  is at least  $\frac{1}{320(K+1)} \cdot (\text{objective value of } \bar{x}) = OPT/O(K)$ .

The running time is polynomial in the time needed to enumerate the quantities in Theorem 4.2, which is  $\text{poly}((n \log B)^{O(\log W \log \log W)}) = O((n + \log B)^{O(\log W \log \log W)})$ . ◀

### 4.2 Polynomial-time $O(\log W)$ -approximation algorithm

The polytime algorithm also proceeds by gleaning some structural insights from an optimal adaptive policy that enable one to reduce the problem to rooted knapsack orienteering, losing an  $O(\log W)$ -factor. Recall that  $L = \lceil \log W \rceil$ .

► **Theorem 4.8.** There exists an index  $j \in \llbracket L \rrbracket$  such that, for the  $\text{KnapOrient}$ -instance with start node  $\rho$ , travel budget  $B$ , knapsack budget  $2^{j+1}$ , knapsack weights  $\{\mu_v^j\}_{v \in V}$ , and rewards  $\{\pi_v(2^j - 1)\}_{v \in V}$ , the optimal value of the LP-relaxation (KO-LP), is at least  $OPT/(L+1)$ .

**Proof of Theorem 1b.** Theorem 4.8 leads to the following simple algorithm. For the index  $j$  in the theorem statement, we solve (KO-LP) and round it to an *integer solution*  $P$  losing a factor of 5 (see Theorem 2.3). We sample each non-root node in  $P$  independently with probability  $\frac{1}{4}$ , and return the resulting rooted path  $P''$ . To analyze this, for any  $v \in P$ , we have that the probability that the non-adaptive policy  $P''$  processes  $v$  by time  $2^j - 1$  is at least  $\frac{1}{8}$ . The claim follows because  $\Pr[\sum_{w \prec_{P''} v} S_w \geq 2^j] = \Pr[\sum_{w \prec_{P''} v} X_w^j \geq 2^j]$ , which is at most

$$\frac{\mathbb{E}[\sum_{w \prec_{P''} v} X_w^j]}{2^j} = \frac{1}{4} \cdot \frac{\mathbb{E}[\sum_{w \prec_P v} X_w^j]}{2^j} \leq \frac{1}{4} \cdot \frac{\sum_{w \in P} \mu_w^j}{2^j} \leq \frac{1}{2}.$$

The probability of the stated event is therefore at least  $\Pr[v \in P'']/2 \geq 1/8$ . Therefore, the expected reward obtained is at least  $\frac{1}{8} \cdot \sum_{v \in P} \pi_v(2^j - 1) \geq \frac{OPT}{L+1} \cdot \frac{1}{5} \cdot \frac{1}{8} = OPT/O(L)$ . ◀

## 5 Refined approximation guarantees and hardness results for CorrKO

In this section, we perform a fine-grained-complexity study of CorrKO. Motivated by the fact that our adaptivity-gap lower bound for CorrKO utilizes distributions of support-size 3, whereas the adaptivity-gap lower-bound example for stochastic orienteering [2] considers *weighted Bernoulli distributions*, we investigate the complexity of CorrKO when we have distributions supported on at most 2 points – we call this special case 2CorrKO – as also the further special case where the vertex-size distributions are weighted Bernoulli distributions.

In stark contrast with stochastic orienteering, we show that the *adaptivity gap is a constant* for 2CorrKO. Moreover, we obtain non-adaptive  $O(1)$ -approximation algorithms that run in polynomial time for weighted Bernoulli distributions (Theorem 5.5), and in time  $(n + \log B)^{O(\log W)}$  for general 2CorrKO (Theorem 5.4).

The chief insight underlying the above results is that one can isolate a novel *deterministic* VRP, that we call *orienteering with knapsack deadlines* (OrientKD), that governs the complexity of 2CorrKO. In OrientKD, we are given an (rooted or P2P) orienteering instance, along with nonnegative knapsack weights  $\{\text{wt}_v\}_{v \in V}$  and *knapsack deadlines*  $\{\text{KD}_v\}$ . A path  $P$  with start node  $a$  is feasible, if it is feasible for the orienteering instance, and  $\sum_{u \in P_{a,v}} \text{wt}_u \leq \text{KD}_v$  for every node  $v \in P$ ; the goal is to find a feasible path  $P$  that obtains the maximum reward. For this problem, we obtain the following approximation results.

► **Theorem 5.1.** *We can obtain the following approximation guarantees for OrientKD:*

- (a)  $O(1)$ -approximation in  $(n + \log B)^{O(\log W)}$  time;
- (b) polytime  $O(\log(\frac{\max_v \text{KD}_v}{\text{KD}_{\min}}))$ -approximation, where  $\text{KD}_{\min}$  is the minimum non-zero knapsack deadline.

We show that, up to constant factors, OrientKD is *equivalent to 2CorrKO in terms of approximability* (Theorem 5.4). The  $O(1)$ -approximation for 2CorrKO, and the polytime  $O(1)$ -approximation for weighted Bernoulli distributions both fall out as direct consequences of this equivalence: the former, because we can devise an  $(n + \log B)^{O(\log W)}$ -time  $O(1)$ -approximation for OrientKD (Theorem 5.1); the latter, because the OrientKD instance that one needs to solve for weighted Bernoulli distributions is in fact a KnapOrient instance. Another corollary is a hardness result for CorrKO showing that an  $\alpha$ -approximation for CorrKO relative to the *non-adaptive optimum* implies an  $O(\alpha)$ -approximation for OrientKD (Theorem 5.6); this follows because such an approximation guarantee for CorrKO implies an  $O(\alpha)$ -approximation for 2CorrKO (since the adaptivity gap for 2CorrKO is  $O(1)$ ).

**Difficult instances of CorrKO.** We begin by distilling the key source of difficulty for CorrKO (Lemma 5.2). This will prove to be useful when we study 2CorrKO, as it will allow us to focus on the core of the problem. We define the size instantiation  $S_v$  of a vertex  $v$  to be large if  $S_v > W/2$ , and small otherwise. We argue that the difficulty of CorrKO stems from instances where most of the optimal reward comes from *vertices that instantiate to a large size with small probability*.

To make this precise, we introduce some notation. For a vertex  $v$ , we can split its reward  $R_v$  as  $R_v = R_v^{>W/2} + R_v^{\leq W/2}$ , where  $R_v^{>W/2} := R_v \mathbb{1}_{S_v > W/2}$  and  $R_v^{\leq W/2} := R_v \mathbb{1}_{S_v \leq W/2}$ . We can consider the modified CorrKO instances  $\mathcal{I}^{>W/2}$  and  $\mathcal{I}^{\leq W/2}$ , where the rewards are given by  $\{R_v^{>W/2}\}_{v \in V}$  and  $\{R_v^{\leq W/2}\}_{v \in V}$  respectively; so in  $\mathcal{I}^{>W/2}$ , we only collect non-zero reward from large instantiations, and in  $\mathcal{I}^{\leq W/2}$ , we only collect non-zero reward from small instantiations. For  $p \in [0, 1]$ , define  $\mathcal{I}^{>W/2}(p)$  to be the instance with vertex set  $V(p) := \{v \in V : \Pr\{S_v > W/2\} \leq p\}$  (note that  $p \in V(p)$ ). Thus, in instance  $\mathcal{I}^{>W/2}(p)$ , we only consider vertices that instantiate to a large size with probability at most  $p$  (i.e., small probability), and collect reward only from large instantiations.

► **Lemma 5.2.** *Suppose we have an  $\alpha$ -approximation algorithm for CorrKO instances of the form  $\mathcal{I}^{>W/2}(0.5)$ . Then, we can obtain an  $(\alpha + O(1))$ -approximation algorithm for all CorrKO instances.*

**Proof.** A CorrKO instance  $\mathcal{I}$  can be decomposed into three instances,  $\mathcal{I}_1 = \mathcal{I}^{\leq W/2}$ ,  $\mathcal{I}_2 = \mathcal{I}^{>W/2}(0.5)$ , and  $\mathcal{I}_3$  with vertex set  $V_3 := \{v \in V : \Pr[S_v > W/2] > 0.5\}$  and rewards  $\{R_v^{>W/2}\}_{v \in V_3}$ . Any vertex  $v$  yields positive reward in at most one of these 3 instances for any size instantiation, and so  $OPT = OPT(\mathcal{I}) \leq OPT(\mathcal{I}_1) + OPT(\mathcal{I}_2) + OPT(\mathcal{I}_3)$ .

We can obtain non-adaptive policies that yield approximation guarantees of  $\beta_1 = O(1)$ ,  $\beta_3 = O(1)$  for  $\mathcal{I}_1$  and  $\mathcal{I}_3$  respectively. Any adaptive policy for  $\mathcal{I}_3$  can collect positive reward from at most one vertex, which is the first vertex that instantiates to a large size; after this the policy may as well stop. The expected number of nodes visited by an adaptive policy is at most  $\sum_{i \geq 1} 2^{-(i-1)} \leq 4$ , so simply visiting the node in  $V_3$  with largest expected reward, yields an  $O(1)$ -approximation to  $OPT(\mathcal{I}_3)$ . For  $\mathcal{I}_1$ , one can argue that an  $O(1)$ -approximation follows by solving the KnapOrient instance with rewards  $\{\mathbb{E}[R_v^{\leq W/2}]\}_{v \in V}$ , travel budget  $B$ , knapsack weights  $\{\mathbb{E}[\min\{S_v, W\}]\}_{v \in V}$ , and knapsack budget  $2W$ .

Let  $\beta_2 = \alpha$ . Consider now the algorithm that With probability  $\frac{\beta_j}{\beta_1 + \beta_2 + \beta_3}$ , runs the corresponding algorithm for instance  $\mathcal{I}_j$ , for  $j = 1, 2, 3$ . The expected reward obtained via this is at least  $\sum_{j=1}^3 \frac{\beta_j}{\beta_1 + \beta_2 + \beta_3} \cdot \frac{OPT(\mathcal{I}_j)}{\beta_j} \geq \frac{OPT}{\beta_1 + \beta_2 + \beta_3} = \frac{OPT}{\alpha + O(1)}$ . ◀

## 5.1 2CorrKO: CorrKO with distributions of support-size at most 2

Recall that 2CorrKO denotes the special case of CorrKO where, for each vertex  $v$ , the distribution of  $S_v$  is supported on at most 2 values, denoted  $S_v^{(1)}, S_v^{(2)}$  with  $S_v^{(1)} \geq S_v^{(2)}$ . By Lemma 5.2, to obtain an  $O(1)$ -approximation for 2CorrKO, it suffices to consider the instance  $\mathcal{I}_2 = \mathcal{I}^{>W/2}(0.5)$ , and we focus on such instances in the sequel. To keep notation simple, we continue to use  $V$  to denote the vertex set of  $\mathcal{I}_2$ . Then we may assume that the (size, reward) distribution for each  $v \in V$  is  $(S_v^{(1)}, R_v)$  with probability  $p_v$ , and  $(S_v^{(2)}, 0)$  with probability  $1 - p_v$ , where (i)  $S_v^{(1)} > W/2 \geq S_v^{(2)}$  and (ii)  $p_v \leq 0.5$ . Property (i) holds because if  $S_v^{(1)} \leq W/2$ , then  $v$  yields 0 reward for  $\mathcal{I}_2$ , so may be discarded; if  $S_v^{(1)} > W/2$ , then  $\Pr[S_v > W/2] = 1$ , which means that  $v$  would not be considered for  $\mathcal{I}_2$ . Given (i) the reward when the size is  $S_v^{(2)}$  must be 0, and (ii) holds because  $p_v = \Pr[S_v > W/2]$ . We first argue that the adaptivity gap for such instances is 1.

► **Theorem 5.3.** *The adaptivity gap for 2CorrKO (instances of the form  $\mathcal{I}^{>W/2}(0.5)$ ) is 1.*

**Proof.** Let  $\mathcal{T}$  be the decision tree of an optimal adaptive policy. Consider the (rooted) path  $\sigma$  of  $\mathcal{T}$  corresponding to the  $S_v^{(2)}$  size instantiations. Then  $\mathcal{T}$  cannot collect any reward outside of  $\sigma$ , since the residual knapsack budget when we reach any node  $v \in \mathcal{T} \setminus \sigma$  is less than  $W/2$ . So the non-adaptive policy represented by  $\sigma$  has the same expected reward as  $\mathcal{T}$ . ◀

We now show that the resulting 2CorrKO problem is equivalent to OrientKD, up to constant-factor approximation losses. By “equivalent”, we always mean equivalent up a multiplicative  $O(1)$  factor. We actually show that 2CorrKO is equivalent to another problem, *knapsack orienteering with knapsack deadlines* (KnapOrientKD), which is the knapsack-constrained version of OrientKD; by Theorem 2.1, OrientKD and its knapsack-constrained version KnapOrientKD are equivalent, so this implies that 2CorrKO and OrientKD are equivalent.

► **Theorem 5.4.** *Given an  $\alpha$ -approximation algorithm for one of the problems, KnapOrientKD or 2CorrKO, one can obtain an  $O(\alpha)$ -approximation algorithm for the other. Hence, the problems 2CorrKO and OrientKD are equivalent. This implies an  $O(1)$ -approximation algorithm for 2CorrKO with running time  $(n + \log B)^{O(\log W)}$ .*

The approximation guarantee above follows from the guarantee for OrientKD stated in Theorem 5.1. We briefly sketch how to reduce 2CorrKO to KnapOrientKD. By essentially “inverting” this reduction, we obtain the opposite reduction, from KnapOrientKD to 2CorrKO.

Let  $\mathcal{I}$  be a 2CorrKO instance. By Theorem 5.3, we can focus on non-adaptive policies for  $\mathcal{I}$ . Let  $\tau$  be a  $\rho$ -rooted path representing a non-adaptive policy. It is not hard to show that the expected reward from a node  $v \in \tau$  is  $p_v R_v \prod_{w \prec_\tau v} (1 - p_w)$  if  $\sum_{w \prec_\tau v} S_w^{(2)} \leq W - S_v^{(1)}$ , and is 0 otherwise. Also, one can argue that the total expected reward from nodes  $v \in \tau$  with  $\sum_{w \prec_\tau v} p_w > 1$  is a small fraction of  $OPT(\mathcal{I})$ . This motivates the following reduction to KnapOrientKD. We set rewards  $\{\pi_v R_v\}_{v \in V}$ . The constraint  $\sum_{w \prec_\tau v} S_w^{(2)} \leq W - S_v^{(1)}$  can be encoded by a knapsack deadline, by considering knapsack weights  $\{S_w^{(2)}\}_{w \in V}$  and knapsack deadlines  $\{W - S_w^{(1)} + S_w^{(2)}\}_{w \in V}$ . The additional knapsack constraint will encode that the total  $p_w$ -weight of the path should be at most 1, so that the expected reward obtained for  $\mathcal{I}$  from each vertex  $v$  on the KnapOrientKD-solution is  $\Omega(p_v R_v)$ .

For weighted Bernoulli size distributions, which is the special case of 2CorrKO where  $S_v^{(2)} = 0$  for all  $v \in V$ , the above reduction actually crates a KnapOrient instance, since the knapsack-deadlines are trivially satisfied by any rooted path. Since we have a polytime  $O(1)$ -approximation for KnapOrient, we obtain the following.

► **Theorem 5.5** (Weighted Bernoulli size distributions). *There is a polytime  $O(1)$ -approximation for CorrKO with weighted Bernoulli size distributions.*

As noted earlier, combining the equivalence of 2CorrKO and OrientKD, and the  $O(1)$  adaptivity gap for 2CorrKO, yields the following hardness result.

► **Theorem 5.6** (Hardness of approximating the non-adaptive optimum). *Given an  $\alpha$ -approximation algorithm for CorrKO with respect to the non-adaptive optimum, we can obtain an  $O(\alpha)$ -approximation algorithm for OrientKD.*

## 6 CorrKO with cancellations

In CorrKO *with cancellations* (CorrKO-Cancel), the input is the same as in CorrKO, but we are now allowed to *cancel* the processing of the current vertex  $v$  at any (integer) timestep before its size and reward get fully realized; if  $v$  is cancelled, then no reward is collected from  $v$  and we cannot process  $v$  again. As with CorrKO, we only collect reward from vertices that complete by the processing-time horizon  $W$ . Gupta et al. [18] showed that even for correlated knapsack (which is the special case of CorrKO where all vertices are co-located), the optimal reward when we allow cancellations can be substantially larger than the optimal reward without cancellations, so we need to develop new algorithms to handle cancellations.

We obtain the same guarantees for CorrKO-Cancel as for CorrKO: that is,  $O(\log \log W)$ -approximation in  $(n + \log B)^{O(\log W \log \log W)}$  time, and a polytime  $O(\log W)$ -approximation.

We proceed as follows. Recall that for a vertex  $v$ , we define  $R_v^{>W/2} := R_v \mathbb{1}_{S_v > W/2}$  and  $R_v^{\leq W/2} := R_v \mathbb{1}_{S_v \leq W/2}$ . Let  $\mathcal{I}^{>W/2}$  and  $\mathcal{I}^{\leq W/2}$  denote the CorrKO-Cancel instances where the rewards are given by  $\{R_v^{>W/2}\}_{v \in V}$  and  $\{R_v^{\leq W/2}\}_{v \in V}$  respectively. As observed by [18], cancellations do not help for the instance  $\mathcal{I}^{>W/2}$ , i.e., the optimal reward is the same both with and without cancellations. This is because if a policy cancels a vertex  $v$  after it has

run for some  $t \leq W/2$  time steps, we can modify the policy to not process  $v$  at all, without decreasing the reward accrued from subsequently-processed vertices; if  $v$  is cancelled after it has run for more than  $W/2$  time steps, then both with and without cancellation, the policy cannot collect any further reward.

We show that we can obtain an  $O(1)$ -approximation for  $\mathcal{I}^{\leq W/2}$ . With probability 0.5 each, we can work on the instance  $\mathcal{I}^{\leq W/2}$ , where we utilize this  $O(1)$ -approximation, or the instance  $\mathcal{I}^{> W/2}$ , where we utilize the approximation results for CorrKO. So this yields: an  $O(\log \log W)$ -approximation in quasi-polytime, and a polytime  $O(\log W)$ -approximation.

So we focus on obtaining an  $O(1)$ -approximation for CorrKO-Cancel instances of the form  $\mathcal{I}^{\leq W/2}$ . Our approach is based on LP-rounding, by combining the LP-rounding approaches for orienteering in [14] and the correlated knapsack problem with cancellations in [18]. We combine the LP-relaxations for these two problems to obtain the following LP, whose optimal value yields an upper bound on the optimal reward. We use  $R_u(t)$  to denote the reward  $R_u$  when the size  $S_u$  is  $t$ ; this is 0 if  $\Pr[S_u = t] = 0$ . Note that  $R_u(t) = 0$  for all  $t > W/2$ , since we are considering  $\mathcal{I}^{\leq W/2}$ .

$$\begin{aligned}
\max \quad & \sum_{u \in V} \sum_{t=1}^{W/2} z_{u,t} \cdot \Pr[S_u = t \mid S_u \geq t] \cdot R_u(t) && \text{(CKOC-LP)} \\
\text{s.t.} \quad & \text{(O1)–(O5)} \\
& \sum_{v \in V} z_u^v = z_{u,0} && \forall u \in V && (4) \\
& z_{u,t} = s_{u,t} + z_{u,t+1} && \forall u \in V, t \in \llbracket W \rrbracket && \text{(CK1)} \\
& s_{u,t} \geq \Pr[S_u = t \mid S_u \geq t] \cdot z_{u,t} && \forall u \in V, t \in \llbracket W \rrbracket && \text{(CK2)} \\
& \sum_{u \in V} \sum_{t=0}^W t \cdot s_{u,t} \leq W && && \text{(CK3)} \\
& x, z, s \geq 0.
\end{aligned}$$

The  $x_a^v$  and  $z_u^v$  variables, and constraints (O1)–(O5) are from the LP for rooted orienteering (and also present in LP (KO-LP) for KnapOrient). They encode the arcs included, and vertices visited, respectively by the rooted path, provided that  $v$  is the furthest node from  $\rho$  that is visited. Constraints (O1)–(O5) are valid because any rooted path  $Q$ , corresponding to an execution of an adaptive policy, satisfies these constraints, where the superscript  $v$  in the non-zero variables is the furthest node from  $\rho$  on  $Q$ .

The  $z_{u,t}$  and  $s_{u,t}$  variables, constraints (CK1)–(CK3), and the objective function are from the LP in [18] for correlated knapsack with cancellations. For any vertex  $u$  and  $t \geq 0$ , variable  $z_t^u$  encodes that  $u$  is processed for a least  $t$  time units, and  $s_{u,t}$  encodes that  $u$  is processed for *exactly*  $t$  time units. Thus, variable  $z_{u,0}$  encodes that  $u$  is visited, and constraint (4) links the orienteering and correlated knapsack LPs. Gupta et al. [18] show (see Theorem 3.1 in [18]) that constraints (CK1)–(CK3) are valid for correlated knapsack with cancellations, and that the objective function provides an upper bound on the expected reward obtained.

We remark that [18] showed that one can replace (CK1)–(CK3) with a polynomial-size formulation losing an  $O(1)$ -factor, which applies here as well.

We round an optimal solution  $(\bar{x}, \bar{z}, \bar{s})$  to (CKOC-LP) in two phases. We first *extract a suitable knapsack orienteering instance from the LP solution*, and use Theorem 2.3 to obtain a good rooted path  $Q$  for this KnapOrient instance. Now, we select a subsequence of  $Q$  to visit by solving a correlated knapsack with cancellations problem involving only vertices in  $Q$ . The KnapOrient-instance is set up so that from  $(\bar{x}, \bar{z}, \bar{s})$ , one can extract a good LP solution to the

correlated knapsack problem restricted to vertices in  $Q$ . We utilize the LP-rounding result in [18] to round this solution to obtain a CorrKO-Cancel solution that visits the vertices in  $Q$  in order, potentially cancelling some vertices along the way. Thus, we obtain a non-adaptive policy for CorrKO-Cancel. In the second phase, we crucially leverage an important aspect of the LP-rounding algorithm in [18] for correlated knapsack with cancellations, namely that it is *order oblivious*: its guarantee does not depend on the order in which the vertices (i.e., items in correlated knapsack) are considered. This flexibility allows us to consider vertices in  $Q$  in the order they are visited, and thereby ensure that the travel-budget constraint is satisfied. (We remark that for the correlated knapsack without cancellations, we do not have this flexibility, when considering large instantiations; see Appendix A. This lack of flexibility is the main obstacle in obtaining a good solution from large instantiations in CorrKO.)

## 7 $O(\log \log B)$ -approximation for CorrO

Our approach in Section 4 for CorrKO can be utilized to yield the guarantees mentioned in Theorem 1.3: that is, an  $O(\alpha \log \log B)$ -approximation algorithm for CorrO in time  $(n + \log B)^{O(\log B \log \log B)} \cdot T$ , where  $T$  is the running time of the given  $\alpha$ -approximation algorithm for deadline TSP. The algorithm in [15] for deadline TSP translates to an  $O(1)$ -approximation in  $n^{O(\log B)}$  time, so this implies an  $O(\log \log B)$ -approximation for CorrO in quasi-polytime. We also simplify the exposition significantly by making use of monotone-reward TSP [15] as a subroutine.

Let  $K = 3 \log(6 \log B) + 12$ ,  $L = \lceil \log B \rceil$ ,  $N_1 = 2(K + 1)$ . Define  $\varphi_{-1} := \rho$ , and  $\pi_v(t) := \mathbb{E}[R_v \cdot \mathbb{1}_{S_v \leq B-t}] = \sum_{t'=0}^{B-t} \Pr[S_v = t'] \cdot \mathbb{E}[R_v | S_v = t']$ . Let  $OPT^{\text{CorrO}}$  denote the optimal reward for the CorrO instance. We may assume that  $\pi_v(d_{\rho,v}) \leq OPT^{\text{CorrO}}/4$  for every  $v \in V$ , as otherwise, we can obtain  $\Omega(OPT^{\text{CorrO}})$  reward by going to a single node. The algorithm in [2] is based on the following structural result, which we have paraphrased (and corrected slightly) to conform to our notation.

► **Lemma 7.1** (Lemma 3.6 in [2]). *There exists a rooted path  $P$  with  $d(P) \leq B$ , and vertices  $\varphi_0 \preceq \varphi_1 \preceq \dots \preceq \varphi_k$  on  $P$  for some  $k \leq L$ , such that:*

- (a)  $\sum_{j=0}^k \sum_{v \in P_{\varphi_{j-1}, \varphi_j - \varphi_j}} \pi_v(d(P_{\rho,v} + 2^j - 1)) \geq OPT^{\text{CorrO}}/4$ ; and
- (b)  $\mu^j(P_{\rho, \varphi_j} - \varphi_j) \leq (K + 1)2^j$  for all  $j \in \llbracket k \rrbracket$ .

We refine this by subdividing each  $P_{\varphi_{j-1}, \varphi_j}$  subpath into at most  $2(K + 1)$  segments each of  $\mu^j$ -weight at most  $2^j$ , and by guessing the two-point regrets of these segments, to obtain a structural result analogous to Theorem 4.2.

► **Theorem 7.2** (Structural result for CorrO). *Let the rooted path  $P$  and node-sequence  $\varphi_0, \dots, \varphi_k$ , where  $k \leq L$ , be as in Lemma 7.1. For each  $j \in \llbracket k \rrbracket$ , there is a vertex-set  $\text{Por}_j \subseteq P_{\varphi_{j-1}, \varphi_j}$  containing  $\varphi_{j-1}, \varphi_j$ , with  $|\text{Por}_j| \leq N_1$ , whose nodes are ordered by the order they appear on  $P$ , and for every node  $a \in (\bigcup_{j=0}^k \text{Por}_j) - \varphi_k$ , there is a path  $\overline{Q}^a$ , node  $m_a$ , integer  $\gamma_a \geq 0$ , satisfying the following properties. For  $a, b \in \text{Por} := \bigcup_{j=0}^k \text{Por}_j$ , let  $\text{next}(a)$  be the next node in  $\text{Por}$  after  $a$ , for  $a \neq \varphi_k$ ; let  $b \prec a$  if  $b$  comes before  $a$  in  $\text{Por}$ .*

- (C1) (Distance)  $d(\overline{Q}^a) \leq D_a := 2^{\gamma_a} - 1 + d(a, m_a) + d(m_a, \text{next}(a))$  for every  $a \in \text{Por} - \varphi_k$ .
- (C2) (Total-length)  $\sum_{a \in \text{Por} - \varphi_k} D_a \leq B$ .
- (C3) (Reward)  $\sum_{j=0}^K \sum_{a \in \text{Por}_j - \varphi_j} \sum_{v \in \overline{Q}^a - \text{next}(a)} \pi_v(\sum_{b \prec a} D_b + d(\overline{Q}_{a,v}^a) + 2^j - 1) \geq OPT^{\text{CorrO}}/8$ .
- (C4) (Prefix-size)  $\sum_{h=0}^j \sum_{a \in \text{Por}_h - \varphi_h} \mu^j(\overline{Q}^a - \text{next}(a)) \leq (K + 1)2^j$  for all  $j \in \llbracket k \rrbracket$ .
- (C5) (Size)  $\mu^j(\overline{Q}^a - \text{next}(a)) \leq 2^j$  for every  $j \in \llbracket k \rrbracket$  and every  $a \in \text{Por}_j - \varphi_j$ .

We now exploit this structural result in much the same way as in Section 4.1 by setting up a configuration LP to find the  $\overline{Q}^a$ -paths. Note that only the (Reward) property C3 is different from the (Reward) property in Theorem 4.2 for CorrKO, and correspondingly, we now exploit monotone-reward TSP to capture the reward of an  $\overline{Q}^a$  path. Assume that we have found the “portal nodes”  $\text{Por}$  and length bounds  $D_a$  for all  $a \in \text{Por} - \varphi_k$  satisfying Theorem 7.2. To capture the reward obtained from an  $a$ -next( $a$ ) path, the configurations  $\mathcal{I}_a$  for a node  $a \in \text{Por} - \varphi_k$  will now consist of feasible solutions to P2P *knapsack monotone-reward TSP*, which is the knapsack-constrained version of P2P-monotone-reward TSP: they are simply all  $a$ -next( $a$ ) paths  $\tau$  with  $\mu^j(\tau - \text{next}(a)) \leq 2^j$ . The length budget  $D_a$  will be captured implicitly, by defining the reward function of a node  $v \neq \text{next}(a)$  to be  $\pi_v(\sum_{b \prec a} D_b + d(\tau_{a,v}) + 2^j - 1)$  if  $d(\tau_{a,v}) \leq D_a - d(v, \text{next}(a))$  and 0 otherwise, which is a non-increasing function of  $d(\tau_{a,v})$ ; for  $v = \text{next}(a)$ , the reward function is defined to be identically 0. For notational convenience, define  $\pi^{a,j}(\tau)$  to be the total reward obtained from nodes in  $\tau$  under the above rewards.

The configuration LP for CorrO now has the same constraints as (CKO-P), but the objective function changes to  $\max \sum_{j=0}^k \sum_{a \in \text{Por}_j - \varphi_j} \sum_{\tau \in \mathcal{I}_a} x_\tau^a \cdot \pi^{a,j}(\tau)$ . Let (CO-P) denote this LP, and  $OPT_{\text{CO-P}}$  denote its optimal value.

We now have  $OPT_{\text{CO-P}} \geq OPT^{\text{CorrO}}/8$ , and one can argue that an  $\alpha$ -approximation algorithm for deadline TSP (and hence, monotone-reward TSP [15]) can be used to obtain a (CO-P)-solution  $\bar{x}$  of value at least  $OPT_{\text{CO-P}}/O(\alpha)$ . The LP-rounding algorithm and conversion to a non-adaptive policy are *exactly* as in Algorithm CSKO-Alg. The analysis is similar, but we now analyze the reward on a path-by-path basis, considering the reward obtained from paths  $\tau \in \mathcal{I}_a$ , for each  $a \in \text{Por} - \varphi_k$ . We can again argue that step 2 succeeds with high probability, and moreover that the expected reward obtained is large conditioned on this. Hence, we obtain an  $O(K)$  approximation.

---

## **A** Adversarial orderings can be arbitrarily bad for correlated knapsack

Consider an instance of correlated stochastic knapsack on the set of items  $[n]$  with budget  $W > 2^{n+1}$ . Let  $S_i$  and  $R_i$  denote respectively the random size and random reward of  $i$ , which follows the following distribution.

$$(S_i, R_i) = \begin{cases} (S_i^{(1)} := W - 2^{n-i} + 1, R_i^{(1)} := 1) & \text{with probability } \frac{1}{n} \\ (S_i^{(2)} := 2^{n-i}, R_i^{(2)} := 0) & \text{with probability } 1 - \frac{1}{n}. \end{cases}$$

At most one item can obtain positive reward since  $W/2 < W - 2^{n-i+1} + 1$  for all  $i \in [n]$ .

## 29:24 Approximation Algorithms for Correlated Knapsack Orienteering

Suppose that we are forced to process the items in the ordering  $1, \dots, n$  deciding at each step whether we attempt to insert the current item into the knapsack or abandon it forever. Let  $j$  be the first item that we choose to insert into the knapsack. It instantiates to size  $2^{n-j}$  with probability  $1 - 1/n$ . If this happens we get zero total reward: the residual budget becomes  $W - 2^{n-j}$ , which is less than the  $S_i^{(1)}$ -sizes of items  $j + 1, \dots, n$  (which yield positive reward). Therefore, by processing the items in this ordering the expected reward is at most  $1/n$ . But suppose we process the items in the reverse order  $n, \dots, 1$ . If we attempt to insert items  $n, n - 1, \dots, j$  and get zero reward from all of them, the residual budget is  $W - \sum_{k=j}^n 2^{n-k} = W - 2^{n-j+1} + 1 > S_{j-1}^{(1)}$ , which means that item  $j - 1$  can be inserted and would yield reward 1 with probability  $\frac{1}{n}$ . Thus, the probability that no item gives positive reward is  $(1 - 1/n)^n \leq e^{-1}$  and the expected reward we obtain in this case is at least  $(1 - e^{-1})$ . This is  $\Omega(n)$  times larger than the expected reward that can be obtained by any policy that is forced to process items in the order  $1, \dots, n$ .

## Abstract

Consider the **Hitting Set** problem where, for a given universe  $\mathcal{X} = \{1, \dots, n\}$  and a collection of subsets  $\mathcal{S}_1, \dots, \mathcal{S}_m$ , one seeks to identify the smallest subset of  $\mathcal{X}$  which has a nonempty intersection with every element in the collection. We study a probabilistic formulation of this problem, where the underlying subsets are formed by including each element of the universe independently with probability  $p$ . We rigorously analyze integrality gaps between linear programming and integer programming solutions to the problem. In particular, we prove the absence of an integrality gap in the sparse regime  $mp \lesssim \log n$  and the presence of a non-vanishing integrality gap in the dense regime  $mp \gg \log n$ . Moreover, for large enough values of  $n$ , we look at the performance of Lovász's celebrated **Greedy** algorithm [12] with respect to the chosen input distribution, and prove that it finds optimal solutions up to multiplicative constants. This highlights separation of **Greedy** performance between average-case and worst-case settings.

## 1 Introduction

**Hitting Set** is a classical problem in combinatorial optimization which, for a given ground set  $\mathcal{X} := \{1, \dots, n\}$  of elements and a collection  $\mathcal{C} := \{\mathcal{S}_1, \dots, \mathcal{S}_m\}$  of subsets of  $\mathcal{X}$ , asks to identify the smallest set  $\mathcal{S} \subseteq \mathcal{X}$  that intersects every subset in  $\mathcal{C}$ . **Hitting Set** arises naturally from the study of *Minimum Vertex Covers on Hypergraphs* (MVCH), upon viewing hyperedges as subsets and vertices as elements of the ground set. This is also known as the *Set Cover* problem [14], which has a rich history in worst-case computational complexity theory, including appearing as one of Karp's 21 NP-complete problems. An important question regards the behaviour of natural random instances of **Hitting Set** where each element of the ground set is independently assigned to any subset with probability  $p$ , motivated, among others, by applications such as group testing [10]. A classical theorem of Lovász [12] gives

an upper bound on the integrality gap in this problem which grows with the degree of the underlying hypergraph, i.e., the maximum number of subsets intersecting any one element. This bound was shown to be tight in the worst-case, but leaves much to be desired from an average-case perspective.

In this paper, we characterize the average-case integrality gap present in random **Hitting Set** and prove that, with high probability, Lovász's greedy algorithm [12] finds the minimal hitting set in polynomial time. Namely, we consider the following integer programming (IP) formulation of the problem,

$$\text{val}_{\text{IP}} := \begin{cases} \text{minimize} & \|\mathbf{x}\|_1 \\ \text{subject to} & \mathbf{Ax} \geq \mathbf{1}, \mathbf{x} \in \{0, 1\}^n, \end{cases} \quad (1.1)$$

where the  $i$ -th row of  $\mathbf{A} \in \{0, 1\}^{m \times n}$  provides a binary encoding of the membership of the elements of  $\mathcal{X}$  in the set  $\mathcal{S}_i$  and  $\mathbf{1} := (1, \dots, 1) \in \mathbb{R}^m$ . With the vertex cover formulation of the problem at hand, we note that  $\mathbf{A}$  consists of the incidence matrix of the underlying hypergraph. In particular, the constraint  $\mathbf{Ax} \geq \mathbf{1}$  ensures that each set in  $\mathcal{C}$  is hit by a prescribed candidate solution vector. A natural convex relaxation is obtained by allowing fractional solutions, and may be expressed as the following linear program (LP),

$$\text{val}_{\text{LP}} := \begin{cases} \text{minimize} & \|\mathbf{x}\|_1 \\ \text{subject to} & \mathbf{Ax} \geq \mathbf{1}, \mathbf{x} \in [0, 1]^n. \end{cases} \quad (1.2)$$

Whilst clearly  $\text{val}_{\text{LP}} \leq \text{val}_{\text{IP}}$ , tightness need not hold in general. In fact, for  $m = n$  and  $\mathbf{A} \in \{0, 1\}^{n \times n}$  chosen such that each row and column contains exactly  $k$  ones, for some fixed  $1 < k < n$ , an optimal solution is provided by  $\mathbf{x}_{\text{LP}}^* = (1/k, \dots, 1/k)$ , which is not integral, thus leading to a strictly smaller objective whenever  $n/k$  is not an integer. This evidences the existence of a multiplicative *integrality gap*, as we define next.

► **Definition 1.** *Given solutions  $\text{val}_{\text{IP}}$  and  $\text{val}_{\text{LP}}$  to Equation (1.1) and Equation (1.2) respectively, we define multiplicative integrality gap as follows:*

$$\text{IPGAP} := \frac{\text{val}_{\text{IP}}}{\text{val}_{\text{LP}}}. \quad (1.3)$$

In [12], Lovász proved an essentially optimal worst-case upper bound on the **Hitting Set** multiplicative integrality gap:  $\text{IPGAP} \leq 1 + \log d_{\max}$ , where  $d_{\max}$  corresponds to the maximum degree in the underlying hypergraph. This is obtained by analysing the **Greedy** algorithm (Algorithm 1), which constructs a vertex cover by sequentially adding vertices with the highest degree amongst the uncovered edges, and will be discussed in more detail in the next sections. However, in many natural examples, the maximum degree  $d_{\max}$  grows with the number of vertices in the hypergraph, thus leading to progressively worse bounds for increasingly large hypergraphs. Besides being arguably the most natural candidate for solving **Hitting Set**, the greedy algorithm has been shown to be the best possible polynomial time approximation algorithm [15] for the worst-case instances of this classical problem.

Despite extensive work conducted on **Hitting Set** in the last decades, a gap remains in our understanding of the typical performance of linear programming and the greedy algorithm on random problem instances. We hence pose the following questions:

1. Are there integrality gaps in random instances of **Hitting Set**?
2. Can near-optimal solutions be found efficiently?

In the present work, we provide answers to the above questions *with high probability* (w.h.p.) in a non-asymptotic sense, in the setting where the cardinality  $n$  of the ground set  $\mathcal{X}$  is large but finite. We will prove the absence of integrality gaps up to constants in a wide regime of  $n, m, p$ , by conducting an average case analysis of an algorithm that outputs integral covers of matching size to the fractional ones. In addition, a rigorous analysis of the greedy routine will follow by a straightforward reduction. The forthcoming results are valid under the conditions listed below, which will be assumed to hold throughout.

► **Assumption 2.** *We assume that*

1. *Each element  $j \in \mathcal{X}$  is assigned to any subset  $\mathcal{S}_i$ ,  $i \in [m]$  with probability  $p \equiv p(n)$ , independently. That is,  $\mathbf{A} \in \{0, 1\}^{m \times n}$  is such that  $A_{ij} \stackrel{iid}{\sim} \text{Bernoulli}(p)$ ;*
2.  *$n$  is intended to be large but finite;*
3.  *$m \equiv m(n) = \text{poly}(n)$ , i.e.  $\exists c, C > 0$ , such that  $cn^c \leq m \leq Cn^C$  for  $n$  large enough;*
4. *There exist  $\delta \in (0, 1)$ , such that  $p \equiv p(n)$  satisfies  $1/n^\delta \leq p \leq 1/2$ , for all  $n$  large enough.*

Note that in Assumption 2.3, the upper bound is chosen to avoid trivial solutions w.h.p. which arise, for example, in the setting where the number of sets grows exponentially in the cardinality of  $\mathcal{X}$ . In addition, Assumption 2.4 is by no means restrictive, since one can show that for  $m = \text{poly}(n)$  and  $np \ll \log n$ , we have that  $\mathbf{A}$  contains an all-zero row w.h.p., yielding an infeasible solution for IP. The requirement  $p \leq 1/2$  is chosen for technical convenience and can be relaxed to any constant  $p$ , encompassing the regime in [10].

Our contributions stem from the study of the size of the inclusion sets  $I_j := \{i \in [m] : j \in \mathcal{S}_i\}$ , for  $j \in [n]$ , which in the MVCH formulation of the problem at hand correspond to the set of hyperedges incident to any given vertex. The key quantity under study is the average inclusion set size, that is  $\mathbb{E}|I_j| = mp$ , for all  $j$ , under the present distributional assumptions. This quantity exhibits two separate regimes of interest, referred to as the *sparse*,  $mp \ll \log n$ , and *dense*,  $mp \gg \log n$ , regimes. These, in turn, determine the size of the maximum inclusion set, or maximum degree,  $d_{\max} := \max_{j \in [n]} |I_j|$ . We characterize the integrality gap behaviour up to multiplicative constants and analyse Lovász's Greedy algorithm [12] in these two regimes w.h.p as  $n \rightarrow \infty$ . We do this by proving the success of a simple greedy heuristic, the BlockGreedy algorithm (Algorithm 2). Throughout, we use the notation  $\text{val}_{\text{Gr}}$ ,  $\text{val}_{\text{BGr}}$  to denote the size of the hitting set returned by Greedy and BlockGreedy respectively. Below we provide an informal description of the main results which hold with high probability, where  $A(n) \sim B(n)$  denotes that  $cA(n) \leq B(n) \leq CA(n)$  for large enough  $n$  and for some constants  $c, C > 0$ :

### Sparse Regime ( $mp \ll \log n$ )

We show that  $\text{IPGAP} \sim 1$  in the sparse regime by proving that the BlockGreedy algorithm succeeds in reaching the LP lower bound of  $\frac{m}{d_{\max}}$ .

$$\text{val}_{\text{BGr}} \sim \text{val}_{\text{IP}} \sim \text{val}_{\text{LP}} \sim \frac{m}{d_{\max}}.$$

### Dense Regime ( $mp \gg \log n$ )

We prove that  $\text{IPGAP} \sim \log \frac{mp}{\log n}$  in the dense regime. We show that the BlockGreedy algorithm performs as well as IP in this regime, i.e.

$$\frac{1}{p} \log \left( \frac{mp}{\log n} \right) \sim \text{val}_{\text{BGr}} \sim \text{val}_{\text{IP}} \gg \text{val}_{\text{LP}} \sim \frac{1}{p} \sim \frac{m}{d_{\max}}.$$

■ **Figure 1** Transition between the sparse and the dense regime for different values of the average inclusion set size  $mp$ .

### Threshold Regime ( $mp \sim \log n$ )

This regime smoothly interpolates between the sparse and dense ones, with  $\text{IPGAP} \sim 1$ . The scaling for all quantities of interest is  $m/d_{\max} \sim 1/p$ .

### Greedy

We prove that  $\text{val}_{\text{Gr}} \sim \text{val}_{\text{IP}}$  when  $\delta < 1/2$ , where  $\delta$  is the parameter from Assumption 2.4.

The results above are also depicted in Figure 1, and the formal statements are given in Corollary 9 and Theorem 10. The rest of the paper is organized as follows. In Section 2, we present relevant notation. In Section 3, we outline and discuss related literature. In Section 4, we prove a number of preliminary results that will be instrumental in developing the core arguments. Subsequently, in Section 5, we delve into the algorithmic aspects of the problem at hand by first providing guarantees for a simple algorithm, **BlockGreedy**. We then analyse **Greedy** by means of a reduction. We conclude in Section 6 by summarizing the results and offering indications for future work. We defer the proofs of more technical results to the appendix, in order to streamline the presentation for the reader's convenience.

## 2 Notation and conventions

For integers  $k \in \mathbb{N}$ , we write  $[k] := \{1, \dots, k\}$ . We denote vectors, matrices by bold-faced Roman letters  $\mathbf{x}, \mathbf{A} \in \mathbb{R}^k, \mathbb{R}^{k \times k}$ , respectively, for some  $k \in \mathbb{N}$ . Define the *inclusion set* of an element, or node,  $j \in [n]$  as  $I_j = \{i \in [m] : j \in \mathcal{S}_i\}$ . We denote the  $\ell_1$  norm of the  $j$ -th column of  $\mathbf{A}$  by  $X_j$ ,  $j \in [n]$ , noting that  $X_j = |I_j|$  and  $X_1, \dots, X_n \stackrel{\text{iid}}{\sim} \text{Binomial}(m, p)$ . In addition, we let  $d_{\max} \equiv d_{\max}(X_1, \dots, X_n) := \max_{i \in [n]} X_i$ . We use  $\mathbb{E}, \text{Var}$  to denote expectation and variance, respectively. By  $\lesssim, \gtrsim$  we denote inequalities up to multiplicative constants. We let  $A \sim B$  denote that  $A \lesssim B \lesssim A$  for large enough  $n$ . We let  $\log$  denote the natural logarithm. For possibly random functions  $f(n), g(n)$ , we let  $\{f \lesssim g\}$  denote a sequence of

events  $\{f(n) \leq Ag(n)\}$  for some constant  $A > 0$  independent of  $n$ . Consequently,  $\mathbb{P}(f \lesssim g)$  is viewed as a function of  $n$ . For deterministic functions  $h(n), w(n)$ , we let  $h \ll w, h \gg w$  denote that  $h/w \rightarrow 0, w/h \rightarrow 0$  respectively, as  $n \rightarrow \infty$ . The notation for other inequalities is defined analogously. We say that a sequence of events  $\{A_n\}$  holds *with high probability* (w.h.p.) with respect to a probability measure  $\mathbb{P}$  if there exists a constant  $c > 0$ , independent of  $n$ , such that  $\mathbb{P}(A_n) \geq 1 - n^{-c}$ , for large enough values of  $n$ .

### 3 Related Work

#### Worst-case analysis of Greedy

Perhaps the most well-known algorithm for solving **Hitting Set**, or equivalently **MVCH**, is the greedy algorithm of Lovász [12], with runtime complexity  $O(mn^2)$ . This algorithm, which constructs a cover by sequentially adding elements of the ground set which hit the largest number of remaining subsets, was initially studied by Lovász [12] and Johnson [11] independently, for deterministic hypergraphs. Lovász analyses the greedy algorithm to obtain an upper bound on the **Hitting Set** integrality gap of  $1 + \log d_{\max}$ . Slavik [15] developed the tightest known approximation lower bound for **Greedy**, constructing an instance where **Greedy** finds coverings at least  $\log m$  times as large as the minimum one. Importantly, Feige [6] proved that an approximation ratio of  $(1 - \epsilon) \log m$  is not achievable in polynomial time for any  $\epsilon > 0$  unless  $NP \subset TIME[n^{O(\log \log n)}]$ , certifying **Greedy** as the best possible polynomial-time approximation algorithm for set cover in the worst-case.

#### Random Hitting Set

Little is known about the typical performance of polynomial-time algorithms on random instances of **Hitting Set**. Closing this gap is important from a theoretical standpoint and for applications in combinatorial inference. A prime example of this is found in *group testing*, a classical inference problem where one aims to identify a small subset of defective items within a large population by conducting the smallest number of pooled tests, with applications ranging from the analysis of communication protocols [8] to DNA sequencing [5] and search problems [4]. In [10], Iliopoulos and Zadik consider the smallest hitting set as an estimator in the setting of the group testing problem, referring to it as the *Smallest Satisfying Set* estimator. In particular, they provide extensive empirical evidence supporting the claim that the class of instances of the random hitting set problem induced by non-adaptive group testing is tractably solvable by computers.

#### Insights from Statistical Physics

The analysis of a random instance of **Hitting Set** appears in the work of Mézard and Tarzia and relies on nonrigorous techniques from statistical physics [13]. This work considers regular uniform hypergraphs, where the degree of vertices and the size of edges are fixed and assumed to be constant. Depending on these values, they evidence sharp transitions between three different phases, the so-called replica symmetry, 1-replica symmetry breaking, and full replica symmetry breaking phases, which characterize the complexity of the optimization landscape for this problem in the average case setting.

### Fixed $p$ regime

Another instance was studied by Telelis and Zissimopoulos [16] in the setting of random Bernoulli hypergraphs, where elements belong to subsets independently with *fixed* probability  $p \in (0, 1)$ . Their analysis concerns the asymptotic regime where the size  $n$  of the ground set scales to infinity. In this setting, they study the average-case performance of a simple deterministic algorithm which approximates random **Hitting Set** within an *additive* error term at most  $o(\log m)$  almost everywhere. This gives an improvement over Lovász's argument in [12] which provides a multiplicative bound. However, the analysis in [16] does not capture the case of sparse hypergraphs, i.e., when  $p \rightarrow 0$  as  $n \rightarrow \infty$ . The analysis in [16] also does not prove guarantees for the **Greedy** algorithm in the chosen parameter regime.

### Related problem formulations

We bring to the reader's attention a more recent line of work [2, 3], where the authors obtain bounds on (additive) integrality gaps between the value of a random integer program  $\max \mathbf{c}^T \mathbf{x}, \mathbf{A}\mathbf{x} \leq \mathbf{b}, \mathbf{x} \in \{0, 1\}^n$  with  $m$  constraints and that of its linear programming relaxation for a wide range of distributions on  $(\mathbf{A}, \mathbf{b}, \mathbf{c})$ , holding w.h.p. as  $n \rightarrow \infty$ . These include the case where the entries of  $\mathbf{A}$  are uniformly distributed on an integer interval consisting of at least three elements and where the columns of  $\mathbf{A}$  are distributed according to an isotropic logconcave distribution. However, these fail to capture the setting where  $\mathbf{A}$  is sparse with entries in  $\{0, 1\}$ , which is of interest for **Hitting Set**.

## 4 Preliminary Bounds

In this section, we outline preliminary bounds on  $\text{val}_{\text{LP}}, \text{val}_{\text{IP}}, d_{\text{max}}$  which will prove crucial to analysing IPGAP and **Greedy**. We begin by characterizing the value of the linear program:

► **Lemma 3.** *There exists  $c > 0$ , independent of  $n$ , such that with probability at least  $1 - \exp(-cn^{1-\delta})$ , we have that*

$$\frac{m}{d_{\text{max}}} \leq \text{val}_{\text{LP}} \lesssim \frac{1}{p}.$$

The proof is included in Appendix A, and follows from a maximum argument and a standard Chernoff bound. We note that the proof also implies  $\mathbb{P}(\text{IP is feasible}) \geq 1 - \exp(-cn^{1-\delta})$ . Although Lemma 3 readily yields  $\text{val}_{\text{IP}} \geq m/d_{\text{max}}$ , we highlight that this lower bound is not tight whenever  $mp \gg \log n$ . Indeed, we apply the first moment method to obtain a tighter lower bound on  $\text{val}_{\text{IP}}$  in this regime:

► **Lemma 4.** *Let  $mp \gg \log n$ . For any  $D \geq 1$  and  $n$  large enough, with probability at least  $1 - n^{-D}$  we have that*

$$\frac{1}{p} \log \left( \frac{mp}{\log n} \right) \lesssim \text{val}_{\text{IP}}$$

The proof of Lemma 4 is provided in Appendix A. Lemmas 3 and 4 come short of providing a full characterization of IPGAP, namely lacking an upper bound on  $\text{val}_{\text{IP}}$ . In this light, we turn our attention to the **Greedy** algorithm, and utilize it to construct a feasible integral solution and hence an upper bound on the value of IP. The analysis of **Greedy** crucially relies on characterizing the maximum inclusion set size,  $d_{\text{max}} := \max_{j \in [m]} |I_j|$ . The following lemma offers such a characterization in expectation, and evidences a key difference between the sparse and dense regimes of our problem:

---

**Algorithm 1** Greedy.

---

```

1:  $\mathcal{I} \leftarrow \{I_1, \dots, I_n\}$  ▷ Inclusion sets
2:  $U \leftarrow [m]$ 
3:  $t \leftarrow 0$ 
4: while  $|U| > 0$  do
5:    $P \leftarrow \operatorname{argmax}_{I \in \mathcal{I}} |I \cap U|$  ▷ Greedy step
6:    $\mathcal{I} \leftarrow \mathcal{I} \setminus \{P\}$ 
7:    $U \leftarrow U \setminus P$ 
8:    $t \leftarrow t + 1$ 
9:  $\operatorname{val}_{\text{Gr}} \leftarrow t$ 
10: return  $\operatorname{val}_{\text{Gr}}$ .
```

---

► **Lemma 5** (Maximum of Binomials). *Let  $X_1, \dots, X_n \stackrel{\text{iid}}{\sim} \text{Bin}(m, p)$ . Under the conditions in Assumption 2, it holds that*

$$\mathbb{E}d_{\max} = \mathbb{E} \max_{i \in [n]} X_i \sim \begin{cases} \frac{\log n}{\log(\log n / mp)} & , \text{ if } mp \ll \log n, \\ mp & , \text{ if } mp \gtrsim \log n. \end{cases}$$

The proof of Lemma 5 is provided in Appendix A, and involves a straight forward application of Markov's and Jensen's inequalities. Lemma 5 indicates a sharp transition between two regimes: the sparse regime  $mp \ll \log n$ , where binomial random variables are known to be well approximated by Poisson random variables, and the dense regime  $mp \gg \log n$ , where binomial random variables are known to be well approximated by Gaussian random variables. Importantly, in the sparse (Poisson-like) regime, the expected maximum of binomial random variables exceeds their individual expectations:  $\mathbb{E}X_1 \ll \mathbb{E}d_{\max}$ . Meanwhile in the dense (Gaussian-like) regime, the expected maximum and individual expectations are asymptotically equivalent up to multiplicative constants:  $\mathbb{E}X_1 \sim \mathbb{E}d_{\max}$ . This fine-grained characterization of the maxima of binomial random variables will prove essential to analysing the behaviour of **BlockGreedy** in Section 5. Finally, we characterize the asymptotic behaviour of  $d_{\max}$  and prove that  $d_{\max} \lesssim \mathbb{E}d_{\max}$  with high probability. Whilst this one sided result suffices for the forthcoming analysis, we expect a matching lower bound to hold as well. Additional insights into the concentration of  $d_{\max}$  may be found in Lemmas 19, 20, in Appendix A.

► **Lemma 6.** *Let  $X_1, \dots, X_n \stackrel{\text{iid}}{\sim} \text{Bin}(m, p)$ . Then, there exist constants  $c, \tilde{c} > 0$ , independent of  $n$ , such that*

$$\mathbb{P} \left( \max_{i \in [n]} X_i \geq c \cdot \mathbb{E} \max_{i \in [n]} X_i \right) \leq \frac{1}{n^{\tilde{c}}}.$$

The proof of Lemma 6 is provided in Appendix A.

## 5 Algorithmic solutions

### 5.1 Challenges of Greedy analysis

The aim of the present section is to conduct a rigorous analysis of the standard **Greedy** algorithm for the **Hitting Set** problem, within the prescribed Bernoulli random setting. In particular, we show that this routine succeeds at constructing hitting sets of optimal size w.h.p., as in the results of Section 4, up to multiplicative constants. This is done by first analysing a variation of the greedy heuristic, and subsequently proceeding by a reduction argument.

---

**Algorithm 2** BlockGreedy.
 

---

```

1: Let  $\mathcal{B}_t \subset \{I_1, \dots, I_n\}$  denote the  $t$ -th block, i.e. inclusion sets that become available at
   step  $t$ .
2:  $\mathcal{I} \leftarrow \emptyset$ 
3:  $U \leftarrow [m]$ 
4:  $t \leftarrow 0$ 
5: while  $|U| > 0$  and  $\mathcal{B}_t \neq \emptyset$  do
6:    $\mathcal{I} \leftarrow \mathcal{I} \cup \mathcal{B}_t$  ▷ Adding elements from the new block
7:    $P \leftarrow \operatorname{argmax}_{I \in \mathcal{I}} |I \cap U|$  ▷ Greedy step
8:    $\mathcal{I} \leftarrow \mathcal{I} \setminus \{P\}$ 
9:    $U \leftarrow U \setminus P$ 
10:   $t \leftarrow t + 1$ 
11:  $\text{val}_{\text{BGr}} \leftarrow t$ 
12: if  $|U| > 0$  then cover the rest of  $U$  with a trivial algorithm,  $\text{val}_{\text{BGr}} \leftarrow \text{val}_{\text{BGr}} + |U|$ 
13: return  $\text{val}_{\text{BGr}}$ .

```

---

The core principle of **Greedy** is to construct a feasible solution in steps, by sequentially adding to the candidate solution an element which hits the largest number of remaining sets. In the chosen setting, where elements are added to sets with equal probability and independently of each other, we have precise estimates on the number of subsets hit by an element which is *picked first*. In fact, the size of this set is given by the maximum of independent Binomial random variables, which was analysed in Section 4. However, this very first step introduces nontrivial dependencies amongst the remaining matrix columns and significantly complicates keeping track of the marginal gains of each subsequent element addition to the candidate solution.

## 5.2 BlockGreedy algorithm

In order to circumvent this issue, we introduce a modified greedy routine, which we refer to as the **BlockGreedy** algorithm, where the elements of the ground set  $[n]$  are split into separate sets of a given size, which we call blocks. At the  $t$ -th iteration, the algorithm picks the element hitting the largest number of remaining sets across *the first  $t$  blocks only*. By choosing the size of the blocks appropriately, we have that at each iteration  $t$  one is guaranteed to find a solution of near-optimal size at least within the set of newly-included independent columns.

**BlockGreedy** is detailed in Algorithm 2, whilst informally, it works as follows.

1. Let  $K$  be the size of the solution (suggested by theoretical analysis);
2. Uniformly at random split  $n$  columns into  $K$  blocks with  $n/K$  columns per block;
3. Start with an empty set of possible choices of columns;
4. At the  $t$ -th iteration, first add the columns from the  $t$ -th block (Step 6). Then, perform one greedy step on the current set of possible choices (Step 7);
5. If after  $K$  iterations of the algorithm, some subsets remain uncovered, we use a trivial covering, i.e., covering each subset by a separate column.

Note that the first selection of the element which hits the most number of subsets again introduces dependencies. However, the columns that are in the newly added block are independent of everything else at time  $t$ . Let  $v_t$  be the element which is picked at the  $t$ -th step

of **BlockGreedy**,  $f_t$  be the number of new subsets that are hit by  $v_t^1$ , and  $F_t := \sum_{i=1}^t f_i$  be the total number of subsets which are hit after  $t$  steps. In order to analyse how many elements **BlockGreedy** has picked, we will consider the sequence  $f_1, f_2, \dots, f_s$ , with  $F_t := \sum_{i=1}^t f_i$ , such that the following holds:

1.  $F_s = m$ ;
2. if  $mp \lesssim \log n$ , then  $s \lesssim \text{val}_{\text{LP}}$ , otherwise,  $s \lesssim \text{val}_{\text{IP}}$ .

The first property ensures that **BlockGreedy** picks at most  $s$  elements, and the second property gives optimal bounds on  $s$ . One way to guarantee that **BlockGreedy** succeeds is to prove that among the choices of **BlockGreedy** at each step  $t$ , there was an element  $\tilde{v}_t$  which hits at least  $f_t$  new subsets w.h.p. We will prove that it is enough to look for  $\tilde{v}_t$  in the new block of columns  $\mathcal{B}_t$ , which are added at step  $t$ . Note that unless  $F_t = m$ , we have that  $f_t \geq 1$ , since each subset is hit by at least one element w.h.p.. Therefore, it will be enough to find a sequence  $\{f_1, f_2, \dots, f_v\}$  such that  $F_v \geq m - v$ , since it implies  $F_{2v} = m$ . This allows us to reduce the problem of proving the effectiveness of **BlockGreedy** to a key technical lemma. This lemma assumes that before step  $t$ , exactly  $F_{t-1}$  subsets are hit, and bounds from below the probability that some vertex in the new block will hit at least  $f_t$  new subsets. This boils down to computing  $\mathbb{P}(\text{Bin}(m - F_{t-1}, p) \geq f_t)$ .

► **Lemma 7** (Informal, see Lemma 26). *Let  $\varepsilon > 0$  and  $mp \lesssim \log n$ . For some constants  $\tau > 0$ ,  $1 < \alpha < \beta$ , and for  $t \in \mathbb{N}$ , let:*

$$f_t = \left\lceil (\alpha/\beta)^k \tau \mathbb{E}d_{\max} \right\rceil \quad \text{where } k \text{ is such that } \beta^{-k-1}m < m - F_{t-1} \leq \beta^{-k}m;$$

*Then there exists a choice of  $\tau, \alpha, \beta$  and  $K$ , such that  $F_K \geq m - K$  and  $K \sim \text{val}_{\text{LP}}$ . Furthermore, for this sequence  $f_t$  (which depends on  $\varepsilon$ ), for any  $t \leq K$ ,*

$$\mathbb{P}(\text{Bin}(m - F_{t-1}, p) \geq f_t) \geq n^{-\varepsilon}. \tag{5.1}$$

*Note that the implicit constants in the statements  $K \sim \text{val}_{\text{LP}}$  depend on  $\varepsilon$ .*

This lemma highlights the crucial dependency of the problem on the relationship between the average degree,  $mp$ , and  $\log n$ . For clarity of exposition, we only state the lemma for the case  $mp \lesssim \log n$  and refer to the Lemma 26 in the Appendix for the full version and corresponding proof. Here we comment on the intuition behind the proof.

When  $mp \lesssim \log n$ , we need to carefully track how the maximum degree changes. We look for an element which (i) covers a large number of subsets, i.e., close to the expected maximum number,  $\mathbb{E}d_{\max}$  and (ii) can be found with large enough probability. The second property is important for the reduction to the standard **Greedy** algorithm, whose direct analysis presents substantial difficulties, and is done later in this section. The quantity  $\mathbb{E}d_{\max}$  is sensitive to  $mp$  whenever the latter is close to  $\log n$ . Hence, we need to adjust which element we look for accordingly. This is done by setting  $f_t = \left\lceil (\alpha/\beta)^k \tau \mathbb{E}d_{\max} \right\rceil$  and increasing the parameter  $k$  as the number of remaining rows,  $m - F_t$ , decreases.

For example, consider the case  $mp = \log n$ . First, we can only pick a random element, since it will be as good (up to a multiplicative constant) as the maximal element. However, during the execution of the algorithm, the problem becomes more sparse, and if we continue to

<sup>1</sup> It may happen that  $v_t$  hits *more* than  $f_t$  new subsets. In this case, we still only count that exactly  $f_t$  are covered, and several extra sets will be covered multiple times in subsequent rounds. This overcounting simplifies the analysis and does not result in suboptimal solution.

### 30:10 Greedy Heuristics and Linear Relaxations for the Random Hitting Set Problem

pick random elements, we will construct a suboptimal solution. Therefore, we gradually increase how much the newly picked element will cover, *with respect to a random element*. This corresponds to the transition between Gaussian-like and Poisson-like behaviour of  $\text{Bin}(m - F_{t-1}, p)$ .

It is now straightforward to prove the following theorem, which makes rigorous the statements in Section 1.

► **Theorem 8.** *Under Assumption 2, we have that*

- (i) if  $mp \lesssim \log n$  then, for any  $\varepsilon > 0$  and  $n$  large enough,
- $$\mathbb{P}\left(\text{val}_{\text{BGr}} \lesssim \frac{m}{\mathbb{E}d_{\max}}\right) \geq 1 - \exp(-n^{1-\delta-\varepsilon});$$
- (ii) if  $mp \gg \log n$ , then, for any  $\varepsilon > 0$  and  $n$  large enough,
- $$\mathbb{P}\left(\text{val}_{\text{BGr}} \lesssim \frac{1}{p} \log\left(\frac{mp}{\log n}\right)\right) \geq 1 - \exp(-n^{1-\delta-\varepsilon}).$$
- (5.2)

Note that if  $mp \gtrsim n^\gamma$  for some  $\gamma > 0$ , then  $\log \frac{mp}{\log n} \sim \log n$ , and the bound in (ii) can be simplified.

**Proof.** The main idea of the proof is to analyse the distribution of the columns that are added at each step  $t$ . These columns are independent, and for each newly added column, the number of additional subsets which it covers is distributed according to  $\text{Bin}(m - F_{t-1}, p)$ , where  $F_{t-1}$  is the number of subsets which are already covered. Lemma 26 (see Lemma 7 above for an informal version) allows us to lower bound  $F_t$ , and we show now that we can do this with high probability.

Fix  $\varepsilon > 0$  and let  $\varepsilon' := \varepsilon/4$ . Let  $f_1, f_2, \dots$  be the sequence from Lemma 26 for  $\varepsilon'$  and let  $K$  be the value for which (C.1) is satisfied, i.e.  $F_K \geq m - K$ . Notice that  $K \leq C \max\left\{\frac{m}{\mathbb{E}d_{\max}}, \frac{1}{p} \log\left(\frac{mp}{\log n}\right)\right\}$  for some constant  $C > 0$ , for  $n$  large enough. We uniformly at random split  $n$  elements (columns) into  $K$  groups of size  $n/K$  each (assuming without loss of generality that  $K$  divides  $n$ , otherwise we consider groups of size  $\lfloor n/K \rfloor$ ), so that  $\mathcal{B}_t$  yields a new set of  $n/K$  elements at each iteration  $t \leq K$  and  $\mathcal{B}_t = \emptyset$  for  $t > K$ . We say that the algorithm fails at step  $t$  if before step  $t$ , at least  $F_{t-1}$  subsets are covered, but after step  $t$  less than  $F_t$  sets are covered. Using that, for  $n$  large enough, (i) columns in each newly added block are independent, (ii)  $\mathbb{P}(\text{Bin}(m - F_{t-1}, p) \geq f_t) \geq n^{-\varepsilon'}$ , and (iii)  $n/K \geq n^{1-\delta-\varepsilon'}$ , we get

$$\begin{aligned} \mathbb{P}(\text{BlockGreedy fails at step } t) &\stackrel{(i)}{\leq} (\mathbb{P}(\text{Bin}(m - F_{t-1}, p) < f_t))^{n/K} \\ &\stackrel{(ii)}{\leq} (1 - n^{-\varepsilon'})^{n/K} \\ &\stackrel{(iii)}{\leq} \exp(-n^{1-\delta-2\varepsilon'}). \end{aligned}$$

We then proceed by applying a union bound to obtain the result,

$$\begin{aligned} &\mathbb{P}(\text{BlockGreedy fails during first } K \text{ steps}) \\ &\leq \sum_{t=1}^K \mathbb{P}(\text{BlockGreedy fails at step } t) \leq K \cdot \exp(-n^{1-\delta-2\varepsilon'}) \leq \exp(-n^{1-\delta-3\varepsilon'}), \end{aligned}$$

where the second inequality holds since, by definition, the algorithm runs for  $K$  iterations, and the third one holds for  $n$  large enough. We proved that **BlockGreedy** succeeds in finding

at most  $K$  elements such that at most  $m - F_K$  sets remain uncovered. Since by construction,  $m - F_K \leq K$ , we can cover the remaining rows trivially using that IP is feasible by Lemma 16 with high probability, which proves that

$$\mathbb{P}(\text{val}_{\text{BGr}} \leq 2K) \geq 1 - \exp\left(-n^{1-\delta-4\varepsilon'}\right) = 1 - \exp\left(-n^{1-\delta-\varepsilon}\right),$$

for  $n$  large enough. Recalling that  $K \lesssim \text{val}_{\text{LP}}$  for  $mp \lesssim \log n$ , and that  $K \lesssim \text{val}_{\text{IP}}$  for  $mp \gg \log n$ , finishes the proof.  $\blacktriangleleft$

► **Corollary 9.** *Under Assumption 2, we have that for any  $D > 0$ ,*

(i) *for any  $n$  large enough,*

$$\mathbb{P}(\text{val}_{\text{BGr}} \sim \text{val}_{\text{IP}}) \geq 1 - n^{-D};$$

(ii) *if  $mp \lesssim \log n$ , then, for any  $n$  large enough,*

$$\mathbb{P}(\text{IPGAP} \sim 1) \geq 1 - n^{-D}; \tag{5.3}$$

(iii) *if  $mp \gg \log n$ , then, for any  $n$  large enough,*

$$\mathbb{P}\left(\text{IPGAP} \sim \log\left(\frac{mp}{\log n}\right)\right) \geq 1 - n^{-D}.$$

**Proof.** Proof follows from Lemma 3, Lemma 4, and Theorem 8.  $\blacktriangleleft$

### 5.3 Reduction from BlockGreedy to Greedy

With the above results at hand, we now proceed to analyse the **Greedy** algorithm by means of a suitable reduction. Recall that we denote outputs of **BlockGreedy** and **Greedy** as  $\text{val}_{\text{BGr}}$  and  $\text{val}_{\text{Gr}}$  respectively.

► **Theorem 10.** *Under Assumption 2 with  $\delta < 1/2$ , we have that, for  $n$  large enough,*

$$\mathbb{P}(\text{val}_{\text{Gr}} \sim \text{val}_{\text{IP}}) \geq 1 - \exp\left(-\sqrt{n}\right).$$

**Proof.** We use Theorem 8 with  $\varepsilon = 1/8 - \delta/4$ , and let  $K, \mathcal{B}_t$  be as defined in the proof of Theorem 8. We have that, for  $n$  large enough,

$$\mathbb{P}(\text{BlockGreedy fails at any step}) \leq \exp\left(-n^\Delta\right),$$

where  $\Delta := 3/4 - \delta/2 > 1/2$ .

Given a matrix  $\mathbf{A}$ , consider running the above definition of **BlockGreedy** for  $J := \exp(\sqrt{n})$  times, each time reshuffling the columns. In what follows, we address **BlockGreedy** and **Greedy** defined with the same tie-breaking strategy when it comes to a number of elements hitting the same number of sets, i.e., selecting the left-most column in the associated matrix  $\mathbf{A}$ . Both  $\text{val}_{\text{BGr}}$  and  $\text{val}_{\text{Gr}}$  are random variables, but conditioned on  $\mathbf{A}$ ,  $\text{val}_{\text{Gr}}$  is deterministic, while  $\text{val}_{\text{BGr}}$  still depends on the randomness of separating columns into blocks. Using the union bound, we have that

$$\begin{aligned} \mathbb{P}(\text{val}_{\text{Gr}} > 2K) &\leq \mathbb{P}(\exists \text{ a failed copy of BlockGreedy}) \\ &\quad + \mathbb{P}(\text{val}_{\text{BGr}} < \text{val}_{\text{Gr}} \text{ over all } J \text{ copies}). \end{aligned} \tag{5.4}$$

Applying the union bound again, we can upper bound the first term in (5.4):

$$\mathbb{P}(\exists \text{ a failed copy of BlockGreedy}) \leq J \exp\left(-n^\Delta\right) = \exp\left(-n^\Delta + n^{1/2}\right). \tag{5.5}$$

## 30:12 Greedy Heuristics and Linear Relaxations for the Random Hitting Set Problem

Now we focus on the second term in (5.4). Let  $v_1, v_2, \dots, v_g$  be the ordered sequence of elements picked by **Greedy**. Let  $M_t := \{v_1 \in \mathcal{B}_1, v_2 \in \mathcal{B}_1 \cup \mathcal{B}_2, \dots, v_t \in \mathcal{B}_1 \cup \dots \cup \mathcal{B}_t\}$ . The event  $\{\text{val}_{\text{BGr}} \geq \text{val}_{\text{Gr}}\}$  contains the event  $M_g$ , since in this case **BlockGreedy** will necessarily pick exactly the same columns  $v_1, v_2, \dots, v_g$ . Given that each reshuffling of the columns generates a uniform distribution of  $\mathcal{B}_i$ 's over possible partitions of  $n$  columns, we get that

$$\mathbb{P}(M_g) = \mathbb{P}(v_1 \in \mathcal{B}_1) \mathbb{P}(v_2 \in \mathcal{B}_1 \cup \mathcal{B}_2 \mid M_1) \dots \mathbb{P}(v_g \in \mathcal{B}_1 \cup \dots \cup \mathcal{B}_g \mid M_{g-1}).$$

The  $t$ -th term in the product above is equal to

$$\mathbb{P}(v_t \in \mathcal{B}_1 \cup \dots \cup \mathcal{B}_t \mid M_{t-1}) = \frac{t \frac{n}{K} - (t-1)}{n - (t-1)} \geq \frac{t}{K} - \frac{t-1}{n} \geq \frac{t}{2(K-1)},$$

where the last inequality holds for  $n \geq 4K$  (recall that  $n \gg K$ ). Since  $M_g \subset \{\text{val}_{\text{BGr}} \geq \text{val}_{\text{Gr}}\}$ , we can lower bound the probability of the latter event as follows (note that when  $g < K$  there will be less terms in the product, hence,  $\mathbb{P}(M_g)$  will be even larger),

$$\begin{aligned} \mathbb{P}(\text{val}_{\text{BGr}} \geq \text{val}_{\text{Gr}} \text{ for 1 copy}) &\geq \mathbb{P}(M_g) \\ &\geq \prod_{t=1}^{K-1} \mathbb{P}(v_t \in \mathcal{B}_1 \cup \dots \cup \mathcal{B}_t \mid M_{t-1}) \geq \prod_{t=1}^{K-1} \frac{t}{2(K-1)} \geq e^{-2K}, \end{aligned}$$

where we used that  $k! \geq (k/e)^k$  in the last inequality. Since  $K \leq C \max\left\{\frac{m}{\mathbb{E}d_{\max}}, \frac{1}{p} \log\left(\frac{mp}{\log n}\right)\right\}$  and  $1/p \leq n^\delta$ , there exists a constant  $\tilde{C} > 0$  large enough, such that  $K \leq \tilde{C} n^\delta \log n$ . Therefore, using independence of the reshuffling between the copies, we can compute

$$\begin{aligned} \mathbb{P}(\text{val}_{\text{BGr}} < \text{val}_{\text{Gr}} \text{ over all } J \text{ copies}) &= (1 - \mathbb{P}(\text{val}_{\text{BGr}} \geq \text{val}_{\text{Gr}} \text{ for 1 copy}))^J \\ &\leq (1 - e^{-2K})^J \\ &\leq \exp\left(-e^{\sqrt{n} - 2\tilde{C}n^\delta \log n}\right). \end{aligned} \tag{5.6}$$

Combining (5.4), (5.5) and (5.6), we showed that  $\mathbb{P}(\text{val}_{\text{Gr}} > 2K) \leq \exp(-\sqrt{n})$  for  $n$  large enough, which finishes the proof.  $\blacktriangleleft$

► **Remark 11.** We note that the  $\delta < 1/2$  condition in Theorem 10 is likely not optimal, and could be relaxed by reducing to **BlockGreedy** with more carefully chosen sets  $\mathcal{B}_t$ . In particular, the appropriate set sizes  $|\mathcal{B}_t|$  may not be identical across  $t \leq K$ . The analysis becomes more technical in this case, and we highlight this as an interesting open direction.

## 6 Discussion and Open Questions

Our work characterises multiplicative integrality gaps for the random hitting set problem. In this section, we discuss the intuition behind our main results, together with open questions and conjectures.

### 6.1 Summary of our results and proof techniques

We identified that the nature of integrality gaps depends on the size of the inclusion set, also viewed as the sparsity of the underlying hypergraph. In particular, when the average degree of a vertex is small, i.e., when each element belongs to a small number of subsets, we proved that there exists only a constant gap between linear and integer program solutions, together with a simple algorithmic solution. The situation changes when the hypergraph

becomes dense, where we show an increasing integrality gap. This separation stems mostly from the property of the binomial distribution, where the maximum of random variables grows identically to the expected value whenever the expected value is large, but is away from it if  $mp \ll \log n$ .

In our analysis of **BlockGreedy**, we track this change of behaviour using a geometric series, which means that the further we are in the execution of the algorithm, the larger the ratio between the element we pick and the average element will be. This picture coincides exactly with how the binomial distribution will behave if we decrease the average degree: for large instances, it will look approximately as a Gaussian, but when the average degree is small, Poisson approximation starts to dominate, the right tail becomes heavier, and the difference between  $d_{\max}$  and  $mp$  increases. Our analysis tracks the transition between Gaussian and Poisson-like behavior.

## 6.2 Multiplicative vs. additive integrality gaps

Our result only concerns multiplicative gaps, but the constants in our analysis can be large. This might be a consequence of the generality of the studied problem. For example, if one focuses only on the case of constant  $p$ , which immediately implies a very dense instance in our characterization, [16] proves that a simple algorithm is optimal for approximating the integer program up to a small additive error. Proving similar upper bounds on the constant in more general cases is an interesting open problem. Based on numerical experiments, we formulate the following conjectures.

► **Conjecture 12** (Very sparse). For  $mp \ll 1$ ,  $\frac{\text{val}_{\text{Gr}}}{\text{val}_{\text{LP}}} \rightarrow 1$ .

► **Conjecture 13** (Sparse). For  $1 \lesssim mp \ll \log n$ ,  $\frac{\text{val}_{\text{Gr}}}{\text{val}_{\text{IP}}} \rightarrow 1$ , and  $\frac{\text{val}_{\text{IP}}}{\text{val}_{\text{LP}}} \rightarrow C_1 \in (1, 1.5)$ .

► **Conjecture 14** (Dense). For  $mp \gg \log n$ ,  $\frac{\text{val}_{\text{Gr}}}{\text{val}_{\text{IP}}} \rightarrow C_2 \in (1, 1.5)$ .

## 6.3 Analysis of a linear program solution.

One motivation for studying the gaps between the integer and linear programs together with the solutions of linear programs themselves is to construct a rounding scheme which converts a fractional solution to an integer one. We believe this is another interesting direction for future work. In particular, numerical experiments show that entries which have large value in the fractional solution have a strong tendency to correspond to elements that are picked for the integer solution. This supports the claim that a combination of the greedy and linear programming approach might be fruitful in efficiently solving **Hitting Set**. One approach for further study consists of first solving a linear program, initializing  $\mathbf{x}$  with the largest elements in the linear solution, and greedily covering the remaining subsets.

## A Auxiliary lemmas

► **Lemma 15** (Lower Bound in Lemma 3). *We have that*

$$\text{val}_{LP} \geq \frac{m}{d_{\max}}.$$

**Proof.** Let  $\mathbf{x}_{LP}^* = (\mathbf{x}_1^*, \mathbf{x}_2^*, \dots, \mathbf{x}_m^*)$  be an optimal solution for (1.2). Since  $A\mathbf{x}_{LP}^* \geq \mathbf{1}$  entrywise, by summing all entries we obtain that

$$m \leq \sum_i \mathbf{x}_i^* X_i \leq d_{\max} \sum_i \mathbf{x}_i^* = d_{\max} \text{val}_{LP}.$$

which upon rearranging yields the desired result. ◀

In addition to the above, we have the following elementary upper bound on  $\text{val}_{LP}$ , which holds both in the sparse and dense regime.

► **Lemma 16** (Upper Bound in Lemma 3). *There exists  $c > 0$ , independent of  $n$ , such that*

$$\mathbb{P}\left(\text{val}_{LP} \lesssim \frac{1}{p}\right) \geq 1 - \exp(-cn^{1-\delta}).$$

*This also implies that  $\mathbb{P}(\text{IP is feasible}) \geq 1 - \exp(-cn^{1-\delta})$ .*

**Proof.** Consider the candidate feasible solution  $\hat{\mathbf{x}} := \frac{1}{\tilde{C}np} \mathbf{1}$ , for some constant  $0 < \tilde{C} < 1$ . The following results from applying a union bound over constraints and the standard Chernoff bound.

$$\begin{aligned} \mathbb{P}(\hat{\mathbf{x}} \text{ not feasible}) &= \mathbb{P}(\exists i \in [m] : (\mathbf{A}\hat{\mathbf{x}})_i < 1) \\ &\leq m\mathbb{P}(\text{Bin}(n, p) < \tilde{C}np) \\ &\leq n^C \exp\left(-\frac{(1-\tilde{C})^2 np}{2}\right) \\ &\leq \exp(-cn^{1-\delta}). \end{aligned}$$

The desired conclusion follows by considering the complementary event to the one above and noting that  $\|\hat{\mathbf{x}}\|_1 \sim 1/p$ . Note that the event  $\{\hat{\mathbf{x}} \text{ is feasible for LP}\}$  implies the event  $\{\text{IP is feasible}\}$ .  $\blacktriangleleft$

► **Lemma 17** (Lambert  $W$  function, [9]). *For any  $x \geq e$ , there holds that*

$$\log x - \log \log x + \frac{\log \log x}{2 \log x} \leq W_0(x) \leq \log x - \log \log x + \frac{e}{e-1} \frac{\log \log x}{\log x}. \quad (\text{A.1})$$

In particular,

$$W_0(x) = \log x - \log \log x + o(1), \quad \text{as } x \rightarrow \infty. \quad (\text{A.2})$$

In addition, for any  $x \geq 1/e$ , the following identity is satisfied

$$W_0(x) = \log \frac{x}{W_0(x)}. \quad (\text{A.3})$$

**Proof of Lemma 4.** Fix  $D \geq 1$ . Let  $Z_k := |\{\mathbf{x} \in \{0, 1\}^m : \mathbf{A}\mathbf{x} \geq \mathbf{1}, \|\mathbf{x}\|_1 = k\}|$  be the number of feasible solutions of norm exactly  $k$ . Clearly,  $Z_k \leq Z_{k+1}$  for any  $k \geq 0$ . We also have that

$$\mathbb{E}Z_k = \sum_{\|\mathbf{x}\|_1=k} \mathbb{P}((\mathbf{A}\mathbf{x})_i \geq 1, \forall i \in [m]) = \binom{n}{k} (1 - (1-p)^k)^m.$$

We will now show that for  $k \ll \frac{1}{p} \log\left(\frac{mp}{\log n}\right)$ , we have  $\mathbb{E}Z_k \leq n^{-D}$ . Using that  $p \leq 1/2$  from Assumption 4 and that for  $x \in (0, \frac{1}{2})$ , we have  $(1-x)^y \geq e^{-2xy}$ , we can bound

$$\begin{aligned} \mathbb{E}Z_k &= \binom{n}{k} (1 - (1-p)^k)^m \leq n^k (1 - e^{-2pk})^m \\ &\leq n^k e^{-me^{-2pk}} = \exp\{k \log n - me^{-2pk}\}. \end{aligned}$$

Therefore,  $\mathbb{E}Z_k \leq n^{-D}$  will follow from

$$2pke^{2pk} \leq -2Dpe^{2pk} + \frac{2mp}{\log n}. \quad (\text{A.4})$$

Since  $k \ll \frac{1}{p} \log\left(\frac{mp}{\log n}\right)$ , we also have that  $k \leq k_* := \frac{1}{2p} W_0\left(\frac{mp}{D \log n}\right)$  for  $n$  large enough. For  $k = k_*$ , the left hand side of (A.4) is equal to  $\frac{mp}{D \log n}$ , while the right hand side is lower bounded by  $\frac{mp}{\log n}$ . Since  $D \geq 1$ , we recover that  $\mathbb{E}Z_k \leq n^{-D}$ . Note that for  $n$  large enough,  $\text{val}_{\text{IP}} \ll \frac{1}{p} \log \frac{mp}{\log n}$  implies that  $Z_{k_*} > 0$ . Therefore, applying Markov's inequality, we get that

$$\mathbb{P}\left(\text{val}_{\text{IP}} \ll \frac{1}{p} \log\left(\frac{mp}{\log n}\right)\right) \leq \mathbb{P}(Z_{k_*} > 0) \leq \mathbb{E}Z_{k_*} \leq n^{-D}, \quad (\text{A.5})$$

### 30:16 Greedy Heuristics and Linear Relaxations for the Random Hitting Set Problem

and the proof follows by considering the complementary events. Note that using similar derivations, one can also show that for  $k^* := \frac{1}{p} \log \left( \frac{1}{\delta} \frac{mp}{\log n} \right)$ , where  $\delta$  is defined in Assumption 4, we have  $\mathbb{E}Z_{k^*} \geq 1$ .  $\blacktriangleleft$

**Proof of Lemma 5.** For ease of notation, let us define  $b_n := \frac{\log n}{mp}$ ,  $b_n^* := \frac{1}{e}(b_n - 1)$ ,  $g_n := \frac{\log n}{\log(\log n/mp)}$ . We begin by proving the desired upper bound. By Jensen's inequality and bounding the maximum of positive values by their sum, for any  $\lambda > 0$ , we obtain

$$\mathbb{E} \max_{i \in [n]} X_i \leq \frac{1}{\lambda} \log \mathbb{E} \exp \left( \lambda \max_{i \in [n]} X_i \right) = \frac{1}{\lambda} \log \mathbb{E} \left( \max_{i \in [n]} \exp(\lambda X_i) \right) \leq \frac{1}{\lambda} \log \sum_{i \in [n]} \mathbb{E} \exp(\lambda X_i).$$

Finally, computing the moment generating function of binomial random variables, together with the inequality  $1 - x \leq e^{-x}$  yields

$$\mathbb{E} \max_{i \in [n]} X_i = \frac{\log n + m \log(1 - p(1 - e^\lambda))}{\lambda} \leq \frac{\log n - mp(1 - e^\lambda)}{\lambda}.$$

In the regime where  $mp \gtrsim \log n$ , we may choose  $\lambda > 0$  arbitrary, independent of  $n$ , from which it immediately follows that  $\mathbb{E} \max_{i \in [n]} X_i \lesssim mp$ .

For  $mp \ll \log n$ , we proceed by differentiating the last line in the above display and setting the resulting expression to zero. From this, we may choose  $\lambda$  as the solution of the following.

$$e^{\lambda-1}(\lambda - 1) = b_n^*$$

Under the present assumptions, this is expressed in terms of the Lambert W function as  $\lambda = 1 + W_0(b_n^*)$ , so that by (A.3), we obtain

$$\mathbb{E} \max_{i \in [n]} X_i \leq \frac{\log n \left( 1 - \frac{1}{b_n} + \frac{b_n^*}{b_n} \frac{e}{W_0(b_n^*)} \right)}{1 + W_0(b_n^*)} \sim g_n.$$

In the dense  $mp \gtrsim \log n$  regime, a matching lower bound is easily obtained by noting that  $\mathbb{E} \max_{i \in [n]} X_i \geq \mathbb{E}X_1 = mp$ .

To deal with the sparse regime, let  $\tau = 1/16$ . From Markov's inequality,

$$\mathbb{E} \max_{i \in [n]} X_i \geq \tau g_n \mathbb{P} \left( \max_{i \in [n]} X_i = \lceil \tau g_n \rceil \right) = \tau g_n (1 - (1 - \mathbb{P}(X_1 = \lceil \tau g_n \rceil))^n).$$

Hence, applying Lemma 25, for  $n$  large enough,

$$\mathbb{E} \max_{i \in [n]} X_i \geq \tau g_n \left( 1 - \left( 1 - n^{-1/2} \right)^n \right) \geq (\tau/2)g_n,$$

thus providing a matching lower bound for the sparse regime.

In the intermediate threshold regime  $mp \sim \log n$ , the average and maximum of  $X_i$ 's become of the same order, that is  $mp \sim \mathbb{E}d_{\max} \sim \log n$ . The smooth transition follows by noting that in this regime,  $b_n, b_n^*, W_0(b_n^*) \sim 1$ .  $\blacktriangleleft$

**► Lemma 18 (Chernoff Bound - upper tail).** *Let  $X_1, \dots, X_n$  be independent random variables taking values in  $\{0, 1\}$ ,  $X$  denote their sum and  $\mu = \mathbb{E}X$ . Then for any  $\delta > 0$ ,*

$$\mathbb{P}(X \geq (1 + \delta)\mu) \leq e^{-\delta^2 \mu / (2 + \delta)}.$$

In order to deal with concentration of  $d_{\max}$  around its expectation, we state the following useful result on tensorization of variance. We introduce notation  $\text{Var}_i$  and  $\mathbb{E}_i$ , where subscript  $i$  indicates conditioning on each component of an underlying random vector, except for the  $i$ -th one.

► **Lemma 19** (Theorem 2.3, [17]). *Let  $X_1, \dots, X_n$  be independent random variables and for each function  $f : \mathbb{R}^n \rightarrow \mathbb{R}$ , define*

$$\text{Var}_i f(x_1, \dots, x_n) := \text{Var}(x_1, \dots, x_{i-1}, X_i, x_{i+1}, \dots, x_n).$$

*Then, there holds that*

$$\text{Var}(f(X_1, \dots, X_n)) \leq \mathbb{E} \sum_{i=1}^n \text{Var}_i f(X_1, \dots, X_n)$$

► **Lemma 20** (Concentration for  $d_{\max}$ ). *Let  $X_1, \dots, X_n \stackrel{\text{iid}}{\sim} \text{Bin}(m, p)$ . Then, for any  $t > 0$ ,*

$$\mathbb{P}(|d_{\max} - \mathbb{E}d_{\max}| > t) \leq \frac{mp}{t^2}.$$

► **Remark 21.** Note that in all regimes of  $m, p$  satisfying Assumption 2, choosing  $t \sim \mathbb{E}d_{\max}$  is sufficient to deduce from the previous lemma that  $d_{\max} \sim \mathbb{E}d_{\max}$  w.h.p..

**Proof.** Proceeding by Chebyshev's inequality, it suffices to show that  $\text{Var}(d_{\max}) \leq mp$ . By Lemma 19, we have that

$$\begin{aligned} \text{Var}(d_{\max}) &\leq \mathbb{E} \sum_{i=1}^n \mathbb{E}_i (d_{\max} - \mathbb{E}_i d_{\max})^2 \\ &= \mathbb{E} \sum_{i=1}^n \mathbb{E}_i \left[ (d_{\max} - \mathbb{E}_i d_{\max})^2 \mid d_{\max} = X_i \right] \mathbb{P}d_{\max} = X_i \\ &\quad + \mathbb{E} \sum_{i=1}^n \mathbb{E}_i \left[ (d_{\max} - \mathbb{E}_i d_{\max})^2 \mid d_{\max} \neq X_i \right] \mathbb{P}d_{\max} \neq X_i \\ &= \frac{1}{n} \mathbb{E} \sum_{i=1}^n \text{Var} X_i \\ &\leq mp, \end{aligned}$$

which is as required. ◀

**Proof of Lemma 6.** Let us consider the sparse and dense regimes separately.

In the dense regime for  $mp \gtrsim \log n$ , there exist constants  $c_1, c_2, c_3 > 0$  such that  $c_1 mp \leq \mathbb{E} \max_{i \in [n]} X_i \leq c_2 mp$ , as argued in Lemma 5, and  $mp \geq c_3 \log n$ . We apply the union and Chernoff bounds as in Lemma 18 to obtain, for any  $t \geq 1/c_1$ ,

$$\begin{aligned} \mathbb{P} \left( \max_{i \in [n]} X_i \geq t \cdot \mathbb{E} \max_{i \in [n]} X_i \right) &\leq n \mathbb{P}(X_1 \geq tc_1 mp) \\ &\leq n \exp \left( - \frac{(tc_1 - 1)^2 mp}{1 + tc_1} \right) \\ &\leq n \exp \left( - \frac{c_3 (tc_1 - 1)^2 \log n}{1 + tc_1} \right). \end{aligned}$$

It now suffices to choose  $t$  as a function of  $c_1, c_3$  such that  $\frac{c_3 (tc_1 - 1)^2}{1 + tc_1} > 1$ . By rearranging and solving the resulting quadratic equation, it follows immediately that any  $t > \frac{1}{c_1} + \frac{1 + \sqrt{1 + 8c_3}}{2c_3 c_1} > \frac{1}{c_1}$  suffices. Hence, there exist universal constants  $c, \bar{c}$ , such that the desired conclusion holds. We now consider the sparse regime  $mp \ll \log n$ , where by Lemma 5 there exists  $c_4 > 0$  such that  $mp \leq c_4 \log n / \log \left( \frac{\log n}{\log mp} \right)$ . Notice that for any  $\lambda > 0$ ,  $\max_{i \in [n]} X_i \leq \frac{1}{\lambda} \log \sum_{i=1}^n e^{\lambda X_i}$ . We apply Markov's inequality to obtain, for any  $t > 0$ ,

$$\begin{aligned}
 \mathbb{P}\left(\max_{i \in [n]} X_i \geq t \cdot \mathbb{E} \max_{i \in [n]} X_i\right) &\leq \mathbb{P}\left(\sum_{i=1}^n e^{\lambda X_i} \geq e^{\lambda t \mathbb{E} \max_{i \in [n]} X_i}\right) \\
 &\leq \frac{n \mathbb{E} e^{\lambda X_1}}{\exp(\lambda t \mathbb{E} \max_{i \in [n]} X_i)} \\
 &= \frac{n(1-p+pe^\lambda)^m}{\exp(\lambda t \mathbb{E} \max_{i \in [n]} X_i)} \\
 &\leq \exp\left(\log n + mp(e^\lambda - 1) - \frac{\lambda t c_4 \log n}{\log\left(\frac{\log n}{mp}\right)}\right),
 \end{aligned}$$

where we used that  $1+x < e^x$  to obtain the last inequality. Finally, by choosing  $t = 3/c_4$  and  $\lambda = \log(\log n/mp)$ , we obtain

$$\mathbb{P}\left(\max_{i \in [n]} X_i \geq \frac{3}{c_4} \cdot \mathbb{E} \max_{i \in [n]} X_i\right) \leq \frac{1}{n}. \quad \blacktriangleleft$$

► **Lemma 22** (Asymptotic expression for binomial probability mass function).

Let  $a \equiv a(n)$  and  $b \equiv b(n)$  be such that

1.  $1 \ll b \ll \sqrt{a}$ ,
2.  $p \ll 1$ .

If  $b \geq Cap$  for  $C > 1$ , then

$$\log \mathbb{P}(\text{Bin}(\lceil a \rceil, p) = \lceil b \rceil) \geq -\left(b \log \frac{b}{ap} - b + ap\right)(1 + o(1)), \quad (\text{A.6})$$

If also  $b \gg ap$ , we have that

$$\log \mathbb{P}(\text{Bin}(\lceil a \rceil, p) = \lceil b \rceil) \geq -\left(b \log \frac{b}{ap}\right)(1 + o(1)), \quad (\text{A.7})$$

Furthermore, all bounds remain valid upon replacing  $\lceil a \rceil$  to  $\lfloor a \rfloor$ .

**Proof.** We defer the proof of Lemma 22 to the extended version of this work found in [1]. ◀

► **Lemma 23** (Binomial Monotonicity). Let  $S_m \sim \text{Bin}(m, p)$ . Then for  $r \geq mp$ , we have that  $\mathbb{P}(S_m = r+1) \leq \mathbb{P}(S_m = r)$  and  $\mathbb{P}(S_{m-1} = r) \leq \mathbb{P}(S_m = r)$ .

**Proof.** The proof follows a similar argument as that presented in [7].

$$\begin{aligned}
 \frac{\mathbb{P}(S_m = r+1)}{\mathbb{P}(S_m = r)} &= \frac{\binom{m}{r+1} p^{r+1} (1-p)^{m-r-1}}{\binom{m}{r} p^r (1-p)^{m-r}} \\
 &= \frac{\frac{m!}{(r+1)!(m-r-1)!} p^{r+1} (1-p)^{m-r-1}}{\frac{m!}{r!(m-r)!} p^r (1-p)^{m-r}} \\
 &= \frac{(m-r)p}{(r+1)(1-p)} \leq 1.
 \end{aligned}$$

Similar arguments show that  $\mathbb{P}(S_{m-1} = r) \leq \mathbb{P}(S_m = r)$ . ◀

## B Main tool for the case $mp \lesssim \log n$ and Proof of Lemma 25

► **Lemma 24.** *If  $mp \lesssim \log n$ , then, for any  $\varepsilon > 0$ , there exist constants  $\tau > 0$  and  $1 < \alpha < \beta$ , such that, for  $k \lesssim \log n$  and for any  $\tilde{m}$ , satisfying  $\beta^{-k-1}m \leq \tilde{m} \leq \beta^{-k}m$ , for all  $n$  large enough,*

$$\mathbb{P}\left(\text{Bin}(\tilde{m}, p) = \lceil (\alpha/\beta)^k \tau \mathbb{E}d_{\max} \rceil\right) \geq n^{-\varepsilon}.$$

**Proof.** The proof is essentially a careful application of Lemma 22. Let  $\tau, \alpha, \beta$  be constants to be fixed later and  $\tilde{m} = \lfloor \beta^{-k-1}m \rfloor$ . Depending on whether we have  $mp \ll \log n$  or  $mp \sim \log n$ , different terms will dominate the asymptotic expression from Lemma 22.

We start with the case  $mp \ll \log n$ . From Lemma 5, this implies that  $mp \ll \mathbb{E}d_{\max} \ll \log n$ . Here we can fix  $\alpha \equiv 2$  and  $\beta \equiv 3$ . Applying (A.7) for  $a = 3^{-k-1}m$  and  $b = (2/3)^k \tau \mathbb{E}d_{\max}$ , we have:

$$\log \mathbb{P}\left(\text{Bin}(\tilde{m}, p) = \lceil (2/3)^k \tau \mathbb{E}d_{\max} \rceil\right) \geq -(2/3)^k \tau \mathbb{E}d_{\max} \log\left(\frac{2^k 3 \tau \mathbb{E}d_{\max}}{mp}\right) (1 + o(1)) \quad (\text{B.1})$$

Recall that our goal is to show  $\log \mathbb{P}\left(\text{Bin}(\tilde{m}, p) = \lceil (2/3)^k \tau \mathbb{E}d_{\max} \rceil\right) \geq -\varepsilon \log n$ . We first show that there exists  $\tau > 0$  satisfying the following two inequalities:

$$\begin{aligned} \text{(i)} \quad & (2/3)^k \tau (\log 3 + k \log 2) \frac{\mathbb{E}d_{\max}}{\log n} \leq \frac{\varepsilon}{4}, \\ \text{(ii)} \quad & (2/3)^k \tau \frac{\mathbb{E}d_{\max}}{\log n} \log\left(\frac{\mathbb{E}d_{\max}}{mp}\right) \leq \frac{\varepsilon}{4}. \end{aligned} \quad (\text{B.2})$$

Indeed, since  $\mathbb{E}d_{\max} \ll \log n$  and  $k \ll (3/2)^k$ , inequality (i) will be satisfied for any  $\tau > 0$  for  $n$  large enough. For (ii) we need to use explicit bound for  $\mathbb{E}d_{\max}$ , in particular from Lemma 5 we know that there exists  $C > 0$ , such that  $\mathbb{E}d_{\max} \leq C \log n / (\log \log n - \log mp)$  for  $n$  large enough. Plugging this into (ii), we get for  $k = 0$ ,

$$\tau \frac{\mathbb{E}d_{\max}}{\log n} \log\left(\frac{\mathbb{E}d_{\max}}{mp}\right) \leq \frac{\tau C (\log C + \log \log n - \log(\log \log n - \log mp) - \log mp)}{\log \log n - \log mp} = \tau C + o(1). \quad (\text{B.3})$$

For  $\tau = \varepsilon/(8C)$ , (ii) holds for  $k = 0$  for  $n$  large enough. By increasing  $k$  we only decrease left hand side of (ii), therefore, the same value of  $\tau$  works for any  $k \geq 0$ .

Finally, by adding (i) and (ii) we showed that, for  $n$  large enough,

$$\log \mathbb{P}\left(\text{Bin}(\tilde{m}, p) = \lceil (\alpha/2)^k \tau \mathbb{E}d_{\max} \rceil\right) \geq -\frac{\varepsilon}{2} \log n (1 + o(1)) > -\varepsilon \log n,$$

which finishes the proof for the case  $mp \ll \log n$ .

Now we focus on the case  $mp \sim \log n$ . Here we apply (A.6) for the values  $a = \beta^{-k-1}m$  and  $b = (\alpha/\beta)^k \tau \mathbb{E}d_{\max}$  keeping in mind the condition  $b \geq Cap$  with  $C > 1$ . We have

$$\begin{aligned} & \log \mathbb{P}\left(\text{Bin}(\tilde{m}, p) = \lceil (\alpha/\beta)^k \tau \mathbb{E}d_{\max} \rceil\right) \\ & \geq -\left((\alpha/\beta)^k \tau \mathbb{E}d_{\max} \log\left(\frac{\beta \alpha^k \tau \mathbb{E}d_{\max}}{mp}\right) - (\alpha/\beta)^k \tau \mathbb{E}d_{\max} + \beta^{-k-1}mp\right) (1 + o(1)) \end{aligned}$$

We pick  $\tau = \gamma mp / \mathbb{E}d_{\max}$ , for some constant  $\gamma > 1$  to be specified later. Note that this way condition for applying (A.6),  $\frac{b}{ap} \geq C > 1$ , is satisfied since  $\frac{b}{ap} \geq \frac{\tau \mathbb{E}d_{\max}}{mp} = \gamma > 1$ . This simplifies the latter expression to the following:

$$\begin{aligned} & \log \mathbb{P} \left( \text{Bin}(\tilde{m}, p) = \lceil (\alpha/\beta)^k \gamma mp \rceil \right) \\ & \geq -mp \left( (\alpha/\beta)^k \gamma \log(\beta \gamma \alpha^k) - (\alpha/\beta)^k \gamma + \beta^{-k-1} \right) (1 + o(1)) \end{aligned}$$

Since in this regime we have  $mp \leq D \log n$  for some  $D > 0$ , for  $n$  large enough, it is enough to show

$$(\alpha/\beta)^k \gamma \log(\beta \gamma \alpha^k) - (\alpha/\beta)^k \gamma + \beta^{-k-1} \leq \varepsilon/(2D).$$

We first show that there exist constants  $1 < \alpha < \beta$  and  $\gamma > 1$ , depending on  $\varepsilon$  and  $D$ , satisfying the following two inequalities for any  $k \geq 0$ :

$$\begin{aligned} \text{(i)} \quad & (\alpha/\beta)^k \left( \gamma \log \beta \gamma - \gamma + \frac{1}{\alpha^k \beta} \right) \leq \frac{\varepsilon}{4D}, \\ \text{(ii)} \quad & (\alpha/\beta)^k k \log \alpha \leq \frac{\varepsilon}{4D}. \end{aligned}$$

Note that left hand side of (i) decreases as  $k$  increases, therefore, it is enough to look at  $k = 0$ . We need to show that there exist  $\beta, \gamma > 1$ , depending on  $\varepsilon, D$  such that

$$f(\beta, \gamma) := \gamma \log \beta \gamma - \gamma + \frac{1}{\beta} \leq \frac{\varepsilon}{4D}.$$

Note that  $\frac{\partial f}{\partial \beta} = \gamma/\beta - 1/\beta^2 > 0$  and  $\frac{\partial f}{\partial \gamma} = \log \beta \gamma > 0$  as long as  $\beta \gamma > 1$ . Since  $f(1, 1) = 0$ , we can find  $\beta, \gamma > 1$ , close enough to 1, such that  $f(\beta, \gamma) \leq \varepsilon/(4D)$ . We use these values of  $\beta$  and  $\gamma$  (or, equivalently,  $\tau$ ). Since  $k \ll (\beta/\alpha)^k$ , there exists  $\alpha \in (1, \beta)$ , such that (ii) holds. Summing (i) and (ii) shows that, for  $n$  large enough,

$$\log \mathbb{P} \left( \text{Bin}(\tilde{m}, p) = \lceil (\alpha/\beta)^k \gamma mp \rceil \right) \geq -\frac{\varepsilon mp}{2D} (1 + o(1)) \geq -\frac{\varepsilon \log n}{2} (1 + o(1)) \geq -\varepsilon \log n.$$

We proved that for  $mp \lesssim \log n$ , for any  $\varepsilon > 0$ , for  $n$  large enough, there exists  $\tau, \alpha, \beta$ , such that

$$\Pr \left( \text{Bin}(\lfloor \beta^{-k-1} m \rfloor, p) = \lceil (\alpha/\beta)^k \tau \mathbb{E}d_{\max} \rceil \right) \geq n^{-\varepsilon}.$$

Since  $\beta^{-k-1} mp < \beta^{-k} mp < \lceil (\alpha/\beta)^k \tau \mathbb{E}d_{\max} \rceil$ , from binomial monotonicity, Lemma 23, we have that for any  $\tilde{m}$  such that  $\beta^{-k-1} m \leq \tilde{m} \leq \beta^{-k} m$ ,

$$\mathbb{P} \left( \text{Bin}(\tilde{m}, p) = \lceil (\alpha/\beta)^k \tau \mathbb{E}d_{\max} \rceil \right) \geq n^{-\varepsilon}.$$

In order to deal with the more delicate sparse regime throughout the paper where  $mp \ll \log n$ , we apply the following technical lemma.

► **Lemma 25.** For  $mp \ll \log n$ ,  $\varepsilon > 0$ , and  $n$  large enough, we have

$$\mathbb{P} \left( \text{Bin}(m, p) = \left\lceil \frac{\varepsilon}{8} \frac{\log n}{\log(\log n / mp)} \right\rceil \right) \geq n^{-\varepsilon}. \quad \blacktriangleleft$$

**Proof of Lemma 25.** We follow the argument in Lemma 24 with  $k = 0$  and  $\mathbb{E}d_{\max}$  replaced by  $\log n / (\log \log n - \log mp)$ . Note that in the proof of Lemma 24, in the case  $mp \ll \log n$ , we only used that  $mp \ll \mathbb{E}d_{\max} \ll \log n$  and  $\mathbb{E}d_{\max} \leq C \log n / (\log \log n - \log mp)$  for some  $C > 0$ . Since both these properties remain true upon replacing  $\mathbb{E}d_{\max}$  with  $\log n / (\log \log n - \log mp)$ , the proof follows. Since  $\tau = \varepsilon/(8C)$ , in the setting of Lemma 25, and  $C = 1$  in this argument, we pick  $\tau = \varepsilon/8$ . ◀

### C

 Lemma 26, formal version of Lemma 7

► **Lemma 26.** Let  $\varepsilon > 0$ . Consider the following choices of  $f_1, f_2, \dots$ :

(i) if  $mp \lesssim \log n$ , for some constants  $\tau > 0$  and  $1 < \alpha < \beta$ ,

$$f_t = \left\lceil (\alpha/\beta)^k \tau \mathbb{E}d_{\max} \right\rceil \quad \text{where } k \text{ is such that } \beta^{-k-1}m < m - F_{t-1} \leq \beta^{-k}m;$$

(ii) if  $mp \gg \log n$ , and  $\log mp \ll \log n$ ,

$$f_t = \lceil mp(1-p)^{t-1} \rceil \quad \text{if } t \leq t^* := \left\lceil \frac{1}{p} \log \left( \frac{mp}{\log n} \right) \right\rceil,$$

$$f_t = \tilde{f}_{t-t^*}, \quad \text{otherwise, where } \tilde{f}_t \text{ is the sequence from the case } mp \lesssim \log n;$$

(iii) otherwise, i.e., when  $\log mp \gtrsim \log n$ ,

$$f_t = \lceil mp(1-p)^{t-1} \rceil.$$

Then, there exists  $K$ , such that

- (i)  $F_K \geq m - K$ ;
  - (ii) if  $mp \lesssim \log n$ , then  $K \sim \text{val}_{LP}$ ;
  - if  $mp \gg \log n$ , then  $K \sim \text{val}_{IP}$ .
- (C.1)

Furthermore, for this sequence  $f_t$  (which depends on  $\varepsilon$ ), for any  $t \leq K$ ,

$$\mathbb{P}(\text{Bin}(m - F_{t-1}, p) \geq f_t) \geq n^{-\varepsilon}. \quad (\text{C.2})$$

Note that the implicit constants in the statements  $K \sim \text{val}_{LP}$  or  $K \sim \text{val}_{IP}$  depend on  $\varepsilon$ .

**Proof.** We proceed in the proof by first showing that there exists  $\tilde{K}$ , such that  $m - F_{\tilde{K}} \lesssim \tilde{K}$ , and then, by increasing  $\tilde{K}$  by a multiplicative factor, we find  $K$  such that  $m - F_K \leq K$ .

**Case  $mp \lesssim \log n$ .** From Lemma 24, there exist constants  $\tau > 0$ ,  $\alpha, \beta$  with  $1 < \alpha < \beta$ , such that, for any  $\tilde{m}$ , satisfying  $\beta^{-k-1}m \leq \tilde{m} \leq \beta^{-k}m$ , for all  $n$  large enough,

$$\mathbb{P}\left(\text{Bin}(\tilde{m}, p) = \lceil (\alpha/\beta)^k \tau \mathbb{E}d_{\max} \rceil\right) \geq n^{-\varepsilon}.$$

Recall that in this case  $f_t = \lceil (\alpha/\beta)^k \tau \mathbb{E}d_{\max} \rceil$ , where  $k$  is such that  $\beta^{-k-1}m \leq m - F_{t-1} \leq \beta^{-k}m$  and  $F_t = \sum_{s=1}^t f_s$ . From Lemma 24 we have that  $\mathbb{P}(\text{Bin}(m - F_{t-1}, p) = f_t) \geq n^{-\varepsilon}$ . Our goal is to prove that there exists  $s \lesssim \text{val}_{LP} \sim m/\mathbb{E}d_{\max}$ , such that  $m - F_s \lesssim s$ .

► **Lemma 27.** Let  $t^{(k)} := \frac{\beta-1}{\beta\tau} \frac{m}{\mathbb{E}d_{\max}} \alpha^{-k}$ .

$$\begin{aligned} \text{If } & m - F_{t-1} \leq \beta^{-k}m \\ \text{then } & m - F_{t+t^{(k)}-1} \leq \beta^{-k-1}m. \end{aligned}$$

Informally, if after  $t-1$  steps of *BlockGreedy*, at most  $\beta^{-k}m$  subsets are uncovered, then after  $t+t^{(k)}-1$  steps, at most  $\beta^{-k-1}m$  subsets remain uncovered.

**Proof.** Let  $s \geq t$ . As long as  $m - F_{s-1} > \beta^{-k-1}m$ , we will always have  $f_s = \lceil (\alpha/\beta)^k \tau \mathbb{E}d_{\max} \rceil$ . We proceed by contradiction. Assume that  $m - F_{t+t^{(k)}-1} > \beta^{-k-1}m$ . This implies that for all  $s \in [t-1, t+t^{(k)}-1]$ , we have  $f_s = f := \lceil (\alpha/\beta)^k \tau \mathbb{E}d_{\max} \rceil$ . Therefore,

$$F_{t+t^{(k)}-1} - F_{t-1} = t^{(k)} f \geq \frac{m(\beta-1)}{\beta^{k+1}} = \beta^{-k}m - \beta^{-k-1}m,$$

## 30:22 Greedy Heuristics and Linear Relaxations for the Random Hitting Set Problem

and

$$\begin{aligned} m - F_{t+t^{(k)}-1} &= m - F_{t-1} - (F_{t+t^{(k)}-1} - F_{t-1}) \\ &\leq \beta^{-k}m - (\beta^{-k}m - \beta^{-k-1}m) = \beta^{-k-1}m. \end{aligned}$$

Therefore, we must have  $m - F_{t+t^{(k)}-1} \leq \beta^{-k-1}m$ .  $\blacktriangleleft$

Note that we always have  $\beta^{-1}m \leq m - F_0 = m$ . If we consecutively apply Lemma 27 starting with  $k = 0$ , then, for  $v(k) := \sum_{s=0}^k t^{(s)}$  we have  $m - F_{v(k)-1} \leq \beta^{-k-1}m$ . Therefore, for  $k := \frac{\log \mathbb{E}d_{\max}}{\log \beta}$ , we have  $m - F_{v(k)-1} \leq \frac{m}{\mathbb{E}d_{\max}}$ . We can bound

$$v(k) \leq \sum_{s=0}^{\infty} t^{(s)} = \frac{\beta - 1}{\beta\tau(\alpha - 1)} \frac{m}{\mathbb{E}d_{\max}} \sim \frac{m}{\mathbb{E}d_{\max}}.$$

From Lemma 6 we have  $d_{\max} \lesssim \mathbb{E}d_{\max}$  with high probability. Together with Lemma 15 this implies  $\text{val}_{\text{LP}} \geq \frac{m}{d_{\max}} \gtrsim \frac{m}{\mathbb{E}d_{\max}}$ . Now, if we pick  $\tilde{K} := v(k) \lesssim \frac{m}{\mathbb{E}d_{\max}}$ , we have that  $\text{val}_{\text{BGr}} \lesssim \frac{m}{\mathbb{E}d_{\max}}$ . Since  $\text{val}_{\text{LP}} \leq \text{val}_{\text{BGr}}$ , we have that  $\tilde{K} \sim \text{val}_{\text{LP}}$  and  $m - F_{\tilde{K}} \lesssim \tilde{K}$ .

**Case  $mp \gg \log n$ .** Here, we have that  $\mathbb{E}d_{\max} = mp(1 + o(1))$ , therefore, picking an element that hits an average number of subsets is approximately the same as picking an element that hits close to maximum number of subsets. From the properties of the mean and the median of the binomial distribution, it follows that  $\mathbb{P}(\text{Bin}(\tilde{m}, p) \geq \lceil \tilde{m}p \rceil) \geq 1/3$ , for any  $\tilde{m}$ .

We begin with the case  $\log mp \ll \log n$ . This means that  $mp$  cannot grow polynomially in  $n$ , but e.g.  $mp \sim \log^2 n$  is possible. In this regime,  $\text{val}_{\text{IP}} \sim \frac{1}{p} \log \left( \frac{mp}{\log n} \right)$ . Let  $K_1 = \left\lceil \frac{1}{p} \log \left( \frac{mp}{\log n} \right) \right\rceil$  and  $f_1, \dots, f_{K_1}$  be a sequence such that  $f_s = \lceil mp(1-p)^s \rceil$ . Then, we have that  $m - F_{K_1} \leq m(1-p)^{K_1} \leq \frac{1}{p} \log n$ . Therefore,  $(m - F_{K_1})p \sim \log n$ , and we can continue with  $\tilde{f}_t$  from the previous section  $mp \sim \log n$ , with  $\tilde{F}_t := \sum_{s=1}^t \tilde{f}_s$ . For this sequence  $\tilde{f}_1, \dots, \tilde{f}_{K_2}$ , we have  $K_2 \lesssim \frac{1}{p}$ , and  $m - F_{K_1} - \tilde{F}_{K_2} \lesssim \frac{1}{p} \ll \frac{1}{p} \log \left( \frac{mp}{\log n} \right)$ . The required statement holds for combined sequences  $f_t$  and  $\tilde{f}_t$  and  $\tilde{K} := K_1 + K_2$ .

Finally, we study the case  $\log mp \gtrsim \log n$ , which implies that  $\text{val}_{\text{IP}} \sim \frac{1}{p} \log n$ . This case is trivial, as one can pick  $\tilde{K} = \left\lceil \frac{1}{p} \log \left( \frac{mp}{\log n} \right) \right\rceil \lesssim \text{val}_{\text{IP}}$  and  $f_1, \dots, f_{\tilde{K}}$  a sequence such that  $f_s = \lceil mp(1-p)^s \rceil$ . Then, we have that  $m - F_{\tilde{K}} \leq m(1-p)^{\tilde{K}} \leq \frac{1}{p} \log n \lesssim \text{val}_{\text{IP}}$ .

**From  $m - F_{\tilde{K}} \lesssim \tilde{K}$  to  $m - F_K \leq K$ .** Finally, using that  $f_t \geq 1$  by Lemma 16 unless  $F_t = m$ , there exists some constant  $C > 0$ , such that for  $K := C\tilde{K}$ ,  $F_K \geq m - K$ , which finishes the proof.  $\blacktriangleleft$

# The Expander Hitting Property When the Sets Are Arbitrarily Unbalanced

## Abstract

Numerous works have studied the probability that a length  $t - 1$  random walk on an expander is confined to a given rectangle  $S_1 \times \dots \times S_t$ , providing both upper and lower bounds for this probability. However, when the densities of the sets  $S_i$  may depend on the walk length (e.g., when all sets are equal and the density is  $1 - 1/t$ ), the currently best known upper and lower bounds are very far from each other. We give an improved confinement lower bound that almost matches the upper bound.

We also study the more general question, of how well random walks fool various classes of test functions. Recently, Golowich and Vadhan proved that random walks on  $\lambda$ -expanders fool *Boolean, symmetric* functions up to a  $O(\lambda)$  error in *total variation distance*, with *no dependence on the labeling bias*. Our techniques extend this result to cases not covered by it, e.g., to functions testing confinement to  $S_1 \times \dots \times S_t$ , where each set  $S_i$  either has density  $\rho$  or  $1 - \rho$ , for arbitrary  $\rho$ .

Technique-wise, we extend Beck’s framework for analyzing what is often referred to as the “flow” of linear operators, reducing it to bounding the entries of a product of  $2 \times 2$  matrices.

## 1 Introduction

Fix a set of vertices  $V = [n]$  and  $t$  subsets  $S_1, \dots, S_t \subseteq V$ . The hitting property of expander graphs [1] says that for a sufficiently good expander graph  $G$  on the set of vertices  $V$ , the probability that for all  $i = 1, \dots, t$  the  $i$ ’th step of a random walk on  $G$  falls inside  $S_i$  is small, and therefore, with a good probability, the walk escapes the confinement  $S_1 \times \dots \times S_t$ . Specifically,

► **Theorem 1** (Expander Hitting Property, based on [10]). *Let  $G = (V, E)$  be a  $\lambda$ -expander. Then, for every sequence of subsets  $S_1, \dots, S_t \subseteq V$  such that  $S_i$  is of density  $\rho_i = |S_i| / |V|$ ,*

$$\Pr_{(v_1, \dots, v_t) \sim \text{RW}_G^t} [\forall i \ v_i \in S_i] \leq \sqrt{\rho_1 \rho_t} \cdot \prod_{i=1}^{t-1} ((1 - \lambda) \sqrt{\rho_i \rho_{i+1}} + \lambda). \quad (1)$$

## 31:2 The Expander Hitting Property When the Sets Are Arbitrarily Unbalanced

We remark that a slightly weaker bound of  $\prod_{i=1}^{t-1} (\sqrt{\rho_i \rho_{i+1}} + \lambda)$  appears in [10]. For the case where all densities  $\rho_i$  are the same  $\rho$ , a bound of  $\rho((1-\lambda)\rho + \lambda)^{t-1}$  appears in [15], and of  $\rho(\rho + \lambda)^{t-1}$  appears in [2]. The bound in the general case (Equation 1) follows by a similar proof, with a slightly more careful analysis. See Subsection 4.1.

However, on a conceptual level, one expects an expander random walk to mimic a truly random walk, each time choosing a vertex uniformly at random independent of all other choices. I.e., ideally, we would have liked a bound stating that the probability of an expander random walk being confined to  $S_1 \times \dots \times S_t$  is roughly the same as the probability of the same event with respect to a walk on the complete graph with self loops (which equals the product of the densities of the sets). Indeed, for the case in which all densities are equal, the following has been proven in [2]:

- **Theorem 2** ([2]). *Let  $G = (V, E)$  be a  $\lambda$ -expander. For every sequence of subsets  $S_1, \dots, S_t \subseteq V$  such that  $S_i$  is of density  $\rho$ ,*
- *If  $\lambda < \rho/6$ , then  $\Pr_{(v_1, \dots, v_t) \sim \text{RW}_G^t} [\forall i v_i \in S_i] \geq \rho \cdot (\rho - 2\lambda)^{t-1}$ .*
  - *If  $\lambda < \rho^2/2$ , then  $\Pr_{(v_1, \dots, v_t) \sim \text{RW}_G^t} [\forall i v_i \in S_i] \geq \rho \cdot (\rho - \lambda)^{t-1}$ .*

How tight are these bounds?

To get a feeling for the upper and lower bounds, let us look at the special case where all densities  $\rho_i$  are the same  $\rho$ . In this case, independent sampling gives the exact answer  $\rho^t$ . The upper bound (Theorem 1) is  $\rho\mu^{t-1}$ , where  $\mu = \rho + (1-\rho)\lambda$ , and

$$|\rho\mu^{t-1} - \rho^t| = \rho(\mu^{t-1} - \rho^{t-1}) = \rho(\mu - \rho) \sum_{j=0}^{t-2} \rho^j \mu^{t-2-j} \leq \rho(1-\rho)\lambda \sum_{j=0}^{t-2} \rho^j \leq \rho \cdot \lambda,$$

where the first equality is because  $\mu \geq \rho$  and the second equality is using  $a^k - b^k = (a-b) \sum_{j=0}^{k-1} a^j b^{k-1-j}$ . We also use  $\mu - \rho = (1-\rho)\lambda$ . In particular the error term is at most  $\lambda$ , and tends to zero when  $\lambda$  tends to 0.

However, for the lower bound (Theorem 2), for any  $\lambda$  we have

$$\begin{aligned} |\rho^t - \rho(\rho - \lambda)^{t-1}| &= \rho(\rho^{t-1} - (\rho - \lambda)^{t-1}) = \rho\lambda \sum_{j=0}^{t-2} \rho^{t-2-j} (\rho - \lambda)^j \\ &\geq \rho\lambda \rho^{t-2} \sum_{j=0}^{t-2} (\rho - \lambda)^j \approx \rho^{t-1} \frac{\lambda}{\lambda + \frac{1}{t}}. \end{aligned}$$

Thus, when  $\lambda$  is some small constant, independent of  $t$  and  $\rho = 1 - 1/t$ , the difference between independent sampling and the lower bound is  $\rho^{t-1} \frac{\lambda}{\lambda + 1/t} \approx 1/e$ . Therefore, even for arbitrarily small  $\lambda$ , if we let  $t$  grow to infinity and we let the density  $\rho$  depend on  $t$ , there is a constant gap between the independent sampling probability and the lower bound! Thus, a natural question is: can we find a better lower bound that matches the independent probability? In this work we prove:

- **Theorem 3** (New confinement lower-bound). *Let  $G = (V, E)$  be a  $\lambda$ -expander, and let  $S_1, \dots, S_t \subseteq V$  be each of density  $\rho$  for some  $\rho^1$ . If  $\lambda \leq \frac{\rho^2}{3}$ , then*

$$\Pr_{(v_1, \dots, v_t) \sim \text{RW}_G^t} [\forall i v_i \in S_i] \geq \rho \cdot (\rho - \lambda(1 - \rho^2))^{t-1}.$$

<sup>1</sup> In fact, we prove the theorem under more general conditions, see Section 4

This bound is close to the independent sampling probability:

$$\begin{aligned} |\rho^t - \rho \cdot (\rho - \lambda(1 - \rho^2))^{t-1}| &= \rho^t - \rho \cdot (\rho - \lambda(1 - \rho^2))^{t-1} \\ &= \rho \cdot \lambda(1 - \rho^2) \sum_{j=0}^{t-2} \rho^j (\rho - \lambda(1 - \rho^2))^{t-2-j} \\ &\leq \lambda \cdot \rho(1 - \rho^2) \cdot \sum_{j=0}^{\infty} \rho^j = \lambda \cdot \rho(1 + \rho) \leq 2\rho\lambda. \end{aligned}$$

Therefore, for any  $\lambda$ , if we let  $t$  grow to infinity, and even if we let the density  $\rho$  depend on  $t$ , the distance between the independent probability ( $\rho^t$ ) and the lower bound is at most  $2\lambda$  (instead of an absolute constant before).

## 1.1 Further Results

Expander random walks are typically used as a randomness-efficient way of generating a uniform-like sequence of vertices  $v_1, \dots, v_t$ . In most applications, the walk is used to “fool” a test function  $f$ . For example, we may think of the confinement problem when all sets  $S_i$  are the same set  $S$ , as taking an expander with  $|V|$  vertices, which we label with 0 or 1 according to membership in  $S$ . We set  $f$  to be the AND function. We compare the probability that  $f(x_1, \dots, x_t)$  evaluates to 1 when  $x_1, \dots, x_t$  are the labels obtained from a random walk on the graph (which is the quantity we want to bound) with the probability that  $f$  evaluates to 1 when the labels are obtained from vertices chosen uniformly at random (which is a known quantity and equals the density  $S$  raised to the power of  $t$ ). We wish to claim these two quantities are close to each other.

More generally, we say a test function  $f : \mathbb{Z}_{d'}^t \rightarrow \mathbb{Z}_d$  is  $\varepsilon$ -fooled by expander random walks if for every  $\lambda$ -expander graph  $G = (V, E)$  and every labeling  $\text{val} : V \rightarrow \mathbb{Z}_{d'}$ ,  $d_{TV}(f(\text{val}(\text{RW}_G^t)), f(\text{val}(\text{Ind}_V^t))) \leq \varepsilon$ , where

- $\text{RW}_G^t$  is the distribution obtained by taking a length  $t - 1$  random walk on  $G$ . That is, we sample  $v_1 \in V$  uniformly at random. Then, for  $i = 2, \dots, t$  sample  $v_i$  uniformly at random from the neighbours of  $v_{i-1}$ .  $f(\text{val}(\text{RW}_G^t))$  is the distribution of  $f(\text{val}(v_1), \dots, \text{val}(v_t))$  when  $(v_1, \dots, v_t)$  is sampled from  $\text{RW}_G^t$ .
- $\text{Ind}_V^t$  is the distribution obtained by sampling  $v_1, \dots, v_t \in V$  uniformly at random. Note that  $\text{Ind}_V^t = \text{RW}_J^t$  where  $J$  is the complete graph on  $V$  with self loops.  $f(\text{val}(\text{Ind}_V^t))$  is the distribution of  $f(\text{val}(v_1), \dots, \text{val}(v_t))$  when  $(v_1, \dots, v_t)$  is sampled from  $\text{Ind}_V^t$ .

Cohen et al. [4] proved that all Boolean *symmetric* functions  $f$  are fooled by expander random walks with up to a  $O(\lambda/\sqrt{\rho_{\min}})$  error in total variation distance, where  $\rho_{\min} = \min\{\rho_0, \rho_1\}$ , and  $\rho_b$  is the *density* of  $b$ , i.e., that fraction of vertices with label  $b$ . Thus, even in the symmetric Boolean case, the error bound of [4] is  $O(\lambda)$  only when  $\rho_{\min}$  is bounded from below by some constant. When  $\rho_{\min}$  is allowed to depend on  $t$ , the error bound of [4] may weaken as  $t$  increases.

A remarkable recent result of Golowich and Vadhan [8] significantly strengthened and extended the results of [4], and using new techniques managed to eliminate the dependence on the bias. That is, they prove that all symmetric *Boolean* functions are fooled by expander random walks with up to  $O(\lambda)$  error in total variation distance, where the constant hidden in the Big-O notation is absolute and does not depend on  $\rho_{\min}$ .

Notice that [8] implies that for confinement to a single set (which is a symmetric function) the difference between independent sampling and RW sampling is bounded by  $O(\lambda)$ , even when the density  $\rho$  may depend on  $t$ . Thus, it implies that Theorem 2, which gives constant

## 31:4 The Expander Hitting Property When the Sets Are Arbitrarily Unbalanced

difference for  $\rho = 1 - 1/t$ , is not tight. In this regard, Theorem 3 gives a bound that replaces the  $O(\lambda)$  difference guaranteed by [8] with a more precise bound (that is in particular at most  $2\lambda$ ).

Let us now discuss whether there are functions for which the [8] bound does not guarantee an  $O(\lambda)$  error, while our technique does.

A first candidate for such a problem is the confinement problem for  $S_1 \times \dots \times S_t$ , where the sets  $S_i$  might be different, and are only guaranteed to all have the same density. Theorem 3 still guarantees the same bound, whereas [8] seems to not apply, because the function is not symmetric anymore. However, the Golowich-Vadhan result might be modified to cover this case as well, by using one fixed set, and adding corresponding permutation operators to the expanders, making them directed (which is still fine for [8]).<sup>2</sup>

However, using our techniques, we prove the following. Let  $\mathbf{1}_S(i)$  equal 1 if  $i \in S$  and 0 otherwise. Then,  $\mathbf{1}_{S_1} \otimes \dots \otimes \mathbf{1}_{S_t}$  equals one if the input is confined to  $S_1 \times \dots \times S_t$  and zero otherwise. We prove:

► **Theorem 4.** *Let  $G = (V, E)$  be a  $\lambda$ -expander where  $\lambda \leq 1/3$ , and  $t \geq 1$  an integer. Let  $S_1, \dots, S_t \subseteq V$  be a sequence of subsets such that the largest subset also has the maximal variance. Then,*

$$d_{TV}(\mathbf{1}_{S_1} \otimes \dots \otimes \mathbf{1}_{S_t}(\text{RW}_G^t), \mathbf{1}_{S_1} \otimes \dots \otimes \mathbf{1}_{S_t}(\text{Ind}_V^t)) < 3\rho_{\max} \cdot \lambda,$$

where  $\rho_{\max}$  is the density of the largest subset.

In particular,

► **Corollary 5.** *Let  $G = (V, E)$  be a  $\lambda$ -expander where  $\lambda \leq 1/3$ , and  $t \geq 1$  an integer. Let  $S \subseteq V$  be a subset of density  $\rho$ , and suppose  $S_1, \dots, S_t \subseteq V$  are subsets such that for every  $i$ ,  $S_i = S$  or  $S_i = \bar{S}$ . Then,*

$$d_{TV}(\mathbf{1}_{S_1} \otimes \dots \otimes \mathbf{1}_{S_t}(\text{RW}_G^t), \mathbf{1}_{S_1} \otimes \dots \otimes \mathbf{1}_{S_t}(\text{Ind}_V^t)) < 3\rho \cdot \lambda.$$

Notice that these functions are not symmetric, and therefore the results of [8] do not apply to them, while our techniques still work.

We also use similar techniques to analyze the extent to which the sum function modulo  $d$  is fooled by expander random walks on graphs with arbitrarily biased labelings, and prove that it is fooled with an  $O(\sqrt{d} \cdot \lambda)$  error in total variation distance, with no dependence on the labeling bias. We prove:

► **Theorem 6.** *For integers  $t \geq 1$ ,  $d' \geq 2$ , and  $d \geq 2$  let  $G = (V, E)$  be a  $\lambda$ -expander where  $\lambda \leq 1/6$ . Let  $\text{val} : V \rightarrow \mathbb{Z}_{d'}$  be any labeling. Then*

$$d_{TV}(\text{Sum}_d(\text{val}(\text{RW}_G^t)), \text{Sum}_d(\text{val}(\text{Ind}_V^t))) \leq 5\sqrt{d} \cdot \lambda.$$

The  $O(\sqrt{d} \cdot \lambda)$  error term also follows from the work of [8] on width- $d$  permutation branching programs, using different techniques.

Additionally, we prove a bound on the bias of a labeling in terms of the density of the most frequent label,  $\rho_{\max}$ . This is in contrast to previous bias-dependent result (e.g [8] for symmetric functions over  $\mathbb{Z}_d$  with  $d > 2$ ) where the total variation bound degrades with  $\rho_{\min}$ , rather than  $1 - \rho_{\max}$  (and notice that always  $\rho_{\min} \leq 1 - \rho_{\max}$ ). This dependence is more

---

<sup>2</sup> We thank the anonymous referee for bringing this to our attention.

resilient as it can tolerate very rare labels, as long as the most common label is not too dominant. We think that this observation could potentially serve as an incentive to shift the bias dependence in previous works from the smallest label weight to the largest. Specifically, we prove,

► **Proposition 7.** *For a prime  $p$ , let  $\text{val} : [n] \rightarrow \mathbb{Z}_p$  be a labeling that assigns label  $a \in \mathbb{Z}_p$  to  $\rho_a$  fraction of the vertices, and denote  $\rho_{\max} = \max_a \rho_a$ . Then, for every non-trivial character  $\chi$  of  $\mathbb{Z}_p$ ,  $\text{bias}_\chi(\text{val}) \leq \sqrt{1 - \left(1 - \cos \frac{2\pi}{p}\right) (1 - \rho_{\max})}$ , where  $\text{bias}_\chi(\text{val}) \stackrel{\text{def}}{=} \left| \mathbb{E}_{i \in [n]} \chi(\text{val}(i)) \right|$ .*

We also point out that our proofs apply even if the graph is different for each of the  $t$  steps, as long as it is a  $\lambda$ -expander at each step. The same property holds in previous works as well, e.g [8].

## 1.2 The Technique

We extend the techniques of Gillman [6], Healy [9] and Beck [3], that established a framework for analyzing what is often referred to as the “flow” of linear operators. The flow of a linear operator  $T$  from the linear subspace  $V_2$  to the linear subspace  $V_1$  is the quantity  $\|\Pi_1 T \Pi_2\|$  where  $\Pi_i$  is the projection operator onto  $V_i$ . In our context,  $V_1$  and  $V_2$  will be either the line spanned by the all-ones vector (The “parallel space”), or its orthogonal complement (The “perpendicular space”).

Let  $G$  also denote the transition matrix of a  $\lambda$ -expander graph, and let  $P$  denote the projection matrix on the set  $S$ . That is,  $P$  is the diagonal matrix satisfying  $P[v, v] = 1$  if  $v \in S$  and 0 otherwise. The probability that a length  $t$  random walk on  $G$  never escapes  $S$  can be expressed algebraically as  $\mathbf{1}^T (PG)^{t-1} P \mathbf{1}$ , where we denote  $\mathbf{1} = \frac{1}{\sqrt{|V|}} (1, \dots, 1)^T$ .

One way to analyze this expression is to decompose the probability distribution at each of the  $t$  steps to its parallel and perpendicular components. The parallel component is identical to the independent sampling case, while the perpendicular component is shrunk by a factor of  $\lambda$  after each step on  $G$ . The above approach underlies many results in the field, and, in particular, the expander Chernoff bound [6, 9]. Beck [3] simplified the analysis by defining a  $2 \times 2$  “flow” matrix for a linear operator  $T$ . The  $i, j$ ’th entry of the flow matrix is the flow of  $T$  from  $V_j$  to  $V_i$ , where  $V_i$  and  $V_j$  are either the perpendicular space or the parallel space. This notation reduced the problem of bounding quantities like  $|\mathbf{1}^T T \mathbf{1}|$  to bounding the  $[0, 0]$  entry of a  $2 \times 2$  matrix with non-negative entries. In this language, the expression  $\mathbf{1}^T (PG)^{t-1} P \mathbf{1}$  is the flow of the operator  $(PG)^{t-1} P$  from the parallel space to itself. For more details about the flow framework see Section 3.

[2] proved their confinement probability lower bound by giving simultaneous upper and lower bounds on flows between the perpendicular and parallel spaces. However, they did it explicitly and specifically for the confinement problem with equal density at each step, and obtained sub-optimal bounds. In this paper we analyze flows emerging from confinement problems (and additional problems) using the  $2 \times 2$  flow matrix notation. As a result, we achieve simpler terms that are easier to follow and generalize to a broader setting of confinement problems with varying densities. These terms also indicate how to improve upon previous work (even when all densities are equal).

## 1.3 Summary and Discussion

As mentioned before, several total variation bounds in previous works depend on the labeling bias, namely on the weights  $\rho_b$  that are induced by a labeling. Cohen et al. [4] proved that all Boolean symmetric functions are fooled by expander random walks with up to a  $O(\lambda/\sqrt{\rho_{\min}})$  error in total variation distance.

Recently, Golowich and Vadhan [8], significantly strengthened and extended these results using new techniques, and in some cases managed to eliminate the dependence on the bias. In particular, they prove that for the Boolean case, all symmetric functions are fooled by expander random walks with up to  $O(\lambda)$  error in total variation distance, where the constant hidden in the Big-O notation is absolute.

For the non-Boolean case much less is known:

- For *symmetric* functions defined on  $\mathbb{Z}_d^t$ , Golowich and Vadhan prove an  $O\left(\left(\frac{d}{\rho_{\min}}\right)^{O(d)} \cdot \lambda\right)$  total-variation bound where  $\rho_{\min} = \min_a \rho_a$ , and  $\rho_a$  is the density of label  $a$ . Notice that in this bound there is a dependence on  $\rho_{\min}$ . It is an intriguing open problem whether the dependence on the bias is necessary.
- Golowich and Vadhan [8] also show that expander random walks fool width- $w$  *permutation* branching programs up to a  $O(\lambda)$  error in  $\ell_2$  distance, and a  $O(\sqrt{w} \cdot \lambda)$  error in total variation distance, a bound that does not depend on the bias of the labeling. Notice that this bias-independent bound also holds for non-symmetric functions, as long as they are computed by a low-width permutation branching program.

In this work we add another example where the error bound does not depend on the labeling bias. We show for the confinement problem, when the set of maximal density  $\rho(S)$  is also of maximal variance (the variance is  $\sqrt{\rho(S)(1-\rho(S))}$ ), the error bound is  $O(\lambda)$  regardless of the densities. Note that this case is not symmetric. We also improve the lower bound for the symmetric case, as previously discussed.

There are many open problems left.

- First, and foremost, is it possible that all symmetric functions over  $\Sigma^t$  are  $O_{|\Sigma|}(\lambda)$  fooled by random-walks? For  $\Sigma = \{0, 1\}$  [8] gave an affirmative answer, but the general case is left open.
- What other non-symmetric functions are fooled by random-walks without a dependence on the bias? [8] showed all small-width permutation branching programs are such. We added the confinement test functions when all sets have the same variance. What other functions have this property?
- As alluded to by Proposition 7, we think that for many functions the parameter dominating the bias-dependent error is  $1 - \rho_{\max}$  rather than  $\rho_{\min}$ . For example, the bias-dependent bound for *any* confinement test function (Proposition 29) is  $O\left(\frac{\lambda}{1-\rho_{\max}}\right)$  where  $\rho_{\max}$  is the density of the largest set. It would be interesting to examine previous results and see if the error terms can be correspondingly amended.

The paper is organized as follows: In Section 2 we give some preliminaries and background, and introduce our notations. In Section 3 we review Beck's flow framework [3] and extend it. In Section 4 we prove Theorem 3, and prove analogous lower bounds in the general setting of varying sets and densities. In Section 5 we study fooling confinement test functions, and in particular prove Theorem 4. In Section 6, we prove Theorem 6 using our techniques. The proof for Proposition 7 appears in the full version of this paper [14].

## 2 Preliminaries

### Notation

For any positive integer  $d$ , let  $\mathbb{Z}_d$  denote the group of integers modulo  $d$ , and  $[d] = \{1, \dots, d\}$ . We define the  $\ell_1$ -norm of a vector  $x \in \mathbb{F}^n$  as  $\|x\|_1 = \sum_i |x_i|$ , and its  $\ell_2$ -norm as  $\|x\| = \sqrt{\sum_i |x_i|^2}$ . For a field  $\mathbb{F} = \mathbb{R}$  or  $\mathbb{C}$ , let  $\mathbf{1}_n = (1/\sqrt{n}, \dots, 1/\sqrt{n}) \in \mathbb{F}^n$  denote the normalized

all-ones vector. When  $n$  is clear from context we simply write  $\mathbf{1}$ . For a matrix  $M \in \mathbb{F}^{n \times n}$ , the operator norm of  $M$  is given by  $\max_{x \in \mathbb{F}^n \setminus \{0\}} \|Mx\| / \|x\|$ . For  $M \in \mathbb{C}^{n \times n}$ , its conjugate transpose is denoted as  $M^*$ . For two real matrices  $L, M \in \mathbb{R}^{n \times n}$ , the notation  $L \leq_{e.w} M$  stands for entry-wise inequality

A symmetric matrix  $W \in [0, 1]^{n \times n}$  is an undirected random walk matrix on  $n$  vertices if the columns and rows of  $W$  sum to 1, which implies that  $W_{j,i} = W_{i,j}$  represents the transition probability between vertex  $i$  and  $j$ , or vice versa. In this context,  $I_n$  denotes the  $n \times n$  identity matrix, and  $J_n = \mathbf{1}_n \mathbf{1}_n^T$  represents a matrix with all entries being  $1/n$ . When the dimension is clear from the context, we use the notations  $I$  and  $J$  respectively. Notably,  $J_n$  is the random walk matrix for a complete graph on  $n$  vertices with self-loops. For a sequence of matrices  $M_1, \dots, M_t$ , we denote  $\prod_{i=1}^t M_i = M_t \cdot M_{t-1} \cdot \dots \cdot M_1$ .

We often use the decomposition  $\mathbb{F}^n = \mathbf{V}_0 \oplus \mathbf{V}_1$  where  $\mathbf{V}_0 = \text{Span}\{\mathbf{1}\}$  is the subspace of  $\mathbb{F}^n$  spanned of the all ones vector, and  $\mathbf{V}_1 = \mathbf{V}_0^\perp$  is its orthogonal complement. We define  $\Pi_0$  as the projection operator onto  $\mathbf{V}_0$ , noting that  $\Pi_0 = J_n$ , and  $\Pi_1$  as the projection on  $\mathbf{V}_1$ , noting that  $\Pi_1 = I_n - J_n$ . For a vector  $x \in \mathbb{F}^n$  we define  $x^\parallel = \Pi_0 x$  and  $x^\perp = \Pi_1 x$ .

For two probability distributions  $p_1$  and  $p_2$  over a finite sample space  $\Omega$ , their total variation distance is  $d_{TV}(p_1, p_2) = \frac{1}{2} \cdot \sum_{s \in \Omega} |p_1(s) - p_2(s)|$ .

### The Information Theoretic XOR-Lemma

The characters of the group  $\mathbb{Z}_d$  are the maps  $\chi_b(a) = \omega_d^{b \cdot a}$  for  $b = 0, \dots, d - 1$ , where  $\omega_d = e^{\frac{2\pi i}{d}}$ . Let  $\mathbb{C}^{\mathbb{Z}_d}$  denote the vector space of all complex valued function on  $\mathbb{Z}_d$ , equipped with the inner product  $\langle h, g \rangle = \sum_{a \in \mathbb{Z}_d} h(a) \overline{g(a)}$ .

The information theoretic XOR-Lemma [7] relates the total variation distance between two distributions over  $\mathbb{Z}_d$  to the heaviest Fourier coefficient of their difference, also called the maximum bias.

► **Lemma 8** (Based on [7]). *For any two distributions  $p_1, p_2$  over  $\mathbb{Z}_d$ :  $d_{TV}(p_1, p_2) \leq \frac{\sqrt{d}}{2} \cdot \max_{b \in \mathbb{Z}_d} |\langle \chi_b, p_1 - p_2 \rangle|$ .*

The proof, based on [7], appears in the full version of this paper.

### Expanders

For a regular, undirected graph  $G = (V, E)$  on  $n$  vertices, the random walk matrix is the normalized adjacency matrix. The *spectral expansion* is defined as the second largest eigenvalue of the graph's random walk matrix in absolute value, namely  $\lambda(G) = \max_{x, y \perp \mathbf{1}} \frac{|\langle x, Gy \rangle|}{\|x\| \cdot \|y\|} = \max_{x \perp \mathbf{1}} \frac{\|Gx\|}{\|x\|}$ , where the maximum is over all non-zero  $x, y \in \mathbb{R}^n$  which are orthogonal to the all-ones vector, and by abuse of notation  $G$  also denotes the random walk matrix of the graph  $G$ . We say  $G$  is a  $\lambda$ -expander if  $\lambda(G) = \lambda$ . For a  $\lambda$ -expander  $G$ , let  $A = \frac{1}{\lambda}(G - J)$ . Since the all-ones vector is an eigenvector of both  $G$  and  $J$  with eigenvalue 1, it follows that  $A$  is zero on the parallel space  $\text{Span}\{\mathbf{1}\}$ . Additionally,  $\|Ax\| = \|Ax^\perp + Ax^\parallel\| = \frac{1}{\lambda} \cdot \|Gx^\perp\| \leq \|x^\perp\| \leq \|x\|$ . This implies a valuable decomposition  $G = J + \lambda A$  where the symmetric “error matrix”  $A$  is zero on the parallel space, and  $\|A\| \leq 1$ . Another useful decomposition follows by setting  $E = \frac{1}{\lambda}(G - (1 - \lambda) \cdot J)$ . One can easily verify that  $E$  acts like the identity on the parallel space, and that the orthogonal space is  $E$ -invariant. Thus, for every vector  $x$  we have

$$\|Ex\|^2 = \|Ex^\parallel\|^2 + \|Ex^\perp\|^2 \leq \|x^\parallel\|^2 + \frac{1}{\lambda} \|Gx^\perp\|^2 \leq \|x\|^2.$$

This gives rise to the decomposition  $G = (1 - \lambda)J + \lambda E$  where the symmetric “error matrix”  $E$  satisfies  $\|E\| \leq 1$ .

### 3 Flow

Let  $\mathbb{F}$  be either  $\mathbb{C}$  or  $\mathbb{R}$ . We decompose  $\mathbb{F}^n = \mathbf{V}_0 \oplus \mathbf{V}_1$  where  $\mathbf{V}_0$  is the span of the all-ones vector  $\text{Span}\{\mathbf{1}\}$  (the “parallel” space) and  $\mathbf{V}_1 = \mathbf{V}_0^\perp$  its orthogonal complement (the “orthogonal” space). Let  $\Pi_0$  be the projection operator onto  $\mathbf{V}_0$ , and  $\Pi_1$  the projection onto  $\mathbf{V}_1$ .

Throughout this work we study linear operators  $T : \mathbb{F}^n \rightarrow \mathbb{F}^n$  by examining  $\|\Pi_{b_1} T \Pi_{b_2}\|$  for  $b_1, b_2 \in \{0, 1\}$ . Intuitively, this can be understood as the “flow of mass” from  $\mathbf{V}_{b_2}$  to  $\mathbf{V}_{b_1}$  under the linear operator  $T$ . To study the flow of a linear operator, we extend upon the techniques introduced by Gillman, Healy, and Beck, using the notation and claims of Beck [3]. These were used mostly in the context of the expander Chernoff bound [6, 9].

► **Definition 9** (The Flow Matrix). *Let  $T : \mathbb{F}^n \rightarrow \mathbb{F}^n$  be any linear operator. Then the flow matrix of  $T$ , denoted  $\tilde{T}$ , is the  $2 \times 2$  non-negative matrix defined by*

$$\tilde{T} = \begin{pmatrix} \|\Pi_0 T \Pi_0\| & \|\Pi_0 T \Pi_1\| \\ \|\Pi_1 T \Pi_0\| & \|\Pi_1 T \Pi_1\| \end{pmatrix}$$

► **Example 10.** Let  $G$  be the random walk operator of a  $\lambda$ -expander graph. Then

$$\tilde{G} \leq_{e.w} \begin{pmatrix} 1 & 0 \\ 0 & \lambda \end{pmatrix}$$

where  $\leq_{e.w}$  stands for entry-wise inequality.

To see this, apply the decomposition  $G = J + \lambda A$  where  $\|A\| \leq 1$  and  $A$  is zero on the parallel space. That is,  $A\Pi_0 = \Pi_0 A = 0$ . We then have

- (i)  $\|\Pi_0 G \Pi_0\| = \|\Pi_0 J \Pi_0\| = \|J\| = 1$ ,
- (ii)  $\|\Pi_0 G \Pi_1\| = \|\Pi_0 (J + \lambda A) \Pi_1\| = \|\Pi_0 J \Pi_1 + \lambda \Pi_0 A \Pi_1\| = 0$ ,
- (iii) By symmetry  $\|\Pi_1 G \Pi_0\| = 0$ .
- (iv) Finally,  $\|\Pi_1 G \Pi_1\| = \lambda \|\Pi_1 A \Pi_1\| \leq \lambda$ .

By submultiplicativity and subadditivity of the operator norm, we have the following submultiplicativity property of the flow operator:

► **Claim 11** ([3]). For every linear operators  $L, M : \mathbb{F}^n \rightarrow \mathbb{F}^n$ , we have  $\widetilde{L \cdot M} \leq_{e.w} \tilde{L} \cdot \tilde{M}$ .

Proof. Let  $i, j \in \{0, 1\}$ . Recall that  $\Pi_0 = J$  and  $\Pi_1 = I - J$ , and thus  $\Pi_0 + \Pi_1 = I$ . We have

$$\begin{aligned} \widetilde{L \cdot M}[i, j] &= \|\Pi_i L M \Pi_j\| = \|\Pi_i L (\Pi_0 + \Pi_1) M \Pi_j\| \leq \|\Pi_i L \Pi_0 M \Pi_j\| + \|\Pi_i L \Pi_1 M \Pi_j\| \\ &\leq \|\Pi_i L \Pi_0\| \cdot \|\Pi_0 M \Pi_j\| + \|\Pi_i L \Pi_1\| \cdot \|\Pi_1 M \Pi_j\| \\ &= \tilde{L}[i, 0] \cdot \tilde{M}[0, j] + \tilde{L}[i, 1] \cdot \tilde{M}[1, j] = \tilde{L} \cdot \tilde{M}[i, j]. \end{aligned} \quad \triangleleft$$

Typically, the primary technical tool utilized for analyzing flow matrices consists of the following bound, which generally hold for non-negative  $2 \times 2$  matrices.

► **Lemma 12** ([3]). *If  $A = \begin{pmatrix} a & b \\ c & d \end{pmatrix} \geq_{e.w} 0$  with  $a \geq 1$  and  $d < 1$ , then*

$$A^t[0, 0] \leq a \cdot \left( a + \frac{bc}{1-d} \right)^{t-1}$$

**Proof.** By induction on  $t$ . The base case  $t = 1$  is clear. Assume for  $1, \dots, t-1$  and let us prove for  $t$ . We have the following recurrence relation

$$A^t[0, 0] = A^{t-1}[0, 0] \cdot A[0, 0] + \sum_{j=0}^{t-2} A^j[0, 0] \cdot A[0, 1] \cdot A[1, 1]^{t-2-j} \cdot A[1, 0]$$

where  $j$  goes over the last time the path was at vertex 0 before taking the final step. As  $A[i, j] \geq 0$  and  $A[0, 0] \geq 1$ , we see that  $A^{k_2}[0, 0] \geq A^{k_1}[0, 0]$  for all  $k_2 \geq k_1$ . Hence,

$$\begin{aligned} A^t[0, 0] &= A^{t-1}[0, 0] \cdot a + \sum_{j=0}^{t-2} A^j[0, 0] \cdot bc \cdot d^{t-2-j} \\ &\leq A^{t-1}[0, 0] \left( a + bc \sum_{j=0}^{\infty} d^j \right) \leq A^{t-1}[0, 0] \left( a + \frac{bc}{1-d} \right) \end{aligned}$$

The proof is complete by applying the induction hypothesis.  $\blacktriangleleft$

A simple way to generalize this lemma to the case where  $A[0, 0] > A[1, 1]$  but not necessarily  $A[0, 0] > 1$  is as follows.

► **Lemma 13.** *If  $A = \begin{pmatrix} a & b \\ c & d \end{pmatrix} \geq_{e.w} 0$  with  $a > d$  then  $A^t[0, 0] \leq a \cdot \left( a + \frac{bc}{a-d} \right)^{t-1}$ .*

**Proof.** Write  $A = a \cdot \begin{pmatrix} 1 & \frac{b}{a} \\ \frac{c}{a} & \frac{d}{a} \end{pmatrix}$ . Then, by the previous lemma

$$A^t[0, 0] \leq a^t \cdot \left( 1 + \frac{\frac{b}{a} \cdot \frac{c}{a}}{1 - \frac{d}{a}} \right)^{t-1} = a \cdot \left( a + \frac{bc}{a-d} \right)^{t-1}. \quad \blacktriangleleft$$

► **Remark 14.** Note that the lemma above is not tight when  $a$  is small. Indeed,  $A^t[0, 0]$  decreases with  $a$ , while the bound of Lemma 13 blows up when  $a$  approaches  $d$ . We do not try to optimize the bound for  $d$  close to  $a$ . Also, it would be nice to have a generalization of this lemma for the case of possibly different  $A_1, \dots, A_t$ .

► **Lemma 15.** *If  $A = \begin{pmatrix} a & b \\ c & d \end{pmatrix} \geq_{e.w} 0$  with  $a > d$ . Then for all  $t \geq 2$ ,*

$$A^t[0, 0] - (A[0, 0])^t \leq \frac{abc}{a-d} \cdot \sum_{k=0}^{t-2} a^k \left( a + \frac{bc}{a-d} \right)^{t-k-2}$$

**Proof.** For every integer  $k \geq 1$   $x^k - y^k = (x-y) \cdot \sum_{i=0}^{k-1} x^i y^{k-i-1}$ . Using this and Lemma 13, we see that

$$\begin{aligned} A^t[0, 0] - (A[0, 0])^t &\leq a \cdot \left( a + \frac{bc}{a-d} \right)^{t-1} - a^t = a \left( \left( a + \frac{bc}{a-d} \right)^{t-1} - a^{t-1} \right) \\ &= a \cdot \frac{bc}{a-d} \cdot \sum_{k=0}^{t-2} a^k \left( a + \frac{bc}{a-d} \right)^{t-k-2} \quad \blacktriangleleft \end{aligned}$$

► **Lemma 16.** *For an integer  $t \geq 1$ , Let  $M_1, \dots, M_t$  be a sequence of  $n \times n$  matrices. Then*

$$\left| \mathbf{1}^T \left( \prod_{i=1}^t M_i \right) \mathbf{1} - \mathbf{1}^T \left( \prod_{i=1}^t \Pi_0 M_i \right) \mathbf{1} \right| \leq \left( \prod_{i=1}^t \widetilde{M}_i \right) [0, 0] - \left( \prod_{i=1}^t \widetilde{M}_i [0, 0] \right).$$

### 31:10 The Expander Hitting Property When the Sets Are Arbitrarily Unbalanced

**Proof.** Writing  $M_i = \Pi_0 M_i + \Pi_1 M_i$  we have

$$\mathbf{1}^T \left( \prod_{i=1}^t M_i \right) \mathbf{1} = \sum_{b \in \{0,1\}^t} \mathbf{1}^T \prod_{i=1}^t (\Pi_{b_i} M_i) \mathbf{1} = \sum_{b \in \{0,1\}^{t-1}} \mathbf{1}^T \Pi_0 M_t \left( \prod_{i=1}^{t-1} (\Pi_{b_i} M_i) \right) \cdot \mathbf{1}$$

Since  $\mathbf{1}^T \Pi_1 = 0$ . To complete the proof let  $LHS = \left| \mathbf{1}^T \prod_{i=1}^t M_i \mathbf{1} - \mathbf{1}^T \left( \prod_{i=1}^t (\Pi_0 M_i) \right) \mathbf{1} \right|$ . Then,

$$\begin{aligned} LHS &= \left| \sum_{\substack{b \in \{0,1\}^{t-1} \\ b \neq 0^t}} \mathbf{1}^T \Pi_0 M_t \left( \prod_{i=1}^{t-1} (\Pi_{b_i} M_i) \right) \cdot \mathbf{1} \right| \\ &\leq \sum_{\substack{b \in \{0,1\}^{t-1} \\ b \neq 0^t}} \left| \mathbf{1}^T \Pi_0 M_t \left( \prod_{i=1}^{t-1} (\Pi_{b_i} M_i) \right) \cdot \Pi_0 \mathbf{1} \right| \leq \sum_{\substack{b \in \{0,1\}^{t-1} \\ b \neq 0^t}} \left\| \Pi_0 M_t \left( \prod_{i=1}^{t-1} (\Pi_{b_i} M_i) \right) \cdot \Pi_0 \right\| \\ &= \sum_{\substack{b \in \{0,1\}^{t-1} \\ b \neq 0^t}} \left\| \Pi_0 M_t \Pi_{b_{t-1}} \left( \prod_{i=2}^{t-1} (\Pi_{b_i} M_i \Pi_{b_{i-1}}) \right) \cdot \Pi_{b_1} M_1 \Pi_0 \right\| \\ &\leq \sum_{\substack{b \in \{0,1\}^{t-1} \\ b \neq 0^t}} \left\| \Pi_0 M_t \Pi_{b_{t-1}} \right\| \cdot \prod_{i=2}^{t-1} \left\| \Pi_{b_i} M_i \Pi_{b_{i-1}} \right\| \left\| \Pi_{b_1} M_1 \Pi_0 \right\| \\ &= \sum_{\substack{b \in \{0,1\}^{t-1} \\ b \neq 0^t}} \widetilde{M}_t[0, b_{t-1}] \left( \prod_{i=2}^{t-1} \widetilde{M}_i[b_i, b_{i-1}] \right) \widetilde{M}_1[b_1, 0] = \left( \prod_{i=1}^t \widetilde{M}_i \right) [0, 0] - \prod_{i=1}^t \widetilde{M}_i[0, 0]. \quad \blacktriangleleft \end{aligned}$$

► **Lemma 17.** Let  $A_1, \dots, A_t$  be a sequence of non-negative  $2 \times 2$  matrices such that for all  $i$ ,  $A_i \leq_{e.w} A$  for some  $2 \times 2$  matrix  $A$ . Then

$$\left( \prod_{i=1}^t A_i \right) [0, 0] - \prod_{i=1}^t (A_i[0, 0]) \leq A^t[0, 0] - (A[0, 0])^t.$$

**Proof.** We have

$$\begin{aligned} \left( \prod_{i=1}^t A_i \right) [0, 0] - \prod_{i=1}^t (A_i[0, 0]) &= \sum_{\substack{b \in \{0,1\}^{t-1} \\ b \neq 0^t}} A_t[0, b_{t-1}] \left( \prod_{i=2}^{t-1} A_i[b_i, b_{i-1}] \right) A_1[b_1, 0] \\ &\leq \sum_{\substack{b \in \{0,1\}^{t-1} \\ b \neq 0^{t-1}}} A[0, b_{t-1}] \left( \prod_{i=2}^{t-1} A[b_{i+1}, b_i] \right) A[b_1, 0] = A^t[0, 0] - (A[0, 0])^t. \quad \blacktriangleleft \end{aligned}$$

We now proceed to establish techniques for proving flow lower bounds. While these concepts were introduced specifically for the confinement problem with the same set density in [2], we extend them to general linear operators and use the flow matrix notation.

► **Lemma 18** (Flow Progress). *For linear operators  $T_1, \dots, T_t$ ,*

$$\widetilde{\prod_{i=1}^t T_i[0, 0]} \geq \widetilde{T_t[0, 0]} \cdot \widetilde{\prod_{i=1}^{t-1} T_i[0, 0]} - \widetilde{T_t[0, 1]} \cdot \widetilde{\prod_{i=1}^{t-1} T_i[1, 0]} \quad (2)$$

$$\widetilde{\prod_{i=1}^t T_i[1, 0]} \leq \widetilde{T_t[1, 0]} \cdot \widetilde{\prod_{i=1}^{t-1} T_i[0, 0]} + \widetilde{T_t[1, 1]} \cdot \widetilde{\prod_{i=1}^{t-1} T_i[1, 0]} \quad (3)$$

**Proof.** We have

$$\begin{aligned} \widetilde{\prod_{i=1}^t T_i[0, 0]} &= \left\| \Pi_0 \prod_{i=1}^t T_i \Pi_0 \right\| = \left\| \Pi_0 (T_t \Pi_0 + T_t \Pi_1) \prod_{i=1}^{t-1} T_i \Pi_0 \right\| \\ &\geq \left\| \Pi_0 T_t \Pi_0 \right\| \cdot \left\| \prod_{i=1}^{t-1} T_i \Pi_0 \right\| - \left\| \Pi_0 T_t \Pi_1 \right\| \cdot \left\| \prod_{i=1}^{t-1} T_i \Pi_0 \right\| \\ &= \widetilde{T_t[0, 0]} \cdot \widetilde{\prod_{i=1}^{t-1} T_i[0, 0]} - \widetilde{T_t[0, 1]} \cdot \widetilde{\prod_{i=1}^{t-1} T_i[1, 0]} \end{aligned}$$

and

$$\begin{aligned} \widetilde{\prod_{i=1}^t T_i[1, 0]} &= \left\| \Pi_1 \prod_{i=1}^t T_i \Pi_0 \right\| = \left\| \Pi_1 (T_t \Pi_0 + T_t \Pi_1) \prod_{i=1}^{t-1} T_i \Pi_0 \right\| \\ &\leq \left\| \Pi_1 T_t \Pi_0 \right\| \cdot \left\| \prod_{i=1}^{t-1} T_i \Pi_0 \right\| + \left\| \Pi_1 T_t \Pi_1 \right\| \cdot \left\| \prod_{i=1}^{t-1} T_i \Pi_0 \right\| \\ &= \widetilde{T_t[1, 0]} \cdot \widetilde{\prod_{i=1}^{t-1} T_i[0, 0]} + \widetilde{T_t[1, 1]} \cdot \widetilde{\prod_{i=1}^{t-1} T_i[1, 0]} \quad \blacktriangleleft \end{aligned}$$

► **Definition 19** (Flow sequence). *For a sequence of linear operators  $T_1, \dots, T_t$ , the flow sequence is defined recursively such that  $c_1 = \frac{\widetilde{T_1[0, 0]}}{\widetilde{T_1[1, 0]}}$  and for  $k \geq 1$*

$$c_{k+1} = \frac{\widetilde{T_{k+1}[0, 0]} \cdot c_k - \widetilde{T_{k+1}[0, 1]}}{\widetilde{T_{k+1}[1, 0]} \cdot c_k + \widetilde{T_{k+1}[1, 1]}}$$

The constants  $c_i$  emerge from recursively dividing Equation 2 of Lemma 18 by Equation 3, as demonstrated by the following lemmas. Therefore, from an intuitive perspective, the constants  $c_i$  in the definition above can be thought of as a lower bound on the ratio between the mass preserved inside the parallel space after the  $i$ -th step and the mass lost to its orthogonal complement.

We remark that the smaller  $\widetilde{T_i[0, 1]}$ ,  $\widetilde{T_i[1, 1]}$  are taken relative to  $\widetilde{T_i[0, 0]}$  and  $\widetilde{T_i[1, 0]}$ , the larger sequence elements will become. In all of our use cases, each operator  $T_i$  includes a step on a  $\lambda$ -expander graph  $G$ . Thus, as we shall later see, we can make  $\widetilde{T_i[0, 1]}$  and  $\widetilde{T_i[1, 1]}$  smaller by taking the expansion parameter  $\lambda$  smaller, and hence the sequence elements larger. Specifically, in all instances considered in this work, the constants  $c_i$  are strictly positive. Therefore, for the remainder of this section, we proceed with the assumption that the provided linear operators  $T_1, \dots, T_t$  are such that their corresponding flow sequence elements are positive.

## 31:12 The Expander Hitting Property When the Sets Are Arbitrarily Unbalanced

► **Lemma 20.** *Let  $T_1, \dots, T_t$  be linear operators with a positive flow sequence. Then, for all  $k = 1, \dots, t$  it holds that  $\widetilde{\prod_{i=1}^k T_i[0, 0]} \geq c_k \cdot \widetilde{\prod_{i=1}^k T_i[1, 0]}$ .*

**Proof.** By induction on  $k$ . For  $k = 1$  the claim holds by definition. For the induction step, assume that  $\widetilde{\prod_{i=1}^k T_i[0, 0]} \geq c_k \cdot \widetilde{\prod_{i=1}^k T_i[1, 0]}$ . Plugging the induction hypothesis into Equation 2 see that

$$\begin{aligned} \widetilde{\prod_{i=1}^{k+1} T_i[0, 0]} &\geq \widetilde{T_{k+1}[0, 0]} \cdot \widetilde{\prod_{i=1}^k T_i[0, 0]} - \widetilde{T_{k+1}[0, 1]} \cdot \widetilde{\prod_{i=1}^k T_i[1, 0]} \\ &\geq \left( \widetilde{T_{k+1}[0, 0]} - \frac{\widetilde{T_{k+1}[0, 1]}}{c_k} \right) \widetilde{\prod_{i=1}^{k-1} T_i[0, 0]}. \end{aligned}$$

Similarly, plugging the induction hypothesis into Equation 3,

$$\begin{aligned} \widetilde{\prod_{i=1}^{k+1} T_i[1, 0]} &\leq \widetilde{T_{k+1}[1, 0]} \cdot \widetilde{\prod_{i=1}^k T_i[0, 0]} + \widetilde{T_{k+1}[1, 1]} \cdot \widetilde{\prod_{i=1}^k T_i[1, 0]} \\ &\leq \left( \widetilde{T_{k+1}[1, 0]} + \frac{\widetilde{T_{k+1}[1, 1]}}{c_k} \right) \widetilde{\prod_{i=1}^k T_i[0, 0]}. \end{aligned}$$

Combining these we obtain

$$\begin{aligned} \widetilde{\prod_{i=1}^{k+1} T_i[0, 0]} &\geq \frac{\left( \widetilde{T_{k+1}[0, 0]} - \frac{\widetilde{T_{k+1}[0, 1]}}{c_k} \right) \widetilde{\prod_{i=1}^k T_i[0, 0]}}{\left( \widetilde{T_{k+1}[1, 0]} + \frac{\widetilde{T_{k+1}[1, 1]}}{c_k} \right)} \widetilde{\prod_{i=1}^k T_i[0, 0]} \\ &= \left( \frac{\widetilde{T_{k+1}[0, 0]} \cdot c_k - \widetilde{T_{k+1}[0, 1]}}{\widetilde{T_{k+1}[1, 0]} \cdot c_k + \widetilde{T_{k+1}[1, 1]}} \right) \widetilde{\prod_{i=1}^k T_i[0, 0]} = c_{k+1} \cdot \widetilde{\prod_{i=1}^k T_i[0, 0]} \quad \blacktriangleleft \end{aligned}$$

Hence we have the following corollary

► **Corollary 21.** *For all  $k = 1, \dots, t$  we have*

$$\widetilde{\prod_{i=1}^k T_i[0, 0]} \geq \widetilde{T_1[0, 0]} \cdot \prod_{i=2}^k \left( \widetilde{T_i[0, 0]} - \frac{\widetilde{T_i[0, 1]}}{c_{i-1}} \right)$$

**Proof.** By induction on  $k$ . For  $k = 1$  the product on the right hand side is empty and the equality trivially holds. For the induction step, Using Equation 2, the previous claim, and the induction hypothesis,

$$\begin{aligned} \widetilde{\prod_{i=1}^{k+1} T_i[0, 0]} &\geq \widetilde{T_{k+1}[0, 0]} \cdot \widetilde{\prod_{i=1}^k T_i[0, 0]} - \widetilde{T_{k+1}[0, 1]} \cdot \widetilde{\prod_{i=1}^k T_i[1, 0]} \\ &\geq \left( \widetilde{T_{k+1}[0, 0]} - \frac{\widetilde{T_{k+1}[0, 1]}}{c_k} \right) \widetilde{\prod_{i=1}^k T_i[0, 0]} \geq \widetilde{T_1[0, 0]} \cdot \prod_{i=2}^{k+1} \left( \widetilde{T_i[0, 0]} - \frac{\widetilde{T_i[0, 1]}}{c_{i-1}} \right). \quad \blacktriangleleft \end{aligned}$$

## 4 Expander Hitting Property Revised

We use the following notations. For a set  $S_i \subseteq [n]$  we define its density as  $\rho_i = |S_i|/n$  and its variance as  $\sigma_i = \sqrt{\rho_i(1-\rho_i)}$ . We let  $P_i$  be the projection matrix on the set  $S_i$ . That is,  $P_i$  is the diagonal matrix satisfying  $P_i[v, v] = 1$  if  $v \in S_i$  and 0 otherwise.  $G$  is the random walk operator of the graph  $G$ .

### 4.1 Confinement Probability Upper-bounds

We begin with the hitting property for sets with possibly different densities. In [10] the authors give the bound  $\prod_{j=1}^{t-1} (\sqrt{\rho_j \rho_{j+1}} + \lambda)$ , which corresponds to  $\|P_t G \dots G P_1\|$  rather than  $\mathbf{1}^T P_t G \dots G P_1 \mathbf{1}$ . However, we observe that this loss is not necessary.

► **Proposition 22** (Expander Hitting Property). *Let  $G = (V, E)$  be a  $\lambda$ -expander. Then, for every sequence of subsets  $S_1, \dots, S_t \subseteq V$  such that  $S_i$  is of density  $\rho_i$ ,*

$$\Pr_{(v_1, \dots, v_t) \sim \text{RW}_G^t} [\forall i \ v_i \in S_i] \leq \sqrt{\rho_1 \rho_t} \cdot \prod_{i=1}^{t-1} ((1-\lambda)\sqrt{\rho_i \rho_{i+1}} + \lambda).$$

**Proof.** First note that for all  $i$ ,  $\|P_i J P_{i+1}\| = \sqrt{\rho_i \rho_{i+1}}$ . Indeed,

$$\|P_i J P_{i+1}\| = \|P_i \mathbf{1} (P_{i+1} \mathbf{1})^T\| = \|P_i \mathbf{1}\| \cdot \|P_{i+1} \mathbf{1}\| = \sqrt{\rho_i \rho_{i+1}}$$

Decomposing  $G = (1-\lambda)J + \lambda E$  with  $\|E\| \leq 1$ , we find that

$$\begin{aligned} \|P_i G P_{i+1}\| &= \|(1-\lambda) \cdot P_i J P_{i+1} + \lambda \cdot P_i E P_{i+1}\| \\ &\leq (1-\lambda) \cdot \|P_i J P_{i+1}\| + \lambda \leq (1-\lambda)\sqrt{\rho_i \rho_{i+1}} + \lambda. \end{aligned}$$

Let  $u = (1/n, \dots, 1/n) \in \mathbb{R}^n$  be the uniform vector. Expressing the probability linear-algebraically we obtain

$$\begin{aligned} \Pr_{(v_1, \dots, v_t) \sim \text{RW}_G^t} [\forall i \ v_i \in S_i] &= \mathbf{1}^T P_t \left( \prod_{i=1}^{t-1} G P_i \right) \mathbf{1} = \mathbf{1}^T P_t \prod_{i=1}^{t-1} (P_{i+1} G P_i) P_1 \mathbf{1} \\ &= \left\| P_t \prod_{i=1}^{t-1} (P_{i+1} G P_i) P_1 u \right\|_1 \leq \sqrt{\rho_t \cdot n} \cdot \left\| \prod_{i=1}^{t-1} (P_{i+1} G P_i) P_1 u \right\| \\ &\leq \sqrt{\rho_t \cdot n} \cdot \left\| \prod_{i=1}^{t-1} (P_{i+1} G P_i) \right\| \cdot \|P_1 u\| = \sqrt{\rho_t \cdot n} \cdot \left\| \prod_{i=1}^{t-1} (P_{i+1} G P_i) \right\|_2 \cdot \sqrt{\frac{\rho_1}{n}} \\ &\leq \sqrt{\rho_t \rho_1} \cdot \prod_{i=1}^{t-1} \|(P_{i+1} G P_i)\| \leq \sqrt{\rho_1 \rho_t} \cdot \prod_{i=1}^{t-1} ((1-\lambda)\sqrt{\rho_i \rho_{i+1}} + \lambda), \end{aligned}$$

where we use  $P_i^2 = P_i$ , and the first inequality is Cauchy-Schwartz, noting that after multiplying by  $P_t$ , the resulting vector has at most  $\rho_t \cdot n$  non-zero entries. ◀

### 4.2 Confinement Probability Lower-bounds

As explained in the introduction, previous lower bounds do not give an  $O(\lambda)$  bound on the error term comparing with the independent sampling case. In this section, we give a tighter lower bound that, in particular, is  $O(\lambda)$ -close to the probability of the same confinement event but with independently chosen samples.

## 31:14 The Expander Hitting Property When the Sets Are Arbitrarily Unbalanced

Expressing the probability linear-algebraically we find that

$$\Pr_{(v_1, \dots, v_t) \sim \text{RW}_G^t} [\forall i v_i \in S_i] = \mathbf{1}^T \prod_{i=2}^t (P_i G) P_1 \mathbf{1} = \left\| \Pi_0 \prod_{i=1}^t (P_i G) \Pi_0 \right\| = \widetilde{\prod_{i=1}^t (P_i G)[0, 0]}.$$

Therefore, we see that this quantity is applicable to bounds via the lower-bound part of the flow framework. Consider the sequence of linear operators  $P_1 G, \dots, P_t G$  with corresponding flow sequence  $c_1, \dots, c_t$ . It follows from Corollary 21 that

$$\widetilde{\prod_{i=1}^t (P_i G)[0, 0]} \geq \widetilde{P_1 G}[0, 0] \cdot \prod_{i=2}^{k+1} \left( \widetilde{P_i G}[0, 0] - \frac{\widetilde{P_i G}[0, 1]}{c_{i-1}} \right)$$

Hence, our next objective is to bound the entries of  $\widetilde{P_i G}$ , and find lower bounds on the constants  $c_1, \dots, c_t$ .

► **Lemma 23.** *For all  $i = 1, \dots, t$  we have  $\widetilde{P_i G} \leq_{e.w} \begin{pmatrix} \rho_i & \lambda \sigma_i \\ \sigma_i & \lambda \end{pmatrix}$  where the first column holds with equality.*

**Proof.** First, observe that

$$\widetilde{P_i G}[0, 0] = \|\Pi_0 P_i G \Pi_0\| = \|\mathbf{1} \mathbf{1}^T P_i G \mathbf{1} \mathbf{1}^T\| = \|\mathbf{1} \mathbf{1}^T P_i \mathbf{1} \mathbf{1}^T\| = |\mathbf{1}^T P_i \mathbf{1}| = \rho_i$$

Following the discussion about the norm of rank-one matrices, we see that for  $b \in \{0, 1\}$ ,

$$\|\Pi_b P_i G \Pi_b\| = \|\Pi_b P_i G \mathbf{1} \mathbf{1}^T\| = \|\Pi_b P_i \mathbf{1}\| \cdot \|\mathbf{1}\| = \|\Pi_b P_i \mathbf{1}\|.$$

Using this, we find that

$$\widetilde{P_i G}[0, 0]^2 + \widetilde{P_i G}[1, 0]^2 = \|\Pi_0 P_i \mathbf{1}\|^2 + \|\Pi_1 P_i \mathbf{1}\|^2 = \|P_i \mathbf{1}\|^2 = \rho_i$$

hence  $\widetilde{P_i G}[1, 0] = \sqrt{\rho_i(1 - \rho_i)} = \sigma_i$ .

Now, let us write  $G = J + \lambda A$  where  $\|A\| \leq 1$  and  $A$  is zero on the parallel space. Then

$$\begin{aligned} \widetilde{P_i G}[0, 1] &= \|\Pi_0 P_i G \Pi_1\| = \|\Pi_0 P_i (J + \lambda A) \Pi_1\| = \lambda \|\Pi_0 P_i A \Pi_1\| = \lambda \|\Pi_0 P_i \Pi_1 A \Pi_1\| \\ &\leq \lambda \|\Pi_0 P_i \Pi_1\| = \lambda \sigma_i \end{aligned}$$

where we have used that  $\Pi_1 A = A$  in the last equality. In the inequality we observe that  $\widetilde{P_i G}[1, 0] = \|\Pi_1 P_i G \Pi_0\| = \|\Pi_1 P_i \Pi_0\| = \|\Pi_0 P_i \Pi_1\|$ . Hence we substitute  $\|\Pi_0 P_i \Pi_1\| = \sigma_i$ .

For the last entry we have  $\widetilde{P_i G}[1, 1] = \|\Pi_1 P_i G \Pi_1\| = \lambda \|\Pi_1 P_i A \Pi_1\| \leq \lambda$ . ◀

By definition of flow sequence (Definition 19) and the previous lemma, we obtain:

► **Corollary 24** (Flow sequence lower-bound). *Let  $G = (V, E)$  be a  $\lambda$ -expander, and let  $S_1, \dots, S_t \subseteq V$  be a sequence of subsets such that  $S_i$  is of density  $\rho_i$  and variance  $\sigma_i$ . Let  $c_1, \dots, c_t$  be the flow sequence of the linear operators  $P_1 G, \dots, P_t G$ . Then  $c_1 = \frac{\rho_1}{\sigma_1}$  and:  $c_{i+1} \geq \frac{c_i \rho_{i+1} - \lambda \sigma_{i+1}}{c_i \sigma_{i+1} + \lambda}$ .*

► **Corollary 25.** *Let  $G = (V, E)$  be a  $\lambda$ -expander, and let  $S_1, \dots, S_t \subseteq V$  be a sequence of subsets such that  $S_i$  is of density  $\rho_i$ . Let  $c_1, \dots, c_t$  be the flow sequence of the linear operators  $P_1 G, \dots, P_t G$ . Suppose that  $\lambda$  is sufficiently small so that  $c_i > 0$  for all  $i$ . Then,*

$$\Pr_{(v_1, \dots, v_t) \sim \text{RW}_G^t} [\forall i v_i \in S_i] \geq \rho_1 \cdot \prod_{i=2}^t \left( \rho_i - \frac{\sigma_i}{c_{i-1}} \lambda \right).$$

Next, we demonstrate how distinct conditions imposed on  $\lambda$  lead to varying bounds on the flow sequence, consequently leading to corresponding confinement probability lower bounds.

► **Lemma 26.** *Let  $G = (V, E)$  be a  $\lambda$ -expander, and let  $S_1, \dots, S_t \subseteq V$  be a sequence of subsets each of density  $\rho_i$ . If for all  $i$ ,  $\lambda < \frac{1}{6} \cdot \sigma_i \sigma_{i+1} \cdot \frac{1+\rho_{i+1}}{1-\rho_{i+1}}$ , then*

$$\Pr_{(v_1, \dots, v_t) \sim \text{RW}_G^t} [\forall i \ v_i \in S_i] \geq \rho_1 \cdot \prod_{i=2}^t \left( \rho_i - 2 \cdot \frac{\sigma_i}{\sigma_{i-1}} \lambda \right).$$

**Proof.** By Corollary 25, it suffices to prove that under our assumption on  $\lambda$ , we have  $c_i \geq \sigma_i/2$  for all  $i$ .

For  $i = 1$ , we clearly have  $c_1 = \frac{\rho_1}{\sigma_1} = \frac{\sigma_1}{1-\rho_1} > \sigma_1$ . Now, assume that  $c_i \geq \sigma_i/2$ . Using Corollary 24, we find that

$$\begin{aligned} c_{i+1} - \frac{\sigma_{i+1}}{2} &\geq \frac{c_i \rho_{i+1} - \lambda \sigma_{i+1}}{c_i \sigma_{i+1} + \lambda} - \frac{\sigma_{i+1}}{2} = \frac{c_i (2\rho_{i+1} - \sigma_{i+1}^2) - 3\lambda \sigma_{i+1}}{2(c_i \sigma_{i+1} + \lambda)} \\ &= \frac{c_i \rho_{i+1} (1 + \rho_{i+1}) - 3\lambda \sigma_{i+1}}{2(c_i \sigma_{i+1} + \lambda)} \end{aligned}$$

Therefore it suffices to show  $3\lambda \sigma_{i+1} \leq c_i \rho_{i+1} (1 + \rho_{i+1})$ . Indeed, using our assumption on  $\lambda$  and the induction hypothesis,

$$\lambda < \frac{1}{6} \cdot \sigma_i \sigma_{i+1} \cdot \frac{1 + \rho_{i+1}}{1 - \rho_{i+1}} \leq \frac{c_i}{3} \cdot \frac{\sigma_{i+1}}{1 - \rho_{i+1}} (1 + \rho_{i+1}) = \frac{c_i}{3} \cdot \frac{\rho_{i+1}}{\sigma_{i+1}} (1 + \rho_{i+1}). \quad \blacktriangleleft$$

The first part of Theorem 2 follows as a special case of the lemma above, in which all sets have the same density. Indeed, in this case, our assumption on  $\lambda$  becomes  $\lambda < \frac{1}{6} \cdot \sigma^2 \cdot \frac{1+\rho}{1-\rho} = \frac{1}{6} \rho (1+\rho)$ .

► **Lemma 27.** *Let  $G = (V, E)$  be a  $\lambda$ -expander, and let  $S_1, \dots, S_t \subseteq V$  be a sequence of subsets each of density  $\rho_i$ . If for all  $i$ ,  $\lambda < \frac{1}{2} \cdot \frac{\sigma_i}{\sigma_{i+1}} \cdot \rho_{i+1}^2$ , then*

$$\Pr_{(v_1, \dots, v_t) \sim \text{RW}_G^t} [\forall i \ v_i \in S_i] \geq \rho_1 \cdot \prod_{i=2}^t \left( \rho_i - \frac{\sigma_i}{\sigma_{i-1}} \lambda \right).$$

**Proof.** By Corollary 25 it suffices to prove that under our assumption on  $\lambda$ , we have  $c_i \geq \sigma_i$  for all  $i$ . The proof is by induction on  $i$ . For  $i = 1$  we clearly have  $c_1 = \sqrt{\frac{\rho_1}{1-\rho_1}} = \frac{\sigma_1}{1-\rho_1} > \sigma_1$ . Assume that  $c_i \geq \sigma_i$ . By Corollary 24, we have

$$\begin{aligned} \frac{c_{i+1}}{\sigma_{i+1}} &\geq \frac{c_i \rho_{i+1} - \lambda \sigma_{i+1}}{c_i \sigma_{i+1}^2 + \lambda \sigma_{i+1}} = \frac{c_i \rho_{i+1} + c_i \sigma_{i+1}^2 + \lambda \sigma_{i+1} - c_i \sigma_{i+1}^2 - 2\lambda \sigma_{i+1}}{c_i \sigma_{i+1}^2 + \lambda \sigma_{i+1}} \\ &= 1 + \frac{c_i (\rho_{i+1} - \sigma_{i+1}^2) - 2\lambda \sigma_{i+1}}{c_i \sigma_{i+1}^2 + \lambda \sigma_{i+1}} = 1 + \frac{c_i \rho_{i+1}^2 - 2\lambda \sigma_{i+1}}{c_i \sigma_{i+1}^2 + \lambda \sigma_{i+1}} \end{aligned}$$

Therefore it suffices to show  $2\lambda \sigma_{i+1} \leq c_i \rho_{i+1}^2$ . Indeed, using our assumption on  $\lambda$  and the induction hypothesis,  $\lambda < \frac{1}{2} \cdot \frac{\sigma_i}{\sigma_{i+1}} \cdot \rho_{i+1}^2 \leq \frac{c_i \rho_{i+1}^2}{2\sigma_{i+1}}$ .  $\blacktriangleleft$

The second part of Theorem 2 follows as a special case of the lemma above, in which all sets have the same density. In that case our assumption on  $\lambda$  becomes  $\lambda < \frac{\rho^2}{2}$ .

The following lemma refines the bound given in [2] and also allows for arbitrary densities with decreasing variances.

## 31:16 The Expander Hitting Property When the Sets Are Arbitrarily Unbalanced

► **Lemma 28.** *Let  $G = (V, E)$  be a  $\lambda$ -expander, and let  $S_1, \dots, S_t \subseteq V$  be a sequence of subsets, each of density  $\rho_i$  and variance  $\sigma_i$ . Suppose that  $\sigma_1 \geq \dots \geq \sigma_t$ . If  $\lambda \leq \frac{\sigma_i}{\sigma_{i-1}} \cdot \frac{\rho_{i-1}\rho_i}{4}$  for all  $i$ , then  $\Pr_{(v_1, \dots, v_t) \sim \text{RW}_G^t} [\forall i \ v_i \in S_i] \geq \rho_1 \cdot \prod_{i=2}^t (\rho_i - \lambda(1 - \rho_{i-1}^2))$ .*

**Proof.** Using our assumption that  $\sigma_i \geq \sigma_{i+1}$  for all  $i = 1, \dots, t$ , it suffices to prove that  $\sigma_i \leq (1 - \rho_i^2)c_i$  for all  $i$ . Indeed, in that case, by Corollary 25 we obtain

$$\begin{aligned} \Pr_{(v_1, \dots, v_t) \sim \text{RW}_G^t} [\forall i \ v_i \in S_i] &\geq \rho_1 \cdot \prod_{i=2}^t \left( \rho_i - \frac{\sigma_i}{c_{i-1}} \lambda \right) \geq \rho_1 \cdot \prod_{i=2}^t \left( \rho_i - \frac{\sigma_{i-1}}{c_{i-1}} \lambda \right) \\ &\geq \rho_1 \cdot \prod_{i=2}^t (\rho_i - (1 - \rho_{i-1}^2) \cdot \lambda) \end{aligned}$$

Now, we prove by induction on  $i$  that  $\sigma_i \leq (1 - \rho_i^2)c_i$ . For  $i = 1$  we clearly have

$$(1 - \rho_1^2)c_1 = (1 - \rho_1^2) \sqrt{\frac{\rho_1}{1 - \rho_1}} = (1 + \rho_1) \sqrt{\rho_1(1 - \rho_1)} > \sigma_1.$$

Assume that  $\sigma_{i-1} \leq (1 - \rho_{i-1}^2)c_{i-1}$ . Then, by Corollary 24

$$\begin{aligned} \frac{1 - \rho_i^2}{\sigma_i} \cdot c_i &\geq \frac{1 - \rho_i^2}{\sigma_i} \cdot \frac{c_{i-1}\rho_i - \lambda\sigma_i}{c_{i-1}\sigma_i + \lambda} = \frac{c_{i-1}\sigma_i(1 + \rho_i) - \lambda(1 - \rho_i^2)}{c_{i-1}\sigma_i + \lambda} \\ &= \frac{c_{i-1}\sigma_i + \lambda + c_{i-1}\sigma_i\rho_i - \lambda(2 - \rho_i^2)}{c_{i-1}\sigma_i + \lambda} = 1 + \frac{c_{i-1}\sigma_i\rho_i - \lambda(2 - \rho_i^2)}{c_{i-1}\sigma_i + \lambda} \end{aligned}$$

where the second equality uses the identity  $\rho(1 - \rho^2)/\sigma = \sigma(1 + \rho)$ . Thus, it remains to prove that  $c_{i-1}\sigma_i\rho_i \geq \lambda(2 - \rho_i^2)$ . Indeed, on the one hand, by our induction hypothesis

$$c_{i-1}\sigma_i\rho_i \geq \frac{\sigma_{i-1}\sigma_i\rho_i}{(1 - \rho_{i-1}^2)} = \frac{\sigma_i}{\sigma_{i-1}} \cdot \frac{\rho_{i-1}\rho_i}{1 + \rho_{i-1}}$$

using the identity  $\rho/\sigma = \sigma/(1 - \rho)$ .

On the other hand, our assumption on  $\lambda$  implies that

$$\lambda \leq \frac{\sigma_i}{\sigma_{i-1}} \cdot \frac{\rho_{i-1}\rho_i}{4} \leq \frac{\sigma_i}{\sigma_{i-1}} \cdot \frac{\rho_{i-1}\rho_i}{(1 + \rho_{i-1})(2 - \rho_i^2)}$$

and the proof is complete. ◀

When all subsets have the same density  $\rho$ , we observe that in fact  $(1 + \rho)(2 - \rho^2) \leq 3$ . Therefore, Theorem 3 follows.

## 5 Fooling Non-Symmetric Confinement Functions

The class of  $t$ -wise confinement functions  $\text{Conf}_n^{\otimes t} \subseteq \{f : [n]^t \rightarrow \{0, 1\}\}$  is defined as  $\text{Conf}_n^{\otimes t} = \{\mathbf{1}_{S_1} \otimes \dots \otimes \mathbf{1}_{S_t} \mid S_1, \dots, S_t \subseteq [n]\}$  where  $\mathbf{1}_S(i)$  equals 1 if  $i \in S$  and 0 otherwise. This class of functions is sometimes referred to as cut-tensors or cut-functions. Generally, confinement functions are not symmetric, hence a density-independent total variation bound for this class is not implied by the previous work of [8]. Nevertheless, we show that the class of confinement functions where the sets have equal variances, is  $O(\lambda)$ -fooled by expander random walks regardless of the densities.

We begin with a density-dependent bound which holds for all confinement functions.

► **Proposition 29.** For  $t \geq 1$ , let  $G = (V, E)$  be a  $\lambda$ -expander, and let  $S_1, \dots, S_t$  be a sequence of subsets such that  $S_i$  is of density  $\rho_i$ . Let  $\rho_{\max} = \max_i \rho_i$ . Then,

$$d_{TV}(\mathbf{1}_{S_1} \otimes \dots \otimes \mathbf{1}_{S_t}(\text{RW}_G^t), \mathbf{1}_{S_1} \otimes \dots \otimes \mathbf{1}_{S_t}(\text{Ind}_V^t)) \leq \left(1 + \frac{1 - \rho_{\max}^{t-1}}{1 - \rho_{\max}}\right) \cdot \lambda.$$

**Proof.** First, observe that we may assume  $t \geq 2$ , as for  $t = 1$  the distributions are identical and claim trivially holds. The decomposition  $G = J + \lambda A$  with  $\|A\| \leq 1$  implies that  $\|G - J\| \leq \lambda$ . Also, recall that  $\|JP_i J\| = \rho_i$ . Let  $LHS$  be left-hand size of the inequality in the proposition. Expressing  $LHS$  linear-algebraically, we see that  $LHS = \left| \mathbf{1}^T \prod_{i=1}^t (P_i G) \mathbf{1} - \mathbf{1}^T \prod_{i=1}^t (P_i J) \mathbf{1} \right|$  and

$$\begin{aligned} LHS &\leq \left\| \prod_{i=1}^t (P_i G) - \prod_{i=1}^t (P_i J) \right\| \leq \sum_{k=1}^t \left\| \left( \prod_{j=k+1}^t (P_j G) \right) P_k (G - J) \left( \prod_{j=1}^{k-1} (P_j J) \right) \right\| \\ &\leq \sum_{k=1}^t \|(G - J)\| \left\| \left( \prod_{j=1}^{k-1} (P_j J) \right) \right\| \leq \sum_{k=1}^t \lambda \cdot \prod_{j=1}^{k-1} \rho_j \leq \lambda \left( 1 + \sum_{\ell=0}^{t-2} \rho_{\max}^\ell \right) \\ &= \lambda \cdot \left( 1 + \frac{1 - \rho_{\max}^{t-1}}{1 - \rho_{\max}} \right) \end{aligned} \quad \blacktriangleleft$$

Note that, in particular, the proof implies a  $t\lambda$  bound for all confinement functions. A similar hybrid idea was used in [12] to derive a generalization of the expander mixing lemma for length- $t$  random walks.<sup>3</sup> Proposition 29 shows that when the all the sets are small, say, of density which is bounded from above by some constant  $\alpha$ , the corresponding confinement function is  $O_\alpha(\lambda)$ -fooled.

We proceed with the main result for this section.

**Proof of Theorem 4.** First, observe that we may assume  $t \geq 2$ , as for  $t = 1$  the distributions are identical and claim trivially holds. Let  $LHS$  be left-hand side of the inequality in the proposition. Let  $n = |V|$  and identify  $V$  with  $[n]$  arbitrarily. Let us denote by  $\rho_i$  the density of  $S_i$ , and by  $\sigma_i$  its variance, so that  $\rho_{\max} = \max_i \rho_i$ . Further denote  $\sigma_{\max} = \max_i \sigma_i$ .

We consider two cases according to the relationship between  $\rho_{\max}$  and  $\lambda$ . Assume first that  $\rho_{\max} \leq 2\lambda$ . Applying the upper-bound Proposition 22 we find that

$$\begin{aligned} LHS &= \left| \Pr_{(v_1, \dots, v_t) \sim \text{RW}_G^t} [\forall i v_i \in S_i] - \prod_{i=1}^t \rho_i \right| \leq \sqrt{\rho_1 \rho_t} \cdot \prod_{i=1}^{t-1} (\lambda + (1 - \lambda) \sqrt{\rho_i \rho_{i+1}}) \\ &\leq \rho_{\max} (\lambda + \rho_{\max} (1 - \lambda))^{t-1} \leq \rho_{\max} (3\lambda)^{t-1} \leq 3 \cdot \rho_{\max} \cdot \lambda \end{aligned}$$

For the first inequality we observe that both terms inside the absolute value are non-negative, hence the magnitude of their difference is bounded by the maximal one. Additionally, the upper-bound provided by the hitting property as presented in Proposition 22 applies to both terms. Then, we bound  $\lambda + 2\lambda(1 - \lambda) \leq 3\lambda$ . The last inequality holds under our assumption that  $\lambda \leq 1/3$  and  $t \geq 2$ .

<sup>3</sup> In fact their result is more general, as it goes beyond random walk on expander graphs. Their “splittable-mixing lemma” holds for what they call “ $\lambda$ -splittable structures”, which are subsets of  $[n]^t$  that admit certain high-dimensional expansion properties.

### 31:18 The Expander Hitting Property When the Sets Are Arbitrarily Unbalanced

Now, Assume that  $\rho_{\max} \geq 2\lambda$ . For  $i = 1, \dots, t$ , let  $P_i$  be the  $n \times n$  projection matrix on the set  $S_i$ . That is,  $P_i$  is the diagonal matrix satisfying  $P_i[v, v] = 1$  if  $v \in S_i$  and 0 otherwise. We have the following entry-wise bounds on the flow matrices:  $\tilde{P}_i \leq_{e.w} \begin{pmatrix} \rho_i & \sigma_i \\ \sigma_i & 1 \end{pmatrix}$  where all entries except for the right bottom are equality. To see this, consider that

$$\|\Pi_0 P_i \Pi_0\| = \|J P_i J\| = \|\mathbf{1} \mathbf{1}^T P_i \mathbf{1} \mathbf{1}^T\| = |\mathbf{1}^T P_i \mathbf{1}| = \rho_i.$$

Moreover, for  $b \in \{0, 1\}$  we have

$$\|\Pi_b P_i \Pi_0\| = \|\Pi_b P_i \mathbf{1} \mathbf{1}^T\| = \|\Pi_b P_i \mathbf{1}\| \cdot \|\mathbf{1}\| = \|\Pi_b P_i \mathbf{1}\|.$$

Since  $\|P_i \mathbf{1}\| = \sqrt{\sum_{i \in S_i} \frac{1}{n}} = \sqrt{\rho_i}$ , we have

$$\|\Pi_1 P_i \Pi_0\| = \|\Pi_1 P_i \mathbf{1}\| = \sqrt{\|P_i \mathbf{1}\|^2 - \|\Pi_0 P_i \mathbf{1}\|^2} = \sqrt{\rho_i(1 - \rho_i)} = \sigma_i.$$

By symmetry we also have  $\|\Pi_1 P_i \Pi_0\| = \sigma_i$ . Finally, we bound  $\|\Pi_1 P_i \Pi_1\| \leq \|\Pi_1\|^2 \|P_i\| \leq 1$ .

Let  $\sigma_{\max} = \max_i \sigma_i$ , and recall that by assumption  $\sigma_{\max} = \sqrt{\rho_{\max}(1 - \rho_{\max})}$ . Through utilizing the submultiplicativity of the flow operator (Claim 11) and Example 10, we find that  $\tilde{G}P_i \leq_{e.w} \begin{pmatrix} \rho_i & \sigma_i \\ \lambda \sigma_i & \lambda \end{pmatrix} \leq_{e.w} A$  for  $A \stackrel{\text{def}}{=} \begin{pmatrix} \rho_{\max} & \sigma_{\max} \\ \lambda \sigma_{\max} & \lambda \end{pmatrix}$ . Now, expressing the total variation distance linear algebraically, we have

$$\begin{aligned} LHS &= \left| \Pr_{(v_1, \dots, v_t) \sim \text{RW}_G^t} [\forall i v_i \in S_i] - \prod_{i=1}^t \rho_i \right| = \left| \mathbf{1}^T \prod_{i=2}^t (P_i G) P_1 \mathbf{1} - \mathbf{1}^T \prod_{i=2}^t (P_i J) P_1 \mathbf{1} \right| \\ &= \left| \mathbf{1}^T \prod_{i=1}^t (G P_i) \mathbf{1} - \mathbf{1}^T \prod_{i=1}^t (J P_i) \mathbf{1} \right| = \left| \mathbf{1}^T \prod_{i=1}^t (G P_i) \mathbf{1} - \mathbf{1}^T \prod_{i=1}^t (\Pi_0 G P_i) \mathbf{1} \right| \\ &\leq \left( \prod_{i=1}^t \tilde{G}P_i \right) [0, 0] - \left( \prod_{i=1}^t \tilde{G}P_i [0, 0] \right) \\ &\leq A^t [0, 0] - (A[0, 0])^t \end{aligned}$$

Where the first inequality is by Lemma 16, and the second is by Lemma 17 Using Lemma 15 we obtain the bound

$$\begin{aligned} A^t [0, 0] - (A[0, 0])^t &\leq \frac{\lambda \rho_{\max} \sigma_{\max}^2}{\rho_{\max} - \lambda} \cdot \sum_{k=0}^{t-2} \rho_{\max}^k \left( \rho_{\max} + \frac{\lambda \sigma_{\max}^2}{\rho_{\max} - \lambda} \right)^{t-k-2} \\ &= \frac{\lambda \rho_{\max}^2 (1 - \rho_{\max})}{\rho_{\max} - \lambda} \cdot \sum_{k=0}^{t-2} \rho_{\max}^k \left( \rho_{\max} + \frac{\lambda \rho_{\max} (1 - \rho_{\max})}{\rho_{\max} - \lambda} \right)^{t-k-2} \\ &\leq 2\rho_{\max} \cdot \lambda \cdot (1 - \rho_{\max}) \sum_{k=0}^{t-2} \rho_{\max}^k (\rho_{\max} + \rho_{\max} (1 - \rho_{\max}))^{t-k-2} \\ &\leq 2\rho_{\max} \cdot \lambda \cdot (1 - \rho_{\max}) \sum_{k=0}^{\infty} \rho_{\max}^k = 2\rho_{\max} \cdot \lambda, \end{aligned}$$

where in the second inequality we have used that  $\rho_{\max}/(\rho_{\max} - \lambda) \leq 2$  and  $\lambda/(\rho_{\max} - \lambda) \leq 1$  under our assumption that  $\rho_{\max} \geq 2\lambda$ .  $\blacktriangleleft$

## 6 Fooling The Sum Function modulo $d$

For integers  $d \geq 2$ ,  $d' \geq 2$  and  $t \geq 1$ , define the function  $\text{Sum}_{d',d} : \mathbb{Z}_{d'}^t \rightarrow \mathbb{Z}_d$  as  $\text{Sum}_{d',d}(a_1, \dots, a_t) = \sum_{i=1}^t a_i \bmod d$ . Given the insignificance of  $d'$  within this context, we will simplify our notation by omitting it, using only  $\text{Sum}_d$ .

In this section we use the flow framework to prove a bias-independent  $O(\sqrt{d} \cdot \lambda)$  total variation bound for  $\text{Sum}_d$ . We also prove a bias amplification result (Lemma 33) from which an  $O(\sqrt{d} \cdot c^t)$  total variation bound can be derived using Lemma 8, where  $c < 1$  is a parameter that depends on the bias of the labeling and  $\lambda$ . [8] obtains a similar bound, which they derive from their results on permutation branching programs.

► **Remark 30.** While characters of  $\mathbb{Z}_d$  are formally defined on values in  $\mathbb{Z}_d$ , throughout this section, we simplify notation by using  $\chi(a)$  for an arbitrary integer  $a$  and character  $\chi$  of  $\mathbb{Z}_d$ , to mean  $\chi(a \bmod d)$ .

### 6.1 Bias Amplification

We begin our discussion with the Boolean case.

► **Definition 31** (bias over  $\mathbb{Z}_2$ ). *The bias of a labeling  $\text{val} : [n] \rightarrow \{0, 1\}$  is defined as  $\text{bias}(\text{val}) \stackrel{\text{def}}{=} |\mathbb{E}_{i \in [n]} (-1)^{\text{val}(i)}|$ .*

The distribution over  $\{0, 1\}$  obtained by sampling a uniformly random element of  $[n]$  and outputting its label is  $\text{bias}(\text{val})$ -biased. However, the distribution obtained by taking  $t$  uniformly random samples from  $[n]$  and computing the parity of the corresponding labels is only  $\text{bias}(\text{val})^t$ -biased. That is, the bias decreases exponentially with  $t$ . To see this, note that

$$\left| \mathbb{E}_{(i_1, \dots, i_t) \in [n]^t} (-1)^{\sum_{j=1}^t \text{val}(i_j)} \right| = \left| \prod_{j=1}^t \mathbb{E}_{i_j \in [n]} (-1)^{\text{val}(i_j)} \right| = \text{bias}(\text{val})^t.$$

It has been observed in [13] that this bias reducing construction can be derandomized by taking length- $(t-1)$  expander random walks on  $[n]$  rather than independent samples. In this case, it is shown that the bias of the resulting distribution is at most  $(\text{bias}(\text{val}) + \lambda)^{\lfloor t/2 \rfloor}$ , where  $\lambda$  is the expansion parameter of the graph. In [13], this property is called *parity sampling*, and it follows that expander random walks are *good parity samplers*. This observation is a key part of the breakthrough construction of almost optimal  $\varepsilon$ -balanced codes [13].

In the context of the sum function modulo  $d$ , we allow labelings with a larger alphabet size. It is therefore natural to ask whether the bias amplification phenomenon extends to  $\mathbb{Z}_d$  where  $d > 2$ . Observe that the bias of a labeling  $\text{val} : [n] \rightarrow \{0, 1\}$  is simply the inner product of the distribution induced by the labeling with the non-trivial character of  $\mathbb{Z}_2$ . This notion extends naturally to characters of  $\mathbb{Z}_d$  as follows.

► **Definition 32** (bias over  $\mathbb{Z}_d$ ). *For integers  $d \geq 2$  and  $d' \geq 2$ , the bias of a labeling  $\text{val} : [n] \rightarrow \mathbb{Z}_{d'}$  with respect to a character  $\chi$  of  $\mathbb{Z}_d$  is defined as  $\text{bias}_\chi(\text{val}) \stackrel{\text{def}}{=} |\mathbb{E}_{i \in [n]} \chi(\text{val}(i))|$ .*

The same argument as before shows that for any character  $\chi$  of  $\mathbb{Z}_d$ , taking  $t$  independent samples from  $[n]$  and outputting the sum of their labels modulo  $d$  yields a distribution on  $\mathbb{Z}_d$  with bias  $\text{bias}_\chi(\text{val})^t$  with respect to the character  $\chi$ . Moreover, we prove that replacing the independent samples by length  $t-1$  random walk on a  $\lambda$ -expander graph obtains a distribution on  $\mathbb{Z}_d$  with bias at most  $(\text{bias}_\chi(\text{val}) + \lambda)^{\lfloor t/2 \rfloor}$  with respect to the character  $\chi$ . (In fact, the bound is slightly better, as here it may be larger than 1). In other words, expander random walks are *good character samplers*. This fact has also been independently observed in [11].

## 31:20 The Expander Hitting Property When the Sets Are Arbitrarily Unbalanced

► **Lemma 33** (Bias Amplification). *For integers  $t \geq 2$ ,  $d \geq 2$ , and  $d' \geq 2$ , let  $G = (V, E)$  be a  $\lambda$ -expander, and let  $\text{val} : V \rightarrow \mathbb{Z}_{d'}$  be any labeling. Let  $\chi$  be a character of  $\mathbb{Z}_d$ . Then*

$$\left| \mathbb{E}_{(v_1, \dots, v_t) \sim \text{RW}_G^t} \chi \left( \sum_{i=1}^t \text{val}(v_i) \right) \right| \leq ((1 - \lambda)^2 \cdot \text{bias}_\chi(\text{val}) + 2\lambda(1 - \lambda) + \lambda^2)^{\lfloor \frac{t}{2} \rfloor}, \quad (4)$$

where  $\text{bias}_\chi(\text{val}) = \left| \mathbb{E}_{i \in [n]} \chi(\text{val}(i)) \right|$  is the bias of  $\text{val}$  with respect to  $\chi$ .

The proof for Lemma 33 appears in the full version of this paper [14]

### 6.2 Bias-independent bound using the flow framework

When the bias is bounded by a constant, the bias amplification property implies that the distributions  $\text{Sum}_d(\text{val}(\text{Ind}_V^t))$  and  $\text{Sum}_d(\text{val}(\text{RW}_G^t))$  are highly unbiased, with bias which is exponentially small in  $t$ . Applying the triangle inequality to the XOR-Lemma (Lemma 8), we see that the total variation distance between these distributions is bounded by the sum of the biases of each distribution with respect to a worst-case non-trivial character. As such, it is decreasing exponentially fast with  $t$  as well. However, this argument hinges on the assumption that the given labeling is balanced. If we have, say,  $\text{bias}_\chi(\text{val}) = 1 - 1/t$  for some non-trivial character  $\chi$  of  $\mathbb{Z}_d$ , the bias amplification argument is insufficient for an effective total variation bound. This constitutes the primary reason why earlier works such as [5] and [4], which rely heavily on the bias-amplification property, result in total variation bounds that are bias-dependent.

Next, we use the flow framework to obtain an  $O(\sqrt{d} \cdot \lambda)$  bias independent bound, similar to that of [8]. The proof in this case is arguably simpler than the more general case in [8], which applies for all small-width permutation branching programs.

**Proof of Theorem 6.** First, observe that we may assume  $t \geq 2$ , as for  $t = 1$  the distributions are identical, and the claim trivially holds. Let  $LHS$  be left-hand side of the inequality in the theorem. Let  $n = |V|$  and identify  $V$  with  $[n]$  arbitrarily. Observe that in order to obtain a total variation bound, it suffices to bound the maximum bias of the difference between the two distributions. Indeed, by the XOR-Lemma (Lemma 8 )

$$LHS \leq \frac{\sqrt{d}}{2} \cdot \max_{\chi \in \widehat{\mathbb{Z}}_d} |\langle \chi, \text{Sum}_d(\text{val}(\text{RW}_G^t)) - \text{Sum}_d(\text{val}(\text{Ind}_V^t)) \rangle|$$

We fix a character  $\chi$  of  $\mathbb{Z}_d$  that attains the maximum. Let  $\mu = \text{bias}_\chi(\text{val})$  be the bias of the labeling  $\text{val}$  with respect to  $\chi$ . We consider two cases according to the relation between  $\mu$  and  $\lambda$ . To begin, let us assume that  $\mu \leq 3\lambda$ . In that case,

$$\begin{aligned} LHS &\leq \frac{\sqrt{d}}{2} \left| \mathbb{E}_{v=(v_1, \dots, v_t) \sim \text{RW}_G^t} \chi \left( \sum_{i=1}^t \text{val}(v_i) \right) - \mathbb{E}_{v \sim \text{Ind}_V^t} \chi \left( \sum_{i=1}^t \text{val}(v_i) \right) \right| \\ &\leq \sqrt{d} \cdot ((1 - \lambda)^2 \cdot \mu + 2\lambda(1 - \lambda) + \lambda^2)^{\lfloor \frac{t}{2} \rfloor} \\ &\leq \sqrt{d} \cdot (3(1 - \lambda)^2 \cdot \lambda + 2\lambda(1 - \lambda) + \lambda^2)^{\lfloor \frac{t}{2} \rfloor} \leq \sqrt{d} \cdot (5\lambda)^{\lfloor \frac{t}{2} \rfloor} \leq 5\sqrt{d} \cdot \lambda, \end{aligned} \quad (5)$$

where the second inequality is implied by the triangle inequality and the bias amplification property established in the previous subsection. The last inequality holds under our assumption that  $t \geq 2$  and  $\lambda \leq 1/6$ .

Now, let us assume that  $\mu \geq 3\lambda$ . Instead of applying the triangle inequality on the second line of Equation 5, we express it linear algebraically. We then give entry-wise bounds for the flow matrices of the involved linear operators. Let  $P$  be the  $n \times n$  diagonal matrix  $P = \text{diag}(\chi(\text{val}(1)), \dots, \chi(\text{val}(n)))$ . We have the following entry-wise bounds on the flow matrix:  $\tilde{P} \leq_{e.w} \begin{pmatrix} \mu & \sqrt{1-\mu^2} \\ \sqrt{1-\mu^2} & 1 \end{pmatrix}$  where all entries except for the right bottom are equality. To see this, note that

$$\tilde{P}[0,0] = \|\Pi_0 P \Pi_0\| = \|J P J\| = \|\mathbf{1} \mathbf{1}^T P \mathbf{1} \mathbf{1}^T\| = |\mathbf{1}^T P \mathbf{1}| = \mu.$$

Moreover, we see that for  $b \in \{0, 1\}$ ,

$$\|\Pi_b P \Pi_0\| = \|\Pi_b P \mathbf{1} \mathbf{1}^T\| = \|\Pi_b P \mathbf{1}\| \cdot \|\mathbf{1}^T\| = \|\Pi_b P \mathbf{1}\|.$$

Now, since  $P$  is unitary,

$$\tilde{P}[0,0]^2 + \tilde{P}[1,0]^2 = \|\Pi_0 P \mathbf{1}\|^2 + \|\Pi_1 P \mathbf{1}\|^2 = \|P \mathbf{1}\|^2 = \|\mathbf{1}\|^2 = 1$$

By symmetry we conclude that  $\tilde{P}[1,0] = \tilde{P}[0,1] = \sqrt{1-\mu^2}$ . Finally, we bound  $\tilde{P}[1,1] = \|\Pi_1 P \Pi_1\| \leq \|\Pi_1\|^2 \|P\| \leq 1$ . By submultiplicativity of the flow operator (Claim 11) and Example 10, We see that  $\widetilde{GP} \leq_{e.w} A$  for  $A \stackrel{\text{def}}{=} \begin{pmatrix} \mu & \sqrt{1-\mu^2} \\ \lambda \sqrt{1-\mu^2} & \lambda \end{pmatrix}$ . Now, Let us pick up Equation 5 after the first inequality. Expressing the bias linear-algebraically,

$$\left| \mathbb{E}_{v \sim \text{RW}_G^t} \chi \left( \sum_{i=1}^t \text{val}(v_i) \right) - \mathbb{E}_{v \sim \text{Ind}_V^t} \chi \left( \sum_{i=1}^t \text{val}(v_i) \right) \right| = |\mathbf{1}^T (PG)^{t-1} P \mathbf{1} - \mathbf{1}^T (PJ)^{t-1} P \mathbf{1}|$$

and,

$$\begin{aligned} |\mathbf{1}^T (PG)^{t-1} P \mathbf{1} - \mathbf{1}^T (PJ)^{t-1} P \mathbf{1}| &= |\mathbf{1}^T (GP)^{t-1} \mathbf{1} - \mathbf{1}^T (JP)^{t-1} \mathbf{1}| \\ &= |\mathbf{1}^T (GP)^{t-1} \mathbf{1} - \mathbf{1}^T (\Pi_0 G P)^{t-1} \mathbf{1}| && (\Pi_0 G = J) \\ &\leq (\widetilde{GP})^{t-1}[0,0] - (\widetilde{GP})^{t-1}[0,0] && (\text{Lemma 16}) \\ &\leq A^{t-1}[0,0] - (A[0,0])^{t-1} && (\text{Lemma 17}) \end{aligned}$$

Applying Lemma 13 we obtain the bound

$$\begin{aligned} A^t[0,0] - (A[0,0])^t &\leq \frac{\lambda \mu (1-\mu^2)}{\mu-\lambda} \sum_{k=0}^{t-2} \mu^k \left( \mu + \frac{\lambda(1-\mu^2)}{\mu-\lambda} \right)^{t-k-2} \\ &\leq \frac{3}{2} \cdot \lambda (1-\mu^2) \sum_{k=0}^{t-1} \mu^k \left( \mu + \frac{1}{2} \cdot (1-\mu^2) \right)^{t-k-1} \leq \frac{3}{2} \cdot \lambda \cdot (1+\mu)(1-\mu) \sum_{k=0}^{\infty} \mu^k \\ &\leq 3 \cdot \lambda. \end{aligned}$$

where the second inequality holds as our assumption  $\mu \geq 3\lambda$  implies that  $\mu/(\mu-\lambda) \leq 3/2$  and  $\lambda/(\mu-\lambda) \leq 1/2$ . In the third inequality we have used that  $\mu + \frac{1}{2} \cdot (1-\mu^2) \leq 1$ . Overall, we have  $d_{TV}(\text{Sum}_d(\text{val}(\text{RW}_G^t)), \text{Sum}_d(\text{val}(\text{Ind}_V^t))) < 5\sqrt{d} \cdot \lambda$  in all cases, and the proof is complete.  $\blacktriangleleft$

## Abstract

We give a  $\tilde{O}(n)$  time almost uniform sampler for independent sets of a matroid, whose ground set has  $n$  elements and is given by an independence oracle. As a consequence, one can sample connected spanning subgraphs of a given graph  $G = (V, E)$  in  $\tilde{O}(|E|)$  time, whereas the previous best algorithm takes  $O(|E||V|)$  time. This improvement, in turn, leads to a faster running time on estimating all-terminal network reliability. Furthermore, we generalise this near-linear time sampler to the random cluster model with  $q \leq 1$ .

## 1 Introduction

Let  $\mathcal{M} = ([n], \mathcal{I})$  be a matroid of rank  $r$  and  $\lambda \in \mathbb{R}_{>0}^n$  be the external fields (namely weights for the ground set elements). Denote its set of bases by  $\mathcal{B} = \mathcal{B}(\mathcal{M})$ , and by  $\mathcal{I} = \mathcal{I}(\mathcal{M})$  the set of independent sets. Suppose that we want to sample a random base  $B \in \mathcal{B}$  from the following distribution:

$$\forall B \in \mathcal{B}, \quad \mu_{\mathcal{B}, \lambda}(B) \propto \prod_{i \in B} \lambda_i.$$

There is a natural Markov chain, namely the bases-exchange walk (also known as the down-up walk) [8], that converges to the distribution above. Anari, Liu, Oveis Gharan, and Vinzant [2] showed that this chain mixes in polynomial time. Subsequently, Cryan, Guo, and Mousa [7] and a follow up work by Anari, Liu, Oveis Gharan, Vinzant, and Vuong [3] refined the mixing time to the optimal  $O(r \log r)$ .

Leibniz International Proceedings in Informatics  
Schloss Dagstuhl – Leibniz-Zentrum für Informatik, Dagstuhl Publishing, Germany

In this work, we focus on another important distribution associated with the matroid  $\mathcal{M}$ , namely, the distribution  $\mu_{\mathcal{M},\lambda}$  over the independent sets of  $\mathcal{M}$ :

$$\forall S \in \mathcal{I}, \quad \mu_{\mathcal{M},\lambda}(S) \propto \prod_{i \in S} \lambda_i. \quad (1)$$

As suggested by the previous work [3], in order to sample from  $\mu_{\mathcal{M},\lambda}$ , we may construct another matroid  $\mathcal{M}_{\mathcal{I}}$  so that there is a one-to-one correspondence between the bases of  $\mathcal{M}_{\mathcal{I}}$  and the independent sets of  $\mathcal{M}$ . Therefore, we may use the bases-exchange walk on  $\mathcal{M}_{\mathcal{I}}$  to approximately generate samples from  $\mu_{\mathcal{M},\lambda}$  within  $O(n \log n)$  steps.

However, an efficient implementation of the bases-exchange walk on  $\mathcal{M}_{\mathcal{I}}$  is far from trivial. Note that the input matroid is usually given succinctly. For example, for a graphic matroid, it is sufficient to input the associated graph, rather than a list of all the bases or independent sets, which can be exponentially large in the size of the graph. The most common and standard way is to give the matroid by an independence oracle  $\mathcal{O}_I$ . Upon receiving a subset of elements, the independence oracle  $\mathcal{O}_I$  returns whether or not the set is independent. Given  $\mathcal{O}_I$ , the naïve implementation of the bases-exchange walk requires  $O(n)$  oracle calls per step. Depending on the application, there may be even further cost of implementing the oracle. This prevents us from getting a near-linear time sampler for many potential applications.

To get a faster algorithm, Anari, Liu, Oveis Gharan, Vinzant, and Vuong considered a different oracle  $\mathcal{O}'$  [3]. One can query  $\mathcal{O}'$  a subset  $S \subseteq [n]$  with the promise that  $S$  contains at most one circuit. If a circuit exists,  $\mathcal{O}'$  will output a uniformly random element of the circuit. In [3], it is showed that there is a sampling algorithm for  $\mu_{\mathcal{M},\lambda}$  using  $O(n \log n)$  queries in total of  $\mathcal{O}'$ . However the downside is that this oracle  $\mathcal{O}'$  is typically more difficult to implement than the independence oracle  $\mathcal{O}_I$ . In our applications to be discussed later (network reliability and the random cluster model), the independence oracle  $\mathcal{O}_I$  can be implemented in logarithmic time (at least in an amortized sense), whereas it appears to require at least linear time to implement  $\mathcal{O}'$ . A straightforward implementation of  $\mathcal{O}'$  requires  $O(r)$  calls to  $\mathcal{O}_I$ , where  $r$  is the rank of the matroid  $\mathcal{M}$ . This leads to a sampling algorithm using  $O(rn \log n)$  oracle calls to  $\mathcal{O}_I$ . Note that the rank  $r$  is often not a constant and can be as large as  $\Omega(n)$ .

We give a sampler which requires  $O((1 + \lambda_{\max})n \log(n/\varepsilon))$  oracle calls in expectation to  $\mathcal{O}_I$ , where  $\lambda_{\max} := \max_{i \in [n]} \lambda_i$  and  $\varepsilon$  is the sampling error. This improves the previously best  $O(rn \log n)$  running time [3]. We use the *total variation distance* (TV distance) to measure the distance between two distributions  $\mu$  and  $\nu$  over a finite space  $\Omega$ , defined by  $D_{\text{TV}}(\mu, \nu) := \frac{1}{2} \sum_{X \in \Omega} |\mu(X) - \nu(X)|$ .

► **Theorem 1.** *Equipped with the independence oracle  $\mathcal{O}_I$  of a matroid  $\mathcal{M} = ([n], \mathcal{I})$ , there exists an algorithm that takes external fields  $\lambda \in \mathbb{R}_{>0}^n$  and  $\varepsilon \in (0, 1)$  as inputs, and outputs a random set  $S \in \mathcal{I}$  satisfying  $D_{\text{TV}}(\mu_{\mathcal{M},\lambda}, S) \leq \varepsilon$ . In expectation, it runs in  $O((1 + \lambda_{\max})n \log(n/\varepsilon)(\log n + t_{\mathcal{O}_I}))$  time, where  $t_{\mathcal{O}_I}$  is the time to answer a query by the independence oracle  $\mathcal{O}_I$  and  $\lambda_{\max} := \max_{i \in [n]} \lambda_i$ .*

The proof of Theorem 1 is given in Section 3.

► **Remark 2.** In particular, instead of the independence oracle  $\mathcal{O}_I$ , for our algorithm in Theorem 1, it suffices to have a data structure maintaining a set  $S \subseteq [n]$  which supports:

- to *insert* an element to  $S$ ;
- to *delete* an element from  $S$ ;
- and to *query* if  $S \in \mathcal{I}$ .

Given such a data structure,  $t_{\mathcal{O}_I}$  in Theorem 1 can be substituted by the worst case or amortized running time of these operations.

The crux of Theorem 1 is a fast implementation of the transition step of the bases-exchange chain for  $\mathcal{M}_{\mathcal{T}}$ . Note that the transition of a Markov chain is in itself yet another sampling problem. We design a rejection sampling procedure for this latter sampling task. There is a constant upper bound for the rejection probability (see Lemma 14), guaranteeing a success with high probability in logarithmic trials.

A consequence of our algorithm is a faster approximation algorithm for the *all-terminal network reliability*. The problem is defined as follows. Given a connected undirected graph  $G = (V, E)$  and failure probabilities  $\mathbf{p} \in \mathbb{R}_{>0}^E$ , the all-terminal network reliability  $Z_{\text{rel}}(G, \mathbf{p})$  is the probability that the graph is connected if each edge  $e$  fails (i.e. is removed) independently with probability  $p_e$ . Formally, for  $S \subseteq E$ , let

$$\text{wt}(S) := \mathbf{1}[G[E \setminus S] \text{ is connected}] \cdot \prod_{e \in S} p_e \prod_{f \in E \setminus S} (1 - p_f), \quad (2)$$

where  $G[E \setminus S]$  is the spanning subgraph of  $G$  on  $E \setminus S$ . Then the reliability of the network is

$$Z_{\text{rel}}(G, \mathbf{p}) := \sum_{S \subseteq E} \text{wt}(S).$$

By standard techniques [16, 20, 17], estimating  $Z_{\text{rel}}(G, \mathbf{p})$  can be reduced to approximate sampling of the (weighted) distribution of connected spanning subgraphs:

$$\forall S \subseteq E, \quad \mu_{G, \mathbf{p}}^{\text{NR}}(S) \propto \text{wt}(S). \quad (3)$$

The study of the computational complexity of network reliability was initiated by Valiant [21]. Exact evaluation of the all-terminal version is known to be  $\#\mathbf{P}$ -hard [15, 19]. Guo and Jerrum [11] gave the first fully polynomial-time randomized approximate scheme (FPRAS) using the *partial rejection sampling* framework [12]. This algorithm samples from  $\mu_{G, \mathbf{p}}^{\text{NR}}$  in  $O(|E| + \frac{p_{\max}|V||E|}{1-p_{\max}})$  time in expectation [10] where  $p_{\max} := \max_i p_i$  is the maximum failure probability, and this bound is tight for the technique. It is also worth mentioning that, using the result in [3] directly, it is possible to get an  $\tilde{O}(|V||E|)$  time sampler, whose running time is of roughly the same order as the partial rejection sampling algorithm.

Using Theorem 1, we obtain an  $\tilde{O}(|V|)$  speed-up to sample from  $\mu_{G, \mathbf{p}}^{\text{NR}}$ . This gives the first near-linear time sampler for connected spanning subgraphs.

► **Corollary 3.** *Let  $G = (V, E)$  be a connected graph with  $n$  vertices and  $m$  edges. Let  $\mathbf{p} \in (0, 1)^E$  be the failure probabilities for edges. There is an algorithm that takes  $G$ ,  $\mathbf{p}$  and  $\varepsilon \in (0, 1)$  as input, and outputs a random subset  $S \subseteq E$  such that  $D_{\text{TV}}(\mu_{G, \mathbf{p}}^{\text{NR}}, S) \leq \varepsilon$  in  $O\left(\frac{m(\log^3 n + \log \frac{1}{\varepsilon})}{1-p_{\max}}\right)$  time in expectation, where  $p_{\max} := \max_{e \in E} p_e$ .*

**Proof.** Let  $\Omega := \{S \subseteq E \mid \mu_{G, \mathbf{p}}^{\text{NR}}(S) > 0\}$  be the support of  $\mu_{G, \mathbf{p}}^{\text{NR}}$ . Recall that  $\mu_{G, \mathbf{p}}^{\text{NR}}(S) > 0$  if and only if  $G[E \setminus S]$  is connected. This means that there is a spanning tree  $T$  of  $G$  contained in  $E \setminus S$ . Note that spanning trees are bases of the graphic matroid  $\mathcal{M}_G$  of a graph  $G$ . Hence, let  $\mathcal{M}_{\text{NR}} := (E, \Omega)$ , it holds that  $\mathcal{M}_{\text{NR}}$  is the dual matroid of  $\mathcal{M}_G$ , namely the co-graphic matroid. This also means that  $\mu_{G, \mathbf{p}}^{\text{NR}} = \mu_{\mathcal{M}, \lambda}$  for  $\mathcal{M} = \mathcal{M}_{\text{NR}}$  and  $\lambda_e = \frac{p_e}{1-p_e}, \forall e \in E$  as defined in (1).

It remains to implement the independence oracle efficiently. For this we use dynamic data structures for connectivity of graphs, which is a topic that has been extensively studied. For  $\mathcal{M}_{\text{NR}}$ , as in Remark 2, we implement the independence oracle  $\mathcal{O}_I$  with amortized cost  $t_{\mathcal{O}_I} = O(\log^2 n)$  by using the data structure in [22, Section 3] directly. The corollary follows by combining this with Theorem 1. ◀

As we can see in the proof, the advantage of our algorithm is that the independence oracle can be implemented in amortized logarithmic time. In contrast, it requires at least linear time to implement the oracle  $\mathcal{O}'$  of Anari, Liu, Oveis Gharan, Vinzant, and Vuong [3]. Our sampling algorithm in Theorem 1 calls the independence oracle only a near-linear number of times, which is crucial to obtain the overall near-linear running time.

Using the counting to sampling reduction in [10], Corollary 3 implies an FPRAS that outputs an  $(1 \pm \varepsilon)$ -approximation of  $Z_{\text{rel}}(G, \mathbf{p})$  in time  $O\left(\frac{mn \log^4(n)}{\varepsilon^2(1-p_{\max})} \log \frac{1}{1-p_{\max}}\right)$ . As before, this improves the previous best running time by a factor of  $\tilde{O}(n)$ . We also note that the running time in Corollary 3 is linear in  $(1 - p_{\max})^{-1}$ . This factor comes from our rejection sampling implementation of the down-up walk, whereas the naïve implementation of the down-up walk has logarithmic dependence. On the other hand, in most applications,  $1 - p_{\max} = \Omega(1)$ . For example, for the uniform distribution over connected spanning subgraphs,  $p_e = 1/2$  for all  $e$ . Moreover, in the simulated annealing counting to sampling reduction [10], we do not need to consider  $p_e$  larger than  $p_{\max}$ . Thus, in this reduction, there is no extra slowdown due to this linear dependence on  $1 - p_{\max}$ . In any case, we leave improving this dependence for near-linear time samplers as an open problem.

The distribution  $\mu_{G, \mathbf{p}}^{\text{NR}}$  in (3) is a special case of the random cluster model on the graph  $G$  with parameter  $q = 0$  [9]. More generally, for a matroid  $\mathcal{M} = ([n], \mathcal{I})$  with a rank function  $\text{rk}(\cdot)$ , the random cluster model with parameter  $q \geq 0$  and external fields  $\boldsymbol{\lambda} \in \mathbb{R}_{>0}^n$  is defined as follows: for  $S \subseteq X$ ,

$$\pi_{RC, q, \boldsymbol{\lambda}}(S) \propto q^{-\text{rk}(S)} \prod_{x_i \in S} \lambda_i. \quad (4)$$

For  $q = 0$ , the support of the distribution in (4) must have the highest rank. For a graphic matroid over a graph  $G$ , this means that  $G[S]$  must be connected, namely  $S$  in (4) corresponds to  $E \setminus S$  in  $\mu_{G, \mathbf{p}}^{\text{NR}}$ .

We also extend our near-linear time sampler to random cluster models with  $q \leq 1$ . Note that the rank of  $S$  plays an important role in the distribution in  $\pi_{RC, q, \boldsymbol{\lambda}}$  (4). Thus, instead of the independence oracle, here we use a rank oracle, which upon a query  $S$  returns the rank of  $S$ .

► **Theorem 4.** *Let  $0 \leq q \leq 1$  be a parameter. Equipped with the rank oracle  $\mathcal{O}_r$  of a matroid  $\mathcal{M} = ([n], \mathcal{I})$ , there exists an algorithm that takes external fields  $\boldsymbol{\lambda} \in \mathbb{R}_{>0}^n$  and  $\varepsilon \in (0, 1)$  as inputs, and outputs a random set  $S$  such that  $D_{\text{TV}}(\pi_{RC, q}, S) \leq \varepsilon$ . It runs in  $O\left((1 + \lambda_{\min}^{-1})n \log(n/\varepsilon)(\log n + t_{\mathcal{O}_r})\right)$  time in expectation, where  $t_{\mathcal{O}_r}$  is the time to answer a query by the rank oracle  $\mathcal{O}_r$  and  $\lambda_{\min} := \min_{i \in [n]} \lambda_i$ .*

Theorem 4 is proved in Section 4.

Similar to Remark 2, it suffices to replace the rank oracle by a data structure that supports insertion/deletion of elements and query if the rank changes after removing an element. For graphs, the rank oracle, once again, can be implemented using the data structure in [22]. This is because  $\text{rk}(S) = |V| - 1 + \kappa(E) - \kappa(S)$ , where  $\kappa(S)$  is the number of connected components in  $G[S]$ . Thus the rank change query in graphs is exactly the same as asking if  $u$  and  $v$  are connected after removing an edge  $(u, v)$ . The amortized cost of using this data structure is  $O(\log^2 n)$ .

► **Corollary 5.** *Let  $G = (V, E)$  be a graph with  $n$  vertices and  $m$  edges. Let  $q \leq 1$  be a parameter and  $\boldsymbol{\lambda} \in \mathbb{R}_{>0}^E$  be the external fields on edges. There is an algorithm that takes  $G$ ,  $\boldsymbol{\lambda}$  and  $\varepsilon \in (0, 1)$  as input, and outputs a random subset  $S \subseteq E$  such that  $D_{\text{TV}}(\pi_{RC, q}, S) \leq \varepsilon$  in  $O\left((1 + \lambda_{\min}^{-1})m(\log^3 n + \log \frac{1}{\varepsilon})\right)$  time in expectation, where  $\lambda_{\min} := \min_{i \in [n]} \lambda_i$ .*

## 2 Preliminaries

### 2.1 Matroid

Matroid is an abstract combinatorial structure that generalizes the notion of linear independence. It is usually specified by a pair  $\mathcal{M} = (U, \mathcal{I})$  where  $U$  is a ground set and  $\mathcal{I} \subseteq 2^U$  is a collection of subsets of  $U$ . The subsets in  $\mathcal{I}$  are known as the independent sets of the matroid and satisfy the following axioms:

- $\emptyset \in \mathcal{I}$ ;
- if  $S \in \mathcal{I}$ ,  $T \subseteq S$ , then  $T \in \mathcal{I}$ ;
- if  $S, T \in \mathcal{I}$  and  $|S| > |T|$ , then there is an element  $i \in S \setminus T$  such that  $T \cup \{i\} \in \mathcal{I}$ .

The first axiom ensures that  $\mathcal{I}$  is non-empty. The second shows that  $\mathcal{I}$  is downward closed, and the third implies that the cardinality of maximal independent sets are the same. This maximum cardinality is known as the *rank* of the matroid  $\mathcal{M}$ . The set of *bases*  $\mathcal{B} = \mathcal{B}(\mathcal{M})$  is the collection of independent sets of maximum cardinality. The rank also extends as a function to subsets of  $U$ . For  $S \subseteq U$ ,  $\text{rk}(S)$  is defined as the size of the maximum independent sets contained in  $S$ .

For a matroid  $\mathcal{M} = (U, \mathcal{I})$ , its *dual matroid*  $M^* = (U, \mathcal{I}^*)$  has the same ground set  $U$  with the collection of independent sets  $\mathcal{I}^* := \{S \subseteq U \mid \exists B \in \mathcal{B}(\mathcal{M}), B \subseteq U \setminus S\}$ . By definition, every base  $B^*$  of  $M^*$  is the complement of the base  $B = U \setminus B^*$  of  $\mathcal{M}$  and vice versa.

### 2.2 Strongly log-concave polynomial

Let  $f \in \mathbb{R}[x_1, x_2, \dots, x_n]$  be a polynomial with non-negative coefficients.  $f$  is called

- *r-homogeneous* if the degree of every monomial in  $f$  is  $r$ ;
- *multiaffine* if every variable appears with degree no more than 1;
- *log-concave over the first orthant* (or *log-concave* for short) if  $\log f$  is concave over  $\mathbb{R}_{>0}^n$ , i.e., for  $x, y \in \mathbb{R}_{>0}^n$  and  $\lambda \in (0, 1)$ ,

$$f(\lambda x + (1 - \lambda)y) \geq f(x)^\lambda f(y)^{1-\lambda};$$

- *strongly log-concave* if  $f$  is either vanishes or log-concave after taking any sequence of partial derivatives.

The notion of strong log-concavity is introduced by Gurvitz [14, 13]. For a homogeneous polynomial, it turns out to be equivalent to related notions of *complete log-concavity* by Anari, Oveis Gharan, and Vinzant [4] and *Lorentzian* by Brändén and Huh [6]. See [6, Theorem 2.30]. For simplicity, we will not define the latter two.

A well known fact is that affine transform  $T : \mathbb{R}^m \rightarrow \mathbb{R}^n$  (i.e.,  $T(\mathbf{y}) = A\mathbf{y} + \mathbf{b}$  for some  $A \in \mathbb{R}^{n \times m}$  and  $\mathbf{b} \in \mathbb{R}^n$ ) preserves log-concavity.

► **Lemma 6** ([4, Lemma 2.1]). *If  $f \in \mathbb{R}[x_1, \dots, x_n]$  is log-concave and  $T : \mathbb{R}^m \rightarrow \mathbb{R}^n$  is an affine transformation such that  $T(\mathbb{R}_{>0}^m) \subseteq \mathbb{R}_{>0}^n$ , then  $f(T(y_1, \dots, y_m)) \in \mathbb{R}[y_1, \dots, y_m]$  is log-concave.*

As observed in [3], for a multiaffine polynomial  $f$ , its partial derivative is given by

$$\partial_1 f = \lim_{c \rightarrow \infty} \frac{f(c, x_2, \dots, x_n)}{c},$$

which means the derivatives of a multiaffine log-concave polynomial are limits of log-concave polynomials, which are also log-concave by definition. It implies that a multiaffine log-concave polynomial is automatically strongly log-concave.

► **Fact 7** ([3]). *If polynomial  $f$  is multiaffine and log-concave, then  $f$  is strongly log-concave.*

We note that most polynomials we consider are multiaffine, which means that log-concavity and strong log-concavity are equivalent within the scope of this work.

## 2.3 Polynomial and distribution

Let  $\mu$  be a distribution over  $2^{[n]}$ . The generating function of  $\mu$  is given by

$$g_\mu = \sum_{S \subseteq [n]} \mu(S) \prod_{i \in S} x_i.$$

It is known that multiaffine polynomials are closely related to generating polynomials of distribution. Let  $f$  be a multiaffine polynomial  $f \in \mathbb{R}[x_1, x_2, \dots, x_n]$  with non-negative coefficients. If  $f \neq 0$ , there exists a distribution  $\mu$  over  $2^{[n]}$  such that its generating polynomial is identical to  $f$  up to a scaling factor. Hence, we may also say  $f$  is the generating polynomial of  $\mu$ .

Furthermore, if the generating function  $g_\mu$  of  $\mu$  is  $r$ -homogeneous and log-concave, then the support of  $\mu$  must be the set of bases of a matroid [6].

## 2.4 Down-up walk

Let  $\mu$  be a distribution over  $\binom{[n]}{r}$ . Let  $\Omega(\mu) := \{S \subseteq [n] \mid \mu(S) > 0\}$  be the support of  $\mu$ . A classical method for sampling from this homogeneous distribution is the down-up walk, described below.

► **Definition 8.** *For a distribution  $\mu$  over  $\binom{[n]}{r}$ , the down-up walk  $P$  updates a configuration  $S \in \binom{[n]}{r}$  according to the following rule:*

1. *select a subset  $T \subseteq S$  of size  $r - 1$  uniformly at random;*
2. *update  $S$  to  $S'$  by selecting  $S' \supseteq T$  with probability proportional to  $\mu(S')$ .*

When the support of  $\mu$  is the set of bases of a matroid, this walk is also known as the *bases-exchange walk*.

If the down-up walk  $P$  connects  $\Omega(\mu)$ , then  $\mu$  is its unique stationary distribution. Its *mixing time* is defined by

$$t_{\text{mix}}(\varepsilon) := \min \left\{ t \mid \max_{S \in \Omega(\mu)} D_{\text{TV}}(P^t(S, \cdot), \mu) \leq \varepsilon \right\}.$$

The down-up walk mixes rapidly if  $g_\mu$  is (strongly) log-concave [7, 3].

► **Proposition 9** ([3, Theorem 1]). *If  $g_\mu$  is  $r$ -homogeneous and log-concave, the mixing time of the down-up walk can be bounded by  $t_{\text{mix}}(\varepsilon) = O(r \log(r/\varepsilon))$ .*

## 3 Our algorithm

In this section, we prove Theorem 1. Our main tool is the down-up walk in Definition 8. As the uniform distribution over independent sets is not homogeneous, in Section 3.1 we first consider a standard homogenization, namely its polarized version. Then standard results imply that the down-up walk for the polarized homogeneous distribution mixes in time  $O(n \log n)$ . In Section 3.2, we show how to implement the down-up walk with  $\tilde{O}(1)$  cost. With these ingredients, the proof of Theorem 1 is given at the end of this section.

### 3.1 Down-up walk for polarized polynomial

Let  $\mathcal{M} = ([n], \mathcal{I})$  be a rank- $r$  matroid and  $\lambda \in \mathbb{R}_{>0}^n$  be the external fields. Consider

$$g(x_1, \dots, x_n) := \sum_{S \in \mathcal{I}} \prod_{i \in S} x_i.$$

It is straightforward to verify that  $g(\lambda_1 x_1, \dots, \lambda_n x_n)$  is the generating polynomial of  $\mu_{\mathcal{M}, \lambda}$ .

Note that  $g$  is not homogeneous, which means that we may not directly employ the down-up walk to sample from the distribution  $\mu_{\mathcal{M}, \lambda}$ . However, there is a homogeneous variant of  $g$ ,

$$g_h(y, x_1, \dots, x_n) := \sum_{S \in \mathcal{I}} y^{n-|S|} \prod_{i \in S} x_i. \quad (5)$$

As a key step in the proof of Mason's ultra-log-concavity conjecture for independent sets of matroid [1, 6], the following result is proved.

► **Lemma 10** ([1, Theorem 4.1]). *The polynomial  $g_h$  in (5) is strongly log-concave.*

However,  $g_h$  is not multiaffine, which means that it is not a generating polynomial of any distribution. Instead, we consider the polarized version of  $g_h$ .

► **Lemma 11.** *If  $g_h$  in (5) is strongly log-concave, then the following polynomial is also strongly log-concave:*

$$g_p(x_1, \dots, x_n, y_1, \dots, y_n) = \sum_{S \in \mathcal{I}} \frac{e_{n-|S|}(\mathbf{y})}{\binom{n}{|S|}} \prod_{i \in S} x_i, \quad (6)$$

where  $e_k(\mathbf{y}) = \sum_{1 \leq i_1 < i_2 < \dots < i_k \leq n} \prod_{j=1}^k y_{i_j}$  is the  $k$ -th elementary symmetric polynomial.

We remark that Lemma 11 is a special case of [6, Proposition 3.1], and it is more explicitly derived in [18, Section 6.6].

The polarized polynomial in (6) corresponds back to a distribution. Let  $X := \{x_1, \dots, x_n\}$  denote elements in  $\mathcal{M}$  and  $Y := \{y_1, \dots, y_n\}$  denote the auxiliary variables introduced by polarization. Let  $\pi$  be the distribution over subsets of  $X \cup Y$  corresponding to the generating polynomial  $g_p(\lambda_1 x_1, \dots, \lambda_n x_n, y_1, \dots, y_n)$ . Then the support of  $\pi$  is given by

$$\Omega(\pi) = \{A \cup B \mid A \in \mathcal{I}, B \subseteq Y, |A| + |B| = n\}.$$

Furthermore, for every  $S = A \cup B \in \Omega(\pi)$ , it holds that

$$\pi(S) \propto \frac{1}{\binom{n}{|A|}} \prod_{x_i \in A} \lambda_i,$$

and  $\sum_{S: S \cap X = A} \pi(S) = \mu_{\mathcal{M}, \lambda}(A)$ .

Therefore, to sample from  $\mu_{\mathcal{M}, \lambda}$  within a TV distance of  $\varepsilon$ , it suffices to sample  $S \in \Omega(\pi)$  such that  $D_{\text{TV}}(S, \pi) \leq \varepsilon$ , and then return  $S \cap X$  as the result.

Note that  $g_p$  is homogeneous and multiaffine. Moreover, according to Lemma 10 and Lemma 11,  $g_p$  is strongly log-concave. Thus, the polynomial  $g_p(\lambda_1 x_1, \dots, \lambda_n x_n, y_1, \dots, y_n)$  is also log-concave by Lemma 6. Hence, by Proposition 9, we have the following result, which gives a powerful framework to build fast sampling algorithm for independent set of matroid.

► **Lemma 12.** *The down-up walk  $P$  of  $\pi$  mixes in time  $O(n \log(n/\varepsilon))$ .*

■ **Algorithm 1** a step of down-up walk  $P$  on  $\pi$ .

- 1 select a subset  $T \subseteq S$  of size  $n - 1$  uniformly at random;
- 2 update  $S$  to  $S'$  by selecting random  $S' \supseteq T$  according to the following law:

$$\Pr[S'] \propto \mathbf{1}[S' \cap X \in \mathcal{I}] \times \begin{cases} \frac{1}{\binom{n}{|T \cap X|}}, & S' \setminus T \in Y; \\ \frac{\lambda_i}{\binom{n}{|T \cap X|+1}}, & S' \setminus T = \{x_i\} \text{ for some } x_i \in X. \end{cases} \quad (7)$$

We note that the mixing time  $O(n \log(n/\varepsilon))$  does not readily imply a sampler which runs in  $O(n \log(n/\varepsilon))$  time, as it may take  $\omega(1)$  time to implement a single transition step of  $P$ . According to Definition 8, in each step,  $P$  updates a state  $S \in \Omega(\pi)$  as in Algorithm 1.

The main obstacle is to implement the second step in Algorithm 1 efficiently. A naïve approach checks whether  $(\{x_i\} \cup T) \cap X \in \mathcal{I}$  for each  $x_i \in X \setminus T$  by calling the independence oracle  $\mathcal{O}_I$ , and then generates a random sample from all “feasible”  $x_i$  and together with all of  $y_i \in Y \setminus T$  according to the desired distribution in (7). In the worst case, this gives an  $O(n)$  overhead and the running time of the sampling algorithm becomes  $O(n^2 \log n)$ .

### 3.2 A fast implementation of the down-up walk

Our main contribution is an efficient implementation of the down-up walk  $P$  on  $\pi$ , where each step of  $P$  takes constant time in expectation given an independence oracle  $\mathcal{O}_I$ . In fact, the implementation task is yet another sampling problem from the distribution in (7), and we do so by rejection sampling, described in Algorithm 2.

■ **Algorithm 2** implementation for the second step of the down-up walk  $P$ .

---

**input** : a subset  $T \subseteq X \cup Y$  of size  $n - 1$  such that  $T \cap X \in \mathcal{I}$   
**output** : a random configuration  $S$  according to the distribution defined in (7)

- 1 **while** *true* **do**
- 2     propose an element  $e \in (X \cup Y) \setminus T$  according to the following distribution  $\nu$ :
 
$$\forall e \in (X \cup Y) \setminus T, \quad \nu(e) \propto \begin{cases} \lambda_i, & e = x_i \in X \setminus T; \\ \frac{n - |T \cap X|}{1 + |T \cap X|}, & e \in Y \setminus T. \end{cases} \quad (8)$$
- 3     **if**  $(T \cup \{e\}) \cap X \in \mathcal{I}$  **then**
- 4         **return**  $S = T \cup \{e\}$ ;

---

The correctness of Algorithm 2 is straightforward.

► **Fact 13.** *The state  $S$  produced by Algorithm 2 follows the distribution defined in (7).*

In terms of efficiency, the **while** loop in Algorithm 2 is anticipated to execute for a constant number of rounds in expectation. This is because the rejection probability is upper bounded by a constant, as shown by the next lemma.

► **Lemma 14.** *It holds that  $\Pr_{e \sim \nu}[(T \cup \{e\}) \cap X \notin \mathcal{I}] \leq \frac{\lambda_{\max}}{1 + \lambda_{\max}}$ , where  $\lambda_{\max} = \max_{i \in [n]} \lambda_i$ .*

**Proof.** Suppose  $|T \cap X| = k$ . Note that if  $e \in Y \setminus T$ , then  $(T \cup \{e\}) \cap X \in \mathcal{I}$ . This means

$$\begin{aligned} \Pr_{e \sim \nu} [(T \cup \{e\}) \cap X \notin \mathcal{I}] &\leq \sum_{x_i \in X \setminus T} \frac{\lambda_i}{\sum_{x_i \in X \setminus T} \lambda_i + \sum_{y \in Y \setminus T} \frac{n-k}{1+k}} \\ &= \frac{\sum_{x_i \in X \setminus T} \lambda_i}{\sum_{x_i \in X \setminus T} (1 + \lambda_i)} \leq \frac{\lambda_{\max}}{1 + \lambda_{\max}}, \end{aligned}$$

where the equality is due to  $|Y \cap T| + k = n - 1$ .  $\blacktriangleleft$

Now, we are ready to prove Theorem 1.

**Proof of Theorem 1.** Our algorithm is just running Algorithm 1 for  $O(n \log(n/\varepsilon))$  steps and then output  $S \cap X$ . Line 2 of Algorithm 1 is implemented by Algorithm 2, to get a random state  $S$ . By Lemma 12 and Fact 13, it holds that  $D_{TV}(S \cap X, \mu) \leq \varepsilon$ .

To implement (8), we maintain two balanced binary search trees  $T_X$  and  $T_Y$  that keep track of the weight of each node and the sum of weights in each subtree. The first tree  $T_X$  maintains elements  $x_i \in X \setminus T$  each assigned with weight  $\lambda_i$ , and the second tree  $T_Y$  maintains elements  $y_i \in Y \setminus T$  with weight 1.

To produce an  $e \sim \nu$ , first choose tree  $T_Z \in \{T_X, T_Y\}$  randomly according to the law:

$$T_Z = \begin{cases} T_X & \text{with prob. } \propto \sum_{x_i \in X \setminus T} \lambda_i \\ T_Y & \text{with prob. } \propto n - |T \cap X| \end{cases},$$

where we note that  $\sum_{x_i \in X \setminus T} \lambda_i$ , and  $|T \cap X|$  could be obtained by a constant number of queries via the binary search trees. To sample an element  $e \in T_Z$  according to the weights of each element, we may consider a binary search algorithm on  $T_Z$  that runs in  $O(\log n)$  time. We initialize a variable  $e$  with the root of  $T_Z$ , and then repeat the following procedure:

1. Let  $L$  be the sum of weights in the left subtrees of  $e$ ,  $R$  be the sum of weights in the right subtrees, and  $W$  be the weights of  $e$ ;
2. Sample a real number  $0 < x < L + R + W$  uniformly at random. If  $x < W$ , return  $e$ ; else if  $x < W + L$ , update  $e$  to the left child of  $e$ ; otherwise, update  $e$  to the right child of  $e$ .

Finally, by Lemma 14, the rejection sampling procedure in Algorithm 2 runs within  $O(1 + \lambda_{\max})$  rounds in expectation. Also note that in each round of the rejection sampling, we need  $t_{\mathcal{O}_I}$  time to query the independence oracle. Together, the algorithm runs in

$$O((1 + \lambda_{\max})n \log(n/\varepsilon)(\log n + t_{\mathcal{O}_I}))$$

time in expectation.  $\blacktriangleleft$

#### 4 Random cluster models with $q \leq 1$

Once again, let  $\mathcal{M} = (X, \mathcal{I})$  be a matroid, equipped with a rank function  $\text{rk}(\cdot)$ . Let  $\lambda = \{\lambda_i\}_{i \in [n]}$ , where  $\lambda_i > 0$  is the weight or external field of  $x_i \in X$ . Let  $0 \leq q \leq 1$  be a parameter. Recall the definition of the random cluster model [9] in (4). Note that when  $q = 0$ , the support of  $\pi_{RC,q,\lambda}$  are all subsets of full rank, namely they are the complements of the independent sets of the dual matroid.

Similar to Section 3.1, as the distribution is not homogeneous, we want to polarize it. Let  $Y$  be a set of  $n = |X|$  auxiliary variables. For  $T \subseteq X \cup Y$  such that  $|T| = n$ , the polarized distribution is given by

$$\widehat{\pi}_{RC,q,\lambda}(T) \propto \frac{q^{-\text{rk}(T \cap X)} \prod_{x_i \in T \cap X} \lambda_i}{\binom{n}{|T \cap Y|}}. \quad (9)$$

### 32:10 Near-Linear Time Samplers for Matroid Independent Sets with Applications

Let the right hand side of (9) be  $\text{wt}(T)$ . Note that the marginal distribution of  $\widehat{\pi}_{RC,q,\lambda}$  on  $X$  is the same as  $\pi_{RC,q,\lambda}$ .

Once homogenized, we may consider the up-down walk for  $\widehat{\pi}_{RC,q,\lambda}$ . For the up step, we uniformly add an element from  $(X \cup Y) \setminus T$ . For the down step, suppose the current set is  $T$  such that  $|T| = n + 1$ . We want to remove an element  $e \in T$  with probability proportional to  $\text{wt}(T \setminus \{e\})$ . Namely, the transition probability  $p(e)$  satisfies

$$p(e) \propto \begin{cases} \frac{q^{-\text{rk}(T \cap X)} \prod_{x_i \in T \cap X} \lambda_i}{\binom{n}{|T \cap Y| - 1}} & \text{if } e \in T \cap Y; \\ \frac{q^{-\text{rk}(T \cap X)} \prod_{x_i \in T \cap X} \lambda_i}{\lambda_j \binom{n}{|T \cap Y|}} & \text{if } e = x_j \in T \cap X \text{ and } \text{rk}(T \cap X \setminus e) = \text{rk}(T \cap X); \\ \frac{q^{-\text{rk}(T \cap X) + 1} \prod_{x_i \in T \cap X} \lambda_i}{\lambda_j \binom{n}{|T \cap Y|}} & \text{if } e = x_j \in T \cap X \text{ and } \text{rk}(T \cap X \setminus e) = \text{rk}(T \cap X) - 1. \end{cases} \quad (10)$$

We may further normalize (10) to get

$$p(e) \propto \begin{cases} \frac{n - |T \cap Y| + 1}{|T \cap Y|} = \frac{|T \cap X|}{|T \cap Y|} & \text{if } e \in T \cap Y; \\ \lambda_j^{-1} & \text{if } e = x_j \in T \cap X \text{ and } \text{rk}(T \cap X \setminus e) = \text{rk}(T \cap X); \\ q \lambda_j^{-1} & \text{if } e = x_j \in T \cap X \text{ and } \text{rk}(T \cap X \setminus e) = \text{rk}(T \cap X) - 1. \end{cases} \quad (11)$$

To implement (11), we may first propose  $e \sim \nu$  where

$$\nu(e) \propto \begin{cases} \frac{|T \cap X|}{|T \cap Y|} & \text{if } e \in T \cap Y; \\ \lambda_j^{-1} & \text{if } e = x_j \in T \cap X, \end{cases}$$

and then reject  $e \in T \cap X$  with probability  $1 - q$  if  $\text{rk}(T \cap X \setminus \{e\}) = \text{rk}(T \cap X) - 1$ . Keep doing this until we accept. To see the efficiency of this implementation. Let  $\mathcal{E}$  be the event that rejection happens. Then,

$$\begin{aligned} \Pr[\mathcal{E}] &\leq \sum_{x_j \in T \cap X} \frac{(1 - q) \lambda_j^{-1}}{\sum_{x_j \in T \cap X} \lambda_j^{-1} + \sum_{e \in T \cap Y} \frac{|T \cap X|}{|T \cap Y|}} \\ &= (1 - q) \frac{\sum_{x_j \in T \cap X} \lambda_j^{-1}}{\sum_{x_j \in T \cap X} (\lambda_j^{-1} + 1)} \leq \frac{1 - q}{1 + \lambda_{\min}}, \end{aligned}$$

where  $\lambda_{\min} := \min_{i \in [n]} \lambda_i$ . Thus, in expectation, we will successfully make a transition after  $O\left(\frac{\lambda_{\min} + 1}{\lambda_{\min} + q}\right) = O(1 + \lambda_{\min}^{-1})$  steps.

One more issue with the implementation is that we need to check the rank of  $T \cap X$  and  $T \cap X \setminus \{e\}$ . This is why we need a rank oracle instead of the independence oracle.

The only missing ingredient to get Theorem 4 is the mixing time of the chain. To this end, we claim that the up-down walk here is just the down-up walk of the corresponding random cluster model on the dual matroid. As the homogenized generating polynomial for random cluster models with  $q \leq 1$  is shown to be strongly log-concave by Brändén and Huh [5], Proposition 9 implies that the mixing time of the up-down walk is  $O(n \log(n/\epsilon))$  as well.

Finally we verify the claim. Let  $\overline{\mathcal{M}} = (X, \overline{\mathcal{I}})$  be the dual matroid of  $\mathcal{M}$ . Consider the random cluster model on  $\overline{\mathcal{M}}$  with external fields  $q/\lambda$ , where  $\lambda = \{\lambda_i\}$  is the external field vector of the original model:

$$\forall U \subseteq X, \quad \pi_{\overline{\mathcal{M}}, q, q/\lambda}(U) \propto q^{-\text{rk}_{\overline{\mathcal{M}}}(U)} \prod_{x_i \in U} \left(\frac{q}{\lambda_i}\right).$$

This is equivalent to having the field  $1/\lambda$ , but the extra  $q$  simplifies some calculation next.

The rank function of the dual matroid satisfies:

$$\text{rk}_{\overline{\mathcal{M}}}(U) = |U| + \text{rk}_{\mathcal{M}}(X \setminus U) - \text{rk}_{\mathcal{M}}(X).$$

As  $\text{rk}_{\mathcal{M}}(X)$  is a constant, we have

$$\forall U \subseteq X, \quad \pi_{\overline{\mathcal{M}},q,q/\lambda}(U) \propto q^{-\text{rk}_{\mathcal{M}}(X \setminus U)} \prod_{x_i \in X \setminus U} \lambda_i.$$

Similarly, the polarized version of  $\pi_{\overline{\mathcal{M}},q,q/\lambda}$  satisfies

$$\forall R \in \binom{X \cup Y}{n}, \quad \widehat{\pi}_{\overline{\mathcal{M}},q,q/\lambda}(R) \propto \frac{q^{-\text{rk}_{\mathcal{M}}(X \setminus R)} \prod_{x_i \in X \setminus R} \lambda_i}{\binom{n}{|R \cap Y|}}.$$

Comparing the above with (9), we have that

$$\widehat{\pi}_{\overline{\mathcal{M}},q,q/\lambda}(R) = \widehat{\pi}_{\mathcal{M},q,\lambda}((X \cup Y) \setminus R). \quad (12)$$

The down-up walk (with  $R$  being the current state) on  $\widehat{\pi}_{\overline{\mathcal{M}},q,q/\lambda}$  is:

- (down) remove an element from  $R$  uniformly at random;
  - (up) add an element  $e \in (X \cup Y) \setminus R$  to  $R$  with probability  $\propto \widehat{\pi}_{\overline{\mathcal{M}},q,q/\lambda}(R \cup \{e\})$ .
- As  $T = (X \cup Y) \setminus R$ , we can rephrase this down-up walk as an up-down walk on the random cluster over  $\mathcal{M}$ :

- (up) add an element from  $(X \cup Y) \setminus T$  to  $T$  uniformly at random;
- (down) remove an element  $e \in T$  from  $T$  with probability  $\propto \widehat{\pi}_{\overline{\mathcal{M}},q,q/\lambda}(R \cup \{e\}) = \widehat{\pi}_{\mathcal{M},q,\lambda}(T \setminus \{e\})$ , where the equality is by (12).

Thus, we conclude that the down-up walk on  $\widehat{\pi}_{\overline{\mathcal{M}},q,q/\lambda}$  is the same as the up-down walk on  $\widehat{\pi}_{\mathcal{M},q,\lambda}$  modulo mapping  $T$  to  $(X \cup Y) \setminus T$ . This verifies the claim and finishes the proof of Theorem 4.

## Abstract

---

Naively storing a counter up to value  $n$  would require  $\Omega(\log n)$  bits of memory. Nelson and Yu [9], following work of Morris [8], showed that if the query answers need only be  $(1 + \epsilon)$ -approximate with probability at least  $1 - \delta$ , then  $O(\log \log n + \log \log(1/\delta) + \log(1/\epsilon))$  bits suffice, and in fact this bound is tight. Morris' original motivation for studying this problem though, as well as modern applications, require not only maintaining one counter, but rather  $k$  counters for  $k$  large. This motivates the following question: for  $k$  large, can  $k$  counters be simultaneously maintained using asymptotically less memory than  $k$  times the cost of an individual counter? That is to say, does this problem benefit from an improved *amortized* space complexity bound?

We answer this question in the negative. Specifically, we prove a lower bound for nearly the full range of parameters showing that, in terms of memory usage, there is no asymptotic benefit possible via amortization when storing multiple counters. Our main proof utilizes a certain notion of “information cost” recently introduced by Braverman, Garg and Woodruff [2] to prove lower bounds for streaming algorithms.

**Acknowledgements** We thank Sidhanth Mohanty for very enlightening discussions on unpredictable paths, half Cauchy random variables, and stochastic processes in general that ultimately led to the discovery of the first version of our main lower bound. We also thank Mark Sellke for answering a certain question regarding stochastic processes. Lastly, we thank Greg Valiant for raising the question of the amortized space complexity of approximate counting.

## 1 Introduction

Maintaining a counter subject to increments is one of the most basic data structural problems in computer science. If the counter value stays below  $n$ , then the naive solution of maintaining the counter explicitly consumes  $O(\log n)$  bits of memory. In 1978, Morris devised a new

*approximate counting* algorithm which could maintain such a dynamic counter using much fewer bits in expectation [8]. His algorithm uses a number of random bits which itself is a random variable, whose expectation is  $O(\log \log n + \log(1/\epsilon) + \log(1/\delta))$ . At query time, this *Morris Counter* returns the correct counter value up to  $(1+\epsilon)$ -multiplicative error with failure probability at most  $\delta$ . Recently, Nelson and Yu [9] showed that a slight alteration to Morris' algorithm improves the dependence on  $\delta$ , consuming only  $O(\log \log n + \log(1/\epsilon) + \log \log(1/\delta))$  bits of memory. They also proved that this bound is asymptotically optimal.

Morris' original motivation for developing his approximate counter in the mid 1970s was, for each of  $26^3$  possible trigrams (sequences of three characters), to count the number of occurrences of that trigram amongst words in some text; these counts were then used by **typo**, an early Unix spellchecker (see more on this history in a survey by Lumbroso [7]). Approximate counters still find use in modern-day applications. For example, Redis is a highly popular in-memory database which is often used as a cache, and one built-in cache replacement policy is Least Frequently Used. To implement LFU, each item stored in cache must have an associated counter, counting the number of queries to that item over some time window. These counters are currently implemented in Redis using a variant of the Morris Counter [6].

Both the original application of Morris as well as modern-day applications of approximate counting, such as that described in Redis, need not store just one counter but many. Even in the 1970s, Morris' computer would have had enough memory to count the number of occurrences of a single trigram, but the difficulty was keeping counts of all  $26^3$  counters in memory simultaneously. Similarly, modern-day computers and mobile devices clearly also contain enough memory to store a single counter for any reasonable counter value, but one may wish to minimize the space per counter in an application where many counters must be stored simultaneously, as in the case of Redis being used to cache a large number of items. Thus even the original motivation of Morris inspires the following question:

*What is the **amortized** space complexity of approximate counting? Specifically, for  $k$  large, is it possible to maintain  $k$  approximate counters using less memory than  $k$  times that of an individual approximate counter?*

Typically such lower bounds are obtained via a direct sum argument in combination with an information complexity lower bound [3]. Specifically, a common way to carry out proving such lower bounds in the streaming context is as follows [1]: first, devise a communication game that you believe is hard (requires a lot of communication) to solve, and which reduces to the streaming problem (i.e., a low-memory streaming algorithm would imply a low-communication protocol). Suppose for illustration that this communication game is one-way, with Alice receiving input  $X$  who sends a single message  $\Pi$  to Bob who holds input  $Y$ . Here we use distributional complexity, in which  $(X, Y)$  is drawn from some distribution  $\mathcal{D}$ , and the goal is to devise a protocol in which Bob computes some  $f(X, Y)$  with success probability at least  $1 - \delta$ . Now, the so-called *external information complexity* of  $\Pi$  is defined as  $I(\Pi; X, Y)$ , which is at most  $|\Pi|$  and thus it suffices to lower bound  $I(\Pi; X, Y)$ . Once one establishes a lower bound on this quantity, then for a sequence  $\{(X_i, Y_i)\}_{i=1}^k$  of  $k$  of independently drawn such inputs, we have the following inequality [3, Theorem 1.5]:  $I(\Pi; X_1, Y_1, X_2, Y_2, \dots, X_k, Y_k) \geq \sum_{i=1}^k I(\Pi; X_i, Y_i)$ . Note though that if we want a lower bound for  $\Pi$  solving the  $k$ -fold problem, then we cannot immediately invoke the single-instance lower bound to bound each summand on the right hand side (since this  $\Pi$  is a protocol solving the  $k$ -fold problem, not a single instance!). One then typically completes the argument by showing how to efficiently embed the single-instance communication game into that of  $k$  parallel instances, to then lift the single-instance lower bound to a lower bound for the  $k$ -fold problem as outlined above.

The trouble with obtaining our desired lower bound for approximate counting via the above paradigm is that the memory lower bound of [9] was not proven via information complexity, and thus it is not clear how to execute the above direct sum argument. Rather, the lower bound proof there followed an approach similar to the proof of the pumping lemma for regular languages [10].

**Our Contribution.** We answer the above question in the negative for nearly the full range of parameters (for technical reasons in our analysis, we require the restriction  $\epsilon < 1/\log \log(1/\delta)$ ). Specifically, for this range of  $\epsilon$  we prove a strong memory lower bound demonstrating that there is no asymptotic benefit from amortization when maintaining multiple approximate counters. Our main approach is to first establish a novel information complexity type lower bound for a single approximate counter, which we then lift to multiple counters using a standard direct sum argument, by constructing an embedding of the single-counter problem into the  $k$ -fold problem.

Below we formally define the problem we solve, then state our main result. The approximate counting problem for a single counter is to maintain a multiplicative approximation to a count  $N$  (initially 0) that undergoes a sequence of increment operations. Specifically, the algorithm should support two operations: `increment()` increments  $N$  by 1, and `query()` returns a value  $\hat{N}$  such that  $\mathbb{P}(|\hat{N} - N| \geq \epsilon N) \leq \delta$ ; that is, at any point in time the data structure should be able to provide a  $(1 + \epsilon)$  multiplicative approximation with probability at least  $1 - \delta$ . Our generalization to approximating  $k$  counters is as follows:

► **Definition 1** ( $(k, \epsilon, \delta)$ -approximate counter). *Let  $N_1, \dots, N_k$  be  $k$  counters all initially set to 0. We say a randomized algorithm  $\mathcal{A}$  is a  $(k, \epsilon, \delta)$ -approximate counter if it supports two operations: `increment( $i$ )` increments  $N_i$  by 1, and `query( $i$ )` returns a value  $\hat{N}_i$  such that*

$$\mathbb{P}\left(|\hat{N}_i - N_i| \geq \epsilon N_i\right) \leq \delta.$$

When  $k = 1$ , we will simply call this an  $(\epsilon, \delta)$ -approximate counter.

The following is then our main theorem, when here and henceforth we use  $n$  in lower bounds to denote an upper bound on the number of `increment` operations:

► **Theorem 2.** *For any  $\delta < c_1$  and  $\epsilon < c_2/\log \log(1/\delta)$ , if  $k < c_3 n$  then after a sequence of at most  $n$  updates any  $(k, \epsilon, \delta)$ -counter must use  $\Omega(k \min\{\log(n/k), \log \log(n/k) + \log(1/\epsilon) + \log \log(1/\delta)\})$  bits of memory in expectation. Else if  $k > c_3 n$ , then a lower bound of  $\Omega(n \log(2k/(c_3 n)))$  holds;  $c_1, c_2, c_3 \geq 0$  are universal constants. Furthermore, for both ranges of  $k$ , these lower bounds are tight up to constant factors.*

## 1.1 Preliminaries and notation

We write  $X \sim \mathcal{D}$  to represent a random variable  $X$  sampled from the probability distribution  $\mathcal{D}$ . If the distribution of  $X$  has not been explicitly defined, we write  $P_X$  to the corresponding probability distribution of  $X$ . For two probability distributions  $P$  and  $Q$  defined on the same domain, we write  $\text{TV}(P, Q) = \int |dP - dQ|$  to be their total variation distance and  $\text{KL}(P||Q) = \int dP \log(dP/dQ)$  their Kullback-Leibler divergence. We frequently make use of Pinsker's inequality  $\text{TV}(P, Q) \leq \sqrt{\text{KL}(P||Q)}/2$ . For random variables  $X$  and  $Y$ , we write  $H(X) = \mathbb{E}_{x \sim P_X}[\log(1/P_X(x))]$  to denote the (Shannon) entropy and  $H(X | Y) = \mathbb{E}_{(x,y) \sim P_{XY}}[\log(1/P_{X|Y}(x | y))]$  to be the conditional (Shannon) entropy. The mutual

### 33:4 On the Amortized Complexity of Approximate Counting

information between two random variables  $X$  and  $Y$  is  $I(X; Y) := H(X) - H(X | Y) = H(Y) - H(Y | X)$ . The conditional mutual information is  $I(X; Y | Z) := H(X | Z) - H(X | Y, Z)$ . We frequently make use of the following inequality:

$$I(X; Y | Z) = \mathbb{E}_{X, Z} [\text{KL}(P_{Y|Z} \| P_{Y|X, Z})].$$

We also use the following well known facts about conditional mutual information [4]:

► **Proposition 3 (Chain rule).** *For random variables  $X_1, X_2, Y, Z$  we have*

$$I(X_1, X_2; Y | Z) = I(X_1; Y | Z, X_2) + I(X_2; Y | Z).$$

► **Proposition 4 (Superadditivity).** *Let  $X_1, \dots, X_n, Y$  and  $Z$  be random variables such that  $X_1, \dots, X_n$  are conditionally independent given  $Z$ . Then*

$$\sum_{i=1}^n I(X_i; Y | Z) \leq I(X_1, \dots, X_n; Y | Z).$$

Lastly,  $c, c_1, c_2, \dots > 0$  represent universal constants that may change from statement to statement.

## 1.2 Proof overview

Now we present an overview of our lower bound proof. It turns out that the terms  $\Omega(k(\log \log(n/k) + \log(1/\epsilon)))$  in the lower bound can be proved using a similar argument to the single counter case, which holds even in the offline setting, and the main challenge is to prove the dependence on  $\delta$ ,  $\Omega(k \log \log(1/\delta))$ . The previous proof, for single counter, of  $\Omega(\log \log(1/\delta))$  is based on a pumping-lemma argument, which crucially uses the fact that all updates are exactly the same, i.e., incrementing the counter. However, this no longer holds with multiple counters – we may increment any one of the  $k$  counters each time, and there are  $k$  different updates we can perform. The previous argument fails to generalize.

As we mentioned in the introduction, we first (re)prove an *information theoretic* lower bound for single counter, then apply the *superadditivity of mutual information* for independent variables to obtain the direct-sum result. For simplicity, in this overview we will focus on the case where  $\delta = 2^{-\Theta(n/k)}$ , and prove an  $\Omega(k \log \log(1/\delta)) = \Omega(k \log(n/k))$  lower bound when  $\epsilon \leq O(1/\log(n/k))$ . This case captures all the main ideas, and generalizing to the full lower bound is straightforward.

To facilitate the argument, we first slightly reformulate the problem:<sup>1</sup> Consider a stream with  $T$  batches of updates (think  $T = (n/k)^{0.1}$ ), and in each batch  $i$ , the inputs are  $k$  nonnegative integers  $X_{i,c}$  for  $c \in [k]$ , which are the number of increments we apply to each counter in this batch. Since the batch number  $i$  takes only  $O(\log T)$  bits to maintain, we may assume without loss of generality that it is given to the algorithm for free. Clearly if there is an algorithm that approximately maintains  $k$  counters, this reformulation also admits a solution using the same space, provided  $\sum_{i,c} X_{i,c} \leq n$ . After the reformulation, the single counter problem simply has  $T$  nonnegative numbers  $X_i$  as the input stream, and we would like to approximate their sum using small space provided that the sum is at most poly  $T$ , again assuming that  $i$  is given to the algorithm for free.

We will design a hard distribution over the input streams, and analyze the failure probability and measure “information” with respect to this distribution. It is crucial that the notion of information cost we use for streaming algorithms is chosen carefully. The

<sup>1</sup> For simplicity, the overview uses slightly different notation and parameters than the actual proof.

information cost defined in [2] turns out to be the right measure for our problem. Fix a streaming algorithm, and let  $M_i$  be its memory state immediately after processing  $X_i$  (see Figure 1). When all numbers  $X_i$  are independent, which will be the case for our distribution, the *information cost* of this algorithm is defined as follows (see Figure 2)

$$\text{IC} := \sum_{i=1}^T \sum_{j=1}^i I(M_i; X_j | M_{j-1}).$$

■ **Figure 1** A depiction of the evolution of the memory state of a randomized streaming algorithm  $\mathcal{A}$ .  $X_1, \dots, X_n$  are the inputs the streaming algorithm receives and  $R_1, \dots, R_n$  are the independent random bits  $\mathcal{A}$  uses as it processes the stream.  $M_0$  is the (possibly random) initial state and  $M_i$  is the state of  $\mathcal{A}$  after processing  $X_i$ . Note that  $M_i$  is a deterministic function of the previous memory state  $M_{i-1}$ , the  $i$ th input  $X_i$ , and the random bits  $R_i$ . When the inputs are random variables, this figure also depicts the dependence structure of the joint distribution of the random variables  $(X_1, \dots, X_n, R_1, \dots, R_n, M_0, M_1, \dots, M_n)$ .

■ **Figure 2** An illustration of a single inner sum of the information cost  $\sum_{j \leq i} I(M_i; X_j | M_{j-1})$  for  $i = 4$ . To simplify the presentation we do not include the random bits that the streaming algorithm uses while processing the stream in this illustration.

As it was shown in [2], this quantity lower bounds  $\sum_{i=1}^T |M_i|$ , i.e.,  $T$  times the memory consumption, and it satisfies the direct-sum property: solving  $k$  independent instances of the problem needs exactly  $k$  times IC. Thus, it suffices to prove an IC lower bound of  $\Omega(T \log T) = \Omega(T \log(n/k))$  for a single approximate counter. Intuitively, such a lower bound means that the algorithm must spend  $\Omega(1)$  bits remembering each bit of the sum (recall that we ensure  $\sum X_i \leq \text{poly } T$ ).

Let us first focus on the lowest bit, i.e., the parity of the sum. Note that one does not have to know the lowest bit in order to return an approximation of the sum. Nevertheless, we will show that the algorithm has to constantly pay attention to this bit in order to output a good approximation with very high probability. To this end, let us consider the distribution where the  $X_i$ 's are independent and uniform in  $\{0, 1\}$ . Let us focus on the terms in IC with  $j = i$ , i.e., those of the form  $I(M_i; X_i | M_{i-1})$ . Intuitively, under this distribution, this term represents how much attention the algorithm is paying to the evolution of the parity at batch  $i$ . This is because  $X_i$  is simply the difference between the parities of the first  $i - 1$  and first  $i$  inputs.

### 33:6 On the Amortized Complexity of Approximate Counting

Suppose that  $I(M_i; X_i \mid M_{i-1}) \ll 1$  for a constant fraction of  $i$ . Then, we can show that the algorithm will make an error of  $\Omega(T)$  with at least  $\delta$  probability. Roughly speaking, this is because for each such  $i$ , conditioned on  $M_i$  and  $M_{i-1}$ , the distribution of  $X_i$  is still close to uniform (as  $X_i$  is uniform conditioned on  $M_{i-1}$ ). Therefore, if we condition on all  $M_0, M_1, \dots, M_T$ , most  $X_i$  can still take both values 0 or 1 with constant probability, and all  $X_i$  are still independent by the Markov property of the algorithm. In particular, by setting all these  $X_i$ 's to 0 or setting all to 1, we reach the same final memory state  $M_T$ , but in the two cases, the total sum differs by  $\Omega(T)$ . Since both happen with probability  $2^{-O(T)} \gg \delta$  given the final memory state  $M_T$ , the algorithm must make an error of at least  $\Omega(T)$  with probability at least  $\delta$ .

We can extend this argument to any specific bit of the sum by considering a stream with  $\Theta(T/B^l)$  independent random increments that are uniform in  $\{0, B^l\}$  for some constant  $B$  and  $l \in [L]$ , where  $L = \log_B T$ . Our final hard distribution interleaves  $L$  such streams, which we call the scales. For each scale  $l \in [L]$ , we evenly spread the  $\Theta(T/B^l)$  random increments in the whole stream with a gap of  $\Theta(B^l)$  batches. Note that now the sum of all inputs is always at most  $O(T \log T)$ . For the sum in the definition of IC, we will only focus on  $L$  terms for each  $i$ :  $I(M_i; X_{\lfloor i \rfloor_l} \mid M_{\lfloor i \rfloor_l - 1})$ , where  $X_{\lfloor i \rfloor_l}$  is the closest scale  $l$  input before  $M_i$ . If  $\text{IC} \ll T \cdot L = O(T \log T)$ , then there must exist some scale  $l^*$  such that  $I(M_i; X_{\lfloor i \rfloor_{l^*}} \mid M_{\lfloor i \rfloor_{l^*} - 1}) \ll 1$  for most  $i$ . Then we apply the above argument, and show that conditioned on the memory states right before each scale- $l^*$  input, most scale- $l^*$  inputs can still take values 0 or  $B^{l^*}$  with constant probability, and the scale- $l^*$  inputs are still independent. We further observe that for most of them, the inputs between  $X_{\lfloor i \rfloor_{l^*}}$  and  $M_i$  are coming from the lower scales  $l < l^*$ . The standard deviation of their sum is much smaller than  $B^{l^*}$ , and we can show that they do not affect the sum by too much as we alter  $X_{\lfloor i \rfloor_{l^*}}$ . Thus, by setting these scale- $l^*$  inputs to 0 or  $B^{l^*}$ , the entire sum will again differ by  $\Omega(T)$ , but they lead to the same final memory state, i.e., the algorithm does not distinguish between the two cases. Since the sum is  $O(T \log T)$ , such a difference is more than  $\epsilon$  times the sum when  $\epsilon < O(1/\log T)$ . A more careful analysis shows that this happens with probability at least  $2^{-O(T)} > \delta$ , leading to a contradiction.

#### Discussion on the choice of the hard distribution

We note here that the independent uniform  $\{0, 1\}$  distribution, by itself, is *not* hard for the information cost. One solution with low information cost is to divide  $X_i$ 's into blocks of size  $S = \Theta(\epsilon^{-2} \log T)$ , and maintain the exact sum within the current block. If *all* blocks have sums  $(1 \pm \epsilon)S/2$ , then we simply remember this fact and use  $T/2$  as the final output. Otherwise, the algorithm finds a block whose sum is not in this range, then it maintains the exact sum for all future blocks. Since all previous blocks have sums  $(1 \pm \epsilon)S/2$ , in particular,  $S/2$  is a  $(1 + \epsilon)$ -approximation for them, the algorithm can also return a  $(1 + \epsilon)$ -approximation of the whole sum. Now note that this case only happens with  $1/\text{poly}(T)$  probability, and the total information cost is at most  $T$  times the expected memory usage. The expected memory is at most  $O(\log(1/\epsilon) + \log \log T)$  bits for maintaining the sum in the current block, plus  $O(T^{-\Theta(1)} \cdot \log T)$  bits in expectation for maintaining the entire exact sum. When  $\epsilon = \Theta(1/\log T)$ , the information cost is only  $O(T \log \log T) \ll T \log T$ .

The above strategy works since the sum of block is concentrated around the expectation, hence, we need extra space to maintain the exact sum only with very small probability. One can also show that the above strategy also applies to any i.i.d. distributions with some concentration.<sup>2</sup> Our hard distribution is inspired by the *discrete half-Cauchy distribution*,

<sup>2</sup> For example, it suffices to have finite  $\mathbb{E}[|X|^{1.01}]$ .

which has probability  $\Theta(1/(x+1)^2)$  at integers  $x \geq 0$ . This distribution does not have an expectation, hence, there is no concentration for blocks of any size. We also have a more involved proof of our main result that uses this distribution instead; the main property that proof relies on is that for every  $W$  random variables, roughly one of them takes value  $\Theta(W)$ . The hard distribution we actually use in this paper is a bounded distribution that can be viewed as extracting this useful property of the half-Cauchy distribution, but which can be analyzed more simply.

## 2 Lower Bounds

In this section we will prove our lower bound for the space complexity of  $(k, \epsilon, \delta)$ -approximate counting. We split the proof into two parts. We first focus on proving the difficult part of the lower bound that depends on the failure probability  $\delta$ . To do so, we derive a lower bound for the space complexity of  $(\epsilon, \delta)$ -approximate counting by appealing to an information theoretic argument. By using a good definition of information cost together with an appropriately chosen hard distribution, we can prove that any accurate algorithm remember a lot of information about many different parts of the stream, i.e. it incurs a high information cost. This immediately gives us a lower bound on the memory size. We then use this result to prove a space lowerbound for  $(k, \epsilon, \delta)$ -approximate counting via a direct sum argument. We conclude the section by proving the portion of the lower bound that depends on the approximation error  $\epsilon$  and the total sum of all counters  $n$  by generalizing the argument used in the single counter case.

### 2.1 Information lower bound for a single counter

Recall that for a randomized streaming algorithm  $\mathcal{A}$  we define  $M_i$  to be the state of  $\mathcal{A}$  after processing the  $i$ th input  $X_i$  together with some additional independent random bits  $R_i$ , i.e.  $M_i$  is a deterministic function of  $M_{i-1}$ ,  $X_i$  and  $R_i$  (equivalently, a deterministic function of  $X_{\leq i}$  and  $R_{\leq i}$ ). The following is a notion of information cost for streaming algorithms originally defined by Braverman, Garg, and Woodruff [2].

► **Definition 5.** *Let  $\mathcal{A}$  be a randomized streaming algorithm. Given a distribution  $\mathcal{D}$  over input sequences of length  $s$ , we define the information cost of algorithm  $\mathcal{A}$  on input  $(X_1, \dots, X_s) \sim \mathcal{D}$  to be*

$$\text{IC}(\mathcal{A}, \mathcal{D}) := \sum_{i=1}^s \sum_{j=1}^i I(M_i; X_j \mid M_{j-1}).$$

The above definition of the information cost is motivated by the following chain of inequalities:

$$\begin{aligned} \mathbb{E}|M_i| &\geq H(M_i) \text{ (source coding theorem}^3\text{)} \\ &\geq I(M_i; X_{\leq i}, M_{<i}) \\ &= \sum_{j=1}^i I(M_i; X_j, M_{j-1} \mid X_{<j}, M_{<j-1}) \\ &= \sum_{j=1}^i I(M_i; M_{j-1} \mid X_{<j}, M_{<j-1}) + I(M_i; X_j \mid X_{<j}, M_{<j}) \\ &= \sum_{j=1}^i I(M_i; X_j \mid X_{<j}, M_{<j}) \\ &= \sum_{j=1}^i I(M_i; X_j \mid M_{j-1}). \end{aligned}$$

### 33:8 On the Amortized Complexity of Approximate Counting

This implies that  $\text{IC}(\mathcal{A}; \mathcal{D}) \leq \sum_{i=1}^s \mathbb{E} |M_i|$ . The main technical part of this paper is proving the following lower bound for a single counter using this notion of information cost.

► **Lemma 6.** *Let  $\mathcal{A}$  be a  $(\epsilon, \delta)$ -approximate counter with parameters  $\delta \in (0, c_1)$  and  $\epsilon \in (0, \frac{c_2}{\log \log(1/\delta)})$  that uses  $|M|$  bits of space. There is a distribution  $\mathcal{D}$  over inputs such that the information cost of  $\mathcal{A}$  on  $(X_1, \dots, X_n) \sim \mathcal{D}$  satisfies*

$$\text{IC}(\mathcal{A}; \mathcal{D}) = \Omega(n \log \log(1/\delta)),$$

where  $\mathbb{P}[\sum_{i=1}^n X_i \leq n] = 1$  and  $n \geq c_3 \log^{c_4}(1/\delta)$ . This implies the space lower bound

$$\frac{1}{n} \sum_{i=1}^n \mathbb{E} |M_i| = \Omega(\log \log(1/\delta)) = \Omega(\min\{\log n, \log \log(1/\delta)\}).$$

**Proof.** We construct the distribution  $\mathcal{D}$  as follows: let  $B \in \mathbb{N}$  be a large integer constant to be specified later, and  $T$  is the largest power of  $B$  such that  $T < \log_{32}(1/\delta)$ . When  $\delta < c_1$  where  $c_1 = c_1(B)$  is a sufficiently small constant, we have  $T \geq B$  and so  $L := \log_B T \in \mathbb{N}$ . The distribution  $\mathcal{D}$  is an interleaving of  $L$  distributions  $\mathcal{D}_\ell$  on  $L$  different scales, where for each scale  $\ell \in [L]$ , the distribution  $\mathcal{D}_\ell$  is a product distribution  $\prod_{i=1}^T \mathcal{D}_{\ell,i}$ :

$$\text{under } \mathcal{D}_{\ell,i}, \quad Y_{\ell,i} \begin{cases} \sim \text{Unif}(\{0, B^\ell\}) & \text{if } B^\ell \text{ divides } (i-1), \\ = 0 & \text{otherwise.} \end{cases}$$

For notational simplicity, we also denote the non-zero entries of  $Y_{\ell,i}$  by  $Z_{\ell,j} = Y_{\ell, B^\ell(j-1)+1}$  for  $j \in [T/B^\ell]$ . The stream under distribution  $\mathcal{D}$  is then generated by interleaving the  $Y_{\ell,i}$  terms to form the sequence  $X^n = (Y_{1,1}, \dots, Y_{L,1}, Y_{1,2}, \dots, Y_{L,2}, \dots, Y_{L,T})$ , where  $n := TL$  is the length of the sequence. The total value of the counter under this stream is at most

$$\sum_{\ell=1}^L B^\ell \cdot \frac{T}{B^\ell} = n.$$

Finally, note that  $n = TL \geq c_3 \log^{c_4}(1/\delta)$  for an appropriate choice of constants  $c_3, c_4 \geq 0$ .

Let  $\mathcal{A}$  be an  $(\epsilon, \delta)$ -approximate counter, and assume towards contradiction that  $\text{IC}(\mathcal{A}; \mathcal{D}) < \alpha n L$  where  $\alpha$  is a small constant. For any index  $i \in [n]$  in the stream, let  $[i]_\ell := B^\ell L \lfloor (i-1)/(B^\ell L) \rfloor + \ell$  be the index of the closest  $Z_{\ell,j}$  to the left of  $X_i$  in the stream, i.e.  $X_{[i]_\ell} = Z_{\ell,j}$ . Similarly, for  $j \in [T/B^\ell]$ , we define  $\lceil j \rceil_\ell := B^\ell L(j-1) + \ell$  to be the index of the  $j$ th non-zero entry of scale  $\ell$  in the stream, i.e.  $X_{\lceil j \rceil_\ell} = Z_{\ell,j}$ . The definition of the information cost tells us that

$$\begin{aligned} \alpha n L &> \text{IC}(\mathcal{A}; \mathcal{D}) \\ &= \sum_{i=1}^n \sum_{j \leq i} I(M_i; X_j \mid M_{j-1}) \\ &\geq \sum_{i=1}^n \sum_{\ell=1}^L I(M_i; X_{[i]_\ell} \mid M_{\lceil [i]_\ell / B^\ell \rceil_\ell}) \end{aligned}$$

<sup>3</sup> The source coding theorem holds for any prefix code. In general we may lose a factor of 2 in this inequality: we have both  $\mathbb{E}[|M_i|] \geq H(M_i \mid |M_i|)$  and  $\mathbb{E}[|M_i|] = \sum_{n \geq 1} n p_n = \sum_{n \geq 1} p_n \log(1/2^{-n}) = \sum_{n \geq 1} p_n \log(p_n/2^{-n}) + H(|M_i|) \geq H(|M_i|)$  for  $p_n := \mathbb{P}(|M_i| = n)$ ; consequently  $2\mathbb{E}[|M_i|] \geq H(M_i \mid |M_i|) + H(|M_i|) \geq H(M_i)$ .

$$\begin{aligned}
&= \sum_{\ell=1}^L \sum_{j=1}^{T/B^\ell} \sum_{i=[j]_\ell}^{[j+1]_\ell-1} I(M_i; X_{[j]_\ell} \mid M_{[j]_\ell-1}) \\
&\geq \sum_{\ell=1}^L \sum_{j=1}^{T/B^\ell} B^\ell L \cdot I(M_{[j+1]_\ell-1}; X_{[j]_\ell} \mid M_{[j]_\ell-1}) \\
&\geq \min_{\ell \in [L]} B^\ell L^2 \sum_{j=1}^{T/B^\ell} I(M_{[j+1]_\ell-1}; X_{[j]_\ell} \mid M_{[j]_\ell-1}) \\
&= \min_{\ell \in [L]} B^\ell L^2 \sum_{j=1}^{T/B^\ell} I(M_{[j+1]_\ell-1}; Z_{\ell,j} \mid M_{[j]_\ell-1})
\end{aligned}$$

where the second last inequality is due to the data processing inequality. By Markov's inequality, there exist  $\ell_0 \in [L]$  and  $J_0 \subseteq [T/B^{\ell_0}]$  with  $|J_0| \geq T/(2B^{\ell_0})$  and

$$I(M_{[j+1]_{\ell_0-1}}; Z_{\ell_0,j} \mid M_{[j]_{\ell_0-1}}) \leq 2\alpha, \quad \forall j \in J_0.$$

For ease of presentation, we abuse notation and write the above inequality as  $I(M_j; Z_j \mid M_{j-1}) \leq 2\alpha$  for  $j \in J_0$ . We shall also keep in mind that the stream between  $M_{j-1}$  and  $M_j$  contains  $(Z_j^<, Z_j, Z_j^>)$ , where  $Z_j^<$  is the collection of all non-zero inputs  $\{Z_{\ell',j'}\}$  inside this window with a lower scale  $\ell' < \ell$ , and  $Z_j^>$  is the counterpart with a higher scale  $\ell' > \ell$  (see Figure 3).

Next we define several good events for the sake of analysis. The first good event  $E_{j,1}$  characterizes the behavior of the contribution of  $Z_j^<$  and is formally defined as

$$\mathbb{1}(E_{j,1}) := \mathbb{1} \left( \left| \text{sum}(Z_j^<) - \mathbb{E}[\text{sum}(Z_j^<) \mid M_{j-1}, M_j] \right| \leq \frac{B^{\ell_0}}{4} \right), \quad j \in J_0.$$

By Chebyshev's inequality, it is clear that

$$\begin{aligned}
\mathbb{E}_{M_{j-1}, M_j} [\mathbb{P}(E_{j,1}^c \mid M_{j-1}, M_j)] &\leq \mathbb{E}_{M_{j-1}, M_j} \left[ \frac{\text{Var}(\text{sum}(Z_j^<) \mid M_{j-1}, M_j)}{(B^{\ell_0}/4)^2} \right] \\
&\leq \frac{\text{Var}(\text{sum}(Z_j^<))}{(B^{\ell_0}/4)^2} \\
&= \frac{16}{B^{2\ell_0}} \sum_{\ell < \ell_0} B^{\ell_0 - \ell} \cdot \frac{B^{2\ell}}{4} \leq \frac{4}{B-1}.
\end{aligned}$$

Consequently, it holds that

$$\begin{aligned}
&\mathbb{E}_{M_{j-1}, M_j} [\text{TV}(P_{Z_j}, P_{Z_j \mid M_{j-1}, M_j, E_{j,1}})] \\
&= \mathbb{E}_{M_{j-1}, M_j} [\text{TV}(P_{Z_j \mid M_{j-1}}, P_{Z_j \mid M_{j-1}, M_j, E_{j,1}})] \\
&\leq \mathbb{E}_{M_{j-1}, M_j} [\text{TV}(P_{Z_j \mid M_{j-1}}, P_{Z_j \mid M_{j-1}, M_j}) + \text{TV}(P_{Z_j \mid M_{j-1}, M_j}, P_{Z_j \mid M_{j-1}, M_j, E_{j,1}})] \\
&= \mathbb{E}_{M_{j-1}, M_j} [\text{TV}(P_{Z_j \mid M_{j-1}}, P_{Z_j \mid M_{j-1}, M_j})] + \mathbb{E}_{M_{j-1}, M_j} [\mathbb{P}(E_{j,1}^c \mid M_{j-1}, M_j)] \\
&\leq \sqrt{\frac{1}{2} \mathbb{E}_{M_{j-1}, M_j} [\text{KL}(P_{Z_j \mid M_{j-1}} \parallel P_{Z_j \mid M_{j-1}, M_j})]} + \frac{4}{B-1} \\
&= \sqrt{I(Z_j; M_j \mid M_{j-1})} + \frac{4}{B-1} \\
&\leq \sqrt{\alpha} + \frac{4}{B-1},
\end{aligned}$$

### 33:10 On the Amortized Complexity of Approximate Counting

which can be made small by choosing  $\alpha > 0$  small enough and  $B \in \mathbb{N}$  large enough. Note that in the above inequality we have used the triangle inequality  $\text{TV}(P, Q) \leq \text{TV}(P, R) + \text{TV}(Q, R)$ , the conditioning relationship  $\text{TV}(P, P|_E) = P(E^c)$ , Pinsker's inequality  $\text{TV}(P, Q) \leq \sqrt{\text{KL}(P||Q)}/2$ , and Jensen's inequality  $\mathbb{E}[\sqrt{X}] \leq \sqrt{\mathbb{E}[X]}$ .

The next good event  $E_2$  concerns the simultaneous occurrence of  $\{E_{j,1}\}$  for a constant proportion of  $j \in J_0$ . Specifically,  $E_2$  is the event that there exists some  $J_1 \subseteq J_0$  such that:

1.  $|J_1| \geq |J_0|/2 \geq T/(4B^{\ell_0})$ ;
2. event  $E_{j,1}$  is true for all  $j \in J_1$ ;
3. a small TV distance  $\text{TV}(P_{Z_j}, P_{Z_j|M_{j-1}, M_j, E_{j,1}}) \leq 1/4$  (denoted by event  $E_{j,2}$ ) for all  $j \in J_1$ .

Since  $\{(Z_j^<, Z_j, Z_j^>)\}$  are conditionally independent given  $\{M_j\}$ ,

$$\begin{aligned} & \mathbb{E}_{\{M_j\}} \left[ \sum_{j \in J_0} \mathbb{1}(E_{j,1} \cap E_{j,2}) \right] \\ &= \sum_{j \in J_0} \mathbb{E}_{M_{j-1}, M_j} [\mathbb{1}(E_{j,1} \cap E_{j,2})] \\ &\geq \sum_{j \in J_0} \left( 1 - \mathbb{E}_{M_{j-1}, M_j} [\mathbb{P}(E_{j,1}^c | M_{j-1}, M_j)] \right. \\ &\quad \left. - 4 \cdot \mathbb{E}_{M_{j-1}, M_j} [\text{TV}(P_{Z_j}, P_{Z_j|M_{j-1}, M_j, E_{j,1}})] \right) \\ &\geq \left( 1 - \frac{4}{B-1} - 4 \left( \sqrt{\alpha} + \frac{4}{B-1} \right) \right) |J_0| \\ &\geq \frac{3}{4} |J_0|, \end{aligned}$$

by choosing  $\alpha$  small enough and  $B$  large enough. Consequently, by Markov's inequality, we have  $\mathbb{P}(E_2) \geq 1/2$  over the randomness of  $\{M_j\}$  and  $\{(Z_j^<, Z_j, Z_j^>)\}$ .

Now we condition on  $E_2$  and arrive at the desired contradiction. For a probability distribution  $P$  over the real line and  $\Delta \geq 0$ , define a quantity  $f(P, \Delta)$  as follows:

$$f(P, \Delta) = \max\{\delta > 0 : \exists L \in \mathbb{R} \text{ such that } P((-\infty, L]) \geq \delta, P([L + \Delta, \infty)) \geq \delta\}.$$

Intuitively, a *small*  $f(P, \Delta)$  implies that the distribution  $P$  assigns a lot of probability to *some* interval of length  $\Delta$ . The following lemma summarizes some properties of  $f(P, \Delta)$ .

► **Lemma 7.** *Let  $P$  and  $Q$  be two probability distributions over  $\mathbb{R}$ , and  $P \star Q$  denote their convolution. For  $\Delta_1, \Delta_2, \Delta \geq 0$ , it holds that*

$$\begin{aligned} f(P \star Q, \Delta_1 + \Delta_2) &\geq f(P, \Delta_1) f(Q, \Delta_2), \\ f(P \star Q, \Delta) &\geq f(P, \Delta)/2. \end{aligned}$$

**Proof.** For the first claim, suppose that

$$\begin{aligned} \min\{P((-\infty, L_1]), P([L_1 + \Delta_1, \infty))\} &\geq f(P, \Delta_1), \\ \min\{Q((-\infty, L_2]), Q([L_2 + \Delta_2, \infty))\} &\geq f(Q, \Delta_2). \end{aligned}$$

Then the first inequality follows from

$$\begin{aligned} P \star Q((-\infty, L_1 + L_2]) &\geq P((-\infty, L_1]) Q((-\infty, L_2]) \geq f(P, \Delta_1) f(Q, \Delta_2), \\ P \star Q([L_1 + L_2 + \Delta_1 + \Delta_2, \infty)) & \\ &\geq P([L_1 + \Delta_1, \infty)) Q([L_2 + \Delta_2, \infty)) \geq f(P, \Delta_1) f(Q, \Delta_2). \end{aligned}$$

The second claim is a direct consequence of the first claim and  $f(Q, 0) \geq 1/2$ . ◀

To apply Lemma 7, we consider the conditional distribution  $P_{S|\{M_j\}}$ , where  $S = \sum_{i=1}^n X_i$  is the total number of counter updates, and  $\{M_j\}$  are the memory states at scale  $\ell_0$  defined before. Since the counter  $\mathcal{A}$  is  $(\epsilon, \delta)$ -approximate, in expectation  $P_{S|\{M_j\}}$  must have probability mass at least  $1 - \delta$  on an interval of size  $2\epsilon n$ . This implies that

$$\mathbb{E}_{\{M_j\}} [f(P_{S|\{M_j\}}, 2\epsilon n)] \leq \delta. \quad (1)$$

On the other hand, since  $\{(Z_j^<, Z_j, Z_j^>)\}$  are conditionally independent given  $\{M_j\}$ , we may invoke Lemma 7 (first part for  $J_1$  and second part for  $J_1^c$ ) to arrive at

$$\begin{aligned} \mathbb{E}_{\{M_j\}} [f(P_{S|\{M_j\}}, 2\epsilon n)] &\geq \mathbb{P}(E_2) \mathbb{E}_{\{M_j\}} [f(P_{S|\{M_j\}}, 2\epsilon n) \mid E_2] \\ &\geq \frac{1}{2} \cdot \mathbb{E}_{\{M_j\}} \left[ \prod_{j \in J_1} f(P_{\text{sum}(Z_j^<, Z_j, Z_j^>)|M_{j-1}, M_j, \frac{2\epsilon n}{|J_1|}}) \cdot \left(\frac{1}{2}\right)^{\frac{T}{B^{\ell_0}} - |J_1|} \mid E_2 \right] \\ &\geq \frac{1}{2T} \cdot \mathbb{E}_{\{M_j\}} \left[ \prod_{j \in J_1} f(P_{\text{sum}(Z_j^<, Z_j, Z_j^>)|M_{j-1}, M_j, 8\epsilon L B^{\ell_0}}) \mid E_2 \right]. \end{aligned}$$

Conditioned on the event  $E_2$ , the event  $E_{j,1}$  implies that the deviation of  $\text{sum}(Z_j^<)$  to its posterior mean is at most  $B^{\ell_0}/4$ , and the event  $E_{j,2}$  implies that the posterior (marginal) distribution of  $Z_j$  puts at least  $1/4$  probability mass on both 0 and  $B^{\ell_0}$ . Moreover,  $\text{sum}(Z_j^>)$  is always an integral multiple of  $B^{\ell_0+1}$ . Now we prove that

$$f(P_{\text{sum}(Z_j^<, Z_j, Z_j^>)|M_{j-1}, M_j, E_{j,1}, E_{j,2}}, \frac{B^{\ell_0}}{3}) \geq \frac{1}{16}.$$

We distinguish into two cases:

1. Case I:  $\mathbb{P}(\text{sum}(Z_j^>) \neq \text{median}(\text{sum}(Z_j^>))) \geq 1/8$ . As  $\text{sum}(Z_j^>)$  is always an integral multiple of  $B^{\ell_0+1}$ , this implies that with probability at least  $\frac{1}{8}$ ,  $|\text{median}(\text{sum}(Z_j^>)) - \text{sum}(Z_j^>)|$  is at least  $B^{\ell_0+1}/2$ . By symmetry, without loss of generality we may assume that  $\text{median}(\text{sum}(Z_j^>)) - \text{sum}(Z_j^>)$  is at least  $B^{\ell_0+1}/2$  with probability at least  $(1/8)/2 = 1/16$ . Moreover, the range of  $Z_j$  is  $B^{\ell_0}$ , and the range of  $\text{sum}(Z_j^<)$  is at most  $B^{\ell_0}/2$  under  $E_{j,1}$ . Consider the interval

$$\left[ \text{median}(\text{sum}(Z_j^<, Z_j, Z_j^>)), \text{median}(\text{sum}(Z_j^<, Z_j, Z_j^>)) + \frac{B^{\ell_0}}{3} \right]$$

of length  $B^{\ell_0}/3$ , it is clear that

$$\begin{aligned} \mathbb{P}(\text{sum}(Z_j^<, Z_j, Z_j^>) \leq \text{median}(\text{sum}(Z_j^<, Z_j, Z_j^>))) &\geq \frac{1}{2}, \\ \mathbb{P}\left(\text{sum}(Z_j^<, Z_j, Z_j^>) \geq \text{median}(\text{sum}(Z_j^<, Z_j, Z_j^>)) + \frac{B^{\ell_0}}{3}\right) \\ &\geq \mathbb{P}\left(\text{sum}(Z_j^>) \geq \text{median}(\text{sum}(Z_j^>)) + \frac{3B^{\ell_0}}{2} + \frac{B^{\ell_0}}{3}\right) \geq \frac{1}{16}, \end{aligned}$$

as long as  $B^{\ell_0+1}/2 \geq 11B^{\ell_0}/6$ , or equivalently  $B \geq 4$ .

2. Case II:  $\mathbb{P}(\text{sum}(Z_j^>) = \text{median}(\text{sum}(Z_j^>))) \geq 7/8$ . In this case, we argue that each of the following two probabilities is at least  $1/16$ :

$$\mathbb{P}\left(\text{sum}(Z_j^<) + Z_j + \text{sum}(Z_j^>) \leq \mathbb{E}[\text{sum}(Z_j^<)] + \frac{B^{\ell_0}}{3} + \text{median}(\text{sum}(Z_j^>))\right),$$

### 33:12 On the Amortized Complexity of Approximate Counting

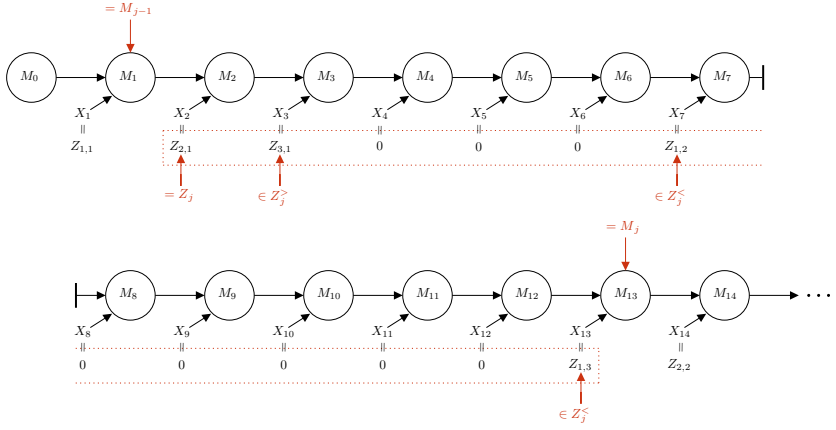

$$\mathbb{P} \left( \text{sum}(Z_j^<) + Z_j + \text{sum}(Z_j^>) \geq \mathbb{E}[\text{sum}(Z_j^<)] + \frac{2B^{\ell_0}}{3} + \text{median}(\text{sum}(Z_j^>)) \right).$$

By symmetry we only prove the first claim, where the event occurs whenever  $Z_j = 0$  and  $\text{sum}(Z_j^>)$  is equal to its median. By the union bound, this happens with probability at least  $1 - (1/8 + 3/4) = 1/8$ .

Consequently, as long as  $\epsilon \leq 1/(24L) = O(1/\log \log(1/\delta))$ ,

$$\mathbb{E}_{\{M_j\}} [f(P_{S|\{M_j\}}, 2\epsilon n)] \geq \left( \frac{1}{32} \right)^T. \quad (2)$$

However, as  $T < \log_{32}(1/\delta)$ , inequalities (1) and (2) are contradictory to each other. Thus, the assumption that  $\text{IC}(\mathcal{A}; \mathcal{D}) < \epsilon n L$  cannot be true.  $\blacktriangleleft$

■ **Figure 3** A simple example that illustrates the interleaving process for our random stream. We set the parameters  $B = 2$  and  $T = 8$  so that we sample from  $L = 3$  scales to get a stream of total length  $n = 24$ . We do not illustrate the entire stream to save space. In this example we consider  $\ell_0 = 2$  and demonstrate what a typical  $Z_j$  looks like. The sequence of random variables inside the red dotted box/window consists of the terms  $(Z_j^<, Z_j, Z_j^>)$  and we highlight the memory states  $M_{j-1}, M_j$ .

## 2.2 Amortized space complexity via direct sum

We will now “lift” the information lower bound for any  $(\epsilon, \delta)$ -approximate counter to a lower bound for any  $(k, \epsilon, \delta)$ -approximate counter from which we can derive a lower bound on the memory size. The proof follows from a simple direct sum argument applied to the information cost.

► **Lemma 8.** *Any  $(k, \epsilon, \delta)$ -approximate counter with parameters  $\delta \in (0, c_1)$  and  $\epsilon \in (0, \frac{c_2}{\log \log(1/\delta)})$  that maintains  $k$  counters with total sum at most  $n \geq k(c_3 \log^{c_4}(1/\delta))$  must use*

$$\Omega(k \log \log(1/\delta)) = \Omega(k \min\{\log(n/k), \log \log(1/\delta)\})$$

*bits of memory in expectation.*

**Proof.** We prove the lower bound via a reduction to the information lower bound for a single counter. That is, we will embed updates from the hard distribution  $\mathcal{D}$  used to prove the single counter lower bound in Lemma 6 into the  $k$  counter problem. Fix a  $(k, \epsilon, \delta)$ -approximate counter  $\mathcal{A}_k$ . Since the distribution  $\mathcal{D}$  is a product distribution, we can write  $\mathcal{D} = \prod_{i=1}^{n'} \mathcal{D}_i$  for  $n' := n/k$ . We define  $X_i^k := (X_{i,1}, \dots, X_{i,k}) \sim (\mathcal{D}_i)^k$  for each  $i \in [n']$ . We consider  $X_i^k$  to be the  $i$ th input to  $\mathcal{A}_k$  where  $X_{i,j}$  is the update applied to  $j$ th counter. The overall input to  $\mathcal{A}_k$  is

$$(X_1^k, \dots, X_{n'}^k) \sim \prod_{i=1}^{n'} (\mathcal{D}_i)^k,$$

and the total sum of all counts is at most  $n = kn' \geq k(c_3 \log^{c_4}(1/\delta))$  (see Lemma 6). Define  $\mathcal{D}_{\text{int}} := \prod_{i=1}^{n'} (\mathcal{D}_i)^k$ . Let  $M_i$  be the memory state of the algorithm after processing the  $i$ th input  $X_i^k$ . We can lower bound the information cost incurred by  $\mathcal{A}_k$ :

$$\text{IC}(\mathcal{A}_k, \mathcal{D}_{\text{int}}) = \sum_{i=1}^{n'} \sum_{j=1}^i I(M_i; X_j^k \mid M_{j-1}) \geq \sum_{u=1}^k \sum_{i=1}^{n'} \sum_{j=1}^i I(M_i; X_{j,u} \mid M_{j-1}),$$

where the inequality follows from the superadditivity of conditional mutual information (Proposition 4).

We now explain how we embed the single counter problem into the  $k$  counter problem using  $\mathcal{A}_k$ . Given the input  $X^{n'} = (X_1, \dots, X_{n'}) \sim \mathcal{D}$  for a single counter, we pick an index  $u \in [k]$  uniformly at random and proceed as if the updates are applied to  $u$ th counter of  $\mathcal{A}_k$ . Denote by  $U$  this uniformly random index. For the other counters, we simulate “fake” updates from the same distribution and apply them to  $\mathcal{A}_k$  as if they were received as inputs. Denote by  $\mathcal{A}'$  the resulting approximate counter that maintains  $X^{n'}$ . We can upper bound the information cost of  $\mathcal{A}'$  by

$$\begin{aligned} \text{IC}(\mathcal{A}', \mathcal{D}) &= \sum_{i=1}^{n'} \sum_{j=1}^i I(M_i; X_{j,U} \mid M_{j-1}, U) \\ &= \frac{1}{k} \sum_{u=1}^k \sum_{i=1}^{n'} \sum_{j=1}^i I(M_i; X_{j,u} \mid M_{j-1}) \\ &\leq \frac{1}{k} \sum_{i=1}^{n'} \sum_{j=1}^i I(M_i; X_j^k \mid M_{j-1}) \\ &= \frac{\text{IC}(\mathcal{A}_k, \mathcal{D}_{\text{int}})}{k}. \end{aligned}$$

Combining the above with Lemma 6 provides a lower bound on  $\text{IC}(\mathcal{A}', \mathcal{D})$ , which further implies the space lower bound

$$\frac{1}{n'} \sum_{i=1}^{n'} \mathbb{E}[|M_i|] \geq \Omega(k \min\{\log(n/k), \log \log(1/\delta)\})$$

for the claimed range of  $\epsilon$  and  $\delta$ . ◀

### 2.3 Offline lower bound

We now state and prove the remaining part of the lower bound.

### 33:14 On the Amortized Complexity of Approximate Counting

► **Lemma 9.** For any  $\epsilon \in (0, c_1)$ ,  $\delta \in (0, c_2)$  and  $1 < k \leq n$ , any  $(k, \epsilon, \delta)$ -approximate counter  $\mathcal{A}$  that maintains  $k$  counters with total sum at most  $n$  must use

$$|M| = \Omega(\min\{k \log(n/k), k \log(1/\epsilon) + k \log \log(n/k)\})$$

bits of memory.

**Proof.** Let  $N(i) = \lceil (e^{4i\epsilon} - 1) \cdot \epsilon^{-1} \rceil$ . Some simple calculations show

$$\begin{aligned} & (1 - \epsilon) \cdot N(i + 1) - (1 + \epsilon) \cdot N(i) \\ & \geq \epsilon^{-1}(1 - \epsilon)(e^{4(i+1)\epsilon} - 1) - \epsilon^{-1}(1 + \epsilon)(e^{4i\epsilon} - 1) - (1 + \epsilon) \\ & = \epsilon^{-1}((1 - \epsilon)e^\epsilon - 1 - \epsilon)e^{4i\epsilon} + 1 - \epsilon \\ & \geq \epsilon^{-1}((1 - \epsilon)e^{4\epsilon} - 1 - \epsilon)e^{4i\epsilon} \\ & \geq \epsilon^{-1}((1 - \epsilon)(1 + 4\epsilon) - 1 - \epsilon) \cdot 1 \\ & = 2 - 4\epsilon > 0. \end{aligned}$$

So for any  $i \neq i'$ ,  $N(i)$  and  $N(i')$  must have a  $(1 \pm \epsilon)$  multiplicative gap. We will consider  $k$  counters that take on such values, i.e.  $k$  counters that receive an (arbitrary) sequence of increments leading to counts  $N(i_1), N(i_2), \dots, N(i_k)$  respectively. It is easy to see that if  $i_r \leq (4\epsilon)^{-1} \cdot \ln(1 + n\epsilon/k)$  for all  $r \in [k]$ , the total sum of all the counters will be at most  $n$ . Let  $q := \lfloor (4\epsilon)^{-1} \cdot \ln(1 + n\epsilon/k) \rfloor$  and define the set of possible counts  $\mathbf{N} := \{N(1), N(2), \dots, N(q)\}$ . We can represent the counts of all  $k$  counters as vectors in  $\mathbf{N}^k$ .

Consider a “large” collection of vectors  $V \subseteq \mathbf{N}^k$  such that for every pair of counts  $u, v \in V$ ,  $u$  and  $v$  differ in at least at least 90% of the coordinates. Notice that this implies that  $u$  and  $v$  differ multiplicatively in at least 90% of the coordinates by definition. Such a  $V$  is equivalent to an error correcting code.

► **Definition 10.** An error correcting code  $C$  of length  $k$  over a finite alphabet  $\Sigma$  is a subset of  $\Sigma^k$ . The elements of  $C$  are called code words. The distance of the code  $C$ , denoted  $\Delta(C)$ , is defined as the minimum hamming distance between any two code words  $c_1, c_2 \in C$ , i.e.

$$\Delta(C) := \min_{\substack{c, c' \in C \\ c \neq c'}} \Delta(c, c'),$$

where  $\Delta(c, c') := |\{i : c_i \neq c'_i\}|$  is the hamming distance between two vectors.

In the language of error correcting codes, we want our collection of counts  $V$  to be a large error correcting code with a minimum distance of  $0.9k$ . Fortunately, the Gilbert-Varshamov bound immediately implies the existence of such a  $V$  that is large enough for our purposes.

► **Lemma 11 (Gilbert-Varshamov bound).** For any alphabet size  $q > 1$ , code length  $k$  and distance  $d \leq k$ , there exists an error correcting code  $C$  with size,

$$|C| \geq \frac{q^k}{\sum_{i=0}^{d-1} \binom{k}{i} (q-1)^i}.$$

Consequently, for  $d = 0.9k$  and any  $q$  larger than a universal constant, there is a code  $C$  with size  $|C| \geq q^{0.05k}$ .

Thus, when  $q$  is a large enough constant (which can be achieved by making for  $\epsilon$  smaller than some universal constant  $c$ ), the Gilbert-Varshamov bound tells us there is a choice of  $V$  such that  $|V| \geq q^{0.05k}$ . Fix a  $(k, \epsilon, \delta)$ -approximate counter  $\mathcal{A}$ . For any  $v \in V$  and  $i \in [k]$ ,  $\mathcal{A}$  must

accurately approximate  $v_i$  with probability at least  $1 - \delta$ . Denote the event that  $\mathcal{A}$  correctly approximates  $v_i$  by  $E_{v,i}$ . Since  $\mathbb{E}[\sum_{i=1}^k \mathbb{1}(E_{v,i}^c)] \leq k \cdot \delta < k/20$ , by Markov's inequality we can conclude the existence of a subset  $I_v \subseteq [k]$  such that:

1.  $|I_v| \geq 0.9k$ ,
2.  $\mathbb{P}[\cap_{i \in I_v} E_{v,i}] > 1/2$ . Put in words, with probability at least  $1/2$ , for every  $i \in I_v$ , the algorithm  $\mathcal{A}$  outputs a  $(1 + \epsilon)$ -approximation for  $v_i$ .

Define the event  $E_v := \cap_{i \in I_v} E_{v,i}$ . Since  $\mathbb{E}[\sum_{v \in V} \mathbb{1}(E_v^c)] \leq |V|/2$ , a standard averaging argument implies the existence of a fixed choice for the random seed of  $\mathcal{A}$  and a subset of counts  $V' \subseteq V$  such that:

1.  $|V'| > |V|/2$ ,
2. and the algorithm is correct on all  $v \in V'$  in the sense of the event  $E_v$  on this random seed.

Fix such a random seed and denote the now deterministic algorithm  $\mathcal{A}'$ . For two counts  $u, v \in V'$  define the set  $D_{u,v} := \{i \in [k] : u_i \neq v_i\}$ . By construction we have that  $|D_{u,v}| \geq 0.9k$ . We have

$$\begin{aligned} |D_{u,v} \cap I_u \cap I_v| &\geq k - |D_{u,v}^c| - |I_u^c| - |I_v^c| \\ &\geq k - 0.3k = 0.7k > 1. \end{aligned}$$

Thus, there is at least one index  $i^* \in [k]$  such that  $u_{i^*} \neq v_{i^*}$  and  $\mathcal{A}'$   $(1 + \epsilon)$ -approximates both  $u_{i^*}$  and  $v_{i^*}$ , so  $\mathcal{A}'$  arrives at a different state for  $u$  and  $v$ . Since this holds for every pair in  $V'$ , we can conclude that  $\mathcal{A}'$  must arrive at a different state for every count in  $V'$ . We can now conclude that

$$2^{|M|} \geq |V'| \geq 0.5 \cdot (\lfloor (4\epsilon)^{-1} \cdot \ln(1 + n\epsilon/k) \rfloor)^{0.05k} = \left( \Omega\left(\frac{\ln(1 + n\epsilon/k)}{\epsilon}\right) \right)^{0.05k},$$

or

$$|M| \geq 0.05k \log\left(\frac{\ln(1 + n\epsilon/k)}{\epsilon}\right) - O(k).$$

We distinguish into three cases:

1. If  $\epsilon < k/n$ , then  $\frac{\ln(1+n\epsilon/k)}{\epsilon} = \Omega(n/k)$ , which implies  $|M| \geq 0.05k \log(n/k) - O(k)$ .
2. If  $k/n \leq \epsilon < \sqrt{k/n}$ , we have

$$\begin{aligned} |M| &\geq 0.05k \log(1/\epsilon) - O(k) \\ &\geq 0.05k \log(1/\epsilon) + k \log \log(n/k) - O(k \log \log(1/\epsilon)). \end{aligned}$$

3. If  $\epsilon > \sqrt{k/n}$ , we have

$$\begin{aligned} |M| &\geq 0.05k \log(1/\epsilon) + 0.05k \log \log(en/k) - O(k) \\ &\geq 0.05k \log(1/\epsilon) + 0.05k \log \log(n/k) - O(k). \end{aligned}$$

Putting all the above bounds together gives us

$$\begin{aligned} |M| &\geq \min\{0.05k \log(n/k) - O(k), 0.05k \log(1/\epsilon) + 0.025k \log \log(n/k) \\ &\quad - O(k \log \log(1/\epsilon))\} \\ &= \Omega(\min\{k \log(n/k), k \log(1/\epsilon) + k \log \log(n/k)\}). \end{aligned}$$

◀

### 3 Upper bounds

We now state matching upper bounds  $(k, \epsilon, \delta)$ -approximate counting that follow immediately from the single counter case. We give upper bounds in two regimes: the case  $k \leq N$ , and the case  $k > N$ . We start by analyzing the first case.

Recall that the space usage of an approximate counter is typically a random variable, and the goal is to then prove an upper bound on the *expected* space (or, say, a high probability bound). The work of Nelson and Yu [9] provided the following bound on expected space usage for a single counter:

► **Theorem 12** ([9]). *For any  $\epsilon, \delta \in (0, 1/2)$ , there is an  $(\epsilon, \delta)$ -approximate counter with expected space usage  $O(\log \log N + \log \log(1/\delta) + \log(1/\epsilon))$  bits.*

The following is then a very simple corollary of Theorem 12.

► **Corollary 13.** *For any  $\epsilon, \delta \in (0, 1/2)$  and  $1 \leq k \leq N$ , there is a  $(k, \epsilon, \delta)$ -approximate counter that uses  $O(k(\log \log(2N/k) + \log \log(1/\delta) + \log(1/\epsilon)))$  bits in expectation.*

**Proof.** We simply instantiate  $k$  independent copies of the data structure from Theorem 12 to provide  $k$  independent approximate counters, one per actual counter. For each  $1 \leq i \leq k$ , let  $S_i$  denote the (random) number of bits of memory used to store the approximate counter representing the  $i$ th counter  $N_i$  and recall  $N := \sum_i N_i$ . Then the total expected space is

$$\begin{aligned} \mathbb{E} \left[ \sum_{i=1}^k S_i \right] &= \sum_{i=1}^k \mathbb{E}[S_i] \\ &\leq C \sum_{i=1}^k (\log \log(N_i) + \log \log(1/\delta) + \log(1/\epsilon)) \quad (\text{Theorem 12}) \\ &= Ck(\log \log(1/\delta) + \log(1/\epsilon)) + \sum_{i=1}^k \log \log(N_i) \\ &\leq Ck(\log \log(4N/k) + \log \log(1/\delta) + \log(1/\epsilon)) \quad (\text{Jensen}), \end{aligned}$$

where the last inequality uses concavity of the function  $x \in (1, \infty) \mapsto \log \log(x)$ . Note that we inject a constant 4 in the iterated logarithm so that the  $\log \log$  term stays nonnegative. ◀

We now turn to the case  $k > N$ . In this case, there is a clear lower bound of  $\Omega(N \log(Ck/N))$  bits, since  $\log(\sum_{j=1}^N \binom{k}{j})$  bits of memory are needed to simply remember which counters are non-zero, and the logarithm of this sum is  $\Theta(N \log(Ck/N))$  [5, Exercise 9.42]. We claim that this is also an upper bound. Specifically, we can use  $O(N \log(Ck/N))$  bits to remember the locations of the  $t \leq N$  non-zero counters. Now we have reduced to the case  $k = t \leq N$  and can apply Corollary 13 to approximately remember their values.

## Abstract

In this paper we study a worst case to average case reduction for the problem of matrix multiplication over finite fields. Suppose we have an efficient *average case* algorithm, that given two random matrices  $A, B$  outputs a matrix that has a non-trivial correlation with their product  $A \cdot B$ . Can we transform it into a *worst case* algorithm, that outputs the correct answer for all inputs without incurring a significant overhead in the running time? We present two results in this direction.

**Two-sided error in the high agreement regime.** We begin with a brief remark about a reduction for high agreement algorithms, i.e., an algorithm which agrees with the correct output on a large (say  $> 0.9$ ) fraction of entries, and show that the standard self-correction of linearity allows us to transform such algorithms into algorithms that work in worst case.

**One-sided error in the low agreement regime.** Focusing on average case algorithms with one-sided error, we show that over  $\mathbb{F}_2$  there is a reduction that gets an  $O(T)$  time *average case* algorithm that given a random input  $A, B$  outputs a matrix that agrees with  $A \cdot B$  on at least 51% of the entries (i.e., has only a slight advantage over the trivial algorithm), and transforms it into an  $\tilde{O}(T)$  time *worst case* algorithm, that outputs the correct answer for *all inputs* with high probability.

## 1 Introduction

The problem of efficiently multiplying two matrices has been extensively studied for decades. Improving on the straightforward  $O(n^3)$  time algorithm, Strassen's algorithm [24] computes the product of two matrices in time  $O(n^{\log_2 7} = n^{2.807})$ , and it is perhaps the most widely used in practice. Since then, a long and exciting line of research ([19, 5, 21, 20, 23, 9, 22, 25, 17, 1]) has led to a significant improvement of the value of the optimal exponent of the running time for matrix multiplication problem. The fastest algorithm known today is due to Duan, Wu, and Zhou [10], and its running time is  $O(n^{2.371866})$ .

Worst-case to average-case reductions serve as a means to convert algorithms that output correct answers on a fraction of inputs into algorithms with correct outputs on all possible inputs. These reductions can be viewed from two different perspectives. From the hardness point of view, they can be used to show that a problem maintains its hardness even in the

## 34:2 Matrix Multiplication Reductions

average case. From the algorithmic side, they provide a framework for developing worst-case algorithms, by first designing weak algorithms with average case guarantees, and then transforming them into algorithms which work on all outputs.

In this paper, we study the following variant of a worst-case to average-case reduction for the matrix multiplication problem. Suppose we have an efficient algorithm that given two random matrices  $A, B \in \mathbb{F}^{n \times n}$ , computes a matrix  $C \in \mathbb{F}^{n \times n}$  that agrees with the product  $A \cdot B$  on a large fraction of the entries of the matrix. Can we transform such an algorithm into one that computes  $A \cdot B$  correctly for all entries of the output matrix without incurring a significant overhead in the running time?

More formally, we define the *agreement* between two matrices as the fraction of entries on which the two matrices agree.

► **Definition 1.** Let  $\mathbb{F}$  be a field, and let  $A, B \in \mathbb{F}^{n \times n}$  be two matrices. We define *agreement* between  $A$  and  $B$ , denoted by  $\text{agr}(A, B)$ , as the fraction of entries  $(i, j)$  on which  $A_{i,j} = B_{i,j}$ , i.e.,

$$\text{agr}(A, B) = \frac{|\{(i, j) : A_{i,j} = B_{i,j}\}|}{n^2} .$$

Then, our goal can be stated as the task of transforming an algorithm that on a random input  $A, B$  outputs a matrix  $C$  such that  $\text{agr}(C, AB) \geq \alpha$  for some parameter  $\alpha \in [0, 1]$  into an algorithm that solves the matrix multiplication problem *correctly on all inputs*.

We present two results in this direction. Both results consider the matrix multiplication problem over finite fields.

### High agreement regime with two-sided error

We show that any algorithm that solves the matrix multiplication problem correctly on a high fraction of the coordinates, can be converted into a worst case algorithm. Specifically, we prove the following theorem.

► **Theorem 2.** Fix a finite field  $\mathbb{F}$ . Let  $\alpha \in (0, 1/8)$ . Let  $\text{ALG}$  be an algorithm that gets as input two matrices  $A, B \in \mathbb{F}^{n \times n}$ , runs in time  $T(n)$ , and outputs a matrix  $\text{ALG}(A, B) \in \mathbb{F}^{n \times n}$ . Suppose that

$$\mathbb{E}_{A, B \in \mathbb{F}^{n \times n}} [\text{agr}(\text{ALG}(A, B), A \cdot B)] > 1 - \alpha .$$

Then, there is an algorithm  $\text{ALG}^*$  that gets as input two matrices  $A, B \in \mathbb{F}^{n \times n}$ , runs in time  $O(T(n) \cdot \log(n))$ , and outputs a matrix  $\text{ALG}^*(A, B) \in \mathbb{F}^{n \times n}$  such that for all  $A, B$  it holds that

$$\Pr[\text{ALG}^*(A, B) = A \cdot B] > 1 - 1/n ,$$

where the randomness is only over the internal coins of  $\text{ALG}^*$ .

The proof of this result relies on rather standard ideas, and essentially uses the self-correction of linear functions [6].

### Low agreement with one-sided error

For this result, we restrict our discussion to the finite field  $\mathbb{F}_2$ . Note that it is trivial to design an  $O(n^2)$  time algorithm such that  $\mathbb{E}_{A, B \in \mathbb{F}_2^{n \times n}} [\text{agr}(\text{ALG}(A, B), A \cdot B)] \geq 1/2$ . Indeed, the algorithm can simply output 0 in all entries irrespective of the input. Alternatively, the algorithm can output a random 0/1 matrix. Hence, it is natural to ask whether it is possible to obtain a better-than-1/2 algorithm for the matrix multiplication over  $\mathbb{F}_2$ .

Below we show that in the special case of *one-sided error* approximation, any better-than- $1/2$  approximation  $O(T)$  time algorithm can be transformed into a worst case algorithm with running time  $\tilde{O}(T)$ . Formally, we prove the following theorem.

► **Theorem 3.** *Let ALG be an algorithm that gets input two matrices  $A, B \in \mathbb{F}_2^{n \times n}$ , runs in time  $T(n)$ , and outputs a matrix  $\text{ALG}(A, B) \in \mathbb{F}_2^{n \times n}$ . Let  $\delta > 0$ , and suppose that*

- $\mathbb{E}_{A, B \in \mathbb{F}_2^{n \times n}}[\text{agr}(\text{ALG}(A, B), A \cdot B)] \geq 1/2 + \delta$ .
- If  $(AB)_{i,j} = 0$ , then  $\text{ALG}(A, B)_{i,j} = 0$ .

*Then, there is an algorithm  $\text{ALG}^*$  that gets as input two matrices  $A, B \in \mathbb{F}_2^{n \times n}$ , runs in time  $\tilde{O}(T(n))$ , and outputs a matrix  $\text{ALG}^*(A, B) \in \mathbb{F}_2^{n \times n}$  such that for all  $A, B$  it holds that*

$$\Pr[\text{ALG}^*(A, B) = A \cdot B] > 1 - 1/n,$$

where the randomness is only over the internal coins of  $\text{ALG}^*$ .

► **Remark 4.** Below we make several comments about Theorem 3.

1. Note that the conditions of the theorem can be written equivalently as follows.
  - $\Pr_{A, B \in \mathbb{F}_2^{n \times n}}[\text{ALG}(A, B)_{i,j} = 1] \geq \delta$ .
  - If  $(AB)_{i,j} = 0$ , then  $\text{ALG}(A, B)_{i,j} = 0$ .
2. The notion of algorithms with one-sided error is typically studied in the context of randomized algorithms, e.g., relating to the classes  $\mathcal{RP}$  (and  $\text{coRP}$ ), where the guarantee is that for *every NO input* the algorithm outputs the correct answer with probability 1, and for *every YES input* it is correct with probability at least  $2/3$ . The error model in Theorem 3 is different, as we consider algorithms that are correct on *random inputs* on all output 0-bits, and on at least some  $\alpha$ -fraction of 1-bits.
3. Alternatively, we can view the one-side error condition of Theorem 3 as an *errorless heuristic*, where in each entry of the matrix ALG outputs either 1 representing the correct answer, or says “I don’t know” and outputs 0.
4. We remark that the standard methods of self-correcting linear functions work in the high agreement regime, but fail when the average case guarantee is low. We apply the techniques from additive combinatorics developed in [2], particularly a version of the probabilistic Bogolyubov-Ruzsa Lemma, to perform a self-correction procedure which helps in this regime.
5. Our proof of Theorem 3 assumes that ALG is deterministic. It is rather straightforward to extend the proof and allow it to be randomized, by appropriately modifying the sets of good inputs  $(X_{i,j}$  and  $Y_{i,j}^A)$  to account for the randomness of the algorithm.

## 1.1 Related work

The study of average-case complexity began with Levin’s work [18], followed by subsequent works like [4]. A substantial body of research (e.g., [16], [15] and related references) identified numerous barriers in formulating worst-case to average-case reductions for NP-complete problems. For a comprehensive overview of this subject, see the classical surveys by Impagliazzo [14], Bogdanov and Trevisan [7] and Goldreich [12].

Asadi et al. [2, 3] presented a new framework for carrying out efficient worst-case to average case reductions for various fundamental problems. Particularly, for the problem of matrix multiplication, they proved that if there exists an  $O(T(n))$  time algorithm  $M$  for matrix multiplication which computes the correct output on an  $\epsilon$  fraction of inputs, then there exists a randomized algorithm  $M'$  which computes the correct output on all inputs, running in time  $O(\exp(O(\log^5(1/\epsilon))) \cdot T(n))$ . The proof relied on additive combinatorial techniques and used the probabilistic Bogolyubov-Ruzsa Lemma.

## 34:4 Matrix Multiplication Reductions

Hirahara and Shimizu [13] improved the  $\exp(O(\log^5(1/\epsilon)))$  overhead to an  $\tilde{O}(1/\epsilon)$  factor. Their idea involved dividing the output matrix into smaller blocks and using the Direct-Product Theorem in a black-box manner.

The aforementioned papers assume that we have access to an algorithm which gives a fully correct output on some fraction of the inputs, i.e., for these inputs *all entries* in the output matrix are correct. The setting presented in this paper, where the output of the given algorithm is not fully correct, seems to differ significantly from the works mentioned above. In particular, we do not see how to apply the Direct-Product theorem to our setting of the problem.

A related problem was studied by [11]. Specifically, they provided an  $\tilde{O}(n^2 + kn)$  time randomized algorithm and an  $\tilde{O}(kn^2)$  time deterministic algorithm for correcting the product of two matrices over a ring, where the product has at most  $k$  incorrect entries. Theorem 2 improves upon their work for a certain range of  $k$ , e.g.,  $n^2/20 < k < n^2/8$ , and Theorem 3 gives a new result for  $k$  closer to  $n^2/2$  in a very specific error model.

### 1.2 Open problems

We mention the following two problems that are left open in this work.

#### Low agreement with two-sided error

Is it possible to transform a two-sided error algorithm over  $\mathbb{F}_2$  with a low agreement guarantee into a worst case algorithm. That is, given an  $O(T(n))$  time algorithm ALG with the guarantee  $\mathbb{E}_{A,B \in \mathbb{F}_2^{n \times n}}[\text{agr}(\text{ALG}(A, B), A \cdot B)] > 1/2 + \delta$ , can we convert it into an algorithm that correctly outputs the correct answer on all inputs and has running time  $\tilde{O}(T(n))$ ?

#### Generalizing over finite fields

Extend Theorem 3 in a meaningful way to work over any finite field.

## 2 Preliminaries

For a positive integer  $n$  we define  $[n] = \{0, 1, \dots, n-1\}$ . We index the coordinates of our matrices starting from 0 rather than 1, which is typically more standard. We refer to the element in the row  $i$  and column  $j$  of the matrix  $A$  as  $A_{i,j}$ .

We define a notion of *row-shift* (or *row-rotation*) and *column-shift* as follows.

► **Definition 5.** Given a matrix  $A \in \mathbb{F}^{n \times m}$ ,  $0 \leq \pi \leq n-1$ , and  $0 \leq \sigma \leq m-1$ , define  $A^{\pi, \sigma}$  to be the matrix obtained from  $A$  by cyclically rotating all its rows downwards by  $\pi$  units and all its columns rightwards by  $\sigma$  units, that is,

$$(A^{\pi, \sigma})_{i,j} = A_{(i-\pi) \bmod n, (j-\sigma) \bmod m}$$

The following proposition is immediate from the definition above.

► **Proposition 6.** For any  $A, B, C \in \mathbb{F}^{n \times n}$  and any  $\pi, \sigma$  we have  $AB = C$  if and only if  $A^{\pi, 0} \cdot B^{0, \sigma} = C^{\pi, \sigma}$ .

## 2.1 Additive Combinatorics Tools

We now present the additive combinatorics toolkit which will be useful in the worst-case to average-case reduction for the low agreement regime with one-sided error.

For a set  $A \subseteq \mathbb{F}_2^n$ , let  $1_A: \mathbb{F}_2^n \rightarrow \{0, 1\}$  denote the indicator function of  $A$ . The Fourier expansion of a function  $f: \mathbb{F}_2^n \rightarrow \mathbb{C}$  is given by  $f(x) = \sum_{r \in \mathbb{F}_2^n} \hat{f}(r) \cdot \chi_r(x)$ , where  $\chi_r(x) = (-1)^{\langle x, r \rangle}$ , and the Fourier coefficients of  $f$  are defined as  $\hat{f}(r) = \langle f, \chi_r \rangle = \mathbb{E}_x[f(x) \cdot \chi_r(x)]$ . Parseval's identity says that  $\sum_{r \in \mathbb{F}_2^n} \widehat{1_A}(r)^2 = \langle 1_A, 1_A \rangle = \alpha$ , where  $\alpha$  is the density of  $A$ .

Define  $\text{Spec}_\gamma(A) = \{r \in \mathbb{F}_2^n : |\widehat{1_A}(r)| \geq \gamma\}$ . Below we state Chang's lemma, which describes a certain structure of  $\text{Spec}_\gamma(A)$ .

► **Lemma 7** (Chang's Theorem [8]). *Let  $A \subseteq \mathbb{F}^n$  be a set of size  $|A| = \alpha \cdot |\mathbb{F}|^n$ , and let  $\gamma > 0$ . Then*

$$\dim(\text{span}(\text{Spec}_{\gamma\alpha}(A))) \leq O\left(\frac{\log(1/\alpha)}{\gamma^2}\right).$$

Recall that the subset sum of two sets  $A$  and  $B$  is defined as  $A+B = \{a+b : a \in A, b \in B\}$ . Analogously, we define  $tA = A+A+\dots+A$  ( $t$  times) as  $tA = \{a_1+a_2+\dots+a_t : a_1, a_2, \dots, a_t \in A\}$ . The following lemma says that for an arbitrary set  $A \subseteq \mathbb{F}^n$ , the sumset  $tA$  contains a large affine subspace.

► **Lemma 8** (Probabilistic Bogolyubov-Ruzsa lemma). *Let  $A \subseteq \mathbb{F}_2^n$  be a set of size  $|A| = \alpha \cdot 2^n$ , for some  $\alpha \in (0, 1]$ , and let  $t \geq 3$  be an integer. Then,  $tA$  contains an affine subspace  $V \subseteq \mathbb{F}_2^n$  of dimension  $\dim(V) \geq n - O(\log(1/\alpha))$  such that for all  $v \in V$  it holds that*

$$\Pr_{a_1, a_2, \dots, a_{t-1} \in \mathbb{F}_2^n} [a_1, a_2, a_3, \dots, a_t \in A] \geq \alpha^t \left(1 + \frac{1}{2^{t-2}}\right) - \frac{\alpha^{t-1}}{2^{t-2}},$$

where  $a_t = v - a_1 - a_2 - \dots - a_{t-1}$ .

In particular, if  $t > \log_2(1/\alpha) + 2$ , then  $tA$  contains an affine subspace  $V \subseteq \mathbb{F}_2^n$  of dimension  $\dim(V) \geq n - k$ , for  $k = O(\log(1/\alpha))$ , such that for all  $v \in V$  it holds that

$$\Pr_{\substack{a_1, a_2, \dots, a_t \in \mathbb{F}_2^n \\ v = \sum_{i=1}^t a_i}} [a_1, a_2, a_3, \dots, a_t \in A] \geq (\alpha/2)^t.$$

Below we prove Lemma 8 only for odd values of  $t$ , which is slightly more complicated than the case of even  $t$ . After the proof, we remark how to modify the proof to work for even  $t$ 's.

**Proof.** Let  $A \subseteq \mathbb{F}_2^n$  be a set of size  $|A| = \alpha \cdot |\mathbb{F}|^n$ , for some  $\alpha \in (0, 1]$ . Consider the set

$$R = \text{Spec}_{\alpha/2} \setminus \{0\} = \{r \in \mathbb{F}_2^n \setminus \{0\} : |\widehat{1_A}(r)| > \frac{\alpha}{2}\}$$

Next we define an affine subspace  $V = \{v \in \mathbb{F}_2^n : \langle v, r \rangle = s_r \ \forall r \in R\}$  for some  $s_r \in \{0, 1\}$  to be defined later, and claim that  $V$  satisfies the conclusions of Lemma 8. We will need the following two claims.

▷ **Claim 9.** For all  $r \in R$  there exists  $s_r \in \{0, 1\}$  such that (1)  $\sum_{r \in R} \widehat{1_A}(r)^t \cdot (-1)^{s_r} \geq 0$  and (2) if  $r^* \in R$  is a linear combination  $r^* = \sum_{r \in R} c_r \cdot r$  of vectors in  $R$  (with  $c_r \in \mathbb{F}_2$ ), then  $s_{r^*} = \sum_{r \in R} c_r \cdot s_r \pmod{2}$ .

### 34:6 Matrix Multiplication Reductions

Proof. Let  $R'$  be a maximal subset of  $R$  of linearly independent vectors. Choose  $s_{r'} \in \{0, 1\}$  independently with probability 0.5 each for every  $r' \in R'$ . Now any  $r \in R \setminus R'$ , can be expressed as a linear combination  $r = \sum_{r'} c_{r'} \cdot r'$  of vectors in  $R'$  with  $c_{r'} \in \{0, 1\}$  define  $s_r = \sum_{r'} c_{r'} \cdot s_{r'}$ . It is immediate to verify that condition (2) is satisfied.

In order to satisfy condition (1) note that by linearity of expectation  $\mathbb{E}[\sum_{r \in R} \widehat{1}_A(r)^t \cdot (-1)^{s_r}] = 0$ , and hence there exists a choice of  $(s_r)_{r \in R}$  such that  $\sum_{r \in R} \widehat{1}_A(r)^t \cdot (-1)^{s_r} \geq 0$ , as required.  $\triangleleft$

$\triangleright$  Claim 10. We have  $\sum_{r \notin R, r \neq 0} |\widehat{1}_A(r)|^t \leq (\alpha/2)^{t-2}(\alpha - \alpha^2)$ .

Proof. For  $t \geq 3$ , it holds that

$$\begin{aligned} \sum_{r \notin R, r \neq 0} |\widehat{1}_A(r)|^t &\leq \max_{r \notin R, r \neq 0} |\widehat{1}_A(r)|^{t-2} \sum_{r \notin R, r \neq 0} |\widehat{1}_A(r)|^2 \\ &\leq (\alpha/2)^{t-2} \sum_{r \in \mathbb{F}_2^n \setminus \{0\}} \widehat{1}_A(r)^2 \\ &< (\alpha/2)^{t-2}(\alpha - \alpha^2) . \end{aligned} \quad \triangleleft$$

Define an affine subspace  $V = \{v \in \mathbb{F}_2^n : \langle v, r \rangle = s_r \ \forall r \in R\}$ , where  $s_r \in \{0, 1\}$  is from Claim 9. Note that if the vectors in  $R$  are linearly dependent, then the second condition of Claim 9 guarantees that we can define  $V = \{v \in \mathbb{F}_2^n : \langle v, r' \rangle = s_{r'} \ \forall r' \in R'\}$  for a maximal set  $R' \subset R$  of linearly independent vectors in  $R$ , and the remaining constraints will be satisfied by linearity. Then, according to Lemma 7 we have

$$\dim(V) \geq n - O(\log(1/\alpha)) .$$

Using the two claims above, and noting that  $\Pr_{a_1, a_2, \dots, a_{t-1} \in \mathbb{F}^n} [a_1, a_2, a_3, \dots, a_t \in A] = 1_A * 1_A * \dots * 1_A(v)$  ( $t$  times), for any  $v \in V$  we have

$$\begin{aligned} \Pr_{a_1, a_2, \dots, a_{t-1} \in \mathbb{F}^n} [a_1, a_2, a_3, \dots, a_t \in A] &= 1_A * 1_A * \dots * 1_A(v) \\ &= \sum_{r \in \mathbb{F}^n} \widehat{1}_A(r)^t \chi_r(v) \\ &= \widehat{1}_A(0)^t + \sum_{r \in R} \widehat{1}_A(r)^t \chi_r(v) + \sum_{r \notin R, r \neq 0} \widehat{1}_A(r)^t \chi_r(v) \\ &\geq \alpha^t + \sum_{r \in R} \widehat{1}_A(r)^t \cdot (-1)^{s_r} - (\alpha/2)^{t-2}(\alpha - \alpha^2) \\ &\geq \alpha^t + 0 - (\alpha/2)^{t-2}(\alpha - \alpha^2) \\ &= \alpha^t \left(1 + \frac{1}{2^{t-2}}\right) - \frac{\alpha^{t-1}}{2^{t-2}} . \end{aligned}$$

In particular, for  $t > \log_2(1/\alpha) + 2$ , we have

$$\begin{aligned} \Pr_{a_1, a_2, \dots, a_{t-1} \in \mathbb{F}^n} [a_1, a_2, a_3, \dots, a_t \in A] &\geq \alpha^t \left(1 + \frac{1}{2^{t-2}}\right) - \frac{\alpha^{t-1}}{2^{t-2}} \\ &\geq \alpha^t \left(1 + \frac{1}{2^{t-2}}\right) - \alpha^t \\ &\geq (\alpha/2)^t , \end{aligned}$$

as required.  $\blacktriangleleft$

► Remark 11. For even values of  $t$  the lemma is slightly easier. Specifically, since  $\widehat{1}_A(r)^t$  is always non-negative, we can take  $s_r = 0$  in Claim 9, and the rest of the proof works the same.

### 3 High Agreement with Two-Sided Error

In this section, we prove Theorem 2. Specifically, we show that if there exists an algorithm which, given two matrices  $A, B \in \mathbb{F}^{n \times n}$ , runs in time  $T(n)$  and correctly computes their product on a large fraction of all entries of output on average, then there exists another algorithm that runs in  $\widetilde{O}(T(n))$  time and correctly computes their product on all entries of output. The proof essentially uses the self-correction of linearity [6].

► **Theorem 2.** Fix a finite field  $\mathbb{F}$ . Let  $\alpha \in (0, 1/8)$ . Let ALG be an algorithm that gets as input two matrices  $A, B \in \mathbb{F}^{n \times n}$ , runs in time  $T(n)$ , and outputs a matrix  $\text{ALG}(A, B) \in \mathbb{F}^{n \times n}$ . Suppose that

$$\mathbb{E}_{A, B \in \mathbb{F}^{n \times n}}[\text{agr}(\text{ALG}(A, B), A \cdot B)] > 1 - \alpha .$$

Then, there is an algorithm  $\text{ALG}^*$  that gets as input two matrices  $A, B \in \mathbb{F}^{n \times n}$ , runs in time  $O(T(n) \cdot \log(n))$ , and outputs a matrix  $\text{ALG}^*(A, B) \in \mathbb{F}^{n \times n}$  such that for all  $A, B$  it holds that

$$\Pr[\text{ALG}^*(A, B) = A \cdot B] > 1 - 1/n ,$$

where the randomness is only over the internal coins of  $\text{ALG}^*$ .

**Proof.** Given the algorithm ALG as in the assumption of the theorem, we design  $\text{ALG}^*$  as follows.

■ **Algorithm 1** Approximation for High Agreement Matrix Multiplication Algorithms.

---

**Input:**  $A, B \in \mathbb{F}^{n \times n}$ , ALG

**Output:**  $A \cdot B$

- 1 Let  $k = O(\log(n))$
  - 2 **for**  $r = 0$  to  $k$  **do**
  - 3     Generate two random matrices  $R, S \in \mathbb{F}^{n \times n}$
  - 4     Select two random variables  $\pi, \sigma \in [n]$  independently
  - 5      $M = \text{ALG}((A + R)^{\pi, 0}, (B + S)^{0, \sigma}) - \text{ALG}(R^{\pi, 0}, (B + S)^{0, \sigma}) - \text{ALG}((A + R)^{\pi, 0}, S^{0, \sigma}) + \text{ALG}(R^{\pi, 0}, S^{0, \sigma})$
  - 6     Let  $C_r = M^{n - \pi, n - \sigma}$
  - 7 Define the matrix  $C \in \mathbb{F}^{n \times n}$  by taking the majority vote of all  $C_r$  in each coordinate.
- 

#### Correctness

Consider an entry  $(i, j)$  in the output matrix  $A \cdot B$ . In each iteration we call ALG four times, and in each of the calls the input is distributed uniformly in  $\mathbb{F}^{n \times n}$ . Furthermore, since  $\pi, \sigma$  are chosen uniformly, it follows that  $(i + \pi, j + \sigma)$  are distributed uniformly. Therefore, the probability that all the four calls of ALG produce the correct answer in this entry is at least  $1 - 4\alpha$ . Therefore, for each repetition  $r$ , we have

$$\Pr[(C_r)_{i, j} = (A \cdot B)_{i, j}] \geq 1 - 4\alpha .$$

## 34:8 Matrix Multiplication Reductions

By Chernoff bound, the probability that the majority vote of the  $k$  repetition will produce an incorrect answer is upper bounded by

$$\Pr[(C_r)_{i,j} = (A \cdot B)_{i,j}] \geq \exp(-\Omega((1 - 4\alpha - 1/2) \cdot k)) < 1/n^3 ,$$

Here we make the assumption that  $\alpha$  is bounded below  $1/8$ .

Hence, the probability that a particular entry  $(i, j)$  is incorrect after  $k$  iterations is at most  $n^{-3}$ . By union bound over all entries, the probability that at least one entry is incorrect in the output matrix is at most  $n^2 \cdot n^{-3} = 1/n$ .

### Running time

The total running time is dominated by  $O(\log(n))$  invocations of ALG, and hence, the runtime of  $\text{ALG}^*$  is  $O(T(n) \cdot \log(n))$ . ◀

## 4 Low Agreement with One-Sided Error

In this section we prove Theorem 3. We restate the theorem here for convenience.

► **Theorem 3.** *Let ALG be an algorithm that gets input two matrices  $A, B \in \mathbb{F}_2^{n \times n}$ , runs in time  $T(n)$ , and outputs a matrix  $\text{ALG}(A, B) \in \mathbb{F}_2^{n \times n}$ . Let  $\delta > 0$ , and suppose that*

- $\mathbb{E}_{A, B \in \mathbb{F}_2^{n \times n}} [\text{agr}(\text{ALG}(A, B), A \cdot B)] \geq 1/2 + \delta$ .
- If  $(AB)_{i,j} = 0$ , then  $\text{ALG}(A, B)_{i,j} = 0$ .

*Then, there is an algorithm  $\text{ALG}^*$  that gets as input two matrices  $A, B \in \mathbb{F}_2^{n \times n}$ , runs in time  $\tilde{O}(T(n))$ , and outputs a matrix  $\text{ALG}^*(A, B) \in \mathbb{F}_2^{n \times n}$  such that for all  $A, B$  it holds that*

$$\Pr[\text{ALG}^*(A, B) = A \cdot B] > 1 - 1/n,$$

where the randomness is only over the internal coins of  $\text{ALG}^*$ .

Before proving the theorem, we need some definitions. We start by defining the notion of a *good* coordinate. We say a coordinate  $(i, j) \in [n] \times [n]$  is *good*, if ALG returns 1 at the entry  $(i, j)$  for more than  $\delta/2$  fraction of possible inputs.

► **Definition 12.** *Denote by  $G$  the set of good coordinates, defined as*

$$G = \{(i, j) \in [n] \times [n] : \Pr_{A, B \in \mathbb{F}_2^{n \times n}} [\text{ALG}(A, B)_{i,j} = 1] > \delta/2\} .$$

The following claim is immediate from the definition and the assumptions of the theorem.

▷ **Claim 13.**  $|G| \geq (\delta/2) \cdot n^2$ .

Proof. Let  $p_{i,j} = \Pr_{A, B \in \mathbb{F}_2^{n \times n}} [\text{ALG}(A, B)_{i,j} = 1]$ . Note that by the assumptions of Theorem 3, we have  $\mathbb{E}_{i,j} [p_{i,j}] \geq \delta$ . Note that

$$\delta \leq \mathbb{E}_{i,j \in [n] \times [n]} [p_{i,j}] \leq \Pr_{i,j} [(i, j) \in G] \cdot 1 + \Pr_{i,j} [(i, j) \notin G] \cdot (\delta/2) \leq \Pr_{i,j} [(i, j) \in G] \cdot 1 + 1 \cdot (\delta/2) ,$$

and hence  $\Pr[(i, j) \in G] \geq \delta/2$ , as required. ◀

Next, we define the notion of good input matrices with respect to a good coordinate.

► **Definition 14.** For a coordinate  $(i, j)$ , define  $X_{i,j}$  as follows.

$$X_{i,j} = \{A : \Pr_B[\text{ALG}(A, B)_{i,j} = 1] \geq \delta/4\} .$$

Given a coordinate  $(i, j)$  and a matrix  $A$ , define  $Y_{i,j}^A$  to be the set of matrices  $B$  for which  $\text{ALG}$  returns 1 at the entry  $(i, j)$ . That is,

$$Y_{i,j}^A = \{B : \text{ALG}(A, B)_{i,j} = 1\} .$$

We make the following claim about the densities of  $X_{i,j}$  and  $Y_{i,j}^A$ .

▷ **Claim 15.** For any  $(i, j) \in G$  it holds that  $\Pr_{A \in \mathbb{F}^{n \times n}}[A \in X_{i,j}] \geq \delta/4$ . Furthermore, if  $A \in X_{i,j}$  then  $\Pr_{B \in \mathbb{F}^{n \times n}}[B \in Y_{i,j}^A] \geq \delta/4$ .

*Proof.* Fix a good coordinate  $(i, j) \in G$ , and for each  $A \in \mathbb{F}^{n \times n}$ , let  $p_A = \Pr_{B \in \mathbb{F}^{n \times n}}[\text{ALG}(A, B)_{(i,j)} = 1]$ . From the definition of  $G$  we have  $\mathbb{E}_A[p_A] \geq \delta/2$ .

$$\delta/2 \leq \mathbb{E}_A[p_A] = \Pr_{A \in \mathbb{F}^{n \times n}}[A \in X_{i,j}] \cdot 1 + \Pr_{A \in \mathbb{F}^{n \times n}}[A \notin X_{i,j}] \cdot \delta/4 \leq \Pr_{A \in \mathbb{F}^{n \times n}}[A \in X_{i,j}] + \delta/4 ,$$

and hence,  $\Pr[A \in X_{i,j}] \geq \delta/4$ .

The furthermore part is by definition of  $X_{i,j}$ . ◁

► **Definition 16.** Denote by  $L^k \in \mathbb{F}^{n \times n}$  a random matrix of rank at most  $k$ , constructed by sampling the first  $k$  columns independently uniformly at random from  $\mathbb{F}^n$ , and then taking the remaining  $n - k$  columns to be uniformly random linear combinations of the first  $k$  vectors.

The following lemma is from [2]. It shows that if  $L_A^{2k}$  is a random matrix of rank at most  $2k$  sampled as in Definition 16, then  $M_A = A - (L_A^{2k})$  belongs to any subspace of matrices of co-dimension  $k$  with a non-negligible probability. We provide the proof of the lemma here for completeness.

► **Lemma 17** (Lemma 4.8 from [2]). Fix a matrix  $A \in \mathbb{F}^{n \times n}$ , let  $k$  be a parameter, and let  $\ell \geq 2k$ . Let  $L_A^\ell$  be a random matrix of rank at most  $\ell$  sampled as in Definition 16, and let  $M_A = A - (L_A^\ell)$ . Then, for any subspace  $V \subseteq \mathbb{F}^{n \times n}$  of  $\dim(V) \geq n^2 - k$  it holds that

$$\Pr[M_A \in V] \geq \frac{1}{2|\mathbb{F}|^k} .$$

**Proof.** Since  $V$  has co-dimension at most  $k$ , a matrix in  $V$  must be orthogonal to all the basis vectors of its orthogonal complement. Since there are up to  $k$  such basis vectors, the membership condition of  $M_A$  in  $V$  can be written down in the form of  $k$  linear constraints. Viewing  $M_A$  as a vector in  $\mathbb{F}^{n^2}$ , we can write the  $k$  linear constraints on the elements of the matrix  $M_A^{2k}$  in the form

$$\alpha_1 \cdot (M_A)_{i_1, j_1} + \alpha_2 \cdot (M_A)_{i_2, j_2} + \dots + \alpha_r (M_A)_{i_t, j_t} = 0 .$$

Here,  $\alpha_i$ 's are constants and  $t \in [n^2]$  is the number of elements upon which the constraints depend. Writing  $M_A$  as  $m \in \mathbb{F}^{n^2}$ , we can represent these linear constraints as a system of equations of the form  $G \cdot m = 0$ , where  $G$  is a  $k \times n^2$  matrix. Now, we perform Gaussian elimination on  $G$ , which gives us a matrix  $G'$ , where each row has a 1 entry such that all the other entries in the column containing this 1 are 0. We refer to such 1's as *leading 1's*. That is, by permuting the columns of  $G'$ , we may think of it as being of the form  $G' = [I_k | G^*]$ .

## 34:10 Matrix Multiplication Reductions

Consider the set of  $k$  coordinates of  $m$  corresponding to the  $k$  leading 1s in  $G'$ , one from each row. These  $k$  coordinates of  $m$  in turn correspond to  $k$  pairs of coordinates  $\{(i_1, j_1), (i_2, j_2) \dots (i_k, j_k)\}$  in  $M_A$ . These  $k$  pairs of coordinates in  $M_A$  can belong to at most  $k$  rows in  $M_A$ . We now bound the probability of none of these  $k$  rows in  $L_A^\ell$  being a linear combination of the other rows. Let us denote this event as  $\Omega$ . Then

$$\begin{aligned} \Pr[\Omega] &= \left(1 - \frac{1}{2^\ell}\right) \left(1 - \frac{2}{2^\ell}\right) \left(1 - \frac{4}{2^\ell}\right) \cdots \left(1 - \frac{2^{k-1}}{2^\ell}\right) \\ &\geq \left(1 - \frac{2^{k-1}}{2^\ell}\right)^k \\ &\geq \left(1 - \frac{1}{2^{k+1}}\right)^k \\ &\geq 1 - \frac{k}{2^{k+1}} \geq \frac{1}{2} \end{aligned}$$

If  $\Omega$  happens, then we get a coordinate  $(i_r, j_r)$  in  $M_A$  corresponding to the  $r^{\text{th}}$  linear constraint, for all  $r \in [k]$ , such that no other constraint depends upon it (as it corresponds to a leading 1) and it is chosen uniformly at random (since the rows containing these coordinates are linearly independent). Therefore, the probability that this random value satisfies the  $i^{\text{th}}$  constraint is  $1/|\mathbb{F}|$ . To see this, assume that the values of all other coordinates involved in the  $i^{\text{th}}$  constraint are fixed, then we are left with only one choice for the value of the coordinate  $(c_i, c'_i)$  which satisfies the constraint. Therefore, we have

$$\begin{aligned} \Pr[M_A \in V] &= \Pr[\text{All } k \text{ linear constraints are satisfied}] \\ &= \Pr[\Omega] \cdot \frac{1}{|\mathbb{F}|^k} \geq \frac{1}{2|\mathbb{F}|^k} . \end{aligned}$$

This completes the proof of Lemma 17. ◀

### 4.1 Computing the good coordinates

Next, we start describing the reduction guaranteed by Theorem 3. As a first step we design Algorithm 2, that gets two matrices  $A, B$  and outputs a matrix  $C$  with values in  $\mathbb{F}_2 \cup \{\perp\}$ , satisfying the following guarantees.

1. If  $C_{i,j} \neq \perp$ , then  $C_{i,j}$  contains the correct values, i.e.,  $C_{i^*,j^*} = (A \cdot B)_{i^*,j^*}$ .
2. For any good coordinate  $(i^*, j^*) \in G$  we have  $\Pr[C_{i^*,j^*} = (A \cdot B)_{i^*,j^*}] \geq \delta_0$ , where  $\delta_0$  is some constant that depends only on  $\delta$ . That is, with non-negligible probability  $C_{i^*,j^*}$  contains the correct answer, and not  $\perp$ .

Then, in Section 4.2 we use Algorithm 2 as a subroutine, in order to compute the entire matrix  $A \cdot B$  correctly.

In lines 3-4 we decompose  $A = L_A^{2k} + M_A$ , and  $B = L_B^{2tk} + M_B$  with the intention of computing  $A \cdot B$  by writing

$$\begin{aligned} AB &= (M_A + L_A^{2k}) \cdot (M_B + L_B^{2tk}) \\ &= M_A \cdot M_B + M_A \cdot L_B^{2tk} + L_A^{2k} \cdot M_B + L_A^{2k} \cdot L_B^{2tk} . \end{aligned}$$

Lines 5-13 try to compute  $C = M_A \cdot M_B$ . Then, in line 14, we sum up the 4 terms. Using the fact that multiplication of matrices of rank  $k$  takes  $O(kn^2)$  time, the last three terms can be computed in  $O(tkn^2)$  time, and hence, it remains to compute  $M_A \cdot M_B$ . The remainder of this subsection is dedicated to analyzing lines 5-13, which contain the most involved part of the algorithm.

■ **Algorithm 2** Approximating good coordinates for one-sided error algorithms.

---

**Input:**  $A, B \in \mathbb{F}_2^{n \times n}$ , ALG  
**Output:** An  $n \times n$  matrix  $C$  with values  $\mathbb{F}_2 \cup \{\perp\}$

- 1 Let  $t > \log(4/\delta) + 2$
- 2 Let  $k = O(\log(1/\delta))$  from the “in particular” part of Lemma 8 with  $\alpha = \delta/4$  and  $t$  chosen above
- 3 Sample two random matrices  $L_A^{2k}$  and  $L_B^{2tk}$  of rank at most  $2k$  and  $2tk$  respectively, as in Definition 16
- 4 Define  $M_A = A - L_A^{2k}$  and  $M_B = B - L_B^{2tk}$
- 5 Let  $C$  be the  $n \times n$  matrix initialized with all  $\perp$
- 6 Sample  $t - 1$  random matrices  $R_1, R_2, \dots, R_{t-1} \in \mathbb{F}_2^{n \times n}$  and set  $R_t = M_A - (R_1 + R_2 + \dots + R_{t-1})$
- 7 **for**  $r = 1, \dots, t$  **do**
- 8     Sample  $t - 1$  random matrices  $S_1^{(r)}, S_2^{(r)}, \dots, S_{t-1}^{(r)} \in \mathbb{F}_2^{n \times n}$  and set  $S_t^{(r)} = M_B - (S_1^{(r)} + S_2^{(r)} + \dots + S_{t-1}^{(r)})$
- 9     **for**  $s = 1, \dots, t$  **do**
- 10         Compute  $\text{ALG}(R_r, S_s^{(r)})$
- 11     **for**  $(i, j) \in [n] \times [n]$  **do**
- 12         **if**  $\text{ALG}(R_r, S_s^{(r)})_{i,j} = 1$  for all  $r, s \in \{1, \dots, t\}$  **then**
- 13             Set  $C_{i,j} = \sum_{r,s} \text{ALG}(R_r, S_s^{(r)})_{i,j} \pmod{2}$
- 14 **return**  $C + M_A \cdot L_B^{2tk} + L_A^{2k} \cdot M_B + L_A^{2k} \cdot L_B^{2tk}$  // if  $C_{i,j} = \perp$ , then we return  $\perp$  in the coordinate  $(i, j)$

---

We would like to compute  $M_A \cdot M_B$  by writing  $M_A = R_1 + R_2 + \dots + R_t$ , and  $M_B = S_1^{(r)} + S_2^{(r)} + \dots + S_t^{(r)}$  for  $r = 1 \dots t$ , and then computing  $\text{ALG}(R_r, S_s^{(r)})$  for all  $r, s$ . Note that if we could guarantee that  $\text{ALG}(R_r, S_s^{(r)})$  returns  $R_r \cdot S_s^{(r)}$ , then, we would have

$$M_A \cdot M_B = \sum_{r,s} R_r \cdot S_s^{(r)} = \sum_{r,s} \text{ALG}(R_r, S_s^{(r)}) . \quad (1)$$

However, ALG is not guaranteed to return the product of the inputs correctly. Instead, we claim that (1) for *some* good coordinates  $(i^*, j^*)$  it holds  $C_{i^*, j^*} = (M_A \cdot M_B)_{i^*, j^*}$ , and (2) the remaining coordinates in  $C$  remain  $\perp$ . This is summarized formally in the next two claims.

▷ **Claim 18.** For any  $(i, j) \in [n] \times [n]$  if  $C_{i,j} \in \{0, 1\}$  (i.e.,  $C_{i,j} \neq \perp$ ), then  $C_{i,j} = (M_A \cdot M_B)_{i,j}$ .

Proof. Fix any coordinate  $(i, j)$ . Note that in line 13 we set  $C_{i,j} = \sum_{r,s} \text{ALG}(R_r, S_s^{(r)})_{i,j} \pmod{2}$  only if  $\text{ALG}(R_r, S_s^{(r)})_{i,j} = 1$  for all  $r, s$ . Recall that by the assumption of the algorithm if  $\text{ALG}(R_r, S_s^{(r)})_{i,j} = 1$ , then  $\text{ALG}(R_r, S_s^{(r)})_{i,j} = (R_r \cdot S_s^{(r)})_{i,j}$ . The claim follows by Equation (1) restricted to the coordinate  $(i, j)$ , as

$$C_{i,j} = \sum_{r,s} \text{ALG}(R_r, S_s^{(r)})_{i,j} = \sum_{r,s} (R_r \cdot S_s^{(r)})_{i,j} = (M_A \cdot M_B)_{i,j} ,$$

as required. ◁

▷ **Claim 19.** Fix a good coordinate  $(i^*, j^*) \in G$ . Then  $\Pr[C_{i^*, j^*} = (M_A \cdot M_B)_{i^*, j^*}] \geq \delta_0 = 0.5^{O(\log^3(1/\delta))}$ .

## 34:12 Matrix Multiplication Reductions

Proof. Consider the set  $X_{i^*,j^*}$  from Definition 14 for a good entry  $(i^*, j^*) \in G$ . By Claim 15, the density of  $X_{i,j}$  is at least  $\delta/4$ , and hence, Lemma 8 guarantees the existence of an affine subspace  $V_{i^*,j^*}$  of dimension  $\dim(V_{i^*,j^*}) \geq n - k$ . Then, using Lemma 17 with  $V_{i^*,j^*}$  we have

$$\Pr[M_A \in V_{X_{i,j}}] \geq \frac{1}{2 \cdot 2^k} . \quad (2)$$

Let us condition on the event that  $M^A \in V_{X_{i^*,j^*}}$ . Then by Lemma 8,

$$\Pr_{\substack{R_1, R_2, \dots, R_t \in \mathbb{F}_n^{n \times n} \\ \sum_r R_r = M_A}} [R_1, R_2, \dots, R_t \in X_{i,j}] \geq (\delta/8)^t . \quad (3)$$

For each of  $R_1, \dots, R_t$  define the sets  $Y^{R_1}, Y^{R_2}, \dots, Y^{R_t}$  as in Definition 14. (Recall  $Y^R$  is the set of all matrices  $S$  such that  $(R \cdot S)_{i^*,j^*} = 1$ . We omit the subscript  $(i^*, j^*)$  for readability.)

From Claim 15, we know each of  $Y^{R_1}, \dots, Y^{R_t}$  has density at least  $\delta/4$ . Hence, by applying Lemma 8 on each of them, we obtain subspaces  $V_{Y^{R_1}}, \dots, V_{Y^{R_t}}$  of co-dimension at most  $k$ . Define  $V_Y = V_{Y^{R_1}} \cap V_{Y^{R_2}} \cap \dots \cap V_{Y^{R_t}}$  to be their intersection, and note that  $\dim(V_Y) \geq n - tk$ . Therefore, by applying Lemma 17 on the matrix  $B$  with the subspace  $V_Y$ , we get <sup>1</sup>

$$\Pr[M_B \in V_Y] \geq \frac{1}{2 \cdot 2^{tk}} . \quad (4)$$

Conditioning further on the event that  $M_B \in V_Y$ , we apply Lemma 8, and for each  $r = 1, \dots, t$  we get

$$\Pr_{\substack{S_1^{(r)}, \dots, S_t^{(r)} \\ \sum_s S_s^{(r)} = M_B}} [S_1^{(r)}, \dots, S_t^{(r)} \in Y^{R_r}] \geq (\delta/8)^t .$$

Since the events above are independent between different  $r$ 's, the probability that the algorithm returns correct output on the entry  $(i^*, j^*)$  is lower bounded by the product of the probabilities in Equations (2)–(4), and hence

$$\Pr[C_{i^*,j^*} = (M_A \cdot M_B)_{i^*,j^*}] \geq \frac{1}{2^{k+1}} \times (\delta/8)^t \times \frac{1}{2 \cdot 2^{tk}} \times ((\delta/8)^t)^t \geq \frac{1}{2^{O(\log^3(1/\delta))}} .$$

This completes the proof of Claim 19.  $\triangleleft$

## 4.2 Proof of Theorem 3

We are now ready to prove Theorem 3. Algorithm 3 uses Algorithm 2 as a subroutine, by running it several times. We claim that Algorithm 3 correctly computes the correct answer with high probability for any input  $A, B$ . Note that Algorithm 2 is guaranteed to be correct only for good coordinates, although it does not get the good coordinates as an input, and the guarantee about the good coordinates only appears in the analysis.

<sup>1</sup> Note that although the algorithm samples  $M_B$  before  $R_1, \dots, R_t$ , in fact they are sampled independently of each other, and hence Lemma 17 is applicable here.

■ **Algorithm 3** Approximation for one-sided Agreement Matrix Multiplication Algorithms.

---

**Input:**  $A, B \in \mathbb{F}_2^{n \times n}$   
**Output:**  $A \cdot B$

- 1 Let  $C$  be the  $n \times n$  matrix initialized with all  $\perp$ .
- 2 Let  $\delta_0$  be the constant from Claim 19
- 3 **repeat**  $O\left(\frac{\log(n)}{\delta \cdot \delta_0}\right)$  **times**
- 4     Sample uniformly random  $\pi, \sigma \in [n]$ .
- 5     Run Algorithm 2 with the inputs as  $A^{\pi,0}, B^{0,\sigma}$ , ALG.
- 6     Let  $C^*$  be the resulting matrix
- 7     **for**  $(i, j) \in [n] \times [n]$  **do**
- 8         **if**  $C_{i+\pi \pmod n, j+\sigma \pmod n}^* \neq \perp$  **then**
- 9             Set  $C_{i,j} = C_{i+\pi, j+\sigma}^*$
- 10 **return**  $C$

---

The following claim completes the proof of Theorem 3.

▷ **Claim 20.** Fix a coordinate  $(i, j) \in [n] \times [n]$ . Algorithm 3 returns the matrix  $C$  such that  $\Pr[C_{i,j} = (A \cdot B)_{i,j}] \geq 1 - 1/n^3$ .

In particular, by taking the union bound over all coordinates  $(i, j)$  it follows that for any input  $A, B$  Algorithm 3 returns their product with probability at least  $1 - 1/n$ .

*Proof.* Fix a coordinate  $(i, j) \in [n] \times [n]$ . The algorithm chooses random  $\pi$  and  $\sigma$ , and runs Algorithm 2 on the shifted matrices  $A^{\pi,0}$  and  $B^{0,\sigma}$ .

Note that since  $\pi$  and  $\sigma$  are chosen uniformly at random, it follows that  $\Pr[(i + \pi \pmod n, j + \sigma \pmod n) \in G] = |G|/n^2 \geq \delta/2$ .

Suppose that  $(i + \pi \pmod n, j + \sigma \pmod n)$  is indeed a good coordinate. Then by Claim 20 with probability  $\delta_0$  we obtain the correct answer in the coordinate  $(i + \pi \pmod n, j + \sigma \pmod n)$ , in which case we set  $C_{i,j}$  to be that answer  $(A \cdot B)_{i,j}$ . Otherwise,  $C_{i,j}$  remains  $\perp$ .

Therefore, with probability at least  $(\delta/2) \cdot \delta_0$  in each iteration  $C_{i,j}$  changes from  $\perp$  to  $(A \cdot B)_{i,j}$ , and once it changes, it never changes its value again.

By repeating the procedure  $R = O\left(\frac{\log(n)}{\delta \cdot \delta_0}\right)$  times, the probability that in the end of the algorithm  $C_{i,j} = \perp$  is upper bounded by  $\Pr[C_{i,j} = \perp] \leq (1 - \delta_0)^R < 1/n^3$ . This completes the proof of the claim. ◁

We conclude the proof with the analysis of the running time of the algorithm.

### Running Time

The total running time of Algorithm 3 is essentially dominated by the running time of Algorithm 2 multiplied by  $O\left(\frac{\log(n)}{\delta \cdot \delta_0}\right)$ . Each iteration of Algorithm 2 involves  $O(t^2)$  calls to ALG plus additional  $O(tn^2)$  time. Therefore, the running time is  $O(t^2 \log(n)T(n)/\delta \cdot \delta_0)$ . Since  $t = O(\log 1/\delta)$ , and  $\delta_0 = 0.5^{O(\log^3(1/\delta))}$  the total running time of the algorithm is  $2^{O(\log^3(1/\delta))} \cdot T(n) \log(n)$ .

In particular, even for a slightly sub-constant  $\delta \geq \exp(-\log^{0.33}(n))$ , our algorithm runs in time  $T(n) \cdot n^{o(1)}$ .

This completes the proof of Theorem 3.

## Abstract

A set family  $\mathcal{F}$  is called intersecting if every two members of  $\mathcal{F}$  intersect, and it is called uniform if all members of  $\mathcal{F}$  share a common size. A uniform family  $\mathcal{F} \subseteq \binom{[n]}{k}$  of  $k$ -subsets of  $[n]$  is  $\varepsilon$ -far from intersecting if one has to remove more than  $\varepsilon \cdot \binom{n}{k}$  of the sets of  $\mathcal{F}$  to make it intersecting. We study the property testing problem that given query access to a uniform family  $\mathcal{F} \subseteq \binom{[n]}{k}$ , asks to distinguish between the case that  $\mathcal{F}$  is intersecting and the case that it is  $\varepsilon$ -far from intersecting. We prove that for every fixed integer  $r$ , the problem admits a non-adaptive two-sided error tester with query complexity  $O(\frac{\ln n}{\varepsilon})$  for  $\varepsilon \geq \Omega((\frac{k}{n})^r)$  and a non-adaptive one-sided error tester with query complexity  $O(\frac{\ln k}{\varepsilon})$  for  $\varepsilon \geq \Omega((\frac{k^2}{n})^r)$ . The query complexities are optimal up to the logarithmic terms. For  $\varepsilon \geq \Omega((\frac{k^2}{n})^2)$ , we further provide a non-adaptive one-sided error tester with optimal query complexity of  $O(\frac{1}{\varepsilon})$ . Our findings show that the query complexity of the problem behaves differently from that of testing intersectingness of non-uniform families, studied recently by Chen, De, Li, Nadimpalli, and Servedio (ITCS, 2024).

## 1 Introduction

A set family  $\mathcal{F}$  is called intersecting if for every two sets  $F_1, F_2 \in \mathcal{F}$ , it holds that  $F_1 \cap F_2 \neq \emptyset$ . The study of intersecting families plays a central role in the area of extremal combinatorics with a particular attention dedicated to the uniform case, where all the sets of the family share a common size. One of the most influential results in this context is the Erdős–Ko–Rado theorem [4], proved in 1938 and published in 1961, which states that for integers  $n$  and  $k$  with  $n \geq 2k$ , the maximum size of an intersecting family of  $k$ -subsets of  $[n] = \{1, 2, \dots, n\}$  is  $\binom{n-1}{k-1}$ , attained by the families of all  $k$ -subsets that include a fixed element. Another prominent result, proved by Lovász [10] in 1978 settling a conjecture of Kneser [9] from 1955, asserts that for  $n \geq 2k$ , the family  $\binom{[n]}{k}$  of all  $k$ -subsets of  $[n]$  cannot be covered by fewer than  $n - 2k + 2$  intersecting families. This result is tight, as follows by considering, for each  $i \in [n - 2k + 1]$ , the family of  $k$ -subsets of  $[n]$  that include  $i$ , and the family of  $k$ -subsets of  $[n] \setminus [n - 2k + 1]$ . A more recent result, proved by Dinur and Friedgut [3] in 2009, provides a structural characterization for large intersecting families of  $k$ -subsets of  $[n]$  when  $k$  is sufficiently smaller than  $n$ . It says, roughly speaking, that every such family is

approximately contained in an intersecting junta, that is, an intersecting family  $\mathcal{J}$  over  $[n]$ , such that the membership of a set  $F$  in  $\mathcal{J}$  depends only on  $F \cap J$  for a fixed set  $J \subseteq [n]$ , where the size of  $J$  is determined by the precision of the containment (see Theorem 7).

In this paper, we investigate intersecting uniform families from the computational perspective of property testing. This field delves into the amount of data required for distinguishing objects that satisfy a prescribed property from those that significantly deviate from satisfying it. The objective is to design a randomized algorithm for this task, called a (two-sided error) tester, that succeeds with high constant probability and minimizes the query complexity, i.e., the number of queries to the input object. If the tester accepts objects that satisfy the given property with probability 1, we say that its error is one-sided. The tester is said to be non-adaptive if its queries are determined independently of the answers provided for prior queries. For a thorough introduction to the field of property testing, the reader is referred to, e.g., [8].

For integers  $n$  and  $k$  with  $n \geq 2k$  and for a real  $\varepsilon \in [0, 1)$ , we say that a family  $\mathcal{F} \subseteq \binom{[n]}{k}$  is  $\varepsilon$ -far from intersecting if one has to remove more than  $\varepsilon \cdot \binom{[n]}{k}$  of its sets to make it intersecting. In the property testing problem  $\text{INTERSECTING}_{n,k,\varepsilon}$ , we are given access to a family  $\mathcal{F} \subseteq \binom{[n]}{k}$ , represented by an indicator function  $f : \binom{[n]}{k} \rightarrow \{0, 1\}$ , and the goal is to distinguish between the case that  $\mathcal{F}$  is intersecting and the case that it is  $\varepsilon$ -far from intersecting. Note that the Erdős–Ko–Rado theorem [4] implies that every intersecting family  $\mathcal{F} \subseteq \binom{[n]}{k}$  includes at most a  $k/n$  fraction of the sets of  $\binom{[n]}{k}$ . This gives impetus to studying the  $\text{INTERSECTING}_{n,k,\varepsilon}$  problem for a proximity parameter  $\varepsilon = \varepsilon(n, k)$  that diminishes faster than the ratio  $k/n$  (see the discussion at the end of Section 3).

Our interest in testing intersectingness of uniform families is sparked and inspired by a recent paper of Chen, De, Li, Nadimpalli, and Servedio [2], who introduced and explored the analogue problem for general (non-uniform) families of sets. In their setting, the input consists of an indicator function  $f : \{0, 1\}^n \rightarrow \{0, 1\}$  of a family  $\mathcal{F}$  of subsets of  $[n]$  (of any size), identified with their characteristic vectors in  $\{0, 1\}^n$ , and the goal is to decide whether  $\mathcal{F}$  is intersecting or  $\varepsilon$ -far from intersecting. Here, since the size of the domain is  $2^n$ , a family is said to be  $\varepsilon$ -far from intersecting if more than  $\varepsilon \cdot 2^n$  of its sets should be removed to make it intersecting. Chen et al. [2] proved that this problem admits a non-adaptive one-sided error tester with query complexity  $\text{poly}(n\sqrt{n \cdot \log(1/\varepsilon)}, \frac{1}{\varepsilon})$ . They further established a nearly matching lower bound, showing that the query complexity of every non-adaptive one-sided error tester for the problem is  $2^{\Omega(\sqrt{n \cdot \log(1/\varepsilon)})}$ , whenever  $\varepsilon \in [2^{-n}, \varepsilon_0]$  for some constant  $\varepsilon_0 > 0$ . For non-adaptive two-sided error testers, they obtained a lower bound of  $2^{\Omega(n^{1/4}/\sqrt{\varepsilon})}$  on the query complexity, assuming that  $\varepsilon \in [1/\sqrt{n}, \varepsilon_0]$  for some constant  $\varepsilon_0 > 0$ . As will be shortly described, the results of the present paper highlight a significant difference between the behavior of the query complexity of testing intersectingness in the uniform and non-uniform settings.

## 1.1 Our Contribution

This paper studies the query complexity of the  $\text{INTERSECTING}_{n,k,\varepsilon}$  testing problem. We offer nearly matching upper and lower bounds for various settings of the integers  $n$  and  $k$  and the proximity parameter  $\varepsilon = \varepsilon(n, k)$ . Let us mention already here that all of our upper bounds are proved via efficient testers, whose running time is polynomial in  $n$ . We further note that the results presented below are applicable for all integers  $n$  and  $k$  for which the conditions on  $\varepsilon$  allow it to be smaller than 1. The precise and formal statements are given in the upcoming technical sections.

Our first result furnishes a non-adaptive two-sided error tester for the case of  $\varepsilon \geq \Omega((k/n)^r)$  for a fixed constant  $r$ . Its analysis borrows the structural characterization of large intersecting uniform families due to Dinur and Friedgut [3]. Note that the multiplicative factors hidden by the  $O(\cdot)$  and  $\Omega(\cdot)$  notations might depend on  $r$ .

► **Theorem 1 (Two-Sided Error Tester).** *For every fixed integer  $r$ , for all integers  $n$  and  $k$  with  $n \geq 2k$  and for any real  $\varepsilon \geq \Omega((\frac{k}{n})^r)$ , there exists a non-adaptive two-sided error tester for  $\text{INTERSECTING}_{n,k,\varepsilon}$  with  $O(\frac{\ln n}{\varepsilon})$  queries.*

In fact, we prove Theorem 1 in a stronger form, adopting the concept of tolerant property testing, introduced by Parnas, Ron, and Rubinfeld [12]. Strengthening the standard notion of property testing, a tolerant tester is required to accept not only objects that satisfy the given property, but also those that are close to satisfying it (and as usual, to reject objects that significantly deviate from the property). Accordingly, the tester given in Theorem 1 is shown to accept with high probability any family that can be made intersecting by removing relatively few of its sets (see Theorem 6). Note that a result of Tell [13] implies that a two-sided error is essentially inherent in tolerant property testing.

We next turn our attention to designing one-sided error testers for the  $\text{INTERSECTING}_{n,k,\varepsilon}$  problem, wherein an intersecting family must be accepted with probability 1. A natural non-adaptive tester for this purpose, termed the canonical tester, selects  $m$  random sets from  $\binom{[n]}{k}$ , uniformly and independently, and checks whether they include two sets that demonstrate the non-intersectingness of the input family, namely, two disjoint sets within the family. This raises the combinatorial question, which might be of independent interest, of determining the smallest number  $m = m(n, k, \varepsilon)$  of random sets from  $\binom{[n]}{k}$  that guarantee with high probability a pair of disjoint sets that lie in a family  $\mathcal{F} \subseteq \binom{[n]}{k}$ , assuming that  $\mathcal{F}$  is  $\varepsilon$ -far from intersecting. As our main technical contribution, we address this question for the case where  $\varepsilon \geq \Omega((k^2/n)^r)$  for a fixed constant  $r$ . Our analysis yields the following result.

► **Theorem 2 (One-Sided Error Tester).** *For every fixed integer  $r$ , for all integers  $n$  and  $k$  with  $n \geq 2k$  and for any real  $\varepsilon \geq \Omega((\frac{k^2}{n})^r)$ , there exists a non-adaptive one-sided error tester for  $\text{INTERSECTING}_{n,k,\varepsilon}$  with  $O(\frac{\ln k}{\varepsilon})$  queries.*

Let us emphasize that the tester provided by Theorem 2 surpasses that of Theorem 1 in two respects: its error is one-sided, and its query complexity is lower, replacing the  $\ln n$  term by  $\ln k$ . On the other hand, Theorem 2 requires  $\varepsilon$  to satisfy  $\varepsilon \geq \Omega((k^2/n)^r)$ , and is thus applicable only for  $n \geq \Omega(k^2)$ , whereas the two-sided error tester of Theorem 1 is applicable already for  $n \geq \Omega(k)$ .

For the special case of  $r = 2$ , we offer a notably simple analysis of the canonical tester, enabling us to enhance the query complexity achieved in Theorem 2 by getting rid of the logarithmic term. This gives the following result.

► **Theorem 3 (One-Sided Error Tester;  $r = 2$ ).** *For all integers  $n$  and  $k$  with  $n \geq 2k$  and for any real  $\varepsilon \geq \Omega((\frac{k^2}{n})^2)$ , there exists a non-adaptive one-sided error tester for  $\text{INTERSECTING}_{n,k,\varepsilon}$  with  $O(\frac{1}{\varepsilon})$  queries.*

We further consider the  $\text{INTERSECTING}_{n,k,\varepsilon}$  problem for integers  $n$  and  $k$  satisfying  $n = \alpha \cdot k$  for an arbitrary constant  $\alpha \geq 2$ . Interestingly, the canonical tester fails in this case, because its random samples are unlikely to include even a single pair of disjoint sets, unless the number of samples is exponential in  $n$ . Nevertheless, we show that for all constants  $\alpha \geq 2$  and  $\varepsilon \in (0, 1)$ , the  $\text{INTERSECTING}_{n,k,\varepsilon}$  problem with  $n = \alpha \cdot k$  admits a non-adaptive one-sided error tester with constant query complexity. The proof employs a result of Friedgut and Regev [7], and the details are given in Section 4.2 (see Theorem 17).

Our final result supplies a lower bound on the query complexity of the  $\text{INTERSECTING}_{n,k,\varepsilon}$  problem. Note that the lower bound applies even to adaptive two-sided error testers. While the result can be derived from a general result of [5], our proof in the full version of the paper explicitly presents hard instances of the problem.

► **Theorem 4 (Lower Bound).** *For all integers  $n$  and  $k$  with  $n \geq 2k$  and for any real  $\varepsilon = \varepsilon(n, k)$  with  $\binom{n}{k}^{-1} \leq \varepsilon < \frac{1}{2}$ , the query complexity of every tester for  $\text{INTERSECTING}_{n,k,\varepsilon}$  is  $\Omega(\frac{1}{\varepsilon})$ .*

It is noteworthy that Theorem 4 implies that the query complexities achieved by our testers for the  $\text{INTERSECTING}_{n,k,\varepsilon}$  problem are nearly tight. Specifically, the query complexity obtained in Theorem 3 is tight up to a multiplicative constant, while those of Theorems 1 and 2 are tight up to multiplicative logarithmic terms. An intriguing task for further research would be to decide whether these logarithmic terms can be avoided. More ambitiously, it would be interesting to determine the query complexity of the  $\text{INTERSECTING}_{n,k,\varepsilon}$  problem for general values of  $n$ ,  $k$ , and  $\varepsilon = \varepsilon(n, k)$ .

## 1.2 Proof Techniques

We provide here a high-level description of the ideas applied in the proofs of Theorems 1 and 2. Let us start with the proof of Theorem 1, which gives a non-adaptive two-sided error tester for the  $\text{INTERSECTING}_{n,k,\varepsilon}$  problem with query complexity  $O(\frac{\ln n}{\varepsilon})$ , where  $\varepsilon \geq \Omega(\frac{k}{n})^r$  for a fixed integer  $r$ . Given access to a family  $\mathcal{F} \subseteq \binom{[n]}{k}$ , our tester attempts to decide whether  $\mathcal{F}$  is approximately contained in an intersecting  $j$ -junta over  $[n]$  for some integer  $j$  that depends solely on  $r$ . To do so, the tester picks random sets from  $\binom{[n]}{k}$ , uniformly and independently, and checks whether they lie in  $\mathcal{F}$ . These samples are used to estimate, for each intersecting  $j$ -junta  $\mathcal{J}$  over  $[n]$ , the fraction of sets in  $\binom{[n]}{k}$  that lie in  $\mathcal{F} \setminus \mathcal{J}$ . Our analysis shows that  $O(\frac{\ln n}{\varepsilon})$  samples suffice for these estimations to be pretty accurate with high probability. Then, if those estimations indicate that  $\mathcal{F}$  is approximately contained in some intersecting  $j$ -junta over  $[n]$ , the tester predicts that  $\mathcal{F}$  is close to intersecting. Otherwise, relying on the aforementioned structural result of Dinur and Friedgut [3], the tester deduces that  $\mathcal{F}$  is far from intersecting with high probability. Let us stress that the tester is two-sided error, because even if  $\mathcal{F}$  is intersecting and is essentially aligned with some intersecting  $j$ -junta  $\mathcal{J}$  over  $[n]$ , the random samples might wrongly suggest, with low probability, that  $\mathcal{F}$  significantly deviates from  $\mathcal{J}$ . As previously noted, Theorem 1 is proved with respect to tolerant property testing. For the precise statement and argument, the reader is referred to Section 3.

We next outline the approach applied in the proof of Theorem 2, which establishes a non-adaptive one-sided error tester for the  $\text{INTERSECTING}_{n,k,\varepsilon}$  problem with query complexity  $O(\frac{\ln k}{\varepsilon})$ , where  $\varepsilon \geq \Omega(\frac{k^2}{n})^r$  for a fixed integer  $r$ . As mentioned earlier, the proof of this result relies on the canonical tester, which selects random sets from  $\binom{[n]}{k}$ , uniformly and independently, and checks if they include two sets that violate the intersectingness of the given family. Therefore, our goal is to show that if a family  $\mathcal{F} \subseteq \binom{[n]}{k}$  is  $\varepsilon$ -far from intersecting, then a collection of  $O(\frac{\ln k}{\varepsilon})$  random sets from  $\binom{[n]}{k}$  includes with high probability two disjoint sets within  $\mathcal{F}$ . Consider a family  $\mathcal{F} \subseteq \binom{[n]}{k}$ , and assume that  $\mathcal{F}$  is  $\varepsilon$ -far from intersecting. Notice that this in particular implies that  $|\mathcal{F}| > \varepsilon \cdot \binom{n}{k}$ , as otherwise, one could remove at most  $\varepsilon \cdot \binom{n}{k}$  of its sets to make it intersecting.

Let us first suppose that the chosen random sets include, for each set  $A \subseteq [n]$  of size at most  $r-1$ , a set  $F_A \in \mathcal{F}$  with  $F_A \cap A = \emptyset$ . A key observation in our approach is that the number of sets in  $\binom{[n]}{k}$  that intersect all of those sets  $F_A$  does not exceed  $k^r \cdot \binom{n-r}{k-r}$ . To see

this, observe that every set that intersects them all includes an element  $j_1 \in F_\emptyset$ , an element  $j_2 \in F_{\{j_1\}}$ , an element  $j_3 \in F_{\{j_1, j_2\}}$ , and so on, up to an element  $j_r \in F_{\{j_1, \dots, j_{r-1}\}}$ , where the  $r$  elements  $j_1, \dots, j_r$  are distinct. It thus follows that there exists a collection of at most  $k^r$  subsets of  $[n]$  of size  $r$ , such that every set in  $\binom{[n]}{k}$  that intersects all the sampled sets that lie in  $\mathcal{F}$  contains at least one of the sets of the collection. This implies that the number of those sets does not exceed  $k^r \cdot \binom{n-r}{k-r} \leq \left(\frac{k^2}{n}\right)^r \cdot \binom{n}{k}$ . Now, by combining our assumption on  $\varepsilon$  with the fact that  $|\mathcal{F}| > \varepsilon \cdot \binom{n}{k}$ , one can show that a random set from  $\binom{[n]}{k}$  lies in  $\mathcal{F}$  and is disjoint from at least one of the previously sampled sets that lie in  $\mathcal{F}$  with non-negligible probability. Therefore, a few additional random sets from  $\binom{[n]}{k}$  are expected to provide with high probability the desired witness for the non-intersectingness of  $\mathcal{F}$ .

The scenario discussed above, however, is somewhat oversimplified. It definitely might be the case that for some set  $A \subseteq [n]$  of size at most  $r - 1$ , the sets of  $\mathcal{F}$  that are disjoint from  $A$  are quite rare, and as such, our random samples are not expected to include them. Following the terminology of [3], we say that such a set  $A$  captures  $\mathcal{F}$  (see Definition 13). To deal with this situation, we show that if a set  $A$  of size at most  $r - 1$  captures  $\mathcal{F}$ , then it admits two disjoint subsets  $B, C \subseteq A$ , such that the sub-families  $\mathcal{F}_1$  and  $\mathcal{F}_2$  of  $\mathcal{F}$ , defined as the restrictions of  $\mathcal{F}$  to the sets whose intersection with  $A$  is, respectively,  $B$  and  $C$ , are far from being cross-intersecting, that is, one has to remove plenty of sets from  $\mathcal{F}_1$  and  $\mathcal{F}_2$  so that every set of  $\mathcal{F}_1$  will intersect every set of  $\mathcal{F}_2$ . Since  $B$  and  $C$  are disjoint, this essentially allows us to ignore from now on the elements of  $A$ , and to analyze the probability that the random samples include two disjoint sets, one from  $\mathcal{F}_1$  and one from  $\mathcal{F}_2$ . By a slight variant of the key observation described above, we wish our samples to include, for each set  $A' \subseteq [n] \setminus A$  of size at most  $r - 1$ , a set  $F_{A'} \in \mathcal{F}_2$  with  $F_{A'} \cap A' = \emptyset$ . If the samples include such sets, then it can be shown that a random set is expected to lie in  $\mathcal{F}_1$  and be disjoint from some previously chosen set of  $\mathcal{F}_2$  with non-negligible probability. However, if some set  $A' \subseteq [n] \setminus A$  of size at most  $r - 1$  captures  $\mathcal{F}_2$ , then a suitable set  $F_{A'}$  is unlikely to be found. In this case, we repeat the above process and further refine  $\mathcal{F}_1$  and  $\mathcal{F}_2$ , fixing the intersections of their sets with  $A'$  to some disjoint subsets and keeping them far from cross-intersecting. It might be needed to repeat this process multiple times, but a crucial component of our argument shows that  $r$  iterations suffice. Indeed, after this number of iterations, it turns out that the refined family  $\mathcal{F}_2$  is already too small to still satisfy the invariant that  $\mathcal{F}_1$  and  $\mathcal{F}_2$  are far from cross-intersecting.

To summarize, our analysis of the canonical tester shows that if a family  $\mathcal{F} \subseteq \binom{[n]}{k}$  is  $\varepsilon$ -far from intersecting for a sufficiently large  $\varepsilon = \varepsilon(n, k)$ , then there exist a set  $A \subseteq [n]$  and two disjoint subsets  $B, C \subseteq A$ , such that (a) the restrictions  $\mathcal{F}_1$  and  $\mathcal{F}_2$  of  $\mathcal{F}$  to the sets whose intersections with  $A$  are  $B$  and  $C$ , respectively, are far from cross-intersecting, and (b) no subset of  $[n] \setminus A$  of size at most  $r - 1$  captures  $\mathcal{F}_2$  (see Lemma 15). This allows us to show that  $O\left(\frac{\ln k}{\varepsilon}\right)$  sets chosen randomly from  $\binom{[n]}{k}$  include with high probability a collection of sets of  $\mathcal{F}_2$ , such that relatively few sets of  $\mathcal{F}_1$  intersect them all. Therefore, a few additional samples from  $\binom{[n]}{k}$  are expected to include a set of  $\mathcal{F}_1$  that is disjoint from one of the previously picked sets of  $\mathcal{F}_2$ , resulting in the desired witness for non-intersectingness (see Lemma 16). For the precise and full argument, the reader is referred to Section 4.1.2.

### 1.3 Related Work

The Erdős–Ko–Rado theorem [4] implies that for all integers  $n$  and  $k$  with  $n \geq 2k$ , every family  $\mathcal{F} \subseteq \binom{[n]}{k}$  whose size exceeds  $\binom{n-1}{k-1}$  is not intersecting. One may thus ask whether such a family  $\mathcal{F}$  must include a set that is disjoint from many of the sets of  $\mathcal{F}$ . This question was recently investigated by Frankl and Kupavskii [6] and by Chau, Ellis, Friedgut, and

Lifshitz [1], who provided a positive answer in a strong sense. Namely, it was shown in [1] that for any  $\delta > 0$ , there exists some  $\alpha > 0$ , such that for all integers  $n$  and  $k$  with  $n \geq \alpha \cdot k$ , every family  $\mathcal{F} \subseteq \binom{[n]}{k}$  of size  $|\mathcal{F}| = \binom{n-1}{k-1} + 1$  includes a set that is disjoint from at least  $(\frac{1}{2} - \delta) \cdot \binom{n-k-1}{k-1}$  of the sets of  $\mathcal{F}$ .

We point out that the combinatorial question arising in our analysis of the canonical tester for the  $\text{INTERSECTING}_{n,k,\varepsilon}$  problem is similar in spirit to the question studied in [6, 1]. Indeed, the analysis requires us to show that if a family  $\mathcal{F} \subseteq \binom{[n]}{k}$  is  $\varepsilon$ -far from intersecting, then a relatively small collection of random sets, chosen uniformly and independently from  $\binom{[n]}{k}$ , includes with high probability two disjoint sets that lie in  $\mathcal{F}$ . For such a statement, one has to show not only the existence of a set in  $\mathcal{F}$  that is disjoint from many of the sets of  $\mathcal{F}$ , but that many of the sets of  $\mathcal{F}$  satisfy this property. Yet, a crucial difference between the two concepts is that in ours, the family  $\mathcal{F}$  is not assumed to exceed the Erdős–Ko–Rado threshold but rather to be  $\varepsilon$ -far from intersecting.

## 1.4 Outline

The rest of the paper is organized as follows. In Section 2, we provide some definitions and tools that will be used throughout the paper. In Section 3, we present and analyze our two-sided error tester for the  $\text{INTERSECTING}_{n,k,\varepsilon}$  problem and confirm Theorem 1. Finally, in Section 4, we present and analyze the one-sided error canonical tester for the  $\text{INTERSECTING}_{n,k,\varepsilon}$  problem and confirm Theorems 2 and 3. We further present there another one-sided error tester, appropriate for integers  $n$  and  $k$  with  $n = \Theta(k)$ . The proof of Theorem 4 can be found in the full version of the paper.

## 2 Preliminaries

Throughout the paper, we omit all floor and ceiling signs, whenever these are not crucial.

### 2.1 Intersecting Families

For integers  $n$  and  $k$ , let  $\binom{[n]}{k}$  denote the family of all  $k$ -subsets of  $[n] = \{1, \dots, n\}$ . A family  $\mathcal{F} \subseteq \binom{[n]}{k}$  is called intersecting if for every two sets  $F_1, F_2 \in \mathcal{F}$ , it holds that  $F_1 \cap F_2 \neq \emptyset$ . For a real  $\varepsilon \in [0, 1]$ , we say that  $\mathcal{F}$  is  $\varepsilon$ -close to intersecting if it is possible to make  $\mathcal{F}$  intersecting by removing at most  $\varepsilon \cdot \binom{n}{k}$  of its sets. Otherwise, we say that  $\mathcal{F}$  is  $\varepsilon$ -far from intersecting.

For two families  $\mathcal{F}_1, \mathcal{F}_2 \subseteq \binom{[n]}{k}$ , the pair  $(\mathcal{F}_1, \mathcal{F}_2)$  is called cross-intersecting if for every two sets  $F_1 \in \mathcal{F}_1$  and  $F_2 \in \mathcal{F}_2$ , it holds that  $F_1 \cap F_2 \neq \emptyset$ . For a real  $\varepsilon \in [0, 1]$ , we say that the pair  $(\mathcal{F}_1, \mathcal{F}_2)$  is  $\varepsilon$ -close to cross-intersecting if it is possible to make  $(\mathcal{F}_1, \mathcal{F}_2)$  cross-intersecting by removing at most  $\varepsilon \cdot \binom{n}{k}$  of the sets of  $\mathcal{F}_1$  and  $\mathcal{F}_2$ . Otherwise, we say that  $(\mathcal{F}_1, \mathcal{F}_2)$  is  $\varepsilon$ -far from cross-intersecting. Note that if a family  $\mathcal{F} \subseteq \binom{[n]}{k}$  is  $\varepsilon$ -far from intersecting, then the pair  $(\mathcal{F}, \mathcal{F})$  is  $\varepsilon$ -far from cross-intersecting.

A function  $f : \binom{[n]}{k} \rightarrow \{0, 1\}$  is called intersecting,  $\varepsilon$ -close to intersecting, and  $\varepsilon$ -far from intersecting, if the family  $f^{-1}(1)$  of the sets of  $\binom{[n]}{k}$  that are mapped by  $f$  to 1 is, respectively, intersecting,  $\varepsilon$ -close to intersecting, and  $\varepsilon$ -far from intersecting. For reals  $\varepsilon_1, \varepsilon_2 \in [0, 1]$  with  $\varepsilon_1 \leq \varepsilon_2$ , let  $\text{INTERSECTING}_{n,k,\varepsilon_1,\varepsilon_2}$  denote the tolerant property testing problem that given query access to a function  $f : \binom{[n]}{k} \rightarrow \{0, 1\}$ , asks to distinguish between the case that  $f$  is  $\varepsilon_1$ -close to intersecting and the case that  $f$  is  $\varepsilon_2$ -far from intersecting. We will be particularly interested in the case of  $\varepsilon_1 = 0$ , hence for a real  $\varepsilon \in [0, 1]$ , we let  $\text{INTERSECTING}_{n,k,\varepsilon}$  denote the  $\text{INTERSECTING}_{n,k,0,\varepsilon}$  problem.

## 2.2 Chernoff–Hoeffding Bound

We will need the following version of the Chernoff–Hoeffding bound.

► **Theorem 5.** *For an integer  $m$  and a real  $p \in (0, 1)$ , let  $X_1, \dots, X_m$  be independent binary random variables satisfying  $\Pr[X_i = 1] = p$  and  $\Pr[X_i = 0] = 1 - p$  for all  $i \in [m]$ , and put  $\bar{X} = \frac{1}{m} \cdot \sum_{i=1}^m X_i$ . Then, for any  $\mu \geq 0$ ,*

1. *if  $p \leq \mu$ , then  $\Pr[\bar{X} \geq 2\mu] \leq e^{-m \cdot \mu/3}$ , and*
2. *if  $p \geq \mu$ , then  $\Pr[\bar{X} \leq \mu/2] \leq e^{-m \cdot \mu/8}$ .*

Note that the assertion of Theorem 5 for  $p = \mu$  follows from standard statements of the Chernoff–Hoeffding bound (see, e.g., [11, Theorem 2.3]). The cases of  $p < \mu$  and  $p > \mu$  stem by monotonicity.

### 3 Two-Sided Error Tester

In this section, we present and analyze a tolerant non-adaptive two-sided error tester for the  $\text{INTERSECTING}_{n,k,\varepsilon_1,\varepsilon_2}$  problem and prove the following result. Its special case with  $\varepsilon_1 = 0$  yields Theorem 1.

► **Theorem 6.** *For every integer  $r \geq 2$ , there exist constants  $c_1 = c_1(r)$  and  $c_2 = c_2(r)$  for which the following holds. For all sufficiently large integers  $n$  and  $k$  with  $n \geq 2k$  and for all reals  $\varepsilon_1, \varepsilon_2 \in [0, 1)$  with  $\varepsilon_2 \geq 4 \cdot \varepsilon_1 + c_1 \cdot (\frac{k}{n})^r$ , there exists a tolerant non-adaptive two-sided error tester for  $\text{INTERSECTING}_{n,k,\varepsilon_1,\varepsilon_2}$  with at most  $c_2 \cdot \frac{\ln n}{\varepsilon_2}$  queries, running time polynomial in  $n$ , and success probability at least  $2/3$ .*

A crucial ingredient in the proof of Theorem 6 is the following theorem due to Dinur and Friedgut [3]. Here, a family  $\mathcal{J}$  of subsets of  $[n]$  is called a  $j$ -junta over  $[n]$  if there exists a set  $J \subseteq [n]$  of size  $|J| = j$  such that the membership of a set  $F$  in  $\mathcal{J}$  depends only on  $F \cap J$ .

► **Theorem 7** ([3]). *For every integer  $r \geq 2$ , there exist constants  $j = j(r)$  and  $a = a(r)$  for which the following holds. For all integers  $n$  and  $k$  with  $n > 2k$  and  $k > j$ , if a family  $\mathcal{F} \subseteq \binom{[n]}{k}$  is intersecting, then there exists an intersecting  $j$ -junta  $\mathcal{J}$  over  $[n]$  such that  $|\mathcal{F} \setminus \mathcal{J}| \leq a \cdot \binom{n-r}{k-r}$ .*

We are ready to prove Theorem 6.

**Proof of Theorem 6.** Fix an integer  $r \geq 2$ , and let  $j = j(r)$  and  $a = a(r)$  be the constants given in Theorem 7. Let  $n$  and  $k$  be sufficiently large integers. Since the theorem trivially holds for  $n = 2k$  (with an appropriate  $c_1$ ), it may be assumed that  $n > 2k$  and  $k > j$ . For an integer  $m$  and for reals  $\varepsilon_1, \varepsilon_2 \in [0, 1)$  with  $\varepsilon_1 \leq \varepsilon_2$ , consider the following tester for the  $\text{INTERSECTING}_{n,k,\varepsilon_1,\varepsilon_2}$  problem.

Input: Query access to a function  $f : \binom{[n]}{k} \rightarrow \{0, 1\}$ .

1. Pick  $m$  sets  $G_1, \dots, G_m$  uniformly and independently at random from  $\binom{[n]}{k}$ .
2. Query  $f$  for the value of  $f(G_i)$  for each  $i \in [m]$ .
3. For each intersecting  $j$ -junta  $\mathcal{J}$  over  $[n]$ , let  $\alpha_{\mathcal{J}}$  denote the fraction of the chosen sets  $G_i$  that are mapped by  $f$  to 1 and do not lie in  $\mathcal{J}$ , that is,

$$\alpha_{\mathcal{J}} = \frac{1}{m} \cdot |\{i \in [m] \mid f(G_i) = 1 \text{ and } G_i \notin \mathcal{J}\}|.$$

4. If there exists an intersecting  $j$ -junta  $\mathcal{J}$  over  $[n]$  with  $\alpha_{\mathcal{J}} \leq \frac{\varepsilon_2}{2}$ , then accept, and otherwise reject.

## 35:8 Testing Intersectingness of Uniform Families

The above tester is clearly non-adaptive. For the analysis of its success probability, suppose that

$$\varepsilon_2 \geq 4 \cdot \left( \varepsilon_1 + a \cdot \left( \frac{k}{n} \right)^r \right) \quad \text{and} \quad m \geq \frac{12 \cdot (j \cdot \ln n + 2^j + 2)}{\varepsilon_2}. \quad (1)$$

Let  $f : \binom{[n]}{k} \rightarrow \{0, 1\}$  be an input function, and consider the family  $\mathcal{F} = f^{-1}(1)$ . Our goal is to prove that if  $\mathcal{F}$  is  $\varepsilon_1$ -close to intersecting then the tester accepts  $f$  with probability at least  $2/3$ , and that if  $\mathcal{F}$  is  $\varepsilon_2$ -far from intersecting then the tester rejects  $f$  with probability at least  $2/3$ .

For each intersecting  $j$ -junta  $\mathcal{J}$  over  $[n]$ , let  $p_{\mathcal{J}}$  denote the fraction of the sets of  $\binom{[n]}{k}$  that are mapped by  $f$  to 1 and do not lie in  $\mathcal{J}$ , that is,

$$p_{\mathcal{J}} = \frac{1}{\binom{[n]}{k}} \cdot \left| \left\{ G \in \binom{[n]}{k} \mid f(G) = 1 \text{ and } G \notin \mathcal{J} \right\} \right|.$$

We shall prove that, with high probability, the values of  $p_{\mathcal{J}}$  are well approximated by the quantities  $\alpha_{\mathcal{J}}$  that our tester computes. Let  $\mathcal{E}$  denote the event that for every intersecting  $j$ -junta  $\mathcal{J}$  over  $[n]$ , it holds that

1. if  $p_{\mathcal{J}} \leq \frac{\varepsilon_2}{4}$ , then  $\alpha_{\mathcal{J}} < \frac{\varepsilon_2}{2}$ , and
2. if  $p_{\mathcal{J}} \geq \varepsilon_2$ , then  $\alpha_{\mathcal{J}} > \frac{\varepsilon_2}{2}$ .

For a fixed intersecting  $j$ -junta  $\mathcal{J}$  over  $[n]$ , apply Item 1 of Theorem 5 with  $\mu = \frac{\varepsilon_2}{4}$  to obtain that if  $p_{\mathcal{J}} \leq \frac{\varepsilon_2}{4}$ , then  $\alpha_{\mathcal{J}} \geq \frac{\varepsilon_2}{2}$  with probability at most  $e^{-m \cdot \varepsilon_2 / 12}$ . Further, apply Item 2 of Theorem 5 with  $\mu = \varepsilon_2$  to obtain that if  $p_{\mathcal{J}} \geq \varepsilon_2$ , then  $\alpha_{\mathcal{J}} \leq \frac{\varepsilon_2}{2}$  with probability at most  $e^{-m \cdot \varepsilon_2 / 8} \leq e^{-m \cdot \varepsilon_2 / 12}$ . The number of intersecting  $j$ -juntas over  $[n]$  is clearly bounded by  $\binom{[n]}{j} \cdot 2^{2^j}$ . Therefore, by the union bound, the probability that there exists an intersecting  $j$ -junta  $\mathcal{J}$  over  $[n]$  for which either  $p_{\mathcal{J}} \leq \frac{\varepsilon_2}{4}$  and  $\alpha_{\mathcal{J}} \geq \frac{\varepsilon_2}{2}$ , or  $p_{\mathcal{J}} \geq \varepsilon_2$  and  $\alpha_{\mathcal{J}} \leq \frac{\varepsilon_2}{2}$  does not exceed

$$\binom{[n]}{j} \cdot 2^{2^j} \cdot e^{-m \cdot \varepsilon_2 / 12} \leq n^j \cdot 2^{2^j} \cdot e^{-m \cdot \varepsilon_2 / 12} \leq e^{-2} < \frac{1}{3},$$

where the second inequality holds by our assumption on  $m$  given in (1). Therefore, the event  $\mathcal{E}$  occurs with probability at least  $2/3$ .

It suffices to show now that if the event  $\mathcal{E}$  occurs, then the answer of our tester is correct. Suppose first that  $\mathcal{F}$  is  $\varepsilon_1$ -close to intersecting. By definition, there exists an intersecting family  $\mathcal{F}' \subseteq \binom{[n]}{k}$  such that  $|\mathcal{F} \setminus \mathcal{F}'| \leq \varepsilon_1 \cdot \binom{[n]}{k}$ . By Theorem 7, using  $n > 2k$  and  $k > j$ , there exists an intersecting  $j$ -junta  $\mathcal{J}$  over  $[n]$  such that  $|\mathcal{F}' \setminus \mathcal{J}| \leq a \cdot \binom{[n-r]}{k-r} \leq a \cdot \left( \frac{k}{n} \right)^r \cdot \binom{[n]}{k}$ . It thus follows that this  $\mathcal{J}$  satisfies

$$|\mathcal{F} \setminus \mathcal{J}| \leq \varepsilon_1 \cdot \binom{[n]}{k} + |\mathcal{F}' \setminus \mathcal{J}| \leq \varepsilon_1 \cdot \binom{[n]}{k} + a \cdot \left( \frac{k}{n} \right)^r \cdot \binom{[n]}{k} \leq \frac{\varepsilon_2}{4} \cdot \binom{[n]}{k},$$

where the last inequality relies on our assumption on  $\varepsilon_1$  and  $\varepsilon_2$  in (1). This implies that  $p_{\mathcal{J}} \leq \frac{\varepsilon_2}{4}$ , and since the event  $\mathcal{E}$  occurs, it follows that  $\alpha_{\mathcal{J}} < \frac{\varepsilon_2}{2}$ , hence our tester accepts  $f$ . Next, suppose that  $\mathcal{F}$  is  $\varepsilon_2$ -far from intersecting. This implies, for each intersecting  $j$ -junta  $\mathcal{J}$  over  $[n]$ , that  $p_{\mathcal{J}} > \varepsilon_2$ , as otherwise, one could remove at most  $\varepsilon_2 \cdot \binom{[n]}{k}$  of the sets of  $\mathcal{F}$  to obtain a sub-family of the intersecting family  $\mathcal{J}$ . Since the event  $\mathcal{E}$  occurs, each such  $\mathcal{J}$  satisfies  $\alpha_{\mathcal{J}} > \frac{\varepsilon_2}{2}$ , hence our tester rejects  $f$ .

Finally, let  $m$  be the smallest integer satisfying the condition in (1). Observe that the running time of our tester is polynomial in  $m$  and in the number of intersecting  $j$ -juntas over  $[n]$ , where  $j$  depends only on  $r$ . It follows that the running time is polynomial in  $n$  and  $1/\varepsilon_2$ , so by our assumption on  $\varepsilon_2$  in (1), it is polynomial in  $n$ . This completes the proof.  $\blacktriangleleft$

► **Remark 8.** The assumption on  $\varepsilon_1$  and  $\varepsilon_2$  in Theorem 6 can be weakened, by an almost identical proof, to  $\varepsilon_2 \geq (1 + \delta) \cdot \varepsilon_1 + c_1 \cdot \left(\frac{k}{n}\right)^r$  with an arbitrary  $\delta > 0$ . For simplicity of presentation, we omit the details.

We conclude this section with the observation that for all integers  $n$  and  $k$  with  $n \geq 2k$  and for all reals  $\varepsilon_1, \varepsilon_2 \in [0, 1]$  with  $\varepsilon_2 \geq 4 \cdot \left(\varepsilon_1 + \frac{k}{n}\right)$ , there exists an efficient tolerant non-adaptive two-sided error tester for  $\text{INTERSECTING}_{n,k,\varepsilon_1,\varepsilon_2}$  with  $O\left(\frac{1}{\varepsilon_2}\right)$  queries and high success probability. To see this, consider the tester that given access to a function  $f : \binom{[n]}{k} \rightarrow \{0, 1\}$  picks  $O\left(\frac{1}{\varepsilon_2}\right)$  sets uniformly and independently at random from  $\binom{[n]}{k}$ , queries  $f$  on them, and computes the fraction  $\alpha$  of the chosen sets that are mapped by  $f$  to 1. If  $\alpha \leq \frac{\varepsilon_2}{2}$ , then the tester accepts, and otherwise it rejects.

For correctness, let  $p$  denote the fraction of the sets of  $\binom{[n]}{k}$  that are mapped by  $f$  to 1. If  $f$  is  $\varepsilon_1$ -close to intersecting, then  $f$  can be made intersecting by flipping at most  $\varepsilon_1 \cdot \binom{[n]}{k}$  of its values. By the Erdős–Ko–Rado theorem [4], the fraction of the sets of  $\binom{[n]}{k}$  in an intersecting family does not exceed  $\frac{k}{n}$ , hence  $p \leq \varepsilon_1 + \frac{k}{n} \leq \frac{\varepsilon_2}{4}$ . In this case, Theorem 5 yields that with high probability, it holds that  $\alpha \leq \frac{\varepsilon_2}{2}$  and the tester accepts. On the other hand, if  $f$  is  $\varepsilon_2$ -far from intersecting, then it holds that  $p > \varepsilon_2$ , so using again Theorem 5, it follows that with high probability, we have  $\alpha > \frac{\varepsilon_2}{2}$  and the tester rejects.

## 4 One-Sided Error Tester

In this section, we present non-adaptive one-sided error testers for the  $\text{INTERSECTING}_{n,k,\varepsilon}$  problem. We start with the canonical tester, which is used to prove Theorems 2 and 3. We then offer another non-adaptive one-sided error tester, appropriate for integers  $n$  and  $k$  with  $n = \Theta(k)$ .

### 4.1 Canonical Tester

Consider the following tester for the  $\text{INTERSECTING}_{n,k,\varepsilon}$  problem.

**CANONICAL TESTER** ( $n, k, m$ )

Input: Query access to a function  $f : \binom{[n]}{k} \rightarrow \{0, 1\}$ .

1. Pick  $m$  sets  $G_1, \dots, G_m$  uniformly and independently at random from  $\binom{[n]}{k}$ .
2. Query  $f$  for the value of  $f(G_i)$  for each  $i \in [m]$ .
3. If for every two indices  $i_1, i_2 \in [m]$  with  $G_{i_1} \cap G_{i_2} = \emptyset$ , it holds that either  $f(G_{i_1}) = 0$  or  $f(G_{i_2}) = 0$ , then accept, and otherwise reject.

The description of **CANONICAL TESTER** immediately implies that it is non-adaptive and that it accepts every intersecting function with probability 1 and is thus one-sided error. In what follows, we analyze the number of queries  $m$  needed to reject with high probability any function  $\varepsilon$ -far from intersecting for  $\varepsilon \geq \Omega\left(\left(\frac{k^2}{n}\right)^r\right)$ , where  $r$  is a fixed integer. We start with the case of  $r = 2$ , for which we offer a simple analysis that yields a bound of  $O\left(\frac{1}{\varepsilon}\right)$  on the query complexity. We then consider the case of a general  $r$ , for which we obtain a bound of  $O\left(\frac{\ln k}{\varepsilon}\right)$  on the query complexity.

#### 4.1.1 The case $r = 2$

We prove the following result, which confirms Theorem 3.

## 35:10 Testing Intersectingness of Uniform Families

► **Theorem 9.** For all integers  $n$  and  $k$  with  $n \geq 2k$  and for any real  $\varepsilon \in [0, 1)$  with  $\varepsilon \geq 2 \cdot \left(\frac{k^2}{n}\right)^2$ , there exists a non-adaptive one-sided error tester for  $\text{INTERSECTING}_{n,k,\varepsilon}$  with  $O\left(\frac{1}{\varepsilon}\right)$  queries, running time polynomial in  $n$ , and success probability at least  $2/3$ .

The proof of Theorem 9 requires two simple lemmas. The first one, given below, may be viewed as an analogue of a lemma of [2] for uniform families. Here, for a collection  $\mathcal{M}$  of pairs of sets, we say that the pairs of  $\mathcal{M}$  are pairwise disjoint if no set lies in more than one pair of  $\mathcal{M}$ .

► **Lemma 10.** For integers  $n$  and  $k$  with  $n \geq 2k$  and for a real  $\varepsilon \in [0, 1)$ , if a family  $\mathcal{F} \subseteq \binom{[n]}{k}$  is  $\varepsilon$ -far from intersecting, then there exists a collection of more than  $\frac{\varepsilon}{2} \cdot \binom{n}{k}$  pairwise disjoint pairs  $(C, D)$  of sets of  $\mathcal{F}$  satisfying  $C \cap D = \emptyset$ .

**Proof.** Let  $\mathcal{F} \subseteq \binom{[n]}{k}$  be a family  $\varepsilon$ -far from intersecting, and consider a maximal collection  $\mathcal{M}$  (with respect to inclusion) of pairwise disjoint pairs  $(C, D)$  of sets of  $\mathcal{F}$  satisfying  $C \cap D = \emptyset$ . The maximality of  $\mathcal{M}$  implies that  $\mathcal{F}$  can be made intersecting by removing all the  $2 \cdot |\mathcal{M}|$  sets that lie in the pairs of  $\mathcal{M}$ . Since  $\mathcal{F}$  is  $\varepsilon$ -far from intersecting, it follows that  $2 \cdot |\mathcal{M}| > \varepsilon \cdot \binom{n}{k}$ . This completes the proof. ◀

Using Lemma 10, we obtain the following.

► **Lemma 11.** For integers  $n$  and  $k$  with  $n \geq 2k$  and for a real  $\varepsilon \in [0, 1)$ , let  $\mathcal{F} \subseteq \binom{[n]}{k}$  be a family  $\varepsilon$ -far from intersecting with  $|\mathcal{F}| > k^2 \cdot \binom{n-2}{k-2}$ . Then, more than  $\frac{\varepsilon}{2} \cdot \binom{n}{k}$  of the sets of  $\mathcal{F}$  are disjoint from at least  $\frac{1}{2} \cdot (|\mathcal{F}| - k^2 \cdot \binom{n-2}{k-2})$  of the sets of  $\mathcal{F}$ .

**Proof.** Let  $\mathcal{F} \subseteq \binom{[n]}{k}$  be a family  $\varepsilon$ -far from intersecting. By Lemma 10, there exists a collection  $\mathcal{M}$  of more than  $\frac{\varepsilon}{2} \cdot \binom{n}{k}$  pairwise disjoint pairs  $(C, D)$  of sets of  $\mathcal{F}$  satisfying  $C \cap D = \emptyset$ . Fix a pair  $(C, D) \in \mathcal{M}$ . The disjointness of  $C$  and  $D$  implies that every set in  $\binom{[n]}{k}$  that intersects both  $C$  and  $D$  includes some element of  $C$  and a different element of  $D$ . It follows that the number of sets in  $\binom{[n]}{k}$  that intersect both  $C$  and  $D$  does not exceed  $k^2 \cdot \binom{n-2}{k-2}$ . Therefore, either  $C$  or  $D$  is disjoint from at least  $\frac{1}{2} \cdot (|\mathcal{F}| - k^2 \cdot \binom{n-2}{k-2})$  of the sets of  $\mathcal{F}$ . Since the pairs of  $\mathcal{M}$  are pairwise disjoint, it follows that more than  $\frac{\varepsilon}{2} \cdot \binom{n}{k}$  sets of  $\mathcal{F}$  are disjoint from at least  $\frac{1}{2} \cdot (|\mathcal{F}| - k^2 \cdot \binom{n-2}{k-2})$  of the sets of  $\mathcal{F}$ , as required. ◀

We are ready to prove Theorem 9.

**Proof of Theorem 9.** For integers  $n, k, m$  and for a real  $\varepsilon \in [0, 1)$ , consider the  $\text{CANONICAL TESTER}(n, k, m)$  for the  $\text{INTERSECTING}_{n,k,\varepsilon}$  problem. As previously mentioned, this tester is non-adaptive and one-sided error. To establish its correctness, it suffices to prove that if a function  $f : \binom{[n]}{k} \rightarrow \{0, 1\}$  is  $\varepsilon$ -far from intersecting, then the  $m$  sets picked by the tester include with probability at least  $2/3$  two disjoint sets that lie in  $f^{-1}(1)$ . Indeed, this implies that the tester rejects such an  $f$  with the desired probability.

For a real  $\varepsilon \geq 2 \cdot \left(\frac{k^2}{n}\right)^2$ , let  $f : \binom{[n]}{k} \rightarrow \{0, 1\}$  be a function  $\varepsilon$ -far from intersecting. Consider the family  $\mathcal{F} = f^{-1}(1)$ , and note that  $\mathcal{F}$  is  $\varepsilon$ -far from intersecting. In particular, it holds that  $|\mathcal{F}| > \varepsilon \cdot \binom{n}{k}$ , because  $\mathcal{F}$  can be made intersecting by removing all of its sets. This implies that

$$|\mathcal{F}| - k^2 \cdot \binom{n-2}{k-2} > \varepsilon \cdot \binom{n}{k} - k^2 \cdot \left(\frac{k}{n}\right)^2 \cdot \binom{n}{k} \geq \frac{\varepsilon}{2} \cdot \binom{n}{k}, \quad (2)$$

where the second inequality relies on our assumption on  $\varepsilon$ . We say that a set of  $\binom{[n]}{k}$  is useful if it lies in  $\mathcal{F}$  and is disjoint from at least  $\frac{\varepsilon}{4} \cdot \binom{n}{k}$  of the sets of  $\mathcal{F}$ . By Lemma 11, combined with (2), the number of useful sets is greater than  $\frac{\varepsilon}{2} \cdot \binom{n}{k}$ . Hence, a random set picked uniformly from  $\binom{[n]}{k}$  is useful with probability at least  $\varepsilon/2$ .

Now, consider the  $m$  sets chosen by CANONICAL TESTER. The probability that no useful set is picked throughout the first  $4/\varepsilon$  choices does not exceed  $(1 - \varepsilon/2)^{4/\varepsilon} \leq e^{-2} < 1/6$ . Therefore, with probability at least  $5/6$ , these choices include a useful set  $A$ . Since  $A$  is useful, it is disjoint from at least  $\frac{\varepsilon}{4} \cdot \binom{n}{k}$  of the sets of  $\mathcal{F}$ . Therefore, once such a set  $A$  is chosen, the probability that a random set picked uniformly from  $\binom{[n]}{k}$  lies in  $\mathcal{F}$  and is disjoint from  $A$  is at least  $\varepsilon/4$ . It follows that the probability that no such set is picked throughout the next  $8/\varepsilon$  choices does not exceed  $(1 - \varepsilon/4)^{8/\varepsilon} \leq e^{-2} < 1/6$ . By the union bound, for  $m = 12/\varepsilon$ , the  $m$  sets picked by our tester include with probability at least  $2/3$  two disjoint sets that lie in  $\mathcal{F}$ . Observe that for this choice of  $m$ , the running time of our tester is polynomial in  $n$  and  $1/\varepsilon$ . By our assumption on  $\varepsilon$ , the running time is polynomial in  $n$ , as desired. ◀

### 4.1.2 General $r$

We proceed by analyzing the more nuanced case in which  $\varepsilon \geq \Omega((k^2/n)^r)$  for a general integer  $r$ . We prove the following result, which confirms Theorem 2.

► **Theorem 12.** *For every integer  $r \geq 1$ , there exist constants  $c_1 = c_1(r)$  and  $c_2 = c_2(r)$  for which the following holds. For all integers  $n$  and  $k$  with  $n \geq 2k$  and for any real  $\varepsilon \in [0, 1]$  with  $\varepsilon \geq c_1 \cdot (\frac{k^2}{n})^r$ , there exists a non-adaptive one-sided error tester for  $\text{INTERSECTING}_{n,k,\varepsilon}$  with at most  $c_2 \cdot \frac{\ln k}{\varepsilon}$  queries, running time polynomial in  $n$ , and success probability at least  $2/3$ .*

The proof of Theorem 12 requires a few lemmas, which involve the following definition.

► **Definition 13.** *For integers  $n$  and  $k$  with  $n \geq 2k$ , a family  $\mathcal{F} \subseteq \binom{[n]}{k}$ , a set  $A \subseteq [n]$ , and a set  $B \subseteq A$ , we let  $\mathcal{F}(A \downarrow B)$  denote the family of sets of  $\mathcal{F}$  whose intersection with  $A$  is  $B$ , that is,*

$$\mathcal{F}(A \downarrow B) = \{F \in \mathcal{F} \mid F \cap A = B\}.$$

We say that the set  $A$   $\varepsilon$ -captures  $\mathcal{F}$  if the number of sets of  $\mathcal{F}$  that are disjoint from  $A$  is smaller than  $\varepsilon \cdot \binom{n}{k}$ , equivalently,  $|\mathcal{F}(A \downarrow \emptyset)| < \varepsilon \cdot \binom{n}{k}$ .

The following lemma shows that if two families are far from cross-intersecting, then for every small set  $A$ , it is possible to restrict the families to disjoint intersections with  $A$ , so that the obtained restrictions are still far from cross-intersecting. The proof can be found in the full version of the paper.

► **Lemma 14.** *For an integer  $r \geq 0$ , integers  $n$  and  $k$  with  $n \geq 2k$ , and a real  $\varepsilon \in [0, 1]$ , let  $\mathcal{F}_1, \mathcal{F}_2 \subseteq \binom{[n]}{k}$  be two families such that the pair  $(\mathcal{F}_1, \mathcal{F}_2)$  is  $\varepsilon$ -far from cross-intersecting, and let  $A \subseteq [n]$  be a set of size  $|A| \leq r$ . Then, there exist two sets  $B, C \subseteq A$  with  $B \cap C = \emptyset$  for which the pair  $(\mathcal{F}_1(A \downarrow B), \mathcal{F}_2(A \downarrow C))$  is  $\frac{\varepsilon}{3^{r-t}}$ -far from cross-intersecting. Moreover, if  $A$   $\frac{\varepsilon}{3^r}$ -captures  $\mathcal{F}_2$ , then the guaranteed set  $C$  is not empty.*

As a consequence of Lemma 14, we obtain the following.

► **Lemma 15.** *For integers  $r, t \geq 0$ , integers  $n$  and  $k$  with  $n \geq 2k$ , and a real  $\varepsilon \in [0, 1]$ , let  $\mathcal{F}_1, \mathcal{F}_2 \subseteq \binom{[n]}{k}$  be families such that the pair  $(\mathcal{F}_1, \mathcal{F}_2)$  is  $\varepsilon$ -far from cross-intersecting. Then, there exist sets  $A \subseteq [n]$  and  $B, C \subseteq A$  with  $B \cap C = \emptyset$ , such that*

1. *the pair  $(\mathcal{F}_1(A \downarrow B), \mathcal{F}_2(A \downarrow C))$  is  $\frac{\varepsilon}{3^{r-t}}$ -far from cross-intersecting, and*
  2. *either there is no subset of  $[n] \setminus A$  of size at most  $r$  that  $\frac{\varepsilon}{3^{r-t}}$ -captures  $\mathcal{F}_2(A \downarrow C)$ , or  $|C| \geq t$ .*
- Moreover, if  $\varepsilon \geq 3^{r-t} \cdot (\frac{k}{n})^t$ , then the guaranteed set  $C$  satisfies  $|C| < t$ .<sup>1</sup>

<sup>1</sup> Note that by combining the second item of the lemma with the “moreover” part, it follows that if  $\varepsilon \geq 3^{r-t} \cdot (\frac{k}{n})^t$ , then there is no subset of  $[n] \setminus A$  of size at most  $r$  that  $\frac{\varepsilon}{3^{r-t}}$ -captures  $\mathcal{F}_2(A \downarrow C)$ .

## 35:12 Testing Intersectingness of Uniform Families

**Proof.** Fix an integer  $r \geq 0$ . We start by proving the first part of the lemma, i.e., the existence of sets  $A \subseteq [n]$  and  $B, C \subseteq A$  with  $B \cap C = \emptyset$  satisfying Items 1 and 2. To do so, we apply induction on  $t$ . The result clearly holds for  $t = 0$ , as follows from the choice  $A = B = C = \emptyset$  (for which we have  $\mathcal{F}_1 = \mathcal{F}_1(A \downarrow_B)$ ,  $\mathcal{F}_2 = \mathcal{F}_2(A \downarrow_C)$ , and  $|C| \geq 0$ ).

Now, take  $t \geq 1$ , and assume that the result holds for  $t - 1$ . To prove it for  $t$ , let  $\mathcal{F}_1, \mathcal{F}_2 \subseteq \binom{[n]}{k}$  be families such that the pair  $(\mathcal{F}_1, \mathcal{F}_2)$  is  $\varepsilon$ -far from cross-intersecting. By the induction hypothesis, there exist sets  $A \subseteq [n]$  and  $B, C \subseteq A$  with  $B \cap C = \emptyset$ , such that the families  $\mathcal{H}_1 = \mathcal{F}_1(A \downarrow_B)$  and  $\mathcal{H}_2 = \mathcal{F}_2(A \downarrow_C)$  satisfy that

1. the pair  $(\mathcal{H}_1, \mathcal{H}_2)$  is  $\frac{\varepsilon}{3^{r \cdot (t-1)}}$ -far from cross-intersecting, and
  2. either there is no subset of  $[n] \setminus A$  of size at most  $r$  that  $\frac{\varepsilon}{3^{r \cdot (t-1)}}$ -captures  $\mathcal{H}_2$ , or  $|C| \geq t - 1$ .
- By  $\frac{\varepsilon}{3^{r \cdot t}} \leq \frac{\varepsilon}{3^{r \cdot (t-1)}}$ , it follows from Item 1 that the pair  $(\mathcal{H}_1, \mathcal{H}_2)$  is  $\frac{\varepsilon}{3^{r \cdot t}}$ -far from cross-intersecting. Therefore, if there is no subset of  $[n] \setminus A$  of size at most  $r$  that  $\frac{\varepsilon}{3^{r \cdot t}}$ -captures  $\mathcal{H}_2$ , then the result holds for  $t$  with the same sets  $A, B, C$ , and we are done. Otherwise, there exists a set  $A' \subseteq [n] \setminus A$  of size at most  $r$  that  $\frac{\varepsilon}{3^{r \cdot t}}$ -captures  $\mathcal{H}_2$ . In particular, there exists a subset of  $[n] \setminus A$  of size at most  $r$  that  $\frac{\varepsilon}{3^{r \cdot (t-1)}}$ -captures  $\mathcal{H}_2$ , hence by Item 2 above, it follows that  $|C| \geq t - 1$ .

We apply Lemma 14 with the pair  $(\mathcal{H}_1, \mathcal{H}_2)$ , which is  $\frac{\varepsilon}{3^{r \cdot (t-1)}}$ -far from cross-intersecting, and with the set  $A'$ . Letting  $B', C' \subseteq A'$  be the sets with  $B' \cap C' = \emptyset$  guaranteed by the lemma, it follows that the pair  $(\mathcal{H}_1(A' \downarrow_{B'}), \mathcal{H}_2(A' \downarrow_{C'}))$  is  $\tilde{\varepsilon}$ -far from cross-intersecting for  $\tilde{\varepsilon} = \frac{1}{3^r} \cdot \frac{1}{3^{r \cdot (t-1)}} = \frac{1}{3^{r \cdot t}}$ . Moreover, since  $A'$   $\tilde{\varepsilon}$ -captures  $\mathcal{H}_2$ , it follows from the lemma that  $C'$  is not empty.

To complete the argument, define  $A'' = A \cup A'$ ,  $B'' = B \cup B'$ , and  $C'' = C \cup C'$ . Recalling that  $A \cap A' = \emptyset$ ,  $B \cap C = \emptyset$ , and  $B' \cap C' = \emptyset$ , we obtain that  $B'' \cap C'' = \emptyset$  and that

$$|C''| = |C| + |C'| \geq (t - 1) + 1 = t.$$

We further have  $\mathcal{H}_1(A' \downarrow_{B'}) = \mathcal{F}_1(A' \downarrow_{B''})$  and  $\mathcal{H}_2(A' \downarrow_{C'}) = \mathcal{F}_2(A' \downarrow_{C''})$ . Hence, the sets  $A'', B'', C''$  satisfy the required properties with respect to  $\mathcal{F}_1, \mathcal{F}_2$  and  $t$ . This completes the proof of the first part of the lemma.

We finally show that if  $\varepsilon \geq 3^{r \cdot t} \cdot \left(\frac{k}{n}\right)^t$ , then the guaranteed set  $C$  satisfies  $|C| < t$ . To establish the contrapositive statement, let  $A, B, C$  be the sets guaranteed by the lemma for two families  $\mathcal{F}_1, \mathcal{F}_2 \subseteq \binom{[n]}{k}$ , and suppose that  $|C| \geq t$ . Since the pair  $(\mathcal{F}_1(A \downarrow_B), \mathcal{F}_2(A \downarrow_C))$  is  $\frac{\varepsilon}{3^{r \cdot t}}$ -far from cross-intersecting, it follows that  $|\mathcal{F}_2(A \downarrow_C)| > \frac{\varepsilon}{3^{r \cdot t}} \cdot \binom{n}{k}$ . On the other hand, each set of  $\mathcal{F}_2(A \downarrow_C)$  contains the set  $C$ , hence  $|\mathcal{F}_2(A \downarrow_C)| \leq \binom{n-t}{k-t} \leq \left(\frac{k}{n}\right)^t \cdot \binom{n}{k}$ . By combining the two inequalities, we obtain that  $\varepsilon < 3^{r \cdot t} \cdot \left(\frac{k}{n}\right)^t$ . This completes the proof.  $\blacktriangleleft$

The following lemma constitutes a key ingredient in our analysis of the canonical tester. Its proof can be found in the full version of the paper.

**► Lemma 16.** *For every integer  $r \geq 1$ , there exists a constant  $c = c(r)$ , such that for all integers  $n$  and  $k$  with  $n \geq 2k$  and for any real  $\varepsilon \in [0, 1)$  with  $\varepsilon \geq 2 \cdot \left(\frac{k^2}{n}\right)^r$ , the following holds. Let  $\mathcal{F} \subseteq \binom{[n]}{k}$  be a family, and suppose that there exist sets  $A \subseteq [n]$  and  $B, C \subseteq A$  with  $B \cap C = \emptyset$ , such that the pair  $(\mathcal{F}(A \downarrow_B), \mathcal{F}(A \downarrow_C))$  is  $\varepsilon$ -far from cross-intersecting, and there is no subset of  $[n] \setminus A$  of size at most  $r - 1$  that  $\varepsilon$ -captures  $\mathcal{F}(A \downarrow_C)$ . Then, if at least  $c \cdot \frac{\ln k}{\varepsilon}$  sets are chosen uniformly and independently at random from  $\binom{[n]}{k}$ , then the probability that they include two disjoint sets that lie in  $\mathcal{F}$  is at least  $2/3$ .*

We are ready to prove Theorem 12.

**Proof of Theorem 12.** For integers  $n, k, m$  and for a real  $\varepsilon \in [0, 1]$ , consider the CANONICAL TESTER  $(n, k, m)$  for the INTERSECTING $_{n,k,\varepsilon}$  problem. As previously mentioned, this tester is non-adaptive and one-sided error. Fix an integer  $r \geq 1$ , let  $c = c(r)$  be the constant given in Lemma 16, and suppose that

$$\varepsilon \geq 2 \cdot 3^{r^2} \cdot \left(\frac{k^2}{n}\right)^r \quad \text{and} \quad m \geq c \cdot 3^{r^2} \cdot \frac{\ln k}{\varepsilon}. \quad (3)$$

It suffices to prove that if a function  $f : \binom{[n]}{k} \rightarrow \{0, 1\}$  is  $\varepsilon$ -far from intersecting, then the  $m$  sets picked by our tester include with probability at least  $2/3$  two disjoint sets that lie in  $f^{-1}(1)$ . Indeed, this implies that the tester rejects such an  $f$  with the desired probability.

Let  $f : \binom{[n]}{k} \rightarrow \{0, 1\}$  be a function  $\varepsilon$ -far from intersecting. Set  $\mathcal{F} = f^{-1}(1)$ , and note that the family  $\mathcal{F}$  is  $\varepsilon$ -far from intersecting, hence the pair  $(\mathcal{F}, \mathcal{F})$  is  $\varepsilon$ -far from cross-intersecting. Apply Lemma 15 with  $\mathcal{F}_1 = \mathcal{F}_2 = \mathcal{F}$  and with  $t = r$ , to obtain that there exist sets  $A \subseteq [n]$  and  $B, C \subseteq A$  with  $B \cap C = \emptyset$ , such that for  $\tilde{\varepsilon} = \frac{\varepsilon}{3^{r^2}}$ , it holds that

1. the pair  $(\mathcal{F}(A \downarrow_B), \mathcal{F}(A \downarrow_C))$  is  $\tilde{\varepsilon}$ -far from cross-intersecting, and
  2. either there is no subset of  $[n] \setminus A$  of size at most  $r$  that  $\tilde{\varepsilon}$ -captures  $\mathcal{F}_2(A \downarrow_C)$ , or  $|C| \geq r$ .
- Moreover, our assumption on  $\varepsilon$  in (3) clearly implies that  $\varepsilon \geq 3^{r^2} \cdot \left(\frac{k}{n}\right)^r$ , hence it follows from the lemma that  $|C| < r$ . We thus derive from Item 2 above that there is no subset of  $[n] \setminus A$  of size at most  $r$  that  $\tilde{\varepsilon}$ -captures  $\mathcal{F}(A \downarrow_C)$ . This obviously implies that there is no subset of  $[n] \setminus A$  of size at most  $r - 1$  that  $\tilde{\varepsilon}$ -captures  $\mathcal{F}(A \downarrow_C)$ .

Now, by our assumptions in (3), it holds that  $\tilde{\varepsilon} \geq 2 \cdot \left(\frac{k^2}{n}\right)^r$  and  $m \geq c \cdot \frac{\ln k}{\tilde{\varepsilon}}$ . Therefore, we can apply Lemma 16 with the family  $\mathcal{F}$ , the sets  $A, B, C$ , the integer  $r$ , and the real  $\tilde{\varepsilon}$ , to obtain that with probability at least  $2/3$ , the  $m$  sets picked by our tester include two disjoint sets that lie in  $\mathcal{F}$ , as required.

Finally, let  $m$  be the smallest integer satisfying the condition in (3). Observe that the running time of our tester is polynomial in  $n$  and  $m$ , hence it is polynomial in  $n$  and  $1/\varepsilon$ . By our assumption on  $\varepsilon$  in (3), the running time is polynomial in  $n$ , and the proof is completed.  $\blacktriangleleft$

## 4.2 The case $n = \Theta(k)$

We turn our attention now to the INTERSECTING $_{n,k,\varepsilon}$  problem, where the integers  $n$  and  $k$  satisfy  $n = \alpha \cdot k$  for an arbitrary constant  $\alpha \geq 2$ . We first observe that for this range of parameters, the canonical tester is not effective, even for a constant  $\varepsilon$ . To see this, observe that two random sets, chosen uniformly and independently from  $\binom{[n]}{k}$ , are disjoint with probability  $\binom{n-k}{k} / \binom{n}{k}$ . For  $n = \alpha \cdot k$ , with  $\alpha \geq 2$  being a constant, this probability decreases exponentially in  $n$ . Therefore, a collection of random sets from  $\binom{[n]}{k}$  is unlikely to include even a single pair of disjoint sets, unless their number grows exponentially in  $n$ . As a result, the canonical tester does not provide a useful upper bound on the query complexity of the INTERSECTING $_{n,k,\varepsilon}$  problem in this setting.

To overcome this difficulty, we consider a slightly different tester for the INTERSECTING $_{n,k,\varepsilon}$  problem, which picks random pairs of disjoint sets from  $\binom{[n]}{k}$  and checks if at least one of the pairs demonstrates a violation of intersectingness for the tested function. This tester allows us to prove the following result.

**► Theorem 17.** *For all reals  $\alpha \geq 2$  and  $\varepsilon \in (0, 1)$ , there exists some  $c = c(\alpha, \varepsilon)$ , such that for all sufficiently large integers  $n$  and  $k$  with  $n = \alpha \cdot k$ , there exists a non-adaptive one-sided error tester for INTERSECTING $_{n,k,\varepsilon}$  with  $c$  queries and success probability at least  $2/3$ .*

Theorem 17 is obtained using the following result, that was proved (in a generalized form) by Friedgut and Regev [7].

► **Theorem 18** ([7]). *For all reals  $\alpha > 2$  and  $\varepsilon \in (0, 1)$ , there exist a real  $\delta = \delta(\alpha, \varepsilon) > 0$  and an integer  $j = j(\alpha, \varepsilon)$ , such that for all sufficiently large integers  $n$  and  $k$  with  $n = \alpha \cdot k$ , the following holds. Suppose that  $\mathcal{F} \subseteq \binom{[n]}{k}$  is a family, such that for every intersecting  $j$ -junta  $\mathcal{J}$  over  $[n]$ , it holds that  $|\mathcal{F} \setminus \mathcal{J}| > \varepsilon \cdot \binom{n}{k}$ . Then, a random unordered pair  $\{A, B\}$  of two disjoint sets of  $\binom{[n]}{k}$ , chosen uniformly from all such pairs, satisfies  $A \in \mathcal{F}$  and  $B \in \mathcal{F}$  with probability at least  $\delta$ .*

**Proof of Theorem 17.** Fix  $\alpha \geq 2$  and  $\varepsilon \in (0, 1)$ , and let  $n$  and  $k$  be sufficiently large integers with  $n = \alpha \cdot k$ . For an integer  $m$ , consider the following tester for the  $\text{INTERSECTING}_{n,k,\varepsilon}$  problem.

Input: Query access to a function  $f : \binom{[n]}{k} \rightarrow \{0, 1\}$ .

1. Pick  $m$  unordered pairs  $\{A_1, B_1\}, \dots, \{A_m, B_m\}$  of sets of  $\binom{[n]}{k}$  with  $A_i \cap B_i = \emptyset$  for all  $i \in [m]$  uniformly and independently at random.
2. Query  $f$  for the values of  $f(A_i)$  and  $f(B_i)$  for each  $i \in [m]$ .
3. If for each  $i \in [m]$ , it holds that  $f(A_i) = 0$  or  $f(B_i) = 0$ , then accept, and otherwise reject.

The above tester is clearly non-adaptive. Since it accepts every intersecting function with probability 1, its error is one-sided. It suffices to show that there exists  $m = m(\alpha, \varepsilon)$ , such that if a function  $f : \binom{[n]}{k} \rightarrow \{0, 1\}$  is  $\varepsilon$ -far from intersecting, then our tester rejects it with probability at least  $2/3$ . Let  $f : \binom{[n]}{k} \rightarrow \{0, 1\}$  be a function  $\varepsilon$ -far from intersecting.

Consider first the simple case of  $\alpha = 2$ . Here, the fact that  $f$  is  $\varepsilon$ -far from intersecting implies that more than  $\varepsilon \cdot \binom{n}{k}$  of the  $\frac{1}{2} \cdot \binom{n}{k}$  unordered pairs of disjoint sets of  $\binom{[n]}{k}$  violate the intersectingness. For  $m = 1/\varepsilon$ , the probability that our tester accepts  $f$  is at most  $(1 - 2\varepsilon)^m = (1 - 2\varepsilon)^{1/\varepsilon} \leq e^{-2}$ . Hence, with the complement probability, which exceeds  $2/3$ , our tester rejects  $f$ , as desired.

Next, suppose that  $\alpha > 2$ , let  $\delta = \delta(\alpha, \varepsilon) > 0$  and  $j = j(\alpha, \varepsilon)$  be the constants given in Theorem 18, and put  $\mathcal{F} = f^{-1}(1)$ . Since  $\mathcal{F}$  is  $\varepsilon$ -far from intersecting, it follows that every intersecting  $j$ -junta  $\mathcal{J}$  over  $[n]$  satisfies  $|\mathcal{F} \setminus \mathcal{J}| > \varepsilon \cdot \binom{n}{k}$ . By Theorem 18, at least  $\delta$  fraction of the unordered pairs of disjoint sets of  $\binom{[n]}{k}$  violate the intersectingness. Letting  $m = 2/\delta$ , the probability that our tester accepts  $f$  is at most  $(1 - \delta)^m = (1 - \delta)^{2/\delta} \leq e^{-2}$ . As before, it follows that with probability at least  $2/3$ , our tester rejects  $f$ , and we are done. ◀

## Abstract

Houdré and Tetali defined a class of isoperimetric constants  $\varphi_p$  of graphs for  $0 \leq p \leq 1$ , and conjectured a Cheeger-type inequality for  $\varphi_{\frac{1}{2}}$  of the form

$$\lambda_2 \lesssim \varphi_{\frac{1}{2}} \lesssim \sqrt{\lambda_2},$$

where  $\lambda_2$  is the second smallest eigenvalue of the normalized Laplacian matrix. If true, the conjecture would be a strengthening of the hard direction of the classical Cheeger's inequality. Morris and Peres proved Houdré and Tetali's conjecture up to an additional log factor, using techniques from evolving sets. We present the following related results on this conjecture.

1. We provide a family of counterexamples to the conjecture of Houdré and Tetali, showing that the logarithmic factor is needed.
2. We match Morris and Peres's bound using standard spectral arguments.
3. We prove that Houdré and Tetali's conjecture is true for any constant  $p$  strictly bigger than  $\frac{1}{2}$ , which is also a strengthening of the hard direction of Cheeger's inequality.

Furthermore, our results can be extended to directed graphs using Chung's definition of eigenvalues for directed graphs.

## 1 Introduction

Motivated by Talagrand's isoperimetric inequality for the hypercubes [20] (see Subsection 1.2), Houdré and Tetali [8] extended Talagrand's isoperimetric constant to general Markov chains and also to different exponents.

► **Definition 1** (Isoperimetric Constants for Markov Chains [8]). *Let  $(V, P, \pi)$  be an irreducible Markov chain with vertex set  $V$ , transition matrix  $P \in \mathbb{R}^{|V| \times |V|}$  and stationary distribution  $\pi : V \rightarrow \mathbb{R}_{\geq 0}$ . For any  $p \in (0, 1]$ , define the isoperimetric constant as*

$$\varphi_p(P) := \min_{S \subset V: \pi(S) \leq \frac{1}{2}} \varphi_p(S) := \min_{S \subset V: \pi(S) \leq \frac{1}{2}} \frac{\sum_{v \in S} \pi(v) \cdot \left( \sum_{u \in \bar{S}} P(v, u) \right)^p}{\pi(S)}.$$

## 36:2 On the Houdré-Tetali Conjecture About an Isoperimetric Constant of Graphs

Let  $\partial S := \{v \in S \mid \sum_{u \in \bar{S}} P(v, u) > 0\}$  be the inner vertex boundary of  $S$ . Then, for  $p = 0$ ,

$$\varphi_0(P) := \min_{S \subset V: \pi(S) \leq \frac{1}{2}} \varphi_0(S) := \min_{S \subset V: \pi(S) \leq \frac{1}{2}} \frac{\pi(\partial S)}{\pi(S)}.$$

Given an undirected graph or a directed graph  $G = (V, E)$ , let  $P_G$  be the transition matrix of the natural random walk, where  $P_G(v, u) = 1/\deg(v)$  in the undirected case and  $P_G(v, u) = 1/\deg^{\text{out}}(v)$  in the directed case. Then the isoperimetric constant  $\varphi_p(G)$  for the graph  $G$  is defined as  $\varphi_p(P_G)$ .

When  $p = 1$ , this is known as the Cheeger isoperimetric constant of a Markov chain (see e.g. [16]) or the edge conductance/expansion of a graph (see Section 2 for definition). When  $p = 0$ , this measures the vertex expansion of an undirected graph or a directed graph. Talagrand studied the case  $p = \frac{1}{2}$  and proved a lower bound on  $\varphi_{\frac{1}{2}}$  for Boolean hypercubes. One can view  $\varphi_{\frac{1}{2}}$  as a quantity that interpolates between edge conductance and vertex expansion, since it follows from the Cauchy-Schwarz inequality that  $\varphi_{\frac{1}{2}}(G)^2 \leq \varphi_1(G) \cdot \varphi_0(G)$ , and Talagrand used his lower bound to recover Margulis' theorem about edge conductance and vertex expansion on hypercubes (see Subsection 1.2).

For an undirected graph  $G$ , one can use the second smallest eigenvalue  $\lambda_2$  of the matrix  $I - P_G$  to give upper and lower bound on  $\varphi_1(G)$ . The classical Cheeger's inequality is

$$\lambda_2(I - P_G) \lesssim \varphi_1(G) \lesssim \sqrt{\lambda_2(I - P_G)}.$$

Houdré and Tetali conjectured that the same relations hold for  $\varphi_{\frac{1}{2}}(G)$  as well when the Markov chain is reversible.

► **Conjecture 2** ([8]). *Let  $(V, P, \pi)$  be an irreducible and reversible Markov chain. Then*

$$\lambda_2(I - P) \lesssim \varphi_{\frac{1}{2}}(P) \lesssim \sqrt{\lambda_2(I - P)}.$$

It is clear from the definition that  $\varphi_p(G)$  increases as  $p$  decreases, and thus  $\lambda_2 \lesssim \varphi_1(G) \leq \varphi_p(G)$  for all  $p < 1$ . Therefore, the Houdré-Tetali conjecture is a strengthening of the hard direction of Cheeger's inequality. It predicts that when the hard direction of Cheeger's inequality is tight for a graph  $G$  such that  $\varphi_1(G) \asymp \sqrt{\lambda_2}$ , then the graph must satisfy  $\varphi_1(G) \asymp \varphi_{\frac{1}{2}}(G)$ . Or, in other words, when  $\varphi_1(G) \ll \varphi_{\frac{1}{2}}(G)$  such as on the hypercube (see Remark 7) or on the dumbbell graphs, then the hard direction of Cheeger's inequality cannot be tight. So, the conjecture can be viewed as an improved Cheeger's inequality in the spirit of [11, 10] and this is a main motivation of this work.

Morris and Peres came close to proving the conjecture with an extra logarithmic factor.

► **Theorem 3** ([18]). *Let  $(V, P, \pi)$  be an irreducible and reversible Markov chain. Suppose that  $P(v, v) \geq \frac{1}{2}$  for all  $v \in V$ . Then*

$$\lambda_2(I - P) \gtrsim \frac{(\varphi_{\frac{1}{2}}(P))^2}{\log(1/\varphi_{\frac{1}{2}}(P))}.$$

Their proof is based on techniques from evolving sets. They lower bounded the "boundary gauge"  $\Psi$  using  $\varphi_{\frac{1}{2}}$ , and also upper bounded the mixing rate using  $\Psi$  so that they can relate  $\lambda_2$  and  $\varphi_{\frac{1}{2}}$ .

### 1.1 Our Results

We found counterexamples to the Houdré-Tetali conjecture, showing that the extra logarithmic factor is needed.

► **Theorem 4.** *There are irreducible and reversible Markov chains  $(V, P, \pi)$  with*

$$\lambda_2(I - P) \lesssim \frac{\log |V|}{|V|^2} \quad \text{and} \quad \varphi_{\frac{1}{2}}(P) \gtrsim \frac{\log |V|}{|V|} \quad \implies \quad \lambda_2(I - P) \lesssim \frac{(\varphi_{\frac{1}{2}}(P))^2}{\log(1/\varphi_{\frac{1}{2}}(P))}.$$

The counterexample is simple to describe, which is a weighted undirected graph with vertex set  $[n]$  and edge weight  $P(i, j)$  inversely proportional to  $\min\{|i - j|, n - |i - j|\}^3$ . See Section 4 for details.

On the positive side, we match the result of Morris and Peres using standard spectral arguments. We show that the simple sweep-cut algorithm can be used to output a set  $S$  with  $\varphi_{\frac{1}{2}}(S)$  satisfying the guarantee in Theorem 3, without the self-loop assumption. See Subsection 3.1.

Perhaps more interestingly, the same arguments can be used to prove that the Houdré-Tetali conjecture is true if we replace  $\frac{1}{2}$  by any constant  $p > \frac{1}{2}$ .

► **Theorem 5.** *Let  $(V, P, \pi)$  be an irreducible and reversible Markov chain. For any  $p \in (\frac{1}{2}, 1]$ ,*

$$(\varphi_p(P))^2 \leq \frac{4}{2p - 1} \cdot \lambda_2(I - P).$$

Similar to the discussion after Conjecture 2, this shows that the tight examples of the hard direction of Cheeger’s inequality must satisfy  $\varphi_{\frac{1}{2}+\epsilon}(G) \lesssim \sqrt{\frac{1}{\epsilon}} \cdot \varphi_1(G)$  for any  $\epsilon \in (0, \frac{1}{2})$ . Also, this provides an improved analysis of Cheeger’s inequality that if  $\varphi_1(G) \ll \sqrt{2p - 1} \cdot \varphi_p(G)$  then  $\varphi_1(G) \ll \sqrt{\lambda_2}$ . So this result has similar consequences as if Houdré and Tetali’s conjecture was true.

Finally, we observe that the same statement as in Theorem 5 can also be proved for non-reversible Markov chains, by replacing  $\lambda_2(I - P)$  with the eigenvalue defined for directed graphs by Chung [5]. See Theorem 9.

► **Remark 6** ( $\varphi_p$  for  $p < \frac{1}{2}$ ). For  $p < \frac{1}{2}$ , a simple argument shows that an inequality of the form in Theorem 5 cannot hold. To see it, consider the transformation  $P \rightarrow (1 - \delta)I + \delta P$  for some parameter  $0 < \delta < 1$  (equivalent to adding a large self loop when  $\delta$  is small) will scale  $\varphi_p$  by a factor  $\delta^p$ , while the second eigenvalue scales by a factor of  $\delta$ , and so the ratio  $\varphi_p(G)/\sqrt{\lambda_2(I - P_G)}$  scales by  $\delta^{p-\frac{1}{2}} \rightarrow \infty$  as  $\delta \rightarrow 0$ . When  $p = \frac{1}{2}$ , adding self loops does not change the ratio. Thus, it is the first exponent where such an inequality makes sense.

### 1.2 Previous Work on Boolean Hypercubes

The isoperimetric constant  $\varphi_{\frac{1}{2}}$  was initially studied by Talagrand in the Boolean hypercubes. Let  $\{0, 1\}^n$  be the  $n$ -dimensional hypercube. For a point  $x \in \{0, 1\}^n$ , let  $x^{\oplus i}$  be the point obtained by flipping the  $i$ -th bit of  $x$ . For a subset  $S \subset \{0, 1\}^n$ , if  $x \notin S$  define  $h_S(x) = 0$  and otherwise if  $x \in S$  define

$$h_S(x) := |\{i \in [n] \mid x^{\oplus i} \notin S\}|,$$

so that  $\sum_x h_S(x)$  is the size of the edge boundary of  $S$ . Let  $\mu$  be the uniform distribution on  $\{0, 1\}^n$  and  $\mu(S) := \sum_{x \in S} \mu(x)$ . The classical Poincaré inequality can be stated as, for any  $S \subset \{0, 1\}^n$ ,

$$\mu(S) \cdot (1 - \mu(S)) \lesssim \mathbb{E}_{x \sim \mu} [h_S(x)]. \tag{1}$$

## 36:4 On the Houdré-Tetali Conjecture About an Isoperimetric Constant of Graphs

Talagrand [20] proved a strengthening of the Poincaré inequality: For any  $S \subset \{0, 1\}^n$ ,

$$\mu(S) \cdot (1 - \mu(S)) \lesssim \mathbb{E}_{x \sim \mu} [\sqrt{h_S(x)}]. \quad (2)$$

The quantity  $\mathbb{E}\sqrt{h_S}$  is always smaller than  $\mathbb{E}h_S$  and can be seen as a different measure of the boundary information of  $S$ . Let  $\partial S := \{x \mid h_S(x) > 0\}$  be the vertex boundary of  $S$ . By the Cauchy-Schwarz inequality, Talagrand's theorem implies Margulis' theorem [17] that

$$\mu(S)^2 \cdot (1 - \mu(S))^2 \lesssim \mathbb{E}_{x \sim \mu} [h_S(x)] \cdot \mu(\partial S),$$

which was an original motivation for Talagrand to consider the quantity  $\mathbb{E}\sqrt{h_S}$ . More recently, both Margulis' and Talagrand's theorems inspired the analogs for directed graphs developed in [3, 9], to make major progresses in analyzing sublinear time algorithms for testing monotone functions. See also [6, 7] for a proof of a Talagrand's conjecture that further sharpens these inequalities.

The following remark clarifies the connection between  $\varphi_p$  and the quantities appearing in Poincaré's inequality and Talagrand's inequality.

► **Remark 7 ( $\varphi_p$  for Hypercubes).** For the  $n$ -dimensional Boolean hypercube  $Q_n$ , the stationary distribution  $\pi$  is simply the uniform distribution  $\mu$ . Note that the numerator in  $\varphi_1(Q_n)$  is exactly  $\frac{1}{n} \mathbb{E}_{x \in \mu} [h_f(x)]$ , and the Poincaré inequality translates to  $\varphi_1(Q_n) \gtrsim \frac{1}{n}$ . Similarly, the numerator of  $\varphi_{\frac{1}{2}}(Q_n)$  is exactly  $\frac{1}{\sqrt{n}} \mathbb{E}_{x \in \mu} [\sqrt{h_f(x)}]$ , and the Talagrand's inequality translates to  $\varphi_{\frac{1}{2}}(Q_n) \gtrsim \frac{1}{\sqrt{n}}$ .

Finally, we note that a parameter similar to  $\varphi_p$ , called  $h_f^p$ , was also studied in [6].

## 2 Preliminaries

Given two functions  $f, g$ , we use  $f \lesssim g$  to denote the existence of a positive constant  $c > 0$ , such that  $f \leq c \cdot g$  always holds. We use  $f \asymp g$  to denote  $f \lesssim g$  and  $g \lesssim f$ . For positive integers  $k$ , we use  $[k]$  to denote the set  $\{1, 2, \dots, k\}$ . For a function  $f : X \rightarrow \mathbb{R}$ ,  $\text{supp}(f)$  denotes the domain subset on which  $f$  is nonzero. The function  $\log x$  refers to the base  $e$  logarithm.

**Undirected Graphs.** Let  $G = (V, E)$  be an undirected graph. Let  $w : E \rightarrow \mathbb{R}_{\geq 0}$  be a weight function on the edges. The weighted degree of a vertex  $v$  is defined as  $\deg_w(v) := \sum_{e: e \ni v} w(e)$ . Let  $S \subset V$  be a nonempty subset of vertices. The edge boundary of  $S$  is defined as  $\delta(S) := \{e \in E \mid e \cap S \neq \emptyset \text{ and } e \cap \bar{S} \neq \emptyset\}$  and  $w(\delta(S))$  be the total edge weight of  $\delta(S)$ . The volume of  $S$  is defined as  $\text{vol}_w(S) := \sum_{v \in S} \deg_w(v)$ . The edge conductance of  $S$  and of  $G$  are defined as

$$\phi(S) := \frac{w(\delta(S))}{\text{vol}_w(S)} \quad \text{and} \quad \phi(G) := \min_{S: \text{vol}_w(S) \leq \text{vol}_w(V)/2} \phi(S).$$

In an undirected graph, the ordinary random walk has transition matrix  $P$  with  $P(u, v) = w(uv) / \deg_w(u)$  for every  $u, v \in V$ . If the graph is connected, then the stationary distribution  $\pi$  is unique with  $\pi(u) = \deg_w(u) / \sum_{v \in V} \deg_w(v)$  for every  $u \in V$ . It is thus straightforward to check that  $\phi(S) = \varphi_1(S)$  and  $\phi(G) = \varphi_1(G)$ , i.e. the two definitions coincide.

**Directed Graphs.** Let  $G = (V, E)$  be a directed graph. Let  $w : E \rightarrow \mathbb{R}_{\geq 0}$  be a weight function on the edges. The weighted indegree of a vertex  $v$  is defined as  $d_w^{\text{in}}(v) := \sum_{u:\vec{uv} \in E} w(\vec{uv})$  and the weighted outdegree of  $v$  is defined as  $d_w^{\text{out}}(v) := \sum_{u:\vec{vu} \in E} w(\vec{vu})$ . In a directed graph, the ordinary random walk has transition matrix  $P$  with  $P(u, v) = w(\vec{uv}) / \deg_w^{\text{out}}(u)$ . The stationary distribution  $\pi$  has no easy description but is unique as long as the directed graph is strongly connected. There are different notions of directed edge conductance for directed graphs. In analyzing random walks, the standard definition is exactly  $\varphi_1(G)$  as described in Definition 1, and this quantity is closely related to the mixing time of random walks; see e.g. [16, 5, 18]. In analyzing graph partitioning, there is a definition that extends the edge conductance above to directed graphs, which will not be used in this paper; see e.g. [21, 13].

**Spectral Graph Theory.** Given an undirected graph  $G = (V, E)$  with a weight function  $w : E \rightarrow \mathbb{R}_{\geq 0}$ , its adjacency matrix  $A = A(G)$  is an  $|V| \times |V|$  matrix where the  $(u, v)$ -th entry is  $w(uv)$ . The Laplacian matrix is defined as  $L := D - A$ , where  $D := \text{diag}(\{\deg_w(v)\}_{v \in V})$  is the diagonal degree matrix. The normalized adjacency matrix is defined as  $\mathcal{A} := D^{-1/2} A D^{-1/2}$ , and the normalized Laplacian matrix is defined as  $\mathcal{L} := I - \mathcal{A}$ . Let  $\lambda_1(\mathcal{L}) \leq \lambda_2(\mathcal{L}) \leq \dots \leq \lambda_n(\mathcal{L})$  be the eigenvalues of  $\mathcal{L}$ . It is known that  $\lambda_1(\mathcal{L}) = 0$  with eigenvector  $D^{1/2} \vec{1}$ , and

$$\lambda_2(\mathcal{L}) = \min_{g \perp D^{1/2} \vec{1}} \frac{g^T \mathcal{L} g}{g^T g} = \min_{f \perp D \vec{1}} \frac{f^T L f}{f^T D f} = \min_{f \perp D \vec{1}} \frac{\sum_{uv \in E} w(uv) \cdot (f(u) - f(v))^2}{\sum_v \deg_w(v) \cdot f(v)^2}.$$

Cheeger's inequality [4, 2, 1] is a fundamental result in spectral graph theory that connects edge conductance of an undirected graph  $G = (V, E)$  to the second smallest eigenvalue of its normalized Laplacian matrix:

$$\frac{\lambda_2}{2} \leq \phi(G) \leq \sqrt{2\lambda_2}.$$

The random walk transition matrix  $P$  is similar to the normalized Laplacian matrix  $\mathcal{A}$ , and the matrix  $I - P$  is similar to the normalized Laplacian matrix  $\mathcal{L}$ . In particular,  $I - P$  enjoys the same spectral properties as  $\mathcal{L}$  with real eigenvalues and a quadratic form characterization of  $\lambda_2$  as above; see Lemma 8.

Chung [5] defined the Laplacian matrix of a directed graph and used it to prove an analog of Cheeger's inequality. These will be stated in Subsection 3.2.

### 3 Positive Results

To prove Theorem 5, we follow standard spectral arguments used in proving Cheeger-type inequalities, in Trevisan's style. First, we start with the second eigenvector  $f_2 : V \rightarrow \mathbb{R}$  and truncate it so that the  $\pi$  weight of its support is at most half while preserving its Rayleigh quotient. The proof of the following lemma is standard and we defer it to the end of this section.

► **Lemma 8.** *Let  $(V, P, \pi)$  be an irreducible and reversible Markov chain. Let  $f_2$  be an eigenvector associated to the second smallest eigenvalue of the matrix  $I - P$ , with  $\pi(\{v \mid f_2(v) > 0\}) \leq \frac{1}{2}$ . Define the truncated vector  $f$  such that  $f(v) := \max\{f_2(v), 0\}$  for all  $v \in V$ . Then*

$$\lambda_2(I - P) \geq \frac{\sum_{f(i) \geq f(j)} \pi(i) \cdot P(i, j) \cdot (f(i) - f(j))^2}{\sum_{i \in V} \pi(i) f(i)^2}.$$

## 36:6 On the Houdré-Totali Conjecture About an Isoperimetric Constant of Graphs

Then the plan is to prove that one of the level sets has small isoperimetric constant. We index the vertices by  $[n]$  and order them so that  $f(i) \leq f(j)$  for  $i \leq j$ . For any  $t \geq 0$ , define the level set  $S_t := \{i \in [n] \mid f(i)^2 > t\}$ . By the construction of  $f$ , it holds that  $\pi(S_t) \leq \frac{1}{2}$  for any  $t \geq 0$ , and so  $\varphi_p(P) \leq \min_{t \geq 0} \varphi_p(S_t)$ . For convenience, we rescale  $f$  so that  $\max_i f(i) = 1$ .

To prove that one of  $S_t$  has small isoperimetric constant, we choose a uniform random  $t \in [0, 1]$  and consider  $\varphi_p(S_t)$ . We will bound the expected value of the numerator of  $\varphi_p(S_t)$  and of the denominator of  $\varphi_p(S_t)$  and conclude that there exists a  $t$  with  $\varphi_p(S_t)$  at most the ratio of the expected values, i.e.  $\min_{t \geq 0} \varphi_p(S_t) \leq \mathbb{E}_t[\text{numerator of } \varphi_p(S_t)] / \mathbb{E}_t[\text{denominator of } \varphi_p(S_t)]$ .

The expected value of the denominator is easy to analyze. Since we choose  $t$  uniformly randomly, each vertex  $i$  is included in  $S_t$  with probability  $f(i)^2$ , and thus

$$\mathbb{E}_t[\pi(S_t)] = \sum_{i \in V} \pi(i) \cdot f(i)^2.$$

The rest of the proof is to analyze the expected value of the numerator  $\sum_{i \in V} \pi(i) \cdot P(i, \overline{S_t})^p$ . For a vertex  $i$ , if the random threshold  $t$  is between  $f(j)^2$  and  $f(j-1)^2$  with  $f(j) > f(j-1)$ , then  $P(i, \overline{S_t}) = P(i, [j-1])$ , and so

$$\begin{aligned} \mathbb{E}_t[P(i, \overline{S_t})^p] &= \sum_{j=1}^i (f(j)^2 - f(j-1)^2) \cdot P(i, [j-1])^p \\ &= \sum_{j=1}^i (f(j)^2 - f(j-1)^2) \cdot \sum_{l=1}^{j-1} (P(i, [l])^p - P(i, [l-1])^p) \\ &= \sum_{l=1}^{i-1} (f(i)^2 - f(l)^2) \cdot (P(i, [l])^p - P(i, [l-1])^p), \end{aligned}$$

where the second equality is by writing a telescoping sum and the third equality is by a change of summation. So, the expected numerator  $\mathbb{E}_t[\sum_{i=1}^n \pi(i) \cdot P(i, \overline{S_t})^p]$  is

$$\begin{aligned} &\sum_{i=1}^n \sum_{j=1}^{i-1} \pi(i) \cdot (f(i)^2 - f(j)^2) \cdot (P(i, [j])^p - P(i, [j-1])^p) \\ &\leq \sqrt{\sum_{i=1}^n \sum_{j=1}^{i-1} \pi(i) \cdot (f(i) - f(j))^2 \cdot P(i, j)} \\ &\quad \cdot \sqrt{\sum_{i=1}^n \sum_{j=1}^{i-1} \pi(i) \cdot (f(i) + f(j))^2 \cdot \frac{(P(i, [j])^p - P(i, [j-1])^p)^2}{P(i, j)}} \\ &\leq \sqrt{\lambda_2 \cdot \sum_{i=1}^n \pi(i) \cdot f(i)^2} \cdot \sqrt{\sum_{i=1}^n 4 \cdot \pi(i) \cdot f(i)^2 \cdot \sum_{j=1}^{i-1} \frac{(P(i, [j])^p - P(i, [j-1])^p)^2}{P(i, [j]) - P(i, [j-1])}}, \end{aligned}$$

where the first inequality is by Cauchy-Schwarz, and the second inequality is by Lemma 8 and  $(f(i) + f(j))^2 \leq 4f(i)^2$  and  $P(i, j) = P(i, [j]) - P(i, [j-1])$ .

To upper bound the inner sum of the second term, we denote  $a_j := P(i, [j])$  and it suffices to upper bound the sum of the form  $\sum_{j=1}^n (a_j^p - a_{j-1}^p)^2 / (a_j - a_{j-1})$  with  $a_0 = 0$  and  $a_n \leq 1$ , with a bound independent of  $n$ . Let  $C(n, a)$  denote the supremum of the sum when  $a_n = a$ . Note that  $C(n, a) = a^{2p-1} \cdot C(n, 1)$  by a simple scaling argument. Let  $(a_i)_{i=1}^n$  be an optimal sequence that achieves the supremum of  $C(n, 1)$ . Then,

$$\begin{aligned} C(n, 1) &= C(n-1, a_{n-1}) + \frac{(1-a_{n-1}^p)^2}{1-a_{n-1}} = a_{n-1}^{2p-1} \cdot C(n-1, 1) + \frac{(1-a_{n-1}^p)^2}{1-a_{n-1}} \\ &\leq a_{n-1}^{2p-1} \cdot C(n, 1) + \frac{(1-a_{n-1}^p)^2}{1-a_{n-1}}. \end{aligned}$$

It follows that

$$C(n, 1) \leq \sup_{a \in [0, 1]} \frac{(1-a^p)^2}{(1-a)(1-a^{2p-1})} \leq \sup_{a \in [0, 1]} \frac{(1-a^p)^2}{(2p-1)(1-a)^2} \leq \frac{1}{2p-1},$$

where the second inequality is by the mean value theorem that  $1-a^{2p-1} \geq (2p-1)(1-a)$  and the last inequality is because  $a \in [0, 1]$  and  $p \in (\frac{1}{2}, 1]$ . Clearly,  $C(n, 1) \geq C(n, a_n)$  for any  $a_n \in [0, 1]$ , and so the inner sum of the second term in the expected numerator is at most  $\frac{1}{2p-1}$ . Putting together, this completes the proof of Theorem 5 as

$$\varphi_p(P) \leq \min_{t: t > 0} \varphi_p(S_t) \leq \frac{\mathbb{E}_t[\sum_{i=1}^n \pi(i) \cdot P(i, \overline{S_t})^p]}{\mathbb{E}_t[\pi(S_t)]} \leq 2\sqrt{\lambda_2} \sqrt{\frac{1}{2p-1}},$$

which implies that  $(\varphi_p(P))^2 \leq \frac{4}{2p-1} \cdot \lambda_2$ .

### 3.1 Recovering Morris and Peres's Result

To recover Theorem 3, we follow the same arguments but add a truncation step so that the sequence  $a_i$  above will start with  $a_0 \approx \varphi_{\frac{1}{2}}(P)$ . In this subsection, we plug in  $p = \frac{1}{2}$ . As above, the main work is to upper bound the expected value of the numerator. Recall that

$$\mathbb{E}_t \left[ \sqrt{P(i, \overline{S_t})} \right] = \sum_{j=1}^{i-1} (f(i)^2 - f(j)^2) \cdot (\sqrt{P(i, [j])} - \sqrt{P(i, [j-1])}),$$

Let  $l_i$  be the index such that  $\sqrt{P(i, [l_i])} \leq \frac{1}{2}\varphi_{\frac{1}{2}}(P)$  but  $\sqrt{P(i, [l_i+1])} > \frac{1}{2}\varphi_{\frac{1}{2}}(P)$ . Then, we can upper bound the right hand side by

$$\begin{aligned} \mathbb{E}_t \left[ \sqrt{P(i, \overline{S_t})} \right] &\leq \frac{1}{2}\varphi_{\frac{1}{2}}(P) \cdot f(i)^2 + (f(i)^2 - f(l_i+1)^2) \left( \sqrt{P(i, [l_i+1])} - \frac{1}{2}\varphi_{\frac{1}{2}}(P) \right) \\ &\quad + \sum_{j=l_i+2}^{i-1} (f(i)^2 - f(j)^2) \left( \sqrt{P(i, [j])} - \sqrt{P(i, [j-1])} \right). \end{aligned}$$

To shorten the expression, let us use the notations

$$a_{i,0} = \frac{1}{2}\varphi_{\frac{1}{2}}(P) \quad \text{and} \quad a_{i,j} = \sqrt{P(i, [l_i+j])}.$$

Summing over  $i$  and using these notations, the expected numerator is

$$\begin{aligned} \mathbb{E}_t \left[ \sum_{i=1}^n \pi(i) \cdot \sqrt{P(i, \overline{S_t})} \right] &\leq \frac{1}{2}\varphi_{\frac{1}{2}}(P) \cdot \sum_{i=1}^n \pi(i) \cdot f(i)^2 \\ &\quad + \underbrace{\sum_{i=1}^n \pi(i) \cdot \sum_{j=1}^{i-l_i-1} (f(i)^2 - f(l_i+j)^2) \cdot (a_{i,j} - a_{i,j-1})}_{(*)} \end{aligned}$$

Applying Cauchy-Schwarz as before gives

$$\begin{aligned}
 (*) &\leq \sqrt{\sum_{i=1}^n \sum_{j=1}^{i-l_i-1} \pi(i) \cdot (f(i) - f(l_i + j))^2 \cdot P(i, l_i + j)} \\
 &\quad \cdot \sqrt{\sum_{i=1}^n \sum_{j=1}^{i-l_i-1} \pi(i) \cdot (f(i) + f(l_i + j))^2 \cdot \frac{(a_{i,j} - a_{i,j-1})^2}{P(i, l_i + j)}} \\
 &\leq \sqrt{\lambda_2 \cdot \sum_{i=1}^n \pi(i) \cdot f(i)^2} \cdot \sqrt{\sum_{i=1}^n 4 \cdot \pi(i) \cdot f(i)^2 \cdot \underbrace{\sum_{j=1}^{i-1} \frac{a_{i,j} - a_{i,j-1}}{a_{i,j} + a_{i,j-1}}}_{(**)}},
 \end{aligned}$$

where the second inequality uses Lemma 8 and  $P(i, l_i + j) = a_{i,j}^2 - a_{i,j-1}^2$ .

To upper bound (\*\*), we let  $b_i := a_{i,j}$  and use that  $\frac{1}{2}\varphi_{\frac{1}{2}}(P) = b_0 \leq b_1 \leq \dots \leq b_m \leq 1 =: b_{m+1}$  to upper bound the function

$$f : (b_0, b_1, \dots, b_m) \rightarrow \frac{b_1 - b_0}{b_1 + b_0} + \frac{b_2 - b_1}{b_2 + b_1} + \dots + \frac{b_m - b_{m-1}}{b_m + b_{m-1}} + \frac{1 - b_m}{1 + b_m}$$

The partial derivative of  $f$  is

$$\frac{\partial f}{\partial b_i} = \frac{2b_{i-1}}{(b_i + b_{i-1})^2} - \frac{2b_{i+1}}{(b_{i+1} + b_i)^2} = \frac{2(b_{i+1} - b_{i-1})(b_{i-1}b_{i+1} - b_i^2)}{(b_i + b_{i-1})^2(b_{i+1} + b_i)^2}.$$

Since  $b_{i+1} - b_{i-1} > 0$  by definition, the function increases up until  $b_i^2 = b_{i-1}b_{i+1}$  and then decreases. So, the maximum is attained when  $b_i = (b_0)^{\frac{m+1-i}{m+1}}$  with  $b_0 = \frac{1}{2}\varphi_{\frac{1}{2}}(P)$  and  $b_{m+1} = 1$ , in which case the sum is

$$\sum_{i=1}^{m+1} \frac{b_i - b_{i-1}}{b_i + b_{i-1}} = \sum_{i=1}^{m+1} \frac{1 - \frac{b_{i-1}}{b_i}}{1 + \frac{b_{i-1}}{b_i}} = \sum_{i=1}^{m+1} \frac{1 - b_0^{\frac{1}{m+1}}}{1 + b_0^{\frac{1}{m+1}}} = (m+1) \cdot \frac{1 - b_0^{\frac{1}{m+1}}}{1 + b_0^{\frac{1}{m+1}}}$$

For  $b_0 \in [0, 1]$ , this value is increasing when  $m$  increases, and so the sum is upper bounded by

$$\begin{aligned}
 (**)&\leq \lim_{x \rightarrow \infty} x \cdot \frac{1 - b_0^{\frac{1}{x}}}{1 + b_0^{\frac{1}{x}}} = \lim_{x \rightarrow \infty} x \cdot \frac{1 - b_0^{\frac{1}{x}}}{2} = \lim_{y \rightarrow 0} \frac{1 - b_0^y}{2y} \\
 &= \lim_{y \rightarrow 0} \frac{-b_0^y \log b_0}{2} = \frac{1}{2} \log \frac{1}{b_0} = \frac{1}{2} \log \frac{2}{\varphi_{\frac{1}{2}}(P)},
 \end{aligned}$$

where the third last equality is by L'Hôpital's rule. Plugging this back into (\*\*) and (\*), the expected numerator is

$$\begin{aligned}
 \mathbb{E}_t \left[ \sum_{i=1}^n \pi(i) \cdot \sqrt{P(i, S_t)} \right] &\leq \frac{1}{2} \varphi_{\frac{1}{2}}(P) \cdot \sum_{i=1}^n \pi(i) \cdot f(i)^2 \\
 &\quad + \sqrt{\lambda_2 \cdot \sum_{i=1}^n \pi(i) \cdot f(i)^2} \cdot \sqrt{\sum_{i=1}^n 2 \log \frac{2}{\varphi_{\frac{1}{2}}(P)} \cdot \pi(i) \cdot f(i)^2}.
 \end{aligned}$$

As before, the expected denominator is  $\mathbb{E}_t[\pi(S_t)] = \sum_{i \in V} \pi(i) \cdot f(i)^2$ . Putting together,

$$\varphi_{\frac{1}{2}}(P) \leq \min_{t:t>0} \varphi_{\frac{1}{2}}(S_t) \leq \frac{\mathbb{E}_t \left[ \sum_{i=1}^n \pi(i) \cdot \sqrt{P(i, S_t)} \right]}{\mathbb{E}_t[\pi(S_t)]} \leq \frac{1}{2} \varphi_{\frac{1}{2}}(P) + \sqrt{2 \log \frac{2}{\varphi_{\frac{1}{2}}(P)}} \lambda_2.$$

Rearranging recovers Theorem 3.

### 3.2 Non-Reversible Markov Chains

Houdré and Tetali only formulated Conjecture 2 for reversible Markov chains of which the eigenvalues of  $I - P$  are real. For non-reversible Markov chains, we observe that Chung's definition of eigenvalues for directed graphs [5] can be used to obtain the same results in Theorem 3 and Theorem 5.

Given a directed graph  $G = (V, E)$  with a weight function  $w : E \rightarrow \mathbb{R}_{\geq 0}$ , let  $P_G$  be the transition matrix of the ordinary random walks on  $G$  with  $P_G(u, v) = w(uv) / \sum_{v \in V} w(uv)$  for each edge  $uv \in E$ . Suppose  $G$  is strongly connected, then there is a unique stationary distribution  $\pi : V \rightarrow \mathbb{R}_+$  such that  $\pi^T P = \pi^T$ . Let  $\Pi = \text{diag}(\pi)$ . Chung defined the Laplacian of the directed graph  $G$  as

$$\vec{L}_G := I - \frac{1}{2} \left( \Pi^{\frac{1}{2}} P \Pi^{-\frac{1}{2}} + \Pi^{-\frac{1}{2}} P^T \Pi^{\frac{1}{2}} \right).$$

Since  $\vec{L}_G$  is a real symmetric matrix, its eigenvalues are real. Let  $\lambda_2$  be the second smallest eigenvalue of  $\vec{L}_G$ . Chung [5] proved an analog of Cheeger's inequality that

$$\frac{1}{2} \varphi_1(G)^2 \leq \lambda_2(\vec{L}_G) \leq 2 \varphi_1(G).$$

We observe that  $\lambda_2(\vec{L}_G)$  can be used to extend our results to non-reversible Markov chains.

► **Theorem 9.** *Let  $(V, P, \pi)$  be an irreducible Markov chain. For any  $p \in (\frac{1}{2}, 1]$ ,*

$$(\varphi_p(P))^2 \leq \frac{4}{2p-1} \cdot \lambda_2(\vec{L}_G).$$

For  $p = 1/2$ ,

$$\lambda_2(\vec{L}_G) \gtrsim \frac{(\varphi_{\frac{1}{2}}(P))^2}{\log(1/\varphi_{\frac{1}{2}}(P))}.$$

Note that the main proofs of Theorem 5 and Theorem 3 (i.e. computing the expected numerator) did not require the Markov chain to be reversible. The reversible assumption was only used in characterizing the second eigenvalue in Lemma 8. The following is an analog of Lemma 8 for non-reversible Markov chains using Chung's definition of the second eigenvalue of directed graphs.

► **Lemma 10.** *Let  $(V, P, \pi)$  be an irreducible Markov chain. Let  $v_2$  be an eigenvector associated to the second smallest eigenvalue of the matrix  $\vec{L}_G$ . Define the reweighted eigenvector  $f_2 := \Pi^{-\frac{1}{2}} v_2$ , with  $\pi(\{v : f_2(v) \geq 0\}) \leq \frac{1}{2}$ . Define the truncated vector  $f := \max(f_2, 0)$ . Then*

$$\lambda_2(\vec{L}_G) \geq \frac{\sum_{u, v \in V: f(u) \geq f(v)} \pi(u) \cdot P(u, v) \cdot (f(u) - f(v))^2}{\sum_{v \in V} \pi(v) f(v)^2}.$$

With this lemma, we can follow the proofs of Theorem 5 and Theorem 3 verbatim as in above, by defining level sets  $S_t$  using the truncated vector  $f$  and computing the expected numerator and denominator and so on.

This concludes the proof of Theorem 9. We will prove Lemma 10 in the next subsection.

### 3.3 Proofs of Auxiliary Lemmas

In this subsection, we prove Lemma 8 and Lemma 10. The proofs are standard but we include them for completeness.

**Proof of Lemma 8.** For  $f, g : V \rightarrow \mathbb{R}$ , we define  $\langle f, g \rangle_\pi := \sum_{i \in V} \pi(i) \cdot f(i) \cdot g(i)$ . By definition of the second eigenvector,  $\langle (I - P)f_2, f_2 \rangle_\pi = \lambda_2 \langle f_2, f_2 \rangle_\pi$ .

For  $f := \max(f_2, 0)$ , note that  $Pf \geq Pf_2$ , as

$$(Pf)(i) = \sum_{j \in V} p(i, j) f(j) \geq \sum_{j \in V} p(i, j) f_2(j) = (Pf_2)(i),$$

and thus

$$\langle Pf, f \rangle_\pi = \sum_{i \in V: f_2(i) \geq 0} \pi(i) \cdot (Pf)(i) \cdot f(i) \geq \sum_{i \in V: f_2(i) \geq 0} \pi(i) \cdot (Pf_2)(i) \cdot f_2(i) = (1 - \lambda_2) \langle f, f \rangle_\pi,$$

where the last equality uses that  $Pf_2 = (1 - \lambda_2)f_2$ . It follows that

$$\lambda_2 \geq \frac{\langle (I - P)f, f \rangle_\pi}{\langle f, f \rangle_\pi}.$$

The denominator is the same as the denominator in the statement. It remains to check that the numerator is also the same as the numerator in the statement. By direct calculation,

$$\begin{aligned} \langle (I - P)f, f \rangle_\pi &= \sum_{i \in V} \pi(i) f(i)^2 - \sum_{i \in V} \pi(i) \sum_{j \in V} P(i, j) f(j) f(i) \\ &= \sum_{i \in V} \sum_{j \in V} \pi(i) P(i, j) f(i)^2 - \sum_{i \in V} \sum_{j \in V} \pi(i) P(j, i) f(j) f(i) \\ &= \sum_{i \in V} \sum_{j \in V} \pi(i) P(i, j) \left( \frac{1}{2} (f(i)^2 + f(j)^2) - f(i) f(j) \right) \\ &= \sum_{i > j} \pi(i) P(i, j) (f(i) - f(j))^2, \end{aligned}$$

where the second equality uses  $\sum_{j \in V} P(i, j) = 1$  and the third equality uses reversibility which gives  $\pi(i) P(i, j) = \pi(j) P(j, i)$  for all  $i, j \in V$ , to get  $\sum_{i, j} \pi(i) P(i, j) f(i)^2 = \sum_{i, j} \pi(i) P(i, j) f(j)^2$ .  $\blacktriangleleft$

To prove Lemma 10, we will use the following facts about  $\lambda_2(\vec{L}_G)$  in [5].

► **Lemma 11 ([5]).** *Let  $G = (V, E)$  be a strongly connected directed graph and  $\pi$  be its stationary distribution. The second smallest eigenvalue  $\lambda_2$  of the directed Laplacian  $\vec{L}_G$  satisfies*

$$\lambda_2 = \inf_{f \perp \pi} \frac{\sum_{u, v \in V} \pi(u) \cdot P(u, v) \cdot |f(u) - f(v)|^2}{\sum_{v \in V} \pi(v) \cdot |f(v)|^2}$$

Suppose  $v_2$  is an eigenvector of  $\vec{L}_G$  associated with eigenvalue  $\lambda_2$ . Then, for the reweighted eigenvector  $f_2 := \Pi^{-\frac{1}{2}} v_2$ , for all  $u \in V$ ,

$$\lambda_2 \cdot f_2(u) \cdot \pi(u) = \frac{1}{2} \sum_v (f_2(u) - f_2(v)) \cdot (\pi(u) P(u, v) + \pi(v) P(v, u)).$$

**Proof of Lemma 10.** We claim that the truncated vector  $f := \max\{f_2, 0\}$  satisfies

$$\lambda_2 \cdot f(u) \cdot \pi(u) \geq \frac{1}{2} \sum_v (f(u) - f(v)) \cdot (\pi(u)P(u, v) + \pi(v)P(v, u)).$$

for all  $u \in V$ . Indeed, for  $u$  such that  $f(u) > 0$ ,

$$\begin{aligned} \lambda_2 \cdot f(u) \cdot \pi(u) &= \lambda_2 \cdot f_2(u) \cdot \pi(u) \\ &= \frac{1}{2} \sum_{v \in V} (f_2(u) - f_2(v)) \cdot (\pi(u)P(u, v) + \pi(v)P(v, u)) \\ &\geq \frac{1}{2} \sum_{v \in V} (f(u) - f(v)) \cdot (\pi(u)P(u, v) + \pi(v)P(v, u)), \end{aligned}$$

where the second equality is by the fact above and the last inequality is by  $f_2(u) - f_2(v) \geq f(u) - f(v)$  for all  $u, v \in V$  due to truncation. For  $u$  such that  $f(u) = 0$ , the inequality holds trivially because

$$\lambda_2 \cdot f(u) \cdot \pi(u) = 0 \geq \frac{1}{2} \sum_v (-f(v)) \cdot (\pi(u)P(u, v) + \pi(v)P(v, u))$$

as  $f(v) \geq 0$  for all  $v$  by truncation. Thus the claim follows. Multiplying both sides of the claim by  $f(u)$  and then summing over all  $u$  gives

$$\begin{aligned} \lambda_2 \cdot \sum_{u \in V} f^2(u) \pi(u) &\geq \frac{1}{2} \sum_{u \in V} f(u) \sum_{v \in V} (f(u) - f(v)) \cdot (\pi(u)P(u, v) + \pi(v)P(v, u)) \\ &= \frac{1}{2} \sum_{u \in V} \sum_{v \in V} \pi(u) \cdot P(u, v) \cdot \left( \frac{1}{2} f(u)^2 + \frac{1}{2} f(v)^2 - f(u)f(v) \right) \\ &= \frac{1}{2} \sum_{u \in V} \sum_{v \in V} \pi(u) \cdot P(u, v) \cdot (f(u) - f(v))^2. \end{aligned}$$

This is equivalent to the statement where the sum is over pairs with  $f(u) \geq f(v)$ . ◀

## 4 Counterexamples

In this section, we prove Theorem 4 by constructing a family of counterexamples and bounding their second eigenvalues and  $\varphi_{\frac{1}{2}}$  value. The construction is simple.

► **Definition 12 (Counterexamples).** Let  $G_n$  be a graph with vertex set  $[n]$ . For each  $i, j \in [n], i \neq j$ , the edge weight is

$$P(i, j) = \frac{1}{C(\min\{|i - j|, n - |i - j|\})^3},$$

where  $C = \sum_{i=1}^n 1/\min\{|i - j|, n - |i - j|\}^3$  is the normalizing constant to make the graph 1-regular.

We will prove the two claims in Theorem 4 about the second smallest eigenvalue and the  $\varphi_{\frac{1}{2}}(G)$  value. First, we analyze the second smallest eigenvalue, based on the construction that  $I - P$  is a circulant matrix.

► **Lemma 13.** For  $G_n$  in Definition 12, the second smallest eigenvalue of  $I - P$  is

$$\lambda_2(I - P) \lesssim \frac{\log n}{n^2}.$$

## 36:12 On the Houdré-Tetali Conjecture About an Isoperimetric Constant of Graphs

**Proof.** By our construction, the graph  $G_n$  is cyclic that  $P(i, j) = P((i+k) \bmod n, (j+k) \bmod n)$  for all  $i, j, k \in [n]$ . So the matrix  $I - P$  is a circulant matrix of the form

$$I - P = \begin{pmatrix} a_0 & a_1 & a_2 & \dots & a_{n-1} \\ a_{n-1} & a_0 & \dots & \dots & a_{n-2} \\ a_{n-2} & a_{n-1} & \ddots & \ddots & a_{n-3} \\ \vdots & \ddots & \ddots & \ddots & \vdots \\ a_1 & a_2 & \dots & \dots & a_0 \end{pmatrix}$$

where  $a_0 = 1$  and  $a_j = -P(1, j+1)$  for all  $j \in [n]$ . It is well-known that an  $n \times n$  circulant matrix with first row entries  $a \in \mathbb{R}^n$  has eigenvalues and corresponding eigenvectors

$$\left\{ \sum_{i=0}^{n-1} a_i \omega_k^i \right\}_{k=0}^{n-1} \quad \text{and} \quad \left\{ (1, \omega_k, \dots, \omega_k^{n-1})^T \right\}_{k=0}^{n-1}$$

where  $\omega_k := e^{\frac{2\pi k i}{n}}$  are the  $n$ -th roots of unity for  $k \in [n]$  (where  $i$  denotes the imaginary number).

So, the second smallest eigenvalue  $\lambda_2$  of  $I - P$  corresponds to the first  $n$ -th root of unity  $\omega := \omega_1 = e^{\frac{2\pi i}{n}}$ , and

$$\lambda_2 = \sum_{i=0}^{n-1} a_i \cdot \omega^i = \sum_{i=2}^n P(1, i) - \sum_{i=2}^{\lfloor n/2 \rfloor + 1} P(1, i) \cdot \omega^{i-1} - \sum_{i=\lfloor n/2 \rfloor + 2}^n P(1, i) \cdot \omega^{i-1}.$$

We consider two cases, when  $n$  is odd and  $n$  is even. When  $n = 2k + 1$  is odd, note that by definition  $P(1, i) = P(1, 2k + 3 - i)$  for  $2 \leq i \leq k + 1$  and so we can pair up the terms in the above equation to get

$$\lambda_2 = \sum_{i=2}^{k+1} P(1, i) \left( 2 - \omega^{i-1} - \frac{1}{\omega^{i-1}} \right) = - \sum_{i=2}^{k+1} P(1, i) \left( \omega^{\frac{i-1}{2}} - \frac{1}{\omega^{\frac{i-1}{2}}} \right)^2.$$

Using the definition of  $\omega^k := e^{\frac{2\pi k i}{n}} = \cos \frac{2k\pi}{n} + i \sin \frac{2k\pi}{n}$ , it follows that

$$\begin{aligned} \lambda_2 &= - \sum_{i=2}^{k+1} P(1, i) \left( \omega^{\frac{i-1}{2}} - \frac{1}{\omega^{\frac{i-1}{2}}} \right)^2 = - \sum_{i=2}^{k+1} P(1, i) \left( 2i \sin \frac{(i-1)\pi}{n} \right)^2 \\ &= 4 \sum_{i=2}^{k+1} P(1, i) \left( \sin \frac{(i-1)\pi}{n} \right)^2. \end{aligned}$$

Finally we use the fact that  $\sin x < x$  and that  $P(1, i) = \frac{1}{C \cdot \min\{|i-1|, n-|i-1|\}^3} < \frac{1}{(i-1)^3}$  for  $2 \leq i \leq k + 1$  as  $C \geq 1$  to conclude that

$$\lambda_2 < 4 \sum_{i=2}^{k+1} \frac{1}{(i-1)^3} \left( \frac{(i-1)\pi}{n} \right)^2 = 4 \sum_{i=1}^k \frac{1}{i} \left( \frac{\pi^2}{n^2} \right) \lesssim \frac{\log n}{n^2}.$$

When  $n = 2k$  is even, the proof follows along the same lines, but we need to remove the term  $k = \frac{n}{2} + 1$  in the sum because  $\omega^{n/2} = -1$ . However, it only contributes a term of  $O\left(\frac{1}{n^3}\right)$  to the sum, which is negligible.  $\blacktriangleleft$

It remains to prove that  $\varphi_{\frac{1}{2}}(P) \gtrsim \frac{\log n}{n}$ . As this graph is symmetric, our intuition is that  $\varphi_{\frac{1}{2}}(P)$  attains its minimum at the set  $S = \{1, \dots, \frac{n}{2}\}$ . In this case, for each vertex  $i \in S$ ,

$$\sqrt{P(i, \bar{S})} \geq \sqrt{\sum_{j=i}^{\frac{i+n}{2}} \frac{1}{j^3}} \approx \frac{1}{i} - \frac{1}{i + \frac{n}{2}} \geq \frac{1}{2i},$$

which implies that

$$\varphi_{\frac{1}{2}}(S) \gtrsim \sum_{i=1}^{\frac{n}{2}} \frac{1}{n} \sqrt{P(i, \bar{S})} \gtrsim \frac{1}{n} \sum_{i=1}^{\frac{n}{2}} \frac{1}{i} \gtrsim \frac{\log n}{n}.$$

Our plan was to prove that  $S$  indeed attains the minimum, but we do not have such a proof. Instead, we will work on a slightly different lower bound, which satisfies a concavity property that allows us to argue that sets of consecutive vertices attain the minimum, in order to prove the lower bound. It turns out that the proof is a bit long and we will present it in the next subsection.

#### 4.1 Proof of $\varphi_{\frac{1}{2}}$ Lower Bound

First, we set up some notations for the proof. Let us partition the vertex set of  $G_n$  into two sets  $A$  and  $B := G \setminus A$  with  $|A| \leq |B|$ . As the graph  $G_n$  is cyclic, we can arrange the vertices  $V = [n]$  in a clockwise manner and without loss of generality we assume  $1 \in A$  and  $n \in B$ . Let us divide the vertices of  $A$  and  $B$  into contiguous sets  $A_1, B_1, A_2, B_2, \dots, A_k, B_k$  in the cyclic representation, and denote their sizes by  $a_i := |A_i|$  and  $b_i := |B_i|$  for  $1 \leq i \leq k$ . More explicitly, for  $1 \leq i \leq k$ , the vertices in  $A_i$  and  $B_i$  are

$$A_i = \left\{ \sum_{j=1}^{i-1} a_j + \sum_{j=1}^{i-1} b_j + 1, \dots, \sum_{j=1}^i a_j + \sum_{j=1}^{i-1} b_j \right\}, B_i = \left\{ \sum_{j=1}^i a_j + \sum_{j=1}^{i-1} b_j + 1, \dots, \sum_{j=1}^i a_j + \sum_{j=1}^{i-1} b_j \right\}.$$

For two disjoint subsets  $S, T \subset V$ , let us define  $f(S, T) := \sum_{u \in S} \sqrt{P(u, T)}$ . Note that  $\varphi_{\frac{1}{2}}(A) = \frac{f(A, B)}{|A|}$ , so our goal is to lower bound

$$f(A, B) = \sum_{i=1}^k f(A_i, B).$$

For two sets  $S, T \in \{A_i\}_{i=1}^k \cup \{B_i\}_{i=1}^k$ , let us define the contiguous block  $[S, T]$  to be the block of sets from  $S$  clockwise up until  $T$ , possibly going around. For example,  $[B_k, A_2] := B_k \cup A_1 \cup B_1 \cup A_2$ , and note that  $[S, T] \neq [T, S]$  since the sets are counted clockwise.

After we set up the notations, we start with a lower bound on  $f(A_i, B)$  by a natural function, the logarithm of the size of contiguous sets, which is the ‘‘slightly different lower bound’’ that we mentioned before this subsection.

► **Lemma 14.** For  $1 \leq i \leq k$ ,

$$\begin{aligned} \sqrt{2C} \cdot f(A_i, B) \geq & \sum_{j=1}^k \left( \log(|[A_i, A_j]| + 1) + \log(|[B_i, B_{j-1}]| + 1) \right. \\ & \left. - \log(|[B_i, A_j]| + 1) - \log(|[A_i, B_{j-1}]| + 1) \right), \end{aligned}$$

where  $C$  is the normalizing constant in Definition 12 and  $|[S, T]|$  denotes the number of vertices in the block  $[S, T]$ .

**Proof.** We prove the statement for  $f(A_1, B)$ . By definition of  $f, A_i, B_i$  stated above,

$$\begin{aligned} \sqrt{2C} \cdot f(A_1, B) &= \sqrt{2C} \cdot \sum_{i \in A_1} \sqrt{\sum_{l=1}^k P(i, B_l)} \\ &= \sqrt{2C} \cdot \sum_{i=1}^{a_1} \sqrt{\sum_{l=1}^k \sum_{j=1}^{b_l} P\left(i, \sum_{m=1}^l a_m + \sum_{m=1}^{l-1} b_m + j\right)}. \end{aligned}$$

### 36:14 On the Houdré-Totali Conjecture About an Isoperimetric Constant of Graphs

By the definition of  $P$  in Definition 12,  $P(i, j) \geq \frac{1}{C|i-j|^3}$  and so

$$\begin{aligned} \sqrt{2C} \cdot f(A_1, B) &\geq \sqrt{2} \cdot \sum_{i=1}^{a_1} \sqrt{\sum_{l=1}^k \sum_{j=1}^{b_l} \left( \sum_{m=1}^l a_m + \sum_{m=1}^{l-1} b_m + j - i \right)^{-3}} \\ &= \sqrt{2} \cdot \sum_{i=0}^{a_1-1} \sqrt{\sum_{l=1}^k \sum_{j=1}^{b_l} \left( \sum_{m=2}^l a_m + \sum_{m=1}^{l-1} b_m + j + i \right)^{-3}}. \end{aligned}$$

We lower bound the inner sum by an integral, so that

$$\begin{aligned} \sqrt{2C} \cdot f(A_1, B) &\geq \sqrt{2} \cdot \sum_{i=0}^{a_1-1} \sqrt{\sum_{l=1}^k \int_1^{b_l+1} \left( \sum_{m=2}^l a_m + \sum_{m=1}^{l-1} b_m + x + i \right)^{-3} dx} \\ &= \sum_{i=0}^{a_1-1} \left( \sum_{l=1}^k \underbrace{\left( \sum_{m=2}^l a_m + \sum_{m=1}^{l-1} b_m + i + 1 \right)^{-2}}_{\alpha_l} \right. \\ &\quad \left. - \underbrace{\left( \sum_{m=2}^l a_m + \sum_{m=1}^{l-1} b_m + i + 1 \right)^{-2}}_{\beta_l} \right)^{1/2}. \end{aligned}$$

Now we use the following simple inequality about decreasing numbers.

▷ **Claim 15.** Let  $(\alpha_i)_{i=1}^k, (\beta_i)_{i=1}^k$  be positive real numbers such that  $\alpha_1 \geq \beta_1 \geq \alpha_2 \geq \beta_2 \geq \dots \geq \alpha_k \geq \beta_k \geq 0$ . Then

$$\sum_{i=1}^k (\alpha_i^2 - \beta_i^2) \geq \left( \sum_{i=1}^k (\alpha_i - \beta_i) \right)^2.$$

*Proof.* The proof is by induction. For  $i = 1$ , the claim is clear as  $\alpha_1^2 - \beta_1^2 \geq (\alpha_1 - \beta_1)^2$ . Suppose that the claim is true for  $i = k$ . Let  $A = \sum_{i=2}^{k+1} (\alpha_i^2 - \beta_i^2)$  and  $B = \sum_{i=2}^{k+1} (\alpha_i - \beta_i)$ . For the induction step, we need to show that  $\alpha_1^2 - \beta_1^2 + A \geq (\alpha_1 - \beta_1 + B)^2$ . Since  $A \geq B^2$  by induction, it suffices to show that  $\alpha_1^2 - \beta_1^2 \geq (\alpha_1 - \beta_1)(\alpha_1 - \beta_1 + 2B)$ , which is equivalent to  $\beta_1 \geq B$ . It follows from the property of decreasing sequence that  $B \leq \alpha_2 \leq \beta_1$ , verifying the induction step. ◁

The  $\sqrt{\alpha_l}$  and  $\sqrt{\beta_l}$  in the right hand side above satisfy the assumptions of the claim, and thus

$$\sqrt{2C} \cdot f(A_1, B) \geq \sum_{l=1}^k \sum_{i=0}^{a_1-1} \left( \left( \sum_{m=2}^l a_m + \sum_{m=1}^{l-1} b_m + i + 1 \right)^{-1} - \left( \sum_{m=2}^l a_m + \sum_{m=1}^{l-1} b_m + i + 1 \right)^{-1} \right)$$

We again lower bound the inner sum by an integral so that  $\sqrt{2C} \cdot f(A_1, B)$  is at least

$$\begin{aligned} &\sum_{l=1}^k \int_0^{a_1} \left( \left( \sum_{m=2}^l a_m + \sum_{m=1}^{l-1} b_m + x + 1 \right)^{-1} - \left( \sum_{m=2}^l a_m + \sum_{m=1}^{l-1} b_m + x + 1 \right)^{-1} \right) dx \\ &= \sum_{l=1}^k \left( \log \left( \sum_{m=1}^l a_m + \sum_{m=1}^{l-1} b_m + 1 \right) - \log \left( \sum_{m=2}^l a_m + \sum_{m=1}^{l-1} b_m + 1 \right) \right. \\ &\quad \left. - \log \left( \sum_{m=1}^l a_m + \sum_{m=1}^{l-1} b_m + 1 \right) + \log \left( \sum_{m=2}^l a_m + \sum_{m=1}^{l-1} b_m + 1 \right) \right) \end{aligned}$$

$$= \sum_{l=1}^k \left( \log (|[A_1, A_l]| + 1) - \log (|[B_1, A_l]| + 1) - \log (|[A_1, B_l]| + 1) + \log (|[B_1, B_l]| + 1) \right),$$

using the definition e.g.  $|[A_1, B_l]| = \sum_{j=1}^l (a_j + b_j)$ .  $\blacktriangleleft$

Next, we are going to sum up the lower bounds in Lemma 14 to obtain a lower bound on  $f(A, B)$ . To write the sum nicely, we use a simple observation on the signs of the logarithm in our sum. Let us call a contiguous block  $[S, T]$  odd if there are an odd number of sets in  $\{A_i\}_{i=1}^k \cup \{B_i\}_{i=1}^k$ , and even otherwise. Note that the odd blocks are exactly those with the first and last sets from the same partition  $A$  or  $B$ , e.g.  $[A_i, A_j], [B_i, B_j]$ . With this definition, the lower bound on  $f(A, B)$  can be written as follows.

► **Lemma 16.** *Using the definitions and notations in this subsection,*

$$\sqrt{2C} \cdot f(A, B) \geq \sum_{S \neq T: [S, T] \text{ odd}} \log (|[S, T]| + 1) - \sum_{S \neq T: [S, T] \text{ even}} \log (|[S, T]| + 1) - (k-1) \log(n+1),$$

where the sum is over  $S, T \in \{A_i\}_{i=1}^k \cup \{B_i\}_{i=1}^k$ .

**Proof.** We sum the inequalities in Lemma 14 from  $1 \leq i \leq k$ . On the right hand side of the inequality in Lemma 14, we see that all contiguous blocks starting from  $A_i$  or  $B_i$  are in the sum, with the odd blocks positive and even blocks negative. Thus, summing over all  $A_i$ , every contiguous block is counted once as it is uniquely determined by the starting and ending sets, except for the whole cycle which appears once on the right hand side for every  $i$  with a negative sign.  $\blacktriangleleft$

To prove a lower bound on the right hand side of Lemma 16, the idea is to use the following concavity property.

► **Lemma 17.** *For  $k \geq 2$ , consider the function*

$$h : (a_1, b_1, \dots, a_k, b_k) \rightarrow \sum_{S \neq T: [S, T] \text{ odd}} \log (|[S, T]| + 1) - \sum_{S \neq T: [S, T] \text{ even}} \log (|[S, T]| + 1) - (k-1) \log(n+1),$$

where the sum is over  $S, T \in \{A_i\}_{i=1}^k \cup \{B_i\}_{i=1}^k$  and so  $|[S, T]|$  depends on  $a_1, b_1, \dots, a_k, b_k$ . Then, for all positive  $j$ , the function

$$g : x \rightarrow h(x, b_1, s - x, b_2, \dots, a_k, b_k),$$

obtained by fixing non-negative integers  $b_1, b_2, a_3, b_3, \dots, a_k, b_k$  as the size of the other sets and  $s$  as the sum of  $a_1 + a_2$ , is concave on  $x \in [0, s]$ .

**Proof.** To prove concavity, we use the second derivative test, where  $g$  is concave if the second derivative  $g''$  is non-positive. We write  $g$  as  $g_0 + g_1(x) + g_2(x)$ , where the  $g_1(x)$  consists of all the log terms which contain  $A_1$  but not  $A_2$ , and similarly  $g_2(x)$  consists of all the log terms which contain only  $A_2$  but not  $A_1$ . The remaining terms are in  $g_0$ , which either contain both  $A_1$  and  $A_2$  or none of  $A_1$  and  $A_2$ . Note that these terms are independent of  $x$ , because if a block  $[S, T]$  contains both  $A_1$  and  $A_2$  then its size  $|[S, T]|$  is the same even when we change  $x$ , so these terms can be ignored when we compute derivatives.

### 36:16 On the Houdré-Tetali Conjecture About an Isoperimetric Constant of Graphs

Let us focus on  $g_1(x)$  first. The blocks that contain  $A_1$  but not  $A_2$  must be of the form  $[S, A_1]$  or  $[S, B_1]$  for some set  $S$ . Let  $\sigma([S, T])$  denote the parity of the block  $[S, T]$ . Note that the parity of  $[S, A_1]$  and  $[S, B_1]$  are different, and so

$$\begin{aligned}
 g_1''(x) &= \sum_S (-1)^{\sigma([S, A_1])+1} \left( (\log(|[S, A_1]| + 1))'' - (\log(|[S, B_1]| + 1))'' \right) \\
 &= \sum_S (-1)^{\sigma([S, A_1])+1} \left( \log(|[S, B_k]| + x + 1)'' - (\log(|[S, B_k]| + x + b_1 + 1))'' \right) \\
 &= \sum_S (-1)^{\sigma([S, A_1])} \left( (|[S, B_k]| + x + 1)^{-2} - (|[S, B_k]| + x + b_1 + 1)^{-2} \right) \\
 &= \sum_S (-1)^{\sigma([S, A_1])} \left( b_1 \cdot (|[S, B_k]| + x + 1)^{-2} \cdot (|[S, B_k]| + x + b_1 + 1)^{-1} \right. \\
 &\quad \left. + b_1 \cdot (|[S, B_k]| + x + 1)^{-1} \cdot (|[S, B_k]| + x + b_1 + 1)^{-2} \right),
 \end{aligned}$$

where the sum is over  $S \in \{A_i\}_{i=1}^k \cup \{B_i\}_{i=1}^k$ . In the special case when  $S = A_1$ , we violate our own notation and let  $|[A_1, B_k]| = 0$  in this proof; all other cases are still the same.

When  $b_1 = 0$ , the sum equals zero and we are done, so assume  $b_1 \neq 0$ . To see that  $g_1''(x)$  is negative, we pair up the terms with  $S = B_i$  and  $S = A_{i+1}$  with indices taken modulo  $k$  so that

$$\begin{aligned}
 \frac{1}{b_1} \cdot g_1''(x) &= \sum_{i=1}^k \left[ (|[B_i, B_k]| + x + 1)^{-2} \cdot (|[B_i, B_k]| + x + b_1 + 1)^{-1} \right. \\
 &\quad \left. + (|[B_i, B_k]| + x + 1)^{-1} \cdot (|[B_i, B_k]| + x + b_1 + 1)^{-2} \right. \\
 &\quad \left. - (|[A_{i+1}, B_k]| + x + 1)^{-2} \cdot (|[A_{i+1}, B_k]| + x + b_1 + 1)^{-1} \right. \\
 &\quad \left. - (|[A_{i+1}, B_k]| + x + 1)^{-1} \cdot (|[A_{i+1}, B_k]| + x + b_1 + 1)^{-2} \right] \\
 &< 0,
 \end{aligned}$$

where the inequality holds because  $|[A_{i+1}, B_k]| < |[B_i, B_k]|$  and so each summand is negative (recall the special case that  $|[A_1, B_k]| = 0$  in this proof).

The function  $g_2(x)$  is handled analogously in view of the symmetry of the second derivative of the logarithm. This proves that  $g$  is concave.  $\blacktriangleleft$

With the concavity property, we can apply a simple “swapping/merging” argument to reduce to the case when there is only one contiguous set, i.e.  $k = 1$ , and then finish the proof.

By concavity, the function  $g(x)$  attains its minimum at one of the endpoints, and so

$$h(a_1, \dots, b_n) \geq \min \{h(0, b_1, a_1 + a_2, b_2, \dots, a_n, b_n), h(a_1 + a_2, b_1, 0, b_2, \dots, a_n, b_n)\}$$

The next observation is that when one set has size zero, we can merge the two adjacent sets in the same partition into one. More formally, let  $b_1 = 0$  without loss of generality, we claim that

$$h(a_1, 0, a_2, b_2, \dots, a_k, b_k) = h(a_1 + a_2, b_2, \dots, a_k, b_k).$$

To see this, note that  $|[S, A_1]|$  and  $|[S, B_1]|$  have the same values but they have different signs so the terms involving them cancel out each other, and similarly the terms involving  $|[B_1, S]|$  and  $|[A_2, S]|$  cancel out each other. Therefore, in  $h(a_1, 0, a_2, b_2, \dots, a_k, b_k)$ , there are no terms ending with  $A_1$  or  $B_1$  and no terms beginning with  $B_1$  or  $A_2$ , and all the remaining terms have a one-to-one correspondence with the terms in  $h(a_1 + a_2, b_2, \dots, a_k, b_k)$ .

This reduces  $k$  by one. Repeating the same argument until  $k = 1$ , we see that

$$\sqrt{2C} \cdot f(A, B) \geq h(|A|, n - |A|) = \log(|A| + 1) + \log(n - |A| + 1) - \log(n + 1),$$

and thus

$$\begin{aligned} \varphi_{\frac{1}{2}}(G) &= \min_{A:|A| \leq \frac{n}{2}} \frac{f(A, B)}{|A|} \gtrsim \min_{l: l \leq \frac{n}{2}} \frac{h(l, n - l)}{l} \\ &= \min_{l: l \leq \frac{n}{2}} \frac{\log(l + 1) + \log(n - l + 1) - \log(n + 1)}{l}, \end{aligned}$$

where we used that  $C$  is upper bounded by an absolute constant.

It remains to lower bound the right hand side. Since  $l \leq \frac{n}{2}$ , it follows that  $\log(n - l + 1) - \log(n + 1) \geq \log((n + 1)/2) - \log(n + 1) = -\log 2$ , and so

$$\frac{\log(k + 1) + \log(n - k + 1) - \log(n + 1)}{k} \geq \frac{\log \frac{k+1}{2}}{k} \gtrsim \frac{\log \frac{k+1}{2}}{\frac{k+1}{2}} \geq \frac{\log n}{n},$$

where the last inequality is because  $\frac{\log n}{n}$  is decreasing for  $n \geq 3$  and for  $1 \leq k \leq 4$  the last inequality clearly holds when  $n$  is large enough. This concludes the proof of Theorem 4.

## Concluding Remarks and Open Questions

We believe that the same analysis of  $\varphi_p(G)$  can be extended to other generalizations of Cheeger's inequality in [15, 11], and also to the directed edge conductance using the recent notions of reweighted eigenvalues in [19, 12, 13, 14]. We leave it as an open question to find a counterexample where the transition matrix is the simple random walk matrix of a graph.

# Nearly Optimal Bounds for Sample-Based Testing and Learning of $k$ -Monotone Functions

Hadley Black   

University of California, San Diego, USA

---

## Abstract

We study monotonicity testing of functions  $f: \{0, 1\}^d \rightarrow \{0, 1\}$  using *sample-based* algorithms, which are only allowed to observe the value of  $f$  on points drawn independently from the uniform distribution. A classic result by Bshouty-Tamon (J. ACM 1996) proved that monotone functions can be learned with  $\exp(\tilde{O}(\min\{\frac{1}{\varepsilon}\sqrt{d}, d\}))$  samples and it is not hard to show that this bound extends to testing. Prior to our work the only lower bound for this problem was  $\Omega(\sqrt{\exp(d)/\varepsilon})$  in the small  $\varepsilon$  parameter regime, when  $\varepsilon = O(d^{-3/2})$ , due to Goldreich-Goldwasser-Lehman-Ron-Samorodnitsky (Combinatorica 2000). Thus, the sample complexity of monotonicity testing was wide open for  $\varepsilon \gg d^{-3/2}$ . We resolve this question, obtaining a nearly tight lower bound of  $\exp(\Omega(\min\{\frac{1}{\varepsilon}\sqrt{d}, d\}))$  for all  $\varepsilon$  at most a sufficiently small constant. In fact, we prove a much more general result, showing that the sample complexity of  $k$ -monotonicity testing and learning for functions  $f: \{0, 1\}^d \rightarrow [r]$  is  $\exp(\Omega(\min\{\frac{rk}{\varepsilon}\sqrt{d}, d\}))$ . For testing with one-sided error we show that the sample complexity is  $\exp(\Omega(d))$ .

Beyond the hypercube, we prove nearly tight bounds (up to polylog factors of  $d, k, r, 1/\varepsilon$  in the exponent) of  $\exp(\tilde{\Theta}(\min\{\frac{rk}{\varepsilon}\sqrt{d}, d\}))$  on the sample complexity of testing and learning measurable  $k$ -monotone functions  $f: \mathbb{R}^d \rightarrow [r]$  under product distributions. Our upper bound improves upon the previous bound of  $\exp(\tilde{O}(\min\{\frac{k}{\varepsilon^2}\sqrt{d}, d\}))$  by Harms-Yoshida (ICALP 2022) for Boolean functions ( $r = 2$ ).

## 1 Introduction

A function  $f: \mathcal{X} \rightarrow \mathbb{R}$  over a partial order  $\mathcal{P} = (\mathcal{X}, \preceq)$  is  $k$ -monotone if there does not exist a chain of  $k + 1$  points  $x_1 \prec x_2 \prec \dots \prec x_{k+1}$  for which (a)  $f(x_{i+1}) - f(x_i) < 0$  when  $i$  is odd and (b)  $f(x_{i+1}) - f(x_i) > 0$  when  $i$  is even. When  $k = 1$ , these are the *monotone* functions, which are the non-decreasing functions with respect to  $\preceq$ . Monotone and  $k$ -monotone *Boolean* functions over domains  $\{0, 1\}^d$ ,  $[n]^d$ , and  $\mathbb{R}^d$  have been the focus of a significant amount of research in property testing and computational learning theory. We give an overview of the literature in Section 1.4.

The field of property testing is concerned with the design and analysis of sub-linear time randomized algorithms for determining if a function has, or is far from having, some specific property. A key aspect in the definition of a property testing algorithm is the type of access it has to the function. Early works on property testing, e.g. [61, 44], focused on the notion of *query-based* testers, which are allowed to observe the value of the function on any point of their choosing, and since then this has become the standard model. The weaker notion of *sample-based* testers, which can only view the function on independent uniform samples, was also considered by [44] and has received some attention over the years, see e.g. [51, 3, 41, 45, 37, 38]. Sample-based algorithms are considered more natural in many settings, for example in computational learning theory, where they are the standard model. In fact, sample-based testing and learning are closely related problems; given a learning algorithm, it is always possible to design a testing algorithm with the same sample complexity, up to an additive  $\text{poly}(1/\varepsilon)$  factor<sup>1</sup>.

For many fundamental properties, there is still a large gap between how much we know in the query-based vs the sample-based models. Monotonicity (and  $k$ -monotonicity) is such a property; despite a vast body of research on query-based monotonicity testing over the hypercube  $\{0, 1\}^d$ , the only work we know of which considers this problem in the sample-based model is [43], who gave an upper bound of  $O(\sqrt{2^d/\varepsilon})$  and a matching lower bound for the case when  $\varepsilon = O(d^{-3/2})$  on the number of samples needed to test monotonicity of functions  $f: \{0, 1\}^d \rightarrow \{0, 1\}$ . The upper bound for learning monotone Boolean functions due to [23, 54] also implies a testing upper bound of  $\exp(\tilde{O}(\frac{1}{\varepsilon}\sqrt{d}))$ . Thus, this question has been wide open for  $\varepsilon \gg d^{-3/2}$ .

Our work addresses this gap in the monotonicity testing literature, proving a lower bound which matches the learning upper bound for all  $\varepsilon$  at most some constant, up to a factor of  $\log d$  in the exponent. More generally, we prove tight lower bounds for  $k$ -monotonicity testing of functions,  $f: \{0, 1\}^d \rightarrow [r]$ , i.e. functions with image size at most  $r$ . To round out our results, we also give an improved learning algorithm for  $k$ -monotone functions over  $\mathbb{R}^d$  under product distributions whose sample complexity matches our sample-based testing lower bound, up to poly-logarithmic factors in the exponent.

## 1.1 Results

Before explaining our results and the context for them, we first provide some terminology and basic notation. Given a domain  $\mathcal{X}$  and a distribution  $\mu$  over  $\mathcal{X}$ , we denote the Hamming distance between two functions  $f, g: \mathcal{X} \rightarrow \mathbb{R}$  under  $\mu$  by  $d_\mu(f, g) = \mathbb{P}_{x \sim \mu}[f(x) \neq g(x)]$ . We say that  $f$  is  $\varepsilon$ -far from  $k$ -monotone if  $d_\mu(f, g) \geq \varepsilon$  for every  $k$ -monotone function  $g$ . The results in this paper pertain to sample-based testing and learning of  $k$ -monotone functions with respect to Hamming distance. We use the following terminology:

- The *example oracle* for  $f$  under  $\mu$ , denoted by  $EX(f, \mu)$ , when queried, generates an example  $(x, f(x))$  where  $x$  is sampled according to  $\mu$ .
- A *sample-based  $k$ -monotonicity tester* under  $\mu$  is a randomized algorithm which is given access to  $EX(f, \mu)$  for an arbitrary input function  $f$  and satisfies the following: (a) if  $f$  is  $k$ -monotone, then the algorithm accepts with probability at least  $2/3$ , and (b) if  $f$  is  $\varepsilon$ -far from  $k$ -monotone, then the algorithm rejects with probability at least  $2/3$ . The tester has *one-sided error* if in case (a) it accepts with probability 1.

<sup>1</sup> See Lemma C.1 in the full version of the paper for a precise statement. Also, note that if the learning algorithm is *proper*, then the time complexity is also preserved. If the learning algorithm is *improper*, then there is a time complexity blow-up, but the sample complexity is still preserved.

- A *sample-based learning algorithm for  $k$ -monotone functions* under  $\mu$  is a randomized algorithm which is given access to  $EX(f, \mu)$  for an arbitrary  $k$ -monotone input function  $f$  and outputs a hypothesis  $h$  such that  $d_\mu(f, h) \leq \varepsilon$  with probability at least  $1 - \delta$ . If left unspecified,  $\delta = 1/3$ .

In all of the above definitions if  $\mu$  is unspecified, then it is the uniform distribution. Testing and learning are closely related problems; any sample-based learning algorithm can be used to construct a sample-based tester with the same sample complexity. We refer to this transformation as the testing-by-learning reduction and although this is not a new idea we provide a proof in Section C in the full version of the paper for completeness.

Finally, we recall some important learning theory terminology. A learning algorithm for concept class  $\mathcal{C}$  is called *proper* if it always outputs a hypothesis  $h \in \mathcal{C}$ , and is called *improper* if it is allowed to output arbitrary  $h$ . Given a function  $f$ , and a concept class  $\mathcal{C}$ , let  $d(f, \mathcal{C}) = \min_{g \in \mathcal{C}} d(f, g)$ . An *agnostic proper* learner is one which, given *any*  $f$  (not necessarily in  $\mathcal{C}$ ), outputs a hypothesis  $h \in \mathcal{C}$  for which  $d(f, h) \leq d(f, \mathcal{C}) + \varepsilon$  with probability at least  $1 - \delta$ .

### 1.1.1 Sample-Based Testing and Learning on the Hypercube

The problem of *learning* monotone Boolean functions over the hypercube  $\{0, 1\}^d$  was studied by [23] who proved an upper bound<sup>2</sup> of  $\exp(O(\min\{\frac{1}{\varepsilon}\sqrt{d} \log d, d\}))$  for improper learning and very recently by [54, 55] who obtained the same upper bound for agnostic proper learning. The improper learning upper bound was extended by [17] who showed an upper bound of  $\exp(O(\min\{\frac{k}{\varepsilon}\sqrt{d} \log d, d\}))$  and a nearly matching lower bound of  $\exp(\Omega(\min\{\frac{k}{\varepsilon}\sqrt{d}, d\}))$  for learning  $k$ -monotone Boolean functions for any  $k \geq 1$ . The testing-by-learning reduction shows that their upper bound also holds for sample-based *testing*. The only prior lower bound for sample-based testing that we're aware of is  $\Omega(\sqrt{2^d/\varepsilon})$  when  $\varepsilon = O(d^{-3/2})$  and  $k = 1$  [43, Theorem 5]. Our main result is the following much more general lower bound for this problem, which we prove in Section 3.

► **Theorem 1 (Testing Lower Bound).** *There is an absolute constant  $c > 0$  such that for all  $\varepsilon \leq c$ , every sample-based  $k$ -monotonicity tester for functions  $f: \{0, 1\}^d \rightarrow [r]$  under the uniform distribution has sample complexity*

$$\exp\left(\Omega\left(\min\left\{\frac{rk}{\varepsilon}\sqrt{d}, d\right\}\right)\right).$$

Even for the special case of sample-based monotonicity testing of Boolean functions ( $k = 1$  and  $r = 2$ ), Theorem 1 is already a new result, which matches the upper bound for learning by [23] and is the first lower bound to hold for  $\varepsilon \gg d^{-3/2}$ . Moreover, our lower bound is much more general, holding for all  $r, k$ , and is optimal in all parameters,  $d, r, k, \varepsilon$ , up to a  $\log d$  factor in the exponent. We show a nearly matching upper bound in Theorem 3.

We also note that the testing-by-learning reduction implies that the same lower bound holds for *learning* with samples. As we mentioned, this result was already known for Boolean

<sup>2</sup> We remark that any function over  $\{0, 1\}^d$  can be learned exactly with  $O(d2^d) = \exp(O(d))$  samples by a coupon-collector argument. Combining this with the  $\exp(O(\frac{1}{\varepsilon}\sqrt{d} \log d))$  upper bound by [23] yields  $\exp(O(\min\{\frac{1}{\varepsilon}\sqrt{d} \log d, d\}))$ . We use this slightly clunkier notation involving the min to emphasize that our upper and lower bounds are nearly matching in all parameter regimes.

## 37:4 Sample-Based Testing and Learning of $k$ -Monotone Functions

functions (the  $r = 2$  case) [17], but the general case of  $r \geq 2$  was not known prior to our work<sup>3</sup>.

► **Corollary 2** (Learning Lower Bound). *There is an absolute constant  $c > 0$  such that for every  $\varepsilon \leq c$ , every sample-based uniform-distribution learning algorithm for  $k$ -monotone functions  $f: \{0, 1\}^d \rightarrow [r]$  has sample complexity*

$$\exp\left(\Omega\left(\min\left\{\frac{rk}{\varepsilon}\sqrt{d}, d\right\}\right)\right).$$

On the upper bound side, a relatively straightforward argument extends the learning algorithm of [17] for Boolean  $k$ -monotone functions, to  $k$ -monotone functions with image size at most  $r$ . We give a short proof in Section 1.5. This shows that our lower bounds in Theorem 1 and Corollary 2 are tight up to a factor of  $\log d$  in the exponent.

► **Theorem 3** (Learning Upper Bound for Hypercubes). *There is a uniform-distribution learning algorithm for  $k$ -monotone functions  $f: \{0, 1\}^d \rightarrow [r]$  which achieves error at most  $\varepsilon$  with time and sample complexity*

$$\exp\left(O\left(\min\left\{\frac{rk}{\varepsilon}\sqrt{d}\log d, d\right\}\right)\right).$$

The testing-by-learning reduction again gives us the following corollary.

► **Corollary 4** (Testing Upper Bound for Hypercubes). *There is a sample-based  $k$ -monotonicity tester for functions  $f: \{0, 1\}^d \rightarrow [r]$  with sample complexity*

$$\exp\left(O\left(\min\left\{\frac{rk}{\varepsilon}\sqrt{d}\log d, d\right\}\right)\right).$$

Lastly, we consider the problem of sample-based testing with *one-sided error*. For monotonicity testing of functions  $f: \{0, 1\}^d \rightarrow \{0, 1\}$  with *non-adaptive queries*, we know that one-sided and two-sided error testers achieve the same query-complexity (up to  $\text{polylog}(d, 1/\varepsilon)$  factors): there is a  $\tilde{O}(\sqrt{d}/\varepsilon^2)$  one-sided error upper bound due to [53] and a  $\tilde{\Omega}(\sqrt{d})$  two-sided error lower bound due to [33]. We show that the situation is quite different for *sample-based* monotonicity testing; while the sample complexity of two-sided error testers is  $\exp(\Theta(\min\{\frac{1}{\varepsilon}\sqrt{d}, d\}))$ , one-sided error testers require  $\exp(\Theta(d))$  samples for all  $\varepsilon$ .

► **Theorem 5** (Testing with One-Sided Error). *For every  $d, r, k$ , and  $\varepsilon > 0$ , sample-based  $k$ -monotonicity testing of functions  $f: \{0, 1\}^d \rightarrow [r]$  with one-sided error requires  $\exp(\Theta(d))$  samples.*

### 1.1.2 Sample-Based Testing and Learning in Continuous Product Spaces

Learning  $k$ -monotone Boolean-valued functions has also been studied over  $\mathbb{R}^d$  with respect to product measures by [49] who gave an upper bound of  $\exp(\tilde{O}(\min\{\frac{k}{\varepsilon^2}\sqrt{d}, d\}))$  where  $\tilde{O}(\cdot)$  hides  $\text{polylog}$  factors of  $d, k$ , and  $1/\varepsilon$ . Our next result gives an upper bound which improves the dependence on  $\varepsilon$  from  $1/\varepsilon^2$  to  $1/\varepsilon$  in the exponent. By the same approach we used to generalize the upper bound in Theorem 3 to arbitrary  $r \geq 2$ , we get the same generalization for product spaces. We obtain the following upper bound which matches our lower bound for  $\{0, 1\}^d$  in Theorem 1 up to  $\text{polylog}$  factors of  $d, k, r$ , and  $1/\varepsilon$ . We say that a function  $f: \mathbb{R}^d \rightarrow [r]$  is *measurable* if the set  $f^{-1}(i)$  is measurable for every  $i \in [r]$ .

<sup>3</sup> It is possible that the techniques from [17] could be extended to provide an alternative proof of Corollary 2, but we have not checked whether this is the case.

► **Theorem 6** (Learning Upper Bound for Product Spaces). *Given an arbitrary product measure  $\mu$ , there is a learning algorithm under  $\mu$  for measurable  $k$ -monotone functions  $f: \mathbb{R}^d \rightarrow [r]$  with time and sample complexity*

$$\exp\left(\tilde{O}\left(\min\left\{\frac{rk}{\varepsilon}\sqrt{d}, d\right\}\right)\right).$$

The  $\tilde{O}(\cdot)$  hides polylogarithmic dependencies on  $d, r, k$ , and  $1/\varepsilon$ .

We prove Theorem 6 in Section 4. Once again the testing-by-learning reduction gives us the following corollary for sample-based testing.

► **Corollary 7** (Testing Upper Bound for Product Spaces). *Given an arbitrary product measure  $\mu$ , there is a  $k$ -monotonicity tester for measurable functions  $f: \mathbb{R}^d \rightarrow [r]$  under  $\mu$  with sample complexity*

$$\exp\left(\tilde{O}\left(\min\left\{\frac{rk}{\varepsilon}\sqrt{d}, d\right\}\right)\right).$$

The  $\tilde{O}(\cdot)$  hides polylogarithmic dependencies on  $d, r, k$ , and  $1/\varepsilon$ .

## 1.2 Proof Overviews

In this section we give an overview of our proofs for Theorem 1 and Theorem 6.

### 1.2.1 The Testing Lower Bound for Hypercubes

Our proof of Theorem 1 uses a family functions known as *Talagrand's random DNFs* introduced by [63] which have been used by [4] and [33] to prove lower bounds for monotonicity testing of Boolean functions  $f: \{0, 1\}^d \rightarrow \{0, 1\}$  against adaptive and non-adaptive query-based testers. Very recently, they have also been used to prove lower bounds for tolerant monotonicity testing [29] and for testing convexity of sets in  $\{-1, 0, 1\}^d$  [10].

To understand our construction, let us first consider the special case of monotonicity of Boolean functions, i.e.  $k = 1$  and  $r = 2$ . We think of a DNF term as a point  $t \in \{0, 1\}^d$  which is said to be satisfied by  $x \in \{0, 1\}^d$  if  $t \preceq x$ , where  $\preceq$  denotes the standard bit-wise partial order over  $\{0, 1\}^d$ . The *width* of a term  $t$  is its Hamming weight,  $|t|$ , and the width of a DNF is the max width among its terms. Consider  $N$  randomly chosen terms  $t^1, \dots, t^N$  each of width  $|t^j| = w$ . We will see later how to choose  $N$  and  $w$ . Let  $B := \{x: \frac{d}{2} \leq |x| \leq \frac{d}{2} + \varepsilon\sqrt{d}\}$  and for each  $j \in [N]$ , let

$$U_j := \{x \in B: t^j \preceq x \text{ and } t^{j'} \not\preceq x \text{ for all } j' \neq j\}$$

be the set of points in  $B$  which satisfy  $t^j$  and no other terms. Let  $U := \bigcup_{j \in [N]} U_j$ . Now observe that any two points lying in different  $U_j$ 's are *incomparable* and therefore independently embedding an arbitrary monotone function into each  $U_j$  will result in a function which globally is monotone if one defines the function outside of  $U$  appropriately. Using this fact we can define two distributions  $\mathcal{D}_{\text{yes}}$  and  $\mathcal{D}_{\text{no}}$  as follows. Let  $A$  denote the set of points in  $x \in \{0, 1\}^d$  for which either  $|x| > \frac{d}{2} + \varepsilon\sqrt{d}$  or  $x \in B$  and  $t^j, t^{j'} \preceq x$  for two different terms  $j \neq j'$ .

- $f \sim \mathcal{D}_{\text{yes}}$  is drawn by setting  $f(x) = 1$  if and only if  $x \in A \cup \left(\bigcup_{j \in T} U_j\right)$  where  $T \subseteq [N]$  contains each  $j \in [N]$  with probability  $1/2$ , independently. Such a function is always monotone.

- $f \sim \mathcal{D}_{\text{no}}$  is drawn by setting  $f(x) = 1$  if and only if  $x \in A \cup R$  where  $R$  contains each  $x \in U$  with probability  $1/2$ , independently. Such a function will be  $\Omega(|U| \cdot 2^{-d})$ -far from monotone with probability  $\Omega(1)$  since its restriction with  $U$  is uniformly random.

Now, each  $x \in U$  satisfies  $\mathbb{P}_{f \sim \mathcal{D}_{\text{yes}}}[f(x) = 1] = \mathbb{P}_{f \sim \mathcal{D}_{\text{no}}}[f(x) = 1] = 1/2$  and for both distributions the events  $f(x) = 1$  and  $f(y) = 1$  are independent when  $x, y$  lie in different  $U_j$ 's. Therefore, any tester will need to see at least two points from the same  $U_j$  to distinguish  $\mathcal{D}_{\text{yes}}$  and  $\mathcal{D}_{\text{no}}$ . Roughly speaking, by birthday paradox this gives a  $\Omega(\sqrt{N})$  lower bound on the number of samples. The lower bound is thus determined by the maximum number of terms  $N$  that can be used in the construction for which  $|U| = \Omega(\varepsilon 2^d)$ .

So how are  $N$  and  $w$  chosen? By standard concentration bounds, we have  $|B| = \Omega(\varepsilon 2^d)$  and observe that a point  $x \in B$  satisfies a random term with probability exactly  $(|x|/d)^w$ . We need  $U$  to contain a *constant fraction* of  $B$ , i.e. we need  $x$  to satisfy exactly 1 term with constant probability. The expected number of satisfied terms is  $N \cdot (|x|/d)^w$  and, roughly speaking, we need this value to be  $\Theta(1)$  for all  $x \in B$ . Applying this constraint to the case when  $|x| = d/2$  forces us to pick  $N \approx 2^w$ . Now when  $|x| = d/2 + \varepsilon\sqrt{d}$ , the expected number of satisfied terms is  $N \cdot 2^{-w} \cdot (1 + 2\varepsilon/\sqrt{d})^w \approx (1 + 2\varepsilon/\sqrt{d})^w$  and we are forced to choose  $w \approx \sqrt{d}/\varepsilon$ . The lower bound for sample-based monotonicity testing of  $f: \{0, 1\}^d \rightarrow \{0, 1\}$  is then  $\Omega(\sqrt{N}) \approx \exp(\Omega(\sqrt{d}/\varepsilon))$ .

Let us now think about generalizing this construction to testing  $k$ -monotonicity of functions  $f: \{0, 1\}^d \rightarrow [r]$ . The moral of the above argument is that the permitted number of terms is controlled by the number of distinct Hamming weights in the set  $B$ . We observe that for larger values of  $k$  and  $r$  we can partition  $B$  into  $k(r-1)$  blocks as  $B := B_1 \cup B_2 \cup \dots \cup B_{k(r-1)}$  each with a window of Hamming weights of size only  $\frac{\varepsilon\sqrt{d}}{k(r-1)}$ . We are able to essentially repeat the above construction independently within each block wherein we can set  $w \approx \frac{k(r-1)\sqrt{d}}{\varepsilon}$  and consequently  $N \approx 2^{\frac{k(r-1)\sqrt{d}}{\varepsilon}}$ .

For each block  $i \in [k(r-1)]$ , the random Talagrand DNF within block  $B_i$  is defined analogously to the above construction, except that it assigns function values from  $\{i \bmod (r-1), i \bmod (r-1) + 1\}$ , instead of  $\{0, 1\}$ . See Figure 1 for an illustration. Since there are  $k(r-1)$  blocks in total, the distribution  $\mathcal{D}_{\text{yes}}$  only produces  $k$ -monotone functions. At the same time, a function  $f \sim \mathcal{D}_{\text{no}}$  assigns uniform random  $\{a, a+1\}$  values within each block  $B_{m(r-1)+a}$ . This results in a large number of long chains through  $B_a \cup B_{(r-1)+a} \cup \dots \cup B_{(k-1)(r-1)+a}$  which alternate between function value  $a$  and  $a+1$ . Considering the union of all such chains for  $a = 0, 1, \dots, r-2$  shows that  $f$  is  $\Omega(\varepsilon)$ -far from  $k$ -monotone with probability  $\Omega(1)$ .

## 1.2.2 The Learning Upper Bound for Product Spaces

As we discussed in Section 1.1, it suffices to prove Theorem 6 for the case of  $r = 2$ , i.e. learning functions  $f: \mathbb{R}^d \rightarrow \{\pm 1\}$  under a product measure  $\mu$ . We use a downsampling technique to reduce this problem to learning a discretized proxy of  $f$  over a hypergrid  $[N]^d$  where  $N = \Theta(kd/\varepsilon)$  with mild label noise. This technique has been used in previous works [46, 12, 49] and our proof borrows many technical details from [49].

Next, for  $N$  which is a power of 2, we observe that a  $k$ -monotone function  $f: [N]^d \rightarrow \{\pm 1\}$  can be viewed as a  $k$ -monotone function over the hypercube  $\{\pm 1\}^{d \log N}$  by mapping each point  $x \in [N]^d$  to its bit-representation. We can then leverage a result of [17] which shows that all but a  $\varepsilon$ -fraction of the mass of the Fourier coefficients of  $k$ -monotone Boolean functions  $f: \{0, 1\}^d \rightarrow \{0, 1\}$  is concentrated on the terms with degree at most  $\frac{k\sqrt{d}}{\varepsilon}$ . We can then use the Low-Degree Algorithm introduced by [57] which was shown to work under random classification noise by [50].

■ **Figure 1** An illustration of the construction used in our proof of Theorem 1. The image represents the set of points in the hypercube  $\{0, 1\}^d$  with Hamming weight in the interval  $[\frac{d}{2}, \frac{d}{2} + \epsilon\sqrt{d}]$ , increasing from bottom to top. The numbers on the left denote the Hamming weight of the points lying in the adjacent horizontal line. The  $B_i$  blocks are the sets of points contained between two adjacent horizontal lines. Each orange shaded region within  $B_i$  represents the set of points satisfied by a term  $t^{i,j}$ . The blue numbers represent the value that functions in the support of  $\mathcal{D}_{\text{yes}}$  and  $\mathcal{D}_{\text{no}}$  can take. We have used the notation “ $r - 1, 2$ ” as shorthand for  $r - 2, r - 1$ .

### 1.3 Discussion and Open Questions

Our results for sample-based testing and learning over the hypercube are tight up to a  $\log d$  factor in the exponent. Our upper bound for product spaces matches the lower bound for hypercubes only up to *polylog* factors of  $d, k, r, 1/\epsilon$  in the exponent. In particular, the upper bound for product spaces goes to  $\infty$  as any one of the parameters  $r, k$ , or  $1/\epsilon$  grow to  $\infty$ , whereas the lower bound for the hypercube can be at most  $\exp(\Theta(d))$  simply because  $|\{0, 1\}^d| = 2^d$  and so any function  $f: \{0, 1\}^d \rightarrow \mathbb{R}$  can be learned *exactly* with  $\exp(O(d))$  samples. It seems intuitive that sample-based testing and learning of  $k$ -monotone functions over  $[n]^d$  should require  $n^{\Omega(d)}$  samples as either of the parameters  $k$  or  $r$  approaches  $\infty$ . A corollary of such a result would be that the sample-complexity of these problems for  $f: \mathbb{R}^d \rightarrow [r]$  grow to  $\infty$  as  $k$  or  $r$  approach  $\infty$ . Moreover, if this is true, then  $k$ -monotonicity of functions  $f: \mathbb{R}^d \rightarrow \mathbb{R}$  is not testable with a finite number of samples. Our results do not address this and it would be interesting to investigate this further.

► **Question 8.** *Is there a lower bound for sample-based  $k$ -monotonicity testing of functions  $f: [n]^d \rightarrow [r]$  which approaches  $n^{\Omega(d)}$  as  $r$  or  $k$  go to  $\infty$ ?*

## 1.4 Related Work

Monotone functions and their generalization to  $k$ -monotone functions have been extensively studied within property testing and learning theory over the last 25 years. We highlight some of the results which are most relevant to our work. Afterwards, we discuss some selected works on sample-based property testing.

### 1.4.1 Sample-Based Monotonicity Testing

Sample-based monotonicity testing of Boolean functions over the hypercube,  $\{0, 1\}^d$ , was considered by [43] (see [43, Theorems 5 and 6]) who gave an upper bound of  $O(\sqrt{2^d/\varepsilon})$  and a lower bound of  $\Omega(\sqrt{2^d/\varepsilon})$  for  $\varepsilon = O(d^{-3/2})$ . Sample-based monotonicity testing over general partial orders was studied by [42] who gave a  $O(\sqrt{N/\varepsilon})$  one-sided error tester for functions  $f: D \rightarrow \mathbb{R}$  where  $D$  is any partial order on  $N$  elements. Sample-based monotonicity testing of functions on the line  $f: [n] \rightarrow [r]$  was studied by [58] who gave a one-sided error upper bound of  $O(\sqrt{r/\varepsilon})$  and a matching lower bound of  $\Omega(\sqrt{r})$  for all sample-based testers.

### 1.4.2 Query-Based Monotonicity Testing

Monotonicity testing has been extensively studied in the standard query model [59, 35, 43, 34, 56, 42, 47, 1, 48, 2, 39, 62, 8, 22, 36, 16, 60, 9, 26, 27, 32, 7, 19, 30, 25, 52, 4, 33, 11, 58, 12, 49, 15, 21, 14, 13, 29]. When discussing these works we treat  $\varepsilon$  as a small constant for brevity. For  $f: \{0, 1\}^d \rightarrow \{0, 1\}$ , the non-adaptive query complexity has been established at  $\tilde{\Theta}(\sqrt{d})$  [53, 33] with an adaptive lower bound of  $\tilde{\Omega}(d^{1/3})$  [33]. This gap for adaptive monotonicity testing of Boolean functions is still an outstanding open question. For  $f: [n]^d \rightarrow \{0, 1\}$  and  $f: \mathbb{R}^d \rightarrow \{0, 1\}$  under product measures, a recent result of [13] established a non-adaptive upper bound of  $d^{1/2+o(1)}$ . For functions  $f: \{0, 1\}^d \rightarrow [r]$ , [15] showed upper and lower bounds of  $\tilde{\Theta}(\min(r\sqrt{d}, d))$  for non-adaptive, one-sided error testers and there is a general (adaptive) lower bound of  $\Omega(\min(d, r^2))$  due to [16]. For real-valued functions  $f: [n]^d \rightarrow \mathbb{R}$ , the query complexity is known to be  $\Theta(d \log n)$ . The upper bound is non-adaptive [26] and the lower bound holds even for adaptive testers [28].

### 1.4.3 $k$ -Monotonicity Testing

The generalization to  $k$ -monotonicity testing has also been studied in the standard query model by [46, 24]. These works show that the query-complexity of non-adaptive one-sided error  $k$ -monotonicity testing is  $\exp(\tilde{\Theta}(\sqrt{d}))$  for all  $k \geq 2$ , demonstrating an interesting separation between (1)-monotonicity and 2-monotonicity.

### 1.4.4 Learning Monotone Functions

Monotone Boolean functions  $f: \{0, 1\}^d \rightarrow \{0, 1\}$  were studied in the context of learning theory by [23] who showed that they can be (improperly) learned to error  $\varepsilon$  under the uniform distribution with  $\exp(\tilde{O}(\frac{1}{\varepsilon}\sqrt{d}))$  time and samples. Very recent works [54, 55] have given *agnostic proper* learning algorithms with the same complexity.

### 1.4.5 Learning $k$ -Monotone Functions

The result of [23] was generalized by [17] who gave upper and lower bounds of  $\exp(\tilde{\Theta}(\frac{k}{\varepsilon}\sqrt{d}))$  for learning  $k$ -monotone Boolean functions  $f: \{0, 1\}^d \rightarrow \{0, 1\}$ . For Boolean functions over hypergrids  $f: [n]^d \rightarrow \{0, 1\}$ , [24] gave an upper bound of  $\exp(\tilde{O}(\min(\frac{k}{\varepsilon^2}\sqrt{d}, d)))$  where  $\tilde{O}(\cdot)$  hides polylog factors of  $d, k, 1/\varepsilon$ . This result was generalized to functions  $f: \mathbb{R}^d \rightarrow \{0, 1\}$  under product measures by [49].

### 1.4.6 Sample-Based Property Testing

The notion of sample-based property testing was first presented and briefly studied by [44]. Broader studies of sample-based testing and its relationship with query-based testing have since been given by [40, 41, 45]. A characterization of properties which are testable with a constant number of samples was given by [20].

As we mentioned, sample-based algorithms are the standard model in learning theory, and learning requires at least as many samples as testing for every class of functions. Thus, it is natural to ask, when is testing *easier* than learning in terms of sample complexity? This question is referred to as *testing vs learning* and has been studied by [51] and more recently by [18, 37, 38].

There has also been work studying models that interpolate between query-based and sample-based testers. For instance, [3] introduced the notion of *active testing*, where the tester may make queries, but only on points from a polynomial-sized batch of unlabeled samples drawn from the underlying distribution. This was inspired by the notion of *active learning* which considers learning problems under this access model.

Sample-based convexity testing of sets over various domains has also seen some recent attention [31, 5, 6, 10].

### 1.5 Learning Functions with Bounded Image Size: Proof of Theorem 3

In this section we give a short proof showing that the learning algorithm of [17] can be extended in a relatively straightforward manner to functions  $f: \{0, 1\}^d \rightarrow [r]$  by increasing the sample-complexity by a factor of  $r$  in the exponent.

**Proof of Theorem 3.** [17, Theorem 1.4] proved this result for the case of  $r = 2$ . In particular, they show that there is a sample-based learning algorithm which given an arbitrary  $k$ -monotone Boolean function  $f$ , outputs  $h$  such that  $\mathbb{P}_h[d(f, h) > \varepsilon] < \delta$  using  $\ln(1/\delta) \cdot \exp(O(\min\{\frac{rk}{\varepsilon}\sqrt{d}\log d, d\}))$  queries<sup>4</sup> to the example oracle,  $EX(f)$ . We will make use of this result.

For each  $t \in [r]$ , let  $f_t: \{0, 1\}^d \rightarrow \{0, 1\}$  denote the thresholded Boolean function defined as  $f_t(x) := \mathbf{1}(f(x) \geq t)$ . Observe that for all  $x \in \{0, 1\}^d$  we have  $f(x) = \operatorname{argmax}_t \{f_t(x) = 1\}$ . Thus, for each  $t \in [r]$ , run the learning algorithm of [17] with error parameters set to  $\varepsilon' := \varepsilon/r$  and  $\delta = 1/3r$  to obtain a hypothesis  $h_t$ . We have  $\mathbb{P}[d(h_t, f_t) > \varepsilon/r] < 1/3r$ . By a union bound, with probability at least  $2/3$ , every  $t \in [r]$  satisfies  $d(h_t, f_t) \leq \varepsilon/r$ . Moreover, if this holds then by another union bound we have  $\mathbb{P}_x[\exists t \in [r]: h_t(x) \neq f(x)] \leq \varepsilon$ . Thus, the hypothesis  $h(x) := \operatorname{argmax}_t \{h_t(x) = 1\}$  satisfies  $d(h, f) \leq \varepsilon$ . The number of samples used is  $\ln(1/\delta) \cdot \exp(O(\min\{\frac{k}{\varepsilon'}\sqrt{d}\log d, d\})) = \exp(O(\min\{\frac{rk}{\varepsilon}\sqrt{d}\log d, d\}))$  and this completes the proof.  $\blacktriangleleft$

## 2 Preliminaries on $k$ -Monotonicity

We use the notation  $[n] := \{0, 1, \dots, n-1\}$ .

**► Definition 9.** Given a poset  $\mathcal{P} = (\mathcal{X}, \preceq)$  and a function  $f: \mathcal{X} \rightarrow \mathbb{R}$ , an  $m$ -alternating chain is a sequence of points  $x_1 \prec x_2 \prec \dots \prec x_m$  such that for all  $i \in \{1, \dots, m-1\}$ ,

1.  $f(x_{i+1}) - f(x_i) < 0$  when  $i$  is odd, and
2.  $f(x_{i+1}) - f(x_i) > 0$  when  $i$  is even.

<sup>4</sup> Their result (Thm 1.4 of [17]) is stated for constant  $\delta$ , but can be easily extended to arbitrary  $\delta$  with the stated query complexity by replacing Thm 3.1 in their proof with the Low-Degree Algorithm stated for general  $\delta$ .

## 37:10 Sample-Based Testing and Learning of $k$ -Monotone Functions

► **Definition 10** ( $k$ -monotonicity). For a poset  $\mathcal{P} = (\mathcal{X}, \preceq)$ , a function  $f: \mathcal{X} \rightarrow \mathbb{R}$  is called  $k$ -monotone if it does not have any  $(k+1)$ -alternating chains.

Let  $\mathcal{M}_{\mathcal{P},k}$  denote the set of all  $k$ -monotone functions  $f: \mathcal{X} \rightarrow \mathbb{R}$  over the poset  $\mathcal{P} = (\mathcal{X}, \preceq)$ . The Hamming distance between two functions  $f, g: \mathcal{X} \rightarrow \mathbb{R}$  is  $d(f, g) = |\mathcal{X}|^{-1} \cdot |\{x \in \mathcal{X}: f(x) \neq g(x)\}|$ . The distance to  $k$ -monotonicity of  $f$  is denoted by  $\varepsilon(f, \mathcal{M}_{\mathcal{P},k}) := \min_{g \in \mathcal{M}_{\mathcal{P},k}} d(f, g)$ . The following claim is our main tool for lower bounding the distance to  $k$ -monotonicity.

▷ **Claim 11.** Let  $f: \mathcal{X} \rightarrow \mathbb{R}$  and  $k' \geq 3k$  be an integer. Let  $\mathcal{C} \subset \mathcal{X}^{k'}$  be a collection of disjoint  $k'$ -alternating chains for  $f$ . Then

$$\varepsilon(f, \mathcal{M}_{\mathcal{P},k}) \geq \frac{1}{3|\mathcal{X}|} \cdot \left| \bigcup_{C \in \mathcal{C}} C \right|.$$

Proof. Observe that every  $k$ -monotone function  $g \in \mathcal{M}_{\mathcal{P},k}$  has the following property: for every  $C = (x_1, x_2, \dots, x_{k'}) \in \mathcal{C}$ , the sequence

$$(1, g(x_2) - g(x_1), g(x_3) - g(x_2), \dots, g(x_{k'}) - g(x_{k'-1}))$$

changes sign at most  $k-1$  times, whereas the sequence

$$(1, f(x_2) - f(x_1), f(x_3) - f(x_2), \dots, f(x_{k'}) - f(x_{k'-1}))$$

changes sign exactly  $k'-1$  times. We have prepended a 1 so that the first sign change occurs as soon as the function value decreases. Now, changing  $f(x_i)$  can only reduce the number of times the sequence changes sign by at most 2 and so  $|\{i: f(x_i) \neq g(x_i)\}| \geq \frac{k'-k}{2}$ . Summing over all chains in  $\mathcal{C}$  and normalizing yields

$$d(f, g) \geq \frac{k'-k}{2} \cdot \frac{|\mathcal{C}|}{|\mathcal{X}|} \geq \frac{k'}{3} \cdot \frac{|\mathcal{C}|}{|\mathcal{X}|} \geq \frac{1}{3|\mathcal{X}|} \cdot \left| \bigcup_{C \in \mathcal{C}} C \right|$$

where the second inequality follows from  $k \leq k'/3$  and the third inequality is due to the fact that the chains in  $\mathcal{C}$  are all disjoint and each of size  $k'$ . This completes the proof since this inequality holds for all  $g \in \mathcal{M}_{\mathcal{P},k}$ . ◁

We use the notation  $\mathcal{M}_{r,k}$  to denote the set of all  $k$ -monotone functions  $f: \{0, 1\}^d \rightarrow [r]$  over the hypercube whose image has at most  $r$  distinct values.

### 3 Lower Bound for Sample-Based Testers

In this section we prove Theorem 1, our lower bound on the sample-complexity of testing  $k$ -monotonicity of functions  $f: \{0, 1\}^d \rightarrow [r]$ . We refer the reader to Section 1.2.1 for a discussion of our main ideas and a proof sketch for the special case of  $k=1$  and  $r=2$ , i.e. *monotone Boolean* functions. Our proof follows the standard approach of defining a pair of distributions  $\mathcal{D}_{\text{yes}}, \mathcal{D}_{\text{no}}$  over functions  $f: \{0, 1\}^d \rightarrow [r]$  which satisfy the following:

- $\mathcal{D}_{\text{yes}}$  is supported over  $k$ -monotone functions.
- Functions drawn from  $\mathcal{D}_{\text{no}}$  are typically  $\Omega(\varepsilon)$ -far from  $k$ -monotone:  $\mathbb{P}_{f \sim \mathcal{D}_{\text{no}}}[\varepsilon(f, \mathcal{M}_{r,k}) = \Omega(\varepsilon)] = \Omega(1)$ .
- The distributions over labeled examples from  $\mathcal{D}_{\text{yes}}$  and  $\mathcal{D}_{\text{no}}$  are close in TV-distance.

Our construction uses a generalized version of a family functions known as random Talagrand DNFs, which were used by [4] and [33] to prove lower bounds for testing monotonicity of Boolean functions with adaptive and non-adaptive queries.

Let  $r, k$  satisfy  $rk \leq \frac{\varepsilon\sqrt{d}}{24300}$ . For convenience, we will assume that  $\frac{k(r-1)}{\varepsilon}$  and  $\sqrt{d}$  are integers and that  $\frac{k(r-1)}{\varepsilon}$  divides  $\sqrt{d}$ . Let  $L_\ell := \{x \in \{0, 1\}^d : |x| = \ell\}$  denote the  $\ell$ 'th Hamming level of the hypercube. We partition  $\bigcup_{\ell \in [0, \varepsilon\sqrt{d}]} L_{d/2+\ell}$  into  $k(r-1)$  blocks as follows. For each  $i \in [k(r-1)]$ , define

$$B_i = \bigcup_{\ell = i \cdot \frac{\varepsilon\sqrt{d}}{k(r-1)}}^{(i+1) \cdot \frac{\varepsilon\sqrt{d}}{k(r-1)} - 1} L_{\frac{d}{2} + \ell}.$$

The idea of our proof is to define a random DNF within each  $B_i$ . The *width* of each DNF will be set to  $w := \frac{(r-1)k\sqrt{d}}{2\varepsilon}$  and for each  $i$ , the number of terms in the DNF within  $B_i$  will be set to  $N_i := 2^w \cdot e^{-i} = 2^{\frac{(r-1)k\sqrt{d}}{2\varepsilon}(1-o(1))}$ . The DNF defined over  $B_i$  will assign function values from  $\{i \bmod (r-1), i \bmod (r-1) + 1\}$ . The terms in each DNF will be chosen randomly from the following distribution. We think of terms as points  $t \in \{0, 1\}^d$  in the hypercube where another point  $x$  *satisfies*  $t$  if  $t \preceq x$ , i.e.  $t_i = 1$  implies  $x_i = 1$ .

► **Definition 12** (Term distribution). *A term  $t \in \{0, 1\}^d$  is sampled from the distribution  $\mathcal{D}_{\text{term}}$  as follows. Form a (multi)-set  $S \subseteq [d]$  by choosing  $w$  independent uniform samples from  $[d]$ . For each  $a \in [d]$ , let  $t_a := \mathbf{1}(a \in S)$ .*

### 3.1 The Distributions $\mathcal{D}_{\text{yes}}$ and $\mathcal{D}_{\text{no}}$

We now define the yes and no distributions over functions  $f: \{0, 1\}^d \rightarrow [r]$ . For each  $i \in [k(r-1)]$ , choose terms  $t^{i,1}, \dots, t^{i,N_i}$  i.i.d. from  $\mathcal{D}_{\text{term}}$  and let  $\mathbf{t} = \{t^{i,j} : i \in [k(r-1)], j \in [N_i]\}$  denote the random set of all terms. Now, for each  $i \in [k(r-1)]$  and  $j \in [N_i]$ , define the set

$$U_{i,j} = \left\{ x \in B_i : x \succeq t^{i,j} \text{ and } x \not\succeq t^{i,j'} \text{ for all } j' \neq j \right\} \quad (1)$$

of all points in the  $i$ 'th block that satisfy the  $j$ 'th term *uniquely*. Let  $U_i = \bigcup_{j \in [N_i]} U_{i,j}$  denote the set of points in  $B_i$  that satisfy a unique term. The following claim is key to our result and motivates our choice of  $w$  and  $N_i$ . We defer its proof to Section 3.2.

► **Claim 13.** For any  $i \in [k(r-1)]$ ,  $j \in [N_i]$ , and  $x \in B_i$ , we have

$$\frac{1}{45N_i} \leq \mathbb{P}_{\mathbf{t}}[x \in U_{i,j}] \leq \frac{3}{N_i}.$$

As a corollary, we have  $\mathbb{P}_{\mathbf{t}}[x \in U_i] \geq 1/45$ .

Functions drawn from  $\mathcal{D}_{\text{yes}}$  are generated as follows. For each  $i \in [k(r-1)]$  choose a uniform random assignment

$$\phi_i: [N_i] \rightarrow \{i \bmod (r-1), i \bmod (r-1) + 1\} \text{ and let } \phi = (\phi_i : i \in [k(r-1)]).$$

For every  $x \in B_i$  define

$$f_{\mathbf{t},\phi}(x) = \begin{cases} i \bmod (r-1), & \text{if } \forall j \in [N_i], x \not\succeq t^{i,j} \\ i \bmod (r-1) + 1, & \text{if } \exists j \neq j' \in [N_i], x \succeq t^{i,j}, t^{i,j'} \\ \phi_i(j), & \text{if } x \in U_{i,j}. \end{cases}$$

## 37:12 Sample-Based Testing and Learning of $k$ -Monotone Functions

Functions drawn  $\mathcal{D}_{\text{no}}$  are generated as follows. For each  $i \in [k(r-1)]$  choose a uniform random function

$$\mathbf{r}_i: U_i \rightarrow \{i \bmod (r-1), i \bmod (r-1) + 1\} \text{ and let } \mathbf{r} = (\mathbf{r}_i: i \in [k(r-1)]).$$

For each  $x \in B_i$  define

$$f_{\mathbf{t}, \mathbf{r}}(x) = \begin{cases} i \bmod (r-1), & \text{if } \forall j \in [N_i], x \not\succeq t^{i,j} \\ i \bmod (r-1) + 1, & \text{if } \exists j \neq j' \in [N_i], x \succeq t^{i,j}, t^{i,j'} \\ \mathbf{r}_i(x), & \text{if } x \in U_i. \end{cases}$$

For  $x$  not belonging to any  $B_i$ : if  $|x| < \frac{d}{2}$ , then both the yes and no distributions assign value 0 and if  $|x| \geq \frac{d}{2} + \varepsilon\sqrt{d}$ , then both the yes and no distributions assign value  $r-1$ .

In summary, a function  $f_{\mathbf{t}, \phi} \sim \mathcal{D}_{\text{yes}}$  assigns the same random value  $\phi_i(j) \in \{i \bmod (r-1), i \bmod (r-1) + 1\}$  to all points in  $U_{i,j}$ , which results in a  $k$ -monotone function, whereas a function  $f_{\mathbf{t}, \mathbf{r}} \sim \mathcal{D}_{\text{no}}$  assigns an i.i.d. uniform random  $\{i \bmod (r-1), i \bmod (r-1) + 1\}$ -value to each point in  $U_i$ , resulting in a function that is far from being  $k$ -monotone. By construction, to detect any difference between these cases a tester will need to sample at least two points from the same  $U_{i,j}$ . Theorem 1 follows immediately from the following three lemmas.

► **Lemma 14.** *Every function in the support of  $\mathcal{D}_{\text{yes}}$  is  $k$ -monotone.*

**Proof.** Consider any  $f_{\mathbf{t}, \phi}(x) \in \text{supp}(\mathcal{D}_{\text{yes}})$ . For each  $a \in [k]$ , consider the union of  $r-1$  blocks formed by

$$Y_a := B_{a(r-1)} \cup B_{a(r-1)+1} \cup \dots \cup B_{(a+1)(r-1)-1}.$$

Recall that if  $|x| < d/2$ , then  $f_{\mathbf{t}, \phi}(x) = 0$  and if  $|x| \geq d/2 + \varepsilon\sqrt{d}$ , then  $f_{\mathbf{t}, \phi}(x) = r-1$ . If  $d/2 \leq |x| < d/2 + \varepsilon\sqrt{d}$ , then  $x \in \bigcup_{a \in [k]} Y_a$ . Therefore, it suffices to show that for any pair of comparable points  $x \prec y \in Y_a$ , we have  $f_{\mathbf{t}, \phi}(x) \leq f_{\mathbf{t}, \phi}(y)$ . Firstly, observe that by construction all points  $z \in B_{a(r-1)+b}$  have function value  $f_{\mathbf{t}, \phi}(z) \in \{b, b+1\}$ . Since  $x \prec y$ , if  $x$  and  $y$  are in different blocks, then  $x \in B_{a(r-1)+b}$  and  $y \in B_{a(r-1)+b'}$  where  $b < b'$  and so the inequality is satisfied. Therefore, we may assume  $x, y \in B_{a(r-1)+b}$  are in the same block. Since  $x \prec y$ , if  $t \prec x$  for some term  $t \in \text{supp}(\mathcal{D}_{\text{term}})$ , then  $t \prec y$  as well. I.e. the set of terms in  $B_{a(r-1)+b}$  satisfied by  $y$  is a superset of the set of terms in  $B_{a(r-1)+b}$  satisfied by  $x$ . By construction, this implies  $f_{\mathbf{t}, \phi}(x) \leq f_{\mathbf{t}, \phi}(y)$ . ◀

► **Lemma 15.** *For  $f_{\mathbf{t}, \mathbf{r}} \sim \mathcal{D}_{\text{no}}$ , we have  $\mathbb{P}_{\mathbf{t}, \mathbf{r}}[\varepsilon(f_{\mathbf{t}, \mathbf{r}}, \mathcal{M}_{r,k}) = \Omega(\varepsilon)] = \Omega(1)$ .*

We prove Lemma 15 in Section 3.4.

► **Lemma 16.** *Given a collection of points  $\mathbf{x} = (x_1, \dots, x_s) \in (\{0, 1\}^d)^s$  and a function  $f: \{0, 1\}^d \rightarrow [r]$ , let  $(\mathbf{x}, f(\mathbf{x})) = ((x_1, f(x_1)), \dots, (x_s, f(x_s)))$  denote the corresponding collection of labelled examples. Let  $\mathcal{E}_{\text{yes}}$  and  $\mathcal{E}_{\text{no}}$  denote the distributions over  $(\mathbf{x}, f(\mathbf{x}))$  when  $\mathbf{x}$  consists of  $s$  i.i.d. uniform samples and  $f \sim \mathcal{D}_{\text{yes}}$  and  $f \sim \mathcal{D}_{\text{no}}$ , respectively. If  $s \leq 2^{\frac{(r-1)k\sqrt{d}}{5\varepsilon}}$ , then the total variation distance between  $\mathcal{E}_{\text{yes}}$  and  $\mathcal{E}_{\text{no}}$  is  $o(1)$ .*

We prove Lemma 16 in Section 3.3.

### 3.2 Proof of Claim 13

Proof. Recall  $w = \frac{(r-1)k\sqrt{d}}{2\varepsilon}$ ,  $N_i = 2^w \cdot e^{-i}$ , the definition of  $\mathcal{D}_{\text{term}}$  from Definition 12, and the definition of  $U_{i,j}$  from Equation (1). Since  $x \in B_i$  we have  $|x| = \frac{d}{2} + \ell$  where  $\frac{i\varepsilon\sqrt{d}}{k(r-1)} \leq \ell < \frac{(i+1)\varepsilon\sqrt{d}}{k(r-1)}$ . Note that  $\mathbb{P}_{t \sim \mathcal{D}_{\text{term}}}[t \preceq x] = (|x|/d)^w$  since  $t \preceq x$  iff the non-zero coordinates of  $t$  are a subset of the non-zero coordinates of  $x$ . Therefore, we have

$$\mathbb{P}_{\mathbf{t}}[x \in U_{i,j}] = \mathbb{P}_{t^{i,j}}[t^{i,j} \preceq x] \cdot \prod_{j' \in [N_i] \setminus \{j\}} \mathbb{P}_{t^{i,j'}}[t^{i,j'} \not\preceq x] = (|x|/d)^w (1 - (|x|/d)^w)^{N_i - 1}.$$

Note that the first term is upper bounded as

$$(|x|/d)^w \leq \left( \frac{\frac{d}{2} + \frac{(i+1)\varepsilon\sqrt{d}}{k(r-1)}}{d} \right)^w = \frac{1}{2^w} \left( 1 + \frac{2\varepsilon}{k(r-1)\sqrt{d}} \cdot (i+1) \right)^w \leq \frac{e^{i+1+o(1)}}{2^w} \leq \frac{e^{1+o(1)}}{N_i}$$

and this immediately implies the upper bound on  $\mathbb{P}_{\mathbf{t}}[x \in U_{i,j}]$ . We can also lower bound this quantity by

$$(|x|/d)^w \geq \left( \frac{\frac{d}{2} + \frac{i\varepsilon\sqrt{d}}{k(r-1)}}{d} \right)^w = \frac{1}{2^w} \left( 1 + \frac{2\varepsilon}{k(r-1)\sqrt{d}} \cdot i \right)^w \geq \frac{e^{i-o(1)}}{2^w} \geq \frac{1}{e^{o(1)}N_i}.$$

Now, combining our upper and lower bounds on  $(|x|/d)^w$  yields

$$\mathbb{P}_{\mathbf{t}}[x \in U_{i,j}] \geq \frac{1}{e^{o(1)}N_i} \left( 1 - \frac{e^{1+o(1)}}{N_i} \right)^{N_i} \geq \frac{1}{e^{o(1)}N_i} e^{-(1+o(1)) \cdot e^{1+o(1)}} \geq \frac{1}{e^{e+1}N_i} \geq \frac{1}{45N_i}.$$

◁

### 3.3 $\mathcal{D}_{\text{yes}}$ and $\mathcal{D}_{\text{no}}$ are Hard to Distinguish: Proof of Lemma 16

**Proof.** Recall the definition of the set  $U_{i,j}$  in Equation (1). For  $a \neq b \in [s]$ , let  $E_{ab}$  denote the event that  $x_a$  and  $x_b$  belong to the same  $U_{i,j}$  for some  $i \in [k(r-1)]$  and  $j \in [N_i]$ . Observe that conditioned on  $\bigvee_{a,b} E_{ab}$ , the distributions  $\mathcal{E}_{\text{yes}}$  and  $\mathcal{E}_{\text{no}}$  are identical. Let  $x, y \in \{0, 1\}^d$  denote two i.i.d. uniform samples. We have

$$\begin{aligned} \mathbb{P}[E_{ab}] &= \mathbb{P}_{x,y,\mathbf{t}} \left[ \bigvee_{i,j} (x \in U_{i,j} \wedge y \in U_{i,j}) \right] \\ &= \sum_{i,j} \mathbb{P}_{x,y,\mathbf{t}} [x \in U_{i,j} \wedge y \in U_{i,j}] = \sum_{i,j} \mathbb{P}_{x,\mathbf{t}} [x \in U_{i,j}]^2 \end{aligned} \quad (2)$$

where the first step holds since the  $U_{i,j}$ 's are disjoint and the second step holds by independence of  $x$  and  $y$ . Now, for a fixed  $i \in [k(r-1)]$  and  $j \in [N_i]$  we have the following: by Claim 13, for  $x \in B_i$  we have  $\mathbb{P}_{\mathbf{t}}[x \in U_{i,j}] \leq \frac{3}{N_i}$  and for  $x \notin B_i$  we have  $\mathbb{P}_{\mathbf{t}}[x \in U_{i,j}] = 0$ . Therefore  $\mathbb{P}_{x,\mathbf{t}}[x \in U_{i,j}] \leq \frac{3}{N_i}$ . Therefore, the RHS of Equation (2) is bounded as

$$\sum_{i,j} \mathbb{P}_{x,\mathbf{t}} [x \in U_{i,j}]^2 \leq \sum_i N_i \cdot \mathbb{P}_{x,\mathbf{t}} [x \in U_{i,j}]^2 \leq \sum_i \frac{9}{N_i} \leq rk \cdot \frac{9}{N_{k(r-1)-1}}$$

since the  $N_i$ 's are decreasing with respect to  $i$ . Therefore,

$$d_{TV}(\mathcal{E}_{\text{yes}}, \mathcal{E}_{\text{no}}) \leq \mathbb{P}_{\mathbf{t}} \left[ \bigvee_{a,b \in [s]} E_{ab} \right] \leq s^2 \cdot rk \cdot \frac{9}{N_{k(r-1)-1}} = o(1)$$

since  $N_{k(r-1)-1} = 2^{\frac{(r-1)k\sqrt{d}}{2\varepsilon}} (1-o(1)) = \omega(s^2 \cdot rk)$ .

◀

### 3.4 Functions Drawn from $\mathcal{D}_{\text{no}}$ are Far from $k$ -Monotone: Proof of Lemma 15

**Proof.** We will use Claim 11, restated below for the special case of  $r$ -valued functions over the hypercube. Recall that  $\mathcal{M}_{r,k}$  is the set of  $k$ -monotone functions  $f: \{0,1\}^d \rightarrow [r]$ .

▷ **Claim 17.** Let  $f: \{0,1\}^d \rightarrow [r]$  and  $k' \geq 3k$  be an integer. Let  $\mathcal{C} \subset (\{0,1\}^d)^{k'}$  be a collection of disjoint  $k'$ -alternating chains for  $f$ . Then

$$\varepsilon(f, \mathcal{M}_{r,k}) \geq \frac{1}{3 \cdot 2^d} \cdot \left| \bigcup_{C \in \mathcal{C}} C \right|.$$

From the above claim, we can lower bound the distance to  $k$ -monotonicity of  $f$  by showing that it contains a collection of disjoint  $k'$ -alternating chains where  $k' \geq 3k$  whose union makes up an  $\Omega(\varepsilon)$ -fraction of the hypercube.

Recall  $U_i = U_{i,1} \cup \dots \cup U_{i,N_i} \subseteq B_i$  and note that  $f_{\mathbf{t},\mathbf{r}} \sim \mathcal{D}_{\text{no}}$  takes values only from  $\{i \bmod (r-1), i \bmod (r-1) + 1\}$  in  $B_i$ . In particular, for  $a \in \{0, 1, \dots, r-2\}$ , let

$$X_a = B_a \cup B_{(r-1)+a} \cup B_{2(r-1)+a} \cup \dots \cup B_{(k-1)(r-1)+a} = \bigcup_{i \in [k]} B_{i(r-1)+a} \quad (3)$$

and note that all points  $x \in X_a$  are assigned value  $f_{\mathbf{t},\mathbf{r}}(x) \in \{a, a+1\}$ . Moreover, this value is chosen uniformly at random when  $x \in \bigcup_{i \in [k]} U_{i(r-1)+a}$ , which occurs with probability  $\geq 1/45$  by Claim 13. Let  $k'' := \frac{\varepsilon\sqrt{d}}{r-1}$  and recall that we are assuming  $rk \leq \frac{\varepsilon\sqrt{d}}{24300}$  and so  $k'' \geq 24300k$ . We first show there exists a large collection  $\mathcal{C}_a$  of length- $k''$  disjoint chains in  $X_a$  for all  $a \in \{0, 1, \dots, r-2\}$ .

▷ **Claim 18.** For every  $a \in \{0, 1, \dots, r-2\}$ , there exists a collection of vertex disjoint chains  $\mathcal{C}_a \subset (X_a)^{k''}$  in  $X_a$  of length  $k''$  of size  $|\mathcal{C}_a| \geq \Omega(\frac{2^d}{\sqrt{d}})$ .

**Proof.** We start by showing that there is a large matching in the transitive closure of the hypercube from  $L_{\frac{d}{2}}$  to  $L_{\frac{d}{2}+\varepsilon\sqrt{d}-1}$ . Consider the bipartite graph  $(U, V, E)$  where  $U := L_{\frac{d}{2}}$ ,  $V := L_{\frac{d}{2}+\varepsilon\sqrt{d}-1}$ , and  $E := \{(x, y) \in U \times V: x \prec y\}$ . Observe that vertices in  $U$  have degree exactly  $\Delta := \binom{\frac{d}{2}}{\varepsilon\sqrt{d}-1}$  while vertices in  $V$  have degree exactly  $\binom{\frac{d}{2}+\varepsilon\sqrt{d}-1}{\varepsilon\sqrt{d}-1} \geq \Delta$ . Note also that  $|V| = \binom{\frac{d}{2}+\varepsilon\sqrt{d}-1}{\varepsilon\sqrt{d}-1} \geq \Omega(\frac{2^d}{\sqrt{d}})$  by Stirling's approximation. We now use the following claim from [10].

▷ **Claim 19 (Claim 5.10 of [10]).** Let  $(U, V, E)$  be a bipartite graph and  $\Delta > 0$  be such that (a) each vertex  $x \in U$  has degree exactly  $\Delta$  and (b) each vertex  $y \in V$  has degree at least  $\Delta$ . Then there exists a matching  $M \subseteq E$  in  $(U, V, E)$  of size  $|M| \geq \frac{1}{2}|V|$ .

By the above claim and the previous observations, there exist subsets  $S \subseteq L_{\frac{d}{2}}$  and  $T \subseteq L_{\frac{d}{2}+\varepsilon\sqrt{d}-1}$  of size  $|S| = |T| = \Omega(\frac{2^d}{\sqrt{d}})$  and a bijection  $\phi: S \rightarrow T$  satisfying  $x \prec \phi(x)$  for all  $x \in S$ . We now use the following routing theorem due to Lehman and Ron to obtain a collection of disjoint chains from  $S$  to  $T$ .

► **Theorem 20 (Lehman-Ron, [56]).** Let  $a < b$  and  $S \subseteq L_a$ ,  $T \subseteq L_b$  where  $m := |S| = |T|$ . Moreover, suppose there is a bijection  $\phi: S \rightarrow T$  satisfying  $x \prec \phi(x)$  for all  $x \in S$ . Then there exist  $m$  vertex disjoint paths from  $S$  to  $T$  in the hypercube.

Now, invoking the above theorem on our bijection  $\phi: S \rightarrow T$  yields a collection  $P$  of  $|P| \geq \Omega(\frac{2^d}{\sqrt{d}})$  vertex disjoint paths from  $L_{\frac{d}{2}}$  to  $L_{\frac{d}{2} + \varepsilon\sqrt{d}-1}$ . For each  $a \in \{0, 1, \dots, r-2\}$ , let  $\mathcal{C}_a$  denote the collection of chains formed by taking a path in  $P$  and including only the vertices from  $X_a$  (recall Equation (3)). Note that the resulting chains in  $\mathcal{C}_a$  are of length  $k'' = \frac{\varepsilon\sqrt{d}}{r-1}$ . This completes the proof of Claim 18.  $\blacktriangleleft$

From Claim 18, we have  $\mathcal{C}_0, \mathcal{C}_1, \dots, \mathcal{C}_{r-2}$  where each  $\mathcal{C}_a \subset (X_a)^{k''}$  is a collection of vertex disjoint chains of length  $k'' \geq 24300k$  of size  $|\mathcal{C}_a| \geq \Omega(\frac{2^d}{\sqrt{d}})$ . Fix a chain  $C = (x_1, x_2, \dots, x_{k''}) \in \mathcal{C}_a$ . Let  $A(C)$  be the random variable which denotes the max-length alternating sub-chain (recall Definition 9) of  $C$  over a random  $f_{\mathbf{t}, \mathbf{r}} \sim \mathcal{D}_{\text{no}}$ . Fix  $x_j$  in the chain and suppose  $x_j \in B_i \subseteq X_a$ . By Claim 13,  $\mathbb{P}_{\mathbf{t}}[x_j \in U_i] \geq 1/45$ . Moreover, conditioned on  $x_j \in U_i$ ,  $f_{\mathbf{t}, \mathbf{r}}(x_j)$  is chosen from  $\{a, a+1\}$  uniformly at random. Thus, any step of the sequence

$$(1, f_{\mathbf{t}, \mathbf{r}}(x_2) - f_{\mathbf{t}, \mathbf{r}}(x_1), f_{\mathbf{t}, \mathbf{r}}(x_3) - f_{\mathbf{t}, \mathbf{r}}(x_2), \dots, f_{\mathbf{t}, \mathbf{r}}(x_{k''}) - f_{\mathbf{t}, \mathbf{r}}(x_{k''-1}))$$

is non-zero *and* differs in sign from the previous non-zero step with probability at least  $1/90$  and so  $\mathbb{E}[A(C)] \geq k''/90$ . I.e.,  $0 \leq \mathbb{E}[k'' - A(C)] < k''(1 - \frac{1}{90})$ . Thus, using Markov's inequality we have

$$\mathbb{P}\left[A(C) < \frac{k''}{8100}\right] = \mathbb{P}\left[k'' - A(C) > k''\left(1 - \frac{1}{90}\right)\left(1 + \frac{1}{90}\right)\right] \leq \frac{1}{(1 + \frac{1}{90})} = 1 - \frac{1}{91}. \quad (4)$$

Now, let  $\mathcal{C} = \mathcal{C}_0 \cup \mathcal{C}_1 \cup \dots \cup \mathcal{C}_{r-2}$  and let  $Z := |\{C \in \mathcal{C} : A(C) \geq \frac{k''}{8100}\}|$ . By Equation (4) we have  $\mathbb{E}[Z] \geq |\mathcal{C}|/91$  and  $0 \leq \mathbb{E}[|\mathcal{C}| - Z] \leq |\mathcal{C}|(1 - \frac{1}{91})$ . Again using Markov's inequality, we have

$$\mathbb{P}\left[Z < \frac{|\mathcal{C}|}{8281}\right] = \mathbb{P}\left[|\mathcal{C}| - Z > |\mathcal{C}|\left(1 - \frac{1}{91}\right)\left(1 + \frac{1}{91}\right)\right] \leq \frac{1}{(1 + \frac{1}{91})} = 1 - \frac{1}{92}. \quad (5)$$

Now, for  $C \in \mathcal{C}$  such that  $A(C) \geq k''/8100$ , let  $C'$  be any  $(k''/8100)$ -alternating sub-chain of  $C$ . Let  $\mathcal{C}' = \{C' : C \in \mathcal{C} \text{ such that } A(C) \geq k''/8100\}$  which is a collection of disjoint  $(k''/8100)$ -alternating chains for  $f_{\mathbf{t}, \mathbf{r}}$ . Now, recall that  $k'' \geq 24300k$  and so  $k''/8100 \geq 3k$ . Thus, if  $Z \geq |\mathcal{C}|/8281$ , then  $|\mathcal{C}'| \geq |\mathcal{C}|/8281$  and so by Claim 17 we have

$$\varepsilon(f_{\mathbf{t}, \mathbf{r}}, \mathcal{M}_{r, k}) \geq \frac{1}{3 \cdot 2^d} \left| \bigcup_{C' \in \mathcal{C}'} C' \right| \geq \frac{1}{3 \cdot 2^d} \cdot |\mathcal{C}'| \cdot \frac{k''}{8100} \geq \frac{k'' \cdot |\mathcal{C}|}{201, 228, 300 \cdot 2^d} \quad (6)$$

By Claim 18 we have  $|\mathcal{C}| \geq (r-1) \cdot \Omega(\frac{2^d}{\sqrt{d}})$  and recall that  $k'' = \frac{\varepsilon\sqrt{d}}{r-1}$ . Thus, the RHS of Equation (6) is  $\Omega(\varepsilon)$ . In conclusion,

$$\mathbb{P}_{\mathbf{t}, \mathbf{r}}[\varepsilon(f_{\mathbf{t}, \mathbf{r}}, \mathcal{M}_{r, k}) \geq \Omega(\varepsilon)] \geq \mathbb{P}\left[Z \geq \frac{|\mathcal{C}|}{8281}\right] \geq \frac{1}{92}$$

by Equation (5) and this completes the proof of Lemma 15.  $\blacktriangleleft$

## 4 Learning Upper Bound over Product Spaces

In this section we prove Theorem 6, our upper bound for learning measurable  $k$ -monotone functions in  $\mathbb{R}^d$ . We restate the theorem below without any hidden logarithmic factors and for the case of  $r = 2$ . The theorem for general  $r \geq 2$  can then be obtained by replacing  $\varepsilon$  with  $\varepsilon/r$  and  $\delta$  by  $1/3r$  following the same approach we used to prove Theorem 3 in Section 1.5.

## 37:16 Sample-Based Testing and Learning of $k$ -Monotone Functions

► **Theorem 21.** *Given an arbitrary product measure  $\mu$ , there is a learning algorithm under  $\mu$  which learns any measurable  $k$ -monotone function  $f: \mathbb{R}^d \rightarrow \{\pm 1\}$  to error  $\varepsilon$  with probability  $1 - \delta$  with time and sample complexity*

$$\ln\left(\frac{1}{\delta}\right) \cdot \min\left\{\left(d \log(dk/\varepsilon)\right)^{O\left(\frac{k}{\varepsilon} \sqrt{d \log(dk/\varepsilon)}\right)}, \left(\frac{dk}{\varepsilon}\right)^{O(d)}\right\} \quad (7)$$

Our proof uses downsampling to reduce our learning problem over  $\mathbb{R}^d$  to learning over a hypergrid,  $[N]^d$ , under the uniform distribution with mild label noise. In Section 4.1 we synthesize the results from [49] which we borrow for our proof. In Section 4.2 we give two learning results for hypergrids whose time complexities correspond to the two arguments inside the min expression in Equation (7). In Section 4.3 we describe the learning algorithm and prove its correctness.

Throughout this section, let  $\mu = \prod_{i=1}^d \mu_i$  be any product measure over  $\mathbb{R}^d$  and let  $N$  be a power of two satisfying  $8kd/\varepsilon \leq N \leq 16kd/\varepsilon$ .

### 4.1 Reduction to Hypergrids via Downsampling

The idea of downsampling is to construct a grid-partition of  $\mathbb{R}^d$  into  $N^d$  blocks such that (a) the measure of each block under  $\mu$  is roughly  $N^{-d}$ , and (b) the function  $f$  we're trying to learn is constant on most of the blocks. Roughly speaking, this allows us to learn  $f$  under  $\mu$  by learning a proxy for  $f$  over  $[N]^d$  under the uniform distribution. The value of  $N$  needed to achieve this depends on what [49] call the “block boundary size” of the function. Formally, the downsampling procedure constructs query access to maps  $\text{block}: \mathbb{R}^d \rightarrow [N]^d$  and  $\text{blockpoint}: [N]^d \rightarrow \mathbb{R}^d$  which have various good properties which we will spell out in the rest of this section. One should think of  $\text{block}$  as mapping each point  $x \in \mathbb{R}^d$  to the block of the grid-partition that  $x$  belongs to and  $\text{blockpoint}$  as mapping each block to some specific point contained in the block. See [49, Def 2.1] for a formal definition. Given these maps and a function  $f: \mathbb{R}^d \rightarrow \{\pm 1\}$  we define the function  $f^{\text{block}}: [N]^d \rightarrow \{\pm 1\}$  as  $f^{\text{block}}(z) = f(\text{blockpoint}(z))$ . We let  $\text{block}(\mu)$  denote the distribution over  $[N]^d$  induced by sampling  $x \sim \mu$  and then taking  $\text{block}(x)$ .

► **Proposition 22** (Downsampling, [49]). *Let  $f: \mathbb{R}^d \rightarrow \{0, 1\}$  be a  $k$ -monotone function and  $N, Q \in \mathbb{Z}^+$ . Using*

$$m := O\left(\frac{NQ^2 d^2}{\min(\delta, \varepsilon)^2} \ln\left(\frac{Nd}{\delta}\right)\right)$$

*samples from  $\mu = \mu_1 \times \dots \times \mu_d$ , there is a downsampling procedure that constructs query access to maps  $\text{block}: \mathbb{R}^d \rightarrow [N]^d$  and  $\text{blockpoint}: [N]^d \rightarrow \mathbb{R}^d$  such that with probability at least  $1 - \delta$  over the random samples, the following two conditions are satisfied:*

1.  $\|\text{block}(\mu) - \text{unif}([N]^d)\|_{TV} \leq \frac{\delta}{Q}$ .
2.  $\mathbb{P}_{x \sim \mu} [f(x) \neq f^{\text{block}}(\text{block}(x))] \leq \varepsilon$ .

*The total running time and number of samples is  $O(m)$ .*

**Proof.** [49, Prop. 2.5] shows that there is a randomized procedure using  $m$  samples from  $\mu$  and  $O(m)$  time which constructs the maps  $\text{block}$  and  $\text{blockpoint}$  such that with probability 1, we get

$$\mathbb{P}_{x \sim \mu} [f(x) \neq f^{\text{block}}(\text{block}(x))] \leq N^{-d} \cdot \text{bbs}(f, N) + \|\text{block}(\mu) - \text{unif}([N]^d)\|_{TV} \quad (8)$$

where  $\text{bbs}(f, N)$  is the  $N$ -block boundary size of  $f$  [49, Def. 2.4], which is at most  $kdN^{d-1}$  when  $f$  is  $k$ -monotone [49, Lemma 7.1]. Thus, the first of the two quantities in the RHS is at most  $kd/N$  which is at most  $\varepsilon/8$  using our definition of  $N$ . Then, [49, Lemma 2.7] states that

$$\mathbb{P} \left[ \left\| \text{block}(\mu) - \text{unif}([N]^d) \right\|_{\text{TV}} > \beta \right] \leq 4Nd \cdot \exp \left( -\frac{\beta^2 m}{18Nd^2} \right) \quad (9)$$

and so invoking this lemma with  $\beta := \min(\delta/4Q, \varepsilon/8)$  and  $m := \frac{18Nd^2}{\beta^2} \ln \left( \frac{16Nd}{\delta} \right)$  completes the proof.  $\blacktriangleleft$

## 4.2 Learning over Hypergrids

For a function  $f: \mathcal{X} \rightarrow \{\pm 1\}$  and a measure  $\mu$  over  $\mathcal{X}$ , recall that the *example oracle* for  $f$  under  $\mu$ , denoted by  $EX(f, \mu)$ , when queried, generates an example,  $(x, f(x))$ , where  $x$  is sampled from  $\mu$ . Given a *noise parameter*  $\eta$ , the *noisy example oracle*  $EX^\eta(f, \mu)$ , when queried, samples  $x$  from  $\mu$ , returns the true example  $(x, f(x))$  with probability  $1 - \eta$ , and returns the corrupted example  $(x, -f(x))$  with probability  $\eta$ . This is referred to as *random classification noise* (RCN).

We prove the following two upper bounds for learning over hypergrids under RCN. The bound in Lemma 23 is relatively straightforward to prove using coupon collector arguments plus some additional work to handle the label noise. We give a proof in the appendix (see Section B in the full version of the paper).

► **Lemma 23** (Coupon Collecting Learner). *Let  $\varepsilon, \delta \in (0, 1)$ ,  $\eta \in (0, 1/2)$ , and  $N \in \mathbb{Z}^+$ . There is an algorithm which, given any  $k$ -monotone function  $f: [N]^d \rightarrow \{\pm 1\}$ , uses at most*

$$\tilde{O} \left( \frac{1}{(1-2\eta)^2} \left( \log \frac{1}{\varepsilon} + \log \frac{1}{\delta} \right) \right) \cdot N^{O(d)}$$

*examples from  $EX^\eta(f, \text{unif}([N]^d))$  and returns  $h: [N]^d \rightarrow \{\pm 1\}$ , satisfying  $\mathbb{P}_h[d(f, h) \leq \varepsilon] \geq 1 - \delta$ .*

► **Lemma 24** (Hypercube Mapping Learner). *Let  $\varepsilon, \delta \in (0, 1)$ ,  $\eta \in (0, 1/2)$ , and  $N \in \mathbb{Z}^+$  be a power of two. There is an algorithm which, given any  $k$ -monotone function  $f: [N]^d \rightarrow \{\pm 1\}$ , uses at most*

$$O \left( \frac{1}{\varepsilon^2(1-2\eta)^2} + \log \frac{1}{\delta} \right) (d \log N)^{O\left(\frac{k}{\varepsilon} \sqrt{d \log N}\right)}$$

*examples from  $EX^\eta(f, \text{unif}([N]^d))$  and returns  $h: [N]^d \rightarrow \{\pm 1\}$ , satisfying  $\mathbb{P}_h[d(f, h) \leq \varepsilon] \geq 1 - \delta$ .*

**Proof.** Let  $b: [N] \rightarrow \{\pm 1\}^{\log N}$  denote the bijection which maps each element of  $[N]$  to its bit representation. Let  $\mathbf{b}: [N]^d \rightarrow \{\pm 1\}^{d \log N}$  be defined as  $\mathbf{b}(x) = (b(x_1), \dots, b(x_d))$ . Given  $f: [N]^d \rightarrow \{\pm 1\}$  define the function  $f^{\text{cube}}: \{\pm 1\}^{d \log N} \rightarrow \{\pm 1\}$  as  $f^{\text{cube}}(z) = f(\mathbf{b}^{-1}(z))$ .

► **Observation 25.** *If  $f$  is  $k$ -monotone over  $[N]^d$ , then  $f^{\text{cube}}$  is  $k$ -monotone over  $\{\pm 1\}^{d \log N}$ .*

**Proof.** Observe that if  $\mathbf{b}(x) \prec \mathbf{b}(y)$  in  $\{\pm 1\}^{d \log N}$ , then  $x \prec y$  in  $[N]^d$ . Thus, if  $\mathbf{b}(x_1) \prec \dots \prec \mathbf{b}(x_m)$  is an  $m$ -alternating chain for  $f^{\text{cube}}$ , then  $x_1 \prec \dots \prec x_m$  is an  $m$ -alternating chain for  $f$ . Therefore, if  $f^{\text{cube}}$  is not  $k$ -monotone, then neither is  $f$ .  $\blacktriangleleft$

## 37:18 Sample-Based Testing and Learning of $k$ -Monotone Functions

Now, given Observation 25 and the bijection  $\mathbf{b}: [N]^d \rightarrow \{\pm 1\}^{d \log N}$ , it suffices to provide a learning algorithm for  $f^{\text{cube}}$ . This is achieved using the Low-Degree Algorithm introduced by [57] which was shown by [50] to be robust to classification noise. Formally, we use the following theorem, which we prove in the appendix for the sake of completeness (see Section A in the full version of the paper).

► **Theorem 26** (Low-Degree Algorithm with Classification Noise). *Let  $\varepsilon, \delta \in (0, 1)$  and  $\eta \in (0, 1/2)$ . Suppose  $\mathcal{C}$  is a concept class of Boolean functions over  $\{\pm 1\}^d$  such that for some fixed positive integer  $\tau$ , all  $f \in \mathcal{C}$  satisfy  $\sum_{S \subseteq [d]: |S| > \tau} \widehat{f}(S)^2 \leq \varepsilon/2$ . Then there is an algorithm  $\mathcal{A}$  which, on any input  $f \in \mathcal{C}$ , uses at most*

$$O\left(\left(\frac{1}{\varepsilon^2(1-2\eta)^2} + \log \frac{1}{\delta}\right) \cdot d^\tau\right)$$

*examples from  $EX^\eta(f, \text{unif}(\{\pm 1\}^d))$  and returns a hypothesis  $h: \{\pm 1\}^d \rightarrow \{\pm 1\}$  where  $\mathbb{P}_h[d(f, h) \leq \varepsilon] \geq 1 - \delta$ .*

We use the following Fourier concentration lemma due to [17] for  $k$ -monotone Boolean functions.

► **Lemma 27** ([17]). *If  $f: \{\pm 1\}^d \rightarrow \{\pm 1\}$  is  $k$ -monotone, then  $\sum_{S: |S| > \frac{k\sqrt{d}}{\varepsilon}} \widehat{f}(S)^2 \leq \varepsilon$ .*

By Lemma 27, we can invoke Theorem 26 with  $\tau = \frac{k\sqrt{d \log N}}{\varepsilon}$ , concluding the proof of Lemma 24. ◀

### 4.3 Putting it Together: Proof of Theorem 21

**Proof.** We now have all the tools to define the algorithm and prove its correctness.

■ **Algorithm 1** Learning algorithm for  $k$ -monotone functions under product measure  $\mu$ .

---

**Input:**  $\varepsilon, \delta \in (0, 1)$  and access to examples from  $EX(f, \mu)$  where  $f: \mathbb{R}^d \rightarrow \{\pm 1\}$  is  $k$ -monotone;

1. Let  $N$  be a power of 2 such that  $\frac{8kd}{\varepsilon} \leq N \leq \frac{16kd}{\varepsilon}$ . Let  $\mathcal{A}$  denote the learning algorithm for  $k$ -monotone functions  $g: [N]^d \rightarrow \{\pm 1\}$  which has the smaller sample-complexity among the algorithms guaranteed by Lemma 23 and Lemma 24. Let  $Q$  be the sample-complexity of  $\mathcal{A}$ ;
2. Run the downsampling procedure of Proposition 22 to obtain the maps **block**, **blockpoint**, and access to the corresponding function  $f^{\text{block}}: [N]^d \rightarrow \{\pm 1\}$ ;
3. Obtain a set of  $Q$  examples  $S \in (\mathbb{R}^d \times \{\pm 1\})^Q$  from  $(EX(f, \mu))^Q$ ;
4. Let  $S^{\text{block}} = \{(\text{block}(x), f(x)): (x, f(x)) \in S\} \in ([N]^d \times \{\pm 1\})^Q$ ;
5. Run  $\mathcal{A}$  using the sample  $S^{\text{block}}$ , which returns a hypothesis  $h^{\text{block}}: [N]^d \rightarrow \{\pm 1\}$  for  $f^{\text{block}}$ ;

**Return** the hypothesis  $h: \mathbb{R}^d \rightarrow \{\pm 1\}$  for  $f: \mathbb{R}^d \rightarrow \{\pm 1\}$  defined as  $h(x) = h^{\text{block}}(\text{block}(x))$

---

Recall that given maps  $\text{block}: \mathbb{R}^d \rightarrow [N]^d$ ,  $\text{blockpoint}: [N]^d \rightarrow \mathbb{R}^d$ , and a function  $f: \mathbb{R}^d \rightarrow \{\pm 1\}$  we define the function  $f^{\text{block}}: [N]^d \rightarrow \{\pm 1\}$  as  $f^{\text{block}}(z) = f(\text{blockpoint}(z))$ . Recall that  $\text{block}(\mu)$  is the distribution over  $\text{block}(x) \in [N]^d$  when  $x \sim \mu$ . By Proposition 22, step (2) of Alg. 1 results in the following items being satisfied with probability at least  $1 - \delta$ .

1.  $\|\text{block}(\mu) - \text{unif}([N]^d)\|_{\text{TV}} \leq \frac{\delta}{Q}$ .
2.  $\mathbb{P}_{x \sim \mu} [f(x) \neq f^{\text{block}}(\text{block}(x))] \leq \varepsilon$ .

Firstly, by item (2), an example  $(\text{block}(x), f(x))$  where  $x \sim \mu$ , is equivalent to an example  $(z, b) \sim EX^\eta(f^{\text{block}}, \text{block}(\mu))$  for some  $\eta \leq \varepsilon$ . I.e. the set  $S^{\text{block}} \in ([N]^d \times \{\pm 1\})^Q$  from step (4) of Alg. 1 is distributed according to  $(EX^\eta(f^{\text{block}}, \text{block}(\mu)))^Q$ . Now, as stated, Lemma 23 and Lemma 24 only hold when  $\mathcal{A}$  is given a sample from  $(EX^\eta(f^{\text{block}}, \text{unif}([N]^d)))^Q$ . However, the following claim shows that since  $\text{block}(\mu)$  and  $\text{unif}([N]^d)$  are sufficiently close (item (1) above), the guarantees on  $\mathcal{A}$  from Lemma 23 and Lemma 24 also hold when  $\mathcal{A}$  is given a sample from  $(EX^\eta(f^{\text{block}}, \text{block}(\mu)))^Q$ .

▷ **Claim 28.** Let  $\mathcal{C}: \mathcal{X} \rightarrow \{\pm 1\}$  be a concept class and let  $\mathcal{A}$  be an algorithm which given any  $f \in \mathcal{C}$ ,  $\varepsilon, \delta \in (0, 1)$ , and  $\eta \in [0, 1/2)$  uses a sample from  $(EX^\eta(f, \text{unif}([N]^d)))^Q$  and produces  $h$  satisfying  $\mathbb{P}_{x \sim \text{unif}([N]^d)}[h(x) \neq f(x)] \leq \varepsilon$  with probability at least  $1 - \delta$ . If  $\mathcal{D}$  is a distribution over  $[N]^d$  with  $\|\mathcal{D} - \text{unif}([N]^d)\|_{TV} \leq \gamma$ , then given a sample from  $(EX^\eta(f, \mathcal{D}))^Q$ ,  $\mathcal{A}$  produces  $h$  satisfying  $\mathbb{P}_{x \sim \mathcal{D}}[h(x) \neq f(x)] \leq \varepsilon + \gamma$  with probability at least  $1 - (\delta + \gamma Q)$ .

Using Claim 28 and item (1) above, if step (2) of Alg. 1 succeeds, then with probability at least  $1 - 2\delta$ , step (5) produces  $h^{\text{block}}$  such that  $\mathbb{P}_{z \sim \text{block}(\mu)}[h^{\text{block}}(z) \neq f^{\text{block}}(z)] \leq 2\varepsilon$ . By the triangle inequality and using our definition of  $h$  in the return statement of Alg. 1, we have

$$\begin{aligned} & \mathbb{P}_{x \sim \mu}[h(x) \neq f(x)] \\ & \leq \mathbb{P}_{x \sim \mu}[f(x) \neq f^{\text{block}}(\text{block}(x))] + \mathbb{P}_{x \sim \mu}[f^{\text{block}}(\text{block}(x)) \neq h^{\text{block}}(\text{block}(x))] \\ & = \mathbb{P}_{x \sim \mu}[f(x) \neq f^{\text{block}}(\text{block}(x))] + \mathbb{P}_{z \sim \text{block}(\mu)}[f^{\text{block}}(z) \neq h^{\text{block}}(z)]. \end{aligned} \quad (10)$$

The first term in the RHS is at most  $\varepsilon$  by item (2) above and the second term is at most  $2\varepsilon$  as we argued in the previous paragraph. Finally, adding up the failure probabilities of steps (2) and (5), we conclude that Alg. 1 produces  $h$  satisfying  $\mathbb{P}_{x \sim \mu}[h(x) \neq f(x)] \leq 3\varepsilon$  with probability at least  $1 - 3\delta$ . ◀

### 4.3.1 Proof of Claim 28

*Proof.* It is a well-known fact that for two distributions  $\mathcal{D}_1$  and  $\mathcal{D}_2$ , the TV-distance between the corresponding product distributions satisfies  $\|\mathcal{D}_1^Q - \mathcal{D}_2^Q\|_{TV} \leq Q \|\mathcal{D}_1 - \mathcal{D}_2\|_{TV}$  and thus we have

$$\|\mathcal{D}^Q - \text{unif}([N]^d)^Q\|_{TV} \leq \gamma Q$$

Given a set of  $Q$  examples  $S \in ([N]^d \times \{\pm 1\})^Q$ , let  $E(S)$  denote the event that the algorithm  $\mathcal{A}$  fails to produce a hypothesis with error at most  $\varepsilon$ , after sampling  $S$ . First, note the distribution over labels for the distributions are the same, and therefore

$$\begin{aligned} & \mathbb{P}_{S \sim (EX^\eta(f, \mathcal{D}))^Q}[E(S)] - \mathbb{P}_{S \sim (EX^\eta(f, \text{unif}([N]^d)))^Q}[E(S)] \\ & = \mathbb{P}_{S \sim \mathcal{D}^Q}[E(S)] - \mathbb{P}_{S \sim \text{unif}([N]^d)^Q}[E(S)]. \end{aligned} \quad (11)$$

Using the definition of TV-distance we have

$$\mathbb{P}_{S \sim \mathcal{D}^Q}[E(S)] - \mathbb{P}_{S \sim \text{unif}([N]^d)^Q}[E(S)] \leq \|\mathcal{D}^Q - \text{unif}([N]^d)^Q\|_{TV} \leq \gamma Q \quad (12)$$

and therefore

$$\mathbb{P}_{S \sim (EX^\eta(f, \mathcal{D}))^Q}[E(S)] \leq \mathbb{P}_{S \sim (EX^\eta(f, \text{unif}([N]^d)))^Q}[E(S)] + \gamma Q \leq \delta + \gamma Q \quad (13)$$

where we used  $\mathbb{P}_{S \sim (EX^\eta(f, \text{unif}([N]^d)))^\circ} [E(S)] \leq \delta$  by the assumption in the statement of the claim. Now, conditioned on  $\neg E(S)$ , we have that  $\mathcal{A}$  produces  $h$  satisfying  $\mathbb{P}_{x \sim \text{unif}([N]^d)} [h(x) \neq f(x)] \leq \varepsilon$ . Again using our bound on the TV-distance, we have

$$\mathbb{P}_{x \sim \mathcal{D}} [h(x) \neq f(x)] - \mathbb{P}_{x \sim \text{unif}([N]^d)} [h(x) \neq f(x)] \leq \|\mathcal{D} - \text{unif}([N]^d)\|_{TV} \leq \gamma$$

and so  $\mathbb{P}_{x \sim \mathcal{D}} [h(x) \neq f(x)] \leq \varepsilon + \gamma$ .  $\triangleleft$

## 5 Sample-Based Testing with One-Sided Error

In this section we prove Theorem 5, our upper and lower bound on sample-based testing with one-sided error over the hypercube.

**Proof of Theorem 5.** By a coupon-collecting argument, there is an  $O(d \cdot 2^d)$  sample upper bound for *exactly learning* any function over  $\{0, 1\}^d$  under the uniform distribution and therefore the upper bound is trivial.

It suffices to prove the lower bound for the case of  $r = 2$  and  $k = 1$ , i.e. for testing monotonicity of Boolean functions. We will need the following fact.

► **Fact 29.** *Let  $A \subset \{0, 1\}^d$  be any anti-chain and let  $\ell: A \rightarrow \{0, 1\}$  be any labelling of  $A$ . Then there exists a monotone function  $f: \{0, 1\}^d \rightarrow \{0, 1\}$  such that  $f(x) = \ell(x)$  for all  $x \in A$ . I.e.  $A$  shatters the class of monotone functions.*

Now, let  $T$  be any monotonicity tester with one-sided error and let  $S \subseteq \{0, 1\}^d$  denote a set of  $s$  i.i.d. uniform samples. Since  $T$  has one-sided error, if the input function is monotone, then  $T$  must accept. In other words, for  $T$  to reject it must be sure without a doubt that the input function is not monotone. By Fact 29 for  $T$  to be sure the input function is not monotone, it must be that  $S$  is *not* an anti-chain. Let  $f: \{0, 1\}^d \rightarrow \{0, 1\}$  be any function which is  $\varepsilon$ -far from monotone. Since  $T$  is a valid tester, it rejects  $f$  with probability at least  $2/3$ . By the above argument we have

$$2/3 \leq \mathbb{P}_S [T \text{ rejects } f] \leq \mathbb{P}_S [S \text{ is not an anti-chain}] \leq s^2 \cdot \mathbb{P}_{x, y \sim \{0, 1\}^d} [x \preceq y] \quad (14)$$

where the last inequality is by a union bound over all pairs of samples. We then have

$$\mathbb{P}_{x, y \sim \{0, 1\}^d} [x \preceq y] = \mathbb{P}_{x, y \sim \{0, 1\}^d} [x_i \leq y_i, \forall i \in [d]] = \prod_{i=1}^d \mathbb{P}_{x_i, y_i \sim \{0, 1\}} [x_i \leq y_i] = (3/4)^d. \quad (15)$$

Thus, combining Equation (14) and Equation (15) yields  $s \geq \sqrt{\frac{2}{3} \left(\frac{4}{3}\right)^d} = \exp(\Omega(d))$ .  $\blacktriangleleft$

---

## Abstract

Consider the model where we can access a parity function through random uniform labeled examples in the presence of random classification noise. In this paper, we show that approximating the number of relevant variables in the parity function is as hard as properly learning parities.

More specifically, let  $\gamma : \mathbb{R}^+ \rightarrow \mathbb{R}^+$ , where  $\gamma(x) \geq x$ , be any strictly increasing function. In our first result, we show that from any polynomial-time algorithm that returns a  $\gamma$ -approximation,  $D$  (i.e.,  $\gamma^{-1}(d(f)) \leq D \leq \gamma(d(f))$ ), of the number of relevant variables  $d(f)$  for any parity  $f$ , we can, in polynomial time, construct a solution to the long-standing open problem of polynomial-time learning  $k(n)$ -sparse parities (parities with  $k(n) \leq n$  relevant variables), where  $k(n) = \omega_n(1)$ .

In our second result, we show that from any  $T(n)$ -time algorithm that, for any parity  $f$ , returns a  $\gamma$ -approximation of the number of relevant variables  $d(f)$  of  $f$ , we can, in polynomial time, construct a  $\text{poly}(\Gamma(n))T(\Gamma(n)^2)$ -time algorithm that properly learns parities, where  $\Gamma(x) = \gamma(\gamma(x))$ .

If  $T(\Gamma(n)^2) = \exp(o(n/\log n))$ , this would resolve another long-standing open problem of properly learning parities in the presence of random classification noise in time  $\exp(o(n/\log n))$ .

**Acknowledgements** We would like to thank the anonymous reviewer of RANDOM for providing another approach for finding the relevant variables in the target function. We also extend our gratitude to the other reviewers for their useful comments and suggestions, which have greatly improved this manuscript.

## 1 Introduction

The problem of PAC learning parity, with and without noise, and approximating its sparsity has been extensively studied in the literature. See [2, 4, 5, 6, 7, 8, 10, 12, 13, 14, 15, 16, 17, 18, 19, 20, 21, 22, 23, 24, 25, 26, 28, 29, 30, 32, 33, 35] and references therein.

In properly learning parities under the uniform distribution, the learner can observe labeled examples  $\{(a_i, b_i)\}_i$ , where  $b_i = f(a_i)$ ,  $a_i$  are drawn independently from the uniform distribution, and  $f$  is the target parity. The goal is to return the target parity function  $f$  exactly.

In the random classification noise model with noise rate  $\eta$ , [1], each label  $b_i$  is independently flipped (misclassified) with probability  $\eta$ . The problem of learning parities with noise (LPN) is known to be computationally challenging. Some evidence of its hardness comes from the fact that it cannot be learned efficiently in the so-called statistical query (SQ) model [27] under the uniform distribution [9, 12]. LPN serves as the foundation for several cryptographic constructions, largely because its hardness in the presence of noise is assumed. See for example [10, 31].

While PAC learning of parities (and thus determining its sparsity) under the uniform distribution can be accomplished in polynomial time using Gaussian elimination, addressing this problem in the presence of random classification noise remains one of the most long-standing challenges in learning theory. The only known algorithm is that of Blum et al. [11], which runs in time  $2^{O(n/\log n)}$ , requires  $2^{O(n/\log n)}$  labeled examples, and handles only a constant noise rate. This algorithm holds the record as the best-known solution for this problem. Finding a  $2^{o(n/\log n)}$ -time learning algorithm for parities or proving the impossibility of such an algorithm remains a significant and unresolved challenge.

When the number of relevant variables<sup>1</sup>  $k$  of the parity function  $f$  is known ( $f$  is called  $k$ -sparse parity), all the algorithms proposed in the literature run in time  $n^{ck}$  for some constant  $c < 1$ , [5, 7, 22, 33, 36]. Finding a polynomial-time algorithm for  $k$ -sparse parities for some  $k = \omega(1)$ , or proving the impossibility of such an algorithm, is another significant and unresolved challenge.

In a related vein, another challenging problem is determining or approximating the sparsity of the parity function, i.e., the number of relevant variables in the target function. This problem was studied in the PAC-learning model [34] under specific<sup>2</sup> distributions [2, 3, 4, 7, 16, 17, 18, 19, 20, 30, 35].

For the problem of determining the sparsity under any distribution and without noise, Downey et al. [18] and Bhattacharyya et al. [4] show that determining the sparsity  $k$  of parities is  $W[1]$ -hard. Bhattacharyya et al. [7] show that the time complexity is  $\min(2^{\Theta(n)}, n^{\Theta(k)})$ , assuming 3-SAT has no  $2^{o(n)}$ -time algorithm. For the problem of approximating the sparsity, Dumer et al. [19] showed that if  $\text{RP} \neq \text{NP}$ , then it is hard to approximate the sparsity within some constant factor  $\gamma > 1$ . See also [2, 16, 17, 30]. When the distribution is uniform, there is a polynomial-time algorithm that uses  $O(n)$  labeled examples and learns parities using Gaussian elimination, thereby determining their sparsity.

In this paper, we pose the question: Can we approximate the sparsity of the parity function in polynomial time using random uniform labeled examples in the presence of random classification noise? We show that approximating the number of relevant variables in the parity function is as hard as properly learning parities.

We first show the following.

► **Theorem 1.** *Let  $\gamma : \mathbb{R}^+ \rightarrow \mathbb{R}^+$  be any strictly increasing function, where  $\gamma(x) \geq x$ . Consider a polynomial-time algorithm that, for any parity  $f$ , uses random uniform labeled examples of  $f$  in the presence of random classification noise and returns an integer  $D$  such that<sup>3</sup>  $\gamma^{-1}(d(f)) \leq D \leq \gamma(d(f))$ , where  $d(f)$  is the number of relevant variables in  $f$ . One can, in polynomial time, construct an algorithm that runs in polynomial time, uses random uniform labeled examples in the presence of random classification noise, and learns  $k(n)$ -sparse parities for some<sup>4</sup>  $k(n) = \omega_n(1)$ .*

This would solve the long-standing open problem of polynomial-time learning  $k$ -sparse parities for some  $k = \omega_n(1)$ .

We then show that

<sup>1</sup> A variable is *relevant* in  $f$  if  $f$  depends on that variable.

<sup>2</sup> Some of the problems are introduced as follows: Given a matrix  $M \in F_2^{m \times n}$ , a vector  $b \in \{0, 1\}^m$ , and an integer  $k$ . Deciding if there exists a weight  $k$  vector  $x \in \{0, 1\}^n$  such that  $Mx = b$ . This is equivalent to the decision problem when the distribution is uniform over the rows of  $M$ .

<sup>3</sup> See Section 1.4 for the justification of why we use this definition and not the standard definition  $d(f) \leq D \leq \gamma(d(f))$ .

<sup>4</sup> Throughout this paper, we also have  $k = n - \omega(1)$ . For  $k = O(1)$  and  $k = n - O(1)$ , there are polynomial-time learning algorithms.

► **Theorem 2.** *From any  $T(n)$ -time algorithm that, for any parity  $f : \{0, 1\}^n \rightarrow \{0, 1\}$ , uses  $Q(n)$  random uniform labeled examples of  $f$  in the presence of random classification noise and returns a  $\gamma$ -approximation of the number of relevant variables  $d(f)$  of  $f$ , one can, in polynomial time, construct a  $\text{poly}(\Gamma(n))T(\Gamma(n)^2)$ -time algorithm that uses  $\text{poly}(\Gamma(n))Q(\Gamma(n)^2)$  random uniform labeled examples in the presence of random classification noise and properly learns parities, where  $\Gamma(x) = \gamma(\gamma(x))$ .*

If  $T(\Gamma(n)^2) = \exp(o(n/\log n))$ , this would resolve another long-standing open problem of proper learning parities in the presence of random classification noise in time  $\exp(o(n/\log n))$ . This is applicable, for example, for any  $\text{poly}(\cdot)$ -approximation and  $\exp(n^{1/c})$ -time algorithm for some sufficiently large constant  $c$ . As well as to quasi- $\text{poly}(\cdot)$ -approximation and  $\exp(\exp(\log n)^{1/c})$ -time algorithm for some sufficiently large constant  $c$ .

In this paper, while the above discussions and the technique section have been primarily focused on parities, that is, linear functions over the binary field  $\mathbb{F}_2$ , the results we present in this paper are not limited to this specific case. We generalize our result to encompass any linear function over any finite field. This extension allows our results to be applicable to a broader range of linear systems beyond the binary paradigm, effectively widening their relevance in coding theory and cryptography.

## 1.1 Our Technique

In this section, we present the technique used in the paper to prove the results in Theorem 1 and 2.

For learning in the presence of random classification noise, when the noise rate  $\eta = 1/2$ , the labels will be randomly uniform, and learning is impossible. Therefore, we must assume that the learner knows some upper bound  $\eta_b < 1/2$  for  $\eta$  [1].

## 1.2 Approximation Implies Learning $k$ -Sparse Parities

In this section, we present two approaches that prove Theorem 1. The first is our method, and the second was suggested by an anonymous reviewer of RANDOM.

While the approach suggested by the anonymous reviewer is truly inspiring, we believe that our method offers significant value, is worth presenting in this paper, and may be useful for solving other problems.

### 1.2.1 First Approach

In this section, we will outline the technique for the binary field, though some essential details are omitted to provide a broader overview of the main concepts and approach. Additionally, proving the result for any field requires more careful treatment.

Let  $\gamma : \mathbb{R}^+ \rightarrow \mathbb{R}^+$  be any strictly increasing function such that for every<sup>5</sup>  $x > 1$ ,  $\gamma(x) > x$ .

Let  $\mathcal{A}$  be a polynomial-time randomized algorithm that  $\gamma$ -approximates the number of relevant variables  $d(f)$  in a parity  $f$ , using random uniform labeled examples of  $f$  in the presence of random classification noise with any noise rate<sup>6</sup>  $\eta \leq \eta_b$ . Thus, for every parity  $f$  with  $d(f)$  relevant variables, with probability at least  $1 - \delta$  we have  $\gamma^{-1}(d(f)) \leq \mathcal{A}(f) \leq \gamma(d(f))$ . We will demonstrate how to construct a polynomial-time learning algorithm for  $k(n)$ -sparse parities, for some  $k(n) = \omega_n(1)$ . First, we will show how to find  $k(n)$ .

<sup>5</sup> We need this constraint to ensure that  $\gamma^{-1}(x) < \gamma(x)$  for every  $x > 1$ .

<sup>6</sup> Here,  $\eta$  is not known to the algorithm, but  $\eta_b$  is known.

## 38:4 Approximating the Number of Relevant Variables in a Parity Implies Proper Learning

Let  $\text{Lin}(d)$  be the class of  $d$ -sparse parities. Assume for now that the noise rate is  $\eta_b$ . Later, we will show how to modify the algorithm to work for any unknown noise rate  $\eta \leq \eta_b$ .

We first use the algorithm  $\mathcal{A}$  to construct a table that provides values which approximate

$$\Psi_{\mathcal{A}}(d) = \mathbf{E}_{(f,s) \sim_u \text{Lin}(d) \times S(f)} [\mathcal{A}(f)]$$

with additive error of  $1/\text{poly}(n)$ , for every  $d \in [n]$  and noise rate  $\eta_b$ . Here  $f$  is a  $d$ -sparse parity chosen uniformly at random from  $\text{Lin}(d)$ , and  $s$  is a uniformly random string in  $S(f)$  - the set of random bits used by the algorithm (for the randomness of the algorithm and the noise) for which the algorithm returns a correct answer, namely, returns  $D$  such that  $\gamma^{-1}(d) \leq D \leq \gamma(d)$ .

To approximate  $\Psi_{\mathcal{A}}(d)$  for some  $d \in [n]$ , we iterate a polynomial number of times. At each iteration, we draw a random uniform  $f \in \text{Lin}(d)$  and run  $\mathcal{A}$ . For each labeled example requested by  $\mathcal{A}$ , we draw a random uniform  $u \in \{0,1\}^n$  and compute  $v = f(u)$ . We then, with probability  $\eta_b$ , return<sup>7</sup>  $(u, v + 1)$  to  $\mathcal{A}$ , and, with probability  $1 - \eta_b$ , return  $(u, v)$ . If the algorithm outputs an integer  $D$  such that  $\gamma^{-1}(d) \leq D \leq \gamma(d)$ , we retain that  $D$ . Otherwise, we repeat the process. Obviously,  $\mathbf{E}[D] = \Psi_{\mathcal{A}}(d)$ , and therefore, using Hoeffding's bound, such a table can be constructed in polynomial time.

Now, using the fact that  $\gamma$  is strictly increasing and  $\gamma^{-1}(d) \leq \Psi_{\mathcal{A}}(d) \leq \gamma(d)$ , and applying a basic averaging argument, we show that there exists a  $k := k(n) = \omega_n(1)$  for which  $\Psi_{\mathcal{A}}(k+1) - \Psi_{\mathcal{A}}(k-1) \geq 1/\text{poly}(n)$ . We now show how to learn  $k$ -sparse parities with noise rate  $\eta_b$  in polynomial time and afterward for any  $\eta \leq \eta_b$ .

Suppose that the target function  $f \in \text{Lin}(k)$  can be accessed through random uniform labeled examples in the presence of random classification noise with noise rate  $\eta_b$ . We first show how to approximate  $\Psi_{\mathcal{A}}(d(f(x) + x_i))$  for any  $i \in [n]$  without knowing  $f$ . Recall that  $d(f(x) + x_i)$  is the number of relevant variables in  $f(x) + x_i$ . The key idea here is that if  $(a, b)$  is a labeled example of  $f$ , then for a random uniform permutation  $\phi$ ,  $((a_{\phi^{-1}(1)}, \dots, a_{\phi^{-1}(n)}), b + a_i)$  is a labeled example of the function  $f(x_{\phi(1)}, \dots, x_{\phi(n)}) + x_{\phi(i)}$  which is a random and uniform drawn function in  $\text{Lin}(d(f(x) + x_i))$ . Therefore, using Hoeffding's Bound, we can approximate  $\Psi_{\mathcal{A}}(d(f(x) + x_i))$  for every  $i \in [n]$ .

Now,  $x_i$  is relevant in  $f(x)$  if and only if  $f(x) + x_i \in \text{Lin}(k-1)$  and then  $\Psi_{\mathcal{A}}(d(f(x) + x_i)) = \Psi_{\mathcal{A}}(k-1)$ . On the other hand,  $x_i$  is not relevant in  $f(x)$  if and only if  $f(x) + x_i \in \text{Lin}(k+1)$ , and then  $\Psi_{\mathcal{A}}(d(f(x) + x_i)) = \Psi_{\mathcal{A}}(k+1)$ . Since  $\Psi_{\mathcal{A}}(k+1) - \Psi_{\mathcal{A}}(k-1) \geq 1/\text{poly}(n)$ , these two cases are distinguishable in polynomial time. Consequently, we can differentiate between variables in  $f$  that are relevant and those that are not. This gives the learning algorithm to  $\text{Lin}(k)$  when the noise rate is  $\eta_b$ .

This algorithm runs in time  $T = \text{poly}(n, 1/(1 - 2\eta_b))$ . When  $\eta$  is not known, we can run the above procedure for all possible values  $\eta^{(j)} = 1/2 - j/T^c$ , where  $c$  is a sufficiently large constant, and  $j \in [T^c/2] \cup \{1\}$ . For each  $j$ , when the algorithm receives a labeled example  $(u, v)$ , we magnify the error rate to  $\eta_b$  by drawing  $\xi \in \{0,1\}$ , which is equal to 1 with probability  $(\eta_b - \eta^{(j)})/(1 - 2\eta^{(j)})$ , and returning  $(u, v + \xi)$  to the algorithm. This new labeled example has noise rate  $\eta_b$ . We collect all the  $T^c/2 + 1$  hypotheses generated from the outputs and then employ a standard algorithm to select the one closest to the target [1]. The result follows because there exists a  $j$  such that<sup>8</sup>  $|\eta^{(j)} - \eta| \leq 1/T^c$ . Consequently, using the total variation distance, one of the hypotheses is the target.

<sup>7</sup> Here, + is exclusive or.

<sup>8</sup> If  $\eta_j = \eta + \epsilon$  then the magnified noise is  $\eta_b + \lambda\epsilon$  where  $\lambda = (\eta + \eta_b - 1 + \epsilon)/(1 - 2(\eta + \epsilon))$ .

In this paper, we extend our result to any linear function over any finite field  $\mathbb{F}$ . The approach used is similar to the case of parities (the binary field  $\mathbb{F} = \{0, 1\}$ ) with some technical but nontrivial modifications.

### 1.2.2 The Second Approach

This second approach was suggested by an anonymous reviewer of RANDOM, whose insightful comments and suggestions significantly improved this manuscript for the case of the binary field. For non-binary fields, this approach can identify the relevant variables of the function. We then use the approach developed in Lemma 9 and Lemma 10 to find the coefficients of the relevant variables.

Suppose there exists a randomized algorithm  $\mathcal{A}(n)$  that runs in time  $T(n)$  and  $\gamma$ -approximates the number of relevant variables in a parity function  $f : \{0, 1\}^n \rightarrow \{0, 1\}$ , using random uniform labeled examples of  $f$  in the presence of random classification noise with a noise rate  $\eta \leq \eta_b$ . Here, too, the algorithm needs to know an upper bound on  $\eta$ . We will explain the reasons for this below.

Let  $k_1 = \omega_n(1)$  be an integer such that  $k_2 = \gamma(\gamma(k_1) + 1) = n - \omega_n(1)$ . For any  $k_1$ -sparse parity  $f$ , the algorithm outputs  $\mathcal{A}(f) \in [\gamma^{-1}(k_1), \gamma(k_1)]$ , and for any  $k_2$ -sparse parity function  $g$ , it outputs  $\mathcal{A}(g) \in [\gamma(k_1) + 1, \gamma(\gamma(k_1) + 1)]$ . Since the two intervals are disjoint, the algorithm can distinguish between  $k_1$ -sparse parities and  $k_2$ -sparse parities in polynomial time. Let  $\mathcal{B}$  be the polynomial-time algorithm that distinguishes between them.

Consider the algorithm  $\mathcal{B}$  when it runs on random uniform examples with random uniform labels. Suppose that with probability  $p$ , the algorithm answers that the function is a  $k_1$ -sparse parity, and with probability  $1 - p$ , it answers that it is a  $k_2$ -sparse parity. If  $p > 1/2$ , then with probability at least  $1/2$ ,  $\mathcal{B}$  can distinguish between  $k_2$ -sparse parities and random uniform examples with random uniform labels. Otherwise, with probability at least  $1/2$ ,  $\mathcal{B}$  can distinguish between  $k_1$ -sparse parities and random uniform examples with random uniform labels.

Suppose, without loss of generality, the latter holds. We now give an algorithm that finds the relevant variables when the target function is a  $k_1$ -parity function and, consequently, learns  $k_1$ -sparse parities. This algorithm is from [10].

For every  $i \in [n]$ , we run the algorithm  $\mathcal{B}$  and change the  $i$ -th coordinate of each example to a random uniform element in  $\{0, 1\}$ . If  $x_i$  is not a relevant variable of  $f$ , then the labeled examples are labeled examples of  $f$ , and the algorithm answers that it is a  $k_1$ -parity function. If  $x_i$  is a relevant variable of  $f$ , then it is easy to see that the new labeled examples are random uniform with random uniform labels, and the algorithm answers accordingly. This distinguishes between variables in  $f$  from those that are not in  $f$ .

In this method, too, we must know some upper bound on  $\eta$ . Otherwise, algorithms  $\mathcal{A}$  and  $\mathcal{B}$  would need to be Las Vegas algorithms, and we would not know when to stop the algorithm when dealing with random uniform examples with random uniform labels.

For the problem of finding the relevant variables of the target in other fields, the generalization of this to any field is straightforward.

## 1.3 Approximation Implies Learning Parities

In this section, we show how  $\gamma$ -approximation implies proper learning parities.

Let  $\gamma(x)$  be any strictly increasing function. Suppose there exists a randomized algorithm  $\mathcal{A}(n)$  that runs in time  $T(n)$  and  $\gamma$ -approximates the number of relevant variables in a parity  $f : \{0, 1\}^n \rightarrow \{0, 1\}$ , using random uniform labeled examples of  $f$  in the presence of random classification noise.

Let  $\Gamma(x) = \gamma(\gamma(x))$ . As in Section 1.2.1, using a basic averaging argument, we show that there exists a sequence of integers  $k_1 < k_2 < \dots < k_t < \Gamma^{-1}(n)$ , where for each  $i$ ,  $k_{i+1} < \Gamma(k_i)$  and  $\Psi_{\mathcal{A}}(k_i + 1) - \Psi_{\mathcal{A}}(k_i - 1) > 1/\text{poly}(n)$ . As before, we obtain algorithms that learn  $\text{Lin}(k_i)$  for each  $i$ .

Now, we show how to obtain a learning algorithm for  $d$ -sparse parities for every  $d < \Gamma^{-1}(\sqrt{n})$ . Given any  $d < \Gamma^{-1}(\sqrt{n})$ , there exists a  $j$  such that  $k_{j-1} < d \leq k_j$  where  $k_0 = 0$ . To learn  $d$ -sparse parities, we uniformly at random choose distinct  $i_1, \dots, i_{k_j-d} \in [n]$ , run the algorithm for learning  $k_j$ -sparse parities and modify each labeled example  $(a, b)$  to  $(a, b + a_{i_1} + \dots + a_{i_{k_j-d}})$ . If  $g(x) = f(x) + x_{i_1} + \dots + x_{i_{k_j-d}}$  is in  $\text{Lin}(k_j)$ , then the algorithm w.h.p learns  $g(x)$ . We then show that because  $d < \Gamma^{-1}(\sqrt{n})$ , with high probability, the variables  $x_{i_1}, \dots, x_{i_{k_j-d}}$  are not relevant variables in  $f$ . We can then conclude that, w.h.p,  $g \in \text{Lin}(k_j)$ . Therefore, w.h.p., we can learn  $g(x)$ , and consequently, we can learn  $f(x) = g(x) + x_{i_1} + \dots + x_{i_{k_j-d}}$ .

This provides a learning algorithm for  $d$ -sparse parities for any  $d \leq \Gamma^{-1}(\sqrt{n})$ . Recognizing that this applies to every  $n$ , we can regard  $f$  as a function over  $N := \Gamma(n)^2$  variables by adding  $\Gamma(n)^2 - n$  dummy variables and appending  $\Gamma(n)^2 - n$  random uniform elements from  $\{0, 1\}$  to each  $a$  in the labeled example  $(a, b)$ . By applying this construction to the algorithm  $\mathcal{A}(N)$ , we obtain a learning algorithm for  $d$ -sparse parity for any  $d \leq \Gamma^{-1}(\sqrt{N}) = n$ .

Now, the algorithm for learning parities can run all the learning algorithms for  $d$ -sparse parities for all  $d \leq n$ . It takes all the outputs and then employs a standard algorithm to select the one closest to the target [1]. See also Lemma 3.

### 1.4 Justification for the Use of the $\gamma$ -Approximation Definition

In our approach, we define a  $\gamma$ -approximation of the number of relevant variables  $d(f)$  in a parity function  $f$  such that  $\gamma^{-1}(d(f)) \leq D \leq \gamma(d(f))$ , instead of using the standard definition  $d(f) \leq D \leq \gamma(d(f))$ .

The key reason for this choice is that the latter definition loses its effectiveness when  $d(f)$  approaches  $n$ , the number of variables. Specifically, if  $d(f)$  is close to  $n$ , say  $O(n)$ , the condition  $d(f) \leq D \leq \gamma(d(f))$ , for  $\gamma(n) = \omega(n)$ , effectively reduces to  $d(f) \leq D \leq n$ . In this scenario, the value of  $\gamma$  becomes less significant because the approximation  $D$  would naturally fall within the trivial range of  $d(f) = O(n)$  to  $n$ .

On the other hand, our chosen definition  $\gamma^{-1}(d(f)) \leq D \leq \gamma(d(f))$  ensures that the approximation  $D$  always depends on the function  $\gamma$ . This definition retains its utility even when  $d(f)$  is large, as  $\gamma^{-1}(d(f))$  provides a lower bound that is influenced by  $\gamma$ , thereby maintaining the approximation's relevance and precision.

Thus, by using the  $\gamma$ -approximation definition  $\gamma^{-1}(d(f)) \leq D \leq \gamma(d(f))$ , we ensure a meaningful and consistent approximation of the number of relevant variables  $d(f)$  across the entire range of possible values, preserving the value and impact of the function  $\gamma$ .

## 2 Definitions and Preliminaries

Let  $\mathbb{F}$  be any finite field and  $\mathbb{F}_q$  be the field with  $q$  elements. We define  $\text{Lin}(\mathbb{F})$  as the class of all linear functions over the field  $\mathbb{F}$ , i.e., functions  $a \cdot x$  where  $a \in \mathbb{F}^n$  and  $x = (x_1, \dots, x_n)$ . A  $d$ -sparse linear function over  $\mathbb{F}$  is a function in  $\text{Lin}(\mathbb{F})$  with  $d$  relevant variables. The class  $\text{Lin}(\mathbb{F}, d)$  is the class of all  $d$ -sparse linear functions over  $\mathbb{F}$ . When  $\mathbb{F}$  is the binary field  $\mathbb{F}_2 = \{0, 1\}$ , the functions in  $\text{Lin}(\mathbb{F}_2)$  are called parity functions, and the functions in  $\text{Lin}(\mathbb{F}_2, d)$  are called  $d$ -sparse parities. We use the notation  $\text{Lin}_n(\mathbb{F})$  and  $\text{Lin}_n(\mathbb{F}, d)$  to emphasize the number of variables.

For  $f \in \text{Lin}(\mathbb{F})$ , we denote by  $d(f)$  the number of variables on which  $f$  depends. For a strictly increasing function  $\gamma : \mathbb{R}^+ \rightarrow \mathbb{R}^+$  such that  $\gamma(x) > x$  for every  $x$ , we say that an algorithm  $\mathcal{A}$   $\gamma$ -approximates  $d(f)$  in time  $T = T(n)$  and  $Q = Q(n)$  labeled examples if the algorithm runs in time  $T$ , uses  $Q$  labeled examples to  $f$ , and with probability at least  $2/3$ , returns an integer  $D$  such that  $\gamma^{-1}(d(f)) \leq D \leq \gamma(d(f))$ .

In proper learning  $\text{Lin}(\mathbb{F})$  under the uniform distribution, the learner can observe labeled examples  $(a, b)$  where  $b = f(a)$  and  $a \in \mathbb{F}^n$  are drawn independently and uniformly distributed over  $\mathbb{F}^n$ , with  $f \in \text{Lin}(\mathbb{F})$  being the target linear function. The goal is to (properly) exactly return the linear function  $f$ . In the random classification noise model with noise rate  $\eta$ , each label  $b$  is equal to  $f(a)$  with probability  $1 - \eta$  and is a random uniform element in  $\mathbb{F} \setminus \{f(a)\}$  with probability  $\eta$ .

When  $\eta = 1 - 1/|\mathbb{F}|$ , the label is a random uniform element of  $\mathbb{F}$ ; hence, learning is impossible. Therefore, we must assume that the learner knows some upper bound  $\eta_b < 1 - 1/|\mathbb{F}|$  for  $\eta$  [1]. When  $\eta = \eta_b$ , to distinguish between labeled examples with random uniform labels and the function  $f(x) = 0$ , we need at least  $1/(1 - \eta_b - 1/|\mathbb{F}|)$  labeled examples. Therefore, a polynomial-time algorithm in this model is an algorithm that runs in time  $\text{poly}(1/(1 - \eta_b - 1/|\mathbb{F}|), n, 1/\delta)$  [1].

The following Lemma shows how to learn when the algorithm has unlimited computational power.

► **Lemma 3.** *Let  $C \subseteq \text{Lin}(\mathbb{F})$ . Then  $C$  is learnable under the uniform distribution in the random classification noise model in time  $\tilde{O}(|C| \log(1/\delta)/(1 - \eta_b - 1/|\mathbb{F}|)^2)$  from*

$$Q = \frac{\log \frac{|C|}{\delta}}{(1 - \eta_b - 1/|\mathbb{F}|)^2}$$

*labeled examples.*

**Proof.** Let  $(a, b)$  be a labeled example and  $f$  be the target function. Then

$$\Pr[f(a) = b] = \eta \Pr[f(a) = b | b \neq f(a)] + (1 - \eta) \Pr[f(a) = b | b = f(a)] = 1 - \eta \geq 1 - \eta_b.$$

If  $g \neq f$  and  $g \in \text{Lin}(\mathbb{F})$  then

$$\Pr[g(a) = b] = \eta \Pr[g(a) = b | b \neq f(a)] + (1 - \eta) \Pr[g(a) = b | b = f(a)] = \frac{1}{|\mathbb{F}|}.$$

The result now follows by applying Chernoff's bound to estimate  $\Pr[g(a) = b]$  for all  $g \in C$  with confidence of  $1 - \delta/|C|$  and an additive error of  $(1 - \eta_b - 1/|\mathbb{F}|)/4$ . ◀

The following lemma shows that, in approximation algorithms, the dependency on  $\delta$  is logarithmic. This is a well-known result. For completeness, a sketch of the proof is provided.

► **Lemma 4.** *If there exists an algorithm  $\mathcal{A}$  that runs in time  $T(n)$ , uses  $Q(n)$  labeled examples to  $f \in \text{Lin}(\mathbb{F}, d)$  according to the uniform distribution in the presence of random classification noise and, with probability at least  $2/3$ , returns a  $\gamma$ -approximation of  $d(f)$ , then there is an algorithm that runs in time  $O(T(n) \log(1/\delta))$ , uses  $O(Q(n) \log(1/\delta))$  labeled examples to  $f \in \text{Lin}(\mathbb{F}, d)$  according to the uniform distribution in the presence of random classification noise, and with probability at least  $1 - \delta$ , returns a  $\gamma$ -approximation of  $d(f)$ .*

**Proof.** We run  $\mathcal{A}$ ,  $O(\log(1/\delta))$  times and take the median of the outputs. The correctness of this algorithm follows from an application of Chernoff's bound. ◀

The same is true for learning.

► **Lemma 5.** *If there exists an algorithm  $\mathcal{A}$  that runs in time  $T(n)$ , uses  $Q(n)$  labeled examples to  $f \in \text{Lin}(\mathbb{F}, d)$  according to the uniform distribution in the presence of random classification noise and, with probability at least  $2/3$ , properly learns the target  $f$ , then there is an algorithm that runs in time  $O(T(n) \log(1/\delta))$ , uses  $O(Q(n) \log(1/\delta))$  labeled examples to  $f \in \text{Lin}(\mathbb{F}, d)$  according to the uniform distribution in the presence of random classification noise, and with probability at least  $1 - \delta$ , learns the target  $f$ .*

**Proof.** Since  $\mathcal{A}$  properly learns  $f$ , we run the algorithm  $O(\log(1/\delta))$  times and output the hypothesis that occurs most frequently in the output. ◀

### 3 Approximation vs. Learning

In this section, we prove the two results.

#### 3.1 Approximation Implies Learning Some $\text{Lin}(\mathbb{F}, k)$

In this section, we prove that approximating the number of relevant variables in the parity function implies polynomial-time properly learning  $\text{Lin}(\mathbb{F}, k(n))$  for some  $k(n) = \omega_n(1)$ .

We prove.

► **Theorem 6.** *Let  $\gamma : \mathbb{R}^+ \rightarrow \mathbb{R}^+$  be any strictly increasing function where  $\gamma(x) > x$  for every  $x$ . Let  $\pi(n)$  be any function such that  $\pi(n) = \omega_n(1)$ . Consider any polynomial-time algorithm  $\mathcal{A}'(n)$  that, for any linear function  $f \in \text{Lin}(\mathbb{F})$ , uses random uniform labeled examples of  $f$  in the presence of random classification noise and, with probability at least  $2/3$ , returns a  $\gamma$ -approximation of the number of relevant variables  $d(f)$  of  $f$ . From  $\mathcal{A}'(n)$ , one can, in polynomial time, construct a  $\text{poly}(n, 1/(1 - \eta_b - 1/|\mathbb{F}|), \min(|\mathbb{F}|, 1/(1 - \eta_b)^{\pi(n)}))$ -time algorithm that properly learns  $\text{Lin}(\mathbb{F}, k(n))$  from a polynomial number of random uniform labeled examples in the presence of random classification noise for some  $k(n) = \omega_n(1)$ .*

We will assume for now that the noise rate  $\eta = \eta_b$  is known. In Section 1.2.1, we showed how to handle unknown noise rates  $\eta \leq \eta_b$ . Recall that a polynomial-time algorithm in this model is an algorithm that runs in time  $\text{poly}(1/(1 - \eta_b - 1/|\mathbb{F}|), n, 1/\delta)$ , [1]. In particular, the algorithm constructed in Theorem 6 runs in polynomial time for either

- Any  $\eta_b$  and fields of size<sup>9</sup>  $|\mathbb{F}| = \text{poly}(n)$ , or
- Any field  $\mathbb{F}$  when  $\eta_b \leq 1 - 1/|\mathbb{F}| - 1/\psi(n)$ , where  $\psi(n) = 2^{o(\log(n))}$ .

Let  $\mathcal{A}'(n, s, f)$  be any algorithm that uses random uniform labeled examples of  $f \in \text{Lin}_n(\mathbb{F})$  in the presence of random classification noise and, with probability at least  $2/3$ , returns a  $\gamma$ -approximation of the number of relevant variables,  $d(f)$ , of  $f$ . The new parameter  $s$  is added for the random bits used in the algorithm for its coin flips and the noise. First, we will use Lemma 4 to make the algorithm's success probability  $1 - \delta'$  for a fixed, sufficient small  $\delta'$  that depends on  $n$  and  $|\mathbb{F}|$ . For the proof of the Theorem in this section,  $\delta' = 1/(|\mathbb{F}|n^7)$  suffices. By Lemma 4, this adds a factor of  $O(\log n + \log |\mathbb{F}|)$  to the time and the number of labeled examples which will be swallowed by the  $\tilde{O}(\cdot)$  in the final time and sample complexity. Second, we will modify the output of the algorithm to  $\min(\gamma(D_f), n)$ , where  $D_f$  is the output of the latter algorithm. Let the resulting algorithm be denoted as  $\mathcal{A}$ . We will denote the algorithm's output by  $\mathcal{A}(n, s, f)$ . Consequently, we will have that, with probability at least  $1 - \delta'$ ,

$$d(f) \leq \mathcal{A}(n, s, f) \leq \Delta(d(f)) \leq n \tag{1}$$

<sup>9</sup> This makes sense when we have a sequence of fields  $\mathbb{F}_i$  such that  $\mathbb{F}_i \subseteq \mathbb{F}_{i+1}$  and  $|\mathbb{F}_n| = \text{poly}(n)$ .

where

$$\Delta(x) = \min(\gamma(\gamma(x)), n).$$

Let  $S_f$  be the set of all random strings  $s'$  for which  $d(f) \leq \mathcal{A}(n, s', f) \leq \Delta(d(f))$ ; that is, it includes all the random strings that yield correct answers. Throughout this section and the next, we say that  $\mathcal{A}$   $\Delta$ -approximates  $d(f)$ . See (1). This should not be confused with the previous definition of  $\gamma$ -approximates  $d(f)$ . Here, we use the capital letter  $\Delta$  to prevent any ambiguity.

Let

$$\Psi_{\mathcal{A}}(d) = \mathbf{E}_{(f,s) \sim_u \text{Lin}(\mathbb{F},d) \times S(f)} [\mathcal{A}(n, s, f)]$$

where  $\sim_u$  indicates that  $f$  is chosen uniformly at random from  $\text{Lin}(\mathbb{F}, d)$  and  $s$  uniformly at random from  $S(f)$ . Since  $d \leq \mathcal{A}(n, s, f) \leq \Delta(d) \leq n$  for  $s \in S(f)$  where  $f \in \text{Lin}(\mathbb{F}, d)$ , we have

$$d \leq \Psi_{\mathcal{A}}(d) \leq \Delta(d) \leq n. \tag{2}$$

We note here that  $\Psi_{\mathcal{A}}(d)$  is independent of  $\delta$ , as in  $\mathcal{A}$ , we set  $\delta = \delta'$  for a fixed  $\delta'$ . This is crucial for ensuring the correctness of the proof. Also,  $\Psi_{\mathcal{A}}(d)$  depends on  $n$ . This will be essential only for the next result in the next section.

We first prove that the values of  $\Psi_{\mathcal{A}}(d)$  for  $d \in [n]$  can be approximated with high probability.

► **Lemma 7.** *Let  $0 < h < 1$ . Let  $\mathcal{A}$  be an algorithm that runs in time  $T(n)$ , uses  $Q(n)$  labeled examples of  $f \in \text{Lin}(\mathbb{F})$  according to the uniform distribution in the presence of random classification noise, and, with probability at least  $1 - \delta'$ ,  $\Delta$ -approximates  $d(f)$ . A table of real values  $\Psi'_{\mathcal{A}}(d)$  for  $1 \leq d \leq n$  can be constructed in time  $\tilde{O}(n^3/h^2)T(n) \log(1/\delta)$ , and without using any labeled examples. This table, with probability at least  $1 - \delta$ , satisfies  $|\Psi'_{\mathcal{A}}(d) - \Psi_{\mathcal{A}}(d)| \leq h$  for all  $d \in [n]$ .*

**Proof.** Define a random variable as the output  $D$  of the algorithm  $\mathcal{A}$ , obtained from running it on a uniformly random  $f$  from  $\text{Lin}(\mathbb{F}, d)$ , provided that the output lies within the interval  $[d, \Delta(d)]$ . The labeled examples of  $f$  can be generated by choosing a random uniform  $u \in \{0, 1\}^n$  and returning  $(u, f(u) + e)$  to  $\mathcal{A}$  where, with probability  $1 - \eta_b$ ,  $e = 0$  and, with probability  $\eta_b$ ,  $e$  is random uniform in  $\mathbb{F} \setminus \{0\}$ . Obviously,  $\mathbf{E}[D] = \Psi_{\mathcal{A}}(d)$ .

By Hoeffding's bound, to compute  $\mathbf{E}[D]$  with an additive error  $h$  and a confidence probability of at least  $1 - \delta/(2n)$ , we need to obtain  $t = O((n^2/h^2) \log(n/\delta))$  values of  $D$ . Since the success probability of obtaining a value of  $D$  in the interval  $[d, \Delta(d)]$  is  $1 - \delta' > 2/3$ , we need to run the algorithm  $O(t + \log(2n/\delta))$  times to acquire  $t$  values with a success probability at least  $1 - \delta/(2n)$ . Therefore, the time complexity is  $O((t + \log(2n/\delta))nT(n)) = O(tnT(n)) = \tilde{O}(n^3/h^2)T(n) \log(1/\delta)$ . ◀

Our next result shows how to estimate  $\Psi_{\mathcal{A}}(d(f))$  of the target  $f$  without knowing  $d(f)$ .

► **Lemma 8.** *Let  $0 < h < 1$  and  $\tau = O((n^2/h^2) \log(1/\delta))$ . Let  $\mathcal{A}$  be an algorithm that runs in time  $T(n)$ , uses  $Q(n)$  labeled examples of  $f \in \text{Lin}(\mathbb{F})$  according to the uniform distribution, in the presence of random classification noise, and, with probability at least  $1 - \delta'$ ,  $\Delta$ -approximates  $d(f)$ . There is an algorithm  $\mathcal{B}(n, h)$  that runs in time  $T' = \tau T(n)$ , uses  $Q' = \tau Q(n)$  labeled examples of  $f \in \text{Lin}(\mathbb{F})$  according to the uniform distribution in the presence of random classification noise and, with probability at least  $1 - \delta/2 - \tau\delta'$ , returns  $\psi$  that satisfies  $|\psi - \Psi_{\mathcal{A}}(d(f))| \leq h$ .*

**Proof.** Suppose  $v \in (\mathbb{F} \setminus \{0\})^n$  is chosen uniformly at random and  $\phi : [n] \rightarrow [n]$  is a uniformly random permutation. If we run  $\mathcal{A}$  with the target  $f = \lambda_1 x_{i_1} + \dots + \lambda_d x_{i_d}$ , and for every labeled example  $(a, b) \in \mathbb{F}^n \times \mathbb{F}$ , we modify the labeled example to  $((v_1^{-1} a_{\phi^{-1}(1)}, \dots, v_n^{-1} a_{\phi^{-1}(n)}), b)$ , then the new labeled examples remain uniform and consistent with the function  $g(x) = \lambda_1 v_{\phi(i_1)} x_{\phi(i_1)} + \dots + \lambda_d v_{\phi(i_d)} x_{\phi(i_d)}$ . This function  $g$  is a uniformly random element of  $\text{Lin}(\mathbb{F}, d)$ . Using this fact, we show how to approximate  $\Psi_{\mathcal{A}}(d)$ .

To this end, let  $\tau = O((n^2/h^2) \log(1/\delta))$ . We iterate  $\tau$  times, and at each iteration, we choose a random uniform  $v \in (\mathbb{F} \setminus \{0\})^n$  and random uniform permutation  $\phi : [n] \rightarrow [n]$ . We request for  $Q(n)$  labeled examples and modify each labeled example  $(a, b) \in \mathbb{F}^n \times \mathbb{F}$  to  $((v_1^{-1} a_{\phi^{-1}(1)}, \dots, v_n^{-1} a_{\phi^{-1}(n)}), b)$ . We then run  $\mathcal{A}$  on these labeled examples. Let  $D_i$  be the output of the  $i$ -th iteration. We then output  $\psi' = (\sum_{i=1}^{\tau} D_i) / \tau$ .

We now prove that, with probability at least  $1 - \delta/2 - \tau\delta'$ , we have  $|\psi' - \Psi_{\mathcal{A}}(d(f))| \leq h$ . Since  $\mathcal{A}(n)$  runs  $\tau$  times, with probability at least  $1 - \tau\delta'$ , all the seeds used by  $\mathcal{A}$  are in  $S(f)$  and  $d(f) \leq D_i \leq \Delta(d(f))$ . Also, since  $\mathcal{A}(n)$  runs on a uniformly random function in  $\text{Lin}(\mathbb{F}, d)$ , we have  $\mathbf{E}[D_i] = \Psi_{\mathcal{A}}(d)$ . By Hoeffding's bound, along with the fact that  $D_i \leq \Delta(d(f)) \leq n$ , we can conclude that, with probability at least  $1 - \delta/2$ , we have  $|\psi' - \Psi_{\mathcal{A}}(d(f))| \leq h$ .  $\blacktriangleleft$

Notice that in Lemma 8,  $\tau$  also depends on  $h$ . As  $h$  eventually will be  $O(1/n)$  and  $\delta' = 1/(|\mathbb{F}|n^7)$ , the success probability  $1 - \delta/2 - \tau\delta'$  will be  $1 - o_n(1)$  for  $\delta = 1/n$ .

We now show that in any large enough sub-interval of  $[0, n]$ , there is  $k$  for which  $\mathcal{A}$  can be used to learn  $\text{Lin}(\mathbb{F}, k)$ .

► **Lemma 9.** *Let  $\mathcal{A}(n)$  be an algorithm that runs in time  $T(n)$ , uses  $Q(n)$  labeled examples of  $f \in \text{Lin}(\mathbb{F})$  according to the uniform distribution in the presence of random classification noise, and, with probability at least  $1 - \delta'$ ,  $\Delta$ -approximates  $d(f)$ . For every  $1 \leq m \leq \min\{j | \Delta(j) = n\} = \gamma^{-1}(\gamma^{-1}(n))$  there exists  $m \leq k \leq \Delta(m) + 1$  and*

1. *An algorithm that, for every  $f \in \text{Lin}(\mathbb{F}, k)$ , with probability at least  $1 - \delta/8 - 2\tau n\delta'$ , where  $\tau = O(n^4 \log(1/\delta))$ , identifies the relevant variables of  $f$  from random uniform labeled examples in the presence of random classification noise. This algorithm runs in time  $\tilde{O}(n^5)T(n) \log(1/\delta)$  and uses  $\tilde{O}(n^4)Q(n) \log(1/\delta)$  labeled examples.*
2. *An algorithm that, with probability at least  $1 - \delta/2 - |\mathbb{F}|kn\delta'$ , properly learns  $\text{Lin}(\mathbb{F}, k)$ , from random uniform labeled examples in the presence of random classification noise. This algorithm runs in time  $\tilde{O}(|\mathbb{F}|kn^5)T(n) \log(1/\delta)$  and uses  $\tilde{O}(n^4)Q(n) \log(|\mathbb{F}|/\delta)$  labeled examples.*

Such  $k$  can be found in time  $\tilde{O}(n^5)T(n) \log(1/\delta)$ .

**Proof.** We first prove the result when the field is not the binary field. Let  $m$  be any integer such that  $1 \leq m \leq \min\{j | \Delta(j) = n\}$ . Since by (2),

$$\begin{aligned} \sum_{i=m}^{\Delta(m)} \Psi_{\mathcal{A}}(i+1) - \Psi_{\mathcal{A}}(i) &= \Psi_{\mathcal{A}}(\Delta(m)+1) - \Psi_{\mathcal{A}}(m) \\ &\geq \Delta(m) + 1 - \Delta(m) = 1, \end{aligned}$$

there is  $k$  such that  $m \leq k \leq \Delta(m)$  and

$$\Psi_{\mathcal{A}}(k+1) - \Psi_{\mathcal{A}}(k) \geq \frac{1}{\Delta(m) - m + 1} \geq \frac{1}{n}.$$

First, we find such  $k$ . By Lemma 7, taking  $h = 1/(16n)$ , with probability at least  $1 - \delta/4$ , we can find  $k$  such that  $\Psi_{\mathcal{A}}(k+1) - \Psi_{\mathcal{A}}(k) \geq 7/(8n)$  in time  $\tilde{O}(n^5)T(n) \log(1/\delta)$ .

We now present an algorithm that learns  $\text{Lin}(\mathbb{F}, k)$ . The algorithm uses the algorithm in Lemma 8 to approximate  $\Psi_{\mathcal{A}}(d(f + x_i))$  and  $\Psi_{\mathcal{A}}(d(f + \alpha x_i))$  for some  $\alpha \in \mathbb{F} \setminus \{0, 1\}$  and all  $i \in [n]$  with an additive error of  $1/(8n)$ . If  $x_i$  is not a relevant variable of the target function  $f$ , then both  $f + x_i$  and  $f + \alpha x_i$  are in  $\text{Lin}(\mathbb{F}, k + 1)$ . Consequently, we obtain two values in the interval  $[\Psi_{\mathcal{A}}(k + 1) - 1/(8n), \Psi_{\mathcal{A}}(k + 1) + 1/(8n)]$ . If  $x_i$  is a relevant variable in the function, then one of the functions, either  $f + x_i$  or  $f + \alpha x_i$  is in  $\text{Lin}(\mathbb{F}, k)$ , and therefore, one of the values is in the interval  $[\Psi_{\mathcal{A}}(k) - 1/(8n), \Psi_{\mathcal{A}}(k) + 1/(8n)]$ . Since  $\Psi_{\mathcal{A}}(k) + 1/(8n) < \Psi_{\mathcal{A}}(k + 1) - 1/(8n)$ , the intervals are disjoint, and thus we can distinguish between the two cases.

By Lemma 8, with probability  $1 - \delta/2 - \tau\delta'$ , we can approximate each  $\Psi_{\mathcal{A}}(d(f + x_i))$  (or  $\Psi_{\mathcal{A}}(d(f + \alpha x_i))$ ) with an additive error  $h = 1/(8n)$  in time  $\tau T(n)$  and  $\tau Q(n)$  labeled examples, where  $\tau = O(n^4 \log(1/\delta))$ . Taking  $\delta/(8n)$  for  $\delta$ , with probability  $1 - \delta/8 - 2\tau n\delta'$ , we can approximate all  $\Psi_{\mathcal{A}}(d(f + x_i))$  and  $\Psi_{\mathcal{A}}(d(f + \alpha x_i))$ ,  $i \in [n]$  with an additive error  $h = 1/(8n)$  in time  $\tau' n T(n)$  and  $\tau' Q(n)$  labeled examples where  $\tau' = O(n^4 \log(n/\delta))$ . This completes the proof of item 1 for the case where the field is not the binary field.

To prove item 2, suppose, without loss of generality, that  $x_1, \dots, x_k$  are the relevant variables in  $f$ . We approximate  $\psi_{\alpha, i} := \Psi_{\mathcal{A}}(d(f - \alpha x_i + x_{k+1}))$  for all  $\alpha \in \mathbb{F}$  and for every  $i \in [n]$ . The result follows from the fact that  $\psi_{\alpha, i} = \Psi_{\mathcal{A}}(k)$  if and only if the coefficient of  $x_i$  is  $\alpha$ . Otherwise,  $\psi_{\alpha, i} = \Psi_{\mathcal{A}}(k + 1)$ . By Lemma 8, to approximate all  $\psi_{\alpha, i}$ , with success probability of  $1 - \delta/4 - |\mathbb{F}|kn\delta'$ , we need time  $O(|\mathbb{F}|kn^5 T(n) \log(|\mathbb{F}|n/\delta))$  and  $O(n^4 T(n) \log(|\mathbb{F}|n/\delta))$  labeled examples. This completes the proof of item 2 for the case where the field is not the binary field.

Similar to the approach described above, for the binary field, we can show that there exists a  $k$  such that  $\Psi_{\mathcal{A}}(k + 1) - \Psi_{\mathcal{A}}(k - 1) \geq 1/n$ . Then, use the algorithm described in Lemma 8 to approximate  $\Psi_{\mathcal{A}}(d(f + x_i))$  for all  $i \in [n]$ . If  $x_i$  is not a relevant variable of the target function  $f$ , then  $\Psi_{\mathcal{A}}(d(f + x_i)) \in [\Psi_{\mathcal{A}}(k + 1) - 1/(8n), \Psi_{\mathcal{A}}(k + 1) + 1/(8n)]$ . If  $x_i$  is a relevant variable in  $f$ , then  $\Psi_{\mathcal{A}}(d(f + x_i)) \in [\Psi_{\mathcal{A}}(k - 1) - 1/(8n), \Psi_{\mathcal{A}}(k - 1) + 1/(8n)]$ . Since both intervals are disjoint, we obtain the desired result.<sup>10</sup> ◀

Notice that in item 2, the success probability  $1 - \delta/2 - |\mathbb{F}|kn\delta'$ , and the time complexity depends on  $|\mathbb{F}|$ . We now present an alternative algorithm for finding the coefficients of the linear function, given that the algorithm knows the relevant variables.

► **Lemma 10.** *Let  $\mathcal{A}$  be an algorithm that, for every  $f \in \text{Lin}(\mathbb{F}, k)$ , runs in time  $T$ , uses  $Q$  random uniform labeled examples in the presence of random classification noise, and identifies the relevant variables of  $f$ . Then there is an algorithm that properly learns  $\text{Lin}(\mathbb{F}, k)$  in time  $T + \tilde{O}((n^3/(1 - \eta_b)^k + n/(1 - \eta_b - 1/|\mathbb{F}|)^2) \log(1/\delta))$  and uses  $Q + O(((1/(1 - \eta_b)^k + n/(1 - \eta_b - 1/|\mathbb{F}|)^2) \log(1/\delta)))$  random uniform labeled examples in the presence of random classification noise.*

**Proof.** We run  $\mathcal{A}$  to find the relevant variables. The algorithm that finds the coefficients iterates  $O((1/(1 - \eta_b)^k) \log(1/\delta))$  times. At each iteration, it requests  $k$  labeled examples and uses Gaussian elimination to find the coefficients. Then, it tests whether the output function matches the target. If not, it proceeds to the next iteration.

<sup>10</sup> Another approach is to utilize the fact that  $\Psi_{\mathcal{A}}(k) - \Psi_{\mathcal{A}}(k - 1) \geq 1/n$ , and for every  $i$ , approximate  $\Psi_{\mathcal{A}}(g_i)$ , where  $g_i = f(x_1, \dots, x_{i-1}, 0, x_{i+1}, \dots, x_n)$ , using all labeled examples  $(a, b)$  that satisfy  $a_i = 0$ .

### 38:12 Approximating the Number of Relevant Variables in a Parity Implies Proper Learning

Since  $\eta = \eta_b$ , the probability that all the labeled examples are correct is  $(1 - \eta_b)^k$ . If  $|\mathbb{F}| = q$ , the probability that  $k$  random entries in the examples form a non-singular matrix is

$$\left(1 - \frac{1}{q^k}\right) \left(1 - \frac{1}{q^{k-1}}\right) \cdots \left(1 - \frac{1}{q}\right) \geq \frac{1}{4}.$$

Therefore, after  $t = O((1/(1 - \eta_b)^k) \log(1/\delta))$  iterations, with probability at least  $1 - \delta/3$ , at least one of the outputs is the target. By Lemma 3, learning the target from a set of  $t$  linear functions with a success probability of  $1 - \delta/3$  requires  $\tilde{O}((1/(1 - \eta_b - 1/q)^2)(k + \log(1/\delta)))$  labeled examples.  $\blacktriangleleft$

We are now ready to prove Theorem 6.

**Proof.** Let  $\mathcal{A}'$  be an algorithm that runs in polynomial time, uses labeled examples according to the uniform distribution in the presence of random classification noise, and outputs  $\gamma^{-1}(d(f)) \leq D \leq \gamma(d(f))$ . Modify the algorithm to output  $\min(\gamma(D), n)$ . The algorithm now is a  $\Delta$ -approximation algorithm, where  $\Delta(x) = \min(\gamma(\gamma(x)), n)$ . Let  $m(n) = \gamma^{-1}(\gamma^{-1}(\pi(n)))$ . Since  $\gamma : \mathbb{R}^+ \rightarrow \mathbb{R}^+$  is strictly increasing and is defined for all  $\mathbb{R}^+$ , we have  $\gamma^{-1} : \mathbb{R}^+ \rightarrow \mathbb{R}^+$ , is also strictly increasing, and  $m(n) = \omega_n(1)$ . Let  $\delta' = 1/(|\mathbb{F}|n^7)$  and  $\delta = 1/n$ . By Lemma 9, item 1, there exists  $m(n) \leq k(n) \leq \Delta(m(n)) = \pi(n)$ , and an algorithm that, for every  $f \in \text{Lin}(\mathbb{F}, k(n))$ , with probability at least  $1 - o_n(1) > 2/3$ , identifies the relevant variables of  $f$  from random uniform labeled examples in the presence of random classification noise. Also, this algorithm runs in polynomial time. Since  $k(n) \leq \pi(n)$ , by Lemma 10 and item 2 in Lemma 9, there is a  $\text{poly}(n, 1/(1 - \eta_b - 1/|\mathbb{F}|), \min(|\mathbb{F}|, 1/(1 - \eta_b)^{\pi(n)}))$  time learning algorithm for  $\text{Lin}(\mathbb{F}, k)$ . Since  $k(n) \geq m(n) = \omega_n(1)$ , the result follows.  $\blacktriangleleft$

## 3.2 Approximation Implies Learning $\text{Lin}(\mathbb{F})$

In this section, we prove.

**► Theorem 11.** *Let  $\gamma : \mathbb{R}^+ \rightarrow \mathbb{R}^+$  be any strictly increasing function, where  $\gamma(x) > x$  for every  $x$ . Let  $\Gamma(x) := \gamma(\gamma(x))$ . Consider any  $T(n)$ -time algorithm  $\mathcal{A}'(n)$  that, for any linear function  $f \in \text{Lin}(\mathbb{F})$ , uses  $Q(n)$  random uniform labeled examples of  $f$  in the presence of random classification noise and, with probability at least  $2/3$ , returns a  $\gamma$ -approximation of the number of relevant variables  $d(f)$  of  $f$ . From  $\mathcal{A}'(n)$ , one can, in polynomial time, construct a  $\tilde{O}(|\mathbb{F}|\Gamma(n)^{12})T(O(\Gamma(n)^2)) \log(1/\delta)$ -time algorithm that properly learns  $\text{Lin}(\mathbb{F})$  from  $\tilde{O}(\Gamma(n)^8)Q(O(\Gamma(n)^2)) \log(|\mathbb{F}|/\delta)$  random uniform labeled examples in the presence of random classification noise.*

We first show that for every  $d$  satisfying  $12\Gamma(d)^2 \leq n$ , there exists a learning algorithm for  $\text{Lin}(\mathbb{F}, d)$ .

**► Lemma 12.** *Suppose that for every  $1 \leq m \leq m' := \Gamma^{-1}(n)$ , there exists a  $k$  such that  $m \leq k \leq \Gamma(m)$ , and an algorithm that runs in time  $T(n)$  and, with probability at least  $2/3$ , properly learns  $f \in \text{Lin}(\mathbb{F}, k)$  under the uniform distribution in the presence of random classification noise, and uses  $Q(n)$  labeled examples. Then, for every  $d$  such that  $12\Gamma(d)^2 \leq n$ , there is an algorithm that runs in time  $O(T(n) \log(1/\delta))$  and properly learns  $\text{Lin}(\mathbb{F}, d)$  under the uniform distribution in the presence of random classification noise, using  $O(Q(n) \log(1/\delta))$  labeled examples.*

**Proof.** Let  $d$  be an integer such that  $12\Gamma(d)^2 < n$ . Since  $\Gamma(d) < n$ , we have  $d \leq m'$ . Consequently, there exists  $k$  such that  $d \leq k \leq \Gamma(d) \leq \Gamma(m') = n$ , along with a proper learning algorithm  $\mathcal{B}(n, k)$  for  $\text{Lin}(\mathbb{F}, k)$ , that runs in time  $T(n)$  and uses  $Q(n)$  labeled examples.

We now present an algorithm for learning  $\text{Lin}(\mathbb{F}, d)$ . We uniformly at random draw  $k - d$  variables  $x_{i_1}, \dots, x_{i_{k-d}}$  and run the algorithm  $\mathcal{B}(n, k)$ . For each labeled example  $(a, b)$  of  $f$ , we feed  $\mathcal{B}$  with the labeled example  $(a, b + a_{i_1} + \dots + a_{i_{k-d}})$ . This modified labeled example serves as a labeled example for the function  $g = f + x_{i_1} + \dots + x_{i_{k-d}}$ . The probability that  $g \in \text{Lin}(\mathbb{F}, k)$  is the probability that none of the variables  $x_{i_1}, \dots, x_{i_{k-d}}$  are relevant in  $f$ . This probability is given by

$$\prod_{i=d}^k \left(1 - \frac{i}{n}\right) \geq 1 - \frac{k^2}{n} \geq 1 - \frac{\Gamma(d)^2}{n} \geq \frac{11}{12}.$$

Therefore, with probability at least  $1 - (1/3 + 1/12) > 1/2$ , algorithm  $\mathcal{B}(n, k)$  learns  $g$  and thus learns  $f$ . By Lemma 5, the result follows.  $\blacktriangleleft$

We now show how to construct a learning algorithm for  $\text{Lin}(\mathbb{F}, d)$  for every  $d \leq n$ .

**► Lemma 13.** *Suppose that for every  $n$  and every  $d$  that satisfies  $12\Gamma(d)^2 \leq n$ , there is an algorithm  $\mathcal{A}(n)$  that runs in time  $T(n)$  and, with probability at least  $2/3$ , properly learns  $f \in \text{Lin}(\mathbb{F}, d)$  under the uniform distribution in the presence of random classification noise, using  $Q(n)$  labeled examples. Let  $N(n) = 12\Gamma(n)^2$ . Then, for every  $n$  and every  $d \leq n$ , there is an algorithm that runs in time  $T(N(n))$  and, with probability at least  $2/3$ , properly learns  $f \in \text{Lin}(\mathbb{F}, d)$  under the uniform distribution in the presence of random classification noise, using  $Q(N(n))$  labeled examples.*

**Proof.** Let  $N = N(n)$ . Then for every  $d \leq n$ , we have  $12\Gamma(d)^2 \leq 12\Gamma(n)^2 = N(n)$ . We run  $\mathcal{A}(N)$ . Whenever the algorithm requests a labeled example, we draw a labeled example  $(a, b) \in \mathbb{F}^n \times \mathbb{F}$ , append  $N - n$  random uniform entries to  $a$ , creating  $a'$ . We then provide  $(a', b)$  to  $\mathcal{A}(N)$ . The algorithm is effective for any  $d$  that satisfies  $12\Gamma(d)^2 \leq N = 12\Gamma(n)^2$  and, thereby, covers all  $d \leq n$ .  $\blacktriangleleft$

Theorem 11 now follows from Lemma 9, 12 and 13.

---

## Abstract

We prove that throughout the satisfiable phase, the logarithm of the number of satisfying assignments of a random 2-SAT formula satisfies a central limit theorem. This implies that the log of the number of satisfying assignments exhibits fluctuations of order  $\sqrt{n}$ , with  $n$  the number of variables. The formula for the variance can be evaluated effectively. By contrast, for numerous other random constraint satisfaction problems the typical fluctuations of the logarithm of the number of solutions are *bounded* throughout all or most of the satisfiable regime.

## 1 Introduction

### 1.1 Background and motivation

The quest for satisfiability thresholds has been a guiding theme of research into random constraint satisfaction problems [7, 17, 24]. But once the satisfiability threshold has been pinpointed a question of no less consequence is to determine the distribution of the number of satisfying assignments within the satisfiable phase [33]. Indeed, the number of solutions is intimately tied to phase transitions that affect the geometry of the solution space, which in turn impacts the computational nature of finding or sampling solutions [4, 15, 28]. However, few tools are currently available to count solutions of random problems. Where precise rigorous results exist (such as in random NAESAT or XORSAT), the proofs typically rely on the method of moments (e.g., [6, 26, 40, 41]). Yet a necessary condition for the success of this approach is that the problem in question exhibits certain symmetries, which are absent in many interesting cases [7, 20].

The aim of the present paper is to shed a closer light on the number of satisfying assignments in random 2-SAT, the simplest random CSP that lacks said symmetry properties. While the random 2-SAT satisfiability threshold has been known since the 1990s [19, 31], a first-order approximation to the number of satisfying assignments has been obtained only recently [5]. This timeline reflects the computational complexity of the respective questions. As is well known, deciding the satisfiability of a 2-CNF reduces to directed reachability, solvable in polynomial time [10].

By contrast, calculating the number of satisfying assignments  $Z(\Phi)$  of a 2-CNF  $\Phi$  is a #P-hard task [45]. Nonetheless, Monasson and Zecchina [36] put forward a delicate physics-inspired conjecture as to the exponential order of the number of satisfying assignments of random 2-CNFs. Achlioptas et al. [5] recently proved this conjecture. Their theorem provides a first-order, law-of-large-numbers approximation of the logarithm of the number of satisfying assignments. The present paper contributes a much more precise result, namely a central limit theorem. We show that throughout the satisfiable phase the logarithm of the number of satisfying assignments, suitably shifted and scaled, converges to a Gaussian. This is the first central limit theorem of this type for any random CSP.

Let  $\Phi = \Phi_{n,m}$  be a random 2-CNF on  $n$  Boolean variables  $x_1, \dots, x_n$  with  $m$  clauses, drawn independently and uniformly from all  $4\binom{n}{2}$  possible 2-clauses. Suppose that  $m \sim dn/2$  for a fixed real  $d > 0$ . Thus,  $d$  gauges the average number of clauses in which a variable  $x_i$  appears. The value  $d = 2$  marks the satisfiability threshold; hence,  $\Phi$  is satisfiable with high probability (“w.h.p.”) if  $d < 2$ , and unsatisfiable w.h.p. if  $d > 2$  [19, 31]. Achlioptas et al. [5] determined a function  $\phi(d) > 0$  such that for all  $d < 2$ , i.e., throughout the entire satisfiable phase we have

$$Z(\Phi) = \exp(n\phi(d) + o(n)) \quad \text{w.h.p. ,} \quad (1)$$

thereby determining the leading exponential order of  $Z(\Phi)$ .

However, (1) fails to identify the limiting distribution of  $Z(\Phi)$ . To be precise, since (1) shows that  $Z(\Phi)$  scales exponentially, we expect this random variable to exhibit *multiplicative* fluctuations. Therefore, the appropriate goal is to find the limiting distribution of the logarithm of this random variable, i.e., of  $\log Z(\Phi)$ . Indeed, physics intuition suggests that  $\log Z(\Phi)$  should be asymptotically Gaussian [34]. The main result of the present paper confirms this hunch. Specifically, letting  $\Gamma_{\eta(d)}$  be a Gaussian with mean 0 and standard deviation  $\eta(d) > 0$ , we prove that for all  $0 < d < 2$ ,  $\log Z(\Phi)$  satisfies

$$\mathbb{P} [\log Z(\Phi) - \mathbb{E}[\log Z(\Phi) \mid Z(\Phi) > 0] < z\sqrt{m}] \sim \mathbb{P} [\Gamma_{\eta(d)} < z] \quad (z \in \mathbb{R}). \quad (2)$$

The order  $\Theta(\sqrt{n})$  of fluctuations confirmed by (2) sets random 2-SAT apart from a large family of other random constraint satisfaction problems. For example, for random graph  $q$ -colouring with  $q \geq 3$  colours the log of the number of  $q$ -colourings *superconcentrates*, i.e., merely has *bounded* fluctuations throughout most of the regime where the random graph is  $q$ -colourable [12].<sup>1</sup> The same is true of random NAESAT, XORSAT and the symmetric perceptron [1, 11, 20, 40]. In each of these cases, certain fundamental symmetry properties (e.g., that the set of  $q$ -colourings remains invariant under permutations of the colours) enable the computation of the number of solutions via the method of moments. Random 2-SAT lacks the respective symmetry (as the set of satisfying assignments is not generally invariant under swapping “true” and “false”), and accordingly (2) establishes that the number of solutions fails to superconcentrate (for more details see [20]).

### 1.2 The main result

The formula for the standard deviation  $\eta(d)$  from (2) comes in terms of a fixed point equation on a space of probability measures. Thus, let  $\mathcal{P}(\mathbb{R}^2)$  be the set of all (Borel) probability measures on  $\mathbb{R}^2$ . For  $0 < d < 2$  and  $0 \leq t \leq 1$  we define an operator

$$\log\text{BP}_{d,t}^{\otimes} : \mathcal{P}(\mathbb{R}^2) \rightarrow \mathcal{P}(\mathbb{R}^2), \quad \rho \mapsto \hat{\rho} = \log\text{BP}_{d,t}^{\otimes}(\rho), \quad (3)$$

as follows. Let

$$(\xi_{\rho,i})_{i \geq 1}, (\xi'_{\rho,i})_{i \geq 1}, (\xi''_{\rho,i})_{i \geq 1}, \quad \xi_{\rho,i} = \begin{pmatrix} \xi_{\rho,i,1} \\ \xi_{\rho,i,2} \end{pmatrix}, \xi'_{\rho,i} = \begin{pmatrix} \xi'_{\rho,i,1} \\ \xi'_{\rho,i,2} \end{pmatrix}, \xi''_{\rho,i} = \begin{pmatrix} \xi''_{\rho,i,1} \\ \xi''_{\rho,i,2} \end{pmatrix}$$

be random vectors with distribution  $\rho$ , let  $\mathbf{d} \stackrel{\text{dist}}{=} \text{Po}(td)$ ,  $\mathbf{d}', \mathbf{d}'' \stackrel{\text{dist}}{=} \text{Po}((1-t)d)$  and let  $\mathbf{s}_i, \mathbf{s}'_i, \mathbf{s}''_i, \mathbf{r}_i, \mathbf{r}'_i, \mathbf{r}''_i$  for  $i \geq 1$  be uniformly random on  $\{\pm 1\}$ , all mutually independent. Then  $\hat{\rho}$  is the distribution of the vector

$$\begin{pmatrix} \sum_{i=1}^{\mathbf{d}} \mathbf{s}_i \log \left( \frac{1}{2} (1 + \mathbf{r}_i \tanh(\xi_{\rho,i,1}/2)) \right) + \sum_{i=1}^{\mathbf{d}'} \mathbf{s}'_i \log \left( \frac{1}{2} (1 + \mathbf{r}'_i \tanh(\xi'_{\rho,i,1}/2)) \right) \\ \sum_{i=1}^{\mathbf{d}} \mathbf{s}_i \log \left( \frac{1}{2} (1 + \mathbf{r}_i \tanh(\xi_{\rho,i,2}/2)) \right) + \sum_{i=1}^{\mathbf{d}''} \mathbf{s}''_i \log \left( \frac{1}{2} (1 + \mathbf{r}''_i \tanh(\xi''_{\rho,i,2}/2)) \right) \end{pmatrix}.$$

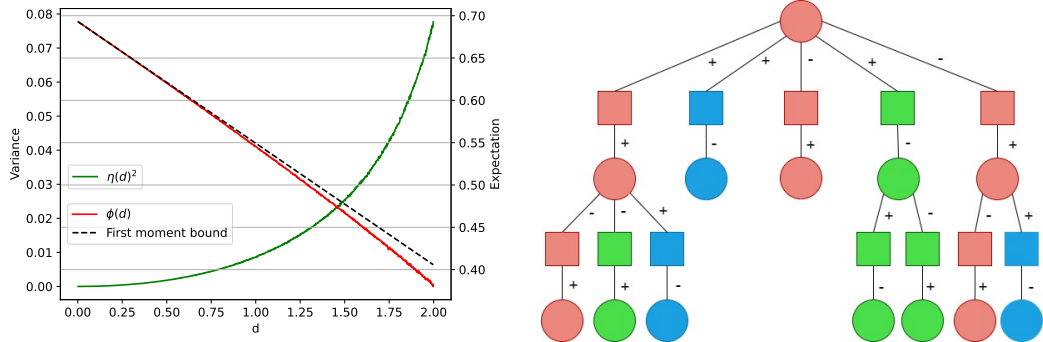

In addition, define a function  $\mathcal{B}_{d,t}^{\otimes} : \mathcal{P}(\mathbb{R}^2) \rightarrow (0, \infty]$  by letting

$$\mathcal{B}_{d,t}^{\otimes}(\rho) = \mathbb{E} \left[ \prod_{h=1}^2 \log \left( 1 - \frac{1}{4} (1 + \mathbf{r}_1 \tanh(\xi_{\rho,1,h}/2)) (1 + \mathbf{r}_2 \tanh(\xi_{\rho,2,h}/2)) \right) \right]. \quad (4)$$

► **Theorem 1.** *For any  $0 < d < 2$ ,  $t \in [0, 1]$ , there exists a unique probability measure  $\rho_{d,t} \in \mathcal{P}(\mathbb{R}^2)$  such that*

$$\rho_{d,t} = \log\text{BP}_{d,t}^{\otimes}(\rho_{d,t}) \quad \text{and} \quad \int_{\mathbb{R}^2} \|\xi\|_2^2 d\rho_{d,t}(\xi) < \infty. \quad (5)$$

<sup>1</sup> Formally, up to the so-called condensation threshold, which precedes the  $q$ -colourability threshold by a small additive constant, the logarithm of the number of  $q$ -colourings minus its expectation converges in distribution to a random variable with bounded moments [12, 13, 20].

**Figure 1** *Left:* Numerical approximations to the function  $\phi(d)$  from (1) (red) and the variance  $\eta(d)^2$  from (7) (green). The black dashed line is the first moment bound  $d \mapsto \log(2) + \frac{d}{2} \log(3/4)$ . *Right:* An illustration of the tree  $T^\otimes$  from Section 2.6.

Furthermore,

$$\lim_{n \rightarrow \infty} \frac{\log Z(\Phi) - \mathbb{E}[\log Z(\Phi) \mid Z(\Phi) > 0]}{\sqrt{m}} = \Gamma_{\eta(d)} \quad \text{in distribution, where} \quad (6)$$

$$\eta(d)^2 = \int_0^1 \mathcal{B}_{d,t}^\otimes(\rho_{d,t}) dt - \mathcal{B}_{d,0}^\otimes(\rho_{d,0}) \in (0, \infty). \quad (7)$$

The conditioning on  $\log Z(\Phi) > 0$  is necessary in (6), because even for  $d < 2$  the formula  $\Phi$  is unsatisfiable with probability  $\Omega(n^{-1})$ , in which case  $\log Z(\Phi) = -\infty$ . Moreover, the  $L^2$ -bound from (5) ensures that the integral (7) is well-defined. Finally, (6) implies (2).

How can the formula (7) be evaluated? Because the proof of the uniqueness of the stochastic fixed point  $\rho_{d,t}$  from (5) is based on the contraction method, a fixed point iteration will converge rapidly. In effect, for any  $d, t$  a discrete distribution that approximates  $\rho_{d,t}$  arbitrarily well (in Wasserstein distance) can be computed via a randomised algorithm called *population dynamics* [34, Chapter 14]. Since  $\mathcal{B}_{d,t}^\otimes(\rho_{d,t})$  varies continuously in  $d$  and  $t$ ,  $\eta(d)^2$  can thus be approximated within any desired accuracy, see Figure 1.

## 2 Proof strategy

The main challenge towards the proof of Theorem 1 is to get a handle on the variance of  $\log Z(\Phi)$  given satisfiability. The key idea, inspired by spin glass theory [18] but novel to random constraint satisfaction, is to count the *joint* number of satisfying assignments of two correlated random formulas. Once this is accomplished Theorem 1 will follow from the careful application of a general martingale central limit theorem. To get acclimatised we first revisit the method of moments, the reasons it fails on random 2-SAT and the combinatorial interpretation of the law of large numbers (1).

### 2.1 The method of moments fails

The default approach to estimating the number of solutions to a random CSP is the venerable second moment method [7]. Its thrust is to show that the second moment of the number of solutions is of the same order as the square of the expected number of solutions. If so then the moment computation together with small subgraph conditioning yields the precise limiting distribution of the number of solutions [23, 42]. However, this approach works only if the log of the number of solutions superconcentrates around the log of the expected number of solutions.

This necessary condition is not satisfied in random 2-SAT. In fact, a straightforward calculation yields

$$\frac{1}{n} \log \mathbb{E}[Z(\Phi)] \sim \log 2 + \frac{d}{2} \log(3/4). \quad (8)$$

The formula on the r.h.s. is displayed as the black dashed line in Figure 1. As can be verified analytically, this line strictly exceeds the function  $\phi(d)$  from (1) for any  $0 < d < 2$ . Consequently, (1) implies that  $\log Z(\Phi) \leq \log \mathbb{E}[Z(\Phi)] - \Omega(n)$  w.h.p. In other words, the expected number of solutions  $\mathbb{E}[Z(\Phi)]$  overshoots the typical number of solutions by an exponential factor w.h.p. ; cf. the discussion in [6, 8].

## 2.2 Belief Propagation

Instead of the method of moments, the prescription of the physics-based work of Monasson and Zecchina [36] is to estimate  $\log Z(\Phi)$  by way of the Belief Propagation (BP) message passing algorithm. This approach was vindicated rigorously by Achlioptas et al. [5].

As we will reuse certain elements of that analysis we dwell on BP briefly. For a clause  $a$  of a 2-CNF  $\Phi$  let  $\partial a = \partial_{\Phi} a$  be the set of variables that  $a$  contains. Moreover, for  $x \in \partial a$  let  $\text{sign}_{\Phi}(x, a) = \text{sign}(x, a) \in \{\pm 1\}$  be the sign with which  $x$  appears in  $a$ . Analogously, let  $\partial x = \partial_{\Phi} x$  be the set of clauses in which variable  $x$  appears. BP introduces “messages” between clauses  $a$  and the variables  $x \in \partial a$ . More precisely, each such clause-variable pair  $a, x$  comes with two messages  $\mu_{x \rightarrow a}, \mu_{a \rightarrow x}$ . The messages are probability distributions on “true” and “false”, which we represent by  $\pm 1$ . Thus,  $\mu_{x \rightarrow a}(\pm 1), \mu_{a \rightarrow x}(\pm 1) \geq 0$  and  $\mu_{x \rightarrow a}(1) + \mu_{x \rightarrow a}(-1) = \mu_{a \rightarrow x}(1) + \mu_{a \rightarrow x}(-1) = 1$ .

The messages get updated iteratively by an operator

$$\text{BP} : (\mu_{x \rightarrow a}, \mu_{a \rightarrow x})_{a, x \in \partial a} \mapsto (\hat{\mu}_{x \rightarrow a}, \hat{\mu}_{a \rightarrow x})_{a, x \in \partial a} = \text{BP}((\mu_{x \rightarrow a}, \mu_{a \rightarrow x})_{a, x \in \partial a}). \quad (9)$$

For a clause  $a$  with adjacent variables  $\partial a = \{x, y\}$  the updated messages  $\hat{\mu}_{a \rightarrow x}(\pm 1)$  are defined by

$$\hat{\mu}_{a \rightarrow x}(\text{sign}(x, a)) = \frac{1}{1 + \mu_{y \rightarrow a}(\text{sign}(y, a))}, \quad \hat{\mu}_{a \rightarrow x}(-\text{sign}(x, a)) = \frac{\mu_{y \rightarrow a}(\text{sign}(y, a))}{1 + \mu_{y \rightarrow a}(\text{sign}(y, a))}. \quad (10)$$

Moreover, for a variable  $x$  and a clause  $a \in \partial x$  we define<sup>2</sup>

$$\hat{\mu}_{x \rightarrow a}(s) = \frac{\prod_{b \in \partial x \setminus \{a\}} \mu_{b \rightarrow x}(s)}{\prod_{b \in \partial x \setminus \{a\}} \mu_{b \rightarrow x}(1) + \prod_{b \in \partial x \setminus \{a\}} \mu_{b \rightarrow x}(-1)} \quad (s \in \{\pm 1\}); \quad (11)$$

The purpose of BP is to heuristically “approximate” the marginal probabilities that a random satisfying assignment  $\sigma = \sigma_{\Phi}$  of  $\Phi$  will set a certain variable to a specific truth value. The “approximation” given by the set  $(\mu_{x \rightarrow a}, \mu_{a \rightarrow x})_{a, x \in \partial a}$  of messages reads

$$\mu_x(s) = \frac{\prod_{b \in \partial x} \mu_{b \rightarrow x}(s)}{\prod_{b \in \partial x} \mu_{b \rightarrow x}(1) + \prod_{b \in \partial x} \mu_{b \rightarrow x}(-1)} \quad (s \in \{\pm 1\}). \quad (12)$$

The BP “ansatz” now asks that we iterate the BP operator until an (approximate) fixed point is reached, i.e., ideally until  $\hat{\mu}_{a \rightarrow x} = \mu_{a \rightarrow x}$  and  $\hat{\mu}_{x \rightarrow a} = \mu_{x \rightarrow a}$  for all  $a, x$ . Then we evaluate the BP marginals (12) and plug them into a generic formula called the *Bethe free*

<sup>2</sup> For the sake of tidyness, if the above denominator vanishes we simply let  $\hat{\mu}_{x \rightarrow a}(\pm 1) = \frac{1}{2}$ .

entropy, which yields the BP “approximation” of  $\log Z(\Phi)$ ; an excellent exposition can be found in [34]. The BP recipe provably yields the correct result if the bipartite graph induced by the clause-variable incidences of the 2-CNF  $\Phi$  is acyclic, but may be totally off otherwise.

Of course, for  $1 < d < 2$  the bipartite graph associated with the random formula  $\Phi$  contains cycles in abundance. Nonetheless, (1) confirms that the BP formula provides a valid approximation to within  $o(n)$ . The proof is based on two observations. First, that the local structure of the clause-variable incidence graph can be described by a Galton-Watson tree. Second, that the Galton-Watson tree enjoys a spatial mixing property called *Gibbs uniqueness*.

Since the proof of Theorem 1 also harnesses Gibbs uniqueness, let us elaborate. To mimic the local structure of  $\Phi$  consider a multitype Galton-Watson tree  $\mathbf{T}$  whose types are *variable nodes* and *clause nodes* of four sub-types  $(s, s')$  with  $s, s' \in \{\pm 1\}$ . The root  $o$  is a variable node. The offspring of any variable node is a  $\text{Po}(d/4)$  number of clause nodes of each of the four sub-types. Finally, the offspring of a clause node is a single variable node. The clause type  $(s, s')$  indicates that  $s$  is the sign with which the parent variable appears in the clause, while  $s'$  determines the sign of the child variable. Thus, the Galton-Watson tree  $\mathbf{T}$  can be viewed as a (possibly infinite) 2-CNF. For an integer  $\ell \geq 0$  let  $\mathbf{T}^{(2\ell)}$  be the finite tree/2-CNF obtained by deleting all variables and clauses at a distance larger than  $2\ell$  from the root.

The tree  $\mathbf{T}$  approximates  $\Phi$  locally in the sense that for any fixed  $\ell$  and any given variable  $x_i$  the distribution of the depth- $2\ell$  neighbourhood of  $x_i$  in  $\Phi$  converges to  $\mathbf{T}^{(2\ell)}$  as  $n \rightarrow \infty$  (in the sense of local weak convergence). Moreover, Gibbs uniqueness posits that under random satisfying assignments of the tree-CNF  $\mathbf{T}^{(2\ell)}$  the truth value  $\sigma_o$  of the root under a random satisfying assignment  $\sigma$  decouples from the values  $\sigma_{\mathbf{T},y}$  of variables  $y \in \partial^{2\ell}o$  at distance precisely  $2\ell$  from  $o$  for large  $\ell$ . Formally, with  $S(\mathbf{T}^{(2\ell)})$  the set of satisfying assignments of the 2-CNF  $\mathbf{T}^{(2\ell)}$ , the following is true.

► **Proposition 2** ([5, Proposition 2.2]). *We have*

$$\lim_{\ell \rightarrow \infty} \mathbb{E} \left[ \max_{\tau \in S(\mathbf{T}^{(2\ell)})} \left| \mathbb{P} \left[ \sigma_o = 1 \mid \mathbf{T}^{(2\ell)}, \sigma_{\partial^{2\ell}o} = \tau_{\partial^{2\ell}o} \right] - \mathbb{P} \left[ \sigma_o = 1 \mid \mathbf{T}^{(2\ell)} \right] \right| \right] = 0. \quad (13)$$

### 2.3 Approaching the variance

The proof of the formula (1) combines the Gibbs uniqueness property and the local convergence to the Galton-Watson tree with a coupling argument called the “Aizenman-Sims-Starr scheme” [5]. Unfortunately, this combination does not seem precise enough to get a handle on the limiting distribution of  $\log Z(\Phi)$  by a long shot. Actually, it is anything but clear how even the *order* of the standard deviation of  $\log Z(\Phi)$  could be derived along these lines. One specific problem is that the rate of convergence of (13) diminishes as  $d$  approaches the satisfiability threshold.

To tackle this challenge we devise a combinatorial interpretation of  $\log^2 Z(\Phi)$ . A key idea, which we borrow from spin glass theory [18], is to set up a family of correlated random formulas. Specifically, given integers  $M, M' \geq 0$  we construct a correlated pair  $(\Phi_1(M, M'), \Phi_2(M, M'))$  of formulas on the variable set  $V_n = \{x_1, \dots, x_n\}$  as follows. Let  $(\mathbf{a}_i)_{i \geq 1}$ ,  $(\mathbf{a}'_i)_{i \geq 1}$ ,  $(\mathbf{a}''_i)_{i \geq 1}$  be sequences of mutually independent uniformly random clauses on  $V_n$ . Then

$$\begin{aligned} \Phi_1(M, M') &= \mathbf{a}_1 \wedge \dots \wedge \mathbf{a}_M \wedge \mathbf{a}'_1 \wedge \dots \wedge \mathbf{a}'_{M'}, \\ \Phi_2(M, M') &= \mathbf{a}_1 \wedge \dots \wedge \mathbf{a}_M \wedge \mathbf{a}''_1 \wedge \dots \wedge \mathbf{a}''_{M'}. \end{aligned} \quad (14)$$

Thus, the two formulas share clauses  $\mathbf{a}_1, \dots, \mathbf{a}_M$ . Additionally, each contains another  $M'$  independent clauses. In particular,  $\Phi_1(m, 0)$ ,  $\Phi_2(m, 0)$  are identical, while  $\Phi_1(0, m)$ ,  $\Phi_2(0, m)$  are independent.

Interpolating between these extreme cases offers a promising avenue for computing the variance: given that  $\Phi_1(M, m - M)$  and  $\Phi_2(M, m - M)$  are satisfiable for all  $M$ , we can write a telescoping sum

$$\begin{aligned} & \log Z(\Phi_1(m, 0)) \cdot \log Z(\Phi_2(m, 0)) - \log Z(\Phi_1(0, m)) \cdot \log Z(\Phi_2(0, m)) \\ &= \sum_{M=1}^m \log Z(\Phi_1(M, m - M)) \cdot \log Z(\Phi_2(M, m - M)) \\ & \quad - \log Z(\Phi_1(M - 1, m - M + 1)) \cdot \log Z(\Phi_2(M - 1, m - M + 1)). \end{aligned} \quad (15)$$

If we *could* take the expectation on the l.h.s. of (15), we would precisely obtain the variance of  $\log Z(\Phi)$ . Moreover, each summand on the r.h.s. amounts to a “local” change of swapping a shared clause for a pair of independent clauses. Yet we cannot just take the expectation of (15), because some  $\Phi_h(M, m - M)$  may be unsatisfiable. To remedy this, we will replace  $\log Z(\Phi)$  by a tamer random variable with the same limiting distribution. Its construction is based on the Unit Clause Propagation algorithm.

## 2.4 Unit Clause Propagation

Employed by all modern SAT solvers as a sub-routine, Unit Clause Propagation is a linear time algorithm that tracks the implications of partial assignments. The algorithm receives as input a 2-CNF  $\Phi$  along with a set  $\mathcal{L}$  of literals. These literals are deemed to be “true”. The algorithm then pursues direct logical implications, thereby identifying additional “implied” literals that need to be true so that no clause gets violated. This procedure is outlined in Steps 1–2 of Algorithm 1; the outcome of Steps 1–2 is independent of the order in which literals/clauses are processed.

■ **Algorithm 1** Pessimistic Unit Clause Propagation (“PUC”).

---

**Data:** A 2-CNF  $\Phi$  along with a set  $\mathcal{L}$  of literals deemed true.

- 1 **while** there exists a clause  $a \equiv l \vee \neg l'$  with  $l' \in \mathcal{L}$  and  $l \notin \mathcal{L}$  **do**
- 2     add literal  $l$  to  $\mathcal{L}$ ;
- 3 For variables  $x \in V(\Phi)$  such that  $x \in \mathcal{L}$  or  $\neg x \in \mathcal{L}$  let

$$\sigma_x = \begin{cases} 1 & \text{if } x \in \mathcal{L} \text{ and } \neg x \notin \mathcal{L}, \\ -1 & \text{if } \neg x \in \mathcal{L} \text{ and } x \notin \mathcal{L}, \\ 0 & \text{otherwise.} \end{cases}$$

---

Let  $\mathcal{C}$  be the set of all clauses  $a$  such that  $\sigma_x = 0$  for all  $x \in \partial a$  and return  $\mathcal{L}, \mathcal{C}, \sigma$ ;

---

Clearly, trouble brews if PUC ends up placing both a literal  $l$  and its negation  $\neg l$  into the set  $\mathcal{L}$ . Our “pessimistic” Unit Clause variant makes no attempt at mitigating such contradictions. Instead, Step 3 just constructs a partial assignment where all conflicting literals are set to a dummy value zero. Additionally, PUC identifies the set  $\mathcal{C}$  of *conflict clauses* that contain conflicted variables only.

## 39:8 The Number of Random 2-SAT Solutions Is Asymptotically Log-Normal

Now consider a 2-CNF  $\Phi$  on a set of variables  $V(\Phi)$ . For each possible literal  $l \in \{x, \neg x : x \in V(\Phi)\}$  we run  $\text{PUC}(\Phi, \mathcal{L} = \{l\})$ . Let  $\mathcal{C}(\Phi, \{l\})$  be the set of conflict clauses returned by PUC. Obtain the *pruned formula*  $\hat{\Phi}$  from  $\Phi$  by removing all clauses in  $\mathcal{C}(\Phi) = \bigcup_l \mathcal{C}(\Phi, \{l\})$ . Then it is easy to verify the following.

► **Fact 3.** *For any 2-CNF  $\Phi$  the pruned 2-CNF  $\hat{\Phi}$  is satisfiable.*

Generally, the pruned formula  $\hat{\Phi}$  could have far fewer clauses than the original formula  $\Phi$ . Accordingly, even if  $\Phi$  is satisfiable the number  $Z(\hat{\Phi})$  of satisfying assignments of  $\hat{\Phi}$  could dramatically exceed  $Z(\Phi)$ . However, the following proposition shows that on a random formula, the impact of pruning is modest.

► **Proposition 4.** *With probability  $1 - o(n^{-1/2})$  we have  $|\log Z(\hat{\Phi}) - \log Z(\Phi)| \leq n^{1/3}$ .*

### 2.5 Variance redux

The error bound from Proposition 4 is tight enough so that towards the proof of Theorem 1 it suffices to establish a central limit theorem for  $\log Z(\hat{\Phi})$ , i.e., the log of the number of satisfying assignments of the pruned formula. Once again the pivotal task to this end is to compute the variance of  $\log Z(\hat{\Phi})$ . Revisiting the telescoping sum (15), we obtain the following expression. Recalling (14), we write  $\hat{\Phi}_h(M, M') = \Phi_h(\widehat{M}, \widehat{M}')$  for the formula obtained by pruning  $\Phi_h(M, M')$ .

► **Lemma 5.** *Let*

$$\Delta(M) = \mathbb{E} \left[ \log \left( \frac{Z(\hat{\Phi}_1(M, m - M))}{Z(\hat{\Phi}_1(M - 1, m - M))} \right) \cdot \log \left( \frac{Z(\hat{\Phi}_2(M, m - M))}{Z(\hat{\Phi}_2(M - 1, m - M))} \right) \right], \quad (16)$$

$$\Delta'(M) = \mathbb{E} \left[ \log \left( \frac{Z(\hat{\Phi}_1(M - 1, m - M + 1))}{Z(\hat{\Phi}_1(M - 1, m - M))} \right) \cdot \log \left( \frac{Z(\hat{\Phi}_2(M - 1, m - M + 1))}{Z(\hat{\Phi}_2(M - 1, m - M))} \right) \right]. \quad (17)$$

$$\text{Then } \text{Var} \left[ \log Z(\hat{\Phi}) \right] = \sum_{M=1}^m (\Delta(M) - \Delta'(M)).$$

Lemma 5 expresses the variance as a sum of local changes. For example,  $\Phi_1(M, m - M)$  is obtained from  $\Phi_1(M - 1, m - M)$  by adding a single random clause, namely  $\mathbf{a}_M$ . Thus,  $\Delta(M)$  equals the expected change upon addition of a single *shared* clause – modulo the effect of pruning, that is.

But fortunately, on random formulas only a few clauses get pruned w.h.p. In effect, we can express the impact of these random changes neatly in terms of random satisfying assignments of the “small” formulas  $\hat{\Phi}_h(M - 1, m - M)$  that appear in (16)–(17). Specifically, the quotients in (16)–(17) boil down to the probabilities that random satisfying assignments of the “small” formulas survive the extra clause that gets added to obtain the 2-CNFs in the respective numerators. Thus, with  $\sigma = (\sigma_y)_{y \in V_n}$  denoting a random satisfying assignment of  $\hat{\Phi}_h(M - 1, m - M)$ , we obtain the following.

► **Proposition 6.** *Let  $1 \leq M \leq m$ . W.h.p. we have*

$$\begin{aligned} \frac{Z(\hat{\Phi}_h(M, m-M))}{Z(\hat{\Phi}_h(M-1, m-M))} &= \\ 1 - \prod_{y \in \partial \mathbf{a}_M} \mathbb{P} \left[ \sigma_y \neq \text{sign}(y, \mathbf{a}_M) \mid \hat{\Phi}_h(M-1, m-M), \mathbf{a}_M \right] + o(1) \quad (h = 1, 2), \\ \frac{Z(\hat{\Phi}_1(M-1, m-M+1))}{Z(\hat{\Phi}_1(M-1, m-M))} &= \\ 1 - \prod_{y \in \partial \mathbf{a}'_{m-M+1}} \mathbb{P} \left[ \sigma_y \neq \text{sign}(y, \mathbf{a}'_{m-M+1}) \mid \hat{\Phi}_1(M-1, m-M), \mathbf{a}'_{m-M+1} \right] + o(1), \\ \frac{Z(\hat{\Phi}_2(M-1, m-M+1))}{Z(\hat{\Phi}_2(M-1, m-M))} &= \\ 1 - \prod_{y \in \partial \mathbf{a}''_{m-M+1}} \mathbb{P} \left[ \sigma_y \neq \text{sign}(y, \mathbf{a}''_{m-M+1}) \mid \hat{\Phi}_2(M-1, m-M), \mathbf{a}'_{m-M+1} \right] + o(1). \end{aligned}$$

## 2.6 Local convergence in probability

To evaluate the expressions from Proposition 6 we need to get a grip on the *joint* distribution of the truth values of  $y$  under random satisfying assignments of the two correlated formulas  $\hat{\Phi}_h(M-1, m-M)$ . To this end we will devise a Galton-Watson tree  $\mathbf{T}^\otimes$  that mimics the *joint* distribution of the local structure of  $(\hat{\Phi}_1(M-1, m-M), \hat{\Phi}_2(M-1, m-M))$ . Subsequently, we will establish Gibbs uniqueness for this Galton-Watson tree to compute the expressions from Proposition 6.

The Galton-Watson tree  $\mathbf{T}$  from Section 2.2 that describes the local topology of the “plain” random formula  $\Phi$  had one type of variable nodes and four types  $(\pm 1, \pm 1)$  of clause nodes. To approach the correlated pair  $(\hat{\Phi}_1(M, m-M-1), \hat{\Phi}_2(M, m-M-1))$  we need a Galton-Watson process with three types of variable nodes and a full dozen types of clause nodes. Specifically, there are *shared*, *1-distinct* and *2-distinct* variable nodes. The root  $o$  of  $\mathbf{T}^\otimes$  is a shared variable node. The clause node types are  $(s, s')$ -*shared*,  $(s, s')$  *1-distinct* and  $(s, s')$  *2-distinct* for  $s, s' \in \{\pm 1\}$ .

In addition to  $d \in (0, 2)$  the offspring distributions of  $\mathbf{T}^\otimes = \mathbf{T}_{d,t}^\otimes$  involve a second parameter  $t \in [0, 1]$ :

- A *shared variable* spawns  $\text{Po}(dt/4)$  shared clauses of type  $(s, s')$  as well as  $\text{Po}(d(1-t)/4)$  1-distinct clauses of type  $(s, s')$  and  $\text{Po}(d(1-t)/4)$  2-distinct clauses of type  $(s, s')$  for any  $s, s' \in \{\pm 1\}$ .
- An *h-distinct variable* begets  $\text{Po}(d/4)$   $h$ -distinct clauses of type  $(s, s')$  for any  $s, s' \in \{\pm 1\}$  ( $h = 1, 2$ ).
- A *shared clause* has precisely one shared variable as its offspring.
- An *h-distinct clause* spawns a single  $h$ -distinct variable ( $h = 1, 2$ ).

Figure 1 provides an illustration of the tree  $\mathbf{T}^\otimes$ . Shared variables/clauses are indicated in red, 1-distinct variables/clauses in green and 2-distinct ones in blue.

From  $\mathbf{T}^\otimes$  we extract a pair  $(\mathbf{T}_1, \mathbf{T}_2)$  of correlated random trees. Specifically,  $\mathbf{T}_h$  is obtained from  $\mathbf{T}^\otimes$  by deleting all  $(3-h)$ -distinct variables and clauses. Hence, the parameter  $t$  determines how “similar”  $\mathbf{T}_1, \mathbf{T}_2$  are. Specifically, if  $t = 1$  then no  $\{1, 2\}$ -distinct clauses exist and thus  $\mathbf{T}_1, \mathbf{T}_2$  are identical. By contrast, if  $t = 0$  then  $\mathbf{T}_1, \mathbf{T}_2$  are independent copies of the tree  $\mathbf{T}$  from Section 2.2.

## 39:10 The Number of Random 2-SAT Solutions Is Asymptotically Log-Normal

For an integer  $\ell \geq 0$  obtain  $\mathbf{T}^{\otimes, (2\ell)}$ ,  $\mathbf{T}_1^{(2\ell)}$ ,  $\mathbf{T}_2^{(2\ell)}$  from  $\mathbf{T}^{\otimes}, \mathbf{T}_1, \mathbf{T}_2$  by omitting all nodes at a distance greater than  $2\ell$  from the root  $o$ . As in Section 2.2, we can interpret these trees as 2-CNFs, with the type  $(s, s')$  of a clause indicating the signs of its parent and child variables. We say that two possible outcomes  $T, T'$  of  $\mathbf{T}^{\otimes, (2\ell)}$  are *isomorphic* if there is a tree isomorphism that preserves the root  $o$  as well as all types.

Further, a variable  $x \in V_n$  is called a  $2\ell$ -instance of  $T$  in  $(\hat{\Phi}_1(M, M'), \hat{\Phi}_2(M, M'))$  if there exist isomorphisms  $\iota_h$  of the 2-CNFs  $T_h$  obtained from  $T$  by deleting all  $(3-h)$ -distinct variables/clauses to the depth- $2\ell$  neighbourhoods  $\partial_{\hat{\Phi}_h(M, M')}^{\leq 2\ell} x$  of  $x$  in  $\hat{\Phi}_h(M, M')$  such that

- the root gets mapped to  $x$ , i.e.,  $\iota_1(o) = \iota_2(o) = x$ ,
- for any shared variable  $y$  of  $T_1, T_2$  the image variables coincide, i.e.,  $\iota_1(y) = \iota_2(y)$ ,
- for any shared clauses  $a$  of  $T_1, T_2$  the image  $\iota_1(a) = \iota_2(a) \in \{\mathbf{a}_1, \dots, \mathbf{a}_M\}$  is a shared clause,
- for any 1-distinct clause  $a$  whose parent in  $T_1$  is a shared variable,  $\iota_1(a) \in \{\mathbf{a}'_1, \dots, \mathbf{a}'_{M'}\}$ , and
- for any 2-distinct clause  $a$  whose parent in  $T_2$  is a shared variable,  $\iota_1(a) \in \{\mathbf{a}''_1, \dots, \mathbf{a}''_{M'}\}$ .

Let  $\mathbf{N}^{(2\ell)}(T, (\Phi_1(M, M'), \Phi_2(M, M')))$  be the number of  $2\ell$ -instances of  $T$  in  $(\Phi_1(M, M'), \Phi_2(M, M'))$ . The following proposition confirms that  $\mathbf{T}^{\otimes}$  models the local structure of  $(\hat{\Phi}_1(M, M'), \hat{\Phi}_2(M, M'))$  faithfully.

► **Proposition 7.** *Let  $\ell > 0$  be a fixed integer, let  $t \in [0, 1]$  and suppose that  $M \sim tdn/2$  and  $M' \sim (1-t)dn/2$ . Then w.h.p. for all possible outcomes  $T$  of  $\mathbf{T}^{\otimes, (2\ell)}$  we have  $\mathbf{N}^{(2\ell)}(T, (\hat{\Phi}_1(M, M'), \hat{\Phi}_2(M, M'))) \sim n\mathbb{P}[\mathbf{T}^{\otimes, (2\ell)} \cong T]$ .*

### 2.7 Correlated Belief Propagation

Now that we have a branching process description of our pair of correlated formulas the next step is to run BP on the random trees  $(\mathbf{T}_1, \mathbf{T}_2)$  to find the joint distribution of the truth values  $\sigma_{\mathbf{T}_1^{(2\ell)}, o}, \sigma_{\mathbf{T}_2^{(2\ell)}, o}$  assigned to the root. Hence, let

$$\boldsymbol{\mu}^{(2\ell)} = \left( \mathbb{P} \left[ \sigma_{\mathbf{T}_1^{(2\ell)}, o} = 1 \mid \mathbf{T}^{\otimes} \right], \mathbb{P} \left[ \sigma_{\mathbf{T}_2^{(2\ell)}, o} = 1 \mid \mathbf{T}^{\otimes} \right] \right) \in (0, 1)^2. \quad (18)$$

Since BP is exact on trees, we could calculate these marginals by iterating (9)–(11) for  $2\ell$  steps, starting from all-uniform messages. But our objective is not merely to calculate the marginals of a specific pair of trees, but the *distribution* of the vector (18) for a random  $\mathbf{T}^{\otimes}$ . Fortunately, due to the Markovian nature of the Galton-Watson tree  $\mathbf{T}^{\otimes}$ , the bottom-up BP computation on a random tree can be expressed by a fixed point iteration on the space of probability distributions on  $\mathbb{R}^2$ . The appropriate operator is the  $\log\text{BP}_{d,t}^{\otimes}$ -operator from (3). To be precise, that operator expresses the updates of the log-likelihood ratios of the BP messages from (10)–(11). Thus, let

$$\mathfrak{t} : (z_1, z_2) \in \mathbb{R}^2 \mapsto ((1 + \tanh(z_1/2))/2, (1 + \tanh(z_2/2))/2) \in (0, 1)^2$$

be the function that maps log-likelihood ratios back to probabilities. Furthermore, for a probability measure  $\rho \in \mathcal{P}(\mathbb{R}^2)$  let  $\mathfrak{t}(\rho)$  be the pushforward probability measure on  $(0, 1)^2$ .<sup>3</sup>

► **Proposition 8.** *Let  $\rho_{d,t}^{(0)} \in \mathcal{P}(\mathbb{R}^2)$  be the atom at the origin and let  $\rho_{d,t}^{(\ell)} = \log\text{BP}_{d,t}^{\otimes}(\rho_{d,t}^{(\ell-1)})$ . Then  $\boldsymbol{\mu}^{(2\ell)}$  has distribution  $\mathfrak{t}(\rho_{d,t}^{(\ell)})$ .*

<sup>3</sup> That is, for a measurable  $\mathfrak{A} \subseteq (0, 1)^2$  we have  $\mathfrak{t}(\rho)(\mathfrak{A}) = \rho(\mathfrak{t}^{-1}(\mathfrak{A}))$ .

■ **Figure 2** The distributions  $t(\rho_{d,t})$  for  $d = 1.9$  and  $t = 0.1, 0.5, 0.9$ .

We employ the contraction method to show that the sequence  $(\rho_{d,t}^{(\ell)})_{\ell \geq 1}$  of measures converges.

► **Proposition 9.** *There exists a unique  $\rho_{d,t} \in \mathcal{P}(\mathbb{R}^2)$  that satisfies (5) and  $\lim_{\ell \rightarrow \infty} \rho_{d,t}^{(\ell)} = \rho_{d,t}$  weakly.*

Furthermore, the Gibbs uniqueness property (13) extends to  $\mathbf{T}_1$  and  $\mathbf{T}_2$ .

► **Corollary 10.** *For all  $t \in [0, 1]$  and  $h = 1, 2$  we have*

$$\mathbb{E} \left[ \max_{\tau \in S(\mathbf{T}_h^{(2\ell)})} \left| \mathbb{P} \left[ \sigma_{\mathbf{T}_h^{(2\ell)}, o} = 1 \mid \mathbf{T}^{\otimes}, \sigma_{\mathbf{T}_h^{(2\ell)}, \partial^{2\ell} o} = \tau_{\partial^{2\ell} o} \right] - \mathbb{P} \left[ \sigma_{\mathbf{T}_h^{(2\ell)}, o} = 1 \mid \mathbf{T}^{\otimes} \right] \right| \right] \rightarrow 0, \tag{19}$$

as  $\ell \rightarrow +\infty$ .

Combining Propositions 8 and 9 and Corollary 10, we are now in a position to pinpoint the joint marginals of  $\hat{\Phi}_1(M, M')$ ,  $\hat{\Phi}_2(M, M')$ . Formally, let

$$\pi_{\hat{\Phi}_1(M, M'), \hat{\Phi}_2(M, M')} = \frac{1}{n} \sum_{i=1}^n \delta_{(\mathbb{P}[\sigma_{\hat{\Phi}_1(M, M'), x_i} = 1 \mid \hat{\Phi}_1(M, M')], \mathbb{P}[\sigma_{\hat{\Phi}_2(M, M'), x_i} = 1 \mid \hat{\Phi}_2(M, M')])} \in \mathcal{P}([0, 1]^2)$$

be the empirical distribution of the joint marginals of  $\hat{\Phi}_1(M, M')$  and  $\hat{\Phi}_2(M, M')$ , which we need to know to evaluate the expressions from Proposition 6. Furthermore, denote by  $W_1(\cdot, \cdot)$  the Wasserstein  $L^1$ -distance of two probability measures on  $[0, 1]^2$ .

► **Corollary 11.** *For any  $t \in [0, 1]$  and any  $M \sim \text{tnd}/2$ ,  $M' \sim (1 - t)dn/2$  we have*

$$\mathbb{E} \left[ W_1 \left( \pi_{\hat{\Phi}_1(M, M'), \hat{\Phi}_2(M, M')}, t(\rho_{d,t}) \right) \right] = o(1).$$

Finally, combining Proposition 6 with Corollary 11, we obtain the variance of  $\log Z(\hat{\Phi})$ .

► **Corollary 12.** *With  $\eta(d)^2$  from (7) we have  $\eta(d) > 0$  and  $\text{Var} \log Z(\hat{\Phi}) \sim m\eta_d^2$ .*

Because the proof of Proposition 9 is based on a contraction argument, for any  $d, t$  the distribution  $\rho_{d,t}$  can be approximated effectively within any given accuracy via a fixed point iteration. Figure 2 displays approximations to  $t(\rho_{d,t})$  for different values of  $t$  and shows how correlations between the two coordinates of the random vector increase with  $t$  (brighter diagonal).

## 2.8 The central limit theorem

With the variance computation done, we have now overcome the greatest hurdle en route to Theorem 1. Indeed, to obtain the desired asymptotic normality we just need to combine the techniques from the variance computation with a generic martingale central limit theorem.

To this end we set up a filtration  $(\mathfrak{F}_{n,M})_{0 \leq M \leq m_n}$  by letting  $\mathfrak{F}_{n,M}$  be the  $\sigma$ -algebra generated by  $\mathbf{a}_1, \dots, \mathbf{a}_M$ . Hence, conditioning on  $\mathfrak{F}_{n,M}$  amounts to conditioning on  $\mathbf{a}_1, \dots, \mathbf{a}_M$ , while averaging on the remaining clauses  $\mathbf{a}_{M+1}, \dots, \mathbf{a}_m$ . The conditional expectations

$$\mathbf{Z}_{n,M} = m^{-1/2} \mathbb{E} \left[ \log Z(\hat{\Phi}) \mid \mathfrak{F}_{n,M} \right] \quad (20)$$

then form a Doob martingale. Let  $\mathbf{X}_{n,M} = \mathbf{Z}_{n,M} - \mathbf{Z}_{n,M-1}$  be the martingale differences.

► **Proposition 13.** *For all  $0 < d < 2$  the martingale (20) satisfies*

$$\lim_{n \rightarrow \infty} \mathbb{E} \left[ \max_{1 \leq M \leq m} |\mathbf{X}_{n,M}| \right] = 0 \quad \text{and} \quad \lim_{n \rightarrow \infty} \mathbb{E} \left| \eta(d)^2 - \sum_{M=1}^m \mathbf{X}_{n,M}^2 \right| = 0. \quad (21)$$

Thanks to pruning, the first condition from (21) is easily checked. Furthermore, the steps that we pursued towards the proof of Corollary 12, i.e., the variance calculation, also imply the second condition without further ado. Finally, as (21) demonstrates that the marginal differences are small and that the variance process converges to a deterministic limit, Theorem 1 follows the general martingale central limit theorem from [27].

## 3 Discussion

The hunt for satisfiability thresholds of random constraint satisfaction problems was launched by the experimental work of Cheeseman, Kanefsky and Taylor [17]. The 2-SAT threshold was the first one to be caught [19, 31]. Subsequent successes include the 1-in- $k$ -SAT threshold [3] and the  $k$ -XORSAT threshold [26, 40]. Furthermore, Friedgut [29] proved the existence of non-uniform (i.e.,  $n$ -dependent) satisfiability thresholds in considerable generality. The plot thickened when physicists employed a compelling but non-rigorous technique called the cavity method to “predict” the exact satisfiability thresholds of many further problems, including the  $k$ -SAT problem for  $k \geq 3$  [35]. A line of rigorous work [6, 8, 22] culminated in the verification of this physics prediction for large  $k$  [24].

Even though the satisfiability threshold of random 2-SAT was determined already in the 1990s, the problem continued to receive considerable attention. For example, Bollobás, Borgs, Chayes, Kim and Wilson [14] investigated the scaling window around the satisfiability threshold, a point on which a recent contribution by Dovgal, de Panafieu and Ravelomanana elaborates [25]. Abbe and Montanari [2] made the first substantial step towards the study of the number of satisfying assignments that  $\frac{1}{n} \log Z(\Phi)$  converges in probability to a deterministic limit  $\varphi(d)$  for Lebesgue-almost all  $d \in (0, 2)$ . However, their techniques do not reveal the value  $\varphi(d)$ . Moreover, Montanari and Shah [37] obtain a “law-of-large-numbers” estimate of the number of assignments that violate all but  $o(n)$  clauses for  $d < 1.16$ . Finally, the aforementioned article of Achlioptas et al. [5] verifies the prediction from [36] as to the number of satisfying assignments for all  $d < 2$ . The main result of the present paper refines these results considerably by establishing a central limit theorem.

For random  $k$ -CNFs with  $k \geq 3$  an upper bound on the number of satisfying assignments can be obtained via the interpolation method from mathematical physics [39]. This bound matches the predictions of the cavity method [34]. However, no matching lower bound is

currently known. The precise physics prediction called the “replica symmetric solution” has only been verified for “soft” versions of random  $k$ -SAT where unsatisfied clauses are penalised but not strictly forbidden, and for clause-to-variable ratios well below the satisfiability threshold [37, 38, 44].

Random CSPs such as random  $k$ -XORSAT or random  $k$ -NAESAT that exhibit stronger symmetry properties than random  $k$ -SAT tend to be amenable to the method of moments [6].<sup>4</sup> Therefore, more is known about their number of solutions. For example, due to the inherent connection to linear algebra, the number of satisfying assignments of random  $k$ -XORSAT formulas is known to concentrate on a single value right up to the satisfiability threshold [11, 26, 40]. Furthermore, in random  $k$ -NAESAT, random graph colouring and several related problems, the logarithm of the number of solutions superconcentrates, i.e., has only bounded fluctuations for constraint densities up to the so-called condensation threshold, a phase transition that shortly precedes the satisfiability threshold [12, 20, 41]. The same is true of random  $k$ -SAT instances with regular literal degrees [23]. A further example is the symmetric perceptron [1], where the number of solutions superconcentrates but the limiting distribution is a log-normal with bounded variance. Going beyond the condensation transition, Sly, Sun and Zhang [43] proved that the number of satisfying assignments of random regular  $k$ -NAESAT formulas matches the “1-step replica symmetry breaking” prediction from physics.

Apart from the superconcentration results for symmetric problems from [12, 23, 20, 41], the limiting distribution of the logarithm of the number of solutions has not been known in any random constraint satisfaction problem. In particular, Theorem 1 is the first central limit theorem for this quantity in any random CSP. We expect that the technique developed in the present work, particularly the use of two correlated random instances in combination with spatial mixing, can be extended to other problems. The present use of correlated instances is inspired by the work of Chen, Dey and Panchenko [18] on the  $p$ -spin model from mathematical physics, a generalisation of the famous Sherrington-Kirkpatrick model. That said, on a technical level the present use of correlated instances is quite different from the approach from [18]. Specifically, while here we construct correlated 2-CNFs that share a specific fraction of their clauses and employ a martingale central limit theorem, Chen, Dey and Panchenko combine a continuous interpolation of two mixed  $p$ -spin Hamiltonians with Stein’s method.

A further line of work deals with central limit theorems for random optimisation problems. Cao [16] provided a general framework based on the “objective method” [9]. Unfortunately, the conditions of Cao’s theorem tend to be unwieldy for MAX CSP problems with hard constraints. Recent work of Kreačič [32] and Glasgow, Kwan, Sah, Sawhney [30] on the matching number therefore instead resorts to the use of stochastic differential equations. A promising question for future work might be whether the present method of considering correlated instances might extend to random optimisation problems.

## Abstract

---

Privately counting distinct elements in a stream is a fundamental data analysis problem with many applications in machine learning. In the turnstile model, Jain et al. [NeurIPS2023] initiated the study of this problem parameterized by the maximum flippancy of any element, i.e., the number of times that the count of an element changes from 0 to above 0 or vice versa. They give an item-level  $(\epsilon, \delta)$ -differentially private algorithm whose additive error is tight with respect to that parameterization. In this work, we show that a very simple algorithm based on the sparse vector technique achieves a tight additive error for item-level  $(\epsilon, \delta)$ -differential privacy and item-level  $\epsilon$ -differential privacy with regards to a different parameterization, namely the sum of all flippancies. Our second result is a bound which shows that for a large class of algorithms, including all existing differentially private algorithms for this problem, the lower bound from item-level differential privacy extends to event-level differential privacy. This partially answers an open question by Jain et al. [NeurIPS2023].

## 1 Introduction

Counting distinct elements in a stream is a fundamental data analysis problem that is widely studied [12, 13, 17, 18, 20] and has many applications [1, 10, 19, 2, 21, 5], including network analysis [21] and detection of denial of service attacks [1, 5]. If the data includes sensitive information, the essential challenge is to give accurate answers while providing privacy guarantees to the data owners. Differential privacy is the de-facto standard in private data analysis and is widely employed both in research and in industry. In the insertions-only model, the problem of counting distinct elements while preserving differential privacy is well-studied [3, 9, 14].

Recent work by Jain, Kalemaj, Raskhodnikova, Sivakumar, and Smith [16] (which was concurrent with an earlier version of the results presented in this paper, see [15, Section 5]) initiated the study of this problem in the more general turnstile model. They give an algorithm which is *item-level*,  $(\epsilon, \delta)$ -differentially private and analyze the additive error

parameterized in the *maximum flippancy* of any element, i.e., the number of times that the count of an element changes from 0 to above 0 or vice versa. They also give lower bounds which show that the additive error of the algorithm is tight for item-level differential privacy (up to log factors) with respect to their parameterization. There is still a gap for event-level differential privacy, which is posed as an open question. The algorithm is based on several instantiations of the binary tree mechanism.

In this paper we show that a simple algorithm based on the sparse vector technique achieves a tight additive error (up to log factors) for item-level  $(\epsilon, \delta)$ -differential privacy and item-level  $\epsilon$ -differential privacy, with regards to a different parameterization, namely the *total flippancy*, i.e., the sum of the flippancies of all elements. The additive error depends polynomially on the total flippancy with a smaller exponent than the exponent of the maximum flippancy in the additive error in [16]. Thus, if there are few elements in total, or few elements which change their count from 0 to above 0 or vice versa, then our algorithm achieves a better additive error. Additionally, we give a reduction which shows that for a large class of algorithms, including all existing differentially private algorithms for this problem, the lower bound from item-level differential privacy extends to event-level differential privacy. This is a step towards answering the open question posed in [16].

## 1.1 Problem Definition

More formally, we assume there are  $d$  different items, and our goal is to maintain a multiset of them and to determine at each time step how many of them are currently at least once in the multiset, i.e., the number of distinct elements in the multiset. The update operations are modeled as follows: The input at every time step is a  $d$ -dimensional vector  $x^t \in \{-1, 0, 1\}^d$ , such that  $x_i^t = 1$  if element  $i$  gets inserted at time  $t$ ,  $x_i^t = -1$  if element  $i$  gets deleted at time  $t$ , and  $x_i^t = 0$  otherwise. Note that this means that we allow *multiple non-zero entries* in  $x^t$ , corresponding to *multiple updates* at every time step. However, the lower bound also extends to the case where we assume that at most one element may be inserted or deleted at any time step, i.e.,  $\|x^t\|_1 \leq 1$ , which we call *singleton update streams*. At every time step  $t$ , we want to output the number of distinct elements in the multiset. By our definition of the input stream, an element  $i$  is present at time  $t$  if and only if  $\sum_{t' \leq t} x_i^{t'} > 0$ .

► **Definition 1** (COUNTDISTINCT). *Let  $x^1, x^2, \dots, x^T$  be an input stream with  $x^t \in \{-1, 0, 1\}^d$  for all  $t \in [1, T]$ . We define  $\text{COUNTDISTINCT}(x)^t = \sum_{i=1}^d \mathbb{1}(\sum_{t' \leq t} x_i^{t'} > 0)$ , where  $\mathbb{1}(E)$  is the indicator function that is 1 if  $E$  is true and 0 otherwise. Then, the COUNTDISTINCT problem is to output  $\text{COUNTDISTINCT}(x)^t$  at all time steps  $t$ . The error of COUNTDISTINCT is defined to be the maximum additive error over all time steps.*

In this paper, we consider two privacy notions: *event-level* differential privacy, and *item-level* differential privacy. They differ in their definition of neighboring input streams. Two input streams  $x$  and  $y$  are *event-level neighboring*, if there exists a time step  $t^*$  and an item  $i^* \in [1, d]$  such that we have  $x_i^t = y_i^t$  for all  $(i, t) \neq (i^*, t^*)$ . That is, two event-level neighboring streams may differ in *at most one item in at most one update operation*. Two input streams  $x$  and  $y$  are *item-level neighboring*, if there exists an item  $i^* \in [1, d]$  such that  $x_i^t = y_i^t$  for all  $t$  and for all  $i \in [1, d] \setminus \{i^*\}$ . That is, two item-level neighboring streams may differ in *all update operations related to one item*.

Finally, we consider two models regarding the input stream. In the *general model* the counts for any item at any time step  $t$  is given by  $\sum_{t' \leq t} x_i^{t'}$ , which can be any integer in  $[-t, t]$  and we only care about whether  $\sum_{t' \leq t} x_i^{t'}$  is larger than zero or not. In the *“likes”-model*<sup>1</sup>

<sup>1</sup> The name was chosen as it models the count of “likes” on a social media website, as motivated by [16].

for every item  $i$  at any time step  $t$ , it must hold that  $\sum_{t' \leq t} x_i^{t'} \in \{0, 1\}$ , i.e., the multiset is a set. Said differently, an item can only be inserted if it is absent in the set and it can only be deleted when it is present.

## 1.2 Summary of Results

In this paper, we give new upper and lower bounds for *item-level* differential privacy, parameterized in the *total flippancy*  $K$ , which is defined as the total number of times any item switches from a non-zero count to a zero count, or vice versa. In detail, let  $f^t(x_i) = \mathbb{1}(\sum_{t' < t} x_i^{t'} > 0)$ . The total flippancy is formally defined as  $K = \sum_{i=1}^d \sum_{t=2}^T \mathbb{1}(f^t(x_i) \neq f^{t-1}(x_i))$ . Note that in the “likes”-model, the total flippancy is equal to the total number of updates. As  $\text{COUNTDISTINCT}(x)^t = \sum_{i=1}^d f^t(x_i)$ , it follows that  $K$  is an upper bound on the number of changes in  $\text{COUNTDISTINCT}(x)$  over time.

### Upper Bounds

As our first main result, we give algorithms solving  $\text{COUNTDISTINCT}$  while providing item-level differential privacy, which work in the general model (thus also in the “likes”-model). In the following, we state the exact bounds for *given*  $K$ . If  $K$  is not given to the algorithm, the error bounds worsen by at most a  $\ln^2 K$  factor.

► **Theorem 2.** *Let  $d$  be a non-zero integer,  $\beta > 0$ ,  $K$  be a known upper bound on the total flippancy, and let  $T$  be a known upper bound on the number of time steps. Then there exists*

1. *an item-level  $\epsilon$ -differentially private algorithm for  $\text{COUNTDISTINCT}$  in the general model with additive error  $O(\min(d, K, \sqrt{\epsilon^{-1} K \ln(T/\beta)}, \epsilon^{-1} T \log(T/\beta)))$  with probability at least  $1 - \beta$  at all time steps simultaneously, for any  $\epsilon > 0$  and  $\beta \in (0, 1)$ ;*
2. *an item-level  $(\epsilon, \delta)$ -differentially private algorithm for  $\text{COUNTDISTINCT}$  in the general model with additive error  $O(\min(d, K, (\epsilon^{-2} K \ln(1/\delta) \ln^2(T/\beta))^{1/3}, \epsilon^{-1} \sqrt{T \ln(1/\delta) \log(T/\beta)}))$  with probability at least  $1 - \beta$  at all time steps simultaneously, for any  $\delta \in (0, 1)$ ,  $\epsilon \in (0, 1)$ , and  $\beta \in (0, 1)$ .*

As our lower bounds (discussed below) show, our bounds for  $\epsilon$ -differential privacy are *tight*, if  $K$  is known and  $K \leq T$ . If  $K > T$ , we incur at most an extra  $\ln T$  factor, and if  $K$  is not known, we incur extra  $\ln K$  factors (see Section 6). For  $(\epsilon, \delta)$ -differential privacy, the upper bounds are tight up to  $\ln T$ ,  $\ln K$  and  $\ln(1/\delta)$  factors.

### Lower bounds

We complement our upper bounds by almost tight lower bounds on the additive error which hold for any item-level differentially private algorithm in the “likes”-model. As this is the “more restricted” of the two models, the lower bounds also carry over to the general model. For  $\epsilon$ -differential privacy, our lower bound follows from a packing argument.

► **Theorem 3** (Simplified version of Theorem 16). *For any  $L \leq T$ , there exists an input stream  $x$  of  $d$ -dimensional vectors from  $\{-1, 0, 1\}^d$ , which is valid in the “likes”-model, with length  $T$  and flippancy  $K = \Theta(L)$ , such that any item-level,  $\epsilon$ -differentially private algorithm for  $\text{COUNTDISTINCT}$  must with constant probability have an error at least  $\Omega(\min(d, K, \sqrt{\epsilon^{-1} K \max(\ln(T/K), 1)}))$ .*

The lower bound above also holds for singleton updates. When multiple updates are allowed, then  $K$  could potentially be larger than  $T$ . In that case, Theorem 16 in Section 5 shows that for any  $T \leq L \leq dT$ , there exists a stream with flippancy  $K = \Omega(T)$ ,

■ **Table 1** Comparison of our results (in blue) and the results in [16] for the different models.  $K$  denotes the total flippancy and  $w$  denotes the maximum flippancy of an input stream  $x$ . For simplicity of exposition, we consider singleton insertions and omit factors polynomial in  $\ln T$ ,  $\ln(1/\delta)$ , and  $\epsilon^{-1}$ . The bounds marked with \* hold for *output dependent* algorithms (see the discussion before Theorem 5 for details). The bounds in the last line follow from a simple application of a continual counting algorithm on the difference sequence.

$K = O(L)$ , such that any item-level,  $\epsilon$ -differentially private algorithm to the COUNT-DISTINCT problem must have error at least  $\Omega(\min(d, \epsilon^{-1}T, \sqrt{\epsilon^{-1}L \max(\ln(T/L), 1)})) = \Omega(\min(d, \epsilon^{-1}T, \sqrt{\epsilon^{-1}K \max(\ln(T/K), 1)}))$  with constant probability. For  $(\epsilon, \delta)$ -differential privacy, we can use a similar strategy as in [16] to get the following bounds:

► **Theorem 4** (Simplified version of Theorem 19). *Let  $\epsilon, \delta \in (0, 1]$ . Let  $K, T$  be sufficiently large parameters. There exists a dimension  $d \in \mathbb{N}$  and an input stream  $x$  of  $d$ -dimensional vectors from  $\{-1, 0, 1\}^d$  of length  $T$  with flippancy at most  $K$  which is valid in the “likes”-model, such that any item-level,  $(\epsilon, \delta)$ -differentially private algorithm for COUNTDISTINCT must have error at least  $\Omega\left(\epsilon^{-1} \cdot \min\left(\frac{\sqrt{T}}{\log T}, \frac{(K\epsilon)^{1/3}}{\log(K\epsilon)}\right)\right)$  with constant probability.*

Note that this lower bound holds for the case where *multiple insertions* are allowed in every time step. In Theorem 19 we also give a lower bound of  $\Omega\left(\frac{K^{1/3}}{\epsilon \log K}\right)$  for singleton-updates.

### Time and Space Complexity

Our main algorithm (achieving the  $O(\sqrt{\epsilon^{-1}K \ln T})$  error bound for  $\epsilon$ -differential privacy and  $O((K \ln(1/\delta) \ln^2 T)^{1/3}/\epsilon^{2/3})$  error bound for  $(\epsilon, \delta)$ -differential privacy) can be implemented using constant time per update, assuming that drawing from a Laplace distribution takes constant time. Specifically, the total running time is  $O(\#\text{updates} + S_K t_{\text{Lap}})$ , where  $t_{\text{Lap}}$  is the time to draw one Laplace random variable,  $S_K = O(\sqrt{K\epsilon/\ln T} + 1)$  for  $\epsilon$ -dp, and  $S_K = O\left(\left(\frac{K\epsilon}{\sqrt{\ln(1/\delta) \ln(T/\beta)}}\right)^{2/3}\right)$  for  $(\epsilon, \delta)$ -dp. The algorithm uses  $O(d)$  words of space. The only information our algorithm needs to store are the true counts for each item, plus a constant number of words of extra information. This holds even for the case where  $K$  is unknown, since we *sequentially* run our known  $K$  algorithm with increasing guesses for  $K$ .

### Comparison to the recent work by Jain, Kalemaj, Raskhodnikova, Sivakumar, and Smith [16]

In recent work, [16] considered the COUNTDISTINCT problem with a similar, but different parameterization. In [16], they parameterize the additive error in the *maximum flippancy*, i.e., they parameterize on  $w_x = \max_{i \in [d]} (\sum_{t=2}^T \mathbb{1}(f^t(x_i) \neq f^{t-1}(x_i)))$ . Recall that  $K$  denotes the

total flippancy of a stream  $x$  and note that  $w_x \leq K \leq d \cdot w_x$ . [16] consider only streams with singleton updates and give algorithms for item-level,  $(\epsilon, \delta)$ -differential privacy in the general model, with an error bound of  $\tilde{O}\left(\min\left(\left(\sqrt{w_x} \log T + \log^3 T\right) \cdot \frac{\sqrt{\log(1/\delta)}}{\epsilon}, \frac{(T \log(1/\delta))^{1/3}}{\epsilon^{2/3}}, T\right)\right)^2$ .

In comparison, our bounds in this setting are  $\tilde{O}\left(\min\left(\frac{(K \ln(1/\delta) \ln^2 T)^{1/3}}{\epsilon^{2/3}}, K\right)\right)$ . Note that  $K \leq T$  for singleton updates, and thus, our upper bounds recover their second and third bound up to a  $\ln^{2/3} T$  factor. Furthermore, ignoring polynomial factors in  $\log T$ ,  $\log(1/\delta)$  and  $\epsilon^{-1}$ , their bound is  $O(\sqrt{w_x})$  while ours is  $O(K^{1/3})$ . Thus, if (roughly)  $K < w_x^{3/2}$ , our algorithm outperforms theirs. Specifically, if  $d \leq \sqrt{w_x}$  or if there are only few items with high flippancy, we expect our algorithm to do better. In cases where the flippancy is well-distributed, i.e., many items have a similar flippancy, and  $d \geq \sqrt{w_x}$ , we expect the algorithm in [16] to perform better.

In terms of space and time complexity, their algorithm, like ours, needs to maintain a count for each element. Thus, the space in terms of words is  $\Omega(d)$ . On top of that, they run a variant of the binary tree mechanism, which depending on the implementation, uses  $\Omega(\log T)$  space. In their final solution, they actually run  $\log T$  copies of the binary tree mechanism in parallel, bringing their space consumption to  $O(d + \log^2 T)$  words. Thus, the space of our algorithm is an additive  $\log^2 T$  term better, which can be crucial for large streams. In terms of time complexity, each of the binary tree mechanism needs to draw  $\Omega(T \log T)$  independent Laplace noises, thus their time complexity is at least  $\Omega(T \log^2 T t_{\text{Lap}})$ , where  $t_{\text{Lap}}$  is the time it takes to draw a Laplace noise. Also here, our algorithm is more efficient.

In terms of lower bounds, for item-level,  $\epsilon$ -differential privacy in the “likes”-model, [16] give a lower bound of  $\Omega(\min(\epsilon^{-1}w, \sqrt{\epsilon^{-1}T}, T))$  for streams of maximum flippancy at most  $w$ . For  $(\epsilon, \delta)$ -differential privacy, they give a lower bound of  $\tilde{\Omega}(\min(\epsilon^{-1}\sqrt{w}, \epsilon^{-2/3}T^{1/3}, T))$  for item-level privacy in the “likes”-model, and  $\tilde{\Omega}(\min(\epsilon^{-1}\sqrt{w}, \epsilon^{-3/4}T^{1/4}, T))$  for event-level privacy in the general model, for streams of maximum flippancy at most  $w$ . Their upper bounds in the item-level setting match their lower bounds up to factors polynomial in  $\log T$  and  $\log(1/\delta)$ . For event-level in the general model, there is a gap for  $\sqrt{T} \leq w \leq T^{2/3}$ , and closing this gap was posed as an explicit open question in [16]. As our second main result, we make a step towards closing this gap, which we explain below.

### Reduction from item-level, “likes”-model to output-dependent event-level, general model

All upper bounds mentioned so far hold for *item-level* differential privacy. As our upper bounds hold in the general model and our lower bounds hold in the “likes”-model, we can conclude that for item-level privacy, the “likes”-model and the general model are roughly equally hard. [16] arrived at this conclusion as well, albeit with a different parameterization.

However, for *event-level* differential privacy, the picture is different: for the “likes”-model, a very simple algorithm gives an error of  $O(\epsilon^{-1} \text{polylog}(T))$  with constant probability. To see this, define the *difference sequence* for the COUNTDISTINCT problem as  $\text{diff}^t(x) = \text{COUNTDISTINCT}(x)^t - \text{COUNTDISTINCT}(x)^{t-1}$  for  $t > 1$ . As can be easily seen,  $(\text{diff}^t(x))_{t>1}$  and  $(\text{diff}^t(y))_{t>1}$  differ by at most 1 in at most one time step  $t$  for any event-level neighboring streams  $x$  and  $y$  in the “likes”-model. Thus, applying a standard continual counting algorithm gives the claimed error, as shown for “well-behaved” difference sequences in general in [11].

<sup>2</sup> For simplicity of exposition, we use  $\tilde{O}(X)$  to denote  $O(X \cdot \text{polylog}(X))$

For event-level differential privacy and the *general model* however, the best known algorithms are the algorithms for item-level differential privacy in this paper and [16]. [16] also present lower bounds for event-level differential privacy in the general model which, however, leave a gap for certain parameter settings. Closing that gap was explicitly posed as an open question in [16]. We make a step towards closing that gap, by noting that all existing differentially private algorithms for the COUNTDISTINCT problem in *any* model share the following property: If  $\text{COUNTDISTINCT}(x) = \text{COUNTDISTINCT}(y)$  for any two input streams  $x$  and  $y$ , then the output distributions of the algorithms are equal. That is, any two streams which produce the same true output, will have the same output distributions. We call such algorithms *output-determined*. We show that if we only consider output-determined algorithms for COUNTDISTINCT, then achieving *event-level differential privacy in the general model is just as hard as item-level differential privacy for the “likes”-model*. Thus our above lower bounds also apply to such algorithms. In particular, this shows that if one were trying to close the gap for event-level differential privacy in the general model, one needs to find an algorithm which does not only depend on the true answers to COUNTDISTINCT.

► **Theorem 5** (Simplified version of Theorem 15). *Let  $\epsilon > 0$  and  $\delta \geq 0$ . Let  $\mathcal{A}_1$  be an event-level,  $(\epsilon, \delta)$ -differentially private, output-determined algorithm for COUNTDISTINCT that works in the general model and has error at most  $\alpha$  for streams of length  $T + 1$  with probability  $1 - \beta$ . Then there exists an item-level,  $(2\epsilon, (1 + e^\epsilon)\delta)$ -differentially private algorithm  $\mathcal{A}_2$  for COUNTDISTINCT that works in the “likes”-model, and has error at most  $\alpha$  for streams of length  $T$  with probability  $1 - \beta$ .*

### Generalizations & Applications

While our algorithms are (nearly) tight for the COUNTDISTINCT problem, they are not tailored specifically to the problem and work in a more general setting as well. In particular, recall that  $\text{COUNTDISTINCT}(x)^t = \sum_{i=1}^d f^t(x_i)$ , where  $f^t(x_i) = \mathbb{1}(\sum_{t' \leq t} x_i^{t'} > 0)$ . Now consider any real-valued function  $Q$  on input streams  $x_1, x_2, \dots$ , with  $x_i \in \{-1, 0, 1\}$ . We use  $Q^t(x)$  to denote  $Q(x_1, \dots, x_t)$ . Our algorithm works for any such function  $Q$  such that the following two conditions are fulfilled: (1) for any  $x$  and  $y$  which are neighboring, we have  $|Q^t(x) - Q^t(y)| \leq 1$  for all time steps  $t$ , and (2)  $\sum_{t=1}^T |Q^t(x) - Q^{t-1}(x)| \leq K$ .

► **Theorem 6.** *Let  $Q$  be a function satisfying properties (1) and (2). Then there exists*

1. *an item-level  $\epsilon$ -differentially private algorithm for computing  $Q$  with additive error*

$$O(\min(K, \sqrt{\epsilon^{-1} K \ln(T/\beta)}), \epsilon^{-1} T \log(T/\beta))$$

*at all time steps with probability at least  $1 - \beta$ , for any  $\epsilon > 0$ ;*

2. *an item-level  $(\epsilon, \delta)$ -differentially private algorithm for computing  $Q$  with additive error*

$$O(\min(K, (\epsilon^{-2} K \ln(1/\delta) \ln^2(T/\beta))^{1/3}, \epsilon^{-1} \sqrt{T \ln(1/\delta) \log(T/\beta)}))$$

*at all time steps with probability at least  $1 - \beta$ , for any  $\epsilon > 0$ ,  $\delta \in (0, 1)$ ;*

The extension to unknown  $K$  also holds, with extra  $\ln K$  factors as earlier. Thus, for a continuous function  $Q$  which has *maximum* sensitivity 1 *over all time steps*, we get a bound parameterized in the sum of all differences, i.e., the  $L_1$ -norm of the difference sequence. While our results hold in the *turnstile model* and the additive error is parameterized by the total flippancy, [11] gave an  $\epsilon$ -differentially private mechanism with additive error  $O(\Gamma \log^{3/2} \log(T/\beta))$  in the *insertions-only* or *deletions-only* setting, where  $\Gamma$  is the *continuous global sensitivity* which is the  $L_1$ -norm of the difference sequence of two neighboring inputs.

We can apply our algorithm to the problem considered in Fichtenberger et al. [11] of continuously counting high degree nodes under differential privacy, which counts the number of nodes with degree at least  $\tau$ , where  $\tau$  is given and public. For user-level, edge-differential privacy (i.e., neighboring streams may differ in all updates of the same edge), they give a lower bound of  $\Omega(n)$ . Our algorithm gives new parameterized bounds for this problem: In particular, choosing  $Q^t(x) = \frac{\# \text{ of high degree nodes}}{2}$ , Theorem 6 gives an error bound of roughly  $O(\sqrt{K})$ , under  $\epsilon$ -differential privacy, and roughly  $O(K^{1/3})$  under  $(\epsilon, \delta)$ -differential privacy, where we ignore an  $O(\epsilon^{-1} \ln T \ln(1/\delta) \ln K)$  factor. Note that  $K$  can be as large as  $T$ , but for many applications, it could be much smaller: for example, in social networks, it has been shown that the degree distribution follows a power-law distribution, which implies that the set of high-degree nodes only changes infrequently.  $K$  does not be given to the algorithm.

### 1.3 Algorithm Overview

The main idea of our algorithm is to use the sparse vector technique first introduced by Dwork, Naor, Reingold, Rothblum, and Vadhan [7] (the form we use it in can be found in Dwork and Roth [8]) on carefully chosen queries and with carefully chosen thresholds. The sparse vector technique can be described as follows: It is given a data set  $x$ , a sequence of  $q$  queries, a threshold  $Thresh$ , and a stopping parameter  $S$ . It will process these queries sequentially, and for each of them answer “yes” or “no” depending on whether or not  $q(x)$  is approximately (up to an additive error  $\alpha$ ) above the threshold. It stops after it has answered “yes”  $S$  times. Dwork and Roth [8] show that it is possible to design an  $\epsilon$ -differentially private algorithm achieving the above with  $\alpha = O(\epsilon^{-1} S \log(q/\beta))$  with probability  $1 - \beta$ , and an  $(\epsilon, \delta)$ -differentially private algorithm with  $\alpha = O(\epsilon^{-1} \sqrt{S \log(1/\delta)} \log(q/\beta))$  with probability  $1 - \beta$ . In the following discussion, we ignore  $\epsilon^{-1}$ ,  $\log(1/\delta)$ ,  $\log q$  and  $\log(1/\beta)$  factors.

Our main idea is to note that the total flippancy  $K$  can be seen as an upper bound on *the total change in the output*, i.e., the sum of the absolute differences in the output in every time step. Our strategy is as follows: We start by estimating the number of distinct elements at the beginning of the stream. Then, we keep reporting this estimate until a significant change occurs in the true number of distinct elements. We track whether such a change has occurred using the sparse vector technique. Once there has been a significant change, i.e., once the sparse vector technique answers “yes”, we update the output. The goal now is to balance the additive error of the sparse vector technique with the error accumulated between updates. The error between updates is roughly  $Thresh$ ; the error of the sparse vector technique is  $\alpha$ ; and the total change of the output is bounded by  $K$ . To balance the two we set  $Thresh = \Theta(\alpha)$ . Furthermore we have to choose  $S$  in a way that makes sure that the sparse vector technique does not abort before we have seen the entire stream. We can show that every time our sparse vector technique answers “yes”, the change in output has been roughly  $Thresh$ . Thus it is enough to set  $S > K/Thresh$ . As mentioned above, for  $\epsilon$ -differential privacy  $\alpha$  (and, thus,  $Thresh$ ) must depend linearly on  $S$ , which implies that  $S$  must be chosen to be  $\Theta(\sqrt{K})$ , giving an additive error of  $O(\sqrt{K})$ . For  $(\epsilon, \delta)$ -differential privacy, we have  $Thresh = \Theta(\alpha) = O(\sqrt{S})$ . This implies that  $S^{3/2}$  must be  $\Theta(K)$ , i.e.,  $S = \Theta(K^{2/3})$ . Thus the additive error is  $O(K^{1/3})$ .

Note that this requires that  $K$  is known at the beginning of the algorithm. If  $K$  is unknown, we run the above algorithm for exponentially increasing guesses of  $K$  ( $K = 2, 4, 8$ , etc.). In particular, we run the algorithm for a guess of  $K$ , and if it terminates preemptively, we double our guess and repeat. Since we do not know beforehand how many instances are needed, in order to make sure the resulting algorithm is still  $\epsilon$ -differentially private, we run the  $j$ th instance with privacy parameter  $\epsilon_j = O(\epsilon/j^2)$ , such that  $\sum_{j=1}^{\infty} \epsilon_j \leq \epsilon$ . At the end of the algorithm,  $j = \Theta(\ln K)$ , therefore we incur an extra  $\ln^2 K$  factor in the additive error.

## 2 Preliminaries

We denote  $\{1, \dots, n\}$  by  $[n]$  and the input stream length by  $T$ , the number of time steps.

### Continual observation algorithm

An algorithm  $A$  in the continual observation model gets an update at every time step  $t \leq T$ , and produces an output  $a^t = A(x^1, \dots, x^t)$  which is a function of  $x^1$  to  $x^t$ ;  $A^T(x) = (a^1, a^2, \dots, a^T)$  denotes the sequence of outputs at all time steps.

► **Definition 7** (Differential privacy [6]). *A randomized algorithm  $A$  is  $(\epsilon, \delta)$ -differentially private  $((\epsilon, \delta)$ -dp) if for all  $S \in \text{range}(A^T)$  and all  $x, y$  neighboring*

$$\Pr[A^T(x) \in S] \leq e^\epsilon \Pr[A^T(y) \in S] + \delta.$$

If  $\delta = 0$  then  $A$  is  $\epsilon$ -differentially private ( $\epsilon$ -dp).

► **Definition 8** (Laplace Distribution). *The Laplace distribution centered at 0 with scale  $b$  is the distribution with probability density function  $f_{\text{Lap}}(b)(x) = (2b)^{-1} \cdot \exp(-|x|/b)$ . We use  $X \sim \text{Lap}(b)$  or just  $\text{Lap}(b)$  to denote a random variable  $X$  distributed according to  $f_{\text{Lap}}(b)(x)$ .*

In our definitions below, we use  $\chi$  to represent a generic universe of elements.

► **Definition 9** (Sensitivity). *Let  $f : \chi \rightarrow \mathbb{R}^k$ . The  $L_p$ -sensitivity  $\Delta_p$  is defined as*

$$\max_{x \in \chi, y \in \chi, x \sim y} \|f(x) - f(y)\|_p,$$

where  $x \sim y$  denotes that  $x$  and  $y$  are neighbouring.

► **Fact 1** (Theorem 3.6 in [8]: Laplace Mechanism). *Let  $f$  be any function  $f : \chi \rightarrow \mathbb{R}^k$  with  $L_1$ -sensitivity  $\Delta_1$ . Let  $Y_i \sim \text{Lap}(\Delta_1/\epsilon)$  for  $i \in [k]$ . The mechanism defined as  $A(x) = f(x) + (Y_1, \dots, Y_k)$  satisfies  $\epsilon$ -differential privacy.*

► **Fact 2** (Laplace Tailbound). *If  $X \sim \text{Lap}(b)$ , then  $\Pr[|X| \geq t \cdot b] \leq e^{-t}$ .*

The following fact follows from Theorem A.1 in [8]:

► **Fact 3** (Gaussian Mechanism). *Let  $f$  be any function  $f : \chi \rightarrow \mathbb{R}^k$  with  $L_2$ -sensitivity  $\Delta_2$ . Let  $Y_i \sim \mathcal{N}(0, \sigma^2)$  for  $i \in [k]$ , where  $\sigma \geq \sqrt{2 \ln(2/\delta)} \Delta_2/\epsilon$ . The mechanism defined as  $A(x) = f(x) + (Y_1, \dots, Y_k)$  satisfies  $(\epsilon, \delta)$ -differential privacy.*

► **Fact 4** (Gaussian tailbound). *If  $X \sim \mathcal{N}(0, \sigma^2)$ , then  $\Pr[|X| \geq \sigma \sqrt{\ln(2/\beta)}] \leq \beta$*

The following facts are respectively given by Theorem 3.16, 3.20 and Corollary 3.21 in [8].

► **Fact 5** (Composition Theorem). *Let  $A_1$  be an  $(\epsilon_1, \delta_1)$ -differentially private algorithm  $A_1 : \chi \rightarrow \text{range}(A_1)$  and  $A_2$  an  $(\epsilon_2, \delta_2)$ -differentially private algorithm  $A_2 : \chi \times \text{range}(A_1) \rightarrow \text{range}(A_2)$ . Then  $B : \chi \rightarrow \text{range}(A_1) \times \text{range}(A_2)$  defined as  $B(x) = (A_1(x), A_2(x, A_1(x)))$  is  $(\epsilon_1 + \epsilon_2, \delta_1 + \delta_2)$ -differentially private.*

► **Fact 6** (Advanced Composition). *Let  $\epsilon, \delta, \delta' \geq 0$ . Let  $A_1$  be an  $(\epsilon, \delta)$ -differentially private algorithm  $A_1 : \chi \rightarrow \text{range}(A_1)$  and  $A_i$  be  $(\epsilon, \delta)$ -differentially private algorithms  $A_i : \chi \times \text{range}(A_{i-1}) \rightarrow \text{range}(A_i)$ , for  $2 \leq i \leq k$ . Then the composition  $B : \chi \rightarrow \text{range}(A_1) \times \dots \times \text{range}(A_k)$  defined as  $B(x) = (A_1(x), A_2(x, A_1(x)), \dots, A_k(x, A_{k-1}(x)))$  is  $(\epsilon', k\delta + \delta')$ -differentially private, where  $\epsilon' = \sqrt{2k \ln(1/\delta')} \epsilon + k\epsilon(e^\epsilon - 1)$ .*

► **Corollary 10**. *Let  $\epsilon^*, \delta, \delta' \geq 0$  and  $\delta', \epsilon^* < 1$ . Let  $A_1, \dots, A_k$  be as in Fact 6 with*

$$\epsilon = \epsilon^*/(2\sqrt{2k \ln(1/\delta')}).$$

*Then the composition  $B$  (defined as in Fact 6) is  $(\epsilon^*, k\delta + \delta')$ -differentially private.*

### 3 Item-Level Algorithms in General Model

In this section, we give algorithms which work for any input sequence in the general model, and thus also for input sequences that fulfill the conditions of the “likes”-model. The upper bounds on the additive error for  $\epsilon$ -differential privacy match the lower bounds in Section 5, except for the  $\log(T/\beta)$  factor in the case where  $K > T$ .

#### 3.1 Known Total Flippancy

We prove Theorem 11 in this section. We give some intuition first on Algorithm 1. The algorithm works by iteratively checking if the true number of distinct elements currently present (called  $Q$ ) is “far” from the current output of our algorithm (called  $out$ ) using a sparse vector technique (SVT) instantiation. We start the algorithm by estimating  $out$  at the beginning of the stream (line 8). Then, we keep outputting  $out$ , while we track the difference between  $out$  and the true number of distinct elements  $Q$  (line 14). Once there has been a significant change, we update the output (line 18).

There are two parameters of interest here. One is the number of times we update the output: we abort after  $S_K$  updates happen (line 21). The other is the parameter  $Thresh$ , which determines how large the current error needs to be such that we satisfy the condition in line 14. The parameter  $S_K$  goes into the error from composition, while the parameter  $Thresh$  directly goes into the additive error bound.

The goal is to balance the error accumulated between updates (which is roughly  $Thresh$ ), and the error from updating  $out$  privately (which is roughly  $S_K$  for  $\epsilon$ -differential privacy, and roughly  $\sqrt{S_K}$  for  $(\epsilon, \delta)$ -differential privacy due to composition). Additionally, we want to make sure our algorithm does not abort before having processed the entire stream. We show that every time SVT returns “yes”, the total flippancy in the stream has increased by at least  $\Omega(Thresh)$ . Since we know the total flippancy is bounded by  $K$ , in order to make sure that we do not abort preemptively, we choose  $S_K$  such that  $S_K \cdot Thresh \approx K$ . Balancing the two error terms yields an additive error of approximately  $\sqrt{K}$  for  $\epsilon$ -differential privacy, and  $K^{1/3}$  for  $(\epsilon, \delta)$ -differential privacy.

► **Theorem 11.** *Let  $d$  and  $T$  be non-zero integers, let  $\beta > 0$ , and let  $K$  be an upper bound on the total flippancy which is given. Let  $T$  be a known upper bound on the number of time steps. Then there exists*

1. *an item-level  $\epsilon$ -differentially private algorithm for COUNTDISTINCT in the general model with error at most  $O(\min(d, K, \sqrt{\epsilon^{-1}K \ln(T/\beta)}, \epsilon^{-1}T \log(T/\beta)))$  at all time steps with probability at least  $1 - \beta$  for  $\epsilon > 0$ ;*
2. *an item-level  $(\epsilon, \delta)$ -differentially private algorithm for COUNTDISTINCT in the general model with error  $O\left(\min(d, K, (\epsilon^{-2}K \ln(1/\delta) \ln^2(T/\beta))^{1/3}, \epsilon^{-1}\sqrt{T \ln(1/\delta) \log(T/\beta)})\right)$  at all time steps with probability at least  $1 - \beta$ , for any  $0 < \delta < 1$  and  $0 < \epsilon < 1$ .*

**Proof.** The  $O(\min(d, K))$  bound follows from the fact that the algorithm that outputs 0 at every time step is  $\epsilon$ -differentially private and has error at most  $\min(d, K)$  for any  $\epsilon$ . The third error bounds in the minimum for Theorem 11 are achieved by Algorithm 1, as shown below. Since we assume here all parameters are known, one can compute the minimum of the three bounds and choose the algorithm accordingly. The fourth bound in Theorem 11 follow by a direct application of the Laplace mechanism Fact 1 with  $\Delta_1 = T$  resp. Gaussian mechanism Fact 3 with  $\Delta_2 = \sqrt{T}$ .

■ **Algorithm 1** COUNTDISTINCT, known  $K$ .

The algorithm for our third bound, given in Algorithm 1, is based on the sparse vector technique, where  $S_K$  is a parameter dependent on  $K$  that we choose suitably below. We omit the proof of the following lemma, since it follows from well-known techniques (Sparse Vector Technique [7, 8], Laplace mechanism (Fact 1) and composition theorems (Facts 5 and 6)).

► **Lemma 12.** *For  $\delta = 0$  and any  $\epsilon > 0$ , Algorithm 1 is  $\epsilon$ -differentially private. For  $0 < \epsilon < 1$  and  $0 < \delta < 1$ , Algorithm 1 is  $(\epsilon, \delta)$ -differentially private.*

We show the claimed accuracy bound using the following lemma.

► **Lemma 13.** *For  $\delta = 0$ , for any time step  $t$  before the algorithm aborts, we have that the maximum error up to time  $t$  is at most  $O(\epsilon^{-1}S_K \ln(T/\beta))$ . Setting  $S_K = \sqrt{K\epsilon/(18\ln(T/\beta))} + 1$ , with probability at least  $1 - \beta$ , Algorithm 1 does not abort before having seen the entire stream, and has error at most  $O(\sqrt{\epsilon^{-1}K \ln(T/\beta)} + \epsilon^{-1} \ln(T/\beta))$ . For  $\delta > 0$ , for any time step  $t$  before the algorithm aborts, we have that the maximum error up to time  $t$  is  $O(\epsilon^{-1}\sqrt{S_K \ln(1/\delta)} \ln(T/\beta))$ . Setting  $S_K = \left(\frac{K\epsilon}{36\sqrt{\ln(1/\delta)} \ln(T/\beta)}\right)^{2/3} + 1$ , with probability at least  $1 - \beta$ , Algorithm 1 does not abort before having seen the entire stream, and has error at most  $O\left(\left(\epsilon^{-2}K \ln(1/\delta) \ln^2(T/\beta)\right)^{1/3} + \epsilon^{-1}\sqrt{\ln(1/\delta)} \ln(T/\beta)\right)$ .*

**Proof.** Note that at every time step  $t$  in Algorithm 1, we set  $Q = \sum_{i=1}^d f^t(x_i)$ . Let  $\alpha = (8/\epsilon_1) \ln(2T/\beta) = (1/2) \cdot \text{Thresh}$ . By Laplace tailbounds (Fact 2), at every time step  $t$ :  
**(a)**  $|\tau_\ell| \leq (2/\epsilon_1) \ln(2T/\beta) = \alpha/4$  with probability at least  $1 - \beta/(2T)$ , where  $\ell$  is the value of variable count at time step  $t$ , and

(b)  $|\mu_\ell| \leq (4/\epsilon_1) \ln(2T/\beta) = \alpha/2$  with probability at least  $1 - \beta/(2T)$ .

Thus, with probability  $\geq 1 - \beta$ , we have at all time steps  $t$  simultaneously:

- (i) Whenever the condition in line 14 is true at time  $t$ , then  $|\text{out} - \sum_{i \in [d]} f^t(x_i)| > \text{Thresh} - 3\alpha/4 = 5\alpha/4$ , and
- (ii) Whenever the condition in line 14 is false at time  $t$ , then  $|\text{out} - \sum_{i \in [d]} f^t(x_i)| \leq \text{Thresh} + 3\alpha/4 < 3\alpha$ .

Further, the random variable  $\nu_\ell$  for  $\ell \in [S_K]$  is distributed as  $\text{Lap}(1/\epsilon_1)$  and is added to  $\sum_{i \in [d]} f^t(x_i)$  at every time step  $t$  where out is updated. By the Laplace tail bound (Fact 2),  $\nu_\ell$  is bounded for all  $\ell \in [S_K]$  by  $\epsilon_1^{-1} \ln(S_K/\beta) \leq \alpha/8$  with probability at least  $1 - \beta$ . Altogether, all of these bounds hold simultaneously with probability at least  $1 - 2\beta$ . We condition on all these bounds being true.

Assume the algorithm has not terminated yet at time  $t$  and let out be the value of variable out at the beginning of time  $t$ . Let  $p_\ell$  be the last time step at which the value of out was updated. It holds that  $|\text{out} - \sum_{i \in [d]} f_i^{p_\ell}(x)| = |\nu_\ell| \leq \alpha/8$ . If the condition in line 14 is true at time  $t$ , then

$$\left| \sum_{i \in [d]} f_i^{p_\ell}(x) - \sum_{i \in [d]} f^t(x_i) \right| \geq \left| \sum_{i \in [d]} f^t(x_i) - \text{out} \right| - \left| \text{out} - \sum_{i \in [d]} f_i^{p_\ell}(x) \right| \geq 5\alpha/4 - \alpha/8 = 9\alpha/8.$$

Thus, between two time steps where the value of out is updated, there is a change of at least  $9\alpha/8$  in the sum value, i.e., the value of  $f^t(x_i)$  has changed at least once for  $\geq 9\alpha/8$  different items  $i$ . Since  $K = \sum_{i=1}^d \sum_{t=2}^T \mathbb{1}(f^t(x_i) \neq f^{t-1}(x_i))$ , to guarantee (under the noise conditions), that the algorithm does not terminate before we have seen the entire stream, it suffices to choose  $S_K$  where  $S_K > K/(9\alpha/8)$ .

For  $\delta = 0$ , we have  $\alpha = (8/\epsilon_1) \ln(2T/\beta) = (16S_K/\epsilon) \ln(2T/\beta)$ , thus we have to choose  $S_K > K\epsilon/(18S_K \ln(2T/\beta))$ . Choosing  $S_K = \lfloor \sqrt{K\epsilon/(18 \ln(2T/\beta))} \rfloor + 1$  fulfills this condition.

Similarly, for  $\delta > 0$ , choosing  $S_K = \left( \frac{K\epsilon}{36\sqrt{\ln(1/\delta)} \ln(T/\beta)} \right)^{2/3} + 1$  fulfills this condition.

Now consider any time step  $t$  and let out be the output at time  $t$ , i.e., the value after processing time step  $t$ . If the condition in line 14 is false, we showed above that  $|\text{out} - \sum_{i \in [d]} f^t(x_i)| < 3\alpha$ . If the condition is true at time  $t$ , we have  $\text{out} = \sum_{i \in [d]} f^t(x_i) + \nu_\ell$  for some  $\ell \in [S_K]$ , and, thus,  $|\text{out} - \sum_{i \in [d]} f^t(x_i)| \leq \alpha/8 < \alpha$ .

For  $\delta = 0$ , we have  $\alpha = (8/\epsilon_1) \ln(2T/\beta) = O(\sqrt{\epsilon^{-1}K \ln(T/\beta)} \ln(T/\beta) + \epsilon^{-1} \ln(T/\beta))$ .

Plugging in  $S_K = \left( \frac{K\epsilon}{36\sqrt{\ln(1/\delta)} \ln(T/\beta)} \right)^{2/3} + 1$  yields the final bound for  $\delta > 0$ . ◀

To finish the proof of Theorem 11, note that if  $\epsilon^{-1} \ln(T/\beta) > \sqrt{\epsilon^{-1}K \ln(T/\beta)}$ , then  $\sqrt{\epsilon^{-1}K \ln(T/\beta)} > K$ , which can be seen by multiplying both sides of the inequality with  $\sqrt{K}/\sqrt{\epsilon^{-1} \ln(T/\beta)}$ . Thus the upper bound  $\min(d, K, \sqrt{\epsilon^{-1}K \ln(T/\beta)})$  holds for  $\delta = 0$ .

Also, if  $\epsilon^{-1} \sqrt{\ln(1/\delta)} \ln(T/\beta) > (\epsilon^{-2}K \ln(1/\delta) \ln^2(T/\beta))^{1/3}$ , then  $\epsilon^{-1} \sqrt{\ln(1/\delta)} \ln(T/\beta) > K$ , which can be seen by first cubing the inequality and then dividing by  $\epsilon^{-2} \ln(1/\delta) \ln^2(T/\beta)$ . Thus, for  $\delta > 0$ , the upper bound of  $\min(d, K, (\epsilon^{-2}K \ln(1/\delta) \ln^2(T/\beta))^{1/3})$  holds. ◀

### 3.2 Generalizations

We now argue about Theorem 6. Let  $Q$  be a real-valued function on input streams from  $\{-1, 0, 1\}$  and let  $Q^t = Q(x_1, \dots, x_t)$ . Further, let  $Q$  be such that 1.) for any  $x$  and  $y$  which are neighboring, we have  $|Q^t(x) - Q^t(y)| \leq 1$  for all time steps  $t$ , and 2.)  $\sum_{t=1}^T |Q^t(x) - Q^{t-1}(x)| \leq$

$K$ . The first bound from Theorem 6 is achieved by an algorithm that never updates the output, and the third bounds for  $\epsilon$  and  $(\epsilon, \delta)$ -differential privacy are obtained by the Laplace and Gaussian mechanisms, respectively. The second bound for both  $\epsilon$  and  $(\epsilon, \delta)$ -differential privacy is obtained by Algorithm 1 by setting  $Q = Q^t(x)$  at every time step  $t$ . The proofs follow by exchanging  $\sum_{i \in [d]} f^t(x_i)$  by  $Q^t(x)$  in the proofs of Lemma 12 and 13.

#### 4 A Connection between the General Model under Event-Level Privacy and the “Likes”-Model under Item-Level Privacy

Our bounds from Theorems 2, 3, and 4 as well as the bounds from [16] imply that under *item-level privacy*, the “likes”-model and the general model are roughly equally hard: all upper bounds hold for the general model and all lower bounds hold for the “likes”-model, and the bounds are tight up to a  $\log T$  factor. However, under *event-level privacy*, the “likes”-model is significantly easier than the general model: It can be solved via continual counting on the difference sequence of the true output, which gives error polylogarithmic in  $\log T$ . This is possible because for event-level privacy in the “likes”-model, the difference sequence of the output (i.e., the difference between the true output value of the current and the preceding time step) has  $\ell_\infty$ -sensitivity 1 for event-level privacy, but for item-level privacy, the sensitivity can be as large as  $T$ .

In the general model, there are no better upper bounds known for event-level differential privacy than for item-level differential privacy, and the upper and lower bounds from [16] for  $(\epsilon, \delta)$ -differential privacy for the event-level setting in the general model leave a polynomial (in  $T$ ) gap, in the case where the maximum flippancy  $w_x \in (T^{1/2}, T^{2/3})$ : In that case, ignoring polynomial factors in  $\epsilon^{-1}$ ,  $\log(1/\delta)$ , and  $\log T$ , the lower bound of [16] is  $\Omega(T^{1/4})$ , while their algorithm gives an additive error of  $O(T^{1/3})$ . Specifically, finding the best achievable error for *event-level privacy* in the general model is explicitly posed as an open question in [16].

We resolve this question for a large class of algorithms, called  $\gamma$ -*output-determined* algorithms. All known algorithms for this problem in *any* model are 0-output-determined. Specifically, we show that for  $\gamma$ -output-determined algorithms our lower bounds and the lower bounds from [16] for *item-level privacy* in the “likes”-model basically carry over to *event-level privacy* in the *general model*. It follows that our algorithm and the algorithm from [16] for event-level privacy in the general model are tight up to a factor that is linear in  $\log T$  *within the class of output-determined algorithms*. Note that our reduction works both for the  $\epsilon$ -differential privacy as well as for  $(\epsilon, \delta)$ -differential privacy and we give the corresponding lower bounds in Theorems 16 and 19. In the following, we denote by  $\text{COUNTDISTINCT}(x)$  the stream of true answers to the  $\text{COUNTDISTINCT}$  problem on stream  $x$ .

► **Definition 14.** Let  $\gamma \geq 0$ . An algorithm  $\mathcal{A}$  for the  $\text{COUNTDISTINCT}$  problem is said to be  $\gamma$ -output-determined, if for all inputs  $x$  and  $y$  such that  $\text{COUNTDISTINCT}(x) = \text{COUNTDISTINCT}(y)$  and any  $S \in \text{range}(\mathcal{A})$  we have:

$$\Pr(\mathcal{A}(x) \in S) \leq \Pr(\mathcal{A}(y) \in S) + \gamma$$

► **Theorem 15.** Let  $\epsilon > 0, \delta \geq 0$  and  $\gamma \geq 0$ . Let  $\mathcal{A}_1$  be an event-level,  $(\epsilon, \delta)$ -differentially private,  $\gamma$ -output-determined algorithm for  $\text{COUNTDISTINCT}$  that works in the general model and has error at most  $\alpha$  for streams of length  $T+1$  with probability  $1 - \beta$ . Then there exists an item-level,  $(2\epsilon, (1 + e^\epsilon)\delta + e^\epsilon\gamma)$ -differentially private algorithm  $\mathcal{A}_2$  for  $\text{COUNTDISTINCT}$  that works in the “likes”-model, and has error at most  $\alpha$  for streams of length  $T$  with probability  $1 - \beta$ .

**Proof.** We describe algorithm  $\mathcal{A}_2$ , that is item-level  $(2\epsilon, (1 + e^\epsilon)\delta + e^\epsilon\gamma)$ -dp in the “likes”-model, derived from a  $\gamma$ -output-determined algorithm  $\mathcal{A}_1$  which is event-level,  $(\epsilon, \delta)$ -dp in the general model: Let  $x$  be an input for COUNTDISTINCT in the “likes”-model of length  $T$ , i.e.,  $x$  is such that  $\sum_{t' \leq t} x_i^{t'}$  can only take the values 0 or 1, for any  $i \in [d]$  and  $t \in [T]$ . Let  $x_0 = 0^d x$ , i.e., we attach a  $d$ -dimensional all-zero vector before  $x$ , and define  $(\mathcal{A}_2(x))^t = (\mathcal{A}_1(x_0))^{t+1}$  for all  $t \in [T]$  (note that  $\mathcal{A}_1$  can take inputs from the “likes”-model). We now show that  $\mathcal{A}_2$  is item-level  $(2\epsilon, (1 + e^\epsilon)\delta + e^\epsilon\gamma)$ -differentially private. Let  $x$  and  $y$  be two item-level neighbouring inputs in the “likes”-model. That is, there exists an item  $i$  such that the streams  $x_i$  and  $y_i$  may be completely different, while  $x_j = y_j$  for all  $j \neq i$ . Additionally, since we are in the “likes”-model, for any time step  $t$ ,  $\sum_{t' \leq t} x_i^{t'} \in \{0, 1\}$  and  $\sum_{t' \leq t} y_i^{t'} \in \{0, 1\}$ .

Next, we define input streams  $z$  and  $w$  in the general model where  $\text{COUNTDISTINCT}(z) = \text{COUNTDISTINCT}(w)$ ,  $z$  is event-level neighbouring to  $x_0$ , and  $w$  is event-level neighbouring to  $y_0$ . Since  $\mathcal{A}_1$  is event-level  $(\epsilon, \delta)$ -dp and works for the general model, we then have for any  $S \in \text{range}(\mathcal{A}_2)$

$$\begin{aligned} \Pr[\mathcal{A}_2(x) \in S] &= \Pr[(\mathcal{A}_1(x_0))_{t=2}^{T+1} \in S] \leq e^\epsilon \Pr[(\mathcal{A}_1(z))_{t=2}^{T+1} \in S] + \delta \\ &\leq e^\epsilon \Pr[(\mathcal{A}_1(w))_{t=2}^{T+1} \in S] + \delta + \gamma \\ &\leq e^{2\epsilon} \Pr[(\mathcal{A}_1(y_0))_{t=2}^{T+1} \in S] + (1 + e^\epsilon)\delta + e^\epsilon\gamma \\ &= e^{2\epsilon} \Pr[\mathcal{A}_2(y) \in S] + (1 + e^\epsilon)\delta + e^\epsilon\gamma, \end{aligned}$$

where the second inequality holds as  $\mathcal{A}_1$  is  $\gamma$ -output-determined.

To define such  $z$  and  $w$ , let  $-e_i$  be the vector such that  $-e_i(j) = 0$  for all  $j \neq i$  and  $-e_i(i) = -1$ . Then  $z = -e_i x$  and  $w = -e_i y$ . Note that  $z$  and  $w$  are valid input streams for the general model, while they are not valid for the “likes”-model. Clearly,  $z$  is event-level neighbouring to  $x_0$ , and  $w$  is event level neighbouring to  $y$ . Recall that  $\text{COUNTDISTINCT}(z)^t = \sum_{j=1}^d \mathbb{1}(\sum_{t' \leq t} z_j^{t'} > 0)$ . Since  $\sum_{t' \leq t} x_i^{t'} \in \{0, 1\}$  for all  $t \in [T]$  we have  $\sum_{t' \leq t} z_i^{t'} \leq 0$  for all  $t \in [T + 1]$ . By the same argument, we have  $\sum_{t' \leq t} w_i^{t'} \leq 0$  for all  $t \in [T + 1]$ . Since  $z$  and  $w$  only differ in the  $i$ th coordinate, which never contributes to the COUNTDISTINCT value as it is never 1, we have  $\text{COUNTDISTINCT}(z) = \text{COUNTDISTINCT}(w)$ .

We are left with analyzing the error of the two algorithms. For this, note that by definition of  $x_0$ , we have  $\text{COUNTDISTINCT}(x_0)^{t+1} = \text{COUNTDISTINCT}(x)^t$ . Thus, running  $\mathcal{A}_2$  on  $x$  gives the same error as running  $\mathcal{A}_1$  on  $x_0$ . ◀

In particular, for any output-determined algorithm, Theorem 15 implies that all lower bounds on the error for the COUNTDISTINCT problem under *item-level* differential privacy which hold for the “likes”-model (and thus, all lower bounds for COUNTDISTINCT under item-level differential privacy shown in this paper in Theorem 19 and in [16]), carry over to *event-level* differential privacy in the *general model*. This means that if there is an algorithm achieving a better error than the bounds stated in Theorem 19 and in [16] for event-level differential privacy in the general model, it cannot be  $\gamma$ -output-determined for  $\gamma = O(\delta)$ , i.e., it must be such that it does not *only* depend on the number of distinct elements at any given time step.

## 5 Item-Level Lower Bounds in the “Likes”-Model

In the following we show lower bounds for solving COUNTDISTINCT under item-level differential privacy, and in the “likes”-model. The lower bounds also apply to the general model. In Section 3, we showed a complementing upper bound which holds in the general model, even if  $K$  is unknown to the algorithm.

► **Theorem 16.** *Let  $d$  and  $T > 4$  be non-negative integers and let  $\epsilon > 0$ .*

1. *Let  $L \geq 8$  be a non-negative integer such that  $L \leq dT$ . There exists an input stream  $x$  of  $d$ -dimensional vectors from  $\{-1, 0, 1\}^d$ , which is valid in the “likes”-model with multiple updates per time step, with length  $T$  and flippancy  $K$  with  $\min(3L/8, T/4 - 1) \leq K \leq \min(L, dT/4)$  such that any  $\epsilon$ -differentially private algorithm to the COUNTDISTINCT problem with item-level privacy with error at most  $\alpha$  at all time steps with probability at least  $2/3$  must satisfy*

$$\begin{aligned} \alpha &= \Omega(\min(d, L, \epsilon^{-1}T, \sqrt{\epsilon^{-1}L \max(\ln(T/L), 1)})) \\ &= \Omega(\min(d, K, \epsilon^{-1}T, \sqrt{\epsilon^{-1}K \max(\ln(T/K), 1)}). \end{aligned}$$

2. *Let  $L \geq 8$  be a non-negative integer such that  $L \leq T$ . There exists an input stream  $x$  of  $d$ -dimensional vectors from  $\{-1, 0, 1\}^d$ , which is valid in the “likes”-model with multiple updates per time step, with length  $T$ , flippancy  $K$  with  $L/16 \leq K \leq \min(L, T/4)$ , and with  $\|x^t\|_1 = 1$  for all  $t$  (i.e., each update modifies at most one item) such that any  $\epsilon$ -differentially private algorithm to the COUNTDISTINCT problem with item-level privacy with error at most  $\alpha$  at all time steps with probability at least  $2/3$  must satisfy*

$$\alpha = \Omega(\min(d, K, \sqrt{\epsilon^{-1}K \ln(T/K)}).$$

**Proof.** Let  $d$ ,  $T$ , and  $L$  be as given in the theorem statement. Assume there is an  $\epsilon$ -differentially private algorithm  $\mathcal{A}$  for the COUNTDISTINCT problem with error at most  $\alpha$  at all time steps with probability at least  $2/3$ . If  $\alpha > d/2$ , then the error is  $\Omega(d)$ . Also, if  $\alpha > L/8$ , then  $\alpha = \Omega(L)$ . Thus, in the following, we consider the case  $\alpha \leq d/2$  and  $\alpha \leq L/8$ . Defining  $m = \lfloor 2\alpha \rfloor$ , it follows that  $m \leq \min(d, L/8)$ .

**Singleton updates.** We first find  $T' \leq T$  and  $L' \leq L$  such that  $4m$  divides  $T'$  and  $m$  divides  $L'$ . If this is not the case for  $T$  and  $L$ , then pick parameters  $T'$  and  $L'$  such that (i)  $4m$  divides  $T'$  and  $m$  divides  $L'$ , (ii)  $\Delta = T - T' \leq 4m < L/2 \leq T/2$  (i.e.  $T' = \Theta(T)$ ) and (iii)  $0 \leq L - \Delta - L' \leq m$ . This implies that  $L' \geq 7L/8 - \Delta \geq 3L/8$ . Thus, as  $L \leq T$ , then  $0 \leq L - \Delta - L' = L - (T - T') - L' = T' - L' - (T - L) \leq T' - L'$ , i.e.,  $L' \leq T'$ .

We use  $T'$  and  $L'$  in the proof below to construct a sequence of length  $T'$  fulfilling the statements of the theorem. To complete the proof of the theorem, we append to the sequence  $T - T'$  many all-zero vectors to guarantee that the stream has length  $T$ . Note that appending to the sequence “blank” operation will not invalidate the statements of the theorem.

We now construct a set of input sequences of length  $T'$  with flippancy  $K := \min(L', T'/4)$  and use them to prove a lower bound for  $\alpha$  of  $\Omega(\min(K \ln(T'/K), \sqrt{\epsilon^{-1}K \ln(T'/K)}))$ . Combined with the above case distinctions giving lower bounds on  $\alpha$  of  $\Omega(d)$ , and  $\Omega(L)$ , the fact that  $K = \Theta(L)$  and that  $T' = \Theta(T)$ , this implies that  $\alpha = \Omega(\min(d, K, \sqrt{\epsilon^{-1}K (\ln(T'/K) + 1)}))$ .

Let  $k := \min(L', T'/4)/m$  be a positive integer. Partition the timeline into  $T'/m$  blocks of length  $m$ , namely  $B_1 = [1, m]$ ,  $B_2 = [m + 1, 2m]$ ,  $\dots$ . Now, for any subset of blocks  $J = (j_1, \dots, j_k)$  with  $1 \leq j_1 < j_2 < \dots < j_k \leq T'/m$ , define an input sequence  $x(J)$  such that for any item  $i \in [m]$  we insert element  $i$  in the  $i$ th time step of every odd block of  $J$  (i.e. the first, third,  $\dots$  block in  $J$ ), and delete it again at the  $i$ th position of every even block of  $J$  (i.e. the second, fourth,  $\dots$  block in  $J$ ). More formally, for any item  $i \in [m]$ , set  $x(J)_i^t = 1$  for all  $t = B_{j_{2p-1}}[i] = (j_{2p-1} - 1)m + i$ ,  $p = 1 \dots, \lfloor k/2 \rfloor$ , and set  $x(J)_i^t = -1$  for all  $t = B_{j_{2p}}[i] = (j_{2p} - 1)m + i$ ,  $p = 1 \dots, \lfloor k/2 \rfloor$ . In all other time steps  $t$ , no updates are performed, i.e.,  $x(J)^t$  is an all-zero vector. Thus, for every  $i \in [m]$ , we have  $f^t(x_i) = 1$

for all time steps  $t \in [j_{2p-1}m, (j_{2p} - 1)m]$ , for all  $p \leq \lceil k/2 \rceil$ , and  $f^t(x_i) = 0$  for all time steps  $t \in [j_{2p}m, (j_{2p+1} - 1)m]$ . For any item  $m < i \leq d$ , we have  $f^t(x_i) = 0$  for all  $t \in [T']$ . Furthermore, items  $i$  with  $i > m$  (if they exist) are never inserted or deleted. In total, there are  $k = \min(L', T'/4)/m$  updates per item  $i \in [m]$ , thus exactly  $K$  updates in total, and, hence, the total flippancy is  $K = \min(L', T'/4)$ . If  $K = L'$ , then  $L \geq K \geq 3L/8$ . If  $K = T'/4$ , then  $L' \leq T'$  implies that  $L \geq L' \geq K = T'/4 \geq L'/4 \geq 3L/32 \geq L/16$ . Thus in either case  $K = \Theta(L')$ . Furthermore  $K \leq T'/4 \leq T/4$ .

Now let  $E_J$ , for  $J = (j_1, \dots, j_k)$  with  $1 \leq j_1 < j_2 < \dots < j_k \leq T'/m$ , be the set of output sequences where  $\mathcal{A}$  outputs (i) a value of  $m/2$  or larger for all time steps  $t \in [j_{2p-1}m, (j_{2p} - 1)m]$  with  $1 \leq p \leq \lceil k/2 \rceil$ , and (ii) smaller than  $m/2$  for all time steps  $t$  such that (a)  $t < j_1m$  or (b)  $t \in [j_{2p}m, (j_{2p+1} - 1)m]$  for some  $0 \leq p < \lceil k/2 \rceil$  or (c)  $t \geq j_km$ . Note that for an input sequence  $x(J)$  every output sequence where  $\mathcal{A}$  has additive error smaller than  $\alpha = m/2$  must belong to  $E_J$ . As the algorithm is correct with probability at least  $2/3$ ,  $\Pr[\mathcal{A}(x(J)) \in E_J] \geq 2/3$ .

Two input sequences are neighboring if they differ in the data of at most one item for item-level differential privacy. As two input sequences  $x(I)$  and  $x(J)$  with  $I \neq J$  differ in the data of at most  $m$  items, it follows by group privacy that  $\Pr[\mathcal{A}(x(J)) \in E_I] \geq e^{-m\epsilon}2/3$  for any  $J = (j_1, \dots, j_k)$  with  $1 \leq j_1 < j_2 < \dots < j_k \leq T'/m$  and  $I = (i_1, \dots, i_k)$  with  $1 \leq i_1 < i_2 < \dots < i_k \leq T'/m$ . Also note that the set of output sequences  $E_J$  for distinct  $J = (j_1, \dots, j_k)$  are disjoint, since for each multiple of  $m$  (i.e., the end of a block), it is clearly defined whether the output is at least  $m/2$  or smaller than  $m/2$ , and as such the values  $j_1, \dots, j_k$  can be uniquely recovered. Thus, there are  $\binom{T'/m}{k}$  disjoint events  $E_J$  and the sum over all  $J$  of the probabilities that the algorithm with input  $x(I)$  outputs an event  $E_J$  is at most 1. More formally, we have:

$$1 \geq \binom{T'/m}{k} e^{-m\epsilon}2/3 \geq \frac{(T'/m)^k}{(k)^k} e^{-m\epsilon}2/3 = \frac{T'^{(K/m)}}{K^{K/m}} e^{-m\epsilon}2/3$$

where the last equality is since  $k = K/m$ . This gives

$$m^2 + \epsilon^{-1}m \ln(3/2) \geq \epsilon^{-1}K \ln(T'/K)$$

which implies

$$m = \Omega(\min(K \ln(T'/K), \sqrt{\epsilon^{-1}K \ln(T'/K)}).$$

Note that since  $T' \geq 4K$ ,  $\ln(T'/K) \geq \ln(4) > 1$ . This completes the proof.

**Multiple updates.** We first find  $T' \leq T$  and  $L' \leq L$  such that 4 divides  $T'$  and  $m$  divides  $L'$ . If this is not the case for  $T$  and  $L$ , then pick parameters  $T'$  and  $L'$  such that (i) 4 divides  $T'$  and  $m$  divides  $L'$ , (ii)  $\Delta = T - T' \leq 4$  (i.e.  $T' = \Theta(T)$ ) and (iii)  $\Delta m \leq L - L' \leq (\Delta + 1)m$ . This implies that  $L' \geq L - (\Delta + 1)m \geq L - 5m \geq 3L/8$ .

We use  $T'$  and  $L'$  in the proof below to construct a sequence of length  $T'$  fulfilling the statements of the theorem. To complete the proof of the theorem, we append to the sequence  $T - T'$  many all-zero vectors to guarantee that the stream has length  $T$ . Note that appending to the sequence “blank” operation will not invalidate the statements of the theorem.

The idea is similar to above, only we do not define blocks, but directly choose  $k := \min(L'/m, T'/4)$  time steps in which all items in  $[m]$  are updated. Thus the flippancy  $K$  will equal  $mk$ . More precisely, we construct the following set of input sequences. For any  $I = (t_1, \dots, t_k)$  with  $1 \leq t_1 < t_2 < \dots < t_k \leq T'$ , we define an input sequence  $x(I)$  as follows: For any item  $i \in [m]$ , set  $x(I)_i^{t_j} = 1$  for all odd  $j$ , and  $x(I)_i^{t_j} = -1$  for all even  $j$ .

## 40:16 Private Counting of Distinct Elements in the Turnstile Model and Extensions

All other coordinates are set to 0. In total, there are  $k$  updates per item in  $[m]$ , thus, exactly  $K$  updates in total, i.e., the total flippancy equals  $K = \min(L', mT'/4)$ . This implies that  $\min(3L/8, T/4 - 1) \leq K \leq \min(L, dT/4)$ .

Now, let  $E_I$ , for  $I = (t_1, \dots, t_k)$  with  $1 \leq t_1 < t_2 < \dots < t_k \leq T'$ , be the set of output sequences with a value of  $m/2$  or larger at all time steps  $t \in [t_{2p-1}, t_{2p})$  for some  $1 \leq p \leq \lceil k/2 \rceil$ , and a value smaller than  $m/2$  at all time steps  $t$  where (a)  $t \leq t_1$  or (b)  $t \in [t_{2p}, t_{2p+1})$  for some  $0 \leq p < \lceil k/2 \rceil$ . Note that for input sequence  $x(I)$  every output sequence where  $\mathcal{A}$  has an additive error smaller than  $m/2$  must be in  $E_I$ . As the algorithm is correct with probability at least  $2/3$ ,  $\Pr[\mathcal{A}(x(I)) \in E_I] \geq 2/3$ . As two input sequences  $x(I)$  and  $x(J)$  with  $I \neq J = (j_1, \dots, j_k)$  with  $1 \leq j_1 < j_2 < \dots < j_k \leq T'$  differ in the data of at most  $m$  items, it follows by group privacy that  $\Pr[\mathcal{A}(x(I)) \in E_J] \geq e^{-m\epsilon} 2/3$  for any such  $J$ .

Let  $J = (j_1, \dots, j_k)$  with  $1 \leq j_1 < j_2 < \dots < j_k \leq T'$ . Note that the events  $E_I$  and  $E_J$  for any  $I \neq J$  are disjoint, since in the event  $E_I$  it is clearly defined for every time step whether the output is at least  $m/2$  or smaller than  $m/2$ , and from that the set  $I$  can be uniquely recovered. Thus, there are  $\binom{T'}{k}$  disjoint events  $E_J$  and the probability that with input  $x(I)$  the algorithm outputs any one of them is at most 1. Thus we have

$$1 \geq \binom{T'}{k} e^{-m\epsilon} 2/3 \geq \frac{T'^k}{k^k} e^{-m\epsilon} 2/3 = \frac{T'^{K/m}}{(K/m)^{K/m}} e^{-m\epsilon} 2/3 \quad (1)$$

where the last equality is since  $k = K/m$ .

Next we consider two cases, the first one resulting in two different lower bounds on  $m$  and the second one giving a third lower bound on  $m$ . The combination of these three lower bounds then gives the claimed bound above of

$$\alpha = m/2 = \Omega(\min(\epsilon^{-1}T', \sqrt{\epsilon^{-1}K \max(\ln(T'/K), 1)}, K \max(\ln(T'/K), 1)))$$

**Case 1.**  $L' < mT'/4$ . In this case  $K = L'$  and we have

$$m^2\epsilon + m \ln(3/2) \geq K \ln(T'm/K) \geq K \max(\ln(T'/K), 1)$$

where the last inequality holds since  $K \leq mT'/4$ , i.e.,  $\ln(T'm/K) \geq \ln(4) > 1$ . Hence

$$m = \Omega(\min(\sqrt{\epsilon^{-1}K \max(\ln(T'/K), 1)}, K \max(\ln(T'/K), 1))).$$

As  $K = L' = \Theta(L)$  it follows that

$$m = \Omega(\min(\sqrt{\epsilon^{-1}L \max(\ln(T'/L), 1)}, L \max(\ln(T'/L), 1))).$$

**Case 2.**  $L' \geq mT'/4$ . This implies that  $K = mT'/4$  and, thus, that there are updates in at least  $T'/4$  many time steps. In this case Inequality 1 can be reformulated as follows:

$$1 \geq \frac{T'^{K/m}}{K/m^{K/m}} e^{-m\epsilon} 2/3 = 4^{T'/4} e^{-m\epsilon} 2/3 = e^{\ln(4)T'/4 - m\epsilon} 2/3,$$

which implies that Inequality 1 is satisfied for  $m = \Omega(\epsilon^{-1}T')$ .

These two cases show  $\alpha = \Omega(\min(\epsilon^{-1}T', \sqrt{\epsilon^{-1}L \max(\ln(T'/L), 1)}, L \max(\ln(T'/L), 1)))$  for the above input sequence. Combined with the above lower bounds on  $\alpha$  of  $\Omega(\min(d, L))$  and the fact that  $T' = \Theta(T)$ , it follows that  $\alpha = \Omega(\min(d, L, \epsilon^{-1}T, \sqrt{\epsilon^{-1}L \max(\ln(T/L), 1)}))$ . ◀

■ **Algorithm 2** COUNTDISTINCT, unknown  $K$ .

## 6 Unknown Total Flippancy

The algorithms from Section 3 can be easily extended to the case where the total flippancy  $K$  is not known beforehand, at the cost of  $\text{polylog}(K)$  factors in the error bound, as shown by Algorithm 2 and the lemmata below. The fact that  $K$  is not known causes no serious problem, as the algorithm repeatedly “guesses”  $K$  and then runs the algorithm from earlier with the current guess.

► **Lemma 17.** *For any  $0 < \epsilon < 1$  and  $0 \leq \delta < 1$ , Algorithm 2 is  $(\epsilon, \delta)$ -differentially private.*

**Proof.** By Lemma 12, the  $j$ th instance of Algorithm 1 is  $(\epsilon_j, \delta_j)$ -differentially private. Since  $\sum_{j=1}^{\infty} \epsilon_j = \epsilon$  and  $\sum_{j=1}^{\infty} \delta_j = \delta$ , by Fact 5, Algorithm 2 is  $(\epsilon, \delta)$ -differentially private. ◀

► **Lemma 18.** *For  $\delta = 0$ , the error of Algorithm 2 is at most*

$$O(\ln K \sqrt{\epsilon^{-1} K \ln(T \ln K/\beta)} + \epsilon^{-1} \ln^2 K \ln(T \ln K/\beta)).$$

*For  $\delta > 0$ , the error of Algorithm 2 is at most*

$$O((\epsilon^{-1} K \ln^2 K \ln(\ln K/\delta) \ln^2(T \ln K/\beta))^{1/3} + \epsilon^{-1} \ln^2 K \sqrt{\ln(\ln K/\delta)} \ln(T \ln K/\beta)).$$

**Proof.** Let  $j_l$  be the value of variable  $j$  after the last element in the stream is processed. For any  $j < j_l$ , note that by Lemma 13, with probability at least  $1 - \beta_j$ , by the choice of  $S_{K_j}$ , the algorithm does not abort before having seen the entire stream if the total flippancy is at most  $K_j$ . Thus, when the algorithm aborts for some  $j < j_l$ , we know that the flippancy is at least  $K_j$ , and the bound from Lemma 13 holds for the  $j$ th instance of Algorithm 1 with  $S_{K_j}$ .

Since the algorithm aborts for all  $j < j_l$ , we can conclude that the total flippancy of the stream processed by the  $j$ th run of Algorithm 1 is at least  $K_j$ . Since  $\sum_j \beta_j = \beta$ , with probability at least  $1 - \beta$ , (1) the total flippancy  $K$  is at least  $\sum_{j < j_l} K_j = 2^{j_l} - 1$ , and

(2) the bound from Lemma 13 holds for all instances of Algorithm 1 (with their respective parameters). It follows (a) that  $K \geq K_{j_i} - 1 \geq K_j$  for all  $j < j_i$  and (b)  $j_i = O(\ln K)$ . The maximum error over the stream is the maximum error of any instance of Algorithm 1. Since  $K_j = O(K)$ ,  $\epsilon_{j_i} \leq \epsilon_j$  and  $\delta_{j_i} \leq \delta_j$  for all  $j \leq j_i$ , the final bound is now obtained by plugging  $K$ ,  $\epsilon_{j_i} = \Theta(\epsilon/j^2)$  for  $\epsilon$ ,  $\delta_{j_i} = \Theta(\delta/j^2)$  for  $\delta$ , and  $\beta_{j_i} = \Theta(\beta/j^2)$  for  $\beta$  into the bound from Lemma 13, and upper bounding  $j^2$  by  $\log^2 K$ . ◀

One can also obtain the minimum of the bound from Lemma 18 and  $\min(K, T, d)$  at the cost of an additive  $\epsilon \ln^2 K \ln(\ln K/\beta)$  factor with a slightly more involved algorithm, which involves choosing to either not update the output or abort if there is a trivial algorithm which performs better for the current estimate of  $K$ . If we knew the value of  $K$  beforehand, we could choose the best algorithm upfront. Not knowing the value of  $K$  makes it slightly more complicated. However, the algorithm and analysis are fairly straightforward, and we defer it to the full version.

## 7 Lower Bounds for Approximate Differential Privacy

In this section, we adapt the lower bounds from [16] for item-level differential privacy to our parameter scheme.

► **Theorem 19.** *Let  $\epsilon, \delta \in (0, 1]$ .*

1. *Let  $K, T$  be sufficiently large parameters. There exists a dimension  $d$  and an input stream  $x$  of  $d$ -dimensional vectors from  $\{-1, 0, 1\}^d$  of length  $T$  and with flippancy at most  $K$  which is valid in the “likes”-model, such that any item-level,  $(\epsilon, \delta)$ -differentially private algorithm to the COUNTDISTINCT problem with error at most  $\alpha$  at all time steps with probability at least 0.99 must satisfy  $\alpha = \Omega\left(\min\left(\frac{\sqrt{T}}{\epsilon \log T}, \frac{(K\epsilon)^{1/3}}{\epsilon \log(K\epsilon)}\right)\right)$ .*
2. *Let  $K$  and  $T$  be sufficiently large parameters satisfying  $K \leq T$ . There exists a dimension  $d$  and an input stream  $x$  of  $d$ -dimensional vectors from  $\{-1, 0, 1\}^d$  of length  $T$  and with flippancy at most  $K$  which is valid in the “likes”-model and satisfies  $\|x^t\|_1 = 1$  for all  $t$ , such that any item-level,  $(\epsilon, \delta)$ -differentially private algorithm to the COUNTDISTINCT problem with error at most  $\alpha$  at all time steps with probability at least 0.99 must satisfy  $\alpha = \Omega\left(\frac{K^{1/3}}{\epsilon \log K}\right)$ .*

The reduction in [16] is based on a lower bound for the 1-way marginals problem. In that problem, the data set  $y$  is a table consisting of  $n$  rows and  $m$  columns, where every entry is in  $\{0, 1\}$ . Two data sets  $y$  and  $y'$  are neighbouring if they differ in at most one row. The goal is to estimate the average column sums, i.e., the vector  $(\sum_{i=1}^n y[i, j])_{j \in [m]}$ . The following lower bound holds for estimating 1-way marginals under  $(\epsilon, \delta)$ -differential privacy:

► **Lemma 20** (Bun, Ullman, and Vadhan [4]). *Let  $\epsilon \in (0, 1]$ ,  $\gamma \in (0, 1)$ , and  $m, n \in \mathbb{N}$ , and  $\delta = o(1/n)$ . Any algorithm which is  $(\epsilon, \delta)$ -differential private and has error at most  $\gamma$  with probability at least 0.99 satisfies  $n = \Omega\left(\frac{\sqrt{m}}{\gamma \epsilon \log m}\right)$ .*

**Proof Sketch of Theorem 19.** We start by arguing about Item 2. For this case, our example stream is exactly the same as in [16], given in Algorithm 5 in [16] (for a formulation using our slightly different notation see Algorithm 3). They give a reduction from the 1-way marginals problem: For any instance  $\mathcal{I}$  of the 1-way marginals problem with  $n$  rows and  $m$  columns, there is an instance  $C(\mathcal{I})$  of COUNTDISTINCT with  $T = 2mn$ , such that if  $\mathcal{I}$  and  $\mathcal{I}'$  are neighbouring, then  $C(\mathcal{I})$  and  $C(\mathcal{I}')$  are item-neighbouring. Further, if we can solve  $C(\mathcal{I})$  within error  $\alpha$ , we can solve  $\mathcal{I}$  within error  $\alpha/n$ . It follows by Lemma 20 that  $\alpha = \Omega\left(\min\left(\frac{\sqrt{m}}{\epsilon \log m}, n\right)\right)$ . In the instance they constructed,  $d = n$ , i.e. each row in the 1-way

marginals problem gives an item in the COUNTDISTINCT problem. Further, the total flippancy  $K$  can be as large as  $2mn$  for worst case inputs. Thus, in order to apply the reduction, we need  $2mn \leq K \leq T$ . Given parameters  $K \leq T$ , we choose  $m = K/(2n)$ . The lower bound  $\Omega\left(\min\left(\frac{\sqrt{m}}{\epsilon \log m}, n\right)\right)$  translates to  $\Omega\left(\min\left(\frac{\sqrt{K/(2n)}}{\epsilon \log(K/(2n))}, n\right)\right)$ . For  $n = \frac{K^{1/3}}{2(\epsilon \log K)^{2/3}}$ , we have

$$\frac{\sqrt{K/(2n)}}{\epsilon \log(K/(2n))} \geq \frac{K^{1/3} \epsilon^{1/3} \log^{1/3} K}{\epsilon \log(K^{1/2})} = \Omega\left(\frac{K^{1/3} \log^{1/3} K}{\epsilon^{2/3} \log K}\right) = \Omega(n).$$

Thus, we get  $\alpha = \Omega\left(\frac{K^{1/3} \log^{1/3} K}{\epsilon^{2/3} \log K}\right)$ .

For Item 1., where we allow general updates, we have to slightly modify the example in [16]: namely, in their Algorithm 5, we collapse every one of their vectors  $z^{(j)}$ ,  $j = 1, \dots, m$ , into vectors of length 2, one time step for all insertions corresponding to column  $j$ , and one time step for all deletions corresponding to column  $j$ . See Algorithm 4. We then again get a reduction with the same properties as before, except that  $T = 2n$  and  $K$  can be as large as  $2mn$ . Now, the analysis from [16] can be repeated with our  $T$  taking the role of  $w_x$  in [16], and our  $K$  taking the role of  $T$  in [16]. ◀

■ **Algorithm 3** Algorithm 5 from [16]: Reduction from 1-way marginals to COUNTDISTINCT.

---

```

1: Input: Data Set  $y[1], \dots, y[n] \in \{0, 1\}^{n \times m}$  and blackbox access to a mechanism  $M$  for
   COUNTDISTINCT
2: Output: Estimates of marginals  $b = (b[1], \dots, b[m])$ 
3: for  $j = 1, \dots, m$  do
4:   for  $i = 1, \dots, n$  do
5:     Set  $z^{(j)}[i] = e_i$ 
6:     Set  $z^{(j)}[i + n] = -e_i$ 
7:   end for
8: end for
9: Run  $M$  on  $x \rightarrow z^{(1)} \circ z^{(2)} \circ \dots \circ z^{(m)}$  and record answer vector  $r$ 
10: for  $j \in [m]$  do do
11:    $b[j] = r[(2j - 1)n]/n$ 
12: end for
13: output  $b$ 

```

---

■ **Algorithm 4** Reduction from 1-way marginals to COUNTDISTINCT for arbitrarily many updates per round.

---

```

1: Input: Data Set  $y[1], \dots, y[n] \in \{0, 1\}^{n \times m}$  and blackbox access to a mechanism  $M$  for
   COUNTDISTINCT
2: Output: Estimates of marginals  $b = (b[1], \dots, b[m])$ 
3: for  $j = 1, \dots, m$  do
4:   Set  $z^{(j)}[1] = y^T[j]$ 
5:   Set  $z^{(j)}[2] = -y^T[j]$ 
6: end for
7: Run  $M$  on  $x \rightarrow z^{(1)} \circ z^{(2)} \circ \dots \circ z^{(m)}$  and record answer vector  $r$ 
8: for  $j \in [m]$  do do
9:    $b[j] = r[(2j - 1)]/n$ 
10: end for
11: output  $b$ 

```

## Abstract

For  $S \subseteq \mathbb{F}^n$ , consider the linear space of restrictions of degree- $d$  polynomials to  $S$ . The Hilbert function of  $S$ , denoted  $h_S(d, \mathbb{F})$ , is the dimension of this space. We obtain a tight lower bound on the smallest value of the Hilbert function of subsets  $S$  of arbitrary finite grids in  $\mathbb{F}^n$  with a fixed size  $|S|$ . We achieve this by proving that this value coincides with a combinatorial quantity, namely the smallest number of low Hamming weight points in a down-closed set of size  $|S|$ .

Understanding the smallest values of Hilbert functions is closely related to the study of degree- $d$  closure of sets, a notion introduced by Nie and Wang (Journal of Combinatorial Theory, Series A, 2015). We use bounds on the Hilbert function to obtain a tight bound on the size of degree- $d$  closures of subsets of  $\mathbb{F}_q^n$ , which answers a question posed by Doron, Ta-Shma, and Tell (Computational Complexity, 2022).

We use the bounds on the Hilbert function and degree- $d$  closure of sets to prove that a random low-degree polynomial is an extractor for samplable randomness sources. Most notably, we prove the existence of low-degree extractors and dispersers for sources generated by constant-degree polynomials and polynomial-size circuits. Until recently, even the existence of arbitrary deterministic extractors for such sources was not known.

## 1 Introduction

### 1.1 Hilbert Functions

Low-degree polynomials are fundamental objects in theoretical computer science, and their properties are extensively studied due to their important role in areas such as error correcting codes and circuit lower bounds. Let  $d \geq 0$  be an integer,  $\mathbb{F}$  be a field, and  $S \subseteq \mathbb{F}^n$  be a set. Each degree- $d$   $n$ -variate polynomial  $p$  over  $\mathbb{F}$  can be naturally viewed as a map  $p : \mathbb{F}^n \rightarrow \mathbb{F}$ , and hence also defines a map  $p|_S : S \rightarrow \mathbb{F}$ . Considering the linear space of all such maps in  $\mathbb{F}^S$ , which is a subspace of the space of all maps from  $S$  to  $\mathbb{F}$ , allows one to tap into a wide array of algebraic techniques in order to prove useful facts about the set  $S$ . This approach was for example utilized in complexity theory famously in the work of Smolensky [39], where proving bounds on the dimension of the aforementioned subspace was used to obtain lower-bounds for  $\text{AC}^0[\oplus]$  circuits computing the indicator function of the set  $S$ , for various  $S \subseteq \{0, 1\}^n$ . The dimension of the space consisting of  $p|_S$  for all degree- $d$  polynomials  $p$  is indeed a well-studied and classical concept in algebraic geometry known as the (affine) Hilbert function of  $S$ , denoted by  $h_S(d, \mathbb{F})$ . Hilbert functions encode important geometric and algebraic information, such as the dimension, degree, and regularity of varieties, in a more general context.

Hilbert functions have previously been studied in complexity theory due to their applications in circuit lower bounds, in particular for  $\text{AC}^0[\oplus]$  circuits, that were established by Smolensky [39] and Razborov [36]. Such applications require finding sets  $S \subseteq \{0, 1\}^n$  where the Hilbert function takes a very large value. However, it is also interesting to prove general lower bounds or find lower-bounding methods for arbitrary sets  $S$ . An example of such a result is the work of Moran and Rashtchian [32], who showed upper and lower bounds on  $h_S(d, \mathbb{F})$  for  $S \subseteq \{0, 1\}^n \subseteq \mathbb{F}^n$  via various concepts in VC theory. [32] treated the Hilbert function as a complexity measure of the set  $S$  and compared it to measures that arise naturally in learning theory, including “shattering” and “strong shattering” values.

Suppose  $r > 0$  is an integer. It is natural to wonder, what the extreme values of  $h_S(d, \mathbb{F})$  are, among all sets  $S$  of size  $|S| = r$ . It is not hard to show that the maximum value is equal to  $\min(r, h_{\mathbb{F}^n}(d, \mathbb{F}))$  when  $S \subseteq \mathbb{F}^n$ . For example, the maximum value of the Hilbert function of a set  $S \subseteq \mathbb{F}_2^n$  of size  $r$  is  $\min(r, \binom{n}{\leq d})$ .

On the other hand, finding the true smallest value of  $h_S(d, \mathbb{F})$  is a natural and intriguing question even when  $S$  is restricted to subsets of some finite and structured set in  $\mathbb{F}^n$ .

► **Question 1.** *Let  $0 \leq d \leq n$  be integers,  $\mathbb{F}$  be a field, and  $A = A_1 \times \dots \times A_n \subseteq \mathbb{F}^n$  where  $A_i \subseteq \mathbb{F}$  are finite sets. For any  $r \leq |A|$ , what is the smallest value of  $h_S(d, \mathbb{F})$  among all subsets  $S \subseteq A$  of cardinality  $|S| = r$ ?*

This question has been answered in the case of  $\mathbb{F} = \mathbb{F}_2$  and  $A = \mathbb{F}_2^n$  by Keevash and Sudakov [27] and Ben-Eliezer, Hod, and Lovett [6], and later generalized to  $\mathbb{F} = \mathbb{F}_p$  and  $A = \mathbb{F}_p^n$  by Beame, Oveis Gharan, and Yan [4]. For simplicity, let  $r = p^k$  for some  $k \geq 0$ . [4] proved that the smallest value of  $h_S(d, \mathbb{F}_p)$  with  $|S| = r$  is equal to the number of degree- $\leq d$  monomials on  $k$  variables, for example when  $p = 2$ , this is equal to simply  $\binom{k}{\leq d} = \binom{\log_2 r}{\leq d}$ .

We prove a more general result that answers Question 1 for arbitrary finite grids  $A \subseteq \mathbb{F}^n$  in arbitrary fields  $\mathbb{F}$ . We show that the smallest values of Hilbert functions are exactly determined by an extremal combinatorial question about the number of low-Hamming-weight elements in down-closed sets, which we solve by building on the work of Beelen and Datta [5].

The prior works discussed above were motivated by applications in bounding the list-size of the Reed-Muller codes and obtaining certain extensions of Frankl–Ray–Chaudhuri–Wilson theorems on cross-intersecting sets. In contrast, in this paper, we are interested in Question 1 due to its applications in pseudorandomness, particularly in randomness extraction.

Understanding the smallest values of Hilbert functions is closely related to the study of *degree- $d$  closure* of sets, a notion introduced by Nie and Wang [33].

► **Definition 1.** *The degree- $d$  closure of a set  $T \subseteq \mathbb{F}^n$  is defined as*

$$\text{cl}_d(T) := \{a \in \mathbb{F}^n \mid \text{for every degree-}d \text{ polynomial } f, f|_T \equiv 0 \Rightarrow f(a) = 0\}.$$

Equivalently,  $\text{cl}_d(T)$  is the set of all points  $a \in \mathbb{F}^n$  such that the values  $f(a)$  of a degree- $d$  polynomial  $f$  are determined by  $f|_T$ .

The existence of a small set with a large degree- $d$  closure has application to hitting-set generators for polynomials [17]. As an application of our answer to Question 1, we obtain an upper bound on the size of  $\text{cl}_d(T)$  in terms of  $|T|$ . Our bound in fact yields an optimal way of creating a small set with a large degree- $d$  closure.

Futhermore, Question 1 has direct implications to the theory of randomness extractors, which we discuss next.

## 1.2 Randomness Extractors

The theory of randomness extractors is an active research area that was initiated in [38, 7] with the motivation of simulating randomized algorithms with access to “weak” randomness sources. The main objective of this theory is to design *extractors* that are capable of purifying imperfect randomness sources into high-quality random bits or bit sequences. Extractors and related objects such as *dispersers*, *samplers*, and *condensers* have since found numerous applications in constructing other pseudorandom objects such as pseudorandom generators [34] and expander graphs [50], as well as applications in other areas of theoretical computer science and mathematics including cryptography [15], combinatorics [30], hardness of approximation [51], error correcting codes [42], and metric embeddings [25].

A deterministic extractor for a family  $\mathcal{X}$  of distributions over  $\{0, 1\}^n$  is a map  $f : \{0, 1\}^n \rightarrow \{0, 1\}^m$  such that for any  $\mathbf{X} \in \mathcal{X}$ ,  $f(\mathbf{X})$  is close to the uniform distribution in statistical distance. It is common to measure the amount of randomness in a random variable  $\mathbf{X}$  by its min-entropy, defined  $H_\infty(\mathbf{X}) := -\log_2 \max_{x \in \{0, 1\}^n} \Pr[\mathbf{X} = x]$ . It is easy to show that no deterministic extractor can extract from general  $n$ -bit randomness sources of min-entropy as high as  $n - 1$  [11]. As a result, researchers in the area have explored two directions. Much of the focus in the area has been given to the more powerful *seeded extractors* that have access to an additional short purely random seed. This article contributes to another line of work that has extensively investigated the extra assumptions on the randomness sources that allow for explicit deterministic extractors and dispersers to exist. A widely studied class of sources in this latter direction, introduced in [43] is “samplable sources”, where the sources of randomness are distributions sampled by applying a low-complexity map (e.g., a decision forest, local map,  $\text{NC}^0$  circuit,  $\text{AC}^0$  circuit, an affine or a low-degree map) to the uniform distribution. Unfortunately, constructing explicit extractors even for sources samplable by really low-complexity maps has been quite challenging, and for example all the known constructions of extractors for local sources require quite high min-entropy of  $\Omega(\sqrt{n})$  [47, 14]. Due to the difficulty of constructing good explicit extractors and motivated by applications in complexity theory such as circuit lower bounds [29] and lower bounds for distribution-sampling [46], researchers have considered the seemingly easier task of proving the existence of low-complexity extractors [45, 19, 10, 44, 8, 16, 24, 12, 1].

The state of affairs is much worse when it comes to randomness extraction from sources sampled by more powerful maps such as  $\text{AC}^0[\oplus]$  or low-degree  $\mathbb{F}_2$ -polynomial maps. In this case obtaining nontrivial explicit constructions and even non-explicit low-complexity

extractors remains open. In fact, the same problems are open even in the case of dispersers. Here a map  $f : \{0, 1\}^n \rightarrow \{0, 1\}$  is a *disperser* for  $\mathcal{X}$  if for every source  $\mathbf{X} \in \mathcal{X}$ , the support of  $f(\mathbf{X})$  is  $\{0, 1\}$ . On the positive side, Chattopadhyay, Goodman, and Gurumukhani [9], recently proved the existence of deterministic (not necessarily low-complexity) extractors for low-degree  $\mathbb{F}_2$ -polynomial sources with logarithmic min-entropy.

### 1.3 Our Results on Hilbert Functions

We obtain our answer to Question 1 by first reducing it to a purely combinatorial problem. In particular, via an algebraic geometric argument, we prove the following theorem which states that the minimum value of Hilbert functions over subsets of a grid is exactly captured by a combinatorial quantity related to down-closed sets. (A set  $T \subseteq \mathbb{N}^n$  is said to be down-closed if  $T$  is closed under decreasing any coordinates of its elements.)

► **Theorem 2** (See Corollary 35). *Let  $\mathbb{F}$  be a field, and  $A_1, \dots, A_n \subseteq \mathbb{F}$  be finite sets of size  $|A_i| = r_i$ . Define  $A = A_1 \times \dots \times A_n$ . For every  $k \leq |A|$ ,*

$$\min_{S \subseteq A: |S|=k} h_S(d, \mathbb{F}) = \min_{\text{down-closed } T \subseteq F: |T|=k} |T_{\leq d}| ,$$

where  $F = \prod_i \{0, \dots, r_i - 1\}$  and  $T_{\leq d} = \{x \in T : \sum_i x_i \leq d\}$ .

For space reasons, we defer the proofs of Theorem 2 and the consequent results to the full version [20].

Let  $I$  be the ideal of  $\mathbb{F}[X_1, \dots, X_n]$  associated with a set  $S \subseteq A$ , that is, the set of all polynomials vanishing on  $S$ .

Classical results in algebraic geometry (such as Hilbert's Nullstellensatz) establish close connections between the structure of  $S$  and the structure of  $I$ , which allows us to focus on studying  $I$ .

The proof of Theorem 2 is based on the idea that the ideal  $I$  can be reasonably approximated by another ideal, *the ideal of leading terms of  $I$* . This approximation preserves important information about  $I$ , and consequently, about  $S$  as well. In particular, when the ideal of leading terms of  $I$  is defined with respect to a specific total order of monomials compatible with the total degree, it can be shown that such an approximation preserves the value of the Hilbert function. One advantage of working with the ideal of leading terms is that it is a *monomial ideal*, that is, an ideal generated by monomials, whose relatively simple structure can be analyzed using combinatorial tools.

We remark that the concept of transforming a general ideal into a monomial ideal is closely related to the theory of Gröbner bases, which serves as a basis of computational algebraic geometry. For a detailed discussion, see, e.g., [3]. This concept is also used in Smolensky's algebraic method for proving circuit lower bounds [40].

Theorem 2 allows us to reduce the problem of determining the smallest value of Hilbert function of a set of size  $k$  to understanding the smallest number of low-Hamming-weight points in down-closed sets of the same size. We then solve this combinatorial problem by proving that the minimum is obtained by the down-closed set  $M_F(k)$  which is defined as the set of  $k$  lexicographically first elements of  $F$ .

► **Theorem 3** (See Theorem 38). *Let  $1 \leq r_1 \leq \dots \leq r_n$  be integers and let  $F = \prod_{i=1}^n \{0, \dots, r_i - 1\}$ . Then*

$$\min_{\text{down-closed } T \subseteq F} |T_{\leq d}| = |M_F(k)_{\leq d}| .$$

In the case of  $r_1 = \dots = r_n = 2$ , we prove the above theorem via an elementary combinatorial argument, that via a series of operations turns any set of  $k$  elements into  $M_F(k)$  without increasing the number of elements of Hamming weight  $\leq d$ . We prove the general case by building on a recent result of Beelen and Datta [5]. This result generalizes the work of Wei [49] and Heijnen–Pelikaan [22, 21] in studying the generalized Hamming weights of certain linear codes.

We record the following corollary of our results specialized to finite fields which generalizes the bounds due to [27, 6, 4], where  $M_q^n(k)$  is the set of  $k$  lexicographically first strings in the set  $\prod_{i=1}^n \{0, 1, \dots, q-1\}$ .

► **Corollary 4** (See Corollary 39). *For every prime power  $q$ , and  $n, k, d \in \mathbb{N}$  where  $k \leq q^n$ , we have*

$$\min_{S \subseteq \mathbb{F}_q^n: |S|=k} h_S(d, \mathbb{F}_q) = |M_q^n(k)_{\leq d}|.$$

*In particular, setting  $q = 2$ , for every  $n, k, d \in \mathbb{N}$  where  $k \leq 2^n$ , and every  $S \subseteq \mathbb{F}_2^n$  of size  $|S| = k$ ,*

$$h_S(d, \mathbb{F}_2) \geq \binom{\lfloor \log(k) \rfloor}{\leq d}.$$

### 1.3.1 Degree- $d$ Closure of Sets

Motivated by its applications to combinatorial geometry, the notion of degree- $d$  closures of subsets of  $\mathbb{F}_q^n$  was introduced in [33]. This concept has since found further applications and connections to complexity theory [28, 35, 41] and pseudorandomness [17].

Recall that the degree- $d$  closure  $\text{cl}_d(T)$  of a set  $T \subseteq \mathbb{F}^n$  over a finite field  $\mathbb{F}$  is the set of all points  $a \in \mathbb{F}^n$  such that any degree- $d$  polynomial vanishing on  $T$  also vanishes at  $a$ . Nie and Wang [33] proved the following result.

► **Theorem 5** ([33, Theorem 5.6]). *Let  $n, d \in \mathbb{N}$  and  $T \subseteq \mathbb{F}_q^n$ . Then*

$$|\text{cl}_d(T)| \leq \frac{q^n}{h_{\mathbb{F}_q^n}(d, \mathbb{F}_q)} \cdot |T|.$$

Building on our results on Hilbert functions, we obtain an improvement of Theorem 5 by obtaining a tight upper bound on the size of degree- $d$  closures of sets.

► **Theorem 6** (See Theorem 47 and Theorem 48). *Let  $n, d, m \in \mathbb{N}$ . Let  $T \subseteq \mathbb{F}_q^n$  be a set of size  $m$ . Then*

$$|\text{cl}_d(T)| \leq \max_{0 \leq k \leq q^n: |M_q^n(k)_{\leq d}| \leq m} k = \begin{cases} \max_{0 \leq k \leq q^n: |M_q^n(k)_{\leq d}| = m} k & \text{if } m \leq h_{\mathbb{F}_q^n}(d, \mathbb{F}_q), \\ q^n & \text{otherwise.} \end{cases} \quad (1)$$

*Moreover, this bound is tight in the sense that for any  $0 \leq m \leq q^n$ , there exists  $T \subseteq \mathbb{F}_q^n$  of size  $m$  for which (1) holds with equality.*

In fact, the set  $T$  of size  $m$  that attains the bound in the above theorem can be constructed explicitly; see Theorem 48 for details.

For convenience, we state the following corollary which is used later in the paper. For  $n, d, \delta \in \mathbb{N}$ , denote by  $N(n, d, \delta)$  the number of monomials  $X_1^{e_1} \dots X_n^{e_n}$  with  $e_1, \dots, e_n \leq \delta$  and  $e_1 + \dots + e_n \leq d$ .

► **Corollary 7.** *Let  $n, d, \ell \in \mathbb{N}$ . If  $T \subseteq \mathbb{F}_q^n$  is a set of size less than  $N(\ell, d, q - 1)$ , then  $|\text{cl}_d(T)| < q^\ell$ . In particular, if  $q = 2$  and  $T \subseteq \mathbb{F}_2^n$  is a set of size less than  $\binom{\ell}{\leq d}$ , then  $|\text{cl}_d(T)| < 2^\ell$ .*

**Proof.** Observe that  $|\text{M}_q^n(q^\ell)_{\leq d}| = N(\ell, d, q - 1)$ . Then apply Theorem 6. ◀

Let us compare our bound with the bound of Nie and Wang in some specific settings.

► **Example 8.** Suppose  $\ell \leq n$ . Let  $T \subseteq \mathbb{F}_2^n$  be a set of size  $\binom{\ell}{\leq d} - 1$ . Then by Corollary 7, we have the bound  $|\text{cl}_d(T)| \leq 2^\ell - 1$ . On the other hand, the bound of Nie and Wang (Theorem 5) gives

$$|\text{cl}_d(T)| \leq \frac{2^n}{\binom{n}{\leq d}} \cdot |T|,$$

which is exponential in  $n$ , rather than in  $\ell$ , at least when  $d \leq (\frac{1}{2} - c)n$  for some constant  $c > 0$ .

► **Example 9.** Suppose  $\ell \leq n$  and  $d < q$ . Let  $T \subseteq \mathbb{F}_q^n$  be a set of size  $N(\ell, d, q - 1) - 1 = \binom{\ell+d}{d} - 1$ . Then by Corollary 7, we have the bound  $|\text{cl}_d(T)| \leq q^\ell - 1$ , which is exponential in  $\ell \log q$ . On the other hand, the bound of Nie and Wang (Theorem 5) gives

$$|\text{cl}_d(T)| \leq \frac{q^n}{\binom{n+d}{d}} \cdot |T|,$$

which is exponential in  $n \log q$ , rather than in  $\ell \log q$ , at least when  $n + d \leq q^{1-c}$  for some constant  $c > 0$ .

In [17], Doron, Ta-Shma, and Tell explicitly asked if there exists a small set  $T \subseteq \mathbb{F}_q^n$  whose degree- $d$  closure is very large. Our Theorem 6 gives an upper bound on the size of the degree- $d$  closure of  $T$  in terms of the size of  $T$ , which is tight in the sense that there exist sets  $T$  that exactly meet this bound for every cardinality of  $T$ . Moreover, such sets  $T$  can be constructed explicitly (see Theorem 48). Thus, we completely resolve the question posed by Doron, Ta-Shma, and Tell.

## 1.4 Our Results on Randomness Extractors

Continuing the line of work on low-complexity extractors, in this paper we investigate the power of low-degree polynomials in randomness extraction.

► **Question 2.** *For which families  $\mathcal{X}$  of sources does there exist a low-degree disperser? Similarly, for which families  $\mathcal{X}$  of sources does there exist a low-degree extractor?*

Let us first discuss the easier task of obtaining low-degree dispersers before moving on to our main application of low-degree extractors. For simplicity, we will focus on the most important case of extracting randomness over  $\mathbb{F}_2$ , but all our results easily generalize to  $\mathbb{F}_q$ . Non-explicit constructions of low-degree dispersers can be obtained via understanding the probability that a random low-degree polynomial is a disperser for a family  $\mathcal{X}$  of distributions over  $\{0, 1\}^n$  which we identify with  $\mathbb{F}_2^n$  in the natural way. Our starting point is the observation that the notion of Hilbert functions can be used to exactly describe the probability that a random degree- $d$  polynomial  $f : \{0, 1\}^n \rightarrow \{0, 1\}$  is a disperser for a fixed source  $\mathbf{X} \in \mathcal{X}$ . Indeed, this probability is exactly equal to  $1 - 2^{1-h_S(d, \mathbb{F}_2)}$ , where  $S = \text{support}(\mathbf{X})$ . Thus, in particular, Corollary 4 can be used to bound the probability that a random degree- $d$  polynomial is not a disperser for a fixed source.

### 1.4.1 Low-Degree Dispersers

Let  $\mathcal{X}$  be a family of sources of min-entropy  $\geq k$ . Observing that the support of any distribution  $\mathbf{X} \in \mathcal{X}$  is of size  $\geq 2^k$ , one gets as an immediate corollary of Corollary 4, the existence of low-degree dispersers  $\mathcal{X}$  as long as  $|\mathcal{X}|$  is small.

► **Theorem 10** (Informal, see Corollary 50). *Let  $n, d, k \geq 1$ . Let  $\mathcal{X}$  be a family of distributions of min-entropy  $\geq k$ . Then a random degree- $d$  polynomial over  $\mathbb{F}_2$  is a disperser for  $\mathcal{X}$  with probability at least*

$$1 - |\mathcal{X}| \cdot 2^{1 - \binom{k}{\leq d}}.$$

This theorem itself implies the existence of low-degree dispersers for several interesting families of samplable sources such as sources sampled by local maps, bounded-depth decision forests, and polynomial-sized bounded-fan-in circuits, to name a few.

A map  $f : \{0, 1\}^m \rightarrow \{0, 1\}^n$  is called  $\ell$ -local if each of its output bits depends on at most  $\ell$  input bits. A depth- $\ell$  decision forest is a map  $f$  where each output bit can be computed as a depth- $\ell$  decision tree. It is easy to obtain an upper bound exponential in  $\text{poly}(n)$  on the number of local or decision forest sources. Hence we get the following as a corollary of Theorem 10.

► **Corollary 11** (Informal, see Corollary 51). *Let  $1 \leq \ell \leq d \leq n$  be integers. There exists a degree- $d$  disperser*

- *for the family of  $\ell$ -local sources on  $\{0, 1\}^n$  with min-entropy  $k > d(2^\ell n + 2\ell n \log n)^{1/d}$ .*
- *for the family of depth- $\ell$  decision forest sources on  $\{0, 1\}^n$  with min-entropy  $k > d((\ell + \log n)2^{\ell+1}n)^{1/d}$ .*

As mentioned above, since in addition to the min-entropy requirement, the only requirement in Theorem 10 about the family  $\mathcal{X}$  is a bound on  $|\mathcal{X}|$ , it can be used to immediately obtain low-degree dispersers for various other families of sources as well. For example, since for any  $c$ , the number of Boolean circuits with  $\leq n^c$  bounded fan-in gates is at most  $2^{O(n^{c+1})}$ , one can also use Theorem 10 to obtain a degree- $O(c)$  disperser for such families of circuits. However, we will not do an exhaustive search for all such applications, and instead our main disperser applications will focus on two powerful families of sources, namely sources sampled by low-degree polynomials over  $\mathbb{F}_2$  and  $\text{AC}[\oplus]$  circuits which we define as the family of unbounded-depth polynomial-size Boolean circuits with AND, OR, XOR, NOT gates of unbounded fan-in, where the input gates are not counted towards the size.

Note that low-degree polynomial maps  $f : \{0, 1\}^m \rightarrow \{0, 1\}^n$ , even affine ones, can depend on the entire input for any  $m \gg n$  and thus one cannot simply bound  $|\mathcal{X}|$  when  $\mathcal{X}$  is the family of sources sampled by low-degree polynomials. This property holds for  $\text{AC}[\oplus]$  circuits, as we allow them to non-trivially depend on an arbitrary number of input gates (since the circuit gates have unbounded fan-in). Nevertheless, utilizing an “input-reduction” trick of [9] which applies to both the foregoing families of sources, it can be shown that for our disperser purposes we may assume the input of both families of sources to be of length  $O(n)$ . This allows us to apply Theorem 10 to obtain low-degree dispersers for both of these families.

► **Theorem 12** (Informal, see Theorems 53 and 54). *For every  $1 \leq \ell < d \leq n$ , there exists a degree- $d$  disperser*

- *for the family of degree- $\ell$  sources on  $\{0, 1\}^n$  with min-entropy  $k \geq (12^\ell \cdot d^d \cdot n)^{\frac{1}{d-\ell}} + 1$ .*
- *for the family of  $n^\ell$ -size  $\text{AC}[\oplus]$  circuit sources on  $\{0, 1\}^n$  with min-entropy  $k \geq (30^2 \cdot d^d \cdot n^{2\ell})^{\frac{1}{d-2}} + 1$ .*

In particular, for every  $\ell \in \mathbb{N}$ , there is a degree- $(\ell + 2)$  disperser for degree- $\ell$  sources on  $\{0, 1\}^n$  with min-entropy  $\Omega(\sqrt{n})$ .

We note that both of these source families are very powerful, and to the best of our knowledge, no nontrivial low-complexity dispersers for either of these families of sources was known prior to this work (except in the easier case of degree-1 sources which corresponds to affine sources for which explicit extractors for logarithmic entropy was recently proved [30]). Let us also point out that the two foregoing classes have incomparable power, and that it is straightforward to use our proof technique to conclude the same result for a class of sources that generalizes both  $\text{AC}[\oplus]$  and constant-degree polynomials. Indeed, the input-reduction and counting idea works for the “hybrid” class of polynomial-size circuits which extends  $\text{AC}[\oplus]$  by allowing additional unbounded fan-in gates computing arbitrary polynomials of fixed constant degree. However, for ease of exposition, we have chosen to present only the results for  $\text{AC}[\oplus]$  and low-degree sources separately.

### 1.4.2 Low-Degree Extractors

Next, we move on to another application concerning the existence of low-degree extractors for samplable sources. Can we prove the existence of low-degree extractors for all the families for which we proved the existence of low-degree dispersers? We prove this by showing an analogue of Theorem 10 for extractors.

► **Theorem 13** (Informal, see Theorem 58 for the more general statement). *Let  $\mathcal{X}$  be a family of distributions of min-entropy  $k \geq 5 \log n$  over  $\{0, 1\}^n$  for large enough  $n$ . Then for every  $d \geq 6$ , a uniformly random degree- $d$  polynomial is an  $\varepsilon$ -extractor for  $\mathcal{X}$  with probability at least*

$$1 - |\mathcal{X}| \cdot e^{3n - O(k^{d/2})/n^2}$$

for  $\varepsilon = (2d)^d \cdot k^{-d/4}$ .

A similar statement (see Theorem 58) holds for families of sources that are close to convex combinations of another small family of sources. Combined with the input-reduction trick, we obtain as a corollary, the existence of low-degree extractors for various families of sources, notably, lower-degree sources and  $\text{AC}[\oplus]$  circuits.

► **Theorem 14** (Informal, see Theorem 60). *For all  $\ell, d \geq 1$ , and all large enough  $n$ , and  $k \geq 5 \log n$ . There exists a degree- $d$   $\mathbb{F}_2$ -polynomial that is an  $\varepsilon$ -extractor for the following families of sources over  $\{0, 1\}^n$  for  $\varepsilon = (2d)^d \cdot k^{-d/4}$ :*

- $\ell$ -local sources for  $k \geq (2^\ell n^3 \log n)^{2/d}$ .
- depth- $\ell$  decision forest sources for  $k \geq (2^\ell n^3 (\log n + \ell))^{2/d}$ .
- degree- $\ell$  sources for  $k \geq (3^\ell n)^{\frac{6}{d-2\ell}}$ .
- $n^\ell$ -size  $\text{AC}[\oplus]$  circuit sources (with unbounded number of input gates) for  $k \geq 3n^{\frac{4(\ell+1)}{d-4}}$ .

In Theorem 61, we further extend our low-degree extractors to multi-output extractors that output  $\Theta(k)$  bits. This is done by independently picking random degree- $d$  polynomials  $p_1, \dots, p_t$  for some  $t = \Theta(k)$ , and analyzing the probability that each  $p_i$  is an extractor for the family of sources obtained by  $\mathcal{X}$  conditioned on the values of  $p_1, \dots, p_{i-1}$ .

Let us now discuss our proof technique for Theorem 13. Recall that Theorem 10 was a corollary to Corollary 4 which showed that a random polynomial is with high probability non-constant on the support of any fixed high min-entropy distribution. A priori it is not clear how to use this bound on the Hilbert function to prove Theorem 13.

Indeed, let us consider the simpler case of a fixed  $k$ -flat source  $\mathbf{X}$  over  $\{0, 1\}^n$ , which is uniformly distributed over a set  $S \subseteq \{0, 1\}^n$  with  $|S| = 2^k$ . Note that a map  $p : \{0, 1\}^n \rightarrow \{0, 1\}$  is an extractor for  $\mathbf{X}$  if it has small bias on  $S$ . Thus, for example, to prove the special

case of Theorem 13 for small families of  $k$ -flat sources, we would need to prove that a random degree- $d$  polynomial is small-biased on  $S$  with high probability. However, Corollary 4 only tells us that  $h_S(d, \mathbb{F}_2) \geq \binom{k}{\leq d}$ , which is not enough to prove concentration bounds for the bias of a random degree- $d$  polynomial on an arbitrary set  $S$ . We note that when  $S$  is highly structured, that is when it is an affine subspace, this problem is equivalent to questions about list-decoding size of Reed-Muller codes, and known results such as one by Kaufman, Lovett, and Porat [26] that show that the number of distinct  $\varepsilon$ -biased degree- $d$  polynomials on a  $k$ -dimensional subspace  $S$  is at most  $(1/\varepsilon)^{k^{d-1}}$  could be utilized. However, for our application we have to deal with arbitrary sets  $S$ .

**Uniform covering by sets of full Hilbert dimension.** We say that a set  $T \subseteq \{0, 1\}^n$  has “full Hilbert dimension” if  $h_T(d, \mathbb{F}_2) = |T|$ . Note that when  $T$  has full Hilbert dimension, then the restriction of a random degree- $d$  polynomial to  $T$  is uniformly distributed over  $\{0, 1\}^T$ . In particular, if  $T$  is a sufficiently large set of full Hilbert dimension, then a random degree- $d$  polynomial is small-biased on  $T$  with high probability. We use this observation to design our technique for bounding the probability that a random degree- $d$  polynomial is small-biased on any fixed source  $\mathbf{X}$  of large min-entropy. For simplicity we describe the idea for flat sources. In this case,  $\mathbf{X}$  is uniformly distributed over a set  $S$  with  $|S| \geq 2^k$ . It is sufficient to prove the existence of an almost-uniform covering of  $S$  by large sets  $T_1, \dots, T_t$  of the same size with full Hilbert dimensions, where we call a covering almost-uniform if each element  $x \in S$  belongs to roughly  $tm/|S|$  many sets, where we assume  $|T_i| = m$ .

We obtain such a covering by analyzing the probability that a uniformly picked subset  $T_i \subseteq S$  has full Hilbert dimension. Using our bound on the Hilbert function, Corollary 4, which allows us to bound the size of the “degree- $d$  closure” of small sets, we prove that a random set  $T_i$  of size  $m$ , for some  $m = \binom{\Theta(k)}{\leq d}$ , has full Hilbert dimension with high probability. Similarly, we prove using the Bayes rule, that we may pick these good sets  $T_i$ ’s of full Hilbert dimension in a way that leads to an almost uniform covering. Since  $T_i$ ’s are of sufficiently large size  $\binom{\Theta(k)}{\leq d}$  and of full Hilbert dimension, we can use the Hoeffding inequality to bound the probability that a random degree- $d$  polynomial is biased on a  $T_i$  to be exponentially small in  $\Theta(k)^d$ , which is good enough for our applications to existence of low-degree extractors. We obtain the following result which can be used to prove Theorem 13.

► **Theorem 15** (Informal, see Theorem 57). *Let  $n, d, k \geq 1$ , and  $\varepsilon > 0$  be a real. Then for every distribution  $\mathbf{X}$  over  $\{0, 1\}^n$  with  $H_\infty(\mathbf{X}) \geq k$ , a uniformly random degree- $d$  polynomial  $f$  is an  $\varepsilon$ -extractor for  $\mathbf{X}$ , with probability at least  $1 - e^{3n - \varepsilon^2 \binom{\ell}{\leq d} / (Cn^2)}$  where  $\ell = k/2 - \log(32n/\varepsilon)$  and  $C = 7 \cdot (32)^2$ .*

We find our technique of obtaining almost uniform coverings with sets of full Hilbert dimension to be powerful, and hope that it will find other applications beyond the ones explored here.

## 1.5 Remarks

**Correlation bounds over arbitrary subsets.** We note that our proof of Theorem 15 (Theorem 58) can be modified to the following correlation bounds with any fixed function.

► **Theorem 16.** *Let  $n, d, k \geq 1$ ,  $\varepsilon > 0$  be a real, and  $g : \mathbb{F}_2^n \rightarrow \mathbb{F}_2$  be a fixed function. Then for every distribution  $\mathbf{X}$  over  $\{0, 1\}^n$  with  $H_\infty(\mathbf{X}) \geq k$ , for a uniformly random degree- $d$  polynomial  $f$  we have*

$$\Pr[f(\mathbf{X}) = g(\mathbf{X})] = \frac{1}{2} \pm \varepsilon,$$

*with probability at least  $1 - e^{3n - \varepsilon^2 \binom{\ell}{\leq d} / (Cn^2)}$  where  $\ell = k/2 - \log(32n/\varepsilon)$  and  $C = 7 \cdot (32)^2$ .*

## 41:10 Hilbert Functions and Low-Degree Randomness Extractors

This generalization is quite straightforward, as once we obtain a uniform covering by sets of maximum Hilbert dimension, then Hoeffding bounds can be used to bound the correlation of a random polynomial with the fixed function restricted to the sets belonging to the cover. This can then be used to bound the over-all correlation with the fixed function in a similar way to the proof of Theorem 58.

**Punctured Reed-Muller codes.** The special case of Theorem 16 when  $\mathbf{X}$  is a flat source can be interpreted as a bound on the list-decoding size of Reed-Muller codes when “punctured” on a large set  $S \subseteq \mathbb{F}_2^n$ . Recall that the binary Reed-Muller code  $\text{RM}[d, n]$  consists of codewords in  $\mathbb{F}_2^n$  that correspond to the evaluation vectors of degree  $\leq d$  polynomials over  $\mathbb{F}_2$ . Given a set  $S \subseteq \mathbb{F}_2^n$ , the resulting punctured code consists of the evaluation of degree  $\leq d$  polynomials on  $S$ . In this context, Theorem 16 can be used to bound the list-size of any puncturing of the Reed-Muller code, showing that for any word  $w$  from  $\mathbb{F}_2^S$ , only a small fraction of codewords are within radius  $\frac{1}{2} - \varepsilon$  of  $w$ . Another interpretation of Theorem 16 is that any puncturing of the Reed-Muller codes over a set  $S$  can be turned into a “small-biased” code without much loss in the rate of the code.

**Sampling lower bound for polynomial sources.** Our low-degree extractor for lower-degree sources (Theorem 14) has a direct application in distributions that are hard to sample by low-degree polynomials. Indeed, an argument similar to the proof of [48, Lemma 3], Theorem 14 implies the existence of a degree- $O(d)$  polynomial  $p$  for which the distribution  $(\mathbf{U}, p(\mathbf{U}))$  cannot be sampled by any degree- $d$  source, where  $\mathbf{U} \sim \mathbf{U}_n$ .

Suppose that  $p$  is a degree- $O(d)$  polynomial that is an  $\varepsilon$ -extractor for the family of degree  $\leq 2d$  sources over  $\{0, 1\}^n$  of min-entropy  $\geq \frac{n}{2}$ , where  $\varepsilon = o(1)$ . The existence of such a polynomial  $p$  is guaranteed by Theorem 14. Now suppose that  $(G(\mathbf{U}'), g(\mathbf{U}'))$ , where  $\mathbf{U}' \sim \mathbf{U}_m$  for some  $m \geq 1$ , is a degree  $\leq d$  source sampling  $(\mathbf{U}, p(\mathbf{U}))$ . In particular,  $G$  is an  $n$ -bit degree  $\leq d$  source and  $g$  is a degree  $\leq d$  polynomial. Consider the  $n$ -bit random variable  $\mathbf{R} = G(\mathbf{U}') \cdot g(\mathbf{U}') + \mathbf{U}_n \cdot (1 - g(\mathbf{U}'))$ . Since  $\mathbf{R}$  is sampled by a degree  $\leq 2d$  source of min-entropy  $n - O(1)$ ,  $\Pr[p(\mathbf{R}) = 1] = \frac{1}{2} + o(1)$ . On the other hand, by the definition  $\mathbf{R}$ , we have  $\Pr[p(\mathbf{R}) = 1] \geq \frac{1}{2} + \Omega(1)$ , which is a contradiction.

**Related Work.** An independent and concurrent paper by Alrabiah, Goodman, Mosheiff, and Ribeiro [2] proves the existence of low-degree extractors for similar families of sources that are considered in our work, as well as sumset sources. While the proofs are quite different, they both rely on bounds on the dimension of punctured Reed-Muller codes (equivalently the Hilbert function).

## 2 Preliminaries

All logarithms in this paper are base 2. By  $\mathbb{N}$  we denote the set of non-negative integers. For a positive integer  $n$ , by  $[n]$  we denote the set  $\{1, \dots, n\}$ . For a prime power  $q$ , denote by  $\mathbb{F}_q$  the finite field  $q$  elements.

For simplicity, throughout this paper, we refer to a polynomial as a degree- $d$  polynomial if its total degree is *at most*  $d$ . When  $q$  is a prime power, by  $\mathcal{P}_q(n, d)$  we denote the set of all degree- $d$  polynomials from  $\mathbb{F}[X_1, \dots, X_n]$  with individual degrees at most  $q - 1$ . Note that each element of  $\mathcal{P}_q(n, d)$  corresponds to a unique map  $\mathbb{F}_q^n \rightarrow \mathbb{F}_q$ .

Let  $r_1, \dots, r_n \geq 1$  be integers and  $F = \prod_{i=1}^n \{0, \dots, r_i - 1\}$ . For  $x \in F$  and  $i \in [n]$ ,  $x_i$  denotes the  $i$ th coordinate of  $x$ . For  $x \in F$ , we define its *generalized Hamming weight* as  $|x| := \sum_i x_i$ , where the summation is over the integers. For an integer  $d \geq 0$ , and a set  $T \subseteq F$ , we denote the set of its elements of generalized Hamming weight  $\leq d$  by

$$T_{\leq d} := \{x \in T : |x| \leq d\}.$$

For  $a, b \in F$ , we write  $a \leq_P b$  if  $a_i \leq b_i$  for all  $i \in [n]$ . We say a subset  $T \subseteq F$  is *down-closed* if for all  $a, b \in F$  such that  $a \leq_P b$ , if  $b$  is in  $T$ , then so is  $a$ . Similarly, we say a subset  $T \subseteq F$  is *up-closed* if for all  $a, b \in F$  such that  $a \leq_P b$ , if  $a$  is in  $T$ , then so is  $b$ .

The *lexicographic order*  $\prec$  on  $F$  is defined as follows. For distinct  $x, y \in F$ ,  $x$  precedes  $y$ , denoted  $x \prec y$ , in lexicographic order if  $x_i < y_i$ , where  $i$  is the smallest index such that  $x_i \neq y_i$ .

We will be studying the following quantity.

► **Definition 17.** For  $F = \prod_{i=1}^n \{0, \dots, r_i - 1\}$  and  $k \leq |F|$ , let

$$\mathcal{H}_F(d, k) := \min_T |T_{\leq d}|,$$

where the minimum is taken over all down-closed sets  $T \subseteq F$  with  $|T| = k$ . Moreover, denote  $\mathcal{H}_F(d, k)$  by  $\mathcal{H}_q^n(d, k)$  in the special case where  $r_1 = \dots = r_n = q$  for some  $q \geq 1$ .

## 2.1 Probability Distributions

We use lowercase letters such as  $x, y$  to denote vectors, uppercase bold letters such as  $\mathbf{X}, \mathbf{Y}$  to denote random variables, and  $\mathcal{X}, \mathcal{Y}$  to denote families of distributions. By  $\mathbf{U}_n$  we denote the uniform distribution over  $\{0, 1\}^n$ .

The statistical distance between two distributions  $\mathbf{A}$  and  $\mathbf{B}$  over a finite domain  $X$  is

$$\Delta(\mathbf{A}, \mathbf{B}) = \frac{1}{2} \left( \sum_{x \in X} |\Pr[x \in \mathbf{A}] - \Pr[x \in \mathbf{B}]| \right).$$

We say two distributions  $\mathbf{A}$  and  $\mathbf{B}$  are  $\varepsilon$ -close if  $\Delta(\mathbf{A}, \mathbf{B}) \leq \varepsilon$ . For a distribution  $\mathbf{X} \sim \{0, 1\}^n$ , the min-entropy of  $\mathbf{X}$  is

$$H_\infty(\mathbf{X}) = \min_{x \in \text{support}(\mathbf{X})} -\log(\Pr[\mathbf{X} = x]).$$

We will use following forms of Chernoff's and Hoeffding's bounds (see, e.g., [31, 23]).

► **Theorem 18** (Chernoff bound). Let  $X_1, \dots, X_n \in \{0, 1\}$  be independent random variables. Let  $X = \sum_{i=1}^n X_i$  and  $\mu = \mathbb{E}(X)$ . Then we have

$$\Pr[|X - \mu| \geq \delta\mu] \leq 2e^{-\mu\delta^2/3}$$

for all  $0 < \delta < 1$ .

► **Theorem 19** (Hoeffding's inequality). Let  $X_1, \dots, X_n \in [0, 1]$  be independent random variables,  $X = \sum_{i=1}^n X_i$  and  $\mu = \mathbb{E}[X]$ . Then,

$$\Pr[|X - \mu| \geq R] \leq 2e^{-\frac{2R^2}{n}}.$$

## 2.2 Randomness Sources, Dispersers, and Extractors

► **Definition 20** (Sources and Their Convex Combinations). *A distribution  $\mathbf{X} \sim \{0, 1\}^n$  is a source from a class  $\mathcal{C}$  of functions, if  $\mathbf{X} = f(\mathbf{U}_m)$  for some  $f : \{0, 1\}^m \rightarrow \{0, 1\}^n \in \mathcal{C}$ . A distribution  $\mathbf{Y}$  is a convex combination of sources  $\mathbf{X}_i$  if  $\mathbf{Y} = \sum_i p_i \mathbf{X}_i$  for some non-negative  $p_i$  satisfying  $\sum_i p_i = 1$ , i.e.,  $\mathbf{Y}$  samples from each  $\mathbf{X}_i$  with probability  $p_i$ .*

One of the most powerful classes of sources that we consider in this work is the class of circuits of polynomial size.

► **Definition 21** ( $\text{AC}[\oplus]$  circuits). *An  $\text{AC}[\oplus]$  circuit is an unbounded-depth Boolean circuit consisting of AND, OR, XOR, NOT gates of unbounded fan-in. The size of such a circuit is the number of non-input gates in it.*

We focus on the class of  $\text{AC}[\oplus]$  circuit as it generalizes circuit classes previously studied in this context: unbounded-depth circuits of bounded fan-in from  $\text{P/poly}$ , and bounded-depth circuits of unbounded fan-in from, say,  $\text{AC}^0$ . We remark that we define  $\text{AC}[\oplus]$  sources (see Definition 22) as sources where each output is computed by an  $\text{AC}[\oplus]$  circuit of polynomial size but with an arbitrary (possibly super-polynomial) number of inputs. This explains why in this context  $\text{P/poly}$  and  $\text{AC}^0$  circuits are incomparable, and why we work with  $\text{AC}[\oplus]$  circuits generalizing both of the aforementioned classes. In fact, our results hold even for a larger class of circuits where not only XOR but arbitrary constant-degree polynomials over  $\mathbb{F}_2$  can be computed at gates (see the discussion at the end of Section 6).

► **Definition 22** (Structured Sources). *Let  $n, d, m \in \mathbb{N}$ ,  $f : \{0, 1\}^m \rightarrow \{0, 1\}^n$ , and  $\mathbf{X}$  be a distribution over  $\{0, 1\}^n$  that is generated as  $f(\mathbf{U}_m)$ .*

- $\mathbf{X}$  is called a  $d$ -local source if every output bit of  $f$  depends only on at most  $d$  of its input bits.
- $\mathbf{X}$  is called a depth- $d$  decision forest source if every output bit of  $f$  is determined by a depth- $d$  decision tree of its input variables.
- $\mathbf{X}$  is called a degree- $d$  source if every output bit of  $f$  is a degree- $d$  polynomial over  $\mathbb{F}_2$ .
- $\mathbf{X}$  is called a size- $n^d$  circuit source if there is an  $\text{AC}[\oplus]$  circuit of size  $n^d$  that computes all output bits of  $f$ .

Note that every  $d$ -local source is a depth- $d$  decision forest source, and a degree- $d$  source. Also, every depth- $d$  decision forest source is a degree- $d$  source and a  $2^d$ -local source.

We will use the following bounds on the numbers of  $d$ -local sources and depth- $d$  decision forest sources.

► **Proposition 23.** *Let  $n, d \geq 1$ .*

- *The number of  $d$ -local sources over  $\{0, 1\}^n$  is bounded from above by  $2^{2^d n + 2dn \log n}$ .*
- *The number of depth- $d$  decision forest sources is bounded from above by  $2^{(d+\log n)2^{d+1}n}$ .*

For polynomial and circuit sources where the number of input bits cannot be bounded by a small function of  $n$  (unlike the sources considered in Proposition 23), we will need the following bounds on the number of such sources for a fixed number of input bits  $m$ .

► **Proposition 24.** *Let  $n, d, m \geq 1$ .*

- *The number of degree- $d$  polynomials  $f : \mathbb{F}_2^m \rightarrow \mathbb{F}_2^n$  is bounded from above by  $2^{n \binom{m}{\leq d}}$ .*
- *The number of  $\text{AC}[\oplus]$  circuits  $C : \{0, 1\}^m \rightarrow \{0, 1\}^n$  of size  $n^d$  is bounded from above by  $2^{4n^d(n^d+m)}$ .*

► **Definition 25** (Disperser). *A function  $\text{Disp} : \{0, 1\}^n \rightarrow \{0, 1\}$  is a disperser for a family  $\mathcal{X}$  of sources over  $\{0, 1\}^n$  with min-entropy  $k$ , if for every source  $\mathbf{X} \in \mathcal{X}$  with  $H_\infty(\mathbf{X}) \geq k$ , the support of  $\text{Disp}(\mathbf{X})$  is  $\{0, 1\}$ .*

► **Definition 26** (Extractor). *A function  $\text{Ext} : \{0, 1\}^n \rightarrow \{0, 1\}^m$  is an  $\varepsilon$ -extractor for a family  $\mathcal{X}$  of sources over  $\{0, 1\}^n$  with min-entropy  $k$ , if for every source  $\mathbf{X} \in \mathcal{X}$  with  $H_\infty(\mathbf{X}) \geq k$ ,  $\Delta(\text{Ext}(\mathbf{X}(U_t)), U_m) \leq \varepsilon$ .*

For clarity of presentation, in this paper when working with sources that are guaranteed to have entropy  $H_\infty(\mathbf{X}) \geq k$ , we will always assume that  $k$  is an integer.

### 2.3 Hilbert Functions and Standard Monomials

In this section, we recall some necessary definitions (see, e.g., [13]). Let  $\mathbb{F}$  be a field,  $X_1, \dots, X_n$  be indeterminates, and  $\mathbb{F}[X_1, \dots, X_n]$  be the polynomial ring in  $n$  indeterminates over  $\mathbb{F}$ . For a polynomial  $f \in \mathbb{F}[X_1, \dots, X_n]$  and  $S \subseteq \mathbb{F}^n$ , let  $f|_S \in \mathbb{F}^S$  be the restriction of  $f$  to  $S$ . For  $d \in \mathbb{N}$ , by  $\Gamma_S(d) \subseteq \mathbb{F}^S$  we denote the vector space spanned by  $f|_S$  for all degree- $d$  polynomials  $f$ :

$$\Gamma_S(d) := \{f|_S : f \in \mathbb{F}[X_1, \dots, X_n], \deg(f) \leq d\}.$$

► **Definition 27** (Hilbert function). *For a set  $S \subseteq \mathbb{F}^n$ , the (affine) Hilbert function of  $S$  over  $\mathbb{F}$ ,  $h_S(\cdot, \mathbb{F}) : \mathbb{N} \rightarrow \mathbb{N}$ , is defined as the dimension of  $\Gamma_S(d)$  over  $\mathbb{F}$ , i.e.,*

$$h_S(d, \mathbb{F}) := \dim_{\mathbb{F}}(\Gamma_S(d)).$$

► **Definition 28** (Monomial order). *Let  $\preceq$  be a total order on the monomials in a polynomial ring  $\mathbb{F}[X_1, \dots, X_n]$ . The order  $\preceq$  is called a monomial order if 1 is the minimal element of  $\preceq$ , and for all monomials  $m_1, m_2, m$  satisfying  $m_1 \preceq m_2$ , we have that  $m_1 m \preceq m_2 m$ . The order  $\preceq$  is degree-compatible if for all monomials  $m_1, m_2$  such that  $\deg(m_1) < \deg(m_2)$ , we have that  $m_1 \preceq m_2$ .*

Examples of degree-compatible monomial orders include the graded lexicographic and graded reverse lexicographic orders.

► **Definition 29** (Graded orders). *The graded lexicographic order  $\leq_{\text{grlex}}$  and the graded reverse lexicographic order  $\leq_{\text{grevlex}}$  are defined as follows. For a pair of monomials  $m_1 = X_1^{\alpha_1} \dots X_n^{\alpha_n}$  and  $m_2 = X_1^{\beta_1} \dots X_n^{\beta_n}$ , let  $\alpha = \sum_{i=1}^n \alpha_i$ ,  $\beta = \sum_{i=1}^n \beta_i$ , and  $\gamma = (\beta_1 - \alpha_1, \dots, \beta_n - \alpha_n)$ . We have that  $m_1 \leq_{\text{grlex}} m_2$  if and only if either  $\alpha < \beta$ , or  $\alpha = \beta$  and the leftmost non-zero entry of  $\gamma$  is positive. Similarly,  $m_1 \leq_{\text{grevlex}} m_2$  if and only if either  $\alpha < \beta$ , or  $\alpha = \beta$  and the rightmost non-zero entry of  $\gamma$  is negative.*

► **Definition 30** (Leading monomial). *For a nonzero polynomial  $f \in \mathbb{F}[X_1, \dots, X_n]$ , the leading monomial of  $f$  under a monomial order  $\preceq$  is the largest monomial of  $f$  under  $\preceq$ .*

Let  $R$  be a commutative ring (such as the polynomial ring  $\mathbb{F}[X_1, \dots, X_n]$ ). An ideal of  $R$  is a subset  $I$  of  $R$  such that for all  $a, b \in I$  and  $r \in R$ , we have that  $a + b \in I$  and  $ra \in I$ .

► **Definition 31** (Standard monomial). *Let  $I$  be an ideal of  $\mathbb{F}[X_1, \dots, X_n]$ , and  $\preceq$  be a monomial order. A standard monomial  $m$  of  $I$  is a monomial in  $X_1, \dots, X_n$  that is not the leading monomial of any nonzero polynomial in  $I$ .*

## 41:14 Hilbert Functions and Low-Degree Randomness Extractors

For an ideal  $I$  and  $d \in \mathbb{N}$ ,  $\text{SM}(I)$  denotes the set of all standard monomials of  $I$ , and  $\text{SM}_{\leq d}(I)$  denotes the set of all standard monomials of  $I$  of degree at most  $d$ :

$$\text{SM}_{\leq d}(I) = \{m \in \text{SM}(I) : \deg(m) \leq d\}.$$

For a set  $S \subseteq \mathbb{F}^n$ , by  $I(S)$  we denote the ideal of polynomials in  $\mathbb{F}[X_1, \dots, X_n]$  vanishing on  $S$ ,

$$I(S) = \{f \in \mathbb{F}[X_1, \dots, X_n] : f|_S = 0^S\}.$$

For an ideal  $I$  of  $\mathbb{F}[X_1, \dots, X_n]$ , define the set  $V(I) \subseteq \mathbb{F}^n$  by

$$V(I) = \{a \in \mathbb{F}^n : f(a) = 0 \text{ for all } f \in I\}.$$

By definition, for all  $f \in I$  and  $a \in V(I)$ , we have  $f(a) = 0$ . So  $I \subseteq I(V(I))$ .

Finally, for a set  $S \subseteq \mathbb{F}^n$ , define

$$\text{SM}(S) = \text{SM}(I(S)) \quad \text{and} \quad \text{SM}_{\leq d}(S) = \text{SM}_{\leq d}(I(S)).$$

We say that a set  $T$  of monomials is *down-closed* if for all monomials  $m$  and  $m'$  such that  $m \in T$  and  $m'$  divides  $m$ , it holds that  $m' \in T$ . It is easy to see that  $\text{SM}(S)$  is down-closed. Indeed, if  $m'$  was the leading monomial of a polynomial  $p \in I(S)$ , then  $m$  would be the leading monomial of the polynomial  $p \cdot (m/m') \in I(S)$ .

We will use the following facts about  $\text{SM}(S)$  and  $\text{SM}_{\leq d}(S)$ , which are proven, for example, in [37, Lemma 1] and [18, Corollary 2.1.21].

► **Lemma 32.** *Let  $S \subseteq \mathbb{F}^n$  be a finite set. Then*

(a) *for every monomial order  $\preceq$ ,*

$$|S| = |\text{SM}(S)|;$$

(b) *for every degree-compatible monomial order  $\preceq$  and every  $d \in \mathbb{N}$ ,*

$$h_S(d, \mathbb{F}) = |\text{SM}_{\leq d}(S)|.$$

### 3 Hilbert Functions of Sets in Finite Grids

Let  $\mathbb{F}$  be a field. We consider Hilbert functions of subsets of a finite grid  $A = \prod_{i=1}^n A_i$ , where each  $A_i$  is a finite subset of the field  $\mathbb{F}$ . The main result of this section is that the minimum value  $h_S(d, \mathbb{F})$  of a set  $S \subseteq A$  of size  $k$  equals the quantity  $\mathcal{H}_F(d, k)$  introduced in Definition 17, where  $F = \prod_{i=1}^n \{0, 1, \dots, |A_i| - 1\}$ .

Consider the following setting: Let  $r_1, \dots, r_n$  be integers such that  $1 \leq r_i \leq |\mathbb{F}|$  for  $i \in [n]$ . For each  $i \in [n]$ , let  $A_i$  be a subset of  $\mathbb{F}$  consisting of  $r_i$  distinct elements  $a_{i,1}, \dots, a_{i,r_i} \in \mathbb{F}$ . Let  $A$  be the Cartesian product  $\prod_{i=1}^n A_i$ . Let  $\mathcal{M}$  be the set of monomials dividing  $\prod_{i=1}^n X_i^{r_i-1}$ . Let  $\sigma_A$  be the bijection from  $\mathcal{M}$  to  $A$  defined by

$$\sigma_A : \prod_{i=1}^n X_i^{e_i} \mapsto (a_{1,e_1+1}, \dots, a_{n,e_n+1}). \quad (2)$$

Finally, fix a degree-compatible monomial order  $\preceq$ .

The next lemma states that every down-closed subset  $T \subseteq \mathcal{M}$  can be realized as the set of standard monomials of the set  $\sigma_A(T) \subseteq A$ .

► **Lemma 33.** *Let  $T$  be a down-closed subset of  $\mathcal{M}$ .*

*Then  $\text{SM}(\sigma_A(T)) = T$ .*

For space reasons, we defer the proofs of Lemma 33 and the consequent results to the full version [20].

► **Lemma 34.** *Let  $k, d \in \mathbb{N}$  such that  $k \leq |A|$ . Then*

$$\min_{S \subseteq A: |S|=k} h_S(d, \mathbb{F}) = \min_{\text{down-closed } T \subseteq \mathcal{M}: |T|=k} |\{m \in T : \deg(m) \leq d\}|.$$

Let  $F = \prod_{i=1}^n \{0, 1, \dots, r_i - 1\}$ . Let  $\phi : \mathcal{M} \rightarrow F$  be the bijection

$$\phi : \prod_{i=1}^n X_i^{e_i} \mapsto (e_1, \dots, e_n). \quad (3)$$

Lemma 34 can now be reformulated as follows.

► **Corollary 35.** *Let  $k, d \in \mathbb{N}$  such that  $k \leq |A|$ . Then*

$$\min_{S \subseteq A: |S|=k} h_S(d, \mathbb{F}) = \mathcal{H}_F(d, k). \quad (4)$$

For the special case of a finite field  $\mathbb{F} = \mathbb{F}_q$ ,  $r_1 = \dots = r_n = q$ , and  $A_1 = \dots = A_n = \mathbb{F}_q$ , we have  $A = \mathbb{F}_q^n$ , and the right-hand side of Equation (4) becomes  $\mathcal{H}_q^n(d, k)$  from Definition 17. This leads us to the following corollary.

► **Corollary 36.** *For every  $n, k, d \in \mathbb{N}$  where  $k \leq q^n$ , a prime power  $q$ , and every set  $S \subseteq \mathbb{F}_q^n$  of size  $|S| = k$ , we have that*

$$h_S(d, \mathbb{F}_q) \geq \mathcal{H}_q^n(d, k).$$

Finally, we state the following lemma, which will be used in Section 5. Its proof reuses ideas from the previous proofs in this section.

► **Lemma 37.** *Let  $n, d \in \mathbb{N}$ . Let  $\sigma_A : \mathcal{M} \rightarrow A$  and  $\phi : \mathcal{M} \rightarrow F$  be the bijections (2) and (3) respectively. Let  $S \subseteq A$  such that  $T := \sigma_A^{-1}(S) \subseteq \mathcal{M}$  is down-closed. Let  $T' = \phi(T) \subseteq F$ . Then  $h_S(d, \mathbb{F}) = T'_{\leq d}$ .*

## 4 Number of Points with Low Hamming Weight in Down-Closed Sets

In this section, we will find the exact values of all  $\mathcal{H}_q^n(d, k)$  which, by Corollary 36, will give us tight lower bounds on the Hilbert function of sets of size  $k$ .

For every  $n, k, q$  where  $k \leq q^n$ , we define  $M_q^n(k)$  as the set of the first  $k$  elements of  $\{0, \dots, q-1\}^n$  in lexicographic order.

The main result of this section is the following theorem.

► **Theorem 38.** *For every  $n, k, d, q \in \mathbb{N}$  where  $k \leq q^n$ ,*

$$\mathcal{H}_q^n(d, k) = |M_q^n(k)_{\leq d}|.$$

Combining Corollary 36 and Theorem 38, we obtain the following bounds on the Hilbert function.

## 41:16 Hilbert Functions and Low-Degree Randomness Extractors

► **Corollary 39.** For every prime power  $q$ , and  $n, k, d \in \mathbb{N}$  where  $k \leq q^n$ , we have

$$\min_{S \subseteq \mathbb{F}_q^n: |S|=k} h_S(d, \mathbb{F}_q) = |M_q^n(k)_{\leq d}|.$$

In particular, setting  $q = 2$ , for every  $n, k, d \in \mathbb{N}$  where  $k \leq 2^n$ , and every  $S \subseteq \mathbb{F}_2^n$  of size  $|S| = k$ ,

$$h_S(d, \mathbb{F}_2) \geq \binom{\lfloor \log(k) \rfloor}{\leq d}.$$

We will use the following notation: For  $t \in \{0, 1, \dots, n\}$ , define  $\mathcal{D}_q^n(t)$  to be the set of  $x \in \{0, \dots, q-1\}^n$  whose first  $n-t$  coordinates are zero.

Note that for every  $q, k$ , and  $n$ ,

$$\mathcal{D}_q^n(\lfloor \log_q k \rfloor) \subseteq M_q^n(k) \subseteq \mathcal{D}_q^n(\lceil \log_q k \rceil).$$

When  $n$  and  $q$  are clear from the context, we omit the superscript  $n$  and the subscript  $q$  from  $M_q^n(k)$ ,  $\mathcal{D}_q^n(t)$ , and  $\mathcal{H}_q^n(d, k)$ .

### 4.1 The Boolean Case, $q = 2$

For a set  $S \subseteq \{0, 1\}^n$ , let  $\min(S)$  and  $\max(S)$  be respectively the smallest and the largest strings in  $S$  in lexicographic order. We say a set  $S \subseteq \{0, 1\}^n$  is a *contiguous  $k$ -set* if  $|S| = k$  and  $S$  consists of all  $x$  such that  $\min(S) \preceq x \preceq \max(S)$ .

We first show that  $M(k)$  has the largest number of low Hamming weight strings among all contiguous  $k$ -sets.

► **Lemma 40.** Let  $n, k, d \in \mathbb{N}$  be integers such that  $k \leq 2^n$ . Let  $S^k \subseteq \{0, 1\}^n$  be a contiguous  $k$ -set. Then  $|M(k)_{\leq d}| \geq |S_{\leq d}^k|$ .

We now use Lemma 40 to prove that if a contiguous  $k$ -set  $S^k$  that does *not* contain any of the first  $k$  strings in lexicographic order, then the result of Lemma 40  $|S_{\leq d}^k| \leq |M(k)_{\leq d}|$  can be strengthened to  $|S_{\leq d}^k| \leq |M(k)_{\leq d-1}|$ .

► **Lemma 41.** Let  $n, k, d \in \mathbb{N}$  be integers such that  $k \leq 2^n$ . Let  $S^k \subseteq \{0, 1\}^n$  be a contiguous  $k$ -set. If  $S^k \cap M(k) = \emptyset$ , then  $|M(k)_{\leq d-1}| \geq |S_{\leq d}^k|$ .

We are finally ready to prove the Boolean case of Theorem 38.

**Proof of Theorem 38, the  $q = 2$  case.** Let  $S \subseteq \{0, 1\}^n$  be a down-closed set of size  $k$ . We prove this theorem by a simultaneous induction on  $k, d \geq 0$ .

For the base cases, we consider pairs  $(k, d)$  such that  $d = 0$  or  $k \leq 2^d$ . The case of  $d = 0$  is trivial. For the case where  $k \leq 2^d$ , a down-closed set  $S$  of size  $k$  cannot have strings of Hamming weight  $> d$ , thereby showing  $|S_{\leq d}| = k$ . Also, by construction,  $M(k)$  is a down-closed set of size  $k$ , implying  $\mathcal{H}(d, k) = |M(k)_{\leq d}| = k$  in this case.

Given  $d \geq 1$  and  $k > 2^d$ , assume that the theorem is true for all  $(k', d')$  such that either  $k' < k$ , or  $k' = k$  and  $d' < d$ . Suppose  $S$  is a down-closed set of size  $k$  and let  $m$  be the smallest integer such that  $S \subseteq \mathcal{D}(m)$ . Define

$$\begin{aligned} S^0 &:= \{x \in S : x_{n-m+1} = 0\}, \\ S^1 &:= \{x - e_{n-m+1} : x \in S \text{ and } x_{n-m+1} = 1\}. \end{aligned}$$

Since  $S$  is down-closed, we have  $S^1 \subseteq S^0$ . Moreover,

$$|S_{\leq d}| = |S_{\leq d}^0| + |S_{\leq d-1}^1|.$$

Applying the induction hypothesis for  $k' = |S^0| < k$  and  $d$ , we get  $|\mathsf{M}(|S^0|)_{\leq d}| \leq |S_{\leq d}^0|$ . Let  $T = \mathsf{M}(k) \setminus \mathsf{M}(|S^0|)$ . Since  $|S^1| \leq |S^0|$ , we have  $\mathsf{M}(|S^1|) \cap T = \emptyset$ , and we may apply Lemma 41 to get  $|T_{\leq d}| \leq |\mathsf{M}(|S^1|)_{\leq d-1}|$ . Now applying the induction hypothesis for  $k' = |S^1|$  and  $d' = d - 1$ , we get  $|\mathsf{M}(|S^1|)_{\leq d-1}| \leq |S_{\leq d-1}^1|$ . Combining these observations, we get

$$\begin{aligned} |\mathsf{M}(k)_{\leq d}| &= |\mathsf{M}(|S^0|)_{\leq d}| + |T_{\leq d}| \\ &\leq |S_{\leq d}^0| + |\mathsf{M}(|S^1|)_{\leq d-1}| \\ &\leq |S_{\leq d}^0| + |S_{\leq d-1}^1| \\ &= |S_{\leq d}|. \end{aligned}$$

This concludes the induction, and shows that for every  $k, d \geq 0$ , and down-closed set  $S$  of size  $k$ ,  $|\mathsf{M}(k)_{\leq d}| \leq |S_{\leq d}|$ .  $\blacktriangleleft$

## 4.2 The General Case of Finite Grids

We prove Theorem 38 in this subsection. In fact, we prove the theorem in a more general setting, described as follows.

Let  $F = \prod_{i=1}^n \{0, 1, \dots, r_i - 1\}$  where  $r_1 \leq r_2 \leq \dots \leq r_n$ . Let  $d \in \mathbb{N}$ . We introduce the following notations:

For  $S \subseteq F$ , define  $\nabla(S) := \{a \in F : b \leq_P a \text{ for some } b \in S\}$ , i.e.,  $\nabla(S)$  is the up-closure of  $S$ . For  $k \in \{0, \dots, |F|\}$ , denote by  $\mathsf{M}(k)$  the set of the smallest  $k$  elements of  $F$  in lexicographic order. And for  $r \in \{0, \dots, |F_{\leq d}|\}$ , denote by  $\mathsf{L}_{\leq d}(r)$  the set of the largest  $r$  elements of  $F_{\leq d}$  in lexicographic order.

The main result of this subsection is the following generalization of Theorem 38.

► **Theorem 42.** *For every  $k \in \mathbb{N}$  such that  $k \leq |F|$ ,*

$$\mathcal{H}_F(d, k) = |\mathsf{M}(k)_{\leq d}|.$$

We derive Theorem 42 from a combinatorial result of Beelen and Datta [5], which generalizes the earlier work of Wei [49] and Heijnen–Pellikaan [22, 21].

► **Theorem 43** ([5, Theorem 3.8]). *Let  $S \subseteq F_{\leq d}$  and  $r = |S|$ . Then  $|\nabla(\mathsf{L}_{\leq d}(r))| \leq |\nabla(S)|$ .<sup>1</sup>*

Define  $\Delta(S) := F \setminus \nabla(S)$  for  $S \subseteq F$ . The next lemma gives a characterization of  $\Delta(S)$ .

► **Lemma 44.** *Let  $T \subseteq F_{\leq d}$  be down-closed and  $S = F_{\leq d} \setminus T$ . Then  $\Delta(S)$  is the unique maximal set with respect to inclusion among all down-closed subsets  $U$  of  $F$  satisfying  $U_{\leq d} = T$ .*

► **Lemma 45.** *Let  $r \in \{0, \dots, |F_{\leq d}|\}$  and  $k = |\Delta(\mathsf{L}_{\leq d}(r))|$ . Then  $\Delta(\mathsf{L}_{\leq d}(r)) = \mathsf{M}(k)$ .*

<sup>1</sup> In [5],  $\mathsf{L}_{\leq d}(r)$  is denoted by  $M(r)$ , while we use  $\mathsf{M}(r)$  to denote the set of the smallest  $r$  elements of  $F$  in lexicographic order.

## 5 A Tight Bound on the Size of Degree- $d$ Closures of Sets

For  $n, d, \delta \in \mathbb{N}$ , denote by  $N(n, d, \delta)$  the number of monomials  $X_1^{e_1} \cdots X_n^{e_n}$  with  $e_1, \dots, e_n \leq \delta$  and  $e_1 + \cdots + e_n \leq d$ . For example,  $N(n, d, 1) = \binom{n}{\leq d}$  and  $N(n, d, \delta) = \binom{n+d}{d}$  for  $d \leq \delta$ .

► **Lemma 46.**  $h_{\mathbb{F}_q^n}(d, \mathbb{F}_q) = N(n, d, q-1)$ .

In particular, Theorem 5, which was proved by Nie and Wang [33], can be restated as

$$|\text{cl}_d(T)| \leq \frac{q^n}{h_{\mathbb{F}_q^n}(d, \mathbb{F}_q)} \cdot |T| = \frac{q^n}{N(n, d, q-1)} \cdot |T|. \quad (5)$$

We now give the following tight bound on the size of the degree- $d$  closure of a set  $T \subseteq \mathbb{F}_q^n$ , improving (5).

► **Theorem 47.** *Let  $n, d, m \in \mathbb{N}$ . Let  $T \subseteq \mathbb{F}_q^n$  be a set of size  $m$ . Then*

$$|\text{cl}_d(T)| \leq \max_{0 \leq k \leq q^n: |\mathbb{M}_q^n(k)_{\leq d}| \leq m} k = \begin{cases} \max_{0 \leq k \leq q^n: |\mathbb{M}_q^n(k)_{\leq d}| = m} k & \text{if } m \leq N(n, d, q-1), \\ q^n & \text{otherwise.} \end{cases} \quad (6)$$

The next theorem states that the bound in Theorem 47 is tight and explicitly constructs sets that meet this bound.

► **Theorem 48.** *Let  $\sigma_A : \mathcal{M} \rightarrow A$  and  $\phi : \mathcal{M} \rightarrow F$  be the bijections (2) and (3) respectively, where  $A = \mathbb{F}_q^n$ ,  $F = \{0, 1, \dots, q-1\}^n$ , and  $\mathcal{M} = \{\prod_{i=1}^n X_i^{e_i} : 0 \leq e_1, \dots, e_n \leq q-1\}$ . Let  $m$  be any integer such that  $0 \leq m \leq q^n$ . Choose the maximum  $k \leq q^n$  such that  $|\mathbb{M}_q^n(k)_{\leq d}| \leq m$ . Let  $T_0 = (\sigma_A \circ \phi^{-1})(\mathbb{M}_q^n(k)_{\leq d}) \subseteq A = \mathbb{F}_q^n$ . If  $|T_0| \geq m$ , let  $T = T_0$ . Otherwise, let  $T$  be an arbitrary set obtained by adding  $m - |T_0|$  elements from  $\mathbb{F}_q^n \setminus T_0$  to  $T_0$ . Then  $T$  is a set of size  $m$  that attains the equality in (6).*

## 6 Low-Degree Dispersers

In this section, we will show how to use Theorem 38 to conclude the existence of low-degree dispersers for various families of sources. In Section 6.1, we will use Corollary 39 to show that for every family of at most  $2^{O(k^d)}$  sources of min-entropy  $k$ , there exists a degree- $d$  disperser. In particular, this will imply dispersers for local sources and bounded-depth decision forest sources. In Section 6.2, we will extend this result to large families of sources, including polynomial and circuit sources.

### 6.1 Dispersers for Small Families of Sources

In Theorem 49, we use the bound of Corollary 39 on the values of Hilbert functions to bound the probability that a random polynomial takes a fixed value on an arbitrary subset of  $\mathbb{F}_2^n$ .

► **Theorem 49.** *Let  $n, d \geq 1$ ,  $S \subseteq \mathbb{F}_2^n$  be an arbitrary nonempty set, and  $f : S \rightarrow \mathbb{F}_2$  be a function. Then,*

$$\Pr_{p \in_u \mathcal{P}_2(n, d)} [p|_S \equiv f] \leq 2^{-h_S(d, \mathbb{F}_2)} \leq 2^{-\binom{\lceil \log_2 |S| \rceil}{d}}. \quad (7)$$

We will now use Theorem 49 to prove the existence of low-degree dispersers for every small family of sources.

► **Corollary 50.** *Let  $n, d, k \geq 1$ , and  $\mathcal{X}$  be a family of distributions of min-entropy  $\geq k$  over  $\{0, 1\}^n$ .*

*Then a uniformly random polynomial  $p \in \mathcal{P}_2(n, d)$  is a disperser for  $\mathcal{X}$  with probability at least*

$$1 - |\mathcal{X}| \cdot 2^{1 - \binom{k}{\leq d}}.$$

**Proof.** Let  $\mathbf{X}$  be a distribution from  $\mathcal{X}$ . Since  $H_\infty(\mathbf{X}) \geq k$ , we have that  $|\text{support}(\mathbf{X})| \geq 2^k$ . By Theorem 49,

$$\Pr_{p \in_u \mathcal{P}_2(n, d)} [p|_{\text{support}(\mathbf{X})} \text{ is constant}] \leq 2^{1 - \binom{k}{\leq d}}.$$

The corollary follows by applying the union bound over all  $|\mathcal{X}|$  sources in  $\mathcal{X}$ . ◀

We will demonstrate two immediate applications of Corollary 50 for the families of local and decision forests sources.

► **Corollary 51 (Low-degree dispersers for local sources).** *Let  $1 \leq \ell \leq d \leq n$  be integers. There exists  $p \in \mathcal{P}_2(n, d)$  that is a disperser*

- *for the family of  $\ell$ -local sources on  $\{0, 1\}^n$  with min-entropy  $k > d(2^\ell n + 2\ell n \log n)^{1/d}$ .*
- *for the family of depth- $\ell$  decision forest sources on  $\{0, 1\}^n$  with min-entropy  $k > d((\ell + \log n)2^{\ell+1}n)^{1/d}$ .*

The recent result of [1] uses further properties of local sources to prove the existence of low-degree dispersers for local sources with min-entropy  $k \geq c\ell^3 d \cdot (n \log n)^{1/d}$  for a constant  $c > 0$ . Noting that every depth- $\ell$  decision forest source is also a  $(2^\ell - 1)$ -local source, the disperser of [1] for local sources implies a result similar to the above.

## 6.2 Dispersers for Polynomial and Circuit Sources

In this section, we will extend the results of the previous section to prove the existence of low-degree dispersers for powerful families of sources including polynomial-size circuits and low-degree polynomial sources. Unlike the previous examples such as local sources, the sources considered here may non-trivially depend on an arbitrary number of inputs. For example, even a degree-1 (i.e. affine) source defined by an affine map  $f : \mathbb{F}_2^m \rightarrow \mathbb{F}_2^n$  can depend on an arbitrary number  $m \gg n$  of input bits. We get around this by restricting the map  $f : \{0, 1\}^m \rightarrow \{0, 1\}^n$  defining the source to a low-dimensional affine subspace. Specifically, we will use the input-reduction procedure from [9], where it was used to prove that random (not necessarily bounded degree) maps extract from low-degree sources.

► **Lemma 52 ([9, Lemma 4.5]).** *Let  $m, n, k \in \mathbb{N}$ ,  $k > 1$ , and  $f : \mathbb{F}_2^m \rightarrow \mathbb{F}_2^n$  be a function. If  $H_\infty(f(\mathbf{U}_m)) \geq k$ , then there exists an affine map  $L : \mathbb{F}_2^{11k} \rightarrow \mathbb{F}_2^m$  such that*

$$H_\infty(f(L(\mathbf{U}_{11k}))) \geq k - 1.$$

Equipped with Lemma 52, we are ready to construct dispersers for low-degree sources.

► **Theorem 53 (Low-degree disperser for lower-degree polynomial sources).** *Let  $1 \leq \ell < d \leq n$  be integers. There exists  $p \in \mathcal{P}_2(n, d)$  that is a disperser for the family of degree- $\ell$  sources on  $\{0, 1\}^n$  with min-entropy  $k \geq (12^\ell \cdot d^d \cdot n)^{\frac{1}{d-\ell}} + 1$ .*

*In particular, for every  $\ell \in \mathbb{N}$ , there is a degree- $(\ell + 2)$  disperser for degree- $\ell$  sources on  $\{0, 1\}^n$  with min-entropy  $\Omega(\sqrt{n})$ .*

► **Theorem 54** (Low-degree disperser for circuit sources). *Let  $\ell \geq 1$  and  $n \geq d \geq 2\ell + 2$  be integers. There exists  $p \in \mathcal{P}_2(n, d)$  that is a disperser for the family of  $n^\ell$ -size circuit sources on  $\{0, 1\}^n$  with min-entropy  $k \geq (30^2 \cdot d^\ell \cdot n^{2\ell})^{\frac{1}{d-2}} + 1$ .*

Theorems 53 and 54 construct low-degree dispersers for sources generated by constant-degree polynomials and polynomial-size  $\text{AC}[\oplus]$  circuits. These two classes of sources are incomparable. Indeed,  $\text{AC}[\oplus]$  computes  $\text{AND}(x_1, \dots, x_m)$  which is not a constant-degree polynomial, while constant-degree polynomials compute polynomials in  $m$  inputs which do not admit circuits of size polynomial in  $n$ . We remark that the techniques of Theorems 53 and 54 can be used to conclude the same result for a class of sources that generalizes both  $\text{AC}[\oplus]$  and constant-degree polynomials. This is the class of polynomial-size circuits which extends  $\text{AC}[\oplus]$  with gates computing arbitrary polynomials in  $m$  inputs of a fixed constant degree. For ease of exposition, we present only the results for more natural sources in Theorems 53 and 54.

## 7 Random Low-Degree Polynomials Extract from Fixed Sources

In this section, we use our bounds on the values of Hilbert functions to prove the existence of a low-degree extractor for a fixed high min-entropy source. Specifically, in Theorem 57 we show that for every source  $\mathbf{X}$  of high min-entropy, a random low-degree polynomial  $p$  has bias  $\leq \varepsilon$ , i.e.,  $\Pr_{x \in_u X}[f(x) = 1] \in 1/2 \pm \varepsilon$  with high probability. One special case of interest is the case of  $k$ -flat sources  $\mathbf{X}$  which are uniform distributions over sets of size  $2^k$ . In Section 8, we will use Theorem 57 to prove the existence of low-degree extractors for various expressive families of sources.

We start this section by using our bounds on the degree- $d$  closure of sets in order to lower-bound the probability that a random somewhat large subset  $T$  of a set  $S$  has “full Hilbert dimension”, i.e.,  $h_T(d, \mathbb{F}_2) = |T|$ . We then use this to prove Lemma 56 which states that for a large enough set  $S \subseteq \{0, 1\}^n$ , a random subset  $T \subseteq S$  of full Hilbert dimension will contain each element  $x \in S$  with almost the same probability. Finally, we present a proof of Theorem 57 which crucially relies on Lemma 56.

▷ **Claim 55.** Let  $1 \leq d \leq n$ ,  $d \leq \ell$ , and  $S \subseteq \{0, 1\}^n$ . Let  $T$  be a uniformly random subset of  $S$  of size  $\binom{\ell}{\leq d}$ . Then

$$\Pr_T \left[ h_T(d, \mathbb{F}_2) = |T| = \binom{\ell}{\leq d} \right] \geq 1 - \binom{\ell}{\leq d} \cdot 2^\ell / |S|.$$

► **Lemma 56.** Let  $1 \leq d \leq n$ ,  $d \leq \ell$ , and  $S \subseteq \{0, 1\}^n$ . Let  $T$  be a uniformly random subset of  $S$  of size  $\binom{\ell}{\leq d}$ . Then for every  $x \in S$ ,

$$(1 - \delta) \cdot \frac{\binom{\ell}{\leq d}}{|S|} \leq \Pr_T [x \in T \mid h_T(d, \mathbb{F}_2) = |T|] \leq \frac{1}{(1 - \delta)} \cdot \frac{\binom{\ell}{\leq d}}{|S|},$$

where  $\delta = \binom{\ell}{\leq d} \cdot 2^\ell / |S|$ .

Equipped with Lemma 56, we are ready to present the proof of Theorem 57.

► **Theorem 57.** Let  $n, d, k \geq 1$ , and  $\varepsilon > 0$  be a real. Then for every distribution  $\mathbf{X}$  over  $\{0, 1\}^n$  with  $H_\infty(\mathbf{X}) \geq k$ , a uniformly random degree- $d$  polynomial  $f$  is an  $\varepsilon$ -extractor for  $\mathbf{X}$ ,

$$\Pr_{x \sim \mathbf{X}} [f(x) = 1] = \frac{1}{2} \pm \varepsilon$$

with probability at least  $1 - e^{3n - \varepsilon^2 \binom{\ell}{\leq d} / (Cn^2)}$  where  $\ell = k/2 - \log(32n/\varepsilon)$  and  $C = 7 \cdot (32)^2$ .

## 8 Low-Degree Extractors

In this section, we extend the results of Section 6 to the setting of extractors. We start with the extractors version of Corollary 50 in Theorem 58, where we show that low-degree polynomials extract from small families of sources. Then, in Theorem 60, we use Theorem 58 to prove the existence of low-degree extractors for a number of families of sources. Finally, in Section 8.1, we prove the existence of low-degree extractors with multi-bit outputs.

► **Theorem 58.** *Let  $\mathcal{X}$  be a family of distributions of min-entropy  $k \geq 5 \log n$  over  $\{0, 1\}^n$  for large enough  $n$ . Let  $\mathcal{Y}$  be a family of distributions each of which is  $\varepsilon'$ -close to a convex combination of distributions from  $\mathcal{X}$ . Then for every  $d \geq 6$ , a uniformly random polynomial  $p \in \mathcal{P}_2(n, d)$  is an  $\varepsilon$ -extractor for  $\mathcal{Y}$  with probability at least*

$$1 - |\mathcal{X}| \cdot e^{3n - 30k^{d/2}/n^2}$$

for  $\varepsilon = (2d/k^{1/4})^d + \varepsilon'$ .

We will use the following input-reduction result from [9].

► **Theorem 59** ([9, Theorem 4.1]). *Let  $m, n, k \in \mathbb{N}$ ,  $k > 1$ , and  $f: \mathbb{F}_2^m \rightarrow \mathbb{F}_2^n$  be a function. If  $H_\infty(f(\mathbf{U}_m)) \geq k$ , then there exist affine maps  $L_1, \dots, L_t: \mathbb{F}_2^{11k} \rightarrow \mathbb{F}_2^m$  such that the distribution  $f(\mathbf{U}_m)$  is  $2^{-k}$ -close to a convex combination of distributions  $f(L_i(\mathbf{U}_{11k}))$ . Moreover, for each  $i \in [t]$ ,*

$$H_\infty(f(L_i(\mathbf{U}_{11k}))) \geq k - 1.$$

We are now ready to prove that low-degree polynomials extract from many sources of interest.

► **Theorem 60.** *For all  $\ell, d \geq 1$ , and all large enough  $n$ , there exists  $p \in \mathcal{P}_2(n, d)$  that is an  $\varepsilon$ -extractor for the following families of sources over  $\{0, 1\}^n$  of min-entropy  $k \geq 5 \log n$  for  $\varepsilon = 2(2d/k^{1/4})^d$ .*

- $\ell$ -local sources for  $k \geq (2^\ell n^3 \log n)^{2/d}$ .
- depth- $\ell$  decision forest sources for  $k \geq (2^\ell n^3 (\log n + \ell))^{2/d}$ .
- degree- $\ell$  sources for  $k \geq (3^\ell n)^{\frac{6}{d-2\ell}}$ .
- $n^\ell$ -size circuit sources for  $k \geq 3n^{\frac{4(\ell+1)}{d-4}}$ .

### 8.1 Extractors Outputting Multiple Bits

In Theorem 61, we show how to extend our single-bit extractors for small families of sources to the multi-bit setting, which combined with input-reduction lemma, will extend all our single-bit extractors from Theorem 60 to  $O(k)$ -bit extractors.

► **Theorem 61.** *Let  $\mathcal{X}$  be a family of distributions of min-entropy  $k \geq 5 \log n$  over  $\{0, 1\}^n$  for large enough  $n$ . Let  $\mathcal{Y}$  be a family of distributions each of which is  $\varepsilon'$ -close to a convex combination of distributions from  $\mathcal{X}$ . Then for every  $d \geq 6$  and  $t < k$ , let  $p_1, \dots, p_t \in \mathcal{P}_2(n, d)$  be independent and uniformly random polynomials. Then  $p = (p_1, \dots, p_t)$  is a  $t\varepsilon$ -extractor for  $\mathcal{Y}$  with probability at least*

$$1 - |\mathcal{X}| \cdot e^{3n+t+1-30(k-2t)^{d/2}/n^2}$$

for  $\varepsilon = (2d/k^{1/4})^d + \varepsilon'$ , assuming  $\varepsilon \leq 1/4$ .

## Abstract

We study the *Matrix Multiplication Verification Problem* (MMV) where the goal is, given three  $n \times n$  matrices  $A$ ,  $B$ , and  $C$  as input, to decide whether  $AB = C$ . A classic randomized algorithm by Freivalds (MFCS, 1979) solves MMV in  $\tilde{O}(n^2)$  time, and a longstanding challenge is to (partially) derandomize it while still running in faster than matrix multiplication time (i.e., in  $o(n^\omega)$  time).

To that end, we give two algorithms for MMV in the case where  $AB - C$  is *sparse*. Specifically, when  $AB - C$  has at most  $O(n^\delta)$  non-zero entries for a constant  $0 \leq \delta < 2$ , we give (1) a deterministic  $O(n^{\omega-\varepsilon})$ -time algorithm for constant  $\varepsilon = \varepsilon(\delta) > 0$ , and (2) a randomized  $\tilde{O}(n^2)$ -time algorithm using  $\delta/2 \cdot \log_2 n + O(1)$  random bits. The former algorithm is faster than the deterministic algorithm of Künnemann (ESA, 2018) when  $\delta \geq 1.056$ , and the latter algorithm uses fewer random bits than the algorithm of Kimbrel and Sinha (IPL, 1993), which runs in the same time and uses  $\log_2 n + O(1)$  random bits (in turn fewer than Freivalds’s algorithm).

Our algorithms are simple and use techniques from coding theory. Let  $H$  be a parity-check matrix of a Maximum Distance Separable (MDS) code, and let  $G = (I \mid G')$  be a generator matrix of a (possibly different) MDS code in systematic form. Our deterministic algorithm uses fast rectangular matrix multiplication to check whether  $HAB = HC$  and  $H(AB)^T = H(C^T)$ , and our randomized algorithm samples a uniformly random row  $\mathbf{g}'$  from  $G'$  and checks whether  $\mathbf{g}'AB = \mathbf{g}'C$  and  $\mathbf{g}'(AB)^T = \mathbf{g}'C^T$ .

We additionally study the *complexity* of MMV. We first show that all algorithms in a natural class of deterministic linear algebraic algorithms for MMV (including ours) require  $\Omega(n^\omega)$  time. We also show a barrier to proving a super-quadratic running time lower bound for matrix multiplication (and hence MMV) under the Strong Exponential Time Hypothesis (SETH). Finally, we study relationships between natural variants and special cases of MMV (with respect to deterministic  $\tilde{O}(n^2)$ -time reductions).

## 1 Introduction

The goal of the *Matrix Multiplication Problem* (MM) is to compute the product  $AB$  of two  $n \times n$  matrices  $A$  and  $B$  given as input. Matrix multiplication has many practical and theoretical applications, and because of this has been studied by an extensive line of work. The primary goal of this work has been to determine the running time  $O(n^\omega)$  of the fastest algorithms for MM, which is captured by the matrix multiplication exponent  $\omega$ .<sup>1</sup> The best upper bounds on  $\omega$  and related quantities continue to improve [23, 3, 11, 22, 25], and [25] recently showed the current best known bound of  $\omega \leq 2.371552$ . The dream of this line of work is to show that  $\omega = 2$ , and this in fact holds under certain plausible combinatorial and group-theoretic conjectures (see [10, Conjecture 4.7 and Conjecture 3.4]). Nevertheless, showing that  $\omega = 2$  seems very challenging for the time being.

In this work, we consider a variant of matrix multiplication where the goal is to *verify* that the product of two matrices is equal to a third matrix. Specifically, we study the *Matrix Multiplication Verification Problem* (MMV) where, given three  $n \times n$  matrices  $A$ ,  $B$ , and  $C$  as input, the goal is to decide whether  $AB = C$ . MMV is clearly no harder than matrix multiplication – it can be solved in  $O(n^\omega)$  time by computing the product  $AB$  and then comparing the product entry-wise against  $C$  – but it is natural to ask whether it is possible to do better. In what became classic work, Freivalds [12] answered this question in the affirmative and gave a simple, randomized algorithm that solves MMV in  $\tilde{O}(n^2)$  time. This  $\tilde{O}(n^2)$  running time bound is essentially the best possible, and so, unlike matrix multiplication, the complexity of MMV is relatively well understood.

However, it is in turn natural to ask whether it is possible to *derandomize* Freivalds’s algorithm partially or completely. More specifically, it is natural to ask whether it is possible to give a *deterministic* algorithm for MMV running in  $\tilde{O}(n^2)$  time or at least  $O(n^{\omega-\varepsilon})$  time for constant  $\varepsilon > 0$ .<sup>2</sup> Or, if it is not possible to give a deterministic algorithm for MMV with these running times, it is natural to ask whether it is possible to use fewer random bits than Freivalds’s algorithm, which uses  $n$  random bits. Trying to answer these questions has become a key goal for derandomization efforts, and has received substantial study [4, 19, 20, 21].

<sup>1</sup> Formally,  $\omega$  is defined as the infimum over  $\omega'$  such that the product of two  $n \times n$  matrices can be computed in  $O(n^{\omega'})$  time. So, MM algorithms are actually only guaranteed to run in  $O(n^{\omega+\varepsilon})$  time for any constant  $\varepsilon > 0$ .

<sup>2</sup> We use the notation  $\tilde{O}(f(n))$  to mean  $f(n) \cdot \text{poly}(\log f(n))$ . Freivalds’s algorithm uses  $O(n^2)$  arithmetic operations, each of which takes  $\text{poly}(\log n)$  time when working over integer matrices with entries bounded in magnitude by  $\text{poly}(n)$ ; we assume this setting in the introduction.

Of course, it is only possible for such a  $O(n^{\omega-\varepsilon})$ -time algorithm to exist if  $\omega > 2$ . We assume that this is the case throughout the introduction.

■ **Table 1** Algorithms for MMV on matrices  $A, B, C \in \mathbb{Z}^{n \times n}$  with entries of magnitude at most  $\text{poly}(n)$  and such that  $AB - C$  has at most  $n^\delta$  non-zero entries for  $0 \leq \delta \leq 2$ . Our new algorithms are shown in bold. We list asymptotic running times, with  $\text{poly}(\log n)$  factors suppressed for readability, and the number of random bits used to achieve success probability  $1/2$ . (Each of the three listed randomized algorithms has one-sided error, so this probability is meaningful.) Here  $\omega(\cdot, \cdot, \cdot)$  is the rectangular matrix multiplication exponent,  $\omega = \omega(1, 1, 1)$  is the (square) matrix multiplication exponent, and  $\varepsilon > 0$  is an arbitrarily small positive constant.

## 1.1 Our Results

Our main results are two new algorithms for the Matrix Multiplication Verification Problem in the *sparse* regime, i.e., in the case where  $AB - C$  is promised to have few non-zero entries (if any). See Table 1 for a summary of our algorithms and how they compare to other known algorithms for MMV. Additionally, we give a barrier for giving a fast algorithm for MMV using a broad class of linear algebraic techniques, a barrier to showing hardness of MMV, and reductions between variants of MMV.

### 1.1.1 Algorithms

Besides being inherently interesting, MMV in the sparse regime is the natural decision version of the well-studied *Output-Sensitive Matrix Multiplication Problem* (OSMM). It is also motivated by the following scenario. Suppose that Alice wants to compute the product  $AB$  of two large matrices  $A$  and  $B$ , but has restricted computational resources. So, she sends  $A$  and  $B$  to Bob, who has more extensive computational resources. Bob computes the product  $AB$ , and sends the result back to Alice over a noisy channel (without error-correction, which increases the size of the message), from which Alice receives a matrix  $C$ . Alice knows that either  $C = AB$  as desired, or that  $C$  is corrupted but (with high probability) only differs from  $AB$  in a few entries. She wants to check which is the case efficiently.

We define  $\|\mathbf{v}\|_0$  (respectively,  $\|M\|_0$ ) to be the number of non-zero entries in (i.e., Hamming weight of) a vector  $\mathbf{v}$  (respectively, matrix  $M$ ). We call a vector  $\mathbf{v}$  (respectively, matrix  $M$ ) *t-sparse* if  $\|\mathbf{v}\|_0 \leq t$  (respectively, if  $\|M\|_0 \leq t$ ).

Our first algorithm (given in Figure 2) is deterministic, and uses fast rectangular matrix multiplication. For  $\alpha, \beta, \gamma \in [0, 1]$ , let the rectangular matrix multiplication exponent  $\omega(\alpha, \beta, \gamma)$  be the infimum over values  $\omega' > 0$  such that the product of a  $n^\alpha \times n^\beta$  matrix and a  $n^\beta \times n^\gamma$  matrix can be computed using  $O(n^{\omega'})$  arithmetic operations. Note that  $\omega = \omega(1, 1, 1)$  is the standard (square) matrix multiplication exponent.

■ **Figure 1** Running times of deterministic algorithms for MMV when  $AB - C$  is  $O(n^\delta)$ -sparse for  $1 \leq \delta \leq 2$ . Our algorithm from Theorem 1 is faster than the best known algorithms for matrix multiplication [25] and faster than Künnemann’s algorithm [21] for all  $1.056 \leq \delta < 2$ . The plotted blue points corresponding to the running time of the algorithm in Theorem 1 are derived from the bounds on  $\omega(1, 1, \delta/2)$  in [25, Table 1]. The line segments connecting them are justified by the fact that  $\omega(1, 1, \cdot)$  is a convex function.

- (1) Let  $k := \lceil \sqrt{t} \rceil$ .
- (2) Compute an arbitrary prime  $p$  that satisfies  $n \leq p \leq 2n$ .
- (3) Compute a (parity check) matrix  $H \in \mathbb{F}_p^{k \times n}$  of a code with distance at least  $k + 1$ .
- (4) Output YES if  $H(AB - C) = 0$  and  $H(AB - C)^T = 0$  (where arithmetic is performed over  $\mathbb{Z}$ ), and output NO otherwise.

■ **Figure 2** Deterministic Algorithm for MMV corresponding to Theorem 1.

► **Theorem 1** (Fast deterministic MMV for sparse matrices, informal). *Let  $A, B, C \in \mathbb{Z}^{n \times n}$  be matrices satisfying  $\max_{i,j} \{|A_{i,j}|, |B_{i,j}|, |C_{i,j}|\} \leq n^c$  for some constant  $c > 0$  and satisfying  $\|AB - C\|_0 \leq n^\delta$  for  $0 \leq \delta \leq 2$ . Then for any constant  $\varepsilon > 0$ , there is a deterministic algorithm for MMV on input  $A, B, C$  that runs in  $O(n^{\omega(1,1,\delta/2)+\varepsilon})$  time.*

We note that  $\omega(1, 1, \beta) < \omega$  for all  $\beta < 1$  (assuming  $\omega > 2$ );<sup>3</sup> and so our algorithm is faster than matrix multiplication when  $AB - C$  is promised to be  $O(n^\delta)$ -sparse for constant  $\delta < 2$ . Furthermore, it is faster than Künnemann’s algorithm [21], which is also for MMV in the regime where  $AB - C$  is sparse, when  $\omega(1, 1, \delta/2) < 1 + \delta$ . The equation  $\omega(1, 1, \delta/2) = 1 + \delta$  whose unique solution corresponds to the crossover point at which our algorithm becomes faster than Künnemann’s turns out to be relevant in other contexts too [27], and [23, 25] both provide bounds on its solution. Specifically, [25] shows that the solution  $\delta$  to this equation satisfies  $\delta \leq 1.056$ , and so our algorithm in Theorem 1 is (strictly) faster than any previously known deterministic algorithm for MMV when  $1.056 \leq \delta < 2$ .

<sup>3</sup> See [7, Theorem 2.3]

- (1) Let  $k := \lceil \sqrt{t}/\varepsilon \rceil$ .
- (2) Compute an arbitrary prime  $p$  satisfying  $k + n \leq p < 2(k + n)$ .
- (3) Compute a  $\lceil \sqrt{t} \rceil$ -regular matrix  $S = (\mathbf{s}_1, \dots, \mathbf{s}_k) \in \mathbb{F}_p^{n \times k}$ .
- (4) Sample a uniformly random column index  $i \sim \{1, \dots, k\}$ .
- (5) Output YES if  $AB\mathbf{s}_i = C\mathbf{s}_i$  and  $(AB)^T \mathbf{s}_i = C^T \mathbf{s}_i$  (where arithmetic is performed over  $\mathbb{Z}$ ), and output NO otherwise.

■ **Figure 3** Randomized Algorithm for MMV corresponding to Theorem 2.

Additional bounds on  $\omega(1, \delta/2, 1) = \omega(1, 1, \delta/2)$  – and hence the running time of the algorithm in Theorem 1 – appear in [25, Table 1]. For example, that table shows that  $\omega(1, 1, 0.55) < 2.067$  and  $\omega(1, 1, 0.95) < 2.333$  (which correspond to  $\delta = 1.1$  and  $\delta = 1.9$ , respectively). We also note that our algorithm runs in essentially optimal  $\tilde{O}(n^2)$  time when  $\delta \leq 0.642 \leq 2\omega^\perp$ , where  $\omega^\perp := \sup\{\omega' > 0 : \omega(1, 1, \omega') = 2\} \geq 0.321$  is the dual matrix multiplication exponent [25], but that Künnemann’s algorithm [21] runs in  $\tilde{O}(n^2)$  time for any  $\delta \leq 1$ .

Our second algorithm runs in  $\tilde{O}(n^2)$  time, but is randomized (see Figure 3). It uses few bits of randomness when  $AB - C$  is sparse.

► **Theorem 2** (Fast randomized MMV for sparse matrices, informal). *Let  $c > 0$  be a constant, let  $A, B, C \in \mathbb{Z}^{n \times n}$  be matrices satisfying  $\max_{i,j} \{|A_{i,j}|, |B_{i,j}|, |C_{i,j}|\} \leq n^c$  and satisfying  $\|AB - C\|_0 \leq n^\delta$  for  $0 \leq \delta \leq 2$ , and let  $\varepsilon = \varepsilon(n) \geq 1/n$ . Then there is a randomized algorithm for MMV on input  $A, B, C$  that runs in  $\tilde{O}(n^2)$  time, succeeds with probability  $1 - \varepsilon$ , and uses at most  $\lceil \delta/2 \cdot \log_2(n) + \log_2(1/\varepsilon) \rceil$  bits of randomness.*

Theorem 2 improves on the number of random bits used by the algorithm of Kimbrel and Sinha [19] when  $\delta < 2$  (which uses  $\log_2(n) + \log_2(1/\varepsilon) + O(1)$  random bits regardless of the sparsity of  $AB - C$ ), and matches the number of random bits used by their algorithm when  $\delta = 2$ . The algorithms both run in  $\tilde{O}(n^2)$  time. In fact, one may think of the algorithm summarized in Theorem 2 as a natural extension of the algorithm in [19] to handle the sparse case more efficiently, although it requires additional techniques to implement. (Our algorithm requires matrices with a stronger pseudorandomness property than theirs; see the “algorithmic techniques” section below.)

We note that Theorem 2 only improves on known algorithms when  $1 < \delta < 2$ , and only by a factor of  $\delta/2$ . Indeed, as mentioned above, when  $\delta \leq 1$  Künnemann’s algorithm [21] solves MMV *deterministically* in  $\tilde{O}(n^2)$  time, and when  $\delta = 2$  our algorithm matches the number of random bits used by Kimbrel and Sinha’s algorithm. Although seemingly modest, this constant-factor improvement is not surprising: any super-constant improvement on the number of bits used by [19] (i.e., an MMV algorithm using  $o(\log n)$  random bits) could be turned into a deterministic algorithm for MMV with only a sub-polynomial (i.e.,  $n^{o(1)}$ ) multiplicative increase in running time.

### 1.1.1.1 Algorithmic techniques

Here we briefly summarize the techniques that we use for the MMV algorithms corresponding to Theorems 1 and 2. We start by remarking that Theorems 1 and 2 hold not just for matrices over  $\mathbb{Z}$  with entries of polynomial magnitude, but also for matrices over all finite

fields  $\mathbb{F}_q$  with  $q \leq \text{poly}(n)$ .<sup>4</sup> In fact, our algorithms work “natively” in the finite field setting – i.e., on  $n \times n$  matrices  $A, B, C$  over finite fields  $\mathbb{F}_q$  – which is directly amenable to using techniques from coding theory. We assume this setting in the description below. Furthermore, there is a linear-time, sparsity-preserving reduction from MMV to the special case of MMV where  $C$  is fixed as  $C = 0$  and the goal is to decide whether  $AB = 0$  for input matrices  $A, B$  (see [21, Proposition 3.1]). We will also generally assume this setting in the introduction.

For both algorithms, we will use the observation that if  $AB - C$  is non-zero and  $t$ -sparse then at least one row or column of  $AB - C$  must be non-zero and  $k$ -sparse for  $k := \lfloor \sqrt{t} \rfloor$ . A similar observation appears in [26].

Our first, deterministic algorithm (Theorem 1) uses a matrix  $H$  over  $\mathbb{F}_q$  such that any  $k$  columns of  $H$  are linearly independent. Equivalently, we require a matrix  $H \in \mathbb{F}_q^{m \times n}$  such that for all non-zero vectors  $\mathbf{x} \in \mathbb{F}_q^n$  with  $\|\mathbf{x}\|_0 \leq k$  (corresponding to a sparse, non-zero column or row of  $AB$ ),  $H\mathbf{x} \neq \mathbf{0}$ . This is exactly the property guaranteed by the parity-check matrix  $H$  of an error correcting code  $\mathcal{C} \subseteq \mathbb{F}_q^n$  with minimum distance  $d > k$ . Moreover, if a code  $\mathcal{C}$  with minimum distance  $d = k + 1$  is a so-called Maximum Distance Separable (MDS) code, then it has a  $k \times n$  parity-check matrix  $H$ . MDS codes with useful parameters exist and have efficiently constructible parity-check matrices. In particular, (generalized) Reed-Solomon codes are MDS codes, and exist when  $k \leq n \leq q$  (see, e.g., [14]). Their parity-check matrices  $H$  are Vandermonde matrices, which are constructible in  $kn \cdot \text{poly}(\log q) \leq n^2 \cdot \text{poly}(\log q)$  time.

Our algorithm then uses fast rectangular matrix multiplication to compute  $HAB = (HA)B$  and  $H(AB)^T = (HB^T)A^T$  using roughly  $n^{\omega(1,1,\delta/2)}$  arithmetic operations, where  $0 \leq \delta \leq 2$  is such that  $t \leq n^\delta$ . If  $AB = 0$ , then  $HAB = H(AB)^T = 0$ . On the other hand, if  $AB \neq 0$  then  $AB$  is  $t$ -sparse and therefore has a  $k$ -sparse row or column. So, at least one of the expressions  $HAB$  and  $H(AB)^T$  is non-zero.

Our second, randomized algorithm (Theorem 2) uses a matrix  $S \in \mathbb{F}_q^{m \times n}$  with the property that all of its  $k \times k$  submatrices are non-singular. Matrices  $S$  with this property are called  $k$ -regular, and matrices  $S$  all of whose square submatrices (of any size) are non-singular are called *super regular*.<sup>5</sup> We note that  $k$ -regularity is stronger than the property we require for  $H$  in the first algorithm. In particular, if a matrix  $S \in \mathbb{F}_q^{m \times n}$  is  $k$ -regular and  $0 < \|\mathbf{x}\|_0 \leq k$ , then  $\|S\mathbf{x}\|_0 \geq m - k + 1$ . I.e.,  $S$  being  $k$ -regular implies not only that  $S\mathbf{x}$  is non-zero, but that  $S\mathbf{x}$  has relatively high Hamming weight for such  $\mathbf{x}$ . This property is useful because it implies that  $\Pr[\langle \mathbf{s}, \mathbf{x} \rangle \neq 0] \geq (m - k + 1)/m$ , where  $\mathbf{s}$  is a random row of  $S$ . Indeed, this observation leads to our second algorithm: we sample a random row  $\mathbf{s}$  from a  $k$ -regular matrix  $S \in \mathbb{F}_q^{m \times n}$  and check whether  $\mathbf{s}AB = \mathbf{0}$  and  $\mathbf{s}(AB)^T = \mathbf{0}$ . Setting, e.g.,  $m = 2k$ , we get that this algorithm succeeds with probability at least  $(2k - k + 1)/(2k) > 1/2$ .

It remains to construct (rows of)  $k$ -regular matrices  $S$  efficiently. Although a priori it is not even obvious that  $k$ -regular matrices exist for arbitrary  $k$ , in fact *super regular* matrices exist and are efficiently constructible. Specifically, we use a family of super regular (and hence  $k$ -regular) matrices called *Cauchy matrices*; the entries of such a matrix  $S$  are defined as  $S_{i,j} = 1/(x_i - y_j)$ , where  $x_1, \dots, x_m, y_1, \dots, y_n$  are distinct elements of  $\mathbb{F}_q$ . In fact, as follows from their definition, given a (random) index  $1 \leq i \leq m$ , it is even possible to construct the  $i$ th row of a Cauchy matrix  $S$  efficiently without computing the rest of the matrix, as needed.

<sup>4</sup> The algorithms also work over larger finite fields, but with slower running times due to the increased bit complexity of performing arithmetic operations over those fields.

<sup>5</sup> For formal definitions see [7, Section 2.4]

Finally, we remark that there is a deep connection between MDS codes and super regular matrices (and between generalized Reed-Solomon codes, Vandermonde matrices, and Cauchy matrices). Specifically, if  $G = (I \mid S)$  is the generator matrix of an MDS code in systematic form, then  $S$  is a super regular matrix [24]. Moreover, if such a matrix  $G$  is the generator matrix of a generalized Reed-Solomon code, then  $S$  is a Cauchy matrix [24].

### 1.1.2 Barriers

The dream for the line of work described in this paper is to give a deterministic,  $\tilde{O}(n^2)$ -time algorithm for MMV on arbitrary matrices. However, achieving this goal has proven to be very difficult despite a substantial amount of work towards it. So, it is natural to ask whether perhaps no such algorithm exists, i.e., whether MMV is in some sense *hard*. We first show a result in this direction, and then show a barrier result to showing SETH hardness of MMV (and even MM).<sup>6</sup>

#### 1.1.2.1 Linear algebraic algorithms barrier

We first prove that a natural class of deterministic linear algebraic algorithms for MMV based on multiplying smaller matrices – including the algorithm in Theorem 1 – cannot run in less than  $n^\omega$  time when using a matrix multiplication subroutine running in worst-case rectangular matrix multiplication time and when performing all multiplications independently. Specifically, the  $\Omega(n^\omega)$  lower bound holds if for all  $\alpha, \beta \geq 0$ , the subroutine requires  $\Omega(n^{\omega(1,1,\alpha)})$  to compute the product of an  $n \times n^\alpha$  matrix and an  $n \times n$ , and  $\Omega(n^{\omega(1,1,\beta)})$  time to compute the product of an  $n \times n$  matrix and an  $n \times n^\beta$  matrix.

The idea is that natural algorithms for verifying that  $AB = C$  for  $n \times n$  matrices  $A, B, C$  including ours amount to performing  $k$  “zero tests.” More specifically, the  $i$ th such test checks that  $L_i(AB - C)R_i = 0$  for some fixed  $n^{\alpha_i} \times n$  matrix  $L_i$  and  $n \times n^{\beta_i}$  matrix  $R_i$ , where  $\alpha_i, \beta_i \in [0, 1]$ . We observe that the conditions  $L_i(AB - C)R_i = 0$  for  $i = 1, \dots, k$  together correspond to a homogeneous system of  $\sum_{i=1}^k n^{\alpha_i + \beta_i}$  linear equations in the  $n^2$  variables corresponding to the entries of  $X = AB - C$  for  $1 \leq i, j \leq n$ . So, for this system to have  $X_{i,j} = 0$  for  $1 \leq i, j \leq n$  as its unique solution, it must be the case that  $\sum_{i=1}^k n^{\alpha_i + \beta_i} \geq n^2$ , which we show implies that  $\sum_{i=1}^k n^{\omega(1,1,\min(\alpha_i,\beta_i))} \geq \sum_{i=1}^k n^{\omega(\alpha_i,1,\beta_i)} \geq n^\omega$ . Therefore, an algorithm that independently computes each product  $L_i A B R_i$  in time  $\Omega(n^{\omega(1,1,\min(\alpha_i,\beta_i))})$  uses  $\Omega(n^\omega)$ .<sup>7</sup>

#### 1.1.2.2 A barrier to SETH-hardness of MM

While under certain reasonable conjectures, the matrix multiplication exponent  $\omega = 2$  (see [10, Conjecture 4.7 and Conjecture 3.4]), the best provable upper bound we have is  $\omega < 2.371552$  by [25]. Nevertheless, given the apparent difficulty of showing  $\omega \approx 2$ , it is natural to ask whether MM is in fact *hard*. To that end, we study showing its hardness under the *Strong Exponential Time Hypothesis* (SETH). However, rather than showing SETH-hardness of MM, we show a *barrier* to proving  $n^\gamma$ -hardness of MM for constant  $\gamma > 2$  under SETH. (Because MMV is trivially reducible to MM, our hardness barrier result also applies to MMV.)

<sup>6</sup> More properly, our first result is a barrier to giving a fast algorithm for MMV, and our second result is a barrier to showing hardness of MMV (i.e., it “gives a barrier to giving a barrier” for a fast MMV algorithm).

<sup>7</sup> For a more detailed exposition of this barrier see [7, Section 3.3]

We informally define several concepts used in the statement of our result. SETH says that for large constant  $k$ ,  $k$ -SAT instances on  $n$  variables take nearly  $2^n$  time to solve, and the *Nondeterministic Strong Exponential Time Hypothesis* (NSETH) says that certifying that such  $k$ -SAT formulas are *not* satisfiable takes nearly  $2^n$  time even for nondeterministic algorithms. We call a matrix *rigid* if the Hamming distance between it and all low-rank matrices is high (the Hamming distance and rank are quantified by two parameters). Rigid matrices have many connections to complexity theory and other areas, and a key goal is to find explicit, deterministic constructions of such matrices.

Intuitively, NSETH rules out showing hardness of problems with non-trivial co-nondeterministic algorithms under SETH. Somewhat more precisely, assuming NSETH, problems contained in  $\text{coTIME}[f(n)]$  (but perhaps only known to be in  $\text{TIME}[g(n)]$  for  $g(n) = \omega(f(n))$ ), cannot be shown to be  $\Omega(f(n)^{1+\varepsilon})$ -hard under SETH.<sup>8</sup> Künnemann [21] noted that, because Freivald’s algorithm shows that MMV is in  $\text{coTIME}[n^2 \cdot \text{poly}(\log n)]$ , NSETH rules out showing  $\Omega(n^\gamma)$  hardness of MMV under SETH for constant  $\gamma > 2$ .

In this work, we extend this observation and give a barrier not only to showing SETH-hardness of MMV but to showing hardness of MM. We demonstrate that, if there exists a constant  $\gamma > 2$  and a reduction from  $k$ -SAT to MM such that a  $O(n^{\gamma-\varepsilon})$ -time algorithm for MM for any constant  $\varepsilon > 0$  breaks SETH, then either (1) the *Nondeterministic Strong Exponential Time Hypothesis* (NSETH) is false, or (2) a new non-randomized algorithm for computing (arbitrarily large) rigid matrices exists. We also note that, by known results, falsifying NSETH implies a new circuit lower bound as a consequence. In short, our barrier result says that showing  $n^\gamma$ -hardness of MM under SETH for  $\gamma > 2$  would lead to major progress on important questions in complexity theory.<sup>9</sup>

A key idea that we use for proving our result is that it is possible to compute the product of two *non-rigid* matrices efficiently using a *nondeterministic* algorithm. This follows from two facts. First, by definition, a non-rigid matrix is the sum of a low-rank matrix  $L$  and a sparse matrix  $S$ , and using nondeterminism it is possible to guess  $L$  and  $S$  efficiently. Second, it is possible to compute the product of two sparse matrices or a low-rank matrix and another matrix efficiently. (In fact, we also use nondeterminism to guess a *rank factorization* of  $L$ , and this factorization is what allows for fast multiplication by  $L$ .)

Very roughly, we prove the barrier result as follows. We first suppose that there is a reduction from  $k$ -SAT to (potentially multiple instances of) matrix multiplication. In particular, such a reduction outputs several pairs of matrices to be multiplied. We then analyze three cases:

1. If the matrices output by this reduction always have small dimension (as a function of  $n$ ), then we can compute the product of each pair quickly using standard matrix multiplication algorithms (even using naïve, cubic-time matrix multiplication). This leads to a fast, deterministic algorithm for  $k$ -SAT, which refutes SETH (and hence NSETH).
2. If the matrices output by this reduction are always *not* rigid, then we can compute the product of each pair quickly using the nondeterministic algorithm sketched above. This leads to a fast, nondeterministic algorithm for showing that  $k$ -SAT formulas are not satisfiable, which refutes NSETH.
3. Finally, if neither of the above cases holds, then the reduction must sometimes output rigid matrices with large dimension as a function of  $n$ . So, we obtain an algorithm for generating arbitrarily large rigid matrices using an NP oracle: iterate through all  $k$ -SAT

<sup>8</sup> We refer the reader to see [7, Definition 2.22] for a formal definition of SETH-hardness.

<sup>9</sup> See see [7, Section 4] for a more detailed exposition.

formulas  $\varphi$  with at most a given number of variables, apply the reduction from  $k$ -SAT to MM to each formula, and then use the NP oracle to check whether each large matrix output by the reduction is rigid.

We remark that although NSETH is a strong and not necessarily widely believed conjecture, [18, 9] showed that refuting it (as in Item 2 above) would nevertheless imply an interesting new circuit lower bound. Specifically, they showed that if NSETH is false, then the complexity class  $E^{NP}$  requires series-parallel circuits of size  $\omega(n)$ .

Additionally, we remark that despite how slow the “iterate through all sufficiently large  $k$ -SAT formulas and apply the  $k$ -SAT-to-MM reduction to each one” algorithm described in Item 3 seems, it would still substantially improve on state-of-the-art non-randomized algorithms for generating rigid matrices. This is also true despite the fact that the algorithm uses an NP oracle.<sup>10</sup>

### 1.1.3 Reductions

Again, motivated by the apparent challenge of fully derandomizing Freivalds’s algorithm, we study relationships between variants of MMV with the goal of understanding what makes the problem hard to solve deterministically in  $\tilde{O}(n^2)$  time but easy to solve in  $\tilde{O}(n^2)$  time using randomness (in contrast to MM). More specifically, we study which variants are potentially easier than MMV (i.e., reducible to MMV, but not obviously solvable deterministically in  $\tilde{O}(n^2)$  time using known techniques), equivalent to MMV, and potentially harder than MMV (i.e., variants to which MMV is reducible, but which are not obviously as hard as MM). We study these questions by looking at deterministic  $\tilde{O}(n^2)$ -time reductions between variants. See Figure 4 for a summary of our results.

First, we show that two apparently special cases of MMV are in fact equivalent to MMV. These special cases are: (1) the *Inverse Verification Problem*, where the goal is to verify that  $B = A^{-1}$  for input matrices  $A$  and  $B$  (equivalently, the special case of MMV where  $C = I_n$ ), and (2) the *Symmetric MMV Problem*, where the input matrices  $A$  and  $B$  (but not necessarily  $C$ ) are symmetric.<sup>11</sup> These reductions are relatively simple, and complement the (also simple) reduction of [21], who showed that the All Zeroes Problem (i.e., the special case of MMV where  $C = 0$ ) is MMV-complete.

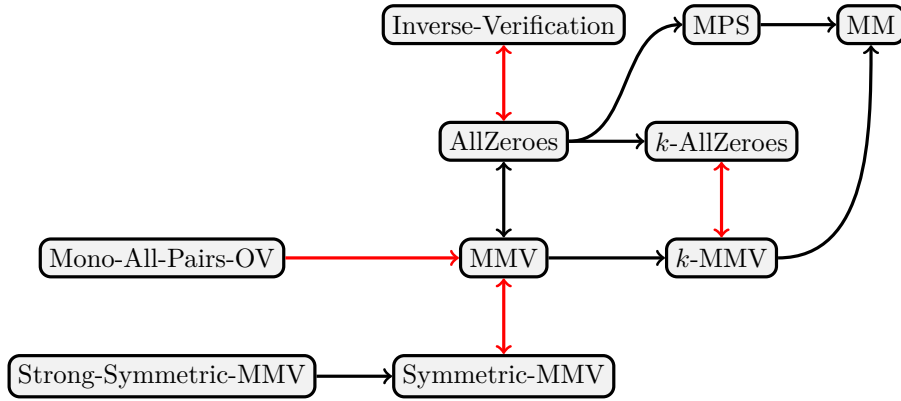

Second, we identify two problems that are  $\tilde{O}(n^2)$ -time reducible to MMV, but are not clearly solvable in  $\tilde{O}(n^2)$  time or equivalent to MMV. These problems are: (1) the *Strong Symmetric MMV Problem*, where all three of the input matrices  $A$ ,  $B$ , and  $C$  are symmetric, and (2) the Monochromatic All Pairs Orthogonal Vectors Problem, where the goal is, given vectors  $\mathbf{a}_1, \dots, \mathbf{a}_n$  to decide whether  $\langle \mathbf{a}_i, \mathbf{a}_j \rangle = 0$  for all  $i \neq j$ .

Third, we identify two problems for which there are  $\tilde{O}(n^2)$ -time reductions from MMV and that are  $\tilde{O}(n^2)$ -time reducible to MM. These “MMV/MM-intermediate problems” are: (1) the Matrix Product Sparsity Problem (MPS), in which the goal is, given matrices  $A$  and  $B$  and  $r \geq 0$  as input, to decide whether  $\|AB\|_0 \leq r$ , and (2) the  $k$ -MMV problem, in which given matrices  $A_1, \dots, A_k, C$  as input, the goal is to decide whether  $\prod_{i=1}^k A_i = C$ . We note that MPS is equivalent to the counting version of the Orthogonal Vectors Problem ( $\#OV$ ).<sup>12</sup> We additionally show that  $k$ -MMV is equivalent to the  $k$ -All Zeroes problem,

<sup>10</sup> See [7, Section 4] for a more thorough discussion.

<sup>11</sup> See [7, Section 5] for the complete reductions

<sup>12</sup> Indeed, Monochromatic All Pairs Orthogonal Vectors is no harder than MMV (and not obviously equivalent), Bichromatic All Pairs Orthogonal Vectors is equivalent to the All Zeroes Problem and is

■ **Figure 4** A diagram of reductions among MMV and related problems on  $n \times n$  matrices. Arrows represent deterministic  $O(n^2)$ -time reductions (and double-headed arrows denote equivalences under such reductions). Red arrows indicate new (non-trivial) reductions.

i.e.,  $k$ -MMV where  $C$  is fixed to be 0. See Figure 4 for a summary of these variants and reductions between them. For a full presentation of definitions and reductions we refer the reader to [7, Section 5].

## 1.2 Related Work

We next discuss other algorithms for MMV and related problems on  $n \times n$  integer matrices  $A$ ,  $B$ , and  $C$ . We summarize these algorithms, as well as ours, in Table 1. We start by noting that it suffices to consider the special case of MMV where  $C = 0$  (i.e., where the goal is to decide whether  $AB = 0$ ), which is called the All Zeroes Problem. Indeed, a result from [21] shows that there is a simple  $O(n^2)$ -time reduction from MMV on  $n \times n$  matrices  $A, B, C$  to the All Zeroes problem on  $2n \times 2n$  matrices  $A', B'$  with the property that  $\|AB - C\|_0 = \|A'B'\|_0$ . So, for this section we consider the All Zeroes Problem without loss of generality.

Perhaps the most closely related works to ours are [17, 1], which use fast rectangular matrix multiplication for the *Output-Sensitive Matrix Multiplication Problem* (OSMM). In  $t$ -OSMM, the goal is, given matrices  $A, B$  as input, to compute the product  $AB$  when it is promised to be  $t$ -sparse. There is a trivial reduction from MMV when the output is promised to be  $t$ -sparse to  $t$ -OSMM – compute  $AB$  and check whether it is equal to 0. Indeed, OSMM is essentially the search version of sparse MMV. In particular, [17] use techniques from compressive sensing to solve OSMM. However, it is not clear that the measurement matrix  $M$  in [17] can be constructed deterministically in  $\tilde{O}(n^2)$  time, and so the algorithm in [17] is a non-uniform algorithm as described. There are other candidate measurement matrices with deterministic constructions that may work for a similar purpose [16], but the exact tradeoffs do not seem to have been analyzed and it is not clear that it is possible to get a (uniform) algorithm with the same parameters. Additionally, [17] only handles the case when all columns or rows of  $AB$  are promised to have a given sparsity, rather than the case where there is a “global bound” of  $t$  on the sparsity of the matrix product itself.

---

therefore equivalent to MMV, and MPS/#OV is at least as hard as MMV. In the fine-grained complexity setting OV variants are usually considered with  $n$  vectors in dimension  $d = \text{poly}(\log n)$ ; here we are considering the regime where  $d = n$ .

The main algorithm in [1] for OSMM (summarized in [1, Theorem 1.4]) runs in randomized time  $O(n^{1.3459\delta})$  when both the input matrices  $A, B$  and their product  $AB$  are  $n^\delta$ -sparse.<sup>13</sup> For the special case when all entries in  $A, B$  are non-negative [1] give a deterministic algorithm with the same running time as their randomized algorithm. We note that [1] was written independently and concurrently with this work.

Besides simply using matrix multiplication, perhaps the most natural idea for an algorithm for the All Zeros problem is to compute a random entry  $(AB)_{i,j}$  of  $AB$  and check whether it is non-zero. If  $\|AB\|_0 \geq n^\delta$ , then sampling, say,  $10n^{2-\delta}$  random entries of  $AB$  independently will find a non-zero entry with good constant probability. Because computing each such entry amounts to computing an inner product, and sampling indices  $i, j \sim \{1, \dots, n\}$  takes roughly  $2 \log_2 n$  random bits, this algorithm overall takes  $\tilde{O}(n^{3-\delta})$  time and  $O(n^{2-\delta} \log n)$  random bits. So, this algorithm is relatively efficient and succeeds with good probability in the case when  $AB$  is dense, but even then requires a relatively large number of random bits. We also note the somewhat odd fact that this algorithm is most efficient when  $AB$  is dense, whereas our algorithms are most efficient when  $AB$  is sparse.

Freivalds’s algorithm [12] works by sampling a uniformly random vector  $\mathbf{x} \sim \{0, 1\}^n$ , and outputting “YES” if  $AB\mathbf{x} = \mathbf{0}$  and “NO” otherwise. If  $AB = \mathbf{0}$ , then this algorithm is always correct, and if  $AB \neq \mathbf{0}$  then it fails with probability at most  $1/2$ .<sup>14</sup> In particular, Freivalds’s algorithm has one-sided error with no false negatives (i.e., it is a **coRP** algorithm).

A key idea for subsequent algorithms was to reduce MMV to a question about polynomials. The main idea is the following. Define  $\mathbf{x} := (1, x, x^2, \dots, x^{n-1})^T$ , where  $x$  is an indeterminate, and define  $p_i(x) := (AB\mathbf{x})_i = \sum_{j=1}^n (AB)_{i,j} \cdot x^{j-1}$ . Note that  $AB = \mathbf{0}$  if and only if the polynomials  $p_i(x)$  are identically zero (as formal polynomials) for all  $i \in \{1, \dots, n\}$ . Furthermore, if the  $i$ th row of  $AB$  is non-zero then  $p_i(x)$  is a non-zero polynomial of degree at most  $n - 1$ , and therefore has at most  $n - 1$  distinct complex (and hence integral) roots. So, for such  $p_i(x)$  and a non-empty set  $S \subset \mathbb{Z}$ ,  $\Pr_{\alpha \sim S}[p(\alpha) = 0] \leq (n - 1)/|S|$ , which is less than  $1/2$  when  $|S| \geq 2n$ . This observation leads to the following algorithm for MMV, which forms the basis for Kimbrel and Sinha’s algorithm [19]. Sample  $\alpha \sim \{1, \dots, 2n\}$ , and output “YES” if and only if  $AB\boldsymbol{\alpha} = \mathbf{0}$  for  $\boldsymbol{\alpha} := (1, \alpha, \alpha^2, \dots, \alpha^{n-1})^T$ . Using associativity, it is possible to compute this product as  $A(B\boldsymbol{\alpha})$  using  $O(n^2)$  arithmetic operations.

However, there is an issue with this algorithm: it requires computing powers of  $\alpha$  up to  $\alpha^{n-1}$ . These powers require  $\Omega(n)$  bits to represent for any integer  $\alpha \geq 2$ , and so performing arithmetic operations with them takes  $\Omega(n)$  time. To solve this, Kimbrel and Sinha instead consider the “test vector”  $\boldsymbol{\alpha}$  modulo an (arbitrary) prime  $2n \leq q \leq 4n$ , which they can find deterministically in  $O(n^2)$  time. They show that their algorithm is still correct with good probability (over the choice of  $\alpha$ ) with this modification.

Korec and Wiedermann [20] showed how to *deterministically* find a good  $\alpha$  for the above test – that is, a value  $\alpha$  such that  $p_i(\alpha) \neq 0$  if  $p_i$  is not identically zero – using *Cauchy’s bound*, which gives an upper bound on the magnitude of the largest root of a polynomial as a function of the polynomial’s coefficients. Namely, they just choose  $\alpha$  larger than Cauchy’s bound. (They note that the maximum magnitude of an entry in  $AB$  – and hence of a coefficient in

<sup>13</sup>A more general version of this theorem, which gives an algorithm whose running time depends both on the sparsity of the input matrices  $A, B$  and of their product  $AB$ , appears as [1, Theorem 1.7].

<sup>14</sup>To see this, note that in the latter case some row  $\mathbf{s}^T$  of  $AB$  must be non-zero, and let  $j^*$  be the index of the last non-zero entry in  $\mathbf{s}$ . Then for uniformly random  $\mathbf{x} \sim \{0, 1\}^n$ ,  $\Pr[AB\mathbf{x} = \mathbf{0}] \leq \Pr[(\mathbf{s}, \mathbf{x}) = 0] = \Pr[s_{j^*}x_{j^*} = -\sum_{k=1}^{j^*-1} s_k x_k] \leq 1/2$ . Moreover, this holds for matrices  $A, B$  over any ring  $R$ , and so Freivalds’s algorithm works for MMV over any ring  $R$ .

any of the polynomials  $p_i(x)$  – is at most  $n\mu^2$ , where  $\mu$  is the maximum magnitude of an entry in  $A$  or  $B$ .) Their algorithm uses only  $O(n^2)$  arithmetic operations, but again requires computing powers of  $\alpha$  up to  $\alpha^{n-1}$ , and therefore the algorithm has bit complexity  $\Omega(n^3)$ .

Additionally, we mention the work of Künnemann [21], which works for MMV over finite fields  $\mathbb{F}_q$  with  $q > n^2$  (he reduces MMV over the integers to MMV over such fields). His algorithm works by considering the bivariate polynomial  $f(x, y) = f_{A,B}(x, y) := \mathbf{x}^T A B \mathbf{y}$  for  $\mathbf{x} = (1, x, x^2, \dots, x^{n-1})$ ,  $\mathbf{y} = (1, y, y^2, \dots, y^{n-1})$ , where  $x$  and  $y$  are indeterminates, and the corresponding univariate polynomial  $g(x) = g_{A,B}(x) := f(x, x^n)$ . The coefficient of  $x^{(i-1)+(j-1)n}$  in  $g(x)$  (and of  $x^{i-1}y^{j-1}$  in  $f(x, y)$ ) is equal to  $(AB)_{i,j}$ , and so to decide whether  $AB = 0$  it suffices to decide whether  $g(x)$  (or  $f(x, y)$ ) is identically zero as a formal polynomial.<sup>15</sup> He shows that to do this it in turn suffices to decide whether  $g(\alpha^i) = 0$  for all  $i \in \{0, \dots, t-1\}$ , where  $\alpha \in \mathbb{F}_q$  is an element of order at least  $n^2$  and  $t = n^\delta$  is an upper bound on the sparsity of  $AB$ . Indeed, he notes that the system of equations  $g(1) = \dots = g(\alpha^{t-1}) = 0$  is a Vandermonde system of homogeneous linear equations in the at most  $t$  non-zero entries  $(AB)_{i,j}$  in  $AB$ , and so its only solution is the solution  $(AB)_{i,j} = 0$  for all  $1 \leq i, j \leq n$  (i.e., it must be the case that  $AB = 0$ ). To evaluate  $g$  on the  $t$  values  $1, \alpha, \dots, \alpha^{t-1}$  quickly, he uses a known result about fast multipoint polynomial evaluation.

We also note that MMV and its variants have also been studied from angles other than derandomization of Freivalds’s algorithm. Notably, [8] gave a  $O(n^{5/3})$ -time *quantum* algorithm for MMV, [15] studied the *Boolean* Matrix Multiplication Verification problem, and [13, 26] study the problem of *correcting* matrix products. I.e., they study the problem of *computing*  $AB$  given matrices  $A$ ,  $B$ , and  $C$  where  $\|AB - C\|_0$  is guaranteed to be small, which Künnemann showed is equivalent to OSMM.

Finally, we remark that other recent works including [9, 5, 2, 6] have also studied “barriers to SETH hardness”.

### 1.3 Open Questions

Of course, the main question that we leave open is whether Freivalds’s algorithm can be fully derandomized, i.e., whether there is a deterministic  $\tilde{O}(n^2)$ -time algorithm for MMV on  $n \times n$  matrices over finite fields  $\mathbb{F}_q$  with  $q \leq \text{poly}(n)$  and integer matrices with entries  $[-n^c, n^c]$  for constant  $c > 0$ . Additionally, it would be interesting to extend our results for MMV in the sparse regime to Output Sensitive Matrix Multiplication. The coding-theoretic techniques that we use seem amenable to this.

## Abstract

---

Interactive coding allows two parties to conduct a distributed computation despite noise corrupting a certain fraction of their communication. Dani et al. (Inf. and Comp., 2018) suggested a novel setting in which the amount of noise is unbounded and can significantly exceed the length of the (noise-free) computation. While no solution is possible in the worst case, under the restriction of *oblivious* noise, Dani et al. designed a coding scheme that succeeds with a polynomially small failure probability.

We revisit the question of conducting computations under this harsh type of noise and devise a computationally-efficient coding scheme that guarantees the success of the computation, except with an *exponentially* small probability. This higher degree of correctness matches the case of coding schemes with a bounded fraction of noise.

Our simulation of an  $N$ -bit noise-free computation in the presence of  $T$  corruptions, communicates an optimal number of  $O(N + T)$  bits and succeeds with probability  $1 - 2^{-\Omega(N)}$ . We design this coding scheme by introducing an intermediary noise model, where an oblivious adversary can choose the locations of corruptions in a worst-case manner, but the effect of each corruption is random: the noise either flips the transmission with some probability or otherwise erases it. This randomized abstraction turns out to be instrumental in achieving an optimal coding scheme.

## 1 Introduction

In many distributed systems nowadays, communication channels suffer various types of noise and interference that may corrupt information exchanged between devices. *Interactive coding*, initiated by the seminal work of Schulman [25, 26] (see also [12]), allows two or more devices to correctly complete their computation despite channel noise, by adding only a moderate amount of redundancy to the computation. The capability of an interactive coding scheme usually depends on the specific type of noise it is designed to withstand. For instance, when

the noise can flip bits, interactive coding schemes withstand up to a fraction of  $1/6$  of flipped bits [8, 20] (a fraction of  $1/4$  can be withstood over channels with larger alphabets [5]); when the noise erases bits (i.e., replaces a bit with a special erasure mark  $\perp$ ), then a fraction of  $1/2$  of bit erasures can be withstood [11, 20], which also applies for larger alphabets [8]. When messages can be inserted and deleted, the maximal corruption rate is again  $1/4$ , see [4, 27].

In a recent work, Dani, Hayes, Movahedi, Saia, and Young [7] suggested a different and interesting model for interactive coding in which the amount of noise is *unbounded*. That is, the number  $T$  of corruptions that affects a given execution, can be arbitrary. Note that this number  $T$  is unknown to the coding scheme; this is in contrast to the standard model of interactive coding, where a limit on the fraction of corrupted transmissions is known by all devices. The scheme in [7] correctly computes any two-party computation that takes  $N$  rounds without noise, by communicating  $N + O(T + \sqrt{N(T+1)\log T})$  bits and succeeds with probability  $1 - O(1/N \log N)$ .

In a nutshell, the idea of the scheme in [7] is as follows. Every message sent between the parties contains the round number it corresponds to and a signature. A device checks that the signature is valid before processing a received message. If the signature does not check out, the device ignores that communication. The coding scheme tracks the progress of both parties via the added information of the round number, so that corrupted messages are re-transmitted until they arrive correctly at the other side.

One significant drawback of the above approach, is that the noise might corrupt a message along with its signature so that the receiver believes that the signature is correct. This occurs with exponentially small probability in the length of the signature, which leads to the polynomially-small failure probability of the scheme. In other words, the scheme in [7] assumes that the noise *never creates a valid signature* and settles with a failure probability of magnitude  $1/N \log N$ .

In this work we aim to achieve an interactive coding scheme that can withstand an unbounded amount of noise, yet, with failure probability exponentially small in  $N$ , similar to most previous work on interactive coding (e.g., [26, 18, 2, 19]). This effectively means that the coding scheme must cope with corrupted messages being processed by some device. That is, the coding scheme must be resilient to the event, that occurs with polynomially small probability in  $N$ , where both the message and the signature are corrupted in a matching way.

Our main result is a coding scheme that is resilient to an arbitrary and a priori unknown number  $T$  of bit flips, with exponentially small failure probability.

► **Theorem 1.1 (Main).** *Given any two-party binary interactive protocol  $\pi$  of length  $N$ , there exists an efficient randomized protocol  $\Pi$  of length  $O(N + T)$  that simulates  $\pi$  with probability  $1 - 2^{-\Omega(N)}$  over a binary channel in the presence of an arbitrary and a priori unknown number  $T$  of corruptions. The noise is assumed to be independent of the parties' randomness.*

We note that the scheme assumes *oblivious noise* in the sense that the  $T$  corrupted transmissions are selected at the beginning of the computation (as a function of the coding scheme and the parties' inputs) and is independent of the parties' (private) randomness. This assumption is crucial, as no coding scheme withstands an unbounded amount of noise that is non-oblivious [7, Theorem 6.1].

## 1.1 Techniques

**Towards an optimal scheme: the code concatenation approach.** The immediate approach towards an improved coding scheme for an unbounded amount of corruptions is of *code concatenation*, namely composing two layers of interactive code. The inner layer would be

responsible for transmitting bits over the channel despite the unbounded amount of noise (e.g., [7, 15]). The outer layer would then “see” only a limited amount of noise (which passes the inner layer with polynomially-small probability) and perform a standard interactive coding (e.g., [25, 26, 5, 21, 19, 14, 20]) using these bits.

Unfortunately, such an approach faces severe difficulties. For the inner layer, the scheme of Dani et al. [7] assumes that no corrupted message is accepted by a party. That is, a message can either be correct or marked as invalid. Requiring the parties to process incorrect messages might cause their inner state to differ in a way that could not be recovered by the scheme. That is, a single corrupted message (that is believed to be correct by one of the parties) might cause the parties to “lose sync”, so that the parties do not agree anymore on when the next phase of the scheme begins and ends, or whether the scheme has terminated or not. The scheme will not recover from this fault because the synchronization information would be sent by one party at certain rounds but expected by the other party at different rounds. The other option for the inner layer is the scheme by Gelles and Iyer [15] designed to withstand an unbounded amount of *erasures*, and thus, on its surface, does not fit our purpose.

**The randomized erasure–flip model.** The key towards solving the above conundrum stems from defining a new random noise model that we name the *unbounded probabilistic Erase–Flip noise model* (UPEF). This model (formally defined in Section 2.2) still allows an unbounded number of corruptions determined by the adversary in an oblivious way. However, when the  $i$ -th transmission is corrupted by the adversary, the *effect* of the corruption is random: the transmitted bit is flipped with some probability  $p_i$  or erased with the complementary probability. The probabilities  $\{p_i\}_{i \in \mathbb{N}}$  are parameters of the model and can be determined by the algorithm’s designer. In a sense, this type of noise matches the effect oblivious noise has on messages that are protected with a signature: with some probability the corruption is detected (the signature does not verify) and the message is marked as corrupted, i.e., erased. On the other hand, with some small probability the corruption is such that the signature verifies the corrupted message; in this case we have a flip. The probabilities are determined by the length of the signatures in use.<sup>1</sup>

This novel randomized model is much simpler to handle, and facilitates the design and analysis of optimal coding schemes. Furthermore, any scheme designed for this model can be translated into a coding scheme that works in the standard unbounded flips (UF) noise model, by employing signatures of respective length to match the erasure–flip probabilities of the UPEF model. Therefore, this model serves as a crucial tool for obtaining optimal coding schemes in the standard model.

Switching to the UPEF model allows us to use the scheme in [15] as the inner code of our concatenated coding scheme, in an almost as-is fashion: by smartly setting the probabilities  $\{p_i\}_{i \in \mathbb{N}}$ , we can guarantee, with very high probability, that any execution experiences an unbounded number of erasures but only a bounded number of bit-flips. The scheme in [15] withstands the erasures and delivers the non-erased bits (either correct or not) to the outer layer, which should be able to cope with this limited amount of bit flips.

One problem still remains, but to explain it, we must first explain how the [15] scheme works. In a nutshell, the parties simulate the underlying (noiseless) protocol  $\pi$  bit-by-bit, where the scheme adds to each bit the parity (mod 2) of the corresponding round number.

<sup>1</sup> We use AMD codes [6] to generate signatures, see the full version of this paper [10, Appendix A] for the exact details.

The scheme works in *challenge-response*-style iterations: The first party (Alice) begins by sending the bit of the next round of  $\pi$  along with the parity of that round (*the challenge*). Bob receives this bit, and if the parity corresponds to the round number he expects, he records this bit and replies with the next bit of  $\pi$  along with the parity of that round in  $\pi$  (*the response*). When this reply reaches Alice, and the parity is correct, Alice records the bit from Bob and moves on to the next iteration. In any case of erasures or if the parity mismatches, the receiver ignores the received message. The analysis in [15] shows that this single parity bit suffices to keep track of the progress despite an unbounded amount of erasures.

However, in the UPEF model, a bit flip can either corrupt the content bit (i.e., the next simulated round of  $\pi$ ) or the parity bit sent along! Corrupting the parity bit damages the correctness of the [15] scheme, but this is the only way the noise can affect correctness. Throughout a detailed case analysis, we prove that corrupting the parity bit has the sole effect of making the parties *out-of-sync*, in the sense that one party advances to the next round in  $\pi$ , while the other does not. Luckily, this type of out-of-sync corruption was already considered in the interactive-coding community, initiated by the work of Braverman, Gelles, Mao, and Ostrovsky [4], which presented a non-efficient scheme that withstands a noise level of up to  $1/18$  fraction of the rounds, where “noise” here means insertions and deletions producing out-of-sync events as described above. That work was followed by a work by Sherstov and Wu [27], who showed that a variant of the [4] scheme withstands the optimal level of noise, namely, up to  $1/4$  of the rounds, and by a work by Haeupler, Shahrasbi, and Vitercik [22], who presented an *efficient* scheme, based on synchronization strings, with noise resilience of  $1/44$ .

Therefore, we can set the scheme in [22] (denoted HSV hereinafter) as the outer layer in our construction, and set the probabilities  $\{p_i\}_{i \in \mathbb{N}}$  such that the total number of insertion and deletion errors will not surpass the threshold expected by the HSV scheme, except with an exponentially small probability. This construction achieves our goal of obtaining a coding scheme in the UPEF model, with optimal length of  $O(N + T)$ , and an exponentially small failure probability.

Unfortunately, once converting this optimal UPEF scheme back to the standard UF model, the overhead increases severely. In particular, the way we set the probabilities  $\{p_i\}_{i \in \mathbb{N}}$  implies a logarithmic overhead on the size of the signatures, leading to a sub-optimal scheme of length  $O((N + T) \log(N + T))$  in the UF model. To avoid this increase in communication, we must maintain the probabilities  $\{p_i\}_{i \in \mathbb{N}}$  “large”, and design a new scheme that is still optimal in the UPEF model despite the high values of  $\{p_i\}_{i \in \mathbb{N}}$ .

**Obtaining an optimal scheme: the iterative approach.** In order to obtain a UF-optimal scheme, we take a different approach, namely, we execute an increasing-length instances of a “standard” interactive coding [7]. As before, we start by constructing a coding scheme over the UPEF model. Our goal now is to maximize the  $p_i$ ’s as much as possible. The main idea is as follows. Let’s fix each  $p_i$  to some constant, say,  $2/3$ . Now, any corruption in the UPEF model will cause an erasure with a fixed probability of  $1/3$ . The number of erasures a party observes is a good estimate of the level of noise during the same transmissions. Hence, the parties can continue running the scheme again and again, until they believe the noise level was low enough to produce the correct output.

In more detail, Alice and Bob run an efficient interactive coding scheme resilient to a constant fraction of adversarial flips (e.g., [2, 19]). After executing the scheme, Alice and Bob count the number of erasures observed during the execution and estimate (with high probability) the fraction of corruption they experienced. They communicate this estimate

to each other, and decide how to continue accordingly. If the noise level seems sufficiently low, the resilient scheme must have produced the correct output, and the parties can safely terminate. Otherwise, the parties re-run the interactive scheme, doubling its length. They repeat this action until they reach an execution where the noise level is low enough to guarantee the success of the underlying interactive coding scheme.

With a correct choice of parameters, this results in a UPEF scheme of length  $O(N + T)$ . However, since all  $\{p_i\}_{i \in \mathbb{N}}$  are fixed to a constant, once we translate this scheme into a UF scheme, we keep its length up to a constant and obtain an optimal length of  $O(N + T)$  in this case as well.

We note that a communication complexity of  $\Theta(N + T)$  is tight for the UF model. A lower bound of  $\Omega(N + T)$  is immediate by considering the case where the adversary corrupts the entirety of the communication between Alice and Bob for  $\Theta(T)$  rounds, e.g., by flipping each bit with probability  $1/2$ , thereby not allowing any information to cross the channel during these rounds. After this corruption,  $N$  rounds are still needed to complete the protocol without noise.

## 1.2 Related Work

As mentioned above, the field of interactive coding was initiated by the work of Schulman [25, 26]. Following this work, many two-party interactive coding schemes were developed, with the goal to optimize various properties, such as efficiency, communication rate, and noise resilience [5, 18, 2, 23, 21, 13, 3, 14, 20]. Two-party coding schemes for different types of noise, such as erasures or insertions and deletions, appeared in [11, 13, 8, 4, 22, 27, 9, 20]. See [12] for an extensive survey on this field.

Closest to our work are coding schemes that withstand an unbounded amount of corruption. As mentioned above, Dani et al. [7] developed a randomized scheme that deals with an unbounded amount  $T$  of oblivious bit-flips, succeeds with high probability, and simulates any  $\pi$  of length  $N$  in  $N + O(T + \sqrt{N(T + 1) \log T})$  rounds. Gelles and Iyer [15] developed a deterministic scheme that deals with an unbounded amount  $T$  of (not necessarily oblivious) erasures in at most  $2N + 4T$  communication rounds. For the multiparty setting, Aggarwal, Dani, Hayes, and Saia [1] developed a coding scheme that correctly simulates any protocol over an arbitrary network withstanding an unbounded amount of oblivious corruptions in  $\tilde{O}(N + T)$  rounds, suppressing logarithmic terms.

## 1.3 Paper Outline

We set up the UPEF and UF models, recall the insertion-deletion model, and review interactive coding protocols in Section 2. In Section 3 we describe an optimal UPEF coding scheme that follows a code concatenation approach. Its analysis is deferred to the full version of this paper [10, Appendix A]. Finally, in Section 4 we describe an optimal coding scheme in the UPEF model that follows an iterative approach. We then show how to translate it into an optimal UF coding scheme.

## 2 Preliminaries

**Notations.** For an integer  $n \in \mathbb{N}$  we use  $[n] = \{1, 2, 3, \dots, n\}$ . All logarithms are taken to base 2 unless otherwise mentioned. For two strings  $a, b$  we denote by  $a \circ b$  their concatenation. We will use  $\bigcirc_{k=1,2,\dots,\ell} a_k \triangleq a_1 \circ a_2 \circ \dots \circ a_\ell$  to abbreviate the concatenation of multiple strings. We use  $O_\varepsilon(\cdot)$ ,  $\Theta_\varepsilon(\cdot)$ , etc., to explicitly remind that the constant inside the  $O(\cdot)$  may depend on (the constant)  $\varepsilon$ .

## 2.1 Interactive Protocols and Coding Schemes

Consider two parties, Alice and Bob, having inputs  $x, y \in \{0, 1\}^k$  respectively, who wish to compute some function  $f(x, y)$  by communicating over a channel with alphabet  $\Sigma$ . Towards that goal, Alice and Bob use an *interactive protocol* composed of two algorithms  $\pi = (\pi_a, \pi_b)$  for Alice and Bob, respectively. These algorithms assume a common clock known by both parties (i.e., the protocol is synchronized) and determine, for each party in each round (timestep), whether the party (1) has to send a message in that round, (2) which symbol the party sends, and (3) if the party should terminate in that round and which output should it give.

Each party records all the messages it receives during the execution of the protocol. The collection of these records is the party's *transcript*. We assume that  $\pi$  has *fixed order of speaking*; this means that in each round exactly one party is transmitting a symbol (the other party listens), and the identity of the transmitting party in a given round is predetermined and independent of the parties' inputs. In particular, a protocol in which Alice speaks in odd rounds, and Bob speaks in even rounds is said to be of an *alternating order*. Note that if  $\pi$  is not alternating, then it can be converted to an alternating-order protocol while increasing the communication complexity by a factor of at most 2. We say that a protocol is *k-alternating*, for some  $k \in \mathbb{N}$ , if during its execution each party transmits bulks of  $k$  bits. The *length* of a protocol is defined to be the number of rounds it includes until both parties have terminated.

**Noisy channels and coding schemes.** Now, assume that the parties are connected by a *noisy channel*. Formally, given an input and output alphabets  $\Sigma_{in}, \Sigma_{out}$ , respectively, a single utilization of a noisy channel is the (possibly randomized) function  $C : \Sigma_{in} \rightarrow \Sigma_{out}$ .

We can now discuss protocols that perform over noisy channels. We say that a protocol  $\pi'$  *simulates*  $\pi$  over the noisy channel  $C$ , if for any inputs  $(x, y)$ , after executing  $\pi'$  over the noisy channel  $C$ , the parties can output their transcripts in an execution of  $\pi$  over a noiseless channel with inputs  $(x, y)$ . When the channel noise or the algorithm  $\pi'$  are probabilistic, we say that  $\pi'$  *simulates*  $\pi$  *with probability*  $p$  if the probability that the parties' output equal the transcript of  $\pi$  is at least  $p$ , for any inputs pair.

A *coding scheme* (for some given noisy channel  $C$ ) is a function  $CS$ , whose input is a noiseless protocol  $\pi$ , and its output is a protocol  $\pi' = CS(\pi)$  which simulates  $\pi$  over the channel  $C$ . When the channel noise or the scheme are probabilistic, we say that the coding scheme has success probability  $p$ , if for any  $\pi$ , the protocol  $\pi' = CS(\pi)$  simulates  $\pi$  with probability  $p$ .

## 2.2 Noise Models

As alluded to in the introduction, our scheme is designed to withstand an unbounded amount of (oblivious) bit flips. However, we design the scheme by reducing the unbounded-flip model to a different noise model with unbounded probabilistic erasures and flips. Furthermore, the effect of probabilistic erasures and flips noise on the inner layer of our coding scheme is such that the outer layer "sees" insertion and deletion noise. We will now define these three noise models in turn.

**The Unbounded Flip noise model (UF).** Our main noise model is the unbounded flip noise model, set forth by Dani et al. [7]. Given a specific execution of  $\pi'$  with inputs  $(x, y)$ , the adversary sets a *noise corruption pattern*  $E \subset \mathbb{N}$  such that the amount of noise,  $|E|$ , satisfies  $|E| = T$  for some number  $T \in \mathbb{N}$  decided by the adversary. The noise pattern can

be set as a function of  $\pi, x, y$  but is independent of any randomness the parties might have (i.e., an *oblivious* noise). The noise pattern  $E$  determines which bits get flipped during the execution of  $\pi$ . Namely, if  $i \in E$ , then the  $i$ -th transmitted bit in  $\pi$  will be flipped. Otherwise, the bit goes through uncorrupted. Note that  $T$  might be arbitrary. When one of the parties terminates, the channel sends zeros to the another party, which may be flipped by the adversary.

**The Unbounded Probabilistic Erasure-Flip noise model (UPEF).** Our coding scheme in this work is designed and analyzed within the following noise model, that combines both erasure and flip noise. This model naturally appears when executing a protocol in the UF model while each message contains a (probabilistic) signature or a message authentication tag that indicates its validity.

In this model, the parties are connected via a noisy communication channel  $C : \{0, 1\} \rightarrow \{0, 1, \perp\}$ , which can either flip bits or erase them (denoted by the erasure mark  $\perp$ ). Similar to the UF model, given any specific execution of  $\pi'$  with inputs  $(x, y)$ , the rounds which are corrupted are predetermined by an adversary that knows  $\pi', x, y$  and the inputs but not the parties' private randomness. This corruption is described via the noise pattern  $E \subset \mathbb{N}$ , where  $i \in \mathbb{N}$  means that the  $i$ -th round is corrupted; otherwise, the bit arrives at the other side intact. When a round is corrupted, the effect is as follows: the bit is flipped with some probability  $p_i$  or is erased with probability  $1 - p_i$ . The probabilities  $\{p_i\}_{i \in \mathbb{N}}$  are parameters of the model and will be specified later.

Terminating in the UPEF is different from terminating in the UF. When Alice terminates, the channel transmits a special “silence” symbol, namely, “ $\square$ ”. Upon the reception of this special symbol, Bob knows that Alice has quit, and terminates as well.

Similar to the UF model, we restrict the discussion to noise patterns in which the total number of corrupted rounds is finite. That is, there exists some number  $T \in \mathbb{N}$ , unknown to the parties and  $\pi$ , such that  $|E| = T$ .

**The Insertion-Deletion noise model.** The insertion-deletion noise model [4], which we briefly describe here, is important for our analysis of the concatenated coding scheme.

In this model we consider *alternating* interactive protocols  $\pi'$ , where no common clock is assumed by the parties. Instead, Alice sends the first symbol (round 1), and Bob is idle until receiving this symbol. Once the first symbol is obtained by Bob he transmits a symbol back to Alice (round 2). Alice will execute round 3 once receiving this symbol, and so on. The noise is allowed to either corrupt a symbol (i.e., the receiver will obtain a different symbol from the one sent, a *substitution*), or to completely delete the symbol, so that the receiver receives nothing. In the latter case, the protocol is “stuck” as both parties await an incoming symbol to proceed. To avoid getting stuck, the noise must inject a new symbol towards the sender of the symbol that got deleted. This causes the parties to get *out of sync*, that is, one of them will believe the current round is  $i$ , while the other will believe the current round is  $i + 2$ . See also [4, 27, 22, 9, 16, 17].

In [22], the authors give an efficient constant-rate coding scheme for insertions and deletion noise, which we will use in our construction.

► **Theorem 2.1** (Theorem 1.2 in [22]). *For any alternating protocol  $\pi$  of length  $n$  and for any  $\varepsilon > 0$ , there exists an efficient randomized protocol  $\pi'$  simulating  $\pi$  in presence of  $\delta = 1/44 - \varepsilon$  fraction of edit-corruptions, whose length is  $\Theta_\varepsilon(n)$  and succeeds with probability  $1 - 2^{-\Theta(n)}$ . The alphabet size of  $\pi'$  is  $\Theta_\varepsilon(1)$ .*

We assume that at its termination,  $\pi'$  has an output, which equals to the output of  $\pi$  (under the conditions in the theorem).

### 3 A UPEF-optimal coding scheme via code concatenation

In this section we give an optimal UPEF coding scheme, based on code-concatenation approach (Algorithms 1 and 2). The analysis of the scheme, presented in the full version of this paper [10, Appendix A], proves the following Theorem.

► **Theorem 3.1.** *Given any two-party binary interactive protocol  $\pi$  of length  $N$ , there exists some constant  $C$  and an efficient randomized protocol  $\Pi$  of length  $O(N + T)$  that simulates  $\pi$  with probability  $1 - 2^{-\Omega(N)}$  over a binary channel in the presence of an arbitrary and a priori unknown number  $T$  of probabilistic Erasure–Flip corruptions, with  $p_i = \min \left\{ \frac{CN}{i^2}, \frac{1}{2} \right\}$ .*

Let  $\pi$  be a binary alternating protocol that assumes noiseless channels of length  $|\pi| = N$ . Our goal is to simulate  $\pi$  in the UPEF model. Let  $\pi'$  be the randomized protocol obtained from  $\pi$  via Theorem 2.1, by setting  $\delta = 1/45$  (i.e.,  $\varepsilon = 1/1980$ ). We denote  $|\pi'| = N'$ . Denote the alphabet of  $\pi'$  by  $\Sigma'$  and note that its size is constant,  $|\Sigma'| = \Theta(1)$ .

Our coding scheme (Algorithms 1 and 2) simulates the communication of  $\pi'$ , symbol by symbol. As the channel in the unbounded probabilistic Erase–Flip noise model is binary, the parties communicate the binary representations of the symbols in  $\pi'$ . Therefore, during each iteration of the simulation, Alice sends a symbol to Bob using  $\log |\Sigma'|$  bit transmissions, and expects a symbol reply from Bob.

■ **Algorithm 1** Simulation over Erasure and Substitution Channel with Unbounded Noise (Alice).

---

**Input:** An alternating binary protocol  $\pi$  of length  $N$ , an input  $x$   
**Initialize:** Let  $\pi'$  be the protocol simulating  $\pi$  given by Theorem 2.1, setting  $\varepsilon = 1/1980$ . Let  $N' = |\pi'|$  and assume  $\Sigma'$  (the alphabet of  $\pi'$ ) is a power of two.

---

```

A.1  $\mathcal{T}_a \leftarrow \emptyset, r_a \leftarrow 0$ 
A.2 while  $r_a < \frac{N'}{2}$  do
A.3   // Send Message
A.4    $r_a \leftarrow r_a + 1$ 
A.5    $m_{send} \leftarrow \pi'(x \mid \mathcal{T}_a)$ 
A.6    $\mathcal{T}_a \leftarrow \mathcal{T}_a \circ m_{send}$ 
A.7   send  $(m_{send}, r_a \bmod 2)$  ▷  $k$  transmissions
A.8
A.9   // Receive Message
A.10  receive  $m' = (m_{rec}, r_{rec})$  ▷  $k$  transmissions
A.11  if  $m'$  does not contain  $\perp$  and  $r_{rec} = r_a \bmod 2$  then
A.12     $\mathcal{T}_a \leftarrow \mathcal{T}_a \circ m_{rec}$ 
A.13  else
A.14    delete the last symbol of  $\mathcal{T}_a$ 
A.15     $r_a \leftarrow r_a - 1$ 
A.16  end if
A.17 end while
A.18 Output the output given by  $\pi'$ 

```

---

The simulation of  $\pi'$  employs a challenge-response paradigm, where Alice sends a symbol (the challenge) and expects one back (the response). The parties maintain a counter to track their respective progress, namely, the variables  $r_a$  and  $r_b$ , which represent the number of successful iterations observed by Alice and Bob, respectively. Every time Alice and Bob send a symbol, they attach to it the parity (mod 2) of their own counter. Hence, the simulation is  $k$ -alternating, with  $k = \lceil \log |\Sigma'| \rceil + 1$ .

---

**Algorithm 2** Simulation over Erasure and Substitution Channel with Unbounded Noise (Bob).
 

---

**Input:** An alternating binary protocol  $\pi$  of length  $N$ , an input  $x$

**Initialize:** Let  $\pi'$  be the protocol simulating  $\pi$  given by Theorem 2.1, setting  $\varepsilon = 1/1980$ . Let  $N' = |\pi'|$  and assume  $\Sigma'$  (the alphabet of  $\pi'$ ) is a power of two.

```

B.1  $\mathcal{T}_b \leftarrow \emptyset, r_b \leftarrow 0, err \leftarrow 0, m \leftarrow (0, 0)$ 
B.2 while  $m' \neq \square$  do
B.3   // Receive Message
B.4   receive  $m' = (m_{rec}, r_{rec})$  ▷  $k$  transmissions
B.5   if  $m'$  does not contain  $\perp$  and  $r_{rec} \neq r_b \pmod 2$  then
B.6      $\mathcal{T}_b \leftarrow \mathcal{T}_b \circ m_{rec}$ 
B.7      $err \leftarrow 0$ 
B.8   else
B.9      $err \leftarrow 1$ 
B.10  end if
B.11
B.12  // Send Message
B.13  if  $err = 0$  then
B.14     $r_b \leftarrow r_b + 1$ 
B.15     $m_{send} \leftarrow \pi'(y \mid \mathcal{T}_b)$ 
B.16     $\mathcal{T}_b \leftarrow \mathcal{T}_b \circ m_{send}$ 
B.17    send  $m \leftarrow (m_{send}, r_b \pmod 2)$  ▷  $k$  transmissions
B.18  else
B.19    send  $m$  ▷  $k$  transmissions;  $m$  from memory
B.20  end if
B.21 end while
B.22 Output the output given by  $\pi'$ 

```

---

When Alice receives a symbol (as a response to the challenge she has previously sent), she checks the counter value attached to it: if it matches her expected counter parity (mod 2), she “believes” this challenge-response iteration, delivers the received symbol to  $\pi'$  and increases  $r_a$  by 1; otherwise, she ignores the reply and tries again in the next iteration.

Bob acts in an analogous manner: if the information received from Alice matches the counter parity (mod 2) he is expecting, then he “believes” the received symbol, delivers it to  $\pi'$ , increases  $r_b$  by 1, obtains from  $\pi'$  the next symbol to communicate to Alice, and sends Alice this symbol and the parity of  $r_b$ . If the information from Alice does not match Bob’s expectation, he ignores this transmission and replies with the previous symbol computed by  $\pi'$  (along with the parity that corresponds to that symbol). When a party “believes” an iteration, it appends the received and transmitted symbols of the iteration to its transcript,  $\mathcal{T}_a$  or  $\mathcal{T}_b$ , respectively. This transcript records all the symbols communicated so far (by  $\pi'$ ) during the “successful” iterations of Algorithms 1 and 2.

To summarize, in each iteration of the loop, Alice generates the next message of  $\pi'$ , denoted  $m \in \Sigma'$ , based on her current transcript  $\mathcal{T}_a$  and her input  $x$ , i.e.,  $m = \pi'(x \mid \mathcal{T}_a)$ . Alice (temporarily) adds  $m$  to  $\mathcal{T}_a$ , and sends its binary representation to Bob, along with the parity of  $r_a$ . After receiving a  $k$ -bit message  $(m_{rec}, r_{rec})$  from Alice, Bob checks that none of the  $k$  bits have been erased (denoted by  $\perp$ ) and that  $r_{rec}$  is opposite to his parity (since Alice added a new symbol and he did not, yet). If everything matches, Bob adds  $m_{rec}$  to his transcript  $\mathcal{T}_b$ , increases  $r_b$  by 1, computes the next message  $m' = \pi'(y \mid \mathcal{T}_b)$  and the new parity of  $r_b$ , and transmits them to Alice. On the other hand, if Bob notices any erasures or the mismatch of the parity, he ignores Alice’s new symbol and replies with the latest computed  $(m', r_b)$  recorded in his memory.

At the end of the iteration, Alice receives a message and a parity from Bob; if there were no erasures and the received parity matches  $r_a$ , she adds that message to her transcript. Otherwise, Alice deletes the (temporary) message she added at the beginning of this iteration.

The algorithm ends once the length of  $\mathcal{T}_a$  reaches the length of  $\pi'$  (for Alice) or when a special symbol  $\square$ , sent by the channel when Alice quits, is received by Bob. We discuss termination in this model and the implication of assuming this special symbol in the full version of this paper [10, Appendix B.1].

The complete detailed analysis of the coding scheme (Algorithms 1 and 2) and the proof of Theorem 3.1, are deferred to the full version of this paper [10, Appendix A].

## 4 A UF Scheme with Optimal Communication

The concatenated scheme in Section 3, while optimal in the UPEF model, implies a UF scheme of length  $O((N + T) \log(N + T))$  in which the  $i$ -th bit is replaced with an AMD code [6] of length  $O(\log(p_i^{-1}))$ ; see the full version of this paper [10, Appendix B] for details. In this section, we take a different approach towards constructing an optimal coding scheme in the UPEF model, namely by executing increasing-length coding schemes in an iterative fashion. This approach eventually leads to an optimal-communication UF scheme.

Here, Alice and Bob utilize a “standard” interactive coding scheme for substitutions and estimate the experienced level of noise. If the estimated noise level is too high, Alice and Bob repeat the execution with a larger amount of redundancy. When the noise level is low enough, the interactive scheme guarantees the success of the computation, and the parties can terminate. This approach, in addition to leading to a UF scheme with optimal communication, is also much simpler and easier to analyze than the scheme of Section 3. The key difference is that, all we need in order to estimate the noise level well, is that the probabilities  $\{p_i\}_{i \in \mathbb{N}}$  are bounded below by a constant, rather than converging to 0. This aligns perfectly with obtaining optimal complexity, as smaller  $\{p_i\}_{i \in \mathbb{N}}$  imply longer encodings.

The scheme in this section utilizes a slight variant of the UPEF model, denoted the modified UPEF (mUPEF) model, which we now describe. Let a noise pattern  $E \subset \mathbb{N}$  be determined adversarially. As before, if  $i \notin E$ , the  $i$ -th transmitted bit reaches the other party intact. For  $i \in E$ , the  $i$ -th transmitted bit is still erased with probability  $1 - p_i$ , and corrupted with probability  $p_i$ . However, the corruption here is not necessarily a bit flip as in the original UPEF. Instead, the adversary determines whether the bit is flipped, erased, or not corrupted at all. The probabilities  $\{p_i\}_{i \in \mathbb{N}}$  are parameters of the model. However, we will actually set them all to have the same value. That is,  $\forall i, p_i = 2/3$ .

In our scheme, we set  $p_e = 1 - p_i = 1/3$  as a lower bound on the probability that a bit is erased. Similar to the UF model, we will assume that when Alice terminates, the channel implicitly sends Bob a default symbol (e.g., a zero).

In the following sections we describe and analyze a coding scheme in the mUPEF model, with optimal  $O(N + T)$  communication that, due to our choice of  $p_e = 2/3$ , results with a UF scheme with  $O(N + T)$  communication as well.

**An optimal mUPEF Coding Scheme.** For the underlying substitution-resilient interactive coding scheme, we can take any (efficient) 2-party scheme with binary alphabet that is resilient to a constant fraction of adversarial noise, e.g., [2, 19]. In particular, let us assume an interactive coding scheme that simulates any (noiseless) protocol  $\pi$  in the presence of up to 0.1 adversarial substitutions with a constant rate over the binary alphabet. Denote the substitution-resilient version by  $\pi'$ , so  $|\pi'| = O(|\pi|) = O(N)$ . We assume that  $\pi'$  is

alternating. We additionally assume that the communication of  $\pi'$  includes a constant fraction of ones. To be concrete, out of the  $|\pi'|/2$  bits Alice sends, at least  $|\pi'|/8$  are the bit 1, in any execution of  $\pi'$ . We must have this property, because in our scheme, a long sequence of zeros will indicate termination. For that reason, we want that  $\pi'$  will not send a long sequence of zeros. This can be achieved, for instance by making the parties communicate a 1 every alternate round, or by means of randomization (see, e.g., [13]).

We proceed to describe our mUPEF resilient scheme  $\Pi$  simulating the substitution-resilient  $\pi'$  defined above. The execution of  $\Pi$  consists of iterations, where the  $i$ -th iteration,  $i = 0, 1, 2, \dots$ , takes  $2L_i$  rounds with  $L_i = |\pi'|2^i$ . The  $i$ -th iteration can be broken down into two parts, each of length  $L_i$ . In the first part, the parties execute  $\pi'$  from scratch, padded to length  $L_i$ ; in this padded protocol, each bit of  $\pi'$  is sent  $2^i$  times, and decoding is performed by majority (defaulting to 0 on ties, considering erased copies as zeros). In the second part of iteration  $i$ , only Bob speaks. He sends Alice the *success string*  $0^{L_i}$  if and only if he observed less than  $0.001p_e L_i$  erasures in the first part; otherwise Bob sends the *error string*  $1^{L_i}$ .

Alice terminates at the end of iteration  $i$  if she observed less than  $0.001p_e L_i$  erasures in each of the parts of iteration  $i$ , and Bob's transmissions at the second part contains more 0's than 1's (i.e., it decodes to the success string rather than to the error string). Alice gives as an output the same output that  $\pi'$  has generated in the iteration in which she terminated. Bob terminates at the end of iteration  $j$  if he observed less than  $0.001p_e L_j$  erasures in the first part of  $j$  and at most  $0.001p_e L_j$  of the received bits in the first part of  $j$  are 1's. Bob gives as an output the output of the latest iteration  $k$ , with  $k < j$ , in which (1) he observed less than  $0.001p_e L_j$  erasures in the first part and (2) he received at least  $L_k/40$  ones from Alice in the first part. We call a *valid iteration* any iteration that satisfies these two conditions.

## 4.1 Analysis

In this section we prove the following theorem.

► **Theorem 4.1.** *Given any two-party binary interactive protocol  $\pi$  of length  $N$ , there exists an efficient randomized protocol  $\Pi$  of length  $O(N + T)$  that simulates  $\pi$  with probability  $1 - 2^{-\Omega(N)}$  over a binary channel in the presence of an arbitrary and a priori unknown number  $T$  of mUPEF corruptions, with  $p_i = 2/3$  for all  $i$ .*

We start with proving the correctness of our coding scheme: we begin by demonstrating that Alice's output is correct with high probability. Additionally, we show that Bob's output at Alice's termination is also correct. Then, we prove that Bob terminates after Alice, that Alice terminates in a *valid* iteration, and that there are no valid iterations afterwards. This would imply that Bob gives the right output as well.

Recall that  $\pi'$  is resilient to 0.1-fraction of substitutions. In addition, recall the padding mechanism; in order to cause a bit substitution in  $\pi'$  in some iteration  $i$ , at least a half of its  $2^i$  transmitted copies must be flipped or erased. Thus, if there are less than  $L_i/20$  corruptions during the first part of iteration  $i$  (that is, indices that the adversary puts in  $E$ ), then  $\pi'$  must give the correct output at the end of iteration  $i$ , for both Alice and Bob.

In the following lemma, we show that if there are *more* than  $L_i/20$  corruptions in some iteration  $i$ , then Alice continues to executing iteration  $i + 1$  and does not terminate at the end of iteration  $i$ , except with a negligible probability of  $2^{-\Omega_{p_e}(L_i)}$ .

► **Lemma 4.2.** *Assume that in the first part of iteration  $i$  there are  $c_i \geq L_i/20$  corruptions. Then, the probability that Alice terminates at the end of iteration  $i$  is  $2^{-\Omega_{p_e}(L_i)}$ .*

## 43:12 Interactive Coding with Unbounded Noise

**Proof.** We divide the proof into two separate cases: (1) each of Alice and Bob observes less than  $0.001p_e L_i$  erasures in the first part, and (2) Bob observes more than  $0.001p_e L_i$  erasures but Alice does not. Of course, if more than  $0.001p_e L_i$  erasures are observed by Alice during the first part, she does not terminate by definition.

First, we find the probability of case (1) to occur. Denote by  $E_i$  the subset of the noise pattern  $E$  containing only rounds in the first part of iteration  $i$ . Then,  $|E_i| \geq c_i \geq L_i/20$ . Let  $e'$  be the number of rounds during the first part of iteration  $i$  that were erased because the event of channel erasure, which happens with probability  $p_e$ , occurred. It holds that  $\mathbb{E}[e'] = |E_i|p_e \geq 0.05p_e L_i$ , and by Chernoff's inequality (Theorem 4.4(2) in [24]),

$$\Pr(e' < 0.002p_e L_i) \leq \Pr(e' < 0.04\mathbb{E}[e']) \leq e^{-\mathbb{E}[e'] \frac{0.96^2}{2}} \leq e^{-0.05p_e L_i \frac{0.96^2}{2}} \in 2^{-\Omega_{p_e}(L_i)}.$$

Thus, if  $c_i \geq L_i/20$ , then  $e' < 0.002p_e L_i$  with probability  $2^{-\Omega_{p_e}(L_i)}$ , which bounds the probability of case (1) to occur.

In case (2), Bob sees a lot of erasures and sends the error string. In order for Alice to terminate, it is necessary for her to decode this message as the success string. For this to happen, it is necessary that the adversary corrupts at least  $L_i/2$  bits during the second part of the  $i$ -th iteration. Similar to the proof of case (1), the adversary succeeds to corrupt so many bits while causing less than  $0.001p_e L_i$  erasures during the second part with probability of at most  $2^{-\Omega_{p_e}(L_i)}$ . We conclude that Alice terminates at the end of iteration  $i$  with probability of at most  $2^{-\Omega_{p_e}(L_i)}$ . ◀

The above lemma indicates that, in the event of an excessive number of corruptions, Alice will not terminate. The following observation complements this idea and states that if Alice does terminate, the computation of  $\pi'$  is successful with high probability, hence, her output in  $\Pi$  is correct.

► **Observation 4.3.** *When Alice terminates,  $\pi'$  gives the correct output, with probability  $1 - 2^{-\Omega_{p_e}(N)}$ .*

**Proof.** If during a given iteration there were less than  $L_i/20$  corruptions, then the resilience of  $\pi'$  guarantees that it gives the right output, and Alice terminates. The event in which Alice terminates and provides incorrect output can only occur when there are more corruptions in a specific iteration, the probability of which was constrained in Lemma 4.2. A union bound over all possible iterations (while recalling that  $L_i = |\pi'|2^i$ ) bounds the probability for Alice to give an incorrect output, by

$$\sum_{i=0}^{\infty} 2^{-\Omega_{p_e}(L_i)} = 2^{-\Omega_{p_e}(|\pi'|)} = 2^{-\Omega_{p_e}(N)}. \quad \blacktriangleleft$$

Next, we prove that Bob terminates only after Alice has already terminated, with high probability.

► **Lemma 4.4.** *Consider an iteration  $i$  in which Alice has not yet terminated. Then, the probability that Bob terminates at the end of iteration  $i$  is at most  $2^{-\Omega_{p_e}(L_i)}$ .*

**Proof.** In order to terminate at the end of iteration  $i$ , Bob must observe less than  $0.001p_e L_i$  erasures in the first part of the iteration. In a manner analogous to the argument presented in Lemma 4.2, it can be shown that, with a probability approaching  $1 - 2^{-\Omega_{p_e}(L_i)}$ , there will be a total of less than  $L_i/20$  corrupted messages received by Bob during the first part of iteration  $i$ . Recall that as long as Alice has not terminated, at least  $L_i/8$  out of the  $L_i/2$

bits she sends in iteration  $i$  are ones. Consider these transmissions only. Even if all the corruptions during the first part of  $i$  occur during these transmissions, then Bob will observe at least  $0.001p_e L_i$  ones in the first part of  $i$ , and will therefore not terminate by definition. Consequently, Bob terminates in iteration  $i$  with probability  $2^{-\Omega_{p_e}(L_i)}$ . ◀

Bob's output is the output of  $\pi'$  in the last *valid* iteration prior to his termination iteration. The following lemma shows that, with high probability, the last valid iteration is the same iteration in which Alice has terminated. By Observation 4.3,  $\pi'$  gives the correct output in that iteration.

► **Lemma 4.5.** *Denote by  $i$  the iteration in which Alice terminates. Then,  $i$  is a valid iteration with probability  $1 - 2^{-\Omega_{p_e}(L_i)}$ . Further, the probability that there is a valid iteration  $j > i$  is  $2^{-\Omega_{p_e}(N)}$ .*

**Proof.** In order to prove that  $i$  is a valid iteration, we have to show that Bob observes less than  $0.001p_e L_i$  erasures in the first part of  $i$ , and that he receives at least  $L_i/40$  ones from Alice in the first part.

First, note that Bob observes less than  $0.001p_e L_i$  erasures in the first part of  $i$  if and only if he sends the success string in the second part. We demonstrate that with probability  $1 - 2^{-\Omega_{p_e}(L_i)}$  this is the case. As illustrated in case (2) of Lemma 4.2, when Bob transmits the error string to Alice in the second part of  $i$ , Alice terminates with probability  $2^{-\Omega_{p_e}(L_i)}$ . Since Alice terminates in  $i$ , there is a probability of  $2^{-\Omega_{p_e}(L_i)}$  that Bob sends the error string in the second part of  $i$  and observes more than  $0.001p_e L_i$  erasures in the first part of  $i$ .

We proceed to show that Bob receives at least  $L_i/40$  ones from Alice in the first part of  $i$ . By Lemma 4.2, during the first part of iteration  $i$  there are less than  $L_i/20$  corruptions with probability  $1 - 2^{-\Omega_{p_e}(L_i)}$ . Additionally, Alice always sends at least  $L_i/8$  ones in the first part. Thus, Bob receives at least  $L_i/40$  ones during the first part of  $i$  with probability  $1 - 2^{-\Omega_{p_e}(L_i)}$ , and this is the probability of  $i$  to be a valid iteration.

Let  $j$  be an iteration such that  $j > i$ . Recall that after Alice terminates the channel sends Bob zeros, by default. We show that  $j$  is not a valid iteration with high probability, by dividing into two cases. If there are at least  $L_j/40$  flips in the transmissions towards Bob during the first part of iteration  $j$ , then with probability  $1 - 2^{-\Omega_{p_e}(L_j)}$  Bob observes at least  $0.001p_e L_j$  erasures, similar to case (1) in Lemma 4.2, thus  $j$  is not valid. If there are less than  $L_j/40$  flips in these transmissions, then Bob receives less than  $L_j/40$  ones and  $j$  is not a valid iteration either. Thus, iteration  $j$  is valid with probability of at most  $2^{-\Omega_{p_e}(L_j)}$ . Since  $L_j = |\pi'|2^j$ , applying a union bound on all the iterations gives a probability of  $\sum_{j=i}^{\infty} 2^{-\Omega_{p_e}(L_j)} = 2^{-\Omega_{p_e}(N)}$  to the event that there is a valid iteration after  $i$ . ◀

We may use a union bound to conclude the correctness part for Bob. The overall probability of Bob to terminate after Alice is  $1 - 2^{-\Omega_{p_e}(N)}$ . The probability of Bob to declare Alice's termination iteration as valid is  $1 - 2^{-\Omega_{p_e}(N)}$ . Bob gives the correct output at this iteration with probability  $1 - 2^{-\Omega_{p_e}(N)}$  by Lemma 4.2, and this iteration is the last valid iteration with probability  $1 - 2^{-\Omega_{p_e}(N)}$ . We may use the inclusion-exclusion principle to show that the probability of the intersection of all these four events is  $1 - 2^{-\Omega_{p_e}(N)}$ . Recall that for any  $A, B$  it holds that  $1 \geq P(A \cup B) = P(A) + P(B) - P(A \cap B)$ . Then, the fact that  $P(A), P(B) \in 1 - 2^{-\Omega_{p_e}(N)}$  implies that  $P(A \cap B) \geq 2(1 - 2^{-\Omega_{p_e}(N)}) - 1 \in 1 - 2^{-\Omega_{p_e}(N)}$ . Thus, the probability of the event in which Bob gives the correct output at his termination is  $1 - 2^{-\Omega_{p_e}(N)}$ , and we have completed the correctness part of Theorem 4.1.

The communication complexity of  $\Pi$  is  $\sum_{i=1}^{i_B} 2L_i$ , with  $i_B$  being the iteration in which Bob terminates. At any iteration  $i$  before Alice terminates, the adversary has to select at least  $0.001p_e L_i$  bits to corrupt in order to prevent Alice from terminating. In addition,

at any iteration  $i$  after Alice's and before Bob's terminations, the adversary has to select at least  $0.001p_e L_i$  bits to corrupt in order to prevent Bob from terminating. Denote the iteration in which Alice terminates by  $i_A < i_B$ . Then,  $\sum_{i=1, i \neq i_A}^{i_B-1} 0.001p_e L_i < T$ , so  $\sum_{i=1, i \neq i_A}^{i_B-1} 2L_i < 2000/p_e \times T$ . Since  $L_i$  satisfies  $L_i = 2L_{i-1}$  for all  $i$ , and since  $L_{i_A-1}, L_{i_B-1}$  are included in  $\sum_{i=1, i \neq i_A}^{i_B-1} 2L_i < 2000/p_e \times T$ , then  $\sum_{i=1}^{i_B} 2L_i < 6000/p_e \times T$  and the communication complexity is  $O_{p_e}(N + T)$ .

## 4.2 Obtaining a UF-optimal coding scheme

In this section we construct a UF-model scheme based on the mUPEF protocol  $\Pi$ , while maintaining a communication complexity of  $O(N + T)$ . Recall, we set  $p_e = 1/3$ . This means that adversarial corruption in the  $i$ -th transmission of  $\Pi$ , becomes detectable (an erasure) with probability at least  $1/3$ . We would like to simulate this property in the UF model.

Towards this goal, we independently encode each bit of  $\Pi$  using a random code of length 5. In particular, we encode a 0 to one of  $\{00000, 10000, 01000\}$  with equal probability, and encode a 1 to one of  $\{00100, 10010, 01001\}$  with equal probability. A received 5-bit word is decoded to a 0 or a 1 only if it belongs to respective set, or otherwise it is considered as an erasure. It can easily be seen that any pattern of 1 to 5 bit-flips decodes to an erasure with probability at least  $1/3$  as desired. We have thus inflated the scheme by only a constant factor. The bit complexity of the resulting UF scheme is then  $5 \cdot |\Pi| = O(N + T)$ .

## Abstract

We construct explicit pseudorandom generators that fool  $n$ -variate polynomials of degree at most  $d$  over a finite field  $\mathbb{F}_q$ . The seed length of our generators is  $O(d \log n + \log q)$ , over fields of size exponential in  $d$  and characteristic at least  $d(d-1)+1$ . Previous constructions such as Bogdanov’s (STOC 2005) and Derksen and Viola’s (FOCS 2022) had either suboptimal seed length or required the field size to depend on  $n$ .

Our approach follows Bogdanov’s paradigm while incorporating techniques from Lecerf’s factorization algorithm (J. Symb. Comput. 2007) and insights from the construction of Derksen and Viola regarding the role of indecomposability of polynomials.

## 1 Introduction

The role of randomness in efficient computation is one of the central topics in complexity theory: random bits are useful for designing algorithms, but producing random bits comes at a cost and it is often desirable to reduce them or eliminate them altogether. One of the simplest yet most profound insights in this area is that efficient algorithms are, by definition, computationally limited, and cannot perform arbitrary statistical tests over their random bits. Therefore, one may hope to construct *pseudorandom* distributions that use less random bits but are able to “fool” some limited classes of tests, that cannot distinguish between them and between truly random bits.

For the pseudorandom distributions to be useful, they need to be efficiently computable themselves. This is usually modeled as a *pseudorandom generator* (PRG, for short). A PRG for a class of  $\mathcal{C}$  is an efficiently computable function  $G : S \rightarrow B$  such that for every function  $f \in \mathcal{C}$ , the distributions  $f(\mathbf{U}_B)$  and  $f(G(\mathbf{U}_S))$  are close in statistical distance, where  $\mathbf{U}_A$  denotes the uniform distribution over the set  $A$ . Namely, the two experiments of applying  $f(\cdot)$  to a uniformly random element of  $B$ , and applying  $f(G(\cdot))$  to a uniformly random element

Schloss Dagstuhl – Leibniz-Zentrum für Informatik, Dagstuhl Publishing, Germany

of  $S$ , give roughly the same results. For this to be useful and non-trivial, obviously the set  $S$  needs to be significantly smaller than  $B$ . The quantity  $\log |S|$  is called the *seed length* of the generator.

There has been a significant amount of work on constructing pseudorandom generators for various types of restricted distinguishers. In its most general form, where the distinguisher is allowed to be an arbitrary efficient (even non-uniform) algorithm, constructing such PRGs would imply breakthrough lower bounds in complexity theory. However, there are also unconditional constructions of PRGs for distinguishers coming from certain smaller complexity classes (see, for example, the surveys [34, 17]).

In this paper, we focus on pseudorandom generators in the algebraic setting. Here, the restriction on the distinguishers is of algebraic nature: we seek to fool distinguishers that are low-degree  $n$ -variate polynomials over finite fields.

The problem of fooling low-degree polynomials is well-studied. The most basic case is polynomials of degree one, i.e., fooling linear functions. Such generators are also known as  $\varepsilon$ -biased sets, and this problem was traditionally studied over  $\mathbb{F}_2$ , although some of the constructions can be generalized to larger fields. This concept was first defined and considered by Naor and Naor [24], with various improved constructions given by [2, 14, 4], culminating in a recent nearly-optimal construction by Ta-Shma [33]. The seed length in those constructions is  $O(\log n + \log q + \log(1/\varepsilon))$ , where  $n$  denotes the number of variables,  $\varepsilon$  the error of the PRG, and  $q$  the field size.

While focusing on polynomials of degree one might seem a bit too restrictive,  $\varepsilon$ -biased sets have found numerous applications throughout the field of pseudorandomness and derandomization, and in the theory of computation in general.

One example relevant to this work is that  $\varepsilon$ -biased sets are in fact a basic building block in a construction of PRGs for higher-degree polynomials, using a paradigm initiated by Bogdanov and Viola [7]. They suggested constructing a generator for degree- $d$  polynomials by summing up  $\ell = \ell(d)$  independent copies of a generator for degree-one polynomials. The paper [7] proved a conditional result when the number of summands is  $d$ , assuming certain additive combinatorics conjectures. Lovett [22] showed how to prove an unconditional result at the cost of making the number of summands  $2^d$ . Finally, Viola [35] showed (unconditionally) that in fact  $d$  summands suffice. The seed length in his construction is  $O(d \log n + d2^d \log(q/\varepsilon))$ . Indeed, even though the construction only sums  $d$  copies of a generator for degree-one polynomials, for the analysis to go through, the error of this generator needs to be as small as  $\varepsilon^{2^d}$  (for the final error of the generator for degree- $d$  polynomials to be  $\varepsilon$ ), which incurs a factor of  $2^d$  in the final seed length. Improving this generator and in particular obtaining meaningful results for polynomials of degree greater than  $\log n$  is an extremely important open problem in complexity theory. One reason is that such pseudorandom generators will yield pseudorandom generators for small constant-depth circuits with parity gates, since Razborov [25] and Smolensky [32] famously proved that functions computed by such circuits are approximated by low-degree polynomials.

All the constructions mentioned above work for any field. There are, however, better results when the field size  $q$  is assumed to be large (typically, at least polynomially large in  $d$  and  $1/\varepsilon$ ). This assumption is useful since it allows one to use powerful tools from algebraic geometry, such as Weil-type estimates [36] on the number of points of varieties over finite fields.

This line of work was initiated by Bogdanov [6], who showed how to use different pseudorandom objects called *hitting set generators* for low-degree polynomials in order to construct pseudorandom generators. Bogdanov's work, followed by the later improved

constructions of hitting set generators [19, 23, 10, 16], resulted in a PRG with seed length  $O(d^4 \log n + \log q)$  assuming  $q \geq Cd^6/\varepsilon^2$  for a sufficiently large constant  $C$ .<sup>1</sup> Over fields of large enough characteristic, combining Bogdanov’s paradigm with the results of Lecerf [21] results in improving the  $d^4$  factor to  $d^2$ . We expand more on Bogdanov’s and Lecerf’s techniques in Section 1.2, as both are very relevant to this work.

More recently, Derksen and Viola [12] introduced fundamentally new techniques for this problem, with tools coming from invariant theory. One of their key ideas is to construct a low-degree polynomial map on a few variables that preserves the *indecomposability* property of a polynomial  $f$  when composed with it (we refer to Section 2 for more on that). Using this new tool in conjunction with other techniques, they are able to construct generators with seed length  $O(d \log(dn) + \log q)$ , assuming  $q \geq Cd^4n^\delta/\varepsilon^2$  (for some large constant  $C$  and small constant  $\delta$ ), or seed length  $O(d \log n \log(d \log n) + \log q)$  for  $q \geq C(d \log n)^4/\varepsilon^2$ . One should note, however, that the optimal parameters in the construction of [12] are obtained after composing their construction with Bogdanov’s original construction.

A related natural question is how small the seed length can potentially be. Alon, Ben-Eliezer and Krivelevich [1] considered this question and proved a lower bound of  $\Omega(d \log(n/d) + \log q + \log(1/\varepsilon))$  on the seed length. Thus, we see that the explicit constructions of [12] come very close to the optimal bound. However, unlike the result of Bogdanov [6], in the construction of Derksen and Viola [12] the minimum field size depends on the number of variables  $n$ .

### 1.1 Our Results

In this paper, we provide an improved construction of PRGs for low-degree polynomials, with an even shorter seed length, assuming the field size is exponentially large in  $d$  (but independent of  $n$ ).

► **Theorem 1.1.** Let  $\mathbb{F}_q$  be a finite field of characteristic at least  $d(d-1)+1$  and size  $q \geq C(d2^d/\varepsilon + d^4/\varepsilon^2)$  (for some sufficiently large absolute constant  $C$ ). Then, there exists an explicit pseudorandom generator that fools  $n$ -variate polynomials of degree at most  $d$  over  $\mathbb{F}_q$  with error  $\varepsilon$  and seed length  $O(d \log n + \log q)$ .

For convenience, we summarize the comparison between Theorem 1.1 and the results of Bogdanov [6], Viola [35] and Derksen and Viola [12] in the following table. All the entries in this table are given up to some constant factors, but for ease of readability, we omit  $O(\cdot)$  notations.

|               | Seed Length                                  | Field Size                             | Characteristic  |
|---------------|--|--|-----------------|
| [35]          | $d \log n + d \cdot 2^d \log(q/\varepsilon)$ | Every $q \geq 2$                       | Any             |
| [6]+[16]      | $d^4 \log n + \log q$                        | $d^6/\varepsilon^2$                    | Any             |
| [6]+[16]+[21] | $d^2 \log n + \log q$                        | $d^6/\varepsilon^2$                    | $\geq d(d-1)+1$ |
| [12]          | $d \log(n) + \log q$                         | $d^4 n^{0.001}/\varepsilon^2$          | Any             |
| [12]          | $d \log n \cdot \log(d \log n) + \log q$     | $(d \log n)^4/\varepsilon^2$           | Any             |
| This paper:   | $d \log n + \log q$                          | $d2^d/\varepsilon + d^4/\varepsilon^2$ | $\geq d(d-1)+1$ |

We also prove that, if we only want to fool polynomials of *prime* degree up to  $d$ , then the required field size in Theorem 1.1 can be improved to  $O(d^4/\varepsilon^2)$ , avoiding an exponential dependence on  $d$ .

<sup>1</sup> One should note that since  $q$  is polynomially large in  $1/\varepsilon$ , the seed length also implicitly depends on  $\log(1/\varepsilon)$  through the  $\log q$  term.

► **Theorem 1.2.** Let  $\mathbb{F}_q$  be a finite field of characteristic at least  $d(d-1)+1$  and size  $q \geq C(d^4/\varepsilon^2)$  (for some sufficiently large absolute constant  $C$ ). Then, there exists an explicit pseudorandom generator that fools  $n$ -variate polynomials of prime degree up to  $d$  over  $\mathbb{F}_q$  with error  $\varepsilon$  and seed length  $O(d \log n + \log q)$ .

## 1.2 Proof Techniques

We start by reviewing the proof of Bogdanov’s PRG. Bogdanov’s idea is to consider restrictions of the polynomial  $f$  we are trying to fool onto planes, and to argue that “most” planes preserve the output distribution of the polynomial. Since a plane is a two-dimensional subspace, after having selected a good plane, we only need to sample two more field elements to select a random element from the plane.

The question now is how to find a good plane. Here, Bogdanov uses results by Kaltofen [18], who proved an effective version of Hilbert’s irreducibility theorem. Kaltofen demonstrated that, for every degree- $d$  irreducible polynomial  $f$ , there exists a polynomial  $P$  of degree roughly  $d^4$ , whose variables correspond to the parameters of the plane, such that every point at which  $P$  is nonzero corresponds to a “good” plane for  $f$  – that is, a plane that preserves the irreducibility of  $f$ . Therefore, we can use a hitting set generator for polynomials of degree  $d^4$  to find a good plane. This results in a factor of  $d^4$  in the final seed length.

Over fields of large characteristic (or characteristic zero), Lecerf [20, 21] obtained an improved upper bound of  $O(d^2)$  on the degree of such polynomials, based on ideas of Ruppert [26, 27] and Gao [15]. However, Lecerf also presents an example where the degree of such a polynomial must be at least  $\Omega(d^2)$ , demonstrating that this approach alone may not suffice to achieve an improvement within Bogdanov’s framework.

Derksen and Viola circumvent this problem by using a different approach: rather than preserving irreducibility (or more generality, if a polynomial is reducible, preserving its number of irreducible factors) as in Bogdanov’s approach, they construct a map that preserves the *indecomposability* of polynomials: a polynomial  $f(x_1, \dots, x_n)$  is indecomposable if it cannot be written as  $f = g(h(x_1, \dots, x_n))$  where  $g$  is a univariate polynomial of degree at least 2. Over large fields, irreducibility and indecomposability both guarantee that the polynomial is roughly equidistributed, and in fact these notions are tightly connected. We refer to Section 2 for the precise definitions and description of those connections.

To prove our result, we revisit Bogdanov’s approach, while noting that by applying Lecerf’s results [21] (rather than Kaltofen’s bounds [18]) in a more careful way, and assuming the field is sufficiently large, it is in fact enough to use hitting sets generators only for polynomials of degree  $O(d)$ , rather than  $O(d^2)$ . We also incorporate the insights from [12] regarding indecomposability and equidistribution. This requires following the outline above but making sure that at each step, we only need to hit polynomials of degree  $O(d)$ .

Following Lecerf’s notation and terminology, suppose  $F(x_1, \dots, x_n, y)$  is an irreducible polynomial of degree at most  $d$ . A point  $\mathbf{a} = (a_1, \dots, a_n)$  is called a *Bertinian good* point if the bivariate polynomial  $H(x, y) = F(a_1x, \dots, a_nx, y)$  remains irreducible. Lecerf proves that there exists a polynomial  $\mathcal{A}(z_1, \dots, z_n)$  of degree  $O(d^2)$  such that if  $\mathcal{A}(a_1, \dots, a_n) \neq 0$  then  $\mathbf{a}$  is a Bertinian good point. This is achieved by transforming the question of irreducibility into a question about the rank of a solution space for a certain linear system that depends on  $a_1, \dots, a_n$  (see Section 4). This transformation naturally leads to defining  $\mathcal{A}$  as a certain minor of the matrix representing that linear system. The minor has dimensions  $O(d) \times O(d)$ , and each entry of the matrix is a polynomial of degree  $O(d)$ , which results in a total bound of  $O(d^2)$  on the degree of its determinant,  $\mathcal{A}$ .

We, however, observe that Lecerf’s results actually imply a much stronger structure of this linear system: its solution space, over any field, is always spanned by vectors whose entries are in  $\{0, 1\}$ . In fact, Lecerf directly characterizes the relationship between the irreducible factors of  $H(x, y)$  and the vectors spanning the solution space, though this detail is irrelevant for the moment.

Thus, in Lecerf’s argument,  $a_1, \dots, a_n$  are chosen such that a particular minor is nonzero, namely, a certain linear system has no non-trivial solutions. But it is enough to select  $a_1, \dots, a_n$  in a way that only guarantees that this linear system has no non-trivial  $0/1$  solutions!

Fixing any vector  $u \in \{0, 1\}^d$ , the requirement that  $u$  is not a solution to the linear system turns out to be a condition expressible as  $u$  being a nonzero of a polynomial of degree  $O(d)$ , rather than  $O(d^2)$ . If we pick  $a_1, \dots, a_n$  from a hitting set generator with error  $\delta$  smaller than  $2^{-d}$ , we can afford to take a union bound over all vectors in  $\{0, 1\}^d$  and ensure that none of them is a solution to the linear system while keeping the total error small. This is not a big price to pay in terms of the seed length of the HSG, which is  $O(d \log n + \log(1/\delta))$ , so requiring  $\delta$  to be exponentially small in  $d$  adds an insignificant additive  $O(d)$  term. Where we do pay the price for the small error is in the field size, since the explicit construction of the HSG we use requires the field size to be at least roughly  $d/\delta$ . Fortunately, however, the dependence of the seed length of our generator on the field size  $q$  is also by an additive  $O(\log q)$  term, which means that once more requiring  $q$  to be exponentially large in  $d$  has no adverse effects even on the total seed length of the PRG.

We briefly remark that, for technical reasons, Lecerf’s result also requires the characteristic of the underlying field to be zero or at least  $d(d-1)+1$ . We further elaborate on Lecerf’s techniques in Section 4.

We finally mention another important technical point. Lecerf’s irreducibility characterization [21] assumes a technical condition on the polynomial, which he called Hypothesis (H) (see Section 3). Such a “preprocessing” step, which makes the polynomial monic in a certain distinguished variable, is common to many factorization algorithms, and can usually be easily guaranteed by applying a random linear transformation to the variables. However, doing this in the naïve way would require the use of too many random bits. To solve this problem, in Section 3 we show that this part can also be derandomized by using a hitting set generator for polynomials of degree  $O(d)$ . As explained in Section 3, this part also uses crucially indecomposability (rather than irreducibility) in a novel way.

## 2 Preliminaries

We now define the basic objects studied in this paper and introduce the fundamental mathematical concepts used.

### Notation

All logarithms are base 2. Denote by  $\mathbb{N}$  the set of natural numbers  $\{0, 1, 2, \dots\}$ . For  $n \in \mathbb{N}$ , define  $[n] = \{1, 2, \dots, n\}$ . For a finite set  $A$ , denote by  $\mathbf{U}_A$  the uniform distribution over  $A$ .

We often use symbols in bold, e.g.,  $\mathbf{a}$  or  $\mathbf{x}$ , as the shorthand for a vector  $(a_1, \dots, a_n)$  or a sequence of variables  $x_1, \dots, x_n$ .

Denote by  $\mathbb{F}_q$  the finite field of size  $q$ . The algebraic closure of a field  $\mathbb{F}$  is denoted by  $\overline{\mathbb{F}}$ . For a commutative ring  $A$  and variables  $x_1, \dots, x_n$ , we denote by  $A[[x_1, \dots, x_n]]$  or  $A[[\mathbf{x}]]$  the *ring of formal power series* over  $A$  in  $x_1, \dots, x_n$ , i.e.,

$$A[[\mathbf{x}]] = \left\{ \sum_{\mathbf{e}=(e_1, \dots, e_n) \in \mathbb{N}^n} a_{\mathbf{e}} x_1^{e_1} \cdots x_n^{e_n} : a_{\mathbf{e}} \in A \right\}.$$

### Pseudorandom Generators and Hitting Set Generators

► **Definition 2.1** (Pseudorandom generator, PRG). Let  $\mathbb{F}_q$  be a finite field. A *pseudorandom generator* (PRG) for  $n$ -variate polynomials of degree at most  $d$  over  $\mathbb{F}_q$  with error  $\varepsilon$  is an efficiently computable map  $G : S \rightarrow \mathbb{F}_q^n$  from a finite set  $S \neq \emptyset$  such that for every such polynomial  $f$  of degree at most  $d$ , the two distributions  $f(G(\mathbf{U}_S))$  and  $f(\mathbf{U}_{\mathbb{F}_q^n})$  are  $\varepsilon$ -close in statistical distance. That is,

$$\frac{1}{2} \sum_{a \in \mathbb{F}_q} \left| \Pr_{\mathbf{x} \in \mathbb{F}_q^n} [f(\mathbf{x}) = a] - \Pr_{\mathbf{y} \in S} [f(G(\mathbf{y})) = a] \right| \leq \varepsilon.$$

The quantity  $\log |S|$  is called the *seed length* of  $G$ .

A weaker object than a PRG is a *hitting set generator*. Here, we only require that a nonzero polynomial is nonzero (with high probability) on the output of the generator.

► **Definition 2.2** (Hitting set generator, HSG). Let  $\mathbb{F}$  be a field. A *hitting set generator* (HSG) with density  $1 - \delta$  for  $n$ -variate polynomials of degree at most  $d$  over  $\mathbb{F}$  is an efficiently computable map  $H : S \rightarrow \mathbb{F}^n$  from a finite set  $S \neq \emptyset$  such that for every such nonzero polynomial  $f$  of degree at most  $d$ ,

$$\Pr_{\mathbf{y} \in S} [f(H(\mathbf{y})) = 0] \leq \delta.$$

The quantity  $\log |S|$  is called the *seed length* of  $G$ .

Building on the earlier work [19, 23] and algebraic-geometric codes, Guruswami and Xing [16] constructed explicit HSGs for low-degree polynomials with asymptotically optimal seed length and density.

► **Theorem 2.3** ([16]). There exists an absolute constant  $C$  such that for any  $n, d, q, \delta$ , such that  $q \geq Cd/\delta$ , there exists an explicit HSG for  $n$ -variate polynomials of degree at most  $d$  over  $\mathbb{F}_q$  with density  $1 - \delta$  and seed length  $O(d \log n + \log(1/\delta))$ .

It should also be noted that for hitting set generators, the field  $\mathbb{F}$  does not have to be finite. This generality is used in the statement of the following fact, that an HSG for a field  $\mathbb{F}$  is also a HSG for any extension field  $\mathbb{K}$  of  $\mathbb{F}$ .

► **Fact 2.4** ([6, 12]). Let  $H : S \rightarrow \mathbb{F}$  be an HSG with density  $1 - \delta$  for polynomials of degree at most  $d$  over a field  $\mathbb{F}$ , and let  $\mathbb{K}$  be an extension of  $\mathbb{F}$ . Then  $H$  is also an HSG with density  $1 - \delta$  for polynomials of degree at most  $d$  over  $\mathbb{K}$ .

**Proof.** Let  $\mathcal{B}$  be a basis of  $\mathbb{K}$  over  $\mathbb{F}$ , and let  $f$  be a nonzero polynomial in  $\mathbb{K}[x_1, \dots, x_n]$  of degree at most  $d$ . By expressing every coefficient  $c \in \mathbb{K}$  of a monomial in  $f$  as a linear combination  $c = \sum_{b \in \mathcal{B}} a_b \cdot b$  with  $a_b \in \mathbb{F}$  for every  $b \in \mathcal{B}$ , we may write  $f = \sum_{b \in \mathcal{B}} f_b \cdot b$  such that  $f_b \in \mathbb{F}[x_1, \dots, x_n]$  is a polynomial of degree at most  $d$  for every  $b \in \mathcal{B}$ , and at least one  $f_b$  is nonzero. Thus, for any  $u \in S$ ,  $f(H(u)) = \sum_{b \in \mathcal{B}} f_b(u) \cdot b$  is nonzero unless  $f_b(H(u)) = 0$  for every  $b$ , which happens with probability at most  $\delta$  over the choice of  $u \in S$ . ◀

### Indecomposable Polynomials

The *indecomposability* of a polynomial is crucially used in the analysis of the PRG construction in [12] as well as in our analysis. We first define this property.

► **Definition 2.5** (Indecomposability). Let  $f \in \mathbb{F}[\mathbf{x}]$  be a non-constant polynomial over a field  $\mathbb{F}$ . It is said to be *decomposable* over  $\mathbb{F}$  if there exist  $h \in \mathbb{F}[\mathbf{x}]$  and a univariate polynomial  $g \in \mathbb{F}[y]$  such that  $\deg(g) \geq 2$  and  $f = g(h)$ . Otherwise,  $f$  is said to be *indecomposable* over  $\mathbb{F}$ .

Obviously, if a polynomial  $f \in \mathbb{F}_q[\mathbf{x}]$  over a finite field  $\mathbb{F}_q$  is indecomposable over  $\overline{\mathbb{F}}_q$ , then it is also indecomposable over  $\mathbb{F}_q$ . The following lemma, which was proved in [3] and generalized in [5], states that the converse is also true.

► **Lemma 2.6** ([3]; see also [5, Theorem 4.2]). A polynomial  $f \in \mathbb{F}_q[\mathbf{x}]$  that is indecomposable over  $\mathbb{F}_q$  is also indecomposable over  $\overline{\mathbb{F}}_q$ .

In [12], Derksen and Viola proved the following result, which states that if a polynomial is indecomposable, then its outputs are equidistributed.

► **Lemma 2.7** ([12, Lemma 12]). There exists an absolute constant  $C > 0$  such that the following holds: Suppose  $f \in \mathbb{F}_q[\mathbf{x}] = \mathbb{F}_q[x_1, \dots, x_n]$  is indecomposable over  $\mathbb{F}_q$ . Then  $f(\mathbf{U}_{\mathbb{F}_q^n})$  is  $\varepsilon$ -close to  $\mathbf{U}_{\mathbb{F}_q}$ , where  $\varepsilon = Cd^2/\sqrt{q}$ .

The proof of Lemma 2.7 is based on the observation that the indecomposability of  $f$  precisely captures the property that for most  $b \in \mathbb{F}_q$ , the variety  $f^{-1}(b)$ , defined by the constraint  $f(\mathbf{x}) = b$ , is *absolutely irreducible*. This condition of absolute irreducibility is required by the *Weil bound* [36]. Consequently, one can apply the Weil bound to show that for most  $b$ , the number of points in  $f^{-1}(b) \cap \mathbb{F}_q^n$  is close to  $q^{n-1}$ , thereby proving the equidistribution of the output of  $f$ . For details, we refer the reader to [12].

Finally, the following lemma connects indecomposability with irreducibility over algebraically closed fields. It is explicitly stated in, e.g., [9].

► **Lemma 2.8** ([9, Lemma 7]). Let  $f \in \mathbb{F}[\mathbf{x}]$  be a non-constant polynomial over a field  $\mathbb{F}$ . Then  $f$  is indecomposable over  $\overline{\mathbb{F}}$  iff  $f - t$  is irreducible over  $\overline{\mathbb{F}(t)}$ , where  $t$  is a new variable.

**Resultants**

Let  $f(y) = \sum_{i=0}^{d_1} a_i y^i$  and  $g(y) = \sum_{i=0}^{d_2} b_i y^i$  be two univariate polynomials in  $y$  over a field  $\mathbb{F}$  and suppose that  $d_1 + d_2 > 0$ . The *Sylvester Matrix* of  $f$  and  $g$  is the  $(d_1 + d_2) \times (d_1 + d_2)$  matrix

$$\begin{pmatrix} a_0 & & & & b_0 & & & & & \\ a_1 & a_0 & & & b_1 & b_0 & & & & \\ a_2 & a_1 & \ddots & & b_2 & b_1 & \ddots & & & \\ \vdots & & \ddots & a_0 & \vdots & & \ddots & & & b_0 \\ & \vdots & & a_1 & b_{d_2} & \vdots & & & & b_1 \\ a_{d_1} & & & & & b_{d_2} & & & & \\ & a_{d_1} & & \vdots & & & & & & \vdots \\ & & \ddots & & & & \ddots & & & \\ & & & a_{d_1} & & & & & & b_{d_2} \end{pmatrix}.$$

The determinant of this matrix is called the *resultant* of  $f$  and  $g$ , and is denoted  $\text{Res}(f, g)$ . It holds that  $f$  and  $g$  have a common factor if and only if  $\text{Res}(f, g) = 0$  ([11, Proposition 3 in Chapter 3, Section 6]).

Thus, in the case where  $g = \frac{\partial f}{\partial y}$ , it holds that  $\text{Res}(f, g) \neq 0$  if and only if  $f$  does not have a root of multiplicity greater than one.

### Hensel Lifting

Hensel lifting is a general technique for “lifting” roots or factorizations of a polynomial modulo an ideal  $I$  of a ring  $R$  to those modulo powers of  $I$ , under some mild conditions. The use of Hensel’s lifting lemma is standard in multivariate factorization algorithms, and it is available in various forms. We state one standard form, which can be derived from [13, Theorem 7.3] as a special case. This form is particularly relevant to our discussion of Lecerf’s techniques in Section 4.

► **Lemma 2.9** (Hensel’s lifting lemma). Let  $f \in \mathbb{F}[x_1, \dots, x_n, y] = \mathbb{F}[\mathbf{x}, y]$  be a nonzero polynomial over a field  $\mathbb{F}$ . Suppose  $\bar{\lambda} \in \mathbb{F}$  is a simple root of  $f(\mathbf{0}, y) \in \mathbb{F}[y]$ . Then there exists unique  $\lambda \in \mathbb{F}[[\mathbf{x}]]$  such that

1.  $f(\mathbf{x}, \lambda) = 0$ , i.e.,  $\lambda$  is a root of  $f$  as a univariate polynomial in  $y$  over  $\mathbb{F}[[\mathbf{x}]]$ , and
2.  $\lambda(\mathbf{0}) = \bar{\lambda}$ .

## 3 Hypothesis (H)

Lecerf’s papers [20, 21] on multivariate polynomial factoring assume a hypothesis about the polynomial  $f$ , which he calls Hypothesis (H). Such a hypothesis can be satisfied with high probability by applying a random linear transformation on the variables.

In this section, we discuss Lecerf’s Hypothesis (H) and show that, for our purpose, the random linear transformation can be derandomized by using a HSG for polynomials of degree  $O(d)$ . The fact that we are interested in the irreducibility of  $f - t$  for an indeterminate  $t$ , rather than that of  $f$ , is crucial in keeping the degree linear in  $d$ .

Let  $\mathbb{F}$  be a field. First, we define Hypothesis (H).

► **Definition 3.1** (Hypothesis (H) [20, 21]). Let  $f \in \mathbb{F}[x_1, \dots, x_n, y] = \mathbb{F}[\mathbf{x}, y]$  be a non-constant polynomial. We say  $f$  satisfies *Hypothesis (H)* if

1.  $f$  is monic in  $y$  and  $\deg_y(f) = \deg(f)$ ,
2.  $\text{Res}\left(f(\mathbf{0}, y), \frac{\partial f}{\partial y}(\mathbf{0}, y)\right) \neq 0$ .

We also need a family of invertible linear transformations defined as follows.

► **Definition 3.2.** For  $\mathbf{a} = (a_1, \dots, a_n) \in \mathbb{F}^n$ , let  $s_{\mathbf{a}}$  be the  $\mathbb{F}$ -linear automorphism of  $\mathbb{F}[\mathbf{x}, y]$  that fixes  $y$  and sends  $x_i$  to  $x_i + a_i y$ .

► **Lemma 3.3.** Let  $f \in \mathbb{F}[\mathbf{x}, y]$  be a nonzero polynomial of degree at most  $d$ . Then there exists a nonzero polynomial  $B \in \mathbb{F}[\mathbf{x}]$  of degree at most  $d$  such that for every  $\mathbf{a} \in \mathbb{F}^n$  satisfying  $B(\mathbf{a}) \neq 0$ , it holds that  $\deg_y(s_{\mathbf{a}}(f)) = d$  and the coefficient of  $y^d$  in  $s_{\mathbf{a}}(f)$  is in  $\mathbb{F}^\times$ .

**Proof.** Let  $f_d$  be the degree- $d$  homogeneous part of  $f$ , so that we can write  $f = f_d + g$  where  $g = f - f_d$  has degree less than  $d$ . Write  $f_d = \sum_{i=0}^d c_i(\mathbf{x})y^i$ , where each  $c_i \in \mathbb{F}[\mathbf{x}]$  is either zero or a homogeneous polynomial of degree  $d - i$ .

Consider  $\mathbf{a} \in \mathbb{F}^n$ . Note that

$$s_{\mathbf{a}}(f) = s_{\mathbf{a}}(f_d) + s_{\mathbf{a}}(g) = \sum_{i=0}^d s_{\mathbf{a}}(c_i(\mathbf{x}))y^i + s_{\mathbf{a}}(g) = \sum_{i=0}^d c_i(\mathbf{x} + y \cdot \mathbf{a})y^i + g(\mathbf{x} + y \cdot \mathbf{a}, y).$$

As  $\deg(g) < d$  and each  $c_i$  is either zero or homogeneous of degree  $d - i$ , we have that  $\deg_y s_{\mathbf{a}}(f) \leq d$ , and that the coefficient of  $y^d$  in  $s_{\mathbf{a}}(f)$  is  $\sum_{i=0}^d c_i(\mathbf{a}) \in \mathbb{F}$ . So we may choose  $B = \sum_{i=0}^d c_i$ , which is a nonzero polynomial of degree at most  $d$ .  $\blacktriangleleft$

► **Lemma 3.4.** Assume  $f \in \mathbb{F}[\mathbf{x}, y]$  is a polynomial of degree  $d \geq 1$  that satisfies Item 1 of Hypothesis (H). Further assume that  $\text{char}(\mathbb{F})$  is either zero or greater than  $d$ . Let  $c \in \mathbb{F}^\times$ . Then  $f + ct$  is a degree- $d$  polynomial satisfying Hypothesis (H) as a polynomial over  $\mathbb{F}(t)$ .

**Proof.** As  $f$  satisfies Item 1 of Hypothesis (H) and has degree  $d \geq 1$ , so does  $f + ct$ . So it suffices to verify Item 2. Write  $f = \sum_{i=0}^d c_i y^i$ , where  $c_i \in \mathbb{F}[\mathbf{x}]$  and  $c_d = 1$ . Then  $\frac{\partial(f+ct)}{\partial y} = \sum_{i=1}^d (i \cdot c_i) y^{i-1}$ , which has degree  $d - 1$  in  $y$  since  $d \cdot c_d = d \neq 0$  by the assumption about  $\text{char}(\mathbb{F})$ .

Let  $\bar{c}_i = c_i(\mathbf{0})$  for  $i = 0, 1, \dots, d$ . Let  $h = \text{Res}\left((f + ct)(\mathbf{0}, y), \frac{\partial(f+ct)}{\partial y}(\mathbf{0}, y)\right)$ . Then  $h$  is the determinant of the following  $(2d - 1) \times (2d - 1)$  matrix:

$$\begin{pmatrix} \bar{c}_0 + ct & 0 & \cdots & 0 & \bar{c}_1 & 0 & \cdots & 0 \\ \bar{c}_1 & \bar{c}_0 + ct & \cdots & 0 & 2\bar{c}_2 & \bar{c}_1 & \cdots & 0 \\ \bar{c}_2 & \bar{c}_1 & \ddots & 0 & 3\bar{c}_3 & 2\bar{c}_2 & \ddots & 0 \\ \vdots & \vdots & \ddots & \bar{c}_0 + ct & \vdots & \vdots & \ddots & \bar{c}_1 \\ \bar{c}_d & \bar{c}_{d-1} & \cdots & \vdots & d\bar{c}_d & (d-1)\bar{c}_{d-1} & \cdots & \vdots \\ 0 & \bar{c}_d & \ddots & \vdots & 0 & d\bar{c}_d & \ddots & \vdots \\ \vdots & \vdots & \ddots & \bar{c}_{d-1} & \vdots & \vdots & \ddots & (d-1)\bar{c}_{d-1} \\ 0 & 0 & \cdots & \bar{c}_d & 0 & 0 & \cdots & d\bar{c}_d \end{pmatrix}.$$

Observe that  $\deg_t h \leq d - 1$ , and that the coefficient of  $t^{d-1}$  in  $h$  is  $c^{d-1}(d\bar{c}_d)^d = c^{d-1}d^d \neq 0$  since only those entries on the diagonal contribute to this coefficient. This implies that  $h \neq 0$ , i.e.,  $f + ct$  satisfies Item 2 of Hypothesis (H).  $\blacktriangleleft$

► **Corollary 3.5.** Assume that  $f \in \mathbb{F}[\mathbf{x}, y]$  is a polynomial of degree  $d \geq 1$  and that  $\text{char}(\mathbb{F})$  is either zero or greater than  $d$ . Then there exists a nonzero polynomial  $B \in \mathbb{F}[\mathbf{x}]$  of degree at most  $d$  such that for every  $\mathbf{a} \in \mathbb{F}^n$  satisfying  $B(\mathbf{a}) \neq 0$ ,  $s_{\mathbf{a}}(f) - t$  equals a product  $c \cdot g$  where  $c \in \mathbb{F}^\times$  and  $g \in \mathbb{F}(t)[\mathbf{x}, y]$  is a degree- $d$  polynomial satisfying Hypothesis (H).

**Proof.** Let  $B$  be as in Lemma 3.3. Consider  $\mathbf{a} \in \mathbb{F}^n$  satisfying  $B(\mathbf{a}) \neq 0$ . By Lemma 3.3, we may write  $s_{\mathbf{a}}(f) = c \cdot \tilde{g}$  where  $c \in \mathbb{F}^\times$  and  $\tilde{g}$  satisfies Item 1 of Hypothesis (H). Then  $s_{\mathbf{a}}(f) - t = c \cdot \tilde{g} - t = c \cdot g$  where  $g = \tilde{g} - c^{-1}t$ . By Lemma 3.4,  $g$  is a degree- $d$  polynomial satisfying Hypothesis (H).  $\blacktriangleleft$

Thus, by choosing good  $\mathbf{a} \in \mathbb{F}$  via an explicit HSG for polynomials of degree at most  $d$  and performing the transformation  $f \mapsto s_{\mathbf{a}}(f)$ , we may assume  $f - t$  satisfies Hypothesis (H).

### Satisfying Hypothesis (H) in Small Characteristics

While our final result needs  $\text{char}(\mathbb{F}) > d(d - 1)$ , the assumption that  $\text{char}(\mathbb{F})$  is zero or large enough is not crucial for the sake of satisfying Hypothesis (H). We now sketch how to modify the proof of Lemma 3.4 when  $0 < \text{char}(\mathbb{F}) \leq d$ .

Let  $p = \text{char}(\mathbb{F}) > 0$ . For our purpose, we may assume  $\mathbb{F}$  is a perfect field and  $f$  is indecomposable over  $\mathbb{F}$ . This implies that  $f \notin \mathbb{F}[x_1^p, \dots, x_n^p, y^p]$ . Then it is not hard to show that there exists an integer  $e > 0$  coprime to  $p$  such that for random  $\mathbf{a} \in \mathbb{F}^n$ , with high

## 44:10 Optimal PRGs for Low-Degree Polynomials over Large Fields

probability, not only is the coefficient of  $y^d$  in  $s_{\mathbf{a}}(f)$  nonzero, but so is the coefficient of  $y^e$ . Choose the largest  $e$  that has this property. After replacing  $f$  by  $s_{\mathbf{a}}(f)$ , the polynomial  $\frac{\partial f + ct}{\partial y}$  in the proof of Lemma 3.4 would have degree  $e - 1$  instead of  $d - 1$  in  $y$ . Then  $\deg_t(h) = e - 1$  and the coefficient of  $t^{e-1}$  in  $h$  is  $c^{e-1}(e\bar{c}_e)^d$ , which is nonzero iff  $\bar{c}_e = c_e(\mathbf{0})$  is nonzero. The latter condition can be guaranteed with high probability by performing the substitutions  $x_i \mapsto x_i + b_i$  for random  $\mathbf{b} = (b_1, \dots, b_n) \in \mathbb{F}^n$ . Finally, it is not difficult to show that the choices of  $\mathbf{a}$  and  $\mathbf{b}$  can be derandomized by using an explicit HSG for polynomials of degree  $O(d)$ .

### 4 Lecerf's Techniques

We describe Lecerf's techniques in this section. For simplicity, our discussion is restricted to the special case where the base field is algebraically closed.

Let  $\mathbb{K}$  be an algebraically closed field, and let  $f \in \mathbb{K}[\mathbf{x}, y]$  be a polynomial of degree  $d \geq 1$  satisfying Hypothesis (H). Define  $\bar{f} := f(\mathbf{0}, y) \in \mathbb{K}[y]$ . As  $\mathbb{K}$  is algebraically closed and  $\text{Res}\left(f(\mathbf{0}, y), \frac{\partial f}{\partial y}(\mathbf{0}, y)\right) \neq 0$ , the univariate polynomial  $\bar{f}$  factorizes into distinct linear factors

$$\bar{f} = \prod_{i=1}^d (y - \bar{\lambda}_i)$$

where  $\bar{\lambda}_i \in \mathbb{K}$  for  $i \in [d]$ . By Hensel's lifting lemma, the above factorization of  $\bar{f}$  over  $\mathbb{K}$  lifts to a factorization of  $f$  into distinct linear factors

$$f = \prod_{i=1}^d (y - \lambda_i),$$

where  $\lambda_i \in \mathbb{K}[[\mathbf{x}]]$  and  $\lambda_i(\mathbf{0}) = \bar{\lambda}_i$  for  $i \in [d]$ .

Now we introduce new variables  $\mathbf{z} = (z_1, \dots, z_n)$  and  $x$ , and define  $g := f(z_1x, \dots, z_nx, y) \in \mathbb{K}[\mathbf{z}, x, y]$ . Then  $g$  factorizes into linear factors

$$g = \prod_{i=1}^d (y - \lambda_i(z_1x, \dots, z_nx))$$

where each  $\lambda_i(z_1x, \dots, z_nx)$  lives in  $\mathbb{K}[\mathbf{z}][[x]]$ . For  $i \in [d]$ , let  $g_i$  be the factor  $y - \lambda_i(z_1x, \dots, z_nx)$  of  $g$ , and let  $\hat{g}_i$  be its cofactor  $\prod_{j \in [d] \setminus \{i\}} g_j$ . So  $g_i, \hat{g}_i \in \mathbb{K}[\mathbf{z}][[x]][y]$ .

For  $h \in A[[x]][y]$  over a commutative ring  $A$  and  $(j, k) \in \mathbb{N}^2$ , denote by  $\text{coeff}(h, x^j y^k) \in A$  the coefficient of  $x^j y^k$  in  $h$ . We are now ready to define the linear system  $D_{\mathbf{z}, \sigma}$  used in [20, 21].

► **Definition 4.1** (Linear system  $D_{\mathbf{z}, \sigma}$  [20, 21]). Let  $\sigma \in \mathbb{N}$ . Define  $D_{\mathbf{z}, \sigma}$  to be the following linear system over  $\mathbb{K}(\mathbf{z})$  in the unknowns  $\ell_1, \dots, \ell_d$ :

$$D_{\mathbf{z}, \sigma} \begin{cases} \sum_{i=1}^d \text{coeff}\left(\hat{g}_i \frac{\partial g_i}{\partial y}, x^j y^k\right) \cdot \ell_i = 0, & k \leq d-1, d \leq j+k \leq \sigma-1, \\ \sum_{i=1}^d \text{coeff}\left(\hat{g}_i \frac{\partial g_i}{\partial x}, x^j y^k\right) \cdot \ell_i = 0, & k \leq d-1, j \leq \sigma-2, d \leq j+k \leq \sigma-1. \end{cases}$$

We have the following easy lemma.

► **Lemma 4.2.** For  $(j, k) \in \mathbb{N}^2$ ,  $\text{coeff}\left(\hat{g}_i \frac{\partial g_i}{\partial x}, x^j y^k\right)$ ,  $\text{coeff}\left(\hat{g}_i \frac{\partial g_i}{\partial y}, x^j y^k\right) \in \mathbb{K}[\mathbf{z}]$  are polynomials of degree at most  $j + 1$  and  $j$  respectively.

**Proof.** Consider arbitrary  $i \in [d]$  and  $(j, k) \in \mathbb{N}^2$ . As  $g_i = y - \lambda_i(z_1 x, \dots, z_n x)$  and  $j \geq 0$ , only terms of degree at most  $j$  in  $z_1, \dots, z_n$  contribute to the coefficient of  $x^j y^k$  in  $g_i$ . Then, as the operator  $\frac{\partial}{\partial x}$  is linear and sends  $x^u y^v$  to  $u x^{u-1} y^v$  for all  $u, v \in \mathbb{N}$ , one can see that only terms of degree at most  $j + 1$  in  $z_1, \dots, z_n$  contribute to the coefficient of  $x^j y^k$  in  $\frac{\partial g_i}{\partial x}$ . Also,  $\frac{\partial g_i}{\partial y} = 1$  by definition.

For any  $h_1, \dots, h_s \in \mathbb{K}[\mathbf{z}][[x]][y]$  and  $h = \prod_{i=1}^s h_i$ , we have

$$\text{coeff}(h, x^j y^k) = \sum_{\substack{j_1, \dots, j_s, k_1, \dots, k_s \in \mathbb{N} \\ \sum_i j_i = j, \sum_i k_i = k}} \prod_{i=1}^s \text{coeff}(h_i, x^{j_i} y^{k_i}). \quad (1)$$

We already know  $\deg(\text{coeff}(g_i, x^j y^k)) \leq j$ ,  $\deg(\text{coeff}(\frac{\partial g_i}{\partial x}, x^j y^k)) \leq j + 1$ , and  $\deg(\text{coeff}(\frac{\partial g_i}{\partial y}, x^j y^k)) = 0$  for  $i \in [d]$  and  $(j, k) \in \mathbb{N}^2$  by the above discussion. Choosing  $(h_1, \dots, h_s)$  to be  $(g_1, \dots, g_{i-1}, g_{i+1}, \dots, g_d, \frac{\partial g_i}{\partial x})$  and  $(g_1, \dots, g_{i-1}, g_{i+1}, \dots, g_d, \frac{\partial g_i}{\partial y})$  respectively and applying (1) proves the claim. ◀

For  $\mathbf{a} = (a_1, \dots, a_n) \in \mathbb{K}^n$ , we can assign  $a_1, \dots, a_n$  to  $z_1, \dots, z_n$  respectively in the polynomials  $\text{coeff}(\hat{g}_i \frac{\partial g_i}{\partial x}, x^j y^k)$ ,  $\text{coeff}(\hat{g}_i \frac{\partial g_i}{\partial y}, x^j y^k) \in \mathbb{K}[\mathbf{z}]$ . This yields a linear system over  $\mathbb{K}$ , called the *specialization* of  $D_{\mathbf{z}, \sigma}$  at  $\mathbf{a}$  and denoted by  $D_{\mathbf{a}, \sigma}$ .

► **Definition 4.3 (Specialization).** For  $\sigma \in \mathbb{N}$  and  $\mathbf{a} = (a_1, \dots, a_n) \in \mathbb{K}^n$ , define  $D_{\mathbf{a}, \sigma}$  to be the following linear system over  $\mathbb{K}$  in the unknowns  $\ell_1, \dots, \ell_d$ :

$$D_{\mathbf{a}, \sigma} \begin{cases} \sum_{i=1}^d \text{coeff}\left(\hat{g}_i \frac{\partial g_i}{\partial y}, x^j y^k\right)(\mathbf{a}) \cdot \ell_i = 0, & k \leq d - 1, d \leq j + k \leq \sigma - 1, \\ \sum_{i=1}^d \text{coeff}\left(\hat{g}_i \frac{\partial g_i}{\partial x}, x^j y^k\right)(\mathbf{a}) \cdot \ell_i = 0, & k \leq d - 1, j \leq \sigma - 2, d \leq j + k \leq \sigma - 1. \end{cases}$$

For  $S \subseteq [d]$ , define  $\delta_S = (\delta_{S,1}, \dots, \delta_{S,d}) \in \mathbb{K}^d$  by

$$\delta_{S,i} = \begin{cases} 1 & i \in S, \\ 0 & i \notin S. \end{cases}$$

For every factor  $\tilde{f}$  of  $f$ , we may associate a set  $S \subseteq [d]$  such that  $\tilde{f} = \prod_{i \in S} (y - \lambda_i)$ , i.e.,  $S$  is the set of indices  $i \in [d]$  such that  $y - \lambda_i$  divides  $\tilde{f}$ . The irreducible factors  $f_1, \dots, f_r$  of  $f$  over  $\mathbb{K}$  are then associated with sets  $S_1, \dots, S_r \subseteq [d]$ , which form a partition of  $[d]$ . In [20, 21], Lecerf proved that, when  $\sigma$  is large enough, the solution space of  $D_{\mathbf{z}, \sigma}$  is exactly spanned by the vectors  $\delta_{S_1}, \dots, \delta_{S_r}$ , and a similar statement holds for the specializations  $D_{\mathbf{a}, \sigma}$ . We state Lecerf's results formally as the following theorem.

► **Theorem 4.4** ([20, 21]). Assume  $\text{char}(\mathbb{K})$  is zero or greater than  $d(d - 1)$ . Let  $\sigma \geq 2d$ . Let  $f \in \mathbb{K}[\mathbf{x}, y]$  be a polynomial of degree  $d \geq 1$  satisfying Hypothesis (H). Then:

1. Suppose  $f = \prod_{i=1}^r f_i$  is the factorization of  $f$  into its irreducible factors over  $\mathbb{K}$ . For  $i \in [r]$ , let  $S_i$  be the set of indices  $j \in [d]$  such that  $y - \lambda_j$  divides  $f_i$ . Then  $\delta_{S_1}, \dots, \delta_{S_r}$  form a basis of the solution space of  $D_{\mathbf{z}, \sigma}$ .

## 44:12 Optimal PRGs for Low-Degree Polynomials over Large Fields

2. Let  $\mathbf{a} = (a_1, \dots, a_n) \in \mathbb{K}^n$  and  $f_{\mathbf{a}} = f(a_1x, \dots, a_nx, y) \in \mathbb{K}[x, y]$ . Suppose  $f_{\mathbf{a}} = \prod_{i=1}^s f_{\mathbf{a},i}$  is the factorization of  $f_{\mathbf{a}}$  into its irreducible factors over  $\mathbb{K}$ . For  $i \in [s]$ , let  $S_{\mathbf{a},i}$  be the set of indices  $j \in [d]$  such that  $y - \lambda_j(a_1x, \dots, a_nx)$  divides  $f_{\mathbf{a},i}$ . Then  $\delta_{S_{\mathbf{a},1}}, \dots, \delta_{S_{\mathbf{a},s}}$  form a basis of the solution space of  $D_{\mathbf{a},\sigma}$ .

The first item of Theorem 4.4 is explicitly stated as [21, Lemma 1]. The second item follows from [20, Theorem 1 and Lemma 4]. For a detailed analysis of the linear systems  $D_{\mathbf{z},\sigma}$  and  $D_{\mathbf{a},\sigma}$ , and for a conceptual interpretation of these linear systems in terms of the closedness condition of differential 1-forms, we refer the reader to [20, 21], as well as to the earlier paper of Gao [15].

### Bertinian Good/Bad Points

The classical Bertini irreducibility theorem [30] states, among other things, that over an algebraically closed field  $\mathbb{K}$ , the intersection of an irreducible affine variety of codimension one (i.e., a hypersurface) with a plane in general position is still irreducible. This motivates the following definition:

► **Definition 4.5** (Bertinian good/bad points [21]). Let  $f \in \mathbb{K}[\mathbf{x}, y]$  be a non-constant polynomial satisfying Hypothesis (H). We say  $\mathbf{a} = (a_1, \dots, a_n) \in \mathbb{K}^n$  is a *Bertinian good point* for  $f$  if for every irreducible factor  $\tilde{f}$  of  $f$  over  $\mathbb{K}$ , the bivariate polynomial  $\tilde{f}_{\mathbf{a}} = \tilde{f}(a_1x, \dots, a_nx, y)$  is also irreducible over  $\mathbb{K}$ . We say  $\mathbf{a} = (a_1, \dots, a_n) \in \mathbb{K}^n$  is a *Bertinian bad point* for  $f$  if it is not a Bertinian good point for  $f$ .

Lecerf [21, Theorem 6] proved that given  $f$ , there exists a nonzero polynomial  $Q \in \mathbb{K}[z_1, \dots, z_n]$  of degree at most  $(d-1)(2d-1)$  that vanishes at all Bertinian bad points for  $f$ , where  $d = \deg(f)$ . Let  $M$  be the matrix representing the linear system  $D_{\mathbf{z},\sigma}$ . Lecerf's proof can be sketched as follows: By Theorem 4.4, the solution space of  $D_{\mathbf{a},\sigma}$  contains that of  $D_{\mathbf{z},\sigma}$ , and  $\mathbf{a}$  is Bertinian good as long as the two are equal. Thus, we may choose  $Q$  to be the determinant of the largest nonsingular submatrix of  $M$ . This is because for such  $Q$ , if  $Q$  does not vanish at  $\mathbf{a}$ , then  $D_{\mathbf{z},\sigma}$  and  $D_{\mathbf{a},\sigma}$  have the same rank, and hence their solution spaces must be equal. The bound  $(d-1)(2d-1)$  on the degree of  $Q$  follows from Lemma 4.2.

In [21], Lecerf also demonstrated that the degree bound  $(d-1)(2d-1)$  is asymptotically tight by providing an example for which a degree of  $\Omega(d^2)$  of the polynomial  $Q$  is necessary. However, our next lemma states that, perhaps surprisingly, the degree bound can be improved to  $2d-1$  if we allow the use of the zero loci of *multiple* polynomials to cover the Bertinian bad points for  $f$ . For simplicity, we state the lemma in the special case where  $f$  is irreducible, which suffices for our purpose.

► **Lemma 4.6.** Assume  $\text{char}(\mathbb{K})$  is zero or greater than  $d(d-1)$ . Let  $f \in \mathbb{K}[\mathbf{x}, y]$  be an irreducible polynomial over  $\mathbb{K}$  of degree  $d \geq 1$  satisfying Hypothesis (H). Let  $m = 2^{d-1} - 1$ . Then there exist nonzero polynomials  $Q_1, \dots, Q_m \in \mathbb{K}[\mathbf{z}] = \mathbb{K}[z_1, \dots, z_n]$  of degree at most  $2d-1$  such that for every Bertinian bad point  $\mathbf{a} \in \mathbb{K}^n$  for  $f$ , at least one polynomial  $Q_i$  vanishes at  $\mathbf{a}$ .

**Proof.** Let  $\sigma = 2d$ . Let  $N$  be the number of equations in  $D_{\mathbf{z},\sigma}$ . Let  $M$  be the  $N \times d$  matrix over  $\mathbb{F}(\mathbf{z})$  representing the linear system  $D_{\mathbf{z},\sigma}$ . Note that by Definition 4.1, the entries of  $M$  are of the form  $\text{coeff}\left(\hat{g}_i \frac{\partial g_i}{\partial x}, x^j y^k\right)$  with  $j \leq \sigma - 2$  or  $\text{coeff}\left(\hat{g}_i \frac{\partial g_i}{\partial y}, x^j y^k\right)$  with  $j \leq \sigma - 1$ . By Lemma 4.2 and the fact that  $\sigma = 2d$ , the entries of  $M$  are polynomials in  $\mathbb{K}[\mathbf{z}]$  of degree at most  $2d-1$ .

There are exactly  $m = 2^{d-1} - 1$  proper subsets of  $[d]$  containing 1. Let  $S_1, \dots, S_m$  be an enumeration of them. Consider  $i \in [m]$ . As  $f$  is irreducible, by Theorem 4.4,  $\delta_{S_i}$  is not in the solution space of  $D_{\mathbf{z}, \sigma}$ . So we can fix a row  $\mathbf{r}_i = (r_{i,1}, \dots, r_{i,d})$  of  $M$  such that the inner product of  $\mathbf{r}_i$  and  $\delta_{S_i}$  is nonzero, i.e.,  $\sum_{j=1}^d r_{i,j} \delta_{S_i,j} \neq 0$ . Let  $Q_i = \sum_{j=1}^d r_{i,j} \delta_{S_i,j}$ , which is a nonzero polynomial in  $\mathbb{K}[\mathbf{z}]$  of degree at most  $2d - 1$ . Choose  $Q_i$  in this way for each  $i = 1, \dots, m$ .

Now let  $\mathbf{a}$  be a Bertinian bad point for  $f$ . Then  $f_{\mathbf{a}} = f(a_1x, \dots, a_nx, y)$  factorizes into more than one irreducible factor over  $\mathbb{K}$ . Let  $\tilde{f}_{\mathbf{a}}$  be the irreducible factor of  $f_{\mathbf{a}}$  divisible by  $y - \lambda_1(a_1x, \dots, a_nx)$ . Let  $S$  be the set of  $j \in [d]$  such that  $\tilde{f}_{\mathbf{a}}$  is divisible by  $y - \lambda_j(a_1x, \dots, a_nx)$ . Then  $S$  is a proper subset of  $[d]$  containing 1. So  $S = S_i$  for some  $i \in [m]$ . By Theorem 4.4,  $\delta_{S_i}$  is in the solution space of  $D_{\mathbf{a}, \sigma}$ . As  $D_{\mathbf{a}, \sigma}$  is the specialization of  $D_{\mathbf{z}, \sigma}$  at  $\mathbf{a}$ , the vector  $(r_{i,1}(\mathbf{a}), \dots, r_{i,d}(\mathbf{a}))$  is a row of the matrix representing  $D_{\mathbf{a}, \sigma}$ . So  $\sum_{j=1}^d r_{i,j}(\mathbf{a}) \delta_{S_i,j} = 0$ , i.e.,  $Q_i(\mathbf{a}) = 0$ . ◀

### The Number of Low-Degree Polynomials Needed

It is an intriguing mathematical question to us how many low-degree polynomials are needed to cover the Bertinian bad points for  $f$ . We now formalize this question.

▶ **Definition 4.7.** Let  $\mathbb{K}$  be an algebraically closed field. For positive integers  $d$  and  $D$ , define  $N(d, D, \mathbb{K})$  to be the smallest  $N \in \mathbb{N}$  such that the following holds: Let  $f \in \mathbb{K}[\mathbf{x}, y]$  be an irreducible polynomial of degree at most  $d$  over  $\mathbb{K}$  satisfying Hypothesis (H). Then there exist  $N$  nonzero polynomials in  $\mathbb{K}[\mathbf{z}]$  of degree at most  $D$  such that the union of the zero loci of these polynomials contains all Bertinian bad points for  $f$  in  $\mathbb{K}^n$ .

If such  $N$  does not exist, define  $N(d, D, \mathbb{K}) = \infty$ .

In our application, it suffices to consider polynomials of the special form  $f + c \cdot t$ , where  $c \in \mathbb{F}^\times$ ,  $f \in \mathbb{F}[\mathbf{x}, y]$  and  $\mathbb{K} = \overline{\mathbb{F}(t)}$ . Moreover, by performing a variable substitution  $t \mapsto -c^{-1}t$ , we may assume  $c = -1$ . This motivates us to introduce the following variant of Definition 4.7:

▶ **Definition 4.8.** Let  $\mathbb{F}$  be a field. For positive integers  $d$  and  $D$ , define  $N^*(d, D, \mathbb{F})$  to be the smallest  $N \in \mathbb{N}$  such that the following holds: Let  $f \in \mathbb{F}[\mathbf{x}, y]$  be a polynomial of degree at most  $d$  such that  $f - t$  is an irreducible polynomial over  $\overline{\mathbb{F}(t)}$  satisfying Hypothesis (H). Then there exist  $N$  nonzero polynomials in  $\overline{\mathbb{F}(t)}[\mathbf{z}]$  of degree at most  $D$  such that the union of the zero loci of these polynomials contains all Bertinian bad points for  $f - t$  in  $\overline{\mathbb{F}^n}$ .

If such  $N$  does not exist, define  $N^*(d, D, \mathbb{F}) = \infty$ .

Lecerf's result [21, Theorem 6] can be interpreted as the statement that when  $\text{char}(\mathbb{K})$  is zero or greater than  $d(d - 1)$ , it holds that

$$N(d, D, \mathbb{K}) = 1 \text{ for } D \geq (d - 1)(2d - 1).$$

Our Lemma 4.6 states that under the same condition, we have

$$N(d, D, \mathbb{K}) \leq 2^{d-1} - 1 \text{ for } D \geq 2d - 1.$$

In [21], Lecerf gave an example showing that the degree bound  $O(d^2)$  for the smallest  $D$  satisfying  $N(d, D, \mathbb{K}) = 1$  is asymptotically tight.<sup>2</sup> As one can always combine the  $N(d, D, \mathbb{K})$  polynomials of degree at most  $D$  into a single polynomial of degree at most  $N(d, D, \mathbb{K}) \cdot D$  by taking their product, this implies  $N(d, D, \mathbb{K}) \cdot D = \Omega(d^2)$ , i.e.,  $N(d, D, \mathbb{K}) = \Omega(d^2/D)$ .

<sup>2</sup> See the example before Theorem 6 in [21].

► **Question 4.9.** Give improved upper bounds (or lower bounds) on  $N(d, D, \mathbb{K})$  and  $N^*(d, D, \mathbb{F})$ , at least when the characteristic of  $\mathbb{K}$  or  $\mathbb{F}$  is zero or large enough.

By definition,  $N^*(d, D, \mathbb{F}) \leq N(d, D, \overline{\mathbb{F}(t)})$ . A subexponential upper bound on  $N^*(d, D, \mathbb{F})$  for  $D = O(d)$  will improve the required field size in Theorem 1.1.

Finally, it might be possible to exploit some extra structure to derive better bounds on  $N^*(d, D, \mathbb{F})$  than those obtained for  $N(d, D, \mathbb{K})$ . For example, if we modify the definition of  $N^*(d, D, \mathbb{F})$  by only considering those polynomials  $f$  of *prime* degree, then  $N^*(d, 2d-1, \mathbb{F}) \leq 1$ . This is because if  $f_{\mathbf{a}} - t$  is reducible over  $\overline{\mathbb{F}(t)}$ , then  $f_{\mathbf{a}}$  is decomposable over  $\overline{\mathbb{F}}$  by Lemma 2.8. But as  $\deg(f)$  is prime,  $f_{\mathbf{a}}$  must be of the form  $g(h)$  with  $\deg(g) = \deg(f)$  and  $\deg(h) = 1$ . This in turn implies that  $f_{\mathbf{a}} - t$  factorizes into  $\deg(f)$  linear factors over  $\overline{\mathbb{F}(t)}$ . In Theorem 5.4, we use this idea to show that the required field size can be improved to  $O(d^4/\varepsilon^2)$  if we only want to fool polynomials whose degrees are prime and at most  $d$ .

## 5 Proofs of the Main Theorems

In this section, we present our PRG construction and prove the main theorems.

Let  $n$  and  $d$  be positive integers. Let  $\mathbb{F}_q$  be a finite field of characteristic at least  $d(d-1)+1$ . We now present the construction of our PRG

$$G : S \rightarrow \mathbb{F}_q^{n+1}$$

for polynomials  $f \in \mathbb{F}_q[\mathbf{x}, y] = \mathbb{F}_q[x_1, \dots, x_n, y]$  of degree at most  $d$ . To simplify our notation, these polynomials are assumed to be  $(n+1)$ -variate rather than  $n$ -variate.

► **Construction 5.1.** The construction is as follows:

- Let  $H : T \rightarrow \mathbb{F}_q^n$  be an explicit HSG for  $n$ -variate polynomials of degree at most  $2d-1$  over  $\mathbb{F}_q$  with density  $1-\delta$  and seed length  $\log |T| = O(d \log n + \log(1/\delta))$ , where  $\delta = C_0(2d-1)/q$  and  $C_0 > 0$  is an absolute constant. For  $i \in [n]$  and  $s \in T$ , denote the  $i$ -th coordinate of  $H(s)$  by  $H(s)_i$ . The existence of  $H$  is guaranteed by Theorem 2.3.
- Let  $S = T \times T \times \mathbb{F}_q \times \mathbb{F}_q$ . Define  $G : S \rightarrow \mathbb{F}_q^{n+1}$  by

$$G(r, s, u, v) = (H(s)_1 \cdot u + H(r)_1 \cdot v, \dots, H(s)_n \cdot u + H(r)_n \cdot v, v).$$

In other words, we use random  $(r, s) \in T \times T$  to pick a plane in  $\mathbb{F}_q^{n+1}$ , and use random  $(u, v) \in \mathbb{F}_q \times \mathbb{F}_q$  to pick a point on the plane. The following lemma states that with high probability, a given indecomposable polynomial  $f \in \mathbb{F}_q[\mathbf{x}, y]$  remains indecomposable when restricted to the plane.

► **Lemma 5.2.** Let  $f \in \mathbb{F}_q[\mathbf{x}, y]$  be an indecomposable polynomial of degree at most  $d$  over  $\mathbb{F}_q$ . Let  $(r, s)$  be a random element of  $T \times T$ . Let  $\mathbf{a} = (a_1, \dots, a_n) = H(r)$  and  $\mathbf{b} = (b_1, \dots, b_n) = H(s)$ . Finally, let  $F = f(b_1x + a_1y, \dots, b_nx + a_ny, y) \in \mathbb{F}_q[x, y]$ . Then

$$\Pr[F \text{ is indecomposable over } \mathbb{F}_q] \geq 1 - 2^{d-1}\delta.$$

**Proof.** Recall that  $s_{\mathbf{a}}$  is the  $\mathbb{F}_q$ -linear automorphism of  $\mathbb{F}_q[\mathbf{x}, y]$  that fixes  $y$  and sends  $x_i$  to  $x_i + a_iy$ . As  $f$  is indecomposable over  $\mathbb{F}_q$ , so is  $s_{\mathbf{a}}(f)$ . By Lemma 2.6,  $s_{\mathbf{a}}(f)$  is also indecomposable over  $\overline{\mathbb{F}_q}$ . So  $s_{\mathbf{a}}(f) - t$  is irreducible over  $\overline{\mathbb{F}_q(t)}$  by Lemma 2.8.

By Corollary 3.5, there exists a nonzero polynomial  $B \in \mathbb{F}_q[\mathbf{x}]$  of degree at most  $d$  such that if  $B(\mathbf{a}) \neq 0$ , then

$$s_{\mathbf{a}}(f) - t = c \cdot g \tag{2}$$

where  $c \in \mathbb{F}_q^\times$  and  $g \in \mathbb{F}_q(t)[\mathbf{x}, y] \subseteq \overline{\mathbb{F}_q(t)}[\mathbf{x}, y]$  is a degree- $d$  polynomial satisfying Hypothesis (H). By the HSG property of  $H$ , the event  $B(\mathbf{a}) \neq 0$  happens with probability at least  $1 - \delta$ . Condition on this event, so that (2) holds. As  $s_{\mathbf{a}}(f) - t$  is irreducible over  $\overline{\mathbb{F}_q(t)}$ , so is  $g$ .

Let  $m = 2^{d-1} - 1$ . By Lemma 4.6, there exist nonzero polynomials  $Q_1, \dots, Q_m \in \overline{\mathbb{F}_q(t)}[z_1, \dots, z_n]$  of degree at most  $2d - 1$  such that the union of the zero loci of these polynomials contains all  $\mathbf{b}^* = (b_1^*, \dots, b_n^*) \in \overline{\mathbb{F}_q}^n$  for which  $g(b_1^*x, \dots, b_n^*x, y)$  is reducible over  $\overline{\mathbb{F}_q(t)}$ . By Fact 2.4,  $H$  is an HSG with density  $1 - \delta$  for polynomials of degree at most  $2d - 1$  over  $\overline{\mathbb{F}_q(t)}$ .<sup>3</sup> Therefore, for each  $i \in [m]$ , the probability that  $Q_i(\mathbf{b}) = 0$  is at most  $\delta$ . Condition on the event  $Q_1(\mathbf{b}), \dots, Q_m(\mathbf{b}) \neq 0$ . Then  $g(b_1x, \dots, b_nx, y)$  is irreducible over  $\overline{\mathbb{F}_q(t)}$ . On the other hand, note that

$$c \cdot g(b_1x, \dots, b_nx, y) \stackrel{(2)}{=} (s_{\mathbf{a}}(f))(b_1x, \dots, b_nx, y) - t = f(b_1x + a_1y, \dots, b_nx + a_ny, y) - t = F - t$$

where the second step uses the definition  $s_{\mathbf{a}}(f) = f(x_1 + a_1y, \dots, x_n + a_ny, y) \in \mathbb{F}_q[\mathbf{x}, y]$ . So  $F - t$  is irreducible over  $\overline{\mathbb{F}_q(t)}$ . By Lemma 2.8,  $F$  is indecomposable over  $\overline{\mathbb{F}_q}$ . So it is indecomposable over  $\mathbb{F}_q$ .

The indecomposability of  $F$  over  $\mathbb{F}_q$  relies on the conditions  $B(\mathbf{a}) \neq 0$  and  $Q_1(\mathbf{b}), \dots, Q_m(\mathbf{b}) \neq 0$ . By the union bound, these conditions are simultaneously satisfied with probability at least  $1 - \delta - m\delta = 1 - 2^{d-1}\delta$ , which completes the proof. ◀

Now we are ready to prove Theorem 1.1.

► **Theorem 5.3** (Theorem 1.1 restated). There exists an absolute constant  $C > 0$  such that for  $\varepsilon > 0$  and  $q \geq C(d2^d/\varepsilon + d^4/\varepsilon^2)$  with  $\text{char}(\mathbb{F}_q) \geq d(d-1) + 1$ ,  $G$  as in Construction 5.1 is a PRG for  $(n+1)$ -variate polynomials of degree at most  $d$  over  $\mathbb{F}_q$  with error  $\varepsilon$  and seed length  $O(d \log n + \log q)$ .

**Proof.** Let  $f \in \mathbb{F}_q[\mathbf{x}, y]$  be a polynomial of degree at most  $d$ . We want to prove that  $f(G(\mathbf{U}_S))$  and  $f(\mathbf{U}_{\mathbb{F}_q^{n+1}})$  are  $\varepsilon$ -close (in statistical distance). We may assume that  $f$  is a non-constant polynomial, i.e.,  $\deg(f) \geq 1$ , since the claim is trivial otherwise.

Our next step is the same as in [12]:  $f$  can always be written in the form  $f = g(h)$ , where  $g \in \mathbb{F}_q[z]$  is a univariate polynomial and  $h \in \mathbb{F}_q[\mathbf{x}, y]$  is indecomposable over  $\mathbb{F}_q$ . Let  $D = h(G(\mathbf{U}_S))$  and  $D' = h(\mathbf{U}_{\mathbb{F}_q^{n+1}})$ . Then  $f(G(\mathbf{U}_S)) = g(D)$  and  $f(\mathbf{U}_{\mathbb{F}_q^{n+1}}) = g(D')$ . If  $D$  and  $D'$  are  $\varepsilon$ -close, then  $g(D)$  and  $g(D')$  are also  $\varepsilon$ -close. Thus, by replacing  $f$  with  $h$ , we may assume that  $f$  is indecomposable over  $\mathbb{F}_q$ .

Let  $r, s, \mathbf{a}, \mathbf{b}$  and  $F$  be as in Lemma 5.2. Then by Lemma 5.2, the probability that  $F$  is decomposable over  $\mathbb{F}_q$  over random  $r$  and  $s$  is at most  $2^{d-1}\delta = C_0 2^{d-1}(2d-1)/q$ , where  $C_0$  is as in Construction 5.1. Fix  $r$  and  $s$  such that  $F$  is indecomposable over  $\mathbb{F}_q$ . Then  $f(G(r, s, u, v)) = F(u, v)$  by definition. Applying Lemma 2.7 to  $F$  shows that, for such fixed  $r$  and  $s$ , the distribution of  $F(u, v)$ , i.e.,  $f(G(r, s, u, v))$ , over random  $u, v \in \mathbb{F}_q$  is  $\varepsilon'$ -close to  $\mathbf{U}_{\mathbb{F}_q}$ , where  $\varepsilon' = C_1 d^2/\sqrt{q}$  and  $C_1 > 0$  is an absolute constant. It follows that the statistical distance between  $f(G(\mathbf{U}_S))$  and  $\mathbf{U}_{\mathbb{F}_q}$  is at most  $2^{d-1}\delta + \varepsilon'$ .

On the other hand, as  $f$  is also indecomposable over  $\mathbb{F}_q$ , applying Lemma 2.7 to  $f$  shows that  $f(\mathbf{U}_{\mathbb{F}_q^{n+1}})$  is  $\varepsilon'$ -close to  $\mathbf{U}_{\mathbb{F}_q}$ . Therefore, the statistical distance between  $f(G(\mathbf{U}_S))$  and  $f(\mathbf{U}_{\mathbb{F}_q^{n+1}})$  is at most

$$(2^{d-1}\delta + \varepsilon') + \varepsilon' = 2^{d-1}\delta + 2\varepsilon' = C_0 2^{d-1}(2d-1)/q + 2C_1 d^2/\sqrt{q} \tag{3}$$

<sup>3</sup> Note that we are applying Fact 2.4 to the infinite extension  $\overline{\mathbb{F}_q(t)}/\mathbb{F}_q$ . In principle, it should be possible to make the argument finitary by making some adaptations, such as considering specific values of  $t$ . However, this may increase the complexity of the proof.

## 44:16 Optimal PRGs for Low-Degree Polynomials over Large Fields

which is bounded by  $\varepsilon$  provided that  $q \geq C(d2^d/\varepsilon + d^4/\varepsilon^2)$  and  $C > 0$  is a large enough absolute constant. The seed length of  $G$  is

$$2 \log |T| + 2 \log q = O(d \log n + \log(1/\delta) + \log q) = O(d \log n + \log q)$$

as  $\delta = C_0(2d - 1)/q$ . ◀

We conclude this section by proving Theorem 1.2, which states that the required field size can be improved to  $O(d^4/\varepsilon^2)$  if we only want to fool polynomials of prime degree.

► **Theorem 5.4** (Theorem 1.2 restated). There exists an absolute constant  $C > 0$  such that for  $\varepsilon > 0$  and  $q \geq C(d^4/\varepsilon^2)$  with  $\text{char}(\mathbb{F}_q) \geq d(d - 1) + 1$ ,  $G$  as in Construction 5.1 is a PRG for  $(n + 1)$ -variate polynomials of *prime* degree up to  $d$  with error  $\varepsilon$  and seed length  $O(d \log n + \log q)$ .

**Proof Sketch.** Let  $f \in \mathbb{F}_q[\mathbf{x}, y]$  be a polynomial whose degree  $d'$  is prime and at most  $d$ . We want to prove that  $f(G(\mathbf{U}_S))$  and  $f(\mathbf{U}_{\mathbb{F}_q^{n+1}})$  are  $\varepsilon$ -close (in statistical distance). Suppose  $f$  is decomposable over  $\mathbb{F}_q$ . Then  $f = g(h)$  for some polynomials  $g, h$  over  $\mathbb{F}_q$  where  $\deg(g) \geq 2$ , and as  $d' = \deg(f)$  is prime, we must have  $\deg(g) = d'$  and  $\deg(h) = 1$ . In this case, the theorem follows by replacing  $f$  with  $h$ , which has degree one, and applying Theorem 5.3. So we may assume that  $f$  is indecomposable over  $\mathbb{F}_q$ .

The rest of the proof follows that of Theorem 5.3, except that we could bound the probability that  $F$  is decomposable over  $\mathbb{F}_q$  by  $2\delta$ , rather than by  $2^{d-1}\delta$ , using the following observation:

In the application of Lemma 4.6, the polynomial has the special form  $g^* = f^* + ct$ , where  $f^* \in \mathbb{F}_q[\mathbf{x}, y]$ ,  $c \in \mathbb{F}_q^\times$ , and  $\deg(f^*) = d'$ . By making the substitution  $t \mapsto -c^{-1}t$ , we may assume  $c = -1$ . Consider any  $\mathbf{a} \in \overline{\mathbb{F}_q}^n$  such that  $g_{\mathbf{a}}^* = g^*(a_1x, \dots, a_nx, y)$  is reducible over  $\overline{\mathbb{F}_q}(t)^n$ . We claim that  $g_{\mathbf{a}}^*$  factorizes into linear factors over  $\overline{\mathbb{F}_q}(t)$ . To see this, note that  $f_{\mathbf{a}}^* = f^*(a_1x, \dots, a_nx, y)$  is a decomposable polynomial over  $\overline{\mathbb{F}_q}$  of degree  $d'$  by Lemma 2.8 and the fact that  $g_{\mathbf{a}}^* = f_{\mathbf{a}}^* - t$  is reducible over  $\overline{\mathbb{F}_q}(t)$ . So we may write  $f_{\mathbf{a}}^* = \alpha(\beta)$  where  $\alpha \in \overline{\mathbb{F}_q}[z]$ ,  $\beta \in \overline{\mathbb{F}_q}[\mathbf{x}, y]$ , and  $\deg(\alpha) > 1$ . As  $d'$  is prime, we must have  $\deg(\alpha) = d'$  and  $\deg(\beta) = 1$ . As  $\alpha$  is univariate,  $\alpha - t$  factorizes into linear factors  $\alpha_1, \dots, \alpha_{d'}$  over  $\overline{\mathbb{F}_q}(t)$ . So  $g_{\mathbf{a}}^* = \alpha(\beta) - t = (\alpha - t)(\beta)$  factorizes into the linear factors  $\alpha_1(\beta), \dots, \alpha_{d'}(\beta)$  over  $\overline{\mathbb{F}_q}(t)$ .

This observation shows that there is only one bad factorization pattern to rule out, namely, the complete factorization into linear factors. This allows us to save a factor of  $2^{d-1} - 1$  and reduce the error probability in Lemma 5.2 from  $(2^d - 1)\delta + \delta$  to  $\delta + \delta = 2\delta$ . The bound on the statistical distance between  $f(G(\mathbf{U}_S))$  and  $f(\mathbf{U}_{\mathbb{F}_q^{n+1}})$  in (3) now becomes  $2\delta + 2\varepsilon' = 2C_0(2d - 1)/q + 2C_1d^2/\sqrt{q}$ , which is bounded by  $\varepsilon$  provided that  $q \geq C(d^4/\varepsilon^2)$  and  $C > 0$  is a large enough absolute constant. ◀

## 6 Open Problems

We conclude with some open problems. The most obvious one is reducing the required field size in our construction. Using Bogdanov's [6] paradigm, it seems necessary for the field to be of size at least polynomial in  $d$ , since this argument relies on the Weil bound (and indeed, as mentioned in Section 1, the seed lengths of the known constructions over small fields like  $\mathbb{F}_2$  are worse). Still, one could hope to obtain seed length  $O(d \log n)$  with  $q$  being polynomial in  $d$ , and not exponential in  $d$ . In our construction,  $q$  is exponential in  $d$  due to the need to apply a union bound over all possible vectors in  $\{0, 1\}^d$  characterizing the factorization pattern of  $f_{\mathbf{a}}$ . It could very well be that there is a more clever argument that rules out

multiple vectors at once. We also mention again Question 4.9. As explained in Section 4, improved upper bounds on the quantity  $N^*(d, D, \mathbb{F})$  in that question would improve the field size required by our construction.

A related open problem is removing the requirement that the characteristic of  $\mathbb{F}_q$  is at least  $d(d-1)+1$ . This requirement comes from using Lecerf’s [21] arguments (dating back to Gao [15] and Ruppert [26, 27]). We remark that our construction can be adapted to work in arbitrary characteristics  $p > 0$  by employing the analysis in [8] and increasing the accuracy parameter  $\sigma$  of Hensel lifting to  $d(d-1)+1$ ; however, this leads to a larger seed length of  $O(d^2 \log n + \log q)$ . A proof of this result will be provided in the full version of this paper.

Finally, low-degree polynomials form a natural “weak” class of polynomials. However, rather than assuming bounds on the degree of polynomials, one can also consider other weak classes of polynomials, where the restriction comes from bounding their algebraic circuit complexity. This forms another interesting avenue for generalizing the results on PRGs for low-degree polynomials. As an analogy, in the context of Boolean computation, the problem of constructing explicit PRGs for weak computational classes (such as bounded-depth circuits or read-once oblivious branching programs) is well studied (see [34]). For algebraic computational models, however, much less is known. Most of the research in this area has focused on constructing *hitting sets* of limited models of algebraic circuits (see [31, 28, 29] for some surveys on this topic), due to the relation to the famous Polynomial Identity Testing Problem. To the best of our knowledge, there is no known explicit construction of PRGs for any natural class of algebraic computation. A concrete and intriguing open problem is to explicitly construct PRGs for the class of sparse polynomials, for which, as described in the references above, there are many known explicit constructions of hitting sets.

# Refining the Adaptivity Notion in the Huge Object Model

Tomer Adar

---

## Abstract

The Huge Object model for distribution testing, first defined by Goldreich and Ron in 2022, combines the features of classical string testing and distribution testing. In this model we are given access to independent samples from an unknown distribution  $P$  over the set of strings  $\{0, 1\}^n$ , but are only allowed to query a few bits from the samples. The distinction between adaptive and non-adaptive algorithms, which occurs naturally in the realm of string testing (while being irrelevant for classical distribution testing), plays a substantial role also in the Huge Object model.

In this work we show that the full picture in the Huge Object model is much richer than just that of the adaptive vs. non-adaptive dichotomy. We define and investigate several models of adaptivity that lie between the fully-adaptive and the completely non-adaptive extremes. These models are naturally grounded by observing the querying process from each sample independently, and considering the “algorithmic flow” between them. For example, if we allow no information at all to cross over between samples (up to the final decision), then we obtain the *locally bounded* adaptive model, arguably the “least adaptive” one apart from being completely non-adaptive. A slightly stronger model allows only a “one-way” information flow. Even stronger (but still far from being fully adaptive) models follow by taking inspiration from the setting of streaming algorithms. To show that we indeed have a hierarchy, we prove a chain of exponential separations encompassing most of the models that we define.

## 1 Introduction

Property testing is the study of sublinear, query-based probabilistic decision-making algorithms. That is, algorithms that return ACCEPT or REJECT after reading only a small portion of their input. The study of (classical) property testing, starting with [6], [14] and [15], has seen an extensive body of work. See for example [10]. Usually, a property-testing algorithm with threshold parameter  $\varepsilon$  is required to accept an input that satisfies the property with high probability, and reject an input whose distance from any satisfying one is more than  $\varepsilon$ , with high probability as well. For string properties, which were the first to be studied (along with functions, matrices, etc. that can also be represented as strings), the distance measure is usually the normalized Hamming distance.

Distribution testing is a newer model, first defined implicitly in [11] (a version of which has already appeared in 2000 as a technical report). In [4] and [5] it was explicitly defined and researched. The algorithms in this model are much weaker, where instead of queries, the

Leibniz International Proceedings in Informatics

Schloss Dagstuhl – Leibniz-Zentrum für Informatik, Dagstuhl Publishing, Germany

decision to accept or reject must be made based only on a sequence of independent samples drawn from an unknown distribution. In such a setting the distance metric is usually the variation distance. For a more comprehensive survey, see [7].

The study of a combination of string and distribution testing was initiated in [12]. Here the samples in themselves are considered to be very large objects, and hence after obtaining a sample (usually modeled as a string of size  $n$ ), queries must be made to obtain some information about its contents. This requires an appropriate modification in the distance notion. This model is appropriately called the *Huge Object model*.

Contrast the above to the original “small object” distribution testing model, where it is assumed that every sample is immediately available to the algorithm in its entirety. In particular, in the original model, the algorithm does not have any choice of queries, as it just receives a sequence of independent samples from the distribution to be tested. Hence one might even call it a “formula” rather than an “algorithm”. Grossly speaking, the only decision made is whether to accept or reject the provided sequence of sampled objects.

On the other hand, in the string testing model, an algorithm is provided with a (deterministic) input string, and may make query decisions based both on internal random coins and on answers to previous queries. An algorithm which makes use of the option of considering answers to previous queries when choosing the next query is called adaptive, while an algorithm that queries based only on coin tosses is called non-adaptive (the final decision on whether to accept or reject the input must, of course, depend on the actual answers).

Algorithms for the Huge Object model, due to their reliance on individual queries to the provided samples, can be adaptive or non-adaptive. This relationship with respect to the Huge Object model was first explored in [8].

However, as we shall demonstrate below, the complete picture here is richer than the standard adaptive/non-adaptive dichotomy used in classical string testing. As it turns out, several categories of adaptivity can be defined and investigated based on the consideration of the shared information between the different samples that are queried.

## 1.1 Adaptivity notions in the Huge Object model

For our purpose, unless we state otherwise, we assume that the sequence of samples is taken in advance (but is not directly disclosed to the algorithm), and is presented as a matrix from which the algorithm makes its queries. For a sequence of  $s$  samples from a distribution whose base set is  $\{0, 1\}^n$ , this would be a binary  $s \times n$  matrix.

We say that an algorithm is *non-adaptive* if it chooses its entire set of queries before making them, which means that it cannot choose later queries based on the answers to earlier ones. This is identical to the definition of a non-adaptive algorithm for string properties.

A *fully adaptive* algorithm is allowed to choose every query based on answers to all queries made before it. This is quite similar to the definition of an adaptive algorithm for string properties, but restricting ourselves to this dichotomy does not give the full picture. We refine the notion of adaptivity by considering more subtle restrictions on the way that the algorithms plan their queries, leading to query models that are not as expressive as those of fully adaptive algorithms, but are still more expressive than those of non-adaptive ones. In this introduction we only introduce the rationale of every model; the formal definitions appear in the preliminaries section.

One interesting restriction, which is surprisingly difficult to analyze, is “being adaptive for every individual sample, without sharing adaptivity between different samples” (the results of random coin tosses are still allowed to be shared). We say that an algorithm is

*locally-bounded* if it obeys this restriction. This model captures the concept of distributed execution, in a way that every node has a limited scope of a single sample, and only when all nodes are done, their individual outcomes are combined to facilitate a decision.

A more natural restriction is “being able to query only the most recent sample”. We say that an algorithm is *forward-only* if it cannot query a sample after querying a later one. This can be viewed (if we abandon the above-mentioned matrix representation) as the algorithm being provided with oracle access to only one sample at a time, not being able to “go back in time” once a new sample was taken. An example for the usage of the model is an anonymous survey. As long as the survey session is alive, we can present new questions based on past interactions and on the current one, but once the session ends, we are not able to recall the same participant for further questioning.

A natural generalization of forward-only adaptiveness is having a bounded memory for holding samples (rather than only having one accessible sample at a time). Once the memory is full, the algorithm must drop one of these samples (making it inaccessible) in order to free up space for a new sample. An additional motivation for this model is the concept of stream processing, whose goal is computing using sublinear memory. Relevant to our work is [2], where the input stream is determined by an unknown distribution, in contrast to the usual streaming setting where the order of the stream is arbitrary. Within the notion of having memory of a fixed size, we actually distinguish two models. In the weak model, when the memory is full, the oldest sample is dropped. In the strong model, the algorithm decides (possibly adaptively) which sample to drop.

We show that every two consecutive models in the above hierarchy have an exponential separation, which means that there is a property that requires  $\Omega(\text{poly}(n))$  queries for an  $\varepsilon$ -test in the first model (for some fixed  $\varepsilon$ ), but is also  $\varepsilon$ -testable using  $O(\text{poly}(\varepsilon^{-1}) \log n)$  queries in the second model (for every  $\varepsilon > 0$ ). Moreover, our upper bounds always have one-sided error, while the lower bounds apply for both one-sided and two-sided error algorithms. The exact relationship between the weak and the strong limited memory models remains open, however.

We believe that investigating limited adaptiveness models can apply to other areas where there are two “query scales”. That is, when investigating a model takes into account collections of objects that are restricted both in the way that whole objects are obtained and in the access model *inside* each obtained object. For example, one could think of a distributed computing scenario where the communication between the nodes follows a LOCAL or a CONGEST scheme (see [13]), but additionally each node holds a “large” input from which it may only perform sub-linear time computation *between* the communication rounds.

## 1.2 Organization of the paper

We start with formal definitions of the models which are required to state our results, followed by an overview of the results themselves and a description of the main ideas of their proofs. This review includes the definitions of the properties showing our separation results, along with a sketch of the lower bounds and the algorithms for the upper bounds. The proofs themselves are deferred to the full version of this paper.

## 2 Preliminaries

The following are the core definitions and lemmas used throughout this paper, including the model definitions used in the overview in Section 3. Here, all distributions are defined over finite sets.

► **Definition 1** (Common notations). For a set  $A$ , the power set of  $A$  is denoted by  $\mathcal{P}(A)$ . For two sets  $A$  and  $B$ , the set of all functions  $f : A \rightarrow B$  is denoted by  $B^A$ . For a finite set  $A$ , the set of all permutations over  $A$  is denoted by  $\pi(A)$ .

► **Definition 2** (Set of distributions). Let  $\Omega$  be a finite set. The set of all distributions that are defined over  $\Omega$  is denoted by  $\mathcal{D}(\Omega)$ .

While parts of this section are generalizable to distributions over non-finite sets  $\Omega$  with compact topologies, we restrict ourselves to distributions over finite sets, which suffice for our application.

► **Definition 3** (Property). A property  $\mathcal{P}$  over a finite alphabet  $\Sigma$  is defined as a sequence of compact sets  $\mathcal{P}_n \subseteq \mathcal{D}(\Sigma^n)$ . Here compactness refers to the one defined with respect to the natural topology inherited from  $\mathbb{R}^{|\Sigma|^n}$ .

All properties are defined over  $\Sigma = \{0, 1\}$  unless we state otherwise.

## 2.1 Distances

The following are the distance measures that we use. In the sequel, we will omit the subscript (e.g. use “ $d(x, y)$ ” instead of “ $d_H(x, y)$ ”) whenever the measure that we use is clear from the context.

► **Definition 4** (Normalized Hamming distance). For two strings  $s_1, s_2 \in \Sigma^n$ , we use  $d_H(s_1, s_2)$  to denote their normalized Hamming distance,  $\frac{1}{n} |\{1 \leq i \leq n \mid s_1[i] \neq s_2[i]\}|$ .

For all our distance measures we also use the standard extension to distances between sets, using the corresponding infimum (which in all our relevant cases will be a minimum). For example, For a string  $s \in \{0, 1\}^n$  and a set  $A \subseteq \{0, 1\}^n$ , we define  $d_H(s, A) = \min_{s' \in A} d_H(s, s')$ .

► **Definition 5** (Variation distance). For two distributions  $P$  and  $Q$  over a common set  $\Omega$ , we use  $d_{\text{var}}(P, Q)$  to denote their variation distance,  $\max_{E \subseteq \Omega} |\Pr_P[E] - \Pr_Q[E]|$ . Since  $\Omega$  is finite there is an equivalent definition of  $d_{\text{var}}(P, Q) = \frac{1}{2} \sum_{s \in \Omega} |P(s) - Q(s)|$ .

► **Definition 6** (Transfer distribution). For two distributions  $P$  over  $\Omega_1$  and  $Q$  over  $\Omega_2$ , we say that a distribution  $T$  over  $\Omega_1 \times \Omega_2$  is a transfer distribution between  $P$  and  $Q$  if for every  $x_0 \in \Omega_1$ ,  $\Pr_{(x, y) \sim T}[x = x_0] = \Pr_P[x_0]$ , and for every  $y_0 \in \Omega_2$ ,  $\Pr_{(x, y) \sim T}[y = y_0] = \Pr_Q[y_0]$ . We use  $\mathcal{T}(P, Q)$  to denote the set of all transfer distributions between  $P$  and  $Q$ .

We note that for finite  $\Omega_1$  and  $\Omega_2$  the set  $\mathcal{T}(P, Q)$  is compact as a subset of  $\mathcal{D}(\Omega_1 \times \Omega_2)$ .

► **Definition 7** (Earth Mover’s Distance). For two distributions  $P$  and  $Q$  over a common set  $\Omega$  with a metric  $d_\Omega$ , we use  $d_{\text{EMD}}(P, Q)$  to denote their earth mover’s distance, defined by the infimum of the “average distance” demonstrated by a transfer distribution,  $\inf_{T \in \mathcal{T}(P, Q)} \mathbb{E}_{(x, y) \sim T} [d_\Omega(x, y)]$ .

In the sequel, the above “inf” can and will be replaced by “min”, by the compactness of  $\mathcal{T}(P, Q)$  for finite  $\Omega$ . Most papers (including the original [12]) use an equivalent definition that is based on linear programming, whose solution is the optimal transfer distribution.

In our theorems,  $\Omega$  is always  $\{0, 1\}^n$  for some  $n$  and the metric is the Hamming distance. Sometimes, as an intermediate phase, we may use a different  $\Omega$  (usually  $\{1, \dots, k\}^n$  for some  $k$ ), and then show a reduction back to the binary case.

► **Definition 8** (Distance from a property). *The distance of a distribution  $P$  from a property  $\mathcal{P} = \langle \mathcal{P}_n \rangle$  is loosely noted as  $d(P, \mathcal{P})$  and is defined to be  $d_{\text{EMD}}(P, \mathcal{P}_n) = \inf_{Q \in \mathcal{P}_n} d_{\text{EMD}}(P, Q)$ .*

It is very easy to show that for any two distributions  $P, Q \in \mathcal{D}(\Sigma^n)$  we have  $d_{\text{EMD}}(P, Q) \leq d_{\text{var}}(P, Q)$ . This means that the topology induced by the variation distance is richer than that induced by the earth mover's distance (actually for finite sets these two topologies are identical). In particular it means that all considered properties form compact sets with respect to the earth mover's distance. We obtain the following lemma.

► **Lemma 9.** *For a property  $\mathcal{P}$  of distributions over strings, and any distribution  $P \in \mathcal{D}(\Sigma^n)$ , there is a distribution realizing the distance of  $P$  from  $\mathcal{P}$ , i.e. a distribution  $Q \in \mathcal{P}_n$  for which  $d(P, Q) = d(P, \mathcal{P}_n)$ . In particular, the infimum in Definition 8 is a minimum.*

## 2.2 The testing model

This model is defined in [12]. We use an equivalent definition which will be the “baseline” for our restricted adaptivity variants.

The input is a distribution  $P$  over  $\Sigma^n$  (our final theorems will be for  $\Sigma = \{0, 1\}$ , but some intermediate arguments require other finite  $\Sigma$ ). An algorithm  $\mathcal{A}$  gets random oracle access to  $s$  samples that are independently drawn from  $P$ . Then it is allowed to query individual bits of the samples. The output of the algorithm is either ACCEPT or REJECT. For convenience we identify the samples with an  $s \times n$  matrix, so for example the query “ $(i, j)$ ” returns the  $j$ th bit of the  $i$ th sample.

The input size  $n$  and the number of samples  $s$  are hard-coded in the algorithm. As with boolean circuits, an algorithm for an arbitrarily sized input is defined as a sequence of algorithms, one for each  $n$ .

For a given algorithm we define another measure of complexity, which is the total number of queries that the algorithm makes. Without loss of generality, we always assume that every sample is queried at least once (implying that  $q \geq s$ ).

For a property  $\mathcal{P}$  and  $\varepsilon > 0$ , we say that an algorithm  $\mathcal{A}$  is an  $\varepsilon$ -test if:

- For every  $P \in \mathcal{P}$ ,  $\mathcal{A}$  accepts the input  $P$  with probability higher than  $\frac{2}{3}$ .
- For every  $P$  that is  $\varepsilon$ -far from  $\mathcal{P}$ ,  $\mathcal{A}$  accepts the input  $P$  with probability less than  $\frac{1}{3}$ .

We say that  $\mathcal{A}$  is an  $\varepsilon$ -test with one sided error if:

- For every  $P \in \mathcal{P}$ ,  $\mathcal{A}$  accepts the input  $P$  with probability 1.
- For every  $P$  that is  $\varepsilon$ -far from  $\mathcal{P}$ ,  $\mathcal{A}$  accepts the input  $P$  with probability less than  $\frac{1}{2}$ .

The choice of the probability bounds in the above definition are somewhat arbitrary. For the one sided error definition  $\frac{1}{2}$  is more convenient than  $\frac{1}{3}$ . We also note that for non- $\varepsilon$ -far inputs that are not in  $\mathcal{P}$ , any answer by  $\mathcal{A}$  is considered to be correct.

## 2.3 Restricted models

As observed by Yao in [16], every probabilistic algorithm can be seen as a distribution over the set of allowable deterministic algorithms. This simplifies the algorithmic analysis, since we only have to consider deterministic algorithms (a distinction between public and private coins can break this picture, but this will not be the case here). We will use Yao's observation to define every probabilistic algorithmic model by defining its respective set of allowable deterministic algorithms. The following definitions formalize the description of the models introduced in Section 1.

► **Definition 10** (Fully adaptive algorithm). *Every deterministic algorithm can be described as a full decision tree  $T$  and a set  $A$  of accepted leaves. Without loss of generality we assume that all leaves have the exactly the same depth (we use dummy queries if “padding” is needed). Every internal node of  $T$  consists of a query  $(i, j) \in \{1, \dots, s\} \times \{1, \dots, n\}$  (the  $j$ th bit of the  $i$ th sample), and every edge corresponds to an outcome element (in  $\Sigma$ ). The number of queries  $q$  is defined as the height of the tree. Every leaf can be described by the string of length  $q$  detailing the answers given to the  $q$  queries, corresponding to its root-to-leaf path. Thus we can also identify  $A$  with a subset of  $\Sigma^q$ .*

Now that we have defined the most general form of a deterministic algorithm in the Huge Object model, we formally define our models for varying degrees of adaptivity.

► **Definition 11** (Non-adaptive algorithm). *We say that an algorithm is non-adaptive if it chooses its queries in advance, rather than deciding each query location based on the answers to its previous ones. Formally, every deterministic non-adaptive algorithm is described as a pair  $(Q, A)$  such that  $Q \subseteq \{1, \dots, s\} \times \{1, \dots, n\}$  (for some sample complexity  $s$ ) is the set of queries, and  $A \subseteq \Sigma^Q$  is the set of accepted answer functions. The query complexity is defined as  $q = |Q|$ .*

► **Definition 12** (Locally-bounded adaptive algorithm). *We call an algorithm locally-bounded if it does not choose its queries to a sample based on answers to queries in other samples. Formally, every  $s$ -sample deterministic locally-bounded algorithm is a tuple  $(T_1, \dots, T_s; A)$ , where every  $T_i$  is a decision tree of height  $q_i$  (where  $q = \sum_{i=1}^s q_i$  is the total number of queries) that is only allowed to query the  $i$ th sample, and  $A \subseteq \Sigma^q$  represents a set of accepted superleaves, where a superleaf is defined as the concatenation of the  $q_1, \dots, q_s$  symbol long sequences that represent the leaves of trees  $T_1, \dots, T_s$  respectively.*

► **Definition 13** (Forward-only adaptive algorithm). *We call an algorithm forward-only if it cannot query a sample after querying a later one. Formally, a forward-only algorithm for  $s$  samples of  $n$ -length strings is defined as a pair  $(T, A)$ , where  $T$  is a decision tree over  $\{1, \dots, s\} \times \{1, \dots, n\}$  and  $A \subseteq \Sigma^q$  (as with general adaptive algorithms), additionally satisfying that for every internal node of  $T$  that is not the root, if its query is  $(i, j)$  and its parent query is  $(i', j')$ , then  $i' \leq i$ .*

► **Definition 14** (Weak memory-bounded adaptive algorithm). *We say that an algorithm is weak  $m$ -memory bounded if it can only query a sliding window of the  $m$  most recent samples at a time. Formally, a weak  $m$ -memory-bounded adaptive algorithm using  $s$  samples of  $n$ -length strings is defined as a pair  $(T, A)$ , where  $T$  is a decision tree over  $\{1, \dots, s\} \times \{1, \dots, n\}$  and  $A \subseteq \Sigma^q$  (as with general adaptive algorithms), additionally satisfying that for every internal node of  $T$  that is not the root, if its query is  $(i, j)$ , then for every ancestor whose query is  $(i', j')$ , it holds that  $i' - m < i$ .*

► **Definition 15** (Strong memory-bounded adaptive algorithm). *A strong memory-bounded adaptive algorithm for  $s$  samples of  $n$ -length strings is defined as a triplet  $(T, A, M)$  where  $T$  is a decision tree,  $A \subseteq \Sigma^q$  is the set of accepted answer vectors, and  $M : \text{nodes}(T) \rightarrow \mathcal{P}(\{1, \dots, s\})$  is the “memory state” at every node. The explicit rules of  $M$  are:*

- For every internal node  $u \in T$ ,  $|M(u)| \leq k$  (there are at most  $k$  samples in memory).
- For every internal node  $u \in T$ , if  $i \in M(u)$ , and if  $v$  is a child of  $u$  for which  $i \notin M(v)$ , then for every descendant  $w$  of  $v$ ,  $i \notin M(w)$  (a “forgotten” sample cannot be “recalled”).
- For every internal node  $u \in T$  whose query is  $(i, j)$ ,  $i \in M(u)$  (the  $i$ th sample must be in memory in order to query it).

Without loss of generality, because the samples are independent, we can assume that:

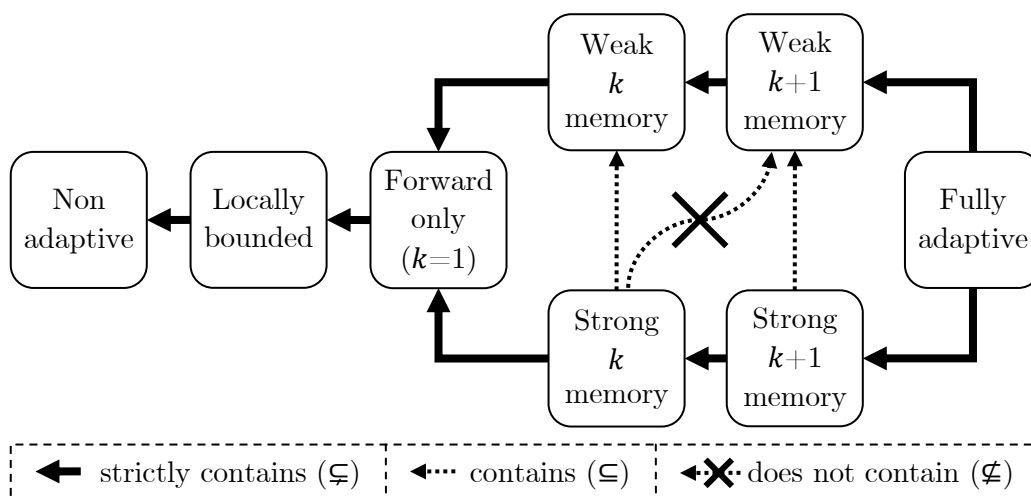

- $M(\text{root}) = \{1, \dots, k\}$  (the algorithm has initial access to the first  $k$  samples).
- For every internal node  $u \in T$  and the set  $V$  of all its ancestors, it holds that  $\max(M(u)) \leq 1 + \max_{v \in V}(\max M(v))$  (new samples are accessed “in order”).

### 3 Overview of results and methods

The following is a semi-formal overview of our work, which is described in extensive details in the full version of the paper. Most of our results are exponential separations between models (that is,  $O(\log n)$  vs  $n^{\Omega(1)}$  bounds).

All separations are with an exponential gap, and are achieved by properties that have an efficient 1-sided error test in one model, but do not even have an efficient 2-sided test in the other model.

Figure 1 provides a visualization of our results. More details about the difference between the weak  $k$ -memory and the strong  $k$ -memory model are provided below.

■ **Figure 1** Graphical summary of our results.

#### 3.1 Non-adaptive algorithms

To showcase what can be done with non-adaptive algorithms, we analyze the property of a distribution having support size at most  $m$ , and the even more basic property of a distribution being *deterministic*, that is, having support size 1.

We show that the determinism property (the property that the distribution draws a specific element with probability 1) can be tested non-adaptively using  $O(\varepsilon^{-1})$  queries, consisting of  $O(\varepsilon^{-1})$  samples (as in the classic model) and  $O(1)$  queries per sample.

► **Observation 16.** *The property of drawing a fixed string has a one-sided error non-adaptive  $\varepsilon$ -test that uses  $O(\varepsilon^{-1})$  queries.*

We also show a non-adaptive  $m$ -support test.

► **Theorem 17.** *The property of being supported on a set of at most  $m$  elements has a one-sided error non-adaptive  $\varepsilon$ -test that uses  $O(\varepsilon^{-2}m \log m)$  queries.*

Algorithm 1 demonstrates this upper bound.

■ **Algorithm 1** One sided  $\varepsilon$ -test for  $m$ -bounded support, non adaptive,  $O(\varepsilon^{-2}m \log m)$  queries.

---

```

take  $s = 1 + \lceil 8\varepsilon^{-1}m \rceil$  samples.
let  $t = \lceil 4\varepsilon^{-1}(\ln m + 2) \rceil$ 
choose  $j_1, \dots, j_t \in [n]$  uniformly and independently at random.
let  $J = \{j_1, \dots, j_t\}$ 
for  $i$  from 1 to  $s$  do
    query sample  $i$  at  $j$  for every  $j \in J$ , giving substring  $y^i$  of length  $|J|$ .
if  $|\{y^1, \dots, y^s\}| > m$  then
    return REJECT
return ACCEPT

```

---

As described in detail in the full version of the paper, in which we prove the correctness of Algorithm 1, our  $\varepsilon$ -test for the  $m$ -support property needs more than a fixed number of queries per sample. Though not necessarily optimal, this algorithm demonstrates the core difference between the Huge Object model and the classic one: the limited ability to distinguish different samples. This limitation holds for adaptive algorithms as well, even though the adaptivity can reduce the number of queries per sample for some properties. A concurrent work [1] shows a lower bound of  $\Omega(\varepsilon^{-1} \log \varepsilon^{-1})$  queries for non-adaptive support testing even for  $m = 2$ , showing that this limitation is unavoidable.

## Locally bounded adaptive algorithms

The locally-bounded adaptive model (Definition 12) allows the algorithm to pick its queries based on answers to previous queries for every *fixed* sample, but lacks the ability to pass information between samples. The ability of being adaptive allows the algorithm more ways to query its samples, but it still lacks the ability to test *relations* between the samples.

### Analysis method

To analyze the locally-bounded model, we define an intermediate model of string testing which we call the *split-adaptive model*.

► **Definition 18** (Split adaptive algorithm). *For a fixed  $k$ , a  $k$ -split adaptive deterministic algorithm for  $n$ -long strings (where  $n$  is divisible by  $k$ ) over some alphabet  $\Sigma$  is a sequence of  $k$  decision trees  $T_1, \dots, T_k$ , where the tree  $T_i$  can only query at indexes between  $(i-1)k + 1$  and  $ik$ , and a set of accepted answer sequences. The query complexity of the algorithm is defined as the sum of heights of its trees.*

In this model, we test properties of  $k$ -tuples of strings, where the queries are made separately for every entry of the tuple (that is, every entry is processed using an adaptive algorithm that is oblivious of the other entries). To obtain a reduction, we consider every  $s$ -sample locally-bounded algorithm over an input distribution  $P$  as a split-adaptive algorithm whose input is drawn from  $P^s$  (that is, an  $s$ -tuple whose entries are independently drawn from  $P$ ).

### Exponential separation from the non-adaptive model

Naturally, there is an exponential separation between the locally-bounded model and the non-adaptive model of the Huge Object model. The property **CPal** (defined below) demonstrates this separation.

► **Definition 19** (string property **cpal**, see [8], [3]). For any fixed  $n$ , the property **cpal** is defined over  $\{0, 1, 2, 3\}^n$  as the set of  $n$ -long strings that are concatenations of a palindrome over  $\{0, 1\}$  and a palindrome over  $\{2, 3\}$  (in this order).

The following lemma is well-known (the adaptive bound, using binary search, is described in [8]).

► **Lemma 20.** Property **cpal** does not have a non-adaptive  $\frac{1}{5}$ -test using  $o(\sqrt{n})$  queries, while having an adaptive  $\varepsilon$ -test using  $O(\log(n) + 1/\varepsilon)$  many queries.

In [8] this was made into a distribution property by using “distributions” that are deterministic.

► **Definition 21** (Distribution property **CPal**, see [8]). For a fixed, even  $n$ , the property **CPal** is defined as the set of distributions over  $\{0, 1\}^n$  that are deterministic (have support size 1), whose support is an element that belongs to **cpal**, with respect to the encoding  $(0, 1, 2, 3) \mapsto (00, 01, 10, 11)$ .

► **Lemma 22.** **CPal** has a locally-bounded  $\varepsilon$ -test that uses  $O(\text{poly}(\varepsilon^{-1}) \log n)$  queries for every  $\varepsilon > 0$ , but there exists some  $\varepsilon_0 > 0$  for which any non-adaptive  $\varepsilon_0$ -test requires  $\Omega(\text{poly}(n))$  queries.

This is an almost-direct corollary of a result from [12] regarding converting string testing problems to the Huge Object model. Essentially, the Huge Object model “contains” the string testing one, and the conversion produces locally adaptive algorithms out of their respective adaptive string algorithms.

## Forward only adaptive algorithms

In the forward-only model (Definition 13), the algorithm virtually gets a stream of samples, and is allowed to query only the current sample without any restriction (but further queries to past samples are not allowed), based on answers to all past queries. In contrast to the locally bounded model, forward algorithms can test a richer collection of binary relations between samples, due to the ability to query one sample and then use the gathered data to choose the queries for the next one.

## Exponential separation from the locally-bounded model

We use the ability of forward-only algorithms to consider a richer collection of relations between samples, as compared to locally-bounded algorithms, to show an exponential separation between these models. The property **Inv\*** (defined below) demonstrates this separation.

In [9] it was shown that  $\varepsilon$ -testing two functions over  $\{1, \dots, n\}$  for being inverses of each other is possible with  $O(\varepsilon^{-1})$  many queries, while testing a single function for having an inverse is harder and requires a polynomial number of queries. Formally, we cite the function property **inv**:

► **Definition 23** (Function property **inv**). For a fixed  $n$ , the property **inv** is defined over  $[n]^{[2n]}$  as the set of ordered pairs of functions  $f, g : [n] \rightarrow [n]$  such that either  $f(i) = g(i)$  for every  $1 \leq i \leq n$  or  $g(f(i)) = i$  for every  $1 \leq i \leq n$ .

## 45:10 Refining the Adaptivity Notion in the Huge Object Model

Note that we modified the definition of the property slightly from the original, by allowing also the case  $f = g$ . This technical change makes it possible to construct a test using forward-only adaptivity that is also with one-sided error.

Here we separate the two functions by setting them in a probability space with support size 2. If we allow forward-only adaptivity, then the original inverse test can be implemented, as it works by verifying that  $g(f(i)) = i$  for sufficiently many  $i$ s. We can call the first sample “ $f$ ”, and after writing down our  $f(i_1), \dots, f(i_q)$ , we “wait” for a sample of  $g$  and then verify that  $g(f(i_j)) = i_j$  for  $i_1, \dots, i_q$ . Formally, we define the property **Inv**:

► **Definition 24** (Distribution property **Inv**). *For a fixed  $n$ , the property **Inv** is defined as the set of distributions over  $[n]^{[n]}$  that are supported by a set of the form  $\{f, g\}$  such that  $(f, g) \in \mathbf{inv}$ . Note that in particular all deterministic distributions satisfy **Inv**, since we allow  $f = g$  to occur.*

To make the above work for binary strings (rather than an alphabet of size  $n$ ) we use an appropriate large distance encoding of the values.

► **Definition 25** (Distribution property **Inv**<sup>\*</sup>). *For a fixed  $n$ , let  $C_n : [n] \rightarrow \{0, 1\}^{2^{\lceil \log_2 n \rceil}}$  be an error-correction code whose distance is at least  $\frac{1}{3}$ . We define **Inv**<sup>\*</sup> as the property of distributions over  $\{0, 1\}^{2^{\lceil \log_2 n \rceil} n}$  that can be constructed by the following procedure: beginning with some  $P \in \mathbf{Inv}$ , we let  $P^*$  denote the distribution that draws  $x \in [n]^n$  according to  $P$ , and then outputs the concatenation  $C_n(x_1) \cdots C_n(x_n)$ .*

The lower bound against locally-bounded adaptivity requires an intricate analysis of the model. Essentially we use the split-adaptive string-testing model to show that when querying each of  $f$  and  $g$  “in solitude”, being adaptive over a function that is drawn at random does not provide an advantage over a non-adaptive algorithm. In particular, the values of a uniformly drawn permutation are “too random” to allow the implementation of a meaningful query strategy without getting some information from the inverse function, even if we allow to “coordinate in advance” the query strategy.

► **Theorem 26**. *Property **Inv**<sup>\*</sup> has a forward-only  $\varepsilon$ -test that uses  $O(\varepsilon^{-2} \log n)$  queries for every  $\varepsilon > 0$ , but any locally-bounded adaptive  $\frac{1}{5}$ -test requires  $\Omega(\sqrt{n})$  queries.*

The upper bound for forward-only testing of **Inv** is demonstrated in Algorithm 2. Applying Algorithm 2 to **Inv**<sup>\*</sup> is pretty straightforward.

■ **Algorithm 2** One sided  $\varepsilon$ -test for **Inv**, forward only,  $O(\varepsilon^{-2})$  queries.

### The query foresight method

Some adaptive algorithms do not obey the forward only restriction but can be modified to do so, using a method we call *query foresight*. Intuitively, an adaptive algorithm that has some knowledge about the structure of the queries it may make in the future can make them speculatively at present (that is, we make all potential queries to satisfy the forward-only constraint, even though we believe that some of them will later be considered as irrelevant). The more knowledge the algorithm has about the potential future queries, the less queries are wasted on the current sample.

As an example to the query foresight method, we analyze and convert a fully adaptive algorithm for the  $m$ -support property (Algorithm 3)

■ **Algorithm 3** One sided  $\varepsilon$ -test for  $m$ -bounded support, strong  $m + 1$ -memory,  $O(\varepsilon^{-1}m^2)$  queries.

---

**Memory storage for samples:**  $z^1, \dots, z^m; x$ , all initialized to **NULL**.  
**Extra cell:** We have another syntactic “write-only” memory storage  $z^{m+1}$  which we never query.

**take**  $s = 1 + \lceil 2\varepsilon^{-1}m \rceil$  samples.  
**set**  $c, t \leftarrow 0$ .  
**set**  $j_1, \dots, j_m \leftarrow \mathbf{NULL}$   
**for**  $k$  **from** 1 **to**  $s$  **do**

**Invariant 1**  $c = m$  or  $z^{c+1} = \mathbf{NULL}$ .  
**Invariant 2** for  $1 \leq i \leq c$ ,  $z_j^i$  are distinct where  $J = \{j_1, \dots, j_t\}$ .  
**store**  $x \leftarrow$  sample  $k$ .  
**query**  $x$  at  $j_1, \dots, j_t$ , giving substring  $y^k$ .  
**for**  $i$  **from** 1 **to**  $c$  **do**

**query** sample  $z^i$  at  $j_1, \dots, j_t$  giving substring  $y^i$ . ▷ the  $y^i$ s are distinct  
**choose**  $j \in [n]$  uniformly at random.  
**query**  $x$  at  $j$ , giving  $x_j$ .  
**if**  $\exists i : y^i = y^k$  **then** ▷ if exists it is unique  
  **query** sample  $z^i$  at  $j$  giving  $z_j^i$ .  
  **if**  $x_j \neq z_j^i$  **then**  
    **store**  $z^{c+1} \leftarrow x$ .  
    **set**  $j^{t+1} \leftarrow j$ . ▷ keep Invariant 2  
    **set**  $t \leftarrow t + 1$  and  $c \leftarrow c + 1$ . ▷ keep Invariant 1

**else**  
  **store**  $z^{c+1} \leftarrow x$ . ▷ Invariant 2 still holds  
  **set**  $c \leftarrow c + 1$ . ▷ keep Invariant 1

**if**  $c > m$  **then**  
  **return** REJECT

**return** ACCEPT

---

► **Theorem 27.** *Algorithm 3 is a one-sided  $\varepsilon$ -test for being supported by at most  $m$  elements.*

We observe that the general structure of Algorithm 3’s queries is highly predictable, and provide a modified version thereof (Algorithm 4) which is also forward-only, without increasing its worst-case query complexity.

The idea is straightforward: we simulate the run of an adaptive algorithm. Every time that the simulation is about to query a new sample, we make additional speculative queries in the current sample, before dropping it as per the requirement of a forward-only algorithm.

## 45:12 Refining the Adaptivity Notion in the Huge Object Model

If the simulated algorithm makes a query to an old sample, we feed it with the answer of the corresponding speculative query. If such a speculative query does not exist, we either accept (for one-sided algorithms) or behave arbitrarily (for two-sided algorithms). If the prediction is conservative, that is, the speculated queries are ensured to cover all queries to past samples, then the construction guarantees the exact acceptance probability for every individual input. This is not guaranteed when the prediction is not conservative, and in this case we need to analyze the effect of bad speculations.

■ **Algorithm 4** One sided  $\varepsilon$ -test for  $m$ -bounded support, forward only,  $O(\varepsilon^{-1}m^2)$  queries.

### $k$ -bounded memory algorithms

As per Definitions 14 and 15 we have two models of bounded memory, which we call *weak* and *strong* respectively. Intuitively, in both models, the algorithm gets a stream of samples, and it has an unrestricted access to  $k$  of these samples. When the algorithm needs an access to a new sample, it must give up the ability to access one of the past samples. In the weak model, the algorithm does not have a choice and it must drop the earliest sample. In other words, the weak model has an unrestricted access to a sliding window of the  $k$  most recent samples. In the strong model, the algorithm is allowed to choose the sample to drop.

For  $k = 1$ , the weak and strong models are both equal to each other and to the forward-only model. Intuitively, as  $k$  increases, the algorithm is able to consider more complicated relations between samples, especially  $k$ -ary relations, which are more challenging for  $k - 1$ -memory algorithms.

### Exponential separation from the forward-only model

We use the ability to fully consider binary relations using 2-memory algorithms, compared to the limited ability to do so using forward-only algorithms, to establish an exponential separation between them.

We define a property **Sym** that catches the idea of symmetric functions. For some symmetric function  $f : [m] \times [m] \rightarrow \{0, 1\}$ , a distribution in the property draws a random key  $a \in [m]$  and returns a vector that contains both  $a$  (using a high distance code of length  $m$ ) and all values of  $f$  at points  $(a, b)$  for  $b \in [m]$ . For technical reasons, we use fixed-distance systematic codes to encode  $a$  as a part of the row.

► **Lemma 28** (Systematic code). *There exists a set  $\mathcal{C}$  of error correction codes, such that for every  $n \geq m \geq 10$ , it has a code  $C_{m,n} : [m] \rightarrow \{0, 1\}^n$  with the following properties: (1) Its minimal codeword distance is at least  $\frac{1}{3}$  and (2) The projection of  $C_{m,n}$  on its first  $\lceil \log_2 m \rceil$  bits is one-to-one, that is,  $C_{m,n}$  can be decoded by reading the first  $\lceil \log_2 m \rceil$  bits.*

From now on, every use of systematic codes refers to the set  $\mathcal{C}$  that is guaranteed by Lemma 28, usually denoted just by  $C$  (rather than the explicit notion  $C_{m,n}$ ).

► **Definition 29** (Matrix property **sym**). *For a fixed  $n$ , the property **sym** of functions with two variables  $f : [n]^2 \rightarrow \{0, 1\}$  is defined as the property of being symmetric, i.e. satisfying  $f(i, j) = f(j, i)$  for all  $i, j \in [n]$ .*

The corresponding distribution property is inspired by considering distributions over the rows of a symmetric matrix, along with properly encoded identifiers.

► **Definition 30** (Distribution property **Sym**). *For any  $m$  and the systematic code  $C : [m] \rightarrow \{0, 1\}^m$  from Lemma 28, the property **Sym** is defined as the set of distributions for which*

$$\Pr_{x \sim P} [\exists a \in [m] : x_{1, \dots, m} = C(a)] = 1$$

(all vectors start with an encoding of a “row identifier”), and for every  $a, b \in [m]$ ,

$$\Pr_{x, y \sim P} [x_{1, \dots, m} = C(a) \wedge y_{1, \dots, m} = C(b) \wedge x_{m+b} \neq y_{m+a}] = 0$$

(if two “identifiers”  $a$  and  $b$  appear with positive probability, then the respective “ $f(a, b)$ ” and “ $f(b, a)$ ” are identical).

► **Theorem 31**. *There exists a one-sided weak 2-memory  $\varepsilon$ -test for **Sym** that makes  $O(\varepsilon^{-2} \log n)$  queries, but every forward-only  $\frac{1}{14}$ -test for **Sym** must use at least  $\Omega(\sqrt{m})$  queries (for sufficiently large  $m$ ).*

The lower bound follows from a forward-only algorithm being given access to every sample without any knowledge about the keys of “future” samples. If the algorithm has only one accessible sample at a time, it can only “guess” the other key, but the probability to actually draw a later sample with that key is too low, unless the algorithm collects queries according to about  $\sqrt{m}$  guessed keys.

## 45:14 Refining the Adaptivity Notion in the Huge Object Model

For the upper-bound, Algorithm 5 performs a sequence of independent iterations using two samples at a time. In every iteration, it gathers their “keys”  $a_1$  and  $a_2$ , verifies the correctness of their codewords, and then checks whether  $f(a_1, a_2) = f(a_2, a_1)$ . There are some cases that should be carefully analyzed, for example the case where the distribution does not correspond to a single  $f$ , or the case where some values for “ $a$ ” appear very rarely or not at all, but these do not defeat the above algorithm (they somewhat affect its number of needed iterations).

■ **Algorithm 5** One-sided  $\varepsilon$ -test for **Sym**, weak 2-memory,  $O(\varepsilon^{-2} \log n)$  queries.

---

```

let  $m \leftarrow n/2$ .
for  $\lceil 8\varepsilon^{-2} \rceil$  times do
  take two samples  $x, y$ .
  query  $x_1, \dots, x_{\lceil \log_2 m \rceil}$ , giving  $\kappa(x)$  as  $a$ .
  query  $y_1, \dots, y_{\lceil \log_2 m \rceil}$ , giving  $\kappa(y)$  as  $b$ .
  choose  $i \in [m]$ , uniformly at random.
  query  $x, y$  at  $i$ , giving  $x_i, y_i$ .
  query  $\phi_x(b), \phi_y(a)$ .
  if  $x_i \neq (C(a))_i$  or  $y_i \neq (C(b))_i$  then
    return REJECT ▷ rejection by key invalidity
  if  $\phi_x(b) \neq \phi_y(a)$  then
    return REJECT ▷ rejection by asymmetry
return ACCEPT

```

---

### Larger memory generalization

We generalize the above theorem to state an exponential separation between the  $k$ -weak model (Definition 14) and the  $k-1$ -strong model (Definition 15). We define a property **Par<sub>k</sub>** based on parity for every  $k \geq 2$  for which:

► **Theorem 32.** *For every  $k \geq 2$ , there exists a one-sided weak  $k$ -memory  $\varepsilon$ -test for **Par<sub>k</sub>** that makes  $O(k\varepsilon^{-k} \log n)$  queries, but every forward-only  $\frac{1}{6k}$ -test for **Par<sub>k</sub>** must use at least  $\Omega(\sqrt{m})$  (for sufficiently large  $n$ ), which is  $\Omega(n^{1/2k})$  queries since  $n \approx \binom{m}{k-1}$ .*

To motivate the definition of **Par<sub>k</sub>**, suppose that  $f : \binom{[m]}{k} \rightarrow \{0, 1\}^k$  is a function such that  $f(A)$  has zero parity for every subset  $A \subseteq [m]$  of size  $k$ . We “encode” such a function as a distribution, making sure to “separate” the  $k$  bits of  $f(A)$  to  $k$  different samples. A typical sample in the distribution would have an encoding (using a high distance code) of a random key  $a \in [m]$ , followed by some information on  $f(A)$  for every  $A$  that contains  $a$ . Specifically, for each such  $A$  we supply the  $i$ th bit of  $f(A)$ , where  $i$  is the “rank” of  $a$  in  $A$  (going by the natural order over  $[m]$ ).

► **Definition 33** (Preliminaries for distribution property **Par<sub>k</sub>**). *Let  $k \geq 2$  be the degree of freedom in the represented function. Let  $m$  be the (sufficiently large) size of the input set and  $n = \binom{m-1}{k-1}$ . Also, consider a systematic code  $C : [m] \rightarrow \{0, 1\}^n$ .*

*For a string  $x \in \{0, 1\}^{2n}$ , let  $\kappa(x) = C^{-1}(x_{1, \dots, n})$  be the key of  $x$  (if the inverse function is not defined we can use an arbitrary key instead). Since we have an implicit mapping between  $k-1$ -subsets of  $\{1, \dots, m\} \setminus \{\kappa(a)\}$  and the indexes  $\{1, \dots, n\}$ , for every  $A \subseteq \{1, \dots, m\} \setminus \{\kappa(a)\}$  of size  $k-1$  we can define  $\Phi_A(x)$  as the corresponding bit in  $x_{n+1, \dots, 2n}$ .*

► **Definition 34** (Distribution property **Par<sub>k</sub>**). *For  $k, m, n, C$  defined above, the property **Par<sub>k</sub>** is defined as the set of distributions over  $\{0, 1\}^{2n}$  for which*

$$\Pr_{x \sim P} [\exists a \in [m] : x_{1, \dots, n} = C(a)] = 1$$

(all vectors start with an encoding of a “row identifier”), and for every  $a_1 < \dots < a_k \in [m]$ ,

$$\Pr_{x^1, \dots, x^k \sim P} \left[ \bigwedge_{i=1}^k (x^i)_{1, \dots, n} = C(a_i) \wedge \bigoplus_{i=1}^k \Phi_{\{a_1, \dots, a_k\} \setminus \{a_i\}}(x^i) = 1 \right] = 0$$

(if all “identifiers”  $a_1, \dots, a_k$  appear with positive probability, then the respective concatenation of values which forms “ $f(\{a_1, \dots, a_k\})$ ” has zero parity).

For the lower bound, if the algorithm has less than  $k$  accessible samples at a time, as with the analysis of the **Sym** property under forward-only testing, the algorithm here can only “guess” the missing key, and the probability to make the right guess is too low.

We go further, and show that even if the  $k - 1$ -memory algorithm is allowed to choose which of the samples are retained in every stage (strong  $k - 1$ -memory) rather than keeping a sliding window of recent history, the exponential separation still holds. The separation is achieved for an  $\varepsilon_k$ -test of the property where  $\varepsilon_k = \Theta(1/k)$ .

For the upper bound, Algorithm 6 makes a sequence of independent iterations of  $k$  samples at a time. In every iteration it gathers the keys  $a_1, \dots, a_k$  and verifies their codewords. If they are all different, the algorithm constructs the value of  $f(\{a_1, \dots, a_k\})$  and checks its parity.

■ **Algorithm 6** One-sided  $\varepsilon$ -test for **Par** $_k$ , weak  $k$ -memory,  $O(\varepsilon^{-k} k \log n)$  queries.

---

```

let  $m$  be such that  $\binom{m-1}{k-1} = n$ .
for  $\lceil 4\varepsilon^{-k} k \rceil$  times do
  take  $k$  new samples  $x^1, \dots, x^k$ .
  for  $t$  from 1 to  $k$  do
    query  $x^1, \dots, x^{\lceil \log_2 m \rceil}$ , giving  $\kappa(x^t)$  as  $a^t$ .
    choose  $i \in [m]$ , uniformly at random.
    query  $x^t$  at  $i$ , giving  $x_i^t$ .
    if  $x_i^t \neq (C(a^t))_i$  then
      return REJECT ▷ reject by key invalidity
  if  $|\{a^1, \dots, a^k\}| = k$  then
    for  $t$  from 1 to  $k$  do
      query  $\Phi_{x^t}(\{a^1, \dots, a^k\} \setminus \{a^t\})$ , giving  $s^t$ .
    if  $\bigoplus_{i=1}^k s^t = 1$  then
      return REJECT ▷ reject by parity-invalidity
return ACCEPT

```

---

## 4 Remaining open problems

It is an open problem whether the weak  $k$ -memory model is indeed strictly weaker than the strong  $k$ -memory model (for the same  $k$ ). And if so, is the separation exponential? Also, we do not know whether or not for every  $k$  there exists  $k^*$  such that the  $k^*$ -weak model contains the  $k$ -strong one.

We believe that there exist some  $\varepsilon_0 > 0$  and  $0 < \alpha < 1$  such that for every sufficiently large  $k$ , there is an exponential separation between the weak  $k$ -memory model and the strong  $\alpha k$ -memory model, with respect to an  $\varepsilon_0$ -test, rather than the separation for  $\varepsilon_k = \Theta(1/k)$  that we show for  $k - 1$  vs  $k$  memory.

Another interesting open problem is whether the fully adaptive model has a simultaneous exponential separation from all fixed  $k$ -memory models. That is, whether there exists a property  $\mathcal{P}$  and some  $\varepsilon_0 > 0$  such that  $\varepsilon_0$ -testing of  $\mathcal{P}$  would require  $\Omega(\text{poly}(n))$  queries in every  $k$ -memory model (the polynomial degree possibly depending on  $k$ ), but  $\mathcal{P}$  is  $\varepsilon$ -testable using  $O(\log n)$  queries using a fully adaptive algorithm for every fixed  $\varepsilon > 0$ .

## Abstract

The Huge Object model is a distribution testing model in which we are given access to independent samples from an unknown distribution over the set of strings  $\{0, 1\}^n$ , but are only allowed to query a few bits from the samples. We investigate the problem of testing whether a distribution is supported on  $m$  elements in this model. It turns out that the behavior of this property is surprisingly intricate, especially when also considering the question of adaptivity.

We prove lower and upper bounds for both adaptive and non-adaptive algorithms in the one-sided and two-sided error regime. Our bounds are tight when  $m$  is fixed to a constant (and the distance parameter  $\epsilon$  is the only variable). For the general case, our bounds are at most  $O(\log m)$  apart. In particular, our results show a surprising  $O(\log \epsilon^{-1})$  gap between the number of queries required for non-adaptive testing as compared to adaptive testing. For one-sided error testing, we also show that an  $O(\log m)$  gap between the number of samples and the number of queries is necessary. Our results utilize a wide variety of combinatorial and probabilistic methods.

## 1 Introduction

Property testing [12, 7] is a framework concerned with analyzing global properties of an input while reading only a small part thereof, in the form of queries. Over the past few decades property testing has become an active field of study in theoretical computer science (see e.g., [6]). The study of distribution property testing was first implicitly explored in [8], and explicitly formulated in [3] and [4]. In the standard model of distribution testing, an algorithm can access a sequence of independently sampled elements drawn from an unknown input distribution  $\mu$ , and it either accepts or rejects the input based on this sequence. An  $\epsilon$ -testing algorithm for a property of distributions is required to accept every input distribution that satisfies the property with high probability (e.g.,  $\frac{2}{3}$ ), and to reject with high probability (e.g.,  $\frac{2}{3}$ ) every input distribution whose variation distance from every distribution satisfying the property is greater than  $\epsilon$ .

The standard model of distribution testing assumes that the elements drawn from the distribution are fully accessible, which might be unreasonable if they have very large descriptions (“huge objects”). The Huge Object model, whose study was initiated in [9], treats the sampled elements as long strings that have to be queried. In this model, for

example, it is possible that the algorithm has two non-identical samples without being able to distinguish between them efficiently. This “two-phase” characteristic of the Huge Object model (“sample then query”, rather than only taking samples or only querying a string) exhibits rich behavior with respect to adaptive querying, as studied in detail in [1].

In the standard model of distribution testing, [13] and [14] show a tight bound of  $\Theta(m/\log m)$  samples for two-sided error  $\varepsilon$ -testing of having a support size bounded by  $m$  in the standard model, for every fixed  $\varepsilon$ . An upper bound of  $O(\varepsilon^{-1}m)$  samples for one-sided algorithms is implicitly shown in [1], and here we show that it is tight (Proposition 24). Based on these tight bounds, the bounded support property is considered to be fully understood in the standard model for one-sided testing, and mostly understood in the two-sided case (for every fixed  $m$  there is still a gap between  $\Omega(\varepsilon^{-1})$  and  $O(\varepsilon^{-2})$  for two-sided testing).

One would expect that having bounded support, which is arguably the simplest of distribution properties, would have simple and easily understood testing bounds also in the Huge Object model. As in the standard model, it is the only label-invariant property that is testable using one-sided error algorithms. However, it turns out that the behaviour of this property under the Huge Object model is surprisingly intricate. One unexpected feature that we show here is a gap between the number of queries required for non-adaptively testing for this property as compared to adaptive testing. Indeed there is no adaptivity in the standard distribution testing model, and one would not expect the label-invariant (and even mapping-invariant as per the definition in [9]) property of having bounded support to exhibit such a gap.

## 1.1 Definition of the model

The Huge Object model differs from the standard sampling model in its distance measure and in the way that the algorithm gathers information about the input distribution.

### Algorithmic model

A probabilistic algorithm  $\mathcal{A}$  with  $q$  queries and  $s$  samples, whose input is a distribution  $P$  over  $\{0, 1\}^n$  accessible via the Huge Object model, is an algorithm that acts in the following manner: at every stage, the algorithm may ask for a new sample  $v$  that is provided by drawing it according to  $P$ , independently of all prior samples, or may ask to query a coordinate  $j \in \{1, \dots, n\}$  of an old sample  $u$  (the algorithm may use internal coin tosses to make its decisions). When this query is made, the algorithm is provided with  $u_j \in \{0, 1\}$  as its answer. The algorithm has no access to the sampled vectors apart from query access. In the end, after taking not more than a total of  $s$  samples and making a total of not more than  $q$  queries, the algorithm provides its output.

We say that the algorithm is *non-adaptive* if it makes all its sampling and querying decisions in advance, prior to receiving all query answers in bulk. Only the final output of a non-adaptive algorithm may depend on the received answers.

### Distances

Here we define some measures of distance. Note that we usually use  $d(\cdot, \cdot)$  without mentioning the measure that we use, if its context is unambiguous. For distributions over  $\{0, 1\}^n$ ,  $d(\cdot, \cdot)$  usually refers to the earth mover’s distance defined below.

► **Definition 1** (String distance). Let  $u, v \in \{0, 1\}^n$  be two strings. We define their distance as the normalized Hamming distance,

$$d_H(u, v) = \frac{1}{n} |\{1 \leq i \leq n \mid u_i \neq v_i\}| = \Pr_{i \sim \{1, \dots, n\}} [u_i \neq v_i]$$

We define the distance of  $u \in \{0, 1\}^n$  from a set  $A \subseteq \{0, 1\}^n$  as  $d_H(u, A) = \min_{v \in A} d_H(u, v)$ .

► **Definition 2** (Transfer distribution). Let  $P$  and  $Q$  be distributions over finite sets  $\Omega_1$  and  $\Omega_2$ , respectively. A distribution  $T$  over  $\Omega_1 \times \Omega_2$  is a transfer distribution from  $P$  to  $Q$  if for every  $a \in \Omega_1$ ,  $\Pr_{(u,v) \sim T} [u = a] = P(a)$ , and for every  $b \in \Omega_2$ ,  $\Pr_{(u,v) \sim T} [v = b] = Q(b)$ . The set of transfer distributions from  $P$  to  $Q$  is denoted by  $\mathcal{T}(P, Q)$ . Note that this is a compact set when considered as a set of real-valued vectors.

► **Definition 3** (Variation distance). Let  $\mu$  and  $\nu$  be two distributions over a finite set  $\Omega$ . Their variation distance is defined as:

$$d_{\text{var}}(\mu, \nu) = \frac{1}{2} \sum_{u \in \Omega} |\mu(u) - \nu(u)| = \max_{E \subseteq \Omega} \left| \Pr_{\mu} [E] - \Pr_{\nu} [E] \right| = \min_{T \in \mathcal{T}(\mu, \nu)} \Pr_{(u,v) \sim T} [u \neq v]$$

► **Definition 4** (Earth mover's distance). Let  $P$  and  $Q$  be two distributions over  $\{0, 1\}^n$ . Their earth mover's distance is defined as:

$$d_{\text{EMD}}(P, Q) = \min_{T \in \mathcal{T}(P, Q)} \mathbb{E}_{(u,v) \sim T} [d_H(u, v)]$$

The above minimum exists since it is in particular the minimum of a continuous function over a compact set.

## Testing model

► **Definition 5** (A property). A property  $\mathcal{P}$  is a sequence  $\mathcal{P}_1, \mathcal{P}_2, \dots$  such that for every  $n \geq 1$ ,  $\mathcal{P}_n$  is a compact subset of the set of all distributions over  $\{0, 1\}^n$ .

► **Definition 6** (Distance of a distribution from a property). Let  $\mathcal{P} = (\mathcal{P}_1, \mathcal{P}_2, \dots)$  be a property and  $P$  be a distribution over  $\{0, 1\}^n$  for some  $n$ . The distance of  $P$  from  $\mathcal{P}$  is defined as  $d_{\text{EMD}}(P, \mathcal{P}) = \min_{Q \in \mathcal{P}_n} \{d_{\text{EMD}}(P, Q)\}$ .

► **Definition 7** ( $\varepsilon$ -test). Let  $\mathcal{P}$  be a property of distributions over  $\{0, 1\}^n$ . We say that a probabilistic algorithm  $\mathcal{A}$  is an  $\varepsilon$ -test for  $\mathcal{P}$  if:

- For every  $P \in \mathcal{P}$ ,  $\mathcal{A}$  accepts with probability higher than  $\frac{2}{3}$ .
- For every probability distribution  $P$  over  $\{0, 1\}^n$  that is  $\varepsilon$ -far from  $\mathcal{P}$  (satisfying  $d(P, \mathcal{P}) > \varepsilon$ ),  $\mathcal{A}$  rejects with probability higher than  $\frac{2}{3}$ .

► **Definition 8** (one-sided and two-sided  $\varepsilon$ -test). Consider the setting of the above definition. If additionally for every input  $P \in \mathcal{P}$ ,  $\mathcal{A}$  accepts  $\mathcal{P}$  with probability 1 (rather than “higher than  $\frac{2}{3}$ ”), then we say that  $\mathcal{A}$  is a one-sided  $\varepsilon$ -test for  $\mathcal{P}$ . Otherwise, we say that  $\mathcal{A}$  has two-sided error.

## 1.2 Summary of our results

### Table of results

The following is a table summarizing the bounds presented here for  $\varepsilon$ -testing for being supported by at most  $m$  elements, along with previously known ones provided for reference (Section 3 contains a sketch on how to derive them). The hidden coefficients in the  $O(\cdot)$  and the  $\Omega(\cdot)$  notations are global numerical constants. The new results appear in purple.

## 46:4 Support Testing in the Huge Object Model

| Model                                 | One-sided Error  | Two-sided Error   |
|---------------------------------------|--|---|
| Standard model<br>(Sample complexity) | $\Theta(\varepsilon^{-1}m)$<br>Folklore, see [1]   | $\Omega(\varepsilon^{-1}m/\log m)$ [13]<br>$O(\varepsilon^{-2}m/\log m)$ [14]                               |
| Huge Object<br>Non-adaptive           | $\Omega(\varepsilon^{-1}m(\log \varepsilon^{-1} + \log m))$<br>$O(\varepsilon^{-1}m \log \varepsilon^{-1} \log m)$ | $\Omega(\varepsilon^{-1} \log \varepsilon^{-1})$<br>$O(\varepsilon^{-3}m \log \varepsilon^{-1})$ [14] + [9] |
| Huge Object<br>Adaptive               | $\Omega(\varepsilon^{-1}m \log m)$<br>$O(\varepsilon^{-1}m \log m \cdot \min\{\log \varepsilon^{-1}, \log m\})$    | $\Omega(\varepsilon^{-1}m/\log m)$ [13]   |

The following are some conclusions to be drawn from the bounds given above. We use  $\mathcal{S}_m$  to denote the property of being supported by at most  $m$  elements.

### Adaptive vs. non-adaptive two-sided asymptotic gap

The most surprising result is that non-adaptively testing a distribution for being supported by at most two elements cannot be done using a number of queries linear in  $\varepsilon^{-1}$ , even with two-sided error. This result applies for every  $m \geq 2$ , and the exact bound is  $\Omega(\varepsilon^{-1} \log \varepsilon^{-1})$  (with the implicit coefficient being independent of  $m$ ). To the best of our knowledge, combined with the  $O(\varepsilon^{-1})$  adaptive upper bound of [1] (which we improve in this paper), “being supported by at most two elements” is the first explicit example of a property that is closed under mapping (and in particular is label-invariant) which has different asymptotic bounds for the number of queries for adaptive algorithms and non-adaptive ones in the Huge Object model (see Theorem 26).

A possible explanation for this is that being label-invariant in the Huge Object model is different from being so in the standard model, because applying a permutation on the labels may change their distinguishability, and in particular it may change the distance from the property.

In this paper we provide a thorough investigation of  $\mathcal{S}_m$  utilizing a variety of methods. In particular, we show several gaps such as the above mentioned one. However, the behaviour of the bounded support property in the Huge Object model, especially when considering it as a problem with two variables (namely the maximal support sized  $m$  and the distance parameter  $\varepsilon$ ) is still not completely understood. We do have tight bounds for the fixed constant  $m$  cases (where only  $\varepsilon$  is variable) for all algorithm types, and bounds up to logarithmic factors for the more general cases.

### One-sided bounds and a gap from the standard model

We have tight bounds for  $\varepsilon$ -testing of  $\mathcal{S}_m$  for every fixed  $m$  (and variable  $\varepsilon$ ) for both non-adaptive algorithms and adaptive ones. These bounds are also tight for every fixed  $\varepsilon$  (and variable  $m$ ). Additionally, our bounds show a gap between the standard model (considering sample complexity) and the Huge Object model (considering query complexity). Consider the bounded support property as a sequence of individual properties, where for every  $m \geq 2$ , the  $m$ -th property is  $\mathcal{S}_m$ . We show that, if we only allow one-sided error tests, there is an  $O(\log m)$  gap between the standard model of distribution testing and the Huge Object model. In the standard model, there exists a one-sided test for  $\mathcal{S}_m$  at the cost of  $O(\varepsilon^{-1}m)$  samples. In the Huge Object model, there is a lower bound of  $\Omega(\varepsilon^{-1}m \cdot \log m)$  many queries for every one-sided  $\varepsilon$ -test, even if it is adaptive. Note that the gap is between the number of *samples* in the standard model and the number of *queries* in the Huge Object model, which is the natural measure of complexity in this model.

## New tools

### A new algorithmic paradigm

For the adaptive one-sided upper bound, we define a standalone algorithmic primitive, the “fishing expedition” paradigm, that repeatedly executes a subroutine until it reaches a predefined goal or when it finds out that it is no longer cost-effective (even if it did not reach the goal). We believe that this primitive will also be useful in future endeavors.

### A hybrid probabilistic-extremal analysis

We define a concept of “valid composition”. Loosely speaking, it is an ordered subset of samples that become closer to each other as the sequence progresses, but are still  $\varepsilon$ -far from each other. We use a hybrid probabilistic-extremal argument to show that for an input distribution that is  $\varepsilon$ -far from  $m$ -support, with high probability, an algorithm with a bounded number of queries will find a valid composition with at least  $m + 1$ -elements.

The hybrid probabilistic-extremal argument works as follows: we define some rank of valid compositions. If for every individual valid composition with at most  $m$  elements, there is a high probability that it is not maximal (according to the rank), then globally there is a high probability that none of them is maximal. Hence, with high probability, the maximally-ranked valid composition within our samples must have at least  $m + 1$  elements.

### A new use for an old combinatorial result

For the adaptive one-sided lower bound, we use an old combinatorial result, that a biclique covering of the  $m$ -clique must have at least  $m \log_2 m$  vertices [10, 11], to show that every witness against  $m$ -support is at least  $m \log m$  bits long, which makes it a lower bound to the number of queries. To apply a multiplicative factor of  $\varepsilon^{-1}$ , which is pretty easy for non-adaptive algorithms, in adaptive algorithms we analyze the effectivity of a decision tree that incrementally constructs a witness based on the queries.

## 1.3 Open problems

### One-sided non-adaptive bounds

We have an  $\Omega(\varepsilon^{-1}m(\log \varepsilon^{-1} + \log m))$  lower bound for one-sided  $\varepsilon$ -testing of  $\mathcal{S}_m$ , as well as an  $O(\varepsilon^{-1}m \log \varepsilon^{-1} \log m)$  upper bound for one-sided  $\varepsilon$ -testing of  $\mathcal{S}_m$ . We believe that the upper bound is tight, but we do not have the corresponding lower bound. What is the true complexity of one-sided  $\varepsilon$ -testing  $\mathcal{S}_m$ ?

### Non-trivial two-sided bounds

Is there a lower bound of  $\omega(m/\log m)$  queries for two-sided testing of  $\mathcal{S}_m$  (noting that [13] only gives  $\Omega(m/\log m)$ ), even for non-adaptive algorithms? We believe that  $\Omega(m)$  should be this lower bound, based on the  $\log m$  gap in the one-sided case (a  $\Theta(m)$  tight bound in the standard model, and a  $\Theta(m \log m)$  tight bound in the Huge Object model).

### One-sided adaptive bounds

Our results for one-sided adaptive  $\varepsilon$ -testing of  $\mathcal{S}_m$  are tight with respect to  $m$ , but have a logarithmic gap with respect to  $\min\{\varepsilon^{-1}, m\}$ . Closing this gap is an open problem.

### The tradeoffs between sample and query complexity

Our bounds apply to the query complexity of the tests. The lower bounds adapted from previous works on the traditional model clearly apply for the sample complexity here, even if we allow a higher query complexity. As for our new upper bounds, most of them have a polylogarithmic average queries per sample ratio. It would be interesting to investigate whether the sample complexity can be reduced if we allow a much higher (but still sub-linear in  $n$ ) number of queries per sample.

## 2 Preliminaries

### 2.1 Algorithmic model

As observed by Yao [16], every probabilistic algorithm can be seen as a distribution over a set of deterministic algorithms. Hence we can analyze probabilistic query-making algorithms by analyzing the deterministic algorithms they are supported on.

We observe that we can assume that all samples are drawn before the first query is made, since they are fully independent: the distribution of every sample made does not depend at all on any calculation or queries that occurred before it was taken, and so we can assume that it was taken before any calculation was performed. Based on this observation we can represent our algorithms using a  $\{0, 1\}$ -valued matrix (whose rows are sampled from the distribution), from which the algorithms are allowed to query.

► **Definition 9** (Matrix representation of input access). *Considering an algorithm with  $s$  samples and  $q$  queries, we assume that the samples are all taken at the beginning of the algorithm and are used to populate a matrix  $M \in \{0, 1\}^{s \times n}$ . Then, during the run of the algorithm, each of its queries is represented as a pair  $(i, j) \in \{1, \dots, s\} \times \{1, \dots, n\}$ , for which the answer is  $M_{i,j}$ .*

► **Definition 10** (Adaptive algorithm). *Every deterministic algorithm in the Huge Object model with  $q$  queries over  $s$  samples is equivalent to a pair  $(T, A)$ , where  $T$  is a decision tree of height  $q$  in which every internal node contains a query  $(i, j)$  (where  $1 \leq i \leq s$  is the index of a sample and  $1 \leq j \leq n$  is the index to query), and  $A$  is the set of accepting leaves.*

► **Definition 11** (Non-adaptive algorithm). *A deterministic algorithm  $(T, A)$  with  $q$  queries is non-adaptive if, for every  $0 \leq i < q$ , all internal nodes at the  $i$ -th level consist of the exact same query. Every non-adaptive algorithm can be represented as a pair  $(Q, A)$ , where  $Q \subseteq \{1, \dots, s\} \times \{1, \dots, n\}$  is a set of queries and  $A \subseteq \{Q \mapsto \{0, 1\}\}$  is the set of accepted answer vectors.*

### 2.2 Technical components

#### Fishing expedition

We define an algorithmic primitive that allows us to repeat an execution of a probabilistic subroutine until it is no longer effective. Consider for example a “coupon-collector” type process, but one in which the number of distinct elements is not known to us. The goal is to collect a preset number of elements, but we also want to stop early if we believe that there are no more elements to be effectively collected.

Consider a (probabilistic) subroutine  $\mathcal{A}$  that can either fail or succeed. We denote the outcome of an execution of  $\mathcal{A}$  by  $R$ . In this discussion the outcome includes both the explicit output of the execution and its side effects, which may affect the probabilities for

future executions of  $\mathcal{A}$ . We thus analyze a *sequence* of executions  $R_1, \dots, R_N$ , where  $R_1$  is performed over the initial state. We define two behaviors of “coupon collection” that such an  $\mathcal{A}$  must present.

► **Definition 12** (Fail stability). *Let  $\mathcal{A}$  be a subroutine that may succeed or fail. Specifically let  $R_1, \dots, R_N$  be random variables that detail the outputs of the first  $N$  executions of  $\mathcal{A}$ . We say that  $\mathcal{A}$  is fail stable with respect to a set  $G$  of outcomes indicating success, if for every  $2 \leq i \leq N$  and every result sequence  $(r_1, \dots, r_{i-1}) \in \text{supp}(R_1, \dots, R_{i-1})$  for which  $r_{i-1} \notin G$ :*

$$\begin{aligned} \Pr[R_i \in G \mid R_1 = r_1, \dots, R_{i-2} = r_{i-2}, R_{i-1} = r_{i-1}] \\ = \Pr[R_{i-1} \in G \mid R_1 = r_1, \dots, R_{i-2} = r_{i-2}] \end{aligned}$$

*In other words, a failure does not affect the probability of further executions to succeed.*

► **Definition 13** (Diminishing returns). *Let  $\mathcal{A}$  and  $R_1, \dots, R_N$  be as in Definition 12. We say that  $\mathcal{A}$  has diminishing returns with respect to a set  $G$  of successful outcomes, if for every  $2 \leq i \leq N$  and every result sequence  $(r_1, \dots, r_{i-1}) \in \text{supp}(R_1, \dots, R_{i-1})$ :*

$$\begin{aligned} \Pr[R_i \in G \mid R_1 = r_1, \dots, R_{i-2} = r_{i-2}, R_{i-1} = r_{i-1}] \\ \leq \Pr[R_{i-1} \in G \mid R_1 = r_1, \dots, R_{i-2} = r_{i-2}] \end{aligned}$$

*That is, if  $\mathcal{A}$  has diminishing returns, then a success in a single execution never increases, but may decrease, the probability of further executions to succeed.*

Recall the coupon-collecting example. We expect it to have both fail stability and diminishing returns (with respect to a common set  $G$  of outcomes indicating success). If we look for a coupon and do not find it in a single try, nothing happens. Further tries will have the same probability to succeed. On the other hand, if we collect a coupon, then in further tries, there are less uncollected coupons left and it is slightly harder to find an additional one.

The fishing expedition paradigm seeks to collect a goal of  $k$  coupons, but “gives up” if it believes that the probability to find an additional coupon is less than some parameter  $p$ .

The desired algorithm (Algorithm 1) has three parameters: a threshold  $p$ , a confidence  $q$  and a goal  $k \geq 1$ . The input is a subroutine  $\mathcal{A}$  with diminishing returns and fail stability (with respect to some common set  $G$ ). Informally, the goal of the algorithm is to have  $k$  successful executions of  $\mathcal{A}$ , but also to terminate earlier if the probability of  $\mathcal{A}$  to succeed becomes lower than  $p$ . Since the algorithm has no actual access to the success probability of  $\mathcal{A}$ , it should terminate early only if it is confident enough that the success probability of further executions is too low for them to be effective.

► **Lemma 14.** *Consider a black box subroutine  $\mathcal{A}$  with fail stability (Definition 12) and diminishing returns (Definition 13) with respect to a common set  $G$  of outcomes indicating success.*

*For an algorithm that repeatedly executes  $\mathcal{A}$ , we define the following random variables:*

- $N$  – the number of executions.
- $R_1, \dots, R_N$  – their outcomes.
- $X_1, \dots, X_N$  – indicators of success (that is,  $X_i = 1$  if and only if  $R_i \in G$ ).
- $H = \sum_{i=1}^N X_i$  – the number of successful executions.
- $\hat{p} = \Pr[X_{N+1} = 1 \mid R_1, \dots, R_N]$  – the success probability of a possible extra execution of  $\mathcal{A}$ .

*Considering the parameters  $p > 0$  (threshold),  $q > 0$  (confidence), and  $k \geq 1$  (goal), there exists an algorithm that repeatedly executes  $\mathcal{A}$  for which  $N \leq p^{-1}(4H + 5(\log q^{-1} + \log(\log k + 1))) + 1$  and  $H \leq k$ , such that with probability higher than  $1 - q$ , either  $H = k$  or  $\hat{p} \leq p$  (or both).*

■ **Algorithm 1** Fishing expedition.

---

**parameters**  $k \geq 1$  (goal),  $p > 0$  (threshold),  $q > 0$  (confidence).  
**input** A subroutine  $\mathcal{A}$  with output, given as a black box, where an output outside a set  $G$  means FAIL.  
**let**  $t_{\max} \leftarrow \lfloor \log k + 1 \rfloor$ .  
**let**  $N_1 \leftarrow 0$ .  
**set**  $H \leftarrow 0$ .  
**for**  $t$  **from** 2 **to**  $t_{\max}$  **do**  
  **let**  $N_t \leftarrow \lceil p^{-1} \max\{2^t, 5(\log q^{-1} + \log(\log k + 1))\} \rceil$ .  
  **for**  $N$  **from**  $N_{t-1} + 1$  **to**  $N_t$  **do** ▷ possibly empty  
    **run**  $\mathcal{A}$ , let  $R_N$  be its outcome.  
    **let**  $X_N$  be an indicator for success ( $X_N = 1$  if  $R_N \in G$ , otherwise  $X_N = 0$ ).  
    **set**  $H \leftarrow H + X_N$ .  
    **if**  $H = k$  **then terminate** with  $N$ . ▷ goal is reached  
  **if**  $H < \frac{1}{2}pN_t$  **then**  
    **terminate** with  $N_t$ . ▷ continuing is ineffective

---

The proof of the lemma follows from two claims. The first claim asserts that for  $t_{\max} = \lfloor \log k + 1 \rfloor$  and for every  $2 \leq t \leq t_{\max}$ , after  $\lceil p^{-1} \cdot \max\{2^t, 5(\log q^{-1} + \log(\log k + 2))\} \rceil$  executions of  $\mathcal{A}$ , the algorithm terminates if the number of successful executions was less than a  $\frac{1}{2}p$ -portion of the total number of executions. The second claim shows that the algorithm reaches one of its goals with probability higher than  $1 - q$ , and uses a variant of Chernoff's inequality to give an upper bound on the probabilities of bad events.

### Contradiction graph

We define here what it means to be a “counter-example” for having support size at most  $m$ .

► **Definition 15** (Contradiction graph). *Let  $x_1, \dots, x_s \in \{0, 1\}^n$  be a sequence of strings. Let  $Q \subseteq \{1, \dots, s\} \times \{1, \dots, n\}$  be a set of queries. We define the contradiction graph of  $(x_1, \dots, x_s; Q)$  as  $G(V, E)$  with  $V = \{1, \dots, s\}$ , and for every  $1 \leq i_1, i_2 \leq s$ :*

$$\{i_1, i_2\} \in E \iff \exists 1 \leq j \leq n : (x_{i_1})_j \neq (x_{i_2})_j \wedge ((i_1, j), (i_2, j) \in Q)$$

*Note that the graph is undirected since the definition of the edges is commutative. It is also clearly without self-loops.*

► **Definition 16** (Witness against  $m$ -support). *Let  $P$  be a distribution that is supported by a set of more than  $m$  elements. We say that  $(x_1, \dots, x_s; Q)$  is a witness against  $m$ -support (of  $P$ ) if  $x_1, \dots, x_s$  are all drawn from  $P$ , and their contradiction graph is not  $m$ -colorable.*

In the full version, we prove that calling the above a witness is indeed justified, in the sense that a distribution  $P$  has  $m$ -support if and only if there is zero probability to draw a tuple  $x_1, \dots, x_s$  for which one can provide a query set  $Q$  that makes it a witness.

► **Lemma 17.** *Let  $x_1, \dots, x_s \in \text{supp}(P)$  be a set of samples and let  $Q \subseteq \{1, \dots, s\} \times \{1, \dots, n\}$  be a query set. Let  $Q_1, \dots, Q_s$  be the sample-specific query sets, that is,  $Q = \bigcup_{i=1}^s (\{i\} \times Q_i)$ , and let  $G$  be the contradiction graph as per Definition 15. If  $G$  is not colorable by  $m$  colors, then  $|\{x_1, \dots, x_s\}| > m$ . And if  $G$  is colorable by  $m$  colors, then there exists  $\hat{P}$  with  $|\text{supp}(\hat{P})| \leq m$  and a sequence  $y_1, \dots, y_s \in \text{supp}(\hat{P})$  such that for every  $1 \leq i \leq s$ ,  $x_i|_{Q_i} = y_i|_{Q_i}$ .*

► **Definition 18** (Explicit witness against  $m$ -support). *Let  $P$  be a distribution that is supported by a set of more than  $m$  elements. We say that  $(x_1, \dots, x_s, Q)$  is an explicit witness against  $m$ -support (of  $P$ ) if  $x_1, \dots, x_s$  are all drawn from  $P$ , and their contradiction graph contains a clique with  $m + 1$  vertices as a subgraph.*

Note that an explicit witness is in particular a witness against  $m$ -support, but the converse does not generally hold.

### 3 Quick bounds from previous results

We recall some known results for the standard model and use them to derive initial bounds on testing  $\mathcal{S}_m$ . Due to space limitation, all proofs are deferred to the full version of the paper.

Observe that, without loss of generality, we can assume that every sample is queried at least once. Using distributions over sets of vectors that are mutually 0.499-far, lower bounds for the standard model can be converted to the Huge Object model, implying in particular the following.

► **Proposition 19** (Proposition 2.8 in [9]). *Every two-sided error  $\varepsilon$ -test for  $\mathcal{S}_m$  makes at least  $\Omega(m/\log m)$  queries (for some fixed  $\varepsilon$ ).*

In the Huge Object model, different samples may be indistinguishable, hence standard-model algorithms cannot be immediately converted to Huge Object model ones. However, we can use the following reduction.

► **Lemma 20** (Theorem 2.2 in [9]). *Suppose that  $\mathcal{P}$  is testable with sample complexity  $s(n, \varepsilon)$  in the standard model, and that  $\mathcal{P}$  is closed under mapping (note that bounded support properties are closed under mapping). Then for every  $\varepsilon > 0$  there exists a non-adaptive  $\varepsilon$ -test for  $\mathcal{P}$  in the Huge Object model that uses  $3 \cdot s(m, \varepsilon)$  samples and  $O(\varepsilon^{-1} \log(\varepsilon^{-1} s(m, \varepsilon/2)))$  queries per sample.*

► **Proposition 21** (combining [14] and [9]). *There exists a two-sided  $\varepsilon$ -test for  $\mathcal{S}_m$  whose query complexity is  $O(\varepsilon^{-3} m \log \varepsilon^{-1})$ .*

In the above we used [14] rather than the more recent [15], since we needed a statement that holds for all values of  $\varepsilon$  (including those smaller than  $1/m$ ). Proposition 21 implies that for every fixed  $\varepsilon$  and variable  $m$ , there exists an  $O(m)$  non-adaptive two-sided error  $\varepsilon$ -test for  $\mathcal{S}_m$ . In this context we also note the following known bounds.

► **Theorem 22** (Corollary 2.3 in [9]). *For every  $\varepsilon > 0$  and  $m \geq 2$ , there exists a non-adaptive one-sided  $\varepsilon$ -testing algorithm for  $\mathcal{S}_m$  that takes  $O(\varepsilon^{-1} m)$  samples and makes  $O(\varepsilon^{-2} m \log(m/\varepsilon))$  queries.*

► **Theorem 23** (Theorem 6.1 in [1]). *For every  $\varepsilon > 0$  and  $m \geq 2$ , there exists an adaptive one-sided  $\varepsilon$ -testing algorithm for  $\mathcal{S}_m$  that takes  $O(\varepsilon^{-1} m)$  samples and makes  $O(\varepsilon^{-1} m^2)$  queries.*

This immediately implies an upper bound of  $O(\varepsilon^{-1} m)$  samples for  $\varepsilon$ -testing  $\mathcal{S}_m$  in the standard model of distribution testing. As can be expected, this is tight. The following proposition is considered common knowledge, but for the sake of completeness we prove it in the full version of the paper.

► **Proposition 24.** *Every one-sided  $\varepsilon$ -test for  $\mathcal{S}_m$  takes at least  $\Omega(\varepsilon^{-1} m)$  samples in the standard model.*

As with Proposition 19, this can be converted to a Huge Object model bound.

► **Proposition 25.** *Every one-sided  $\varepsilon$ -test for  $\mathcal{S}_m$  in the Huge Object model must make at least  $\Omega(\varepsilon^{-1}m)$  queries as well.*

In this paper we improve this proposition, showing a gap between the standard model and the Huge Object model for one-sided error tests.

## 4 Overview of our proofs

In this section we state our main results and give an overview of how to obtain them. The full proofs appear in the full version.

### 4.1 Two-sided, non-adaptive lower-bound

► **Theorem 26.** *Every non-adaptive  $\varepsilon$ -test for  $\mathcal{S}_m$  must make  $\Omega(\varepsilon^{-1} \log \varepsilon^{-1})$  queries, even if it has two-sided error.*

We first describe our lower bound for  $\mathcal{S}_2$ , which holds the main ideas also for  $\mathcal{S}_m$ . We begin by analyzing a restricted form of non-adaptive algorithms, which we call *rectangle algorithms*. A rectangle algorithm is characterized by the number of samples  $s$  and a set  $I$  of indices. Every sample is queried at the indices of  $I$ , hence the query complexity is  $s \cdot |I|$ . We say that  $|I|$  is the “width” of the rectangle and that the number of samples is its “height”.

Consider the following  $O(\varepsilon^{-1})$ -query rectangle algorithm: for some hard-coded parameter  $\beta > 0$ , it chooses a set  $I$  of  $O(\beta^{-1})$  indices, and then it takes  $O(\beta\varepsilon^{-1})$  samples, and queries every sample on all indices of  $I$ .

Now consider the following form of inputs. For some  $\alpha > 0$  and two strings  $a$  and  $b$  for which  $d(0, a), d(0, b), d(a, b) = \Theta(\alpha)$ , let  $P$  be the following distribution. The string 0 is picked with probability  $1 - c\alpha^{-1}\varepsilon$ , the string  $a$  with probability  $\frac{c}{2} \cdot \alpha^{-1}\varepsilon$  and the string  $b$  with probability  $\frac{c}{2} \cdot \alpha^{-1}\varepsilon$ , where  $c > 1$  is some global constant.

Intuitively, the algorithm finds a witness against 2-support if there is a query common to  $a$  and  $b$ , at an index  $j$  that is not always zero (we call such  $j$  a *non-zero index*). That is, there are two necessary conditions to reject: the algorithm must get both  $a$  and  $b$  as samples, and it must query at an index  $j$  for which  $(a)_j \neq (b)_j$ .

The expected number of non-zero samples that the algorithm gets is  $O(\alpha^{-1}\beta)$ . If  $\alpha$  is much greater than  $\beta$ , then with high probability the algorithm only gets all-zero samples and cannot even distinguish the input distribution from the deterministic all-zero one.

If  $\alpha$  is much smaller than  $\beta$ , then with high probability all queries are made in “zero indices” and the algorithm again cannot even distinguish the input distribution from the deterministic all-zero one. Thus, the algorithm can reject the input with high probability only if  $\alpha \approx \beta$ .

Our construction of  $D_{\text{no}}$  chooses  $\alpha = 2^k$  where  $k$  is distributed uniformly over its relevant range, to ensure that a rectangle algorithm (with a fixed  $\beta$ ) “misses”  $\alpha$  with high probability. Intuitively, the idea is that a non-adaptive algorithm must accommodate a large portion of the possible values of  $\alpha$ , which would lead to an additional  $\log \varepsilon^{-1}$  factor. Then, we show that given an input drawn from  $D_{\text{no}}$ , if the algorithm did not distinguish two non-zero elements, then the distribution of runs looks exactly the same as the distribution of runs of the same algorithm given an input drawn from  $D_{\text{yes}}$ , which is supported over 0 and a single  $a$ .

To show that the above distributions defeat any non-adaptive algorithm (not just rectangle algorithms), we analyze every index  $1 \leq j \leq n$  according to the number of samples which are queried in that index. If few samples are queried, then this index has a high probability of not hitting two non-zero samples, rendering it useless (we gain an important advantage by noting

that querying  $j$  from at least two non-zero samples is required for it to be useful). If many samples are queried on  $j$  then this index may hit many samples, but only few indices can host many queries, which gives us a high probability of all of them together not containing a non-zero index among them.

To extend this result to  $m \geq 2$ , for every  $t \geq 2$  we define a distribution  $D_{\text{no}}^t$  over inputs that are supported by  $t + 1$  elements (one of them being the zero vector), and also  $\varepsilon$ -far from being supported by  $m$  elements (for every  $m \leq t/2 + 1$ ). As before, we define  $D_{\text{yes}}$  as a distribution over inputs supported by 2 elements, which is identical to  $D_{\text{no}}^1$ , and then we proceed with the same argument as before.

► **Definition 27** ( $D_{\text{no}}^t, D_{\text{yes}}$ ). *The distribution  $D_{\text{no}}^t$  (over a set of distributions) is obtained by the following process. Draw  $\alpha$  such that  $\log_2 \alpha^{-1}$  is uniform over  $\{2, \dots, \lfloor \log_2 \varepsilon^{-1} \rfloor - 2\}$ . Draw a set  $D \subseteq \{1, \dots, n\}$  such that for every  $1 \leq j \leq n$ ,  $\Pr[j \in D] = 4\alpha$ , independently. Then, for every  $1 \leq k \leq t$ , draw a set  $A_k \subseteq D$  such that for every  $j \in D$ ,  $\Pr[j \in A_k | j \in D] = \frac{1}{2}$ , independently. The resulting input is defined as the following distribution over  $\{0, 1\}^n$ :*

$$P : \begin{cases} 0 & \text{with probability } 1 - 2\alpha^{-1}\varepsilon \\ 1_{A_1} & \text{with probability } 2\alpha^{-1}\varepsilon/t \\ \vdots & \\ 1_{A_t} & \text{with probability } 2\alpha^{-1}\varepsilon/t \end{cases}$$

The distribution  $D_{\text{yes}}$  is identical to  $D_{\text{no}}^1$

## 4.2 One-sided, non-adaptive upper bound

► **Theorem 28.** *There exists a one sided  $\varepsilon$ -testing algorithm for  $\mathcal{S}_m$  making  $O(\varepsilon^{-1} \log \varepsilon^{-1} \cdot m \log m)$  queries.*

Let us first consider a “reverse engineering” algorithm: for every  $\ell = 2^0, 2^1, \dots, 2^{\log \varepsilon^{-1}}$ , we query  $\Theta((\varepsilon^{-1}/\ell) \cdot \log m)$  indices that are common to at least  $\ell \cdot m$  samples. Intuitively, according to the analysis of the two-sided lower bound, the algorithm should have roughly  $\Omega(m \log m)$  indices that distinguish pairs of elements, which suffice for a contradiction graph that contains an  $m + 1$ -clique.

This intuition appears to be lacking when it comes to showing the correctness of this construction for inputs that lack the special form of  $D_{\text{no}}^t$  from Definition 27. To be able to handle distance combinations (instead of just one “ $\alpha$ ” as above), we use a concept of “valid compositions”.

► **Definition 29.** *A valid composition is an ordered combination of samples  $(x_1, \dots, x_k)$  and a sequence of non-decreasing scales  $(a_2, \dots, a_k)$ , for which the distances are bounded by  $d(x_i, \{x_1, \dots, x_{i-1}\}) > 2^{-a_i-1}$ .*

Querying according to index sets whose random choice follows the prescribed distances distinguishes all elements in a composition with high probability. Our goal is to show the existence of valid compositions of  $m + 1$  elements in order to ensure that we find an explicit witness, and thus establish the upper bound. In particular, the algorithm (Algorithm 2) works as follows. It looks for a set  $A$  for of size at least  $m + 1$  whose elements are fully distinguishable using queries.

At first, the algorithm chooses  $I_0 \subseteq I_1 \subseteq \dots \subseteq I_{\log \varepsilon^{-1}} \subseteq \{1, \dots, n\}$ , where  $I_a$  consists of  $\lceil 2^{a+2} \log(m + 1) \rceil$  indices drawn uniformly and independently.

## 46:12 Support Testing in the Huge Object Model

The algorithm takes  $1 + 32\varepsilon^{-1}m$  samples. Except for the first sample, they are partitioned into  $2m$  “blocks” of at most  $16\varepsilon^{-1}$  samples each. For every  $1 \leq k \leq 2m$  and  $0 \leq a \leq \log \varepsilon^{-1}$ , the algorithm takes a sequence  $S_{a,k}$  of  $2^{3-a}\varepsilon^{-1}$  new samples, and queries every sample in it at the indices of  $I_a$ .

The algorithm rejects if there exists a *distinguishable composition* of size  $m + 1$  (which in particular is also a witness against  $\mathcal{S}_m$ ).

► **Definition 30.** *We say that a composition is a distinguishable composition if for every  $1 \leq i_1 < i_2 \leq k$  there exists a query  $j \in I_{a_{i_1}} \cap I_{a_{i_2}}$  for which  $(x_{i_1})_j \neq (x_{i_2})_j$ .*

■ **Algorithm 2** Non-adaptive construction of a valid composition.

---

```

choose indices  $i_1, \dots, i_{\lceil 4\varepsilon^{-1} \log(m+1) \rceil}$  uniformly and independently, with repetitions.
for  $0 \leq a \leq \log \varepsilon^{-1}$  do
    let  $I_a = \{i_1, \dots, i_{\lceil 2^{a+2} \log(m+1) \rceil}\}$ .
take a sample  $u$ .
query  $u$  at  $I_{\log \varepsilon^{-1}}$ .
for  $k$  from 1 to  $2m$  do
    for  $a$  from 0 to  $\log \varepsilon^{-1}$  do
        take  $2^{3-a}\varepsilon^{-1}$  new samples, denoting the sequence by  $S_{a,k}$ .
        query all samples in  $S_{a,k}$  at  $I_a$ .
if there exists a distinguishable composition of size  $m + 1$  then
    return REJECT
else
    return ACCEPT

```

---

However, it is not clear that “long” valid compositions even exist. To show their existence with high probability whenever the input is  $\varepsilon$ -far from having support size at most  $m$ , we use an extremal probabilistic argument. For this purpose, for a composition  $A$  we define its rank to be its scale sequence  $\vec{r}(A) = (a_2, \dots, a_k)$ , and refer to the lexicographic order over ranks (in particular considering a proper prefix of a sequence to be smaller in that order).

We then show that if the input is  $\varepsilon$ -far from having support size  $m$ , then with high probability no composition with at most  $m$  elements has maximal rank. This implies that the maximally ranked composition cannot have less than  $m + 1$  elements, leading with high probability to finding an explicit witness against  $m$ -support through the queries made to this composition.

To show the above in the full version, for every  $K \subseteq \{1, \dots, 2m\}$  we define the event that the blocks indexed by  $K$  are exactly those that contain the maximally ranked composition. We then show that if the length of this composition is at most  $m$ , (and the input is  $\varepsilon$ -far from the property), then the probability of this event happening is small enough to deploy a union bound argument against all such events.

### 4.3 One-sided, adaptive upper bound

► **Theorem 31.** *There exists a one-sided  $\varepsilon$ -testing algorithm for  $\mathcal{S}_m$  making  $O(\varepsilon^{-1}m \log m \cdot \min\{\log \varepsilon^{-1}, \log m\})$  queries.*

We adaptively construct a distinguishing sequence that resembles a valid composition (see Definition 29), but at some point we decide to “give up” and change phase to another way of querying that is more efficient under some conditions. Luckily, the condition that makes us give up implies them. For every distance scale, from  $\Omega(1)$  to  $\frac{1}{m}$ , we use the “fishing expedition” paradigm (Lemma 14) using Algorithm 3 as the subroutine  $\mathcal{A}$ , to extend our sequence with as many elements as we can until we are certain enough that it is no longer effective to look for them (or until we find a witness against  $m$ -support). This phase is described in Algorithm 4.

■ **Algorithm 3** Adaptive one-sided  $\varepsilon$ -test for  $\mathcal{S}_m$ , a single batch.

---

**parameters**  $\varepsilon > 0$ ,  $A$ ,  $m \geq 2$ ,  $0 \leq a \leq \lceil \log m \rceil$  where  $|A| \leq m$ .  
**input** A distribution  $P$ .  
**choose** a set  $J$  of  $\lceil 2^{a+2} \log m \rceil$  indices uniformly and independently.  
**query**  $X$  at  $J$  for every  $X \in A$ .  
**take**  $\lceil 2^{2-a} \varepsilon^{-1} \log m \rceil$  samples.  
**query** each new sample at  $J$ .  
**if** there exists a sample  $Y$  for which  $Y|_J \neq X_J$  for every  $X \in A$  **then**  
    **set**  $A \leftarrow A \cup \{Y\}$ .  
    **return** SUCCESS with  $(Y, J)$ .  
**else**  
    **return** FAIL

---

■ **Algorithm 4** Adaptive one-sided  $\varepsilon$ -test for  $\mathcal{S}_m$ , first phase.

---

**parameters**  $\varepsilon > 0$ ,  $m \geq 2$ .  
**input** A distribution  $P$ , a set  $A \subseteq \text{supp}(P)$  of distinguishable elements.  
**for**  $a$  **from** 0 **to**  $\lceil \log m \rceil$  **do**  
    **let**  $k_a = m + 1 - |A|$ .  
    **run** Algorithm 1 (“fishing expedition”) with parameters  $k = k_a$ ,  $q = \frac{1}{4^{\lceil \log m + 1 \rceil}}$ ,  $p = \frac{1}{3}$ ,  
    and  $\mathcal{A} =$  Algorithm 3 (a single batch).  
    **if**  $|A| \geq m + 1$  **then**  
        **return** REJECT  
    Proceed to the second phase with  $A$ .

---

Unfortunately, it is possible that at some point the algorithm is certain enough that it is no longer effective to look for elements in any of these scales. At this point, we observe that the contribution of elements with small distance scale to the distance of the input from  $\mathcal{S}_m$  is still  $\Omega(\varepsilon)$  (that is, we can safely ignore the “rare large-distance elements”). To make use of this observation, the algorithm shifts to the second phase, looking for elements with small distances in a way which does not follow the theme of looking for valid compositions.

In the small distance scale phase we construct and maintain a “decision tree” data structure over the existing elements, so that for every element that we need to compare to the existing elements, we can rule out in advance, using only  $O(m)$  many queries, all but one of them. This allows us to save queries, since the smaller distances require the querying of relatively many indices for a comparison, which would have been very inefficient to perform for all existing elements. See Algorithm 5 for precise details.

■ **Algorithm 5** Adaptive one-sided  $\varepsilon$ -test for  $\mathcal{S}_m$ , a single iteration of the second phase.

---

**input** A sample  $Y \in \text{supp}(P)$ ,  $A \subseteq \text{supp}(P)$ , a decision tree  $\mathcal{T}$ ;  $|A| \geq 1$ .  
**invariant**  $\mathcal{T}$  has  $|A|$  leaves corresponding to  $A$ 's elements.  
**choose** a set  $J$  of  $m$  indices uniformly, independently, with repetitions.  
**let**  $X \in A$  for which  $\mathcal{T}(Y) = \mathcal{T}(X)$  (using up to  $|A|$  queries to  $Y$  to follow  $\mathcal{T}$  and find  $X$ ).  
**query**  $X, Y$  at  $J$ .  
**if**  $Y|_J \neq X|_J$  **then**  
    **set**  $A \leftarrow A \cup \{Y\}$ .  
    **add**  $Y$  to  $\mathcal{T}$  (using a distinguishing index  $j \in J$  to split the leaf of  $X$ ).

---

Finally, we combine the above procedure to obtain our desired algorithm:

■ **Algorithm 6** Adaptive one-sided  $\varepsilon$ -test for  $\mathcal{S}_m$ .

---

**input** A distribution  $P$ .  
**if**  $\varepsilon \geq \frac{1}{m^2}$  **then**  
    **run** Algorithm 2 and **return** its answer.  
**take** the first sample  $u$ .  
**set**  $A \leftarrow \{u\}$ .  
**run** Algorithm 4 (possibly modifying  $A$ , possibly rejecting).  
**construct** a decision tree  $\mathcal{T}$  based on  $A$ .  
**invariant**  $\mathcal{T}$  has  $|A|$  leaves corresponding to  $A$ 's elements.  
**for**  $\lceil 48\varepsilon^{-1} \rceil$  **times do**  
    **draw** another sample  $Y$ .  
    **run** Algorithm 5 with  $(Y, A, \mathcal{T})$  (note that  $A, \mathcal{T}$  may have been modified).  
    **if**  $|A| \geq m + 1$  **then**  
        **return** REJECT  
**return** ACCEPT

---

#### 4.4 One-sided lower-bounds

► **Theorem 32.** *Every one-sided (possibly adaptive)  $\varepsilon$ -test for  $\mathcal{S}_m$  must make  $\Omega(\varepsilon^{-1}m \log \varepsilon^{-1})$  queries.*

We prove that an algorithm obtains a witness against  $m$ -support if and only if the contradiction graph (Definition 15) is not  $m$ -colorable. Hence we look for the lower bound on the number of queries needed to construct a non- $m$ -colorable contradiction graph.

We observe that, given a query set, every index  $j$  describes a biclique contradiction graph whose classes are “all samples queried at  $j$  for which  $x_j = 0$ ” and “all samples queried at  $j$  for which  $x_j = 1$ ”. The contradiction graph is the union of these graphs. Specifically, we define the notion of *capacity*.

► **Definition 33** (Capacity of an edge cover). *Let  $G$  be a graph over a set  $V$  vertices and let  $\mathcal{G} = (G_1, \dots, G_k)$  be a sequence of graphs over  $V_1, \dots, V_k \subseteq V$  such that  $G = \bigcup_{i=1}^k G_i$ . We define the capacity of  $\mathcal{G}$  as  $\text{cap}(\mathcal{G}) = \sum_{i=1}^k |V_k|$ .*

The following observation follows directly from the definition of capacity.

► **Observation 34.** *Let  $P$  be a distribution over  $\{0, 1\}^n$ ,  $x_1, \dots, x_s \in \text{supp}(P)$  be a set of samples and  $Q \subseteq \{1, \dots, s\} \times \{1, \dots, n\}$  be a query set. Let  $S_1, \dots, S_n$  be the index-specific query sets, that is,  $Q = \bigcup_{j=1}^n (S_j \times \{j\})$ . In other words, for every  $j$ , all samples in  $S_j$*

are queried at the index  $j$ . Let  $\mathcal{G} = (G_1, \dots, G_n)$  be the edge cover of the contradiction graph (Definition 15) implied by  $(x_1, \dots, x_s; Q)$ : for every  $1 \leq j \leq n$ ,  $G_j$  is the complete bipartite graph whose vertices are  $S_j$  and the sides are  $L_j = \{i \in S_j | (x_i)_j = 0\}$  and  $R_j = \{i \in S_j | (x_i)_j = 1\}$ . In this setting,  $\text{cap}(\mathcal{G}) = |Q|$ .

The following lemma is crucial for our one-sided testing lower bounds.

► **Lemma 35** ([10, 11, 2]). *Let  $V$  be a set of vertices, and let  $\mathcal{G} = (G_1, \dots, G_k)$  be an edge cover of the  $V$ -clique such that all graphs  $G_1, \dots, G_k$  are bipartite. Then  $\text{cap}(\mathcal{G}) \geq |V| \log_2 |V|$ .*

It can be extended to any non- $m$ -colorable graph, which is what we need.

► **Lemma 36.** *Let  $G$  be a graph over a set  $V$  of vertices that is not  $m$ -colorable, and let  $\mathcal{G} = (G_1, \dots, G_k)$  be an edge cover of  $G$  such that all graphs  $G_1, \dots, G_k$  are bipartite. Then  $\text{cap}(\mathcal{G}) \geq (m+1) \log_2(m+1)$ .*

Then we extend our analysis in two ways, one of which applies to non-adaptive algorithms (giving a  $\log \varepsilon^{-1}$  factor) and the other also applies to adaptive ones (giving a  $\log m$  factor).

For non-adaptive algorithms, we extend the analysis of the two-sided bound to show that a one-sided algorithm for  $\mathcal{S}_m$  requires  $\Omega(\varepsilon^{-1} m \log \varepsilon^{-1})$  many queries. The following shows the hardness of “gathering a witness against  $\mathcal{S}_m$ ”, which allows for a more versatile argument as compared to the indistinguishability argument that we use for the lower bound of Theorem 26.

We use  $D_{\text{no}}^t$  (Definition 27) using  $t = 4m/3$ . For a non-adaptive algorithm that makes less than  $O(\varepsilon^{-1} m \log \varepsilon^{-1})$  queries, the probability that it distinguishes two specific non-zero elements is  $\frac{1}{16}$ . Considering the contradiction graph, excluding the vertex corresponding to the zero vector, we show that the expected number of edges is at most  $\frac{1}{16} \binom{t}{2}$ . By Markov’s inequality, with probability higher than  $\frac{2}{3}$ , there are less than  $\binom{3t/4-1}{2} = \binom{m-1}{2}$  edges, meaning that this subgraph is colorable using  $m-1$  colors. Combined with the vertex corresponding to the zero vector, the contradiction graph is colorable by  $m$  colors, hence it cannot be a witness against being supported on only  $m$ -support.

For the other bounds we use Lemma 36. To show a lower bound against non-adaptive algorithms, we construct a distribution in which a single, “anchor” element is drawn with probability  $1 - \Theta(\varepsilon)$ . This way, for every non-adaptive algorithm that makes only  $o(\varepsilon^{-1} m \log m)$  many queries, the expected number of queries applied to other elements is  $o(m \log m)$ . By Markov’s inequality, with probability  $\frac{2}{3}$ , only  $o(m \log m)$  queries are made in non-zero elements, and in this case, there cannot be a witness against  $m-1$  other elements.

This construction cannot be immediately applied to adaptive algorithms, since they can use adaptivity to avoid wasting queries on the anchor element. To overcome this issue, we use two additional methods. The first one is using very short strings, that is, we focus on distributions over  $\{0, 1\}^{O(\log m)}$  that are  $\varepsilon$ -far from having  $m$  elements in their support (later we prove that the bound also holds for arbitrarily large  $n$  using a simple repetition technique). The second method involves using shared-secret code ensembles [5] that guarantee, in an appropriate setting, that if the algorithm makes less than  $O(\log m)$  queries in an individual sample, then it gathers no information at all. This way, for every individual sample, the algorithm either behaves similarly to a non-adaptive algorithm or makes at least a fixed portion of the maximum number of queries. The exact argument requires a careful analysis of the decision tree of the algorithm.

## Abstract

For a large class of random constraint satisfaction problems (CSP), deep but non-rigorous theory from statistical physics predict the location of the sharp satisfiability transition. The works of Ding, Sly, Sun (2014, 2016) and Coja-Oghlan, Panagiotou (2014) established the satisfiability threshold for random regular  $k$ -NAE-SAT, random  $k$ -SAT, and random regular  $k$ -SAT for large enough  $k \geq k_0$  where  $k_0$  is a large non-explicit constant. Establishing the same for small values of  $k \geq 3$  remains an important open problem in the study of random CSPs.

In this work, we study two closely related models of random CSPs, namely the 2-coloring on random  $d$ -regular  $k$ -uniform hypergraphs and the random  $d$ -regular  $k$ -NAE-SAT model. For every  $k \geq 3$ , we prove that there is an explicit  $d_*(k)$  which gives a satisfiability upper bound for both of the models. Our upper bound  $d_*(k)$  for  $k \geq 3$  matches the prediction from statistical physics for the hypergraph 2-coloring by Dall'Asta, Ramezanzpour, Zecchina (2008), thus conjectured to be sharp. Moreover,  $d_*(k)$  coincides with the satisfiability threshold of random regular  $k$ -NAE-SAT for large enough  $k \geq k_0$  by Ding, Sly, Sun (2014).

## 1 Introduction

In this work, we study the 2-coloring on random  $d$ -regular  $k$ -uniform hypergraphs and the random  $d$ -regular  $k$ -NAE-SAT model for  $k \geq 3$ . We establish an explicit well-defined upper bound on the satisfiability/colorability threshold that holds for every  $k \geq 3$ , which is conjectured to be sharp in statistical physics [25] for hypergraph 2-coloring, and matches the previous rigorous results for random regular  $k$ -NAE-SAT model for  $k$  large enough [28].

Given a  $k$ -uniform hypergraph with  $n$  nodes and  $m$  hyperedges, where every edge consists of  $k$  nodes, a hypergraph 2-coloring is an assignment of colors from  $\{\text{red}, \text{blue}\} \equiv \{0, 1\}$  to the nodes such that there is no monochromatic hyperedge. If there is such a 2-coloring, the hypergraph is said to be colorable or satisfiable. It is a typical example of a constraint satisfaction problem (CSP) that has been studied extensively in combinatorics and computer science literature [54, 7, 2, 24, 34, 38, 39].

A  $k$ -NAE-SAT problem is another closely related CSP studied in computer science [19, 28, 57, 50, 56], which can be viewed as a variant of the infamous  $k$ -SAT problem [41]. A  $k$ -SAT formula is a boolean CNF formula with  $n$  variables formed by taking the AND of  $m$  clauses, which is the OR of  $k$  variables or their negations. Then, a NAE-SAT solution  $\underline{x} \in \{0, 1\}^n$  is an assignment such that  $\underline{x}$  and its negation  $\neg \underline{x}$  evaluates true in the formula. Thus, denoting each clause as a hyperedge, if no variable is negated in every clause, then a NAE-SAT solution is equivalent to a hypergraph 2-coloring.

A significant direction of research on satisfiability has involved examining the large-system limit of randomly generated problem instances. The study of random constraint satisfaction problems (CSPs) aims to discern typical behaviors and phase transitions in these systems as the number of variables  $n$  and the number of constraints  $m$  tends to infinity with a fixed ratio  $\alpha \equiv \frac{m}{n}$ . In this sparse regime, there has been considerable effort into identifying the satisfiability transition, or the critical density, denoted by  $\alpha_{\text{sat}}$ , beyond which solutions cease to exist [6, 5, 3, 23].

Many of the sparse CSPs belong to a broad universality class called the one-step-replica-symmetry-breaking (1RSB) class from statistical physics [43] (see Chapter 19 of [47] for a survey) - including 2-coloring on random regular  $k$ -uniform hypergraphs, random regular  $k$ -NAE-SAT, and random  $k$ -SAT for  $k \geq 3$ . The 1RSB class refers to CSPs which are predicted to possess a single layer of hierarchy of well-separated clusters, where a cluster roughly refers to a dense region of the solution space. A shared characteristic of these problems is that in a non-trivial regime below  $\alpha_{\text{sat}} \equiv \alpha_{\text{sat}}(k)$ , the number of solutions fails to concentrate about its mean due to the clustering effect. This effect thus prevents standard first and second moment methods from locating the exact transition, presenting a significant mathematical challenge.

Despite such difficulties, breakthroughs were made to successfully locate the satisfiability threshold of the random regular  $k$ -NAE-SAT [31], the random  $k$ -SAT [32], and random regular  $k$ -SAT [21] for large enough  $k \geq k_0$ , where  $k_0$  is a non-explicit large absolute constant. These works carried out a demanding second moment method to the number of clusters instead of the number of solutions based on intuitions from statistical physics [46] and previous mathematical works [6, 20, 21]. See Section 1.1 for further literature.

However, for small values of  $k \geq 3$ , locating the satisfiability threshold for CSPs in the 1RSB class remains an important open problem. Indeed, for all the aforementioned models in 1RSB class, the physicists conjecture an explicit value  $\alpha_*(k)$  for  $\alpha_{\text{sat}}(k)$ , the 1RSB threshold, which is expected to be correct for all  $k \geq 3$  [45, 46, 25]. The methods of [31, 32, 21] crucially uses the fact that  $k$  is large enough for their second moment method to succeed.

In this work, we consider 2-coloring on random  $d$ -regular  $k$ -uniform hypergraphs, where the random hypergraph is generated uniformly at random from the set of  $k$ -uniform hypergraphs such that every variable participates in exactly  $d$  hyperedges. We also consider random  $d$ -regular NAE-SAT, where  $k$ -SAT formula is generated uniformly at random with the condition that every variable participates in exactly  $d$  clauses. We establish an upper bound  $d_*(k)$  on the satisfiability thresholds for these problems for every  $k \geq 3$ , which is sharp [28] for random regular  $k$ -NAE-SAT for large  $k \geq k_0$  and conjectured to be sharp [25] for  $k \geq 3$  for hypergraph 2-coloring.

► **Theorem 1.1.** For  $k \geq 3$  and  $d_{\text{lb}}(k) \leq d \leq d_{\text{ub}}(k)$ , where  $d_{\text{lb}}(k), d_{\text{ub}}(k)$  are defined in (1.4) below, there exists a unique solution  $x_\star \equiv x_\star(k, d)$  to the equation

$$d = 1 + \left( \log \frac{1-2x}{1-x} \right) / \log \left( \frac{1-2x^{k-1}}{1-x^{k-1}} \right) \quad \text{on the interval} \quad \frac{1}{2} - \frac{1}{2^k} \leq x \leq \frac{1}{2}. \quad (1.1)$$

Define  $d_\star(k)$  by the largest zero of the explicit function

$$\star\Phi(d) := -\log(1-x) - d(1-k^{-1} - d^{-1}) \log(1-2x^k) + (d-1) \log(1-x^{k-1}), \quad (1.2)$$

where the existence of the root of  $\star\Phi(d)$  is guaranteed in the interval  $[d_{\text{lb}}(k), d_{\text{ub}}(k)]$ .

Then, for  $k \geq 3$ , and  $d > d_\star(k)$ , the random  $d$ -regular  $k$ -uniform hypergraph is not 2-colorable with probability tending to one as the graph size  $n \rightarrow \infty$ . Similarly for  $k \geq 3$  and  $d > d_\star(k)$ , then the random  $d$ -regular  $k$ -NAE-SAT instance is not satisfiable with probability tending to one as  $n \rightarrow \infty$ .

A matching lower bound was obtained in [28] for large enough  $k \geq k_0$  in random  $d$ -regular NAE-SAT by a demanding second moment method. Our proof is based on an interpolation method from statistical physics [35, 37, 52]. We give a proof outline in Section 1.2.

We emphasize that for any  $k \geq 3$ , determining the colorability threshold for 2-coloring on random  $d$ -regular  $k$ -uniform hypergraphs was previously open, thus Theorem 1.1 for 2-coloring is novel even for large  $k$ . Although it is expected that the colorability threshold for the model matches the satisfiability threshold for random regular  $k$ -NAE-SAT, it is highly non-trivial to modify the proof techniques for random regular NAE-SAT [31] to the 2-coloring model since many of the arguments in [31] crucially take advantage of the randomness of clauses. For example, any  $\underline{x} \in \{0, 1\}^n$  has the same probability of being a NAE-SAT solution by the randomness of the clauses while this is obviously not true for the 2-coloring model. As we see below, even the calculation of the first moment of the solutions is substantially more involved for the 2-coloring model. Let  $Z_{\text{NAE}}$  be the number of solutions of random  $d$ -regular  $k$ -NAE-SAT, then it is trivial to calculate  $\mathbb{E}Z_{\text{NAE}}$  exactly by taking advantage of the randomness of the clauses:

$$\mathbb{E}Z_{\text{NAE}} = 2^n (1 - 2^{-k+1})^m = \exp \left( n \left( \log 2 + \alpha \log (1 - 2^{-k+1}) \right) \right) =: \exp(n\Phi_k(\alpha)). \quad (1.3)$$

On the other hand, if we denote  $Z_{\text{COL}}$  by the number of 2-colorings on random  $d$ -regular  $k$ -uniform graphs, then estimating  $\mathbb{E}Z_{\text{COL}}$  is more delicate: we appeal to the idea of exponential tilting from large deviations theory [26] and local central limit theorem [13] to prove that  $\mathbb{E}Z_{\text{COL}}$  is of the same order as  $\exp(n\Phi_k(\alpha))$  in Lemma 1.7 below. Using the interpolation bound which is simpler than moment calculations, we clarify a simple mechanism (cf. Lemma 2.2) behind the identical satisfiability upper bounds for both models.

The solution  $x_\star(k, d)$  to the equation (1.1) has a mathematical interpretation. Namely,  $2x_\star(k, d)$  is the fraction of the so-called *frozen* variables in the *cluster* model. The solution  $x_\star(k, d)$  is called the *Belief Propagation* (BP) fixed point for the cluster model in statistical physics. We emphasize that addressing the uniqueness of the BP fixed point is a well-known major obstacle for many combinatorial optimization and statistical inference problems that exhibit sharp phase transitions (e.g. for spherical perceptron model [55]; see [59, Chapter 3] for a further discussion). We establish the uniqueness of the BP fixed point by showing that the *Belief Propagation recursion* (cf. (1.12)) is a contraction for  $k \geq 3$  and  $[d_{\text{lb}}(k), d_{\text{ub}}(k)]$ , which might be also useful in obtaining a matching lower bound to Theorem 1.1.

■ **Table 1** A comparison with the upper bound  $d_*(k)$  in Theorem 1.1 with the first moment threshold  $d_1(k) := \frac{k \log 2}{-\log(1-2^{-k+1})}$  for small values of  $k$ . For  $3 \leq k \leq 10$ , the values also appear in Table 1 of [25].

| k                      | 3 | 4  | 5  | 6   | 7   | 8   | 9    | 10   | 11   | 12    | 13    | 14    | 15     |
|------------------------|---|----|----|-----|-----|-----|------|------|------|-------|-------|-------|--------|
| $\lceil d_*(k) \rceil$ | 7 | 20 | 53 | 130 | 307 | 705 | 1592 | 3543 | 7802 | 17028 | 36902 | 79488 | 170340 |
| $\lceil d_1(k) \rceil$ | 8 | 21 | 54 | 131 | 309 | 708 | 1594 | 3546 | 7804 | 17031 | 36905 | 79491 | 170343 |

Since  $\mathbb{E}Z_{\text{NAE}}$  and  $\mathbb{E}Z_{\text{COL}}$  are given by  $\exp(n\Phi_k(\alpha))$  up to a constant (cf. (1.3) and Lemma 1.7), the first moment thresholds for both of the models are given by  $d_1(k) := \frac{k \log 2}{-\log(1-2^{-k+1})}$ . In Table 1, we report  $\lceil d_*(k) \rceil$  and  $\lceil d_1(k) \rceil$  for  $3 \leq k \leq 15$ . For every  $3 \leq k \leq 15$ , the upper bound  $\lceil d_*(k) \rceil$  in Theorem 1.1 improves over the first moment threshold. For large values of  $k$ ,  $d_*(k)$  improves over  $d_1(k)$  by  $\Omega(k)$  (see (1.5) below). The quantities  $d_{\text{ibd}}(k)$ , and  $d_{\text{ubd}}(k)$  are defined by

$$d_{\text{ibd}}(k) = \begin{cases} 6.74 & k = 3, \\ 16.7 & k = 4, \\ (2^{k-1} - 2)k \log 2 & k \geq 5. \end{cases} \quad d_{\text{ubd}}(k) = \begin{cases} 7.5 & k = 3, \\ 2^{k-1}k \log 2 & k \geq 4. \end{cases} \quad (1.4)$$

► **Remark 1.1.** For  $d \leq d_{\text{ibd}}(k)$  and large  $k \geq k_0$ , the second moment method applied to  $Z_{\text{NAE}}$  succeeds in showing the satisfiability for the random  $d$ -regular  $k$ -NAE-SAT model (see [28, Section 2.1]). For  $k \in \{3, 4\}$ ,  $d_{\text{ibd}}(k)$  must be adjusted to be higher to guarantee that  $\star\Phi(d)$  is well-defined, i.e. there exists a unique solution to (1.1). The value  $d_{\text{ubd}}(k) \equiv 2^{k-1}k \log 2 > d_1(k)$  for  $k \geq 4$  is a convenient upper bound for satisfiability. For  $k = 3$ , we take  $d_{\text{ubd}}(3)$  to be  $7.5 > \frac{3 \log 2}{-\log(3/4)} = d_1(3)$ , which does not change  $d_*(3)$ , but is more convenient for the proof.

Finally, we note that the large  $k$  asymptotics of  $d_*(k)$  was proven in [58, Appendix B]:

$$\alpha_*(k) \equiv \frac{d_*(k)}{k} = \left( 2^{k-1} - \frac{1}{2} - \frac{1}{4 \log 2} \right) \log 2 + o_k(1), \quad (1.5)$$

where  $o_k(1)$  denotes an error tending to zero as  $k \rightarrow \infty$ . Since  $d_1(k) = (2^{k-1} - 1/2)k \log 2 + o_k(1)$ , we have that  $d_*(k) \leq d_1(k) - \Omega(k)$ .

## 1.1 Related work

Many of the earlier mathematical works on CSPs focused on determining their satisfiability thresholds and verifying the sharpness of SAT-UNSAT transitions. For models that are known not to exhibit RSB, such goals were established. These models include random 2-SAT [15, 12], random 1-IN- $k$ -SAT [1],  $k$ -XOR-SAT [33, 27, 53], and random linear equations [8]. On the other hand, for the models which are predicted to belong to 1RSB class, intensive studies have been conducted to estimate their satisfiability threshold, as shown in [42, 6, 21] (random  $k$ -SAT), [3, 24, 19] (random  $k$ -NAE-SAT), and [4, 16, 23, 17] (random graph coloring).

More recently, the satisfiability thresholds for rCSPs that exhibits RSB have been rigorously determined for several models, namely the random regular  $k$ -NAE-SAT [31], maximum independent set on  $d$ -regular graphs [30], random regular  $k$ -SAT [21] and random  $k$ -SAT [32] for large  $k$  and  $d$ . Although determining the location of  $q$ -colorability threshold for the sparse Erdős Rényi graph is left open, the *condensation threshold*  $\alpha_{\text{cond}}$  for random graph coloring, where the *free energy* becomes non-analytic, was settled in [11]. They carried out a

technically challenging analysis based on a clever “planting” technique, where the results were further generalized to other models in [18]. Similarly, [10] identified the condensation threshold for random regular  $k$ -SAT, where each variable appears  $d/2$ -times positive and  $d/2$ -times negative. Further, in the condensation regime  $\alpha \in (\alpha_{\text{cond}}, \alpha_{\text{sat}})$ , many quantities of interest were established for random regular  $k$ -NAE-SAT with large enough  $k$ , matching the statistical physics prediction. Namely, the number of solutions at exponential scale (free energy) [58], the concentration of the *overlap* [49, 51], and the local weak limit [56] were established. Establishing the same quantities for other models in the condensation regime is still open.

The closest result to ours in the literature is by Ayre, Coja-Oghlan, and Greenhill [9], where they lower bound the chromatic number (or equivalently, upper bound the colorability threshold) of the random regular graph of any degree, which is conjectured to be tight. [9] also considers the sparse Erdős-Rényi graph, which is more complicated since the conjectured chromatic number is defined in terms of a distributional (rather than real-valued) optimization due to the randomness of the local neighborhoods. In this work, we do not consider Erdős-Rényi type problems, but we additionally address the question of the uniqueness of the BP fixed point for any  $k \geq 3$  (unique solution to the equation (1.1)). As in [9], we use an interpolation bound, which gives an upper bound of the satisfiability threshold also for the (non-regular) random  $k$ -NAE-SAT model. It would be interesting to address the uniqueness of the BP fixed point for random  $k$ -NAE-SAT and random  $k$ -sat for small  $k \geq 3$ . We refer to [55, 48, 60, 36] which addresses the uniqueness of BP fixed point for various models.

## 1.2 Proof methods

We aim to rigorously establish the upper bound for the satisfiability threshold predicted by the so-called “1RSB cavity method” from statistical physics [25]. To do so, instead of using moment methods, we use a theorem derived from the so called “interpolation method” from the theory of spin glasses developed by [35, 37, 52]. The interpolation method has been successful in upperbounding the satisfiability threshold for random  $k$ -SAT [29] for large  $k$ , the free energy for random regular  $k$ -NAE-SAT [57], and the colorability threshold for random graphs [9].

We first introduce the notations and mathematical framework that we use throughout the paper. For both the  $d$ -regular  $k$ -uniform hypergraphs and the  $k$ -NAE-SAT formula, we can represent them as (labelled)  $(d, k)$ -regular bipartite graph. Let  $V = \{v_1, \dots, v_n\}$  be the set of variables or nodes and  $F = \{a_1, \dots, a_m\}$  be the set of clauses or hyperedges. An edge is formed if the variable or node  $v_i$  is included in the clause or hyperedge  $a_j$ . For an edge  $e$ , we denote  $v(e)$  (resp.  $a(e)$ ) by the variable (resp. clause) adjacent to it.

Denote  $G = (V, F, E)$  by the resulting bipartite graph. Each variable  $v \in V$  has incident half-edges  $\delta v$ , while each clause  $a \in F$  has incident half-edges  $\delta a$ . Throughout, we denote  $\alpha \equiv \frac{m}{n} = \frac{d}{k}$ . For the NAE-SAT formula, there is an extra label for each edge  $e \in E$ , namely the *literal*  $L_e \in \{0, 1\}$ , which specifies how the variable  $v(e)$  participates in the clause  $a(e)$ . Then, the labelled graph  $\mathcal{G} = (V, F, E, \underline{L}) \equiv (V, F, E, (L_e)_{e \in E})$  represents a NAE-SAT instance.

► **Definition 1.2.** Given a NAE-SAT instance  $\mathcal{G} = (V, F, E, \underline{L})$ ,  $\underline{x} \in \{0, 1\}^V$  is a (NAE-SAT) **solution** if

$$\prod_{a \in F} \varphi((x_{v(e)} \oplus L_e)_{e \in \delta a}) = 1,$$

where for  $\underline{z} = (z_i)_{i \leq k} \in \{0, 1\}^k$ ,  $\varphi(\underline{z}) \equiv \mathbb{1}(z_1 = \dots = z_k)$ , and  $\oplus$  denotes addition mod 2. Given a graph  $G = (V, F, E)$ ,  $\underline{x} \in \{0, 1\}^V$  is a (hypergraph 2-) **coloring** if  $\underline{x}$  is a NAE-SAT solution on  $G$  with literals identically zero  $(G, \underline{0})$ .

The configuration model can be described as follows. Add  $d$  (resp.  $k$ ) half-edges adjacent to each variable (resp. each clause) so that there are total  $nd = mk$  number of half-edges adjacent to variables (resp. clauses). Thus,  $E$  can be regarded as a perfect matching between to the set of half-edges adjacent to variables to those adjacent to clauses, and hence a permutation in  $S_{nd}$ . Then, the configuration model  $\mathbf{G} = (V, F, \mathbf{E})$  is defined by taking  $\mathbf{E} \sim \text{Unif}(S_{nd})$ . For a random  $d$ -regular  $k$ -NAE-SAT instance  $\mathcal{G} = (\mathbf{G}, \mathbf{L})$ , we take the literals  $\mathbf{L} \equiv (\mathbf{L}_e)_{e \in E} \stackrel{i.i.d.}{\sim} \text{Unif}(\{0, 1\})$ .

Note that the configuration model  $\mathbf{G}$  may induce multi-edges. However, if we denote  $\mathcal{S}$  to be the event that  $\mathbf{G}$  is simple, then it is well-known that  $\mathbb{P}(\mathbf{G} \in \mathcal{S}) = \Omega(1)$  (see e.g. Chapter 9 of [40]). Thus, the configuration model is mutually contiguous with respect to the uniform distribution among all  $(d, k)$ -regular graphs, so to prove Theorem 1.1, it suffices to work with the configuration model.

In order to use the interpolation method, we consider the *positive temperature* analogs of the 2-coloring or the NAE-SAT model, which have more desirable properties due to the softness of the constraints - e.g. the concentration of the free energy as seen in Lemma 1.3 below. We introduce notations that allow us to set up the positive temperature models. Let  $S$  be a finite set and  $\underline{b} \equiv (b_s)_{s \in S}$  be a vector with  $b_s \geq 0$ . Also, let  $\mathcal{X}$  be a finite set encoding the spins and denote  $\mathfrak{F}(\mathcal{X})$  by the set of functions  $\mathcal{X} \rightarrow \mathbb{R}_{\geq 0}$ . Let  $f : S \rightarrow \mathfrak{F}(\mathcal{X})$  be a random function which may be chosen randomly according to any distribution, i.e.  $f(\cdot; s) \in \mathfrak{F}(\mathcal{X})$  is random for  $s \in S$ , and  $f_1, \dots, f_k$  be i.i.d. copies of  $f$ . Then, define the random function  $\theta : \mathcal{X}^k \rightarrow \mathbb{R}$  as follows. For  $\underline{x} = (x_1, \dots, x_k) \in \mathcal{X}^k$ , let

$$\theta(\underline{x}) = \sum_{s \in S} b_s \prod_{i=1}^k f_i(x_i; s). \quad (1.6)$$

We will consider  $S = \mathcal{X} = \{0, 1\}$  in Definition 1.4 below, but one may also consider the case  $S \neq \mathcal{X}$  in general. We assume that there exists a constant  $\varepsilon \in (0, 1)$  such that for any  $\underline{x} \in \mathcal{X}^k$ ,

$$\varepsilon \leq 1 - \theta(\underline{x}) \leq \varepsilon^{-1} \quad \text{almost surely.} \quad (1.7)$$

On a  $(d, k)$ -regular bipartite graph  $G = (V, F, E)$ , let  $(\theta_a)_{a \in F}$  be i.i.d. copies of the random function  $\theta$ , and define the (random) Gibbs measure on  $\mathcal{X}^V$  by

$$\mu_G(\underline{x}) \equiv \frac{1}{Z(G)} \prod_{a \in F} (1 - \theta_a(\underline{x}_{\delta a})),$$

where  $Z(G)$  is the normalizing constant explicitly given by

$$Z(G) \equiv \sum_{\underline{x} \in \mathcal{X}^V} \prod_{a \in F} (1 - \theta_a(\underline{x}_{\delta a})). \quad (1.8)$$

We note that the condition (1.7) on  $\theta$  guarantees that the Gibbs measure  $\mu_G$  is “finite temperature”. In particular, if we define the free energy

$$F_n \equiv \frac{1}{n} \mathbb{E} \log Z(\mathbf{G}), \quad (1.9)$$

where  $\mathbf{G}$  is drawn from the configuration model and  $\mathbb{E}$  above is over the randomness of  $\mathbf{G}$  and randomness of  $(\theta_a)_{a \in F}$ , we have the following concentration of the free energy.

► **Lemma 1.3.** *Assume that  $\theta$  satisfies (1.7) with some constant  $\varepsilon \in (0, 1)$ . Then, for any  $\delta > 0$ , there exists a constant which only depends on  $\varepsilon, \delta > 0$  such that*

$$\mathbb{P} \left( \left| \frac{1}{n} \log Z(\mathbf{G}) - F_n \right| \geq \delta \right) \leq e^{-cn}.$$

The concentration of free energy in Lemma 1.3 is standard in literature [11, 22, 9], and we provide the proof in Section 2 for completeness.

► **Definition 1.4.** (Positive temperature models) For  $\beta > 0$ , called the inverse temperature, the positive temperature NAE-SAT model  $\theta_{\text{NAE}}(\cdot) \equiv \theta_{\text{NAE}}(\cdot; \beta)$  is defined as follows. Let  $\underline{L} \equiv (\mathbf{L}_i)_{i \leq k} \stackrel{i.i.d.}{\sim} \text{Unif}(\{0, 1\})$  be a sequence of i.i.d. Bernoulli(1/2) random variables. Then for  $\underline{x} = (x_i)_{i \leq k} \in \{0, 1\}^k$ , define

$$\theta_{\text{NAE}}(\underline{x}) \equiv \theta_{\text{NAE}}(\underline{x}; \beta) \equiv (1 - e^{-\beta}) \cdot \left( \prod_{i=1}^k (\mathbf{L}_i \oplus x_i) + \prod_{i=1}^k (\mathbf{L}_i \oplus x_i \oplus 1) \right). \quad (1.10)$$

That is, in the general form (1.6), we take  $S = \mathcal{X} = \{0, 1\}$ ,  $b_i \equiv 1 - e^{-\beta}$ , and  $f(x; 0) \equiv 1 - f(x; 1) \equiv \mathbb{1}(x \oplus \mathbf{L})$  for  $\mathbf{L} \sim \text{Unif}(\{0, 1\})$ . Moreover, the positive temperature hypergraph 2-coloring model  $\theta_{\text{COL}}(\cdot) \equiv \theta_{\text{COL}}(\cdot; \beta)$  is defined by taking  $\mathbf{L}_i \equiv 0$  above:

$$\theta_{\text{COL}}(\underline{x}) \equiv \theta_{\text{COL}}(\underline{x}; \beta) \equiv (1 - e^{-\beta}) \cdot \sum_{s \in \{0, 1\}} \prod_{i=1}^k \mathbb{1}(x_i = s), \quad (1.11)$$

which is taking  $f(x; s) = \mathbb{1}(x = s)$  in (1.6).

We note that formally taking  $\beta = \infty$  and  $\theta = \theta_{\text{COL}}(\underline{x}; \beta)$ , the corresponding partition function  $Z(G)$  equals the number of 2-coloring on  $G$ . A similar statement holds for the NAE-SAT model.

By constructing a certain sequential coupling of the given factor graph  $(\mathbf{G}, (\theta)_{a \in F})$  to a set of disjoint trees so that the free energy is monotone at every step, the interpolation method [35, 37, 52] gives an upper bound on the free energy  $F_n$  as follows: for  $\zeta \in \mathcal{P}(\mathcal{P}(\mathcal{X}))$ , where  $\mathcal{P}(A)$  denotes the set of probability measures on  $A$ , and  $\lambda \in (0, 1)$ , there exists an explicit functional  $\mathcal{P}(\zeta, \lambda) \equiv \mathcal{P}_{d, k, \theta}(\zeta, \lambda)$  such that we have  $F_n \leq \inf_{\zeta, \lambda} \mathcal{P}(\zeta, \lambda) + o_n(1)$ . By taking advantage of the interpolation method applied to positive temperature models in Definition 1.4 and the concentration of the free energy in Lemma 1.3, we prove the proposition below in Section 2.

► **Proposition 1.5.** *For a given  $k \geq 3$  and  $d$ , suppose that there is a solution  $x \in [1/2 - 1/2^k, 1/2]$  to the BP equation (1.1). Further, suppose that  $\star \Phi(d)$  in (1.2) defined with such  $x$  satisfies  $\star \Phi(d) < 0$ . Then, with probability tending to one, no NAE-SAT solution exists on  $\mathcal{G}$ . Also, with probability tending to one, no 2-coloring exists on  $\mathcal{G}$ .*

Moreover, we show that  $d_\star(k)$  in Theorem 1.1 is well-defined and that the assumptions of Proposition 1.5 are meaningful. Note that the BP equation (1.1) is equivalent to  $\Psi_d(x) = x$ , where  $\Psi_d \equiv \Psi_{k, d} : [0, 1] \rightarrow [0, 1]$  is defined by  $\Psi_d \equiv \dot{\Psi} \circ \hat{\Psi}$  with

$$\dot{\Psi}(x) \equiv \dot{\Psi}_d(x) \equiv \frac{1 - x^{d-1}}{2 - x^{d-1}}, \quad \hat{\Psi}(x) \equiv \hat{\Psi}_k(x) \equiv \frac{1 - 2x^{k-1}}{1 - x^{k-1}}. \quad (1.12)$$

The function  $\dot{\Psi}(\cdot)$  is *variable BP recursion* and  $\hat{\Psi}(\cdot)$  is *clause BP recursion* (see [31, Section 3.1] for the motivation).

► **Proposition 1.6.** *For  $k \geq 3$  and  $d \in [d_{\text{lb}d}(k), d_{\text{ub}d}(k)]$ , there exists a unique root to  $\Psi_d(x) \equiv (\hat{\Psi} \circ \hat{\Psi})(x) = x$  in the interval  $x \in [1/2 - 1/2^k, 1/2]$ . Thus,  $\star\Phi(d)$  in equation (1.2) is well-defined. Furthermore,  $d \rightarrow \star\Phi(d)$  is continuous in the interval  $d \in [d_{\text{lb}d}(k), d_{\text{ub}d}(k)]$  with  $\star\Phi(d_{\text{lb}d}(k)) > 0$  and  $\star\Phi(d_{\text{ub}d}(k)) < 0$ .*

The proof of Proposition 1.6 is given in Section 3 for  $k \geq 4$ . We refer to the full version [14] for the proof of Proposition 1.6 for  $k = 3$ , which requires extra numerical estimates. Finally, we show that the first moment  $\mathbb{E}Z_{\text{COL}}$  of the number of 2-colorings on random  $d$ -regular  $k$ -uniform hypergraphs is the same with  $\mathbb{E}Z_{\text{NAE}}$  up to a constant.

► **Lemma 1.7.** *For  $k \geq 3$ , there exist constants  $C_{k,d,i}$  for  $i = 1, 2$ , which only depends on  $k, d$  such that  $\mathbb{E}Z_{\text{COL}}/\mathbb{E}Z_{\text{NAE}} \in [C_{k,d,1}, C_{k,d,2}]$*

**Proof of Theorem 1.1.** By Proposition 1.6, the function  $\star\Phi(d)$  is well-defined and has a root in the interval  $[d_{\text{lb}d}(k), d_{\text{ub}d}(k)]$ . Moreover, since  $\star\Phi(d_{\text{ub}d}(k)) < 0$  holds and  $\star\Phi(\cdot)$  is continuous, we have  $\star\Phi(d) < 0$  for  $d \in (d_{\star}(k), d_{\text{ub}d}(k)]$ . Hence, Proposition 1.5 shows that if  $d \in (d_{\star}(k), d_{\text{ub}d}(k)]$ , then the 2-coloring of random  $d$ -regular  $k$ -uniform hypergraph and random  $d$ -regular  $k$ -NAE-SAT is not satisfiable, both with probability tending to one as  $n \rightarrow \infty$ . Further, since  $\mathbb{E}Z_{\text{COL}} \asymp_{k,d} \mathbb{E}Z_{\text{NAE}} = \exp(n(\log 2 + \alpha \log(1 - 2^{-k+1})))$  by Lemma 1.7 and  $\log 2 + \alpha \log(1 - 2^{-k+1}) < 0$  holds for  $d > d_{\text{ub}d}(k)$ , the same is true for  $d > d_{\text{ub}d}(k)$  by Markov's inequality. ◀

## 2 Satisfiability upper bound by interpolation

In this section, we prove Lemma 1.3, Proposition 1.5, and Lemma 1.7. We prove Proposition 1.5 in Section 2.1 based on the interpolation bound from statistical physics [35, 37]. In Section 2.2, we prove Lemma 1.3 based on Azuma Hoeffding's inequality applied to the Doob martingale with respect to clause revealing filtration. In Section 2.3, we prove Lemma 1.7 based on the local central limit theorem.

### 2.1 Proof of Proposition 1.5

Throughout, we assume that we are given  $k \geq 3$  and  $d$  such that there is a solution  $x \in [1/2 - 1/2^k, 1/2]$  to the equation (1.1). We use the following *one-step-replica-symmetry-breaking bound* proven in [58, Theorem E.3] for random regular graphs (see also [44]), which is the analog of [52, Theorem 3] for Erdős-Rényi graphs.

► **Theorem 2.1** (Theorem E.3 in [58]). *Let  $\mathcal{X}$  and  $S$  be finite sets and consider the partition function  $Z(G)$  (cf. Eq. (1.8)), where  $\theta$  in (1.6) satisfies the condition (1.7) for some  $\varepsilon > 0$  and  $b_s \geq 0$  holds for  $s \in S$ . Let  $\mathcal{M}_0 \equiv \mathcal{P}(\mathcal{X})$  be the space of probability measures over  $\mathcal{X}$ ,  $\mathcal{M}_1 \equiv \mathcal{P}(\mathcal{M}_0)$  be the space of probability measures over  $\mathcal{M}_0$ , and  $\mathcal{M}_2 \equiv \mathcal{P}(\mathcal{M}_1)$  be the space of probability measures over  $\mathcal{M}_1$ . For  $\zeta \in \mathcal{M}_2$ , let  $\underline{\eta} = (\eta_{a,j})_{a \geq 0, j \geq 0}$  be an array of i.i.d. samples from  $\zeta$ . For each index  $(a, j)$  let  $\rho_{a,j} \in \mathcal{P}(\mathcal{X})$  be a conditionally independent sample from  $\eta_{a,j}$ , and denote  $\underline{\rho} = (\rho_{a,j})_{a \geq 0, j \geq 0}$ . For  $x \in \mathcal{X}$  define random variables*

$$u_a(x) \equiv \sum_{\underline{x} \in \mathcal{X}^k} \mathbb{1}\{x_1 = x\} (1 - \theta_a(\underline{x})) \prod_{j=2}^k \rho_{a,j}(x_j), \quad u_a \equiv \sum_{\underline{x} \in \mathcal{X}^k} (1 - \theta_a(\underline{x})) \prod_{j=1}^k \rho_{a,j}(x_j),$$

where we recall that  $(\theta_a)_{a \geq 0}$  are i.i.d. copies of the random function  $\theta$ . For any  $\lambda \in (0, 1)$  and any  $\zeta \in \mathcal{M}_2$ ,

$F_n \leq \mathcal{P}(\zeta, \lambda) + O_\varepsilon(n^{-1/3})$ , where

$$\mathcal{P}(\zeta, \lambda) \equiv \mathcal{P}_\theta(\zeta, \lambda) := \lambda^{-1} \mathbb{E} \log \mathbb{E}' \left[ \left( \sum_{x \in \mathcal{X}} \prod_{a=1}^d u_a(x) \right)^\lambda \right] - (k-1) \alpha \lambda^{-1} \mathbb{E} \log \mathbb{E}' \left[ (u_0)^\lambda \right]. \quad (2.1)$$

Here,  $F_n$  is the free energy for the configuration model defined in (1.9),  $\mathbb{E}'$  denotes the expectation over  $\underline{\rho}$  conditioned on all else, and  $\mathbb{E}$  denotes the overall expectation.

► **Remark 2.1.** [58, Theorem E.3] is stated more general than Theorem 2.1 by considering independent *external field*  $\{h_v\}_{v \in V}$  and random  $(b_s)_{s \in S}$ . For our purposes, it suffices to consider non-random  $b_s \geq 0$  and  $h_v \equiv 1$ .

We use Theorem 2.1 for the positive temperature models in Definition 1.4. Note that  $\theta_{\text{NAE}}(\cdot; \beta)$  and  $\theta_{\text{COL}}(\cdot; \beta)$  satisfies the condition (1.7) with  $\varepsilon = e^{-\beta}$ . Furthermore, in the bound (2.1), we take  $\lambda = \beta^{-1/2}$  and  $\zeta \equiv \zeta_{k,d,\beta} \in \mathcal{P}(\mathcal{P}(\mathcal{P}(\{0,1\})))$  given by a point mass at  $\eta_{k,d,\beta}$ :

$$\zeta_{k,d,\beta} \equiv \delta_{\eta_{k,d,\beta}}, \quad (2.2)$$

where  $\eta_{k,d,\beta} \in \mathcal{P}(\mathcal{P}(\{0,1\}))$  is defined as follows. Identify  $\mathcal{P}(\{0,1\})$  with  $[0,1]$  by the map

$$\rho \in \mathcal{P}(\{0,1\}) \leftrightarrow \rho(1) \in [0,1].$$

Thus, denoting  $\eta \equiv \eta_{k,d,\beta} \in \mathcal{P}([0,1])$ , define

$$\eta \left( \frac{e^\beta}{e^\beta + e^{-\beta}} \right) = \eta \left( \frac{e^{-\beta}}{e^\beta + e^{-\beta}} \right) = x, \quad \eta \left( \frac{1}{2} \right) = 1 - 2x, \quad (2.3)$$

where  $x_\star \equiv x_\star(k,d)$  is the BP fixed point, i.e. the solution to the equation (1.1). Such choice of  $\zeta_{k,d,\beta}$  is motivated from physics [43] and previous mathematical works [31, Section 3] and [32, Section 4].

Before proceeding further, we show that if  $\zeta$  is given as in (2.2), (2.3), then  $\mathcal{P}(\zeta, \lambda)$  does not depend on literals. More precisely, suppose that  $\zeta = \delta_{\eta_0}$ , where  $\eta_0 \in \mathcal{P}([0,1])$  is such that  $\eta_0(dx) = \eta_0(d(1-x))$ , i.e.  $\rho \stackrel{d}{=} 1 - \rho$  holds for  $\rho \sim \eta_0$ . For a fixed  $\underline{\mathbf{L}} = (\mathbf{L}_i)_{i \leq k} \in \{0,1\}^k$ , let

$$\theta_{\underline{\mathbf{L}}}(\underline{x}) = (1 - e^{-\beta}) \cdot \left( \prod_{i=1}^k (\mathbf{L}_i \oplus x_i) + \prod_{i=1}^k (\mathbf{L}_i \oplus x_i \oplus 1) \right).$$

With abuse of notation, for  $x \in \{0,1\}$  and independent samples  $\rho_{a,j} \in \mathcal{P}(\{0,1\})$  from  $\eta_0$ , let

$$u_{a,\underline{\mathbf{L}}}(x) \equiv \sum_{\underline{x} \in \{0,1\}^k} \mathbb{1}\{x_1 = x\} (1 - \theta_{\underline{\mathbf{L}}}(\underline{x})) \prod_{j=2}^k \rho_{a,j}(x_j), \quad u_{\underline{\mathbf{L}}} \equiv \sum_{\underline{x} \in \{0,1\}^k} (1 - \theta_{\underline{\mathbf{L}}}(\underline{x})) \prod_{j=1}^k \rho_{0,j}(x_j),$$

where we consider  $\underline{\mathbf{L}} \in \{0,1\}^k$  to be fixed. Then, for a given sequence of literals  $\underline{\mathbf{L}}_a \in \{0,1\}^k$  for  $0 \leq a \leq d$ , let

$$\mathcal{P}(\delta_{\eta_0}, \lambda; (\underline{\mathbf{L}}_a)_{0 \leq a \leq d}) := \lambda^{-1} \log \mathbb{E}' \left( \sum_{x \in \{0,1\}} \prod_{a=1}^d u_{a,\underline{\mathbf{L}}_a}(x) \right)^\lambda - (k-1) \alpha \lambda^{-1} \mathbb{E} \log \mathbb{E}' (u_{\underline{\mathbf{L}}_0})^\lambda, \quad (2.4)$$

where  $\mathbb{E}'$  is the expectation with respect to the independent samples  $\rho_{a,j} \in \mathcal{P}(\{0,1\})$  from  $\eta_0$ . Note that if  $\underline{\mathbf{L}}_a \stackrel{i.i.d.}{\sim} \text{Unif}(\{0,1\}^k)$ , then  $\mathcal{P}_{\theta_{\text{NAE}}}(\delta_{\eta_0}, \lambda) = \mathbb{E}_{\underline{\mathbf{L}}} \mathcal{P}(\delta_{\eta_0}, \lambda; (\underline{\mathbf{L}}_a)_{0 \leq a \leq d})$  holds, and if  $\underline{\mathbf{L}}_a \equiv \underline{\mathbf{0}}$  for  $0 \leq a \leq d$ , then  $\mathcal{P}_{\theta_{\text{COL}}}(\delta_{\eta_0}, \lambda) = \mathcal{P}(\delta_{\eta_0}, \lambda; \underline{\mathbf{0}})$  holds. The following lemma then clarifies the mechanism behind the identical satisfiability upper bound in Theorem 1.1.

## 47:10 Upper Bounds on the Colorability Threshold for Random Regular Graph

► **Lemma 2.2.** Consider  $\zeta = \delta_{\eta_0}$  for some  $\eta_0 \in \mathcal{P}([0, 1])$  such that  $\eta_0(dx) = \eta_0(d(1-x))$ . Then, for any literals  $\underline{L}_a \in \{0, 1\}^k$  for  $0 \leq a \leq d$ , the value  $\mathcal{P}(\delta_{\eta_0}, \lambda; (\underline{L}_a)_{0 \leq a \leq d})$  does not depend on  $(\underline{L}_a)_{0 \leq a \leq d}$ . Thus,  $\mathcal{P}_{\theta_{\text{NAE}}}(\delta_{\eta_0}, \lambda) = \mathcal{P}_{\theta_{\text{COL}}}(\delta_{\eta_0}, \lambda)$  holds.

**Proof.** For fixed  $\underline{L}_a \in \{0, 1\}^k$  for  $0 \leq a \leq d$ , note that the vectors  $(u_{a, \underline{L}_a}(0), u_{a, \underline{L}_a}(1))$  are independent for  $0 \leq a \leq d$ . Thus, it suffices to show that for given  $\underline{L}, \underline{L}' \in \{0, 1\}^k$  and  $1 \leq a \leq d$ ,

$$u_{\underline{L}} \stackrel{d}{=} u_{\underline{L}'} \quad \text{and} \quad (u_{a, \underline{L}}(0), u_{a, \underline{L}}(1)) \stackrel{d}{=} (u_{a, \underline{L}'}(0), u_{a, \underline{L}'}(1)). \quad (2.5)$$

To this end, let  $\underline{L}' = \underline{0}$  and we first prove that  $u_{\underline{L}} \stackrel{d}{=} u_{\underline{0}}$  holds. Since  $\theta_{\underline{L}}(x) = \theta_{\underline{0}}(x \oplus \underline{L})$ ,

$$u_{\underline{L}} \equiv \sum_{\underline{x} \in \{0, 1\}^k} (1 - \theta_{\underline{L}}(\underline{x})) \prod_{j=1}^k \rho_{0,j}(x_j) = \sum_{\underline{x} \in \{0, 1\}^k} (1 - \theta_{\underline{0}}(\underline{x})) \prod_{j=1}^k \rho_{0,j}(x_j \oplus \underline{L}_j).$$

Note that since  $(\rho_{0,j})_{1 \leq j \leq k}$  are i.i.d. samples from  $\eta_0$  and  $\eta_0(dx) = \eta_0(d(1-x))$  holds, the sequence  $(\rho_{0,j}(\cdot \oplus \underline{L}_j))_{1 \leq j \leq k}$  are also i.i.d. from  $\eta_0$ . Hence, the equation above shows that  $u_{\underline{L}} \stackrel{d}{=} u_{\underline{0}}$  holds.

Next, we prove that  $(u_{a, \underline{L}}(0), u_{a, \underline{L}}(1)) \stackrel{d}{=} (u_{a, \underline{0}}(0), u_{a, \underline{0}}(1))$  holds. Without loss of generality, let  $a = 1$ . Again since  $\theta_{\underline{L}}(x) = \theta_{\underline{0}}(x \oplus \underline{L})$ ,

$$u_{1, \underline{L}}(x) = \sum_{\underline{x} \in \{0, 1\}^k} \mathbb{1}\{x_1 \oplus \underline{L}_1 = x\} (1 - \theta_{\underline{0}}(\underline{x})) \prod_{j=2}^k \rho_{1,j}(x_j \oplus \underline{L}_j)$$

Now, observe that  $\theta_{\underline{0}}(\cdot)$  is invariant under global flip, i.e.  $\theta_{\underline{0}}(x) = \theta_{\underline{0}}(x \oplus 1)$ . Thus, it follows that

$$u_{1, \underline{L}}(x) = \sum_{\underline{x} \in \{0, 1\}^k} \mathbb{1}\{x_1 = x\} [1 - \theta_{\underline{0}}(\underline{x})] \prod_{j=2}^k \rho_{1,j}(x_j \oplus \underline{L}_1 \oplus \underline{L}_j).$$

By the same reasons as above,  $(\rho_{1,j}(\cdot \oplus \underline{L}_1 \oplus \underline{L}_j))_{2 \leq j \leq k}$  have the same distribution as  $(\rho_{1,j})_{2 \leq j \leq k}$ , which are i.i.d. from  $\eta_0$ . Thus, we have that  $(u_{1, \underline{L}}(0), u_{1, \underline{L}}(1)) \stackrel{d}{=} (u_{1, \underline{0}}(0), u_{1, \underline{0}}(1))$ . Therefore, (2.5) holds, which concludes the proof. ◀

The following lemma relates  $\mathcal{P}_{\theta_{\text{COL}}}(\zeta_{k,d,\beta}, \beta^{-1/2}) = \mathcal{P}_{\theta_{\text{NAE}}}(\zeta_{k,d,\beta}, \beta^{-1/2})$ , and  $\star \Phi(d)$ , which plays a crucial role in proving Proposition 1.5. Recall the definition of  $\zeta_{k,d,\beta}$  in (2.2) and (2.3).

► **Lemma 2.3.**  $\mathcal{P}_{\theta_{\text{COL}}}(\zeta_{k,d,\beta}, \beta^{-1/2}) \leq C + \beta^{1/2} \times \star \Phi(d)$  holds for some constant  $C \in \mathbb{R}$ , which does not depend on  $\beta > 0$ .

**Proof.** Throughout, let  $(\rho_{a,j})_{a \geq 0, j \geq 0}$  denote i.i.d. samples from  $\eta_{k,d,\beta}$  defined in (2.3), and let  $\mathbb{E}'$  (resp.  $\mathbb{P}'$ ) denote the expectation (resp. probability) with respect to  $(\rho_{a,j})_{a \geq 0, j \geq 0}$ . Also, we use the generic notation  $C$  by a constant that does not depend on  $\beta > 0$ . Note that since  $\theta_{\text{COL}}$  and  $\eta_{k,d,\beta}$  are non-random, the outer expectation  $\mathbb{E}$  in the definition of  $\mathcal{P}(\zeta, \lambda)$  in (2.1) is redundant.

First, we bound the second term of the definition of  $\mathcal{P}_{\theta_{\text{COL}}}(\zeta_{k,d,\beta}, \beta^{-1/2})$  in (2.1):

$$\begin{aligned} & (k-1)\alpha\beta^{1/2} \log \mathbb{E}' \left[ (u_0)^{\beta^{-1/2}} \right] \\ &= (k-1)\alpha\beta^{1/2} \log \mathbb{E}' \left[ \left( 1 - (1 - e^{-\beta}) \left( \prod_{j=1}^k \rho_{0,j}(0) + \prod_{j=1}^k \rho_{0,j}(1) \right) \right)^{\beta^{-1/2}} \right] \end{aligned}$$

Note that the expectation inside the log in the right hand side above is bounded below by

$$2^{-\beta^{-1/2}} \cdot \mathbb{P}' \left( 1 - (1 - e^{-\beta}) \left( \prod_{j=1}^k \rho_{0,j}(0) + \prod_{j=1}^k \rho_{0,j}(1) \right) \geq \frac{1}{2} \right) = 2^{-\beta^{-1/2}} (1 - 2x^k),$$

where  $x$  is the solution to the BP equation (1.1) and the equality holds for large enough  $\beta \geq \beta_0$  since for large  $\beta$  and  $k \geq 3$ ,  $(1 - e^{-\beta}) \left( \prod_{j=1}^k \rho_{0,j}(0) + \prod_{j=1}^k \rho_{0,j}(1) \right) \geq \frac{1}{2}$  holds if and only if either  $\rho_{0,j}(1) = \frac{e^\beta}{e^\beta + e^{-\beta}}$  holds for all  $1 \leq j \leq k$ , or  $\rho_{0,j}(1) = \frac{e^{-\beta}}{e^\beta + e^{-\beta}}$  holds for all  $1 \leq j \leq k$ . Thus, it follows that

$$-(k-1)\alpha\lambda^{-1}\mathbb{E} \log \mathbb{E}' \left[ (u_0)^\lambda \right] \leq C - \beta^{1/2}(k-1)\alpha \log(1 - 2x^k). \tag{2.6}$$

Next, we estimate the first term of the definition of  $\mathcal{P}_{\theta_{\text{col}}}(\zeta_{k,d,\beta}, \beta^{-1/2})$  in (2.1), which equals

$$\begin{aligned} & \beta^{1/2} \log \mathbb{E}' \left[ \left( \sum_{x \in \{0,1\}} \prod_{a=1}^d u_a(x) \right)^{\beta^{-1/2}} \right] \\ &= \beta^{1/2} \log \mathbb{E}' \left[ \left( \prod_{a=1}^d \left( 1 - (1 - e^{-\beta}) \prod_{j=2}^k \rho_{a,j}(0) \right) + \prod_{a=1}^d \left( 1 - (1 - e^{-\beta}) \prod_{j=2}^k \rho_{a,j}(1) \right) \right)^{\beta^{-1/2}} \right] \end{aligned} \tag{2.7}$$

We upper bound the expectation inside the log in the above expression by

$$2^{\beta^{-1/2}} \cdot \mathbb{P}'(\mathcal{A}) + (3e^{-\beta})^{\beta^{-1/2}},$$

where

$$\mathcal{A} := \left\{ \prod_{a=1}^d \left( 1 - (1 - e^{-\beta}) \prod_{j=2}^k \rho_{a,j}(0) \right) + \prod_{a=1}^d \left( 1 - (1 - e^{-\beta}) \prod_{j=2}^k \rho_{a,j}(1) \right) \geq 3e^{-\beta} \right\}.$$

Define the events  $\mathcal{E}_0$  and  $\mathcal{E}_1$  involving  $(\rho_{a,j})_{1 \leq a \leq d, 2 \leq j \leq k}$  as follows.

- $\mathcal{E}_0$  is the event such that for each  $1 \leq a \leq d$ , we have for some  $j \in \{2, \dots, k\}$  that  $\rho_{a,j}(0) \neq \frac{e^\beta}{e^\beta + e^{-\beta}}$ .
- $\mathcal{E}_1$  is the event such that for each  $1 \leq a \leq d$ , we have for some  $j \in \{2, \dots, k\}$  that  $\rho_{a,j}(1) \neq \frac{e^\beta}{e^\beta + e^{-\beta}}$ .

We now claim that for large enough  $\beta$ , the event  $\mathcal{A}$  is included in  $\mathcal{E}_0 \cup \mathcal{E}_1$ . To this end, suppose that the event  $(\mathcal{E}_0 \cup \mathcal{E}_1)^c = \mathcal{E}_0^c \cap \mathcal{E}_1^c$  holds. Then, for each  $x \in \{0, 1\}$ , for some  $a \equiv a(x) \in \{1, \dots, d\}$  such that  $\rho_{a,j}(x) = \frac{e^\beta}{e^\beta + e^{-\beta}}$  holds for all  $2 \leq j \leq k$ . Thus, for  $x \in \{0, 1\}$ , we have

$$\prod_{a=1}^d \left( 1 - (1 - e^{-\beta}) \prod_{j=2}^k \rho_{a,j}(x) \right) \leq 1 - (1 - e^{-\beta}) \left( \frac{e^\beta}{e^\beta + e^{-\beta}} \right)^{k-1} \leq e^{-\beta} + ke^{-2\beta} < \frac{3}{2}e^{-\beta},$$

where the last inequality holds for large enough  $\beta \geq \beta_k$  and we used  $(1-x)^{k-1} \geq 1 - (k-1)x$  for  $x > 0$  in the second inequality. Hence, summing over  $x \in \{0, 1\}$  gives that the event  $\mathcal{A}$  cannot hold, which proves our claim that  $\mathcal{A} \subset \mathcal{E}_0 \cup \mathcal{E}_1$ . Consequently, the term (2.7) is bounded above by

$$\beta^{1/2} \log \left( 2^{\beta^{-1/2}} \cdot \mathbb{P}'(\mathcal{E}_0 \cup \mathcal{E}_1) + (3e^{-\beta})^{\beta^{-1/2}} \right) \leq \beta^{1/2} \log \mathbb{P}'(\mathcal{E}_0 \cup \mathcal{E}_1) + C.$$

## 47:12 Upper Bounds on the Colorability Threshold for Random Regular Graph

Note that  $\mathbb{P}'(\mathcal{E}_0 \cup \mathcal{E}_1)$  can be calculated explicitly by

$$\mathbb{P}'(\mathcal{E}_0 \cup \mathcal{E}_1) = 2(1 - x^{k-1})^d - (1 - 2x^{k-1})^d = \frac{(1 - x^{k-1})^{d-1}(1 - 2x^k)}{1 - x},$$

where in the final equality, we used the fact that  $x$  is the solution to the equation (1.1). Therefore, we have proven that

$$\begin{aligned} \beta^{1/2} \log \mathbb{E}' \left[ \left( \sum_{x \in \{0,1\}} \prod_{a=1}^d u_a(x) \right)^{\beta^{-1/2}} \right] \\ \leq C + \beta^{1/2} (-\log(1-x) + (d-1) \log(1-x^{k-1}) + \log(1-2x^k)). \end{aligned} \quad (2.8)$$

In conclusion, combining (2.6) and (2.8), and recalling the definition of  $\star\Phi(d)$  in (1.2), we have

$$\mathcal{P}_{\theta_{\text{COL}}}(\zeta_{k,d,\beta}, \beta^{-1/2}) \leq C + \beta^{1/2} \star\Phi(d),$$

which concludes the proof.  $\blacktriangleleft$

**Proof of Proposition 1.5.** Given a NAE-SAT instance  $\mathcal{G}$ , let  $\text{SOL}(\mathcal{G}) \subset \{0,1\}^V$  denotes the set of NAE-SAT solutions. Also, let  $Z_{\beta, \text{NAE}}(\mathcal{G})$  denotes the partition function (1.8) for  $\theta = \theta_{\text{NAE}}(\cdot; \beta)$ . Note that if  $\underline{x} \in \text{SOL}(\mathcal{G})$ , then  $\theta_{\text{NAE}}(\underline{x}_{\delta_a}) = 0$  for any  $a \in F$ , thus we have for any  $\beta > 0$  that

$$Z_{\beta, \text{NAE}}(\mathcal{G}) \equiv \sum_{\underline{x} \in \{0,1\}^V} \prod_{a \in F} (1 - \theta_{\text{NAE}}(\underline{x}_{\delta_a}; \beta)) \geq |\text{SOL}(\mathcal{G})|. \quad (2.9)$$

On the other hand, since  $\theta_{\text{NAE}}(\cdot; \beta)$  satisfies the condition (1.7) with  $\varepsilon = e^{-\beta}$ , we have by Theorem 2.1 that

$$\frac{1}{n} \mathbb{E} \left[ \log Z_{\beta, \text{NAE}}(\mathcal{G}) \right] \leq \mathcal{P}_{\theta_{\text{NAE}}}(\zeta_{k,d,\beta}, \beta^{-1/2}) + o_n(1) = \mathcal{P}_{\theta_{\text{COL}}}(\zeta_{k,d,\beta}, \beta^{-1/2}) + o_n(1),$$

where the last equality is due to Lemma 2.2. By Lemma 2.3, the right hand side is further bounded by

$$\frac{1}{n} \mathbb{E} \left[ \log Z_{\beta, \text{NAE}}(\mathcal{G}) \right] \leq \beta^{1/2} \cdot \star\Phi(d) + C + o_n(1),$$

for some constant  $C$  that does not depend on  $n$  nor  $\beta$ . If  $\star\Phi(d) < 0$ , then for large enough  $\beta > 0$ ,  $\beta^{1/2} \cdot \star\Phi(d) + C < -1$  holds, thus  $n^{-1} \mathbb{E} \left[ \log Z_{\beta, \text{NAE}}(\mathcal{G}) \right] < -1$  holds for large enough  $n$ . For such  $\beta = \beta_0(k, d) > 0$ , we have by (2.9) and Lemma 1.3 that for large enough  $n$ ,

$$\mathbb{P} \left( |\text{SOL}(\mathcal{G})| \geq 1 \right) \leq \mathbb{P} \left( \left| \frac{1}{n} \log Z_{\beta_0, \text{NAE}}(\mathcal{G}) - \frac{1}{n} \mathbb{E} \left[ \log Z_{\beta_0, \text{NAE}}(\mathcal{G}) \right] \right| \geq 1 \right) \leq e^{-cn},$$

for some constant  $c$  that depends only on  $\beta_0 > 0$ , which finishes the proof for the NAE-SAT model.

Given a configuration model  $\mathbf{G}$ , let  $Z_{\beta, \text{COL}}(\mathbf{G})$  denote the partition function (1.8) for  $\theta = \theta_{\text{COL}}(\cdot; \beta)$ . Then, by the same reasoning, Theorem 2.1 and Lemma 2.3 shows that if  $\star\Phi(d) < 0$  then  $\frac{1}{n} \mathbb{E} \left[ \log Z_{\beta, \text{COL}}(\mathbf{G}) \right] < -1$  holds for large enough  $\beta = \beta_0(k, d) > 0$  and  $n$  large enough. On the event that there exists a 2-coloring on  $\mathbf{G}$ ,  $Z_{\beta, \text{COL}}(\mathbf{G}) \geq 1$  holds, so Lemma 1.3 again concludes the proof.  $\blacktriangleleft$

## 2.2 Proof of Lemma 1.3

Recall that  $\mathbf{G} = (V, F, \mathbf{E})$  is generated from the configuration model, where the  $\mathbf{E}$  is drawn uniformly from  $S_{nd}$ . Thus,  $\mathbf{E}$  has the same law as sequentially drawing random clauses  $\mathbf{a}_1, \dots, \mathbf{a}_m$  as follows. At times  $t \in \{1, \dots, m\}$  clause  $\mathbf{a}_t$  is drawn by connecting the  $k$  adjacent half-edges to previously unmatched half-edges adjacent to variables. For  $1 \leq t \leq m$ , let  $\mathcal{F}_t$  be the  $\sigma$ -algebra generated by  $\mathbf{a}_1, \dots, \mathbf{a}_t$ , and  $\mathcal{F}_0 \equiv \emptyset$ . Denote  $M_t \equiv \mathbb{E}[\log Z(\mathbf{G}) \mid \mathcal{F}_t]$  by the associated Doob martingale. Note that if  $\mathbf{G} = (V, F, E)$  and  $\mathbf{G}' = (V, F, E')$  has the same set of edges except for those adjacent to two clauses  $a_1 \neq a_2 \in F$ , then by our assumption of  $\theta$  in (1.7) and the definition of  $Z(G)$  in (1.8), it follows that  $\varepsilon^2 \leq Z(G)/Z(G') \leq \varepsilon^{-2}$  holds. Thus, we have for every  $t \in \{0, 1, \dots, m-1\}$  that

$$\left| M_{t+1} - M_t \right| \equiv \left| \mathbb{E}[\log Z(\mathbf{G}) \mid \mathcal{F}_{t+1}] - \mathbb{E}[\log Z(\mathbf{G}) \mid \mathcal{F}_t] \right| \leq 2 \log(1/\varepsilon), \quad (2.10)$$

from which Lemma 1.3 follows.

**Proof of Lemma 1.3.** Note that  $M_m = \log Z(\mathbf{G})$  and  $M_0 = \mathbb{E}[\log Z(\mathbf{G})]$  holds and  $(M_t)_{0 \leq t \leq m}$  is a martingale with bounded difference by (2.10). Therefore, the conclusion follows from Azuma Hoeffding's inequality.  $\blacktriangleleft$

## 2.3 Proof of Lemma 1.7

The following notations are convenient for the proof of Lemma 1.7. For non-negative quantities  $f = f_{d,k,n}$  and  $g = g_{d,k,n}$ , we use any of the equivalent notations  $f = O_{k,d}(g)$ ,  $g = \Omega_{k,d}(f)$ ,  $f \lesssim_{k,d} g$  and  $g \gtrsim_{k,d} f$  to indicate that there exists a constant  $C_{k,d}$ , which only depends on  $k, d$  such that  $f \leq C_{k,d} \cdot g$ . We drop the subscripts  $d$  (resp.  $k, d$ ) if the constant  $C_{k,d}$  does not depend on  $d$  (resp.  $k, d$ ). When  $f \lesssim_{k,d} g$  and  $g \lesssim_{k,d} f$ , we write  $f \asymp_{k,d} g$ . Similarly when  $f \lesssim g$  and  $g \lesssim f$ , we write  $f \asymp g$ .

Note that  $\mathbb{E}Z_{\text{COL}}$  is the sum over  $\underline{x} \in \{0, 1\}^V$  of the probabilities that  $\underline{x}$  is a 2-coloring on  $\mathbf{G}$ . By symmetry, the probability of  $\underline{x} \in \{0, 1\}^V$  being a 2-coloring depends only on the number  $n\gamma$  of nodes having color 1, which we denote by  $\mathbf{p}_\gamma$ . Thus,  $\mathbb{E}Z_{\text{COL}} = \sum_\gamma \binom{n}{n\gamma} \mathbf{p}_\gamma$ , where the sum is over  $\gamma \in (0, 1)$  such that  $n\gamma \in \mathbb{Z}$ . Moreover, we can express  $\mathbf{p}_\gamma$  as follows. Let  $X_1, \dots, X_m$  be i.i.d. Binom( $k, \gamma$ ) random variables and denote  $\mathbb{P}_\gamma$  by the probability with respect to  $(X_i)_{i \leq m}$ . Then, we have

$$\begin{aligned} \mathbf{p}_\gamma &= \mathbb{P}_\gamma \left( X_i \notin \{0, k\} \text{ for all } 1 \leq i \leq m \mid \sum_{i=1}^m X_i = km\gamma \right) \\ &\leq \frac{\mathbb{P}_\gamma(X_i \notin \{0, k\} \text{ for all } 1 \leq i \leq m)}{\mathbb{P}_\gamma(\sum_{i=1}^m X_i = km\gamma)} \lesssim_k \sqrt{m} (1 - \gamma^k - (1 - \gamma)^k)^m, \end{aligned} \quad (2.11)$$

where the last inequality is due to a Stirling's approximation. It follows that

$$\begin{aligned} \mathbb{E}Z_{\text{COL}} &\leq n^{O(1)} \sum_\gamma \exp(nF_\alpha(\gamma)), \quad \text{where} \\ F_\alpha(\gamma) &:= H(\gamma) + \alpha \log(1 - \gamma^k - (1 - \gamma)^k). \end{aligned} \quad (2.12)$$

Here,  $H(\gamma) \equiv -\gamma \log \gamma - (1 - \gamma) \log(1 - \gamma)$  is the entropy of  $\gamma$ . Note that  $\gamma \rightarrow \gamma^k + (1 - \gamma)^k$  is uniquely minimized at  $\gamma = 1/2$ . Further, the entropy  $H(\gamma)$  is strictly concave and is maximized at  $\gamma = 1/2$ . Thus,  $\gamma \rightarrow F_\alpha(\gamma)$  is uniquely maximized at  $\gamma = 1/2$  with  $\frac{\partial^2 F_\alpha}{\partial \gamma^2}(1/2) < 0$ . Since  $\mathbb{E}Z_{\text{NAE}} = \exp(nF_\alpha(1/2))$ , it follows from (2.12) that

$$\mathbb{E}Z_{\text{COL}} \leq n^{O(1)} \exp(nF_\alpha(1/2)) = n^{O(1)} \cdot \mathbb{E}Z_{\text{NAE}}. \quad (2.13)$$

We now show that the polynomial factor  $n^{O(1)}$  can actually be removed with a matching lower bound.

## 47:14 Upper Bounds on the Colorability Threshold for Random Regular Graph

First, by (2.11) and the fact that  $\gamma \rightarrow F_\alpha(\gamma)$  is uniquely maximized at  $\gamma = 1/2$  with strictly negative second derivative, the contribution to  $\mathbb{E}Z_{\text{COL}}$  from  $\gamma$  such that  $|\gamma - 1/2| \geq n^{-1/3}$  is negligible:

$$\sum_{|\gamma - 1/2| \geq n^{-1/3}} \binom{n}{n\gamma} \mathbf{p}_\gamma \lesssim_{k,d} \exp(-\Omega_{k,d}(n^{1/3})) \cdot \mathbb{E}Z_{\text{NAE}}. \quad (2.14)$$

Thus, we focus on the regime  $|\gamma - 1/2| \leq n^{-1/3}$ . Note that we can calculate  $\mathbf{p}_\gamma$  by summing over the empirical distribution  $\nu$  of  $(X_i)_{i \leq m}$ . Consider  $\nu \in \mathcal{P}(\{1, \dots, k-1\})$  and let  $p_\gamma(j) := \binom{k}{j} \gamma^j (1-\gamma)^{k-j}$ . Then,

$$\mathbf{p}_\gamma = \frac{\sum_\nu \mathbb{1}\left(\sum_j j\nu_j = km\gamma\right) e^{-km\gamma\lambda} \binom{m}{m\nu} \prod_j (p_\gamma(j)e^{\lambda j})^{m\nu_j}}{\mathbb{P}_\gamma\left(\sum_{i=1}^m X_i = km\gamma\right)},$$

where  $\binom{m}{m\nu} \equiv \frac{m!}{\prod_j (m\nu_j)!}$  and we introduced a lagrange parameter  $\lambda \in \mathbb{R}$  in the last equality. Let

$$\nu_{\gamma,\lambda}(x) := \frac{p_\gamma(x)e^{\lambda x}}{\sum_{j=1}^{k-1} p_\gamma(j)e^{\lambda j}} \quad \text{for } 1 \leq x \leq k-1,$$

and denote  $\mathbb{P}_{\gamma,\lambda}$  by the probability with respect to  $\tilde{X}_1, \dots, \tilde{X}_m \stackrel{i.i.d.}{\sim} \nu_{\gamma,\lambda}$ . Then, it follows that

$$\mathbf{p}_\gamma = \frac{\mathbb{P}_{\gamma,\lambda}\left(\sum_{i=1}^m \tilde{X}_i = km\gamma\right)}{\mathbb{P}_\gamma\left(\sum_{i=1}^m X_i = km\gamma\right)} \exp(-m \cdot \Xi(\gamma, \lambda)), \quad \text{where } \Xi(\gamma, \lambda) := k\gamma\lambda - \log\left(\sum_{j=1}^{k-1} p_\gamma(j)e^{\lambda j}\right). \quad (2.15)$$

In order to use the local central limit theorem, we take  $\lambda = \lambda(\gamma)$  such that  $\mathbb{E}_{\gamma,\lambda}\tilde{X} = k\gamma$ , where  $\tilde{X} \sim \nu_{\gamma,\lambda}$ . The existence of such  $\lambda(\gamma)$  is guaranteed by the lemma below.

► **Lemma 2.4.** *For large enough  $n$  and all  $\gamma$  such that  $|\gamma - 1/2| \leq n^{-1/3}$ , there exists a unique  $\lambda = \lambda(\gamma)$  such that  $\mathbb{E}_{\gamma,\lambda}\tilde{X} = k\gamma$  holds. Furthermore, we have  $\lambda(1/2) = 0$  and  $|\lambda(\gamma)| \lesssim_k n^{-1/3}$  holds uniformly over  $|\gamma - 1/2| \leq n^{-1/3}$ .*

**Proof.** Note that we have  $\frac{\partial \Xi}{\partial \lambda}(\gamma, \lambda) = k\gamma - \mathbb{E}_{\gamma,\lambda}\tilde{X}$  by definition of  $\nu_{\gamma,\lambda}$  and  $\Xi(\gamma, \lambda)$ . Further, we have that

$$\frac{\partial \Xi}{\partial \lambda}\left(\frac{1}{2}, 0\right) = \frac{k}{2} - \mathbb{E}_{\frac{1}{2}, 0}\tilde{X} = \frac{k}{2} - \mathbb{E}_{\frac{1}{2}}[X | X \notin \{0, k\}] = 0,$$

where  $\mathbb{E}_{\frac{1}{2}}$  is with respect to  $X \sim \text{Binom}(1/2)$ . Since  $\lambda \rightarrow \log\left(\sum_{j=1}^{k-1} p_\gamma(j)e^{\lambda j}\right)$  is strongly convex, we have  $\frac{\partial^2 \Xi}{\partial \lambda^2}\left(\frac{1}{2}, 0\right) < 0$ . Thus, implicit function theorem shows that for  $\gamma \in (1/2 - \varepsilon, 1/2 + \varepsilon)$ , where  $\varepsilon = \varepsilon(k) > 0$  depends only on  $k$ , there exists  $\lambda = \lambda(\gamma)$  such that  $\frac{\partial \Xi}{\partial \lambda}(\gamma, \lambda(\gamma)) = 0$  holds, and that  $\gamma \rightarrow \lambda(\gamma)$  is continuously differentiable. Therefore, for large enough  $n$  and  $\gamma \in (1/2 - n^{-1/3}, 1/2 + n^{-1/3})$ , there exists a unique  $\lambda = \lambda(\gamma)$  such that  $\mathbb{E}_{\gamma,\lambda(\gamma)}\tilde{X} = k\gamma$ , and  $|\lambda(\gamma)| \lesssim_k n^{-1/3}$  holds uniformly over  $\gamma \in (1/2 - n^{-1/3}, 1/2 + n^{-1/3})$ . ◀

Having Lemma 2.4 in hand, we prove Lemma 1.7 by appealing to the local central limit theorem.

**Proof of Lemma 1.7.** The contribution to  $\mathbb{E}Z_{\text{COL}}$  from  $\gamma$  such that  $|\gamma - 1/2| \geq n^{-1/3}$  is negligible by (2.14), thus we consider  $\gamma$  such that  $|\gamma - 1/2| \leq n^{-1/3}$  holds. To this end, we take  $\lambda = \lambda(\gamma)$  from Lemma 2.4 in equation (2.15). Then, by the local central limit theorem [13],

$$\mathbf{p}_\gamma \asymp \left( \frac{\text{Var}_\gamma(X)}{\text{Var}_{\gamma, \lambda(\gamma)}(\tilde{X})} \right)^{1/2} \cdot \exp\left(-m \cdot \Xi(\gamma, \lambda(\gamma))\right), \quad (2.16)$$

where  $X \sim \text{Binom}(k, \gamma)$  and  $\tilde{X} \sim \nu_{\gamma, \lambda(\gamma)}$ . Lemma 2.4 further shows that  $|\lambda(\gamma)| \lesssim_k n^{-1/3}$ , thus we have

$$\text{Var}_{\gamma, \lambda(\gamma)}(\tilde{X}) \asymp_k \text{Var}_\gamma(X \mid 1 \leq X \leq k-1) \asymp_k \text{Var}_\gamma(X), \quad (2.17)$$

where the final estimate holds because  $|\gamma - 1/2| \leq n^{-1/3}$ . Combining with (2.14), it follows that

$$\mathbb{E}Z_{\text{COL}} = (1 + o_n(1)) \sum_{|\gamma - 1/2| \leq n^{-1/3}} \binom{n}{n\gamma} \mathbf{p}_\gamma \asymp_{k,d} n^{-1/2} \sum_{|\gamma - 1/2| \leq n^{-1/3}} \exp(nG_\alpha(\gamma)), \quad (2.18)$$

where

$$G_\alpha(\gamma) := H(\gamma) - \alpha \cdot \Xi(\gamma, \lambda(\gamma)).$$

Note that by comparing (2.16) and (2.17) with (2.11), we have  $G_\alpha(\gamma) \leq F_\alpha(\gamma)$  for  $|\gamma - 1/2| \leq n^{-1/3}$ . Also, note that for  $\gamma = 1/2$ ,  $G_\alpha(1/2) = F_\alpha(1/2)$  holds since

$$G_\alpha(1/2) = H(1/2) - \alpha \cdot \Xi(1/2, 0) = H(1/2) + \alpha \log(1 - \gamma^k - (1 - \gamma)^k),$$

where we used  $\lambda(1/2) = 0$  by Lemma 2.4. Recalling that  $\gamma \rightarrow F_\alpha(\gamma)$  is uniquely maximized at  $\gamma = 1/2$  with strictly negative second derivative at the maximizer, it follows that the same holds for  $\gamma \rightarrow G_\alpha(\gamma)$ . Therefore, the sum in the right hand side of (2.18) can be approximated by a Gaussian integration, which shows that

$$\mathbb{E}Z_{\text{COL}} \asymp_{k,d} \exp(nG_\alpha(1/2)) = \mathbb{E}Z_{\text{NAE}}.$$

This concludes the proof. ◀

### 3 Proof of Proposition 1.6

In this section, we prove Proposition 1.6 for  $k \geq 4$ . The proof of Proposition 1.6 for  $k = 3$  is available in the arXiv version [14]. The proof of Proposition 1.6 for  $k \geq 4$  can be split into the following two lemmas. In Section 3.1, we prove Lemma 3.1 which guarantees the existence and the uniqueness of the BP fixed point for  $k \geq 4$ .

► **Lemma 3.1.** *For  $k \geq 4$  and  $d \in [d_{\text{lb}}(k), d_{\text{ub}}(k)]$ , there exists a unique solution to  $\Psi_d(x) = x$  in the range  $x \in [\frac{1}{2} - \frac{1}{2^k}, \frac{1}{2}]$ .*

By Lemma 3.1, the function  $d \rightarrow \star\Phi(d)$  is well-defined. In Section 3.2, we prove Lemma 3.2 which guarantees that  $d_\star(k)$  is well-defined for  $k \geq 4$ .

► **Lemma 3.2.** *For  $k \geq 4$ , the function  $d \rightarrow \star\Phi(d)$  is continuous for  $d \in [d_{\text{lb}}(k), d_{\text{ub}}(k)]$ . Further,  $\star\Phi(d_{\text{lb}}(k)) > 0$  and  $\star\Phi(d_{\text{ub}}(k)) < 0$  hold.*

**Proof of Proposition 1.6 for  $k \geq 4$ .** This is immediate from Lemma 3.1 and Lemma 3.2. ◀

### 3.1 Proof of Lemma 3.1

Recall the variable BP recursion  $\dot{\Psi}$  and the clause BP recursion  $\hat{\Psi}$  defined in (1.12). To prove the uniqueness of the BP fixed point, we show that the BP recursion  $\Psi_d \equiv \dot{\Psi} \circ \hat{\Psi}$  is a contraction for  $k \geq 4$ .

► **Lemma 3.3.** *For  $k \geq 4$  and  $d \in [d_{\text{lb}}(k), d_{\text{ub}}(k)]$ ,  $|(\Psi_d)'(x)| < 1$  holds uniformly over  $x \in [\frac{1}{2} - \frac{1}{2^k}, \frac{1}{2}]$ .*

**Proof.** Throughout, we let  $x \in [1/2 - 1/2^k, 1/2]$  and denote  $v = \hat{\Psi}(x)$ . We first consider  $k \geq 5$ . Observe that the derivative of the clause BP recursion can simply be bounded in absolute value by

$$|(\hat{\Psi})'(x)| = \frac{(k-1)x^{k-2}}{(1-x^{k-1})^2} \leq \frac{(k-1) \cdot 2^{-k+2}}{(1-2^{-k+1})^2} = \frac{4(k-1)}{2^k(1-2^{-k+1})^2}, \quad (3.1)$$

where the inequality holds since  $x \rightarrow \frac{x^{k-2}}{(1-x^{k-1})^2}$  is increasing. Similarly, we bound the derivative of the variable BP recursion:

$$|(\dot{\Psi})'(v)| = \frac{(d-1)v^{d-2}}{(2-v^{d-1})^2} \leq \frac{(d-1)v_0^{d-2}}{(2-v_0^{d-1})^2} \leq \frac{(d-1)v_0^{d-2}}{(2-v_0^{d-2})^2}, \quad (3.2)$$

where we denoted  $v_0 := \hat{\Psi}(x_0)$  for  $x_0 = 1/2 - 1/2^k$ . The first inequality holds because  $x \rightarrow \hat{\Psi}(\cdot)$  is decreasing on  $[1/2 - 1/2^k, 1/2]$ , and the last inequality holds since  $v_0 < 1$ . To this end, we upper bound  $v_0^{d-2}$  by

$$v_0^{d-2} = \left(1 - \frac{x_0^{k-1}}{1-x_0^{k-1}}\right)^{d-2} \leq (1-x_0^{k-1})^{d-2} \leq e^{-(d-2)x_0^{k-1}}. \quad (3.3)$$

Note that  $x_0^{k-1} = (\frac{1}{2})^{k-1} (1 - \frac{2}{2^k})^{k-1} \geq (\frac{1}{2})^{k-1} (1 - \frac{2(k-1)}{2^k})$  and  $d \geq (2^{k-1} - 2)k \log 2$  hold, thus we can lower bound  $(d-2)x_0^{k-1}$  by

$$(d-2)x_0^{k-1} \geq \left(k \log 2 - \frac{4k \log 2 + 4}{2^k}\right) \cdot \left(1 - \frac{2(k-1)}{2^k}\right).$$

Thus, combining with (3.3) shows that

$$v_0^{d-2} \leq 2^{-k} e^{\varepsilon_k}, \quad \text{where } \varepsilon_k := \frac{2(k-1)k \log 2}{2^k} + \frac{4k \log 2 + 4}{2^k} \left(1 - \frac{2(k-1)}{2^k}\right). \quad (3.4)$$

Plugging this bound into (3.2), we have

$$|(\dot{\Psi})'(v)| < (d-1) \frac{v_0^{d-2}}{(2-v_0^{d-2})^2} \leq (2^{k-1}k \log 2 - 1) \cdot \frac{2^{-k} \cdot e^{\varepsilon_k}}{(2-2^{-k}e^{\varepsilon_k})^2}.$$

Combining with the contraction of clause BP recursion in (3.1), we have

$$|(\Psi_d)'(x)| \leq \alpha_k := \frac{2k(k-1) \log 2}{2^k} \cdot \left(1 - \frac{1}{2^{k-1}k \log 2}\right) \cdot \frac{e^{\varepsilon_k}}{(1-2^{-k+1})^2(2-2^{-k}e^{\varepsilon_k})^2}.$$

By comparing  $\varepsilon_k$  and  $\varepsilon_{k+1}$  for  $k \geq 5$ , it can be easily checked that  $k \rightarrow \varepsilon_k$  is decreasing, and the same holds for  $k \rightarrow \frac{2k(k-1) \log 2}{2^k} \cdot \left(1 - \frac{1}{2^{k-1}k \log 2}\right)$ . Thus,  $k \rightarrow \alpha_k$  is decreasing for  $k \geq 5$ . Furthermore,  $\alpha_5$  can be calculated up to arbitrary precision (e.g. by Mathematica), which satisfies  $\alpha_5 < 0.99 < 1$ . Consequently,  $|(\Psi_d)'(x)| < 1$  holds for  $k \geq 5$ .

The case where  $k = 4$  is more delicate, and the previous strategy of bounding the derivative of clause and variable BP recursions separately no longer is successful. To this end, we bound  $(\Psi_d)'(x)$  directly. If we denote  $v = \hat{\Psi}_k(x)$ , then

$$|(\Psi_d)'(x)| = |(\hat{\Psi})'(x)| \cdot |(\dot{\Psi})'(v)| = \frac{(k-1)(d-1)v^{d-2}}{(2-v^{d-1})^2} \cdot \frac{x^{k-1}}{(1-x^{k-1})^2} \cdot \frac{1}{x}.$$

Since  $v \equiv \hat{\Psi}_k(x) \equiv \frac{1-2x^{k-1}}{1-x^{k-1}}$ , rearranging gives  $x^{k-1} = \frac{1-v}{2-v}$ . Substituting this in for  $x^{k-1}$ , we have that

$$|(\Psi_d)'(x)| = (k-1)(d-1) \cdot \frac{v^{d-2}(2-v)(1-v)}{(2-v^{d-1})^2} \cdot \frac{1}{x}. \quad (3.5)$$

We now claim that  $v \rightarrow \frac{v^{d-2}(2-v)(1-v)}{(2-v^{d-1})^2}$  is increasing for  $v \in [\hat{\Psi}_4(1/2), \hat{\Psi}_4(1/2 - 1/2^4)]$  and  $d \in [24 \log 2, 32 \log 2]$  (recall that  $24 \log 2 > 16.7 \equiv d_{\text{ibd}}(4)$  holds). Since  $v \rightarrow (2-v^{d-1})^2$  is decreasing, it suffices to show that  $v \rightarrow v^{d-2}(2-v)(1-v)$  is increasing. Note that

$$\frac{d}{dv} \left( v^{d-2}(2-v)(1-v) \right) = (dv^2 - 3(d-1)v + 2(d-2))v^{d-3} > 0 \iff d > \frac{4-3v}{(2-v)(1-v)}.$$

Note that  $v \rightarrow \frac{4-3v}{(2-v)(1-v)}$  is increasing since its derivative is given by  $\frac{3v^2-8v+6}{(2-v)^2(1-v)^2} > 0$ . Thus, to prove our claim, it suffices to check that for  $d_0 := 24 \log 2$  and  $v_0 = \hat{\Psi}_4(1/2 - 1/2^4)$  that  $d_0 > \frac{4-3v_0}{(2-v_0)(1-v_0)}$  holds. By a direct calculation,  $v_0 = 3410/3753 < 0.91$  and  $24 \log 2 > 16 > \frac{4-3 \cdot 0.91}{(2-0.91)(1-0.91)}$  holds, thus the claim that  $v \rightarrow \frac{v^{d-2}(2-v)(1-v)}{(2-v^{d-1})^2}$  is increasing is proven for  $d, v$  in the regime of interest.

Note that  $x \rightarrow v = \hat{\Psi}_4(x)$  is decreasing, thus (3.5) and our previous claim shows that for all  $x_0 \leq x \leq 1/2$ , where  $x_0 = 1/2 - 1/2^4$ , we have

$$|(\Psi_d)'(x)| \leq (d-1)(k-1) \frac{v_0^{d-2}(2-v_0)(1-v_0)}{(2-v_0^{d-1})^2} \cdot \frac{1}{x_0},$$

where  $v_0 = \hat{\Psi}_4(x_0) = 3410/3753$ . We next show that the right hand side as a function of  $d \in [24 \log 2, 32 \log 2]$  is decreasing: since  $d \rightarrow (2-v_0^{d-1})^2$  is increasing, it suffices to show that  $d \rightarrow (d-1)v_0^{d-2}$  is decreasing. Note that

$$\frac{d}{dd} \left( (d-1)v_0^{d-2} \right) = v_0^{d-2} \left( 1 - (d-1) \log(1/v_0) \right) < 0 \iff d > \frac{1}{\log(1/v_0)} + 1,$$

and it can be verified that  $24 \log 2 > 16 > 1/\log(3753/3410) + 1$  holds. Therefore, for  $k = 4$ , it follows that for  $d_0 = 24 \log 2$ ,

$$|(\Psi_d)'(x)| \leq 3(d_0-1) \frac{v_0^{d_0-2}(2-v_0)(1-v_0)}{(2-v_0^{d_0-1})^2} \cdot \frac{1}{x_0}.$$

The right hand side can be computed to arbitrary precision (e.g. by Mathematica), it can be verified that  $3(d_0-1) \frac{v_0^{d_0-2}(2-v_0)(1-v_0)}{(2-v_0^{d_0-1})^2} \cdot \frac{1}{x_0} < 0.9 < 1$ . This concludes the proof for the case  $k = 4$ .  $\blacktriangleleft$

In the proof of Lemma 3.3, we did not use the adjustment for  $d_{\text{ibd}}(4) \equiv 16.7 > 24 \log 2$ . That is,  $\max_{\frac{1}{2} - \frac{1}{2^4} \leq x \leq \frac{1}{2}} |(\Psi_d)'(x)| < 1$  holds for  $d \in [24 \log 2, 32 \log 2]$ . The adjustment  $d_{\text{ibd}}(4) \equiv 16.7$  is needed for the following lemma, which guarantees the existence of the solution to  $\Psi_d(x) = x$ .

► **Lemma 3.4.**  $\Psi_d(\frac{1}{2} - \frac{1}{2^k}) > \frac{1}{2} - \frac{1}{2^k}$  holds for  $k \geq 4$  for  $d \in [d_{\text{lb}d}(k), d_{\text{ub}d}(k)]$ .

**Proof.** Let  $v_0 \equiv v_0(k) = \hat{\Psi}(\frac{1}{2} - \frac{1}{2^k})$  as before. Then, from the definition of  $\hat{\Psi}, \hat{\Psi}$  in (1.12),  $\Psi_d(\frac{1}{2} - \frac{1}{2^k}) > \frac{1}{2} - \frac{1}{2^k}$  is equivalent to  $v_0^{d-1} < \frac{4}{2^{k+2}}$ , which we aim to show for  $k \geq 4$ . We start with the case  $k \geq 5$ . We have shown in (3.4) that  $v_0^{d-2} \leq 2^{-k}e^{\varepsilon_k}$ , holds, and by an analogous proof,  $v_0^{d-1} \leq 2^{-k}e^{\beta_k}$  holds, where  $\beta_k \equiv \varepsilon_k - \frac{1}{2^{k-1}}(1 - \frac{2(k-1)}{2^k})$ . Thus, it suffices to show that

$$e^{\beta_k} \left(1 + \frac{1}{2^{k-1}}\right) < 4, \quad \text{where} \quad \beta_k \equiv \frac{2(k-1)k \log 2}{2^k} + \frac{4k \log 2 + 2}{2^k} \left(1 - \frac{2(k-1)}{2^k}\right).$$

For  $k = 5$ ,  $e^{\beta_5}(1 + 1/2^4)$  can be computed to arbitrary precision (e.g. by Mathematica), and it can be numerically verified that  $e^{\beta_5}(1 + 1/2^4) < 3.7$ . Further,  $k \rightarrow \beta_k$  is decreasing by comparing  $\beta_k$  and  $\beta_{k+1}$ , thus this concludes the proof for  $k \geq 5$ .

Next, we consider the case  $k = 4$ . Since  $d \rightarrow v_0^{d-1}$  is maximized at  $d = d_{\text{lb}d}(4) \equiv 16.7$ , it suffices to show that  $v_0^{15.7} \leq \frac{2}{9}$  holds, where  $v_0 \equiv \hat{\Psi}_4(1/2 - 1/2^4) = 3410/3753$ . Since  $v_0^{15.7} = (3410/3753)^{15.7}$  can be computed to arbitrary precision (e.g. by Mathematica), it can be checked that  $v_0^{15.7} = (3410/3753)^{15.7} < 0.2221 < \frac{2}{9}$  holds, so this concludes the proof. ◀

**Proof of Lemma 3.1.** By Lemma 3.4,  $\Psi_d(\frac{1}{2} - \frac{1}{2^k}) > \frac{1}{2} - \frac{1}{2^k}$  holds for  $k \geq 4$ . Note that  $\Psi_d(1/2) < 1/2$  holds since  $\hat{\Psi}(x) < 1/2$  holds for any  $x \geq 0$ . Thus, since  $x \rightarrow \Psi_d(x)$  is continuous and differentiable, intermediate value theorem guarantees the existence of the solution to  $\Psi_d(x) = x$  for  $x \in [\frac{1}{2} - \frac{1}{2^k}, \frac{1}{2}]$ . Moreover,  $|(\Psi_d)'(x)| < 1$  holds uniformly over  $x \in [\frac{1}{2} - \frac{1}{2^k}, \frac{1}{2}]$  by Lemma 3.3, thus mean value theorem guarantees the uniqueness of the solution to  $\Psi_d(x) = x$  for  $x \in [\frac{1}{2} - \frac{1}{2^k}, \frac{1}{2}]$ . ◀

## 3.2 Proof of Lemma 3.2

Recall that  $\star\Phi(d)$  is defined in (1.2) as  $\star\Phi(d) \equiv \Phi(d, x_\star(k, d))$ , where  $x_\star(k, d) \in [\frac{1}{2} - \frac{1}{2^k}, \frac{1}{2}]$  is the solution to  $\Psi_d(x) = x$ , and we defined the function  $\Phi(d, x)$  by

$$\Phi(d, x) \equiv \Phi_k(d, x) := -\log(1-x) - d(1-k^{-1} - d^{-1}) \log(1-2x^k) + (d-1) \log(1-x^{k-1}). \quad (3.6)$$

To prove  $\star\Phi(d_{\text{lb}d}(k)) > 0$  and  $\star\Phi(d_{\text{ub}d}(k)) < 0$ , we show respectively in Lemmas 3.5 and 3.6 that  $\Phi(d_{\text{lb}d}(k), x) > 0$  and  $\Phi(d_{\text{ub}d}(k), x) < 0$  hold uniformly over  $x \in [\frac{1}{2} - \frac{1}{2^k}, \frac{1}{2}]$ .

► **Lemma 3.5.** For  $k \geq 4$ ,  $\Phi(d_{\text{lb}d}(k), x) > 0$  holds uniformly over  $x \in [\frac{1}{2} - \frac{1}{2^k}, \frac{1}{2}]$ .

**Proof.** Note that rearranging  $\Phi(d, x)$  gives

$$\begin{aligned} \Phi(d, x) &= -\log(1-x) - d((1-k^{-1}) \log(1-2x^k) - \log(1-x^{k-1})) + \log(1-2x^k) - \log(1-x^{k-1}) \\ &\geq -\log(1-x) - d((1-k^{-1}) \log(1-2x^k) - \log(1-x^{k-1})), \end{aligned} \quad (3.7)$$

where the inequality holds since  $\log(1-2x^k) \geq \log(1-x^{k-1})$  holds for  $x \in [0, 1/2]$ . Note that the first term in the right hand side  $x \rightarrow -\log(1-x)$  is convex, so the linear approximation at  $x = 1/2$  shows that  $-\log(1-x) \geq \log 2 + 2(x - 1/2)$  holds. Further, the function  $x \rightarrow (1-k^{-1}) \log(1-2x^k) - \log(1-x^{k-1})$  is increasing since

$$\frac{d}{dx} \left( (1-k^{-1}) \log(1-2x^k) - \log(1-x^{k-1}) \right) = \frac{(k-1)x^{k-2}(1-2x)}{(1-2x^k)(1-x^{k-1})} \geq 0.$$

Thus, the right hand side in (3.7) for  $d = d_{\text{ibd}}(k)$  can further be lower bounded by

$$\begin{aligned}\Phi(d_{\text{ibd}}(k), x) &\geq \log 2 + 2(x - 1/2) + \frac{d_{\text{ibd}}(k)}{k} \cdot \log(1 - 2^{-k+1}) \\ &\geq \log 2 - 2^{-k+1} + \frac{d_{\text{ibd}}(k)}{k} \cdot \log(1 - 2^{-k+1}) =: F(k),\end{aligned}\quad (3.8)$$

where we used  $x \geq 1/2 - 1/2^k$  in the last inequality. Using the inequality  $\log(1 - a) \geq -a - \frac{a^2}{2} - \frac{a^3}{2}$  for  $a = 2^{-k+1} \leq \frac{1}{8}$ , we have, for  $k \geq 5$ , that

$$F(k) = \log 2 - 2^{-k+1} + (2^{k-1} - 2) \log 2 \cdot \log(1 - 2^{-k+1}) \geq \frac{1}{2^k} \left( 3 \log 2 - 2 - \frac{6 \log 2}{2^k} + \frac{8 \log 2}{2^{2k}} \right).$$

For  $k \geq 6$ , the right hand side above is positive since  $3 \log 2 - 2 - \frac{3 \log 2}{32} > 0.01$ , thus (3.8) shows that  $\Phi(d_{\text{ibd}}(k), x) > 0$  holds for  $k \geq 6$  and  $x \in [\frac{1}{2} - \frac{1}{2^k}, \frac{1}{2}]$ . For  $k \in \{4, 5\}$ , we can explicitly calculate  $F(k)$  by  $F(4) \equiv \log 2 - 1/8 + (16.7/4) \log(7/8) > 0.01 > 0$ , and  $F(5) \equiv \log 2 - 1/16 + 14 \log 2 \cdot \log(15/16) > 0.004 > 0$ , thus (3.8) again concludes the proof for  $k \in \{4, 5\}$ .  $\blacktriangleleft$

► **Lemma 3.6.** For  $k \geq 4$ ,  $\Phi(d_{\text{ubd}}(k), x) < 0$  holds uniformly over  $x \in [\frac{1}{2} - \frac{1}{2^k}, \frac{1}{2}]$ .

**Proof.** We first claim that for  $k \geq 5$ , the function  $x \rightarrow \Phi(d_{\text{ubd}}(k), x)$  is increasing for  $x \in [\frac{1}{2} - \frac{1}{2^k}, \frac{1}{2}]$  and  $d_{\text{ubd}}(k) \equiv 2^{k-1} k \log 2$ . A direct calculation shows that

$$\begin{aligned}\frac{\partial \Phi}{\partial x}(d_{\text{ubd}}(k), x) &= \frac{1}{1-x} - (2^{k-1} k \log 2 - 1)(k-1) \cdot \frac{x^{k-2}(1-2x)}{(1-x^{k-1})(1-2x^k)} - \frac{2x^{k-1}}{1-2x^k} \\ &\geq \frac{1}{\frac{1}{2} + \frac{1}{2^k}} - (2^{k-1} k \log 2 - 1)(k-1) \cdot \frac{x^{k-2}(1-2x)}{(1-x^{k-1})(1-2x^k)} - \frac{4}{2^k - 2},\end{aligned}\quad (3.9)$$

where the inequality holds since  $x \rightarrow (1-x)^{-1}$  increasing, so it is minimized at  $x = 1/2 + 1/2^k$ , and  $x \rightarrow 2x^{k-1}/(1-2x^k)$  is increasing, so it is maximized at  $x = 1/2$ . Further, it is straightforward to check that  $x \rightarrow x^{k-2}(1-2x)$  is decreasing for  $x \in [\frac{1}{2} - \frac{1}{2^k}, \frac{1}{2}]$ , thus it is maximized at  $x = 1/2 - 1/2^k$ . Also,  $x \rightarrow (1-x^{k-1})(1-2x^k)$  is minimized at  $x = 1/2$ . Thus, by plugging in these bounds, we can further bound

$$\begin{aligned}\frac{\partial \Phi}{\partial x}(d_{\text{ubd}}(k), x) &\geq 2 - \left( \frac{2}{2^{k-1} + 1} + \frac{4}{2^k - 2} + \frac{(2^{k-1} k \log 2 - 1)(k-1)}{2^{2k-3}} \cdot \left( 1 - \frac{1}{2^{k-1}} \right)^{k-4} \right) \\ &\geq 2 - \left( \frac{2}{2^{k-1} + 1} + \frac{4}{2^k - 2} + \frac{(2^{k-1} k \log 2 - 1)(k-1)}{2^{2k-3}} \right) =: 2 - G(k).\end{aligned}\quad (3.10)$$

Note that the function  $k \rightarrow G(k)$  is increasing for  $k \geq 5$ . Furthermore, using the bound  $\log 2 < 0.7$ , we can bound  $G(5) = \frac{2}{17} + \frac{2}{15} + \frac{80 \log 2 - 1}{32} < 1.97 < 2$ . Therefore,  $\frac{\partial \Phi}{\partial x}(d_{\text{ubd}}(k), x) > 0$  holds for  $k \geq 5$  and  $x \in [\frac{1}{2} - \frac{1}{2^k}, \frac{1}{2}]$ , which proves our first claim.

Consequently, for the case  $k \geq 5$ , it suffices to show that  $\Phi(2^{k-1} k \log 2, x) < 0$  holds for  $x = 1/2$ . A direct calculation gives

$$\Phi\left(2^{k-1} k \log 2, \frac{1}{2}\right) = \log 2 + 2^{k-1} \log 2 \cdot \log\left(1 - \frac{1}{2^{k-1}}\right) < 0,\quad (3.11)$$

where the inequality holds since  $\log(1 - a) < -a$  holds for  $a \in (0, 1)$ . This concludes the proof for  $k \geq 5$ .

It remains to consider the case  $k = 4$ . For  $k = 4$ , we claim that  $x \rightarrow \Phi_4(d_{\text{ubd}}(4), x)$  is convex in the interval  $x \in [\frac{7}{16}, \frac{1}{2}]$ . From the computation of  $\frac{\partial \Phi}{\partial x}(d_{\text{ubd}}(k), x)$  in (3.9), we can calculate the second derivative by

$$\frac{\partial^2 \Phi}{\partial x^2}(d_{\text{ubd}}(4), x) = \frac{d}{dx} \left( \frac{1}{1-x} - \frac{2x^3}{1-2x^4} \right) + 3(32 \log 2 - 1) \cdot \frac{d}{dx} \left( \frac{x^2(2x-1)}{(1-x^3)(1-2x^4)} \right). \quad (3.12)$$

The first term in the right hand side can be bounded by

$$\frac{d}{dx} \left( \frac{1}{1-x} - \frac{2x^3}{1-2x^4} \right) = \frac{1}{(1-x)^2} - \frac{6x^2 + 4x^6}{(1-2x^4)^2} > \frac{1}{(1-\frac{7}{16})^2} - \frac{6(\frac{1}{2})^2 + 4(\frac{1}{2})^6}{(1-2(\frac{1}{2})^4)^2} > 0, \quad (3.13)$$

where the final inequality is equivalent to  $\frac{256}{81} - \frac{100}{49} > 0$ . The second term can be calculated as

$$\frac{d}{dx} \left( \frac{x^2(2x-1)}{(1-x^3)(1-2x^4)} \right) = \frac{x(-16x^8 + 10x^7 + 4x^5 - 4x^4 - x^3 + 6x - 2)}{(1-x^3)^2(1-2x^4)^2}.$$

Note that by neglecting the terms  $10x^7 + 4x^5$  above, we can lower bound

$$-16x^8 + 10x^7 + 4x^5 - 4x^4 - x^3 + 6x - 2 > 6 \cdot \frac{7}{16} - 2 - \left(\frac{1}{2}\right)^3 - 4\left(\frac{1}{2}\right)^4 - 16\left(\frac{1}{2}\right)^8 > 0,$$

thus  $\frac{d}{dx} \left( \frac{x^2(2x-1)}{(1-x^3)(1-2x^4)} \right) > 0$  holds for  $x \in [\frac{7}{16}, \frac{1}{2}]$  as well. Therefore, combining with (3.12) and (3.13) finishes the proof of our claim that  $x \rightarrow \Phi_4(d_{\text{ubd}}(4), x)$  is convex in the interval  $x \in [\frac{7}{16}, \frac{1}{2}]$ .

Thus, by convexity,  $x \rightarrow \Phi_4(d_{\text{ubd}}(4), x)$  is maximized at the end points  $x \in \{7/16, 1/2\}$ , and it suffices to show that  $\Phi_4(d_{\text{ubd}}(4), 7/16) < 0$  and  $\Phi_4(d_{\text{ubd}}(4), 1/2) < 0$ . For  $x = 7/16$ ,  $\Phi_4(d_{\text{ubd}}(4), 7/16)$  can be computed to arbitrary precision (e.g. by Mathematica), and it can be checked that  $\Phi_4(d_{\text{ubd}}(4), 7/16) < -0.08 < 0$ . For  $x = 1/2$ , (3.11) shows that  $\Phi_4(d_{\text{ubd}}(4), 1/2) < 0$  holds. This concludes the proof for the case  $k = 4$ . ◀

**Proof of Lemma 3.2.** By definition,  $\star \Phi(d) = \Phi(d, x_\star(k, d))$  holds, and  $(d, x) \rightarrow \Phi(d, x)$  is clearly continuous. Thus, in order to show the continuity of  $\star \Phi(\cdot)$ , it suffices to show that  $d \rightarrow x_\star(k, d)$  is continuous for any fixed  $k \geq 4$ . To that end, note that the function  $\psi(d, x) := \Psi_d(x) - x$  satisfies  $\frac{\partial \psi}{\partial x} < 0$  by Lemma 3.3. Since  $x_\star(k, d)$  is defined to be the root of  $\psi(d, \cdot)$ , this implies that  $d \rightarrow x_\star(k, d)$  is continuous by the implicit function theorem. As a consequence, we conclude that  $d \rightarrow \star \Phi(d)$  is continuous. Since  $\star \Phi(d_{\text{lb}}(k)) > 0$  holds by Lemma 3.5 and  $\star \Phi(d_{\text{ubd}}(k)) < 0$  holds by Lemma 3.6, we conclude the proof. ◀

## Abstract

We study property testing in the subcube conditional model introduced by Bhattacharyya and Chakraborty (2017). We obtain the first equivalence test for  $n$ -dimensional distributions that is quasi-linear in  $n$ , improving the previously known  $\tilde{O}(n^2/\varepsilon^2)$  query complexity bound to  $\tilde{O}(n/\varepsilon^2)$ . We extend this result to general finite alphabets with logarithmic cost in the alphabet size.

By exploiting the specific structure of the queries that we use (which are more restrictive than general subcube queries), we obtain a cubic improvement over the best known test for distributions over  $\{1, \dots, N\}$  under the interval querying model of Canonne, Ron and Servedio (2015), attaining a query complexity of  $\tilde{O}((\log N)/\varepsilon^2)$ , which for fixed  $\varepsilon$  almost matches the known lower bound of  $\Omega((\log N)/\log \log N)$ . We also derive a product test for  $n$ -dimensional distributions with  $\tilde{O}(n/\varepsilon^2)$  queries, and provide an  $\Omega(\sqrt{n}/\varepsilon^2)$  lower bound for this property.

## 1 Introduction

Property testing seeks to efficiently distinguish between objects that have some property and objects that are  $\varepsilon$ -far from any object that has it, with respect to a predefined metric and a proximity parameter  $\varepsilon$ . Property testing of functions, and in particular string testing, was initiated in [18, 6]. The term “efficiently” usually refers to a sublinear amount of resources for moderately-sized tasks, but for high-dimensional inputs practicality mandates to restrict this amount further to the poly-logarithmic scale.

The study of distribution testing was implicitly initiated in [14] (motivated by a problem in graph testing), and formally defined as the *sampling model* in [2, 1]. In this model, the algorithm gets access to a sequence of independent unconditional samples from the input distribution, and then decides whether to accept or reject based on them. A major topic of investigation concerns testing that a distribution over  $\{1, \dots, n\}$  is the uniform one. A long string of results, starting with the original [14] and culminating in [17], has reached the tight bound of  $\Theta(\sqrt{n}/\varepsilon^2)$ .

A square-root lower bound on one of the most basic of properties is impractical in many real-world settings. For example, the square-root sample complexity of uniformity testing is impractical when the input ranges over 100-bit binary strings, an example which is still

smaller than real-world inputs. There are three approaches to overcome this problem: the first, on which we expand below, is moving to stronger query models. The second is narrowing the scope of the allowable inputs, such as *product distributions* and *Bayesian networks* [8]. The third is moving to a model where the metric is more lax (usually coupled with an even weaker query model), such as the Huge Object Model defined in [15] that is concerned with the earth-mover distance metric.

We focus here on the first (and most common) approach to the scaling problem, that of considering a model with stronger queries. In the distribution testing setting, this usually focuses on *conditional sampling*. Instead of drawing a sequence of independent unconditional samples, we allow the algorithm to choose a subset of the possible outcomes and draw a sample conditioned on belonging to it. The models within this paradigm differ in the subset conditions they allow.

The first investigation of such a model was the fully conditional model [10, 9]. In this model, the algorithm can choose *any* subset to condition on. This model is very powerful but not realistic. If we are able to restrict the input distribution to any subset, we probably already have access to an explicit description of the distribution and thus have no need to sample it.

Further studies consider restricted forms of the conditional model. For example, [9] considers two additional models: the pair model and the interval model. In the pair model, the algorithm can still draw unconditional samples, and additionally it can draw conditional samples from any subset of two elements. Uniformity testing in the pair model requires  $\tilde{\Theta}(1/\varepsilon^2)$  samples. In the interval model, we test distributions over  $\Omega = \{1, \dots, N\}$  (for some  $N$ ), and the algorithm can condition on interval sets, which are sets of the form  $\{a \leq x \leq b\}$ . The lower bound for uniformity testing in the interval model is  $\tilde{\Omega}(\log N)$ . The best known upper bound is  $\tilde{O}((\log N)^3/\varepsilon^2)$ .

The subcube conditional model [4] is motivated by database analysis. In this model, we test distributions over the set  $\prod_{i=1}^n \Omega_i$ , and the algorithm can query *subcube subsets*, which are sets of the form  $\prod_{i=1}^n A_i$  where  $A_i \subseteq \Omega_i$  for every  $1 \leq i \leq n$ . While not being extremely restrictive, its queries correspond to selection by attribute values, which is common in practice. Some of the prior work refers to a weaker variant of this model, where each  $A_i$  is either trivial ( $A_i = \Omega_i$ ) or a singleton ( $A_i = \{a_i\}$  for some  $a_i \in \Omega_i$ ). In this paper we mainly deal with the strong model, where general  $A_i \subseteq \Omega_i$  are allowed. In the most investigated setting, the binary setting where  $\Omega_i = \{0, 1\}$  for all  $i$ , the two models are the same.

Uniformity testing [7, 12] can be done in the weak model using  $\tilde{O}(m^{21}\sqrt{n}/\varepsilon^2)$  queries where  $m = \max_i |\Omega_i|$ , and requires at least  $\Omega(\sqrt{mn}/\varepsilon^2)$  queries [3]. Other properties studied under the subcube model include identity to some fixed distribution [4, 5] and having a probability density function supported on a low-dimensional subspace [11].

Two related properties are of particular interest in distribution testing, the identity property and the equivalence property. In the identity property, a *reference distribution* is given to the algorithm in advance, and the task is to check whether the input distribution is identical to it. The equivalence property (henceforth: EQUIVALENCE) has an input consisting of *two* distributions, both of which accessible through the testing model, and the task is to check whether they are equal to each other.

In the subcube conditional model, since the input distribution is defined over a set of tuples, another natural property is that of being a product distribution (henceforth: PRODUCT). A distribution over tuples is called a product if its entries are independently distributed.

Our main upper bound result is a test for EQUIVALENCE that for the binary setting ( $\Omega_i = \{0, 1\}$ ) uses only  $\tilde{O}(n/\varepsilon^2)$  subcube queries, which improves on the previously known result of  $\tilde{O}(n^2/\varepsilon^2)$  from [4]. Additionally our result uses only *prefix queries* from one distribution and *marginal prefix queries* from the other, which we define below and are rather restricted forms of subcube queries. One can think of prefix queries as the queries that can be made fast when the database is sorted according to a concatenation of its attributes in a pre-defined order (functioning as its primary key). Importantly, the use of restricted queries allows us to derive an improved test also for PRODUCT, and to generalize the test to general  $\Omega_1, \dots, \Omega_n$  with a logarithmic cost in the alphabet size.

The restricted form of our queries also allows us to tighten the previously known upper bound on equivalence testing (and through it the special case of uniformity testing) in the interval conditional model, obtaining an upper bound of  $\tilde{O}(\log N/\varepsilon^2)$  interval queries, which matches the lower bound for every fixed  $\varepsilon$  up to poly-double-logarithmic factors in  $N$ .

We complement our upper bound for PRODUCT with an  $\Omega(\sqrt{n}/\varepsilon^2)$  lower bound. The question of whether we can go below  $O(n)$  for testing our properties (even for the binary setting and a fixed  $\varepsilon$ ) remains open.

## 2 Organization of the paper

In Section 3 we summarize our contributions. After some preliminaries in Section 4, we provide the core of our main proofs, followed by the more technical details. In Section 5 we provide the EQUIVALENCE testing upper bound in the binary setting, and a short proof of the corollary about interval queries. In Section 6 we provide the PRODUCT testing lower bound.

The technical part of the paper follows. In Section 7 we prove the technical lemmas whose proofs were deferred from Section 5. Then we prove the theorems derived from this upper bound: in Section 8 we extend the EQUIVALENCE test to the non-binary setting, and in Section 9 we derive a test for PRODUCT. In Section 10 we prove the technical lemmas from Section 6.

All upper bound proofs implicitly construct their algorithms. For reference, explicit representations of the binary setting algorithms for EQUIVALENCE and PRODUCT are given in the appendix.

## 3 Our results

We improve on the previously known result of  $\tilde{O}(n^2/\varepsilon^2)$  queries for equivalence testing of two distributions over  $\{0, 1\}^n$  [4]. Our methods can also supersede the  $\tilde{O}(n/\varepsilon)$  algorithm of [5] which tests identity with a distribution given in advance that belongs to a very restricted class of inputs (their parameter refers to KL-divergence, which indeed incurs a quadratic gap when converted to total-variation distance). We provide more details on the latter below (before Lemma 25).

► **Theorem 20.** *Let  $\tau, \mu$  be two distributions over  $\{0, 1\}^n$ , where  $\tau$  is accessible through the prefix oracle access and  $\mu$  is accessible through the marginal prefix oracle access. For every  $\varepsilon > 0$  we can distinguish between  $\tau = \mu$  and  $d_{\text{TV}}(\tau, \mu) > \varepsilon$  using  $\tilde{O}(n/\varepsilon^2)$  queries.*

The prefix queries in the statement above are a special case of subcube queries, but they can also be seen as interval queries, allowing us to prove the following corollary:

► **Corollary 21.** *Let  $\tau, \mu$  be two distributions over  $\{1, \dots, N\}$ , both accessible through the interval oracle. Then we can distinguish between  $\tau = \mu$  and  $d_{\text{TV}}(\tau, \mu) > \varepsilon$  using  $\tilde{O}((\log N)/\varepsilon^2)$  queries.*

We show a lower bound for testing a distribution  $\mu$  over  $\{0, 1\}^n$  for being a product. To the best of our knowledge, it is the first lower bound for product testing in the binary setting. Our construction is similar to the lower bound for uniformity testing of [8].

► **Theorem 26.** *Every  $\varepsilon$ -test for PRODUCT must make at least  $\Omega(\sqrt{n}/\varepsilon^2)$  subcube queries.*

We generalize our upper bound for equivalence testing to strings of size  $n$  over larger alphabets. Our result is incomparable with the previously known result of  $\tilde{O}(\frac{n^5}{\varepsilon^5} \log \log |\Omega|)$  [4]. Note that the cited result refers to strings over a single alphabet (that is,  $\Omega^n$ ), whereas our result refers to strings over mixed alphabets (that is,  $\prod_{i=1}^n \Omega_i$ ). Additionally, our result is more efficient when  $|\Omega|$  is not very large with respect to  $n$ .

► **Theorem 40.** *Let  $\mu$  and  $\tau$  be two distributions over  $\prod_{i=1}^n \Omega_i$ , where  $\Omega_1, \dots, \Omega_n$  are all finite. If  $\mu$  is accessible through the marginal prefix oracle and  $\tau$  is accessible through the prefix oracle, then we can distinguish between  $\tau = \mu$  and  $d_{\text{TV}}(\tau, \mu) > \varepsilon$  using  $\tilde{O}(\sum_{i=1}^n \log_2 |\Omega_i|/\varepsilon^2)$  queries.*

We apply the same generalization for product testing as well. In the binary setting, it also improves on the previously known result of  $\tilde{O}(n^2/\varepsilon^2)$  [4].

► **Theorem 45.** *Let  $\mu$  be a distribution over  $\prod_{i=1}^n \Omega_i$ . For every  $0 < \varepsilon < 1$ , we can distinguish between the case where  $\mu$  is a product distribution and the case where it is  $\varepsilon$ -far from every product distribution at the cost of  $\tilde{O}(\sum_{i=1}^n \log |\Omega_i|/\varepsilon^2)$  subcube queries. Moreover, if  $|\Omega_i| = 2$  for every  $1 \leq i \leq n$ , then all these queries are prefix queries.*

## 4 Preliminaries

For brevity, for  $m \in \mathbb{N}$  we let  $[m]$  denote the set  $\{1, \dots, m\}$ .

► **Definition 1** (Bernoulli distribution). *Let  $0 \leq p \leq 1$ . The Bernoulli distribution with parameter  $p$ , denoted by  $\text{Ber}(p)$ , is the distribution over  $\{0, 1\}$  whose probability to draw 1 is  $p$ .*

► **Definition 2** (Conditional distribution). *Let  $\mu$  be a distribution over  $\Omega$ , and let  $B \subseteq \Omega$  be an event. The corresponding conditional distribution is denoted by  $\mu|_B$  and is defined by  $\mu|_B(x) = 0$  for  $x \notin B$  and  $\mu|_B(x) = \mu(x)/\Pr_\mu[B]$  for  $x \in B$ .*

► **Definition 3** (Index-restricted distribution). *Let  $\mu$  be a distribution over  $\prod_{i=1}^n \Omega_i$ , and let  $I \subseteq [n]$  be a set of indices. We use  $\mu|_I$  to denote the distribution that draws  $x \sim \mu$ , and returns the restricted string  $x|_I \in \prod_{i \in I} \Omega_i$ .*

Note that the correct way to parse the overloaded notation  $\mu|_I^B$  is “ $(\mu|_B)|_I$ ”, that is, we first apply the condition and then restrict the indices.

► **Definition 4** (Common statistical divergence measures). *Let  $\mu$  and  $\tau$  be two distributions over a finite set  $\Omega$ . We use two well known divergence measures, namely the total-variation distance  $d_{\text{TV}}(\mu, \tau) = \frac{1}{2} \sum_{x \in \Omega} |\mu(x) - \tau(x)| = \max_{E \subseteq \Omega} |\mu(E) - \tau(E)|$  and the KL-divergence  $D_{\text{KL}}(\mu, \tau) = \mathbb{E}_{x \sim \mu} \left[ \log_2 \frac{\mu(x)}{\tau(x)} \right]$ .*

Here we define the query model for distributions over binary strings. The definitions for general alphabets appear in Section 8.

► **Definition 5** (Subcube oracle access). *Let  $\mu$  be an unknown distribution over  $\{0, 1\}^n$ . The subcube oracle has a set  $I \subseteq [n]$  and a string  $w \in \{0, 1\}^I$  as input, and its output distributes as  $\mu|^{x_I=w}$ . For technical reasons, if  $\Pr_\mu[x_I = w] = 0$ , then the oracle indicates an error. Note that the answers of the oracle are fully independent of the answers that were given to previous queries.*

We note that the “error behavior” in the above definition does not really affect our results, since all our upper bounds use only restrictions to guaranteed positive probability outcomes, while our lower bounds use distributions that have no zero-probability elements.

► **Definition 6** (Prefix oracle access). *Let  $\mu$  be an unknown distribution over  $\{0, 1\}^n$ . The prefix oracle is a restricted case of the subcube oracle, where  $I = [k]$  for some  $0 \leq k \leq n - 1$ .*

► **Definition 7** (Marginal subcube oracle access). *Let  $\mu$  be an unknown distribution over  $\{0, 1\}^n$ . The marginal subcube oracle has a set  $I \subseteq [n]$ , an index  $i \in [n] \setminus I$  and a string  $w \in \{0, 1\}^I$  as input, and its output is a single bit that distributes as  $\mu|_i^{x_I=w}$ . For technical reasons, if  $\Pr_\mu[x_I = w] = 0$ , then the oracle indicates an error.*

► **Definition 8** (Marginal prefix oracle access). *Let  $\mu$  be an unknown distribution over  $\{0, 1\}^n$ . The marginal prefix oracle is a restricted case of the marginal subcube oracle, where  $I = [i - 1]$ .*

We now define the interval querying model for which we derive a new bound.

► **Definition 9** (Interval oracle access). *Let  $\mu$  be an unknown distribution over  $[N]$ . The interval oracle has two elements  $1 \leq a \leq b \leq N$  as input, and its output distributes as  $\mu|_{\{a, \dots, b\}}$ .*

We next define our properties for distributions over general alphabet strings, and what it means to test for a property.

► **Definition 10** (EQUIVALENCE). *A pair of distributions  $\mu, \tau$  over  $\prod_{i=1}^n \Omega_i$  belongs to the equivalence property if  $\mu = \tau$ . The distance of a given pair  $(\mu, \tau)$  from EQUIVALENCE is explicitly defined as  $d_{\text{TV}}(\mu, \tau)$  instead of the natural  $\inf_\nu (d_{\text{TV}}(\mu, \nu) + d_{\text{TV}}(\tau, \nu))$ . The two quantities are easily seen to be identical using the triangle inequality.*

► **Definition 11** (PRODUCT). *A distribution  $\mu$  over  $\prod_{i=1}^n \Omega_i$  is called a product distribution if there exist distributions  $\mu_1, \dots, \mu_n$  over  $\Omega_1, \dots, \Omega_n$  respectively, for which  $\mu \sim \mu_1 \times \dots \times \mu_n$ . We denote by PRODUCT the set of all product distributions over  $\prod_{i=1}^n \Omega_i$ .*

► **Definition 12** ( $\varepsilon$ -test). *For some property  $\mathcal{P}$  of distributions (which is a set of distributions) and  $\varepsilon > 0$ , we say that an algorithm  $\mathcal{A}$  is an  $\varepsilon$ -test for  $\mathcal{P}$  if:*

- For every input distribution  $\mu \in \mathcal{P}$ ,  $\mathcal{A}$  accepts with probability at least  $\frac{2}{3}$ .
- For every input distribution  $\mu$  for which  $d_{\text{TV}}(\mu, \nu) > \varepsilon$  for all  $\nu \in \mathcal{P}$ ,  $\mathcal{A}$  rejects with probability at least  $\frac{2}{3}$ .

## 5 Linear algorithm for Equivalence

To construct our improvement on the algorithm of [4], we first define some templates for analyzing and comparing differences between distributions.

► **Definition 13** (Single-bit divergence). We call  $d : [0, 1] \times [0, 1] \rightarrow [0, \infty)$  a single-bit divergence if:

- For every  $p, q \in [0, 1]$ ,  $d(p, q) = 0$  if and only if  $p = q$  (Positivity).
- For every  $p' \leq p \leq q \leq q'$ ,  $d(p, q) \leq d(p', q')$  and  $d(q, p) \leq d(q', p')$  (Monotonicity).

Three useful single-bit divergences are  $\text{TV}(p, q) = |p - q|$ ,  $\text{KL}(p, q) = p \log_2 \frac{p}{q} + (1 - p) \log_2 \frac{1-p}{1-q}$  and  $\chi^2(p, q) = \frac{(p-q)^2}{(p+q)(2-(p+q))}$ . Note that all three are derived from their probability-theoretic counterparts for  $\text{Ber}(p)$  and  $\text{Ber}(q)$ . We have two motivations to prefer this non-standard form of  $\chi^2$ : first, the symmetry matches the idea of two unknown distributions, which is not the case in standard  $\chi^2$ -tests, and second, it is bounded by 1, which makes the analysis more similar to total-variation distance than to KL-divergence.

► **Definition 14** (Slice-wise divergence). Let  $d$  be a single-bit divergence. For every  $n$  and two distributions  $\tau, \mu$  over  $\{0, 1\}^n$ , the slice-wise divergence of  $\tau$  and  $\mu$  with respect to  $d$  is:

$$\Delta_d(\tau, \mu) = \sum_{i=1}^n \mathbb{E}_{w \sim \tau} [d(\tau|_i^{x_{[i-1]}=w_{[i-1]}}(1), \mu|_i^{x_{[i-1]}=w_{[i-1]}}(1))]$$

(note that the  $d$ -divergence is fed the probabilities of the two single-bit distributions to draw 1).

Recall the  $\tilde{O}(n^5/\text{poly}(\varepsilon))$  algorithm of [4], which is actually  $\tilde{O}(n^2/\varepsilon^2)$  for the binary setting. As a motivation, the paper uses (and has a self-contained proof of) the following bound:

$$d_{\text{TV}}(\tau, \mu) \leq \sum_{i=1}^n \mathbb{E}_{w \sim \tau} [d_{\text{TV}}(\tau|_i^{x_{[i-1]}=w_{[i-1]}}(1), \mu|_i^{x_{[i-1]}=w_{[i-1]}}(1))] = \Delta_{\text{TV}}(\tau, \mu)$$

The algorithm then distinguishes between  $\Delta_{\text{TV}}(\tau, \mu) = 0$  (which always holds if  $\tau = \mu$ ) and  $\Delta_{\text{TV}}(\tau, \mu) > \varepsilon$  (which always holds if  $d_{\text{TV}}(\tau, \mu) > \varepsilon$ ).

To improve their test, inside the slice-wise divergence expression we substitute the single-bit total-variation distance with the single-bit  $\chi^2$ -distance, and analyze the more convenient  $\Delta_{\chi^2}(\tau, \mu)$ .

The following is immediate, and in fact holds for every slice-wise divergence:

► **Observation 15.** Let  $\tau, \mu$  be two distributions over  $\{0, 1\}^n$ . If  $\tau = \mu$  then  $\Delta_{\chi^2}(\tau, \mu) = 0$ .

The following lemma, which we prove in Subsection 5.1, provides the conversion from the total variation distance to the slice-wise chi-square divergence.

► **Lemma 16.** Let  $\tau, \mu$  be two distributions over  $\{0, 1\}^n$ . If  $\tau \neq \mu$ , then  $\Delta_{\chi^2}(\tau, \mu) \geq \frac{(d_{\text{TV}}(\tau, \mu))^2}{24 \log(2n/d_{\text{TV}}(\tau, \mu))}$ .

The following lemma, which we prove in Section 7, states that we can distinguish between single bit distributions using linearly many samples with respect to the inverse of their  $\chi^2$ -divergence.

► **Lemma 17.** Let  $p, q \in [0, 1]$  be two probabilities. Given unconditional sampling access to  $\text{Ber}(p)$  and  $\text{Ber}(q)$ , we can distinguish, with probability  $\frac{2}{3}$ , between the case where  $p = q$  and the case where  $\chi^2(p, q) > \varepsilon$ , at the cost of  $O(1/\varepsilon)$  samples from each of them.

We use a common variant of the Levin's work balance method:

► **Lemma 18** ([16], optimization exercise in [13]). *Let  $X$  be a non-negative random variable that is bounded by 1. Assume that there exists some random variable  $Y$  such that for every  $y \in \text{supp}(Y)$  and every  $\varepsilon' > 0$ , we can distinguish between  $\mathbb{E}[X|Y = y] = 0$  and  $\mathbb{E}[X|Y = y] > \varepsilon'$  using some black-box algorithm whose resource cost is  $O(1/\varepsilon')$ . Also, assume that we can draw independent unconditional samples from  $Y$  at resource cost  $O(1)$  per sample. Then we can distinguish between  $\mathbb{E}[X] = 0$  and  $\mathbb{E}[X] > \varepsilon$  at a total resource cost of  $O(\varepsilon^{-1} \log^2(1/\varepsilon))$ .*

Using the above we can efficiently detect a large slicewise  $\chi^2$  divergence between two distributions.

► **Lemma 19.** *Let  $\tau, \mu$  be two distributions over  $\{0, 1\}^n$ . Then for every  $\rho > 0$ , we can distinguish between  $\Delta_{\chi^2}(\tau, \mu) = 0$  and  $\Delta_{\chi^2}(\tau, \mu) > \rho$  using  $O(\frac{n}{\rho} \log^2 \frac{n}{\rho})$  prefix queries.*

**Proof.** We normalize the divergence:

$$\begin{aligned} \frac{1}{n} \Delta_{\chi^2}(\tau, \mu) &= \frac{1}{n} \sum_{i=1}^n \mathbb{E}_{w \sim \tau} [\chi^2(\tau|_i^{x_{[i-1]}=w_{[i-1]}}(1), \mu|_i^{x_{[i-1]}=w_{[i-1]}}(1))] \\ &= \mathbb{E}_{\substack{w \sim \tau \\ i \sim [n]}} [\chi^2(\tau|_i^{x_{[i-1]}=w_{[i-1]}}(1), \mu|_i^{x_{[i-1]}=w_{[i-1]}}(1))] \end{aligned}$$

Then we apply Levin's method, Lemma 18, with the following input.  $Y$  is a random variable that receives a value  $(i, w)$  where  $i$  is uniformly drawn from  $[n]$  and  $w$  is drawn from  $\tau$  (independently of  $i$ ). The parameter  $\varepsilon$  is set to  $\rho/n$ , and the random variable  $X$  is defined as a function of  $Y = (i, w)$  (meaning that it is constant when conditioned on a specific value of  $Y$ ) by

$$X(i, w) = \chi^2(\mu|_i^{x_{[i-1]}=w_{[i-1]}}(1), \tau|_i^{x_{[i-1]}=w_{[i-1]}}(1))$$

The distinction between the cases  $X(Y) = 0$  and  $X(Y) > \varepsilon'$  is performed using  $O(1/\varepsilon')$  many queries (our resource cost) through the single-bit  $\chi^2$ -test of Lemma 17. ◀

Our main theorem follows immediately from the above statements:

► **Theorem 20.** *Let  $\tau, \mu$  be two distributions over  $\{0, 1\}^n$ , where  $\tau$  is accessible through the prefix oracle access and  $\mu$  is accessible through the marginal prefix oracle access. For every  $\varepsilon > 0$  we can distinguish between  $\tau = \mu$  and  $d_{\text{TV}}(\tau, \mu) > \varepsilon$  using  $\tilde{O}(n/\varepsilon^2)$  queries.*

**Proof.** Apply Lemma 19 using  $\rho = \frac{\varepsilon^2}{24 \log(2n/\varepsilon)}$ . Completeness follows from Observation 15 and soundness follows from Lemma 16. ◀

► **Corollary 21.** *Let  $\tau, \mu$  be two distributions over  $\{1, \dots, N\}$ , both accessible through the interval oracle. Then we can distinguish between  $\tau = \mu$  and  $d_{\text{TV}}(\tau, \mu) > \varepsilon$  using  $\tilde{O}((\log N)/\varepsilon^2)$  queries.*

**Proof.** Without loss of generality, assume that  $N = 2^\ell$  for some integer  $\ell$  (otherwise we just pad the two distributions with zero-probability elements). For every  $i \geq 0$ , let  $\text{bin}_i : \{0, \dots, 2^i - 1\} \rightarrow \{0, 1\}^i$  and  $\text{unbin}_i : \{0, 1\}^i \rightarrow \{0, \dots, 2^i - 1\}$  be the mappings between small integers and their representation as  $i$ -bit strings. That is,  $\text{unbin}_i(x_1, \dots, x_i) = \sum_{j=1}^i 2^{i-j} x_j$  and  $\text{bin}_i = (\text{unbin}_i)^{-1}$ .

To apply our equivalence algorithm on distributions over  $[N]$ , every  $t \in [N]$  is interpreted as an  $\ell$ -bit string (using the map  $t \rightarrow \text{bin}_\ell(t - 1)$ ). Then every prefix query  $\tau|^{x_{[i-1]}=w}$  (respectively  $\mu|^{x_{[i-1]}=w}$ ) is simulated using the interval query  $\tau|^{a, \dots, b}$  (respectively  $\mu|^{a, \dots, b}$ ), where  $a = 2^{N-i} \text{unbin}_{i-1}(w) + 1$  and  $b = 2^{N-i} (\text{unbin}_{i-1}(w) + 1)$ . Since the simulated algorithm uses  $\tilde{O}(\ell/\varepsilon^2)$  prefix queries, the simulation uses  $\tilde{O}((\log N)/\varepsilon^2)$  interval queries. ◀

## 5.1 Proof of Lemma 16

The proof works by comparing the TV-distance and the slice-wise chi-square divergence with the KL-divergence, which is equal to its slice-wise version as per the following lemmas.

► **Lemma 22** (Basic chain rule for  $D_{\text{KL}}$ , folklore). *Let  $\mu$  and  $\tau$  be distributions over  $\Omega$ . Then for every random variable  $X : \Omega \rightarrow R$ , we have the equality  $D_{\text{KL}}(\mu, \tau) = D_{\text{KL}}(X(\mu), X(\tau)) + \mathbb{E}_{x \sim X(\tau)} [D_{\text{KL}}(\mu|^{X=x}, \tau|^{X=x})]$ .*

► **Lemma 23** (Chain rule for  $D_{\text{KL}}$ , repeated form). *Let  $\mu$  and  $\tau$  be distributions over  $\{0, 1\}^n$ . Then  $D_{\text{KL}}(\mu, \tau) = \sum_{i=1}^n \mathbb{E}_{w \sim \mu} [D_{\text{KL}}(\mu|_i^{x_{[i-1]}=w^{[i-1]}}, \tau|_i^{x_{[i-1]}=w^{[i-1]}})] = \Delta_{\text{KL}}(\mu, \tau)$ .*

**Proof.** We obtain this result by repeatedly applying the basic chain rule using induction. ◀

The following technical lemma, proved in Section 7, provides some connection between the chi-square distance and the KL-divergence of Bernoulli distributions.

► **Lemma 24.** *Let  $p, q \in [0, 1]$ . Then  $\chi^2(p, q) \geq \frac{1}{12} \text{KL}(p, q) / \log \max\{\frac{1}{q}, \frac{1}{1-q}\}$ .*

At this point we prove a version of Lemma 16 for a parameterized restricted case. We then reduce the general case to this lemma using an appropriate parameter. We note here that if we were to use the following parameterized lemma directly instead of Lemma 16, we would have obtained a direct generalization of the binary setting part of [5, Theorem 4.1].

► **Lemma 25.** *Let  $0 < q < \frac{1}{2}$ . Assume that for every  $1 \leq i \leq n$  and for every condition  $w \in \{0, 1\}^{i-1}$ , the prefix marginal  $\mu|_i^{x_{[i-1]}=w}$  is equivalent to  $\tau|_i^{x_{[i-1]}=w}$  or equivalent to  $\text{Ber}(p_{i,w})$  for some  $q \leq p_{i,w} \leq 1 - q$  (or both). Then  $\Delta_{\chi^2}(\tau, \mu) \geq \frac{1}{6} (d_{\text{TV}}(\tau, \mu))^2 / \log q^{-1}$ .*

**Proof.** By Pinsker's inequality and Lemma 23 we obtain:

$$2(d_{\text{TV}}(\tau, \mu))^2 \leq D_{\text{KL}}(\tau, \mu) = \sum_{i=1}^n \mathbb{E}_{w \sim \tau} [\text{KL}(\tau|_i^{x_{[i-1]}=w^{[i-1]}}(1), \mu|_i^{x_{[i-1]}=w^{[i-1]}}(1))]$$

By our assumption, for every  $1 \leq i \leq n$ , if  $D_{\text{KL}}(\tau|_i^{x_{[i-1]}=w^{[i-1]}}, \mu|_i^{x_{[i-1]}=w^{[i-1]}}) \neq 0$  then the probability of  $\mu|_i^{x_{[i-1]}=w^{[i-1]}}$  to draw 1 is between  $q$  and  $1 - q$ . By Lemma 24 we obtain:

$$2(d_{\text{TV}}(\tau, \mu))^2 \leq \sum_{i=1}^n \mathbb{E}_{w \sim \tau} [\chi^2(\tau|_i^{x_{[i-1]}=w^{[i-1]}}(1), \mu|_i^{x_{[i-1]}=w^{[i-1]}}(1)) \cdot 12 \log q^{-1}]$$

That is,

$$\frac{(d_{\text{TV}}(\tau, \mu))^2}{6 \log q^{-1}} \leq \sum_{i=1}^n \mathbb{E}_{w \sim \tau} [\chi^2(\tau|_i^{x_{[i-1]}=w^{[i-1]}}(1), \mu|_i^{x_{[i-1]}=w^{[i-1]}}(1))] = \Delta_{\chi^2}(\tau, \mu) \quad \blacktriangleleft$$

We could bound the KL-divergence of single bits using the  $\chi^2$  distance only because we assumed that the marginal probabilities of  $\mu$  are not too close to 0 or 1 (unless they are equal to their counterparts in  $\tau$ ). In the general case we cannot assume it, hence we need to instead consider a distribution  $\mu'$  which is close to  $\mu$  while satisfying this assumption.

We consider  $\mu$  as a “probability tree”, where the root represents the empty string, every edge represents an additional bit, and every leaf represents a complete sample. This tree (and hence the distribution  $\mu$ ) is fully determined using probabilities of the form  $\Pr_{x \sim \mu}[x_i = 1 | x_{[i-1]} = w]$ , where  $1 \leq i \leq n$  and  $w \in \{0, 1\}^{i-1}$ .

We construct another distribution  $\mu'$  based on such a tree pattern. For every  $1 \leq i \leq n$  and  $w \in \{0, 1\}^{i-1}$ , we set  $\Pr_{x \sim \mu'}[x_i = 1 | x_{[i-1]} = w]$  as follows:

$$\begin{aligned} & \min \left\{ \frac{d_{\text{TV}}(\tau, \mu)}{2n}, \Pr_{x \sim \tau}[x_i = 1 | x_{[i-1]} = w] \right\} & \text{if } \Pr_{x \sim \mu}[x_i = 1 | x_{[i-1]} = w] < \frac{d_{\text{TV}}(\tau, \mu)}{2n} \\ 1 - & \min \left\{ \frac{d_{\text{TV}}(\tau, \mu)}{2n}, \Pr_{x \sim \tau}[x_i = 0 | x_{[i-1]} = w] \right\} & \text{if } \Pr_{x \sim \mu}[x_i = 1 | x_{[i-1]} = w] > 1 - \frac{d_{\text{TV}}(\tau, \mu)}{2n} \\ & \Pr_{x \sim \mu}[x_i = 1 | x_{[i-1]} = w] & \text{otherwise} \end{aligned}$$

Observe that for every  $1 \leq i \leq n$  and  $w \in \{0, 1\}^{i-1}$ ,  $d_{\text{TV}}(\mu|_i^{x_{[i-1]}=w}, \mu'|_i^{x_{[i-1]}=w}) \leq \frac{d_{\text{TV}}(\tau, \mu)}{2n}$ . Hence,  $d_{\text{TV}}(\mu, \mu') \leq \Delta_{\text{TV}}(\mu, \mu') \leq \frac{1}{2}d_{\text{TV}}(\tau, \mu)$ . By the triangle inequality,  $d_{\text{TV}}(\tau, \mu') \geq \frac{1}{2}d_{\text{TV}}(\tau, \mu)$ .

Since the assumptions of Lemma 25 hold for  $\mu'$  (with  $q = \frac{1}{2n}d_{\text{TV}}(\tau, \mu)$ ), we can now conclude the proof of Lemma 16:

$$\begin{aligned} \Delta_{\chi^2}(\tau, \mu) &= \sum_{i=1}^n \mathbb{E}_{w \sim \tau} [\chi^2(\tau|_i^{x_{[i-1]}=w(i)}, \mu|_i^{x_{[i-1]}=w(i)})] \\ [\text{Monotonicity of } \chi^2] &\geq \sum_{i=1}^n \mathbb{E}_{w \sim \tau} [\chi^2(\tau|_i^{x_{[i-1]}=w(i)}, \mu'|_i^{x_{[i-1]}=w(i)})] \\ [\text{Lemma 25 with } q = \frac{1}{2n}d_{\text{TV}}(\tau, \mu)] &\geq (d_{\text{TV}}(\tau, \mu'))^2 / 6 \log \frac{2n}{d_{\text{TV}}(\tau, \mu)} \\ [d_{\text{TV}}(\tau, \mu') \geq \frac{1}{2}d_{\text{TV}}(\tau, \mu)] &\geq (d_{\text{TV}}(\tau, \mu))^2 / 24 \log \frac{2n}{d_{\text{TV}}(\tau, \mu)} \quad \blacktriangleleft \end{aligned}$$

## 6 Lower bound for Product

This section is devoted to the following lower bound:

► **Theorem 26.** *Every  $\varepsilon$ -test for PRODUCT must make at least  $\Omega(\sqrt{n}/\varepsilon^2)$  subcube queries.*

Let  $\pi_n$  denote the uniform distribution over  $\{0, 1\}^n$ . We show that distinguishing between  $\pi_n$  (which is in particular a product distribution) and a distribution that is  $\varepsilon$ -far from every product distribution requires  $\tilde{\Omega}(\sqrt{n}/\varepsilon^2)$  many queries.

Before we present our construction, we cite the corresponding lower bound for uniformity of a product distribution [8]:

► **Lemma 27** ([8]). *Let  $\mathcal{N}$  be the following distribution over inputs: draw  $b_1, \dots, b_n \sim \{+1, -1\}$  uniformly and independently, and return the distribution  $\prod_{i=1}^n \text{Ber}\left(\frac{1}{2} + b_i \frac{\varepsilon}{\sqrt{n}}\right)$ . Then the drawn input is always  $\Omega(\varepsilon)$ -far from  $\pi_n$ , and any unconditional sampling algorithm that distinguishes between inputs drawn from  $\mathcal{N}$  and  $\pi_n$  must take at least  $\Omega(\sqrt{n}/\varepsilon^2)$  many samples.*

In our construction, instead of adding a random bias for each coordinate, we partition the coordinates into pairs, and in each pair introduce a random “anti-product bias” as follows.

For  $b \in \{0, +1, -1\}$ , let  $\nu_b$  be the following distribution over  $\{0, 1\}^2$ :

$$\begin{aligned} \nu_b(00) &= \frac{1}{4} + b_i \frac{\varepsilon}{\sqrt{n}} & \nu_b(01) &= \frac{1}{4} - b_i \frac{\varepsilon}{\sqrt{n}} \\ \nu_b(10) &= \frac{1}{4} - b_i \frac{\varepsilon}{\sqrt{n}} & \nu_b(11) &= \frac{1}{4} + b_i \frac{\varepsilon}{\sqrt{n}} \end{aligned}$$

That is,  $\nu_0$  is the uniform distribution over two bits, and  $\nu_{+1}, \nu_{-1}$  are non-product distributions over two bits.

## 48:10 Improved Bounds for High-Dim. Testing Using Subcube Queries

Let  $\mathcal{Y}$  be the distribution over inputs that always returns the uniform distribution over  $\{0, 1\}^n$ , and let  $\mathcal{N}$  be the following distribution over “bad” inputs over  $\{0, 1\}^n$ : we partition  $[n]$  into fixed pairs (for example,  $(2i - 1, 2i)$  for every  $1 \leq i \leq \lfloor n/2 \rfloor$ ). For every pair we draw  $b_i \in \{+1, -1\}$  uniformly and independently. The distribution of the  $i$ th pair is  $\nu_{b_i}$ . All pairs are independent of each other. We assume that  $n$  is even, since for an odd  $n$  we can just assume that the  $n$ th bit is distributed uniformly and independently of the rest.

The following lemma, whose proof appears in Section 10, states that  $\mathcal{N}$  always draws a distribution far from PRODUCT.

► **Lemma 28.** *Every input distribution drawn from  $\mathcal{N}$  is  $\Omega(\varepsilon)$ -far from any product distribution.*

We now prove the indistinguishability of  $\mathcal{N}$  from the uniform distribution, starting with the sampling model, to which we later show a reduction from the subcube conditional model.

► **Lemma 29.** *An unconditional sampling algorithm that distinguishes between the uniform distribution and inputs that are drawn from  $\mathcal{N}$  must make  $\Omega(\sqrt{n}/\varepsilon^2)$  many queries.*

**Proof.** Without loss of generality, assume that  $n$  is even. Consider the following bijection over  $\{0, 1\}^2$ :  $(x, y) \rightarrow (x \oplus y, y)$ . For  $b \in \{+1, 0, -1\}$ , Let  $\nu'_b$  be the distribution that draws  $(x, y) \sim \nu_b$  and returns  $(x \oplus y, y)$ . Observe that  $\nu'_b$  is identical to the product distribution  $\text{Ber}(\frac{1}{2} + \frac{2b\varepsilon}{\sqrt{n}}) \times \text{Ber}(\frac{1}{2})$ . Let  $f : \{0, 1\}^n \rightarrow \{0, 1\}^n$  be a bijection that applies the above mapping for every pair individually.

Let  $\mathcal{N}'$  be the distribution over inputs that draws  $\mu \sim \mathcal{N}$ , and then returns the distribution that draws  $x \sim \mu$  and returns  $f(x)$ . Note also that the distribution that drawn  $x \sim \pi_n$  and returns  $f(x)$  is identical to  $\pi_n$ . Since  $f$  is a bijection, this means that the number of samples needed to distinguish between the uniform distribution and  $\mathcal{N}$  is exactly the same as the number of samples needed to distinguish between the uniform distribution and  $\mathcal{N}'$ .

Note that the form of a distribution resulting from  $\mathcal{N}'$  is  $\prod_{i=1}^{n/2} \left( \text{Ber} \left( \frac{1}{2} + \frac{2b_i\varepsilon}{\sqrt{n}} \right) \times \text{Ber} \left( \frac{1}{2} \right) \right)$ . The restriction of  $\mathcal{N}'$  to odd indexes is identical to the construction of Lemma 27 (with parameters  $\sqrt{2}\varepsilon$  and  $n/2$ ), which requires at least  $\Omega(\sqrt{n}/\varepsilon^2)$  many unconditional samples to distinguish between it and the uniform distribution. Hence, this is also a lower bound for the number of samples needed to distinguish between the uniform distribution and inputs drawn from  $\mathcal{N}$ . ◀

► **Lemma 30.** *Let  $b \in \{0, +1, -1\}$ . Then for every subcube restriction  $q \in \{0, 1, *\}^2$ , we can simulate a  $q$ -conditioned sample from  $\nu_b$  by drawing a single unconditional sample from  $\nu_b$ , without having any knowledge about  $b$ .*

**Proof.** Let  $q \in \{0, +1, *\}^2$  and let  $b \in \{0, +1, -1\}$ . We first draw an unconditional sample  $x \sim \nu_b$ . There are three kinds of subcube restrictions:

- Trivial:  $q \in \{00, 01, 10, 11\}$ . To simulate such a query, we simply return  $q$ , ignoring the unconditional sample we have.
- Unconditional:  $q = **$ . To simulate such a query, we simply return  $x$ .
- Single restriction:  $q \in \{0*, 1*, *0, *1\}$ . We denote the parity of  $x$  by  $p = x|_1 \oplus x|_2$ , and construct the output as the concatenation of the two bits  $\text{out}_1$  and  $\text{out}_2$ , based on the following table:

|                |     |              |     |              |
|----------------|-----|--------------|-----|--------------|
| $q$            | 0*  | 1*           | *0  | *1           |
| $\text{out}_1$ | 0   | 1            | $p$ | $1 \oplus p$ |
| $\text{out}_2$ | $p$ | $1 \oplus p$ | 0   | 1            |

The correctness of the output in the trivial case and the unconditional case is trivial. We prove the correctness of the single-restriction case only for  $q = 0*$ , since the other cases are analogous.

$$\Pr_{\nu_b}[00|0*] = \frac{\Pr_{\nu_b}[00]}{\Pr_{\nu_b}[0*]} = \frac{\frac{1}{4} + \frac{b_i \varepsilon}{\sqrt{n}}}{\frac{1}{4} + \frac{b_i \varepsilon}{\sqrt{n}} + \frac{1}{4} - \frac{b_i \varepsilon}{\sqrt{n}}} = \frac{1}{2} + 2 \frac{b_i \varepsilon}{\sqrt{n}} = \Pr_{\nu_b}[00 \vee 11] = \Pr_{x \sim \nu_b}[x|_1 \oplus x|_2 = 0] \blacktriangleleft$$

At this point we can prove Theorem 26.

**Proof of Theorem 26.** By Lemma 28,  $\mathcal{N}$  draws an input distribution that is  $\Omega(\varepsilon)$ -far from any product distribution. Observe that since the structure of the pairs is known in advance and since they are independent, we can simulate every  $q$ -subcube-query algorithm using a  $q$ -unconditional-sample algorithm: for each query we draw a single sample and then use the simulation procedure of Lemma 30 for every pair in itself.

Since an unconditional test requires  $\Omega(\sqrt{n}/\varepsilon^2)$  queries to distinguish inputs drawn from  $\mathcal{N}$  from the uniform distribution by Lemma 29, and every subcube query to the uniform distribution or an input drawn from  $\mathcal{N}$  can be simulated using a single unconditional query, the lower bound holds for subcube algorithms as well.  $\blacktriangleleft$

## 7 Technical proofs for Equivalence testing

Here we prove the lemmas deferred from Section 5. We start with some helper lemmas.

► **Lemma 31.** *Let  $0 \leq p \leq q \leq 1$  for which  $p + q \leq 1$  and let  $X$  be the sum of  $N$  independent bits drawn from  $\text{Ber}(p)$ . Then,*

$$\Pr[X \geq \frac{1}{2}(p + q)N] \leq e^{-\frac{1}{12}\chi^2(p,q)}$$

**Proof.** Let  $\delta = q - p$ . If  $\delta \leq 2p$  then by Chernoff's bound:

$$\begin{aligned} \Pr[X \geq \frac{1}{2}(p + q)N] &= \Pr[X \geq (1 + \frac{\delta}{2p})\mathbb{E}[X]] \\ &\leq e^{-\frac{\delta^2}{12p^2}pN} = e^{-\frac{\delta^2}{12p}N} \leq e^{-\frac{(p-q)^2}{12(p+q)(2-(p+q))}N} = e^{-\frac{1}{12}\chi^2(p,q)N} \end{aligned}$$

If  $\delta > 2p$  then:

$$\begin{aligned} \Pr[X \geq \frac{1}{2}(p + q)N] &= \Pr[X \geq (1 + \frac{\delta}{2p})\mathbb{E}[X]] \\ &\leq e^{-\frac{\delta}{6p}pN} = e^{-\frac{\delta}{6}N} \leq e^{-\frac{(q-p)^2}{6(p+q)}} \leq e^{-\frac{1}{12}\chi^2(p,q)N} \blacktriangleleft \end{aligned}$$

► **Lemma 32.** *Let  $0 \leq p \leq q \leq 1$  for which  $p + q \leq 1$  and let  $X$  be the sum of  $N$  independent bits drawn from  $\text{Ber}(q)$ . Then,*

$$\Pr[X \leq \frac{1}{2}(p + q)N] \leq e^{-\frac{1}{8}\chi^2(p,q)} \leq e^{-\frac{1}{12}\chi^2(p,q)}$$

**Proof.** Let  $\delta = q - p \leq q$ . By Chernoff's bound:

$$\begin{aligned} \Pr[X \leq \frac{1}{2}(p + q)N] &= \Pr[X \leq (1 - \frac{\delta}{2q})\mathbb{E}[X]] \\ &\leq e^{-\frac{\delta^2}{8q^2}qN} = e^{-\frac{\delta^2}{8q}N} \leq e^{-\frac{(p-q)^2}{8(p+q)(2-(p+q))}N} = e^{-\frac{1}{8}\chi^2(p,q)N} \blacktriangleleft \end{aligned}$$

## 48:12 Improved Bounds for High-Dim. Testing Using Subcube Queries

► **Lemma 33.** *Let  $p, q \in [0, 1]$ . Let  $X$  be the sum of  $N$  independent bits drawn from  $\text{Ber}(p)$  and  $Y$  be the sum of  $N$  independent bits drawn from  $\text{Ber}(q)$ . Then, with probability at least  $\left(1 - e^{-\frac{1}{12}\chi^2(p,q)N}\right)^2$ , the sign of  $X - Y$  matches the sign of  $p - q$ .*

**Proof.** Without loss of generality,  $p + q \leq 1$  (otherwise use  $1 - q$  and  $1 - p$  instead of  $p$  and  $q$ , noting that  $d(1 - q, 1 - p) = d(p, q)$  and that the sign of  $(1 - q) - (1 - p)$  matches the sign of  $p - q$ ).

If  $p = q$  then the lemma is vacuously correct. If  $p < q$ , then by Lemma 31,

$$\begin{aligned} \Pr[X - Y < 0] = \Pr[X < Y] &\geq \Pr[X < \frac{1}{2}(p + q)N] \Pr[Y > \frac{1}{2}(p + q)N] \\ &\geq \left(1 - e^{-\frac{1}{12}\chi^2(p,q)N}\right)^2 \end{aligned}$$

The case where  $p > q$  is analogous, using Lemma 32. ◀

We recall and prove Lemma 17:

► **Lemma 17.** *Let  $p, q \in [0, 1]$  be two probabilities. Given unconditional sampling access to  $\text{Ber}(p)$  and  $\text{Ber}(q)$ , we can distinguish, with probability  $\frac{2}{3}$ , between the case where  $p = q$  and the case where  $\chi^2(p, q) > \varepsilon$ , at the cost of  $O(1/\varepsilon)$  samples from each of them.*

**Proof.** We repeat the following procedure 64 times: let  $N = \lceil 24/\varepsilon \rceil$ . Also, let  $X$  be the sum of  $N$  independent samples drawn from  $\text{Ber}(p)$  and  $Y$  be the sum of  $N$  independent samples drawn from  $\text{Ber}(q)$ . To conclude a single trial we check whether  $A > B$  or  $A < B$  (or neither) holds.

Let  $A$  be the number of trials with  $X > Y$  and  $B$  be the number of trials with  $X < Y$ . If  $|A|, |B| \leq 40$  we accept ( $p = q$ ), and otherwise we reject ( $\chi^2(p, q) > \varepsilon$ ).

If  $p = q$ , then by symmetry,  $\mathbb{E}[X < Y] = \mathbb{E}[X > Y] \leq \frac{1}{2}$ . That is,  $\mathbb{E}[A] = \mathbb{E}[B] \leq 32$ . By Chernoff's bound,  $\Pr[A \geq 41] < e^{-2 \cdot 9^2/64} < \frac{1}{6}$  and  $\Pr[B \geq 41] < \frac{1}{6}$ . Hence, the probability to accept is at least  $1 - \frac{2}{6} = \frac{2}{3}$ .

If  $\chi^2(p, q) > \varepsilon$ , then by Lemma 33, one of  $\Pr[X < Y]$  and  $\Pr[X > Y]$  is at least  $(1 - e^{-\frac{1}{12}\chi^2(p,q)N})^2 \geq (1 - e^{-2})^2 > 0.74$ . Without loss of generality, we assume that  $p < q$ . In this case,  $\mathbb{E}[A] > 47.36$ . By the Chernoff bound, the probability to reject is at least  $1 - \Pr[A \leq 40] \geq 1 - e^{-2 \cdot 7.36^2/64} > \frac{2}{3}$ . ◀

► **Lemma 34** (Well known). *For  $p, q \in [0, 1]$ ,  $\text{KL}(p, q) \leq \frac{(p-q)^2}{q(1-q)}$ . More formally, in  $(0, 1) \times (0, 1)$ , the ratio between these expressions is a non-negative continuous function that is bounded by 1.*

► **Lemma 35** (Direct corollary). *Let  $p, q \in [0, 1]$ . If  $p = aq$  for some real  $a$ , then*

$$\text{KL}(aq, q) \leq \frac{(a-1)^2}{1-q}q$$

Finally, we recall and prove Lemma 24:

► **Lemma 24.** *Let  $p, q \in [0, 1]$ . Then  $\chi^2(p, q) \geq \frac{1}{12} \text{KL}(p, q) / \log \max\{\frac{1}{q}, \frac{1}{1-q}\}$ .*

**Proof.** We actually prove that  $\chi^2(p, q) / \text{KL}(p, q) \geq \frac{1}{12 \log \max\{\frac{1}{q}, \frac{1}{1-q}\}}$  for every  $p \in [0, 1]$  and  $q \in (0, 1)$ . For the edge cases of  $q$  (which we do not use in our proofs anyway except when  $p = q$ ), the bound remains correct by considering the limit of  $\text{KL}(p, q) / \log \max\{\frac{1}{q}, \frac{1}{1-q}\}$ .

Without loss of generality,  $q \leq \frac{1}{2}$ . We can assume so since  $\chi^2(p, q) = \chi^2(1-p, 1-q)$ ,  $\text{KL}(p, q) = \text{KL}(1-p, 1-q)$  and  $\max\{\log 1/q, \log 1/(1-q)\} = \max\{\log 1/(1-q), \log 1/(1-(1-q))\}$ . Based on this assumption it is sufficient to show that  $\frac{\chi^2(p, q)}{\text{KL}(p, q)} \geq \frac{1}{12 \log q^{-1}}$ .

Let  $a = p/q$  ( $0 < a \leq 1/q$ ). If  $a \geq 2$ :

$$\begin{aligned}\chi^2(aq, q) &\geq \frac{(a-1)^2}{2(a+1)q} \\ \text{KL}(aq, q) &\leq p \log \frac{p}{q} \leq a \log q^{-1} \cdot q \\ \frac{\chi^2(aq, q)}{\text{KL}(aq, q)} &\geq \frac{(a-1)^2}{2a(a+1) \log q^{-1}} \geq \frac{1}{12 \log q^{-1}}\end{aligned}$$

If  $a \leq 2$ :

$$\begin{aligned}\chi^2(aq, q) &\geq \frac{(a-1)^2}{2(a+1)q} \\ \text{KL}(aq, q) &\leq \frac{(a-1)^2}{1-q}q \\ \frac{\chi^2(aq, q)}{\text{KL}(aq, q)} &\geq \frac{1-q}{2(a+1)} \geq \frac{1}{12 \log q^{-1}}\end{aligned}$$

where the very last inequality uses the assumption that  $q \leq \frac{1}{2}$ . ◀

## 8 Extending the Equivalence test to general alphabets

We extend the definitions of the prefix oracle to non-binary settings.

► **Definition 36** (Subcube oracle access in non-binary strings). *Let  $\mu$  be an unknown distribution over  $\prod_{i=1}^n \Omega_n$ , where  $\Omega_1, \dots, \Omega_n$  are all finite. The subcube oracle has as input a tuple  $(A_1, \dots, A_n)$  where  $A_i \subseteq \Omega_i$  for every  $1 \leq i \leq n$ . The output distributes as  $\mu|_{\prod_{i=1}^n A_i}$ . For technical reasons, if  $\Pr_\mu[\prod_{i=1}^n A_i] = 0$ , then the oracle indicates an error. Note that the answers of the oracle are fully independent of the answers that were given to previous queries.*

In the corresponding definition for a prefix oracle, we still demand that until the “break-off index”  $i$  all conditions force single outcomes from the sets  $\Omega_j$ , while after the break-off index there are no restrictions at all. However, at index  $i$  we allow conditions to any subset of  $\Omega_i$  to take place. There is no such distinction in the binary case, where  $|\Omega_i| = 2$  and hence all non-trivial conditions are to a single outcome.

► **Definition 37** (Prefix oracle access in non-binary settings). *Let  $\mu$  be an unknown distribution over  $\prod_{i=1}^n \Omega_n$ , where  $\Omega_1, \dots, \Omega_n$  are all finite. The input of the prefix oracle consists of an index  $1 \leq i \leq n$ , which we refer to as the index of the prefix, elements  $a_j \in \Omega_j$  for every  $1 \leq j \leq i-1$ , and a condition  $A \subseteq \Omega_i$ . The output of the oracle distributes like  $\mu|_{\{x: x_i \in A \wedge x_1 = a_1, \dots, x_{i-1} = a_{i-1}\}}$ .*

► **Definition 38** (Marginal subcube oracle access in non-binary settings). *Let  $\mu$  be an unknown distribution over  $\prod_{i=1}^n \Omega_n$ , where  $\Omega_1, \dots, \Omega_n$  are all finite. The marginal subcube oracle has as input an index  $i$  and a tuple  $(A_1, \dots, A_n)$  where  $A_j \subseteq \Omega_j$  for every  $1 \leq j \leq n$ . The output distributes as  $\mu|_{\prod_{j=1}^n A_j}$ . For technical reasons, if  $\Pr_\mu[\prod_{i=1}^n A_i] = 0$ , then the oracle indicates an error.*

► **Definition 39** (Marginal prefix oracle access in non-binary settings). Let  $\mu$  be an unknown distribution over  $\prod_{i=1}^n \Omega_i$ , where  $\Omega_1, \dots, \Omega_n$  are all finite. The input of the marginal prefix oracle consists of an index  $1 \leq i \leq n$ , which we refer to as the index of the prefix, elements  $a_j \in \Omega_j$  for every  $1 \leq j \leq i-1$ , and a condition  $A \subseteq \Omega_i$ . The output of the oracle distributes like  $\mu|_{\{x: x_i \in A \wedge x_1 = a_1, \dots, x_{i-1} = a_{i-1}\}}$ .

Based on these definitions, we state Theorem 40:

► **Theorem 40.** Let  $\mu$  and  $\tau$  be two distributions over  $\prod_{i=1}^n \Omega_i$ , where  $\Omega_1, \dots, \Omega_n$  are all finite. If  $\mu$  is accessible through the marginal prefix oracle and  $\tau$  is accessible through the prefix oracle, then we can distinguish between  $\tau = \mu$  and  $d_{\text{TV}}(\tau, \mu) > \varepsilon$  using  $\tilde{O}(\sum_{i=1}^n \log_2 |\Omega_i| / \varepsilon^2)$  queries.

Before we prove Theorem 40, we need the following.

► **Lemma 41** (Binary form of a composite distribution). Let  $\mu$  be a distribution over  $\prod_{i=1}^n \Omega_i$ , where  $\Omega_1, \dots, \Omega_n$  are non-empty finite sets. There exists a distribution  $\mu^*$  over the set  $\{0, 1\}^{\sum_{i=1}^n \lceil \log_2 |\Omega_i| \rceil}$  that is equivalent to  $\mu$  up to relabeling, for which every subcube (respectively prefix) query to  $\mu^*$  can be simulated using a single subcube (respectively prefix) query to  $\mu$ , and every marginal subcube (respectively prefix) query to  $\mu^*$  can be simulated using a single marginal subcube (respectively prefix) query to  $\mu$ .

**Proof.** For every  $1 \leq i \leq n$ , let  $f_i : \Omega_i \rightarrow \{0, 1\}^{\lceil \log_2 |\Omega_i| \rceil}$  be an arbitrary injective function from  $\Omega_i$  to  $\{0, 1\}^{\lceil \log_2 |\Omega_i| \rceil}$ . Let  $f : \prod_{i=1}^n \Omega_i \rightarrow \{0, 1\}^{\sum_{i=1}^n \lceil \log_2 |\Omega_i| \rceil}$  be the concatenation of these mappings. More precisely,  $f((x_1, \dots, x_n)) = \text{concatenate}(f_1(x_1), \dots, f_n(x_n))$ . Let  $N = \sum_{i=1}^n \lceil \log_2 |\Omega_i| \rceil$ .

For every  $1 \leq i \leq n$ , we define a projection function  $g_i : \{0, 1\}^{\sum_{j=1}^n \lceil \log_2 |\Omega_j| \rceil} \rightarrow \Omega_i$  by

$$g_i(x) = (f_i)^{-1} \left( x|_{\{\sum_{j=1}^{i-1} \lceil \log_2 |\Omega_j| \rceil + 1, \dots, \sum_{j=1}^i \lceil \log_2 |\Omega_j| \rceil\}} \right)$$

where  $g_i(x)$  is defined arbitrarily if the corresponding binary string is not in  $f_i$ 's image, as this will be a zero-probability event. Observe that for every  $(x_1, \dots, x_n) \in \prod_{i=1}^n \Omega_i$  and for every  $1 \leq i \leq n$ ,  $x_i = g_i(f(x_1, \dots, x_n))$ .

Let  $\mu^*$  be the distribution over  $\{0, 1\}^{\sum_{i=1}^n \lceil \log_2 |\Omega_i| \rceil}$  that draws  $x \sim \mu$  and returns  $f(x)$ . Since  $f$  is an injective function,  $\mu^*$  is equivalent to  $\mu$  up to relabeling.

For simulating subcube queries consider some  $I^* \subseteq [N]$  and  $w^* \in \{0, 1\}^{I^*}$ . For every  $1 \leq i \leq n$  and  $x^* \in \{0, 1\}^N$ , let  $x_i = g_i(x^*)$  (that is, we decompose  $x^*$  using  $x^* = f(x_1, \dots, x_n)$ ). Also, for every  $1 \leq i \leq n$ , let  $A_i(I^*, w^*) = \{g_i(s^*) : s^* \in \{0, 1\}^N \wedge s^*|_{I^*} = w^*\}$ . Based on this composition, we obtain:

$$\{x^* \in \{0, 1\}^N : x^*|_{I^*} = w^*\} = \left\{ f(x_1, \dots, x_n) : \bigwedge_{i=1}^n (x_i \in A_i(I^*, w^*)) \right\}$$

The last expression is the  $f$ -image of all elements in the  $\mu$ -subcube condition  $\prod_{i=1}^n A_i(I^*, w^*)$ . Hence, every subcube query of  $\mu^*$  can be simulated using a single subcube query to  $\mu$ .

Observe that this construction preserves prefix queries. That is, if a subcube query to  $\mu^*$  is a prefix query, then the simulated subcube query to  $\mu$  is a prefix query as well. Note that this argument holds for marginal queries as well, since we can extract the relevant bit of the sampled coordinate. ◀

Theorem 40 now follows.

**Proof of Theorem 40.** Let  $\mu$  and  $\tau$  be two distributions over  $\prod_{i=1}^n \Omega_i$ , where  $\Omega_1, \dots, \Omega_n$  are all finite. We use Lemma 41 to define two distributions  $\mu^*, \tau^*$  that are identical to  $\mu, \tau$  respectively up to relabeling (which is the same in both constructions). Based on this lemma:

- $d_{\text{TV}}(\tau^*, \mu^*) = d_{\text{TV}}(\tau, \mu)$ , since  $\mu^*, \tau^*$  are the same as  $\mu, \tau$  up to relabeling (which is the same for both constructions  $\mu \rightarrow \mu^*$  and  $\tau \rightarrow \tau^*$ ).
- Every prefix query to  $\tau^*$  can be simulated using a single prefix query to  $\tau$ .
- Every marginal prefix query to  $\mu^*$  can be simulated using a single marginal prefix query to  $\mu$ .

Hence, we can distinguish between  $\tau = \mu$  and  $d_{\text{TV}}(\tau, \mu) > \varepsilon$  using Theorem 20 with the input  $(\mu^*, \tau^*, \varepsilon)$  by simulating every query to  $\tau^*$  or  $\mu^*$  through a single query to the corresponding input distribution  $\tau$  or  $\mu$ . ◀

## 9 Upper bound for Product

We reduce a test for PRODUCT to a test for EQUIVALENCE, based on the following key observation:

► **Observation 42.** *Let  $\mu$  be a distribution over  $\prod_{i=1}^n \Omega_i$ . If  $\mu$  is  $\varepsilon$ -far from any product distribution, then in particular it is  $\varepsilon$ -far from the product of its marginals,  $\prod_{i=1}^n \mu|_i$ .*

In the binary setting, simulating a marginal prefix query to the product of marginals is pretty straightforward and can be done using one unconditional query to  $\mu$ , which is in particular a prefix query:

► **Observation 43.** *Let  $\mu$  be a distribution over  $\{0,1\}^n$ , and let  $\mu' = \prod_{i=1}^n \mu|_i$  be the product of  $\mu$ 's marginals. Then we can simulate every marginal prefix query to  $\mu'$  using one unconditional sample from  $\mu$  (and keeping its  $i$ th entry).*

In the general setting, we need the stronger subcube access. The reason is that when taking a prefix marginal query at index  $i$  from the binary representation of  $\mu' = \prod_{j=1}^n \mu|_j$ , it may be that that  $i$  is “in the middle” of the  $\lceil \log |\Omega_j| \rceil$ -bit representation of  $j$ th coordinate of  $\mu'$ , and then this query must translate to a non-trivial set  $A_j \subseteq \Omega_j$  when simulating it using query access to  $\mu$ .

► **Observation 44.** *Let  $\mu$  be a distribution over  $\prod_{i=1}^n \Omega_i$ , and let  $\mu' = \prod_{i=1}^n \mu|_i$  be the product of  $\mu$ 's marginals. Then we can simulate every marginal prefix query to  $\mu'$  using one subcube query to  $\mu$ .*

At this point, we can prove Theorem 45.

► **Theorem 45.** *Let  $\mu$  be a distribution over  $\prod_{i=1}^n \Omega_i$ . For every  $0 < \varepsilon < 1$ , we can distinguish between the case where  $\mu$  is a product distribution and the case where it is  $\varepsilon$ -far from every product distribution at the cost of  $\tilde{O}(\sum_{i=1}^n \log |\Omega_i| / \varepsilon^2)$  subcube queries. Moreover, if  $|\Omega_i| = 2$  for every  $1 \leq i \leq n$ , then all these queries are prefix queries.*

**Proof.** Let  $\mu' = \prod_{i=1}^n \mu|_i$  be the product of  $\mu$ 's marginals. If  $\mu$  is a product distribution then  $\mu' = \mu$ , and if  $\mu$  is  $\varepsilon$ -far from every product distribution, then in particular  $d_{\text{TV}}(\mu, \mu') > \varepsilon$ .

Since  $\mu$  is accessible through the subcube oracle, we can use Observation 44 to simulate every marginal prefix query to  $\mu'$  at the cost of one subcube query to  $\mu$ . If  $|\Omega_i| = 2$  for every  $1 \leq i \leq n$ , then we can use an unconditional sample instead of a subcube query by Observation 43.

Hence, we can reduce the  $\varepsilon$ -test of  $\mu$  for PRODUCT to an  $\varepsilon$ -test of the equivalence of  $\mu'$  and  $\mu$ , which we perform using Theorem 40. As noted above, this produces subcube queries for general alphabets, and only prefix queries for the binary setting. ◀

## 10 Technical proofs for the Product lower bound

Recall that we denote the uniform distribution over  $\{0, 1\}^n$  by  $\pi_n$ .

Before we prove Lemma 28, we need the following technical lemmas.

► **Lemma 46.** *For a string  $y \in \{0, 1\}^n$ , let  $C_1(y)$  be the number of 1s in  $y$ . If  $n \geq 70$ , then  $\Pr_{y \sim \pi_n} [C_1(y) > \frac{1}{2}n + \frac{1}{4}\sqrt{n}] \geq \frac{1}{4}$ .*

**Proof.** We use the well-known bound  $\binom{n}{\lfloor n/2 \rfloor} \leq 2^n \cdot \sqrt{\frac{2}{\pi n}}$  (for all  $n \geq 1$ ) to obtain for  $n \geq 70$ :

$$\begin{aligned} \Pr_{y \sim \pi_n} \left[ \left| C_1(y) - \frac{1}{2}n \right| \leq \frac{1}{4}\sqrt{n} \right] &= \sum_{k=\lceil \frac{1}{2}n - \frac{1}{4}\sqrt{n} \rceil}^{\lfloor \frac{1}{2}n + \frac{1}{4}\sqrt{n} \rfloor} \Pr_{y \sim \pi_n} [C_1(y) = k] \\ \text{[Since } \binom{n}{k} \leq \binom{n}{\lfloor n/2 \rfloor}] &\leq \left( 2 \cdot \frac{1}{4}\sqrt{n} + 1 \right) 2^{-n} \binom{n}{\lfloor n/2 \rfloor} \\ &\leq \left( \frac{1}{2}\sqrt{n} + 1 \right) \frac{\sqrt{2}}{\sqrt{\pi n}} \leq \frac{1}{2} \end{aligned}$$

By symmetry reasons, if  $n \geq 70$  then:

$$\begin{aligned} \Pr_{y \sim \pi_n} \left[ C_1(y) > \frac{1}{2}n + \frac{1}{4}\sqrt{n} \right] &= \frac{1}{2} \Pr_{y \sim \pi_n} \left[ \left| C_1(y) - \frac{1}{2}n \right| > \frac{1}{4}\sqrt{n} \right] \\ &= \frac{1}{2} \left( 1 - \Pr_{y \sim \pi_n} \left[ \left| C_1(y) - \frac{1}{2}n \right| \leq \frac{1}{4}\sqrt{n} \right] \right) \geq \frac{1}{4} \quad \blacktriangleleft \end{aligned}$$

► **Lemma 47.** *Let  $0 < \delta < \frac{1}{4\sqrt{n}}$  and  $\tau$  be a product distribution over  $\{0, 1\}^n$ . For sufficiently large  $n$ , if  $|\Pr_{\tau}[x_i = 1] - \frac{1}{2}| > \delta$  for every  $1 \leq i \leq n$ , then the distance of  $\tau$  from the uniform distribution over  $\{0, 1\}^n$  is at least  $\frac{1}{16}\delta\sqrt{n}$ .*

**Proof.** Without loss of generality, we can assume that  $\Pr_{\tau}[x_i = 1] \geq \frac{1}{2}$  for every  $1 \leq i \leq n$ . Otherwise, we can negate the “wrong” bits while preserving the distance from the uniform distribution. Based on this assumption, we have a product distribution whose probability to draw 1 at any individual index is at least  $\frac{1+\delta}{2}$ .

Let  $\tau'$  be the product distribution whose probability to draw 1 at any index is exactly  $\frac{1+\delta}{2}$ . Observe that the distance of  $\tau'$  from the uniform distribution is a lower bound of the distance of  $\tau$  from the uniform distribution.

Let  $y \in \{0, 1\}^n$  be a string, and let  $C_1(y)$  (respectively  $C_0(y)$ ) be the number of 1s (respectively 0s) in  $y$ . If  $C_1(y) \geq \frac{1}{2}n + \frac{1}{4}\sqrt{n}$ , then:

$$\begin{aligned} \frac{\Pr_{\tau'}[y]}{\Pr_{\pi_n}[y]} &= (1 + \delta)^{C_1(y)} \cdot (1 - \delta)^{n - C_1(y)} \\ &= (1 + \delta)^{C_1(y) - C_0(y)} \cdot ((1 + \delta)(1 - \delta))^{C_0(y)} \\ &\geq (1 + \delta)^{\sqrt{n}/2} \cdot ((1 + \delta)(1 - \delta))^{\frac{1}{2}n - \frac{1}{4}\sqrt{n}} \\ &= (1 + \delta)^{\sqrt{n}/2} \cdot (1 - \delta^2)^{\frac{1}{2}n - \frac{1}{4}\sqrt{n}} \\ &\geq (1 + \delta)^{\sqrt{n}/2} \cdot (1 - \delta^2)^{\frac{1}{2}n} \\ [(1 + a)^b \geq 1 + ab \text{ for } b \geq 1, |a| < 1] &\geq \left( 1 + \frac{1}{2}\delta\sqrt{n} \right) \cdot \left( 1 - \frac{1}{2}\delta^2 n \right) \\ [\delta < \frac{1}{4\sqrt{n}}] &\geq 1 + \frac{1}{4}\delta\sqrt{n} \end{aligned}$$

In particular,

$$\frac{\Pr_{y \sim \tau'} [C_1(y) > \frac{1}{2}n + \frac{1}{4}\sqrt{n}]}{\Pr_{y \sim \pi_n} [C_1(y) > \frac{1}{2}n + \frac{1}{4}\sqrt{n}]} \geq 1 + \frac{1}{4}\delta\sqrt{n}$$

Since  $\Pr_{y \sim \pi_n} [C_1(y) > \frac{1}{2}n + \frac{1}{4}\sqrt{n}] \geq \frac{1}{4}$  by Lemma 46, we obtain that  $d_{\text{TV}}(\tau', \pi_n) \geq \frac{1}{4}\delta\sqrt{n} \cdot \frac{1}{4} = \frac{1}{16}\delta\sqrt{n}$ .  $\blacktriangleleft$

We recall and prove Lemma 28:

**► Lemma 28.** *Every input distribution drawn from  $\mathcal{N}$  is  $\Omega(\varepsilon)$ -far from any product distribution.*

**Proof.** Without loss of generality, we assume that  $n$  is even. Let  $b_1, \dots, b_{n/2} \in \{+1, -1\}$  be the parameters of the construction, that is, the drawn input is  $\mu = \prod_{i=1}^{n/2} \nu_{b_i}$ . Recall that for  $b \in \{+1, -1\}$ ,  $\Pr_{\nu_b}[x_1 = 1] = \Pr_{\nu_b}[x_2 = 1] = \frac{1}{2}$  and  $\Pr_{\nu_b}[x_1 \oplus x_2 = 1] = \frac{1}{2} - \frac{2b\varepsilon}{\sqrt{n}}$ . We assume that  $n$  is sufficiently large so that  $\lfloor n/6 \rfloor$  satisfies the constraints of Lemma 47.

For a given product distribution  $\tau$ , for every  $1 \leq i \leq n/2$ , let:

$$\begin{aligned} \delta_{i,0} &= \Pr_{\tau}[x_{2i} = 1] - \frac{1}{2} \\ \delta_{i,1} &= \Pr_{\tau}[x_{2i-1} = 1] - \frac{1}{2} \\ \delta_{i,2} &= \Pr_{\tau}[x_{2i} \oplus x_{2i-1} = 1] - \frac{1}{2} \end{aligned}$$

Let  $I_0$  be the set of indexes for which  $|\delta_{i,0}| > \frac{\varepsilon}{10\sqrt{n}}$ . Let  $I_1$  be defined analogously for  $\delta_{i,1}$ , and let  $I_2 = [n/2] \setminus (I_0 \cup I_1)$  be the set of all other indexes. Since  $|I_0| + |I_1| + |I_2| = n/2$ , at least one of them contains at least  $\frac{1}{6}n$  elements.

**Case I.**  $|I_0| \geq \frac{1}{6}n$ . Let  $I = \{2i : i \in I_0\}$ . Observe that  $\mu|_I$  is uniform over  $\{0, 1\}^{n/2}$ , since  $\mu$  is the product of  $n/2$  independent distributions over pairs whose marginals are  $\frac{1}{2}$ , and every pair contributes exactly one index. According to Lemma 47,

$$d_{\text{TV}}(\tau, \mu) \geq d_{\text{TV}}(\tau|_I, \mu|_I) \geq \frac{1}{16} \cdot \frac{\varepsilon}{10\sqrt{n}} \cdot \sqrt{\frac{1}{6}n} = \frac{1}{160\sqrt{6}}\varepsilon > \frac{1}{400}\varepsilon$$

**Case II.**  $|I_1| \geq \frac{1}{6}n$ . Completely analogous to Case I. Again  $d_{\text{TV}}(\tau, \mu) > \frac{1}{400}\varepsilon$ .

**Case III.**  $|I_2| \geq \frac{1}{6}n$ . For every  $i \in I_2$ ,  $|\delta_{i,0}|, |\delta_{i,1}| \leq \frac{\varepsilon}{10\sqrt{n}}$ . Hence,

$$\begin{aligned} |\delta_{i,2}| &= \left| \Pr_{\tau}[x_{2i-1} \oplus x_{2i} = 1] - \frac{1}{2} \right| = \left| \left( \frac{1}{2} - \delta_{i,0} \right) \left( \frac{1}{2} + \delta_{i,1} \right) + \left( \frac{1}{2} + \delta_{i,0} \right) \left( \frac{1}{2} - \delta_{i,1} \right) - \frac{1}{2} \right| \\ &= 2|\delta_{i,0}||\delta_{i,1}| \leq \frac{\varepsilon^2}{50n} \end{aligned}$$

Let  $I = \{2i : i \in I_2\} \cup \{2i-1 : i \in I_2\}$ . Let  $f : \{0, 1\}^I \rightarrow \{0, 1\}^{|I_2|}$  be the function that maps every pair in  $I_2$  to its parity bit. In other words, for every  $i \in I_2$ , the bits  $x_{2i-1}, x_{2i}$  are mapped to a single bit  $x_{2i-1} \oplus x_{2i}$ . Let  $\mu'$  (respectively  $\tau'$ ) be the distribution over  $\{0, 1\}^{|I_2|}$  that draws a sample  $x \sim \mu$  (respectively  $x \sim \tau$ ) and returns  $f(x)$ . Observe that both  $\mu'$  and  $\tau'$  are product distributions over  $\{0, 1\}^{|I_2|}$ , since the pairs are independent and every pair is mapped into a single bit.

Note that  $d_{\text{TV}}(\tau', \pi_{|I_2|}) \leq \Delta_{\text{TV}}(\tau', \pi_{|I_2|}) = \sum_{i=1}^{|I_2|} d_{\text{TV}}(\tau'|_i, \text{Ber}(1/2)) \leq |I_2| \cdot \frac{\varepsilon^2}{50n} \leq \frac{1}{50}\varepsilon^2$ . In  $\mu'$ , by definition of the  $\nu_b$ s, all marginals have the form  $\frac{1}{2} \pm \frac{\varepsilon}{\sqrt{n}}$ , hence by Lemma 47,

$$d_{\text{TV}}(\mu', \pi_{|I_2|}) \geq \frac{1}{16} \cdot \frac{\varepsilon}{\sqrt{n}} \cdot \sqrt{\frac{1}{6}n} = \frac{\varepsilon}{16\sqrt{6}} \geq \frac{1}{40}\varepsilon$$

By a data processing inequality and the triangle inequality,

$$d_{\text{TV}}(\mu, \tau) \geq d_{\text{TV}}(\mu', \tau') \geq d_{\text{TV}}(\mu', \pi_{|I_2|}) - d_{\text{TV}}(\tau', \pi_{|I_2|}) \geq \frac{1}{40}\varepsilon - \frac{1}{50}\varepsilon^2 > \frac{1}{400}\varepsilon \quad \blacktriangleleft$$

## A Explicit algorithms

We provide here explicit representations for the binary setting algorithms constructed in this paper.

### Levin’s work-balance method

For a random variable  $X$  that is bounded between 0 and 1, it distinguishes between  $E[X] = 0$  and  $E[X] > \varepsilon$ . To do that, we use another random variable  $Y$ , for which we can distinguish between  $E[X|Y = y] = 0$  and  $E[X|Y = y] > \rho$  for every  $0 < \rho < 1$ , at a cost of  $O(1/\rho)$ . Overall, the cost of the algorithm is  $O(\log^2 \varepsilon^{-1}/\varepsilon)$ . The original construction is found in [16] and the following optimized version appears as an exercise in [13].

The black box is run a logarithmic number of times for every  $y$  that we draw (as opposed to once in, for example, [13, Exercise 8.4]) since it refers here to a procedure with two-sided error.

■ **Algorithm 1** Levin’s work-balance procedure.

**$\chi^2$ -test of single-bit distributions**

The following is the algorithm that detects the difference between two Bernoulli distributions as it was described in Lemma 17.

■ **Algorithm 2**  $\chi^2$ -test of single-distributions.

---

**input** Two Bernoulli distributions  $\text{Ber}(p)$  and  $\text{Ber}(q)$ , accessible through samples.  
**completeness** If  $p = q$ , then the algorithm accepts with probability at least  $2/3$ .  
**soundness** If  $\chi^2(p, q) > \varepsilon$ , then the algorithm rejects with probability at least  $2/3$ .  
**complexity**  $O(1/\varepsilon)$  samples.  
**let**  $N \leftarrow \lceil 16/\varepsilon \rceil$ .  
**set**  $A, B \leftarrow 0$ .  
**for** 64 **times do**  
    **draw**  $N$  independent samples from  $\text{Ber}(p)$ , let  $X$  be their sum.  
    **draw**  $N$  independent samples from  $\text{Ber}(q)$ , let  $Y$  be their sum.  
    **if**  $X > Y$  **then**  
        **set**  $A \leftarrow A + 1$ .  
    **if**  $X < Y$  **then**  
        **set**  $B \leftarrow B + 1$ .  
**if**  $A \leq 40$  and  $B \leq 40$  **then**  
    **return** ACCEPT.  
**else**  
    **return** REJECT.

---

**Testing Equivalence**

The proof of Theorem 20 translates to the following explicit algorithm.

■ **Algorithm 3**  $\varepsilon$ -test for binary-alphabet EQUIVALENCE.

---

**input**  $n, \varepsilon > 0$ , two distributions  $\mu, \tau$  over  $\{0, 1\}^n$ .  
     $\mu$  is accessible through the marginal prefix oracle.  
     $\tau$  is accessible through the prefix oracle.  
**completeness** If  $\tau = \mu$ , then the output is ACCEPT with probability at least  $\frac{2}{3}$ .  
**soundness** If  $d_{\text{TV}}(\tau, \mu) > \varepsilon$ , then the output is REJECT with probability at least  $\frac{2}{3}$ .  
**let**  $\pi$  be the uniform distribution over  $[n]$ .  
**let**  $Y$  be a random variable that distributes as  $\pi \times \tau$ .  
**let**  $X$  be a random variable defined as a function of  $Y = (i, w)$ :

$$X(i, w) = \chi^2 \left( \mu_i^{x_{[i-1]=w_{[i-1]}}}(1), \tau_i^{x_{[i-1]=w_{[i-1]}}}(1) \right)$$

**let**  $\rho \leftarrow \frac{\varepsilon^2}{24 \log(\varepsilon/2n)}$ .  
**run** Levin's procedure (Algorithm 1), where its input consists of  $Y, \rho/n$ , and the black box  $((i, w), \varepsilon') \rightarrow (\text{Algorithm 2 with input } \mu_i^{x_{[i-1]=w_{[i-1]}}}, \tau_i^{x_{[i-1]=w_{[i-1]}}} \text{ and } \varepsilon')$ .  
**if** Levin's procedure accepts **then**  
    **return** ACCEPT.  
**else**  
    **return** REJECT.

---

### Testing Product

The proof of Theorem 45 translates in the binary setting to the following explicit algorithm. Note that it is almost identical to Algorithm 3, since we only substitute the marginal prefix oracle  $\tau|_i^{x^{[i-1]}=w^{[i-1]}}$  with the marginal oracle of  $\mu$ .

■ **Algorithm 4**  $\varepsilon$ -test for binary-alphabet PRODUCT.

---

**input**  $n, \varepsilon > 0$ , a distribution  $\mu$  over  $\{0, 1\}^n$ .

$\mu$  is accessible through the prefix oracle.

**completeness** If  $\mu \in \text{PRODUCT}$ , then the output is ACCEPT with probability at least  $\frac{2}{3}$ .

**soundness** If  $\min_{\tau \in \text{PRODUCT}} d_{\text{TV}}(\mu, \tau) > \varepsilon$ , then the output is REJECT with probability at least  $\frac{2}{3}$ .

**let**  $\pi$  be the uniform distribution over  $[n]$ .

**let**  $Y$  be a random variable that distributes as  $\pi \times \mu$ .

**let**  $X$  be a random variable defined as a function of  $Y = (i, w)$ :

$$X(i, w) = \chi^2(\mu|_i^{x^{[i-1]}=w^{[i-1]}}(1), \mu|_i(1))$$

**let**  $\rho \leftarrow \frac{\varepsilon^2}{24 \log(\varepsilon/2n)}$ .

**run** Levin's procedure (Algorithm 1), where its input consists of  $Y, \rho/n$ , and the black box  $((i, w), \varepsilon') \rightarrow (\text{Algorithm 2 with input } \mu|_i^{x^{[i-1]}=w^{[i-1]}}, \mu|_i \text{ and } \varepsilon')$ .

**if** Levin's procedure accepts **then**

**return** ACCEPT.

**else**

**return** REJECT.

# Parallelising Glauber Dynamics

Holden Lee  

Department of Applied Mathematics and Statistics, The Johns Hopkins University,  
Baltimore, MD, USA

---

## Abstract

For distributions over discrete product spaces  $\prod_{i=1}^n \Omega'_i$ , Glauber dynamics is a Markov chain that at each step, resamples a random coordinate conditioned on the other coordinates. We show that  $k$ -Glauber dynamics, which resamples a random subset of  $k$  coordinates, mixes  $k$  times faster in  $\chi^2$ -divergence, and assuming approximate tensorization of entropy, mixes  $k$  times faster in KL-divergence. We apply this to obtain parallel algorithms in two settings: (1) For the Ising model  $\mu_{J,h}(x) \propto \exp(\frac{1}{2} \langle x, Jx \rangle + \langle h, x \rangle)$  with  $\|J\| < 1 - c$  (the regime where fast mixing is known), we show that we can implement each step of  $\tilde{\Theta}(n/\|J\|_F)$ -Glauber dynamics efficiently with a parallel algorithm, resulting in a parallel algorithm with running time  $\tilde{O}(\|J\|_F) = \tilde{O}(\sqrt{n})$ . (2) For the mixed  $p$ -spin model at high enough temperature, we show that with high probability we can implement each step of  $\tilde{\Theta}(\sqrt{n})$ -Glauber dynamics efficiently and obtain running time  $\tilde{O}(\sqrt{n})$ .

## 1 Introduction

A key problem in computer science and statistics is to sample from a probability distribution given its probability mass function up to a constant of proportionality. The problem has been studied both over discrete spaces (such as  $\Omega^n$  for a finite set  $\Omega$ ) and continuous spaces (such as  $\mathbb{R}^n$ ); the goal is to give efficient algorithms for general classes of distributions, and in particular, to obtain optimal scaling in the dimension  $n$ . In this work we focus on minimizing the parallel running time, assuming a polynomial number of processors. In  $\mathbb{R}^n$ , it is natural to change multiple coordinates at a time using gradient-based algorithms such as Langevin dynamics and Hamiltonian Monte Carlo; many results have given algorithms that require a sublinear number of steps for log-concave distributions in various settings.

However, on discrete product spaces  $\Omega^n$ , the canonical algorithm, Glauber dynamics, involves resampling coordinates one at a time, and hence requires at least  $n$  steps in general. A natural attempt to speed up Glauber dynamics with parallel computation is to resample  $k$  coordinates at a time. We establish that under general conditions, this simple idea does indeed speed up Glauber dynamics by a factor of approximately  $k$ .

To obtain a parallel algorithm, the task remains to give a fast parallel method of resampling  $k$  coordinates. We show that this can be done in the case of the Ising model  $\mu_{J,h}$  over  $\{\pm 1\}^n$  when the interaction matrix  $J$  is bounded away from 1 in operator norm,  $\|J\| < 1 - c$ , and in the case of the mixed  $p$ -spin model at high enough temperature, both of which are known to enjoy rapid mixing of standard Glauber dynamics.

Editors: Amit Kumar and Noga Ron-Zewi; Article No. 49; pp. 49:1–49:24

Leibniz International Proceedings in Informatics

Schloss Dagstuhl – Leibniz-Zentrum für Informatik, Dagstuhl Publishing, Germany

The Ising model is a classical model from statistical physics which has probability mass function on  $\{\pm 1\}^n$  given by

$$\mu_{J,h}(x) = \frac{1}{Z_{J,h}} \exp\left(\frac{1}{2} \langle x, Jx \rangle + \langle h, x \rangle\right), \quad \text{where } Z_{J,h} = \sum_{x \in \{\pm 1\}^n} \exp\left(\frac{1}{2} \langle x, Jx \rangle + \langle h, x \rangle\right).$$

The regime  $\|J\| < 1$  is exactly where (based on information of the operator norm alone) Glauber dynamics is known to have fast mixing [24, 8]. To sample  $k$  coordinates, we use approximate rejection sampling with a product distribution and a further recursion for certain “bad” sets. By taking  $k = \tilde{\Theta}(n/\|J\|_F)$ , we obtain an algorithm with parallel running time  $\tilde{O}(\|J\|_F) = \tilde{O}(\sqrt{n})$ .

The **mixed  $p$ -spin model** with coefficients  $\beta_2, \beta_3, \dots$  and external field  $h \in \mathbb{R}^n$  is the random measure on  $\{\pm 1\}^n$  given by<sup>1</sup>

$$\begin{aligned} \mu_{\beta,g,h}(x) &\propto \exp(H_{\beta,g,h}(x)), \\ \text{where } H_{\beta,g,h}(x) &= \sum_{p=2}^{\infty} \frac{\beta_p \sqrt{p!}}{n^{\frac{p-1}{2}}} \sum_{1 \leq i_1 < \dots < i_p \leq n} g_{i_1, \dots, i_p} x_{i_1} \cdots x_{i_p} + \sum_{i=1}^n h_i x_i \end{aligned} \quad (1)$$

and  $g_{i_1, \dots, i_p} \sim N(0, 1)$ . By taking  $k = \Theta(\sqrt{n})$ , we obtain an algorithm with parallel running time  $\tilde{O}(\sqrt{n})$ .

## 1.1 Main results

Let  $\mu$  be a distribution on  $\prod_{i=1}^n \Omega'_i$ . We define  $k$ -Glauber dynamics as the Markov chain which given a sample  $x \in \prod_{i=1}^n \Omega'_i$ , chooses a subset  $S \subseteq [n]$  uniformly at random among subsets of size  $k$ , and resamples the coordinates in  $S$  conditional on coordinates in  $S^c$ , according to the distribution of  $\mu$ . Let  $P_{\mu,k}$  denote its Markov kernel.

We show that under general conditions,  $k$ -Glauber dynamics mixes  $k$  times faster in both  $\chi^2$  and KL-divergence. We say that a Markov kernel  $P$  with stationary distribution  $\mu$  satisfies  $\rho$ -contraction in  $\chi^2$ -divergence if  $\mathcal{D}_{\chi^2}(\nu P \|\mu) \leq \rho \mathcal{D}_{\chi^2}(\nu \|\mu)$  and similarly for  $\mathcal{D}_{\text{KL}}$ ; this can be iterated to give a mixing time bound. See Section 2.2 for background on functional inequalities (Poincaré inequality and approximate tensorization of entropy).

► **Theorem 1.1** ( *$k$ -Glauber mixes  $k$  times faster*). *Let  $\mu$  be a distribution on  $\Omega = \prod_{i=1}^n \Omega'_i$ , and let  $1 \leq k \leq n$ . Below, let  $C \geq 1$ .*

1. *If  $\mu$  satisfies a Poincaré inequality with constant  $Cn$ , then  $P_{\mu,k}$  satisfies a Poincaré inequality with constant  $O\left(\frac{Cn}{k}\right)$ , and satisfies  $(1 - \Omega\left(\frac{k}{Cn}\right))$ -contraction in  $\chi^2$ -divergence.*
2. *If  $\mu$  satisfies  $C$ -approximate tensorization of entropy (so that  $P_{\mu}$  satisfies  $(1 - \Omega\left(\frac{1}{Cn}\right))$ -contraction in KL-divergence), then  $P_{\mu,k}$  satisfies  $(1 - \Omega\left(\frac{k}{Cn}\right))$ -contraction in KL-divergence.*

Here, the  $O(\cdot)$  and  $\Omega(\cdot)$  hide only universal constants. The Poincaré inequality is equivalent to contraction in  $\chi^2$ -divergence, so part (1) gives a  $\Omega(k)$ -factor speedup to mixing in  $\chi^2$ . The analogue of the Poincaré inequality for KL is a modified log-Sobolev inequality. Although we need the slightly stronger notion of approximate tensorization of entropy to prove a speedup to mixing in KL, we note that many works that establish a modified log-Sobolev inequality do so using tensorization of entropy [12, 8]. See Section 2 for relevant background on mixing for Markov chains.

<sup>1</sup> The factor  $\sqrt{p!}$  arises as we index only over increasing sequences.

We prove Theorem 1.1 as Corollary 3.6 of the more general Theorem 3.5. We view  $k$ -Glauber dynamics as randomly erasing  $k$  coordinates one by one, and then adding them back one by one according to the right conditional distributions. This realizes  $k$ -Glauber dynamics as a composition of down and up operators  $D_{n \rightarrow n-1} \cdots D_{n-k+1 \rightarrow n-k} U_{n-k \rightarrow n-k+1} \cdots U_{n-1 \rightarrow n}$ . The assumptions give contraction of  $D_{n \rightarrow n-1}$ , and our general theorem shows that the contraction of each  $D_{j \rightarrow j-1}$  is at least as good as  $D_{n \rightarrow n-1}$  (except for an additive factor). To do this, we realize  $D_{j \rightarrow j-1}$  as  $D_{n \rightarrow n-1}$  tensorized with erasure “noise” and projected, and bound how the factor of contraction changes under these operations. We make an analogy to bounding the Poincaré and log-Sobolev constants of a distribution  $\mu$  on  $\mathbb{R}^n$  convolved with Gaussian noise, and the proximal sampler based on iteratively adding and removing Gaussian noise (more specifically, sampling from the posterior distribution given a noisy Gaussian observation of the sample from  $\mu$ ).

Algorithmically, the challenge with implementing  $k$ -Glauber dynamics is that naive enumeration for the transition kernel takes  $2^k$  time, and hence we must find a way to use the structure of the distribution to implement each step more efficiently. We show that in the case of the Ising model, we can efficiently simulate  $k$ -Glauber dynamics for  $k = \tilde{O}\left(\frac{n}{\|J^\otimes\|_F}\right)$ , to obtain a parallel algorithm running in time  $\tilde{O}\left(\|J^\otimes\|_F\right)$ , where  $J^\otimes$  denotes  $J$  with diagonal entries set to  $0^2$ . Under the assumption that  $\|J\| < 1$ , this is always at most  $\tilde{O}(\sqrt{n})$ .

► **Theorem 1.2.** *Let  $c > 0$ . With appropriate choice of constants depending only on  $c$ , if  $J$  is symmetric positive semi-definite with  $\|J\| \leq 1 - c$ , then `ParallellisingSampler` (Algorithm 1) with appropriate constants outputs a sample  $\varepsilon$ -close in TV distance from the Ising model  $\mu_{J,h}$  and, with probability at least  $1 - \varepsilon$ , runs in time  $O\left(\max\left\{\|J^\otimes\|_F, 1\right\} \text{poly log}\left(\frac{n}{\varepsilon}\right)\right)$  on a parallel machine with  $\text{poly}(n)$  processors.*

We note that our algorithm is a high-accuracy sampler: the only dependence on  $\varepsilon$  is a poly-logarithmic dependence in the running time. Notably, the number of processors does not depend on  $\varepsilon$ . We rely on the result [8] that gives optimal ( $O(n \ln n)$ ) mixing times for the Ising model for  $\|J\| < 1$  based on the theory of entropic independence.

The first attempt to implement  $k$ -Glauber dynamics is to approximate the conditional distribution of  $k$  coordinates using a carefully chosen product distribution and use rejection sampling. Using concentration results (the Hanson-Wright inequality), if  $\|J_{S \times S}^\otimes\|_F$  is small for the randomly chosen set  $S$ , then this succeeds with high probability. The complication is that  $\|J_{S \times S}^\otimes\|_F$  can sometimes be large. If this is the case, then we recurse on  $J_{S \times S}$ . By controlling the expected size of  $\|J_{S \times S}^\otimes\|_F$ , we show that the recursive calls form a subcritical branching process and with high probability, add at most a polylogarithmic overhead to the running time.

► **Theorem 1.3.** *Consider the mixed  $p$ -spin model (1). There exists an absolute constant  $\delta > 0$  such that if  $\sum_{p \geq 2} \sqrt{p^3 \ln p} \cdot \beta_p < \delta$  and  $D(\beta) = \sum_{p \geq 2} \sqrt{2^p p^3 \ln p} \cdot \beta_p < \infty$ , then with probability  $1 - \exp(-\Omega(n))$  over  $g$ , given query access to  $H_{\beta,g,h}$ , there is an algorithm which outputs a sample  $\varepsilon$ -close in TV distance from  $\mu_{\beta,g,h}$  and, with probability at least  $1 - \varepsilon$ , runs in time  $O_{D(\beta)}\left(\sqrt{n} \text{poly log}\left(\frac{n}{\varepsilon}\right)\right)$  on a parallel machine with  $\text{poly}\left(\frac{n}{\varepsilon}\right)$  processors.*

<sup>2</sup> While changing the diagonal entries of  $J$  does not change the Ising model, we need to allow  $J$  to have nonzero diagonal entries in order to be positive semi-definite.

---

**Algorithm 1** Parallel Ising Sampler (ParallellisingSampler).

---

- 1: **Input:** Interaction matrix  $J \in \mathbb{R}^{n \times n}$ , subset  $R$  of size  $m$ , external field  $h \in \mathbb{R}^R$ , error parameter  $\varepsilon \in (0, \frac{1}{2})$ .
  - 2: Let  $\varepsilon_{\text{step}} = \frac{\varepsilon}{2n^{c_4}}$ .
  - 3: **if**  $\left\| J_{R \times R}^{\otimes} \right\|_F \leq \frac{c_3}{\ln\left(\frac{2}{\varepsilon_{\text{step}}}\right)+1}$  ( $J^{\otimes}$  denotes  $J$  with diagonal entries set to 0) **then**
  - 4:    $y \leftarrow \text{QuadraticApproxRejectionSampler} \left( H(x) = \frac{1}{2} \langle x, J_{R \times R} x \rangle + \langle h, x \rangle, \frac{c_3}{\ln\left(\frac{2}{\varepsilon_{\text{step}}}\right)+1}, \varepsilon_{\text{step}} \right)$ .  
     (See Algorithm 2.)
  - 5: **else**
  - 6:   Let  $s = \left\lceil \frac{c_1 m}{\left(\ln\left(\frac{2}{\varepsilon_{\text{step}}}\right)+1\right) \ln\left(\frac{n}{\varepsilon}\right) \left\| J_{R \times R}^{\otimes} \right\|_F} \right\rceil$ .
  - 7:   Let  $T = \lfloor C_2 \ln\left(\frac{n}{\varepsilon}\right) \frac{m}{s} \rfloor$ .
  - 8:   Draw  $y$  from the product distribution  $\nu_0(x) \propto e^{\langle h, x \rangle}$ .
  - 9:   **for**  $t$  from 1 to  $T$  **do**
  - 10:     Choose  $S \subseteq R$  a random subset of size  $s$ .
  - 11:      $z \leftarrow \text{ParallellisingSampler}(J, S, J_{S \times R \setminus S} y_{R \setminus S} + h_S, \varepsilon)$
  - 12:     Set  $y_S = z$ .
  - 13:   **end for**
  - 14: **end if**
  - 15: **Output:**  $y$  (Approximate sample from  $\mu_{J_{R \times R}, h}$ ).
- 

Note that a recursion is not necessary in this algorithm. Intuitively, the mean-field nature of the  $p$ -spin model ensures that with high probability all marginal distributions of  $O(\sqrt{n})$  coordinates are well-approximated by a product distribution. Though we do not investigate this further, a recursive algorithm could potentially eliminate the  $\text{poly}(1/\varepsilon)$  dependence on the number of processors as in Theorem 1.2. The proof of Theorem 1.3 is in Section 5 in the full version.

We view our result on the Ising model and the  $p$ -spin model as proofs of concept for parallelisation using  $k$ -Glauber dynamics, and hope it serves as a useful framework for constructing parallel algorithms for other families of discrete distributions. As discussed in the next section, using a different parallel algorithm, the work [35] obtains Theorem 1.2 but not Theorem 1.3.

## 1.2 Related work

We note that our Theorem 1.1 can be viewed as a complement of “local-to-global” results for mixing of the down-up walks [41, 1, 19], and is not implied by those results. Those results aim to establish mixing of Glauber dynamics (or the down-up walk) from mixing of simpler chains, while we start by assuming mixing of Glauber dynamics. In particular, [19] apply the reverse strategy: for the spin systems on graphs they consider, they show that mixing of  $\theta n$ -Glauber dynamics (for appropriate  $\theta$ ) implies mixing of Glauber dynamics.

When contraction of Glauber dynamics is derived directly from either spectral or entropic independence using local-to-global arguments, then the same arguments can be used to establish mixing of the  $k$ -Glauber (e.g., using  $k$ -uniform block factorization of entropy [19], the analogue of approximate tensorization of entropy). However, this does not apply for distributions for which mixing is established through other methods. The recent work [9]

shows that a Poincaré inequality implies spectral independence, but the bound obtained for  $k$ -Glauber through spectral independence is lossy (resulting in a power of  $n$ ). Our work can be seen as giving a general conceptual reason why mixing for Glauber must imply mixing for  $k$ -Glauber.

### 1.2.1 Continuous sampling

For log-concave distributions on  $\mathbb{R}^n$ , a long line of works on the underdamped Langevin algorithm and Metropolis-adjusted Langevin algorithm have led to high-accuracy sampling using  $\tilde{O}(n^{1/2})$  steps [3]. The randomized midpoint method for underdamped Langevin dynamics allows sampling in the weaker Wasserstein metric in  $\tilde{O}(n^{1/3})$  steps [45], and can furthermore be fully parallelised to obtain  $\varepsilon$  error with  $\text{poly}(\frac{n}{\varepsilon})$  processors. These dependencies are assuming the condition number is  $O(1)$ .

We note that the Ising model for  $\|J\| < 1$  can be decomposed as a log-concave mixture of product distributions [30, 10, 32], so these algorithms give an alternative approach to parallel algorithms for the Ising model. However, this decomposition is highly specific to the Ising model. Moreover, the Wasserstein guarantee is incompatible with a TV guarantee, and the complexity of our approach scales with  $\|J\|_F$ .

### 1.2.2 Parallel algorithms for discrete sampling

Recent work [6, 4, 7] has investigated the question of obtaining fast parallel algorithms for approximate sampling in settings where fast parallel algorithms for approximate *counting* (or computing a partition function) exist. In particular, for distributions satisfying transport stability and where the *log-Laplace* transform can be efficiently calculated (e.g., using the efficient algorithm for computing partition functions), [7] gives a  $\text{poly} \log(n/\varepsilon)$ -time algorithm with  $\text{poly}(n/\varepsilon)$  many processors (i.e., a RNC algorithm). This includes problems such as determinantal point processes and Eulerian tours. Notably they use the continuous algorithm (randomized midpoint method, discussed above) even though the problem is discrete.

In the setting of Ising models, however, we do not have a fast parallel algorithm for counting. Several works [26, 35] have studied the problem assuming the associated Dobrushin influence matrix has bounded norm. By using simultaneous updates, [35] obtains a factor- $\frac{n}{C}$  speedup for distributions whose Dobrushin influence matrix has norm bounded by  $C$ , in particular giving RNC algorithms when  $C = O(1)$  and the mixing time is  $O(n \ln n)$ . The result of [35] can also give Theorem 1.2 with a different algorithm, but cannot be used to derive Theorem 1.3. See Appendix A in the full version for details.

On the practical side, designers of Markov chain Monte Carlo algorithms in discrete spaces have taken inspiration from continuous algorithms, for example, by using gradient information to inform the proposal distribution and allow updating multiple coordinates at once [29, 50, 42]. Theoretical guarantees for these algorithms remain to be understood.

### 1.2.3 Diffusion models and the proximal sampler

Stochastic localization [23] is a measure-valued stochastic process that converges to a point mass, which is distributed according to a desired distribution  $\mu$ . As a technique, it gives a way of decomposing probability distributions that has been useful in proving functional inequalities and mixing time [17, 18], and more recently, in constructing new, *time-inhomogeneous* algorithms for sampling [22, 39].

Diffusion models [46, 47, 48] are a successful paradigm for generative modeling in machine learning, where the task is to learn and then generate samples from a distribution where only samples are given. Though the details may differ, they consist of a forward process which

adds noise to the data; reversing the process can then generate a sample from random noise. It has been observed [38] that a stochastic localization process can be viewed as the reverse process of a diffusion model.

Our analysis of  $k$ -Glauber dynamics is inspired by the analysis of the proximal sampler [34, 16, 25], which does alternating Gibbs sampling by adding Gaussian noise to the current sample, and then “de-noising” by sampling from the posterior distribution; this fits in the framework discussed above. In their analysis, [16] show that proximal sampler mixes at least as fast as Langevin in terms of  $\chi^2$  and KL-divergence. [25] show a  $\tilde{O}(n^{1/2})$  dimension dependence using a carefully chosen Gaussian proposal distribution to implement the posterior sampling step. We view the  $k$ -Glauber dynamics as a discrete analogue of the proximal Langevin algorithm, where the noise consists of erasing  $k$  coordinates, and our proof follows this analogy. In our application, we also require a careful choice of product distribution for the proposal.

## 2 Preliminaries

While many of the notions are generalizable, we will restrict ourselves to finite state spaces, and identify all measures with their probability mass functions. For more background on Markov chains, see [40].

### 2.1 Markov kernels

For finite sets  $A$  and  $B$ , a Markov kernel  $K$  from  $A$  to  $B$  is a function  $A \times B \rightarrow \mathbb{R}_{\geq 0}$  or equivalently, a matrix  $\mathbb{R}_{\geq 0}^{A \times B}$ , where the rows sum to 1. If  $\mu$  is a measure on  $A$ , then  $\mu K$  is a measure on  $B$ ; if  $f$  is a function  $B \rightarrow \mathbb{R}$ , then  $Kf$  is a function  $A \rightarrow \mathbb{R}$ ; these correspond to matrix-vector multiplication. Composition of kernels  $K_1$  from  $A$  to  $B$  and  $K_2$  from  $B$  to  $C$  gives a kernel  $K_1 K_2$  from  $A$  to  $C$ , which corresponds to matrix multiplication. For  $f, g$  functions on  $A$  and  $\mu$  a measure on  $A$ , let  $\langle f, g \rangle_\mu = \sum_{x \in A} \mu(x) f(x) g(x)$ . For a kernel  $K : A \times B \rightarrow \mathbb{R}_{\geq 0}$ , given measures  $\mu_1, \mu_2$  on  $A$  and  $B$  respectively, we think of  $K$  as a linear map  $L^2(\mu_1) \rightarrow L^2(\mu_2)$ ; then its adjoint  $K^* : B \times A \rightarrow \mathbb{R}_{\geq 0}$  is a linear map  $L^2(\mu_2) \rightarrow L^2(\mu_1)$  satisfying  $\langle f, Kg \rangle_{\mu_1} = \langle K^* f, g \rangle_{\mu_2}$  for any  $f \in L^2(\mu_1), g \in L^2(\mu_2)$ .

► **Definition 2.1.**  *$k$ -Glauber dynamics with stationary distribution  $\mu$  on  $\Omega$  is the Markov chain where at each step, if the current sample is  $x$ , we choose a subset  $S$  uniformly at random in  $\binom{\Omega}{k}$  (subsets of size  $k$ ), and resample the coordinates in  $S$  according to  $\mu(X_S | X_{S^c} = x_{S^c})$ . Let  $P_{\mu, k}$  denote the transition operator. For  $k = 1$ , we simply call it Glauber dynamics, and let  $P_\mu$  denote the Markov kernel.*

► **Definition 2.2.** *Let  $0 \leq \ell \leq k \leq n$ . Let  $\mu$  be a distribution on  $\binom{[n]}{k}$ . Define the **down operator**  $D_{k \rightarrow \ell}$  and **up operator**  $U_{\ell \rightarrow k}$  as Markov kernels  $\binom{[n]}{k} \times \binom{[n]}{\ell} \rightarrow \mathbb{R}_{\geq 0}$  and  $\binom{[n]}{\ell} \times \binom{[n]}{k} \rightarrow \mathbb{R}_{\geq 0}$ , respectively, with*

$$D_{k \rightarrow \ell}(A, B) = \mathbb{1}_{B \subseteq A} \frac{1}{\binom{k}{\ell}} \quad U_{\ell \rightarrow k}(B, A) = \mathbb{1}_{B \subseteq A} \frac{\mu(A)}{\sum_{A' \supseteq B} \mu(A')}.$$

Let  $\mu_\ell = \mu D_{k \rightarrow \ell}$  for  $0 \leq \ell \leq k$ , and define the  $k \leftrightarrow \ell$  **down-up walk** and  $\ell \leftrightarrow k$  **up-down walk** by

$$P_{k \leftrightarrow \ell}^\nabla = D_{k \rightarrow \ell} U_{\ell \rightarrow k} \quad P_{\ell \leftrightarrow k}^\Delta = U_{\ell \rightarrow k} D_{k \rightarrow \ell}.$$

Note that  $D_{k \rightarrow \ell}$  does not depend on  $\mu$  while  $U_{\ell \rightarrow k}$  does; we suppress the dependency in the notation. Note that  $D_{k \rightarrow \ell} D_{\ell \rightarrow m} = D_{k \rightarrow m}$  and  $U_{m \rightarrow \ell} U_{\ell \rightarrow k} = U_{m \rightarrow k}$ . As operators,  $D_{k \rightarrow \ell} : L^2(\mu_\ell) \rightarrow L^2(\mu_k)$  and  $U_{\ell \rightarrow k} : L^2(\mu_k) \rightarrow L^2(\mu_\ell)$  are adjoint.

► **Definition 2.3.** Let  $\mu$  be a measure on  $\Omega' = \Omega'_1 \times \cdots \times \Omega'_n$ . Define the **homogenization** of  $\mu$  to be the measure  $\mu^{\text{hom}}$  over  $\binom{\Omega}{n}$ , where  $\Omega = \bigcup_{i=1}^n \Omega'_i \times \{i\}$  and  $\sigma \in \Omega'$  is identified with  $\{(\sigma_1, 1), \dots, (\sigma_n, n)\}$ . (For short, we will write  $\Omega = \bigsqcup_{i=1}^n \Omega'_i$  in the following.) For any property  $\mathcal{P}$  defined for measures  $\binom{\Omega}{n}$ , we say that  $\mu$  satisfies  $\mathcal{P}$  if  $\mu^{\text{hom}}$  satisfies  $\mathcal{P}$ .

Under this identification,  $k$ -Glauber dynamics corresponds to the  $n \leftrightarrow n - k$  down-up walk, as the down step corresponds to erasing  $k$  coordinates and the up step corresponds to restoring them with the correct conditional probabilities.

## 2.2 Functional inequalities

► **Definition 2.4.** Let  $M = (\Omega, P)$  be an ergodic, reversible Markov chain with stationary distribution  $\mu$ . Define the associated Dirichlet form as the inner product

$$\mathcal{E}_P(f, g) = \langle f, (I - P)g \rangle_\mu = \frac{1}{2} \sum_{x, y \in \Omega} \mu(x) P(x, y) (f(x) - f(y))(g(x) - g(y))$$

When  $\mu$  is a distribution on  $\Omega = \prod_{i=1}^n \Omega'_i$ , we write  $\mathcal{E}_\mu = \mathcal{E}_{P_\mu}$ ; we will similarly make other such replacements without comment.

► **Definition 2.5.** Keeping the assumptions above, we say that  $P$  satisfies a **Poincaré inequality** with constant  $C$  if for all  $f : \Omega \rightarrow \mathbb{R}$ ,

$$\text{Var}_\mu(f) \leq C \mathcal{E}_P(f, f).$$

We say  $\mu$  satisfies a Poincaré inequality with constant  $C$  if the Glauber dynamics with stationary distribution  $\mu$ ,  $P_\mu$ , satisfies a Poincaré inequality with constant  $C$ .

When  $P$  is self-adjoint ( $M$  is reversible), this is the same as saying that  $\lambda_2(P) \leq 1 - \frac{1}{C}$ , where  $\lambda_k(\cdot)$  denotes the  $k$ th largest eigenvalue.

► **Definition 2.6.** Let  $f : \mathbb{R}_{\geq 0} \rightarrow \mathbb{R}_{\geq 0}$  be a strictly convex function with  $f(1) = 0$ . For measures  $\nu \ll \mu$  on  $\Omega$ , define the  **$f$ -divergence** by

$$\mathcal{D}_f(\nu \parallel \mu) = \mathbb{E}_{x \sim \mu} f\left(\frac{\nu(x)}{\mu(x)}\right).$$

In particular, define the  $\chi^2$  and KL-divergences by  $\mathcal{D}_{\chi^2} = D_{(x-1)^2}$  and  $\mathcal{D}_{\text{KL}} = D_{x \ln x}$ .

► **Definition 2.7.** We say that Markov kernel  $P : \Omega_1 \times \Omega_2 \rightarrow \mathbb{R}$  satisfies  **$\rho$ -contraction in  $f$ -divergence** with respect to  $\mu_1$  if for all  $\nu_1 \ll \mu_1$ ,

$$\mathcal{D}_f(\nu_1 P \parallel \mu_1 P) \leq \rho \mathcal{D}_f(\nu_1 \parallel \mu_1).$$

Contraction in  $\chi^2$  and KL-divergence is also referred to as variance or entropy contraction, respectively.

► **Proposition 2.8.** Let  $P : \Omega_1 \times \Omega_2 \rightarrow \mathbb{R}_{\geq 0}$  be a Markov kernel. The following are equivalent, for  $C \leq 1$ :

1.  $P$  satisfies  $(1 - C)^2$ -contraction in  $\chi^2$ -divergence with respect to  $\mu$ .
2. For all  $f : \Omega_1 \rightarrow \mathbb{R}$ ,

$$\text{Var}_{\mu P}(Pf) \leq (1 - C)^2 \text{Var}_\mu(f).$$

3. (For  $\Omega_1 = \Omega_2$ ,  $P$  reversible)  $P$  satisfies a Poincaré inequality with constant  $\frac{1}{C}$ .
  4. (For  $P$  of the form  $P = DD^*$ , e.g.,  $P_{k \leftrightarrow k-1}^\nabla = D_{k \rightarrow k-1} U_{k-1 \rightarrow k}$ )  $D$  satisfies  $(1 - C)$ -contraction in  $\chi^2$ -divergence.
  5. (For  $P = DD^*$ )  $D^*$  satisfies  $(1 - C)$ -contraction in  $\chi^2$ -divergence.
- Here, the adjoint is with respect to the measures  $\mu$  and  $\mu D$ .

**Proof sketch.** See full version. ◀

► **Definition 2.9.** A measure  $\mu$  on  $\binom{[n]}{k}$  satisfies *C-approximate tensorization of entropy* if  $D_{k \rightarrow k-1}$  satisfies  $(1 - \frac{1}{Ck})$ -contraction in KL-divergence, i.e., for any  $\nu \ll \mu$ ,

$$\mathcal{D}_{\text{KL}}(\nu D_{k \rightarrow k-1} \| \mu D_{k \rightarrow k-1}) \leq \left(1 - \frac{1}{Ck}\right) \mathcal{D}_{\text{KL}}(\nu \| \mu).$$

We have the following alternate characterization for a measure defined on a product space. Define the entropy of a function  $f$  on a probability space by  $\text{Ent}_\mu[f] = \mathbb{E}_\mu[f \ln f] - \mathbb{E}_\mu[f] \ln \mathbb{E}_\mu[f]$ .

► **Proposition 2.10** ([19, Lemma 2.7]). Let  $\mu$  be a measure on  $\Omega = \Omega'_1 \times \cdots \times \Omega'_n$ . Then  $\mu$  satisfies *C-approximate tensorization of entropy* iff for all  $f : \Omega \rightarrow \mathbb{R}_{\geq 0}$ ,

$$\text{Ent}_\mu[f] \leq C \sum_{k=1}^n \mathbb{E}_\mu \left[ \text{Ent}_{\mu(X_k = \cdot | X_{\sim k} = x_{\sim k})}[f] \right],$$

where  $\sim k$  denotes the coordinates besides  $k$ .

► **Remark 2.11.** Proposition 2.8 shows that for contraction in  $\chi^2$ -divergence, nothing is lost if we consider  $P_{k \leftrightarrow k-1}^\nabla$  or  $D_{k \rightarrow k-1}$ ,  $U_{k-1 \rightarrow k}$  separately. However, the distinction is important for KL, as contraction of  $P_{k \leftrightarrow k-1}^\nabla$  may not imply contraction of  $D_{k \rightarrow k-1}$  or  $U_{k-1 \rightarrow k}$  separately; hence the definition of approximate tensorization of entropy. Approximate tensorization of entropy is stronger than the modified log-Sobolev inequality (which implies mixing for  $P_{k \leftrightarrow k-1}^\nabla$ ), but weaker than the log-Sobolev inequality.

### 2.3 Additional notation

For  $f : \prod_{i=1}^n \Omega'_i \rightarrow \mathbb{R}$ , and  $x \in \prod_{i \in S^c} \Omega'_i$ , define the restriction  $f_x : \prod_{i \in S} \Omega'_i$  by  $f_x(y) = f(x, y)$  with  $(x, y)$  treated as an element of  $\prod_{i=1}^n \Omega'_i$ .

Let  $x_{i \leftarrow b}$  denote  $x$  with  $x_i$  set to  $b$ . For  $f : \{\pm 1\}^n$ , let  $D_i f(x) := \frac{1}{2}[f(x_{i \leftarrow 1}) - f(x_{i \leftarrow -1})]$  and define  $\nabla f : \{\pm 1\}^n \rightarrow \mathbb{R}^n$  by

$$\nabla f(x) = (D_1 f(x), \dots, D_n f(x))$$

and  $\nabla^2 f : \{\pm 1\}^n \rightarrow \mathbb{R}^{n \times n}$  by  $(\nabla^2 f(x))_{i,j} = D_i D_j f(x)$  (note  $(\nabla^2 f(x))_{i,i} = 0$ ).

For  $x \in \{\pm 1\}^n$  and  $S \subseteq [n]$ , let  $x^S$  denote  $\prod_{i \in S} x_i$ . For a function  $f : \{\pm 1\}^n \rightarrow \mathbb{R}$ , we denote the degree  $d$  part of  $f$  by  $f^{(d)}$ , and define  $f^{\geq d} = \sum_{p \geq d} f^{(p)}$ , etc., so that we have the decomposition

$$f(x) = \sum_{p=0}^n f^{(p)}(x) = \sum_{p=0}^n \sum_{|I|=p} a_I x^I$$

for some coefficients  $a_I$ . We take  $f_x^{(d)}$  to mean that we take the restriction first and then the degree- $d$  part.

For a scalar-valued function  $f$  and  $x \in \mathbb{R}^n$ , we let  $f(x)$  denote coordinate-wise evaluation.

### 3 $k$ -Glauber mixes $k$ times as fast

To show that  $k$ -Glauber mixes  $k$  times more quickly than Glauber dynamics, write  $P_\mu = D_{n \rightarrow n-1} U_{n-1 \rightarrow n}$  and  $P_{\mu,k} = D_{n \rightarrow n-1} \cdots D_{n-k+1 \rightarrow n-k} U_{n-k \rightarrow n-k+1} \cdots U_{n-1 \rightarrow n}$ ; the task is then to show that  $D_{j \rightarrow j-1}$ ,  $j \leq n$  are roughly at least as contractive as  $D_{n \rightarrow n-1}$ . We note that this is like the reverse of the usual “local-to-global” argument for high-dimensional expanders [1] (and will be easier!). We also note this approach relates to inductive arguments in prior work (e.g., [20, Lemma 11]).

Viewing the problem in this way, we note the similarity to the proximal sampler [16], each step of which involves adding and removing Gaussian noise; they bound the contraction in  $\chi^2$  and KL-divergence of this process based on the Poincaré and log-Sobolev constants of the original distribution.

As inspiration, we first recall the following fact, which bounds the Poincaré or log-Sobolev constant of a convolution of two measures on  $\mathbb{R}^n$ . (The convolution  $\mu_1 * \mu_2$  is defined as the distribution of  $X + Y$  where  $X \sim \mu_1$  and  $Y \sim \mu_2$  are independent.) As we will not cover the theory of functional inequalities over  $\mathbb{R}^n$ , this is meant only as a suggestion of how we might proceed. For details and generalizations, see [14].

► **Lemma.** *Suppose that  $\mu_1, \mu_2$  are distributions on  $\mathbb{R}^n$  with Poincaré constants  $C_1, C_2$ , respectively. Then  $\mu_1 * \mu_2$  has Poincaré constant bounded by  $C_1 + C_2$ . The same holds true for the log-Sobolev constant. In particular, this holds true for  $\mu_2$  being a Gaussian of variance  $C_1$ .*

**Proof sketch.** Let  $M_m$  denote multiplication by  $m$ . Then  $\mu_i M_{m_i}^{-1}$  has Poincaré constant  $m_i^2 C_i$ . By tensorization,  $\mu = \mu_1 M_{m_1}^{-1} \otimes \mu_2 M_{m_2}^{-1}$  has Poincaré constant  $\max\{C_1 m_1^2, C_2 m_2^2\}$ . Consider the projection  $\pi(x_1, x_2) = \frac{x_1}{m_1} + \frac{x_2}{m_2}$ . When  $\frac{1}{m_1} + \frac{1}{m_2} = 1$ , this can be realized as projection onto the vector  $(\frac{1}{m_1}, \frac{1}{m_2})$ , so the Poincaré constant does not increase:  $C_P(\mu \pi^{-1}) \leq C_P(\mu)$ . Note that we exactly have  $\mu \pi^{-1} = \mu_1 * \mu_2$ . Choosing  $\frac{1}{m_1} = \frac{C_1}{C_1 + C_2}$  and  $\frac{1}{m_2} = \frac{C_2}{C_1 + C_2}$  gives the bound. The same argument works for the log-Sobolev constant. ◀

We will carry out the same steps as in this proof: define a tensorization operation which preserves the Poincaré or approximate tensorization of entropy constant, and a projection which can only improve it. As in the sketch above, it will help to weight the components appropriately in the tensorization step.

To obtain the  $D_{k \rightarrow k-1}$  operator from the  $D_{n \rightarrow n-1}$  operator, we will tensorize with the appropriate “noise” distribution, which in this case is that of erasing  $n - k$  coordinates. We note that while bit-flip noise is the more natural analogue of gaussian noise, the “denoising” step is more difficult to implement, while erasure noise connects more nicely with existing notions.

### 3.1 Tensorization and projection

The following proposition is similar to classical results on preservation of functional inequalities under tensorization, which corresponds to taking a product of Markov chains. However, we need to work with operators between different spaces to obtain contraction for the down operator, so we need the result given in Proposition 3.1. As in Remark 2.11, nothing would be lost for  $\chi^2$ -divergence if we considered the down-up walk – so we could use existing results – but for KL we need to bound contraction for just the down operator. This is important because we aim to bound contraction for  $P_{n \leftrightarrow n-k}^\nabla = D_{n \rightarrow n-1} \cdots D_{n-k+1 \rightarrow n-k} U_{n-k \rightarrow n-k+1} \cdots U_{n-1 \rightarrow n}$ , and in the case of KL, we cannot obtain this by bounding contraction for just operators of the form  $P_{k \leftrightarrow k-1}^\nabla = D_{k \rightarrow k-1} U_{k-1 \rightarrow k}$ .

► **Proposition 3.1** (Contraction under tensorization). *Suppose that  $P_i$  is a Markov kernel from  $\Omega_i$  to  $\Omega'_i$ , for  $i = 1, 2$ . Let  $I_i$  denote the identity kernel on  $\Omega_i$  and define  $P = p(P_1 \otimes I_2) + (1-p)(I_1 \otimes P_2)$  as a Markov kernel from  $\Omega_1 \times \Omega_2$  to  $(\Omega'_1 \times \Omega_2) \sqcup (\Omega_1 \times \Omega'_2)$ .*

*Let  $\mathcal{D}_f = \mathcal{D}_{\text{KL}}$  or  $\mathcal{D}_{\chi^2}$ . If  $P_i$  satisfies  $(1 - \kappa_i)$ -contraction in  $f$ -divergence with respect to  $\mu_i$ , then  $P$  satisfies  $(1 - \kappa)$ -contraction in  $f$ -divergence with respect to  $\mu_1 \otimes \mu_2$ , where  $\kappa = \min\{p\kappa_1, (1-p)\kappa_2\}$ . In particular, if  $p = \frac{\kappa_2}{\kappa_1 + \kappa_2}$ , then  $\kappa = \frac{\kappa_1 \kappa_2}{\kappa_1 + \kappa_2} = \frac{1}{\kappa_1^{-1} + \kappa_2^{-1}}$ .*

**Proof.** First consider KL-divergence. Let  $\nu$  be a measure on  $\Omega_1 \times \Omega_2$ . Let  $\Pi_i$  and  $\Pi'_i$  denote the projection kernels to  $\Omega_i$  and  $\Omega'_i$  respectively, for  $i = 1, 2$  (i.e., taking marginals). We calculate

$$\begin{aligned} B &:= \mathcal{D}_{\text{KL}}(p\nu(P_1 \otimes I_2) + (1-p)\nu(I_1 \otimes P_2) \| p(\mu'_1 \times \mu_2) + (1-p)(\mu_1 \times \mu'_2)) \\ &= p\mathcal{D}_{\text{KL}}(\nu(P_1 \otimes I_2) \| \mu'_1 \times \mu_2) + (1-p)\mathcal{D}_{\text{KL}}(\nu(I_1 \otimes P_2) \| \mu_1 \times \mu'_2), \end{aligned} \quad (2)$$

since the spaces  $\Omega'_1 \times \Omega_2$  and  $\Omega_1 \times \Omega'_2$  are disjoint. Now, by the chain rule of KL-divergence and entropy contraction,

$$\begin{aligned} \mathcal{D}_{\text{KL}}(\nu(P_1 \otimes I_2) \| \mu'_1 \times \mu_2) &= \mathbb{E}_{x_2 \sim \mu_2} \mathcal{D}_{\text{KL}}((\nu(P_1 \otimes I_2))(\cdot | x_2) \| \mu'_1) + \mathcal{D}_{\text{KL}}(\nu(P_1 \otimes I_2) \Pi_2 \| \mu_2) \\ &= \mathbb{E}_{x_2 \sim \mu_2} \mathcal{D}_{\text{KL}}(\nu(\cdot | x_2) P_1 \| \mu'_1) + \mathcal{D}_{\text{KL}}(\nu \Pi_2 \| \mu_2) \\ &\leq (1 - \kappa_1) \mathbb{E}_{x_2 \sim \mu_2} \mathcal{D}_{\text{KL}}(\nu(\cdot | x_2) \| \mu_1) + \mathcal{D}_{\text{KL}}(\nu \Pi_2 \| \mu_2). \end{aligned}$$

By symmetry, the same calculation holds for the second term in (2), giving us

$$\begin{aligned} B &\leq p[(1 - \kappa_1) \mathbb{E}_{x_2 \sim \mu_2} \mathcal{D}_{\text{KL}}(\nu(\cdot | x_2) \| \mu_1) + \mathcal{D}_{\text{KL}}(\nu \Pi_2 \| \mu_2)] \\ &\quad + (1-p)[(1 - \kappa_2) \mathbb{E}_{x_1 \sim \mu_1} \mathcal{D}_{\text{KL}}(\nu(\cdot | x_1) \| \mu_2) + \mathcal{D}_{\text{KL}}(\nu \Pi_1 \| \mu_1)]. \end{aligned}$$

We wish to compare this with

$$\begin{aligned} A &:= \mathcal{D}_{\text{KL}}(\mu \| \mu_1 \times \mu_2) \\ &= \underbrace{\mathbb{E}_{x_2 \sim \mu_2} \mathcal{D}_{\text{KL}}(\nu(\cdot | x_2) \| \mu_1)}_{C_{2,1}} + \underbrace{\mathcal{D}_{\text{KL}}(\nu \Pi_2 \| \mu_2)}_{C_2} \\ &= \underbrace{\mathbb{E}_{x_1 \sim \mu_1} \mathcal{D}_{\text{KL}}(\nu(\cdot | x_1) \| \mu_2)}_{C_{1,2}} + \underbrace{\mathcal{D}_{\text{KL}}(\nu \Pi_1 \| \mu_1)}_{C_1}. \end{aligned}$$

By convexity of KL-divergence,  $C_{1,2} \geq C_2$  and  $C_{2,1} \geq C_1$ . Hence

$$\begin{aligned} B &\leq p((1 - \kappa_1)C_{2,1} + C_2) + (1-p)((1 - \kappa_2)C_{1,2} + C_1) \\ &\leq \max\{(1-p)(1 - \kappa_2) + p, p(1 - \kappa_1) + (1-p)\} [p(C_{2,1} + C_2) + (1-p)(C_{1,2} + C_1)] \\ &= (1 - \min\{(1-p)\kappa_2, p\kappa_1\}) A. \end{aligned}$$

Next consider  $\chi^2$ -divergence. It suffices to prove the following equivalent statement on contraction of variance (Proposition 2.8): for any  $f : \Omega_1 \times \Omega_2 \rightarrow \mathbb{R}$ , considering  $P^* = p(P_1^* \otimes I_2) \oplus (1-p)(I_1 \otimes P_2^*)$ , we have

$$\text{Var}_{\mu P}(P^* f) \leq (1 - \kappa) \text{Var}_{\mu}(f),$$

which is equivalent to  $\sigma_2(P^*) \leq 1 - \kappa$  and hence to  $\lambda_2(PP^*)^2 = \sigma_2(PP^*)^2 \leq (1 - \kappa)^2$ . Now  $PP^* = p(P_1 P_1^* \otimes I_2) + (1-p)(I_1 \otimes P_2 P_2^*)$  is exactly the transition matrix of the weighted product of two Markov chains with  $\lambda_2(P_i P_i^*) \leq 1 - \kappa_i$ , so it is well-known that

$$\lambda_2(PP^*) \leq \max\{p + (1-p)(1 - \kappa_2), (1-p) + p(1 - \kappa_1)\} = 1 - \max\{(1-p)\kappa_2, p\kappa_1\}.$$

(A quick way to see this is as follows: if  $\{f_i\}$  are the eigenvectors of  $P_1 P_1^*$  and  $\{g_j\}$  are the eigenvectors of  $P_2 P_2^*$ , then  $\{f_i g_j\}$  are the eigenvectors of  $P^* P$ , and the second largest eigenvalue is when  $f_i = 1$  or  $g_j = 1$ .) ◀

Though we do not do it here, the proofs can be put on the same footing and generalized using the notion of  $f$ -entropy [14].

► **Proposition 3.2** (Contraction under projection). *Suppose that  $P$  is a Markov kernel from  $\Omega_1$  to  $\Omega_2$ , and  $\mu_1, \mu_2$  are measures on  $\Omega_1, \Omega_2$  such that  $\mu_1 P = \mu_2$ . Let  $\pi_i : \Omega_i \rightarrow \Omega'_i$  be maps and  $\mu'_i = \mu_i \pi_i^{-1}$ . Define the projected Markov kernel  $P' : \Omega'_1 \times \Omega'_2 \rightarrow \mathbb{R}_{\geq 0}$  by*

$$P'(x'_1, x'_2) = \sum_{\substack{x_1 \in \Omega_1 \\ \pi_1(x_1) = x'_1}} \sum_{\substack{x_2 \in \Omega_2 \\ \pi_2(x_2) = x'_2}} \mu_1(x_1 | \pi(x_1) = x'_1) P(x_1, x_2).$$

If  $P$  satisfies  $\rho$ -contraction in  $f$ -divergence with respect to  $\mu_1$ , then  $P'$  also satisfies  $\rho$ -contraction in  $f$ -divergence with respect to  $\mu'_1$ .

In words, in the projected Markov chain, given  $x'_1$ , we draw  $x_1$  projecting to  $x'_1$  from the “prior”, move according to  $P$ , and then project back down; then the projected kernel always has at least as much contraction as the original one. See e.g., [37] for the statement for the Poincaré constant.

**Proof.** Let  $\nu'_1 \ll \mu'_1$  be a measure on  $\Omega'_1$ . Define  $\nu_1(x) = \nu'_1(\pi_1(x)) \mu_1(X = x | \pi_1(X) = \pi_1(x))$ . Then  $\mathbb{E}_{\mu_1(\cdot | \pi_1(X) = x'_1)} f\left(\frac{\nu_1(x)}{\mu_1(x)}\right) = \frac{\nu'_1(x'_1)}{\mu'_1(x'_1)}$ , so

$$\mathcal{D}_f(\nu'_1 \| \mu'_1) = \mathbb{E}_{x'_1 \sim \mu'_1} f\left(\frac{\nu'_1(x'_1)}{\mu'_1(x'_1)}\right) = \mathcal{D}_f(\nu_1 \| \mu_1).$$

By contraction of  $P$  and the data processing inequality,

$$\mathcal{D}_f((\nu_1 P) \pi_2^{-1} \| \mu'_2) \leq \mathcal{D}_f(\nu_1 P \| \mu_2) \leq \rho \mathcal{D}_f(\nu_1 \| \mu_1) = \rho \mathcal{D}_f(\nu'_1 \| \mu'_1).$$

Finally, note that  $(\nu_1 P) \pi_2^{-1} = \nu'_1 P'$  by definition of  $P'$ . ◀

### 3.2 Contraction improves going down

We now show that for  $k < n$ , contraction in KL and  $\chi^2$  for  $D_{k \rightarrow k-1}$  will only be better than contraction of  $D_{n \rightarrow n-1}$ , except up to an additive constant.

► **Lemma 3.3.** *Let  $\mu$  be the uniform distribution on  $\binom{[n]}{k}$ . Then  $D_{k \rightarrow k-1}$  has  $(1 - \frac{1}{k})$ -contraction in KL, and  $\mu$  satisfies 1-approximate tensorization of entropy. Moreover,  $D_{k \rightarrow k-1}$  and  $U_{k-1 \rightarrow k}$  satisfy  $(1 - \frac{n}{k(n-k+1)})$ -contraction in  $\chi^2$ .*

We note that the down-up walk on the uniform distribution on  $\binom{[n]}{k}$  is a rescaling of the Bernoulli-Laplace diffusion model, for which mixing and functional inequalities have been extensively studied [21, 33, 27, 13, 43], and we have not attempted to find the best result for KL.

**Proof.** Note that  $\mu$  is log-concave, by the results of [5] and the fact that  $\binom{[n]}{k}$  is a matroid. Then 1-approximate tensorization of entropy follows from [8, Theorem 5].

To note the improved bound for  $\chi^2$ , note first that the probability of staying at the same set is  $\frac{1}{n-k+1}$ , so  $P_{k \leftrightarrow k-1}^\nabla = \frac{1}{n-k+1} I + \frac{n-k}{n-k+1} P_{k \leftrightarrow k-1}^\vee$  where  $P_{k \leftrightarrow k-1}^\vee$  is the “non-lazy” walk which swaps an occupied and non-occupied space at random. Hence  $I - P_{k \leftrightarrow k-1}^\nabla = \frac{n-k}{n-k+1} (I - P_{k \leftrightarrow k-1}^\vee)$ . This in turn satisfies

$$I - P_{k \leftrightarrow k-1}^\nabla = \frac{n(n-1)/2}{k(n-k)} \cdot \frac{2}{n-1} \cdot L$$

## 49:12 Parallelising Glauber Dynamics

where  $L$  is the generator of the Bernoulli-Laplace diffusion model with parameters  $(n, k)$  (a random transposition occurs with rate 1). Here, the  $\frac{2}{n-1}$  is the scaling factor to convert to a discrete-time walk and  $\frac{n(n-1)/2}{k(n-k)}$  takes into account that we are randomly choosing from  $k(n-k)$  transpositions that move a particle to an unoccupied space, rather than an arbitrary transposition. By [43],  $\lambda_{\min}(L) = 1$ . Hence the spectral gap for  $P_{k \leftrightarrow k-1}^{\nabla}$  is

$$\frac{n-k}{n-k+1} \cdot \frac{n(n-1)/2}{k(n-k)} \cdot \frac{2}{n-1} = \frac{n}{k(n-k+1)}. \quad \blacktriangleleft$$

► **Lemma 3.4.** *Let  $\mu$  be a distribution on  $\prod_{i=1}^n \Omega'_i$  and  $\mu^{\text{hom}}$  its homogenization on  $\binom{\Omega}{n}$ , where  $\Omega = \bigsqcup_{i=1}^n \Omega'_i$ , and  $\mu_m = \mu^{\text{hom}} D_{n \rightarrow m}$ . Let  $\mathcal{D}_f = \mathcal{D}_{\text{KL}}$  or  $\mathcal{D}_{\chi^2}$ . For each  $k$ , let  $\kappa_k$  be the largest number such that  $D_k := D_{k \rightarrow k-1}$  satisfies  $(1 - \kappa_k)$ -contraction in  $f$ -divergence with respect to  $\mu_k$ . Suppose that for the uniform distribution  $\binom{[n]}{k}$  that  $D_{k \rightarrow k-1}$  satisfies  $(1 - \kappa_{\text{BL},k})$ -contraction in  $f$ -divergence. Then*

$$\kappa_k \geq \frac{n\kappa_n \kappa_{\text{BL},k}}{n\kappa_n + k\kappa_{\text{BL},k}} \geq \begin{cases} \frac{n\kappa_n}{k((n-k+1)\kappa_n+1)}, & \mathcal{D}_f = \mathcal{D}_{\chi^2} \\ \frac{n\kappa_n}{k(n\kappa_n+1)}, & \mathcal{D}_f = \mathcal{D}_{\text{KL}}. \end{cases}$$

**Proof.** Consider the kernel  $P = p(D_n \otimes I_{\binom{[n]}{k}}) + (1-p)(I_{\binom{\Omega}{n}} \otimes D_k)$  from  $\binom{\Omega}{n} \times \binom{[n]}{k}$  to  $\binom{\Omega}{n-1} \times \binom{[n]}{k} \cup \binom{\Omega}{n} \times \binom{[n]}{k-1}$ , where  $D_k$  denotes the down operator  $\binom{[n]}{k} \times \binom{[n]}{k-1} \rightarrow \mathbb{R}_{\geq 0}$ . By tensorization (Proposition 3.1), for  $p = \frac{\kappa_{\text{BL},k}}{\kappa_n + \kappa_{\text{BL},k}}$  and  $\kappa = \frac{1}{\kappa_n^{-1} + \kappa_{\text{BL},k}^{-1}}$ ,  $P$  satisfies  $(1 - \kappa)$ -contraction in  $f$ -divergence with respect to  $\mu_n \otimes \text{Uniform}\left(\binom{[n]}{k}\right)$ . Define the projections  $\pi_1 : \binom{\Omega}{n} \times \binom{[n]}{k} \rightarrow \binom{\Omega}{k}$  and  $\pi_2 : \binom{\Omega}{n-1} \times \binom{[n]}{k} \cup \binom{\Omega}{n} \times \binom{[n]}{k-1} \rightarrow \binom{\Omega}{k-1} \cup \binom{\Omega}{k}$  both as

$$\pi(S, A) = S \cap \bigcup_{i \in A} \Omega_i,$$

i.e., if  $S$  corresponds to  $x \in \prod_{i=1}^n \Omega'_i$ , we keep only the coordinates in the set  $A \in \binom{[n]}{k}$ .

We claim the projected kernel as defined in Proposition 3.2 is

$$P' = \underbrace{\left(1 - \frac{p(n-k)}{n}\right)}_{\text{(I)}} D_k + \underbrace{\frac{p(n-k)}{n} I}_{\text{(II)}}$$

from  $\binom{\Omega}{k}$  to  $\binom{\Omega}{k-1} \cup \binom{\Omega}{k}$ . To see this, we first identify  $x_A \in \prod_{i=1}^{i \in A} \Omega'_i$  with its homogenization in  $\binom{\Omega}{|A|}$  (Definition 2.3). Then  $\mu_1(\cdot | \pi_1(x_1) = x_A)$  is the distribution of  $(x, A)$  where  $x_{A^c}$  is distributed as  $\mu(X_{A^c} = x_{A^c} | X_A = x_A)$ . Under the transition  $P$ :

1. With probability  $p$ , we remove a coordinate  $i$  of  $x$ . In this case,
  - a. with probability  $\frac{k}{n}$ ,  $i \in A$ , and projection by  $\pi_2$  then gives  $x_{A \setminus \{i\}}$  for a random index  $i$ .
  - b. with probability  $\frac{n-k}{n}$ ,  $i \notin A$ , and projection by  $\pi_2$ .
2. With probability  $1-p$ , we remove an element  $i$  of  $A$ , and projection gives  $x_{A \setminus \{i\}}$  for a random  $i \in A$ .

Then (1a) and (2) give the term (I) and (1b) gives the term (II).

Because

$$\begin{aligned} \mathcal{D}_f \left( \nu P' \parallel \left(1 - \frac{p(n-k)}{n}\right) \mu_{k-1} + \frac{p(n-k)}{n} \mu_k \right) \\ = \left(1 - \frac{p(n-k)}{n}\right) \mathcal{D}_{\text{KL}}(\nu D_k \parallel \mu_{k-1}) + \frac{p(n-k)}{n} \mathcal{D}_{\text{KL}}(\nu \parallel \mu_k) \end{aligned}$$

(the component measures have disjoint support), we have that  $D_k$  satisfies  $(1 - \kappa_k)$ -contraction in  $f$ -divergence iff  $P'$  satisfies  $(1 - \kappa_k (1 - \frac{p(n-k)}{n}))$ -contraction in  $f$ -divergence. Proposition 3.2 then gives us

$$\begin{aligned} \kappa_k \left( 1 - \frac{\kappa_{\text{BL},k}}{\kappa_n + \kappa_{\text{BL},k}} \cdot \frac{n-k}{n} \right) &\geq \frac{1}{\kappa_n^{-1} + \kappa_{\text{BL},k}^{-1}} \\ \implies \kappa_k &\geq \frac{n\kappa_n\kappa_{\text{BL},k}}{n\kappa_n + k\kappa_{\text{BL},k}}. \end{aligned}$$

Plugging in the result of Lemma 3.3 then gives the result.  $\blacktriangleleft$

**► Theorem 3.5.** *Let  $\mu$  be a distribution on  $\Omega = \prod_{i=1}^n \Omega'_i$ , and consider the down and up operators defined with respect to its homogenization  $\mu^{\text{hom}}$ .*

1. *If  $D_{n \rightarrow n-1}$  satisfies  $(1 - \frac{1}{Cn})$ -contraction in  $\chi^2$ , then  $D_{k \rightarrow \ell}$  satisfies  $\prod_{j=\ell+1}^k \left( 1 - \frac{1}{j(C + \frac{n-j+1}{n})} \right)$ -contraction in  $\chi^2$ .*
2. *If  $D_{n \rightarrow n-1}$  satisfies  $(1 - \frac{1}{Cn})$ -contraction in KL (i.e.,  $\mu$  satisfies  $C$ -approximate tensorization of entropy), then  $D_{k \rightarrow \ell}$  and  $P_{k \rightarrow \ell}^\nabla$  satisfy  $\prod_{j=\ell+1}^k \left( 1 - \frac{1}{j(C+1)} \right)$ -contraction in KL.*

We note that our tensorization construction in Lemma 3.1 currently depends on  $\mu$  being a homogeneous distribution; it would be interesting to extend it beyond this case.

**Proof.** If  $D_{n \rightarrow n-1}$  satisfies  $(1 - \frac{1}{Cn})$ -contraction in  $\chi^2$ -divergence, then by Lemma 3.4,  $D_{j \rightarrow j-1}$  satisfies  $\left( 1 - \frac{1}{j(C + \frac{n-j+1}{n})} \right)$ -contraction in  $\chi^2$ -divergence. If  $D_{n \rightarrow n-1}$  satisfies  $(1 - \frac{1}{Cn})$ -contraction in  $\chi^2$ -divergence, then we have  $\left( 1 - \frac{1}{j(C+1)} \right)$ -contraction in KL-divergence. Because  $D_{k \rightarrow \ell} = D_{k \rightarrow k-1} \cdots D_{\ell+1 \rightarrow \ell}$ , taking the product from  $\ell + 1$  to  $k$  gives the result.  $\blacktriangleleft$

From this, we can conclude that  $k$ -Glauber dynamics mixes at least  $\Omega(k)$  times as fast in  $\chi^2$ -divergence as Glauber dynamics, and assuming approximate tensorization of entropy, mixes at least  $\Omega(k)$  times as fast in KL-divergence.

**► Corollary 3.6** ( $k$ -Glauber mixes  $k$  times as fast). *Let  $\mu$  be a distribution on  $\Omega = \prod_{i=1}^n \Omega'_i$ .*

1. *If  $\mu$  satisfies a Poincaré inequality with constant  $Cn$ , then*

$$\lambda_2(P_{\mu,k}) \leq \left( 1 - \frac{k}{n+1} \right)^{\frac{1}{C+1}} = 1 - \Omega \left( \max \left\{ \frac{k}{(C+1)n}, 1 \right\} \right)$$

*and  $P_{\mu,k}$  satisfies a Poincaré inequality with constant  $\Omega \left( \frac{(C+1)n}{k} \right)$ .*

2. *If  $\mu$  satisfies  $C$ -approximate tensorization of entropy, then  $P_{\mu,k}$  satisfies contraction in KL-divergence with constant*

$$\left( 1 - \frac{k}{n+1} \right)^{\frac{1}{C+1}} = 1 - \Omega \left( \max \left\{ \frac{k}{(C+1)n}, 1 \right\} \right).$$

**Proof.** Note that  $P_{\mu,k}$  corresponds to  $P_{n \leftrightarrow n-k}^\nabla$  after homogenization. For variance, we recall Proposition 2.8 which relates the Poincaré constant of  $P_\mu$  and  $D_{n \rightarrow n-1}$ , and the Poincaré constant of  $P_{\mu,k}$  and  $D_{n \rightarrow n-k}$ . The corollary then follows from Theorem 3.5 and the calculation

$$\begin{aligned} \prod_{j=n-k+1}^n \left(1 - \frac{1}{j(C+1)}\right) &\leq e^{-\frac{1}{C+1} \sum_{j=n-k+1}^n \frac{1}{j}} \leq e^{-\frac{1}{C+1} \ln\left(\frac{n+1}{n-k+1}\right)} \\ &= \left(1 - \frac{k}{n+1}\right)^{\frac{1}{C+1}} = 1 - \Omega\left(\frac{k}{(C+1)n}\right). \quad \blacktriangleleft \end{aligned}$$

Our theorem also implies contraction for  $D_{2 \rightarrow 1}$ ; this forms a kind of converse to local-to-global arguments that start with contraction of  $D_{2 \rightarrow 1}$  [2].

► **Corollary 3.7.** *Let  $\mu$  be a distribution on  $\Omega = \prod_{i=1}^n \Omega'_i$ , and consider the down and up operators defined with respect to its homogenization  $\mu^{\text{hom}}$ .*

1. *If  $D_{n \rightarrow n-1}$  satisfies  $(1 - \frac{1}{Cn})$ -contraction in  $\chi^2$ , then  $D_{2 \rightarrow 1}$  satisfies  $(1 - \frac{1}{2(C+1)})$ -contraction in  $\chi^2$  and  $\lambda_2(P_{1 \leftrightarrow 2}^\Delta) \leq 1 - \frac{1}{2(C+1)}$ .*
2. *If  $D_{n \rightarrow n-1}$  satisfies  $(1 - \frac{1}{Cn})$ -contraction in KL (i.e.,  $\mu$  satisfies  $C$ -approximate tensorization of entropy), then  $D_{2 \rightarrow 1}$  satisfies  $(1 - \frac{1}{2(C+1)})$ -contraction in KL.*

**Proof.** This follows from substituting  $k = 2$ ,  $\ell = 1$  into Theorem 3.5, appealing to Proposition 2.8 for the  $\chi^2$  result. ◀

## 4 Parallel sampling for Ising models

To apply Corollary 3.6 to the Ising model for  $\|J\| < 1$ , we use the fact that the Ising model satisfies approximate tensorization of entropy.

► **Theorem 4.1.** *Suppose  $\|J\| < 1$ . Then  $\mu_{J,h}$  satisfies approximate tensorization of entropy with constant  $\frac{1}{1-\|J\|}$ .*

The proof is in Section 4.1. We first introduce a generic guarantee for approximate rejection sampling in Section 4.2, based on establishing concentration for the difference of the log-pdfs. In Section 4.3, we show that using an approximating product distribution – chosen as the solution to a variational problem – is sufficient as a proposal distribution for  $\mu_{J,h}$  when  $\|J\|_F$  is small enough, using the Hanson-Wright inequality. We put everything together in Section 4.4, combining the speedup of  $k$ -Glauber dynamics, known mixing for the Ising model, guarantee on the approximate rejection sampler, with a careful analysis of the recursion in the algorithm.

### 4.1 Approximate tensorization of entropy for the Ising model

For  $\|J\| < 1$ , we prove approximate tensorization of entropy for the Ising model  $\mu_{J,h}$  (Theorem 4.1) by using the fact that it holds for rank-1 Ising models and using the needle decomposition in [24]. This is the same way that the modified log-Sobolev inequality is proved in [24].

► **Proposition 4.2** ([8, Proposition 32]). *Suppose  $\|u\| < 1$ . Then  $\mu_{uu^\top, h}$  satisfies approximate tensorization of entropy with constant  $\frac{1}{1-\|u\|^2}$ .*

► **Theorem 4.3** (Needle decomposition of Ising measures [24]). *Consider an Ising model  $\mu = \mu_{J,h}$  on  $\{\pm 1\}^n$  with  $J \geq 0$ . Let  $f : \{\pm 1\}^n \rightarrow \mathbb{R}$  be any function. There exists a mixture decomposition (depending on  $f$ )*

$$\mu(x) = \int \mu_{u,v}(x) d\pi(u, v)$$

where  $\pi$  is a probability measure on  $\mathbb{R}^{2n}$  such that:

1.  $\pi$ -almost surely,  $\mu_{u,v}$  is a probability measure of the form

$$\mu_{u,v}(x) = \frac{1}{Z_{u,v}} \exp\left(\frac{1}{2} \langle u, x \rangle^2 + \langle v, x \rangle\right),$$

i.e., a rank one Ising model (“needle”). Furthermore  $\|u\| \leq \|J\|$ .

2.  $\mathbb{E}_{\mu_{u,v}} f(X) = \mathbb{E}_{\mu} f(X)$   $\pi$ -almost surely.

**Proof of Theorem 4.1.** See full version. ◀

## 4.2 Approximate rejection sampling

Conditional distributions of the Ising model are again Ising models. We will show that with large probability, if we pick a random subset of not-too-large size, then we can approximate the distribution of those coordinates with a product distribution, and hence use the product distribution as a proposal for approximate rejection sampling. We discuss further the choice of product distribution (given in Algorithm 2) in Section 4.3.

First, we give a generic guarantee for the rejection sampling Algorithm 3, which can be used whenever the log-ratio between desired and proposal distributions  $\ln \frac{dP}{dQ}$  has sufficiently decaying exponential tails. Note that because the normalizing constants are unknown, we draw two samples and use one as a reference to decide whether to accept the other. Lemma 4.4 appears as [25, Lemma 2] specialized to the distribution they consider, but holds more generally. We give the proof for completeness.

■ **Algorithm 2** Quadratic approximate rejection sampler (QuadraticApproxRejectionSampler).

- 
- 1: **Input:** Hamiltonian  $H$  in the form  $H(x) = C + \langle h, x \rangle + \frac{1}{2} \langle x, Ax \rangle + H_{\geq 3}(x)$ ,  $\delta$  such that  $\|A^{\otimes}\|_F \leq \delta < c_3$  and  $0 \preceq A \preceq (1-c)I$ , error  $\varepsilon$ .
  - 2: Let  $u_0 = \mathbf{0}$ .
  - 3: **for**  $t$  from 1 to  $T = \Theta\left(\frac{1}{c} \ln\left(\frac{\sqrt{n}}{\delta}\right)\right)$  **do**
  - 4:     Let  $u_t = A^{\otimes} \tanh(h + u_{t-1})$ .
  - 5: **end for**
  - 6: Let  $\hat{h} = u_T$ .
  - 7: **Output:**  $\text{ApproxRejectionSampler}(q(x) \propto \exp(\langle h + \hat{h}, x \rangle), g(x) = H(x) - \langle h + \hat{h}, x \rangle, (\frac{2}{\varepsilon})^{\frac{\delta}{c_3 - \delta}})$   
(See Algorithm 3.)
- 

■ **Algorithm 3** Approximate rejection sampler (ApproxRejectionSampler).

- 
- 1: **Input:** Oracle for sampling from  $Q$ , function  $g$  such that  $\frac{dP}{dQ} \propto e^g$ , error parameter  $c$ .
  - 2: **repeat** (For parallel implementation, run  $\lceil c \rceil$  times simultaneously and take the first success.)
  - 3:     Draw  $X, Z \sim Q$ .
  - 4:     Let  $R = \exp(g(X) - g(Z))$ .
  - 5:     Draw  $U \sim \text{Uniform}([0, 1])$ .
  - 6: **until**  $U \leq \frac{1}{c}R$
  - 7: **Output:**  $X$ .
- 

► **Lemma 4.4.** Let  $\hat{P}$  be the distribution of the output of Algorithm 3. Then

$$\frac{dP}{dQ}(X) = \frac{\mathbb{E}[R|X]}{\mathbb{E}R} \qquad \frac{d\hat{P}}{dQ}(X) = \frac{\mathbb{E}[\min\{R, c\}|X]}{\mathbb{E}[\min\{R, c\}]}$$

## 49:16 Parallelising Glauber Dynamics

The acceptance probability is  $p_{\text{accept}} = \frac{1}{c} \mathbb{E} \min\{R, c\} = \frac{1}{c} (\mathbb{E}R - \mathbb{E}[(R - c)\mathbb{1}_{R \geq c}])$  and the TV distance is bounded by

$$\mathcal{D}_{\text{TV}}(\widehat{P}, P) \leq \frac{\mathbb{E}[(R - c)\mathbb{1}_{R \geq c}]}{\mathbb{E}R}.$$

For  $c \geq 1$ , the acceptance probability is at least  $\frac{1}{2c}$ .

**Proof.** We calculate

$$\begin{aligned} \mathbb{E}[R|X] &= \mathbb{E}[e^{g(X)-g(Z)}|X] = e^{g(X)} \mathbb{E}[e^{-g(Z)}] \\ \mathbb{E}[R] &= \mathbb{E}[\mathbb{E}[R|X]] = \mathbb{E}[e^{g(X)}] \mathbb{E}[e^{-g(Z)}], \end{aligned}$$

so  $\frac{\mathbb{E}[R|X]}{\mathbb{E}[R]} = \frac{e^{g(X)}}{\mathbb{E}[e^{g(X)}]} = \frac{d\widehat{P}}{dQ}(X)$ . Note  $\frac{d\widehat{P}}{dQ}(X)$  is the probability of acceptance given  $X$  divided by the total probability of acceptance, which we calculate:

$$\begin{aligned} p_{\text{accept}}(X) &:= \mathbb{P}\left[U \leq \frac{1}{c}R|X\right] = \mathbb{E}\left[\min\left\{\frac{R}{c}, 1\right\}|X\right] = \frac{1}{c} \mathbb{E}[\min\{R, c\}|X] \\ p_{\text{accept}} &= \mathbb{P}\left[U \leq \frac{1}{c}R\right] = \mathbb{E}\left[\mathbb{P}\left[U \leq \frac{1}{c}R|X\right]\right] = \frac{1}{c} \mathbb{E}[\mathbb{E}[\min\{R, c\}|X]] = \frac{1}{c} \mathbb{E}[\min\{R, c\}]. \end{aligned}$$

Dividing gives  $\frac{d\widehat{P}}{dQ} = \frac{\mathbb{E}[\min\{R, c\}|X]}{\mathbb{E}[\min\{R, c\}]}$ . Then

$$\begin{aligned} \mathcal{D}_{\text{TV}}(\widehat{P}, P) &\leq \mathbb{E}_{X \sim Q} \max\left\{0, \frac{dP}{dQ}(X) - \frac{d\widehat{P}}{dQ}(X)\right\} \\ &\leq \mathbb{E}_{X \sim Q} \max\left\{0, \frac{\mathbb{E}[R|X]}{\mathbb{E}R} - \frac{\mathbb{E}[\min\{R, c\}|X]}{cp_{\text{accept}}}\right\} \\ &\leq \mathbb{E}_{X \sim Q} \max\left\{0, \frac{\mathbb{E}[R|X]}{\mathbb{E}R} - \frac{\mathbb{E}[\min\{R, c\}|X]}{\mathbb{E}R}\right\} && \text{because } cp_{\text{accept}} \leq \mathbb{E}R \\ &\leq \mathbb{E}_{X \sim Q} \frac{\mathbb{E}[(R - c)\mathbb{1}_{R \geq c}|X]}{\mathbb{E}R} = \frac{\mathbb{E}[(R - c)\mathbb{1}_{R \geq c}]}{\mathbb{E}R}. \end{aligned}$$

Finally, note that  $\mathbb{P}(R \geq 1) \geq \frac{1}{2}$  by symmetry, so  $p_{\text{accept}} \geq \frac{1}{c} \mathbb{P}(R \geq 1) \geq \frac{1}{2c}$ .  $\blacktriangleleft$

### 4.3 Concentration

To obtain concentration of the ratio in Lemma 4.4, we need a version of the Hanson-Wright inequality. We first state the classical inequality.

► **Theorem 4.5** (Hanson-Wright Inequality, [49, Theorem 6.2.1]). *There is a constant  $c$  such that the following holds. Let  $X = (X_1, \dots, X_n) \in \mathbb{R}^n$  be a random vector with independent, mean-zero,  $K$ -sub-gaussian coordinates. Let  $A \in \mathbb{R}^{n \times n}$  be a matrix. Then for every  $t \geq 0$ ,*

$$\mathbb{P}(|\langle X, AX \rangle - \mathbb{E}\langle X, AX \rangle| \geq t) \leq 2 \exp\left[-c \min\left\{\frac{t^2}{K^4 \|A\|_F^2}, \frac{t}{K^2 \|A\|}\right\}\right].$$

We will use the following version, which is a consequence of [44, Corollary 2] (by taking  $\Gamma(f) = \|\nabla f\|$  and noting that product distributions on  $\{\pm 1\}^n$  satisfy a uniform modified log-Sobolev inequality) and allows a general function  $f$ .

► **Theorem 4.6** ([44]). *There is a constant  $c$  such that the following holds. Let  $X = (X_1, \dots, X_n) \in \{\pm 1\}^n$  be a random vector with independent coordinates. Let  $f : \{\pm 1\}^n \rightarrow \mathbb{R}$  be a function. Then for every  $t \geq 0$ ,*

$$\mathbb{P}(|f(X) - \mathbb{E}f(X)| \geq t) \leq 2 \exp\left[-c \min\left\{\frac{t^2}{\mathbb{E}[\|\nabla f\|^2]}, \frac{t}{\max_{x \in \{\pm 1\}^n} \|\nabla^2 f\|_F}\right\}\right].$$

Note the extra term  $\mathbb{E}[\|\nabla f\|^2]$  compared to Theorem 4.5 which requires the random variables to be centered. This means that we cannot simply take  $Q = \mu_h := \mu_{O,h}$  and  $P = \mu_{J,h}$  for the reason that  $\mathbb{E}[\|\nabla_x(\langle x, Ax \rangle)\|^2]$  can be  $\Omega(n)$ , while we need concentration to  $O(1)$ . Instead, in order to apply Theorem 4.6 for  $f = \ln \frac{dP}{dQ}$ , we would like to  $\nabla f$  to be centered, that is,  $\mathbb{E}_Q \nabla f = 0$ . For this, we need to solve the variational problem

$$\mathbb{E}_{\mu_{h+h^*}} A^{\otimes} x = h^*. \quad (3)$$

We do this by fixed point iteration. Note this is a special case of “gradient” descent for Lipschitz and strongly monotone operators [15, 36].

► **Lemma 4.7** (Fixed point iteration). *Let  $(X, d)$  be a metric space,  $c > 0$ , and suppose  $F : X \rightarrow X$  is  $(1-c)$ -Lipschitz (so it is a contraction mapping). Let  $x_0 \in X$  and  $x_t = F^{(t)}(x_0)$ . Then*

$$d(F(x_t), x_t) \leq (1-c)^t d(F(x_0), x_0)$$

and hence for  $t = \Omega\left(\frac{1}{c} \ln\left(\frac{d(F(x_0), x_0)}{\varepsilon}\right)\right)$ , we have  $d(F(x_t), x_t) \leq \varepsilon$ .

**Proof.** We have  $d(F(x_t), x_t) = d(F^{(t+1)}(x_0), F^{(t)}(x_0)) \leq (1-c)^t d(F(x_0), x_0)$  by induction. Hence, it suffices to choose  $t$  such that  $t \ln\left(\frac{1}{1-c}\right) \geq \ln\left(\frac{d(F(x_0), x_0)}{\varepsilon}\right)$ , which gives the result. ◀

► **Lemma 4.8.** *Suppose that  $A$  is symmetric positive semi-definite with  $A \preceq (1-c)I$ . Let*

$$F(u) = A^{\otimes} \tanh(h + u).$$

Then for  $t = \Omega\left(\frac{1}{c} \log\left(\frac{\sqrt{n}}{\varepsilon}\right)\right)$ , we have that  $\hat{h} := F^{(t)}(\mathbf{0})$  satisfies

$$\left\| \mathbb{E}_{\mu_{h+\hat{h}}} A^{\otimes} x - \hat{h} \right\| \leq \varepsilon. \quad (4)$$

**Proof.** Note that all diagonal entries of  $A$  are contained in  $[0, 1-c]$ , so  $-(1-c)I \preceq A^{\otimes} \preceq (1-c)I$ . Combining this with the fact that  $\tanh$  is 1-Lipschitz, we obtain that  $F$  is  $(1-c)$ -Lipschitz. Note that  $\|F(\mathbf{0}) - \mathbf{0}\| \leq \sqrt{n}$ . The result then follows from Lemma 4.7 and the fact that  $F(u) = \mathbb{E}_{\mu_{h+u}} A^{\otimes} x$ . ◀

Using this, for small enough  $\|A\|_F$ , we can obtain the exponential tails necessary to bound the TV-distance in Lemma 4.4. This fits in with the general fact that Ising models with small  $\|J\|_F$  are well-approximated by product distributions [31], giving approximation guarantees for variational methods in this regime. We state the following lemma more generally with a higher-order term, so that we can also apply it for the  $p$ -spin model.

► **Lemma 4.9.** *There is a constant  $c_3$  such that the following holds. Suppose  $H(x) = \langle h, x \rangle + \frac{1}{2} \langle x, Ax \rangle + H_{\geq 3}(x)$  where  $A$  is symmetric and  $H_{\geq 3}(x) = \sum_{|I| \geq 3} a_I x^I$  contains the terms of degree  $\geq 3$ . If  $\delta < c_3$ ,*

$$\max_{x \in \{\pm 1\}^n} \|\nabla^2 H(x)\|_F \leq \delta \quad \text{and} \quad \max_{x \in \{\pm 1\}^n} \|\nabla H_{\geq 3}(x)\| \leq \delta,$$

then the output of `QuadraticApproxRejectionSampler` (Algorithm 2) is at most  $\varepsilon$  in TV distance from  $\mu$ , and the acceptance probability in the call to `ApproxRejectionSampler` is at least  $\frac{1}{2c} = \frac{1}{2} \left(\frac{\varepsilon}{2}\right)^{\frac{\delta}{c_3 - \delta}}$ .

In the special case that  $H_{\geq 3}(x) = 0$ , the assumption simplifies to  $\|A^{\otimes}\|_F \leq \delta$ .

**Proof.** Let

$$f(x) = H(x) - \langle h + \hat{h}, x \rangle = \frac{1}{2} \langle x, Ax \rangle - \langle \hat{h}, x \rangle + H_{\geq 3}(x).$$

To use Theorem 4.6, we calculate  $\mathbb{E}[\|\nabla f\|^2]$ . First note that  $\mathbb{E}_{x \sim \text{Uniform}(\{\pm 1\}^n)} \nabla^2 H_{\geq 3}(x) = O$  (because for any  $i, j \in [n]$  and  $|I| \geq 3$ , we have  $\mathbb{E}_{x \sim \text{Uniform}(\{\pm 1\}^n)} x^I \setminus \{i, j\} = 0$ ) so by Jensen's inequality

$$\begin{aligned} \left\| A^{\otimes} \right\|_F &= \left\| A^{\otimes} + \mathbb{E}_{x \sim \text{Uniform}(\{\pm 1\}^n)} \nabla^2 H_{\geq 3}(x) \right\|_F \\ &\leq \mathbb{E}_{x \sim \text{Uniform}(\{\pm 1\}^n)} \left\| A^{\otimes} + \nabla^2 H_{\geq 3}(x) \right\|_F \leq \max_{x \in \{\pm 1\}^n} \left\| \nabla^2 H(x) \right\|_F \leq \delta. \end{aligned}$$

Let  $\bar{x} = \mathbb{E}_{\mu_{h+\hat{h}}} x$ . From Lemma 4.8 we have that the output  $\hat{h}$  of fixed point iteration satisfies  $\left\| A^{\otimes} \bar{x} - \hat{h} \right\| \leq \delta$ . We then have

$$\begin{aligned} \mathbb{E}_{\mu_{h+\hat{h}}} [\|\nabla f\|^2] &= \mathbb{E}_{\mu_{h+\hat{h}}} \left[ \left\| A^{\otimes} x - \hat{h} + \nabla H_{\geq 3}(x) \right\|^2 \right] \\ &\leq 2\mathbb{E}_{\mu_{h+\hat{h}}} \left[ \left\| A^{\otimes} (x - \bar{x}) + A^{\otimes} \bar{x} - \hat{h} \right\|^2 \right] + 2\mathbb{E}_{\mu_{h+\hat{h}}} \left[ \|\nabla H_{\geq 3}(x)\|^2 \right] \\ &= 2\mathbb{E}_{\mu_{h+\hat{h}}} \left[ \left\| A^{\otimes} \bar{x} - \hat{h} \right\|^2 + \left\| A^{\otimes} (x - \bar{x}) \right\|^2 + \|\nabla H_{\geq 3}(x)\|^2 \right] \\ &\leq 2 \left[ \left\| A^{\otimes} \bar{x} - \hat{h} \right\|^2 + \left\| A^{\otimes} \right\|_F^2 + \mathbb{E}_{\mu_{h+\hat{h}}} \|\nabla H_{\geq 3}(x)\|^2 \right] \leq 6\delta^2 \end{aligned} \quad (5)$$

using the fact that the entries of  $x - \bar{x}$  are independent, mean 0, with variance at most 1. Hence, by Theorem 4.6,  $f(X) - \mathbb{E}f(X)$  is  $O(\delta)$ -sub-exponential, and so is  $f(Z) - f(X)$ , and there exists  $c_3$  so that

$$\mathbb{P}(|f(Z) - f(X)| \geq t) \leq 2e^{-\frac{c_3 t}{\delta}}.$$

Then for  $c = \left(\frac{2}{\varepsilon}\right)^{\frac{\delta}{c_3 - \delta}}$ ,

$$\begin{aligned} \mathbb{E}[(R - c)\mathbb{1}_{R \geq c}] &\leq \int_{\ln c}^{\infty} e^t \cdot \mathbb{P}(f(Z) - f(X) \geq t) dt \\ &\leq \int_{\ln c}^{\infty} e^t 2e^{-\frac{c_3 t}{\delta}} dt \leq 2 \int_{\ln c}^{\infty} e^{-(\frac{c_3}{\delta} - 1)t} dt = 2c^{-(\frac{c_3}{\delta} - 1)} = \varepsilon. \end{aligned} \quad (6)$$

Moreover, by Jensen's inequality,  $\mathbb{E}R \geq e^{\mathbb{E}[f(Z) - f(X)]} = 1$ . Hence by Theorem 4.6, the output is at most  $\varepsilon$  in TV distance from  $\mu$  and the acceptance probability is at least  $\frac{1}{2c}$ . ◀

#### 4.4 Analysis of the Parallel Ising Sampler

► **Lemma 4.10.** *Let  $S \subseteq [n]$ , fix  $x_{S^c} \in \{\pm 1\}^{S^c}$ , and let  $P$  be the distribution on  $\{\pm 1\}^S$  with mass function  $p(x) = \mu_{J,h}(X_S = x | X_{S^c} = x_{S^c})$ , and let  $Q$  be the product distribution in on  $\{\pm 1\}^S$  with mass function  $q(x) \propto \exp(\langle J_{S \times S^c} x_{S^c} + h_S, x \rangle)$ . Then the following hold.*

1.  $\frac{dP}{dQ}(x) \propto \exp\left(\frac{1}{2} \langle x, J_{S \times S} x \rangle\right)$ .
2.  $\mathcal{D}_{\text{KL}}(P \| Q) \leq \|J_{S \times S}\| \cdot |S|$ .

**Proof.** Because  $x_{S^c}$  is constant, expanding the quadratic gives

$$\mu_{J,h}(X_S = x_S | X_{S^c} = x_{S^c}) \propto \exp\left(\frac{1}{2} (2 \langle x_S, J_{S \times S^c} x_{S^c} \rangle + \langle x_S, J_{S \times S} x_S \rangle) + \langle h_S, x_S \rangle\right).$$

Dividing by  $q(x_S)$  gives (1).

For (2), we note that for  $x \in \{\pm 1\}^S$ ,  $|\frac{1}{2} \langle x, J_{S \times S} x \rangle| \leq \frac{1}{2} \|J_{S \times S}\| \|x\|^2 \leq \frac{1}{2} \|J_{S \times S}\| |S|$ . Hence

$$\frac{dP}{dQ}(x) = \frac{\exp\left(\frac{1}{2} \langle x, J_{S \times S} x \rangle\right)}{\int \exp\left(\frac{1}{2} \langle x, J_{S \times S} x \rangle\right) dQ(x)} \leq \frac{e^{\frac{1}{2} \|J_{S \times S}\| |S|}}{e^{-\frac{1}{2} \|J_{S \times S}\| |S|}} = e^{\|J_{S \times S}\| |S|}$$

and  $\mathcal{D}_{\text{KL}}(P \| Q) = \mathbb{E}_P \ln \frac{dP}{dQ} \leq \|J_{S \times S}\| |S|$ .  $\blacktriangleleft$

► **Lemma 4.11** (Bernstein's inequality for supermartingales [28, (1.6)]). *Let  $X_n$  be a martingale adapted to  $\mathcal{F}_n$ . Suppose that  $|X_{n+1} - X_n| \leq L$  and  $\mathbb{E}[|X_{n+1} - X_n|^2 | \mathcal{F}_n] \leq \sigma^2$  with probability 1. Then*

$$\mathbb{P}(X_n - X_0 \geq t) \leq \exp\left(-\frac{t^2}{2(tL + n\sigma^2)}\right).$$

We are now ready to prove our main theorem on the parallel Ising sampler.

**Proof of Theorem 1.2.** We first note that all lines in Algorithm 1 take logarithmic time with  $\text{poly}(n)$  processors (e.g., by a parallel implementation of matrix-vector multiplication). Note that a random subset of specified size  $s$  can be selected by generating a random number for each index, using a parallel sorting algorithm [11], and then selecting the smallest  $s$  elements. We will ignore logarithmic overhead for the rest of the proof.

**Running time is bounded with high probability.** We consider a tree associated with a run of the algorithm, where each node is labeled with a set, constructed as follows. Each node represents a time that `ParallelsingSampler` is called, and each leaf node represents a time that `ApproxRejectionSampler`. Start with a root node  $v_1$  labeled with  $S_1 = [n]$ . A node has  $T$  children, where  $T$  is the number calculated in line 7 of the algorithm. Each node is labeled with subset of indices marking out the submatrix  $J_{S \times S}$  it is given.

Now consider exploring the tree in the following breadth-first manner. We will define a list  $B_t$  which will contain the vertices at the boundary of explored territory and a filtration  $\mathcal{F}_t$ . Let  $B_0 = (v_1)$  and  $\mathcal{F}_0$  be the trivial  $\sigma$ -algebra. Given  $B_t$  and  $\mathcal{F}_t$ , if  $B_t$  is non-empty, define  $B_{t+1}$  and  $\mathcal{F}_{t+1}$  as follows. Let  $v_{t+1}$  be the first vertex in the list  $B_t$ , and let  $B_{t+1}$  be defined from  $B_t$  by removing  $v_{t+1}$  from  $B_t$  and adding its children. Let  $S_{t+1}$  denote the set of indices associated with  $v_{t+1}$ , considered as a set-valued random variable, and  $\mathcal{F}_{t+1} = \sigma(\mathcal{F}_t, S_{t+1})$ . Let  $M_t = |B_t|$ . We have  $M_1 = \lfloor C_2 \ln\left(\frac{n}{\varepsilon}\right) \frac{n}{s} \rfloor$ , and wish to bound the first time  $\tau$  such that  $M_\tau = 0$ . We redefine  $M_{\tau+k} = -k$  (for sake of making  $M_t$  a supermartingale, as we will show below).

For  $t \geq 2$ , consider  $M_t - M_{t-1} | \mathcal{F}_{t-1}$ . Let  $v$  denote the parent of  $v_t$ , and suppose  $v$  is

associated with the set  $R$ , with  $|R| = m$ . Then  $|S_t| = s := \left\lceil \frac{c_1 m}{\left(\ln\left(\frac{2}{\varepsilon_{\text{step}}}\right) + 1\right) \ln\left(\frac{n}{\varepsilon}\right)} \left\| J_{R \times R}^\otimes \right\|_F \right\rceil$ .

(We choose  $c_1 \leq \frac{1}{2} c_3$  to ensure that we always have  $s \leq m$ .) Let  $D_t$  be the number of new children added. If  $\left\| J_{S_t \times S_t}^\otimes \right\|_F \leq c_3$  or  $s = 1$ , then  $v_t$  is a leaf and  $D_t = 0$ . Now consider

$\left\| J_{S_t \times S_t}^\otimes \right\|_F > c_3$ . In the current call to the algorithm,  $s' = \left\lceil \frac{c_1 s}{\left(\ln\left(\frac{2}{\varepsilon_{\text{step}}}\right) + 1\right) \ln\left(\frac{n}{\varepsilon}\right)} \left\| J_{S_t \times S_t}^\otimes \right\|_F \right\rceil$ .

Then  $D_t \leq C_2 \ln\left(\frac{n}{\varepsilon}\right) \frac{s}{s'} \leq \frac{C_2 \left(\ln\left(\frac{2}{\varepsilon_{\text{step}}}\right) + 1\right) \ln\left(\frac{n}{\varepsilon}\right)^2 \left\| J_{S_t \times S_t}^\otimes \right\|_F}{c_1}$ . In either case,  $M_t - M_{t-1} = D_t - 1$ . We have that

$$D_t \leq \frac{C_2 \left(\ln\left(\frac{2}{\varepsilon_{\text{step}}}\right) + 1\right) \ln\left(\frac{n}{\varepsilon}\right)^2 \left\| J_{S_t \times S_t}^\otimes \right\|_F \mathbb{1} \left[ \left\| J_{S_t \times S_t}^\otimes \right\|_F > c_3 \right]}{c_1}. \quad (7)$$

Hence, by Cauchy-Schwarz and Chebyshev's inequality,

$$\begin{aligned}
\mathbb{E}[D_t | \mathcal{F}_{t-1}] &\leq \frac{C_2 \left( \ln \left( \frac{2}{\varepsilon_{\text{step}}} \right) + 1 \right) \ln \left( \frac{n}{\varepsilon} \right)^2}{c_1} \mathbb{E} \left[ \left\| J_{S_t \times S_t}^{\otimes} \right\|_F^2 | \mathcal{F}_{t-1} \right]^{1/2} \\
&\quad \mathbb{P} \left[ \left\| J_{S_t \times S_t}^{\otimes} \right\|_F > \frac{c_3}{\ln \left( \frac{2}{\varepsilon_{\text{step}}} \right) + 1} | \mathcal{F}_{t-1} \right]^{1/2} \\
&\leq \frac{C_2 \left( \ln \left( \frac{2}{\varepsilon_{\text{step}}} \right) + 1 \right) \ln \left( \frac{n}{\varepsilon} \right)^2}{c_1} \mathbb{E} \left[ \left\| J_{S_t \times S_t}^{\otimes} \right\|_F^2 | \mathcal{F}_{t-1} \right]^{1/2} \cdot \frac{\mathbb{E} \left[ \left\| J_{S_t \times S_t}^{\otimes} \right\|_F^2 | \mathcal{F}_{t-1} \right]^{1/2}}{c_3 / \left( \ln \left( \frac{2}{\varepsilon_{\text{step}}} \right) + 1 \right)} \\
&= \frac{C_2 \left( \ln \left( \frac{2}{\varepsilon_{\text{step}}} \right) + 1 \right)^2 \ln \left( \frac{n}{\varepsilon} \right)^2}{c_1 c_3} \mathbb{E} \left[ \left\| J_{S_t \times S_t}^{\otimes} \right\|_F^2 | \mathcal{F}_{t-1} \right]. \tag{8}
\end{aligned}$$

Now because  $S_t$  is uniformly chosen at random from subsets of  $R$  of size  $s$ ,

$$\begin{aligned}
\mathbb{E} \left[ \left\| J_{S_t \times S_t}^{\otimes} \right\|_F^2 | \mathcal{F}_{t-1} \right] &= \mathbb{E}_{S \sim \text{Uniform} \binom{R}{s}} \left[ \left\| J_{S \times S}^{\otimes} \right\|_F^2 \right] \\
&= \sum_{i,j \in R, i \neq j} \binom{s}{m} J_{ij}^2 = \binom{s}{m}^2 \left\| J_{R \times R}^{\otimes} \right\|_F^2 \leq \frac{4c_1^2}{\left( \ln \left( \frac{2}{\varepsilon_{\text{step}}} \right) + 1 \right)^2 \ln \left( \frac{n}{\varepsilon} \right)^2}, \tag{9}
\end{aligned}$$

where we use the fact that  $J_{ii}^{\otimes} = 0$ , all off-diagonal entries have probability  $\left(\frac{s}{m}\right)^2$  of being included in  $S_t$ , and  $s > 1$ . Combining (8) and (9) gives

$$\mathbb{E}[D_t | \mathcal{F}_{t-1}] \leq \frac{4C_2 c_1}{c_3}.$$

Choosing  $c_1$  small enough (depending on  $C_2, c_3$ ), we can ensure that  $\mathbb{E}[M_t - M_{t-1} | \mathcal{F}_{t-1}] = \mathbb{E}[D_t - 1 | \mathcal{F}_{t-1}] \leq -\frac{1}{2}$ , so that  $M_t + \frac{t}{2}$  is a supermartingale for  $t \geq 1$ . By Doob's decomposition we can write  $M_t = A_t + M'_t$  where  $A_{t+1} \leq A_t - \frac{t}{2}$  is a predictable decreasing sequence and  $M'_t$  is a martingale.

We now bound the variance. Using (7),

$$\begin{aligned}
\mathbb{E}[(M'_t - M'_{t-1})^2 | \mathcal{F}_{t-1}] &\leq \mathbb{E}[D_t^2 | \mathcal{F}_{t-1}] \\
&\leq \frac{C_2^2 \left( \ln \left( \frac{2}{\varepsilon_{\text{step}}} \right) + 1 \right)^2 \ln \left( \frac{n}{\varepsilon} \right)^4}{c_1^2} \mathbb{E} \left[ \left\| J_{S_t \times S_t}^{\otimes} \right\|_F^2 | \mathcal{F}_{t-1} \right] \\
&\leq 4C_2^2 \ln \left( \frac{n}{\varepsilon} \right)^2,
\end{aligned}$$

where we use the bound (9). Finally,  $|M'_{t+1} - M'_t| \leq \frac{C_2 \left( \ln \left( \frac{2}{\varepsilon_{\text{step}}} \right) + 1 \right) \ln \left( \frac{n}{\varepsilon} \right)^2}{c_1} \left\| J^{\otimes} \right\|_F$  with probability 1. Let  $T_0$  be the  $T$  computed in line 7 in the first step of the algorithm. By Bernstein's inequality for martingales (Lemma 4.11), for  $t \geq C \ln^4 \left( \frac{n}{\varepsilon} \right) \max \left\{ \left\| J^{\otimes} \right\|_F, 1 \right\} \geq T_0$  for an appropriate constant  $C$  (depending on  $C_2, c_1, C_4$ ),

$$\mathbb{P}(M_{t+1} > 0) = \mathbb{P}((M_{t+1} - M_1) > -T_0) \leq \mathbb{P} \left( M'_{t+1} - M'_1 > \frac{t}{2} - T_0 \right) \leq \frac{\varepsilon}{2}.$$

This shows that with probability  $\geq 1 - \frac{\varepsilon}{4}$ , there are at most  $t_{\max} = C \ln^4 \left( \frac{n}{\varepsilon} \right) \max \{ \|J\|_F, 1 \}$  nodes.

Finally, we note that in the call to `ApproxRejectionSampler`, the parameter needed to obtain error  $\varepsilon_{\text{step}}$  is

$$c = \left( \frac{2}{\varepsilon_{\text{step}}} \right)^{\frac{\delta}{c_3 - \delta}} = \left( \frac{2}{\varepsilon_{\text{step}}} \right)^{\frac{1}{\log(2/\varepsilon_{\text{step}})}} = e$$

and the acceptance probability is  $\geq \frac{1}{2c} = \frac{1}{2e}$ .

The number of tries until acceptance is a geometric random variable, which is subexponential, so standard concentration bounds show that the total number of tries is at most  $O(\ln(\frac{1}{\varepsilon}))$  times the number of calls, with probability  $\geq 1 - \frac{\varepsilon}{2}$ . Putting everything together, we obtain  $O(\max\{\|J\|_F, 1\} \text{poly log}(\frac{n}{\varepsilon}))$  running time with probability  $\geq 1 - \varepsilon$ .

**Output is close in TV distance.** Let  $A$  be a large constant to be determined.

Now consider coupling  $y = y^{(0)}$  with a sequence of random variables  $y^{(1)}, \dots$ , defined inductively as follows. Start with all vertices of the tree of recursive calls unmarked. Now given  $y^{(t)}$ , choose a node (in a fixed manner) all of whose children are marked, and mark it; then replace the output of that call to `ParallellisingSampler` by a sample from the true distribution. We now choose constants so that  $\mathcal{D}_{\text{TV}}(\mathcal{D}(y^{(t)}), \mathcal{D}(y^{(t+1)})) \leq \frac{\varepsilon}{n^A}$ . There are two kinds of replacements to consider, a leaf node and a non-leaf node.

A leaf node corresponds to a call to `ApproxRejectionSampler`. If  $c_3$  is small enough and  $C_4 = A$ , then by Lemma 4.9 and 4.4, the output of `ApproxRejectionSampler` is within  $\frac{\varepsilon}{n^A}$  of the  $\mu_{J_{R \times R}, h}$ .

A non-leaf node corresponds to  $T$  recursive calls to `ParallellisingSampler`. Here we must appeal to mixing for the Ising model. By Theorem 4.1, approximate tensorization of entropy holds with constant  $\frac{1}{c}$ . Hence by Theorem 3.6, there is a constant  $C'_0$  such that if  $C_0 = C'_0 c$ , then for any  $s, t \cdot \frac{n}{s}$  steps of  $s$ -Glauber dynamics results in a distribution  $\nu_t$  satisfying

$$\mathcal{D}_{\text{TV}}(\nu_t \| \mu_{J, h}) \leq \sqrt{\frac{1}{2} \mathcal{D}_{\text{KL}}(\nu_t \| \mu_{J, h})} \leq \sqrt{\frac{1}{2} \mathcal{D}_{\text{KL}}(\nu_0 \| \mu_{J, h})} e^{-C_0 t}.$$

With the product initialization, we have by Lemma 4.10(2) (applied to the whole matrix) that  $\mathcal{D}_{\text{KL}}(\nu_0 \| \mu_{J, h}) \leq \|J\| n \leq 2n$ . Hence there exists a constant  $C'_2$  such that if  $C_2 = C'_2 A/c$ , then with  $T = C_2 \ln(\frac{n}{\varepsilon}) \frac{n}{s}$  steps,  $\mathcal{D}_{\text{TV}}(\nu_T \| \mu_{J, h}) \leq \frac{\varepsilon}{n^A}$ . By Lemma 4.10(1), for the Ising model  $\mu_{J_{R \times R}, h}$  the conditional distribution of  $X_S$  given  $X_{R \setminus S} = y_{R \setminus S}$  is exactly the Ising model  $\mu_{J_{S \times S}, J_{S \times R \setminus S} y_{R \setminus S} + h_S}$ . Given that the conditional distributions are sampled exactly, then the only error is that from not having fully mixed, which we set to be  $\frac{\varepsilon}{n^A}$ .

This chain of coupled random variables establishes  $\mathcal{D}_{\text{TV}}(\mathcal{D}(y), \mathcal{D}(y^{(t)})) \leq \frac{\varepsilon}{n^A}$ . Moreover, for  $t > t_{\text{max}}$ ,  $\mathcal{D}_{\text{TV}}(\mathcal{D}(y^{(t)}), \mu_{J, h}) \leq \frac{\varepsilon}{2}$  by our high-probability bound, as the root node in  $y^{(t)}$  will have been replaced with a perfect sample with probability  $\geq 1 - \frac{\varepsilon}{2}$ . It remains to note that  $t_{\text{max}} = C \ln^4(\frac{n}{\varepsilon}) \max\{\|J\|_F, 1\}$  with  $C$  depending polynomially on  $A$ . Hence we can choose  $A$  such that  $\frac{t_{\text{max}} \varepsilon}{n^A} \leq \frac{\varepsilon}{2}$ , and this finishes the proof. ◀

## Abstract

In this paper, we study the problem of computing the majority function by low-depth monotone circuits and a related problem of constructing low-depth sorting networks. We consider both the classical setting with elementary operations of arity 2 and the generalized setting with operations of arity  $k$ , where  $k$  is a parameter. For both problems and both settings, there are various constructions known, the minimal known depth being logarithmic. However, there is currently no known efficient deterministic construction that simultaneously achieves sub-log-squared depth, simplicity, and has a potential to be used in practice. In this paper we make progress towards resolution of this problem.

For computing majority by standard monotone circuits (gates of arity 2) we provide an explicit monotone circuit of depth  $O(\log_2^{5/3} n)$ . The construction is a combination of several known and not too complicated ideas. Essentially, for this result we gradually derandomize the construction of Valiant (1984).

As one of the intermediate steps in our result we need an efficient construction of a sorting network with gates of arity  $k$  for arbitrary fixed  $k$ . For this we provide a new sorting network architecture inspired by representation of inputs as a high-dimensional cube. As a result we obtain a simple construction that improves previous upper bound of  $4\log_k^2 n$  to  $2\log_k^2 n$ . We prove the similar bound for the depth of the circuit computing majority of  $n$  bits consisting of gates computing majority of  $k$  bits. Note, that for both problems there is an explicit construction of depth  $O(\log_k n)$  known, but the construction is complicated and the constant hidden in  $O$ -notation is huge.

## 1 Introduction

More than 50 years ago, Foster and Stockton [10] devised, in modern terms, an  $O(\log n)$ -depth Boolean circuits (with AND and OR gates of fan-in 2 and also NOT gates) that, given  $n$  input bits, computes the binary representation of their sum. Their construction is explicit, that is, the circuit can be computed in deterministic  $n^{O(1)}$ -time. Moreover, it is relatively simple, where the main trick is to compute in *constant* depth, for any 3 numbers, given in binary, 2 numbers with the same sum, also given in binary. In about  $\log_{3/2} n$  steps, we get from  $n$  input bits to just two numbers, both  $O(\log n)$ -bit long. After that, one can compute their sum in depth  $O(\log n)$ , say, by the grade school algorithm.

An easy consequence of this [20] is that all *symmetric* Boolean functions (those whose value is determined by the number of 1s in the input) are in the class  $NC^1$ , that is, can be computed by  $O(\log n)$ -depth fan-in 2 Boolean circuits. It should be noted, however, that in this construction, it is unavoidable to use NOT gates, even for symmetric functions that are monotone, like the *majority function*, outputting 1 if and only if more than half of the input bits are 1's. This is because inside the construction we compute the sum of input bits in binary, and the digits of this sum are non-monotone functions. Thus, if we want, say, a *monotone* Boolean circuit (only fan-in 2 AND and OR gates with no NOT gates) for the majority function that has depth  $O(\log n)$ , we need other ideas.

Monotone Boolean circuits of depth  $O(\log n)$  for the majority function are known to exist, but to this day, there is no explicit construction as simple as the construction of Foster and Stockton. Namely, there are two constructions, one is extremely simple but randomized (due to Valiant [32]), and the other is explicit but extremely involved (due to Ajtai, Komlós and Szemerédy [1]).

One can represent the construction of Valiant as a ternary tree of depth  $C \cdot \log n$ , where every node computes the majority of its three children [12]. As for the leaves, we simply put a random input variable to every leaf in the tree, independently for different leaves. It is relatively easy to show that, for every input  $x \in \{0, 1\}^n$  and for a large enough absolute constant  $C > 0$ , the probability that the tree computes the value of the majority function on  $x$  is larger than  $1 - 2^{-n}$ . Thus, there exists a choice of putting input variables to leaves that gives us a circuit, computing the majority function for all inputs.

*Derandomizing* the Valiant's construction seems a tempting approach for constructing an explicit  $O(\log n)$ -depth monotone circuit for the majority function. Nevertheless, there has been limited progress in this direction. Hoory, Magen and Pitassi [13] have improved the size of the Valiant's construction, but their construction is still randomized. In turn, Cohen et al. [7] observed how to use hash functions to reduce the number of random bits to  $O(\log n)$  but at the cost of having the probability of error about  $1/\text{polylog}(n)$ , which is not enough for the complete derandomization.

Using a completely different approach, Ajtai, Komlós and Szemerédy [1] constructed an explicit (computable in deterministic polynomial time)  $O(\log n)$ -depth monotone circuit for the majority function. It is worth mentioning that the approach of [1] uses randomness as well, however, they derandomize their construction on the later steps. In fact, they did much more than that – they constructed an explicit *sorting network* with  $O(\log n)$  layers. A sorting network receives on input an array with  $n$  numbers and outputs the same array but with numbers going in the non-decreasing order. In each layer, there is a fixed partition of the entries of the array into pairs, where to each pair one applies a *comparator*, swapping the numbers in a pair if they are not in the non-decreasing order. A sorting network can be easily turned into a monotone circuit for the majority function whose depth is equal to the number of layers of the network. This is because on binary inputs, the comparator can be simulated with one AND gate and one OR gate. The value of the majority function then can be found as the value of the median entry of the sorted array.

For sorting networks, there are several simple and practical constructions with  $\Theta(\log^2 n)$  layers [16, 2, 22]. The construction of Ajtai, Komlós and Szemerédy [1], usually referred to as the AKS sorting network, has  $O(\log n)$  layers, which is asymptotically optimal. However, despite some further simplifications by Paterson [24] and Seiferas [26], this construction is famously very involved with a constant above 1000 before  $\log n$ . As for the lower bounds, there is a folklore  $(2 - o(1)) \log_2 n$  lower bound on the number of layers for networks sorting  $n$  numbers. It was improved by Yao [34] and later by Kahale et al. [15] with the current record about  $3.27 \log_2 n$ .

For constructing just an explicit  $O(\log n)$ -depth monotone circuit for the majority function, we do not necessarily have to construct a sorting network. This gives us a hope that the difficulty of the AKS construction can be avoided. In this paper, we make a progress in this direction, giving the first explicit monotone circuit for the majority function that has sub- $O(\log^2 n)$  depth while not using the AKS methodology at all.

► **Theorem 1.** *There is a polynomial time constructable monotone circuit for  $\text{MAJ}_n$  of polynomial size and depth  $O(\log^{5/3} n)$ .*

Our proof combines several relatively simple steps. The principle component is a *partial derandomization* of the Valiant's construction, using some ideas of Cohen et al. [7] but with different setting of parameters. Next, we repeatedly apply two operations to the resulting randomized circuit. The first operation is a brute-force derandomization, that searches through all possible random bits of the randomized circuit. The second one is a composition with a circuit for  $\text{MAJ}_n$  that consists of  $\text{MAJ}_k$  gates and has depth  $O(\log_k^2 n)$ . Existence of such circuits is known [23, 8], but in this paper, we also give a new simple construction, based on alternative ideas and with better constant before  $\log_k^2 n$ .

In fact, all known construction of such circuits, including a new one from this paper, come from sorting networks with comparators that can simultaneously sort  $k > 2$  positions of the array. We will call them  $k$ -sorting networks. They appear in the literature since the 70s, the setting is mentioned already in the Knuth's book [16, Problem 5.3.4.54], followed by numerous works [30, 23, 3, 21, 8, 18, 28, 11, 35]. They are usually studied to better understand the structure of ordinary sorting networks (for example, a version of AKS sorting network with improved constant relies on  $k$ -sorting network in intermediate constructions [6]). In particular,  $k$ -sorting networks are closely related to recursive constructions of sorting networks. Having a good construction of a  $k$ -sorting network, one can apply it to its own comparators, getting a construction with smaller  $k$ , until eventually  $k$  becomes 2, and we get an ordinary sorting network.

Chvátal shows in his lecture notes [6], the AKS sorting network also generalizes to this setting, giving a construction of depth  $O(\log_k n)$ . However, as with the AKS sorting network itself, this construction is complicated and impractical. In fact, even constructing a  $k$ -network of depth  $O(\log_k^2 n)$  is significantly harder for general  $k$  than just for  $k = 2$ . Standard  $O(\log_2^2 n)$  constructions for 2-sorting networks are based on divide and conquer approach, in which we first recursively sort parts of input and then merge sorted parts together. For the case of  $k$ -sorting networks to get a network of depth  $O(\log_k^2 n)$  with the same approach merging step needs to merge many parts simultaneously and this task becomes non-trivial [19, 27, 25, 5]. We are aware of just two constructions like that: Cypher and Sanz [8] gave a simple and potentially practical  $k$ -sorting network of depth  $\leq 5 \log_k^2 n$  (for  $k \geq \log^4 n$ ) and Parker and Parbery [23] gave a construction of depth  $\leq 4 \log_k^2 n$  (in case when  $n$  is an integral power of  $k$ ). As for the lower bounds, any  $k$ -sorting network with  $n$  inputs must have depth at least  $\log_k n$  because otherwise outputs cannot be connected to all  $n$  inputs. Dobrokhotova-Maikova et al. [9] improved this bound to roughly  $2 \log_k n$ . They also found optimal values of  $k$  for small values of depth  $d$ . More specifically, for sorting networks of depth  $d = 1, 2$  they show that  $k$  cannot be smaller than  $n$ , for  $d = 3$  the optimal value is  $k = \lceil \frac{n}{2} \rceil$  and for  $d = 4$  the optimal value is  $k = \Theta(n^{2/3})$ . These results indicate that small depth  $k$ -sorting networks are not enough for iterative approach to sub-log-squared sorting network and we need either good  $k$ -sorting network constructions of depth greater than 4 or additional ideas.

Our second result is a new architecture for  $k$ -sorting networks. An application of this architecture is a  $k$ -sorting network of depth  $2 \log_k^2 n$ , improving the constant compared to the results of [8, 23]. More precisely, we prove the following theorem.

► **Theorem 2.** *For any  $n$  and for any  $k$  such that  $\log k = \omega(\log \log n)$  (or, to put it differently,  $k$  is growing faster than any  $\text{polylog}(n)$ ), there exists a  $k$ -sorting network of depth at most  $(2 + o(1)) \log_k^2 n$ . The sorting network can be computed in polynomial time.*

The key idea behind this construction is to represent the input array as a hypercube of high dimension and sort various sections of this cube. We note that the idea of representing an array as a multidimensional structure is not new, for example, Leighton [19] in his ColumnSort represented the array as a two dimensional table and Cypher and Sanz [8] use a representation of larger dimension. In our construction it is important that we use the dimension greater than 2 and that the sections of the cube that are used for sorting have non-trivial intersection. On the conceptual level, the main novelty in our construction is the notion of  $s$ -sorting. We call the array  $s$ -sorted if the whole array is sorted correctly apart from some interval of length at most  $s$ . Most (if not all) log-squared-depth sorting network constructions adopt the divide and conquer strategy. The  $O(\log_k^2 n)$ -depth construction in [23] is not an exception, to sort an array of size  $n$ , they split it into subarrays of size  $n/k$ , sort them recursively and merge them afterward. However, merging  $k$  subarrays using  $k$ -sorting network is relatively expensive. To improve over previous construction, we work with  $s$ -sorted subarrays instead. We show how to merge them effectively (using the hypercube idea) and then show how we can build a recursive construction based on them.

It is not hard to see that all outputs of a comparator with  $k$  inputs can be computed by  $\text{MAJ}_{2k}$  gates. This means that Theorem 2 yields an  $(2 + o(1)) \log_k^2 n$ -depth circuit for  $\text{MAJ}_n$ , consisting of  $\text{MAJ}_k$  gates, which is a final component for our construction in Theorem 1

To additionally illustrate applications of our construction, we consider constant depth sorting networks and circuits for majority. We show that there is a depth-4  $\text{MAJ}_k$ -circuit for  $\text{MAJ}_n$  for  $k = O(n^{3/5})$ . As another application we address the question of  $k$ -sorting networks for  $k = O(n^{1/2})$ . In [16] Knuth posed a problem of constructing a minimal depth  $k$ -sorting network for the input of size  $k^2$ . Parker and Parbery [23] gave a construction of depth 9. We improve this to depth 8 at the cost of using comparators of size  $O(k)$  for  $k^2$  input size. The results of [9] show that the depth of such a network must be at least 5.

The rest of the paper is organized as follows. In Section 2 we provide necessary preliminary information. In Section 3 we construct a monotone circuit for majority of depth  $O(\log^{5/3} n)$ . In Section 4 we provide a new construction of  $k$ -sorting networks and deduce the corollaries. In Section 5 we discuss some open problems.

## 2 Preliminaries

We use the standard notation  $[n] = \{1, \dots, n\}$ . We sometimes omit the base of the logarithms, by default we assume that the base is 2.

### 2.1 Sorting Networks

A depth- $d$   $k$ -sorting network with  $n$  inputs consists of  $d + 1$  arrays  $A_1, \dots, A_{d+1}$ , each of length  $n$ . Between any two arrays  $A_i$  and  $A_{i+1}$  there is a *layer of comparators* (the first layer is between  $A_1$  and  $A_2$ , the second layer is between  $A_2$  and  $A_3$ , and so on). A layer of comparators is a partition of the set  $\{1, 2, \dots, n\}$  into subsets of size at most  $k$  called *comparators*.

The input is given in an array  $A_1$  and all other arrays are computed by the network one by one in the following way. If  $S \subseteq [n]$  is a comparator from the  $i$ th layer, then it is applied to the entries  $\{A_i[j] \mid j \in S\}$ . It sorts their values in the non-decreasing order and puts the results into the entries  $\{A_{i+1}[j] \in A_{i+1} \mid j \in S\}$ . We say that a network is *sorting* if for any input  $A_1$  the array  $A_{d+1}$  is sorted.

We reserve the name *sorting network* for 2-sorting networks.

It is well known that to check that the sorting network sorts all possible inputs, it is enough to check that it sorts just 0/1-inputs.

► **Lemma 3** (Zero-one principle [16]). *A network with  $n$  inputs sorts all integer sequences in the non-decreasing order if and only if it sorts all sequences from  $\{0, 1\}^n$  in the non-decreasing order.*

By this principle, when constructing sorting networks, we can assume that each input cell receives either 0 or 1.

The following simple observation will be useful to us.

► **Lemma 4.** *If the  $t$  largest or the  $t$  smallest entries in the array are positioned correctly (i.e., in the last  $t$  cells and in the first  $t$  cells, respectively), then after the application of several comparators they are still positioned correctly.*

**Proof.** We can show by induction on  $i$  that the smallest and the largest entries do not move if they are already positioned correctly. The key observation is that if some of these entries are inputted into one of the comparators  $S$ , they will not be moved. ◀

## 2.2 From Sorting Networks to Majority Circuits

We use the standard notion of Boolean circuits (see, e.g. [14]). As inputs, we allow Boolean variables and Boolean constants 0 and 1. The size of the circuit is the number of gates in it.

Given a  $k$ -sorting network we can get a circuit computing majority from it. More specifically, restrict the inputs to the network to  $\{0, 1\}^n$  and consider one  $k$ -comparator  $S$ . Note that its  $k$ th output is equal to 1 if and only if there is at least one 1 in the input. In other words, the  $k$ th output is equal to OR of input bits. Its  $(k - 1)$ th output is equal to 1 if and only if there are at least two 1s in the input. More generally, it is easy to see that the  $(k - i)$ th output of the  $k$ -comparator outputs a threshold function

$$\text{THR}_k^i(x) = \begin{cases} 1 & \text{if } |x| > i, \\ 0 & \text{otherwise,} \end{cases}$$

where  $|x|$  denotes the weight of the vector  $x \in \{0, 1\}^k$ , that is, the number of 1s in it. We reserve the notation  $\text{MAJ}_k(x)$  for the function  $\text{THR}_k^{k/2}(x)$ .

We can substitute each comparator in the network by  $k$  majority functions. Note that by adding several constants 0 or 1 as inputs to the gate we can convert any  $\text{THR}_k^i$  function into  $\text{MAJ}_{k'}$  with  $k' \leq 2k$ .

Now, it remains to observe that the median bit in the output array computes exactly  $\text{MAJ}_n$ . Thus, as a result, we get the following lemma.

► **Lemma 5.** *Any  $k$ -sorting network of depth  $d$  and size  $s$  can be effectively converted into a circuit of depth  $d$  and size  $ks$  consisting of  $\text{MAJ}_{2k}$  gates and computing majority. In the case  $k = 2$ , we get just a monotone circuit consisting of AND and OR.*

## 2.3 Approximate Majority

By  $\varepsilon$ -approximate majority function  $\text{MAJ}_n^\varepsilon$  we denote the partial function that outputs  $\text{MAJ}_n$  of its input but is defined only on the inputs where the fraction of ones in it is bounded away by  $\varepsilon$  from  $1/2$ .

We need the following result by Viola [33] which can be viewed as a derandomization of the Sipser–Lautemann theorem [29, 17]

► **Theorem 6** ([33]). For any constant  $\varepsilon > 0$ , one can compute  $\text{MAJ}_n^\varepsilon$  explicitly by a monotone circuit of size  $\text{poly}(n)$  and depth  $O(\log n)$ .

(Monotonocity condition is implicit in [33] but easily observable from the construction).

### 2.4 $t$ -Wise Independent Hash Functions

We need the notion of  $t$ -wise independent hash functions.

► **Definition 7.** For integers  $N$  and  $t$  such that  $t \leq N$ , a family of function  $\mathcal{H} = \{h: [N] \rightarrow [N]\}$  is  $t$ -wise independent if for all distinct  $x_1, \dots, x_t \in [N]$  the random variables  $h(x_1), \dots, h(x_t)$  are independent and uniformly distributed in  $[N]$ , when  $h \in \mathcal{H}$  is drawn uniformly.

► **Theorem 8** ([31]). For every integer  $n$  and  $t$  such that  $t \leq 2^n$  there is a family of  $t$ -wise independent functions  $\mathcal{H} = \{h: \{0, 1\}^n \rightarrow \{0, 1\}^n\}$  such that choosing a random function from  $\mathcal{H}$  takes  $nt$  random bits and evaluating a function from  $\mathcal{H}$  takes time  $\text{poly}(n, t)$ .

► **Theorem 9** ([4]). Let  $X$  be the average of  $N$   $t$ -wise independent random variables  $X_1, \dots, X_N \in [0, 1]$  for even  $t$ . Then for any  $\varepsilon > 0$  we have

$$\Pr [|X - \mathbb{E}[X]| \geq \varepsilon] \leq 1.1 \left( \frac{t}{N\varepsilon^2} \right)^{t/2}.$$

## 3 Sub-log-squared Circuit for Majority

In this section, we provide a proof of Theorem 1.

Our goal is to compute  $\text{MAJ}_n$  by an explicit circuit of polynomial size and  $o(\log^2 n)$  depth. We assume for convenience that  $n$  is odd (for even  $n$  we can consider a circuit for  $n + 1$  and substitute one variable by a constant). We start with some inferior circuit and perform several operations that allow us to gradually improve the parameters. However, on our way, we need to consider randomized circuits as well, and apart from size and depth, we will also be interested in the number of random bits and the error probability. More specifically, a circuit is an  $(s, d, r, \text{err})$ -circuit for majority if its size is at most  $2^s$ , depth is at most  $d$ , we can construct a circuit using at most  $r$  random bits and the error probability on each input is at most  $2^{-\text{err}}$ . Here all parameters are functions in the number of inputs  $n$  (we write  $\text{err} = \infty$  when the circuit is correct with probability 1). All circuits we are going to consider are effectively constructible: there is an algorithm that given the values of random bits constructs a circuit in polynomial time in the size of the circuit.

Given a circuit with some parameters, we will use two operations to obtain new circuits. We are introducing these operations in the next two lemmas. Their effect on the circuit is summarized in the table below.

| Initial circuit | Brute-force derandomization | Downward self-reduction  |
|-----------------|-----------------------------|--|
| $s(n)$          | $O(s(n) + r(n))$            | $O(\log n) + s(2k)$  |
| $d(n)$          | $d(n) + O(r(n))$            | $O\left(\left(\frac{\log_2 n}{\log_2 k}\right)^2 d(2k)\right)$ |
| $r(n)$          | 0                           | $r(2k)$  |
| $\text{err}(n)$ | $\infty$                    | $\text{err}(2k) - O(\log n)$                                   |

► **Lemma 10** (Brute-force derandomization). *If there is an  $(s, d, r, 2)$ -circuit  $C$ , then there is an  $(O(s + r), d + O(r), 0, \infty)$ -circuit.*

This lemma allows us to get rid of randomness but increases the depth and the size of the circuit if  $r$  is large.

**Proof.** Consider a randomized circuit  $C_y(x)$ , where  $x \in \{0, 1\}^n$  is an input and  $y \in \{0, 1\}^r$  is the sequence of random bits. Assume  $C_y(x)$  has the parameters, as in the statement of the lemma. Consider circuits  $C_y(x)$  for all possible values of  $y$  and observe that for any  $x$  the fraction of circuits that output  $\text{MAJ}_n(x)$  is at least  $1 - 1/4 = 3/4$ . Thus, if we feed  $C_y(x)$  for all  $y$  into a circuit from Theorem 6 computing  $\text{MAJ}_{2^r}^\varepsilon$ , the output is exactly  $\text{MAJ}_n(x)$ .

The size of the resulting circuit is at most  $2^r \cdot 2^s + \text{poly}(2^r)$ , where the first term corresponds to computing  $C_y(x)$  for all  $y$  and the second term corresponds to computing  $\text{MAJ}_{2^r}^\varepsilon$ . Thus, the size is  $2^{O(s+r)}$ . Since all  $C_y(x)$  can be computed in parallel, the depth of the circuit is at most  $d + O(r)$ . The resulting circuit does not use random bits and is always correct. ◀

► **Lemma 11** (Downward self-reduction). *If there is an  $(s(n), d(n), r(n), \text{err}(n))$ -circuit  $C$ , then for any  $k < n$  there is an  $(O(\log n) + s(2k), O(\log_k^2 n \cdot d(2k)), r(2k), \text{err}(2k) - O(\log n))$ -circuit.*

This operation increases the depth (if  $d(n)$  is sub-log-squared), but allows to reduce other parameters.

**Proof.** Consider a  $k$ -sorting network of depth  $O(\log_k^2 n)$ , given by [23] or by our Theorem 2 (the latter allows only for limited values of  $k$ , but the values we will actually use in the construction below are within the limits). By Lemma 5 this network gives us a monotone circuit with the same parameters consisting of  $\text{MAJ}_{2k}$  gates computing  $\text{MAJ}_n$ , denote this circuit by  $C(x)$ , where  $x \in \{0, 1\}^n$ .

Consider a  $(s(2k), d(2k), r(2k), \text{err}(2k))$ -circuit  $C_y$  on  $k$  inputs, where  $y \in \{0, 1\}^{r(2k)}$ . Fix  $y$  and substitute each  $\text{MAJ}_{2k}$  gate in  $C$  by  $C_y$ . Denote the resulting circuit by  $D_y(x)$ . This is a standard monotone Boolean circuit, its size is  $\text{poly}(n) \cdot 2^{s(2k)}$ , its depth is  $O(\log_k^2 n \cdot d(2k))$  and the number of random bits is  $r(2k)$ .

It remains to show that the error probability is not too large. For this fix some input  $x \in \{0, 1\}^n$ . Consider all  $\text{MAJ}_{2k}$  gates in  $C(x)$  and denote their inputs when  $x$  is fed to  $C$  by  $z^1, z^2, \dots, z^t$ . Here  $t$  is the size of  $C$  and is polynomial in  $n$ .

For each  $z^i$  the probability over random  $y$  that  $C_y(z^i)$  computes  $\text{MAJ}_{2k}(z^i)$  incorrectly is at most  $2^{-\text{err}(2k)}$ . By union bound, with probability at least  $1 - t2^{-\text{err}(2k)}$  we have  $C_y(z^i) = \text{MAJ}_k(z^i)$  for all  $i$  and thus  $D_y(x)$  computes  $\text{MAJ}_n(x)$  correctly. Thus, the probability of error of the resulting circuit is at most

$$t \cdot 2^{-\text{err}(2k)} = 2^{-\text{err}(2k) + O(\log n)}.$$

Now we describe our starting circuit. Interestingly, it is constructed as a partial derandomization of Valiant's construction.

► **Lemma 12.** *There is an explicit circuit for majority with parameters  $(O(\log n), O(\log n), O(\log^3 n), \Omega(\log^2 n))$ .*

We provide the proof of Lemma 12 in Section 3.1 below, but before that, we explain how to finish the construction of the desired circuit for  $\text{MAJ}_n$ .

Starting with the circuit provided by Lemma 12, we first apply downward self-reduction with the parameter  $k$  satisfying  $\log k = C\sqrt{\log n}$  for some big enough constant  $C > 0$ , then we apply brute-force derandomization, and then we apply downward self-reduction again with  $k$  satisfying  $\log k = \log^{2/3} n$ . We summarize the changes in the parameters after each step in the table below.

|                 | Initial circuit    | Step 1   | Step 2                         | Step 3  |
|-----------------|--------------------|--|--------------------------------|---|
|                 |                    | Self-reduction<br>with<br>$\log k = \sqrt{\log n}$ | Brute-force<br>derandomization | Self-reduction<br>with<br>$\log k = \log^{2/3} n$ |
| $s(n)$          | $O(\log n)$        | $O(\log n)$  | $O(\log^{3/2} n)$              | $O(\log n)$                                       |
| $d(n)$          | $O(\log n)$        | $O(\log^{3/2} n)$                                  | $O(\log^{3/2} n)$              | $O(\log^{5/3} n)$                                 |
| $r(n)$          | $O(\log^3 n)$      | $O(\log^{3/2} n)$                                  | 0                              | 0   |
| $\text{err}(n)$ | $\Omega(\log^2 n)$ | $\Omega(\log n)$                                   | $\infty$                       | $\infty$  |

► Remark 13. Note that with the two operations in hand, there are not that many options to apply them to a given initial construction. It is not hard to check that applying downward self-reduction two times in a row is not better than applying it once with the appropriate value of  $k$ . Clearly, there is no need to apply the derandomization step twice. From this, it is not hard to see that our sequence of operations is actually optimal. Once the optimal sequence of operations is established, it is not hard to check that our choice of parameters in downward self-reductions is optimal as well.

### 3.1 Proof of Lemma 12

In this subsection, we are going to prove Lemma 12. The high-level idea is to partially derandomize Valiant's construction. To make the presentation self-contained we first recall the idea behind this construction.

Suppose we have independent random bits  $x, y, z$  that are equal to 1 with probability  $p$  and consider  $\text{MAJ}_3(x, y, z)$ . It is not hard to see that it outputs 1 with probability  $f(p) = p^3 + 3p^2(1-p)$ . Consider  $p = \frac{1}{2} + \varepsilon$  for some  $\varepsilon > 0$  and denote  $\varepsilon' = f(p) - \frac{1}{2}$ . Then

$$\varepsilon' = f(p) - \frac{1}{2} = f(p) - f\left(\frac{1}{2}\right) = f'(\alpha) \left(p - \frac{1}{2}\right) = f'(\alpha)\varepsilon$$

for some  $\alpha \in [\frac{1}{2}, p]$ . Note that  $f'(p) = 6p - 6p^2 = 6p(1-p)$ . It is easy to see that for  $\alpha \in [\frac{1}{2}, \frac{2}{3}]$  we have  $f'(\alpha) \geq \frac{4}{3}$ . Thus, for  $\varepsilon \in [0, \frac{1}{6}]$  we have  $\varepsilon' \geq \frac{4}{3}\varepsilon$ .

Now, we can use this in the following way. Consider  $\text{MAJ}_n$  for odd  $n$  and consider its arbitrary input  $x$ . Without loss of generality, assume that  $\text{MAJ}_n(x) = 1$ . If we draw one variable from  $x$  uniformly at random, it is equal to 1 with probability at least  $\frac{1}{2} + \frac{1}{n}$ . Consider a  $\text{MAJ}_3$  gate and feed to it three independently and uniformly drawn input variables. By the analysis above the output of such a  $\text{MAJ}_3$  gate is equal to 1 with probability at least  $\frac{1}{2} + \frac{4}{3} \cdot \frac{1}{n}$ . Now we can repeat this: consider three such  $\text{MAJ}_3$  gates and feed their outputs to another  $\text{MAJ}_3$  gates. The result is equal to 1 with probability  $\frac{1}{2} + \left(\frac{4}{3}\right)^2 \frac{1}{n}$ . After  $O(\log n)$  many iterations, we get a  $O(\log n)$ -depth randomized circuit consisting of  $\text{MAJ}_3$  gates that output the correct value with probability at least  $\frac{2}{3}$ . Valiant's argument further improves this probability, but we will not need this part of the argument.

The randomized circuit above uses too many random bits. Now we are going to modify the construction in a way, that uses randomness more efficiently. We will use some ideas from [7].

Construct the following circuit consisting of MAJ<sub>3</sub> gates. The circuit contains  $\Theta(\log n)$  layers, each containing  $N = n^3$  gates. The bottom layer consists of input variables, each repeated  $\frac{N}{n} = n^2$  times (it is redundant to copy variables several times, we do this exclusively for the sake of uniformity of the construction). In other layers, each gate computes the MAJ<sub>3</sub> function of some gates from the previous layer. To assign the inputs to each gate, for each layer  $j$  we draw three fresh (and independent of each other)  $t$ -wise independent hash functions  $f_j, g_j, h_j: [N] \rightarrow [N]$  for  $t = \Theta(\log n)$ . For a gate with number  $i$  in layer  $j$  we set its inputs to be gates with numbers  $f_j(i), g_j(i)$  and  $h_j(i)$  in layer  $(j - 1)$ .

Before we finish the construction of the circuit, let us analyze the current part. Consider some input  $x \in \{0, 1\}^n$ , assume without loss of generality that  $\text{MAJ}_n(x) = 1$ . Denote by  $\frac{1}{2} + \varepsilon_i$  the fraction of gates on level  $i$  that output 1. For  $i = 1$  we have  $\varepsilon_1 \geq \frac{1}{n}$ .

Each gate on level  $i$  receives three independent inputs from the previous level. Thus, the probability that it outputs 1 is at least  $\frac{1}{2} + \frac{4}{3}\varepsilon_{i-1}$  (we have shown this above only for  $\varepsilon_{i-1} \leq \frac{2}{3}$ , but these values of  $\varepsilon_{i-1}$  are enough for our construction as well). Thus, the expected fraction of ones in level  $i$  is also at least  $\frac{1}{2} + \frac{4}{3}\varepsilon_{i-1}$ .

Now we would like to use concentration inequality to show that with high probability the fraction of correct values is not much smaller than its expectation. Note that once the outputs of the gates on level  $i - 1$  are fixed, the outputs of the gates on level  $i$  are  $t$ -wise independent.

Let  $\varepsilon = \frac{1}{6n}$  and denote by  $X_i$  the output of  $i$ -th gate. Then by Theorem 9 we have

$$\Pr \left[ \left| \sum_i X_i/N - \left( \frac{1}{2} + (4/3)\varepsilon_{j-1} \right) \right| \geq \varepsilon \right] \leq 1.1 \left( \frac{t}{N\varepsilon^2} \right)^{t/2} = 2^{-\Theta(\log^2 n)}.$$

By union bound the probability that on each level  $\varepsilon_j \geq \frac{4}{3}\varepsilon_{j-1} - \varepsilon$  is at least

$$1 - O(\log n) \cdot 2^{-\Theta(\log^2 n)} = 1 - 2^{-\Theta(\log^2 n)}.$$

Thus, we can show by induction on  $j$  that with probability at least  $1 - 2^{-\Theta(\log^2 n)}$  we have

$$\varepsilon_j \geq \frac{4}{3}\varepsilon_{j-1} - \varepsilon \geq \frac{7}{6}\varepsilon_{j-1} + \frac{1}{6}\varepsilon_{j-1} - \frac{1}{6n} \geq \frac{7}{6}\varepsilon_{j-1},$$

where in the last inequality we use that by induction hypothesis we have  $\varepsilon_{j-1} \geq \left(\frac{7}{6}\right)^{j-1} \cdot \varepsilon_1 \geq \frac{1}{n}$ .

Thus, just like in Valiant's argument, after  $O(\log n)$  iterations, with probability  $1 - 2^{-\Theta(\log^2 n)}$ , we have  $\varepsilon_j \geq \frac{2}{3}$ . At this point, it remains to apply to the last layer a circuit from Theorem 6.

It is easy to see that the size of the resulting circuit is  $\text{poly}(n)$ , the depth is  $O(\log n)$ , error probability is  $2^{-\Theta(\log^2 n)}$ . As for the random bits, note that in the construction we need  $O(\log n)$   $t$ -wise independent hash functions from  $[N]$  to  $[N]$ . By Theorem 8 there are families of such functions defined using  $O(t \log N)$  random bits. In total we need

$$O(\log n) \cdot O(t \log N) = O(\log^3 n)$$

random bits.

This finishes the proof of Lemma 12.

► **Remark 14.** Instead of applying a circuit for Approximate Majority to the last layer, we could do the following: sample  $m = O(\log^2 n)$  gates from the last layer uniformly at random and then compute the majority on these  $m$  gates using some simple circuit of depth  $O(\log^2 m)$ . By Chernoff's inequality, this adds at most  $2^{-\Omega(m)} = 2^{-\Theta(\log^2 n)}$  to the error probability, and we need  $O(\log^3 n)$  random bits. In turn, the increase in depth and size is negligible.

**4** *k*-Sorting Network Construction

**4.1** Proof Strategy

Before we proceed to the proof we would like to illustrate the idea considering some specific value of *k*. For convenience, we assume that *n* is a perfect cube.

► **Lemma 15.** *Assume that  $n = t^3$  for natural  $t$ . Then there is a depth-4 *k*-sorting network with  $k = 2t^2 = 2n^{2/3}$ .*

We present the proof using a geometric interpretation of an input array as a three-dimensional cube. However, note that a similar result is implicit in [19] and it is essentially the same construction, just stated in different terms. We also note that it is known that this is the optimal (up to a constant factor) value of *k* for depth-4 sorting networks [9].

■ **Figure 1** Sorting network for  $k = 2n^{2/3}$  (here  $n = 125$ ,  $k = 50$  and  $t = 5$ ).

**Proof.**

**Step 1 – construction.** We represent entries of an input array as a 3-dimensional cube with the side *t* (see Figure 1a). We place the first *t*<sup>2</sup> entries of an array in the bottom layer of the cube, the next *t*<sup>2</sup> entries in the second layer of the cube and so on. In each layer the entries are positioned row by row.

To be more precise, assume that the array *A* is enumerated as  $[a_1, \dots, a_n]$ . We reenumerate the same array as

$$[a_{111}, a_{112}, \dots, a_{11t}, a_{121}, \dots, a_{12t}, \dots, a_{ttt}].$$

That is, entries of an array are enumerated by sequences  $(x, y, z) \in \{1, \dots, t\}^3$  in the lexicographic order. In Figure 1  $a_{xyz}$  corresponds to a subcube with coordinates  $(x, y, z)$ .

In the first layer of the sorting network we split the cube into vertical slices of width 1 and feed each slice to a  $t^2$ -comparator (see Figure 1b). To be more precise, for each  $i = 1, \dots, t$  we feed entries  $a_{xyi}$  for all  $x, y$  into one comparator. On the second layer of the network we split the cube into vertical slices of width 1 in another direction and feed each slice to a  $t^2$ -comparator (see Figure 1c). In other words, for each  $i = 1, \dots, t$  we feed entries  $a_{xiz}$  for all  $x, z$  into one comparator. On the third layer we split the cube into horizontal slices of width 2 (for odd  $t$  the last slice is of width 1) and feed the slices to comparators of arity at most  $2t^2$  (see Figure 1d). Finally, on the fourth layer of the network we split the cube into horizontal slices of width 2 again, but now the first slice is of width 1 (for even  $t$  the last slice is of width 1 as well). Thus, the slices on this layer are shifted compared to the previous one (see Figure 1e).

**Step 2 – correctness.** It remains to prove that this sorting network sorts correctly. Consider any input  $x \in \{0, 1\}^n$ . Note that the cube consists of  $t^2$  vertical columns with  $t$  entries in each column: each column  $A_{yz}$  is obtained by fixing  $y$  and  $z$  in  $a_{xyz}$  and considering all possible  $x$ . We are interested in the weight  $w_{yz}$  of each column, that is the number of 1s in it. For the input  $A$  the weights of the columns can be any numbers from 0 to  $t$ . Now consider the array after the first layer of the network. Note that now each vertical slice of the first layer of the network is sorted. This means that in each of these slices in the first several rows (from bottom to top) there are only 0s, then there might be a row containing both 0s and 1s, and then all remaining rows contain 1s. In particular, the weights of two columns in the same slice differ by at most 1.

Now consider the second layer of the network and consider two different slices  $S_i = \{a_{x,i,z} \mid x, z \in [t]\}$  and  $S_j = \{a_{x,j,z} \mid x, z \in [t]\}$ . Note that each of them contains exactly one column from each slice of the first layer. We know that the weights of the columns in the same slice of the first layer differ by at most 1. Thus, in total, the number of 1s in two slices of the second layer differ by at most  $t$ . In other words, for each  $z$  the first slice contains the column  $A_{iz}$  and the second slice contains the column  $A_{jz}$ . We know that on the input of the second layer of the network  $|w_{iz} - w_{jz}| \leq 1$ . Thus,

$$\left| \sum_z w_{iz} - \sum_z w_{jz} \right| \leq t.$$

Denote by  $r_i$  the number of rows in slice  $S_i$  that consists of only 1s after the second layer of the network. We just showed that the slice  $S_i$  can have one more extra row of 1s, one less row of 1s or something in between. Overall, for the number  $r_j$  of rows consisting of 1s in  $S_j$  we have  $|r_i - r_j| \leq 1$ . As a result, the weights of columns in slices  $S_i$  and  $S_j$  can differ by at most 2. Since this is true for any  $i$  and  $j$ , we have that the weights of all columns in the cube after the second layer of the sorting network differ by at most 2.

To put it another way, there is a horizontal slice of width 2, such that below this slice we have only 0s and above this slice we have only 1s. Thus it remains to sort entries of this slice. Note that on layers 3 and 4 of the network there is a comparator that sorts exactly this slice. Note that by Lemma 4 all other comparators of layers 3 and 4 do not harm the sorting. ◀

This argument can be extended to the cubes of arbitrary dimension  $d$ . More specifically, for  $n = t^d$  and for  $k = (d-1)t^{d-1}$  we can represent entries of an input array as a  $d$ -dimensional cube with side  $d$ , sort “vertical” slices (we need to fix one of the coordinates in  $d$ -dimensional space as vertical) in all  $d - 1$  directions and then sort horizontal slices. This results into

$(d - 1)$  layers of the sorting network and for horizontal slices we need recursive calls for the arrays of size approximately  $2dt^{d-1}$ . Actually, it is expensive to make two recursive calls for horizontal layers, instead we use an additional trick to make just one recursive call.

Although our  $k$ -sorting network construction can be expressed in terms of high dimensional hypercubes, we prefer to give a more general exposition, using a concept of  $s$ -sorted arrays.

## 4.2 Merging $s$ -Sorted Arrays

The following definition plays a key role in our sorting network construction.

► **Definition 16.** *A 0/1-array  $A$  of length  $n$  is  $s$ -sorted if there is an integer interval  $I = \{i, \dots, i + s - 1\} \subseteq [n]$ , such that  $A[j] = 0$  for  $j < i$  and  $A[j] = 1$  for  $j \geq i + s$ . We call  $I$  unsorted interval.*

As an immediate corollary of Lemma 4, we get the following.

► **Corollary 17.** *Suppose a sorting network gets an  $s$ -sorted array with unsorted interval  $I$ . Then the output is also  $s$ -sorted with  $I$  as an unsorted interval.*

We give a construction of a depth-1 sorting network that “merges”  $p$  arrays of length  $n$  that are already  $s$ -sorted into one array which is  $(sp + O(np^2/k))$ -sorted, where  $k$  is the arity of the sorting network.

► **Lemma 18.** *Assume that  $k \geq tp$  for some integers  $t$  and  $p$ . Suppose we have  $p$   $s$ -sorted arrays of size  $n$  each. Assume additionally that  $n$  is divisible by  $t$ . Then there is a depth-1  $k$ -sorting network that merges these arrays into one array of size  $np$  that is  $(sp + 2\frac{np}{t})$ -sorted. If additionally we assume that  $s$  is divisible by  $n/t$ , then the resulting array is  $(sp + \frac{np}{t})$ -sorted.*

**Proof.** Represent each array as a table with  $\frac{n}{t}$  columns and  $t$  rows. We assume the following ordering on the entries of this table: to compare two entries, we first compare the indices of their rows, and then the indices of their columns. Position the tables one under another in a unified table with  $tp$  rows. Note that  $tp \leq k$  and apply  $k$ -comparator to each column in parallel. We claim that the resulting array in the large table is  $(sp + 2\frac{np}{t})$ -sorted.

To see that observe, that in each small table, an unsorted interval of length at most  $s$  occupies at most  $\lceil \frac{st}{n} \rceil + 1$  rows (any other row either consists entirely of 0s or entirely of 1s). In the large table, this gives us at most  $p \left( \lceil \frac{st}{n} \rceil + 1 \right)$  non-constant rows. After sorting each column individually, 0-rows will move to the top, 1-rows will move to the bottom and all other  $p \left( \lceil \frac{st}{n} \rceil + 1 \right)$  rows will be in between on them. They constitute an unsorted interval and the size of it is at most

$$\frac{n}{t} \cdot p \left( \left\lceil \frac{st}{n} \right\rceil + 1 \right).$$

For general  $s$  we can upper bound this as follows

$$\frac{n}{t} \cdot p \left( \left\lceil \frac{st}{n} \right\rceil + 1 \right) \leq \frac{n}{t} \cdot p \left( \frac{st}{n} + 2 \right) = sp + 2\frac{np}{t}.$$

If  $s$  is divisible by  $n/t$ , note that we can just drop the rounding operation and the size of an unsorted interval is at most

$$\frac{n}{t} \cdot p \left( \left\lceil \frac{st}{n} \right\rceil + 1 \right) = \frac{n}{t} \cdot p \left( \frac{st}{n} + 1 \right) = sp + \frac{np}{t}. \quad \blacktriangleleft$$

Applying previous lemma several times we get the following.

► **Lemma 19.** Consider arbitrary  $n$  and  $k$  and denote  $t = \lfloor \sqrt{k} \rfloor$ . Then there is a  $k$ -sorting network of depth  $\lceil \log_t n \rceil - 1$  that on any input outputs an  $s$ -sorted array for  $s \leq \frac{2\lceil \log_t n \rceil n}{t}$ .

**Proof.** Denote  $d = \lceil \log_t n \rceil$  and observe that  $n \leq t^d$ . Introduce the following notation:

$$n_i = \begin{cases} t^{i+1} & \text{for } i = 1, \dots, d-2, \\ t^{d-1}p & \text{for } i = d-1, \end{cases}$$

where  $p$  is such that  $t^{d-1}(p-1) < n \leq t^{d-1}p$ . In particular, since  $p \geq 2$ , we have  $p-1 \geq p/2$  and

$$n > t^{d-1}(p-1) \geq t^{d-1}p/2.$$

For the convenience of presentation, we add  $t^{d-1}p - n$  dummy inputs equal to 1 to the end of the array to make the size of the input to be equal to  $t^{d-1}p$ . By Lemma 4 these inputs will never change their position and can be removed from the sorting network.

We start with an unsorted array as an input. Applying Lemma 18 several times, we get the array consisting of blocks that are  $s$ -sorted for some  $s$ . More specifically, after level  $i$  of the network we get the blocks of size  $n_i$  that are  $s_i$  sorted for

$$s_i = \begin{cases} (i-1)t^i & \text{for } i = 1, \dots, d-2, \\ (d-2)t^{d-2}p & \text{for } i = d-1. \end{cases}$$

On the first step we split the input into blocks of size  $t^2$  and apply comparators to them, the resulting blocks are 0-sorted.

On the  $i$ -th step for  $i = 2, \dots, d-1$  we already have blocks of size  $n_{i-1} = t^i$  from the previous step that are  $s_{i-1}$ -sorted for  $s_{i-1} = (i-2)t^{i-1}$ . Note that  $n_{i-1} = t^i$  is divisible by  $t$  and  $s_{i-1}$  is divisible by  $n_i/t = t^{i-1}$ . We apply Lemma 18 and for  $i < d-1$  get blocks of size  $n_{i-1}t = n_i$  that are  $s$ -sorted for  $s = s_{i-1}t + n_{i-1} = (i-1)t^i$ . For  $i = d-1$  we have just  $p$  subarrays to merge and after the step we get the whole array of size  $t^{d-1}p$  that is  $s$ -sorted for  $s = (d-3)t^{d-2}p + \frac{t^{d-1}p}{t} = (d-2)t^{d-2}p$ .

Finally, observe that

$$s \leq (d-2)t^{d-2}p \leq d \frac{2n}{t}$$

as desired. ◀

### 4.3 Computing Majority

Before constructing a sorting network we solve a simpler task of computing majority function.

► **Theorem 20.** For any  $n$  and for any  $k$  such that  $\log k = \omega(\log \log n)$  (or, to put it differently,  $k$  is growing faster than any  $\text{polylog}(n)$ ), there exists a  $\text{MAJ}_k$ -circuit for  $\text{MAJ}_n$  of depth at most  $(2 + o(1)) \log_k^2 n$ .

The rest of the section is devoted to the proof of Theorem 20.

First observe that to compute  $\text{MAJ}_n$  correctly by a monotone circuit it is enough to compute it correctly on minterm and maxterm inputs: the computation on other inputs follows by monotonicity. Thus, we can assume in our construction that the input contains almost the same number of 0s and 1s. We will construct a sorting network that sorts all such inputs correctly. From the sorting network we get the circuit of the same depth.

## 50:14 Towards Simpler Sorting Networks and Monotone Circuits for Majority

Suppose we need to sort an array of size  $n$  with approximately the same number of 0s and 1s. We apply Lemma 19 to the array. This results in a  $Y$ -sorted array for  $Y = \frac{2\lceil \log_t n \rceil n}{t}$  for  $t = \lfloor \sqrt{k} \rfloor$ . Since the number of 0s and 1s in the array is approximately equal, the smallest  $\frac{n}{2} - Y$  and the largest  $\frac{n}{2} - Y$  elements are sorted correctly (otherwise, the length of the unsorted interval is larger than  $Y$ ). Thus, it remains to sort a specific interval of length  $2Y$  and we can do this recursively.

Overall, we get the following recursive relation.

$$T(n) \leq \lceil \log_t n \rceil - 1 + T(2Y) \leq \log_t n + T\left(\frac{4\lceil \log_t n \rceil n}{t}\right).$$

To solve this recursive relation we use the following lemma.

► **Lemma 21.** *Assume that  $\log k = \omega(\log \log n)$ . Suppose that  $T(n) = \text{const}$  for  $n$  up to some constant and*

$$T(n) \leq 2\log_k n + C + T\left(\left\lceil \frac{D(\log_k n)n}{\sqrt{k}} \right\rceil\right)$$

for some constants  $C$  and  $D > 0$ . Then  $T(n) \leq (2 + o(1))\log_k^2 n$ .

**Proof.** To simplify the presentation, we ignore rounding of the argument of  $T$  first, and address it later. Denote  $\alpha = \frac{\sqrt{k}}{D\log_k n}$ .

We have

$$\begin{aligned} T(n) &\leq 2\log_k n + C + T\left(\frac{n}{\alpha}\right) \\ &\leq 2\log_k n + C + 2\log_k \frac{n}{\alpha} + C + T\left(\frac{n}{\alpha^2}\right) \\ &\leq 2 \sum_{i=0}^{\log_\alpha n} \left(\log_k \frac{n}{\alpha^i} + C\right) \\ &= 2(\log_k n + (\log_k n - \log_k \alpha) + (\log_k n - 2\log_k \alpha) + \dots + 0) + 2C \log_\alpha n \\ &\leq 2 \frac{\log_k n \log_k n}{\log_k \alpha} + 2C \log_\alpha n = \log_k^2 n \log_\alpha k + 2C \log_\alpha n. \end{aligned}$$

It is easy to see that the term  $2C \log_\alpha n$  is negligible, since  $\alpha \gg k^{1/3}$ .

We analyze  $\log_\alpha k$  factor separately:

$$\begin{aligned} \log_\alpha k &= \log_{\frac{\sqrt{k}}{D\log_k n}} k = \frac{\log_2 k}{\log_2 \frac{\sqrt{k}}{D\log_k n}} \leq \frac{\log_2 k}{\frac{1}{2} \log_2 k - D - \log_2 \log_k n} \\ &= \frac{\log_2 k}{\frac{1}{2} \log_2 k - D - \log_2 \log_2 n + \log_2 \log_2 k}. \end{aligned}$$

For  $\log k = \omega(\log \log n)$  this term is  $2 + o(1)$  and we have

$$T(n) \leq (2 + o(1))\log_k^2 n.$$

To address the rounding operation, note that  $\lceil \frac{n}{\alpha} \rceil \leq \frac{n}{\alpha} + 1 \leq \frac{2n}{\alpha}$  for  $\frac{n}{\alpha} \geq 1$ . Thus, in the presence of rounding we will have  $\sum_i \log_k \frac{2n}{\alpha}$  in the calculation above instead of  $\sum_i \log_k \frac{n}{\alpha}$ . This amounts to substituting  $D$  by  $2D$  and does not change the result of the calculation since  $D$  is an arbitrary constant. ◀

## 4.4 Constructing Sorting Network

In this section, we finish the proof of Theorem 2.

We adopt the same strategy as for the computation of majority. More specifically, we apply Lemma 19 recursively to get  $s$ -sorted array for smaller and smaller  $s$ . However, now our task is more tricky. In the proof of Theorem 20 when we get to an  $s$ -sorted array we know exactly where the unsorted interval is located (in the middle of the array). However, now we need to sort arbitrary input arrays and an unsorted interval can be anywhere.

We construct the network recursively. We assume that at the beginning of each step, we have an  $s$ -sorted array (at the beginning of the process  $s = n$ ). Denote the unsorted interval by  $A$ ,  $|A| \leq s$ . Split the array into consecutive blocks  $B_1, \dots, B_p$  of size  $s$  (the last block  $B_p$ ) might be smaller.

The recursive step consists of two stages. In the first stage, we split the array into blocks  $B_1 \cup B_2, B_3, \cup B_4$ , and so on, each block of size  $2s$  (one last block might be smaller). In the second stage, we split the array into blocks  $B_1, B_2 \cup B_3, B_4 \cup B_5$ , and so on (again the last block might be smaller than  $2s$ ). Before describing each of the stages, observe that either in the first stage or in the second stage (or in both) the interval  $A$  falls completely into one of the blocks. Indeed,  $A$  can intersect with at most two consecutive blocks  $B_i, B_{i+1}$  and in one of the stages, they form a single block.

In the first stage, we apply Lemma 19 to each of the blocks  $B_1 \cup B_2, B_3, \cup B_4, \dots$  separately. As a result, each block is  $s'$ -sorted for  $s' \leq \frac{4 \lceil \log_{\lfloor \sqrt{k} \rfloor} n \rceil s}{\lfloor \sqrt{k} \rfloor}$ . Moreover, if the block consisted of only 0s and 1s, then it does not change.

If  $A$  is contained in one of the blocks of the first stage, we are already done: there is only one initially unsorted block that by Lemma 19 after the step is  $s'$ -sorted. By Corollary 17 this property remains true after the additional comparators we apply for the other case.

If  $A$  is split between two blocks of the first stage, then after the stage we have two consecutive unsorted blocks, each of them is  $s'$ -sorted. Denote unsorted parts by  $C_1, C_2$ . Note that by Corollary 17  $C_1, C_2 \subseteq A$  and thus,  $C_1$  and  $C_2$  fall into one block of the second stage. It is tempting to apply Lemma 19 to the blocks of the second stage as well. However, this application is too expensive and will not result in the desired bound.

Instead we do the following. We represent each block of the second stage (of size at most  $2s$ ) as a table with  $p = \lceil 2s/k \rceil$  columns and  $k$  rows, filled in row by row from top to bottom. For convenience, if the last row is not complete, add dummy variables equal to 1 to complete the row.

Each of the intervals  $C_1, C_2$  occupy at most  $\lceil s'/p \rceil + 1$  rows. There might be another row that contain a switch between blocks  $B_i$  and  $B_{i+1}$ . Each other row consist either entirely of 0s, or entirely of 1s. Denote the number of all 0 rows by  $a$  and the number of all 1 rows by  $b$ .

We apply a comparator to each column separately. As a result, each column will contain  $a$  zeros in the beginning,  $b$  ones in the end and some part in between. The number of rows in the middle part is at most  $2 \lceil s'/p \rceil + 3$ . The number of entries in these rows is at most

$$s'' = p(2 \lceil s'/p \rceil + 3) \leq 2s' + 5p \leq 3s'$$

for large enough input size. Thus, after the second stage we get  $s''$ -sorted array and we are done with the recursion step.

Thus, we get that  $s'' \leq 12 \frac{\lceil \log_t n \rceil s}{t}$  and we get the following recursive relation

$$T(n) \leq \log_t n + T\left(\frac{12 \lceil \log_t n \rceil n}{t}\right).$$

We apply Lemma 21 again to get  $T(n) \leq (2 + o(1)) \log_k^2 n$ .

This finishes the proof of Theorem 2.

## 4.5 Other Applications

In this section we give two more examples of results that follow from our construction.

► **Lemma 22.** *There is a MAJ<sub>k</sub>-circuit of depth 4 computing MAJ<sub>n</sub> for  $k = O(n^{3/5})$ .*

**Proof.** Denote  $r = \lceil n^{1/5} \rceil$ . For simplicity we pad the input with constants 0 and 1 to make the size of the array  $r^5$  without changing the output of majority. We will use  $k$ -sorters for  $k = 4r^3$ .

As in the proof of Theorem 20 it is enough to compute MAJ<sub>n</sub> on minterms and maxterms, thus we can assume that there are approximately equal number of 0s and 1s in the input.

We will build a  $k$ -sorting network and the existence of the circuit follows. On the first layer of the network we split the input into blocks of size  $r^3$  and sort them. On the second layer we use Lemma 18 with  $p = r$  and  $t = r^2$ . As a result we get blocks of size  $r^4$  that are  $r^2$ -sorted. On the third level we apply Lemma 18 again with the same values of  $p$  and  $t$ . As a result we have that the whole input is now  $2r^3$ -sorted. On the last layer of the network just as in the proof of Theorem 20 we apply  $4r^3$ -comparator to the middle of the array. ◀

In [16] Knuth posed a problem of constructing a minimal depth  $k$ -sorting network for the input of size  $k^2$ . Parker and Parbery [23] gave a construction of depth 9. Here we slightly improve on this at the cost of using comparators of size  $O(k)$ .

► **Lemma 23.** *There is a  $k$ -sorting network of depth 8 that sorts an array of size  $n$  with  $k = O(n^{1/2})$ .*

**Proof.** As usual pad an array with constants to make  $n = r^4$  for some integer  $r$ . Thus  $k = O(r^2)$ .

We follow the same strategy as in Section 4.4. First we apply Lemma 19 that uses three layers of network and results in a  $s$ -sorted array for  $s = O(r^3)$ . Then, we apply Lemma 19 again to the blocks of size  $O(r^3)$  to get a network of depth 2 that results in each block being  $O(r^2)$ -sorted. Then we apply one more layer to merge unsorted intervals in different blocks to get the array that is  $O(r^2)$ -sorted. Finally, we again split the array into blocks, this time of size  $O(r^2)$  to complete the sorting using two layers. In total we use  $3 + 2 + 1 + 2 = 8$  layers. ◀

## 5 Conclusion

The obvious open problems are to come up with explicit constructions of sorting networks and monotone circuits for majority of smaller depth. One specific problem is to extend our  $O(\log^{5/3} n)$  construction to sorting networks. The obstacle that we encountered is that there is no randomized construction of a low-depth sorting network that we can use as a start. Another interesting question is to extend our  $O(\log^{5/3} n)$  construction to get a MAJ<sub>k</sub>-circuit for MAJ<sub>n</sub> of depth  $O(\log_k^{5/3} n)$ . Such a construction can be used instead of  $O(\log_k^2 n)$ -depth circuit in downward self-reduction to further improve the upper bound. Again, the obvious obstacle is that it is not clear how to get a starting construction.

## Abstract

A central open question within meta-complexity is that of NP-hardness of problems such as MCSP and  $MK^tP$ . Despite a large body of work giving consequences of and barriers for NP-hardness of these problems under (restricted) deterministic reductions, very little is known in the setting of randomized reductions. In this work, we give consequences of randomized NP-hardness reductions for both approximating and exactly computing time-bounded and time-unbounded Kolmogorov complexity.

In the setting of *approximate*  $K^{\text{poly}}$  complexity, our results are as follows.

1. Under a derandomization assumption, for any constant  $\delta > 0$ , if approximating  $K^t$  complexity within  $n^\delta$  additive error is hard for SAT under an honest randomized non-adaptive Turing reduction running in time polynomially less than  $t$ , then  $\text{NP} = \text{coNP}$ .
2. Under the same assumptions, the worst-case hardness of NP is equivalent to the existence of one-way functions.

Item 1 above may be compared with a recent work of Saks and Santhanam [39], which makes the same assumptions except with  $\omega(\log n)$  additive error, obtaining the conclusion  $\text{NE} = \text{coNE}$ .

In the setting of *exact*  $K^{\text{poly}}$  complexity, where the barriers of Item 1 and [39] do not apply, we show:

3. If computing  $K^t$  complexity is hard for SAT under reductions as in Item 1, then the average-case hardness of NP is equivalent to the existence of one-way functions. That is, “Pessiland” is excluded.

Finally, we give consequences of NP-hardness of *exact time-unbounded* Kolmogorov complexity under randomized reductions.

4. If computing Kolmogorov complexity is hard for SAT under a randomized many-one reduction running in time  $t_R$  and with failure probability at most  $1/(t_R)^{16}$ , then  $\text{coNP}$  is contained in non-interactive statistical zero-knowledge; thus  $\text{NP} \subseteq \text{coAM}$ . Also, the worst-case hardness of NP is equivalent to the existence of one-way functions.

We further exploit the connection to NISZK along with a previous work of Allender et al. [7] to show that hardness of K complexity under randomized many-one reductions is highly robust with respect to failure probability, approximation error, output length, and threshold parameter.

## 1 Introduction

Meta-complexity aims to determine the computational complexity of the tasks to compute various intrinsic complexity measures of given binary strings. Two prominent examples of such complexity measures are the minimum circuit size of a given truth table of a Boolean function, and the minimum time-bounded Kolmogorov complexity (denoted  $K^t$ ) of a given binary string. The corresponding meta-complexity problems are the *Minimum Circuit Size Problem* (MCSP):

given a binary string  $x \in \{0, 1\}^{2^n}$  and a parameter  $s \leq 2^n$ , decide if there is an  $n$ -input boolean circuit of size at most  $s$  whose truth table equals  $x$ ,

and the *Minimum  $K^t$  Problem* ( $MK^tP$ ):

given a binary string  $x \in \{0, 1\}^n$ , and a parameter  $s \leq n$ , decide if there is a binary input  $w$  of length at most  $s$  such that some fixed universal Turing machine  $U$  on input  $w$  prints  $x$  within  $t$  time steps.

The history of these two problems goes back to at least the 1950s and '60s. In the Soviet Union, during that period, those involved in “theoretical cybernetics” were keenly interested in problems related to switching circuits and Kolmogorov’s new theory of the complexity of strings. It was widely suspected that one could not avoid *perebor* (exhaustive search) in the solution of the corresponding minimization problems. Levin’s interest in *perebor*, culminating in his discovery of NP-completeness in the early 1970s, was motivated in particular by questions about the complexity of time-bounded Kolmogorov complexity [40]. Since then, both MCSP and  $MK^tP$  have resisted categorization as efficiently decidable or as NP-complete, a somewhat uncommon state of affairs for natural problems in NP.

In 2000, Kabanets and Cai took up the study of circuit minimization again, with a result suggesting that NP-hardness of MCSP may be very difficult to resolve: if MCSP is NP-hard under a deterministic many-one reduction such that output length depends only on input length, then one gets the lower bound  $E \not\subseteq P/\text{poly}$  [32]. At least, if MCSP is NP-hard, then showing its hardness would seem to require different techniques than those applied in the past, barring any further major breakthroughs. A line of work has continued to push further in this negative direction, progressively obtaining (1) “stronger” consequences, and (2) consequences of NP-hardness under more powerful forms of reducibility. An example of the former is a result of Murray and Williams, which obtains  $NP \not\subseteq P/\text{poly}$  from NP-hardness of MCSP under log-time uniform  $AC^0$  reductions [35]. An example of the latter is a result of Hitchcock and Pavan, which obtains  $EXP \neq ZPP$  from NP-hardness of MCSP under deterministic non-adaptive Turing reductions [27]. There are many more examples of this kind of work relying essentially on the determinism of the reductions in question; see, e.g., [6, 38, 8, 26].<sup>1</sup>

In contrast to the negative line of work for deterministic reductions, there is a positive line of work obtaining NP-hardness of variants of MCSP and  $MK^tP$  that seem to come progressively closer to the standard definitions of these problems. Examples include [29, 23, 30, 28]. A common feature of these results is their employment of randomness in the NP-hardness reductions. An impressive example of such a result is Hirahara’s recent proof of NP-hardness of partial-function versions of MCSP and  $MK^tP$  [23]. Additionally, from [5], MCSP is hard

<sup>1</sup> One result of [26] deals with one-query randomized reductions to  $MCSP^{\mathcal{O}}$  working for *every* oracle  $\mathcal{O}$ , which may be seen as an exception. Other results of that work give consequences of deterministic reductions to, for example, approximating circuit size and Levin’s  $K^t$  complexity.

for SZK (statistical zero-knowledge) under randomized reductions, which is the strongest unconditional hardness known for MCSP. All of this begs the question whether randomness is the key ingredient for the hardness of problems in meta-complexity: most barriers apply to deterministic reductions, whereas most progress has been made via randomized reductions.

As for the negative direction for randomized reductions, there has been far less headway. In fact, prior to this work, only two such results were known for MCSP and  $\text{MK}^t\text{P}$ . Murray and Williams ruled out NP-hardness of MCSP in the very restrictive setting of poly-logarithmic-time randomized projections [35]. More recently, Saks and Santhanam showed that  $\text{NE} = \text{coNE}$  if approximating  $\text{K}^t$ -complexity is NP-hard under randomized non-adaptive polynomial-time reductions (with some caveats, including a derandomization assumption and that the time-bound  $t$  in the superscript of  $\text{K}^t$  must be greater than the running time of the reduction) [39].

Of course, any NP-hardness of  $\text{MK}^t\text{P}$  or MCSP would be a major breakthrough for complexity theory, including hardness under a non-black-box reduction. In that sense, the *kind* of reduction in question is hardly important in itself. That being said, obtaining consequences of restricted forms of reduction can certainly help guide the “search for NP-hardness”. For example, a recent work of Ilango proved that approximating  $\text{K}^t$  within  $\Omega(n)$  additive error is NP-hard in the random oracle model [29]. As mentioned in that paper, the reduction circumvents the barrier of [39] by requiring more time than the superscript  $t$ . As with much of complexity theory, one can always take negative results as putting into focus the space for positive progress.

In this paper, we advance in the negative direction for randomized reductions, obtaining results with stronger consequences and from reductions to harder problems compared to prior work.

## 2 Main Results

We show a number of consequences of the assumptions that there exist restricted randomized NP-hardness reductions for the exact and approximate variants of the problem to determine the (time-bounded) Kolmogorov complexity of a given binary string.

In addition to the problem  $\text{MK}^t\text{P}$  introduced above, we shall also consider its time-unbounded version, MKP, where given a binary string  $x \in \{0, 1\}^n$  and a threshold parameter  $s \leq n$ , one needs to decide if there is a string  $w \in \{0, 1\}^{\leq s}$  such that a fixed universal TM  $U(w)$  outputs  $x$ . We also consider the probabilistic variant of  $\text{K}^t$ , denoted by  $\text{pK}^t$ , where  $\text{pK}^t(x)$  is defined as the minimum length  $s$  such that, for each of at least  $2/3$  of random strings  $r$ , there exists some input  $w_r \in \{0, 1\}^{\leq s}$  such that  $U(w_r, r)$  outputs  $x$  within  $t$  time steps. The corresponding Minimum  $\text{pK}^t$  Problem is denoted by  $\text{MpK}^t\text{P}$ . For  $g : \mathbb{N} \rightarrow \mathbb{N}$  and  $\mu \in \{\text{K}, \text{pK}\}$ ,  $\text{Approx}_g\text{-}\mu^t$  refers to the problem of approximating  $\mu^t$  complexity of a given  $x \in \{0, 1\}^n$  to within a  $g(n)$  additive error.  $\text{Approx}_g\text{-K}[s]$  refers to the problem of approximating K complexity except with threshold parameter fixed to  $s$ .

### 2.1 Consequences of showing the NP-hardness of an approximation to $\text{pK}^t$ or $\text{K}^t$

Informally, our first results show that NP-hardness of  $\text{Approx}_{n^s}\text{-pK}^t$  under honest non-adaptive randomized reductions with runtime sufficiently smaller than  $t$  implies that

- $\text{NP} \subseteq \text{coAM}$  (and hence, the polynomial-time hierarchy collapses [12]), and
- if, in addition, no one-way functions exist, then  $\text{NP} \subseteq \text{BPP}$ ;

here “honest” reductions are those that make queries of length at least some polynomial of the input to the reduction. We also get a similar result for  $\text{Approx}_{n^\delta}\text{-K}^t$ , under a derandomization assumption that  $\text{E}$  requires exponential-size nondeterministic circuits.

More precisely, we show that under the same NP-hardness assumptions, there is a black-box non-adaptive reduction from SAT to inverting an auxiliary input one-way function.<sup>2</sup> Moreover, this reduction is of a restricted form in which the oracle only needs to invert the function on auxiliary input  $\varphi$ , where  $\varphi$  is the input to SAT; this is called a “fixed-auxiliary-input reduction” [9]. The “ $\gamma$ -honesty” condition below means that all queries  $q \in \{0,1\}^*$  made by the reduction are such that  $|q| \geq n^\gamma$ , where  $n$  is the length of the input to the reduction.

► **Theorem 1** (Collapsing the Polynomial Hierarchy). *For any constants  $\delta, \gamma > 0$ , there is a polynomial  $p$  such that, for any  $t, t_R : \mathbb{N} \rightarrow \mathbb{N}$  satisfying  $p(t_R(n)) \leq t(n)$  for all  $n \in \mathbb{N}$ , we have the following.*

1. *If  $\text{Approx}_{n^\delta}\text{-pK}^t$  is hard for SAT under a  $\gamma$ -honest non-adaptive randomized reduction running in time  $t_R$ , then there is a black-box non-adaptive fixed-auxiliary-input reduction from SAT to inverting an auxiliary-input OWF. The latter implies that*

$$\text{NP} \subseteq \text{coAM}.$$

2. *Assume  $\text{E} \not\subseteq \text{io-NSIZE}[2^{o(n)}]$ . If  $\text{Approx}_{n^\delta}\text{-K}^t$  is hard for SAT under an honest non-adaptive randomized reduction running in time  $t_R$ , then*

$$\text{NP} = \text{coNP}.$$

As a consequence of the above non-adaptive black-box reduction from SAT to inverting an auxiliary-input one-way function, we further obtain from the hypothesis of Theorem 1 that the existence of a standard one-way function can be based on the worst-case hardness of NP. That is, proving NP-hardness of  $\text{Approx}_{n^\delta}\text{-K}^t$  (under restricted randomized reductions) is as hard as achieving the “holy grail of cryptography”.

We obtain both adaptive black-box and non-adaptive BPP-black-box<sup>3</sup> reductions from SAT to the problem of inverting a standard OWF. The former follows immediately from our Theorem 1 and a recent work of Nanashima [36], and the latter is implicit in [24], though we provide a short, self-contained proof building on Theorem 1.

► **Theorem 2** (Excluding Pessiland and Heuristica). *For any constants  $\delta, \gamma > 0$ , there is a polynomial  $p$  such that, for any  $t_R, t : \mathbb{N} \rightarrow \mathbb{N}$  satisfying  $p(t_R(n)) \leq t(n)$  for all  $n \in \mathbb{N}$ , we have the following.*

1. *If  $\text{Approx}_{n^\delta}\text{-pK}^t$  is hard for SAT under a  $\gamma$ -honest non-adaptive randomized reduction running in time  $t_R$ , then there exist both (I) a black-box adaptive randomized polynomial-time reduction, and (II) a BPP-black-box non-adaptive randomized polynomial-time reduction, from SAT to inverting a OWF. As a consequence, we get*

$$\text{NP} \not\subseteq \text{BPP} \iff \exists \text{ OWF}.$$

2. *Assume  $\text{E} \not\subseteq \text{io-NSIZE}[2^{o(n)}]$ . If  $\text{Approx}_{n^\delta}\text{-K}^t$  is hard for SAT under an honest non-adaptive randomized reduction running in time  $t_R$ , then*

$$\text{NP} \neq \text{P} \iff \exists \text{ OWF}.$$

<sup>2</sup> We consider auxiliary input functions  $f = \{f_\varphi\}_{\varphi \in \{0,1\}^*}$  as defined in [37].

<sup>3</sup> As defined by [18], a BPP-black-box reduction  $R$  from a problem  $L$  to a problem  $L'$  is an efficient oracle Turing machine that correctly decides  $L$ , given any oracle  $A \in \text{BPP}$  such that  $A$  decides  $L'$ .

With a similar argument, we also get the following statement for Levin's  $K^t$  complexity.

► **Corollary 3.** *For any constant  $\delta > 0$ , we have the following. Assume  $E \not\subseteq \text{io-NSIZE}[2^{o(n)}]$ . If  $\text{Approx}_{n^\delta}\text{-K}^t$  is hard for SAT under an honest non-adaptive randomized reduction, then  $\text{NP} = \text{coNP}$ . Moreover, if no one-way functions exist, then  $\text{NP} = \text{P}$ .*

## 2.2 Consequences of showing the NP-hardness of $K^t$

Though the conclusions of Theorems 1 and 2 are incomparable, one may find  $\text{NP} \subseteq \text{coAM}$  unbelievable, in which case Theorem 2 would not appear to yield a promising route for actually excluding Pessiland and Heuristica. Indeed, the earlier barrier result of [39] was part of Hirahara's motivation to introduce a harder "distributional" variant of  $K^t$  complexity in a recent work [24], delineating an intact positive approach for excluding Impagliazzo's worlds via NP-hardness of meta-complexity.

As a counterpoint, building on a work of Liu and Pass [33], we show that NP-hardness of *exact*  $K^t$  complexity would still suffice to exclude Pessiland while circumventing the barrier of Theorem 1 (and [39]). As noted in [33], problems of exact and approximate  $K^t$  complexity are qualitatively different: approximating  $K^t$  within  $\omega(\log n)$  additive error is unconditionally easy on average (in the "error-prone" sense) over the uniform distribution, but the argument fails in the setting of exact  $K^t$ . Thus, there is still room for optimism with regard to excluding Pessiland via NP-hardness of standard  $K^t$  complexity.

► **Theorem 4** (Excluding Pessiland). *There is a polynomial  $p$  such that, for any  $t, t_R : \mathbb{N} \rightarrow \mathbb{N}$  satisfying  $t(n) \geq p(t_R(n))$  for all  $n \in \mathbb{N}$ , we have the following.*

1. *If  $\text{Mpk}^t\text{P}$  is hard for SAT under an honest non-adaptive randomized reduction running in time  $t_R$ , then there is a black-box average-case reduction from SAT to inverting OWFs. As a consequence, we get that*

$$\text{DistNP} \not\subseteq \text{HeurBPP} \iff \exists \text{OWF}.$$

2. *Assume  $E \not\subseteq \text{io-NSIZE}[2^{o(n)}]$ . If  $\text{MK}^t\text{P}$  is hard for SAT under an honest non-adaptive randomized reduction running in time  $t_R$ , then*

$$\text{DistNP} \not\subseteq \text{HeurP} \iff \exists \text{OWF}.$$

## 2.3 Consequences of showing the NP-hardness of $K$

Finally, we show that NP-hardness of Kolmogorov complexity under randomized many-one reductions would imply  $\text{NP} \subseteq \text{coAM}$  and a collapse of the polynomial hierarchy. To the best of our knowledge, this is the first evidence against NP-hardness of exact Kolmogorov complexity under randomized many-one reductions. We also get under the same assumption that if  $\text{NP} \not\subseteq \text{BPP}$  then one-way functions exist.

► **Theorem 5** (Collapsing the Polynomial Hierarchy). *There is a polynomial  $p$  such that, for any  $t_R : \mathbb{N} \rightarrow \mathbb{N}$ , we have the following. If MKP is hard for SAT under a randomized polynomial time many-one reduction running in time  $t_R(n)$  and with failure probability at most  $1/p(t_R(n))$ , then*

$$\text{NP} \subseteq \text{coAM}.$$

*If, in addition, no one-way functions exist, then  $\text{NP} \subseteq \text{BPP}$ .*

## 2.4 Robustness of reductions to K

In fact, we can get a stronger result than that stated above: namely, we show that if a decidable language  $L$  reduces to MKP as in Theorem 5, then  $\bar{L} \subseteq \text{NISZK}$ , where NISZK is the class of promise problems admitting *non-interactive* statistical zero-knowledge proofs. In particular, we prove the following.

► **Theorem 6.** *For any polynomial  $t_R$  and decidable language  $L$ , if MKP is hard for  $L$  under a randomized many-one reduction running in time  $t_R(n)$  and with failure probability at most  $1/t_R(n)^{16}$ , then  $\bar{L} \subseteq \text{NISZK}$ .*

Since it is known that  $\text{NISZK} \subseteq \text{SZK} \subseteq \text{AM} \cap \text{coAM}$  [17, 14, 1], where SZK is the class of problems admitting statistical zero-knowledge proofs, Theorem 6 captures Theorem 5. It also improves on the following statement implicit in a previous work of Allender et al. [7].

► **Theorem 7 ([7]).** *For any decidable language  $L$ , if  $\text{Approx}_{\omega(\log n)}\text{-K}[n/2]$  is hard for  $L$  under an honest randomized many-one reduction with failure probability at most  $1/n^{\omega(1)}$ , then  $\bar{L} \subseteq \text{NISZK}$ .*

Note that Theorem 6 improves on Theorem 7 in three respects: we do not require the reduction to be honest, we do not require an  $\omega(\log n)$  approximation term, and we do not require the threshold parameter to be fixed.

Combining the above with a converse provided in [7], we show that hardness of MKP under randomized many-one reductions (with sufficiently small failure probability) is remarkably robust with respect to approximation error, failure probability, honesty, and threshold parameter (fixed or unfixed). For instance, if MKP is NP-hard under a  $t_R(n)$ -time many-one reduction with failure probability  $1/\text{poly}(t_R(n))$ , then it is also NP-hard under a polynomial-time many-one reduction with exponentially small failure probability. More specifically,

► **Theorem 8.** *There is a polynomial  $p$  such that for any decidable language  $L$  and polynomial  $t_R$ , the following are equivalent.*

1.  $\bar{L} \subseteq \text{NISZK}$ ;
2. MKP is hard for  $L$  under a randomized many-one reduction running in time  $t_R(n)$  and with two-sided failure probability at most  $1/p(t_R(n))$ ;
3.  $\text{Approx}_{n^{o(1)}}\text{-K}[n/2]$  is hard for  $L$  under an honest randomized many-one reduction with one-sided failure probability at most  $2^{-\text{poly}(n)}$ .

## 3 Related Work

Saks and Santhanam obtain a barrier result similar to our Theorem 1, Item 2, for the regime of super-logarithmic additive error. Specifically, they prove the following.

► **Theorem 9 ([39]).** *Assume  $\text{E} \not\subseteq \text{io-NSIZE}[2^{o(n)}]$ . There is a polynomial  $p$  satisfying the following. For any  $t, t_R : \mathbb{N} \rightarrow \mathbb{N}$  such that  $p(t_R(n)) \leq t(n)$ , if  $\text{Approx}_{\omega(\log n)}\text{-K}^t$  is hard for SAT under an honest, fixed query length, non-adaptive randomized reduction running in time  $t_R$ , then  $\text{NE} = \text{coNE}$ .*

Here, “fixed query length” means that the lengths of all queries made in the reduction are identical and depend only on the length of the input to the reduction, independent of randomness. In comparison, at the cost of increasing the approximation error term from  $\omega(\log n)$  to  $n^\delta$  for any constant  $\delta > 0$ , we obtain the stronger (and presumably less believable) consequence  $\text{NP} = \text{coNP}$ . Moreover, we do not require that the reduction have fixed query

length: in our case, the length of queries need not be the same, and they can depend on the input and the randomness of the reduction. The honesty condition is identical in this work and [39]. We also note that our proof techniques can be made to capture the regime of  $\omega(\log n)$  additive error, in which case we recover the statement of [39] improved to reductions without fixed query length.

Our Theorem 2 is related to a recent work of Hirahara [24], which introduces a “distributional” variant of  $K^t$  complexity, denoted  $dK^t$ , defined as follows: for a string  $x \in \{0, 1\}^*$ , a time bound  $t \in \mathbb{N}$ , and a distribution  $\mathcal{D}$ ,

$$dK^t(x \mid \mathcal{D}) = \min_{s \in \mathbb{N}} \left\{ \exists d \in \{0, 1\}^s \mid \Pr_{r \sim \mathcal{D}} [U(d, r) \text{ halts and outputs } x \text{ within } t \text{ steps}] \geq 2/3 \right\}.$$

Using the techniques of that work, it is possible to recover a part of our Theorem 2 exactly: namely, the existence of a BPP-black-box non-adaptive reduction from SAT to inverting a OWF. This is essentially due to the fact that if, for example, approximating  $K^t$  is NP-hard, then approximating  $dK^t$  is also NP-hard, since  $dK^t$  captures  $K^t$  when the provided distribution  $\mathcal{D}$  always outputs the empty string. A probabilistic variant of  $dK^t$  is also introduced in [24], which similarly generalizes  $pK^t$ .

However, our proof of Theorem 2 takes a partly different approach to that implicit in [24]. In particular, though both our proof and that work employ a non-black-box worst-case to average-case reduction as in [19, 20, 16], the latter approach would use this kind of reduction in two places: once to reduce NP to inverting an auxiliary-input one-way function, and once to obtain  $\text{NP} \not\subseteq \text{BPP} \implies \text{DistNP} \not\subseteq \text{AvgBPP}$ . To accommodate the reduction to inverting an auxiliary-input OWF, Hirahara introduces a new kind of mildly black-box reduction, which is more restrictive than the standard notion of a class-specific black-box reduction [18]. In contrast, as an intermediate step, we obtain a completely black-box non-adaptive reduction from NP to inverting an auxiliary-input OWF. We employ a class-specific worst-to-average reduction only to obtain  $\text{NP} \not\subseteq \text{BPP} \implies \text{DistNP} \not\subseteq \text{AvgBPP}$ .

As noted above, we could alternatively simply combine our Theorem 1 with [36] to obtain the statement

$$\text{NP} \not\subseteq \text{BPP} \implies \exists \text{OWF}.$$

However, we provide in [15] a self-contained proof of a BPP-black-box non-adaptive reduction. This is for completeness and to clarify the connection to Theorem 1.

Finally, we mention a few previous works related to our Theorem 5. Interestingly, by Allender et al., computing Kolmogorov complexity is known to be hard for PSPACE under deterministic adaptive Turing reductions [4]. This was improved by Hirahara to show that Kolmogorov complexity is hard for  $\text{EXP}^{\text{NP}}$  under deterministic adaptive Turing reductions and hard for NEXP under randomized non-adaptive reductions [21]. Thus, Theorem 5 indicates a sharp contrast between the power of randomized many-one reductions and more powerful reductions with respect to the hardness of Kolmogorov complexity. Saks and Santhanam also prove that NP-hardness of *approximating* Kolmogorov complexity within  $\omega(\log n)$  additive error under honest randomized non-adaptive reductions would imply  $\text{NP} \subseteq \text{coAM}$  [39]. Note that Theorem 5 does not assume honesty.

## 4 Techniques

In this section, we give an overview of the techniques used to prove our main results. Formal details can be found in the full version of the paper [15].

#### 4.1 Proof sketch of Theorem 1

As a warm-up, first consider the case of a deterministic length-increasing many-one reduction. In particular, let  $R$  be such a reduction from SAT to  $\text{Approx}_{n^\delta}\text{-K}^t$  mapping inputs  $\varphi \in \{0, 1\}^n$  to outputs  $(x, 1^s)$  with  $|x| \geq n^{2/\delta}$  and with the superscript  $t$  greater than the running time of  $R$ . It is easy to see that, for any output  $(x, 1^s)$  of  $R(\varphi)$ ,

$$\begin{aligned} \text{K}^t(x) &\leq |\varphi| + O(\log n) \\ &\leq |x|^\delta \\ &\leq s + |x|^\delta. \end{aligned}$$

This follows from the procedure that, given  $\varphi$  hard-coded, simulates  $R(\varphi)$  and returns its output. Accordingly, a reduction of this kind cannot exist: since all of its outputs are Yes-instances, it would imply  $\varphi \in \text{SAT}$  for every formula  $\varphi$ .

When moving to the more general case of a randomized many-one reduction, one can think of  $R(\varphi)$  as a distribution over instances of  $\text{Approx}_{n^\delta}\text{-K}^t$ , and a given output  $x$  is made with probability according to  $R(\varphi)$ . Observe that in the deterministic case, it held trivially that with high probability over  $x \sim R(\varphi)$ ,

$$\text{K}^t(x) \lesssim s \iff \Pr[R(\varphi) = x] > \beta,$$

for any choice of  $\beta \in (0, 1)$ . We would like to show that something similar is true in the randomized setting. That is, there is still a correspondence between the  $\text{K}^t$  complexity of outputs and their probability under  $R(\varphi)$ . This means that  $\text{Approx}_{n^\delta}\text{-K}^t$  (and thereby SAT) will reduce to a problem of probability estimation.

There exists unconditionally a  $\text{coAM}$  protocol  $A$  that, given  $(\varphi, x, \beta)$  as input, accepts iff  $\Pr[R(\varphi) = x]$  is roughly greater than  $\beta$ , with high probability over  $x \sim R(\varphi)$  [14, 11]; see also [25, Appendix A]. Under our derandomization assumption,  $A$  can be implemented in  $\text{coNP}$ . For simplicity, assume that every output  $(x, 1^s)$  of  $R$  has the same threshold parameter  $s \in \mathbb{N}$ , so we may omit this part of the outputs. Define a parameter

$$\beta = \frac{1}{2^s \cdot \text{poly}(n)}.$$

We claim that for every  $\varphi \in \{0, 1\}^n$ ,  $A(\varphi, x, \beta)$  will work well at deciding  $\text{Approx}_{n^\delta}\text{-K}^t$  on outputs  $x$  of  $R(\varphi)$ .

On one hand, we will show that with high probability over  $x \sim R(\varphi)$ , if  $\text{K}^t(x) \leq s$ , then  $\Pr[R(\varphi) = x] > \beta$ . The idea is to use a counting argument, giving an upper bound on  $x$  such that  $\text{K}^t(x) \leq s$ , to show that  $R(\varphi)$  must be “concentrated” on these inputs. In particular, the probability over  $x \sim R(\varphi)$  that  $\text{K}^t(x) \leq s$  and  $\Pr[R(\varphi) = x] \leq \beta$  is roughly at most

$$2^s \cdot \beta = \frac{1}{\text{poly}(n)}.$$

So, with high probability over  $x \sim R(\varphi)$ , if  $x$  is a Yes-instance of  $\text{Approx}_{n^\delta}\text{-K}^t$ , then  $\Pr[R(\varphi) = x] > \beta$ , in which case  $A(\varphi, x, \beta)$  correctly outputs 1.

On the other hand, we will show that if an output  $x$  has probability greater than  $\beta$  under  $R(\varphi)$ , then  $x$  must have  $\text{K}^t$  complexity roughly upper-bounded by  $s$ . In the realm of time-unbounded Kolmogorov complexity, we could rely on the well-known Coding Theorem to prove a statement of this kind. Namely, for any samplable distribution  $D$ , it holds that

$$\text{K}(x) \leq \log(1/D(x)) + O(\log n).$$

Similarly, if  $D$  is samplable given some non-uniform input  $\varphi$ , then

$$K(x) \leq \log(1/D(x)) + |\varphi| + O(\log n).$$

Observe that our distribution  $R(\varphi)$  is samplable in polynomial time given  $\varphi$  as input. Thus, if  $x$  is samplable with probability greater than  $\beta$  under  $R(\varphi)$ , then it holds that

$$\begin{aligned} K(x) &< \log(1/\beta) + |\varphi| + O(\log n) \\ &\leq s + |\varphi| + O(\log n) \\ &\leq s + |x|^\delta. \end{aligned}$$

Of course, bounding  $K$ -complexity does not suffice for our purposes. Instead, we apply a recent work of Lu, Oliveira, and Zimand [34], which gives unconditionally a coding theorem for *probabilistic*  $K^t$  complexity, denoted  $\mathbf{p}K^t$ . Specifically, we use a version of the coding theorem for distributions samplable in polynomial time given an auxiliary non-uniform input. For some polynomial  $p_{sc}$  and time-bound  $t_0 = \text{poly}(n)$  at least the running time of  $R$ , this yields

$$\mathbf{p}K^{p_{sc}(t_0)}(x) \leq s + |\varphi| + O(\log n).$$

Roughly speaking,  $\mathbf{p}K^t$ -complexity refers to the time-bounded Kolmogorov complexity of a string in the presence of some uniform randomness. This notion is in some sense intermediate between  $K^t$  complexity and  $K$  complexity. Moreover, under the derandomization assumption  $\mathbf{E} \not\subseteq \text{io-NSIZE}[2^{o(n)}]$ ,  $\mathbf{p}K^t$  and  $K^t$  turn out to be nearly equal: for some polynomial  $p_0$ ,  $K^{p_0(t)}(x) \leq \mathbf{p}K^t(x) + \log p_0(t)$  [16]. So, for  $t \geq p_0(p_{sc}(t_0))$ , the above implies

$$\begin{aligned} K^t(x) &\leq s + |\varphi| + O(\log n) \\ &\leq s + |x|^\delta. \end{aligned}$$

To summarize, with a sufficiently large  $t = \text{poly}(n)$  and a derandomization assumption, we obtain an auxiliary-input coding theorem for  $K^t$  complexity. This yields the required converse, namely, that high probability under  $R(\varphi)$  implies bounded  $K^t$ .<sup>4</sup>

We conclude that the  $\text{coNP}$  procedure  $A$  can be used to decide  $\text{SAT}$ . Therefore,  $\text{NP} \subseteq \text{coAM} = \text{coNP}$ .

To obtain Theorem 1 for *honest* reductions rather than polynomially length-increasing reductions, we can simply rely on the “paddability” of  $\text{SAT}$ . That is, given a  $\text{SAT}$ -instance  $\varphi \in \{0, 1\}^n$ , it is trivial to append some terms to  $\varphi$  in a way that does not affect its satisfiability but increases its length as desired. Since our assumed reduction  $R$  is honest, for some constant  $\gamma > 0$ , for any query  $x$  of  $R(\varphi)$ , it holds that  $|x| \geq |\varphi|^\gamma$ . If we let  $R'$  be the reduction that, on input  $\varphi \in \{0, 1\}^n$ , pads to obtain  $\varphi' \in \{0, 1\}^{n^{c/\gamma}}$  and then runs  $R(\varphi')$  to obtain  $x$ , we will now have  $|x| \geq |\varphi'|^\gamma = n^c$ . To summarize, if there is an honest reduction from  $\text{SAT}$  to some language  $L$ , then there is also a polynomially length-increasing reduction from  $\text{SAT}$  to  $L$ .<sup>5</sup>

For the full statement of Theorem 1, we need techniques that can handle randomized non-adaptive Turing reductions. We exploit the fact from [31] that the non-existence of a one-way function would provide an algorithm  $A$  for probability estimation as described above. In particular, for any distribution  $D \in \text{PSAMP}$ , for some poly-time computable

<sup>4</sup> We note that the use of the coding theorem for  $\mathbf{p}K^t$  is the main reason why we need to require that the runtime of our randomized  $\text{NP}$ -hardness reductions for  $\text{Approx}_{n,\delta}\text{-}K^t$  must be polynomially smaller than the parameter  $t$ .

<sup>5</sup> A similar application of padding is in [24].

function  $f$ , there is an oracle algorithm  $A$  such that  $A^I(x)$  outputs an estimate of  $\Pr[D = x]$  with high probability over  $x \sim D$ , where  $I$  is any inverter for  $f$ . Thus, in the presence of a non-adaptive reduction from SAT to  $\text{Approx}_{n^\delta}\text{-K}^t$ , we also get a non-adaptive reduction from SAT to the inversion of a one-way function. It was shown in [2, 3], with the construction of a sophisticated protocol building on techniques from [13, 11], that such a reduction would imply  $\text{SAT} \in \text{coAM}$ . However, as mentioned above, our distributions of interest  $R(\varphi)$  are not in PSAMP, but require  $\varphi$  as a non-uniform input. Luckily, a result of [9] transposes [2] to this non-uniform setting. Specifically, we have a reduction from SAT to the inversion of an *auxiliary-input* function  $f = \{f_\varphi\}_{\varphi \in \{0,1\}^*}$ , where on input  $\varphi$  to SAT, the reduction only needs to invert  $f$  on auxiliary input  $\varphi$ ; given this, [9] yields  $\text{SAT} \in \text{coAM}$ . This completes our overview of the proof of Theorem 1.

## 4.2 Proof Sketch of Theorem 2

Our proof of Theorem 2 builds on that of Theorem 1, making use of a few more ideas to obtain a reduction from NP to inversion of a standard OWF. The first idea is the fact that any inverter for an appropriate function can be used as an *errorless average-case* inverter for a desired auxiliary-input function. In particular, let  $f = \{f_\varphi\}_{\varphi \in \mathbb{N}}$  be an auxiliary-input function, and define  $g$  to be the function that randomly samples  $\varphi$  from a distribution  $D'$  and then applies  $f_\varphi$  to a uniformly random input  $z$ . It is not hard to show by an averaging argument that any inverter for  $g$  works as an inverter for  $f_\varphi$  with high probability over  $\varphi \sim D'$ . Moreover, crucially, if the inverter fails to invert some  $f_\varphi$ , then it can be made to output a special failure symbol  $\perp$  when given the auxiliary input  $\varphi$ , with high probability. This is due to the fact that successful inversion can be verified in poly-time: given a candidate pre-image  $y$  of some string  $z$  under  $f_\varphi$ , simply run  $f_\varphi(y)$  to verify; see [24, Theorem 10.3]. This, along with a reduction from SAT to inverting an auxiliary-input OWF, yields an errorless randomized heuristic for SAT over any distribution  $D' \in \text{PSAMP}$ .

The final piece of Theorem 2 is a worst-case to average-case reduction. The goal is to obtain

$$(\text{SAT}, D') \in \text{AvgBPP} \implies \text{SAT} \in \text{BPP},$$

which will complete the proof given the discussion above. To that end, we employ tools from [19] and follow-up works. A difficulty is that, from  $(\text{SAT}, D') \in \text{AvgBPP}$ , the available worst-case to average-case reductions only yield

$$\text{Gap}_{\tau, n^\delta} \text{pK}^t \in \text{BPP}.$$

The promise-problem  $\text{Gap}_{\tau, n^\delta} \text{pK}^t$  is potentially easier than  $\text{Approx}_{n^\delta}\text{-pK}^t$ , since it involves a polynomial gap  $\tau$  between time-bounds in Yes-instances and No-instances. As a result, the gap version may not be NP-hard, so its easiness would not yield  $\text{SAT} \in \text{BPP}$ . Fortunately, by a different application of the coding theorem for  $\text{pK}^t$ , we are able to show that NP-hardness of  $\text{Approx}_{n^\delta}\text{-pK}^t$  implies NP-hardness of  $\text{Gap}_{\tau, n^\delta} \text{pK}^t$ . Roughly, with high probability over the randomness of the reduction from SAT to  $\text{Approx}_{n^\delta}\text{-pK}^t$ , the  $\text{pK}^t$  complexity of queried strings will be somewhat close to their time-unbounded K complexity. Thus, granted the leeway of the  $n^\delta$  approximation term, the difference in time-bounds between  $t$  and  $\tau(t)$  does not affect the correctness of the (slightly modified) reduction when we use  $\text{Gap}_{\tau, n^\delta} \text{pK}^t$  as an oracle in lieu of  $\text{Approx}_{n^\delta}\text{-pK}^t$ .

To summarize, an outline of the proof is as follows.

1. Arguing as in Theorem 1, we get a black-box non-adaptive fixed-auxiliary input reduction from SAT to inverting an auxiliary-input function,  $f = \{f_\varphi\}_{\varphi \in \{0,1\}^*}$ .

2. Under our assumption of the non-existence of OWFs, we get, for any polynomial-time samplable distribution  $D$ , a PPT machine that inverts  $f_\varphi$  with high probability over  $\varphi \sim D$ . Combined with step (1), this yields that  $(\text{SAT}, D) \in \text{AvgBPP}$ .
3. From the worst-case to average-case reduction of [19] (and subsequent works [22] and [16]), for some distribution  $D' \in \text{PSAMP}$ , there is a BPP-black-box non-adaptive randomized polynomial-time reduction from  $\text{Gap}_{\tau, O(\log n)} \text{pK}^t$  to the average-case problem of solving SAT over  $D'$ . That is,

$$(\text{SAT}, D') \in \text{AvgBPP} \implies \text{Gap}_{\tau, O(\log n)} \text{pK}^t \in \text{BPP}$$

for a sufficiently large polynomial  $\tau$  depending on the running time of the heuristic for SAT. Combined with step (2), we get that  $\text{Gap}_{\tau, O(\log n)} \text{pK}^t \in \text{BPP}$ .

4. For a sufficiently large  $t$ , if  $\text{Approx}_{n^\delta} \text{pK}^t$  is NP-hard, then  $\text{Gap}_{\tau, O(\log n)} \text{pK}^t$  is also NP-hard. Combined with step (3), this yields  $\text{NP} \subseteq \text{BPP}$ .

### 4.3 Proof Sketch of Theorem 4

For the proof of Theorem 4 in the setting of exact  $\text{pK}^t$  and  $\text{K}^t$ , the approach discussed above does not work; recall that the approximation term  $n^\delta$  was critical at a number of points. Thus, our starting point is the following statement from a recent work of Liu and Pass [33].

Assuming  $\text{E} \not\subseteq \text{io-NSIZE}[2^{o(n)}]$ , if  $\{\text{MK}^t \text{P}\} \times \text{SAMP}[t_D(n)] \not\subseteq \text{HeurP}$  for some time bound  $t_D$  polynomially less than  $t$ , then one-way functions exist.

That is, the average-case hardness of  $\text{MK}^t \text{P}$  with respect to *any* distribution samplable within some polynomial running time smaller than  $t$  would suffice to imply one-way functions.

Our goal now is to show that if  $\text{MK}^t \text{P}$  is NP-hard, then  $\{\text{MK}^t \text{P}\} \times \text{SAMP}[t_D(n)]$  is “hard for distributional NP”: namely, if  $\text{MK}^t \text{P}$  is easy on average over every distribution  $D$  samplable in time  $t_D$ , then every distributional problem  $(L, D') \in \text{NP} \times \text{PSAMP}$  is likewise easy on average. Combining this with the statement from [33], we would get

$$\begin{aligned} \text{DistNP} \not\subseteq \text{HeurP} &\implies \{\text{MK}^t \text{P}\} \times \text{SAMP}[t_D(n)] \not\subseteq \text{HeurP} \\ &\implies \exists \text{OWF}. \end{aligned}$$

To show the distributional NP-hardness of  $\text{MK}^t \text{P}$ , we reduce from an arbitrary distributional problem  $(L, D') \in \text{DistNP}$ . Under the assumed NP-hardness of  $\text{MK}^t \text{P}$ , there is a randomized non-adaptive reduction  $R$  from  $L$  to  $\text{MK}^t \text{P}$ . With a large enough choice of the polynomial  $t$ , we can ensure that the reduction from  $L$  to  $\text{MK}^t \text{P}$  runs in time polynomially less than  $t$ . In particular, we get that the following distribution  $Q$  is samplable in time at most  $t_D$ :

Sample  $x \sim D'$ , and then output a sample from the query distribution of  $R(x)$ .

From there, it is not too hard to show that, if  $H$  is a heuristic for  $\text{MK}^t \text{P}$  working over  $Q$ , then the algorithm  $R^H$  (that simulates  $R$  and answers any oracle queries with  $H$ ) is a heuristic for  $L$  over  $D'$ . This yields the desired result.

### 4.4 Proof Sketch of Theorem 5

Finally, the proof of Theorem 5 proceeds along the lines of that of Theorem 1, but with several important changes.<sup>6</sup> The main challenge is that the Coding Theorem for  $\text{K}$  only gives us an *approximate* equality between  $\text{K}(x)$  and  $\log(1/D(x))$  for  $x$ 's sampled from a distribution

<sup>6</sup> As mentioned above, we actually give two different proofs of Theorem 5. We describe the first one here.

*D.* This was not a problem for Theorem 1 as it dealt with an *approximate* version of  $K^t$ , and we could absorb some slack of the Coding Theorem into an approximation error of  $K^t$ . But Theorem 5 is for the *exact* version of  $K$ , and we cannot apply the same strategy here. Instead, we show that this slack can be absorbed by a different argument, crucially relying on the fact that the randomized reductions  $R$  in the assumption of Theorem 5 are *many-one* and have the error probability *inverse-polynomially small* in their runtime  $t_R$ .

Namely, for  $\varphi \in \{0, 1\}^n$ , consider the distribution of queries  $(x, 1^s)$  made by the reduction  $R(\varphi)$ . We call such a query “heavy” if its probability (according to  $R(\varphi)$ ) is at least  $1/(\text{poly}(t_R(n)) \cdot 2^s)$ .

Our SAT algorithm (using a probability estimation protocol as in Theorem 1) essentially behaves as follows:

On input  $\varphi$ , sample a query  $(x, 1^s)$  according to  $R(\varphi)$ , and accept if  $(x, 1^s)$  is heavy.

For  $\varphi \notin \text{SAT}$  (which is the difficult case to analyze), heavy queries will cause our SAT algorithm to make a mistake by incorrectly accepting  $\varphi$ . We bound the error probability of our SAT algorithm by upperbounding the total probability mass of such heavy queries.

Roughly speaking, we upperbound the total probability mass of “heavy” queries  $(x, 1^s)$  by

$$\text{poly}(t_R(n)) \cdot \Pr[K(x) \leq s].$$

Note that, since  $\varphi \notin \text{SAT}$ , we have by the condition of correctness of the many-one reduction  $R$  that  $R(\varphi)$  must place a very small  $\gamma$  probability on its queries that are Yes-instances of MKP, i.e.,  $\Pr[K(x) \leq s] \leq \gamma$ . Hence, the error probability of our SAT algorithm is at most  $\text{poly}(t_R(n)) \cdot \gamma$ , which can be made sufficiently small if the error probability  $\gamma$  of the reduction  $R$  is inverse-polynomially small in the runtime  $t_R(n)$ .

## 5 NP-hardness of $(K^t \text{ vs. } K)$ and $(K^t \text{ vs. } K)^*$

In this section, we examine promise problems of the form  $(K^t \text{ vs. } K^{t'})$ , for time bounds  $t, t' \in \mathbb{N}$ , in comparison with the “partial function” versions  $(K^t \text{ vs. } K^{t'})^*$  recently shown NP-complete by Hirahara [23]. While NP-hardness of  $(K^t \text{ vs. } K)$  would imply  $\text{NP} \subseteq \text{coAM}$  via our proof techniques above, the consequence does not seem to follow in the partial setting, as we discuss further below. We then show that NP-hardness via *deterministic Turing* reductions of either  $(K^t \text{ vs. } K^{t'})$  or  $(K^t \text{ vs. } K^{t'})^*$  (with appropriate settings of  $t$  and  $t'$ ) would imply  $\text{NP} = \text{P}$ . It follows that these problems are NP-intermediate with respect to deterministic Turing reductions, provided the existence of one-way functions.

### 5.1 Randomized Reductions

We start with formal definitions of the partial version of  $K^t$  complexity and the promise problems mentioned above.

► **Definition 10** (Partial (Time-bounded) Kolmogorov Complexity). *For a time bound  $t \in \mathbb{N}$ , a string  $x \in \{0, 1, *\}^*$ , and a complexity measure  $\mu \in \{\text{p}K^t, K^t, K\}$ , the partial ( $t$ -time-bounded, probabilistic) Kolmogorov complexity of  $x$ , denoted  $(\mu)^*(x)$ , is equal to*

$$\min \{ \mu(x') \mid x' \text{ consistent with } x \},$$

where a string  $x' \in \{0, 1, *\}^*$  is said to be consistent with  $x \in \{0, 1, *\}^*$  if  $|x'| = |x|$  and, for every index  $i \in [|x|]$  such that  $x[i] \neq *$ , it holds that  $x[i] = x'[i]$ .

► **Definition 11** ( $(K^t$  vs.  $K^{t'})$ ). Let  $t, t' : \mathbb{N} \rightarrow \mathbb{N}$ . For  $\mu_1 \in \{K^t, pK^t\}$  and  $\mu_2 \in \{K^{t'}, pK^{t'}, K\}$ ,  $(\mu_1$  vs.  $\mu_2)$  is the following promise problem.

- $\Pi_Y = \{(x, 1^s) \mid \mu_1(x) \leq s\}$
- $\Pi_N = \{(x, 1^s) \mid \mu_2(x) > s\}$

$(\mu_1$  vs.  $\mu_2)^*$  is defined analogously, with the partial complexity measures  $(\mu_1)^*$  and  $(\mu_2)^*$  in place of the standard (“complete function”) ones.

By a proof analogous to that of Theorem 5, we get the following statement.

► **Lemma 12.** Let  $t : \mathbb{N} \rightarrow \mathbb{N}$  be arbitrary and  $t_R : \mathbb{N} \rightarrow \mathbb{N}$  a polynomial. If  $(K^t$  vs.  $K)$  is NP-hard under a randomized many-one reduction running in time  $t_R(n)$  and with failure probability at most  $1/(t_R(n))^7$ , then  $\text{NP} \subseteq \text{coAM}$ .

One may contrast Lemma 12 with Hirahara’s recent proof that  $(K^t$  vs.  $K)^*$  is in fact NP-hard under a randomized many-one reduction with the same properties. This suggests that the techniques of [23] will not extend to the setting of standard  $(K^t$  vs.  $K)$  without leveraging some more powerful notion of reducibility. Viewed another way, to obtain NP-hardness of  $\text{MK}^t\text{P}$  complexity under randomized many-one reductions, one would need techniques that apply more narrowly to smaller-gap versions of the problem.

Note that the statement gives NP-hardness of  $\text{MK}^t\text{P}^*$  under a randomized reduction even when  $t \in \mathbb{N}$  is arbitrarily larger than the running time of the reduction. In the case of a randomized reduction, it is not unreasonable to make the assumption that  $t \gg t_R$ , as is done in [39] and in this work. This is because randomized reductions may easily sample strings of maximum Kolmogorov complexity, so it is easy to generate No-instances of  $\text{MK}^t\text{P}$  (or  $\text{MK}^t\text{P}^*$ ) within time  $t_R$ . Note that this would be impossible for a deterministic reduction.

► **Lemma 13** (Implicit in [23]). There exists a polynomial  $t_R : \mathbb{N} \rightarrow \mathbb{N}$  such that for any constant  $c \in \mathbb{N}$  and any sufficiently large polynomial  $t : \mathbb{N} \rightarrow \mathbb{N}$ ,  $(K^t$  vs.  $K)^*$  is NP-hard under a randomized many-one reduction running in time  $t_R(n)$  and with failure probability at most  $1/t_R(n)^c$ .

**Proof sketch.** One needs to verify that the failure probability of the reduction is at most  $1/n^c$  for an arbitrary large constant  $c \in \mathbb{N}$ . Recall that in the proof of [23] Lemma 8.3, the reduction samples random strings  $f_i \sim \{0, 1\}^{\lambda \cdot w(i)}$  for  $i \in [n]$ , where  $n \in \mathbb{N}$  is the number of variables in the input CMMSA instance,  $w : [n] \rightarrow \mathbb{N}$  is a weight function, and  $\lambda$  is some fixed polynomial in  $n$ . The reduction succeeds provided, for every  $T \subseteq [n]$ , for some constant  $c \in \mathbb{N}$ ,

$$K(f_T) \geq \lambda \cdot w(T) - c \cdot |T| \cdot \log n. \tag{1}$$

This is used in the “soundness” part of the proof to argue that the set  $B \subseteq [n]$  is not authorized. In particular, one must prove that  $w(B) < \theta$  from the fact that  $K(f_B) \leq o(\lambda \cdot w(B)) + |M|$ , where  $|M|$  is an arbitrary program of size  $\lambda\theta/2$ . To see that Eq. (1) is sufficient for this purpose, observe that for any  $c \in \mathbb{N}$ ,

$$\begin{aligned} \lambda \cdot w(B) - c \cdot |B| \cdot \log n &\leq K(f_B) \\ &\leq o(\lambda \cdot w(B)) + |M| \end{aligned}$$

implies that

$$\begin{aligned} \lambda \cdot w(B) &\leq c \cdot |B| \cdot \log n + o(\lambda \cdot w(B)) + |M| \\ &\leq o(\lambda \cdot w(B)) + |M|, \end{aligned}$$

## 51:14 Consequences of Randomized Reductions from SAT to Kolmogorov Complexity

since  $c \cdot |B| \cdot \log n \leq cn \log n = o(\lambda)$ . Thus,

$$\begin{aligned} w(B) \cdot \lambda \cdot (1 - o(1)) &\leq |M| \\ &\leq \lambda \cdot \theta/2, \end{aligned}$$

which implies that  $w(B) < \theta$ , as desired.

Now we will show that, for any  $c \in \mathbb{N}$ , Eq. (1) holds with probability at least  $1 - 1/n^{c-2}$ . First observe that by a standard counting argument, with probability  $1 - 1/n^{c-2}$ ,

$$\mathsf{K}(f_{[n]}) \geq \lambda \cdot w([n]) - (c - 2) \cdot \log n.$$

Moreover,

$$\mathsf{K}(f_{[n]}) \leq \mathsf{K}(f_T) + \lambda \cdot w([n] \setminus T) + 2 \cdot |T| \cdot \log n,$$

since one may describe  $f_{[n]}$  by describing  $f_T$ , hard-wiring  $f_{[n] \setminus T}$ , and describing the set  $T \subseteq [n]$  itself. Thus,

$$\begin{aligned} \mathsf{K}(f_T) &\geq \mathsf{K}(f_{[n]}) - \lambda \cdot w([n] \setminus T) - 2 \cdot |T| \cdot \log n \\ &\geq \lambda \cdot w([n]) - (c - 2) \cdot \log n - \lambda \cdot w([n] \setminus T) - 2 \cdot |T| \cdot \log n \\ &\geq \lambda \cdot w(T) - c \cdot |T| \cdot \log n, \end{aligned}$$

so the reduction does not fail in this case.  $\blacktriangleleft$

One may wonder why the barrier of Lemma 12 does not apply to the partial  $\mathsf{K}^t$  setting. The primary issue is that a correspondence between the compressibility of queries and their probability under the query distribution  $Q_\varphi$  appears to be missing. As a result, we cannot apply our central proof technique of reducing meta-complexity to a problem of probability estimation.

Roughly speaking, there is a difference between the Kolmogorov complexity  $\mathsf{K}(z)$  of the *description* of a query  $z := (x, 1^s)$  with  $x \in \{0, 1, *\}^*$  and the *partial complexity*  $\mathsf{K}^*(x)$  of  $x$ . By the Coding Theorem for  $\mathsf{K}$ , we still have an approximate correspondence between the logarithm of the inverse probability of (the description of the query)  $z$  output by the randomized reduction and the complexity  $\mathsf{K}(z)$ . However,  $\mathsf{K}^*(x)$  can differ significantly from  $\mathsf{K}(z)$ . For example, consider a string  $y = 0^n$ , and let  $y'$  be a uniformly random string in  $\{0, *\}^n$ . Since  $y'$  is a uniformly random string over the binary alphabet  $\{0, *\}$ , it's almost certainly true that  $\mathsf{K}(y') \geq n - O(\log n)$ . On the other hand,  $\mathsf{K}^*(y') \leq \mathsf{K}(y) \leq O(\log n)$ .

More concretely, for example, consider a reduction from SAT to the problem of approximating  $(\mathsf{K}^t)^*$  (with a fixed threshold parameter  $s \in \mathbb{N}$ ). Here, the queries  $x \in \{0, 1, *\}^*$  may contain unspecified “\*” positions. On one hand, we can use a standard coding theorem (adapted appropriately) to show that a query  $x$  having probability greater than  $\beta \approx 1/(2^s \cdot \text{poly}(n))$  under the query distribution  $Q_\varphi$  would imply that  $(\mathsf{K}^t)^*(x) \lesssim s$ .

However, the converse does not seem to hold. Previously we showed that, for strings queried in the reduction, it was unlikely for a string to be both of low complexity and low probability. This followed from a counting argument and a union bound: there are roughly at most  $2^s$  strings  $x \in \{0, 1\}^*$  with  $\mathsf{K}^t(x) \leq s$ , so the cumulative probability of strings with both this property and  $Q_\varphi(x) \leq \beta$  is at most  $1/\text{poly}(n)$ . In the case of partial  $\mathsf{K}^t$ , it is no longer true that there are “few” strings of low complexity. In particular, any one short description  $d \in \{0, 1\}^s$  can witness  $(\mathsf{K}^t)^*(x) \leq s$  for  $2^n$  distinct strings  $x \in \{0, 1, *\}^n$  (unlike standard  $\mathsf{K}^t$ , where one description only “maps” to one string). Thus, partial  $\mathsf{K}^t$  complexity is not readily connected to probability under efficiently samplable distributions, which was the key connection exploited in the previous sections.

## 5.2 Deterministic Reductions

As another point of comparison, in Lemmas 15 and 16, we show that if either of  $(\mathsf{K}^t \text{ vs. } \mathsf{K}^{t'})$  or  $(\mathsf{K}^t \text{ vs. } \mathsf{K}^{t'})^*$  is NP-hard with respect to deterministic adaptive Turing reductions (for a sufficiently large exponential function  $t'$ ), then one obtains the stronger consequence that  $\text{NP} = \text{P}$ . This implies that if one-way functions exist,  $(\mathsf{K}^t \text{ vs. } \mathsf{K}^{t'})$  and  $(\mathsf{K}^t \text{ vs. } \mathsf{K}^{t'})^*$  are both NP-intermediate with respect to deterministic Turing reductions.<sup>7</sup>

Note that Lemmas 15 and 16 hold for Turing reductions with *arbitrary* polynomial running time (i.e., less than or greater than the time-bound  $t$ ), and there is no honesty requirement. After this, we show similar results for honest reductions and superpolynomial  $t'$ .

We will use the “dream-breaker” of Bogdanov et al. [10].

► **Lemma 14** ([10]). *Suppose  $\text{NP} \neq \text{P}$ . There is an algorithm  $B$  and a universal constant  $d$  with the following properties. Let  $A$  be any poly-time algorithm that attempts to solve search-SAT and only errs by incorrectly outputting  $\perp$ .<sup>8</sup> For infinitely many  $n \in \mathbb{N}$ ,  $B(A, 1^n)$  outputs a formula  $\varphi \in \{0, 1\}^n$  and a witness  $a$  such that  $\varphi(a) = 1$  but  $A(\varphi) = \perp$ . Moreover, if  $A$  runs in time at most  $n^b$  on inputs of length  $n$ , then  $B(A, 1^n)$  runs in time at most  $(n^b)^d$ .*

► **Lemma 15.** *For every constant  $c$ , there is a constant  $c'$  with the following property. Let  $t, t' : \mathbb{N} \rightarrow \mathbb{N}$  be such that for all  $n \in \mathbb{N}$ ,  $t(n) \leq n^c$  and  $t'(n) \geq 2^{c'n}$ . Then  $(\mathsf{K}^t \text{ vs. } \mathsf{K}^{t'})$  is NP-hard under deterministic polynomial-time Turing reductions iff  $\text{NP} = \text{P}$ .*

**Proof.** Let  $M$  be a Turing reduction from search-SAT to  $(\mathsf{K}^t \text{ vs. } \mathsf{K}^{t'})$  running in time at most  $n^b$  on inputs of length  $n \in \mathbb{N}$ . Define a machine  $M'$  that on input  $\varphi \in \{0, 1\}^n$  simulates  $M(\varphi)$  and answers its queries as follows. If the query  $(x, 1^s)$  is such that  $s \leq 4b \log n$  and  $s \leq 2|x|$ , answer the query by brute force; otherwise simply accept the query. Note that  $M'$  runs in time at most  $n^{6bc}$ .

Let  $B$  be the refuter of Lemma 14, and let  $n \in \mathbb{N}$  and  $\varphi \in \{0, 1\}^n$  be such that  $B(M', 1^n) = (\varphi, a)$  with  $M'(\varphi) = \perp$  but  $\varphi(a) = 1$ .

Clearly, if a query  $(x, 1^s)$  is such that  $s \leq 4b \log n$  or  $2|x| < s$ ,  $M'$  answers it correctly. We now claim that for every query  $(x, 1^s)$  of  $M'(\varphi)$ , it holds that  $\mathsf{K}^{t'}(x) \leq 4b \log n$ . In particular, one may compute  $x$  from advice  $(n, i)$ , where  $x$  is the  $i^{\text{th}}$  query of  $M'(\varphi)$ , in time at most

$$(n^{6bc})^d + n^{6bc} < 2^{c' \cdot |x|},$$

assuming  $2|x| \geq s > 4b \log n$  and choosing  $c' = 4cd$ , where  $d$  is the constant from Lemma 14. For  $t' : \mathbb{N} \rightarrow \mathbb{N}$  such that  $t'(m) \geq 2^{c'm}$ , this implies

$$\mathsf{K}^{t'}(x) \leq s.$$

Thus,  $M'(\varphi)$  answers all of its queries correctly with respect to  $(\mathsf{K}^t \text{ vs. } \mathsf{K}^{t'})$ , and

$$M'(\varphi) = M^{(\mathsf{K}^t \text{ vs. } \mathsf{K}^{t'})}(\varphi) = \text{search-SAT}(\varphi),$$

a contradiction. ◀

The following statement for  $(\mathsf{K}^t \text{ vs. } \mathsf{K}^{t'})^*$  indicates that Lemma 13 makes essential use of randomness, unless  $\text{NP} = \text{P}$ .

<sup>7</sup> Since either of these problems could be used to break a cryptographic PRG, the existence of OWFs means they must not be efficiently decidable.

<sup>8</sup> Note that any poly-time algorithm may be transformed into such an algorithm by verifying any candidate satisfying assignment to the input before returning it.

► **Lemma 16.** *For every constant  $c$ , there is a constant  $c'$  with the following property. Let  $t, t' : \mathbb{N} \rightarrow \mathbb{N}$  be such that for all  $n \in \mathbb{N}$ ,  $t(n) \leq n^c$  and  $t'(n) \geq 2^{c'n}$ . Then  $(K^t \text{ vs. } K^{t'})^*$  is NP-hard under deterministic polynomial-time Turing reductions iff  $\text{NP} = \text{P}$ .*

**Proof sketch.** The proof is nearly identical to that of Lemma 15. One may still compute a string *consistent* with  $x$  from advice  $(n, i)$  by simulating the reduction, obtaining the query  $x$ , and replacing any  $*$ 's in  $x$  with 0's. Let  $\tilde{x}$  be the string  $x$  with all  $*$ 's replaced by 0's. It is easy to verify that  $(K^{t'})^*(x) \leq K^{t'}(\tilde{x}) \leq 4b \log n$ . ◀

Note that we could prove the above lemmas for  $(K^t \text{ vs. } K)$  and  $(K^t \text{ vs. } K)^*$  (that is, with time-unbounded  $K$  and  $K^*$  in  $\Pi_N$ ) without the use of a dreambreaker. If we additionally assume that the NP-hardness reductions are honest, we obtain the same results but with  $t'$  any superpolynomial function.

► **Lemma 17.** *Let  $t : \mathbb{N} \rightarrow \mathbb{N}$  be polynomial and  $t' : \mathbb{N} \rightarrow \mathbb{N}$  superpolynomial.  $(K^t \text{ vs. } K^{t'})$  is NP-hard under honest deterministic polynomial-time Turing reductions iff  $\text{NP} = \text{P}$ .*

**Proof.** Argue as in Lemma 15. Since the reduction is honest, we have

$$|x| \geq n^\gamma$$

for some constant  $\gamma > 0$ , for any string  $x$  queried in the reduction  $M$ . Recall that any such  $x$  of  $M$  may be computed from advice  $(n, i)$  in time at most

$$\begin{aligned} (n^{6bc})^d + n^{6bc} &< n^{7bcd} \\ &\leq |x|^{7bcd/\gamma} \\ &< t'(|x|), \end{aligned}$$

as desired. ◀

► **Lemma 18.** *Let  $t : \mathbb{N} \rightarrow \mathbb{N}$  be polynomial and  $t' : \mathbb{N} \rightarrow \mathbb{N}$  superpolynomial.  $(K^t \text{ vs. } K^{t'})^*$  is NP-hard under honest deterministic polynomial-time Turing reductions iff  $\text{NP} = \text{P}$ .*

## 6 Open Questions

We have shown various consequences of (time-bounded) Kolmogorov complexity being NP-hard under randomized notions of reducibility. Some of these consequences may be taken optimistically (Theorem 4), while others may be viewed as barriers to the kinds of NP-hardness in question (Theorems 1, 5), which include kinds of reduction that have previously been used to show NP-hardness of variants of  $K^t$  complexity (e.g., [23]).

This work leaves open a number of directions; here, we indicate a few.

1. Can we remove the requirement, in Theorems 1, 2, and 4, that the time bound  $t$  in the superscript be larger than the running time of the reduction? Recall that this requirement was due to our use of the coding theorem for  $\text{pK}^t$ .
2. Can we show consequences of randomized NP-hardness reductions to MKTP or MCSP (i.e., minimization problems for Allender's KT complexity or boolean circuit size)?
3. Can we extend Theorems 1, 2, or 4 to *adaptive* randomized Turing reductions? Note that this kind of extension is unlikely in the case of Theorem 5, given the prior work discussed in Section 3 [4, 21].
4. Can we improve Theorem 5 to hold for randomized many-one reductions with constant failure probability? In particular, can we improve the "robustness" of many-one reductions to  $K$ , as in Theorem 8, to hold for constant failure probability and exponentially small failure probability?

## Abstract

The goal of *trace reconstruction* is to reconstruct an unknown  $n$ -bit string  $x$  given only independent random *traces* of  $x$ , where a random trace of  $x$  is obtained by passing  $x$  through a deletion channel. A *Statistical Query* (SQ) algorithm for trace reconstruction is an algorithm which can only access statistical information about the distribution of random traces of  $x$  rather than individual traces themselves. Such an algorithm is said to be  $\ell$ -*local* if each of its statistical queries corresponds to an  $\ell$ -*junta* function over some block of  $\ell$  consecutive bits in the trace. Since several – but not all – known algorithms for trace reconstruction fall under the local statistical query paradigm, it is interesting to understand the abilities and limitations of local SQ algorithms for trace reconstruction.

In this paper we establish nearly-matching upper and lower bounds on local Statistical Query algorithms for both worst-case and average-case trace reconstruction. For the worst-case problem, we show that there is an  $\tilde{O}(n^{1/5})$ -local SQ algorithm that makes all its queries with tolerance  $\tau \geq 2^{-\tilde{O}(n^{1/5})}$ , and also that any  $\tilde{O}(n^{1/5})$ -local SQ algorithm must make some query with tolerance  $\tau \leq 2^{-\tilde{\Omega}(n^{1/5})}$ . For the average-case problem, we show that there is an  $O(\log n)$ -local SQ algorithm that makes all its queries with tolerance  $\tau \geq 1/\text{poly}(n)$ , and also that any  $O(\log n)$ -local SQ algorithm must make some query with tolerance  $\tau \leq 1/\text{poly}(n)$ .

## 1 Introduction

In the *trace reconstruction* problem, the goal is to reconstruct an unknown string  $x \in \{0, 1\}^n$  given access to independent random *traces* of  $x$ , where a random trace of  $x$  is a string obtained by passing  $x$  through a deletion channel that independently deletes each bit with probability  $\delta$  and concatenates the surviving bits. Trace reconstruction has been a well-studied problem since the early 2000s [30, 29, 2], and some combinatorial variants of the problem were already considered in the 1970s [26]. Over the past decade, a wide range of algorithmic results and lower bounds have been established for many variants of the trace reconstruction problem,

including worst-case [32, 19, 36, 22, 10, 11], average-case [37, 23, 24, 38], and smoothed analysis [13] versions, the low deletion rate regime [12], approximate trace reconstruction [18, 8, 9, 14], coded trace reconstruction [16, 6], variants in which different bits of the source string have different deletion probabilities [21], circular trace reconstruction [35], trace reconstruction on trees [17, 5], population recovery variants [1, 33, 34], connections to other problems such as mixture distribution learning [28], and more [20, 39].

The original, and arguably most fundamental, versions of the problem are the “worst-case” and “average-case” versions with constant deletion rate  $\delta \in (0, 1)$ . In the worst-case problem the source string  $x$  is an arbitrary (worst-case) element of  $\{0, 1\}^n$ , and in the average-case problem the source string  $x$  is selected uniformly at random from  $\{0, 1\}^n$ ; equivalently, an average-case algorithm is only required to succeed for a  $1 - o_n(1)$  fraction of all  $2^n$  possible source strings  $x \in \{0, 1\}^n$ . These two problems are the focus of our work, so in the rest of this paper we consider worst-case and average-case trace reconstruction and we always assume that the deletion rate  $\delta$  is an arbitrary (known) constant in  $(0, 1)$ .

Despite much effort, there are mildly exponential gaps between the best known upper bounds and lower bounds for both worst-case and average-case trace reconstruction. Improving on earlier  $2^{\tilde{O}(n^{1/2})}$ -trace and  $2^{\tilde{O}(n^{1/3})}$ -trace algorithms of [25, 19, 36], in [11] Chase gave an algorithm for worst-case trace reconstruction that uses  $2^{\tilde{O}(n^{1/5})}$  traces. The best known lower bound, also due to Chase [10], is  $\tilde{\Omega}(n^{3/2})$  traces (improving on earlier  $\tilde{\Omega}(n^{5/4})$  and  $\Omega(n)$  lower bounds [22, 2]). For the average-case problem, improving on earlier  $\exp(O((\log n)^{1/2}))$ -trace and  $\exp(O((\log n)^{1/3}))$ -trace algorithms [37, 23, 24], Rubinfeld [38] recently gave an  $\exp(\tilde{O}((\log n)^{1/5}))$ -trace algorithm. The best known average-case lower bound, due to Chase [10], is  $\tilde{\Omega}((\log n)^{5/2})$  traces, improving on an earlier  $\tilde{\Omega}((\log n)^{9/4})$  lower bound [22].

These substantial gaps naturally suggest the study of restricted classes of algorithms for trace reconstruction, with the hope that it may be possible to obtain sharper results. This is the starting point of our work: we propose to study the trace reconstruction problem from the vantage point of *statistical query* algorithms. As our main contribution we obtain fairly sharp upper and lower bounds on *local* statistical query algorithms for trace reconstruction, as described below.

**Statistical Query trace reconstruction algorithms.** The *Statistical Query* (SQ) model [27] was first introduced by Kearns as a means to obtain PAC learning algorithms that can tolerate random classification noise. In the decades since then, the SQ model has emerged as a major topic of study in its own right in computational learning theory and related fields such as differential privacy and optimization. An attractive feature of the SQ model is that it is powerful enough to capture state-of-the-art algorithms in a variety of different settings, yet it is also amenable to proving *unconditional* lower bounds.

SQ algorithms can only access data through noisy estimates of the expected values of user-generated query functions. In the context of trace reconstruction, an SQ oracle takes as input a bounded *query function*  $q : \{0, 1\}^n \rightarrow [-1, 1]$  and a *tolerance parameter*  $\tau \in (0, 1)$  that are provided by the reconstruction algorithm. It returns a value  $\hat{P}_q$  which satisfies  $|\hat{P}_q - P_q| \leq \tau$ , where  $P_q$  is the expected value of  $q$  on a random trace, i.e.  $P_q := \mathbf{E}_{\mathbf{y} \sim \text{Del}_\delta(x)}[q(\mathbf{y})]$ .<sup>1</sup> Thus an SQ algorithm for trace reconstruction does not receive any actual traces of  $x$ ; rather, it can only use aggregate statistical information about the overall distribution of traces.

<sup>1</sup> Since the length of each trace is at most  $n$ , we view each trace  $\mathbf{y}$  as padded with a suffix of  $n - |\mathbf{y}|$  zeros, so the argument to  $q$  is actually  $\mathbf{y}0^{n-|\mathbf{y}|}$ . This is equivalent to assuming that the  $n$ -bit source string  $x$  is padded with an infinite suffix of 0-bits.

To the best of our knowledge, the current paper is among the first works that explicitly considers the trace reconstruction problem from the perspective of statistical queries (see also [15], which we discuss in more detail below). However, in hindsight the earliest nontrivial algorithms for worst-case trace reconstruction [25, 19, 36] already made it evident that SQ algorithms – in fact, SQ algorithms which use extremely simple query functions – could be effective for trace reconstruction. The algorithms of [25, 19, 36] all work by using the traces from  $\mathbf{Del}_\delta(x)$  only to obtain high-accuracy estimates of the  $n$  values  $\mathbf{E}_{\mathbf{y} \sim \mathbf{Del}_\delta(x)}[\mathbf{y}_i]$  for  $i \in [n]$  and then doing some subsequent computation on those estimated values; thus they correspond to SQ algorithms in which each query function is simply a Boolean dictator function, i.e. a 1-junta. On the other hand, the highly efficient average-case trace reconstruction algorithms of [37, 23, 24, 38], which use a sub-polynomial number of traces, involve various “alignment” routines which attempt to identify locations in individual received traces that correspond to specific locations in the source string. These algorithms seem to make essential use of individual traces and do not seem to be compatible with the SQ model. So given that some, but not all, known trace reconstruction algorithms correspond to SQ algorithms, it is of interest to study both the abilities and limitations of SQ algorithms for trace reconstruction.

In this work we consider a natural class of SQ algorithms, which we call  $\ell$ -local SQ algorithms. An  $\ell$ -local query function  $q : \{0, 1\}^n \rightarrow [-1, 1]$  is an  $\ell$ -junta over some  $\ell$  consecutive bits of its input string, i.e. for all  $y$ ,  $q$  satisfies  $q(y) = q'(y_i, y_{i+1}, \dots, y_{i+\ell-1})$  for some index  $i$  and some function  $q' : \{0, 1\}^\ell \rightarrow [-1, 1]$ . We say that an algorithm is an  $\ell$ -local SQ algorithm with tolerance  $\tau_0$  if all of its calls to the SQ oracle are made with  $\ell$ -local query functions and the tolerance parameter for each call is at least  $\tau_0$ .

The results of [19, 36] already show that 1-local SQ algorithms with tolerance  $\tau_0 = 2^{-\tilde{O}(n^{1/3})}$  can successfully perform worst-case trace reconstruction, and moreover [19, 36] additionally show that tolerance  $\tau_0 = 2^{-\tilde{\Omega}(n^{1/3})}$  is required for any 1-local SQ worst-case trace reconstruction algorithm. Thus, in analyzing the abilities and limitations of  $\ell$ -local algorithms for trace reconstruction for a particular value of  $\ell$ , our goal is to determine the tolerance which is necessary and sufficient for such algorithms to succeed in worst-case or average-case trace reconstruction. A simple argument which we give in Section 2.1 shows that any  $\ell$ -local SQ algorithm (which may be adaptive) using tolerance  $\tau_0$  can be converted to a nonadaptive SQ algorithm that makes at most  $n2^\ell$  queries, all of which are  $\ell$ -local “subword” queries (defined in Section 2.1) of tolerance  $\tau_0 2^{-\ell}$ . Moreover, a standard argument shows that any nonadaptive SQ algorithm which makes  $M$  statistical queries, each with tolerance at least  $\tau_0$ , can be simulated in the obvious way by a standard trace reconstruction algorithm that uses  $\text{poly}(\log M, 1/\tau_0)$  independent traces from  $\mathbf{Del}_\delta(x)$ . Thus, we will be particularly interested in identifying the value  $\ell$  of the locality parameter for which tolerance (roughly)  $2^{-\ell}$  is both necessary and sufficient for trace reconstruction. As we explain next, our main results do precisely this, for both worst-case and average-case trace reconstruction.

## 1.1 Our results

We give upper and lower bounds on local SQ algorithms for both worst-case and average-case trace reconstruction. Our upper and lower bounds match each other up to fairly small factors for both the worst-case and average-case versions of the problem.

**The worst-case problem.** Our main lower bound is the following result, which gives a lower bound on the tolerance for  $n^{1/5}$ -local SQ algorithms performing worst-case trace reconstruction:

► **Theorem 1** (Worst-case lower bound, informal version of Theorem 6). *Fix any constant deletion rate  $0 < \delta < 1$ . For  $\ell = \tilde{\Theta}(n^{1/5})$ , any  $\ell$ -local SQ algorithm for worst-case trace reconstruction must have tolerance  $\tau_0 = \exp(-\Omega(n^{1/5}))$ .*

Our algorithmic result for the worst-case problem shows that this lower bound is essentially optimal:

► **Theorem 2** (Worst-case upper bound, informal version of Theorem 15). *Fix any constant deletion rate  $0 < \delta < 1$ . There is a  $\tilde{O}(n^{1/5})$ -local SQ algorithm for the worst-case trace reconstruction problem with tolerance  $\tau_0 = \exp(-\tilde{O}(n^{1/5}))$ .*

**The average-case problem.** As mentioned earlier, the state-of-the-art average-case trace reconstruction algorithms of [37, 23, 24, 38] do not seem to be compatible with the SQ model. Recall that those algorithms use  $2^{O((\log n)^c)}$  traces, for  $c \in \{1/5, 1/3, 1/2\}$ , and thus any SQ analogue of those algorithms would have tolerance  $\approx 2^{-O((\log n)^c)}$ . We show that no  $O(\log n)$ -local (or even  $n^{0.49}$ -local) SQ algorithm for average-case trace reconstruction can succeed with such a coarse tolerance parameter:

► **Theorem 3** (Average-case lower bound, informal version of Theorem 23). *Fix any constant deletion rate  $0 < \delta < 1$ . Any  $\ell$ -local SQ algorithm for average-case trace reconstruction must have tolerance  $\tau_0 \leq \ell/\sqrt{n}$ .*

Finally, we give an average-case  $O(\log n)$ -local SQ algorithm that has inverse polynomial tolerance:

► **Theorem 4** (Average-case upper bound, informal version of Theorem 25). *Fix any constant deletion rate  $0 < \delta < 1$ . There is an  $O(\log n)$ -local SQ algorithm for average-case trace reconstruction with tolerance  $\tau_0 = 1/\text{poly}(n)$ .*

Our results can be summarized as follows: As discussed immediately before Section 1.1, we may say that an  $\ell$ -local SQ algorithm with tolerance  $\tau_0$  has overall complexity  $\text{poly}(n2^\ell, 1/\tau_0)$ . Theorems 1 and 2 together say that the optimal complexity of worst-case local SQ trace reconstruction is  $2^{\tilde{\Theta}(n^{1/5})}$ , and Theorems 3 and 4 together say that the optimal complexity of average-case local SQ trace reconstruction is  $n^{\Theta(1)}$ .

## 1.2 Discussion and techniques

**The worst-case setting.** Theorem 1 and Theorem 2 should be contrasted with recent results of Cheng et al. [15], which consider a restricted class of local SQ algorithms known as  *$\ell$ -mer based* algorithms. As defined by Mazooji and Shomorony [31], the  *$\ell$ -mer density map* is a certain vector of statistics about the frequency of length- $\ell$  subwords<sup>2</sup> of the source string  $x \in \{0, 1\}^n$ . [31] gave an algorithm which, for constant deletion rate  $0 < \delta < 1/2$ , constructs an  $\varepsilon$ -accurate (in  $\ell_\infty$  distance) estimate of the  $\ell$ -mer density map using  $\text{poly}(n, 2^\ell, 1/\varepsilon)$  traces. Cheng et al. [15] defined a trace reconstruction algorithm to be  *$\ell$ -mer based* if it only uses the  $\ell$ -mer density map of  $x$ , and observed that the algorithm of [31] (see in particular Lemma 6 of [31] and its proof) only uses local statistical information about traces, and hence is a local SQ algorithm.

<sup>2</sup> Recall that a *subword* of  $x$  is a sequence of bits that occur consecutively in  $x$ , i.e.  $x_i x_{i+1} \cdots x_{i+\ell-1}$ , whereas a *substring* of  $x$  is a subsequence of bits that need not occur consecutively, i.e.  $x_{i_1} x_{i_2} \cdots x_{i_\ell}$ .

The main result of Cheng et al. is a proof that any  $n^{1/5}$ -mer based algorithm for worst-case trace reconstruction must have tolerance  $\tau_0 = 2^{-\tilde{\Omega}(n^{1/5})}$ . Our Theorem 1 generalizes this result because it gives a lower bound for the entire class of  $n^{1/5}$ -local SQ algorithms, which includes the class of  $n^{1/5}$ -mer based algorithms by the results described above. We remark that Theorem 1 also has a shorter and simpler proof than Theorem 2 of [15].

At a high-level, we obtain Theorem 1 by a reduction to proving a 1-local SQ lower bound on  $n$ -bit source strings that are “gappy.” These are strings in which every two 1s are separated by  $\gg n^{1/5}$  zeros (see Definition 8 for the precise definition). The intuition here is that for a gappy string, any  $n^{1/5}$ -bit subword in its traces is very unlikely to contain two 1s, and so all the useful information is contained in subword queries of Hamming weight at most 1, which can then be further reduced to 1-bit queries. Then we can adapt the lower bound arguments in [19] to gappy strings to obtain our lower bound.

Turning to Theorem 2, Cheng et al. observed that the  $2^{\tilde{O}(n^{1/5})}$ -trace algorithm of [11] for worst-case trace reconstruction can be interpreted as a  $\tilde{O}(n^{1/5})$ -mer based algorithm with tolerance  $\tau_0 = 2^{-\tilde{O}(n^{1/5})}$ . By the earlier observation of Cheng et al. mentioned in the first paragraph and the [31] algorithm, which works provided that the deletion rate  $\delta$  lies in  $(0, 1/2)$ , this means that Chase’s algorithm can be expressed as a  $\tilde{O}(n^{1/5})$ -local SQ algorithm which has tolerance  $\tau_0 = 2^{-\tilde{O}(n^{1/5})}$  when  $\delta \in (0, 1/2)$ . Our Theorem 15 is based on a similar observation about Chase’s algorithm, but applied directly to the local SQ model without going through the notion of  $k$ -mer statistics. Our approach is based on techniques and arguments from [13]; using these techniques allows our argument to apply more generally to the entire range of deletion rates  $\delta \in (0, 1)$ .

**Average-case.** The average-case lower bound of Theorem 3 is proved using a fairly simple argument based on “hiding” a bit which might be either 0 or 1 in the middle of the source string. We turn to the average-case upper bound.

The average-case SQ algorithm described in Theorem 4 is obtained by adapting an algorithm for *smoothed* trace reconstruction to the SQ model. The [13] paper gives an algorithm for “smoothed” trace reconstruction, which is a generalization of the average-case trace reconstruction problem. While the algorithm of [13] only interacts with the input traces by using them to form empirical estimates of subword frequencies in traces, it is not trivially an SQ algorithm. This is because the [13] algorithm estimates these subword frequencies across a range of different deletion probabilities  $\delta, \delta + \Delta, \delta + 2\Delta, \dots$  up to  $(\delta + 1)/2$ . In the usual (non-SQ) trace reconstruction setting where traces are available, it is trivial to simulate access to  $\mathbf{Del}_{\delta'}(x)$  given access to  $\mathbf{Del}_{\delta}(x)$  for any  $\delta' > \delta$ , simply by drawing  $\mathbf{y} \sim \mathbf{Del}_{\delta}(x)$  and deleting each bit of  $\mathbf{y}$  independently with probability  $\frac{1-\delta'}{1-\delta}$ . But in the SQ setting, we only have access to statistical queries of traces drawn from  $\mathbf{Del}_{\delta}(x)$  rather than individual traces. We circumvent this issue by showing that any algorithm that makes  $\ell$ -local statistical queries with tolerance  $\tau$  to  $\mathbf{Del}_{\delta'}(x)$ , for  $\delta' > \delta$ , can be simulated by an algorithm that makes only  $\ell'$ -local statistical queries with tolerance  $\tau'$  to  $\mathbf{Del}_{\delta}(x)$ , where (roughly speaking)  $\ell' \approx \ell/(1-\delta')$  and  $\tau' = \Theta(\tau)$ . With this ingredient in hand, the algorithm of [13] is easily adapted to give Theorem 4.

### 1.3 Future work

Several natural questions suggest themselves for future work. Perhaps the foremost among these is the following: Given Theorem 2, the current state-of-the-art unrestricted algorithm for the general worst-case trace reconstruction problem is an  $\tilde{O}(n^{1/5})$ -local SQ algorithm. Might it be the case that this is in fact an optimal algorithm for trace reconstruction? We

currently seem quite far from being able to resolve this (recall that the state of the art in lower bounds for unrestricted worst-case trace reconstruction algorithms is only  $\tilde{\Omega}(n^{3/2})$  traces [11]).

A partial step towards answering the above bold question would be to establish lower bounds on general SQ algorithms for worst-case trace reconstruction, i.e. SQ algorithms that are not assumed to have bounded locality. It is difficult to imagine how queries that depend on far-separated portions of an input trace could be useful, but proving this seems quite challenging.

As a concrete first goal along these lines, a generalization of the notion of an  $\ell$ -local SQ is the notion of a *size- $s$*  SQ. A size- $s$  SQ is an SQ which asks for the expected value of some  $s$ -junta function  $q'(\mathbf{y}_{i_1}, \dots, \mathbf{y}_{i_s})$  of a random trace  $\mathbf{y}$ , but unlike an  $\ell$ -local SQ the input bits of the junta do not need to form a consecutive block of positions in  $\mathbf{y}$ . Similar to Lemma 5, a size- $s$  SQ algorithm can be assumed without loss of generality to use only query functions of the form  $\mathbf{1}[y_{i_1}, \dots, y_{i_s}] = w$  as  $(i_1, \dots, i_s)$  ranges over  $\binom{[n]}{s}$  and  $w$  ranges over  $\{0, 1\}^s$ . Even the following goal appears to be quite challenging:

Show that any SQ algorithm for the worst-case trace reconstruction problem that makes only size-2 queries must have tolerance  $\tau = 1/n^{\omega(1)}$ .

We believe that this is an interesting target problem for future work.

## 2 Preliminaries

**Notation.** Given integers  $a \leq b$  we write  $[a : b]$  to denote  $\{a, \dots, b\}$ . It will be convenient for us to index a binary string  $x \in \{0, 1\}^n$  using  $[0 : n - 1]$  as  $x = (x_0, \dots, x_{n-1})$ . We write  $\ln$  to denote natural logarithm and  $\log$  to denote logarithm to the base 2. We write  $|x|$  to denote the length of a string  $x$ .

We denote the set of non-negative integers by  $\mathbb{Z}_{\geq 0}$ . We write  $D_r(z)$  to denote the closed disk in the complex plane of radius  $r$  centered at  $z \in \mathbb{C}$ , and  $\partial D_r(z)$  to denote the circle which is the boundary of that disk.

**Subwords.** Fix a string  $x \in \{0, 1\}^n$  and an integer  $k \in [n]$ . A  $k$ -subword of  $x$  is a (contiguous) subword of  $x$  of length  $k$ , given by  $(x_a, x_{a+1}, \dots, x_{a+k-1})$  for some  $a \in [0 : n - k]$ . Given such a string  $x$  and integers  $0 \leq a < b \leq n - 1$ , we write  $x[a : b]$  to denote the subword  $(x_a, x_{a+1}, \dots, x_b)$ . For a string  $w \in \{0, 1\}^k$ , let  $\#(w, x)$  denote the number of occurrences of  $w$  as a subword of  $x$ .

**Distributions.** We use bold font letters to denote probability distributions and random variables, which should be clear from the context. We write “ $\mathbf{x} \sim \mathbf{X}$ ” to indicate that random variable  $\mathbf{x}$  is distributed according to distribution  $\mathbf{X}$ .

**Deletion channel and traces.** Throughout this paper the parameter  $\delta : 0 < \delta < 1$  denotes the *deletion probability*, and we write  $\rho$  to denote the retention probability  $\rho = 1 - \delta$ . Given a string  $x \in \{0, 1\}^n$ , we write  $\mathbf{Del}_\delta(x)$  to denote the distribution of the string that results from passing  $x$  through the  $\delta$ -deletion channel (so the distribution  $\mathbf{Del}_\delta(x)$  is supported on  $\{0, 1\}^{\leq n}$ ), and we refer to a string drawn from  $\mathbf{Del}_\delta(x)$  as a *trace* of  $x$ . Recall that a random trace  $\mathbf{y} \sim \mathbf{Del}_\delta(x)$  is obtained by independently deleting each bit of  $x$  with probability  $\delta$  and concatenating the surviving bits.<sup>3</sup>

<sup>3</sup> For simplicity in this work we assume that the deletion probability  $\delta$  is known to the reconstruction algorithm.

For  $x \in \{0, 1\}^n$  (recall that we index the bits of  $x$  as  $(x_0, \dots, x_{n-1})$ ) we view a draw of a trace  $\mathbf{y} \sim \mathbf{Del}(x)$  as corresponding to a  $\rho$ -biased random draw of a subset  $\mathbf{R} \subseteq [0 : n - 1]$ , where the elements of  $\mathbf{R}$  are the bits that are *retained* in  $x$  to obtain  $\mathbf{y}$ . So if the sorted elements of  $\mathbf{R}$  are  $\mathbf{R} = \{r_0 < r_1 < \dots < r_{m-1}\}$  for some  $m \leq n$ , then the bits of the trace  $\mathbf{y} = (\mathbf{y}_0, \mathbf{y}_1, \dots, \mathbf{y}_{m-1})$  are  $\mathbf{y}_0 = x_{r_0}, \mathbf{y}_1 = x_{r_1}$ , and so on.

## 2.1 Local Statistical Query algorithms

As described earlier, an  $\ell$ -local query function  $q : \{0, 1\}^n \rightarrow [-1, 1]$  is a function

$$q(\mathbf{y}) = q'(y_i, y_{i+1}, \dots, y_{i+\ell-1})$$

for some index  $i$  and some function  $q' : \{0, 1\}^\ell \rightarrow [-1, 1]$ , i.e. a real-valued bounded  $\ell$ -junta over consecutive input variables. An algorithm is an  $\ell$ -local SQ algorithm with tolerance  $\tau_0$  if all of its calls to the SQ oracle are made with  $\ell$ -local query functions and the tolerance parameter for each call is at least  $\tau_0$ .

Let us say that an  $\ell$ -local query function is a *subword query* if it is of the form

$$q'(\mathbf{y}) = \mathbf{1}[(y_i, \dots, y_{i+\ell-1}) = w] \tag{1}$$

for some string  $w \in \{0, 1\}^\ell$ . The following simple lemma shows that without loss of generality, every  $\ell$ -local SQ algorithm makes at most  $n2^\ell$  (non-adaptive) queries, corresponding to all possible length- $\ell$  subword queries:

► **Lemma 5.** *Let  $A$  be an  $\ell$ -local SQ algorithm with tolerance  $\tau_0$  (note that  $A$  may make any number of calls to the SQ oracle and may be adaptive, i.e. the choice of later queries may depend on the responses received on earlier queries). Then there is an algorithm  $A'$  with the same behavior as  $A$  which makes  $n2^\ell$  queries (all possible length- $\ell$  subword queries), each with tolerance  $\tau_0/2^\ell$ .*

**Proof.** The algorithm  $A'$  makes all  $n2^\ell$  subword queries of the form given in Equation (1), where  $i$  ranges over  $[n]$  and  $w$  ranges over  $\{0, 1\}^\ell$ . It makes each such subword query with tolerance parameter  $\tau_0/2^\ell$ . Let  $p_{i,w} = \Pr_{\mathbf{y} \sim \mathbf{Del}(x)}[(y_i, \dots, y_{i+\ell-1}) = w]$  and let  $\hat{p}_{i,w}$  be the value received from the SQ oracle in response to the query (1), so  $|\hat{p}_{i,w} - p_{i,w}| \leq \tau_0/2^\ell$ .

Let  $(q, \tau_0)$  be any (query function, tolerance) pair that  $A$  may make in the course of its execution. We show that a  $\pm\tau_0$ -accurate estimate  $\hat{P}_q$  of  $P_q$  can be computed from the responses to the  $n2^\ell$  queries of  $A'$ . This is easily seen to imply the lemma.

Since  $A$  is  $\ell$ -local, the expected value  $P_q$  is

$$P_q = \mathbf{E}_{\mathbf{y} \sim \mathbf{Del}_\rho(x)}[q'(\mathbf{y}_i, \dots, \mathbf{y}_{i+\ell-1})]$$

for some  $q' : \{0, 1\}^\ell \rightarrow [-1, 1]$  and some  $i \in [n]$ . Since

$$P_q = \sum_{w \in \{0, 1\}^\ell} p_{i,w} \cdot q'(w),$$

by setting  $\hat{P}_q$  to be

$$P_q = \sum_{w \in \{0, 1\}^\ell} \hat{p}_{i,w} \cdot q'(w),$$

recalling that  $|q'(w)| \leq 1$  for all  $w$ , the triangle inequality gives

$$|\widehat{P}_q - P_q| = \left| \sum_{w \in \{0,1\}^\ell} (\widehat{p}_{i,w} - p_{i,w}) \cdot q'(w) \right| \leq \max_w |q'(w)| \cdot \sum_w |\widehat{p}_{i,w} - p_{i,w}| \leq \sum_w \tau_0 / 2^\ell \leq \tau_0$$

as desired.  $\blacktriangleleft$

### 3 Worst-case lower bounds

In this section we prove the following lower bound on local SQ algorithms for the worst-case trace reconstruction problem:

► **Theorem 6 (Worst-case lower bound).** *Fix any constant deletion rate  $0 < \delta < 1$ . For a suitable absolute constant  $c_0$ , any  $c_0 n^{1/5} / (\log n)^{2/5}$ -local SQ algorithm for worst-case trace reconstruction must have tolerance  $\tau_0 < \exp(-\Omega(n^{1/5} / (\log n)^{2/5}))$ .*

**Setup.** Fix any  $0 < \delta < 1$ . For notational clarity let us write  $\ell := c_0 n^{1/5} / (\log n)^{2/5}$ . Given an  $n$ -bit source string  $x$ , an index  $i \in [0 : n - 1]$ , and an  $\ell$ -bit string  $w$ , we define the value

$$p_{x,i,w} := \Pr_{\mathbf{y} \sim \text{Del}_\delta(x)}[(\mathbf{y}_i, \dots, \mathbf{y}_{i+\ell-1}) = w], \quad (2)$$

so  $p_{x,i,w}$  is the probability that a random trace of  $x$  has  $w$  as the subword starting in position  $i$ . We refer to the vector  $(p_{x,i,w})_{i \in [0:n-1], w \in \{0,1\}^\ell}$  as the  $\ell$ -subword signature of  $x$ .

We will prove the following:

► **Lemma 7.** *For a suitable absolute constant  $c_0$ , there are distinct  $n$ -bit strings  $a \neq a' \in \{0,1\}^n$  whose  $\ell$ -subword signatures are very close to each other in  $\ell_\infty$ -distance: more precisely,*

$$\text{For all } i \in [0 : n - 1], w \in \{0,1\}^\ell, \text{ we have } |p_{a,i,w} - p_{a',i,w}| \leq \exp(-2c_0 n^{1/5} / (\log n)^{2/5}). \quad (3)$$

To see why Lemma 7 implies Theorem 6, let  $A$  be any  $\ell$ -local SQ algorithm with tolerance  $\exp(-c_0 n^{1/5} / (\log n)^{2/5})$ . By Lemma 5, there is an algorithm  $A'$  with the same behavior as  $A$  which makes only subword queries for subwords of length  $\ell$ , where each query of  $A'$  has tolerance  $\exp(-c_0 n^{1/5} / (\log n)^{2/5}) / 2^\ell > \exp(-2c_0 n^{1/5} / (\log n)^{2/5})$ . By Equation (3), a query for the value of  $p_{x,i,w}$  can be answered with the value  $q_{i,w} = \frac{p_{a,i,w} + p_{a',i,w}}{2}$  whether the source string  $x$  is  $a$  or  $a'$ . But this means that it is impossible for  $A$  to be an algorithm which successfully solves the worst-case trace reconstruction problem.

In the rest of this section, we focus on establishing Lemma 7.

We require the following simple definition:

► **Definition 8.** *Given  $t > 1$ , we say that a string  $x \in \{0,1\}^n$  is  $t$ -gappy if it is of the form*

$$x = b_0 0^{t-1} b_1 0^{t-1} \dots b_{n/t-1} 0^{t-1}$$

for some string  $b_0, b_1, \dots, b_{n/t-1} \in \{0,1\}^{n/t}$ .

Recall  $\rho = 1 - \delta$ . Fix

$$t := \frac{100 \log(n) \ell}{\rho} = \Theta(n^{1/5} (\log n)^{3/5}). \quad (4)$$

The two strings  $a, a'$  whose existence is asserted by Lemma 7 will both be  $t$ -gappy. (We note that the argument of Cheng et al. [15] also used gappy strings.)

One reason that gappy strings are useful for us because they make it very easy to handle almost all of the  $\ell$ -bit strings  $w \in \{0, 1\}^\ell$  that we need to consider in order to establish Lemma 7. To see this, observe that any string  $w$  containing at least two ones is very unlikely to be a length- $\ell$  subword of a random trace  $\mathbf{y}$ : since the source string is  $t$ -gappy, we expect consecutive ones in a random trace  $\mathbf{y}$  to be at least  $\rho t \gg \ell$  positions apart from each other. More precisely, we have the following lemma:

► **Lemma 9.** *Let  $x \in \{0, 1\}^n$  be any  $t$ -gappy string, and let  $w \in \{0, 1\}^\ell$  be any string with at least two ones. Then for any  $i \in [0 : n - 1]$  we have  $p_{x,i,w} \leq 1/n^{49\ell}$ .*

**Proof.** Fix  $0 \leq \alpha < \beta \leq \ell - 1$  to be any two positions in  $w$  such that  $w_\alpha = w_\beta = 1$ , and let  $\mathbf{y} \sim \text{Del}_\delta(x)$ . Observe that we have  $p_{x,i,w} \leq \Pr[\mathbf{y}_{i+\alpha} = \mathbf{y}_{i+\beta} = 1]$ .

Let  $\mathbf{R} = \{r_0 < r_2 < \dots < r_{m-1}\} \subseteq [0 : n - 1]$  be the  $\rho$ -biased random subset of  $[0 : n - 1]$  consisting of the indices that are retained in  $x$  to obtain  $\mathbf{y}$ . We may view the draw of  $\mathbf{R}$  as being carried out sequentially in independent stages  $0, 1, \dots$ , where in each stage  $s$  the element  $s$  is included in  $\mathbf{R}$  with probability  $\rho$ . Fix any outcome of stages  $0, 1, \dots$  up until  $r_{i+\alpha}$  has been included in  $\mathbf{R}$ . Even supposing that  $x_{r_{i+\alpha}} = 1$  (so that  $y_{i+\alpha} = 1$ ), the probability that  $x_{r_{i+\beta}} = 1$  (which equals  $\Pr[\mathbf{y}_{i+\beta} = 1]$ ) is at most (writing  $k$  for  $\beta - \alpha$ )

$$\begin{aligned} & \sum_{j \geq 1} \Pr[\text{exactly } k \text{ of the } jt \text{ indices in } r_{i+\alpha} + 1, \dots, r_{i+\alpha} + jt \text{ are retained}] & (5) \\ &= \sum_{j \geq 1} \binom{jt}{k} \rho^k \delta^{jt-k} \\ &\leq \sum_{j \geq 1} (\rho jt)^k \cdot \delta^{jt/2} = (\rho t)^k \sum_{j \geq 1} j^k \delta^{jt/2} & (\text{since } k \leq jt/2) \\ &\leq (\rho t)^\ell \sum_{j \geq 1} j^\ell (1 - \rho)^{jt/2} & (\text{using } k \leq \ell) \\ &\leq (100 \log(n)\ell)^\ell \sum_{j \geq 1} j^\ell e^{-50 \log(n)\ell j}. & (\text{by the choice of } t, \text{ and using } (1 - \rho)^{1/\rho} \leq e^{-1}) \end{aligned}$$

When  $j = 1$  the first term of the sum  $\sum_{j \geq 1} j^\ell e^{-50 \log(n)\ell j}$  is  $e^{-50 \log(n)\ell}$ . The ratio of successive terms of the sum is

$$\frac{(j+1)^\ell e^{-50 \log(n)\ell(j+1)}}{j^\ell e^{-50 \log(n)\ell j}} \leq 2^\ell e^{-50 \log(n)\ell} = (2/n^{50})^\ell \ll 1/2.$$

So the sum  $\sum_{j \geq 1} j^\ell e^{-50 \log(n)\ell j}$  is at most  $2e^{-50 \log(n)\ell} = 2/n^{50\ell}$ , and since  $100 \log(n)\ell < n$  for  $n$  sufficiently large, we get that (5)  $\leq 1/n^{49\ell}$ . It follows that  $p_{x,i,w} \leq \Pr[\mathbf{y}_{i+\alpha} = \mathbf{y}_{i+\beta} = 1] \leq 1/n^{49\ell}$  as claimed. ◀

Given Lemma 9 it remains to argue about the  $\ell + 1$  strings  $w \in \{0, 1\}^\ell$  of Hamming weight 0 or 1. We handle the weight-1 strings by reducing their analysis to the analysis of *one-bit* strings as follows: fix any  $\alpha \in [0 : \ell - 1]$  and let  $w = e_\alpha \in \{0, 1\}^\ell$  be the string with a single 1 coordinate in position  $\alpha$ . The following lemma, which we prove using Lemma 9, shows that for any gappy source string  $x$  the value of  $p_{x,i,e_\alpha}$  is very close to the expected value of a *single* location in a random trace. (A sharper bound could be obtained with a bit more work, but the bound given by Lemma 10 is sufficient for our purposes.)

► **Lemma 10.** *Let  $x \in \{0, 1\}^n$  be any  $t$ -gappy string, and let  $w = e_\alpha \in \{0, 1\}^\ell$  be the string containing a single 1 in coordinate  $\alpha$ . Then for any  $i \in [0 : n - 1]$  we have*

$$\left| \Pr_{\mathbf{y} \sim \text{Del}_\delta(x)}[\mathbf{y}_{i+\alpha} = 1] - p_{x,i,e_\alpha} \right| \leq 2^{\ell-1}/n^{49\ell}.$$

**Proof.** We have

$$\Pr_{\mathbf{y} \sim \text{Del}_\delta(x)}[\mathbf{y}_{i+\alpha} = 1] = \sum_{w \in \{0,1\}^\ell: w_\alpha=1} p_{x,i,w}, \quad \text{so}$$

$$0 \leq \Pr_{\mathbf{y} \sim \text{Del}_\delta(x)}[\mathbf{y}_{i+\alpha} = 1] - p_{x,i,e_\alpha} = \sum_{w \in \{0,1\}^\ell: w_\alpha=1, |w| \geq 2} p_{x,i,w} \leq (2^{\ell-1} - 1)/n^{49\ell}$$

where the inequality is Lemma 9.  $\blacktriangleleft$

The one remaining  $\ell$ -bit string to consider is  $w = 0^\ell$ . However, if all  $2^\ell - 1$  other strings have been handled successfully then this string is automatically handled as well:

► **Lemma 11.** Fix  $a, a' \in \{0,1\}^n$  and  $i \in [0 : n-1]$ . Suppose that for all  $w \in \{0,1\}^\ell \setminus \{0^\ell\}$  we have  $|p_{a,i,w} - p_{a',i,w}| \leq \kappa$ . Then  $|p_{a,i,0^\ell} - p_{a',i,0^\ell}| \leq (2^\ell - 1)\kappa$ .

**Proof.** This is an immediate consequence of  $\sum_{w \in \{0,1\}^\ell} p_{x,i,w} = 1$ , which holds for every  $x$  and  $i$ .  $\blacktriangleleft$

Thus, it suffices to construct two  $t$ -gappy strings  $a, a'$  whose one-bit statistics are very close:

► **Lemma 12.** For  $x \in \{0,1\}^n$  and  $i \in [0 : n-1]$  define

$$p_{x,i} := \Pr_{\mathbf{y} \sim \text{Del}_\delta(x)}[\mathbf{y}_i = 1]. \quad (6)$$

Suppose that  $a \neq a' \in \{0,1\}^n$  are two  $t$ -gappy strings such that for each  $i \in [0 : n-1]$  we have  $|p_{a,i} - p_{a',i}| \leq \exp(-\Omega(n^{1/5}/(\log n)^{2/5}))$ . Then for all  $i \in [0 : n-1]$ ,  $w \in \{0,1\}^\ell$  we have

$$|p_{a,i,w} - p_{a',i,w}| \leq 2^\ell \cdot \exp(-\Omega(n^{1/5}/(\log n)^{2/5})) + 4^\ell/n^{49\ell} \leq \exp(-2c_0 n^{1/5}/(\log n)^{2/5}).$$

**Proof.** Lemma 9 gives  $|p_{a,i,w} - p_{a',i,w}| \leq 1/n^{49\ell}$  for  $|w| \geq 2$ . Lemma 10 and the assumption on  $|p_{a,i} - p_{a',i}|$  gives  $|p_{a,i,w} - p_{a',i,w}| \leq \exp(-\Omega(n^{1/5}/(\log n)^{2/5})) + 2^\ell/n^{49\ell}$  for  $|w| = 1$ . Given these bounds, Lemma 11 gives  $|p_{a,i,0^\ell} - p_{a',i,0^\ell}| \leq 2^\ell \cdot \exp(-\Omega(n^{1/5}/(\log n)^{2/5})) + 4^\ell/n^{49\ell}$ .  $\blacktriangleleft$

### 3.1 Establishing closeness of one-bit statistics

Let us write  $p_x = (p_{x,0}, \dots, p_{x,n-1})$  to denote the  $n$ -dimensional vector in  $[0,1]^n$  whose coordinates are given by Equation (6). From the results in the previous subsection it suffice to prove the following:

► **Lemma 13.** There are two distinct  $t$ -gappy strings  $a, a' \in \{0,1\}^n$  such that for all  $i \in [0 : n-1]$  we have  $\|p_a - p_{a'}\|_\infty \leq \exp(-\Omega(n^{1/5}/(\log n)^{2/5}))$ .

This is very similar to the main lower bound statement that was established in the two works [19, 36] (independently of each other); those papers considered “one-bit statistics” which correspond precisely to our  $p_{x,i}$  quantities, and showed that there are two distinct strings  $x, x' \in \{0,1\}^n$  (not restricted to be gappy) such that  $|p_{x,i} - p_{x',i}| \leq \exp(-\Omega(n^{1/3}))$  for all  $i \in [0 : n-1]$ . In what follows we adapt their techniques to deal with  $t$ -gappy source strings.

Following [19], given a pair of source strings  $a, a' \in \{0,1\}^n$  we define the corresponding *deletion-channel polynomial* (over  $\mathbb{C}$ ) to be

$$P_{a,a'}(z) := \sum_{i=0}^{n-1} (p_{a,i} - p_{a',i}) \cdot z^i. \quad (7)$$

We have

$$\|p_a - p_{a'}\|_\infty \leq \|p_a - p_{a'}\|_1 \leq \sqrt{n} \max_{z \in \partial D_1(0)} |P_{a,a'}(z)|, \quad (8)$$

where the second inequality is by Proposition 3.5 of [19] (the proof is a simple and standard computation about complex polynomials). Thus our goal is to establish the existence of two distinct  $t$ -gappy strings  $a \neq a' \in \{0, 1\}^n$  for which  $\max_{z \in \partial D_1(0)} |P_{a,a'}(z)|$  is small. To do this, we begin by observing that since bit  $j$  of a source string ends up in location  $i$  of a trace with probability  $\binom{j}{i} \rho^{i+1} \delta^{j-i}$ , we have

$$p_{a,i} = \Pr_{\mathbf{y} \sim \text{Del}_\delta(a)}[\mathbf{y}_i = 1] = \sum_{j=0}^{n-1} \binom{j}{i} \rho^{i+1} \delta^{j-i} a_j, \text{ and hence } p_{a,i} - p_{a',i} = \sum_{j=0}^{n-1} (a_j - a'_j) \binom{j}{i} \rho^{i+1} \delta^{j-i}.$$

Hence (following [19, 36]) we get

$$\begin{aligned} P_{a,a'}(z) &= \sum_{i=0}^{n-1} \left( \sum_{j=0}^{n-1} (a_j - a'_j) \binom{j}{i} \rho^{i+1} \delta^{j-i} \right) z^i = \rho \sum_{j=0}^{n-1} (a_j - a'_j) \delta^j \sum_{i=0}^{n-1} \binom{j}{i} \left( \frac{\rho z}{\delta} \right)^i \\ &= \rho \sum_{j=0}^{n-1} (a_j - a'_j) w^j \quad (\text{taking } w = 1 - \rho + \rho z) \end{aligned} \quad (9)$$

where the last line used the binomial theorem and  $\delta = 1 - \rho$ . Now, let us write the  $t$ -gappy strings  $a, a'$  as

$$a := b_0 0^{t-1} b_1 0^{t-1} \dots b_{n/t} 0^{t-1}, \quad a' := b'_0 0^{t-1} b'_1 0^{t-1} \dots b'_{n/t} 0^{t-1} \quad (10)$$

for some  $b, b' \in \{0, 1\}^{n/t}$ . From Equation (9) we get that

$$P_{a,a'}(z) = \rho \cdot \sum_{j=0}^{n/t-1} (b_j - b'_j) w^{jt} \quad (11)$$

(the structure afforded by Equation (11) is another reason why  $t$ -gappy strings are useful for us). Since  $0 < \rho = 1 - \delta < 1$  is a constant, recalling Equation (8) our goal is to establish the existence of a string  $0^{n/t} \neq v = (v_0, \dots, v_{n/t-1}) \in \{-1, 0, 1\}^{n/t}$  such that

$$\max_{\theta \in (-\pi, \pi]} \left| \sum_{j=0}^{n/t-1} v_j \left( (1 - \rho + \rho e^{i\theta})^t \right)^j \right| \quad (12)$$

is small.

As described in Theorem 6.2 of [19], a result of Borwein and Erdélyi [3] (specifically, the first proof of Theorem 3.3 in the “special case” on p. 11 of [3]) establishes the following:

► **Theorem 14** ([3]). *There are universal constants  $c_1, c_2, c_3 > 0$  such that the following holds: For all  $0 < a \leq c_1$  there exists an integer  $2 \leq k \leq c_2/a^2$  and a nonzero vector  $u \in \{-1, 0, 1\}^{k+1}$  such that  $\max_{w \in D_{6a}(1)} \left| \sum_{j=0}^k u_j w^j \right| \leq \exp(-c_3/a)$ .*

Let  $m = n^{1/5}/(\log n)^{2/5} = 1/a$ , so  $a = 1/m = (\log n)^{2/5}/n^{-1/5}$ . Recalling Equation (4), we have that  $c_2/a^2 = c_2 m^2 \ll n/(2t)$ , so we get that there exists a vector  $0^{n/(2t)} \neq u \in \{-1, 0, 1\}^{n/(2t)}$  such that

$$\max_{w \in D_{6/m}(1)} \left| \sum_{j=0}^{n/(2t)-1} u_j w^j \right| \leq \exp(-c_3 m). \quad (13)$$

## 52:12 Trace Reconstruction from Local Statistical Queries

Routine geometry shows that if  $|\theta| \leq \frac{1}{mt}$  then  $|1 - (1 - \rho + \rho e^{i\theta})^t| \leq 6/m$ , so we get that

$$\max_{|\theta| \leq 1/(mt)} \left| \sum_{j=0}^{n/(2t)-1} u_j ((1 - \rho + \rho e^{i\theta})^t)^j \right| \leq \exp(-c_3 m). \quad (14)$$

Now we can describe our final desired string  $v \in \{-1, 0, 1\}^{n/t}$ : it is obtained by padding  $u$  with a prefix of  $n/(2t)$  many zeros. We thus have

$$\begin{aligned} (12) &= \max_{\theta \in (-\pi, \pi]} \sum_{j=0}^{n/t-1} v_j ((1 - \rho + \rho e^{i\theta})^t)^j \\ &= \max_{\theta \in (-\pi, \pi]} \left( \overbrace{(1 - \rho + \rho e^{i\theta})^{n/2}}^A \cdot \overbrace{\sum_{j=0}^{n/(2t)-1} u_j ((1 - \rho + \rho e^{i\theta})^t)^j}^B \right). \end{aligned} \quad (15)$$

Since  $|1 - \rho + \rho e^{i\theta}| \leq 1$  for all  $\theta \in (-\pi, \pi]$ , we have that  $|A|$  is always at most 1 and  $|B|$  is always at most  $n/(2t)$ . We bound Equation (15) by considering two possible ranges for  $|\theta|$ . If  $|\theta| \leq 1/(mt)$ , then since  $|A| \leq 1$ , from Equation (14) we have that  $(15) \leq 1 \cdot |B| \leq \exp(-c_3 m)$ . On the other hand, if  $|\theta| > 1/(mt)$  then since  $|B| \leq n/(2t)$  and  $\rho$  is a constant between 0 and 1, we get that  $|1 - \rho + \rho e^{i\theta}| \leq 1 - \frac{c_\rho}{(mt)^2}$ , and hence

$$(15) \leq \frac{n}{2t} \cdot |A| \leq \frac{n}{2t} \cdot \left(1 - \frac{c_\rho}{(mt)^2}\right)^{n/2} \leq \exp(-c'_\rho n/(mt)^2)$$

for two constants  $c_\rho, c'_\rho > 0$  that depend only on  $\rho$ . Since  $m = n^{1/5}/(\log n)^{2/5}$  and  $n/(mt)^2 = \Theta(n^{1/5}/(\log n)^{2/5})$ , for all  $\theta \in (-\pi, \pi]$  we have that  $(12) \leq \exp(-\Omega(n^{1/5}/(\log n)^{2/5}))$ , so the proof of Lemma 13 and hence of Theorem 6 is complete.

### 4 Worst-case upper bounds

In this section we will give a local SQ algorithm for worst-case trace reconstruction, proving Theorem 2.

► **Theorem 15** (Worst-case upper bound). *Fix any constant deletion rate  $0 < \delta < 1$ . There is a worst-case SQ trace reconstruction algorithm that makes only  $(O(n^{1/5} \log^5 n))$ -local queries with tolerance  $\tau = 2^{-O(n^{1/5} \log^5 n)}$ .*

**Overview.** As discussed in the introduction, [15] showed that the state-of-the-art worst-case trace reconstruction algorithm of Chase [11] can be interpreted as a  $\tilde{O}(n^{1/5})$ -mer based algorithm, and further observed that the work [31] implicitly showed that for deletion rate  $\delta < 1/2$ , any  $k$ -mer based algorithm only relies on local statistics of random traces. The same observation can also be inferred from the work [13]; more generally, that work implicitly showed that for *any* deletion rate  $0 < \delta < 1$  (not just  $\delta < 1/2$ ), Chase's algorithm can be interpreted as a local SQ algorithm. We obtain Theorem 15 by making this interpretation explicit, without going through the notion of  $k$ -mer statistics.

In the case of  $\delta < 1/2$ , the observation in [13, 31] is the following. Chase's algorithm is based on estimating (from below) a certain univariate polynomial  $Q_x(z_0)$  at some point  $z_0$  inside the shifted complex disc  $D := \{\frac{z-\delta}{1-\delta} : |z| \leq 1\}$ . Moreover, the degree- $\ell$  coefficient of  $Q_x$  can be estimated using  $\ell$ -local statistics. When  $\delta$  is bounded away from  $1/2$ , these

works observed that the magnitude of the degree- $\ell$  term of  $Q_x$  decays exponentially in  $\ell$ , and so the contribution from the high-degree terms is negligible and can be truncated from the evaluation.

In the case of  $\delta \geq 1/2$ , a point in  $D$  can have magnitude 1 or more, and so the high-degree terms in  $Q_x$  need not decay in magnitude. Instead of evaluating the polynomial on some point in  $D$ , [13] applies a result by Borwein, Erdélyi, and Kós [4] (see Lemma 18 below) which shows that there exists a value  $t_0$  in the real interval  $[\delta, \frac{1}{4} + \frac{3}{4}\delta]$  such that  $Q_x(t_0)$  is almost as large as  $Q_x(z_0)$ , and as a result, we can estimate the truncation of  $Q_x(t_0)$  instead.

We now proceed to a detailed proof of Theorem 15. Let  $\ell := 2n^{1/5}$ . Our  $(O(n^{1/5} \log^5 n))$ -local SQ algorithm in Theorem 15 is based on the following two lemmas. (Throughout this section, it will be more convenient for us to phrase various quantities in terms of the retention rate  $\rho = 1 - \delta$ .) For a source string  $x \in \{0, 1\}^n$  and an  $\ell$ -bit pattern  $w \in \{0, 1\}^\ell$ , let  $P_{x,w}(z, t)$  be the following bivariate polynomial:

$$P_{x,w}(z, t) := \sum_{0 \leq i_1 < \dots < i_\ell \leq n-1} \prod_{k=1}^{\ell} \mathbf{1}[x_{i_k} = w_k] z^{i_1} \cdot t^{i_\ell - i_1 - (\ell-1)}.$$

► **Lemma 16.** *For every deletion rate  $\delta \in (0, 1)$ , there is a constant  $C_\rho$  such that the following holds. For every distinct pair of source strings  $x, x' \in \{0, 1\}^n$ , there is a pattern  $w \in \{0, 1\}^\ell$ , a point  $z_0 \in \{e^{i\theta} : |\theta| \leq n^{-2/5}\} \cup [1 - \rho, 1 - \frac{3}{4}\rho]$ , and a real value  $t_0 \in [1 - \rho, 1 - \frac{3}{4}\rho]$ , such that*

$$|P_{x,w}(z_0, t_0) - P_{x',w}(z_0, t_0)| \geq \exp(-C_\rho n^{1/5} \log^5 n).$$

► **Lemma 17.** *For every deletion rate  $\delta \in (0, 1)$ , there exists an SQ algorithm that makes  $C_\rho n^{1/5} \log^5 n$ -local queries with tolerance  $\exp(-C_\rho n^{1/5} \log^5 n)$  such that for every  $w \in \{0, 1\}^\ell$ ,  $z \in \{e^{i\theta} : |\theta| \leq n^{-2/5}\} \cup [1 - \rho, 1 - \frac{3}{4}\rho]$ , and  $t \in [1 - \rho, 1 - \frac{3}{4}\rho]$  it outputs an estimate  $\widehat{P}_{x,w}(z, t)$  of  $P_{x,w}(z, t)$  that is accurate to within  $\pm 0.1 \cdot \exp(-C_\rho n^{1/5} \log^5 n)$ .*

### Our $\ell$ -local SQ algorithm (Proof of Theorem 15 assuming Lemmas 16 and 17)

Given an unknown source string  $x \in \{0, 1\}^n$ , our reconstruction algorithm enumerates every pair of distinct strings  $x_1 \neq x_2 \in \{0, 1\}^n$ . For each such pair, it considers the triple  $(w, z_0, t_0)$  for that pair whose existence is given by Lemma 16. (Hence there are at most  $2^{2n}$  many such triples  $(w, z_0, t_0)$  considered in total.) Then it uses the SQ algorithm in Lemma 17 to obtain an accurate estimate  $\widehat{P}_{x,w}(z_0, t_0)$  of  $P_{x,w}(z_0, t_0)$  for each  $w$  within an additive factor of  $\pm 0.1 \cdot \exp(-C_\rho n^{1/5} \log^5 n)$ , and outputs the  $x'$  such that  $\widehat{P}_{x,w}(z_0, t_0)$  and  $P_{x',w}(z_0, t_0)$  are  $\pm 0.5 \cdot \exp(-C_\rho n^{1/5} \log^5 n)$ -close to each other for every  $w, z_0, t_0$ . The correctness follows immediately from Lemma 16, because if  $x' \neq x$ , then by that lemma there is some  $(w, z_0, t_0)$  such that by the triangle inequality we have

$$\begin{aligned} |\widehat{P}_{x,w}(z_0, t_0) - P_{x',w}(z_0, t_0)| &\geq |P_{x,w}(z_0, t_0) - P_{x',w}(z_0, t_0)| - |\widehat{P}_{x,w}(z_0, t_0) - P_{x,w}(z_0, t_0)| \\ &\geq 0.9 \cdot \exp(-C_\rho n^{1/5} \log^5 n). \end{aligned}$$

## 4.1 Proof of Lemma 16

In this subsection we prove Lemma 16. We first recall the following result from [4].

► **Lemma 18** (Theorem 5.1 in [4]). *There are constants  $c_1, c_2 > 0$  such that for every analytic function  $f$  on the open unit disc  $\{z : |z| < 1\}$  with  $|f(z)| < \frac{1}{1-|z|}$  and every  $a \in (0, 1]$ , we have*

$$|f(0)|^{\frac{c_1}{a}} \leq \exp(c_2/a) \sup_{t \in [1-a, 1-\frac{3}{4}a]} |f(t)|.$$

Note that polynomials with coefficients bounded by 1 are clearly analytic and satisfy the condition that  $|f(z)| < \frac{1}{1-|z|}$  on the open unit disc  $\{z : |z| < 1\}$ .

We note that in the actual statement in [4, Theorem 5.1], the interval containing  $t$  is  $[1-a, 1]$ . However, a close inspection of the proof reveals that the interval can be restricted to be  $[1-a, 1 - \frac{3}{4}a]$ . Specifically, their Theorem 5.1 is based on their Corollary 5.3, which in turn is based on their Corollary 5.2, where the interval is taken to be  $[1-a, 1-a + \frac{1}{4}a]$ . A self-contained proof using essentially the same argument can also be found in [13, Theorem 9].

We further note that the difference between  $[1-a, 1]$  and  $[1 - \frac{3}{4}a]$  is crucial in showing that the contribution of the high-degree terms of the relevant polynomial (Equation (16)) is negligible. Had  $t$  been 1, then  $\frac{t-(1-\rho)}{\rho} = 1$  and there would have been no exponential decay in the high-degree terms.

Lemma 16 follows from two cases below.

**Case 1:  $x_i \neq x'_i$  for some  $0 \leq i \leq \ell - 1$**

In this case, we consider the  $\ell$ -bit pattern  $w := x[0 : \ell - 1]$ . Note that  $P_{x,w}(0, 0) - P_{x',w}(0, 0) = \mathbf{1}[x[0 : \ell - 1] = w] - \mathbf{1}[x'[0 : \ell - 1] = w] = 1$ . We now apply Lemma 18 twice. The first application is to the polynomial  $Q_1(z_1) := P_{x,w}(z_1, 0) - P_{x',w}(z_1, 0)$ , which implies that there exists some  $z_0 \in [1 - \rho, 1 - \frac{3}{4}\rho]$  such that

$$|Q_1(z_0)| \geq e^{-c_2/\rho} |Q_1(0)|^{c_1/\rho} = e^{-c_2/\rho} |P_{x,w}(0, 0) - P_{x',w}(0, 0)|^{c_1/\rho} = e^{-c_2/\rho}.$$

We now apply Lemma 18 again to the polynomial

$$Q_2(z_2) := \frac{P_{x,w}(z_0, z_2) - P_{x',w}(z_0, z_2)}{\binom{n}{\ell}}.$$

Note that all coefficients in  $Q_2$  have magnitude at most 1. This implies the existence of some  $t_0 \in [1 - \rho, 1 - \frac{3}{4}\rho]$  such that

$$\begin{aligned} |P_{x,w}(z_0, t_0) - P_{x',w}(z_0, t_0)| &= \binom{n}{\ell} |Q_2(t_0)| \geq \binom{n}{\ell} e^{-c_2/\rho} |Q_2(0)|^{c_1/\rho} = \binom{n}{\ell} e^{-c_2/\rho} \left( \frac{|Q_1(z_0)|}{\binom{n}{\ell}} \right)^{c_1/\rho} \\ &\geq \frac{e^{-\frac{c_2}{\rho} - \frac{c_1 c_2}{\rho^2}}}{\binom{n}{\ell}^{\frac{c_1}{\rho} - 1}} \geq e^{-\Omega_\rho(\ell \log n)} = e^{-\Omega_\rho(n^{1/5} \log n)}, \end{aligned}$$

where the last inequality used  $\binom{n}{\ell} \geq (n/\ell)^\ell$ , and the last equality follows from our choice of  $\ell = 2n^{1/5}$ . To conclude, there exists some  $(z_0, t_0) \in [1 - \rho, 1 - \frac{3}{4}\rho]^2$  such that  $|P_{x,w}(z_0, t_0) - P_{x',w}(z_0, t_0)| \geq \Omega_\rho \binom{n}{\ell}^{-c_1/\rho}$ .

**Case 2:  $x_i = x'_i$  for all  $0 \leq i \leq \ell - 1$**

For this case, [11, Corollary 6.1] (with the interval  $[1 - 2\rho, 1]$  replaced with  $[1 - \rho, 1 - \frac{3}{4}\rho]$ ) can be restated, using Lemma 18 in a similar fashion as Case 1, as follows:

► **Lemma 19** (Corollary 6.1 in [11], slightly rephrased and refined). *For every  $\rho > 0$ , there exists a constant  $C_\rho$  such that the following holds. Let  $\ell = 2n^{1/5}$ . For every distinct  $x, x' \in \{0, 1\}^n$  where  $x_i = x'_i$  for every  $0 \leq i < \ell - 1$ , there exists a pattern  $w \in \{0, 1\}^\ell$ , a  $z_0 = e^{i\theta}$  for some  $\theta \in [-n^{-2/5}, n^{-2/5}]$  and a  $t_0 \in [1 - \rho, 1 - \frac{3}{4}\rho]$  such that*

$$\left| \sum_{0 \leq i_1 < \dots < i_\ell \leq n-1} \left( \prod_{k=1}^{\ell} \mathbf{1}[x_{i_k} = w_k] - \prod_{k=1}^{\ell} \mathbf{1}[x'_{i_k} = w_k] \right) z_0^{i_1} \cdot t_0^{i_\ell - i_1 - (\ell-1)} \right| \geq \exp(-C_\rho n^{1/5} \log^5 n).$$

Combining the two cases proves Lemma 16.

## 4.2 Proof of Lemma 17

We now prove Lemma 17. We first state the following identity relating two multivariate polynomials, each of which is defined in terms of an arbitrary  $f : \{0, 1\}^\ell \rightarrow \mathbb{C}$ . One of these involves the evaluation of  $f$  on the  $\ell$ -bit (not necessarily consecutive) substrings of the source string  $x$ , and the other involves the expectation of  $f$  evaluated on the  $\ell$ -bit substrings of a random trace  $\mathbf{y} \sim \mathbf{Del}_\delta(x)$ . This identity has now appeared in several places such as [13, 11] (see [13, Section 5.2] for a proof).

► **Fact 20.** For every  $f : \{0, 1\}^\ell \rightarrow \mathbb{C}$ ,  $x \in \{0, 1\}^n$ ,  $\rho \in [0, 1]$ , and  $z \in \mathbb{C}^\ell$ ,

$$\begin{aligned} & \rho^\ell \sum_{0 \leq i_1 < \dots < i_\ell \leq n-1} f(x_{i_1}, \dots, x_{i_\ell}) ((1-\rho) + \rho z_1)^{i_1} \prod_{k=2}^{\ell} ((1-\rho) + \rho z_k)^{i_k - i_{k-1} - 1} \\ &= \sum_{0 \leq j_1 < \dots < j_\ell \leq n-1} \mathbf{E}_{\mathbf{y} \sim \mathbf{Del}_{1-\rho}(x)} [f(\mathbf{y}_{j_1}, \dots, \mathbf{y}_{j_\ell})] z_1^{j_1} \prod_{k=2}^{\ell} z_k^{j_k - j_{k-1} - 1}. \end{aligned}$$

Letting  $f(u_1, \dots, u_\ell)$  be the indicator function  $\mathbf{1}[u = w]$  for some pattern  $w \in \{0, 1\}^\ell$ , then performing a simple change of variable  $z_i \mapsto \frac{z_i - (1-\rho)}{\rho}$ , and then identifying the variables  $z_3, \dots, z_\ell$  with the variable  $z_2$ , we obtain the following corollary.

► **Corollary 21.** For every  $\rho \in (0, 1]$ ,  $x \in \{0, 1\}^n$ ,  $w \in \{0, 1\}^\ell$ , and  $(z_1, z_2) \in \mathbb{C}^2$ ,

$$\begin{aligned} & P_{x,w}(z_1, z_2) = \\ & \rho^{-\ell} \sum_{0 \leq j_1 < \dots < j_\ell \leq n-1} \mathbf{E}_{\mathbf{y} \sim \mathbf{Del}_{1-\rho}(x)} \left[ \prod_{k=1}^{\ell} \mathbf{1}[\mathbf{y}_{j_k} = w_k] \right] \left( \frac{z_1 - (1-\rho)}{\rho} \right)^{j_1} \left( \frac{z_2 - (1-\rho)}{\rho} \right)^{j_\ell - j_1 - (\ell-1)}. \end{aligned} \quad (16)$$

Let  $Q(z_1, z_2)$  be the bivariate polynomial on the right hand side of Equation (16). Observe that for every fixed  $z_1$ , viewing  $Q(z_1, z_2)$  as a univariate polynomial in  $z_2$ , its  $z_2$ -coefficient of degree  $d$  (a univariate polynomial in  $z_1$ ) can be estimated using  $d$ -local SQs. We will first prove that  $Q$ , as a univariate polynomial in the second variable  $z_2$ , is close to its low-degree truncation  $Q_{\leq d}$  (for a suitable choice of  $d$ ), defined by

$$Q_{\leq d}(z_1, z_2) := \rho^{-\ell} \sum_{\substack{0 \leq j_1 < \dots < j_\ell \leq n-1: \\ j_\ell - j_1 - (\ell-1) \leq d}} \mathbf{E}_{\mathbf{y}} \left[ \prod_{k=1}^{\ell} \mathbf{1}[\mathbf{y}_{j_k} = w_k] \right] \left( \frac{z_1 - (1-\rho)}{\rho} \right)^{j_1} \left( \frac{z_2 - (1-\rho)}{\rho} \right)^{j_\ell - j_1 - (\ell-1)}, \quad (17)$$

when both  $z_1, z_2$  belong to the domain in Lemma 16.

► **Claim 22.** Let  $C''_\rho$  be a constant, and  $d_0 \geq C''_\rho(\ell + n^{1/5}) + 2 \log n$ . For every  $z \in \{e^{i\theta} : |\theta| \leq n^{-2/5}\} \cup [1-\rho, 1-\frac{3}{4}\rho]$  and  $t \in [1-\rho, 1-\frac{3}{4}\rho]$ , we have  $|Q_{\leq d_0}(z, t) - Q(z, t)| \leq 4 \cdot 2^{-d_0/2}$ .

Proof. It suffices to show that for every  $d \geq d_0$ , the homogeneous degree- $d$  (in the variable  $t$ ) term of  $Q$ , that is,

$$\rho^{-\ell} \sum_{\substack{0 \leq j_1 < \dots < j_\ell \leq n-1 \\ 0 \leq j_\ell - j_1 - (\ell-1) = d}} \mathbf{E} \left[ \prod_{k=1}^{\ell} \mathbf{1}[\mathbf{y}_{j_k} = w_k] \right] \left( \frac{z - (1-\rho)}{\rho} \right)^{j_1} \left( \frac{t - (1-\rho)}{\rho} \right)^{j_\ell - j_1 - (\ell-1)}, \quad (18)$$

is bounded by  $2^{-d/2}$ , as then we have  $|Q(z, t) - Q_{\leq d_0}(z, t)| \leq \sum_{d > d_0} 2^{-d/2} = 4 \cdot 2^{-d_0/2}$ , as desired.

## 52:16 Trace Reconstruction from Local Statistical Queries

We now bound Equation (18) as follows. First, the expectation in each term of the summation can be bounded by 1. Second, writing  $z$  as  $e^{i\theta}$  for some  $|\theta| \leq n^{-2/5}$ , and using  $|\cos \theta| \geq 1 - \theta^2/2$ , we have

$$\begin{aligned} |z - (1 - \rho)|^2 &= (\cos \theta - (1 - \rho))^2 + \sin^2 \theta = 1 - 2(1 - \rho) \cos \theta + (1 - \rho)^2 \\ &= 2(1 - \rho)(1 - \cos \theta) + \rho^2 \leq (1 - \rho)\theta^2 + \rho^2. \end{aligned}$$

Using  $|\theta| \leq n^{-2/5}$  and  $j_1 \leq n$ , when  $z = e^{i\theta}$  for some  $|\theta| \leq n^{-2/5}$  we have that

$$\left| \frac{z - (1 - \rho)}{\rho} \right|^{j_1} \leq \left( 1 + (1 - \rho) \left( \frac{\theta}{\rho} \right)^2 \right)^{j_1/2} \leq e^{C'_\rho n^{1/5}} \quad (19)$$

for some constant  $C'_\rho$ . And when  $z \in [1 - \rho, 1 - \frac{3}{4}\rho]$  we have  $0 \leq \frac{z - (1 - \rho)}{\rho} \leq 1/4$  and so Equation (19) is again satisfied (with room to spare). Similarly, for  $t \in [1 - \rho, 1 - \frac{3}{4}\rho]$  we have  $0 \leq \frac{t - (1 - \rho)}{\rho} \leq 1/4$ , and so  $\left| \left( \frac{t - (1 - \rho)}{\rho} \right)^d \right| \leq 4^{-d}$ .

Finally, the number of indices  $0 \leq j_1 < \dots < j_\ell \leq n - 1$  with  $j_\ell - j_1 - (\ell - 1) = d$  is at most  $n \cdot \binom{(\ell - 2) + d}{\ell - 2} \leq n \cdot 2^{d + (\ell - 2)}$ . So the degree- $d$  term (18) can be bounded by

$$\rho^{-\ell} \cdot n \cdot 2^{d + \ell - 2} \cdot e^{C'_\rho n^{1/5}} \cdot 4^{-d} \leq n \cdot (2/\rho)^\ell \cdot e^{C'_\rho n^{1/5}} \cdot 2^{-d},$$

which is at most  $2^{-d/2}$  whenever  $d \geq C''_\rho(\ell + n^{1/5}) + 2 \log n$ , for some constant  $C''_\rho$ .  $\triangleleft$

We now describe our local SQ algorithm to approximate the low-degree polynomial  $Q_{\leq d}(z, t)$ , for any  $(z, t) \in \{e^{i\theta} : |\theta| \leq n^{-2/5}\} \cup [1 - \rho, 1 - \frac{3}{4}\rho] \times [1 - \rho, 1 - \frac{3}{4}\rho]$ . Set  $d_0 := C''_\rho n^{1/5} \log^5 n \geq C''_\rho(\ell + n^{1/5}) + 2 \log n$ . Our  $d_0$ -local algorithm makes the following  $d_0$ -local queries:

$$\mathbf{E}_{\mathbf{y} \sim \text{Del}_{1-\rho}(x)} \left[ \mathbf{1}[\mathbf{y}[j : j + d_0 - 1] = u] \right] \text{ for every } u \in \{0, 1\}^{d_0} \text{ and } j \in \{0, \dots, n - 1\}.$$

Let  $\widehat{p}_{u,j}$  be the estimate of  $\mathbf{E}[\mathbf{1}[\mathbf{y}[j : j + d_0 - 1] = u]]$  that is received as a response to the query. For every fixed tuple  $0 \leq j_1 < \dots < j_\ell \leq n - 1$  such that  $j_\ell - j_1 - (\ell - 1) \leq d_0$ , using the identity

$$\mathbf{E} \left[ \prod_{k=1}^{\ell} \mathbf{1}[\mathbf{y}_{j_k} = w_k] \right] = \sum_{u \in \{0,1\}^{d_0} : \forall k \in [\ell] : u_{j_k - j_1 + 1} = w_k} \mathbf{E} \left[ \mathbf{1}[\mathbf{y}[j_1 : j_1 + d_0 - 1] = u] \right],$$

which is a sum of  $2^{d_0 - \ell}$  terms, the algorithm computes the estimate  $\widehat{p}_{w, j_1, \dots, j_\ell}$  of  $\mathbf{E} \left[ \prod_{k=1}^{\ell} \mathbf{1}[\mathbf{y}_{j_k} = w_k] \right]$  (using the estimates  $\widehat{p}_{u, j_1}$  of  $\mathbf{E}[\mathbf{1}[\mathbf{y}[j_1 : j_1 + d_0 - 1] = u]]$ ) by

$$\widehat{p}_{w, j_1, \dots, j_\ell} := \sum_{u \in \{0,1\}^{d_0} : \forall k \in [\ell] : u_{j_k - j_1 + 1} = w_k} \widehat{p}_{u, j_1},$$

for each  $w \in \{0, 1\}^\ell$  and tuple of indices  $0 \leq j_1 < \dots < j_\ell \leq n - 1$  such that  $j_\ell - j_1 - (\ell - 1) \leq d_0$ . If the tolerance for each query is  $\tau_0$ , then the error of each estimate  $\widehat{p}_{w, j_1, \dots, j_\ell}$  is  $\pm 2^{d_0 - \ell} \cdot \tau_0$ . Finally, the algorithm computes the estimate  $\widehat{Q}_{\leq d_0}(z, t)$  of  $Q_{\leq d_0}(z, t)$  using Equation (17), as

$$\widehat{Q}_{\leq d_0}(z, t) := \rho^{-\ell} \sum_{\substack{0 \leq j_1 < \dots < j_\ell \leq n-1: \\ j_\ell - j_1 - (\ell - 1) \leq d_0}} \widehat{p}_{w, j_1, \dots, j_\ell} \left( \frac{z - (1 - \rho)}{\rho} \right)^{j_1} \left( \frac{t - (1 - \rho)}{\rho} \right)^{j_\ell - j_1 - (\ell - 1)}.$$

There are at most  $n \cdot \binom{d_0 + (\ell - 1)}{\ell - 1} \leq n \cdot 2^{d_0 + (\ell - 1)}$  such tuples. So the total error is  $n \cdot 2^{d_0 + (\ell - 1)} \cdot 2^{d_0 - \ell} \cdot \tau_0 \leq n \cdot 2^{2d_0} \cdot \tau_0$ .

By Claim 22, we have that for every  $(z, t)$  in the domain specified in Lemma 17

$$\begin{aligned} |\widehat{Q}_{\leq d_0}(z, t) - P_{x,w}(z, t)| &= |\widehat{Q}_{\leq d_0}(z, t) - Q(z, t)| \\ &\leq |\widehat{Q}_{\leq d_0}(z, t) - Q_{\leq d_0}(z, t)| + |Q_{\leq d_0}(z, t) - Q(z, t)| \\ &\leq n \cdot 2^{2d_0} \cdot \tau_0 + 4 \cdot 2^{-d_0/2} \\ &= 2^{2C''_\rho} n^{1/5} \log^5 n \tau_0 + \exp(-C''_\rho n^{1/5} \log^5 n). \end{aligned}$$

Setting the tolerance parameter  $\tau_0$  to be  $\exp(-C''_\rho n^{1/5} \log^5 n)$  proves Lemma 17.

## 5 Average-case lower bounds

► **Theorem 23** (Average-case lower bound). *Fix any constant deletion rate  $0 < \delta < 1$ . Any  $\ell$ -local SQ algorithm for average-case trace reconstruction must have tolerance  $\tau_0 \leq O(\ell/\sqrt{n})$ .*

Let  $x$  be an arbitrary fixed string in  $\{0, 1\}^n$  and let  $x'$  be the string obtained from  $x$  by flipping the bit  $x_{n/2}$  in the middle. Let  $q : \{0, 1\}^n \rightarrow [-1, 1]$  be any  $\ell$ -junta query (which is not necessarily  $\ell$ -local), i.e., there are  $0 \leq i_1 < \dots < i_\ell < n$  such that  $q(x) = q'(x_{i_1}, \dots, x_{i_\ell})$  for some  $q' : \{0, 1\}^\ell \rightarrow [-1, 1]$ . We will prove the following claim:

▷ **Claim 24.** Let  $P_q := \mathbf{E}_{\mathbf{y} \sim \text{Del}_\delta(x)}[q(\mathbf{y})]$  and  $P'_q := \mathbf{E}_{\mathbf{y} \sim \text{Del}_\delta(x')}[q(\mathbf{y})]$ . Then  $|P_q - P'_q| \leq O(\ell/\sqrt{n})$ .

*Proof.* Let  $\mathbf{R}$  be a  $\rho$ -biased random draw of a subset of  $[0 : n-1]$  with  $\mathbf{R} = \{r_0, r_1, \dots, r_{m-1}\}$  for some  $m \leq n$ . Given that the only difference between  $x$  and  $x'$  is the middle bit, we have

$$|P_q - P'_q| \leq 2 \cdot \mathbf{Pr}_{\mathbf{R}} [r_{i_j} = n/2 \text{ for some } j \in [\ell]] \leq 2 \sum_{j \in [\ell]} \mathbf{Pr}_{\mathbf{R}} [r_{i_j} = n/2].$$

Since  $\delta \in (0, 1)$  is a constant,  $\mathbf{Pr}_{\mathbf{R}}[r_i = n/2] \leq O(1/\sqrt{n})$  for any  $i$ , from which the claim follows. ◀

We now prove Theorem 23:

**Proof.** (of Theorem 23) Indeed we will show that any SQ algorithm for average-case trace reconstruction that uses  $\ell$ -junta queries with tolerance  $\tau$  must satisfy  $\tau \leq O(\ell/\sqrt{n})$ . To see this, consider any SQ algorithm for trace reconstruction that uses  $\ell$ -junta queries with tolerance  $\tau$  that is larger than the  $O(\ell/\sqrt{n})$  in Claim 24. It follows from Claim 24 that, for any string  $x \in \{0, 1\}^n$ , such an algorithm cannot distinguish between  $x$  and  $x'$ . As a result, such an algorithm fails to reconstruct  $\mathbf{x} \sim \{0, 1\}^n$  with probability at least  $1/2$ . ◀

## 6 Average-case upper bounds

► **Theorem 25** (Average-case upper bound). *Fix any constant deletion rate  $0 < \delta < 1$ . There is an SQ algorithm for average-case trace reconstruction that uses  $\ell = O(\log n)$ -local queries with tolerance  $\tau = 1/\text{poly}(n)$ .*

We will prove Theorem 25 by showing that the algorithm in [14] can be simulated with local SQ queries. To do so, we will need to recall the smoothed analysis model.

► **Definition 26.** Let  $x^{\text{worst}}$  be an unknown and arbitrary string in  $\{0,1\}^n$  and  $0 < \sigma < 1$  be a “smoothing parameter.” Let  $\mathbf{x}$  be generated by flipping every bit of  $x^{\text{worst}}$  independently with probability  $\sigma$ .

For parameters  $\eta, \tau > 0$ , a  $(T, \eta, \tau)$ -trace reconstruction algorithm in the smoothed analysis model (with smoothing parameter  $\sigma$ ) has the following guarantee: With probability at least  $1 - \eta$  (over the random generation of  $\mathbf{x}$  from  $x^{\text{worst}}$ ), it is the case that the algorithm, given access to independent traces drawn from  $\text{Del}_\delta(\mathbf{x})$ , outputs the string  $\mathbf{x}$  with probability at least  $1 - \tau$  (over the random traces drawn from  $\text{Del}_\delta(\mathbf{x})$ ). The time complexity as well as the number of traces is bounded by  $T$ .

Observe that the average case trace reconstruction setting corresponds to the smoothed analysis setting with  $\sigma = 1/2$  and  $x^{\text{worst}}$  set to the all zeros string (though any fixed choice of  $x^{\text{worst}}$  works equally well).

[14] gave a polynomial-time algorithm for trace reconstruction in the smoothed analysis setting. Taking  $\sigma = 1/2$ , the main result of [14] gives the following:

► **Theorem 27** (Theorem 1 in [14]). *There is an algorithm for trace reconstruction which for any  $\eta, \tau$  and  $\delta > 0$ , has the following guarantee: With probability  $1 - \eta$  over  $\mathbf{x}$  drawn uniformly at random from  $\{0,1\}^n$ , it is the case that the algorithm, given access to independent traces drawn from  $\text{Del}_\delta(\mathbf{x})$ , outputs the string  $\mathbf{x}$  with probability at least  $1 - \tau$  (over the random traces drawn from  $\text{Del}_\delta(\mathbf{x})$ ). Its running time and sample complexity are upper bounded by*

$$T = \left(\frac{n}{\eta}\right)^{O\left(\frac{1}{(1-\delta)} \cdot \log\left(\frac{1}{(1-\delta)}\right)\right)}.$$

We begin with a short description of the algorithm in [14] (page 27 of the Arxiv version of [14]), giving only the level of detail necessary for the current paper. We set the following parameters:

$$\begin{aligned} k &= O(\log(n/\eta)), \quad \kappa = \left(\frac{1}{n} \cdot \left(\frac{1-\delta}{2}\right)^k\right)^{O(1/(1-\delta))}, \quad \theta = (1-\delta)^2/2, \\ d &= \frac{C}{\theta} \left(\ln n + k \ln \frac{C}{\theta}\right), \quad \Delta = \frac{\kappa}{2d^2 \cdot n \cdot \binom{d+k-2}{k-2}}. \end{aligned} \quad (20)$$

Set  $L$  to be the largest integer such that  $\delta + L \cdot \delta \leq (1 + \delta)/2$ .

Given two strings  $x \in \{0,1\}^n$  and  $w \in \{0,1\}^k$ , [14] define a univariate polynomial  $\text{SW}_{x,w}(\cdot)$ . The precise formal definition of this polynomial is not important for us; rather, the following relation (Equation 6 in the Arxiv version of [14]) is sufficient for our purposes:

$$\mathbf{E}_{\mathbf{y} \sim \text{Del}_{\delta'}(x)} [\#(w, \mathbf{y})] = (1 - \delta')^k \cdot \text{SW}_{x,w}(\delta'), \quad (21)$$

where  $\#(w, \mathbf{y})$  is the number of times  $w$  appears a subword of  $\mathbf{y}$ . We remark to the reader that  $\#(w, \mathbf{y})$  is a sum of  $k$ -local query functions (we will elaborate on this shortly). The algorithm in [14] proceeds as follows:

1. Define set  $S := \{\delta, \delta + \Delta, \delta + 2\Delta, \dots, \delta + L\Delta\}$ .
2. For every  $w \in \{0,1\}^k$  and  $\delta' \in S$ , the algorithm computes  $\pm\kappa$ -accurate estimates of  $\text{SW}_{x,w}(\delta')$ , using Equation (21).
3. With these estimates of  $\text{SW}_{x,w}(\delta')$  (for  $\delta' \in S$  and  $w \in \{0,1\}^k$ ), the algorithm runs a linear program followed by a greedy algorithm to reconstruct the original string.

In particular, excluding the part of Step (2) in which the estimates of  $\text{SW}_{x,w}(\delta')$  are computed, the rest of the reconstruction algorithm is deterministic and does not use the traces. Note that the reason why the [14] algorithm does not immediately translate to a local SQ algorithm for us is the following: in our model the permissible statistical queries are with respect to  $\mathbf{y} \sim \mathbf{Del}_\delta(x)$ , whereas the [14] algorithm, as sketched above, uses estimates of probabilities corresponding to statistical queries over  $\mathbf{y} \sim \mathbf{Del}_{\delta'}(x)$  for various values of  $\delta' > \delta$ .

Thus, to obtain a local SQ algorithm, it suffices to show that the values  $\{\text{SW}_{x,w}(\delta')\}_{\delta' \in S, w \in \{0,1\}^k}$  can be estimated using local SQ queries corresponding to  $\mathbf{Del}_\delta(x)$ . More precisely, we have the following claim whose proof is immediate from the description of the above algorithm and (21).

▷ **Claim 28.** For any  $\delta' \in S$ , to compute  $\text{SW}_{x,w}(\delta')$  to error  $\kappa$ , it is sufficient to estimate the value of  $\mathbf{E}_{\mathbf{y} \sim \mathbf{Del}_{\delta'}(x)}[\#(w, \mathbf{y})]$  up to error  $\tau'$ , where

$$\tau' := \left( \frac{1}{n} \left( \frac{1-\delta}{2} \right)^k \right)^{O(1/(1-\delta))}. \quad (22)$$

*Proof.* We need to compute  $\text{SW}_{x,w}(\delta')$  for  $\delta' \in S$  to error  $\kappa$ . By (21), it suffices to compute  $\mathbf{E}_{\mathbf{y} \sim \mathbf{Del}_{\delta'}(x)}[\#(w, \mathbf{y})]$  to error  $\kappa \cdot (1-\delta')^k$ ; noting that  $\delta' \leq (1+\delta)/2$ , the claim follows. ◀

The main technical lemma of this section is the following.

▶ **Lemma 29.** *For the parameters defined as above, the following holds: Given the values of all subword queries of length  $\ell$  with tolerance  $\tau'/2$  (with  $\tau'$  defined in (22)) corresponding to  $\mathbf{Del}_\delta(x)$ , we can compute  $\text{SW}_{x,w}(\delta')$  for all  $\delta' \in S$  and  $w \in \{0,1\}^k$  to within error  $\pm\kappa$ . Here  $\ell$  is defined to be*

$$\ell = \Theta \left( \frac{k}{1-\delta} \cdot \ln \left( \frac{2}{1-\delta} \right) + \frac{\ln n}{(1-\delta)} \right).$$

Before proving this lemma, we observe that Theorem 25 follows immediately from the lemma:

**Proof.** (of Theorem 25) For any constant  $0 < \delta < 1$  and  $\eta = n^{-\Theta(1)}$ , by our choice of parameters we have  $k = O(\log n)$  (see (20)). With this choice,  $\ell = O(\log n)$  and  $\tau' = n^{-\Theta(1)}$ . By Lemma 29, using the values of all subword queries of length  $\ell$  (with tolerance  $\tau'/2$ ), we can compute  $\text{SW}_{x,w}(\delta')$  for all  $\delta' \in S$  and  $w \in \{0,1\}^k$  to within error  $\pm\kappa$ . By the guarantee of the algorithm in [14], this suffices to recover  $x$ . Thus, we get Theorem 25. ◀

## 6.1 Proof of Lemma 29

We start with the following observation.

▶ **Fact 30.** *For  $\delta' \geq \delta$ , let  $0 \leq \beta_r = (1-\delta')/(1-\delta) \leq 1$ . Then  $\mathbf{Del}_{\delta'}(x) = \mathbf{Del}_{\beta_r}(\mathbf{Del}_\delta(x))$ . In other words, we can simulate traces from the deletion channel  $\mathbf{Del}_{\delta'}(\cdot)$  by first getting a trace from  $\mathbf{Del}_\delta(\cdot)$  and then passing it through the deletion channel  $\mathbf{Del}_{\beta_r}$ .*

As stated earlier, we will assume that our original string  $x$  is padded with infinitely many 0-symbols to its right. This means that for any  $i$ , the  $i^{\text{th}}$  position of the trace is well-defined. We now consider the process of getting a trace  $\mathbf{y}$  from  $\mathbf{Del}_{\delta'}(x)$  given a trace  $\mathbf{z} \sim \mathbf{Del}_\delta(x)$ . We will do this by thinking of  $\mathbf{Del}_{\beta_r}(\cdot)$  as a “selector process”. We start with the following definition.

► **Definition 31.** For a parameter  $p \in (0, 1)$  and integers  $k > 0$  and  $\ell \geq 0$ , we define the distribution  $\text{Hypernb}(p, k, \ell)$  as follows: Define an infinite random string  $\mathbf{w} = (\mathbf{w}_0, \dots)$  in  $\{0, 1\}^*$  where each bit is independently 0 with probability  $p$  and 1 with probability  $(1 - p)$ . Let  $\mathbf{i}_s$  be the location of the  $s^{\text{th}}$  one in  $\mathbf{w}$ . Then a sample from  $\text{Hypernb}(p, k, \ell)$  is given by  $(\mathbf{i}_k, \dots, \mathbf{i}_{k+\ell-1})$ .

Finally, we say that an outcome from  $\text{Hypernb}(p, k, \ell)$  is  $t$ -bounded if  $|\mathbf{i}_{k+\ell-1} - \mathbf{i}_k| \leq t$ .

We note that for any fixed  $s$ , the process generating  $\mathbf{i}_s$  is *memoryless*, in the sense that for any fixed  $r$  and  $s$  (with  $r \geq s$ ), the random variable  $\mathbf{i}_r - \mathbf{i}_s$  is distributed as a negative binomial random variable.

With the above definition, we can now state the following claim:

▷ **Claim 32.** Fix  $\delta' \geq \delta$ ,  $k \geq 1$ , and  $\ell \geq 0$ . Let  $\mathbf{y} \sim \text{Del}_{\delta'}(x)$  and  $\mathbf{z} \sim \text{Del}_{\delta}(x)$ . For  $\beta_r = (1 - \delta')/(1 - \delta)$ , let  $(\mathbf{i}_k, \dots, \mathbf{i}_{k+\ell-1}) \sim \text{Hypernb}(\beta_r, k, \ell)$ . Then the distribution of  $(\mathbf{y}_k, \dots, \mathbf{y}_{k+\ell-1})$  is identical to the distribution of  $(\mathbf{z}_{\mathbf{i}_k}, \dots, \mathbf{z}_{\mathbf{i}_{k+\ell-1}})$ .

*Proof.* The proof is essentially obvious from Fact 30 and Definition 31. In particular, from Fact 30, given  $\mathbf{z} \sim \text{Del}_{\delta}(x)$ , to get  $\mathbf{y} \sim \text{Del}_{\delta'}(x)$ , we need to simulate the deletion channel  $\text{Del}_{\beta_r}$  on the string  $\mathbf{z}$ . By definition of the deletion channel  $\text{Del}_{\beta_r}$ , the location of the positions  $(k, \dots, k + \ell - 1)$  is given by  $(\mathbf{i}_k, \dots, \mathbf{i}_{k+\ell-1})$  sampled from  $\text{Hypernb}(p, k, \ell)$ . This finishes the proof. ◁

We next need a lower bound on the probability that  $\text{Hypernb}(p, k, \ell)$  is bounded. To obtain this, we first state a tail bound on negative binomial random variables:

▷ **Claim 33 ([7]).** Let  $\text{Negbin}(m, p)$  be a negative binomially distributed random variable with parameters  $m$  and  $p$ , i.e. it is the number of trials needed to get  $m$  heads from independent coin tosses with heads probability  $p$ . Then  $\mathbf{E}[\text{Negbin}(m, p)] = m/p$  and furthermore, for any  $t > 1$ ,

$$\Pr[\text{Negbin}(m, p) > tm/p] \leq \exp\left(-\frac{tm(1 - 1/t)^2}{2}\right).$$

From this we can obtain the following claim which lower bounds the probability that  $\text{Hypernb}(\beta_r, k, \ell)$  is  $s$ -bounded.

▷ **Claim 34.** For any  $k$ , an outcome  $(\mathbf{i}_k, \dots, \mathbf{i}_{k+\ell-1}) \sim \text{Hypernb}(\beta_r, k, \ell)$  is  $s$ -bounded with probability at least  $1 - \xi$  for  $s = t(\ell - 1)/\beta_r$ , where  $\xi = \exp(-t(\ell - 1)/8)$  for  $t \geq 2$ .

*Proof.* The gap  $\mathbf{i}_{k+\ell-1} - \mathbf{i}_k$  is a negative binomial random variable which is distributed as  $\text{Negbin}(\ell - 1, \beta_r)$ . Thus, by Claim 33, it follows that

$$\Pr\left[\mathbf{i}_{k+\ell-1} - \mathbf{i}_k > \frac{t(\ell - 1)}{\beta_r}\right] \leq \exp\left(\frac{-t(\ell - 1)(1 - 1/t)^2}{2}\right).$$

For  $t \geq 2$ , we can simplify the upper bound as

$$\Pr\left[\mathbf{i}_{k+\ell-1} - \mathbf{i}_k > \frac{t(\ell - 1)}{\beta_r}\right] \leq \exp\left(\frac{-t(\ell - 1)}{8}\right).$$

Defining  $\xi$  as  $\exp(-\frac{t(\ell-1)}{8})$ , we get the claim. ◁

We now state the following technical claim.

▷ **Claim 35.** Given the value of all  $\ell$ -local subword queries for deletion channel  $\mathbf{Del}_\delta(x)$  with tolerance  $\eta$ , we can compute the value of all  $\ell'$ -local subword queries for  $\mathbf{Del}_{\delta'}(x)$  with tolerance  $\tau'$  where

$$\eta = \tau'/2; \quad \ell = C \cdot \left( \frac{\ell'}{1-\delta'} \cdot \ln \left( \frac{2}{1-\delta} \right) + \frac{\ln n}{(1-\delta')} \right), \quad \text{for a suitably large constant } C.$$

*Proof.* Fix any  $w \in \{0, 1\}^{\ell'}$  and consider the quantity

$$p'_{x,k,w} := \Pr_{\mathbf{y} \sim \mathbf{Del}_{\delta'}(x)}[(\mathbf{y}_k, \dots, \mathbf{y}_{k+\ell'-1}) = w].$$

Then, by Claim 32, it follows that

$$p'_{x,k,w} := \Pr_{\mathbf{z} \sim \mathbf{Del}_\delta(x), (\mathbf{i}_k, \dots, \mathbf{i}_{k+\ell'-1}) \sim \text{Hypernb}(\beta_r, k, \ell')}[\mathbf{z}_{\mathbf{i}_1}, \dots, \mathbf{z}_{\mathbf{i}_{k+\ell'-1}} = w], \quad (23)$$

where  $\beta_r = (1-\delta')/(1-\delta)$ . Define the parameter  $t = C \cdot \left( \frac{1}{1-\delta} \cdot \ln \left( \frac{2}{1-\delta} \right) + \frac{\ln n}{\ell'(1-\delta)} \right)$ , where the constant  $C$  is set so that  $\exp\left(\frac{t(\ell'-1)}{8}\right) = \frac{\tau'}{2}$ . As  $\ell = t(\ell'-1)/\beta_r$ , by Claim 34 we have

$$\Pr[\mathbf{i}_{\ell'+k-1} - \mathbf{i}_{\ell'} > \ell] \leq \exp\left(\frac{t(\ell'-1)}{8}\right) = \frac{\tau'}{2}. \quad (24)$$

Now, define  $\mathcal{E}$  as the event (over the samples  $(\mathbf{i}_k, \dots, \mathbf{i}_{k+\ell'-1})$ ) that  $|\mathbf{i}_{k+\ell'-1} - \mathbf{i}_k| \leq \ell$ . We now re-express

$$\begin{aligned} p'_{x,k,w} &= \Pr_{\mathbf{z} \sim \mathbf{Del}_\delta(x), (\mathbf{i}_k, \dots, \mathbf{i}_{k+\ell'-1})}[\mathbf{z}_{\mathbf{i}_1}, \dots, \mathbf{z}_{\mathbf{i}_{k+\ell'-1}} = w \wedge \mathcal{E}] \\ &+ \Pr_{\mathbf{z} \sim \mathbf{Del}_\delta(x), (\mathbf{i}_k, \dots, \mathbf{i}_{k+\ell'-1})}[\mathbf{z}_{\mathbf{i}_1}, \dots, \mathbf{z}_{\mathbf{i}_{k+\ell'-1}} = w \wedge \bar{\mathcal{E}}]. \end{aligned}$$

From the bound (24), the second term is at most  $\tau'/2$  in magnitude and thus,

$$\left| p'_{x,k,w} - \Pr_{\mathbf{z} \sim \mathbf{Del}_\delta(x), (\mathbf{i}_k, \dots, \mathbf{i}_{k+\ell'-1})}[\mathbf{z}_{\mathbf{i}_1}, \dots, \mathbf{z}_{\mathbf{i}_{k+\ell'-1}} = w \wedge \mathcal{E}] \right| \leq \tau'/2.$$

Furthermore, for any particular outcome of  $(\mathbf{i}_k, \dots, \mathbf{i}_{k+\ell'-1})$  for which event  $\mathcal{E}$  happens, the quantity  $\Pr_{\mathbf{z} \sim \mathbf{Del}_\delta(x)}[\mathbf{z}_{\mathbf{i}_1}, \dots, \mathbf{z}_{\mathbf{i}_{k+\ell'-1}} = w]$  is a  $\ell$ -local subword query. Since we have the value of all  $\ell$ -local subword queries up to error  $\tau'/2$ , we can compute  $p'_{x,k,w}$  to error  $\tau'$ . ◁

**Proof.** (of Lemma 29) By Claim 32, to compute  $\text{SW}_{x,w}(\delta')$  to error  $\pm\kappa$ , it suffices to compute  $\mathbf{E}_{\mathbf{y} \sim \mathbf{Del}_{\delta'}(x)}[\#(w, \mathbf{y})]$  for every  $w \in \{0, 1\}^{\ell'}$  up to error  $\pm\tau'$  where  $\tau'$  is defined in (22). Now, by Claim 35, for any given  $\delta' \geq \delta$ , to compute  $\mathbf{E}_{\mathbf{y} \sim \mathbf{Del}_{\delta'}(x)}[\#(w, \mathbf{y})]$  to error  $\tau$ , it suffices to have the value of all  $\ell$ -local subword queries to error  $\tau'/2$  where

$$\ell = C \cdot \left( \frac{\ell'}{1-\delta'} \cdot \ln \left( \frac{2}{1-\delta} \right) + \frac{\ln n}{(1-\delta')} \right).$$

Since  $\delta' \leq (1+\delta)/2$ , it follows that

$$\ell \leq C \cdot \left( \frac{2\ell'}{1-\delta} \cdot \ln \left( \frac{2}{1-\delta} \right) + \frac{2 \ln n}{(1-\delta)} \right).$$

Thus, if we have the value of all  $k$ -local subword queries to error  $\tau'/2$ , where  $k$  is set to

$$k = \Theta \left( \frac{\ell'}{1-\delta} \cdot \ln \left( \frac{2}{1-\delta} \right) + \frac{\ln n}{(1-\delta)} \right),$$

we can recover  $x$ . This finishes the proof. ◀

## Abstract

The *Gilbert–Varshamov* (GV) bound is a classical existential result in coding theory. It implies that a random linear binary code of rate  $\varepsilon^2$  has relative distance at least  $\frac{1}{2} - O(\varepsilon)$  with high probability. However, it is a major challenge to construct *explicit* codes with similar parameters.

One hope to derandomize the Gilbert–Varshamov construction is with code concatenation: We begin with a (hopefully explicit) outer code  $\mathcal{C}_{\text{out}}$  over a large alphabet, and concatenate that with a small binary random linear code  $\mathcal{C}_{\text{in}}$ . It is known that when we use *independent* small codes for each coordinate, then the result lies on the GV bound with high probability, but this still uses a lot of randomness. In this paper, we consider the question of whether code concatenation with a *single* random linear inner code  $\mathcal{C}_{\text{in}}$  can lie on the GV bound; and if so what conditions on  $\mathcal{C}_{\text{out}}$  are sufficient for this.

We show that first, there *do* exist linear outer codes  $\mathcal{C}_{\text{out}}$  that are “good” for concatenation in this sense (in fact, *most* linear codes codes are good). We also provide two sufficient conditions for  $\mathcal{C}_{\text{out}}$ , so that if  $\mathcal{C}_{\text{out}}$  satisfies these,  $\mathcal{C}_{\text{out}} \circ \mathcal{C}_{\text{in}}$  will likely lie on the GV bound. We hope that these conditions may inspire future work towards constructing explicit codes  $\mathcal{C}_{\text{out}}$ .

## 1 Introduction

An *error correcting code* (or just a *code*) is a subset  $\mathcal{C} \subseteq \Sigma^n$ , for some alphabet  $\Sigma$ . We think of a code  $\mathcal{C}$  being used to encode messages in  $\Sigma^k$  for  $k = \log_{|\Sigma|} |\mathcal{C}|$ . That is, for any  $m \in \Sigma^k$ , we can identify  $m$  with a codeword  $\mathcal{C}(m) \in \mathcal{C}$ .<sup>1</sup> The idea is that encoding  $m$  into the

---

<sup>1</sup> Here and throughout the paper, we will abuse notation and use  $\mathcal{C}$  both as the code itself (a subset of  $\Sigma^n$ ) and also as an encoding map  $\mathcal{C}: \Sigma^k \rightarrow \Sigma^n$ .

codeword  $\mathcal{C}(m)$  will introduce redundancy that can later be used to correct errors. In this work we focus on *linear* codes  $\mathcal{C}$ , which are codes where  $\Sigma = \mathbb{F}$  is a finite field and  $\mathcal{C} \subseteq \mathbb{F}^n$  is a linear subspace of  $\mathbb{F}^n$ .

Two important properties of error correcting codes are the *rate*  $R$  and the *relative distance*  $\delta$ . For a code  $\mathcal{C} \subseteq \Sigma^n$ , the rate is defined as  $R = \frac{\log_{|\Sigma|} |\mathcal{C}|}{n} = \frac{k}{n}$ , and it quantifies how large the code is. The rate is between 0 and 1, and typically we want it to be as close to 1 as possible; this means that the encoding map does not introduce much redundancy. The (relative) distance of  $\mathcal{C} \subseteq \Sigma^n$  is defined as  $\delta = \frac{1}{n} \min_{c \neq c' \in \mathcal{C}} \Delta(c, c')$ , where  $\Delta(\cdot, \cdot)$  is Hamming distance. Again, the relative distance is between 0 and 1, and again we typically want it to be as close to 1 as possible; this means that the code can correct many worst-case errors.

These two quantities – rate and distance – are in tension. The larger the rate is, the smaller the distance must be. For binary codes (that is, codes where  $\Sigma = \mathbb{F}_2$ ), it is a major open question to pin down the best trade-off possible between rate and distance. However, we know that good trade-offs are possible: The best known possibility result in general is the *Gilbert–Varshamov* (GV) bound (Theorem 2.1 in the full version).

In this paper we focus on *low rate* codes. In this parameter regime, the GV bound implies that there *exist* binary linear codes with relative distance  $\frac{1-\varepsilon}{2}$  and rate  $\Omega(\varepsilon^2)$ , for small  $\varepsilon > 0$ . In fact, Varshamov’s proof shows that a random binary linear code achieves this with high probability.

Constructing such codes explicitly, hopefully accompanied by an efficient decoding algorithm, has been subject to extensive and fruitful research in the past decades (e.g., [24, 2, 3, 6, 11, 28, 7]), with several exciting breakthroughs in recent years. These breakthroughs include explicit constructions of codes with distance  $\delta = \frac{1-\varepsilon}{2}$  and rate  $R = \Omega(\varepsilon^{2+o(1)})$ , even with efficient algorithms (see Section 1.1). However, there are still open questions. For example, we do not know how to attain  $\delta = \frac{1-\varepsilon}{2}$  and  $R = \Omega(\varepsilon^2)$  (without any  $o(1)$  term) explicitly, and we do not have explicit constructions approaching the GV bound with rates bounded away from zero. Motivated by these questions, we consider *concatenated codes*, possibly with some randomness, which we discuss next.

### Concatenated Codes, and Our Question

A natural candidate for explicit (for low randomness) codes on the GV bound are *concatenated linear codes*. These codes are built out of two ingredients: a (hopefully explicit) linear outer code  $\mathcal{C}_{\text{out}} \subseteq \mathbb{F}_q^n$  with dimension  $k$  for some large  $q$ ; and a smaller inner binary linear code  $\mathcal{C}_{\text{in}} \subseteq \mathbb{F}_2^{n_0}$ , with dimension  $k_0 = \log_2 q$ . We define the concatenated code  $\mathcal{C} = \mathcal{C}_{\text{out}} \circ \mathcal{C}_{\text{in}} \subseteq \mathbb{F}_2^{n_0 \cdot n}$  by first encoding a message  $m \in \mathbb{F}_q^k$  (which can also be thought of as  $m \in \mathbb{F}_2^{k_0 \cdot k}$ ) with  $\mathcal{C}_{\text{out}}$ . Then, we encode each symbol of the resulting codeword using  $\mathcal{C}_{\text{in}}$ . That is, for a message  $m$ ,

$$\mathcal{C}(m) = (\mathcal{C}_{\text{in}}(\mathcal{C}_{\text{out}}(m)_1), \mathcal{C}_{\text{in}}(\mathcal{C}_{\text{out}}(m)_2), \dots, \mathcal{C}_{\text{in}}(\mathcal{C}_{\text{out}}(m)_n)) \in \mathbb{F}_2^{n_0 \cdot n}.$$

It is not hard to see that the rate of  $\mathcal{C}$  is the product of the rates of  $\mathcal{C}_{\text{in}}$  and  $\mathcal{C}_{\text{out}}$ , and that the distance of  $\mathcal{C}$  is *at least* the product of the distances of  $\mathcal{C}_{\text{in}}$  and  $\mathcal{C}_{\text{out}}$ .

The natural approach to constructing a good concatenated code is to choose  $\mathcal{C}_{\text{out}}$  and  $\mathcal{C}_{\text{in}}$  with the best known trade-offs: Since  $\mathcal{C}_{\text{out}}$  is over a large alphabet, we know explicit constructions of codes with optimal rate-distance trade-off<sup>2</sup>; and if  $n_0$  is sufficiently small, we can find a  $\mathcal{C}_{\text{in}}$  on the GV bound either deterministically by brute force or else with low randomness, depending on the size of  $n_0$ .

<sup>2</sup> For codes over large alphabets, the best possible trade-off is the *Singleton bound*, or  $R = 1 - \delta$ . This is achievable, for example, by Reed–Solomon codes.

However, in general this approach will not achieve the GV bound. If we do not assume any additional properties of  $\mathcal{C}_{\text{out}}$  and  $\mathcal{C}_{\text{in}}$ , and simply use the concatenation properties, then setting the parameters so that  $\mathcal{C} = \mathcal{C}_{\text{out}} \circ \mathcal{C}_{\text{in}}$  has distance  $\frac{1-\varepsilon}{2}$ , the rate of  $\mathcal{C}$  will be at most roughly  $\varepsilon^3$ . This is known as the *Zyablov bound* [31] (see also [14]). As we discuss more in Section 1.1, concatenation has been a popular approach to obtain fully explicit codes with good rate-distance trade-offs, but none of these constructions are known to beat the Zyablov bound.

Instead of using a *single* inner code, several works have focused on a related construction originally due to Thommesen [29], which uses multiple inner codes. More precisely, this construction uses i.i.d. random linear inner codes for each coordinate. It can be shown [29] that the resulting code does lie on the GV bound with high probability, and if  $\mathcal{C}_{\text{out}}$  is chosen appropriately there are even efficient decoding algorithms for it [10, 27, 15]. However, this approach relies heavily on the fact that the inner codes are independent, and as a result uses a lot of randomness.

This state of affairs motivates the following question (also asked in the title of this paper):

► **Question 1.** *Are there concatenated linear codes  $\mathcal{C}_{\text{out}} \circ \mathcal{C}_{\text{in}}$  (with a single random linear inner code  $\mathcal{C}_{\text{in}}$ ) that meet the GV bound with high probability over  $\mathcal{C}_{\text{in}}$ ?<sup>3</sup> If so, are there sufficient conditions on  $\mathcal{C}_{\text{out}}$  that will guarantee this?*

In this paper, we show that *yes*, there are concatenated codes that meet the GV bound, and we also give two sufficient conditions on  $\mathcal{C}_{\text{out}}$  for this to hold. Our existential result is non-constructive, but it is our hope that our sufficient conditions will lead to explicit constructions of appropriate  $\mathcal{C}_{\text{out}}$ -s, which would lead to explicit (or at least pseudo-random, depending on the alphabet size of  $\mathcal{C}_{\text{out}}$ ) concatenated codes on the GV bound.

► **Remark 1 (Motivation for Question 1).** Above, we have motivated Question 1 as an avenue towards explicit or pseudo-random binary codes on the GV bound, and indeed this is our original motivation. But we point out that Question 1 is also interesting in its own right. Concatenated codes are a classical construction, going back to the 1960's [9], and have been used in many different settings over the decades. It seems like a fundamental question to understand when these codes can attain the GV bound.

► **Remark 2 (Focus on Linear Codes).** In Question 1 and in this paper, we focus on *linear* codes. This is because if we used, say, a uniformly random non-linear code as the inner code, it would require exponentially more randomness than a random linear inner code, so this does not seem like a hopeful avenue for derandomization. We note however that the question is much easier for non-linear codes. For example, suppose that  $\mathcal{C}_{\text{out}}$  is a Reed–Solomon code of rate  $\varepsilon$  so that each symbol is additionally tagged with its evaluation point: that is, the symbol corresponding to  $\alpha \in \mathbb{F}_q$  is  $(\alpha, f(\alpha)) \in \mathbb{F}_q^2$ . For the inner code, we use a completely random (non-linear) code of rate  $\varepsilon$ . Then since all of the symbols in each outer codeword are different by construction, each codeword is essentially uniformly random, and it is not hard to show that the result is close to the GV bound in the sense that a code of rate  $O(\varepsilon^2)$  will have distance  $1/2 - O(\varepsilon)$  with high probability. This same argument will not work when  $\mathcal{C}_{\text{in}}$  is linear, since the different symbols of codewords of  $\mathcal{C}_{\text{out}}$  will still have  $\mathbb{F}_2$ -linear relationships.

<sup>3</sup> Of course, if the length of either the inner code or the outer code is 1, this question reduces to the non-concatenated setting; we are interested in parameter regimes where  $n_0$  is non-trivial.

### Our Contributions

Our main results are:

1. **Existence of concatenated codes on the GV bound.** We answer the first part of Question 1: there *are* concatenated codes  $\mathcal{C}_{\text{out}} \circ \mathcal{C}_{\text{in}}$  that achieve the GV bound, in a wide variety of parameter regimes. In particular, we show that *most* codes  $\mathcal{C}_{\text{out}}$  are actually good:

► **Theorem 3** (Informal; Theorem 4.2 in the full version). *Suppose that  $\mathcal{C}_{\text{out}} \subseteq \mathbb{F}_q^n$  and  $\mathcal{C}_{\text{in}} \subseteq \mathbb{F}_2^{n_0}$  are random linear codes of rate  $\varepsilon$ , so that  $q \geq 2^{\Omega(\varepsilon^{-3})}$ . Then  $\mathcal{C} = \mathcal{C}_{\text{out}} \circ \mathcal{C}_{\text{in}}$  has rate  $\varepsilon^2$ , and with high probability, the relative distance of  $\mathcal{C}$  is at least  $1/2 - O(\varepsilon)$ .*

While Theorem 3 seems intuitive (in the sense that a random linear code lies on the GV bound with high probability, so why not concatenated random linear codes?), to the best of our knowledge it has not appeared in the literature before, and the proof was not obvious (to us).<sup>4</sup> One challenge is that a codeword  $c \in \mathcal{C}_{\text{out}} \circ \mathcal{C}_{\text{in}}$  is not uniformly random in  $\mathbb{F}_2^N$ . In particular, the natural strategy of “show that each non-zero codeword has high weight with high probability and union bound” that is used to establish the Gilbert–Varshamov bound will not work in this setting, as we do not have enough concentration.

2. **Sufficient conditions for  $\mathcal{C}_{\text{out}}$ .** Our existence result above uses a random linear code as the outer code, which does not help in the quest for explicit constructions. However, our proof techniques inspire two sufficient conditions on  $\mathcal{C}_{\text{out}}$ . That is, if  $\mathcal{C}_{\text{out}}$  satisfies these conditions, then  $\mathcal{C}_{\text{out}} \circ \mathcal{C}_{\text{in}}$  will meet the GV bound with high probability when  $\mathcal{C}_{\text{in}}$  is a random linear code. Our hope is that formalizing these will lead to explicit constructions in the future.

We give an overview and intuition for our two sufficient conditions here. We note that both conditions are only sufficient when the alphabet size  $q$  for  $\mathcal{C}_{\text{out}}$  is suitably large (exponential in  $1/\text{poly}(\varepsilon)$ ); see Theorems 5.1 and 6.2 in the full version for details.

- **Sufficient Condition 1: A soft-decoding-like condition on  $\mathcal{C}_{\text{out}}^\perp$ .** Our first sufficient condition, formalized in Theorem 5.1 in the full version, is a soft-list-decoding-like condition on  $\mathcal{C}_{\text{out}}^\perp$ . More precisely, we define a distribution  $\mathcal{D}^5$  on the alphabet  $\mathbb{F}_q$ ; the condition is that

$$\Pr_{x \sim \mathcal{D}^n} [x \in \mathcal{C}_{\text{out}}^\perp \setminus \{0\}] \leq \frac{1}{q^k} (1 + \Delta) \quad (1)$$

for some small  $\Delta$ . Note that  $1/q^k$  is the probability that a completely random vector is in  $\mathcal{C}_{\text{out}}^\perp$ , so this condition is saying that if the coordinates of  $x$  are drawn i.i.d. from the same distribution  $\mathcal{D}$ , then  $x$  not much more likely to be in  $\mathcal{C}^\perp$  than in a uniformly random vector. We show that if this holds, then  $\mathcal{C}_{\text{out}} \circ \mathcal{C}_{\text{in}}$  lies on the GV bound with high probability over the choice of a random linear inner code  $\mathcal{C}_{\text{in}}$ .

It’s not hard to see (Remark 8 in the full version) that this condition holds in expectation for a random linear code  $\mathcal{C}_{\text{out}}$ , and in particular there exist linear codes  $\mathcal{C}_{\text{out}}$  that have this property.

<sup>4</sup> We note that earlier work by Barg, Justesen and Thomessen [4] also addresses random linear outer codes concatenated with an arbitrary (fixed) inner code, using very different techniques than we do. They do not explicitly state a statement like Theorem 3 above, though it is plausible that their techniques could be used to prove something similar. We discuss their techniques and the relationship to our work in Section 1.1.

<sup>5</sup> The distribution  $\mathcal{D}$  is intuitively defined as follows. Let  $\mathcal{C}_{\text{in}}$  be the inner code, and suppose that it has a generator matrix  $G_0 \in \mathbb{F}_2^{n_0 \times k_0}$ . Then to sample from  $\mathcal{D}$ , we take a random sparse linear combination of the rows of  $G_0$  (over  $\mathbb{F}_2$ ), and interpret the result in  $\mathbb{F}_2^{k_0}$  as an element of  $\mathbb{F}_q$ , which we return.

This condition is reminiscent of  $\mathcal{C}_{\text{out}}^\perp$  being list-decodable from soft information (e.g., [20]). In soft-list-decoding, one typically gets a distribution  $\mathcal{D}_i$  for each  $i \in [n]$ , interpreted as giving “soft information” about the  $i$ 'th symbol. If one can show that a vector drawn from  $\mathcal{D}_1 \times \cdots \times \mathcal{D}_n$  is unlikely to be in the code, this implies that there are not too many codewords that are likely given the soft information we have received. However, there are several differences between existing work on soft list-decoding and our work, notably that our distribution  $\mathcal{D}$  is a particular one and is the same for all  $i$ , and also there are some differences in the parameter settings.

This condition can also be seen as a soft form of *list-recovery*, where we have the same list in each coordinate.<sup>6</sup> In more detail, if the support of  $\mathcal{D}$  is concentrated on a small set  $S$  (which ours is for reasonable settings of  $n_0, \varepsilon$ , see Remark 7 in the full version), then the condition in Theorem 5.1 is related to asking that the number of codewords that lie in the combinatorial rectangle given by  $S \times S \times \cdots \times S$  is about what it should be. Unfortunately, the definition of “small” here does not seem to be small enough for existing constructions of list-recoverable codes (for example folded RS codes or multiplicity codes) to yield any results.

- **Sufficient Condition 2:  $\mathcal{C}_{\text{out}}$  has good min-entropy.** Our second sufficient condition, formalized in Theorem 6.2, requires the codewords of  $\mathcal{C}_{\text{out}}$  to be “smooth”, meaning, roughly, that every nonzero codeword has a fairly uniform distribution of symbols from  $\mathbb{F}_q$ . To illustrate why a smoothness condition is desirable, let us consider two extreme cases.

The bad extreme is when there exists a codeword  $c$  that is supported on very few symbols, say even on a single symbol. If  $c = (\sigma, \sigma, \dots, \sigma)$  for some  $\sigma \in \mathbb{F}_q$ , then the relative weight of  $c \circ \mathcal{C}_{\text{in}}$ , for a random binary inner code  $\mathcal{C}_{\text{in}}$  of rate  $\varepsilon$ , might be  $\frac{1}{2} - \Omega(\sqrt{\varepsilon})$ , much worse than the  $\frac{1}{2} - O(\varepsilon)$  that we would want for the GV bound.

The good (possibly unrealistic) extreme is where each nonzero codeword of  $\mathcal{C}_{\text{out}}$  has a symbol distribution that is *uniform* over  $\mathbb{F}_q$ . In this case it is not hard to see that  $\mathcal{C}_{\text{out}} \circ \mathcal{C}_{\text{in}}$  will be close to the GV bound with high probability over a random linear code  $\mathcal{C}_{\text{in}}$ . (For this, all we need is that  $\mathcal{C}_{\text{in}}$  has about the “right” weight distribution, which a random linear code will have with high probability).

The natural question is thus *how smooth* the codewords of  $\mathcal{C}_{\text{out}}$  should be in order for  $\mathcal{C}$  to have distance  $\frac{1}{2} - O(\varepsilon)$ . In Section 6 in the full version, we quantify this by the *smooth min-entropy* of the codewords’ empirical distributions on symbols. We show in Theorem 6.2 that if this smooth min-entropy is large enough for all  $c \in \mathcal{C}_{\text{out}}$ , then  $\mathcal{C} = \mathcal{C}_{\text{out}} \circ \mathcal{C}_{\text{in}}$  is likely to lie near the GV bound when  $\mathcal{C}_{\text{in}}$  is a random linear binary code.

How large is “large enough”? For this informal discussion, we give one example of the parameter settings from Theorem 6.2: It is enough for every non-zero codeword  $c \in \mathcal{C}_{\text{out}}$  to have a symbol distribution that has  $\Theta(\varepsilon n)$  copies of the same symbol (say, the zero symbol), while the remaining symbols in  $c$  are uniformly distributed over a set of size only  $q^{1-\varepsilon}$ . By some metrics this is still a fairly “spiky” distribution, but it is “smooth enough” for our purposes.

Note that while our soft-decoding-like condition considers  $\mathcal{C}_{\text{out}}^\perp$ , our smooth min-entropy condition here considers  $\mathcal{C}_{\text{out}}$  itself.

<sup>6</sup> Informally, a code  $\mathcal{C} \subseteq \Sigma^n$  is said to be list-recoverable if for any small sets  $S_1, \dots, S_n \subseteq \Sigma$ , there are not too many codewords  $c \in \mathcal{C}$  so that  $c_i \in S_i$  for many values of  $i$ .

## 1.1 Related Work

### Explicit Concatenated Codes

Concatenation (with a single inner code) has been a common approach to obtain explicit codes close to the GV bound. Here we mention a few such places this comes up. Choosing  $\mathcal{C}_{\text{out}}$  to be the Reed–Solomon code, and  $\mathcal{C}_{\text{in}}$  to be the Hadamard code, gets a code of length  $O(k^2/\varepsilon^2)$  for any dimension  $k$  [3], and replacing Reed–Solomon with the Hermitian code gets length  $O((k/\varepsilon)^{5/4})$  [6]. Choosing a different AG code for  $\mathcal{C}_{\text{out}}$  can result in non-vanishing rate and in fact approach rate  $\varepsilon^3$  (see [28]). Moreover, concatenating Reed–Solomon with the Wozencraft ensemble gives the *Justesen* code [19], having constant relative rate and constant relative distance. Note that none of these concatenation-based constructions thus far have beat the Zyablov bound.

### Concatenated Codes with Random Linear $\mathcal{C}_{\text{out}}$

Relevant to Theorem 3, [4] studies a random linear code  $\mathcal{C}_{\text{out}}$  concatenated with a *fixed* inner code  $\mathcal{C}_{\text{in}}$ . (See also [5], which applies the same techniques for an application in compressive sensing). The work [4] derives bounds on the distance of  $\mathcal{C}_{\text{out}} \circ \mathcal{C}_{\text{in}}$  in terms of (moments of) the weight distribution of  $\mathcal{C}_{\text{in}}$ . These bounds imply that  $\mathcal{C}_{\text{out}} \circ \mathcal{C}_{\text{in}}$  approaches the GV bound in some cases, but doesn't seem to immediately imply Theorem 3.

Before discussing their techniques more, we note that the biggest difference between [4] and our work is that their question is about the behavior of random linear codes, and so naturally their approach crucially uses the fact that  $\mathcal{C}_{\text{out}}$  is random. In contrast, the motivation for our work is to find deterministic sufficient conditions on  $\mathcal{C}_{\text{out}}$ , and we invoke a random linear outer code as a proof of concept that our approach is realizable.

Next, we briefly describe the techniques and implications of [4], relative to Theorem 3. The key result of [4] is an expression of the limiting trade-off between the rate  $R$  and the distance  $\delta$  of  $\mathcal{C}_{\text{out}} \circ \mathcal{C}_{\text{in}}$ , in terms of the function  $\phi(\tau) = \ln \mathbb{E}_X[e^{\tau X}]$ , where  $X$  is the weight of a random codeword from  $\mathcal{C}_{\text{in}}$  and where  $\tau \leq 0$  parameterizes the trade-off.<sup>7</sup> They show that this trade-off meets the GV bound when  $\mathcal{C}_{\text{in}}$  is the identity (trivial) code, and investigate how it behaves when  $\mathcal{C}_{\text{in}}$  is a non-trivial code. Towards this, one can use their trade-off to work out the Taylor series for  $R$  around  $\delta = 1/2$ . It is not hard to see that under mild conditions on  $\mathcal{C}_{\text{in}}$ , the first two terms of this Taylor expansion vanish and hence we obtain  $R = \Theta(\varepsilon^2) + O_{\mathcal{C}_{\text{in}}}(\varepsilon^3)$  when  $\delta = 1/2 - \varepsilon$ , where the  $O_{\mathcal{C}_{\text{in}}}(\cdot)$  notation hides constants that depend on  $\mathcal{C}_{\text{in}}$ . This implies that if  $n_0$  is a constant, independent even of  $\varepsilon$ , then  $\mathcal{C}_{\text{out}} \circ \mathcal{C}_{\text{in}}$  approaches the GV bound. However, if  $n_0$  is growing relative to  $\varepsilon$  (which it is in our case, as we take  $\mathcal{C}_{\text{in}}$  to have rate  $\varepsilon$ ), then the “constant” terms hiding in the  $O_{\mathcal{C}_{\text{in}}}(\varepsilon^3)$  term may depend on  $n_0$ , which in turn may depend on  $\varepsilon$ . It seems plausible that when  $\mathcal{C}_{\text{in}}$  is a random linear code, this dependence is mild<sup>8</sup> and something like Theorem 3 could be established with these techniques, but to the best of our knowledge such a proof has not appeared in the literature and does not seem to follow immediately.

<sup>7</sup> In more detail, this trade-off is given by  $R = \frac{1}{n_0 \ln(2)}(\tau\phi'(\tau) - \phi(\tau))$  and  $\delta = \frac{\phi'(\tau)}{n_0}$ , for  $\tau \leq 0$ .

<sup>8</sup> In particular, as pointed out in [4], the first  $d^\perp - 1$  terms of the Taylor series will agree with the GV bound, where  $d^\perp$  is the dual distance of  $\mathcal{C}_{\text{in}}$ , which for a random linear code  $\mathcal{C}_{\text{in}}$  is quite large.

### Non-Concatenation-Based Explicit Constructions

As mentioned above, there have been several breakthroughs in the past few years obtaining explicit constructions of binary codes near the GV bound, and even efficient algorithms for them. In a breakthrough result, Ta-Shma [28] constructed *explicit* linear codes of relative distance  $\frac{1-\varepsilon}{2}$  having rate  $\varepsilon^{2+o(1)}$ . Ta-Shma's codes are also  $\varepsilon$ -balanced, i.e.,  $\Delta(x, y) \in [\frac{1-\varepsilon}{2}, \frac{1+\varepsilon}{2}]$ , and thus give rise to explicit  $\varepsilon$ -biased sample spaces, which are ubiquitous in pseudorandomness and derandomization. Works that followed gave efficient *decoding* of Ta-Shma codes and their variants [1, 16, 17, 26, 18] (see also [7] for a different, randomized, construction that slightly improves upon the rate of [28], and admits efficient decoding). We note that these codes are graph-based, and do not in general have a concatenated structure.

### Results with Multiple i.i.d. Inner Codes

Thommesen showed that when the outer code is a Reed–Solomon code, and it is concatenated with  $n$  different random linear codes, one for each coordinate, chosen independently, then the resulting code lies on the GV bound with high probability [29]. Guruswami and Indyk devised efficient decoding algorithms for these codes, based on *list-recoverability* of the outer code [10]. That work used a Reed–Solomon code as the outer code, which is list-recoverable up to the Johnson bound. Later, Rudra [27] observed that the parameters could be improved by swapping out the Reed–Solomon code for a code that can be list-recovered up to capacity, for example a Folded Reed–Solomon code. Later work obtained nearly-linear-time decoding algorithms by swapping out the outer code for a capacity-achieving list-recoverable code with near-linear-time list-recovery algorithms [15, 21]. Codes with multiple i.i.d. inner codes have also been studied in [32, 8].

We also mention the work of Guruswami and Rudra [13], who show that the same construction (a list-recoverable code concatenated with  $n$  different i.i.d. random linear codes) is *list-decodable* up to capacity with high probability. In the results [10, 27, 15, 21] mentioned above, list-recovery of the outer code was needed for *algorithms*, not the combinatorial result (which follows already from [29]). In contrast, in [13], the list-recoverability of the outer code is needed for the combinatorial result itself. In that sense, the flavor is similar to our sufficient condition in Section 5 in the full version, although the techniques are very different, and in our work we only use one inner code.

### Further Low-randomness Constructions of Binary Codes on GV Bound

If one's goal is to explicitly construct a binary code that achieves that GV bound, at least two types of partial results may be considered as subgoals. In the first class of results, one seeks explicit codes whose rate vs. distance tradeoff is as close to the GV bound as possible. This includes the works discussed in the first two paragraphs of Section 1.1 above. A second path is to seek codes that fully attain the GV bound, and strive to minimize the amount of randomness used in their construction.

Varshamov's classic result [30] is that a random linear code likely achieves the GV bound. Constructing such a code of length  $n$  and rate  $R$  requires sampling either a random generating matrix or a random parity-check matrix, and thus  $O(\min\{R, 1 - R\} \cdot n^2)$  random bits are needed. Two classical elementary constructions – the Wozencraft ensemble [22] and the random Toeplitz Matrix construction (e.g., [14, Exercise 4.6]) – are able to reduce the needed randomness to  $O(n)$ .

So far, no codes achieving the GV bound using  $o(n)$  randomness are known. Moreover, there is a certain natural obstacle, which we now describe, that needs to be tackled before sublinear randomness can be achieved. Say that a random code  $\mathcal{C} \subseteq \mathbb{F}_2^n$  is *uniform* if

every  $x \in \mathbb{F}_2^n \setminus \{0\}$  appears in the code with the same probability, namely,  $p_{R,n} = \frac{2^{Rn}-1}{2^n-1}$ . It is not hard to prove via a union bound that a uniform linear code achieves the GV bound with high probability (this is exactly Varshamov's observation). To the best of our knowledge, every known GV-bound construction to date, including the linear randomness constructions mentioned above, is uniform. Unfortunately, a uniform code ensemble with sublinear randomness cannot exist as long as  $R$  is bounded away from 1. Indeed, to have events that occur with probability  $p_{R,n}$ , at least  $\log_2 \frac{1}{p_{R,n}} \approx (1-R)n$  random bits are required. Therefore, a code construction obtaining the GV bound with sublinear randomness would have to do so without being uniform (see also [23, Section 5]). We have hope that our sufficient conditions in Theorems 5.1 and 6.2 could be attained by non-uniform codes. For example, as discussed above, the soft-decoding-like condition of Theorem 5.1 is reminiscent of results on soft-list-decoding and soft-list-recovery, which in different parameter regimes can even be achieved by deterministic codes.

A related line of work [12, 25, 23] attempts to construct codes that enjoy a broad class of desirable combinatorial properties similar to those of random linear codes using as little randomness as possible. Such properties include not just the GV bound, but also list decodability up to the *Elias bound* (see [23]), list recoverability, and, more generally, *local similarity* (see [23, Definition 2.14]) to a random linear code.

## 1.2 Technical Overview

In this section we give an overview of the main technical ideas. This section also serves as an outline of the full version of the paper.

### Section 3: A moment-based framework

In Section 3, we set up a framework that will be useful for the results in Section 4 and Section 5. We describe this approach here.

Suppose that we are trying to encode a message  $m \in \mathbb{F}_q^k$  with our concatenated code  $\mathcal{C} = \mathcal{C}_{\text{out}} \circ \mathcal{C}_{\text{in}}$ , to obtain  $\mathcal{C}(m) = w \in \mathbb{F}_2^{n \cdot n_0}$ . Each symbol of  $w$  is indexed by some  $\alpha \in [n]$  and some  $\beta \in [n_0]$ ; this symbol is equal to

$$(\mathcal{C}_{\text{in}}(\mathcal{C}_{\text{out}}(m)_\alpha))_\beta = \langle \mathcal{C}_{\text{out}}(m)_\alpha, b_\beta \rangle,$$

where  $b_\beta$  is the  $\beta$ 'th row for a generator matrix  $G_0 \in \mathbb{F}_2^{n_0 \times k_0}$  for  $\mathcal{C}_{\text{in}}$ , and where the  $\langle \cdot, \cdot \rangle$  notation denotes the dot product over  $\mathbb{F}_2$ . This motivates the definition of a variable  $X_m \in \mathbb{R}$  defined by

$$X_m = \sum_{\alpha \in [n]} \sum_{\beta \in [n_0]} (-1)^{\langle \mathcal{C}_{\text{out}}(m)_\alpha, b_\beta \rangle}.$$

Indeed,  $X_m$  is the bias of  $w = \mathcal{C}(m)$ ; the weight of  $w$  is at least  $\frac{1}{2} - O(\varepsilon N)$  if and only if  $X_m$  is at most  $O(\varepsilon N)$ . Thus, to show that the code  $\mathcal{C}$  has distance at least  $\frac{1}{2} - O(\varepsilon N)$ , it suffices to show that

$$\max_{m \in \mathbb{F}_q^k \setminus \{0\}} X_m = O(\varepsilon N).$$

Our strategy will be to consider a large moment of  $X_m$  over the choice of a random nonzero message  $m$ :

$$\mathbb{E}_{m \sim \mathbb{F}_q^k \setminus \{0\}} [X_m^r]$$

for some appropriate  $r$ . If we can show that this is smaller than  $(c\varepsilon N)^r/q^k$ , then Markov’s inequality will imply that

$$\Pr_{m \sim \mathbb{F}_q^k \setminus \{0\}} [X_m \geq c\varepsilon N] \leq \frac{\mathbb{E}_{m \sim \mathbb{F}_q^k \setminus \{0\}} [X_m^r]}{(c\varepsilon N)^r} < \frac{1}{q^k},$$

and in particular that there are no messages  $m$  so that  $X_m \geq c\varepsilon N$ .

In Lemma 3.3, we take a Fourier transform in order to re-write  $\mathbb{E}[X_m^r]$  as a quantity involving  $\mathcal{C}_{\text{out}}^\perp$ . This quantity can be thought of as follows. For every integer-valued matrix<sup>9</sup>  $V \in \mathbb{Z}_{\geq 0}^{n_0 \times n}$  with entries that sum to  $r$ , we consider a vector  $g_V \in \mathbb{F}_q^n$  defined by considering the matrix  $G_0^T \cdot V \in \mathbb{F}_2^{k_0 \times n}$  and then treating it as a vector  $g_V \in \mathbb{F}_q^n$  by identifying each of the columns in  $\mathbb{F}_2^{k_0}$  with elements of  $\mathbb{F}_q$ . Then the quantity in Lemma 3.3 has to do with the number of these vectors  $g_V$  that are in  $\mathcal{C}_{\text{out}}^\perp$ . The exact expression doesn’t matter too much for this informal discussion; instead we explain below how we use this re-writing to prove Theorem 4.2 and Theorem 5.1.

#### Section 4: Most codes $\mathcal{C}_{\text{out}}$ are good

Theorem 4.2 informally says that if  $\mathcal{C}_{\text{out}}$  is a random linear code, then with high probability  $\mathcal{C}_{\text{out}} \circ \mathcal{C}_{\text{in}}$  is near the GV bound. In the proof, we use our framework from Section 3, and show that with high probability over  $\mathcal{C}_{\text{out}}$ , the moment  $\mathbb{E}_m[X_m^r]$  is small for an appropriate  $r$ . To do this, we need to count the number of matrices  $V$  described above that are likely to land in  $\mathcal{C}_{\text{out}}^\perp$ . Since  $\mathcal{C}_{\text{out}}$  is a random linear code, so is  $\mathcal{C}_{\text{out}}^\perp$ , and so the probability of any particular *non-zero*  $g_V$  landing in it is small (about  $1/q^k$ ), while of course the probability that 0 is contained in  $\mathcal{C}_{\text{out}}^\perp$  is 1. Thus, the challenge is understanding how many  $g_V$ -s are actually zero. There are two ways that a matrix  $V$  as described above could lead to  $g_V = 0$ : Either  $V = 0 \pmod 2$ , or else  $V$  is non-zero mod 2 but  $G_0^T V = 0$ . The first case can be counted straightforwardly. For the second, we leverage the weight distribution that the inner code  $\mathcal{C}_{\text{in}}$  is likely to have. We note that this is the only place (in any of our arguments) that we need  $\mathcal{C}_{\text{in}}$  to be a random linear code: We just need it to have approximately the “right” weight distribution.

#### Section 5: A soft-decoding-like sufficient condition

The expression that we get for  $\mathbb{E}_m[X_m^r]$  in Lemma 3.3 directly inspires our soft-decoding-like sufficient condition in Theorem 5.1. One can view the task of counting the matrices  $V$  so that  $g_V \in \mathcal{C}_{\text{out}}^\perp$  as choosing a random  $V$  and asking about the probability that  $g_V \in \mathcal{C}_{\text{out}}^\perp$ . If the columns of  $V$  were independent, then this would be the same as choosing the coordinates of  $g_V$  i.i.d. from some distribution  $\mathcal{D}$ . Thus we would get a requirement on  $\Pr_{x \sim \mathcal{D}^n} [x \in \mathcal{C}_{\text{out}}^\perp]$ , similar to the condition in Equation (1) that we end up with.

Of course, the coordinates are not independent (because the total weight of  $V$  is fixed to be  $r$ ), but this can be solved. In more detail, we choose  $r$  to be a Poisson random variable, which in this setting makes the columns of  $V$  independent. One hiccup is that the “Poisson-ized” distribution turns out to be meaningfully different than the original distribution, in the sense that it is much more likely that  $g_V = 0$  in the Poisson-ized version. This means that the “natural” soft-decoding-like condition that one would get out of this is not realizable: The probability that  $g_V \in \mathcal{C}_{\text{out}}^\perp$  is much bigger than we want it to be, for *any*

<sup>9</sup> In the actual quantity, the entries of this matrix are ordered, and we denote it  $\mathcal{V}$  instead of  $V$ ; we ignore the ordering in this discussion for simplicity.

$\mathcal{C}_{\text{out}}$ , just because  $g_V$  is too likely to be zero. Fortunately, this seems to be the only obstacle: as in Equation (1), we separate out the  $g_V = 0$  term (using the analysis from Section 4) to arrive at a condition that *is* realizable. We explain why the condition is realizable – that is, why there exists a  $\mathcal{C}_{\text{out}}$  that meets it – in Remark 8.

### Section 6: A smoothness condition on $\mathcal{C}_{\text{out}}$

For our second sufficient condition, we depart from our moment-based framework and work from first principles. Our main theorem in Section 6 is Theorem 6.2, which informally says that if the elements of  $\mathcal{C}_{\text{out}}$  have “smooth” enough distributions of symbols, in the sense that they each have large enough min-entropy, that  $\mathcal{C} = \mathcal{C}_{\text{out}} \circ \mathcal{C}_{\text{in}}$  will lie near the GV bound with high probability. The basic idea is to consider a *worst-case* assignment of symbols in  $\mathbb{F}_q$  to codewords in  $\mathcal{C}_{\text{in}}$ ; this assignment need not be linear and can depend on a particular codeword  $c \in \mathcal{C}_{\text{out}}$ . Such a worst-case assignment would simply assign the lowest-weight codewords in  $\mathcal{C}_{\text{in}}$  to the most frequent symbols in a codeword  $c \in \mathcal{C}_{\text{out}}$ . Using the weight distribution that  $\mathcal{C}_{\text{in}}$  is likely to have, along with the min-entropy assumption, we can show that this worst-case assignment will *still* result in codewords  $w \in \mathcal{C}$  of weight at least  $\frac{1}{2} - O(\varepsilon)$ .

We note that, unlike our sufficient condition from Section 5, we don’t have a proof of feasibility for our smoothness condition. That is, as far as we know, there may not be any linear code  $\mathcal{C}_{\text{out}}$  that is smooth in this sense. However, as a proof of concept we mention in Remark 9 that a random linear code will have a similar property with high probability. Moreover, we find it plausible that codewords of *algebraically structured* codes (say, Folded Reed–Solomon codes, Folded Multiplicity, or even large sub-codes of plain Reed–Solomon codes), would satisfy this property, even if a random code does not.

---

## Abstract

We study parallel repetition of  $k$ -player games where the constraints satisfy the *projection* property. We prove exponential decay in the value of a parallel repetition of projection games with a value less than 1.

**2012 ACM Subject Classification** Theory of computation  $\rightarrow$  Interactive proof systems

**Keywords and phrases** Parallel Repetition, Multiplayer games, Projection games

## 1 Introduction

We study  $k$ -player one-round games and the effect on the value of the game when we repeat the game in parallel.

In a  $k$ -player game  $G$ , a verifier chooses  $k$  questions  $(x^1, x^2, \dots, x^k)$  from a distribution  $\mu$  on the set of questions  $\mathcal{X}_1 \times \mathcal{X}_2 \times \dots \times \mathcal{X}_k$  and sends  $x^i$  to player  $i$ . Player  $i$  responds to the verifier's question by sending an answer  $a^i \in \mathcal{A}_i$  without communicating with the other players. The verifier accepts the answers based on a fixed predicate  $V((x^1, x^2, \dots, x^k), (a^1, a^2, \dots, a^k))$ . The value of the game, denoted by  $\text{val}(G)$ , is the maximum, over the players' strategies, accepting probability of the verifier.

The  $n$ -fold parallel repetition of  $G$ , denoted by  $G^{\otimes n}$ , is defined as follows. The verifier sends questions  $\vec{x}^j = (x_1^j, x_2^j, \dots, x_n^j)$  to the  $k$  players where for each  $j \in [n]$ ,  $(x_1^j, x_2^j, \dots, x_n^j)$  is sampled from the original distribution  $\mu$  independently. The  $i^{\text{th}}$  player responds with answers  $\vec{a}^i \in \mathcal{A}_i^n$ . The verifier accepts the answers iff  $V((x_1^j, x_2^j, \dots, x_n^j), (a_1^j, a_2^j, \dots, a_n^j)) = 1$  for each  $j \in [n]$ .

If  $\text{val}(G) = 1$ , then it is easy to observe that  $\text{val}(G^{\otimes n})$  is also 1. Also,  $\text{val}(G^{\otimes n}) \geq \text{val}(G)^n$  as the players can achieve value  $\text{val}(G)^n$  in the game  $G^{\otimes n}$  by simply repeating an optimal strategy for the game  $G$  independently in all the  $n$  coordinates. The question of interest is how does the quantity  $\text{val}(G^{\otimes n})$  decay with  $n$  if the value of the game  $G$  is less than 1?

Verbitsky [30] showed that for any  $k$ -player game  $G$ , if  $\text{val}(G) < 1$ , then  $\text{val}(G^{\otimes n}) \leq \frac{1}{\alpha(n)}$  where  $\alpha(n)$  is an inverse Ackermann function. This result uses the Density Hales-Jewett Theorem [15, 27] as a black box. For 2-player games, Raz [29] showed that if  $\text{val}(G) < 1$ , then  $\text{val}(G^{\otimes n}) \leq 2^{-\Omega_G(n)}$ , where we use  $\Omega_G(\cdot)$  to clarify that the constant depends on the game  $G$ . There have been many improvements that improve the constants in the bounds, and even get better bounds based on the value  $\text{val}(G)$  of the initial game [21, 28, 12, 7]. These results on parallel repetition of 2-player games have found many applications in probabilistically checkable proofs and hardness of approximation [4, 13, 23].

Mittal and Raz [26] showed that a strong parallel repetition theorem (i.e., the value of  $G^{\otimes n}$  decays exponentially in  $n$  in a certain strong sense) for a particular class of more than 2-player games implies super-linear lower bounds for Turing machines in the non-uniform model. For any  $k \geq 2$ , Dinur, Harsha, Venkat, and Yuen [10] showed that for a large class of  $k$ -player games, called the *connected games*, the exponential decay indeed holds. The class of connected games is defined as follows: define the graph  $H_G$ , whose vertices are the ordered  $k$ -tuples of questions to the  $k$ -players, and there is an edge between questions  $q$  and  $q'$  if they differ in the question to exactly one of the  $k$  players, and are the same for the remaining  $k - 1$  players. The game is said to be connected if the graph  $H_G$  is connected.

A special 3-player (non-connected) game, called the GHZ Game [10], has received much attention. The GHZ game, first introduced by Greenberger, Horne, and Zeilinger [19], is a central game in the study of quantum entanglement. Holmgren and Raz [22] gave the first polynomial decay in the parallel repetition of the GHZ game. Girish, Holmgren, Mittal, Raz, and Zhan [16] later gave a simpler proof of the polynomial decay. Very recently, Braverman, Khot, and Minzer [8], using a much simpler proof, improved these previous results and showed an exponential decay in the GHZ game.

Girish, Holmgren, Mittal, Raz, and Zhan [17] considered the problem of parallel repetition for 3-player games with binary questions and answers and showed polynomial decay for these games. This was later improved by a subset of the authors [18] to all 3-player games over binary questions and *arbitrary* answer lengths. They also study [17] *player-wise connected* games  $G$  that are defined as follows. For each player  $i$ , define the graph  $H_i(G)$ , whose vertices are the possible questions for player  $i$ , and two questions  $x$  and  $x'$  are connected by an edge if there exists a vector  $y$  of questions for all other players, such that both  $(x, y)$  and  $(x', y)$  are asked by the verifier with non-zero probability. The game  $G$  is player-wise connected if, for every  $i$ , the graph  $H_i(G)$  is connected. Girish *et al.* [17] showed polynomial decay in the value of  $n$ -fold parallel repetition of all player-wise connected games. Observe that the notion of player-wise connectedness is more general than the notion of connected games defined above.

In this paper, we will study a special type of  $k$ -player games, that we refer to as projection games. The formal definition is as follows.

► **Definition 1.** For any  $k \geq 2$ , a  $k$ -player game  $G$  is called a *projection game* if for every  $k$ -tuple of question  $q = (x^1, x^2, \dots, x^k)$ , there is  $D_q \geq 1$  and projections  $\sigma_q^i : \mathcal{A}_i \rightarrow [D_q]$  for  $i \in [k]$ , such that  $V((x^1, x^2, \dots, x^k), (a^1, a^2, \dots, a^k))$  is true iff  $\sigma_q^i(a^i) = \sigma_q^{i'}(a^{i'})$  for any  $i \neq i'$ .

For every question  $q = (x^1, x^2, \dots, x^k)$ , consider a  $k$ -partite hypergraph  $\mathcal{H}_q$  on the vertex set  $(\mathcal{A}_1, \mathcal{A}_2, \dots, \mathcal{A}_k)$  where  $(a^1, a^2, \dots, a^k)$  is an hyperedge if and only if  $V((x^1, x^2, \dots, x^k), (a^1, a^2, \dots, a^k))$  is true. Then, the projection property means that for every  $k$ -tuple of

questions  $q$  in the support of  $\mu$ , each connected component in  $\mathcal{H}_q$  is a complete  $k$ -partite hypergraph. Note that this definition of projection games is slightly more general than the usual notion of projection 2-player games [29, 28] where one of the maps  $\sigma_q^i$  (either  $\sigma_q^1$  or  $\sigma_q^2$ ) is an injective map.

Our main theorem shows that if the value of a projection game  $G$  is less than 1, then the value of  $n$ -fold parallel repetition of  $G$  decays exponentially in  $n$ .

► **Theorem 2.** *For any  $k \geq 2$ , a projection  $k$ -player game  $G$  and  $\varepsilon > 0$ , if  $\text{val}(G) = 1 - \varepsilon$ , then  $\text{val}(G^{\otimes n}) \leq \exp(-\Omega_{\varepsilon, G}(n))$ .*

Projection games are a natural subclass of general games. They played a key role in the development [2, 3, 14] of Probabilistically Checkable Proofs (PCPs). In fact, parallel repetition from 2-player projection games had been useful in proving many [20, 25, 24, 9, 11] tight hardness of approximation results, starting with the work of Arora, Babai, Stern, and Sweedyk [1], Bellare, Goldreich, and Sudan [4], and Håstad [23].

Feige [13] used a  $k$ -player projection game, and parallel repetition of the game, to show almost tight hardness of approximating the Set-Cover problem. The decay in the value of a parallel-repeated game, in that case, follows easily from the parallel-repetition theorem for the 2-player game, as the subgame restricted to any two players has a value less than 1.

There are  $k$ -player projection games where the decay in the value of a parallel-repeated game does not trivially follow from the parallel-repetition theorem for the 2-player game. To give a concrete example, consider a simultaneous Max-3-SAT instance problem defined in [6]: the instance consists of  $n$  variables  $X = \{x_1, x_2, \dots, x_n\}$  and  $k$  instances,  $\phi_1, \phi_2, \dots, \phi_k$ , of Max-3-SAT defined over the same set of variables  $X$ . The verifier chooses a variable  $x \in X$  at random and selects clauses  $C_i \in \phi_i$  independently such that  $x \in C_i$  for all  $i \in [k]$ . The verifier sends clause  $C_i$  to player  $i$  and expects a satisfying assignment from  $\{0, 1\}^3$  to  $C_i$  from player  $i$ . The verifier checks if the assignments returned by the players agree on  $x$ . Consider the scenario when it is possible to satisfy any  $(k - 1)$  out of  $k$  instances of Max-3-SAT simultaneously, but there is no assignment to  $X$  that will satisfy all the  $k$  instances. In this case, the value of the game is less than 1. For any  $k'$ -player subgame, where  $k' < k$ , the value of the subgame is 1. Therefore, we cannot use the parallel repetition of 2-player games to conclude that the value of  $n$ -fold parallel repetition of projection games decays with  $n$ .

## 1.1 Proof outline

As mentioned in the introduction, Dinur, Harsha, Venkat, and Yuen [10] showed that for any connected  $k$ -player games  $H$  with  $\text{val}(H) < 1$ , the exponential decay holds for the value of  $H^{\otimes n}$ . We start with a  $k$ -player game  $G$  which is not connected to begin with. At a high level, we transform the game  $G$  to another game  $H$  where  $H$  is connected. While doing such a transformation, we want to make sure we have the following two properties.

1. If  $\text{val}(G) < 1$ , then  $\text{val}(H) < 1$ .
2. There is a way to relate  $\text{val}(G^{\otimes n})$  with  $\text{val}(H^{\otimes n})$ , possibly with a small loss in the constants in the exponent.

As  $H$  is connected, we have  $\text{val}(H^{\otimes n}) = \exp(-\Omega_H(n))$  and this will complete the proof.

There is a trivial transformation that makes any game connected – add all possible  $k$ -tuple of questions, play the game  $G$  on the original questions, and accept all the newly added questions by default. It is easy to see that if  $\text{val}(G) < 1$ , then the value of the transformed game is less than 1. However, in this case, there does not seem to be an easy way to relate  $\text{val}(G^{\otimes n})$  to the value of  $n$ -fold parallel repetition of the transformed game.

## 54:4 Parallel Repetition of k-Player Projection Games

In order to overcome the issue, we make the game  $G$  connected gradually. More concretely, we start with a game  $G_0 = G$  and iteratively, we convert the game  $G_\ell$  to  $G_{\ell+1}$  for  $\ell = 0, 1, \dots$  with the following three properties.

1. For every  $\ell \geq 0$ , the game  $G_\ell$  is a  $k$ -player game with the questions from the set  $\mathcal{X}_1 \times \mathcal{X}_2 \times \dots \times \mathcal{X}_k$ .
2. The game  $G_{\ell+1}$  is *richer* than the game  $G_\ell$ . In our case, we would be interested in increasing the support of distribution on questions, i.e.,  $\text{supp}(\mu(G_{\ell+1})) \supseteq \text{supp}(\mu(G_\ell))$  (unless, of course,  $\text{supp}(\mu(G_\ell))$  is full).
3. We can relate the value of the game  $G_\ell^{\otimes n}$  to the value of the game  $G_{\ell+1}^{\otimes n}$  up to a fixed polynomial factor. Furthermore,  $\text{val}(G_{\ell+1}) < 1$  if  $\text{val}(G_\ell) < 1$ .

Let us see that this is enough to prove our main theorem. Using properties 1 and 2, for some  $t \geq 1$ , which only depends on the size of the game  $G$ , we can conclude that the game  $G_t$  has full support and hence is *connected*. Using property 3, we have  $\text{val}(G^{\otimes n}) \approx \text{val}(G_t^{\otimes n})^{C_t}$ , where  $C_t > 0$  is a constant that only depends on  $t$ , and furthermore  $\text{val}(G_t) < 1$  if  $\text{val}(G) < 1$  to begin with. Finally, using the result by Dinur, Harsha, Venkat, and Yuen [10] on connected games, we have,  $\text{val}(G_t^{\otimes n}) = \exp(-\Omega_{\varepsilon, G_t}(n))$ , and hence  $\text{val}(G^{\otimes n}) = \exp(-\Omega_{\varepsilon, t, G}(n))$  if  $\text{val}(G) < 1$ .

### The transformation $G_\ell$ to $G_{\ell+1}$

The key idea is to use the *path-trick* from [5] to transform the game  $G_\ell$  (and  $G_\ell^{\otimes n}$ ) to another game  $G_{\ell+1}$  (and  $G_{\ell+1}^{\otimes n}$ ) such that the support of the transformed game is potentially larger than the original game. We illustrate the idea of such a transformation in a 3-player game  $G_\ell$ .

We start with the game  $G_\ell$  and let  $\mu(G_\ell)$  be the distributions on the questions in  $G_\ell$ . For every pair of question-triples  $q = (x, y, z)$  and  $q' = (x', y', z')$  from  $\text{supp}(\mu(G_\ell))$  such that  $x = x'$ , we add a question triple  $\Pi^3((q, q')) := (x, y, z')$  to the game  $G_{\ell+1}$ . Note that in this case, we took two question-triples  $(q, q')$  that share player 1's question and generate a question-triple in the new game with the first two players' questions from  $q$  and player 3's question from  $q'$ . We now state the set of accepting assignments for  $\Pi^3((q, q'))$  as follows. If  $q \neq q'$ , then accept the question  $\Pi^3((q, q'))$  by default, otherwise accept  $\Pi^3((q, q'))$  according to the verifier from the original game  $G_\ell$  on the question  $q(=q')$ .<sup>1</sup> We call such a transformation  $\mathcal{T}_3^1$  – the superscript stands for the common player's question from  $(q, q')$  and the subscript 3 stands for taking player 3's question from  $q'$  and rest of the questions from  $q$  in generating the question-triple in the new game. Succinctly, we write  $G_{\ell+1}$  as the game  $\mathcal{T}_3^1(G_\ell)$ . Likewise, we can define transformations  $\mathcal{T}_p^i$  for any  $1 \leq i, p \leq 3$ .

We show the following key properties of these transformations.

1. If  $\text{val}(G_\ell) < 1$ , then  $\text{val}(\mathcal{T}_p^i(G_\ell)) < 1$ . Furthermore,  $\mathcal{T}_p^i(G_\ell)$  remains a projection game if  $G_\ell$  is a projection game.
2. For every  $n \geq 1$ ,  $\text{val}(G_\ell^{\otimes n}) \leq \text{val}(\mathcal{T}_p^i(G_\ell)^{\otimes n})^{1/2}$ , if  $G_\ell$  is a projection game.

The first property is trivial – in the game  $\mathcal{T}_p^i(G_\ell)$ , we are still playing the game  $G_\ell$  as a subgame, and hence its value is less than 1 if  $\text{val}(G_\ell) < 1$ . For the furthermore part, we are either accepting everything by default or using the same predicate as in the original game, and hence, this transformation maintains the projection property of the game.

<sup>1</sup> Note that the way the game  $G_{\ell+1}$  is defined, the set of accepting answers for the same question-triple changes based on the underlying pair of questions  $(q, q')$ . For simplicity, we ignore this issue in this proof overview, and it will be handled in the main proof.

For the second property, we crucially use the **projection property** of the game  $G_\ell$ . We show that for any strategy  $(\alpha^1, \alpha^2, \alpha^3)$ , where  $\alpha^i : \mathcal{X}_i^n \rightarrow \mathcal{A}_i^n$ , for the game  $G_\ell^{\otimes n}$  with value  $\varepsilon$ , the *same* strategy gives value at least  $\varepsilon^2$  to the game  $\mathcal{T}_p^i(G_\ell)$ . We illustrate this for the game  $\mathcal{T}_3^1(G_\ell)$ . Let  $\mu$  be the distribution of questions from  $G_\ell$  and  $\mu|_1$  be the marginal distribution on player 1's questions, we have

$$\begin{aligned}
\varepsilon^2 &\leq \mathbf{E}_{(\mathbf{x}, \mathbf{y}, \mathbf{z}) \sim \mu^{\otimes n}} [V((\mathbf{x}, \mathbf{y}, \mathbf{z}), (\alpha^1(\mathbf{x}), \alpha^2(\mathbf{y}), \alpha^3(\mathbf{z})))^2 \\
&= \left( \mathbf{E}_{\mathbf{v} \in \mu^{\otimes n}|_1} \left[ \mathbf{E}_{\substack{(\mathbf{x}, \mathbf{y}, \mathbf{z}) \sim \mu^{\otimes n}, \\ \mathbf{x} = \mathbf{v}}} [V((\mathbf{x}, \mathbf{y}, \mathbf{z}), (\alpha^1(\mathbf{x}), \alpha^2(\mathbf{y}), \alpha^3(\mathbf{z}))) \right] \right)^2 \\
&\leq \mathbf{E}_{\mathbf{v} \in \mu^{\otimes n}|_1} \left[ \mathbf{E}_{\substack{(\mathbf{x}, \mathbf{y}, \mathbf{z}) \sim \mu^{\otimes n}, \\ \mathbf{x} = \mathbf{v}}} [V((\mathbf{x}, \mathbf{y}, \mathbf{z}), (\alpha^1(\mathbf{x}), \alpha^2(\mathbf{y}), \alpha^3(\mathbf{z}))) \right]^2 \quad (\text{Cauchy-Schwarz}) \\
&= \mathbf{E}_{\mathbf{v} \in \mu^{\otimes n}|_1} \mathbf{E}_{\substack{(\mathbf{x}, \mathbf{y}, \mathbf{z}) \sim \mu^{\otimes n}, \\ (\mathbf{x}', \mathbf{y}', \mathbf{z}') \sim \mu^{\otimes n}, \\ \mathbf{x} = \mathbf{x}' = \mathbf{v}}} \left[ \frac{V((\mathbf{x}, \mathbf{y}, \mathbf{z}), (\alpha^1(\mathbf{x}), \alpha^2(\mathbf{y}), \alpha^3(\mathbf{z}))) \cdot V((\mathbf{x}', \mathbf{y}', \mathbf{z}'), (\alpha^1(\mathbf{x}'), \alpha^2(\mathbf{y}'), \alpha^3(\mathbf{z}'))}{V((\mathbf{x}', \mathbf{y}', \mathbf{z}'), (\alpha^1(\mathbf{x}'), \alpha^2(\mathbf{y}'), \alpha^3(\mathbf{z}'))} \right]
\end{aligned}$$

Now, if we look at the triple  $(\mathbf{x}, \mathbf{y}, \mathbf{z}')$  sampled according to the above distribution, then for each  $j \in [n]$ , we have that the triple  $(x_j, y_j, z'_j)$  is distributed according to the game  $\mathcal{T}_3^1(G_\ell)$  independently. In the game,  $\mathcal{T}_3^1(G_\ell)$ , for any  $j \in [n]$  such that  $(x_j, y_j, z_j) \neq (x'_j, y'_j, z'_j)$  the new verifier is accepting by default. As for  $j \in [n]$  such that  $(x_j, y_j, z_j) = (x'_j, y'_j, z'_j)$ , the new verifier is accepting according to the original verifier on the question  $(x_j, y_j, z_j)$ . In this case, suppose  $(\alpha^1(\mathbf{x})_j, \alpha^2(\mathbf{y})_j, \alpha^3(\mathbf{z})_j)$  and  $(\alpha^1(\mathbf{x}')_j, \alpha^2(\mathbf{y}')_j, \alpha^3(\mathbf{z}')_j)$  are two satisfying assignments to the same question  $(x_j, y_j, z_j)$  according to the original game  $G_\ell$  with  $\alpha^1(\mathbf{x})_j = \alpha^1(\mathbf{x}')_j$  (as  $\mathbf{x} = \mathbf{x}'$ ), then because of the projection property of the game, we have that  $(\alpha^1(\mathbf{x})_j, \alpha^2(\mathbf{y})_j, \alpha^3(\mathbf{z}'_j))$  must be a satisfying assignment for  $(x_j, y_j, z_j)$ . As in the game  $\mathcal{T}_3^1(G_\ell)^{\otimes n}$ , we are precisely checking this for all such  $j \in [n]$ , we get that the same strategy  $(\alpha^1, \alpha^2, \alpha^3)$  gives

$$\text{val}(\mathcal{T}_3^1(G_\ell)^{\otimes n}) \geq \varepsilon^2.$$

### Putting everything together

Using the above two properties of the transformations  $\mathcal{T}_p^i$ , we conclude that if  $\text{val}(G) < 1$ , then for any  $t \geq 1$  and vectors  $\vec{i}, \vec{p} \in [3]^t$ ,

$$\text{val}(G^{\otimes n}) \leq \text{val}(\mathcal{T}_{p_t}^{i_t}(\dots(\mathcal{T}_{p_2}^{i_2}(\mathcal{T}_{p_1}^{i_1}(G))))^{\otimes n})^{1/2^t}, \text{ and } \mathcal{T}_{p_t}^{i_t}(\dots(\mathcal{T}_{p_2}^{i_2}(\mathcal{T}_{p_1}^{i_1}(G))) < 1.$$

Finally, we show that there exist  $t \geq 1$  and vectors  $\vec{i}, \vec{p} \in [3]^t$ , where  $t$  depends on the size of the game  $G$ , such that the game  $\mathcal{T}_{p_t}^{i_t}(\dots(\mathcal{T}_{p_2}^{i_2}(\mathcal{T}_{p_1}^{i_1}(G)))$  is connected (in fact, has full support). This implies that

$$\text{val}(G^{\otimes n}) \leq \text{val}(\mathcal{T}_{p_t}^{i_t}(\dots(\mathcal{T}_{p_2}^{i_2}(\mathcal{T}_{p_1}^{i_1}(G))))^{\otimes n})^{1/2^t} \leq \exp(-\Omega_{t,G}(n)),$$

where the last inequality follows from the result of a parallel repetition theorem [10] on connected games.

## 2 Preliminaries

We start with a few notations. We use  $\mu(G)$  to denote the distribution on the questions in the game  $G$ . For  $i \in [k]$ , let  $\mu|_i$  be the marginal distribution on the questions to player  $i$ . For a  $k$ -tuple of questions  $q = (x^1, x^2, \dots, x^k)$ , we denote the question to player  $i$  by  $q|_i$ , i.e.,  $q|_1 = x^1$ ,  $q|_2 = x^2$ , and so on. For an assignment  $\alpha := (\alpha^1, \alpha^2, \dots, \alpha^k)$  to the game  $G$ , where  $\alpha^i : \mathcal{X}_i \rightarrow \mathcal{A}_i$ , and any question  $q = (x^1, x^2, \dots, x^k)$ , we use the notation  $\alpha|_q$  to denote the assignment-tuple  $(\alpha^1(x^1), \alpha^2(x^2), \dots, \alpha^k(x^k))$ .

The size of the game  $G$  is referred to as the quantity  $k \cdot M \cdot \prod_{i=1}^k |\mathcal{X}_i| |\mathcal{A}_i|$ . Here, the probability of every atom in  $\text{supp}(\mu(G))$  is a multiple of  $1/M$ , where  $M$  is a finite integer. We note that as far as proving exponential decay in the  $n$ -fold repeated value of the game  $G$  with  $\text{val}(G) < 1$ , the last assumption is without loss of generality. For instance, see [18, Lemma 3.14] which lets us assume that the distribution of questions in  $G$  is uniform on the support without loss of generality.

### 2.1 Parallel repetition of connected games

As mentioned earlier, Dinur, Harsha, Venkat, and Yuen [10] showed that for a large class of  $k$ -player games, called *connected games*, the exponential decay indeed holds. Here, we define the notion of connected games for  $k$ -player games formally.

► **Definition 3** (Connected game). *A game  $G$  is called connected if for every two question pairs  $(x^1, x^2, \dots, x^k)$  and  $(x'^1, x'^2, \dots, x'^k)$  from  $\text{supp}(\mu(G))$ , there is an ordered list of questions from  $\text{supp}(\mu(G))$ ,  $((x_\ell^1, x_\ell^2, \dots, x_\ell^k))_{\ell=1}^t$  for some  $t \geq 1$ , such that the pairs  $((x^1, x^2, \dots, x^k), (x_1^1, x_1^2, \dots, x_1^k))$ ,  $((x_t^1, x_t^2, \dots, x_t^k), (x'^1, x'^2, \dots, x'^k))$ , and  $((x_\ell^1, x_\ell^2, \dots, x_\ell^k), (x_{\ell+1}^1, x_{\ell+1}^2, \dots, x_{\ell+1}^k))$  for all  $1 \leq \ell \leq t-1$  differ in only one out of the  $k$  questions.*

We will relate the value of  $G^{\otimes n}$ , where  $G$  is a projection game, with a value of  $n$ -fold parallel repetition of another game  $H$  that is connected. The following theorem shows that for connected games with a value less than 1, the value of repeated games goes down exponentially in  $n$ .

► **Theorem 4** ([10]). *For any  $k \geq 2$  and  $\varepsilon > 0$ , if  $H$  is a connected  $k$ -player game with  $\text{val}(H) = 1 - \varepsilon$ , then  $\text{val}(H^{\otimes n}) \leq \exp(-\Omega_{\varepsilon, H}(n))$ .*

### 2.2 Variants of multiplayer games

In this section, we simplify the class of games that we study. Towards this, we define the notion of *loosely-connected* games as follows.

► **Definition 5** (Loosely-connected game). *A game on the question set  $\mathcal{X}_1 \times \mathcal{X}_2 \times \dots \times \mathcal{X}_k$  is loosely-connected if it is not possible to partition  $\mathcal{X}_i = \mathcal{X}'_i \cup \mathcal{X}''_i$  for all  $i \in [k]$ , so that all  $k$ -tuple of questions from the support of  $\mu(G)$  are in  $\mathcal{X}'_1 \times \mathcal{X}'_2 \times \dots \times \mathcal{X}'_k$  or  $\mathcal{X}''_1 \times \mathcal{X}''_2 \times \dots \times \mathcal{X}''_k$ .*

The following lemma states that we can assume without loss of generality that the game  $G$  is *loosely-connected*.

► **Lemma 6.** *If the exponential decay in the  $k$ -player parallel repetition holds for all projection loosely-connected games, then it also holds for all projection games.*

**Proof.** The proof of this lemma is similar to the proof of [18, Lemma 2.7]. We include the proof of this lemma here for completeness.

Let  $G$  be any projection game that is not loosely-connected with  $\mathbf{val}(G) = 1 - \varepsilon$  for some  $\varepsilon > 0$ . Without loss of generality, we can assume that there are partitions  $\mathcal{X}_i = \mathcal{X}'_i \cup \mathcal{X}''_i$  for all  $i \in [k]$  such that all the questions from the support of  $\mu(G)$  are from  $\mathcal{X}'_1 \times \mathcal{X}'_2 \times \dots \times \mathcal{X}'_k$  or  $\mathcal{X}''_1 \times \mathcal{X}''_2 \times \dots \times \mathcal{X}''_k$ , and furthermore, the game restricted to  $\mathcal{X}'_1 \times \mathcal{X}'_2 \times \dots \times \mathcal{X}'_k$  (call it  $G'$ ) and  $\mathcal{X}''_1 \times \mathcal{X}''_2 \times \dots \times \mathcal{X}''_k$  (call it  $G''$ ) are loosely-connected individually. The verifier's distribution  $\mu(G)$  on the question-tuples can be thought of as  $\mu = (1 - \delta)\mu' + \delta\mu''$  where the support of  $\mu'$  is from  $\mathcal{X}'_1 \times \mathcal{X}'_2 \times \dots \times \mathcal{X}'_k$  and the support of  $\mu''$  is from  $\mathcal{X}''_1 \times \mathcal{X}''_2 \times \dots \times \mathcal{X}''_k$ .

Now, since the value of the game  $G$  is at most  $1 - \varepsilon$ , we have  $\min\{\mathbf{val}(G'), \mathbf{val}(G'')\} \leq 1 - \varepsilon$ . Without loss of generality, suppose we have  $\mathbf{val}(G') \leq 1 - \varepsilon$ . Let the value of  $G^{\otimes n}$  be  $\eta$ . We will show that the value of the game  $G'^{\otimes n'}$  is also at least  $\eta - 2^{-\Omega_\delta(n)}$  for some  $n' = \Omega_\delta(n)$ . This will finish the proof of the lemma as we have  $\mathbf{val}(G'^{\otimes n'}) \leq \exp(-\Omega_\varepsilon(n'))$  using the fact that  $G'$  is a loosely-connected projection game.

Fix a strategy  $(\alpha^1, \alpha^2, \dots, \alpha^k)$  for  $G^{\otimes n}$  with value  $\eta$ . The  $k$ -tuple questions from  $G$  can be alternatively sampled as follows. First sample a set  $T \subseteq [n]$  by adding  $i \in T$  independently with probability  $(1 - \delta)$ . Then for each  $i \in T$ , sample a  $k$ -tuple question from the distribution  $\mu'$  independently. Similarly, for each  $i \notin T$ , sample a  $k$ -tuple question from the distribution  $\mu''$  independently. We have,

$$\mathbf{E}_{\substack{T \subseteq [n] \\ (\bar{x}^1 |_{\bar{T}}, \dots, \bar{x}^k |_{\bar{T}}) \sim \mu''^{\otimes |\bar{T}|}}} \mathbf{E}_{(\bar{x}^1 |_T, \dots, \bar{x}^k |_T) \sim \mu'^{\otimes |T|}} [V((\bar{x}^1, \bar{x}^2, \dots, \bar{x}^k), (\alpha^1(\bar{x}^1), \alpha^2(\bar{x}^2), \dots, \alpha^k(\bar{x}^k)))] = \eta.$$

From this, by the Chernoff Bound and an averaging argument, it follows that there exists  $T \subseteq [n]$  such that  $|T| \geq (1 - \delta)n/2$  and  $(\bar{y}^1, \bar{y}^2, \dots, \bar{y}^k) \sim \mu''^{\otimes |T|}$  such that

$$\mathbf{E}_{(\bar{x}^1, \bar{x}^2, \dots, \bar{x}^k) \sim \mu'^{\otimes |T|}} [V(((\bar{y}^1, \bar{x}^1), \dots, (\bar{y}^k, \bar{x}^k)), (\alpha^1((\bar{y}^1, \bar{x}^1)), \dots, \alpha^k((\bar{y}^k, \bar{x}^k))))] \geq \eta - 2^{-\Omega_\delta(n)}.$$

Here, the string  $(\bar{y}, \bar{x})$  is formed by plugging  $\bar{y}$  in the coordinates  $\bar{T}$  and  $\bar{x}$  in the coordinates  $T$ . The distribution of the questions in the expectation above precisely corresponds to the game  $G'^{\otimes |T|}$ . Thus, the strategy  $\alpha^i(\bar{y}, \bar{x}) := \alpha^i(\bar{y}^i, \bar{x}^i)$  for all  $i \in [k]$  gives the value at least  $\eta - 2^{-\Omega_\delta(n)}$  for the game  $G'^{\otimes |T|}$ .  $\blacktriangleleft$

We also consider a slight variation in the definition of  $k$ -player games, which we call *random-predicate  $k$ -player games*, where we allow a verifier to use a random predicate instead of a fixed predicate during verification.

► **Definition 7** (Random-predicate game). *A random-predicate game  $G$  is defined as follows. There exists  $R \geq 1$  such that the verifier chooses the  $k$ -tuple of questions  $(x^1, x^2, \dots, x^k)$  according to the distribution  $\mu(G)$  on the set of questions and  $r \in [R]$  uniformly at random, sends  $x^i$  to player  $i$ . The player  $i$  responds with the answer  $a^i$ . Finally, the verifier accepts the answers based on a fixed predicate  $V_r((x^1, x^2, \dots, x^k), (a^1, a^2, \dots, a^k))$ . We denote such games by  $(G, \mu, [R])$ .*

The following lemma states that for this variation of connected  $k$ -player games  $G$  the exponential decay from [10] still holds.

► **Lemma 8.** *For any connected random-predicate  $k$ -player game  $H$  and  $\varepsilon > 0$ , if  $\mathbf{val}(H) = 1 - \varepsilon$ , then  $\mathbf{val}(H^{\otimes n}) \leq \exp(-\Omega_{\varepsilon, H}(n))$ .*

**Proof.** We can think of a random-predicate  $k$ -player game  $H$  as a  $(k + 1)$ -player game  $H'$  as follows. In  $H'$ , the verifier selects the questions  $(x^1, x^2, \dots, x^k)$  from the game  $H$  and  $r \in [R]$  uniformly at random. The verifier sends  $x^i$  to players  $i$  for  $i \in [k]$ , and

sends  $r$  to player  $k + 1$ . The player  $i \in [k + 1]$  responds with the answer  $a^i$  ( $a^{k+1}$  can be anything). The verifier's predicate in  $H'$  is  $V((x^1, x^2, \dots, x^k, r), (a^1, a^2, \dots, a^k, a^{k+1})) := V_r((x^1, x^2, \dots, x^k), (a^1, a^2, \dots, a^k))$ .

It is easy to observe that if the game  $H'$  is connected then the game  $H$  is connected. Furthermore, we have  $\mathbf{val}(H^{\otimes n}) = \mathbf{val}(H'^{\otimes n})$  for any  $n \geq 1$ . Using this, the lemma follows from Theorem 4.  $\blacktriangleleft$

We can also add the projection property to a random-predicate game. The formal definition is as follows.

**► Definition 9** (Random-predicate projection game). *For any  $k \geq 2$ , a random-predicate  $k$ -player game  $(G, \mu, [R])$  is called a random-predicate projection game if for every  $k$ -tuple of question  $q = (x^1, x^2, \dots, x^k)$  and  $r \in [R]$ , there is  $D_{q,r} \geq 1$  and projections  $\sigma_{q,r}^i : \mathcal{A}_i \rightarrow [D_{q,r}]$  for  $i \in [k]$ , such that  $V_r((x^1, x^2, \dots, x^k), (a^1, a^2, \dots, a^k))$  is true iff  $\sigma_{q,r}^i(a^i) = \sigma_{q,r}^{i'}(a^{i'})$  for any  $i \neq i'$ .*

From this point onwards, we will incorporate the property of random-predicate whenever we refer to projection games.

In our proof, we will encounter random-predicate games where the choice of the verifier's predicate  $V_r$  is not uniform and may depend on the question  $q$ . The following claim says that we can assume that the distribution on verifier's predicate is uniform from a set of predicates and independent of the questions. This transformation preserves the support of the question-distribution.

**▷ Claim 10.** Suppose  $G$  is a random-predicate  $k$ -player game where on the  $k$ -tuple of question  $q \in \mathcal{X}_1 \times \mathcal{X}_2 \times \dots \times \mathcal{X}_k$ , the distribution on the verifier's predicate  $V_r$  is sampled according to some distribution  $\nu_q$  over  $[R]$ , then there is another game  $H$  with the same distribution on the questions as in  $G$  such that the verifier for  $H$  samples a random predicate  $\tilde{V}_m$  where  $m \in [M]$  is distributed uniformly over  $[M]$ , and such that  $\mathbf{val}(G^{\otimes n}) = \mathbf{val}(H^{\otimes n})$  for all  $n \geq 1$ . Furthermore, a)  $M$  only depends on the size of the game  $G$ , and b) if  $G$  is a random-predicate projection game, then  $H$  is also a random-predicate projection game.

*Proof.* Let  $M \in \mathbb{Z}^+$  be a number such that for every question  $q$  from the game  $G$ , each atom from  $\text{supp}(\nu_q)$  has probability weight  $c/M$  for  $1 \leq c \leq M$ . In the game  $G$ , for a question  $q$  if  $\nu_q(r) = c/M$ , then in game  $H$ , we make  $c$  copies  $\tilde{V}_{i_1}(q, \cdot), \tilde{V}_{i_2}(q, \cdot), \dots, \tilde{V}_{i_c}(q, \cdot)$  of the verifier predicate  $V_r(q, \cdot)$  for the same question  $q$ . Thus, for a given question  $q$ , the verifier in  $H$  samples a random  $m \in [M]$  and decides based on the predicate  $\tilde{V}_m(q, \cdot)$ .

The a) and b) from the furthermore part follow the above construction.  $\triangleleft$

### 3 Proof of Theorem 2

Throughout this section, we fix a random-predicate  $k$ -player projection game  $(G, \mu, [R])$ , succinctly written as  $G$ , on the questions from the set  $\mathcal{X}_1 \times \mathcal{X}_2 \times \dots \times \mathcal{X}_k$  and let  $\mu(G)$  be the distribution on the questions in  $G$ . Using Claim 10, we can assume without loss of generality, that along with the  $k$ -tuple questions  $(x^1, x^2, \dots, x^k) \sim \mu$ , the verifier selects  $r \in [R]$  uniformly at random, and after getting answers  $(a^1, a^2, \dots, a^k)$  from the players, applies the predicate  $V_r((x^1, x^2, \dots, x^k), (a^1, a^2, \dots, a^k))$ .

The key idea is to use the *path-trick* from [5] to relate the value of the game  $G$  (and  $G^{\otimes n}$ ) to another game  $H$  (and  $H^{\otimes n}$ ) which is connected.

### 3.1 The path-trick and the $i$ -links

In this section, we define the notion of a *link* which is analogous to the notion of the path-trick [5] that was used in connection to studying dictatorship tests towards showing hardness of approximation of constraint satisfaction problems.

Fix a player  $i \in [k]$ . An  $i$ -link from a game  $G$  is an ordered pair of original  $k$ -tuple of questions from  $G$  with possible repetition. We will induce the following distribution on  $i$ -links from  $G$ .

- Pick a question  $v$  to player  $i$  according to the distribution of  $\mu|_i$  and sample two  $k$ -tuple of questions  $q = (x^1, x^2, \dots, x^k)$  and  $q' = (y^1, y^2, \dots, y^k)$ , independently from  $\mu$  but conditioned on  $x^i = y^i = v$  and output  $(q, q')$ .

We denote the above distribution on the  $i$ -links with  $L_i(G)$ .

To see the utility of  $i$ -links, the following claim shows that the distribution  $L_i(G^{\otimes n})$  on the  $i$ -links in  $G^{\otimes n}$  is the same as the product distribution on the  $i$ -links from  $G$ .

▷ **Claim 11.** For every game  $G$ ,  $i \in [k]$ , and  $n \geq 1$ , the following two distributions are identical.

1. The distribution  $L_i(G^{\otimes n})$ .
2. The distribution  $\mathcal{D}_i$  on the  $i$ -links from  $G^{\otimes n}$  defined as follows:
  - For each  $j \in [n]$ , independently sample  $(q_j, q'_j)$  from the distribution  $L_i(G)$  where  $q_j = (x_j^1, x_j^2, \dots, x_j^k)$  and  $q'_j = (y_j^1, y_j^2, \dots, y_j^k)$ .
  - Let  $\vec{q} = (q_1, q_2, \dots, q_n)$  and  $\vec{q}' = (q'_1, q'_2, \dots, q'_n)$ . Output  $(\vec{q}, \vec{q}')$ .

Proof. Note that  $\vec{q}$  and  $\vec{q}'$ , sampled from  $\mathcal{D}_i$ , are the following  $k$ -tuple of questions

$$\begin{array}{cc} (x_1^1, x_2^1, \dots, x_n^1) & (y_1^1, y_2^1, \dots, y_n^1) \\ (x_1^2, x_2^2, \dots, x_n^2) & (y_1^2, y_2^2, \dots, y_n^2) \\ \vdots & \vdots \\ \underbrace{(x_1^k, x_2^k, \dots, x_n^k)}_{\vec{q}} & \underbrace{(y_1^k, y_2^k, \dots, y_n^k)}_{\vec{q}'} \end{array}$$

For each  $j \in [n]$ , the pair of  $k$ -tuple of questions  $(x_j^1, x_j^2, \dots, x_j^k)$  and  $(y_j^1, y_j^2, \dots, y_j^k)$  share a common pivot question  $p_j = x_j^i = y_j^i$ . This means that the question-pair  $(\vec{q}, \vec{q}')$  share a common  $n$ -tuple question  $\vec{p}$  from player  $i$ , where we think of  $\vec{q}, \vec{q}'$  as questions from the game  $G^{\otimes n}$ . This precisely corresponds to the distribution  $L_i(G^{\otimes n})$ . ◁

Consider the game  $G$  the assignments  $\alpha^i : \mathcal{X}_i \rightarrow \mathcal{A}_i$  for  $i \in [k]$ . We say that the link  $(q, q')$  from the game  $G$  is  $r$ -consistent with respect to the global assignments  $(\alpha^1, \alpha^2, \dots, \alpha^k)$  if  $q$  as well as  $q'$  are satisfied by the predicate  $V_r$  on the assignments  $(\alpha^1, \alpha^2, \dots, \alpha^k)$ .

▷ **Claim 12.** Let  $n \geq 1$ ,  $(\alpha^1, \alpha^2, \dots, \alpha^k)$  be a strategy for  $(G, \mu, [R])$  with  $\mathbf{val}(G) \geq \varepsilon$ . Then with probability at least  $\varepsilon^2$ , the link  $(q, q')$  is  $r$ -consistent with the assignments  $(\alpha^1, \alpha^2, \dots, \alpha^k)$ , where the probability is over  $(q, q')$  sampled according to  $L_i(G)$  and  $r \in [R]$  uniformly at random.

Proof. Fix the provers' strategies  $\alpha^i : \mathcal{X}_i \rightarrow \mathcal{A}_i$  for  $i \in [k]$  with value at least  $\varepsilon$ . We have,

$$\mathbf{E}_{\substack{(x^1, x^2, \dots, x^k) \sim \mu, \\ r \in [R]}} [V_r((x^1, x^2, \dots, x^k), (\alpha^1(x^1), \alpha^2(x^2), \dots, \alpha^k(x^k)))] \geq \varepsilon.$$

## 54:10 Parallel Repetition of $k$ -Player Projection Games

Using the Cauchy-Schwarz inequality, we have,

$$\begin{aligned}
\varepsilon^2 &\leq \mathbf{E}_{\substack{(x^1, x^2, \dots, x^k) \sim \mu, \\ r \in [R]}} [V_r((x^1, x^2, \dots, x^k), (\alpha^1(x^1), \alpha^2(x^2), \dots, \alpha^k(x^k)))]^2 \\
&= \left( \mathbf{E}_{\substack{v \in \mu|_i \\ r \in [R]}} \left[ \mathbf{E}_{\substack{(x^1, x^2, \dots, x^k) \sim \mu \\ x^i = v}} [V_r((x^1, x^2, \dots, x^k), (\alpha^1(x^1), \alpha^2(x^2), \dots, \alpha^k(x^k)))] \right] \right)^2 \\
&\leq \mathbf{E}_{\substack{v \in \mu|_i \\ r \in [R]}} \left[ \mathbf{E}_{\substack{(x^1, x^2, \dots, x^k) \sim \mu \\ x^i = v}} [V_r((x^1, x^2, \dots, x^k), (\alpha^1(x^1), \alpha^2(x^2), \dots, \alpha^k(x^k)))] \right]^2 \\
&\hspace{25em} \text{(Cauchy-Schwarz)} \\
&= \mathbf{E}_{\substack{v \in \mu|_i \\ r \in [R]}} \left[ \mathbf{E}_{\substack{(x^1, x^2, \dots, x^k) \sim \mu, \\ (y^1, y^2, \dots, y^k) \sim \mu, \\ x^i = y^i = v}} \left[ \begin{array}{l} V_r((x^1, x^2, \dots, x^k), (\alpha^1(x^1), \alpha^2(x^2), \dots, \alpha^k(x^k))) \\ V_r((y^1, y^2, \dots, y^k), (\alpha^1(y^1), \alpha^2(y^2), \dots, \alpha^k(y^k))) \end{array} \right] \right].
\end{aligned}$$

The expression inside the expectation above is precisely the probability that the  $i$ -link  $((x^1, x^2, \dots, x^k), (y^1, y^2, \dots, y^k))$  sampled from the distribution  $L_i(G)$  is  $r$ -consistent with respect to the assignments  $(\alpha^1, \alpha^2, \dots, \alpha^k)$ . This shows that

$$\Pr_{\substack{(q, q') \sim L_i(G) \\ r \in [R]}} [(q, q') \text{ is } r\text{-consistent with respect to the assignments } (\alpha^1, \alpha^2, \dots, \alpha^k)] \geq \varepsilon^2,$$

and this completes the proof.  $\triangleleft$

### 3.2 The transformations $\mathcal{T}_p^i$

We are now ready to define the transformation on the game  $G$  that was alluded to at the beginning of this section. We denote the transformed games by  $\mathcal{T}_p^i(G)$  for  $1 \leq i, p \leq k$ .

The distribution on the  $k$ -tuple of questions in the game  $\mathcal{T}_p^i(G)$  is over  $\mathcal{X}_1 \times \mathcal{X}_2 \times \dots \times \mathcal{X}_k$  which is defined as follows.

1. The verifier samples a link  $(q, q') \sim L_i(G)$  where  $q = (x^1, \dots, x^k)$  and  $q' = (y^1, \dots, y^k)$ .
2. The verifier constructs a question-tuple by taking  $x^p$  from  $q$  and  $(y^1, \dots, y^{p-1}, y^{p+1}, \dots, y^k)$  from  $q'$ . Succinctly, we denote this operation as  $(y^1, \dots, y^{p-1}, x^p, y^{p+1}, \dots, y^k) := \Pi^p((q, q'))$  (the  $p$  stands for taking player  $p$ 's question from the first question and the remaining players' questions from the second question).

Before we define the set of satisfying assignments in the transformed game, we first define the set of  $r$ -consistent assignments, where  $r \in [R]$ , to an  $i$ -link. An assignment to a link  $(q, q')$  is an assignment to both  $q$  and  $q'$  (note that each  $k$ -tuple of question receives a separate assignment from  $\mathcal{A}_1 \times \mathcal{A}_2 \times \dots \times \mathcal{A}_k$ ). For an  $i$ -link  $(q, q')$ , we define the set of  $r$ -consistent assignments to  $(q, q')$  as follows. An  $r$ -consistent assignment to an  $i$ -link  $(q, q')$  is an assignment  $\sigma$  to the link such that

- the verifier accepts  $\sigma|_q$  on  $q$  and  $\sigma|_{q'}$  on  $q'$  according to the predicate  $V_r$ , and
- $\sigma|_{q|_i} = \sigma|_{q'|_i}$ , i.e.,  $\sigma$  gives the same value to the common question  $v$  to the player  $i$  from  $q$  and  $q'$ .

Note that an  $i$ -link  $(q, q')$  may share more than one common question with the players, but the  $r$ -consistency only cares about the question to player  $i$ .

We now define the set of accepting assignments for a  $k$ -tuple of questions in the random-predicate transformed game. The verifier chooses  $r \in [R]$  uniformly at random. Suppose a  $k$ -tuple of questions  $\tilde{q} = (z^1, z^2, \dots, z^k)$  is coming from an  $i$ -link  $(q, q')$ , i.e.,  $\tilde{q} = \Pi^p((q, q'))$ , then

- Case 1: If  $q \neq q'$ , then accept by default.
- Case 2: If  $q = q'$ , then  $\tilde{q} = q$ . In this case, accept according to the verifier's predicate  $V_r$  from the game  $G$  on question  $\tilde{q}$ .

Note that the game  $\mathcal{T}_p^i(G)$  is a random-predicate  $k$ -player game (the accepting answers for a question  $\tilde{q}$  depends on the underlying sampled link as well as the sampled  $r \in [R]$ ), and as described, the distribution on the underlying predicate is not uniform among the set of predicates. However, using Claim 10, without loss of generality, we can assume that the underlying distribution on the predicate that the verifier applies in  $\mathcal{T}_p^i(G)$  is uniform from a set of predicates (and independent of the questions). We need this as we will be applying a series of these transformations on the original game, and the transformation above is only defined on games where the verifier's predicate is uniform and independent of the question  $q$ .

In the transformed game, the verifier either accepts all the answers or accepts answers based on the predicates from the original game  $G$ . We have the following simple, but important, fact.

► **Fact 13.** *If  $G$  is a random-predicate  $k$ -player projection game, then for every  $i, p \in [k]$ , the game  $\mathcal{T}_p^i(G)$  is also a random-predicate projection game.*

### 3.2.1 Properties of the transformations $\mathcal{T}_p^i$

We start with the first claim that shows that the value of the transformed games is less than 1 if the value of  $G$  is less than 1.

▷ **Claim 14.** Fix any  $k$ -player game  $(G, \mu, [R])$ . For every  $\varepsilon \in (0, 1)$  and  $i, p \in [k]$ , if  $\text{val}(G) = 1 - \varepsilon$ , then  $\text{val}(\mathcal{T}_p^i(G)) = 1 - \varepsilon'$  where  $\varepsilon' > 0$  that depends on  $\varepsilon$  and the size of the game  $G$ .

Proof. First, observe that for every question-tuple  $q = (x^1, x^2, \dots, x^k)$  from the game  $G$ , the  $i$ -link  $(q, q)$  is present in the support of  $L_i(G)$ . Therefore, for every question-tuple  $q = (x^1, x^2, \dots, x^k)$  from the game  $\mathcal{T}_p^i(G)$  that is given by the  $i$ -link  $(q, q)$ , the verifier of the transformed game selects  $r \in [R]$  uniformly at random and uses the predicate  $V_r$ . Therefore, the transformed game  $\mathcal{T}_p^i(G)$  is a convex combination of the original game  $G$  and another game  $G'$ . Let  $\tilde{\mu}$  be the distribution on question-tuples in  $\mathcal{T}_p^i(G)$ , then it can be written as  $\tilde{\mu} = \delta\mu + (1 - \delta)\mu'$ , where  $\mu'$  corresponds to the distribution of questions from game  $G'$  and  $\delta \in (0, 1]$  that depends on the size of the game  $G$ . Thus,

$$\text{val}(\mathcal{T}_p^i(G)) \leq \delta \cdot \text{val}(G) + (1 - \delta) = \delta(1 - \varepsilon) + (1 - \delta) = 1 - \varepsilon\delta < 1. \quad \triangleleft$$

The following claim relates the value of the original game with the value of the transformed games. This claim crucially uses the fact that the original game  $G$  is a projection game.

▷ **Claim 15.** For any  $k$ -player projection game  $(G, \mu, [R])$ ,  $n \geq 1$ , and  $i, p \in [k]$ , we have  $\text{val}(\mathcal{T}_p^i(G)^{\otimes n}) \geq \text{val}(G^{\otimes n})^2$ .

## 54:12 Parallel Repetition of k-Player Projection Games

Proof. As the statement of the claim is symmetric with respect to  $p \in [k]$ , we prove the claim when  $p = 1$ . For other  $p$ , the proof is similar.

Using Claim 11, the game  $\mathcal{T}_1^i(G)^{\otimes n}$  can be described as follows: Sample an  $i$ -link  $(\vec{q}, \vec{q}')$  from the distribution  $L_i(G^{\otimes n})$ , sample  $\vec{r} \in [R]^n$  uniformly at random, and for every  $j \in [n]$  such that  $q_j = q'_j$ , apply the predicate  $V_{r_j}$  for the question  $\Pi^1((q_j, q_j))$ .

Let's fix the players' strategy  $\alpha := (\alpha^1, \alpha^2, \dots, \alpha^k)$  for the game  $G^{\otimes n}$  that gives the value  $\mathbf{val}(G^{\otimes n})$ . For an  $i$ -link  $(\vec{q}, \vec{q}')$  from  $G^{\otimes n}$ , consider the assignments  $\alpha|_{\vec{q}}$  and  $\alpha|_{\vec{q}'}$  to the link  $(\vec{q}, \vec{q}')$ . Using Claim 12, for a random  $\vec{r} \in [R]^n$  and a randomly selected  $i$ -link  $(\vec{q}, \vec{q}')$ ,  $(\vec{q}, \vec{q}')$  is  $\vec{r}$ -consistent with respect to the global assignment  $\alpha$  with probability at least  $\mathbf{val}(G^{\otimes n})^2$ . When this happens, we show that the assignment  $\alpha$  satisfies the constraint on  $\Pi^1((\vec{q}, \vec{q}'))$  from the game  $\mathcal{T}_1^i(G)^{\otimes n}$ . Indeed, pick any  $j \in [n]$  such that the  $j^{\text{th}}$  coordinate of the link  $(\vec{q}, \vec{q}')$  is  $(q_j, q_j)$  (i.e, the same question-tuple). Here, the verifier is using the predicate  $V_{r_j}$  on the question  $q_j$  in the game  $\mathcal{T}_1^i(G)^{\otimes n}$ . If the link  $(\vec{q}, \vec{q}')$ , is  $\vec{r}$ -consistent with respect to the global assignment  $\alpha$ , then we have the following

$$V_{r_j}((q_j|_1, q_j|_2, \dots, q_j|_k), (\alpha^1(\vec{q}|_1)_j, \alpha^2(\vec{q}|_2)_j, \dots, \alpha^k(\vec{q}|_k)_j)) = 1,$$

$$V_{r_j}((q_j|_1, q_j|_2, \dots, q_j|_k), (\alpha^1(\vec{q}'|_1)_j, \alpha^2(\vec{q}'|_2)_j, \dots, \alpha^k(\vec{q}'|_k)_j)) = 1.$$

In the game  $\mathcal{T}_1^i(G)^{\otimes n}$ , the verifier is checking the following condition in the coordinate  $j$ .

$$V_{r_j}((q_j|_1, q_j|_2, \dots, q_j|_k), (\alpha^1(\vec{q}|_1)_j, \alpha^2(\vec{q}'|_2)_j, \dots, \alpha^k(\vec{q}'|_k)_j)) = 1.$$

As  $G$  and the predicates  $V_r$  satisfy the projection property, and  $\vec{q}|_i = \vec{q}'|_i$  because  $(\vec{q}, \vec{q}')$  is an  $i$ -link, we see that if  $(\alpha^1(\vec{q}|_1)_j, \alpha^2(\vec{q}|_2)_j, \dots, \alpha^k(\vec{q}|_k)_j)$  and  $(\alpha^1(\vec{q}'|_1)_j, \alpha^2(\vec{q}'|_2)_j, \dots, \alpha^k(\vec{q}'|_k)_j)$  are the accepting answers for a question according to the predicate  $V_{r_j}$ , then it can be seen easily that  $(\alpha^1(\vec{q}|_1)_j, \alpha^2(\vec{q}'|_2)_j, \dots, \alpha^k(\vec{q}'|_k)_j)$  is also an accepting answer for the same question according to the same predicate  $V_{r_j}$ . This shows that the assignment  $\alpha$  passes the verifier's check on all  $j \in [n]$  such that the  $j^{\text{th}}$  coordinate of the link  $(\vec{q}, \vec{q}')$  is  $(q_j, q_j)$ . For the other coordinates, the game  $\mathcal{T}_1^i(G)$  always accepts.

Hence the same players' strategy  $\alpha$  gives  $\mathbf{val}(\mathcal{T}_1^i(G)^{\otimes n}) \geq \mathbf{val}(G^{\otimes n})^2$ .  $\triangleleft$

Finally, we compose these transformations to get a connected game, starting with a loosely-connected game. Towards this, for any string  $\beta \in ([k] \times [k])^m$ , where  $\beta_j = (\beta_j^1, \beta_j^2) \in [k] \times [k]$ , define the transformation  $\mathcal{T}^\beta(G)$  as the following transformation

$$\mathcal{T}_{\beta_2^m}^{\beta_1^1}(\dots(\mathcal{T}_{\beta_2^2}^{\beta_2^1}(\mathcal{T}_{\beta_1^1}^{\beta_1^1}(G))))).$$

For a string  $\beta$  of length  $m$ , define a string  $\beta^T$  as a  $T$  repeated copy of  $\beta$ . We have the following claim.

$\triangleright$  **Claim 16.** Let  $\beta$  be any permutation of the set  $[k] \times [k]$ . For large enough  $T \geq 1$ , the game  $\mathcal{T}^{\beta^T}(G)$  is connected (in fact, has full support) if  $G$  is loosely-connected to begin with. Furthermore,  $T \leq \prod_{i=1}^k |\mathcal{X}_i|$  which only depends on the size of the game  $G$ .

Proof. First, any transformation  $\mathcal{T}_p^i$  does not shrink the support of the questions of the previous game. By looking closely at the transformation  $\mathcal{T}_p^i$ , we conclude the following: if  $(x^1, x^2, \dots, x^k)$  and  $(y^1, y^2, \dots, y^k)$  are both in the support of  $\mu(G)$  with  $x^i = y^i$ , then the following question  $(y^1, \dots, y^{p-1}, x^p, y^{p+1}, \dots, y^k)$  will be in the support of  $\mu(\mathcal{T}_p^i(G))$ . Using this, we also observe that if we start with any game  $H$  with the property that the series of transformations  $\mathcal{T}^\beta(H)$  does not change the support of the questions, then no future transformations will change the support on the questions (as  $\beta$  contains every possible transformation  $\mathcal{T}_p^i$ ).

From the above discussion, we conclude that after some finite (only depends on the size of the game  $G$ ) series of such transformations  $\mathcal{T}^{\beta^T}(\cdot)$ , the support of the questions does not increase after another series of transformations  $\mathcal{T}^\beta$ . We denote the saturated game by  $G_{\text{final}} := \mathcal{T}^{\beta^T}(G)$  and the underlying distribution on the questions by  $\mu_{\text{final}}$ . We show that  $\mu_{\text{final}}$  has full support on  $\mathcal{X}_1 \times \mathcal{X}_2 \times \dots \times \mathcal{X}_k$ .

Suppose towards a contradiction, the support of  $\mu_{\text{final}}$  is not full. For any tuple  $q$  of length  $k$  and  $S \subseteq [k]$ , define the tuple  $q|_S$  by taking the  $S$  entries from  $q$ . Take the *smallest*  $i \in [k]$  such that there is an  $i$ -tuple  $(z^1, z^2, \dots, z^i)$  where  $(z^1, z^2, \dots, z^i) \neq q|_{[i]}$  for any  $q \in \text{supp}(\mu_{\text{final}})$ . Let  $z^* := (z^1, z^2, \dots, z^{i-1})$ . For each  $i \leq \ell \leq k$ , define the following sets.

$$\mathcal{S}_\ell = \{x \in \mathcal{X}_\ell \mid \exists q \in \text{supp}(\mu_{\text{final}}) \text{ s.t. } (z^*, x) = q|_{[i-1] \cup \{\ell\}}\}.$$

In other words,  $\mathcal{S}_\ell$  is a set of all  $x \in \mathcal{X}_\ell$  that  $(z^*, x)$  can be extended to a valid question tuple from the game  $G_{\text{final}}$ . Note that by the definition of  $z^*$ ,  $\mathcal{S}_i \subsetneq \mathcal{X}_i$  and furthermore  $\mathcal{S}_{i'} \neq \emptyset$  for any  $i' \geq i$ , as by the minimality of  $i$ , there is a valid question  $q$  in  $G_{\text{final}}$  such that  $q|_{[i-1]} = z^*$ , and hence  $q|_{i'} \in \mathcal{S}_{i'}$  for all  $i' \geq i$ .

▷ **Claim 17.** There is no  $q \in \text{supp}(\mu_{\text{final}})$  such that  $q|_i \in \overline{\mathcal{S}_i}$  and for some  $i' > i$ ,  $q|_{i'} \in \mathcal{S}_{i'}$ .

Proof. Suppose there is such a question  $q \in \text{supp}(\mu_{\text{final}})$  such that  $q|_i \in \overline{\mathcal{S}_i}$  and for some  $i' > i$ ,  $q|_{i'} \in \mathcal{S}_{i'}$ . Consider a question  $q' = (z^1, z^2, \dots, z^{i-1}, *, *, \dots)$  where  $q'|_{i'} = q|_{i'}$ . Note that such a  $q'$  is in the  $\text{supp}(\mu_{\text{final}})$  from the definition of the set  $\mathcal{S}_{i'}$ . Furthermore,  $(q, q')$  is an  $i'$ -link in the game  $G_{\text{final}}$ . Therefore, the question  $\Pi^i((q, q'))$  will be present in the game  $\mathcal{T}_{i'}^{i'}(G_{\text{final}})$ . Recall that  $\Pi^i((q, q')) = (z^1, z^2, \dots, z^{i-1}, q|_i, *, \dots)$ . However, the question  $(z^1, z^2, \dots, z^{i-1}, q|_i, *, \dots)$  is not in  $\text{supp}(\mu_{\text{final}})$  as  $q|_i \in \overline{\mathcal{S}_i}$ . This means that the game  $G_{\text{final}}$  is not saturated, which is a contradiction. ◁

This claim implies that  $\mathcal{S}_{i'} \subsetneq \mathcal{X}_{i'}$  for all  $i' > i$ . Indeed, if  $\mathcal{S}_{i'} = \mathcal{X}_{i'}$  for some  $i' > i$ , then the above claim shows that every question  $q \in \text{supp}(\mu_{\text{final}})$ ,  $q|_i \in \mathcal{S}_i$ . Hence,  $G_{\text{final}}$  (and hence  $G$ ) is not a loosely-connected game.

This claim also implies that for every question  $q \in \text{supp}(\mu_{\text{final}})$  such that  $q|_i \in \overline{\mathcal{S}_i}$ , we have  $q|_{i'} \in \overline{\mathcal{S}_{i'}}$  for every  $i' > i$ . Consider the partition of the players' question sets  $\mathcal{X}_\ell = \mathcal{X}'_\ell \cup \mathcal{X}''_\ell$  such that

- For all  $\ell \leq i-1$ ,  $\mathcal{X}'_\ell = \{z^\ell\}$ , and  $\mathcal{X}''_\ell = \mathcal{X}_\ell \setminus \mathcal{X}'_\ell$ ,
- for all  $t \geq \ell$ ,  $\mathcal{X}'_t = \mathcal{S}_\ell$ , and  $\mathcal{X}''_t = \mathcal{X}_t \setminus \mathcal{X}'_t$ .

Because  $G$  (and hence  $G_{\text{final}}$ ) is loosely connected, there must be a question  $q \in \text{supp}(\mu_{\text{final}})$  such that  $q|_{i'} \in \overline{\mathcal{S}_{i'}}$  for every  $i' \geq i$  and  $q|_t = z^t$  for some  $1 \leq t \leq i-1$ . Consider a question  $q' = (z^1, z^2, \dots, z^{i-1}, *, *, \dots)$  such that  $q'$  is in the  $\text{supp}(\mu_{\text{final}})$ . Now, the pair of questions  $(q', q)$  is an  $t$ -link in the game  $G_{\text{final}}$ , furthermore, for a questions  $q'' := \Pi^i((q, q'))$ , we have  $q'' = (z^1, z^2, z^3, \dots, z^{i-1}, q|_i, \dots)$  where  $q|_i \in \overline{\mathcal{S}_i}$ . As  $G_{\text{final}}$  is saturated,  $q'' \in \text{supp}(\mu_{\text{final}})$  but this contradicts the definition of  $\mathcal{S}_i$ . ◁

### 3.3 Finishing the proof

Let us see why these claims above are enough to prove Theorem 2.

#### Proof of Theorem 2

We start with a projection game  $G$  with  $\text{val}(G) = 1 - \varepsilon$  for some  $\varepsilon > 0$ . First, using Lemma 6, we can assume without loss of generality that  $G$  is loosely-connected. Let  $(\vec{i}, \vec{p}) \in ([k] \times [k])^{Tk^2}$  with  $(\vec{i}, \vec{p}) = \beta^T$ , i.e.,  $(i_t, p_t)$  is the  $t^{\text{th}}$  entry from the string  $\beta^T$ , where  $\beta$  and  $T$  are from Claim 16. Let  $T' = T \cdot k^2$ .

Using Claim 15 on the (random-predicate) projection game  $G$  with  $i_1, p_1 \in [k]$ , we have

$$\mathbf{val}(G^{\otimes n}) \leq \mathbf{val}(\mathcal{T}_{p_1}^{i_1}(G)^{\otimes n})^{1/2}.$$

Fact 13 shows that  $\mathcal{T}_{p_1}^{i_1}(G)$  is a projection game, and hence applying Claim 15 on the projection game  $\mathcal{T}_{p_1}^{i_1}(G)$  with  $i_2, p_2 \in [k]$ , we get

$$\mathbf{val}(\mathcal{T}_{p_1}^{i_1}(G)^{\otimes n}) \leq \mathbf{val}(\mathcal{T}_{p_2}^{i_2}(\mathcal{T}_{p_1}^{i_1}(G))^{\otimes n})^{1/2}.$$

Repeating this process  $T'$  times, we get

$$\mathbf{val}(G^{\otimes n}) \leq \mathbf{val}(\mathcal{T}_{p_{T'}}^{i_{T'}}(\dots(\mathcal{T}_{p_2}^{i_2}(\mathcal{T}_{p_1}^{i_1}(G))))^{\otimes n})^{1/2^{T'}}.$$

Using Claim 14 repeatedly, we have

$$\mathbf{val}(\mathcal{T}_{p_{T'}}^{i_{T'}}(\dots(\mathcal{T}_{p_1}^{i_1}(\mathcal{T}_{p_1}^{i_1}(G)))) \leq 1 - \varepsilon',$$

where  $\varepsilon' > 0$ , that only depends on  $\varepsilon, T'$ , and the size of the game  $G$ . Finally, using Claim 16, we have that the game  $\mathcal{T}_{p_{T'}}^{i_{T'}}(\dots(\mathcal{T}_{p_2}^{i_2}(\mathcal{T}_{p_1}^{i_1}(G))))$  is connected and hence by Lemma 8,

$$\mathbf{val}(\mathcal{T}_{p_{T'}}^{i_{T'}}(\dots(\mathcal{T}_{p_2}^{i_2}(\mathcal{T}_{p_1}^{i_1}(G))))^{\otimes n} \leq \exp(-\Omega_{\varepsilon, T, G}(n)).$$

Overall, we get  $\mathbf{val}(G^{\otimes n}) \leq \exp(-\Omega_{\varepsilon, T, G}(n))$  and the proof is completed as  $T$  only depends on the size of the original game  $G$ .

## Abstract

We study algorithms for the Schatten- $p$  Low Rank Approximation (LRA) problem. First, we show that by using fast rectangular matrix multiplication algorithms and different block sizes, we can improve the running time of the algorithms in the recent work of Bakshi, Clarkson and Woodruff (STOC 2022). We then show that by carefully combining our new algorithm with the algorithm of Li and Woodruff (ICML 2020), we can obtain even faster algorithms for Schatten- $p$  LRA.

While the block-based algorithms are fast in the real number model, we do not have a stability analysis which shows that the algorithms work when implemented on a machine with polylogarithmic bits of precision. We show that the LazySVD algorithm of Allen-Zhu and Li (NeurIPS 2016) can be implemented on a floating point machine with only logarithmic, in the input parameters, bits of precision. As far as we are aware, this is the first stability analysis of any algorithm using  $O((k/\sqrt{\varepsilon}) \text{poly}(\log n))$  matrix-vector products with the matrix  $A$  to output a  $1 + \varepsilon$  approximate solution for the rank- $k$  Schatten- $p$  LRA problem.

## 1 Introduction

Low Rank Approximation (LRA) is an important primitive in large scale data analysis. Given an  $m \times n$  matrix  $A$ , and a rank parameter  $k$ , the task is to find a rank- $k$  matrix  $B$  that minimizes  $\|A - B\|$  where  $\|\cdot\|$  is some matrix norm. Typically, we also require that the algorithms output a factorization  $B = XY$  such that  $X \in \mathbb{R}^{m \times k}$  and  $Y \in \mathbb{R}^{k \times n}$ . Such a factorization lets us compute the product  $Bz$  with an arbitrary vector  $z$  in time  $O(k(n + m))$  which can be significantly smaller than the  $\text{nnz}(A)$  time required to multiply a vector with the original matrix  $A$ . Here  $\text{nnz}(A)$  denotes the number of non-zero entries of the matrix  $A$ . Thus, replacing  $A$  with a low rank approximation can make downstream tasks much faster. Additionally, if the matrix  $A$  has a low rank structure but is corrupted by noise, a low rank approximation of  $A$  can recover the underlying structure under suitable assumptions on the noise. We note that many low rank approximation algorithms, including ours, compute a rank- $k$  orthonormal matrix  $W$  such that  $\|A(I - WW^\top)\|$  is small and then define  $X = AW$  and  $Y = W^\top$ .

In this paper, the error metric we consider is given by the Schatten- $p$  norm for  $p \geq 1$ . Given a matrix  $M$ , the Schatten- $p$  norm of  $M$  denoted by  $\|M\|_{S_p}$  is defined as  $(\sum_i \sigma_i(M)^p)^{1/p}$  where  $\sigma_i(M)$  denotes the  $i$ -th singular value of  $M$ . Note that Schatten-2 norm is the same as the Frobenius norm, denoted by  $\|M\|_F = (\sum_{i,j} M_{ij}^2)^{1/2}$  and the Schatten- $\infty$  norm is the same as the operator norm, denoted by  $\|M\|_2 = \max_{x \neq 0} \|Mx\|_2 / \|x\|_2$ . In the presence of outliers, the Schatten-1 norm,  $\sum_i \sigma_i(M)$ , is considered to be more robust since the errors introduced by the outliers are not “squared” as it is done in the case of the Frobenius norm.

The Schatten- $p$  norm low rank approximation problem asks to find a rank- $k$  matrix  $B$  that minimizes  $\|A - B\|_{S_p}$ . As the Schatten- $p$  norms are unitarily invariant, we have from Eckart-Young-Mirsky’s theorem that  $\|A - A_k\|_{S_p} = \min_{\text{rank-}k B} \|A - B\|_{S_p}$  for all  $p \geq 1$ , where  $A_k$  is the matrix obtained by truncating the Singular Value Decomposition (SVD) of  $A$  to only the top  $k$  singular values. This implies that a single matrix  $A_k$  is a *best* rank- $k$  approximation for  $A$  for all values of  $p$ . However, computing the SVD of an  $m \times n$  matrix takes  $O(\min(mn^{\omega-1}, nm^{\omega-1}))$  time (see Appendix A), where  $\omega$  is the matrix multiplication exponent. This time complexity is prohibitive when  $m$  and  $n$  are large. Thus, we relax the requirements and ask for a rank- $k$  matrix  $B$  satisfying  $\|A - B\|_{S_p} \leq (1 + \varepsilon)\|A - A_k\|_{S_p}$  in the hope of obtaining faster algorithms than the SVD.

While a single matrix  $A_k$  is a best low rank approximation for  $A$  in all Schatten- $p$  norms, it is not the case for approximate solutions, i.e., if  $B$  is a rank- $k$  matrix that satisfies  $\|A - B\|_{S_p} \leq (1 + \varepsilon)\|A - A_k\|_{S_p}$  for some  $p$ , it may not be the case that  $\|A - B\|_{S_q} \leq (1 + \varepsilon)\|A - A_k\|_{S_q}$  for  $q \neq p$ . Thus, many approximation algorithms for Schatten- $p$  LRA are tailored to the particular value  $p$ . There are two different lines of works for Schatten- $p$  LRA in the literature: (i) Sketching based algorithms of Li and Woodruff [9] and (ii) Iterative algorithms of Bakshi, Clarkson and Woodruff [2]. We summarize the running times of the algorithms in Table 1. The sketch-based algorithms are usually non-adaptive and the iterative algorithms adaptively pick their matrix-vector product queries depending on the results in the previous round which makes them powerful as we can see from the superior running time over sketch-based algorithms when we desire solutions with small  $\varepsilon$ .

**Sketching Algorithms.** Li and Woodruff [9] gave (almost) input-sparsity time algorithms for Schatten- $p$  LRA, extending the earlier input-sparsity time algorithms for Frobenius norm LRA from [4]. For  $p < 2$ , their algorithm runs in  $\tilde{O}(\text{nnz}(A) + \max(m, n) \cdot \text{poly}(k/\varepsilon))$  time and for  $p > 2$ , their algorithm runs in  $\tilde{O}(\text{nnz}(A) + \max(m, n) \cdot \min(m, n)^{\alpha_p} \text{poly}(k/\varepsilon))$  time, where  $\alpha_p = (\omega - 1)(1 - 2/p)$ . Note that for the current value of  $\omega \approx 2.37$ , their algorithm runs in  $\Omega(mn)$  time for  $p \geq 7.4$  and hence is not an “input-sparsity time” algorithm but for all constant  $p, k, \varepsilon$ , their algorithm runs in  $o(\min(mn^{\omega-1}, nm^{\omega-1}))$  time and therefore is faster than computing the SVD.

■ **Table 1** Running times for  $1 + \varepsilon$  rank- $k$  Schatten- $p$  LRA algorithms for  $m \times n$  matrices assuming  $m \geq n$ .

|  | Time Complexity   |
|--|---|
| Li and Woodruff [9] ( $p \in [1, 2)$ ) | $O(\text{nnz}(A) \log n) + \tilde{O}_p(mk^{2(\omega-1)/p} / \varepsilon^{(4/p-1)(\omega-1)})$<br>$+ \tilde{O}_p(k^{2\omega/p} / \varepsilon^{(4/p-1)(2\omega+2)})$                |
| Li and Woodruff [9] ( $p > 2$ )        | $O(\text{nnz}(A) \log n) + \tilde{O}_p(n^{\omega(1-2/p)} k^{2\omega/p} / \varepsilon^{2\omega/(p+2)})$<br>$+ \tilde{O}_p(mn^{(\omega-1)(1-2/p)} (k/\varepsilon)^{2(\omega-1)/p})$ |
| Bakshi et al. [2]                      | $O(p^{1/6} \varepsilon^{-1/3} \text{nnz}(A) k \log(n/\varepsilon) + mp^{(\omega-1)/6} k^{\omega-1} \varepsilon^{-(\omega-1)/3})$  |

**Iterative Algorithms.** Recently, Bakshi, Clarkson, and Woodruff [2] gave an iterative algorithm for Schatten- $p$  LRA. Their algorithm runs the Block Krylov iteration algorithm of Musco and Musco [11] at *two* different block sizes for different number of iterations respectively. They show that the algorithm succeeds in computing a low rank approximation at one of the block sizes and show how to compute which block size succeeds in computing the approximation. For Schatten- $p$  LRA, their algorithm requires  $O(kp^{1/6} \text{poly}(\log n)/\varepsilon^{1/3})$  matrix-vector products with the matrix  $A$  and hence can be implemented in  $\tilde{O}(\text{nnz}(A)kp^{1/6}/\varepsilon^{1/3})$  time. At a high level, their algorithm runs the Block Krylov iteration algorithm with block size  $k$  for  $O(p^{1/6}\varepsilon^{-1/3} \text{poly}(\log n))$  iterations and with block size  $O(p^{-1/3}\varepsilon^{-1/3}k)$  for  $O(\sqrt{p} \text{poly}(\log n))$  iterations. They set these parameters such that the algorithm requires an overall same number of matrix-vector products with  $A$  at both block sizes. They argue that for a matrix with a “flat” spectrum, the low rank approximation computed by the block size  $k$  algorithm is a  $1 + \varepsilon$  approximation and for a matrix with a “non-flat” spectrum, the solution computed by block size  $O(p^{-1/3}\varepsilon^{-1/3}k)$  algorithm is a  $1 + \varepsilon$  approximation.

**Comparison.** As we can see from Table 1, the running times of these algorithms depend in a quite complicated way on the parameters  $\text{nnz}(A)$ ,  $m$ ,  $n$ ,  $\varepsilon$  and  $p$ . Throughout the paper, we assume that  $m = n$ ,  $\text{nnz}(A) = n^2$  (i.e., the matrix  $A$  is dense) and  $k \leq n^c$  for a small constant  $c$  so that  $k \ll n$ . In some cases, where sparsity in the datasets cannot be well exploited, such as when processing the datasets using GPUs, it is natural to analyze the time complexities of the algorithms and compare the performances assuming that the inputs are dense.

For  $p \in [1, 2)$ , we have that the time complexity of the algorithm of [9] is  $O(n^2 \log n + n \text{poly}(k)/\varepsilon^{(4/p-1)(\omega-1)} + \text{poly}(k)/\varepsilon^{(4/p-1)(2\omega+2)})$  and the time complexity of the algorithm of [2] is  $O(\varepsilon^{-1/3}n^2k \log(n) + n \text{poly}(k)/\varepsilon^{(\omega-1)/3})$ . We see that only when

$$1/\varepsilon > n^{\frac{1}{(4/p-1)(\omega+1)-1/6}},$$

the algorithm of [2] is faster than the sketching based algorithm of [9]. For  $\omega \approx 2.371$  and  $p = 1$ , the above is achieved only when  $1/\varepsilon \geq n^{\approx 0.1}$ . Hence, in the high accuracy regime, the algorithm of [2] is faster than that of the sketching based algorithm of [9]. For other values of  $p \in [1, 2)$ ,  $\varepsilon$  has to be even smaller than  $1/n^{0.1}$  for the algorithm of [2] to be faster than the algorithm of [9].

For comparing the algorithms in the case  $p > 2$ , first we pick  $\varepsilon$  to be a constant and obtain that the running time of the algorithm of [9] is  $O(n^2 \log n + n^{1+(\omega-1)(1-2/p)} \text{poly}(k))$  and the algorithm of [2] has a running time of  $O(p^{1/6}n^2k \log(n))$ . Thus, as long as  $(\omega-1)(1-2/p) \leq 1$ , the sketch-based algorithm is faster than the iterative algorithm. We call  $p$  such that  $(\omega-1)(1-2/p) \leq 1$ , the *crossover point* from “sketch” to “iterative”. For the current value of  $\omega \approx 2.371$ , the crossover point is  $\approx 7.39$ .

Now consider the case of  $\varepsilon = 1/n$  and constant  $p$ . The iterative algorithm of [2] has a running time of  $O(n^{2+1/3}k \log(n))$  and the sketch based algorithm of [9] has a running time of  $O(n^\omega \text{poly}(k))$  and thus offers no improvement over the naïve SVD algorithm. This again shows that in the high precision regime, the small dependence on  $\varepsilon$  in the running time of the algorithm of [2] is crucial to obtain better than  $O(n^\omega)$  time algorithm. Overall, we summarize the comparison between the algorithms in Table 2.

**Our Improvements.** We first *improve* the time complexity of the iterative algorithm of [2] for *all* parameter regimes. While the focus of their paper was to minimize the number of matrix-vector products required, we observe that by using fast rectangular matrix multiplication algorithms, we can obtain even faster algorithms using their technique of running the block

■ **Table 2** In the case of  $m = n$ ,  $\text{nnz}(A) = n^2$  and  $k = n^{o(1)}$ , the table lists which of the previous works is asymptotically faster for the current value of  $\omega \approx 2.371$ . **Iterative** algorithm refers to the algorithm of [2] and the **Sketching** algorithm refers to the algorithm of [9]. In the above, crossover  $\approx 7.4$ .

|                            | Small $\varepsilon$ ( $\approx 1/n$ ) | Large $\varepsilon$ |
|----------------------------|---------------------------------------|---------------------|
| $p \in [1, 2)$             | Iterative                             | Sketching           |
| $2 < p < \text{crossover}$ | Iterative                             | Sketching           |
| $p > \text{crossover}$     | Iterative                             | Iterative           |

Krylov iteration algorithm at different block sizes. Fast rectangular matrix multiplication algorithms let us obtain a different block-size vs iteration trade-off giving us faster algorithms. This algorithm directly achieves the fastest running times for small  $\varepsilon$  since we improve upon [2] in all regimes.

We saw above that for constant  $\varepsilon$ , the sketch based algorithm takes only  $O(n^2 \log n)$  time when  $p \lesssim 7.4$  and hence cannot be improved upon over asymptotically by more than  $\text{polylog}(n)$  factors in that regime. We show that using a combination of our fast iterative algorithm and the algorithm of [9] gives an algorithm that runs in near-linear time<sup>1</sup> for all  $p \lesssim 22$  for appropriate  $\varepsilon$  values extending the values of  $p$  for which a Schatten- $p$  LRA can be computed in  $O(n^2 \log n)$  time, when the rank parameter  $k \leq n^c$ .

Our combined algorithm works as follows: to solve a sub-problem in the algorithm of [9], we run our improved iterative algorithm for Schatten- $p$  LRA with accuracy parameter  $\varepsilon = 1/n$ . As our improved iterative algorithm has a better dependence on  $\varepsilon$  than earlier algorithms, we obtain a faster algorithm for solving the sub-problem and hence obtain an  $O(n^2 \log n)$  time algorithm for all  $p \lesssim 22$ . Thus, improving the performance of iterative algorithms in the small  $\varepsilon$  regime let us obtain faster algorithms overall in the large  $\varepsilon$  regime!

### Numerically Stable Algorithms

While the algorithm of [2] and our modification give fast algorithms for Schatten- $p$  Low Rank Approximation, it is not known if the Block Krylov iteration algorithm is stable when implemented on a floating point machine with  $O(\log(n/\varepsilon))$  bits of precision. It is a major open question in numerical linear algebra to show if the Block Krylov iteration algorithm is stable. Obtaining fast algorithms that provably work on finite precision machines is a tricky problem in general. We note that until the recent work of Banks, Garza-Vargas, Kulkarni and Srivastava [3], it was not clear if an eigendecomposition of a matrix could be computed in  $\tilde{O}(n^\omega)$  time on a finite precision machine. Building on these ideas, another recent work [14] obtains fast and stable algorithms for the generalized eigenvalue problem. The sketch-and-solve methods, such as the algorithm of [9], are usually stable as the operations do not blow up the magnitude of the entries. As we note above, for large  $p$ , the algorithms in [9] are not input-sparsity time and hence an important question is if there are any stable input-sparsity time algorithms for large  $p$ . We answer this question in affirmative by showing that the LazySVD algorithm of [1] can be stably implemented on a floating point machine with  $O(\log m\kappa/\varepsilon)$  bits of precision where  $\kappa = \sigma_1(A)/\sigma_{k+1}(A)$ . The LazySVD algorithm computes a low rank approximation for all  $p \geq 2$ .

<sup>1</sup> Note the near-linear here means  $\tilde{O}(n^2)$  as the input-matrix is assumed to have  $n^2$  nonzero entries.

Similar to the Block Krylov iteration algorithm, LazySVD also needs  $O(k \text{ poly}(\log n)/\sqrt{\varepsilon})$  matrix-vector products with  $A$ . Additionally, the factorization output by LazySVD is *simultaneously* a  $1 + \varepsilon$  approximation for all  $p \geq 2$ . To find a rank- $k$  approximation of  $A$ , the LazySVD algorithm first computes a unit vector  $v$  which is an approximation to the top eigenvector of  $A^\top A$ . Then the algorithm deflates  $A^\top A$  and forms the matrix  $(I - vv^\top)A^\top A(I - vv^\top)$  and proceeds to find an approximation to the top eigenvector of  $(I - vv^\top)A^\top A(I - vv^\top)$  and so on for a total of  $k$  rounds. The authors show that the span of  $k$  vectors found across all the iterations contains a  $1 + \varepsilon$  approximation if the eigenvector approximations satisfy an appropriate condition. Thus, to implement the LazySVD algorithm on a floating point machine, we first need a stable routine that can compute approximations to the top eigenvector of a given matrix. We show that such a routine can be implemented stably using the Lanczos algorithm [12]. We additionally modify the LazySVD algorithm and show that the modification allows us to compute matrix-vector products with the deflated matrix to a good enough approximation which lets the Lanczos algorithm compute an approximation to the top eigenvector of the deflated matrix. Our slight modification to LazySVD turns out to be important in making the stability analysis go through.

The novelty of our stability analysis is that instead of showing each of the vectors  $\tilde{v}_1, \dots, \tilde{v}_k$  computed by a finite precision algorithm are close to the vectors  $v_1, \dots, v_k$  that would be computed by an algorithm with unbounded precision, we essentially argue that for all  $i$ , the projection matrices onto the subspaces spanned by  $\tilde{v}_1, \dots, \tilde{v}_i$  and  $v_1, \dots, v_i$  are close using induction. This change makes the stability analysis work with only a polylogarithmic number of bits of precision whereas showing all  $\tilde{v}_i$ s are individually close to corresponding  $v_i$ s would require polynomially many bits of precision.

### 1.1 Our Results

In the following,  $\alpha$  denotes the constant such that an arbitrary  $n \times n$  matrix can be multiplied with an arbitrary  $n \times n^\alpha$  matrix using  $O(n^{2+\eta})$  arithmetic operations for any constant  $\eta > 0$ . The matrix multiplication exponent  $\omega$  is the smallest constant such that an arbitrary  $n \times n$  matrix can be multiplied with an arbitrary  $n \times n$  matrix using  $O(n^{\omega+\eta})$  arithmetic operations for any constant  $\eta > 0$ . For simplicity, we ignore the constant  $\eta$ , and write as if the matrices can be multiplied in  $O(n^\omega)$  time. We define  $\beta := (\omega - 2)/(1 - \alpha)$ . Note that  $\beta \leq 1$ .<sup>2</sup>

► **Theorem 1** (Informal, Theorem 5). *Given an  $n \times n$  matrix  $A$ , a rank parameter  $k$  and an accuracy parameter  $\varepsilon$ , there is an algorithm that outputs a rank- $k$  orthonormal matrix  $W$  that with probability  $\geq 0.9$  satisfies,  $\|A(I - WW^\top)\|_{S_p} \leq (1 + O(\varepsilon))\|A - A_k\|_{S_p}$ . If  $k \leq \varepsilon \cdot n^\alpha$ , then the algorithm runs in  $\tilde{O}(\sqrt{pn}^{2+\eta})$  time for any constant  $\eta > 0$ .*

Combining the algorithm in the above theorem and the algorithm of [9], we obtain the following result:

► **Theorem 2** (Informal, Theorem 8). *Given an  $n \times n$  matrix  $A$ , a rank parameter  $k$  independent of  $n$  and any constant  $\eta > 0$ , there is a randomized algorithm that runs in time  $\tilde{O}((n^{1-2/p})^{2+\eta+(1-\alpha)\beta/(1+2\beta)} \text{ poly}(1/\varepsilon) + n^2)$  and outputs a rank- $k$  projection  $\hat{Q}$  that satisfies  $\|A(I - \hat{Q})\|_{S_p}^p \leq (1 + \varepsilon)\|A - A_k\|_{S_p}^p$ , with probability  $\geq 0.9$*

The above theorem shows that for all  $p$  at most a suitable constant, the algorithm runs in  $\tilde{O}(n^2)$  time for  $\varepsilon > 1/n^{c_p}$  for a small enough constant  $c_p$  and hence is faster than using the algorithm of [9] or the algorithm in Theorem 1.

<sup>2</sup> See Section 2.2.

The following result shows that our modification of LazySVD can be stably implemented on a floating point machine.

► **Theorem 3 (Informal, Theorem 11).** *Given an  $n \times d$  matrix  $A$  with condition number  $\kappa(A) = \sigma_1(A)/\sigma_{k+1}(A)$ , an accuracy parameter  $\varepsilon$ , a rank parameter  $k$  and probability parameter  $\eta$ , if the machine precision  $\varepsilon_{\text{mach}} \leq \text{poly}(\varepsilon\eta/n\kappa(A))$ , then there is an algorithm that outputs a  $d \times k$  matrix  $V_k$  such that  $\kappa(V_k) \leq 4$  and with probability  $\geq 1 - \eta$ , for all  $p \in [2, \infty]$ ,*

$$\|A(I - \text{Proj}_{\text{colspace}(V_k)})\|_{S_p} \leq (1 + O(\varepsilon))\|A - A_k\|_{S_p},$$

and runs in time  $O(\frac{\text{nnz}(A)k}{\sqrt{\varepsilon}} \text{poly}(\log(d\kappa(A)/\varepsilon\eta)) + d \text{poly}(k, \log(dk/\eta\varepsilon)))$ .

In the above theorem,  $\text{Proj}_{\text{colspace}(M)}$  denotes the orthogonal projection matrix onto the column space of  $M$ .

## 1.2 Implications to Practice

While the theoretical fast rectangular matrix multiplication algorithms are not practically efficient, the message of this paper is that by optimizing for the number of matrix-vector products as in [2], we are leaving a lot of performance on the table. In modern computing architectures, multiplying an  $n \times n$  and an  $n \times b$  matrix is, for example, much faster than  $b$  times the time required to multiply the  $n \times n$  and an  $n \times 1$  vector because of data locality and the opportunities for parallelization. Thus, in the algorithm of [2], running the block size  $k$  version for fewer iterations while increasing the larger block size  $b$  can give faster algorithms in practice than using the parameters that optimize for the number of matrix-vector products. We include a small experiment in the appendix which compares the time required to compute the product of an  $n \times n$  matrix with matrices that have different numbers of columns.

LazySVD with our stability analysis uses a similar number of matrix vector products as the widely used Block Krylov iteration algorithm while requiring only polylogarithmic bits of precision. While as mentioned above, block-based algorithms such as Block Krylov iteration can be much faster than single-vector algorithms such as LazySVD and our modification of it, it is only the case when the matrix is directly given to us. When the matrix is implicitly defined in other ways (for e.g., as the Hessian of a neural network where we can efficiently compute Jacobian-Vector products), the difference in performance between block-based algorithms and single-vector algorithms is less pronounced. When guarantees of stability are required, the fastest algorithms in practice for Low Rank Approximation should use some combination of sketching as in [9] to reduce dimension stably and then use our modification of LazySVD algorithm to find the necessary top  $k$  subspace.

## 2 Preliminaries

### 2.1 Notation

For a positive integer  $n$ , we use  $[n]$  to denote the set  $\{1, \dots, n\}$ . We use the notation  $\tilde{O}(f(n))$  to denote  $O(f(n) \text{poly}(\log(f(n))))$  and  $\tilde{O}_q(f(n))$  to hide the multiplicative factors that depend only on the parameter  $q$ . For a vector  $x$ , we use  $\|x\|_2 = (\sum_i |x_i|^2)^{1/2}$  to denote the Euclidean norm of  $x$ . Given an  $m \times n$  matrix  $A$ , we use  $A_{i,j}$  to denote the entry in the index  $(i, j)$  of  $A$ . We use  $A_{i*}$  to denote the  $i$ -th row of  $A$  and  $A_{*j}$  to denote the  $j$ -th column. We identify the multiplication of an  $m \times n$  matrix with an  $n \times k$  matrix with the notation  $[m, n, k]$ . For a matrix  $A$ , we use  $\text{colspace}(A)$  to denote the vector space  $\{Ax \mid x \in \mathbb{R}^n\}$ . For

any vector space  $V \in \mathbb{R}^n$ , we use  $\text{Proj}_V$  to denote the linear operator which maps a vector  $x$  to the projection of  $x$  in the subspace  $V$  i.e., the nearest vector to  $x$  in  $V$  in terms of Euclidean distance. If the columns of  $X$  are an orthonormal basis for  $V$ , then  $\text{Proj}_V = XX^\top$ .

Let  $A = U\Sigma V^\top$  be the singular value decomposition (SVD) of  $A$  and let  $\sigma_1 \geq \dots \geq \sigma_n$  (recall  $m \geq n$ ) denote the singular values of  $A$ . For  $k \leq n$ , let  $A_k := \sum_{i=1}^k \sigma_i U_{*i} (V^\top)_{i*}$  be the matrix obtained by truncating the SVD of  $A$  to the top  $k$  singular values.

We use  $\|A\|_F$  to denote the Frobenius norm  $(\sum_{i,j} A_{i,j}^2)^{1/2}$  and  $\|A\|_2$  to denote the operator norm  $\max_{x \neq 0} \|Ax\|_2 / \|x\|_2$ . For  $p \geq 1$ , we define  $\|A\|_{S_p} = (\sum_{i=1}^n \sigma_i^p)^{1/p}$  to be the Schatten- $p$  norm. As  $\|\cdot\|_{S_p}$  defines a norm, we have  $\|A+B\|_{S_p} \leq \|A\|_{S_p} + \|B\|_{S_p}$  for any two  $m \times n$  matrices  $A$  and  $B$ . Additionally, we have  $\|A^\top\|_{S_p} = \|A\|_{S_p}$  and for any unitary matrices  $U', V'$ , we have  $\|U'AV'\|_{S_p} = \|A\|_{S_p}$ .

## 2.2 Fast Rectangular Matrix Multiplication

Let  $\omega$  denote the best matrix multiplication exponent. The current upper bound on  $\omega$  is  $\approx 2.371$  [5] and for  $\gamma < 1$ , let  $\omega(\gamma)$  denote the exponent such that the product of an  $n \times n$  with an  $n \times n^\gamma$  matrix can be computed using  $O(n^{\omega(\gamma)+n})$  arithmetic operations for any constant  $\eta > 0$ . There exists  $\alpha > 0.31$  [8, 6] such that for all  $\gamma < \alpha$ ,  $\omega(\gamma) = 2$  and for all  $\gamma \geq \alpha$ ,

$$\omega(\gamma) \leq 2 + (\omega - 2) \frac{\gamma - \alpha}{1 - \alpha}.$$

See [7, 10] for the above bound on  $\omega(\gamma)$ . Recall  $\beta := \frac{\omega-2}{1-\alpha}$ . We now observe that  $n^{1-\alpha}n^2 \geq n^\omega$  since a matrix product of the form  $[n, n, n]$  can be computed using  $n^{1-\alpha}$  matrix products of the form  $[n, n, n^\alpha]$ . Hence,  $1 - \alpha \geq \omega - 2$ , which implies  $\beta \leq 1$ .

## 3 Schatten- $p$ LRA using Fast Matrix Multiplication

■ **Algorithm 1** Block Krylov Iteration Algorithm [11].

---

**Input:** An  $n \times n$  matrix  $A$ , rank parameter  $k$ , block size  $b$  and number  $q$  of iterations

**Output:** An orthonormal matrix  $Z \in \mathbb{R}^{n \times k}$

- 1  $\Pi \sim \mathcal{N}(0, 1)^{n \times b}$
  - 2  $K \leftarrow [A\Pi \quad (AA^\top)A\Pi \quad \dots \quad (AA^\top)^q A\Pi]$  // The Krylov Matrix
  - 3 Orthonormalize columns of  $K$  to get an  $n \times qb$  matrix  $Q$
  - 4 Compute  $M := Q^\top AA^\top Q$
  - 5 Set  $\bar{U}_k$  to the top  $k$  singular vectors of  $M$
  - 6 **return**  $Z = Q\bar{U}_k$
- 

### 3.1 Block Krylov Iteration Algorithm

The block Krylov Iteration algorithm of Musco and Musco [11] is stated as Algorithm 1. For any  $b$ , let  $T(n, b)$  be the time to multiply an  $n \times n$  matrix with an  $n \times b$  matrix. The Block Krylov iteration algorithm with rank parameter  $k$ , block size  $b \geq k$  and iteration count  $q$  (with  $bq \leq n$ ) runs in time at most  $(2q+1)T(n, b) + n(qb)^{\omega-1} + 3T(n, qb) + (qb)^\omega + T(n, k)$ .<sup>3</sup>

---

<sup>3</sup> Assuming that SVD of the  $qb \times qb$  matrix  $M$  in Algorithm 1 can be computed in time  $O((qb)^\omega)$ .

Using the fact that  $T(n, qb) \leq qT(n, b)$  and  $qb \leq n$ , we obtain that the time complexity of the algorithm is  $O(qT(n, b) + n(qb)^{\omega-1})$ . We now have  $T(n, b) \geq (b/n)n^\omega$  since otherwise the matrix product of the form  $[n, n, n]$  can be computed quicker than in  $n^\omega$  time by computing the  $n/b$  products of the form  $[n, n, b]$ . Hence,  $qT(n, b) \geq qbn^{\omega-1} \geq n(qb)^{\omega-1}$  using  $qb \leq n$ . Thus, we obtain that the time complexity of the Block Krylov Iteration algorithm with parameters  $k, b, q$  satisfying  $b \geq k$  and  $bq \leq n$  is  $O(qT(n, b))$ . We now state a few properties of the Block Krylov algorithm that we use throughout the paper.

► **Theorem 4.** *With a large probability over the Gaussian matrix  $\Pi$ , the following properties hold for the matrix  $Z$  computed by Algorithm 1:*

1. *There is a universal constant  $c$  such that for all  $i \in [k]$ ,*

$$\sigma_i(Z^\top A)^2 \geq \|A^\top(Z)_{*i}\|_2^2 \geq \sigma_i^2 - (c \log^2 n/q^2)\sigma_{k+1}^2.$$

*This follows from the per-vector error guarantee of Theorem 1 in [11].*

2. *If  $\text{gap} := (\sigma_k/\sigma_{b+1}) - 1$  and  $q \geq C \log(n/\varepsilon)/\sqrt{\min(1, \text{gap})}$  for a large enough constant  $C$ , then for all  $i \in [k]$ ,  $\sigma_i(Z^\top A)^2 \geq \|A^\top(Z)_{*i}\|_2^2 \geq \sigma_i^2 - \varepsilon\sigma_{k+1}^2$ .*

The second guarantee in the above theorem follows from the gap-dependent error bounds in Theorem 11 in [11]. Note the logarithmic dependence of  $q$  on  $1/\varepsilon$ .

■ **Algorithm 2** Schatten- $p$  Norm Subspace Approximation.

---

**Input:** An  $n \times n$  matrix  $A$ , rank parameter  $k$  and an accuracy parameter  $\varepsilon$

**Output:** Approximate Solution to the Schatten- $p$  Norm Subspace Approximation problem

$$1 \quad q \leftarrow \begin{cases} \sqrt{p} & k \leq \varepsilon \cdot n^\alpha \\ \max(\sqrt{p}, p^{\frac{1}{2(1+2\beta)}} (k/n^\alpha \varepsilon)^{\frac{\beta}{1+2\beta}}) & \varepsilon \cdot n^\alpha \leq k \leq n^\alpha \\ \max(\sqrt{p}, p^{\frac{1}{2(1+2\beta)}} / \varepsilon^{\frac{\beta}{1+2\beta}}) & k \geq n^\alpha \end{cases}$$

$$2 \quad b' \leftarrow \lceil (3/2) \max(1, k/q^2 \varepsilon) \rceil$$

$$3 \quad Z_1 \leftarrow \text{BLOCKKRYLOV}(A, \text{rank} = k, \text{block size} = k, \text{iterations} = O(q \log(n)))$$

$$4 \quad Z_2 \leftarrow \text{BLOCKKRYLOV}(A, \text{rank} = k, \text{block size} = b' + k, \text{iterations} = O(\sqrt{p} \log(n/\varepsilon)))$$

$$5 \quad W_1 \leftarrow \text{colspan}(A^\top Z_1)$$

$$6 \quad W_2 \leftarrow \text{colspan}(A^\top Z_2)$$

$$7 \quad W \leftarrow W_2 \text{ if } \hat{\sigma}_k \geq (1 + 1/2p)\hat{\sigma}_{b'+k} \text{ and } W_1 \text{ otherwise // These approximations to } \sigma_k \text{ and } \sigma_{b'+k} \text{ can be computed using the } M \text{ matrix computed in}$$

Algorithm 1

---

### 3.2 Main Theorem

► **Theorem 5.** *Given an  $n \times n$  matrix  $A$ , a rank parameter  $k$  and an accuracy parameter  $\varepsilon$ , Algorithm 2 outputs a  $k$  dimensional orthonormal matrix  $W$  that with probability  $\geq 0.9$  satisfies,  $\|A(I - WW^\top)\|_{S_p} \leq (1 + O(\varepsilon))\|A - A_k\|_{S_p}$ . For any constant  $\eta > 0$ , the running time of the algorithm is as follows:*

1. *For  $k \leq \varepsilon n^\alpha$ , the algorithm runs in time  $\tilde{O}(\sqrt{p}n^{2+\eta})$ .*

2. *For  $\varepsilon n^\alpha \leq k \leq n^\alpha$ , the algorithm runs in time  $\tilde{O}(\max(\sqrt{p}n^{2+\eta}, p^{\frac{1}{2(1+2\beta)}} n^{2+\eta} (k/n^\alpha \varepsilon)^{\beta/(1+2\beta)}))$ .*

3. *For  $k \geq n^\alpha$ , the algorithm runs in time  $\tilde{O}((p^{1/2} \varepsilon^{-\beta})^{1/(1+2\beta)} n^{2+\eta-\alpha\beta} k^\beta)$ .*

Assuming  $p$  is a constant independent of  $\varepsilon$ , the dependence on  $\varepsilon$  is at least better than  $\varepsilon^{-1/3}$  as  $\beta \leq 1$  which implies  $\beta/(1+2\beta) \leq 1/3$ . The proof of this theorem is similar to that of [2].

We include the proof in the full version.

#### 4 Comparison with the Algorithm of Li and Woodruff [9]

For  $n \times n$  matrices and  $p > 2$ , the algorithm of [9] for the Schatten- $p$  norm Subspace Approximation problem, shown in Algorithm 3 runs in time

$$O(n^2 \log n) + \tilde{O}_p \left( \frac{n^{\omega(1-2/p)} k^{2\omega/p}}{\varepsilon^{2\omega/p+2}} + n^{1+(\omega-1)(1-2/p)} (k/\varepsilon)^{2(\omega-1)/p} \right). \quad (1)$$

Let  $K = k + \varepsilon/\eta_1 = k + n^{1-2/p} k^{2/p} / \varepsilon^{2/p}$ . To obtain the above running time, they use a ridge leverage score sampling algorithm to compute a matrix  $S$  with  $s = O(\varepsilon^{-2} K \log n)$  rows that satisfies (2) with a large probability. The same guarantee can instead be obtained by using the Sub-sampled Randomized Hadamard Transform (SRHT) [16] with  $s = O(\varepsilon^{-2} K \log n)$  rows and the matrix-product  $SA$  can be computed in time  $O(n^2 \log n)$ . To obtain the subspace embedding guarantee for  $T$  as required in Algorithm 3, we can let the matrix  $T$  again be an SRHT with  $r = O(\varepsilon^{-2} s \log n)$  columns and the product  $SAT$  can be computed in time  $O(ns \log s) = O(\varepsilon^{-2} n(k + n^{1-2/p} k^{2/p} / \varepsilon^{2/p}))$ .

The singular value decomposition of the matrix  $SAT$  can be computed in  $O(rs^{\omega-1}) = O(\varepsilon^{-2\omega} (k + n^{1-2/p} k^{2/p} / \varepsilon^{2/p})^\omega \text{polylog}(n))$  time and a basis for the rowspace of  $W^\top SA$  can be computed in  $O(skn)$  time. Overall, for constant  $k$  and  $\varepsilon$ , the algorithm of [9] runs in time  $\tilde{O}(n^2 + (n^{1-2/p})^\omega)$ . For  $p > 2\omega/(\omega - 2)$ , their algorithm runs in  $n^{2+c_p}$  time for a constant  $c_p > 0$  that depends on  $p$ . For the same parameters, our algorithm runs in  $\tilde{O}(n^2)$  time and hence we have an improvement. For  $k \leq n^\alpha$  and  $\varepsilon = 1/n$ , their algorithm runs in time  $\Omega(n^\omega)$  which means that computing the SVD of  $A$  is already faster whereas our algorithm runs in time  $\tilde{O}(n^{2+\frac{(1-\alpha)\beta}{1+2\beta}}) = o(n^\omega)$  if  $\omega > 2$ . Hence, our algorithm improves upon the algorithm of [9] for a wide range of parameters. We note that computing the SVD of  $SAT$  turns out to be the most expensive step for large  $p$ . In the next subsection, we show that our Algorithm 2 can be used to sidestep the computation of the SVD of  $SAT$ , thereby giving an even faster algorithm.

We call  $p^* = 2\omega/(\omega - 2)$ , the *crossover* point. For  $p > p^*$ , our Algorithm 2 is faster than the algorithm of [9]. For the current value of  $\omega \approx 2.37$ ,  $p^* \approx 12.8$ . For  $p < p^*$ , the leading order term in the time complexity of Algorithm 3 is  $O(n^2 \log n)$  for  $\varepsilon > n^{-c_p}$  for a constant  $c_p$  depending on  $p$ , and hence is faster than Algorithm 2.

■ **Algorithm 3** Schatten- $p$  Norm Low Rank Approximation for  $p > 2$  [9].

---

**Input:** A matrix  $A \in \mathbb{R}^{m \times n}$  and an accuracy parameter  $\varepsilon$

**Output:** A rank- $k$  orthonormal projection  $Q$  satisfying

$$\|A(I - Q)\|_{S_p} \leq (1 + \varepsilon) \|A - A_k\|_{S_p}$$

1  $\eta_1 \leftarrow O(\varepsilon^{1+2/p} / k^{2/p} n^{1-2/p})$

2  $S$  be a matrix with  $s$  rows that satisfies

$$(1 - \varepsilon) A^\top A - \eta_1 \|A - A_k\|_F^2 \cdot I \preceq A^\top S^\top SA \preceq (1 + \varepsilon) A^\top A + \eta_1 \|A - A_k\|_F^2 \cdot I. \quad (2)$$

3  $T \leftarrow$  Subspace embedding for  $s$ -dimensional subspaces with error  $O(\varepsilon)$

4  $W \leftarrow$  Top  $k$  left singular vectors of  $SAT$

5  $Z \leftarrow$  Matrix whose columns are an orthonormal basis for the row space of  $W^\top SA$

6  $Q \leftarrow ZZ^\top$

---

#### 4.1 Further Improving the running time of [9] using our algorithm

Given an  $n \times n$  matrix  $A$ ,  $p \geq 1$  and  $r \leq n$ , let  $\|A\|_{(p,r)} = (\sum_{i=1}^r \sigma_i(A)^p)^{1/p}$ . We can show that  $\|\cdot\|_{(p,r)}$  is a norm over  $n \times n$  matrices. As  $\|\cdot\|_{(p,r)}$  is unitarily invariant, we have by Eckart-Young-Mirsky's theorem that  $\|A - A_k\|_{(p,r)} = \min_{\text{rank-}k B} \|A - B\|_{(p,r)}$ . In Lemma 4.2 of [9], they show that for  $S$  satisfying (2), if  $\hat{Q}$  is a rank- $k$  projection matrix with

$$\|SA(I - \hat{Q})\|_{(p,r)} \leq (1 + \varepsilon) \min_{\substack{\text{rank-}k \\ \text{projections } Q}} \|SA(I - Q)\|_{(p,r)}, \quad (3)$$

then  $\|A(I - \hat{Q})\|_{S_p}^p \leq (1 + C_p \varepsilon) \|A - A_k\|_{S_p}^p$ , for a constant  $C_p$  that only depends on  $p$ . They show that the matrix  $Q$  returned by Algorithm 3 satisfies (3) and then conclude that the matrix  $Q$  is a  $1 + O(\varepsilon)$  approximation to the Schatten- $p$  norm low rank approximation problem. We will now argue that there is a faster algorithm for computing a projection that satisfies (3). The algorithm does not require the computation of the SVD of the matrix  $SA$  and hence does not incur the  $O_{p,k,\varepsilon}(n^{(1-2/p)\omega})$  term in the running time. We first show that a  $1 + \varepsilon$  approximate solution to the Schatten- $p$  norm subspace approximation problem, is a  $1 + \varepsilon n/r$  approximation to the  $(p, r)$  subspace approximation problem.

► **Lemma 6.** *For an arbitrary  $m \times n$  matrix  $A$  ( $m \leq n$ ), if  $\hat{Q}$  is a rank- $k$  projection matrix satisfying  $\|A(I - \hat{Q})\|_{S_p}^p \leq (1 + \varepsilon) \|A - A_k\|_{S_p}^p$  and  $\text{colspan}(\hat{Q}) \subseteq \text{rowspan}(A)$ , then for any  $r \leq n$ ,*

$$\|A(I - \hat{Q})\|_{(p,r)}^p \leq (1 + \varepsilon \lceil (m - k)/r \rceil) \|A - A_k\|_{(p,r)}^p.$$

**Proof.** Let  $\hat{Q}$  be a rank- $k$  projection such that

$$\|A(I - \hat{Q})\|_{S_p}^p \leq (1 + \varepsilon) \min_{\text{rank-}k \text{ projections } Q} \|A(I - Q)\|_{S_p}^p = (1 + \varepsilon) \sum_{i=k+1}^n \sigma_i(A)^p.$$

Note that  $\|A(I - \hat{Q})\|_{S_p}^p = \sum_{i=1}^{m-k} \sigma_i(A(I - \hat{Q}))^p$  since the matrix  $A(I - \hat{Q})$  has rank at most  $m - k$  from our assumption that  $\text{colspan}(\hat{Q}) \subseteq \text{rowspan}(A)$ . Now,  $\|A(I - \hat{Q})\|_{(p,r)}^p = \sum_{i=1}^r \sigma_i(A(I - \hat{Q}))^p$  and therefore,

$$\begin{aligned} \|A(I - \hat{Q})\|_{(p,r)}^p &= \|A(I - \hat{Q})\|_{S_p}^p - \sum_{i=r+1}^{m-k} \sigma_i(A(I - \hat{Q}))^p \\ &\leq (1 + \varepsilon) \sum_{i=k+1}^m \sigma_i(A)^p - \sum_{i=r+1}^{m-k} \sigma_i(A(I - \hat{Q}))^p. \end{aligned}$$

Since the matrix  $A\hat{Q}$  has rank at most  $k$ , by Weyl's inequality,  $\sigma_i(A(I - \hat{Q})) \geq \sigma_{i+k}(A)$  which implies

$$\begin{aligned} \|A(I - \hat{Q})\|_{(p,r)}^p &\leq \sum_{i=k+1}^{k+r} \sigma_i(A)^p + \varepsilon \|A - A_k\|_{S_p}^p + \left( \sum_{i=k+r+1}^m \sigma_i(A)^p - \sum_{i=r+1}^{m-k} \sigma_i(A(I - \hat{Q}))^p \right) \\ &\leq \min_{\text{rank-}k \text{ projections } Q} \|A(I - Q)\|_{(p,r)}^p + \varepsilon \|A - A_k\|_{S_p}^p. \end{aligned}$$

Finally, using the fact that  $\|A - A_k\|_{S_p}^p \leq \lceil (m - k)/r \rceil \|A - A_k\|_{(p,r)}^p$ , we obtain

$$\|A(I - \hat{Q})\|_{(p,r)}^p \leq (1 + \varepsilon \lceil (m - k)/r \rceil) \|A - A_k\|_{(p,r)}^p. \quad \blacktriangleleft$$

Finally, we have the following lemma which shows how to find an approximate solution to the  $(p, r)$  Low Rank Approximation problem.

► **Lemma 7.** *Let  $A \in \mathbb{R}^{m \times n}$  be an arbitrary matrix with  $m \leq n$ . Given parameters  $k, p, r$  and  $\varepsilon$ , there is a randomized algorithm to find a rank- $k$  projection  $\hat{Q}$ , that with probability  $\geq 9/10$  satisfies,*

$$\|A(I - \hat{Q})\|_{(p,r)}^p \leq (1 + \varepsilon) \|A - A_k\|_{(p,r)}^p.$$

For constant  $p$  and  $k \leq m^\alpha$  and any constant  $\eta > 0$ , the randomized algorithm runs in time  $\tilde{O}(m^{2+\eta+(1-\alpha)\beta/(1+2\beta)} k^{\beta/(1+2\beta)} \text{poly}(1/\varepsilon) + nm + nk^{\omega-1})$  and for  $k \geq m^\alpha$ , the algorithm runs in  $\tilde{O}(m^{2+\eta-\alpha\beta+\frac{\beta}{1+2\beta}} k^{\beta} \text{poly}(1/\varepsilon) + nm^{1-\alpha\beta} k^{\beta} + nk^{\omega-1})$  time.

**Proof.** First we note that

$$\min_{\text{rank-}k \text{ projections } Q} \|A(I - Q)\|_{(p,r)}^p = \min_{\text{rank-}k \text{ projections } W} \|(I - W)A\|_{(p,r)}^p = \|A - A_k\|_{(p,r)}^p.$$

Let  $T$  be an SRHT matrix with  $O(\varepsilon^{-2} m \text{polylog}(n))$  rows. With a large probability,  $T$  is an  $\varepsilon$  subspace embedding for the rowspace of matrix  $A$ . Then

$$(1 - \varepsilon)AA^\top \preceq ATT^\top A^\top \preceq (1 + \varepsilon)AA^\top$$

and further for all rank- $k$  projections  $W$ ,

$$(1 - \varepsilon)(I - W)AA^\top(I - W) \preceq (I - W)ATT^\top A^\top(I - W) \preceq (1 + \varepsilon)(I - W)AA^\top(I - W).$$

We then have for all  $i$  that  $\sigma_i((I - W)AT) = (\sqrt{1 \pm \varepsilon})\sigma_i((I - W)A)$ . Therefore,  $\|(I - W)AT\|_{(p,r)}^p = (1 \pm \varepsilon)^{p/2} \|(I - W)A\|_{(p,r)}^p$  for all rank- $k$  projections  $W$ . Let Algorithm 2 be run on the matrix  $T^\top A^\top$  with rank parameter  $k$  and approximation parameter  $\varepsilon/pm$ . By Theorem 5, we obtain a rank- $k$  projection  $\widehat{W}$  satisfying

$$\|T^\top A^\top(I - \widehat{W})\|_p \leq (1 + \varepsilon/pm) \min_{\text{rank-}k \text{ projections } W} \|T^\top A^\top(I - W)\|_p$$

Using, Lemma 6, we obtain that

$$\|T^\top A^\top(I - \widehat{W})\|_{(p,r)}^p \leq (1 + \varepsilon) \min_{\text{rank-}k \text{ projections } W} \|T^\top A^\top(I - W)\|_{(p,r)}^p.$$

By using the relation between  $\|(I - W)AT\|_{(p,r)}^p$  and  $\|(I - W)A\|_{(p,r)}^p$  for all projections  $W$ , we get

$$\begin{aligned} \|A^\top(I - \widehat{W})\|_{(p,r)}^p &\leq \frac{(1 + \varepsilon)^{p/2+1}}{(1 - \varepsilon)^{p/2}} \min_{\text{rank-}k \text{ projections } W} \|A^\top(I - W)\|_{(p,r)}^p \\ &\leq (1 + O(\varepsilon p)) \|A - A_k\|_{(p,r)}^p. \end{aligned}$$

Now,  $\|A - A(\widehat{W}A)^\dagger(\widehat{W}A)\|_{(p,r)}^p \leq \|A - \widehat{W}A\|_{(p,r)}^p = \|(I - \widehat{W})A\|_{(p,r)}^p \leq (1 + O(\varepsilon p)) \|A - A_k\|_{(p,r)}^p$ . Scaling  $\varepsilon$ , we obtain the result.

**Runtime Analysis.** The matrix  $AT$  can be computed in time  $O(mn \log n)$ . For constant  $p$ , Algorithm 2 runs on the matrix  $T^\top A$  in time  $\tilde{O}(m^{2+\eta+(1-\alpha)\beta/(1+2\beta)} k^{\beta/(1+2\beta)} \text{poly}(1/\varepsilon))$  for  $k \leq m^\alpha$  and in time  $\tilde{O}(m^{2+\eta-\alpha\beta+\frac{\beta}{1+2\beta}} k^{\beta} \text{poly}(1/\varepsilon))$  for  $k \geq m^\alpha$ . Finally, the rowspace of  $\widehat{W}^\top A$  can be computed in time  $O(nm + nk^{\omega-1})$  for  $k \leq m^\alpha$  and  $O(nm^{1-\alpha\beta} k^{\beta} + nk^{\omega-1})$  for  $k \geq m^\alpha$ . ◀

Using the above lemma, we can find a rank- $k$  projection  $\hat{Q}$  that satisfies

$$\|SA(I - \hat{Q})\|_{(p,r)}^p \leq (1 + \varepsilon)\|A - A_k\|_{(p,r)}^p$$

in time  $\tilde{O}((n^{1-2/p})^{2+\eta+(1-\alpha)\beta/(1+2\beta)} \text{poly}(1/\varepsilon) + n^2)$  for constant  $k$  improving on the  $\tilde{O}(n^2 + (n^{1-2/p})^\omega \text{poly}(1/\varepsilon))$  running time of [9] for the current value of  $\omega$  since  $2 + \frac{(1-\alpha)\beta}{1+2\beta} = 2 + \frac{\omega-2}{1+2\beta} < \omega$  if  $\beta \neq 0$ . We thus have the following theorem.

► **Theorem 8.** *Given a dense  $n \times n$  matrix  $A$ , a constant rank parameter  $k$  and any constant  $\eta > 0$ , there is a randomized algorithm that runs in time  $\tilde{O}((n^{1-2/p})^{2+\eta+(1-\alpha)\beta/(1+2\beta)} \text{poly}(1/\varepsilon) + n^2)$  and outputs a rank- $k$  projection  $\hat{Q}$  that, with probability  $\geq 9/10$ , satisfies  $\|A(I - \hat{Q})\|_{S_p}^p \leq (1 + \varepsilon)\|A - A_k\|_{S_p}^p$ .*

For this algorithm, the crossover point is  $\tilde{p} = \frac{4(1+2\beta)}{\omega-2} + 2$  i.e., only when  $p > \tilde{p}$ , Algorithm 2 is faster than the algorithm in the above theorem for constant  $k$  and  $\varepsilon$ . For current values of  $\omega, \alpha$ , we have  $\tilde{p} \approx 22$ . In particular, for constant  $k$  and  $\varepsilon > n^{-c_p}$ , for  $p \lesssim 22$ , the algorithm has a time complexity of only  $\tilde{O}(n^2)$ .

## 5 Stability of LazySVD

### 5.1 Finite Precision Preliminaries

Following the presentation of [12], we say that a floating point machine has precision  $\varepsilon_{\text{mach}}$  if it can perform computations to relative error  $\varepsilon_{\text{mach}}$ . More formally, let  $\text{fl}(x \circ y)$  be the result of the computation  $x \circ y$  on the floating point machine where  $\circ \in \{+, -, \times, \div\}$ . We say that the floating point machine has a precision  $\varepsilon_{\text{mach}}$  if for all  $x$  and  $y$ ,  $\text{fl}(x \circ y) = (1 + \delta)(x \circ y)$  where  $|\delta| \leq \varepsilon_{\text{mach}}$ . Additionally, we also require  $\text{fl}(\sqrt{x}) = (1 + \delta)\sqrt{x}$  for some  $\delta$  with  $|\delta| \leq \varepsilon_{\text{mach}}$ . Ignoring overflow or underflow, a machine which implements the IEEE floating point standard with  $\geq \log_2(1/\varepsilon_{\text{mach}})$  bits of precision satisfies the above requirements (see [12, Section 5]). Given matrices  $A$  and  $B$  with at most  $n$  rows and columns, we can compute a matrix  $C$ , on a floating point machine, that satisfies  $\|C - A \cdot B\|_2 \leq \varepsilon_{\text{mach}} \text{poly}(n)\|A\|_2\|B\|_2$  by directly computing  $C_{ij}$  as  $\text{fl}(\sum_k A_{ik}B_{kj})$ .

### 5.2 Stability Analysis

■ **Algorithm 4** LazySVD [1].

---

**Input:** A positive semidefinite matrix  $M \in \mathbb{R}^{d \times d}$ ,  $k \leq d, \varepsilon, \varepsilon_{\text{pca}}, \eta$   
**Output:** Vectors  $v_1, \dots, v_k$

- 1  $M_0 \leftarrow M$  and  $V_0 \leftarrow []$
- 2 **for**  $s = 1, \dots, k$  **do**
- 3      $v'_s \leftarrow \text{AppxPCA}_{\varepsilon/2, \varepsilon_{\text{pca}}, \eta/k}(M_{s-1})$
- 4      $v_s \leftarrow (I - V_{s-1}V_{s-1}^\top)v'_s / \|(I - V_{s-1}V_{s-1}^\top)v'_s\|_2$
- 5      $V_s \leftarrow [V_{s-1} \ v_s]$
- 6      $M_s \leftarrow (I - V_sV_s^\top)M(I - V_sV_s^\top)$  // The matrix  $M_s$  is not computed as we only need matrix vector products with  $M_s$
- 7 **return**  $V_k$

---

The LazySVD algorithm (Algorithm 4) of [1] crucially requires a routine called **AppxPCA** that computes an approximation to the top eigen vector of the given positive semidefinite matrix. While they use a particular **AppxPCA** algorithm in their results, any routine that satisfies the following definition can be plugged into the LazySVD algorithm.

► **Definition 9** (AppxPCA). We say that an algorithm is **AppxPCA** with parameters  $\varepsilon, \varepsilon_{\text{pca}}$  and  $\eta$  if given a positive semidefinite matrix  $M \in \mathbb{R}^{d \times d}$  with an orthonormal set of eigenvectors  $u_1, \dots, u_d$  corresponding to eigenvalues  $\lambda_1 \geq \dots \geq \lambda_d \geq 0$ , the algorithm outputs a unit vector  $w$  such that with probability  $\geq 1 - \eta$ ,  $\sum_{i \in [d]: \lambda_i \leq (1-\varepsilon)\lambda_1} \langle w, u_i \rangle^2 \leq \varepsilon_{\text{pca}}$ .

We now show that Lanczos algorithm can be used to stably compute a vector that satisfies the AppxPCA guarantee.

► **Lemma 10.** *If for any vector  $x$ , we can compute a vector  $y$  such that*

$$\|y - M_s x\|_2 \leq O(\varepsilon_{\text{mach}} \text{poly}(n)\kappa) \|M_s\|_2 \|x\|_2$$

and if  $\varepsilon_{\text{mach}} \leq \text{poly}(\varepsilon_{\text{pca}}\eta/n\kappa)$ , then we can compute a unit vector  $v$  such that with probability  $\geq 1 - \eta$ ,  $\sum_{i: \lambda_i(M_s) \leq (1-\varepsilon)\lambda_1(M_s)} \langle v, u_i(M_s) \rangle^2 \leq \varepsilon$ . The algorithm uses  $O(\frac{1}{\sqrt{\varepsilon}} \text{poly}(\log(d/\varepsilon\eta\varepsilon_{\text{pca}})))$  matrix vector products with  $M_s$ .

**Proof.** Let  $\mathbf{z}$  be a  $d$  dimensional random vector with each coordinate being an independent Gaussian random variable. Let  $M_s = \sum_i \lambda_i u_i u_i^\top$  be the eigendecomposition. Let  $r$  be the largest index such that  $\lambda_r \geq (1 - \varepsilon)\lambda_1$ . Consider the vector  $M_s^q \mathbf{z}$  for a  $q$  we choose later. We have

$$\mathbf{y} = M_s^q \mathbf{z} = \sum_{i=1}^d \lambda_i^q \langle u_i, \mathbf{z} \rangle u_i.$$

Consider  $\langle u_1, \mathbf{z} \rangle$ . By 2-stability of Gaussian random variables,  $\langle u_1, \mathbf{z} \rangle \sim N(0, \|u_1\|_2^2) = N(0, 1)$ . Hence with probability  $1 - \eta$ ,  $|\langle u_1, \mathbf{z} \rangle| \geq \eta$ . We also have that with probability  $\geq 1 - \eta$ , for all  $i = 1, \dots, d$   $|\langle u_i, \mathbf{z} \rangle| \leq O(\sqrt{\log d/\eta})$ . Condition on these events. Now,  $\|\mathbf{y}\|_2^2 = \sum_{i=1}^d \lambda_i^{2q} \langle u_i, \mathbf{z} \rangle^2 \geq \lambda_1^{2q} \langle u_1, \mathbf{z} \rangle^2 \geq \lambda_1^{2q} \eta^2$ . Define  $\hat{\mathbf{y}} = \mathbf{y}/\|\mathbf{y}\|_2$ . Let  $i > r$  so that  $\lambda_i < (1 - \varepsilon)\lambda_1$  by definition of  $r$ . We have

$$|\langle u_i, \hat{\mathbf{y}} \rangle| = \frac{|\langle u_i, \mathbf{y} \rangle|}{\|\mathbf{y}\|_2} \leq \frac{\lambda_i^q |\langle u_i, \mathbf{z} \rangle|}{\lambda_1^q \eta} \leq \frac{\lambda_i^q \sqrt{\log d/\eta}}{\lambda_1^q \eta} \leq (1 - \varepsilon)^q \frac{C \sqrt{\log d/\eta}}{\eta}.$$

If  $q \geq C\varepsilon^{-1} \log(d/\varepsilon_{\text{pca}}\eta)$  for a large enough constant  $C$ , we get  $|\langle u_i, \hat{\mathbf{y}} \rangle| \leq \text{poly}(\varepsilon_{\text{pca}}/d)$ . Thus,  $\sum_{i=r+1}^d |\langle u_i, \hat{\mathbf{y}} \rangle|^2 \leq \text{poly}(\varepsilon_{\text{pca}})$ .

Now define  $f(x) = x^q$  so that  $f(M_s)\mathbf{z} = \mathbf{y}$  and define  $\rho = \lambda_1/q$ . From [13, Chapter 3] there is a polynomial  $p(x)$  of degree  $\sqrt{2q \log 1/\gamma}$  such that for all  $x \in [-\rho, \lambda_1 + \rho]$ ,

$$|p(x) - x^q| \leq e\gamma\lambda_1^q.$$

As we can compute matrix-vector products with  $M_s$  up to an additive error of  $O(\varepsilon_{\text{mach}} \text{poly}(n)\kappa)$ , using Theorem 1 of [12] as long as  $\varepsilon_{\text{mach}} \leq \varepsilon'\rho/(\text{poly}(n)\kappa\|M_s\|_2) \leq \varepsilon'/\text{poly}(n)\kappa$ , we can compute a vector  $\mathbf{y}'$  on a floating point machine, using  $\sqrt{2q \log 1/\gamma}$  iterations such that

$$\begin{aligned} \|\mathbf{y} - \mathbf{y}'\|_2 &= \|(M_s)^q \mathbf{z} - \mathbf{y}'\|_2 \leq ((7e\gamma\sqrt{2q \log 1/\gamma})\lambda_1^q + \varepsilon'\lambda_1^q) \|\mathbf{z}\|_2 \\ &\leq O(\gamma\sqrt{2q \log 1/\gamma} + \varepsilon')\lambda_1^q \sqrt{d}. \end{aligned}$$

where we used that  $\|\mathbf{z}\|_2 \leq O(\sqrt{d})$  with high probability. As  $\|\mathbf{y}\|_2 \geq \lambda_1^q \eta$ , we further obtain that

$$\|\mathbf{y} - \mathbf{y}'\|_2 \leq O(\gamma\sqrt{2q \log 1/\gamma} + \varepsilon')\sqrt{d}\|\mathbf{y}\|_2/\eta.$$

## 55:14 Schatten- $p$ Low Rank Approximation

We set  $\gamma = \text{poly}(\varepsilon_{\text{pca}}\eta/dq)$  and  $\varepsilon' = \text{poly}(\varepsilon_{\text{pca}}\eta/d)$  to obtain that  $\|\mathbf{y} - \mathbf{y}'\|_2 \leq \text{poly}(\varepsilon_{\text{pca}}/d)\|\mathbf{y}\|_2$ . Thus,

$$\|\hat{\mathbf{y}} - \mathbf{y}'/\|\mathbf{y}'\|_2\|_2 \leq \|\mathbf{y}/\|\mathbf{y}\|_2 - \mathbf{y}'/\|\mathbf{y}'\|_2\|_2 \leq \text{poly}(\varepsilon_{\text{pca}}/d).$$

On a floating point machine, we can normalize the vector  $\mathbf{y}'$  to obtain a vector  $\hat{\mathbf{y}}'$  such that  $\|\hat{\mathbf{y}}'\|_2 = (1 \pm \varepsilon_{\text{mach}} \text{poly}(d))$  and  $\|\hat{\mathbf{y}}' - \mathbf{y}'/\|\mathbf{y}'\|_2\|_2 \leq \varepsilon_{\text{mach}} \text{poly}(d)$ . By triangle inequality, we then obtain  $\|\hat{\mathbf{y}} - \hat{\mathbf{y}}'\|_2 \leq \text{poly}(\varepsilon/d) + \varepsilon_{\text{mach}} \text{poly}(d)$ . Finally, for  $i > r$

$$|\langle u_i, \hat{\mathbf{y}}' \rangle| \leq |\langle u_i, \hat{\mathbf{y}} \rangle| + \|\hat{\mathbf{y}} - \hat{\mathbf{y}}'\|_2 \leq \text{poly}(\varepsilon_{\text{pca}}/d) + \varepsilon_{\text{mach}} \text{poly}(d)$$

which then implies that as long as  $\varepsilon_{\text{mach}} \leq \text{poly}(\varepsilon_{\text{pca}}/d)$ , we get  $\sum_{i=r+1}^d \langle u_i, \hat{\mathbf{y}} \rangle^2 \leq \text{poly}(\varepsilon_{\text{pca}})$ .

Thus, we overall obtain that if  $\varepsilon_{\text{mach}} \leq \text{poly}(\varepsilon_{\text{pca}}\eta/d\kappa)$ , we can obtain a vector  $\hat{\mathbf{y}}'$  by running the Lanczos method for  $O(\frac{1}{\sqrt{\varepsilon}} \text{poly}(\log(d/\varepsilon_{\text{pca}}\eta\varepsilon)))$  iterations such that with probability  $\geq 1 - \eta$ ,  $\|\hat{\mathbf{y}}'\|_2 = (1 \pm \varepsilon_{\text{mach}} \text{poly}(d))$  and

$$\sum_{i: \lambda_i(M_s) \leq (1-\varepsilon)\lambda_1(M_s)} \langle \hat{\mathbf{y}}', u_i \rangle^2 \leq \varepsilon_{\text{pca}}.$$

Overall, the algorithm uses  $O(\frac{1}{\sqrt{\varepsilon}} \text{poly}(\log(d/\varepsilon\eta\varepsilon)))$  matrix vector products with  $M_s$  and uses an additional  $O(\frac{d}{\sqrt{\varepsilon}} \text{poly}(\log(d/\varepsilon_{\text{pca}}\eta\varepsilon)))$  floating point operations. ◀

Finally, we modify the LazySVD algorithm (see Algorithm 5) to make it more stable when implemented on a floating point machine. The modification preserves the semantics of the algorithm in the real number model while allowing the stability analysis to go through. For the matrices that we need to run the routine `AppxPCA` on, we show that we can compute very accurate matrix-vector products so that the Lanczos algorithm can be used to approximate the top eigenvector to obtain the following theorem:

► **Theorem 11.** *Given an  $n \times d$  matrix  $A$  with condition number  $\kappa(A) = \sigma_1(A)/\sigma_{k+1}(A)$ , an accuracy parameter  $\varepsilon$ , a rank parameter  $k$  and probability parameter  $\eta$ , if  $\varepsilon_{\text{mach}} \leq \text{poly}(\varepsilon\eta/n\kappa(A))$ , there is an algorithm that outputs a  $d \times k$  matrix  $V_k$  such that  $\kappa(V_k) \leq 4$  and for all  $p \in [2, \infty]$ ,*

$$\|A(I - \text{Proj}_{\text{colspace}(V_k)})\|_{S_p} \leq (1 + O(\varepsilon))\|A - A_k\|_{S_p}$$

and runs in time  $O(\frac{\text{nnz}(A)k}{\sqrt{\varepsilon}} \text{poly}(\log(d\kappa(A)/\varepsilon\eta)) + d \text{poly}(k, \log(dk/\eta\varepsilon)))$ .

### ■ Algorithm 5 Modified LazySVD.

---

**Input:** A positive semidefinite matrix  $M \in \mathbb{R}^{d \times d}$ ,  $k \leq d$ ,  $\varepsilon, \varepsilon_{\text{pca}}, \eta$

**Output:** Vectors  $v'_1, \dots, v'_k$

1  $M_0 \leftarrow M$  and  $V_0 \leftarrow []$

2 **for**  $s = 1, \dots, k$  **do**

3      $v'_s \leftarrow \text{AppxPCA}_{\varepsilon, \varepsilon_{\text{pca}}, \eta/k}((I - \text{Proj}_{\text{colspace}(V_{s-1})})M(I - \text{Proj}_{\text{colspace}(V_{s-1})}))$

4      $V_s \leftarrow [V_{s-1} \ v'_s]$

5 **return**  $V_k$

---

For convenience, we denote any algorithm that satisfies Definition 9 as `AppxPCA` $_{\varepsilon, \varepsilon_{\text{pca}}, \eta}$ . We abuse notation and say that if a unit vector  $w$  satisfies  $\sum_{i \in [d]: \lambda_i(M) \leq (1-\varepsilon)\lambda_1(M)} \langle w, u_i(M) \rangle^2 \leq \varepsilon_{\text{pca}}$ , then “ $w$  is `AppxPCA` $_{\varepsilon, \varepsilon_{\text{pca}}}(M)$ ”.

In [1], the authors show that if  $\varepsilon_{\text{pca}} = \text{poly}(\varepsilon, 1/d, \lambda_{k+1}/\lambda_1)$ , then with probability  $\geq 1 - \eta$  (union bounding over the success of all  $k$  calls to the **AppxPCA** routine), the orthonormal matrix  $V_k$  output by Algorithm 4 satisfies

1.  $\|(I - V_k V_k^\top)M(I - V_k V_k^\top)\|_2 \leq \frac{\lambda_{k+1}(M)}{(1-\varepsilon)}$ ,
2.  $(1 - \varepsilon)\lambda_k(M) \leq v_k^\top M v_k \leq \frac{1}{1-\varepsilon}\lambda_k(M)$  and
3. for every  $p \geq 1$ ,  $\|(I - V_k V_k^\top)M(I - V_k V_k^\top)\|_{S_p} \leq (1 + O(\varepsilon))(\sum_{i=k+1}^d \lambda_i^p)^{1/p}$ .

Since, the modified algorithm (Algorithm 5) has the same semantics as Algorithm 4, the properties 1 and 3 continue to hold for the modified LazySVD algorithm.

The advantage of the modification is that given any vector  $x$ , we can compute  $(I - \text{Proj}_{\text{colspace}(V_s)})x$  very accurately on a floating point machine using stable algorithms for the least squares problem, thereby obtaining a vector  $y$  on a floating point machine that is a very good approximation to  $M_s x = (I - \text{Proj}_{\text{colspace}(V_s)})M((I - \text{Proj}_{\text{colspace}(V_s)}))x$  for any given  $x$ . Below we have a result that states the stability of solving the Least Squares problem on a floating point machine.

► **Theorem 12** (Theorem 19.1 of [15]). *The algorithm for solving the least squares problem  $\min_x \|Ax - b\|_2^2$  using Householder triangulation is backwards stable in the sense that the solution  $\tilde{x}$  satisfies*

$$\|(A + \delta A)\tilde{x} - b\|_2^2 = \min_x \|(A + \delta A)x - b\|_2^2$$

for some matrix  $\delta A$  satisfying  $\|\delta A\|_2 \leq O(\varepsilon_{\text{mach}}\|A\|_2)$ .

Let  $x^* = A^+b$  and from the above theorem, we have  $\tilde{x} = (A + \delta A)^+b$ . Assuming  $\varepsilon_{\text{mach}} \leq 1/2\kappa(A)$ , we have  $A + \delta A$  is full rank and therefore  $(A + \delta A)^+ = ((A + \delta A)^\top(A + \delta A))^{-1}(A + \delta A)^\top$  using which we obtain that  $\|A\tilde{x} - Ax^*\|_2 \leq O(\varepsilon_{\text{mach}} \text{poly}(\kappa(A))\|b\|_2)$ . Note that  $Ax^* = \text{Proj}_{\text{colspace}(A)}b$ . Thus, given a matrix  $A$  and a vector  $x$ , we can compute a vector  $y$  on a floating point machine such that  $\|y - \text{Proj}_{\text{colspace}(A)}x\|_2 \leq O(\varepsilon_{\text{mach}} \text{poly}(\kappa(A), d)\|x\|_2)$ .

Finally, we can compute another vector  $y'$  satisfying  $\|y' - (I - \text{Proj}_{\text{colspace}(A)})x\|_2 \leq O(\varepsilon_{\text{mach}} \text{poly}(\kappa(A), d)\|x\|_2)$ . Thus, given any vector  $x$ , if operations are computed using machine precision  $\varepsilon_{\text{mach}}$  and if we assume that for any arbitrary vector  $x$ , we can compute a vector  $y$  satisfying  $\|y - Mx\|_2 \leq \varepsilon_M\|M\|_2\|x\|_2$ , then given any vector  $x$ , we can compute a vector  $y$  on a floating point machine satisfying  $\|y - M_s x\|_2 \leq O(\varepsilon_{\text{mach}} \text{poly}(\kappa(V_s), d) + \varepsilon_M)\|M\|_2\|x\|_2$ .

We now bound  $\kappa(V_s)$ . Assume that the vector  $v'_s$  satisfies  $\|v'_s\|_2 = (1 \pm \text{poly}(d)\varepsilon_{\text{mach}})$ . If the vector  $v'_s$  is **AppxPCA** $_{\varepsilon, \varepsilon_{\text{pca}}}(M_{s-1})$ , then

$$\|\text{Proj}_{\text{colspace}(V_{s-1})}v'_s\|_2^2 \leq \sum_{i \in [d]: \lambda_i(M_{s-1}) \leq (1-\varepsilon)\lambda_1(M_{s-1})} \langle v'_s, u_i(M_s) \rangle^2 \leq \varepsilon_{\text{pca}}$$

where the first inequality follows from the fact that  $\text{colspace}(V_{s-1})$  is spanned by the eigenvectors of  $M_{s-1}$  corresponding to zero eigenvalues. Using the above inequality, we can upper bound  $\sigma_{\max}(V_s)$  and lower bound  $\sigma_{\min}(V_s)$ .

► **Lemma 13.** *Suppose  $V_{s-1}$  is a  $d \times (s-1)$  matrix such that  $\sigma_{\max}(V_{s-1}) = \alpha_{s-1}$  and  $\sigma_{\min}(V_{s-1}) = \beta_{s-1}$ . Let  $v'_s$  be a vector with  $\|v'_s\|_2 = (1 \pm \text{poly}(d)\varepsilon_{\text{mach}})$  and satisfies  $\|\text{Proj}_{\text{colspace}(V_{s-1})}v'_s\|_2^2 \leq \varepsilon_{\text{pca}}$ . Let  $V_s = [V_{s-1} \ v'_s]$ . Then  $\sigma_{\max}(V_s) \leq \max(\sigma_{\max}(V_{s-1}), 1 + \text{poly}(d)\varepsilon_{\text{mach}}) + \sqrt{\varepsilon_{\text{pca}}}$  and*

$$\sigma_{\min}(V_s) \geq \sqrt{\max(0, \min(\sigma_{\min}(V_{s-1})^2, 1 - \text{poly}(d)\varepsilon_{\text{mach}}) - \sigma_{\max}(V_{s-1})\sqrt{\varepsilon_{\text{pca}}})}$$

**Proof.** Let  $Q$  be an orthonormal basis for the column space of  $V_{s-1}$  and let  $V_{s-1} = QR$  for a matrix  $R$  with  $\sigma_{\max}(R) = \sigma_{\max}(V_{s-1}) = \alpha_{s-1}$  and  $\sigma_{\min}(R) = \sigma_{\min}(V_{s-1}) = \beta_{s-1}$ . We have that  $\|Q^\top v'_s\|_2^2 = \|QQ^\top v'_s\|_2^2 = \|\text{Proj}_{\text{colspace}(V_{s-1})} v'_s\|_2^2 \leq \varepsilon_{\text{pca}}$ . Let  $x \in \mathbb{R}^s$  be an arbitrary unit vector. Let  $x_1 \in \mathbb{R}^{s-1}$  and  $x_2 \in \mathbb{R}$  be such that  $x = (x_1, x_2)$ . Now,

$$\begin{aligned} \|V_s x\|_2^2 &= \|QRx_1 + v'_s x_2\|_2^2 = \|Rx_1\|_2^2 + x_2^2 \|v'_s\|_2^2 + (2x_2)x_1^\top R^\top Q^\top v'_s \\ &\leq \alpha_{s-1}^2 \|x_1\|_2^2 + (1 + \text{poly}(d)\varepsilon_{\text{mach}})x_2^2 + (2|x_2|)\alpha_{s-1}\|x_1\|_2\sqrt{\varepsilon_{\text{pca}}} \\ &\leq \max(\alpha_{s-1}^2, 1 + \text{poly}(d)\varepsilon_{\text{mach}}) + \alpha_{s-1}\sqrt{\varepsilon_{\text{pca}}}(\|x_1\|_2^2 + |x_2|^2) \end{aligned}$$

which implies that  $\|V_s\|_2 \leq \max(\alpha_{s-1}, 1 + \text{poly}(d)\varepsilon_{\text{mach}}) + \sqrt{\varepsilon_{\text{pca}}}$ . Similarly,

$$\begin{aligned} \|V_s x\|_2^2 &= \|QRx_1 + v'_s x_2\|_2^2 = \|Rx_1\|_2^2 + x_2^2 \|v'_s\|_2^2 + (2x_2)x_1^\top R^\top Q^\top v'_s \\ &\geq \beta_{s-1}^2 \|x_1\|_2^2 + (1 - \text{poly}(d)\varepsilon_{\text{mach}})x_2^2 - 2|x_2|\|x_1\|_2\alpha_{s-1}\sqrt{\varepsilon_{\text{pca}}} \\ &\geq \min(\beta_{s-1}^2, 1 - \text{poly}(d)\varepsilon_{\text{mach}}) - \alpha_{s-1}\sqrt{\varepsilon_{\text{pca}}}. \end{aligned}$$

Hence,  $\sigma_{\min}(V_s) \geq \sqrt{\max(0, \min(\sigma_{\min}(V_{s-1})^2, 1 - \text{poly}(d)\varepsilon_{\text{mach}}) - \sigma_{\max}(V_{s-1})\sqrt{\varepsilon_{\text{pca}}})}$ .  $\blacktriangleleft$

Conditioned on the event that  $\|\text{Proj}_{\text{colspace}(V_{s-1})} v'_s\|_2^2 \leq \varepsilon_{\text{pca}}$  and  $\|v'_s\|_2^2 = (1 \pm \text{poly}(d)\varepsilon_{\text{mach}})$  for all  $s = 1, \dots, k$ , from the above lemma, we obtain that  $\|V_s\|_2 \leq 1 + \text{poly}(d)\varepsilon_{\text{mach}} + k\sqrt{\varepsilon_{\text{pca}}}$ . If  $\varepsilon_{\text{pca}} \leq 1/\text{poly}(k)$  and  $\varepsilon_{\text{mach}} \leq 1/\text{poly}(d)$ , then  $\|V_s\|_2 \leq 2$  for all  $s = 1, \dots, k$  which in turn implies that for all  $s = 1, \dots, k$ ,  $\sigma_{\min}(V_s) \geq \sqrt{1 - \text{poly}(d)\varepsilon_{\text{mach}} - 2k\sqrt{\varepsilon_{\text{pca}}}} \geq 1/2$  assuming  $\varepsilon_{\text{pca}} \leq 1/\text{poly}(k)$  and  $\varepsilon_{\text{mach}} \leq 1/\text{poly}(d)$ .

Hence,  $\kappa(V_s) \leq 4$  for all  $s = 1, \dots, k$  in Algorithm 5 conditioned on the success of all the calls to **AppxPCA**. Thus, we can assume that given any vector  $x$ , we can compute a vector  $y$  on a floating point computer with precision  $\varepsilon_{\text{mach}} \leq 1/\text{poly}(d)$  such that  $\|y - M_s x\|_2 \leq O(\varepsilon_{\text{mach}} \text{poly}(d) + \varepsilon_M)\|M\|_2\|x\|_2$ .

Let  $A \in \mathbb{R}^{n \times d}$  be an arbitrary matrix with  $n \geq d$ . Define  $M = A^\top A$  to be a  $d \times d$  matrix. Given any vector  $x$ , we can compute a vector  $y$  satisfying  $\|A^\top A x - y\|_2 \leq O(\varepsilon_{\text{mach}} \text{poly}(n)\|A\|_2^2\|x\|_2)$ . As  $\|A\|_2^2 = \|M\|_2$ , we thus have that for any  $x$ , we can compute  $y$  satisfying  $O(\varepsilon_{\text{mach}} \text{poly}(d)\|M\|_2\|x\|_2)$ . Thus,  $\varepsilon_M$  as defined above can be taken as  $\varepsilon_{\text{mach}} \text{poly}(d)$ . Let  $\kappa = \lambda_1(M)/\lambda_{k+1}(M)$ . By definition of eigenvalues, for any matrix  $V$  with at most  $k$  columns, we have  $\|(I - \text{Proj}_{\text{colspace}(V)})M(I - \text{Proj}_{\text{colspace}(V)})\|_2 \geq \lambda_{k+1}$ . Hence for all  $s = 1, \dots, k$ ,  $\|M_s\|_2 \geq \|M\|_2/\kappa$ . Thus, given any vector  $x$ , we can compute a vector  $y$  satisfying  $\|y - M_s x\|_2 \leq O(\varepsilon_{\text{mach}} \text{poly}(n)\kappa)\|M_s\|_2\|x\|_2$ .

Finally, we have the main theorem showing the stability of the LazySVD algorithm.

**Proof of Theorem 11.** Note that the algorithm in Lemma 10 satisfies the **AppxPCA** $_{\varepsilon, \varepsilon_{\text{pca}}, \eta}$  definition. Thus, if  $\varepsilon_{\text{pca}} \leq \text{poly}(\varepsilon/d\kappa)$ , by Theorem 4.1 of [1], Algorithm 5 when run on the  $d \times d$  matrix  $A^\top A$  outputs a matrix  $V_k$  such that with probability  $\geq 1 - \eta$ ,  $\|(I - \text{Proj}_{\text{colspace}(V_k)})A^\top A(I - \text{Proj}_{\text{colspace}(V_k)})\|_2 \leq \frac{1}{1-\varepsilon}\sigma_{k+1}(A)^2$  and for all  $p' \geq 1$ ,

$$\|(I - \text{Proj}_{\text{colspace}(V_k)})A^\top A(I - \text{Proj}_{\text{colspace}(V_k)})\|_{S_{p'}} \leq (1 + O(\varepsilon))\left(\sum_{i=k+1}^d \sigma_i(A)^{2p'}\right)^{1/p'}.$$

Thus, we have  $\|A(I - \text{Proj}_{\text{colspace}(V_k)})\|_2 \leq (1 + O(\varepsilon))\sigma_{k+1}(A)$  and using the fact that  $\|A^\top A\|_{S_p}^p = \|A\|_{S_{2p}}^{2p}$ , for all  $p \geq 2$ ,  $\|A(I - \text{Proj}_{\text{colspace}(V_k)})\|_{S_p} \leq (1 + O(\varepsilon))\|A - A_k\|_p$ . We additionally have  $\kappa(V_k) \leq 4$  from Lemma 13.

**Runtime Analysis.** In each iteration of Algorithm 5, we require  $O(\varepsilon^{-1/2} \text{poly}(\log(d\kappa/\eta\varepsilon)))$  matrix vector products with the matrices  $A$  and  $A^\top$ . For iterations  $s = 1, \dots, k$ , we solve  $O(\varepsilon^{-1/2} \text{poly}(\log(d\kappa/\eta\varepsilon)))$  least squares problems on a fixed  $d \times s$  matrix and different label vectors. Thus, the overall time complexity of the algorithm is

$$O\left(\frac{\text{nnz}(A)k}{\sqrt{\varepsilon}} \text{poly}(\log(d\kappa/\eta\varepsilon)) + d \text{poly}(k, \log(d\kappa/\eta\varepsilon))\right). \quad \blacktriangleleft$$

## A Time Complexity of SVD in the Real RAM model

Consider an  $m \times n$  matrix  $A$  where  $m \leq n$ . We can compute the matrix  $M = A^\top A$  in time  $O(nm^{\omega-1})$ , where  $\omega$  is the matrix multiplication exponent. Using the eigendecomposition algorithm of [3], we can then compute a matrix  $V$  and a diagonal matrix  $D$  satisfying  $\|M - VDV^{-1}\|_2 \leq \|M\|_2 / \text{poly}(n)$  in time  $\tilde{O}(m^\omega)$ . Although the matrix  $M$  is symmetric, the matrix  $V$  output by the algorithm may not be orthonormal. In the real RAM model, we can perform the following changes to their algorithm:

1. The Ginibre perturbation step is replaced with the symmetric Gaussian Orthogonal Ensemble perturbation as mentioned in Remark 6.1 of [3].
2. In step 5 of the algorithm EIG in [3], after computing the orthonormal matrices  $\tilde{Q}_+$  and  $\tilde{Q}_-$ , we modify  $\tilde{Q}_-$  to an orthonormal basis of the column space of the matrix  $(I - \tilde{Q}_+ \tilde{Q}_+^\top) \tilde{Q}_-$ . This ensures that  $\tilde{Q}_+^\top \tilde{Q}_- = 0$ , while preserving the properties of  $\tilde{Q}_-$  guaranteed by the algorithm DEFLATE. Note that the matrix  $\tilde{Q}_-$  can be updated in time  $\tilde{O}(n^\omega)$  in the real RAM model.

Thus, the algorithm of [3] can be used to compute an orthonormal matrix  $V$  and a diagonal matrix  $D$  such that  $\|M - VDV^\top\|_2 \leq \|M\|_2 / \text{poly}(n)$  in  $\tilde{O}(nm^{\omega-1})$  time in the real RAM model.

If we define  $U = AV \cdot D^{-1/2}$ , then  $U, D^{1/2}, V^\top$  is an approximate singular value decomposition of the matrix  $A$ , where the matrices  $U, V$  are orthonormal up to a  $1/\text{poly}(n)$  error. Since the matrix  $AV$  can be computed in  $\tilde{O}(nm^{\omega-1})$ , we obtain that SVD of a well conditioned matrix can be computed in  $\tilde{O}(nm^{\omega-1})$  time.

## B An Experiment

We consider multiplying an  $n \times n$  matrix with an  $n \times d$  matrix while varying  $d$ . We set  $n = 10,000$  and vary  $d$  to take values in the interval  $[10, 100]$ . If  $t_d$  is the median amount of time (over 5 repetitions) to compute the product of an  $n \times n$  matrix with an  $n \times d$  matrix, we obtain a color map (Figure 1) of the values  $(j/i)/(t_j/t_i)$  for  $j \geq i$ . If  $(j/i)/(t_j/t_i)$  is large then  $t_j$  is much smaller than  $t_i(j/i)$  which is what we would expect if the matrix-multiplication time scales linearly with the dimension.

The experiment was performed using NumPy on a machine with 2 cores. We see that fixing an  $i$ , as we increase  $j$ ,  $t_j$  becomes smaller compared to  $t_i \cdot (j/i)$ . Hence, it is advantageous to run with larger block sizes if it means that it reduces the number of iterations for which the smaller block size is to be run. In the proof of Theorem 5, we see that if we increase the larger block to 4 times the original, then the number of iterations the smaller block size is to be run decreases to 0.5x the original. Based on the characteristics of the machine, we can obtain significant improvements over the parameters obtained by optimizing for matrix-vector products.

## Abstract

We study the worst-case mixing time of the global Kawasaki dynamics for the fixed-magnetization Ising model on the class of graphs of maximum degree  $\Delta$ . Proving a conjecture of Carlson, Davies, Kolla, and Perkins, we show that below the tree uniqueness threshold, the Kawasaki dynamics mix rapidly for all magnetizations. Disproving a conjecture of Carlson, Davies, Kolla, and Perkins, we show that the regime of fast mixing does not extend throughout the regime of tractability for this model: there is a range of parameters for which there exist efficient sampling algorithms for the fixed-magnetization Ising model on max-degree  $\Delta$  graphs, but the Kawasaki dynamics can take exponential time to mix. Our techniques involve showing spectral independence in the fixed-magnetization Ising model and proving a sharp threshold for the existence of multiple metastable states in the Ising model with external field on random regular graphs.

## 1 Introduction

The Ising model on a finite graph  $G = (V, E)$  is the following probability distribution on  $\Omega = \{+1, -1\}^V$ :

$$\mu_{G,\beta,\lambda}(\sigma) = \frac{\lambda^{|\sigma|^+} e^{\beta m_G(\sigma)}}{Z_G(\beta, \lambda)} \quad (1)$$

where  $|\sigma|^+ = |\{\sigma^{-1}(+1)\}|$  is the number of vertices assigned a  $+1$  spin under  $\sigma$  which we call the *size* of  $\sigma$ , and  $m_G(\sigma)$  is the number of monochromatic edges in  $G$  under the 2-coloring given by  $\sigma \in \Omega$ . The measure  $\mu_{G,\beta,\lambda}$  is called the *Gibbs measure* on  $G$  with *inverse temperature*

$\beta \geq 0$  and *external field*  $\lambda \geq 0$ . The normalizing constant  $Z_G(\beta, \lambda) = \sum_{\sigma \in \Omega} \lambda^{|\sigma|^+} e^{\beta m_G(\sigma)}$  is the *partition function* of the Ising model. Throughout this paper, we focus on the *ferromagnetic* case,  $\beta \geq 0$ , in which agreeing spins on edges are preferred.

Spin models on graphs are the source of many interesting computational problems. Questions about the tractability of approximate counting (estimating the partition function) and approximate sampling (from the Gibbs distribution) are studied extensively.

In the case of the ferromagnetic Ising model, Jerrum and Sinclair [35] showed that there is a polynomial-time approximation algorithm on all graphs at all temperatures, and Randall and Wilson [42] gave an efficient sampling algorithm.

In other cases, such as the anti-ferromagnetic Ising model ( $\beta < 0$ ) and the hard-core model of weighted independent sets, approximate counting and sampling can be computationally hard (e.g., no polynomial-time algorithm exists unless NP=RP). For the class  $\mathcal{G}_\Delta$  of graphs of maximum degree  $\Delta$ , these two models exhibit *computational thresholds*: as the activity or external field parameter  $\lambda$  varies, there is a sharp threshold between tractability (efficient approximate counting and sampling) and intractability (NP-hardness) [28, 46–48]. Moreover, the critical value  $\lambda_c = \lambda_c(\Delta, \beta)$  is the phase transition point of the corresponding model on the infinite  $\Delta$ -regular tree  $\mathbb{T}_\Delta$  (more precisely, it is the threshold for the *uniqueness of Gibbs measure* on  $\mathbb{T}_\Delta$ , a notion which we discuss shortly). Thus there is a remarkable connection between computational thresholds and statistical physics phase transitions. Even further, the threshold  $\lambda_c$  has recently been shown to be a *dynamical threshold*: it is the threshold for rapid mixing of the Glauber dynamics, a natural Markov chain for sampling from spin models like the Ising or hard-core models, on graphs in  $\mathcal{G}_\Delta$  [2, 15, 41, 48]. So in these cases, three different thresholds (computational, dynamical, uniqueness on the tree) coincide.

A very similar picture has emerged for the model of a uniformly random independent set of a given size. For the class of graphs  $\mathcal{G}_\Delta$ , there is a critical density  $\alpha_c(\Delta)$  so that if  $\alpha < \alpha_c$ , there are efficient algorithms to approximately count and sample independent sets of density  $\alpha$ , while if  $\alpha > \alpha_c$  no such algorithms exist unless NP=RP [22]. Jain, Michelen, Pham, and Vuong [33] recently proved that this computational threshold  $\alpha_c$  also marks the dynamical threshold – for  $\alpha < \alpha_c$ , the natural “down-up” random walk on independent sets of a given size mixes rapidly. The threshold  $\alpha_c(\Delta)$  is closely connected to a uniqueness threshold on the tree: it is the smallest expected density of an independent set in the hard-core model on  $G \in \mathcal{G}_\Delta$  at activity  $\lambda_c(\Delta)$ .

Returning to the ferromagnetic Ising model ( $\beta \geq 0$ ), the picture is fundamentally different and not completely understood. While there is no computational threshold (there are efficient algorithms for all parameters) one can still ask about the relationship between uniqueness and dynamical thresholds. The natural dynamics in this setting are the *Glauber dynamics*, a Markov chain on the state space  $\Omega$  with stationary distribution  $\mu_{G, \beta, \lambda}$  which at each step chooses a uniformly random vertex and updates its spin according to the conditional distribution given the spins of its neighbors. For the case  $\lambda = 1$  (“no external field”) the dynamical threshold has been identified, and it coincides with the uniqueness threshold. For  $\Delta \geq 3$ , let the *critical inverse temperature* of the Ising model on  $\mathbb{T}_\Delta$  be denoted by

$$\beta_u(\Delta) := \ln \left( \frac{\Delta}{\Delta - 2} \right).$$

The value  $\beta_u(\Delta)$  is the Gibbs uniqueness threshold for the Ising model (with  $\lambda = 1$ ) on  $\mathbb{T}_\Delta$  (see e.g. [6] and below in Section 2.1 for a precise definition). Mossel and Sly [40] proved that for  $0 \leq \beta < \beta_u$  and any  $\lambda$ , the Glauber dynamics are rapidly mixing for any  $G \in \mathcal{G}_\Delta$ . This threshold in  $\beta$  is sharp due to the analysis of the random  $\Delta$ -regular graph in [23, 31]: for  $\beta > \beta_u$  and  $\lambda = 1$ , the Glauber dynamics for the Ising model take exponential time to mix.

For general  $\lambda \geq 0$ , in the regime  $\beta > \beta_u$ , the threshold landscape is not as well understood. Note that the model is symmetric around  $\lambda = 1$  by swapping the role of  $+$  and  $-$  spins and so for each threshold, its inverse is also a threshold; for clarity we will define thresholds for the case  $\lambda \geq 1$ . Let  $\lambda_u(\Delta, \beta)$  be the Gibbs uniqueness threshold of the ferromagnetic Ising model on  $\mathbb{T}_\Delta$ ; that is,  $\lambda_u$  is the smallest  $\lambda_0 \geq 1$  so that there is a unique Gibbs measure for the Ising model on  $\mathbb{T}_\Delta$  with inverse temperature  $\beta$  and external field  $\lambda$ , for all  $\lambda > \lambda_0$  (again see [6] and Section 2.1 for details). The value of  $\lambda_u$  can be given implicitly as the solution to an equation involving  $\Delta, \beta$ , and  $\lambda$ . Unlike in the above mentioned examples, while  $\lambda_u$  marks a phase transition on the tree, it does not mark a computational transition (since sampling from the ferromagnetic Ising model is tractable on all graphs and all parameters) and it has not been established as a dynamical threshold (though this also has not been ruled out). Below in Theorem 2 we show that the worst-case mixing time of Glauber dynamics over  $\mathcal{G}_\Delta$  is exponential when  $|\log \lambda| < \log \lambda_u$ .

The complementary result (fast mixing of the Glauber dynamics for  $G \in \mathcal{G}_\Delta$  when  $|\log \lambda| > \log \lambda_u$ ) is not known to hold. Instead, sufficient conditions for fast mixing have been given that require  $\lambda$  to be somewhat larger than  $\lambda_u$ . An interesting insight is that upper bounds on the dynamical threshold are often connected to zero-freeness of the map  $\lambda \mapsto Z_G(\beta, \lambda)$  considered as a complex polynomial. Throughout this paper, we particularly focus on the *analytic threshold*  $\lambda_a(\Delta, \beta)$ , defined by the following requirement: for all  $G \in \mathcal{G}_\Delta$ , every compact  $D \subset (\lambda_a(\Delta, \beta), \infty)$  and every partial spin assignment  $\tau_U : U \rightarrow \{-1, +1\}$ ,  $U \subset V$  it holds that  $Z_G^{\tau_U}(\beta, \lambda)$  (the partition function restricted to configurations that are consistent with  $\tau_U$ ) is non-zero for all  $\lambda$  in some uniform complex neighborhood of  $D$ . A formal definition of  $\lambda_a$  is given in Section 2.5. In contrast to the uniqueness threshold,  $\lambda_a(\Delta, \beta)$  has not been determined. It is known that  $\lambda_a(\Delta, \beta) \geq \lambda_u(\Delta, \beta)$  and the best known upper bound is

$$\lambda_a(\Delta, \beta) \leq \min \left\{ \frac{(\Delta - 2)e^{2\beta} - \Delta}{e^{\beta(2-\Delta)}}, e^{\beta\Delta} \right\} =: \bar{\lambda}_a. \tag{2}$$

The first expression in the minimum of (2) was proven by Shao and Sun [44], and the second bound of  $e^{\beta\Delta}$  (which is smaller than the first expression for  $\Delta \geq 4$  and  $\beta$  large enough) was proven by Shao and Ye [45].

It turns out that this analytic threshold  $\lambda_a$  is closely related to the dynamical threshold. More precisely, Chen, Liu, and Vigoda [17] proved that the first bound in (2) can be used to define a regime in which the ferromagnetic Ising model satisfies  $\ell_\infty$ -independence (see Section 2.4), a stronger version of spectral independence that implies rapid mixing of Glauber dynamics. Their derivation of the threshold used techniques similar to those of Shao and Sun [44] which resulted in coinciding bounds, but a more systematic connection was provided by Chen, Liu and Vigoda in [16]. They showed that for a broad class of spin systems, sufficiently strong zero-freeness assumptions imply  $\ell_\infty$ -independence. With small adjustments, we use their technique to argue that the ferromagnetic Ising model satisfies  $\ell_\infty$ -independence for all  $|\log \lambda| > \log \lambda_a(\Delta, \beta)$  (see Theorem 22).

The main focus of this paper is on dynamical thresholds of the *fixed-magnetization* Ising model with inverse temperature  $\beta$  and magnetization  $\eta$ . The magnetization (per vertex) of an Ising configuration  $\sigma$  is  $\eta(\sigma) := \frac{\sum_{v \in V(G)} \sigma_v}{|V(G)|}$ . A configuration  $\sigma$  of magnetization  $\eta$  has size (number of  $+1$  spins) exactly  $k = \lfloor n \frac{\eta+1}{2} \rfloor$ . We denote by  $\Omega_k$  the configurations of size  $k$ .

The fixed-magnetization Ising model with inverse temperature  $\beta \geq 0$  and magnetization  $\eta \in [-1, 1]$  is then a probability distribution defined similarly to (1) but on  $\Omega_k$ , where  $k = \lfloor n \frac{\eta+1}{2} \rfloor$ , as

$$\hat{\mu}_{G,\beta,\eta}(\sigma) = \frac{e^{\beta m_G(\sigma)}}{\hat{Z}_{G,\eta}(\beta)},$$

where

$$\hat{Z}_{G,\eta}(\beta) = \sum_{\sigma \in \Omega_k} e^{\beta m_G(\sigma)}$$

is the fixed-magnetization partition function. Here we use floors to avoid restricting to values of  $\eta$  where  $n \frac{\eta+1}{2}$  is an integer. The distribution  $\hat{\mu}_{G,\beta,\eta}$  is exactly that of  $\mu_{G,\beta,\lambda}$  conditioned on the event  $\{\sigma \in \Omega_k\}$ . Note that the external field plays no role in the fixed-magnetization model since  $\lambda^{|\sigma|^+}$  is constant on  $\Omega_k$ .

In statistical physics, the fixed-magnetization Ising model is the *canonical ensemble* while the Ising model is the *grand canonical ensemble*. The fixed-magnetization model on lattices is studied in, e.g., [13, 24], where interesting geometric behavior is described; the behavior of the Kawasaki dynamics (the natural analogue of Glauber dynamics) on  $\mathbb{Z}^d$  has been studied extensively in, e.g., [9–11, 38]. Here we focus on dynamical behavior over the class of all graphs of maximum degree  $\Delta$ .

To understand algorithmic and dynamical thresholds in the fixed-magnetization Ising model, we need to define some further parameters. The mean magnetization of the  $+$  measure on  $\mathbb{T}_\Delta$  (explained in detail in Section 2.1) is

$$\eta_{\Delta,\beta,\lambda}^+ := \tanh(L^* + \operatorname{artanh}(\tanh(L^*) \tanh(\beta/2)))$$

where  $L^*$  is the largest solution to

$$L = \log(\lambda) + (\Delta - 1) \operatorname{artanh}(\tanh(L) \tanh(\beta/2)).$$

We are specifically interested in the following three quantities:

$$\eta_c(\Delta, \beta) = \eta_{\Delta,\beta,1}^+ \quad \eta_u(\Delta, \beta) = \eta_{\Delta,\beta,\lambda_u}^+ \quad \eta_a(\Delta, \beta) = \eta_{\Delta,\beta,\lambda_a}^+.$$

For  $\beta > \beta_u$ , we have  $0 < \eta_c < \eta_u \leq \eta_a$ . It is not known if the last inequality is strict or not (just as it is not known if  $\lambda_a = \lambda_u$ ).

Carlson, Davies, Kolla, and Perkins [12] showed recently that the fixed-magnetization Ising model exhibits quite different algorithmic behavior than the Ising model: it exhibits a computational threshold. In particular, for  $\beta < \beta_u$  and any  $\eta$ , as well as for  $\beta > \beta_u$  and  $|\eta| > \eta_c$ , there are efficient approximate counting and sampling algorithms for the Ising model at fixed mean magnetization  $\eta$  on  $\mathcal{G}_\Delta$ , while for  $\beta > \beta_u$  and  $|\eta| < \eta_c$ , there are no such algorithms unless NP=RP. Thus  $\beta_u$  and  $\eta_c$  mark the computational threshold in the fixed-magnetization Ising model.

Here we study dynamical thresholds for the fixed-magnetization Ising model on  $\mathcal{G}_\Delta$ . Given a distribution, one candidate for an efficient approximate sampling algorithm is a Markov chain whose stationary distribution is our target distribution, but the efficiency of this algorithm depends on the mixing time. Recall that the mixing time of a Markov chain is the number of steps, in the worst-case over initial distribution, required for a Markov chain to reach  $1/4$  total variation distance of its stationary distribution (see Section 2.4 for a formal definition). As mentioned above, the natural dynamics associated to the fixed-magnetization

Ising model are the *Kawasaki dynamics*, which is a reversible Markov chain on  $\Omega_k$ . At each step of the chain, a  $+1$  vertex and a  $-1$  vertex are chosen uniformly at random and have their spins swapped with a probability depending on the ratio of the Ising probabilities of the two configurations. This is sometimes referred to as the *global* Kawasaki dynamics, whereas the *local* Kawasaki dynamics restrict to swapping spins of neighboring vertices.

Our main contributions concern the *mixing time* of the Kawasaki dynamics. Taking  $\|\mu - \nu\|_{\text{TV}} := \sup_{A \in \mathcal{A}} |\mu(A) - \nu(A)|$  to be the total variation distance between probability distributions  $\mu$  and  $\nu$  on a probability space  $(\Omega, \mathcal{A})$ , the mixing time of a Markov chain on  $\Omega$  that has transition matrix  $P$  and stationary distribution  $\pi$  is

$$\tau_{\text{mix}} := \inf \left\{ t : \max_{x \in \Omega} \|P^t(x, \cdot) - \pi\|_{\text{TV}} \leq \frac{1}{4} \right\}.$$
