## APPROX

|  |            |
|--|------------|
| A $(3/2 + 1/e)$ -Approximation Algorithm for Ordered TSP   |            |
| <i>Susanne Armbruster, Matthias Mnich, and Martin Nägele</i> .....                                 | 1:1–1:18   |
| Online Time-Windows TSP with Predictions   |            |
| <i>Shuchi Chawla and Dimitris Christou</i> .....   | 2:1–2:21   |
| Degrees and Network Design: New Problems and Approximations  |            |
| <i>Michael Dinitz, Guy Kortsarz, and Shi Li</i> .....  | 3:1–3:17   |
| Hybrid $k$ -Clustering: Blending $k$ -Median and $k$ -Center                                       |            |
| <i>Fedor V. Fomin, Petr A. Golovach, Tanmay Inamdar, Saket Saurabh, and Meirav Zehavi</i> .....    | 4:1–4:19   |
| Asynchronous Majority Dynamics on Binomial Random Graphs   |            |
| <i>Divyarthi Mohan and Pawel Pralat</i> .....  | 5:1–5:20   |
| Bipartizing (Pseudo-)Disk Graphs: Approximation with a Ratio Better than 3                         |            |
| <i>Daniel Lokshтанov, Fahad Panolan, Saket Saurabh, Jie Xue, and Meirav Zehavi</i> ..              | 6:1–6:14   |
| A Logarithmic Approximation of Linearly-Ordered Colourings   |            |
| <i>Johan Håstad, Björn Martinsson, Tamio-Vesa Nakajima, and Stanislav Živný</i> ....               | 7:1–7:6    |
| Speed-Robust Scheduling Revisited  |            |
| <i>Josef Minařík and Jiří Sgall</i> .....  | 8:1–8:20   |
| On the Generalized Mean Densest Subgraph Problem: Complexity and Algorithms                        |            |
| <i>Karthekeyan Chandrasekaran, Chandra Chekuri, Manuel R. Torres, and Weihao Zhu</i> .....         | 9:1–9:21   |
| Improved Online Load Balancing with Known Makespan   |            |
| <i>Martin Böhm, Matej Lieskovský, Sören Schmitt, Jiří Sgall, and Rob van Stee</i> ....             | 10:1–10:21 |
| On the NP-Hardness Approximation Curve for Max-2Lin(2)   |            |
| <i>Björn Martinsson</i> .....  | 11:1–11:38 |
| Universal Optimization for Non-Clairvoyant Subadditive Joint Replenishment                         |            |
| <i>Tomer Ezra, Stefano Leonardi, Michał Pawłowski, Matteo Russo, and Seeun William Umboh</i> ..... | 12:1–12:24 |

Approximation, Randomization, and Combinatorial Optimization. Algorithms and Techniques (APPROX/RANDOM 2024).

## ■ Preface

This volume contains the papers presented at the 27th International Conference on Approximation Algorithms for Combinatorial Optimization Problems (APPROX 2024) and the 28th International Conference on Randomization and Computation (RANDOM 2024). APPROX focuses on algorithmic and complexity issues surrounding the development of efficient approximate solutions to computationally-difficult problems, and the 2024 edition was the 27th in the series. RANDOM is concerned with applications of randomness to computational and combinatorial problems, and the 2024 edition was the 28th in the series. The two conferences were held in parallel at the London School of Economics and Political Science (LSE), London, UK during August 28–30, 2024. This year, the plenary speaker for APPROX was Anupam Gupta from New-York University, and the plenary speaker for RANDOM was Mark Jerrum from Queen Mary University of London.

Topics of interest for APPROX include approximation algorithms, hardness of approximation, small space, sub-linear time and streaming algorithms, online algorithms, approaches that go beyond worst case analysis, distributed and parallel approximation, embeddings and metric-space methods, mathematical-programming methods, spectral methods, combinatorial optimization, algorithmic game theory, mechanism design and economics, computational-geometry problems, approximate learning. Those at RANDOM include the design and analysis of randomized algorithms, randomized complexity theory, pseudorandomness and derandomization, random combinatorial structures, random walks/Markov chains, expander graphs and randomness extractors, probabilistic proof systems, random projections and embeddings, error-correcting codes, average-case analysis, smoothed analysis, property testing, sublinear-time and local algorithms, computational learning theory, and the role of (pseudo)randomness in other areas of computer science such as cryptography, data privacy, and quantum information.

Prior to 2003, APPROX took place in Aalborg (1998), Berkeley (1999), Saarbrücken (2000), Berkeley (2001), and Rome (2002), while RANDOM took place in Bologna (1997), Barcelona (1998), Berkeley (1999), Geneva (2000), Berkeley (2001), and Harvard (2002). Since 2003, APPROX and RANDOM have been co-located, taking place in Princeton (2003), Cambridge (2004), Berkeley (2005), Barcelona (2006), Princeton (2007), Boston (2008), Berkeley (2009), Barcelona (2010), Princeton (2011), Boston (2012), Berkeley (2013), Barcelona (2014), Princeton (2015), Paris (2016), Berkeley (2017), Princeton (2018), Boston (2019) and Atlanta (2023). In 2020, 2021, and 2022, the conferences were held online.

The volume contains 30 contributed papers selected by the APPROX Program Committee out of 58 submissions, and 45 contributed papers selected by the RANDOM Program Committee out of 95 submissions. We would like to thank all the authors who submitted papers, the members of the program committees, and the external reviewers. We are grateful for the guidance of the steering committees: Jarosław Byrka, Samir Khuller, Monaldo Mastrolili, Nicole Megow, Laura Sanità, Chaitanya Swamy, László Végh, Virginia Vassilevska Williams, and David P. Williamson for APPROX, and Oded Goldreich, Raghu Meka, Cris Moore, Anup Rao, Omer Reingold, Dana Ron, Ronitt Rubinfeld, Amit Sahai, Ronen Shaltiel, Alistair Sinclair, and Paul Spirakis. for RANDOM. We would also like to thank the local organizing committee at LSE Ahmad Abdi, Tugkan Batu, Neil Olver, and Gergory Sorokin, and the Dagstuhl Publishing Team for their dedicated handling of the proceedings.

It was our pleasure to serve as chairs of the Approx/Random 2024 Program Committees, and to edit this volume of the proceedings.

## Abstract

We present a new  $(3/2 + 1/e)$ -approximation algorithm for the Ordered Traveling Salesperson Problem (Ordered TSP). Ordered TSP is a variant of the classic metric Traveling Salesperson Problem (TSP) where a specified subset of vertices needs to appear on the output Hamiltonian cycle in a given order, and the task is to compute a cheapest such cycle. Our approximation guarantee of approximately 1.868 holds with respect to the value of a natural new linear programming (LP) relaxation for Ordered TSP. Our result significantly improves upon the previously best known guarantee of  $5/2$  for this problem and thereby considerably reduces the gap between approximability of Ordered TSP and metric TSP. Our algorithm is based on a decomposition of the LP solution into weighted trees that serve as building blocks in our tour construction.

## 1 Introduction

The classic metric Traveling Salesperson Problem (TSP) is one of the most fundamental and well-studied problems in Combinatorial Optimization and has a large number of applications. A metric TSP instance is given by a complete undirected graph  $G = (V, E)$  with metric edge cost  $c: E \rightarrow \mathbb{R}_{\geq 0}$ . The task is to find a cycle of minimum cost that visits each vertex exactly once, where the cost of a cycle equals the sum of the edge costs over all edges it contains. Metric TSP is highly relevant in many practical applications and thus, a lot of different

---

<sup>1</sup> Most of this work was done while M. Nägele was employed at University of Bonn.

variants are studied (see, e.g., [34]). The problem is NP-hard and APX-hard [32]; concretely, assuming  $P \neq NP$ , it is known that no polynomial-time algorithm can guarantee to find a cycle of cost at most  $1^{23}/122$  times the cost of a cheapest cycle [24]. For a long time, the best-known approximation algorithm for metric TSP was the Christofides-Serdyukov  $3/2$ -approximation algorithm [10, 11, 35]. This was recently improved to a breakthrough  $(3/2 - \varepsilon)$ -approximation algorithm, for some  $\varepsilon > 10^{-36}$ , by Karlin, Klein, and Oveis Gharan [22, 23].

In this work, we focus on a generalization of metric TSP known as *Ordered TSP*, in which some of the vertices must be visited in a given order.

**Ordered TSP (OTSP):** Given a complete undirected graph  $G = (V, E)$  with metric edge cost  $c: E \rightarrow \mathbb{R}_{\geq 0}$  and pairwise distinct vertices  $d_1, \dots, d_k \in V$ , the task is to find a cheapest spanning cycle  $C$  in  $G$  that contains the vertices  $d_1, \dots, d_k$  in this order.

We typically refer to an input of OTSP as an *OTSP instance*  $(G, c, (d_1, \dots, d_k))$ ; solutions are often called *tours*. Our goal in this paper is to further the understanding of the approximability of OTSP, i.e., we aim to design  $\alpha$ -approximation algorithms for OTSP with  $\alpha$  as small as possible.

Clearly, OTSP is at least as hard as metric TSP, and therefore APX-hard. Surprisingly, not much more is known on the approximability of OTSP. Böckenhauer, Hromkovič, Kneis, and Kupke [6] observed that a  $5/2$ -approximate solution can be readily obtained by first traversing  $d_1, \dots, d_k$  in this order and subsequently appending a tour on  $V \setminus \{d_1, \dots, d_k\}$  constructed through the Christofides-Serdyukov algorithm. The black-box use of a metric TSP approximation algorithm allows to reduce this guarantee by the same additive improvement of  $\varepsilon > 10^{-36}$  as in the  $(3/2 - \varepsilon)$ -approximation by Karlin, Klein, and Oveis Gharan. Besides that, Böckenhauer, Mönke, and Steinová [7] gave a  $(5/2 - 2/k)$ -approximation algorithm, where  $k \geq 2$  is the number of ordered vertices in the OTSP input. Note that their result does not directly inherit the improvement achieved for metric TSP, making its approximation ratio asymptotically inferior to the earlier approach of Böckenhauer, Hromkovič, Kneis, and Kupke. Finally, the intuition that OTSP should become easier once  $k$  approaches  $n$  is confirmed by a dynamic programming approach of Deĭneko, Hoffmann, Okamoto, and Woeginger [14] that runs in  $O(2^r r^2 n)$  time and  $O(2^r r n)$  space, i.e., in polynomial time and space if  $r := n - k$ , the number of vertices that are not in the input order, is of magnitude  $O(\log n)$ .

OTSP is in fact a special case of a the following significantly more general TSP variation termed *TSP with Precedence Constraints*.

**TSP with Precedence Constraints (TSP-PC):** Given a complete undirected graph  $G = (V, E)$  with metric edge cost  $c: E \rightarrow \mathbb{R}_{\geq 0}$  and a partial order  $\prec$  on  $V$ , the task is to find a cheapest spanning cycle  $C$  in  $G$  that respects  $\prec$ , i.e.,  $C$  can be traversed such that whenever  $u \prec v$  for two vertices  $u, v \in V$ , then  $u$  appears earlier on  $C$  than  $v$ .

Compared to the total order constraints in OTSP, general partial orders allow for modeling a much wider range of problems. One among many applications of TSP-PC is, e.g., tour planning for mixed pickup and delivery services, where one needs to make sure that a pickup happens before a delivery (but apart from that, pickups and deliveries can be intertwined arbitrarily). There is a considerable body of research on the structure of the

TSP-PC polyhedron, different dynamic programming algorithms, enhanced branch-and-bound methods, and various other exact and heuristic approaches, typically even for the more general version of TSP-PC with asymmetric edge cost (see, e.g., [2, 18, 25, 33] and references therein). Despite that, essentially no positive results on the approximability of TSP-PC are known, which is possibly explained by an influential hardness result of Charikar, Motwani, Raghavan, and Silverstein [9]: By relating the problem to the *Shortest Common Supersequence Problem*, they are able to show that there is no  $(\log n)^\delta$ -approximation for the path version of TSP-PC for any constant  $\delta$ , unless  $\text{NP} \subseteq \text{DTIME}(n^{O(\log \log n)})$ , even if the underlying metric space is a line. This motivates our study of the approximability of TSP-PC on general metric spaces with special partial orders, i.e., OTSP.

## 1.1 Our results and techniques

Our main contribution is to significantly improve the state of the art for OTSP by giving an LP-relative approximation guarantee of  $3/2 + 1/e \approx 1.868$ , as stated in the following theorem.

► **Theorem 1.** *There is a polynomial-time  $(3/2 + 1/e)$ -approximation algorithm for OTSP.*

This constitutes a significant improvement over the previous  $(5/2 - \varepsilon)$ -approximation algorithm. We achieve this improvement by introducing a new linear programming (LP) relaxation for OTSP and devising a suitable rounding procedure. The LP relaxation is based on the Held-Karp relaxation that is typically leveraged in the context of TSP, but allows for taking the prescribed order of the vertices  $d_1, \dots, d_k$  into account by using disjoint sets of variables to represent the  $d_i$ - $d_{i+1}$  strolls<sup>2</sup> that a solution is composed of. Our rounding procedure crucially relies on a result on decomposing (fractional)  $s$ - $t$  strolls into a convex combination of trees. This decomposition resembles an existential result by Bang-Jensen, Frank, and Jackson [3, Theorem 2.6] on packing branchings in a directed multigraph. Variations thereof have recently been used for advances on another variant of TSP, namely *Prize-Collecting TSP* [4, 5], and motivate the application here. (See Lemma 5 for the precise statement of the decomposition result.) The trees obtained from stroll decompositions enable the construction of a subgraph that spans a reasonably large part of  $V$  at cost no more than the LP solution cost, and contains a walk with visits at  $d_1, \dots, d_k$  in this order. Our tour construction is completed by connecting the remaining isolated vertices in a cheapest possible way, and applying a parity correction step as typical for TSP-like problems.

Our approach crucially relies on being able to split a solution into  $d_i$ - $d_{i+1}$  strolls upfront, hence it is not directly suitable for handling arbitrary precedence constraints other than total orders. While one can always try to guess a suitable total order that is compatible with the given partial order, and then apply Theorem 1, this is generally not efficient. We can, though, obtain approximation algorithms for some special cases of precedence constraints, as for example in the following result that is a direct generalization of Theorem 1.

► **Theorem 2.** *Consider a TSP-PC instance  $(G, c, \prec)$  on a complete graph  $G = (V, E)$  with a partial order  $\prec$  that can be equivalently given as independent total orders on disjoint subsets  $D_1, \dots, D_\ell \subseteq V$ . There is a polynomial-time  $(\ell + 1/2 + 1/e^\ell)$ -approximation algorithm for this class of TSP-PC problems.*

<sup>2</sup> We use the term *s-t stroll* instead of *s-t path* for a path from  $s$  to  $t$  in the underlying graph to emphasize that we do not require all vertices to be covered. Also, for convenience of notation, we use  $d_{k+1} := d_1$  throughout the paper.

The total orders on the sets  $D_i$  are also called *chains*. We remark that losing a factor of  $\ell$  in Theorem 2 is intrinsic to our approach: We never merge the given chains, but traverse them one after another. Still, the result of Theorem 2 is superior to a black-box algorithm that independently applies the algorithm from Theorem 1 to the  $\ell$  chains and concatenates the resulting tours (while shortcutting to avoid repeated visits).

## 1.2 Related Work

Variations of OTSP and TSP-PC are also studied in the context of scheduling with precedence constraints. In a classic setup, denoted by  $Pm|prec|C_{\max}$  in the scheduling literature, one needs to find a schedule for a set  $\mathcal{J}$  of  $n$  jobs on  $m$  identical machines subject to precedence constraints between the jobs. Formally, each job  $j \in \mathcal{J}$  is characterized by a processing time  $p_j \in \mathbb{Z}_{\geq 0}$ , and a schedule  $\sigma: \mathcal{J} \rightarrow \mathbb{Z}_{\geq 0} \times \{1, \dots, m\}$  assigns each job  $j \in \mathcal{J}$  to a pair  $(\sigma_1(j), \sigma_2(j))$  consisting of an integer start time  $\sigma_1(j)$  and a machine  $\sigma_2(j)$  such that no other job scheduled on that machine has their start time in the time interval  $[\sigma_1(j), \sigma_1(j) + p_j]$ , and for any two jobs  $j, j' \in \mathcal{J}$  related as  $j \prec j'$  it holds that  $\sigma_1(j) < \sigma_2(j')$ . The makespan objective  $C_{\max}$  of a schedule  $\sigma$  is the maximum completion time  $C_j = \sigma_1(j) + p_j$  over all jobs  $j \in \mathcal{J}$ . Generally, precedence constraints of this type are studied extensively in a wide range of scheduling problems, including different settings and objectives (see, e.g., [13, 19, 28, 36]). The three-machine problem  $P3|prec, p_j \equiv 1|C_{\max}$  is one of the few famous open problems by Garey and Johnson [17] whose computational complexity has not yet been resolved.

The complexity of many scheduling problems with precedence constraints that are chains has been well-investigated. An influential paper of Lenstra and Rinnooy Kan [27] shows strong NP-hardness for minimizing the number of chain-constrained unit-size jobs that miss their deadline on a single machine. Several other works with chain constraints have appeared [15, 21, 26, 37].

Towards analogues of TSP-PC, we may consider the problem  $Pm|prec|C_{\max}$  on a single machine, but add sequence-dependent setup times  $s_{ij} \in \mathbb{Z}_{\geq 0}$  between any two jobs  $i$  and  $j$ , which add to the makespan of the schedule. This problem, which is denoted as  $1|prec, s_{ij}|C_{\max}$ , was discussed by Liaee and Emmons [29, Section 3.1.2]. In case of TSP-PC, the setup times are metric (i.e.,  $s_{ij} \leq s_{ik} + s_{kj}$  for any triple  $(i, j, k)$  of distinct jobs), and all jobs have equal processing time  $p_j \equiv 0$ . To be precise, the objective function for TSP-PC takes into account the cost for returning to the origin city whereas no such cost occurs in the objective function for  $1|prec, s_{ij}|C_{\max}$ , hence the latter in fact models a path version of TSP-PC.

We remark that shortly after the first dissemination of this work [1], Böhm, Friggstad, Mömke, and Spoerhase [8] provided an independent paper on TSP variants, including a result matching the guarantee in Theorem 1. Albeit different at first sight, their approach is very similar at its core to the one presented here: They use a directed analogue of the LP relaxation that we also build our work on here, and thereby facilitate a direct application of the original result by Bang-Jensen, Frank, and Jackson on packing branchings in a directed multigraph.

## 1.3 Organization of the paper

In Section 2, we introduce our new linear programming formulation for OTSP (Section 2.1) and analyze a randomized algorithm giving the guarantee of Theorem 1 in expectation (Section 2.2). We show how this algorithm can be derandomized in Section 2.3. Finally, Section 3 extends our framework to yield Theorem 2, and Section 4 shows how our main technical lemma is implied by a closely related known result.

## 2 Our algorithm

### 2.1 The LP relaxation and polyhedral basics

The most commonly used LP relaxation in approximation algorithms for classic TSP is the so-called *Held-Karp relaxation*. It was first introduced by Dantzig, Fulkerson, and Johnson [12] and is given by

$$P_{\text{HK}}(G) := \left\{ x \in \mathbb{R}_{\geq 0}^E : \begin{array}{l} x(\delta(v)) = 2 \quad \forall v \in V \\ x(\delta(S)) \geq 2 \quad \forall S \subsetneq V, S \neq \emptyset \end{array} \right\},$$

where  $G = (V, E)$  is the underlying complete graph.<sup>3</sup> While TSP simply asks for a spanning cycle, OTSP requires that the vertices  $d_1, \dots, d_k$  appear on the cycle in this order. Thus, a solution is naturally composed of  $k$  strolls, namely a  $d_i$ - $d_{i+1}$  stroll for every  $i \in \{1, \dots, k\}$ . For a polyhedral description of  $s$ - $t$  strolls in a complete graph  $G = (V, E)$ , we modify the Held-Karp relaxation for  $s$ - $t$  path TSP<sup>4</sup> to allow partial coverage of vertices. Concretely, the variables  $y \in \mathbb{R}_{\geq 0}^V$  in the following formulation indicate the extent at which vertices are covered.<sup>5</sup>

$$P_{s-t \text{ stroll}}(G) := \left\{ (x, y) \in \mathbb{R}_{\geq 0}^E \times \mathbb{R}_{\geq 0}^V : \begin{array}{l} x(\delta(v)) = 2y_v \quad \forall v \in V \\ x(\delta(S)) \geq 1 \quad \forall S \subseteq V \setminus \{t\}, s \in S \\ x(\delta(S)) \geq 2y_v \quad \forall S \subseteq V \setminus \{s, t\}, v \in S \\ y_s = y_t = 1/2 \end{array} \right\}. \quad (1)$$

Note that setting  $y_s = y_t = 1/2$  corresponds to  $s$  and  $t$  having degree 1 in an  $s$ - $t$  stroll, while all interior vertices of an integral stroll have degree 2, which corresponds to a  $y$ -value of 1. Using the above polyhedral relaxation (1) for all  $d_i$ - $d_{i+1}$  strolls, it remains to link the strolls by requiring full joint coverage of every  $v \in V$ . This results in the following LP relaxation for OTSP:

$$\begin{aligned} \min \quad & \sum_{e \in E} c_e \sum_{i=1}^k x_e^i \\ & \sum_{i=1}^k y_v^i = 1 \quad \forall v \in V \\ & (x^i, y^i) \in P_{d_i-d_{i+1} \text{ stroll}}(G) \quad \forall i \in \{1, \dots, k\}. \end{aligned} \quad (\text{OTSP LP relaxation})$$

Here and throughout the paper, note that we use superscripts to distinguish different strolls. It is clear that any OTSP solution can be turned into a feasible solution to the above LP of the same objective value, hence the above LP is indeed a relaxation of OTSP. We first observe that this OTSP LP relaxation strengthens the Held-Karp relaxation in the following sense.

► **Observation 3.** *Let  $(x^i, y^i)_{i \in \{1, \dots, k\}}$  be feasible for the OTSP LP relaxation. Then  $x := \sum_{i=1}^k x^i \in P_{\text{HK}}(G)$ .*

<sup>3</sup> For  $S \subseteq V$  we denote by  $\delta(S)$  the set of edges with exactly one endpoint in  $S$ . For  $v \in V$ , we abbreviate  $\delta(v) := \delta(\{v\})$ .

<sup>4</sup> Given a complete graph  $G = (V, E)$  with metric edge costs and vertices  $s, t \in V$ ,  $s$ - $t$  path TSP is the variant of TSP that seeks a path of smallest total cost from  $s$  to  $t$  while visiting every vertex exactly once.

<sup>5</sup> The constraints of  $P_{s-t \text{ stroll}}$  imply that for  $v \in V \setminus \{s, t\}$ , we have  $2y_v \leq x(\delta(V \setminus \{s, t\})) \leq x(\delta(s)) + x(\delta(t)) \leq 2$ , and thus  $y_v \leq 1$ , legitimating the proposed interpretation.

**Proof.** To see that  $x$  satisfies the degree constraints in  $P_{\text{HK}}(G)$ , note that for all  $v \in V$ , we have

$$x(\delta(v)) = \sum_{i=1}^k x^i(\delta(v)) = 2 \cdot \sum_{i=1}^k y_i = 2 .$$

To verify the cut constraints, let  $S \subsetneq V$  be a non-empty set of vertices. If both  $S \cap \{d_1, \dots, d_k\} \neq \emptyset$  and  $(V \setminus S) \cap \{d_1, \dots, d_k\} \neq \emptyset$ , then there exist two distinct indices  $i_1, i_2 \in \{1, \dots, k\}$  such that  $d_{i_1} \in S$  but  $d_{i_1+1} \notin S$ , and  $d_{i_2} \notin S$  but  $d_{i_2+1} \in S$ . This implies that  $x^{i_1}(\delta(S)) \geq 1$  and  $x^{i_2}(\delta(V \setminus S)) \geq 1$ , so we get

$$x(\delta(S)) = \sum_{i=1}^k x^i(\delta(S)) \geq x^{i_1}(\delta(S)) + x^{i_2}(\delta(S)) = x^{i_1}(\delta(S)) + x^{i_2}(\delta(V \setminus S)) \geq 2 .$$

Otherwise, assume without loss of generality that  $S \cap \{d_1, \dots, d_k\}$  is empty (if not,  $V \setminus S$  has this property) and fix a vertex  $v \in S$ . We then know that  $x^i(\delta(S)) \geq 2y_v$  for all  $i \in \{1, \dots, k\}$ , hence

$$x(\delta(S)) = \sum_{i=1}^k x^i(\delta(S)) \geq 2 \cdot \sum_{i=1}^k y_v = 2 . \quad \blacktriangleleft$$

The point  $x \in P_{\text{HK}}(G)$  constructed in Observation 3 has the property that its cost  $c^\top x$  equals the objective value  $c_{\text{LP}}$  of the feasible point of the OTSP LP relaxation that we started with. Thus, following the arguments of Wolsey's polyhedral analysis [38] of the Christofides-Serdyukov algorithm, we immediately obtain the following.

► **Corollary 4.** *Let  $c_{\text{LP}}$  denote the optimal objective value of the OTSP LP relaxation. Then in the underlying graph  $G$  with edge costs  $c$ , the following holds true.*

- (i) *A shortest spanning tree  $T$  satisfies  $c(T) \leq c_{\text{LP}}$ .*
- (ii) *For any even cardinality set  $Q \subseteq V$ , a shortest  $Q$ -join  $J$  satisfies  $c(J) \leq \frac{1}{2} \cdot c_{\text{LP}}$ .*

**Proof.** Let  $(x^i, y^i)_{i \in \{1, \dots, k\}}$  be an optimal solution of the OTSP LP relaxation. By Observation 3,  $x := \sum_{i=1}^k x^i \in P_{\text{HK}}(G)$ . It is well-known due to Held and Karp [20] that then,  $\frac{|V|-1}{|V|} \cdot x$  is feasible for the spanning tree polytope, and due to Wolsey [38] that  $\frac{1}{2}x$  is feasible for the dominant of the  $Q$ -join polytope, hence  $c(T) \leq \frac{|V|-1}{|V|} \cdot c^\top x < c^\top x$  and  $c(J) \leq \frac{1}{2}c^\top x$ . Using that  $c^\top x = c_{\text{LP}}$ , the result follows. ◀

## 2.2 Rounding an LP solution

At its core, our algorithm for rounding a typically fractional solution  $(x^i, y^i)_{i \in \{1, \dots, k\}}$  of the OTSP LP relaxation is based on leveraging a decomposition result for each of the points  $(x^i, y^i) \in P_{d_i-d_{i+1} \text{ stroll}}$ . By scaling up  $(x^i, y^i)$  by a large enough factor  $M$  such that  $Mx^i$  is integral, this decomposition can be viewed as a result on packing trees into the multigraph that has  $Mx_e^i$  copies of every edge  $e \in E$  and such that every vertex  $v$  appears in  $My^i$  many of the trees. While most results of this type deal with packing spanning trees (or, in the directed case, arborescences), i.e., consider uniform packings, Bang-Jensen, Frank, and Jackson [3] gave one of few results in a non-uniform setting as we are facing here. Their splitting-off based construction was revised by Blauth and Nägele [5] to obtain more fine-grained control over the output components of the decomposition when starting from a solution of a Held-Karp-type relaxation that allows partial coverage of vertices (similar to what we allow in  $P_{s-t \text{ stroll}}$ ). We observe that these findings can be immediately carried over to solutions of  $P_{s-t \text{ stroll}}$ , giving Lemma 5 below. We defer a formal proof to Section 4.

► **Lemma 5.** *Let  $G = (V, E)$  be an undirected graph,  $s, t \in V$ , and let  $(x, y) \in P_{s-t \text{ stroll}}(G)$ . We can in polynomial time compute a family  $\mathcal{T}$  of subtrees of  $G$  that each contain the vertices  $s$  and  $t$ , and weights  $\mu \in [0, 1]^{\mathcal{T}}$  with  $\sum_{T \in \mathcal{T}} \mu_T = 1$  such that<sup>6</sup>*

$$\sum_{T \in \mathcal{T}} \mu_T \chi^{E[T]} = x \quad \text{and} \quad \sum_{T \in \mathcal{T}: v \in V[T]} \mu_T = y_v \quad \forall v \in V \setminus \{s, t\} .$$

In other words, Lemma 5 allows to decompose a fractional  $s$ - $t$  stroll into a convex combination of trees in a family  $\mathcal{T}$  that all connect  $s$  and  $t$ , and such that for every other vertex  $v \in V \setminus \{s, t\}$ , the weighted number of trees that contain  $v$  equals the coverage  $y_v$  of  $v$  in the stroll. An example of a feasible solution  $(x, y)$  and a decomposition satisfying the properties of Lemma 5 is given in Figure 1.

(a) Solution  $(x, y)$  with  $x_e = 1/4$  for dotted edges,  $x_e = 1/2$  for dashed edges, and  $x_e = 3/4$  for solid edges. Likewise,  $y_v = 1/4$  for blank vertices,  $y_v = 1/2$  for dashed vertices, and  $y_v = 3/4$  for full vertices.

(b) A decomposition of the solution  $(x, y)$  given in (a) into four trees with uniform weight  $\mu \equiv 1/4$  satisfying the properties of Lemma 5.

■ **Figure 1** A solution  $(x, y) \in P_{s-t \text{ stroll}}$  along with a decomposition into trees, exemplifying Lemma 5.

After applying Lemma 5 to all strolls  $(x^i, y^i) \in P_{d_i-d_{i+1} \text{ stroll}}$  obtained from an optimal solution of the OTSP LP relaxation, we choose one tree from each of the decompositions and consider the (multi-)union of all edges obtained this way. This results in a graph that already contains a closed walk with visits at  $d_1, \dots, d_k$  in this order, giving the basis for our construction of an OTSP solution. Also, we can easily bound the expected cost of the edge set obtained in this way by randomly choosing the trees with marginals given by the weights  $\mu$  from Lemma 5.

<sup>6</sup> For a graph  $H$  we denote by  $V[H]$  the set of vertices and by  $E[H]$  the set of edges of  $H$ . Furthermore, for an edge set  $F \subseteq E$ , we denote by  $\chi^F \in \{0, 1\}^E$  the characteristic vector of  $F$ , i.e., the  $\{0, 1\}$ -vector with, for all  $e \in E$ ,  $\chi_e^F = 1$  if and only if  $e \in F$ .

To obtain an actual OTSP solution, the missing steps are to

- (i) connect vertices that are not covered by any of the trees  $T_i$ ,
- (ii) perform parity correction to guarantee that there exists an Eulerian tour, and
- (iii) shortcut appropriately to obtain an actual OTSP solution.

Altogether, this leads to the randomized Algorithm 1 as laid out below; also see Figure 2 for an example illustration of the different edge sets that are constructed in Algorithm 1.

■ **Algorithm 1** A randomized approximation algorithm for OTSP.

---

**Input:** OTSP instance  $(G, c, \{d_1, \dots, d_k\})$  on graph  $G = (V, E)$ .

- 1 Compute an optimal solution  $(x^i, y^i)_{i \in \{1, \dots, k\}}$  to the OTSP LP relaxation.
- 2 **foreach**  $i \in \{1, \dots, k\}$  **do**
- 3     Apply Lemma 5 to decompose  $(x^i, y^i)$  into trees  $\mathcal{T}_i$  with weights  $\mu^i$ .
- 4     Sample one tree  $T_i$  from  $\mathcal{T}_i$  with marginals given by  $\mu^i$ .
- 5 Compute a minimum-cost edge set  $F \subseteq E$  such that the multigraph

$$H := \left( V, F \cup \bigcup_{i \in \{1, \dots, k\}} E[T_i] \right)$$

is connected.

- 6 Let  $Q = \text{odd}(H)$  and compute a minimum cost  $Q$ -join  $J$  in  $G$ .
  - 7 **return** Spanning cycle  $C$  in  $G$  obtained from  $H \dot{\cup} J$  through Lemma 10.
- 

We first show that Algorithm 1 gives the guarantees claimed by Theorem 1 in expectation and – even stronger – with respect to the value  $c_{\text{LP}}$  of the OTSP LP relaxation, as stated in the subsequent theorem. In Section 2.3, we show that Algorithm 1 admits an immediate derandomization using the method of conditional expectation, thereby completing the proof of Theorem 1.

■ **Figure 2** Exemplifying the construction of Eulerian graph  $H \dot{\cup} J$  from Algorithm 1: Trees  $T_1, T_2, T_3, T_4$  drawn as solid blueish edges, the edge set  $F$  connecting all vertices to the trees drawn as curly red edges, and the  $\text{odd}(H)$ -join  $J$  drawn as dashed green edges.

► **Theorem 6.** *Let  $c_{LP}$  be the cost of an optimal solution of the OTSP LP relaxation. Algorithm 1 returns in polynomial time an OTSP solution  $C$  satisfying*

$$\mathbb{E}[c(E[C])] \leq \left(\frac{3}{2} + \frac{1}{e}\right) \cdot c_{LP} .$$

To prove Theorem 6, we first study the random graph  $H_0 := (V, \dot{\bigcup}_{i \in \{1, \dots, k\}} E[T_i])$  obtained from taking the union of trees  $T_i \in \mathcal{T}_i$  for all  $i \in \{1, \dots, k\}$  as sampled in Algorithm 1. In order for the following statements to also be applicable in a proof of Theorem 2, we refer to the tree distributions of the type generated in Algorithm 1 as *connecting tree distributions*.

► **Definition 7** (Connecting tree distribution). *Let  $G = (V, E)$  be a graph and let  $d_1, \dots, d_k \in V$ . A connecting tree distribution  $(\mathcal{T}_i, \mu^i)_{i \in \{1, \dots, k\}}$  consists of a family  $\mathcal{T}_i$  of subtrees of  $G$  and marginals  $\mu^i: \mathcal{T}_i \rightarrow (0, 1]$  for every  $i \in \{1, \dots, k\}$  with the following properties.*

- (i)  $\sum_{T \in \mathcal{T}_i} \mu_T^i = 1$  for all  $i \in \{1, \dots, k\}$ .
- (ii)  $V[T] \cap \{d_1, \dots, d_k\} = \{d_i, d_{i+1}\}$  for all  $T \in \mathcal{T}_i$  and  $i \in \{1, \dots, k\}$ .
- (iii)  $\sum_{i=1}^k \sum_{T \in \mathcal{T}_i: v \in V[T]} \mu_T^i = 1$  for all  $v \in V \setminus \{d_1, \dots, d_k\}$ .

The distributions  $(\mathcal{T}_i, \mu^i)$  obtained in Algorithm 1 by applying Lemma 5 indeed satisfy the constraints of the above definition; in particular, Item iii is fulfilled because

$$\sum_{i=1}^k \sum_{T \in \mathcal{T}_i: v \in V[T]} \mu_T^i = \sum_{i=1}^k y_v^i = 1 \quad \forall v \in V \setminus \{d_1, \dots, d_k\} ,$$

where the first equality follows from Lemma 5, and the second one is implied by constraints of  $P_{d_i-d_{i+1}}^{\text{stroll}}$ .

► **Lemma 8.** *Let  $G = (V, E)$  be a graph,  $d_1, \dots, d_k \in V$ , and let  $(\mathcal{T}_i, \mu^i)$  be a connecting tree distribution.*

- (i) *For any choice of trees  $T_i \in \mathcal{T}_i$  for  $i \in \{1, \dots, k\}$ , the multigraph  $H_0 := (V, \dot{\bigcup}_{i \in \{1, \dots, k\}} E[T_i])$  consists of one large connected component and potentially several isolated vertices. The large connected component contains a walk with visits at  $d_1, \dots, d_k$  in this order that can be constructed efficiently from the trees  $T_i$ .*
- (ii) *If, in the above construction, the trees  $T_i$  are sampled with marginals  $\mu^i$ , we have that for all  $v \in V \setminus \{d_1, \dots, d_k\}$ ,*

$$\mathbb{P}[v \text{ is isolated in } H_0] \leq \frac{1}{e} .$$

**Proof.** For Item i observe that each tree  $T_i$  is connected within itself by definition and, as it contains  $d_i$  and  $d_{i+1}$ , the union of all trees form one large connected component, while all other components must be isolated vertices. Also, because each tree  $T_i$  contains a  $d_i-d_{i+1}$  path, we may concatenate these paths to obtain the desired walk with visits at  $d_1, \dots, d_k$  in this order.

To prove Item ii, we calculate the probability that a vertex  $v \in V \setminus \{d_1, \dots, d_k\}$  is isolated in  $H_0$ . First, note that for any such vertex  $v$  and any  $i \in \{1, \dots, k\}$ , we have

$$\mathbb{P}[v \notin V[T_i]] = 1 - \sum_{T \in \mathcal{T}_i: v \in V[T]} \mu_T^i .$$

**1:10 A  $(3/2 + 1/e)$ -Approximation Algorithm for Ordered TSP**

Thus, the probability that a vertex  $v \in V \setminus \{d_1, \dots, d_k\}$  is not contained in any tree  $T_i$  for  $i \in \{1, \dots, k\}$ , and hence is isolated in  $H_0$ , can be bounded as follows:

$$\begin{aligned} \mathbb{P}\left[v \notin \bigcup_{i=1}^k V[T_i]\right] &= \prod_{i=1}^k \mathbb{P}[v \notin V[T_i]] = \prod_{i=1}^k \left(1 - \sum_{T \in \mathcal{T}_i: v \in V[T]} \mu_T^i\right) \\ &\leq \exp\left(-\sum_{i=1}^k \sum_{T \in \mathcal{T}_i: v \in V[T]} \mu_T^i\right) = \frac{1}{e}, \end{aligned}$$

where we used that  $1 - t \leq \exp(-t)$  for all  $t \in \mathbb{R}$ , and  $\sum_{i=1}^k \sum_{T \in \mathcal{T}_i: v \in V[T]} \mu_T^i = 1$  because  $(\mathcal{T}_i, \mu^i)$  is a connecting tree distribution.  $\blacktriangleleft$

Next, we bound the cost of the minimum-cost connector  $F$  computed in Line 1 of Algorithm 1.

► **Lemma 9.** *Let  $G = (V, E)$  be a graph with metric edge costs  $c$ , let  $d_1, \dots, d_k \in V$ , and let  $T$  be a minimum-cost spanning tree of  $(G, c)$ .*

- (i) *For all  $v \in V \setminus \{d_1\}$ , let  $e_v$  denote the unique edge outgoing of  $v$  when orienting  $T$  towards  $d_1$ . For every graph  $H_0$  on the vertex set  $V$  with components that are – up to possibly the component containing  $d_1$  – singleton vertices, the minimum-cost edge set  $F$  that connects  $H_0$  satisfies*

$$c(F) \leq \sum_{v \text{ isolated in } H_0} c(e_v).$$

- (ii) *Let  $(\mathcal{T}_i, \mu^i)$  for  $i \in \{1, \dots, k\}$  be a connecting tree distribution. If the trees  $T_i \in \mathcal{T}_i$  are sampled with marginals  $\mu^i$  and  $H_0 := (V, \bigcup_{i \in \{1, \dots, k\}} E[T_i])$ , we obtain*

$$\mathbb{E}[c(F)] \leq \frac{1}{e} c(T).$$

**Proof.** In order to prove Item i, we construct a feasible connecting edge set  $F'$  as the set of all edges  $e_v$  for which  $v$  is an isolated vertex. Then  $H_0 \cup F'$  is indeed connected, because each isolated vertex of  $H_0$  is connected to its predecessor in  $T$  by an edge of  $F'$ , hence inductively, the component of  $H_0$  containing  $d_1$  can be reached along edges of  $F'$ . As the minimum-cost connector  $F$  has cost at most  $c(F')$ , we have

$$c(F) \leq c(F') \leq \sum_{v \text{ isolated in } H_0} c(e_v).$$

To prove Item ii, we note that in this case,  $H_0$  consists of one large connected component and some isolated vertices by Item i of Lemma 8. Using Item ii of Lemma 8 on top of the above, we get

$$\mathbb{E}[c(F)] \leq \mathbb{E}[c(F')] = \sum_{v \in V \setminus \{d_1\}} \mathbb{P}[v \text{ isolated in } H_0] \cdot c(e_v) \leq \frac{1}{e} \sum_{v \in V \setminus \{d_1\}} c(e_v) = \frac{1}{e} c(E[T]). \blacktriangleleft$$

The cost of the odd( $H$ )-join  $J$  constructed in Line 1 of Algorithm 1 can be bounded by  $\frac{1}{2}c^\top x$  by Item ii of Corollary 4. Hence, to complete the analysis of Algorithm 1, it is left to show that from the Eulerian graph  $H \cup J$  constructed in Line 1 of Algorithm 1, we can obtain an OTSP solution of no larger cost. We remark that such a step has also been used by Böckenhauer, Mömke, and Steinová [7]; we repeat it here explicitly and give a slightly

different proof for completeness. In the proof, we repeatedly use the operation of *shortcutting* a vertex  $v$  on a walk, which is the following: If the predecessor and successor of  $v$  on the walk are  $u$  and  $w$ , respectively, we delete the edges  $\{u, v\}$  and  $\{v, w\}$  from the walk and add the direct edge  $\{u, w\}$  instead. It is clear that this operation results in a walk again; furthermore, by the triangle inequality, the costs of the walk do not increase under such operations.

► **Lemma 10.** *Let  $G = (V, E)$  be a complete graph with metric edge costs  $c$ , and let  $d_1, \dots, d_k \in V$  be distinct. Given an undirected connected Eulerian multigraph  $M = (V, E_M)$  together with a closed walk in  $M$  with visits at  $d_1, \dots, d_k$  in this order, we can in polynomial time determine a spanning cycle  $C$  in  $G$  with visits at  $d_1, \dots, d_k$  in this order of cost at most  $c(E_M)$ .*

**Proof.** Let  $C$  be the given closed walk on which  $d_1, \dots, d_k$  appear in this order, delete  $C$  from  $M$  and partition the remaining Eulerian graph into a set  $\mathcal{W}$  of closed walks. Shortcut  $C$  to a cycle while maintaining visits at  $d_1, \dots, d_k$  in this order. This can, for example, be done by traversing  $C$  starting at  $d_1$ , and shortcutting

- (i) vertices that have already been visited, and
- (ii) vertices  $d_i$  that are not yet to be visited due to the order constraint.

Afterwards, as long as  $\mathcal{W}$  is non-empty, pick a closed walk  $W$  from  $\mathcal{W}$  that intersects  $C$ , and let  $v$  be a vertex in the intersection. Traversing  $W$  starting from  $v$ , shortcut  $W$  to a cycle by skipping, except for  $v$  itself, all vertices that are already contained in  $C$ . Then, merge  $W$  into  $C$  by first traversing  $C$  up to (and including)  $v$ , then completely traversing  $W$  until (but not including)  $v$  before continuing on  $C$ , thereby including only one visit at  $v$  in the updated  $C$ . It is immediate that  $C$  is still a cycle after any such operation, and the vertices  $d_1, \dots, d_k$  still appear on  $C$  once and in this order. By connectivity of  $M$ , this procedure only terminates once  $\mathcal{W}$  is empty, and in that case,  $C$  is a spanning cycle of  $G$ . Also, all steps can be implemented to run in polynomial time. Clearly, the final length of  $C$  with respect to  $c$  is at most  $c(E_M)$  because  $c$  is metric. ◀

From the above ingredients, we can readily prove Theorem 6.

**Proof of Theorem 6.** The solution returned by Algorithm 1 is a spanning cycle  $C$  in  $G$  obtained from  $H \dot{\cup} J$  through Lemma 10, hence it is feasible and of cost at most  $c(E[H \dot{\cup} J])$ . Note that the required closed walk in  $H \dot{\cup} J$  with visits at  $d_1, \dots, d_k$  in this order is guaranteed and can be constructed efficiently from the trees  $T_i$  by Item i of Lemma 8. Furthermore, by Item ii of Lemma 9 and Corollary 4, we know that  $\mathbb{E}[c(F)] \leq 1/e \cdot c(T) \leq 1/e \cdot c_{\text{LP}}$ , where  $T$  is a minimum-cost spanning tree. In addition, Corollary 4 also implies that  $c(E[J]) \leq \frac{1}{2} \cdot c_{\text{LP}}$ . Last but not least, we can express the expected cost of each  $T_i$  as

$$\mathbb{E}[c(E[T_i])] = \sum_{T \in \mathcal{T}_i} \mu_T^i c(E[T]) = \sum_{T \in \mathcal{T}_i} \mu_T^i c^\top \chi^{E[T]} = c^\top x^i \quad \forall i \in \{1, \dots, k\} .$$

Thus, by summing over all constructed trees, we obtain  $\sum_{i=1}^k \mathbb{E}[c(E[T_i])] = \sum_{i=1}^k c^\top x^i = c_{\text{LP}}$ . Together, this yields the proclaimed bound

$$\mathbb{E}[c(C)] \leq \mathbb{E}[c(E[H \dot{\cup} J])] \leq \left( \frac{3}{2} + \frac{1}{e} \right) \cdot c_{\text{LP}} .$$

It remains to note that Algorithm 1 can be implemented to run in polynomial time. To start with, an optimal solution of the OTSP LP relaxation can be found in polynomial time because  $P_{s-t \text{ stroll}}$  admits a polynomial-time separation oracle through polynomially many calls to a minimum-cut algorithm. Next, the decomposition in Line 1 is obtained in

polynomial time, finding an optimal edge set  $F$  in Line 1 can be implemented by Prim's algorithm, and the odd( $H$ )-join is well-known to be computable in polynomial time. Finally, also the computation of the cycle  $C$  in Line 1 is polynomial due to Lemma 10, concluding the proof.  $\blacktriangleleft$

### 2.3 Derandomizing Algorithm 1

To complete a proof of our main result, Theorem 1, we now show how to derandomize Algorithm 1 using the method of conditional expectations, which results in the following proof.

**Proof of Theorem 1.** By the construction of the solution  $C$  in Algorithm 1, using Item i of Lemma 9 to bound the cost of  $F$ , and Item ii of Corollary 4 to bound the cost of  $J$ , we know that

$$\begin{aligned} c(C) &\leq \sum_{i=1}^k c(E[T_i]) + c(F) + c(E[J]) \\ &\leq \underbrace{\sum_{i=1}^k c(E[T_i]) + \sum_{v \notin \bigcup_{i=1}^k V[T_i]} c(e_v)}_{=:g(T_1, \dots, T_k)} + \frac{1}{2} \cdot c_{\text{LP}} \ , \end{aligned} \quad (2)$$

where we recall that  $e_v$ , for  $v \in V \setminus \{d_1\}$ , is the unique outgoing edge at  $v$  when orienting a minimum-cost spanning tree of  $G$  towards  $d_1$ . For Theorem 6, we showed that  $\mathbb{E}[g(T_1, \dots, T_k)] \leq (3/2 + 1/e) \cdot c_{\text{LP}}$ . Following the method of conditional expectations, in order to derandomize the choices of the trees  $T_i$  in Line 1 of Algorithm 1 while maintaining the upper bound on the solution cost, we sequentially choose trees  $S_i$  for  $i \in \{1, \dots, k\}$  such that

$$S_i = \arg \min_{S \in \mathcal{T}_i} \mathbb{E}[g(T_1, \dots, T_k) \mid T_1 = S_1, \dots, T_{i-1} = S_{i-1}, T_i = S] \ . \quad (3)$$

Note that feasibility of the cycle  $C$  and the bound of (2) on its cost are unaffected by fixing  $T_i = S_i$ . By definition of conditional expectation, we know that

$$\begin{aligned} \mathbb{E}[g(T_1, \dots, T_k) \mid T_1 = S_1, \dots, T_{i-1} = S_{i-1}] \\ = \sum_{S \in \mathcal{T}_i} \mu_S^i \cdot \mathbb{E}[g(T_1, \dots, T_k) \mid T_1 = S_1, \dots, T_{i-1} = S_{i-1}, T_i = S] \ , \end{aligned}$$

hence the sequence of conditional expectations

$$(\mathbb{E}[g(T_1, \dots, T_k) \mid T_1 = S_1, \dots, T_i = S_i])_{i \in \{1, \dots, k\}}$$

is non-increasing by the choice in (3), because  $\sum_{S \in \mathcal{T}_i} \mu_S = 1$ . Thus, it remains to observe that the conditional expectations in (3) can be computed. To this end, observe that

$$\begin{aligned} \mathbb{E}[g(T_1, \dots, T_k) \mid T_1 = S_1, \dots, T_\ell = S_\ell] \\ = \sum_{i=1}^{\ell} c(E[S_i]) + \sum_{i=\ell+1}^k \mathbb{E}[c(E[T_i])] + \sum_{v \notin \bigcup_{i=1}^{\ell} V[S_i]} \mathbb{P}\left[v \notin \bigcup_{i=\ell+1}^k V[T_i]\right] c(e_v) + \frac{1}{2} \cdot c_{\text{LP}} \ , \end{aligned}$$

and we can readily compute

$$\mathbb{E}[c(E[T_i])] = \sum_{T \in \mathcal{T}_i} \mu_T^i c(E[T]) \quad \text{and} \quad \mathbb{P}\left[v \notin \bigcup_{i=\ell+1}^k V[T_i]\right] = \prod_{i=\ell+1}^k (1 - y_v^i) \ . \quad \blacktriangleleft$$

### 3 Extending to several independent total orders: Proving Theorem 2

In this section, we show how our approach can be extended to TSP-PC with a specific structure of precedence constraints that corresponds to having total orders on disjoint subsets  $D_1, \dots, D_\ell \subseteq V$  of the input graph  $G = (V, E)$ .

As mentioned in the introduction, our approach is inherently tied to handle total orders – which is why, in the aforementioned setup, our solutions will not interleave vertices from different chains  $D_j$ , but rather treat the chains  $D_j$  one after another. Still, our approach allows to do better than simply constructing OTSP solutions for all subinstances  $(G, c, D_j)$  in a black-box way and concatenating them with appropriate shortcutting. The latter would lead to an immediate  $(3/2 + 1/e)\ell$ -approximate solution by using Algorithm 1 on each subinstance. Instead, we observe that after solving the OTSP LP relaxation and sampling trees for each subinstance as in Algorithm 1, we may join all edges obtained this way and only *once* need to connect remaining singletons and do parity correction. This leads to Algorithm 2 as stated below.

Note that, deviating from the above outline, Algorithm 2 starts by guessing a root node  $d_0$  among the minimal nodes in all sets  $D_j$  with respect to  $\prec$ ; this node is used as a common anchor of the given partial orders and results in connectivity of the multigraph containing all sampled trees. To be able to compare the obtained solution to an optimal solution, we need  $d_0$  to be, among the minimal nodes in all sets  $D_j$ , the first one to appear on an optimal solution. We remark that for one  $j \in \{1, \dots, \ell\}$ , we already have  $d_0 \in D_j$ . For the sake of uniform notation, we still add a copy of  $d_0$  to  $D_j$  in Line 2 of Algorithm 2.

■ **Algorithm 2** Approximating a special case of TSP-PC.

---

**Input:** TSP-PC instance  $(G, c, \prec)$  on graph  $G = (V, E)$ , where  $\prec$  precisely induces total orders on disjoint subsets  $D_1, \dots, D_\ell \subseteq V$ .

- 1 Guess a root node  $d_0$  among the minimal nodes in  $D_i$  with respect to  $\prec$ .
- 2 **foreach**  $j \in \{1, \dots, \ell\}$  **do**
- 3     Compute an optimal solution  $(x^{ji}, y^{ji})_{i \in \{0, 1, \dots, |D_j|\}}$  to the OTSP LP relaxation for the OTSP instance  $(G, c, \{d_0\} \dot{\cup} D_j)$  with an order given by  $\prec$  extended by  $d_0 \prec D_j$ .
- 4     **foreach**  $i \in \{0, 1, \dots, |D_j|\}$  **do**
- 5         Apply Lemma 5 to decompose  $(x^{ji}, y^{ji})$  into trees  $\mathcal{T}_{ji}$  with weights  $\mu^{ji}$ .
- 6         Sample one tree  $T_{ji}$  from  $\mathcal{T}_{ji}$  with marginals given by  $\mu^{ji}$ .
- 7 Compute a minimum-cost edge set  $F \subseteq E$  such that the multigraph

$$H := \left( V, F \cup \bigcup_{j=1}^{\ell} \bigcup_{i \in \{1, \dots, |D_j|\}} E[T_{ji}] \right)$$

is connected.

- 8 Let  $Q = \text{odd}(H)$  and compute a minimum cost  $Q$ -join  $J$  in  $G$ .
  - 9 **return** Shortest spanning cycle  $C$  in  $G$  (over all guesses of  $d_0$ ) that visits  $d_0, D_1 \setminus \{d_0\}, \dots, D_\ell \setminus \{d_0\}$  in this order (while respecting  $\prec$  in each  $D_i$ ) and is obtained from  $H \dot{\cup} J$  through Lemma 10.
-

## 1:14 A $(3/2 + 1/e)$ -Approximation Algorithm for Ordered TSP

We show that this algorithm gives the guarantee claimed by Theorem 2 in expectation, and that it can be derandomized using the method of conditional expectations in a way analogous to the derandomization of Algorithm 1.

**Proof of Theorem 2.** Let  $c_{\text{OPT}}$  denote the cost of an optimal solution of the given TSP-PC instance. For every  $j \in \{1, \dots, \ell\}$ , note that the value  $c_{\text{LP}}^j$  of the optimal solution  $(x^{j_i}, y^{j_i})_{i \in \{1, \dots, |D_j|\}}$  to the OTSP instance  $(G, c, \{d_0\} \dot{\cup} D_j)$  generated in Line 2 of Algorithm 2 satisfies  $c_{\text{LP}}^j \leq c_{\text{OPT}}$ . For every  $j \in \{1, \dots, \ell\}$ , denote

$$H_j := \left( V, \bigcup_{i=0}^{|D_j|} E[T_{j_i}] \right) .$$

Every such graph is composed of trees from a connecting tree distribution. Hence, by Item i of Lemma 8,  $H_j$  consists of a large connected component that contains a walk with visits at  $d_0$  and all vertices of  $D_j$  in the desired order, and potentially isolated vertices. For all  $v \notin \{d_0\} \cup D_j$ , Item ii of Lemma 8 implies that

$$\mathbb{P}[v \text{ is isolated in } H_j] \leq \frac{1}{e} .$$

Also, observe that

$$\mathbb{E}[c(E[H_j])] = \sum_{i=0}^{|D_j|} \mathbb{E}[c(T_{j_i})] = \sum_{i=0}^{|D_j|} \sum_{T \in \mathcal{T}_{j_i}} \mu_T^{j_i} c(E[T]) = \sum_{i=0}^{|D_j|} c^\top x^{j_i} = c_{\text{LP}}^j \leq c_{\text{OPT}} .$$

Consequently, the multigraph  $H_0 := \bigcup_{j \in \{1, \dots, \ell\}} H_j$  has total edge cost at most  $\ell \cdot c_{\text{OPT}}$ . Furthermore,  $H_0$  has one large connected component that contains a walk with visits at  $d_0, D_1 \setminus \{d_0\}, \dots, D_j \setminus \{d_0\}$  in this order (obtained by concatenating the walks obtained in the graphs  $H_j$  above), i.e., a walk that respects  $\prec$ . Also, because the graphs  $H_1, \dots, H_\ell$  are independent,

$$\mathbb{P}[v \text{ is isolated in } H_0] = \prod_{j=1}^{\ell} \mathbb{P}[v \text{ is isolated in } H_j] \leq \frac{1}{e^\ell} .$$

Hence, by Item i of Lemma 9, the cost of the minimum-cost edge set  $F$  connecting  $H_0$ , as constructed in Line 2 of Algorithm 2, can be bounded as follows:

$$\mathbb{E}[c(F)] \leq \sum_{v \text{ isolated in } H_0} \mathbb{P}[v \text{ is isolated in } H_0] \cdot c(e_v) \leq \frac{1}{e^\ell} \cdot c(T) \leq \frac{1}{e^\ell} \cdot c_{\text{OPT}} .$$

Here, we used that for any  $j \in \{1, \dots, \ell\}$ , we have  $c(T) \leq c_{\text{LP}}^j$  by Item i of Corollary 4, and  $c_{\text{LP}}^j \leq c_{\text{OPT}}$  as mentioned above. Similarly, by Item ii of Corollary 4, we know that the cost of a cheapest odd( $H$ )-join  $J$  in the multigraph  $H = H_0 \cup F$  can be bounded by  $c(E[J]) \leq \frac{1}{2} \cdot c_{\text{LP}}^j$  for any  $j \in \{1, \dots, \ell\}$ , hence  $c(E[J]) \leq \frac{1}{2} \cdot c_{\text{OPT}}$ .

Altogether, we obtain a connected Eulerian multigraph  $H \dot{\cup} J$  together with a walk that has visits at  $d_0, D_1 \setminus \{d_0\}, \dots, D_j \setminus \{d_0\}$  in the order given by  $\prec$ , and

$$\mathbb{E}[c(E[H \dot{\cup} J])] \leq \left( \ell + \frac{1}{2} + \frac{1}{e^\ell} \right) \cdot c_{\text{OPT}} .$$

Thus, by Lemma 10, we can efficiently find a cycle with visits at  $d_0, D_1 \setminus \{d_0\}, \dots, D_j \setminus \{d_0\}$  in the order given by  $\prec$  of at most the above expected cost.

Finally, to derandomize the random selection of trees  $T_{ji}$  in Algorithm 2, we observe that the present randomized analysis relies on a bound of the form

$$c(C) \leq \sum_{j=1}^{\ell} \sum_{i=0}^{|D_j|} c(T_{ji}) + \sum_{v \notin \dot{\bigcup}_{j \in \{1, \dots, \ell\}} \dot{\bigcup}_{i \in \{1, \dots, |D_j|\}} V[T_{ji}]} c(e_v) + \frac{1}{2} \cdot c_{\text{OPT}} .$$

The conditional expectations of this bound with respect to fixing any subset of the trees  $T_{ji}$  can be readily computed. Thus, the derandomization works analogously to Algorithm 1 by the method of conditional expectations, in each iteration fixing one of the  $T_{ji}$ . To complete the proof of Theorem 6, we observe that all steps of Algorithm 2 can be implemented to run in polynomial time.  $\blacktriangleleft$

► **Remark 11.** We remark that the analysis of Algorithm 2 above is with respect to the actual cost  $c_{\text{OPT}}$  of an optimal TSP-PC solution. Alternatively, after guessing a root node  $d_0$ , one could also write an LP relaxation generalizing the OTSP LP relaxation by introducing independent copies of the variables for each chain  $\{d_0\} \cup D_j$  and minimizing the cost of a point  $x \in P_{\text{HK}}(G)$  that dominates the edge usage within each of the copies. For the ease of presentation, though, we decided to present the above analysis only.

## 4 Proof of Lemma 5

As mentioned earlier, we derive Lemma 5 from a closely related result used by Blauth and Nägele [5, Lemma 4.2]. We restate their result here in a slightly simplified form that follows immediately from the original formulation.

► **Lemma 12** ([5, Lemma 4.2]). *Let  $G = (V, E)$  be a graph with  $r \in V$ , let  $(x, y) \in \mathbb{R}_{\geq 0}^E \times \mathbb{R}_{\geq 0}^V$  be feasible for the system*

$$\begin{aligned} x(\delta(v)) &= 2y_v \quad \forall v \in V \\ x(\delta(S)) &\geq 2y_v \quad \forall S \subseteq V \setminus \{r\}, v \in S \\ y_r &= 1 \end{aligned} \tag{4}$$

and assume that there is a vertex  $u \in V \setminus \{r\}$  such that  $y_u = 1$  and  $e_0 = \{u, r\}$  satisfies  $x_{e_0} \geq 1$ . We can in polynomial time construct a set  $\mathcal{T}$  of trees that all contain the vertices  $r$  and  $u$ , and weights  $\mu \in [0, 1]^T$  with  $\sum_{T \in \mathcal{T}} \mu_T = 1$  and the following properties.

(i) *The point  $x \in \mathbb{R}_{\geq 0}^E$  is a conic combination of the trees in  $\mathcal{T}$  with weights  $\mu$  and the edge  $e_0$ , i.e.,*

$$x = \sum_{T \in \mathcal{T}} \mu_T \chi^{E[T]} + \chi^{e_0} .$$

(ii) *For every  $v \in V \setminus U$ ,*

$$\sum_{T \in \mathcal{T}: v \in V[T]} \mu_T = y_v .$$

The proof of Lemma 12 relies on the well-known *splitting-off* technique (see, e.g., [16,30,31]) applied in the graph  $G$  with weights  $x$ . Indeed, the constraints in the system (4) can be interpreted as  $r$ - $v$  connectivity requirements for all  $v \in V \setminus \{r\}$ , hence splitting-off allows to remove a vertex from the graph while preserving the connectivity properties of the remaining graph. An inductive construction of the desired family of trees is then achieved by reverting the splitting-off operations and extending trees appropriately. For a complete proof, we refer to Blauth and Nägele [5].

To deduce Lemma 5 from Lemma 12, we note that a point  $(x, y) \in P_{s-t \text{ stroll}}$  can be easily transformed into a point  $(x', y')$  satisfying the assumptions of Lemma 12 by adding one unit to  $x_{\{s,t\}}$  and adjusting  $y_s$  and  $y_t$  accordingly. Note that intuitively, this corresponds to closing an  $s$ - $t$  stroll to obtain a tour by adding a copy of the edge  $\{s, t\}$ .

**Proof of Lemma 5.** Given  $(x, y) \in P_{s-t \text{ stroll}}$ , we assume without loss of generality that  $e_0 := \{s, t\} \in E$  and define  $x' := x + \chi^{\{s,t\}}$  and  $y' = y + \frac{1}{2}(\chi^s + \chi^t)$ . We claim that  $(x', y')$  with  $r = s$  and  $u = t$  satisfy the assumptions of Lemma 12. Indeed,  $y'_s = y'_t = 1$ , and  $x'_{e_0} = x_{e_0} + 1 \geq 1$ . Moreover, for  $v \notin \{s, t\}$ , we have  $x'(\delta(v)) = x(\delta(v)) = 2y_v$ ; for  $v \in \{s, t\}$ , we have  $x'(\delta(v)) = x(\delta(v)) + 1 = 2 = 2y'_v$ , hence the degree constraints in (4) are satisfied. Finally, to verify that the cut constraints of (4) are satisfied, too, let  $S \subseteq V \setminus \{r\}$  and  $v \in S$ . If  $t \notin S$ , then  $x'(\delta(S)) = x(\delta(S)) \geq 2y_v = 2y'_v$  follows from the corresponding constraint of  $P_{s-t \text{ stroll}}$ . If otherwise  $t \in S$ , we know that  $x(\delta(S)) \geq 1$ , hence

$$x'(\delta(S)) = x(\delta(S)) + 1 \geq 2 \geq 2y'_v \text{ ,}$$

where we use that  $y'_v = y_v \leq 1$  is implied by the constraints of  $P_{s-t \text{ stroll}}$  for  $v \in V \setminus \{s, t\}$  (see Footnote 5), and  $y'_s = y'_t = 1$ .

Consequently, by applying Lemma 12 to  $(x', y')$ , we obtain in polynomial time a set  $\mathcal{T}$  of trees that all contain  $s$  and  $t$ , and weights  $\mu \in [0, 1]^{\mathcal{T}}$  with  $\sum_{T \in \mathcal{T}} \mu_T = 1$  such that

$$x + \chi^{e_0} = x' = \sum_{T \in \mathcal{T}} \mu_T \chi^{E[T]} + \chi^{e_0} \text{ ,}$$

i.e.,  $x = \sum_{T \in \mathcal{T}} \mu_T \chi^{E[T]}$ , and, for every  $v \in V \setminus \{s, t\}$ ,

$$\sum_{T \in \mathcal{T} : v \in V[T]} \mu_T = y'_v = y_v \text{ .} \quad \blacktriangleleft$$

## Abstract

In the *Time-Windows TSP* (TW-TSP) we are given requests at different locations on a network; each request is endowed with a reward and an interval of time; the goal is to find a tour that visits as much reward as possible during the corresponding time window. For the online version of this problem, where each request is revealed at the start of its time window, no finite competitive ratio can be obtained. We consider a version of the problem where the algorithm is presented with predictions of where and when the online requests will appear, without any knowledge of the quality of this side information.

Vehicle routing problems such as the TW-TSP can be very sensitive to errors or changes in the input due to the hard time-window constraints, and it is unclear whether imperfect predictions can be used to obtain a finite competitive ratio. We show that good performance can be achieved by explicitly building slack into the solution. Our main result is an online algorithm that achieves a competitive ratio logarithmic in the diameter of the underlying network, matching the performance of the best offline algorithm to within factors that depend on the quality of the provided predictions. The competitive ratio degrades smoothly as a function of the quality and we show that this dependence is tight within constant factors.

## 1 Introduction

Many optimization problems exhibit a large gap in how well they can be optimized offline versus when their input arrives in online fashion. In order to obtain meaningful algorithmic results in the online setting, a natural direction of investigation is to consider “beyond worst case” models that either limit the power of the adversary or increase the power of the algorithm. A recent line of work in this direction has considered the use of *predictions* in bridging the offline versus online gap. Predictions in this context are simply side information about the input that an online algorithm can use for its decision making; the true input is still adversarially chosen and arrives online. The goal is to show that on the one hand, if the predictions are aligned with the input, the algorithm performs nearly as well as in the offline setting (a property known as *consistency*); and on the other hand, if the predictions are completely unrelated to the input, the algorithm nevertheless performs nearly as well as the best online algorithm (a.k.a. *robustness*). *Put simply, good predictions should help, but bad predictions should not hurt, and ideally we should reap the benefits without any upfront knowledge about the quality of the predictions.*

Predictions have been shown to effectively bypass lower bounds for a variety of different online decision-making problems including, for example, caching [30, 31, 25], scheduling [12, 24, 3], online graph algorithms [4], load balancing [27, 28], online set cover [6], matching problems [17],  $k$ -means [19], secretary problems [1, 18], network design [20, 33, 9] and more.<sup>1</sup>

In this paper, we consider a problem whose objective function value is highly sensitive to changes in the input, presenting a significant challenge for the predictions setting. In the Traveling Salesman Problem with Time Windows (TW-TSP for short), we are given a sequence of service requests at different locations on a weighted undirected graph. Each request is endowed with a reward as well as a time window within which it should be serviced. The goal of the algorithm is to produce a path that maximizes the total reward of the requests visited within their respective time windows. In the online setting, the requests arrive one at a time at the start of their respective time windows, and the algorithm must construct a path incrementally without knowing the locations or time windows of future requests.

Vehicle routing problems such as the TW-TSP that involve hard constraints on the lengths of subpaths (e.g. the time at which a location is visited) are generally more challenging than their length-minimization counterparts. In particular, a small bad decision at the beginning of the algorithm, such as taking a slightly suboptimal path to the first request, can completely obliterate the performance of the algorithm by forcing it to miss out on all future reward. In the offline setting, this means that the approximation algorithm has to carefully counter any routing inefficiency in some segments by intentionally skipping reachable value in other segments. In the online setting, this means that no sublinear competitive ratio is possible.

*Given the sensitivity of the TW-TSP objective to small routing inefficiencies, is it possible to design meaningful online algorithms for this problem using imperfect predictions?*

We consider a model where the algorithm is provided with a predicted sequence of requests at the beginning, each equipped with a predicted location and a predicted time window. The true sequence of requests is revealed over time as before. Of course if the predicted sequence is identical to the true request sequence, the algorithm can match the performance of the best offline algorithm. But what if the predictions are slightly off? Could these small errors cause large losses for the online algorithm? Can the algorithm tolerate large deviations?

Our main result is an online algorithm for the TW-TSP based on predictions whose performance degrades smoothly as a function of the errors in prediction. We obtain this result by explicitly building slack into our solution and benchmark. In a slight departure from previous work on TW-TSP, we require the server to spend one unit of idle “service time” at each served request. We show that this is necessary to obtain a sublinear approximation even with predictions (Theorem 9). (However, in the absence of predictions, the setting with service times continues to admit a linear lower bound on the competitive ratio; See Theorem 8.) We then use service times judiciously in planning a route and accounting for delays caused by prediction errors.

There are two primary sources of error in predictions: (1) the predicted locations of requests may be far from the true locations; and, (2) the predicted time windows may be different from the true time windows. The competitive ratio of our algorithm depends linearly on each of these components, taking the maximum error over each predicted request and normalizing appropriately.<sup>2</sup> This dependence is tight to within constant factors. Besides this

---

<sup>1</sup> A comprehensive compendium of literature on the topic can be found at [29].

<sup>2</sup> Formally, the competitive ratio depends linearly on the ratio of the maximum location error of any predicted request to the minimum service time, as well as the ratio of the maximum time window error to the minimum time window length.

dependence on the prediction error, the competitive ratio depends logarithmically on the diameter of the underlying network, matching the performance of the best known offline algorithm for TW-TSP.

Although our competitive ratio is stated in terms of the maximum location or time window errors, where the maximum is taken over all requests in the instance, our algorithm performs well even when some of the errors are large and most errors are small. In particular, our algorithm’s performance is *simultaneously* competitive against the maximum achievable reward over *any* subset of requests, scaled down by the maximum prediction error over that subset. (See “Extensions” in Section 3 for a formal statement.) In this respect, our guarantees fall within the framework of *metric error with outliers* proposed by [4]. On the other hand, when all or most requests are predicted poorly, our algorithm also inevitably performs poorly as it inherits lower bounds from fully online instances.

Importantly, our algorithm requires little to no information about how the predictions match up against the true requests. For the purpose of analysis, we measure the error in predictions with respect to some underlying matching between the predicted and true requests – the error parameters are then defined in terms of the maximum mismatch between any predicted request and its matched true request. This matching is never revealed to the algorithm and in fact the performance of the algorithm depends on the quality of the *best* possible matching between the predicted and true requests. The only information the algorithm requires about the quality of the predictions is the location error – the maximum distance between any prediction and its matched true request. Even for this parameter, an upper bound suffices (and at a small further loss, a guess suffices).

Our overall approach has several components. The first of these is to construct an instance of the TW-TSP over predicted requests that requires the server to spend some idle time at each request as a “service delay”. We then extend offline TW-TSP algorithms to this service delay setting, obtaining a logarithmic in diameter approximation. We then follow and adapt this offline solution in the online setting. Every time the offline solution services a predicted request, we match this request to a previously revealed true request, take a detour from the computed path to visit and service the true request, and then resume the precomputed path. Altogether this provides the desired competitive ratio.

Our results further generalize to a setting where predictions are coarse in that each single predicted location captures multiple potential true requests that are nearby. We show that with prediction errors defined appropriately, we can again achieve a competitive ratio for this “many to one matching” setting that is logarithmic in the diameter of the graph and polynomial in the prediction error.

Finally, our algorithm and analysis incorporates error in estimating rewards of requests in a straightforward manner achieving the optimal dependence on this third source of error.

## Further related work

Using predictions in the context of online algorithm design was first proposed by [30] for the well-studied caching problem. Since that work, the literature on online algorithm design with predictions has grown rapidly. We point the interested reader to a compendium at [29] for further references.

## Metric error with outliers

Azar et al. [4] initiated the study of predictions in the context of online graph optimization problems, and proposed a framework for quantifying errors in predictions, called *metric error with outliers*, that we adapt. The idea behind this framework is to capture two sources of

error: (1) Some true requests may not be captured by predictions and some predictions may not correspond to any true requests; (2) For requests that are captured by predictions, the predictions may not be fully faithful or accurate. The key observation is that it is possible to design algorithms with performance that depends on these two sources of error *without explicit upfront knowledge of the (partial) correspondence between predicted and true requests*.

In this work, we focus mostly on the second source of error, which we further subdivided into three kinds of error in order to obtain a finer understanding of the relationship between the competitive ratio and different kinds of error. As in the work of Azar et al. [4], we assume that the correspondence between predicted and true requests is never explicitly revealed to the algorithm. The performance of the algorithm nevertheless depends on the error of the *best* matching between predicted and true requests. In Section 3 we describe how the first source of error in Azar et al.’s framework can also be incorporated into our bounds.

### TSP with predictions

Recently a few papers [10, 23, 22] have considered the online TSP and related routing problems with predictions. The input to the online TSP is similar to ours: requests arrive over time in a graph, and a tour must visit each request after its arrival time. However, the objective is different. In our setting, requests also have deadlines, and the algorithm cannot necessarily visit all requests. The goal therefore is to visit as many as possible. In the online TSP, there are no deadlines, and so the objective is to visit *all* requests as quickly as possible, or in other words to minimize the makespan. This makespan minimization objective is typically much easier than the deadline setting, as evidenced by constant factor approximations for it in the offline, online, and predictions settings, as opposed to logarithmic or worse approximations for the latter problem.

The algorithmic idea of precomputing an offline path based on the predictions and then adapting it to the online input has also been used in [10, 23]. The main challenge in the setting that our works considers, is that due to the existence of deadlines, our algorithm needs to be careful on how it adapts its path, as taking a large detour could result in entirely missing the time-windows of future (unrevealed) requests. We circumvent this issue by introducing appropriately large idle times on the predicted requests that our offline solution visits.

### TW-TSP *without* predictions

The (offline) TW-TSP problem has a rich literature and has been studied for over 20 years. The problem is known to be NP-hard even for special cases, e.g. on the line [32], and when all requests have the same release times and deadlines (a.k.a. Orienteering) [11]. Orienteering admits constant factor approximations [11, 7, 14], and even a PTAS when requests lie in a fixed dimensional Euclidean space [2, 16]. For general time windows, constant factor approximations are only known for certain special cases: e.g. constant number of distinct time windows [15]; and on line graphs [32, 26, 8, 21]. For general graphs and time-windows, the best approximations known are logarithmic in input parameters [7, 14].

To the best of our knowledge, the online setting for TW-TSP has only been considered by Azar and Vardi [5]. Azar and Vardi assume that service times are non-zero and present competitive algorithms under the assumption that the smallest time window length  $L_{\min}$  is comparable to the diameter  $D$  of the graph, as no sublinear competitive ratio can be achieved if  $L_{\min} < D/2$ . We are able to beat this lower bound by relying on predictions.

## Organization of the paper

We formally define the problem and our error model in Section 2. Section 3 describes our results and provides an outline for our analysis. All of our main results are covered in that section. Proofs of these results can be found in subsequent sections. In particular, Sections 4, 5, and 6 fill in the details of our upper bound, and Section 7 proves the stated lower bounds. Proofs omitted from the main body of this paper can be found in the appendix of the full version [13].

## 2 Definitions

### 2.1 The Traveling Salesman Problem with Time-Windows

An instance of the TW-TSP consists of a network  $G$  and a (finite) sequence of service requests  $I$ . Here,  $G = (V, E, \ell)$  is an undirected network with edge lengths  $\{\ell_e\}_{e \in E}$ . Extending the notion of distance to all vertex pairs in  $G$ , we define  $\ell(u, v)$  for  $u, v \in V$  to be the length of the shortest path from  $u$  to  $v$ . We assume without loss of generality that  $G$  is connected and that the edge lengths  $\ell_e$  are integers. A service request  $\sigma = (v_\sigma, r_\sigma, d_\sigma, \pi_\sigma)$  consists of a vertex  $v_\sigma \in V$  at which the request arrives, a release time  $r_\sigma \in \mathbb{Z}^+$ , a deadline  $d_\sigma \in \mathbb{Z}^+$  with  $d_\sigma > r_\sigma$ , and a reward  $\pi_\sigma \in \mathbb{Z}^+$ . We use  $\Sigma \subseteq V \times \mathbb{Z}^+ \times \mathbb{Z}^+ \times \mathbb{Z}^+$  to denote the set of all possible client requests and  $I \subset \Sigma$  to denote the set of requests received by the algorithm.

The solution to TW-TSP is a continuous *walk* on  $G$  that is allowed to remain idle on the vertices of the graph.<sup>3</sup> Formally, the walk starts from some vertex at time  $t = 0$ ; at every time-step that it occupies a vertex  $u \in V$ , it can either remain idle on  $u$  for some number of time-steps or it can move to some  $v \in V$  by spending time  $t = \ell(u, v)$ ; we comment that while the path is mid-transition, no more decisions can be made. Notice that this creates a notion of a discrete time-horizon that will be important towards formalizing the online variant of the problem.

We use  $\mathcal{W}(G)$  to denote the set of all walks on  $G$ . Given a request  $\sigma \in \Sigma$ , we say that a walk  $W$  *covers* it if  $W$  remains idle on vertex  $v_\sigma$  for at least one time-step,<sup>4</sup> starting on some step  $\tau \in [r_\sigma, d_\sigma - 1]$ . For a sequence of requests  $I \subset \Sigma$ , we use  $\text{Cov}(W, I) \subseteq I$  to denote the set of requests in  $I$  that are covered by  $W$ . Then, the reward obtained by walk  $W$  is denoted by  $\text{Rew}(W, I) := \sum_{\sigma \in \text{Cov}(W, I)} \pi_\sigma$ . The objective of TW-TSP is to compute a walk  $W \in \mathcal{W}(G)$  of maximum reward. We denote this by  $\text{OPT}(G, I) := \max_{W \in \mathcal{W}(G)} [\text{Rew}(W, I)]$ .

### 2.2 The offline, online, and predictions settings

We assume that the network  $G$  is known to the algorithm upfront in all of the settings we consider. In the **offline** version of the problem, the sequence of requests  $I$  is given to the algorithm in advance. In the **online** version, requests  $\sigma \in I$  arrive in an online fashion; specifically, each request  $\sigma \in I$  is revealed to the algorithm at its release time  $r_\sigma$ .

In the **predictions** setting, the true sequence of requests  $I$  arrives online, as in the online setting. However, the algorithm is also provided with a predicted sequence  $I' \subset \Sigma$  in advance, where every request  $\sigma' \in I'$  is endowed with a location, a time window, and a reward. The

<sup>3</sup> To keep our exposition simple, we do not specify a starting location for the walk. However, all of our algorithms can be adapted without loss to the case where a starting location is fixed, as described towards the end of Section 3.

<sup>4</sup> As we mentioned in the introduction, this requirement of a minimal one-unit service time is necessary in order to achieve any sublinear approximation for the online TW-TSP even with predictions. See Theorem 9 in Section 7.

quality of predictions is expressed in terms of their closeness to true requests. To this end, we define three notions of mismatch or error. For a true request  $\sigma$  and predicted request  $\sigma'$ , the location error, time windows error, and reward error are defined as:

$$\begin{aligned}\text{LocErr}(\sigma, \sigma') &:= \ell(v_\sigma, v_{\sigma'}) \\ \text{TWErr}(\sigma, \sigma') &:= \max\{|r_\sigma - r_{\sigma'}|, |d_\sigma - d_{\sigma'}|\} \\ \text{RewErr}(\sigma, \sigma') &:= \max\{\pi_\sigma/\pi_{\sigma'}, \pi_{\sigma'}/\pi_\sigma\}\end{aligned}$$

We extend these definitions to the entire sequences  $I$  and  $I'$  through an underlying (but unknown to the algorithm) matching between the requests in the two lists:

► **Definition 1.** *Given two request sequences  $I, I' \subset \Sigma$  with  $|I| = |I'|$  and a perfect matching  $M : I \mapsto I'$ , we define the location, time window, and reward errors for the matching  $M$  as:*

$$\begin{aligned}\Lambda_M &:= \max_{\sigma \in I} \text{LocErr}(\sigma, M(\sigma)) \\ \tau_M &:= \max_{\sigma \in I} \text{TWErr}(\sigma, M(\sigma)) \\ \rho_M &:= \max_{\sigma \in I} \text{RewErr}(\sigma, M(\sigma))\end{aligned}$$

We use  $n = |V|$  to denote the number of vertices in  $G$ ,  $D$  to denote the diameter of the graph, and  $L_{\min}$  and  $L_{\max}$  to denote the size of the smallest and largest time windows respectively (of a true or predicted request) in the given instance; that is, we denote  $L_{\min} = \min_{\sigma \in I \cup I'} |d_\sigma - r_\sigma|$  and  $L_{\max} = \max_{\sigma \in I \cup I'} |d_\sigma - r_\sigma|$ . The competitive ratios of the algorithms we develop depend on these parameters.

### Knowns and unknowns

We denote an instance of the TW-TSP with predictions by  $(G, I, I', M)$ . All components of the instance are chosen adversarially. As mentioned earlier, the network  $G$  and the predicted sequence  $I'$  are provided to the algorithm at the start. The sequence  $I$  arrives online. We assume that the algorithm receives no direct information about the matching  $M$ , but is provided with an upper bound on the error  $\Lambda_M$ . We will also assume that the algorithm knows the parameter  $L_{\min}$ , although this is without loss of generality as the parameter can be inferred within constant factor accuracy from the predictions.<sup>5</sup>

## 2.3 The TW-TSP with service times

At a high level our algorithm has two components: an offline component that computes a high-reward walk over the predicted locations of requests, and an online component that largely follows this walk but takes “detours” to cover the arriving true sequence of requests. In particular, as the algorithm follows the offline walk, for each predicted location it visits where a “close by” true request is available, the algorithm takes a “detour” to this true request, returns back to the predicted location, and resumes the remainder of the walk. In order to incorporate the time spent taking these detours in our computation of the offline walk, we require the walk to spend some “service time” at each predicted location it covers. Accordingly, we define a generalization of the TW-TSP:

<sup>5</sup> In particular, assuming  $\tau_M \leq L_{\min}/2$ , which is necessary for our results to hold, the time window of any true request can be no shorter than half the smallest time window of any predicted request.

► **Definition 2.** The TW-TSP with Service Times (TW-TSP-S) takes as input a network  $G$ , a sequence of service requests  $I$ , and a service time  $S \in \mathbb{Z}^+$ , and returns a walk  $W \in \mathcal{W}(G)$ . We say that  $W$  covers a request  $\sigma \in I$ , denoted  $\sigma \in \text{Cov}(W, I, S)$ , if it remains idle on vertex  $v_\sigma$  for at least  $S$  time steps, starting at some step  $t \in [r_\sigma, d_\sigma - S]$ . We define the reward of  $W$  as  $\text{Rew}(W, I, S) := \sum_{\sigma \in \text{Cov}(W, I, S)} \pi_\sigma$ . The optimal value of the instance is given by:

$$\text{OPT}(G, I, S) := \max_{W \in \mathcal{W}(G)} [\text{Rew}(W, I, S)].$$

Note that the original version of TW-TSP as defined previously simply corresponds to the special case of TW-TSP-S with service time  $S = 1$ , and in particular, we have  $\text{Rew}(W, I) = \text{Rew}(W, I, 1)$ , and  $\text{OPT}(G, I) = \text{OPT}(G, I, 1)$ .

### 3 Our results and an outline of our approach

Our main result is as follows.

► **Theorem 3.** Given any instance  $(G, I, I', M)$  of the TW-TSP with predictions whose errors satisfy  $\tau_M \leq L_{\min}/2$  and  $\Lambda_M \leq (L_{\min} - 1)/4$ , there exists a polynomial-time online algorithm that takes the tuple  $(G, I', \Lambda_M)$  as offline input and  $I$  as online input, and constructs a walk  $W \in \mathcal{W}(G)$  such that

$$\mathbb{E}[\text{Rew}(W, I)] \geq \frac{1}{O(\Lambda_M \cdot \rho_M^2 \cdot \log \min(D, L_{\max}))} \cdot \text{OPT}(G, I).$$

As mentioned previously, our algorithm consists of two components. The offline component constructs a potential walk in the network with the help of the predicted requests. Then an online component adapts this walk to cover true requests that arrive one at a time. We break up the design and analysis of our algorithm into four steps. The first two steps relate the offline instance we solve to the hindsight optimal solution for the online instance. The third step then applies an offline approximation to the predicted instance with appropriate service times. The final step deals with the online adaptation of the walk to the arriving requests.

The following four lemmas capture the four steps. First, we show (Section 4) that introducing a service time of  $S$  hurts the optimal value by at most a factor of  $2S - 1$ . As we prove in Lemma 14 of Section 4, this dependency on  $S$  is tight. Observe that we require  $S \leq L_{\min}$ , as for any tour to feasibly cover a request, the service time for that request must fit within its time window.

► **Lemma 4.** For any instance  $(G, I)$  of the TW-TSP with service times, and any integer  $S \leq L_{\min}$ , we have

$$\text{OPT}(G, I, S) \geq \frac{1}{2S - 1} \cdot \text{OPT}(G, I, 1).$$

Our second step (also in Section 4) relates the value of the optimal solution over the true requests  $I$  to the optimum over the predicted sequence  $I'$ . In both cases, we impose some service time requirements. Note that this argument needs to account for the discrepancy in locations, time windows, as well as the rewards of the true and predicted requests.

► **Lemma 5.** Let  $(G, I, I', M)$  be an instance of the TW-TSP with predictions, where  $\Lambda_M$ ,  $\rho_M$ , and  $\tau_M$  denote the maximum location, reward, and time window errors of the instance respectively. Define  $S := 4\Lambda_M + 1$  and  $S' := 2\Lambda_M + 1$ . Then, if  $\tau_M \leq L_{\min}/2$  and  $\Lambda_M \leq (L_{\min} - 1)/4$ , we have

$$\text{OPT}(G, I', S') \geq \frac{1}{3\rho_M} \cdot \text{OPT}(G, I, S).$$

Our third step (Section 5) captures the offline component of our algorithm: computing an approximately optimal walk over the predicted requests with the specified service times. For this we leverage previous work on the TW-TSP without service times and show how to adapt it to capture the service time requirement.

► **Lemma 6.** *Given any instance  $(G, I', S')$  of the TW-TSP with service times, there exists a polynomial time algorithm that returns a walk  $W \in \mathcal{W}(G)$  with reward*

$$\text{Rew}(W, I', S') = \frac{1}{\mathcal{O}(\log \min(D, L_{\max}))} \cdot \text{OPT}(G, I', S').$$

Finally, the fourth component (Section 6) addresses the online part of our algorithm. Given a walk computed over the predicted request sequence, it solves an appropriate online matching problem to construct detours to capture true requests. As in Lemma 5, this part again needs to account for the discrepancy in locations, time windows, as well as the rewards of the true and predicted requests.

► **Lemma 7.** *Given an instance  $(G, I, I', M)$  of the TW-TSP with predictions satisfying  $\tau_M \leq L_{\min}/2$  and  $\Lambda_M \leq (L_{\min} - 1)/4$ ; a walk  $W' \in \mathcal{W}(G)$ ; and any integer  $S' \geq 2\Lambda_M + 1$ , there exists an online algorithm (Algorithm 1) that returns a walk  $W \in \mathcal{W}(G)$  with expected reward*

$$\mathbb{E}[\text{Rew}(W, I, 1)] \geq \frac{1}{6\rho_M} \cdot \text{Rew}(W', I', S').$$

Theorem 3 follows immediately by putting Lemmas 4, 5, 6 and 7 together.

### Lower bounds and tightness of our results

We show that the online TW-TSP does not admit sublinear competitive algorithms in the absence of predictions if  $L_{\min} < D$ , even with non-zero service times. Furthermore, if the service times are all 0, no sublinear competitive ratio is possible even using predictions that are accurate in all respects except the request location. Therefore, in order to achieve a nontrivial competitive ratio, it is necessary to use predictions as well as to impose non-zero service times on the optimum. The proofs are presented in Section 7.

► **Theorem 8.** *The competitive ratio of any randomized online algorithm for Online TW-TSP on instances with  $L_{\min} \leq D$  and all service times equal to 1 is at most  $1/n$ .*

► **Theorem 9.** *For any  $S > 0$ , there exists an instance  $(G, I, I', M)$  of the TW-TSP with predictions and service times 0, satisfying  $\tau_M = 0$ ,  $\rho_M = 1$ , and  $\Lambda_M = S$ , such that any randomized online algorithm taking the tuple  $(G, I', \Lambda_M)$  as offline input and  $I$  as online input achieves a reward no larger than  $O(1/n) \cdot \text{OPT}(G, I, 0)$ . Here  $n$  is the number of vertices in  $G$ .*

As mentioned earlier, the best known approximation factor for the offline TW-TSP is  $O(\log L_{\max})$  (which we show can be improved slightly to  $O(\log \min(D, L_{\max}))$ ). We inherit this logarithmic dependence on  $D$  and  $L_{\max}$  in the predictions setting. Furthermore, any improvements to the offline approximation would immediately carry through into our competitive ratio as well. In particular, given an offline TW-TSP algorithm that achieves a competitive ratio of  $\alpha(D, L_{\max})$ , we obtain an online algorithm that achieves a competitive ratio of  $O(\Lambda_M \cdot \rho_M^2 \cdot \alpha(D, L_{\max}))$ .

The dependence of our bound on  $\rho_M$  can easily be seen to be tight – consider a star graph with requests on leaves, and edge lengths and time windows defined in such a manner that any feasible walk can cover at most one request. Then an uncertainty of a factor of

$\rho_M$  in the predicted rewards can force any online algorithm to obtain an  $\Omega(\rho_M^2)$  competitive ratio even if the predictions are otherwise perfect. Finally, we show in Section 7.2 that the dependence of our competitive ratio on  $\Lambda_M$  is also tight:

► **Theorem 10.** *For any  $S > 0$ , there exists an instance  $(G, I, I', M)$  of the TW-TSP with predictions satisfying  $\tau_M = 0$ ,  $\rho_M = 1$ , and  $\Lambda_M = S$  such that the competitive ratio of any randomized online algorithm taking the tuple  $(G, I', \Lambda_M)$  as offline input and  $I$  as online input asymptotically approaches  $1/(S + 1)$ .*

## Extensions and generalizations

We now describe some ways in which we can weaken the assumptions in Theorem 3 while maintaining its competitive ratio guarantee:

- **Lack of knowledge of  $\Lambda_M$ .** Our algorithm continues to work as intended if it is provided with an upper bound on  $\Lambda_M$  rather than the exact value of the parameter, with the performance of the algorithm degrading linearly with the upper bound, as in the theorem above. One such upper bound is simply  $L_{\min}/4$ . Moreover, by guessing  $\Lambda_M$  within a factor of 2 in the range  $[0, L_{\min}/4]$ , we can obtain the claimed approximation with a further loss of  $\mathcal{O}(\log L_{\min})$ . Thus, our algorithm can achieve non-trivial guarantees that scale with the location error even in settings where no information is given about any of the prediction errors  $\Lambda_M, \tau_M, \rho_M$ .
- **Assumptions on  $\tau_M$  and  $\Lambda_M$ .** It is easy to see that it is necessary to assume  $\Lambda_M \leq L_{\min}$  to obtain a nontrivial competitive ratio, as predictions with a location error larger than the time window size are of no value to the online algorithm. On the other hand, assuming  $\tau_M \leq L_{\min}$  is not necessary. We can accommodate larger time window errors by following one out of roughly  $\tau_M/L_{\min}$  different time shifts of the offline walk. This worsens our approximation factor by an additional factor of  $\tau_M/L_{\min}$ . In particular, this algorithm achieves a competitive ratio of  $O(\Lambda_M \cdot \rho_M^2 \cdot \tau_M/L_{\min} \cdot \log \min(D, L_{\max}))$ .
- **Random rewards.** Our results also hold in the case of random rewards. Specifically, consider a setting where the rewards  $\{\pi_\sigma\}_{\sigma \in I}$  are drawn from some joint (not necessarily product) distribution  $D$  over  $\mathbb{R}_+^I$ . In that case, we define  $\text{Rew}(W, I) := \sum_{\sigma \in \text{Cov}(W, I)} \mathbb{E}[\pi_\sigma]$ , and  $\text{OPT}(G, I)$  as the maximum reward obtained by any walk  $W \in \mathcal{W}(G)$ .<sup>6</sup> Finally, we define  $\text{RewErr}(\sigma, \sigma')$  as the mismatch between  $\pi'_\sigma$  and  $\mathbb{E}[\pi_\sigma]$ . Our analysis provides the same approximation as before in this setting. See the full version for a formal proof.

► **Corollary 11.** *Given an instance  $(G, I, I', M)$  of the TW-TSP with predictions where requests have randomly drawn rewards, and predictions errors satisfy that  $\tau_M \leq L_{\min}/2$  and also  $\Lambda_M \leq (L_{\min} - 1)/4$ , there exists a polynomial-time online algorithm that takes the tuple  $(G, I', \Lambda_M)$  as offline input and  $I$  as online input, and constructs a walk  $W \in \mathcal{W}(G)$  such that*

$$\mathbb{E}[\text{Rew}(W, I)] \geq \frac{1}{O(\Lambda_M \cdot \rho_M^2 \cdot \log \min(D, L_{\max}))} \cdot \text{OPT}(G, I)$$

<sup>6</sup> Note that we do not allow the optimal walk to adapt to instantiations of rewards. Adaptive walks cannot be competed against in an online setting even with predictions.

- **Routed instances.** Next, we consider the case where a starting vertex  $v_0$  is also specified, and the solution space  $\mathcal{W}(G)$  includes all walks on  $G$  that *start* on vertex  $v_0$  at  $t = 0$ . We can easily see that this setting is essentially equivalent to its unrooted counterpart, under the extra assumption that each request  $\sigma = (v_\sigma, r_\sigma, d_\sigma, \pi_\sigma)$  satisfies the conditions  $\ell(v_0, v_\sigma) \leq r_\sigma$ . This is a reasonable assumption as no algorithm can visit a request  $\sigma$  before time  $\ell(v_0, v_\sigma)$  anyway. Clearly, for any rooted instance  $(G, I, v_0)$ , the unrooted optimal  $\text{OPT}(G, I)$  is an upper bound on the rooted optimal  $\text{OPT}(G, I, v_0)$ . On the other hand, the unrooted path computed by our algorithm can be transformed to a path of same reward rooted at  $v_0$  by going directly from  $v_0$  to the predicted request serviced first, as this distance is at most equal to the request's release time.
- **Partial matching.** Next we consider the case where not all true requests are captured by the predicted requests and, on the flip side, where some predicted requests do not correspond to true requests at all. Following the framework of [4], we consider partial matchings between  $I$  and  $I'$ , and define  $\Delta_1^M$  to be the total reward of all true requests that are unmatched, and  $\Delta_2^M$  to be the total predicted reward of predicted requests that are unmatched. Then, it is easy to see that our analysis goes through for the subsets of  $I$  and  $I'$  that are matched to each other, costing us an additive amount of no more than  $\Delta_1^M + \Delta_2^M$ . See the full version for a formal proof.

► **Corollary 12.** *Given an instance  $(G, I, I')$  of the TW-TSP with predictions, let  $M$  be any (incomplete) matching between  $I$  and  $I'$ , and let the error parameters  $\Lambda_M, \rho_M, \tau_M, \Delta_1^M$ , and  $\Delta_2^M$  be defined as above. Then, there exists an online algorithm that takes  $(G, I', \Lambda_M)$  as offline input and  $I$  as online input, and returns a walk  $W \in \mathcal{W}(G)$  such that*

$$\mathbb{E}[\text{Rew}(W, I)] \geq \Omega\left(\frac{1}{\Lambda_M \cdot \rho_M^2 \cdot \log \min(D, L_{\max})}\right) \cdot (\text{OPT}(G, I) - \Delta_1^M) - \frac{\Delta_2^M}{\rho_M}.$$

- **Many to one matching.** Consider a setting where predictions are coarse in that each single predicted location captures multiple potential true requests. We can model such a setting within our predictions framework and obtain almost the same guarantee as in Theorem 3. In particular, for this setting, let  $M$  be a many-to-one matching from  $I$  to  $I'$ . We define the location error of a predicted request  $\sigma' \in I'$  as the length of the shortest path that starts at  $\sigma'$ , visits all of the locations of the true requests that are preimages of  $\sigma'$  in  $M$ , spending one unit of time at each, and returns back to  $\sigma'$ . Observe that this location error is the length of the optimal solution to an orienteering problem rooted at  $\sigma'$ . Correspondingly, we want the reward associated with  $\sigma'$  to capture the total reward of all the true requests matched to  $\sigma'$ , and define its reward error accordingly. Finally, the time window error is defined as before, as a maximum over all pairs  $\sigma$  and  $\sigma'$  that are matched to each other. Our algorithm for the setting of Theorem 3 constructs a matching between  $I'$  and  $I$  in an online fashion. For this one to many setting, we solve instances of the orienteering problem rooted at each predicted request we visit. The performance of the algorithm accordingly worsens by a small constant factor and we achieve a competitive ratio of  $O(\Lambda_M \rho_M^2 \log \min(D, L_{\max}))$  as before. Due to space limitations, the details of the proof are omitted from this version. See Section 8 of the full version [13] for further details.

► **Theorem 13.** *Given an instance  $(G, I, I', M)$  of the TW-TSP with predictions where  $M$  is a many-to-one matching with errors as defined above, and satisfying  $\tau_M \leq L_{\min}/2$  and  $\Lambda_M \leq L_{\min}/2$ , there exists a polynomial-time online algorithm that takes the tuple  $(G, I', \Lambda_M)$  as offline input and  $I$  as online input, and constructs a walk  $W \in \mathcal{W}(G)$  such that*

$$\mathbb{E}[\text{Rew}(W, I)] \geq \frac{1}{O(\Lambda_M \cdot \rho_M^2 \cdot \log \min(D, L_{\max}))} \cdot \text{OPT}(G, I).$$

#### 4 Relating the Optima

In this section we provide the proofs of Lemmas 4 and 5 that relate the optima over the true and the predicted request sequences, using service times as a mechanism to capture the prediction errors. We begin by proving that a service time of  $S$  can hurt the optimal by at most a factor of  $2S - 1$ .

► **Lemma 4.** *For any instance  $(G, I)$  of the TW-TSP with service times, and any integer  $S \leq L_{\min}$ , we have*

$$\text{OPT}(G, I, S) \geq \frac{1}{2S - 1} \cdot \text{OPT}(G, I, 1).$$

**Proof.** Let  $W \in \mathcal{W}(G)$  be the walk that achieves the optimum  $\text{OPT}(G, I, 1)$ , and let the requests in  $I$  that are covered by  $W$  be denoted as  $\sigma_i = (v_i, r_i, d_i, \pi_i)$  and ordered in the sequence in which they are covered by  $W$ . The lemma follows directly from the simple observation that if we don't service the  $(S - 1)$ -requests *prior* and *after* some request  $\sigma_i$ , then we can save enough time to service  $\sigma_i$  for  $S$  time-steps within its time window.

Formally, if  $t_i \in [r_i, d_i - 1]$  is the step at which  $W$  begins servicing request  $\sigma_i$ , then by skipping the idle times on the  $(S - 1)$ -previous and next requests we can remain idle on  $v_i$  from step  $t_i - (S - 1)$  until step  $t_i + S$  (since  $W$  already remained idle on  $v_i$  for 1 step) while still being able to keep up with walk  $W$ . Since  $S \leq L_{\min}$ , it is easy to verify that at least  $S$  of these time-steps are going to fall in the time-window  $[r_i, d_i]$ .

We now partition the requests  $\sigma_i = (v_i, r_i, d_i, \pi_i)$  into  $2S - 1$  sub-sequences, each of which starts at some request  $i \in [S]$ , and covers the requests  $\sigma_i, \sigma_{i+(2S-1)}, \sigma_{i+2(2S-1)}$ , and so forth. Each such sequence can be covered with a walk, with idle times built in as above, so as to be feasible for the instance  $(G, I, S)$ . Clearly, one of these walks obtains a reward of at least  $\text{OPT}(G, I, 1)/(2S - 1)$ , completing the proof. ◀

In the appendix of the full version, we show that the above lemma obtains a tight gap between the optima at different service times.

► **Lemma 14.** *For any pair of integers  $(L, S)$  such that  $L \geq 2S - 2 \geq 1$ , there exists a rooted instance  $(G, I)$  of the TW-TSP with service costs such that  $L_{\min} = L$  and*

$$\text{OPT}(G, I, S) = \frac{1}{2S - 1} \cdot \text{OPT}(G, I, 1).$$

Next, we provide the proof of Lemma 5 that relates the optima between the predicted and true request sequences, by appropriately addressing all three possible types of prediction errors.

► **Lemma 5.** *Let  $(G, I, I', M)$  be an instance of the TW-TSP with predictions, where  $\Lambda_M$ ,  $\rho_M$ , and  $\tau_M$  denote the maximum location, reward, and time window errors of the instance respectively. Define  $S := 4\Lambda_M + 1$  and  $S' := 2\Lambda_M + 1$ . Then, if  $\tau_M \leq L_{\min}/2$  and  $\Lambda_M \leq (L_{\min} - 1)/4$ , we have*

$$\text{OPT}(G, I', S') \geq \frac{1}{3\rho_M} \cdot \text{OPT}(G, I, S).$$

**Proof.** Let  $W$  be the walk that achieves the optimum  $\text{OPT}(G, I, S)$ , and let the requests in  $I$  covered by  $W$  be denoted as  $\sigma_i = (v_i, r_i, d_i, \pi_i)$  and ordered in the sequence in which they are visited by  $W$ . Let  $\sigma'_i = (v'_i, r'_i, d'_i, \pi'_i)$  denote the predicted request matched to  $\sigma_i$ , that is,  $\sigma'_i = M(\sigma_i)$ . Observe that the total reward of all requests  $\{\sigma'_i\}$  corresponding to  $\sigma_i \in \text{Cov}(W, I, S)$  is at least  $\text{Rew}(W, I, S)/\rho_M$ .

We will consider a walk  $W'$  in  $G$  defined as follows. The walk  $W'$  follows  $W$ , visiting the requests  $\sigma_i$  in sequence. As soon as  $W$  starts servicing  $\sigma_i$ ,  $W'$  takes a detour to visit  $\sigma'_i$ ; remains idle at  $\sigma'_i$  for  $S'$  time steps; returns back to  $\sigma_i$ ; remains idle at  $\sigma_i$  for  $S - 2\ell(v_i, v'_i) - S' \geq 0$  time steps; and then resumes the walk  $W$ . Observe that  $W'$  is identical to  $W$  outside of the detours it takes to visit the  $\sigma'_i$ 's.

Our goal is to feasibly capture all of the reward contained in the  $\sigma'_i$ 's. The problem is that the walk  $W'$  may miss some of this reward due to the mismatch in the time windows of the true and predicted requests. To this end, we will consider two variations of the walk  $W'$ . Let  $K := L_{\min}/2 \geq \tau_M$ . The walk  $W'_1$  is identical to  $W'$  except that it starts  $K$  steps after  $W'$  starts, and accordingly visits every location exactly  $K$  steps after  $W'$  visits it. The walk  $W'_2$  is identical to  $W'$  except that it starts  $K$  steps *before*  $W'$  starts,<sup>7</sup> and accordingly visits every location exactly  $K$  steps before  $W'$  visits it.

Now consider some  $\sigma'_i$  corresponding to a request  $\sigma_i$  covered by  $W$  in the instance  $(G, I, S)$ . We claim that at least one of the walks  $W'$ ,  $W'_1$ , and  $W'_2$  covers  $\sigma'_i$  in  $(G, I', S')$ . Let  $t$  be the time at which  $W'$  arrives at  $v'_i$ ; recall that  $W'$  remains at the node until at least  $t + S'$ . Note that  $t \geq r_i$  and  $t + S' \leq d_i$  due to  $\sigma_i \in \text{Cov}(W, I, S)$ .

First, suppose that  $r'_i \leq t$  and  $d'_i \geq t + S'$ , then  $\sigma'_i$  is covered by  $W'$  in  $(G, I', S')$ . Next suppose that  $r'_i > t$ . Then,  $W'_1$  arrives at  $v'_i$  at time  $t + K \geq r_i + K \geq r_i + \tau_M \geq r'_i$ . On the other hand, it remains at  $v'_i$  until time  $t + K + S' < r'_i + K + S' \leq r'_i + L_{\min} \leq d'_i$ . Therefore,  $\sigma'_i$  is covered by  $W'_1$ . Finally, suppose that  $d'_i < t + S'$ . Then,  $W'_2$  arrives at  $v'_i$  at time  $t - K > d'_i - S' - K \geq d'_i - L_{\min} \geq r'_i$ . On the other hand, it remains at  $v'_i$  until time  $t - K + S' \leq d_i - K \leq d_i - \tau_M \leq d'_i$ . Therefore,  $\sigma'_i$  is covered by  $W'_2$ .

We get that at least one of  $W'$ ,  $W'_1$ , or  $W'_2$  obtains at least a  $1/3\rho_M$  fraction of  $\text{OPT}(G, I, S)$ , where the factor of  $\rho_M$  is lost due to the mismatch in the predicted rewards. The lemma follows directly from this.  $\blacktriangleleft$

## 5 The offline approximation

In this section, we design an  $O(\log \min(D, L_{\max}))$  deterministic and polynomial-time approximation algorithm for the TW-TSP with service times, providing the proof of Lemma 6. Our proof relies on a series of reductions between different offline problems, applications of existing algorithms as well as the design of novel algorithmic components. We break up our argument into a series of lemmas. Due to space limitations, all the proofs are moved to the appendix of the full version [13].

1. First, we designing an  $O(\log \min(D, L_{\max}))$  approximation algorithm for TW-TSP (without service times). Since the work of [14] already provides a  $O(\log L_{\max})$  approximation for the setting with integer time-windows (see Lemma 5.3 of [14]), it suffices to prove the following:

► **Lemma 15.** *Given an instance of the TW-TSP (without service times) with  $L_{\min} \geq 4D$ , there exists a polynomial time algorithm that achieves an  $O(1)$  approximation.*

Our proof relies on the observation that when time-windows are sufficiently large compared to the diameter of the graph, the problem essentially reduces to an instance of the well-studied Orienteering problem, for which constant approximation algorithms are

<sup>7</sup> To be precise, this walk starts at the location where  $W'$  is at at step  $K$ .

known. We comment that similar ideas have been used in [5]. Then, it is straightforward to combine this algorithm together with the algorithm of [14] to acquire an  $O(\log \min(L_{\max}, D))$  approximation of TW-TSP.

► **Lemma 16.** *There exists an  $O(\log \min(D, L_{\max}))$  approximation algorithm for the TW-TSP problem.*

2. Next, we design a simple approximation-preserving reduction from TW-TSP with service times to TW-TSP (without service times). The main idea behind this reduction is to treat service times as edge lengths in an augmented graph whose diameter is roughly  $D + S$ . For instances with  $S \leq D$ , this increase becomes negligible and thus by combining our reduction with Lemma 16, we immediately get the following:

► **Lemma 17.** *Given an instance  $(G, I, S)$  of the TW-TSP with service times such that  $S \leq D$ , there exists a polynomial time algorithm that achieves an  $O(\log \min(D, L_{\max}))$  approximation.*

3. Finally, we handle the case of large service times, specifically  $S \geq D$ . In that case, it turns out that we can reduce the instance to one over a uniform complete graph. Then, the TW-TSP-S essentially becomes equivalent to the well-studied *Job Scheduling* problem, for which constant approximations are known.

► **Lemma 18.** *Given an instance  $(G, I, S)$  of the TW-TSP with service costs such that  $S \leq D$ , there exists a polynomial time algorithm that achieves an  $O(1)$  approximation.*

The proof of Lemma 6 follows immediately from Lemma 17 and Lemma 18. We comment that any improvement in the best known approximation algorithm for TW-TSP will immediately imply an improvement for all the results that this work presents. Lemma 18 essentially enables us to assume that in all instances of interest,  $S \leq D$ . Under this assumption, our reduction used in the proof of Lemma 17 essentially states that TW-TSP-S becomes equivalent to TW-TSP in graphs of diameter  $\mathcal{O}(D)$  and maximum window size  $\mathcal{O}(L_{\max})$ . As an immediate corollary, given an offline TW-TSP algorithm that achieves a competitive ratio of  $\alpha(D, L_{\max})$ , we immediately obtain an offline  $O(\alpha(D, L_{\max}))$  approximation for TW-TSP-S, that can be used in order to substitute Lemma 6 in our analysis and improve the competitive ratio of Theorem 3.

## 6 The online algorithm

In this section we present an online algorithm that takes as input a pre-computed walk over the predicted request sequence and solves an appropriate online matching problem in order to construct detours that capture true requests, while taking into account the possible errors in the predictions. The formal guarantee of our algorithm is given in Lemma 7, which we restate for the reader's convenience:

► **Lemma 7.** *Given an instance  $(G, I, I', M)$  of the TW-TSP with predictions satisfying  $\tau_M \leq L_{\min}/2$  and  $\Lambda_M \leq (L_{\min} - 1)/4$ ; a walk  $W' \in \mathcal{W}(G)$ ; and any integer  $S' \geq 2\Lambda_M + 1$ , there exists an online algorithm (Algorithm 1) that returns a walk  $W \in \mathcal{W}(G)$  with expected reward*

$$\mathbb{E}[\text{Rew}(W, I, 1)] \geq \frac{1}{6\rho_M} \cdot \text{Rew}(W', I', S').$$

We begin by establishing some notation. Let  $W' \in \mathcal{W}(G)$  be any walk that services some predicted requests in  $I'$  with a service time of  $S'$ . We use  $\sigma'_i = (v'_i, r'_i, d'_i, \pi'_i)$  to denote the predicted requests in  $I'$  that are covered by  $W'$ , ordered in the sequence in which they are visited by  $W'$ . Likewise, we use  $\sigma_i = (v_i, r_i, d_i, \pi_i) \in I$  to denote the true request matched to the prediction  $\sigma'_i$ , that is,  $\sigma'_i = M(\sigma_i)$ .

At a high level, our algorithm follows the walk  $W'$ , but when it reaches a predicted request  $\sigma'_i$ , it considers taking a detour to service a true request that is available at that point of time. To this end, we define the set of “reachable” true requests as follows.

► **Definition 19.** *Given a partial walk  $W$  that is at request  $\sigma'_i \in I'$  at time  $t$ , we define the set of reachable requests  $R_i(W, t)$  to be the set of all  $\sigma \in I$  such that:*

1.  $r_\sigma \leq t \leq d_\sigma - \ell(v'_i, v_\sigma) - 1$ , and
2.  $2\ell(v'_i, v_\sigma) + 1 \leq S'$ .

Our algorithm considers all of the reachable requests that have not been covered by the walk as yet, chooses the one with the highest reward, and takes a detour to visit and cover the request, before returning to  $\sigma'_i$  and resuming the walk. In order to deal with time window errors, our algorithm starts the walk a little early, or on time, or a little late, as in the proof of Lemma 5. The algorithm is described below formally.

■ **Algorithm 1** Online algorithm for TSP-TW with predictions.

---

**Offline input:** Graph  $G$ , predicted requests  $I'$ , walk  $W' \in \mathcal{W}(G)$ , service times  $S'$ .

**Online input:** True requests  $I$ .

**Output:** Walk  $W \in \mathcal{W}(G)$ .

- 1: Let  $K = L_{\min}/2$ . Select  $\epsilon$  uniformly at random from  $\{-1, 0, 1\}$ .
  - 2: Define the set of covered requests  $C = \emptyset$ .
  - 3: **for**  $i \leftarrow 1$  to  $|\text{Cov}(W', I', S')|$  **do**
  - 4:   Let  $t'_i$  denote the time at which  $W'$  visits  $\sigma'_i$ .
  - 5:   Set  $t_i \leftarrow t'_i + \epsilon K$ .
  - 6:   Visit  $v'_i$  at time  $t_i$ .
  - 7:   Construct the set  $R_i(W, t_i)$  of requests in  $I$  reachable at time  $t_i$ .
  - 8:   **if**  $R_i(W, t_i) \setminus C = \emptyset$  **then**
  - 9:     Do nothing.
  - 10:   **else**
  - 11:     Let  $\hat{\sigma}$  be the highest reward request in  $R_i(W, t_i) \setminus C$ .
  - 12:     Visit  $v_{\hat{\sigma}}$ ; spend one unit of idle time at  $v_{\hat{\sigma}}$ ; return to  $v'_i$ .
  - 13:     Set  $C \leftarrow C \cup \{\hat{\sigma}\}$ .
- 

We begin our analysis by noting that the walk  $W$  constructed by the algorithm is always able to visit the vertices  $v'_i$  corresponding to requests  $\sigma'_i \in \text{Cov}(W', I', S')$  feasibly at the desired times  $t_i$ . This is because, by construction, the length of the detours that the walk  $W$  takes in Step 12 is always at most  $S'$  – the amount of idle time  $W'$  spends at  $v'_i$  – by virtue of the fact that  $\hat{\sigma} \in R_i(W, t_i)$  and therefore,  $2\ell(v'_i, v_{\hat{\sigma}}) + 1 \leq S'$ . Therefore, all of the requests  $\hat{\sigma}$  visited in Step 12 are indeed visited by the walk  $W$ .

We now relate the total reward covered by  $W$  to the reward contained in the true requests  $\sigma_i$  corresponding to  $\sigma'_i \in \text{Cov}(W', I', S')$ . To do so, we first note that with constant probability each such request is reachable by  $W$ .

► **Claim 20.** For each  $i$ ,  $\sigma_i \in R_i(W, t_i)$  with probability at least  $1/3$ .

Proof. Recall that by definition we have  $\sigma'_i = M(\sigma_i)$  and so,  $2\ell(v'_i, v_i) + 1 \leq 2\Lambda_M + 1 \leq S'$ . So the request  $\sigma$  always satisfies the second requirement in the definition of the reachable set  $R_i(W, t_i)$ . Let us now consider the first requirement and recall that  $t_i = t'_i + \epsilon K$  where  $\epsilon \in \{-1, 0, 1\}$ . We will now argue that  $t_i \in [r_i, d_i - 1 - \ell(v'_i, v_i)]$  for at least one of the three choices of  $\epsilon$ . The claim then follows from the uniformly random choice of  $\epsilon$ .

1. If  $t'_i \in [r_i, d_i - 1 - \ell(v'_i, v_i)]$ , then the claim holds for  $\epsilon = 0$  and  $t_i = t'_i$ .
2. Suppose that  $t'_i < r_i$ . Then, for  $\epsilon = 1$  we have that  $t_i = t'_i + K \geq r'_i + \tau_M \geq r_i$ , and also  $t_i = t'_i + K < r_i + K < d_i - L_{min} + L_{min}/2$  and thus  $t_i = t'_i + K \leq d_i - 1 - \ell(v'_i, v_i)$  since  $\ell(v'_i, v_i) \leq \Lambda_M \leq L_{min}/2$ . Thus, in this case we have  $t_i = t'_i + K \in [r_i, d_i - 1 - \ell(v'_i, v_i)]$  with the choice of  $\epsilon = 1$ .
3. Finally, suppose that  $t'_i > d_i - 1 - \ell(v'_i, v_i)$ . Then, for  $\epsilon = -1$  we have that  $t_i = t'_i - K \leq d'_i - S' - \tau_M \leq d_i - S'$  and thus  $t'_i - K \leq d_i - 1 - \ell(v'_i, v_i)$  since  $S' \geq 2\Lambda_M + 1 \geq \ell(v'_i, v_i) + 1$ . Also,  $t_i = t'_i - K > d_i - 1 - \ell(v_i, v'_i) - L_{min}/2 > r_i + L_{min}/2 - \ell(v_i, v'_i) - 1$  and thus  $t'_i - K \geq r_i$ , since  $\ell(v_i, v'_i) \leq \Lambda_M \leq L_{min}/2$ . Thus, in this case we have obtained that  $t_i = t'_i - K \in [r_i, d_i - 1 - \ell(v'_i, v_i)]$  with the choice of  $\epsilon = -1$ .  $\square$

We are now ready to prove Lemma 7 via a matching-type argument. To account for the reward covered by the walk  $W$  constructed by the algorithm, we will employ a standard charging scheme. Every time the algorithm takes a detour to cover some true request  $\hat{\sigma}$  from a predicted request  $\sigma'_i$  in Step 12, we will credit half of the earned reward  $\pi_{\hat{\sigma}}$  to  $\hat{\sigma}$  itself, and half of the reward to the request  $\sigma_i$ . Formally, let  $\text{Cr}(\sigma)$  denote the total credit received by  $\sigma \in I$ . Then during Step 12 we will increment both  $\text{Cr}(\hat{\sigma})$  and  $\text{Cr}(\sigma_i)$  by  $\pi_{\hat{\sigma}}/2$ .

Now consider some  $\sigma_i \in I$  corresponding to  $\sigma'_i \in \text{Cov}(W', I', S')$ . By Claim 20, this request is in  $R_i(W, t_i)$  with probability at least  $1/3$ . If at time  $t_i$ , the request has already been covered by  $W$ , then we get  $\text{Cr}(\sigma_i) \geq \pi_i/2$ . Otherwise, we pick a  $\hat{\sigma} \in R_i(W, t_i)$  with  $\pi_{\hat{\sigma}} \geq \pi_i$ , and therefore, once again we get  $\text{Cr}(\sigma_i) \geq \pi_i/2$ .

Putting everything together, we get

$$\begin{aligned} \mathbb{E}[\text{Rew}(W, I, S)] &= \mathbb{E}\left[\sum_{\sigma \in I} \text{Cr}(\sigma)\right] \geq \sum_{i: \sigma'_i \in \text{Cov}(W', I', S')} \mathbb{E}\left[\frac{\pi_i}{2} \mathbb{1}[\sigma_i \in R_i(W, t_i)]\right] \\ &\geq \frac{1}{3} \cdot \sum_{i: \sigma'_i \in \text{Cov}(W', I', S')} \frac{\pi_i}{2} \\ &\geq \frac{1}{6} \cdot \frac{1}{\rho_M} \cdot \sum_{i: \sigma'_i \in \text{Cov}(W', I', S')} \pi'_i \\ &= \frac{1}{6\rho_M} \cdot \text{Rew}(W', I', S') \end{aligned}$$

This completes the proof of the lemma.

## 7 Lower bounds

In this section, we present lower bounds that complement our results. First, we will motivate the need for predictions in Section 7.1. Then, in Section 7.2 we will show that the competitive ratio of TW-TSP with predictions must scale linearly with the error in locations. Finally, in Section 7.3 we argue the need for non-zero service times in the definition of TW-TSP with predictions.

### 7.1 Lower bounds for online TW-TSP without predictions

We argue that Online TW-TSP does not admit any reasonable competitive ratio in the absence of predictions. In the case of deterministic algorithms where their entire behavior is predictable, simple instances with only 2 vertices and appropriately small time-windows suffice to argue that no bounded guarantee for the approximation ratio is achievable.

► **Lemma 21.** *The competitive ratio of any deterministic online algorithm for Online TW-TSP on instances with  $L_{\min} \leq D$  is unbounded.*

**Proof.** Let DET be any deterministic algorithm and let  $G$  be the line graph with just two vertices  $v_1, v_2$  connected via an edge of length  $D$ . Since DET is deterministic, we can assume knowledge of its position at any step  $t$  as soon as we have specified all requests with release time  $\leq t$ . We will now construct a request sequence  $I$  that uses the information.

For the first  $D$  time-steps, we don't release any request. Then, at  $t = D$ , let  $v_D \in \{v_1, v_2\}$  be the position that DET's walk is currently at and likewise let  $v'_D$  be the other vertex of  $G$ . We construct the first request to be  $\sigma = (v'_D, D, D + L, 1)$  for any  $L \leq D$ . Clearly, DET cannot service this request as even for  $L = D$  it arrives on  $v'_D$  at deadline and cannot service it for one step. Then, we don't release any new request for the next  $2D$  steps, and at  $t = 3D$  we repeat the same process, by requesting the vertex that DET doesn't currently occupy. Likewise, we repeat the same process at  $t = 5D, t = 7D$  etc. Independently of the size of our request sequence, the total reward collected by DET is 0.

On the other hand, it is not hard to see that if our request sequence  $I$  has  $N$  requests in total, then  $\text{OPT}(G, I, 1) = N$ . This is due to the fact that requests are spaced  $2D$ -steps from each other, and thus an optimal offline algorithm that had knowledge of the entire sequence in advance would always be able to arrive at each request on time, servicing it within its respective time-window. ◀

For randomized algorithms, a slight improvement can be achieved. In particular, the randomized algorithm that picks a vertex uniformly at random and then remains idle on it for the entire sequence achieves a competitive ratio of  $1/n$ . It turns out that this is actually the best possible ratio that a randomized algorithm can achieve on Online TW-TSP:

► **Theorem 8.** *The competitive ratio of any randomized online algorithm for Online TW-TSP on instances with  $L_{\min} \leq D$  is at most  $1/n$ .*

**Proof.** Let  $G(V, E, \ell)$  be the uniform complete graph of  $n = |V|$  vertices, where all edges have a length of  $D$ . Fix any integer  $N$  and let vertices  $v_1, v_2, \dots, v_N \in V$  be drawn independently and uniformly at random. Next, we fix any window length  $L \leq D$  and consider the (random) request sequence on these vertices  $I = \{\sigma_i\}_{i=1}^N$  for  $\sigma_i = (v_i, (2i-1)D, (2i-1)D + L, 1)$ . From Yao's minimax principle, a lower bound on the (expected) competitive ratio of deterministic algorithms on this randomized instance will imply the same lower bound for randomized algorithms.

Since the time-windows are spaced  $2D$ -away from each other, it is not hard to see that for any realization of  $I$ ,  $\text{OPT}(G, I, 1) = N$ . On the other hand, since  $D \geq L$ , we get that the only way to service a request is to be on its corresponding vertex on release time. Since the vertices are random, for any deterministic algorithm this happens with probability precisely  $1/n$ , and thus the expected reward of any deterministic algorithm on this instance is  $N/n$ , proving the claim. ◀

## 7.2 Tight dependence on location error

In this section we show that a linear dependency on the location error is unavoidable for any randomized online algorithm for the TW-TSP with predictions, even assuming exponential computational power. In other words, we formally prove Theorem 10, which we re-state for the reader's convenience:

► **Theorem 10.** *For any  $S > 0$ , there exists an instance  $(G, I, I', M)$  of the TW-TSP with predictions satisfying  $\tau_M = 0$ ,  $\rho_M = 1$ , and  $\Lambda_M = S$  such that the competitive ratio of any randomized online algorithm taking the tuple  $(G, I', \Lambda_M)$  as offline input and  $I$  as online input asymptotically approaches  $1/(S + 1)$ .*

**Proof.** Fix any  $S > 0$  and let  $K, C$  and  $N$  be integer parameters that will be specified later. We construct a graph  $G = \cup_{i=0}^{N-1} G_i$  that consists of  $N$  copies  $G_0, \dots, G_{N-1}$  of the complete graph on  $C$  vertices with all edge lengths equal to  $S$ , arranged in a way so that each vertex in  $G_i$  connects to each vertex in  $G_{i+1}$  with an edge of length  $KS$ . A pictorial example for small values of  $C$  and  $N$  is shown in Figure 1.

■ **Figure 1** An example of  $G$  for  $C = 3$  and  $N = 4$ . Black edges have a length of  $S$  and red edges have a length of  $KS$ .

Next, we select independently and uniformly at random one vertex  $v_i$  from each sub-graph  $G_i$  and construct the (randomized) request sequence  $I = \{\sigma_i\}_{i=0}^{N-1}$  where we denote  $\sigma_i = (v_i, r_i, r_i + KS, 1)$  for  $r_i = i \cdot (KS + 1)$ . As for the predictions, we simply construct a second instance  $I'$  in the same manner and offer it as an offline prediction for  $I$ . Observe that for all possible constructions of  $I$  and  $I'$  it holds that there exists a matching  $M$  between them with  $\tau_M = 0$ ,  $\rho_M = 1$  and  $\Lambda_M = S$ , namely the matching that pairs together vertices from the same sub-graphs. This prediction provides no information to the algorithm other than the fact that the (true) instance  $I$  was constructed via the above randomized approach. Also, notice that the location error  $\Lambda_M$  can be arbitrarily small compared to the window length  $L = KS$  by choosing appropriately large  $K$ .

It is easy to see that for all possible realizations of  $I$  it holds that  $\text{OPT}(G, I, 1) = N$ . Indeed, consider the walk that starts from the (random) vertex  $v_0$ , remains idle for 1 step and then visits vertex  $v_1$ , remains idle for one step, visits  $v_2$ , etc. Such a walk would visit each vertex  $v_i$  at step  $t = i \cdot KS + i = r_i$  and thus would service all the requests in  $I$ , achieving a total reward of  $N$ . Next, we will show that the expected reward of any deterministic algorithm on the random sequence  $I$  approaches  $N/S$ . Using Yao's minimax principle, this will immediately translate to a lower bound that approaches  $1/S$  for randomized algorithms, completing the proof of the theorem.

Fix any deterministic algorithm for TW-TSP with predictions on instance  $(G, I, I', M)$ . Note that since the predictions  $I'$  supply zero information, it suffices to analyze the algorithm as a deterministic online algorithm for Online TW-TSP on instance  $I$ . The key observation is that due to the fact that both the time windows of the requests and the edges that connect different sub-graphs have a length of  $KS$ , it is impossible for the algorithm to know on what vertex  $v_i$  of subgraph  $G_i$  the request is going to arrive before visiting some possibly different vertex of the same subgraph. In particular, if the algorithm is in subgraph  $G_j$  for  $j < i$  at time  $r_i$ , then it cannot reach vertex  $v_i$  before the time window of request  $i$  ends. Thus, in order for any deterministic algorithm to serve the request on sub-graph  $G_i$ , it first has to visit some vertex  $v'_i$  of  $G_i$ . If it so happens that  $v'_i = v_i$  then it can immediately service the request, otherwise it has to travel a distance of  $S$  in order to reach  $v_i$ .

We partition the set of requests into two sets  $N_+$  and  $N_-$  based on whether the deterministic algorithm happens to arrive on the correct vertex of the sub-graph or not. All the requests in  $N_+$  can be serviced without any extra delay, exactly as done by the optimal walk. On the other hand, servicing a request in  $N_-$  requires the algorithm to spend an extra time of  $S$  in order to transition to the right vertex. Since the time-windows have a length of  $KS$ , this can be done at most  $K$  times before the algorithm runs out of slack to spare. When this happens, the algorithm would have to skip the next  $S$  requests in order to recover enough slack to fix its next mistake.

Formally, consider the last request in  $N_-$  that the algorithm feasibly serves, call it  $l$ . Let  $A$  be the number of requests in  $N_-$  the algorithm serves through extra delay prior to  $l$ , and let  $B$  be the number of requests the algorithm skips in  $N_+$  or  $N_-$  prior to  $l$ . Then in order for the algorithm to have reached  $l$  before its time window ends, it must be the case that the total extra delay incurred by the algorithm, namely  $AS - B$ , is no more than  $KS$ . Rearranging we get:

$$A(S + 1) - (A + B) \leq KS, \quad \text{or,} \quad A \leq \frac{A + B}{S + 1} + \frac{KS}{S + 1} < \frac{N}{S + 1} + K$$

Thus, we get that the total expected reward gathered by the algorithm is at most

$$\mathbb{E}[|N_+|] + A + 1 \leq \mathbb{E}[|N_+|] + \frac{N}{S + 1} + K + 1$$

Finally, using the fact that  $\mathbb{E}[|N_+|] = N/C$ , we get that the competitive ratio of any deterministic algorithm on the random instance  $I$  is at most

$$\frac{1}{C} + \frac{K + 1}{N} + \frac{1}{S + 1}$$

Choosing  $N \gg K$  and  $C$  sufficiently large, we can make this competitive ratio asymptotically approach  $1/(S + 1)$  as desired.  $\blacktriangleleft$

### 7.3 Comparing the optimal with and without service times

As we saw in Lemma 4, the gap between  $\text{OPT}(G, I, 1)$  and  $\text{OPT}(G, I, S)$  depends linearly on the service time  $S$ . In this section, we study the gap between  $\text{OPT}(G, I, 1)$  and  $\text{OPT}(G, I, 0)$ , showing that there exists a much sharper separation between them.

► **Theorem 22.** *For any integers  $L$  and  $D$ ,  $L \leq D$ , there exists an offline instance  $(G, I)$  of the TW-TSP where  $D$  is the diameter of the network and every request has a time window length equal to  $L$ , such that  $\text{OPT}(G, I, 1) \leq \frac{L}{D+1} \cdot \text{OPT}(G, I, 0)$ .*

**Proof.** Consider the line graph  $G$  with vertices  $v_0$  through  $v_D$  connected sequentially via edges of length 1. Clearly, the diameter of  $G$  is  $D$ . Next, consider the sequence of  $(D + 1)$ -requests  $I = \{\sigma_i\}_{i=0}^D$  where  $\sigma_i = (v_i, i, L + i, 1)$ . Observe that  $\text{OPT}(G, I, 0) = D + 1$  as simply following the walk from  $v_0$  to  $v_D$  will cover all the requests if the service costs are 0.

On the other hand, it is not very hard to see that  $\text{OPT}(G, I, 1) = L$ . First, observe that without loss we can assume that the optimal walk starts on  $v_0$ . If not, let  $\sigma_i$  be the *first* request served by the optimal. Since  $\sigma_i$  cannot be served prior to step  $r_i = i$ , we could instead start at  $v_0$  and take  $i$  steps in order to reach  $v_i$  and then follow the original walk, achieving precisely the same reward.

Our argument is completed by the simple observation that any walk that starts from  $v_0$  and has served  $x$  requests with service cost 1 *cannot* visit vertex  $v_j$  prior to step  $j + x$ . Thus, as soon as  $x$  becomes  $L$  all the future time-windows will be missed. ◀

Theorem 22 states that  $\text{OPT}(G, I, 0)$  is a much stronger benchmark than  $\text{OPT}(G, I, 1)$ . However, it doesn't exclude the possibility of designing an algorithm that is competitive against this stronger benchmark  $\text{OPT}(G, I, 0)$ . We will next show that no randomized online algorithm with predictions can obtain a better than linear competitive ratio against this benchmark. Intuitively, requiring the algorithm to spend non-zero time at each request also allows the algorithm to recover from possible mistakes due to the prediction errors by skipping requests that the optimum services with a delay of 1. A similar approach is not possible in the 0 service time setting.

► **Theorem 9.** *For any  $S > 0$ , there exists an instance  $(G, I, I', M)$  of the TW-TSP with predictions and service times 0, satisfying  $\tau_M = 0$ ,  $\rho_M = 1$ , and  $\Lambda_M = S$ , such that any randomized online algorithm taking the tuple  $(G, I', \Lambda_M)$  as offline input and  $I$  as online input achieves a reward no larger than  $O(1/n) \cdot \text{OPT}(G, I, 0)$ . Here  $n$  is the number of vertices in  $G$ .*

**Proof.** We construct the same graph  $G = \cup_{i=0}^{N-1} G_i$  as in Theorem 10, that consists of  $N$  copies of the complete graph with edge lengths  $S$ , connected sequentially with edges of length  $KS$  (see Figure 1). As for the request sequence, we once again select independently and uniformly at random one vertex  $v_i$  from each sub-graph  $G_i$  and construct the (randomized) request sequence  $I = \{\sigma_i\}_{i=0}^{N-1}$  where  $\sigma_i = (v_i, iKS, (i + 1)KS - 1, 1)$ ; notice that release times are slightly different from Theorem 10 to account for the absence of service costs.

For the predictions, we simply construct a second instance  $I'$  in the same manner and offer it as an offline prediction for  $I$ . By matching the requests on the same sub-graph together, we get  $\tau_M = 0$ ,  $\rho_M = 1$  and  $\Lambda_M = S$ . As it clearly holds that  $\text{OPT}(G, I, 0) = N$  for any realization of  $I$ , to prove our theorem it suffices to argue that any deterministic algorithm for TW-TSP with predictions on instance  $(G, I, I', M)$  gets an expected reward of  $\mathcal{O}(N/n)$  and apply *Yao's minimax principle*. Furthermore, since the prediction  $I'$  does not provide any information on  $I$ , it suffices to bound the reward of deterministic algorithms for Online TW-TSP on (online) instance  $I$ .

Fix any deterministic algorithm for Online TW-TSP on instance  $I$ . Observe that since edges between different sub-graphs have a length of  $KS$  and time-windows have a length of  $KS - 1$ , it is impossible for the algorithm to service some request  $\sigma_i$  unless at  $t = r_i$  it is already in some vertex of sub-graph  $G_i$ . For the same reason, it is not possible to service any request  $\sigma_j$  after servicing some other request  $\sigma_i$  with  $i > j$ . Finally, since all requests can be reached by their release time if the algorithm starts from a vertex in  $G_0$ , we can assume without loss that this is indeed the case.

We partition our set of  $N$  requests into two sets  $N_+$  and  $N_-$  based on whether the deterministic algorithm *happens* to arrive on the correct vertex of the sub-graph before the request's release time or not. From the random construction of our instance, we have that  $\mathbb{E}[|N_+|] \leq N/C$ . For requests in  $N_-$ , if the algorithm wishes to service them it has to take a detour of length  $S$  in order to reach the correct vertex. Our proof relies on the fact that after servicing  $K$  requests in  $N_-$ , the algorithm can no longer service any other request. To see this, let  $v_j$  be the  $K$ -th request in  $N_-$  that was serviced by the deterministic algorithm. As we can already established, any request  $v_i$  with  $i < j$  can no longer be serviced. On the other hand, since without loss the algorithm starts at a vertex of  $G_0$ , just reaching a vertex in  $G_i$  while taking  $K$  detours of length  $S$  requires at least  $iKS + K > d_i$  time-steps. Putting everything together, we get that the expected reward of the algorithm is at most  $N/C + K = \mathcal{O}(N/n)$  by setting  $K = \mathcal{O}(1)$  and  $N = 2K$ , since  $n = NC$ . ◀

## Abstract

While much of network design focuses mostly on cost (number or weight of edges), node degrees have also played an important role. They have traditionally either appeared as an objective, to minimize the maximum degree (e.g., the Minimum Degree Spanning Tree problem), or as constraints that might be violated to give bicriteria approximations (e.g., the Minimum Cost Degree Bounded Spanning Tree problem). We extend the study of degrees in network design in two ways. First, we introduce and study a new variant of the Survivable Network Design Problem where in addition to the traditional objective of minimizing the cost of the chosen edges, we add a constraint that the  $\ell_p$ -norm of the node degree vector is bounded by an input parameter. This interpolates between the classical settings of maximum degree (the  $\ell_\infty$ -norm) and the number of edges (the  $\ell_1$ -degree), and has natural applications in distributed systems and VLSI design. We give a constant bicriteria approximation in both measures using convex programming. Second, we provide a polylogarithmic bicriteria approximation for the Degree Bounded Group Steiner problem on bounded treewidth graphs, solving an open problem from [17] and [12].

## 1 Introduction

The overarching theme of network design problems is to find “inexpensive” subgraphs that satisfy some type of connectivity constraints. The notion of “inexpensive” is often either the number of edges (unweighted cost) or the sum of edge costs (weighted cost). However, it has long been recognized that in many applications *vertex degrees* matter as much (or more) than cost. This is particularly true in the context of networking and distributed systems, where the degree of a node often corresponds to the “load” on that node, as well as in VLSI design. So there has been a significant amount of work on handling degrees, either instead of or in addition to cost, which has led to many seminal papers and results. With degrees as an objective, these include the well known local search approach of Fürer and Raghavachari [8] for the Minimum Degree Spanning Tree problem and the Minimum Degree Steiner Tree problem. With degrees as a constraint, these include the iterative rounding [16] approach of Singh and Lau [23] for the Minimum-Cost Bounded-Degree Spanning Tree problem, as well as many extensions (most notably to Survivable Network Design with degree bounds [20], but see [19] for many other examples).

In this paper we extend the study of degrees in network design in two ways. First, we introduce what is (to the best of our knowledge) a new class of problems. Instead of bounding the cost and individual degrees as in [23, 20], our objective is to obtain minimum cost while satisfying a bound on the  $\ell_p$ -norm of the node degree vector. This interpolates between the maximum degree (the  $\ell_\infty$ -norm) and the total number of edges or unweighted cost (the  $\ell_1$ -degree). Second, we solve a well known open problem: We give a poly-logarithmic bicriteria approximation for the Group Steiner Tree problem with degree bounds on bounded treewidth graphs.

**$\ell_p$ -Objective.** While the maximum degree is often a reasonable objective, as is minimizing the total cost (either with or without degree bounds), there are many natural situations where none of these approaches are fully satisfactory. If we simply ignore the degrees and focus on cost (weighted or unweighted), then we might end up with a solution with highly imbalanced degrees, leading to large load at particular nodes. If we ignore costs and simply optimize the maximum degree, then we might return a solution with far more edges than are needed: if the structure of the graph forces some node to have large degree, then if we simply try to minimize the maximum degree we will not even try to make the degrees of other nodes small. Finally, optimizing under individual degree bounds implicitly assumes that nodes “really have” these degree bounds, i.e., they come from some external constraint. But this is of course not always the case: often we do not have real bounds on individual nodes, but rather a more vague desire to “keep degrees small”.

Hence we want some way of making sure that the maximum degree is small, but also encouraging few edges. A natural function that simultaneously accomplishes both of these goals is the  $\ell_p$ -norm of the degree vector, i.e., the function  $(\sum_{v \in V} (\deg_v)^p)^{1/p}$  for  $p \geq 1$  (and in particular for  $p = 2$ ), where  $\deg_v$  is the degree of  $v$  in the output subgraph. When  $p = 1$  this is simply (twice) the number of edges (i.e., the unweighted cost), and when  $p = \infty$  this is the maximum degree. But for intermediate values of  $p$ , it discourages very large degrees (in particular the maximum degree) since  $p > 1$  implies that large degrees have a larger effect on the norm than smaller degrees, while still also being effected on a non-trivial way by the smaller degrees. So we can either use the  $\ell_p$ -norm as an objective function, or we can use it as a constraint that is far more flexible than having simple degree constraints at every node.

This intuition, that the  $\ell_p$ -norm takes into account both the maximum and the distribution simultaneously, is one reason why the  $\ell_p$ -norm has been an important objective function for combinatorial problems. For example, the Set Cover problem was studied under the  $\ell_p$  norm of the vector of number of elements assigned to each set [10]. It was also extensively studied in scheduling problems (see for example [1, 2, 18, 15]). To the best of our knowledge, the  $\ell_p$  norm has not been studied in the context of network design, with the notable recent exception of *graph spanners* [6, 5], where the direct applications of spanners to distributed systems led to exactly this motivation. Similarly, MST with  $\ell_p$  norm is very important for VLSI design, since in many such settings we are forced to use spanning trees and hence the number of edges is fixed. So minimizing the  $\ell_p$  norm will likely derive a balanced degree vector which is of key importance for these VLSI application (see, for example, [24, 22]).

Motivated by the above discussion, we introduce and give the first approximation for the Survivable Network design problem with low cost under a bound on the  $\ell_p$  norm of the degree vector.

**Group Steiner Tree with Degree Bounds.** In addition to the study of  $\ell_p$ -norm problems, we also make significant progress on a known open problem: approximating Group Steiner Tree with degree bounds on bounded treewidth graphs. The Group Steiner Tree problem

(without degree bounds) is a classical optimization problem [9] which has played a central role in network design. In this problem there is a designated root node  $r$ , and a collection of (not necessarily disjoint) *groups* of vertices. The goal is to find a subtree which connects at least one vertex from each group to  $r$ , while minimizing the total cost of all edges in the subtree. The Degree Bounded Group Steiner problem was first raised by Hajiaghayi in [13] (in the 8th Workshop on Flexible Network Design), motivated by the online version of the problem and applications to VLSI design. In particular, while low cost is highly desirable, this cost is paid only once, while later the VLSI circuit is applied (evaluated) constantly. Low degrees imply that the computation of the value of the circuit can be done faster. See a discussion of why low degrees are important for Group Steiner in [17].

Unfortunately, despite significant recent interest in this problem [12, 17], progress has been elusive. In particular, polylogarithmic bicriteria approximations were not even known for simple classes such as *series-parallel* graphs, i.e., for graphs with treewidth 2. We go far beyond series-parallel graphs, and give results for bounded treewidth graphs.

## 1.1 Our Results and Techniques

We begin in Section 2 with a study of the  $\ell_p$ -Survivable Network Design problem. We are given the input graph  $G = (V, E)$ , with edge costs  $c \in \mathbb{R}_{\geq 0}^E$ . There is a connection requirement vector  $r \in \mathbb{Z}_{\geq 0}^{\binom{V}{2}}$ , a number  $p \geq 1$  and a bound  $A$  on the  $\ell_p$  norm of the degree vector of the output graph. The goal of the problem is to find the minimum-cost subgraph  $H$  of  $G$  satisfying the following:

- **(connection requirements)** for every  $u, v \in V$  with  $u \neq v$ , there are at least  $r_{u,v}$  edge disjoint paths between  $u$  and  $v$  in  $H$ , and
- **(degree constraint)**  $(\sum_{v \in V} d_H^p(v))^{1/p} \leq A$ , where  $d_H(v)$  is the degree of  $v$  in  $H$ .

We assume the input instance is feasible; that is, there is a valid sub-graph  $H$  satisfying both requirements. Let  $\text{opt}$  be the minimum cost of a valid subgraph  $H$ . The main theorem we prove for the problem is the following:

► **Theorem 1.** *There is a (randomized) algorithm which, given an instance of  $\ell_p$ -SURVIVABLE NETWORK DESIGN, outputs a subgraph  $H$  satisfying the connection requirements and which has the following properties.*

- *The expected cost of  $H$  is at most  $2 \cdot \text{opt}$ .*
- *The expectation of the  $\ell_p$ -norm of the degree vector is at most  $2^{1/p} 5^{1-1/p} \cdot A$ .*

For the special case of  $\ell_p$ -Spanning Tree problem, where  $r_{uv} = 1$  for all  $u, v \in V$ , we improve the expected cost to at most  $\text{opt}$  (rather than  $2 \cdot \text{opt}$ ) and the expectation of the  $\ell_p$ -norm of the degree vector to at most  $2^{1-1/p} \cdot A$ .

Our main approach is to leverage the fact that the  $\ell_p$ -norm is *convex*. This allows us to write a convex relaxation for the problem, which can then be solved efficiently using standard convex programming techniques. We then round this solution using an iterative rounding approach. Making this work requires overcoming a number of issues, possibly the trickiest of which is handling fractional degrees that are less than 1. Note that a fractional solution could have many nodes with very small fractional degree (e.g.,  $1/n$ ). Due to the structure of the  $\ell_p$ -norm, such small values contribute far less to the  $\ell_p$ -norm than they “should” (in an integral solution). To get around this, we actually *change* the  $\ell_p$ -constraint in a way that acts differently for values less than 1, while still maintaining convexity. With this change in place, we can solve the relaxation, interpret the fractional degrees “as if” they are true degree bounds, and then round using existing results on iterative rounding for degree-bounded network design.

We then move to our second problem, Group Steiner Tree with Degree Bounds on bounded treewidth graphs. In the problem, we are given a graph  $G = (V, E)$  with treewidth  $\text{tw}$ , a cost vector  $c \in \mathbb{R}_{\geq 0}^E$ , a root  $r$ , and  $k$  sets  $S_1, S_2, \dots, S_k$ . We are additionally given a degree bound  $\text{db}_v \in \mathbb{Z}_{>0}$  for every  $v \in V$ . The goal of the problem is to choose a minimum-cost subgraph  $H$  of  $G$  such that for every  $t \in k$ ,  $H$  contains a path from  $r$  to some vertex in  $S_t$ , and  $d_H(v) \leq \text{db}_v$  for every  $v \in V$ . By minimality, the optimum  $H$  is always a tree. We solve an open problem from [12] and [17] by giving a polylogarithmic bicriteria algorithm as long as the treewidth is bounded. In particular, we prove the following theorem.

► **Theorem 2.** *There is an  $n^{O(\text{tw} \log \text{tw})}$ -time randomized algorithm for the Group Steiner Tree with Degree Bounds problem on bounded treewidth graphs which has  $O(\log^2 n)$  approximation ratio and  $O(\log^2 n)$ -degree violation.*

In order to achieve this result, we reduce the problem to a “tree labeling” problem in Section 3, which has been used in prior results [11, 12, 21]. There is a rooted full binary tree, and we need to give a label  $\ell_u$  for each node  $u$  in the tree from a subset  $L_u$  of potential labels. For every internal node  $u$  with two children  $v$  and  $v'$  there are some consistency constraints on the labels, which say that the triple  $(\ell_u, \ell_v, \ell_{v'})$  must be from some given subset  $\Gamma_u \in L_u \times L_v \times L_{v'}$ . Then we have some covering constraints, each specified by a set  $S$  of labels: the constraint requires that at least one node has its label in  $S$ . Finally, we have many cost constraints. For each such constraint, a label is given a cost, and we require that the total cost of all labels used is at most 1. For this problem we give a randomized algorithm that outputs a labeling that satisfies all consistency constraints, and approximately satisfies the covering and cost constraints with reasonable probability, assuming the given instance is feasible. It runs in polynomial time when the depth of the tree is  $O(\log n)$  and each  $L_u$  has  $O(1)$ -size. The main techniques of the algorithm are adaptations of the LP-rounding algorithm in [12] for their degree-bounded network design problem. We introduce the tree labeling problem as a host for these techniques, and adapt them for the problem.

Due to space limitations, we leave the reduction of Group Steiner Tree with Degree Bounds on bounded treewidth graphs to this tree labeling problem to Appendix B, and give a high-level idea here. Let  $\text{tw}$  be the treewidth of the graph; it is known from [3] that we can assume the decomposition tree of  $G$  is an  $O(\log n)$ -depth binary tree, with bag size  $O(\text{tw})$ . This decomposition tree will be the tree in the tree-labeling instance. For each bag in the tree, a label will contain the set of edges we take from the bag, and some connectivity information on the vertices in the bag. We define the consistency constraints so that if they are satisfied, then the connectivity information is correct. A group being connected can be captured by a covering constraint in the tree labeling instance, and the edge cost constraint and degree constraints can be formulated as cost constraints in the instance. Using the algorithm for the tree labeling instance, we obtain a tree with small cost that satisfies degree bounds approximately, and connects a group with reasonable probability. The final output then is obtained by running the procedure many times and taking the union.

## 1.2 Other Related Work

For the survivable network design problem without any degree constraints, the classic result of Jain [16] gives a 2-approximation algorithm using the iterative rounding method. In [9] an  $O(\log^2 n)$  approximation is given for the Group Steiner problem on tree inputs, and an  $O(\log^3 n)$  for the Group Steiner problem (without degree constraints) for bounded treewidth graphs. The approximation for trees is almost the best possible, unless NP problems can be solved in quasi-polynomial time [14]. [12] gave a bicriteria approximation for the Group

Steiner Tree Problem with degree bounds on tree inputs, with approximation ratio  $O(\log^2 n)$  and degree violation  $O(\log n)$ . Both bounds are nearly optimal [14, 7]. In [4] the authors gave an  $O(\log^2 n)$ -approximation ratio for Group Steiner problem on bounded treewidth graphs (without degree bounds). In [17] an  $O(\log^2 n)$  approximation is given for the Group Steiner problem with minimum maximal degree, but without costs.

**Notations.** Given a graph  $H$  and a vertex  $v$  in  $H$ , we shall use  $\delta_H(v)$  to denote the set of edges in  $H$  incident to  $v$ , and  $d_H(v) = |\delta_H(v)|$  to denote its degree. Given a rooted tree  $T$  and a vertex  $v$  in  $T$ , we use  $\Lambda_T(v)$  to denote the set of children of  $v$  in  $T$ , and  $\Lambda_T^*(v)$  to denote the set of descendants of  $v$  in  $T$  (including  $v$  itself). When  $H$  and  $T$  are clear from the context, we shall omit them in the subscript. For example, this happens when  $H = G$  is the input graph. For a real vector  $z$  over some domain, and a subset  $S$  of elements in the domain, we define  $z(S) := \sum_{i \in S} z_i$  to denote the sum of  $z$  values of elements in  $S$ .

## 2 $\ell_p$ -Survivable Network Design

In this section, we give our iterative rounding algorithm for  $\ell_p$ -survivable network design problem. Recall that we are given a graph  $G = (V, E)$  with cost vector  $c \in \mathbb{R}_{\geq 0}^E$ , a connection requirement vector  $r \in \mathbb{Z}_{\geq 0}^{\binom{V}{2}}$ , and a bound  $A$  on the  $\ell_p$  norm of the degree vector.

► **Definition 3.** We say a polytope  $\mathcal{P} \in [0, 1]^E$  is good if it is upward-closed<sup>1</sup> and the following holds: For every vector  $x \in \{0, 1\}^E$ , we have that  $x \in \mathcal{P}$  if and only if the graph  $(V, \{e \in E : x_e = 1\})$  satisfies the connection requirements.

Notice that the above definition does not capture the degree constraints. This is done using the following definition. For a real vector  $B \in [1, \infty]^V$ , we define  $\mathcal{Q}_B := \{x \in [0, 1]^E : \forall v \in V, x(\delta(v)) \leq B_v\}$  to be the set of all vectors satisfying the degree bounds defined by  $B$ .

► **Definition 4.** Let  $\alpha \geq 1$  and  $\beta \geq 0$  be two real numbers and  $\mathcal{P}$  be a good polytope. We say  $\mathcal{P}$  is  $(\alpha, \beta)$ -integral if for every  $B \in [1, \infty]^V$ , every non-integral extreme point  $x$  of  $\mathcal{P} \cap \mathcal{Q}_B$  satisfies at least one of the following two properties:

(4a) there exists an edge  $e \in E$  with  $1/\alpha \leq x_e < 1$ ,

(4b) there is a vertex  $v \in V$  such that  $x(\delta(v)) = B_v$  and  $|\{e \in \delta(v) : x_e > 0\}| \leq B_v + \beta$ .

It is well known that for Survivable Network Design there is a  $(2, 3)$ -integral polytope  $\mathcal{P}$  [20]. For the special case of spanning tree, i.e.,  $r \equiv 1$ , there is a  $(1, 1)$ -integral polytope [23].

We will use these polytopes in our algorithm, and will show that their existence implies good approximation algorithms. More formally, we prove the following theorem.

► **Theorem 5.** Assuming the existence of an  $(\alpha, \beta)$ -integral polytope, there is a randomized algorithm which outputs a subgraph  $H$  of  $G$  satisfying the connection requirements. The expected cost of  $H$  is at most  $\alpha \cdot \text{opt}$  and the expectation of the  $p$ -norm of degree vector is at most  $\alpha^{1/p}(\alpha + \beta)^{1-1/p} A$ ; recall that  $\text{opt}$  is the value of the instance.

Note that this theorem, together with the existence of a  $(2, 3)$ -integral polytope for the general case and a  $(1, 1)$ -integral polytope for the spanning tree case, imply Theorem 1. So we focus on proving Theorem 5.

<sup>1</sup> This means for every  $x \in \mathcal{P}$  and  $x' \in [0, 1]^E$  with  $x' \geq x$ , we have  $x' \in \mathcal{P}$ .

(a) The function  $f$  for  $p = 2$ .

- 1: Solve LP(1) to obtain a solution  $x$
- 2: let  $B_v \leftarrow \max\{x(\delta(v)), 1\}$  for every  $v \in V$
- 3: **while true do**
- 4:   randomly choose an extreme point  $x'$  of  $\mathcal{P} \cap \mathcal{Q}_B$  such that  $\mathbb{E}[x'] = x$
- 5:    $x \leftarrow x'$
- 6:   **if**  $x$  is integral **then return**  $x$
- 7:   **if** case a happens for some  $e = (u, v) \in E$  **then**
- 8:        $x_e \leftarrow 1, B_v \leftarrow x(\delta(v)), B_u \leftarrow x(\delta(u))$
- 9:   **else**                            $\triangleright$  case b happens for some  $v$
- 10:      $B_v \leftarrow \infty$

## 2.1 The Convex Program

Define a function  $f : \mathbb{R}_{\geq 0} \rightarrow \mathbb{R}_{\geq 0}$  as follows:  $f(x) = \begin{cases} x & \text{if } x \in [0, 1] \\ x^p & \text{if } x > 1 \end{cases}$ . Figure (1a) shows this function for  $p = 2$ . This is a convex function for  $p \geq 1$ .

Let  $\mathcal{P}$  be an  $(\alpha, \beta)$ -integral polytope. The following is our convex programming relaxation for the problem:

$$\min \sum_{e \in E} c_e x_e \quad \text{s.t.} \quad x \in \mathcal{P}, \quad \sum_{v \in V} f(x(\delta(v))) \leq A^p. \quad (1)$$

Recall that using our notation,  $x(\delta(v))$  is the sum of  $x$  values of edges incident to  $v$  in  $G$ . (1) is a convex program and can be solved efficiently. Since the indicator vector of the optimum subgraph  $H$  satisfies all the constraints, the value of the convex program is at most opt.

We note that if we instead used the function  $f(x) = x^p$  (i.e., without handling the  $0 \leq x \leq 1$  case separately), we would still have a convex relaxation of our problem. However, it is not hard to show that this relaxation has an extremely large integrality gap (even if we are allowed to violate the  $\ell_p$ -norm constraint by a polylogarithmic factor). Treating  $0 \leq x \leq 1$  differently from  $x > 1$  is one of the key ideas in our approximation algorithm.

## 2.2 The Iterative Rounding Algorithm

Our iterative rounding algorithm is described in Figure (1b). In Step 1, we solve the convex relaxation (1) to obtain an extreme solution  $x$ , which can be done in polynomial time using standard techniques. Then in Step 2 we define  $B_v = \max\{x(\delta(v)), 1\}$  for every  $v$  to be the upper bound on the degree of  $v$ . So, before Loop 3, we have  $x \in \mathcal{P} \cap \mathcal{Q}_B$ . We shall maintain this property before and after each iteration of the loop.

In each iteration of Loop 3, we randomly choose a vertex point  $x'$  of  $\mathcal{P} \cap \mathcal{Q}_B$  such that  $\mathbb{E}[x'] = x$  (Step 4) and then update  $x$  to be the  $x'$  (Step 5). This is possible since at the beginning of the iteration we have  $x \in \mathcal{P} \cap \mathcal{Q}_B$ . If  $x$  is integral, we then return  $x$  in Step 6. If we did not return, by that  $\mathcal{P}$  is  $(\alpha, \beta)$ -integral, either a or b happens. In the former case, we update  $x_e$  to 1, and change  $B_v$  and  $B_u$  for the two end vertices  $u, v$  of  $e$  so that we still have  $B_{v'} = \max\{x(\delta(v')), 1\}$  for every  $v' \in V$  (Step 8). In the latter case, we change  $B_v$  to  $\infty$  so that there will be no degree constraint for  $v$  from now on. Notice that in either case, we maintain the invariant that  $x \in \mathcal{P} \cap \mathcal{Q}_B$  as  $\mathcal{P}$  is upward-closed.

Notice that once  $x_e$  becomes 0 or 1 in some iteration, it will remain unchanged. This holds since for  $\mathbb{E}[x'_e] = x_e \in \{0, 1\}$  to hold, we must always have  $x'_e = x_e$ . When the algorithm terminates, it returns an integral  $x$  which satisfies the connectivity requirements. This holds since we have  $x \in \mathcal{P}$  and  $\mathcal{P}$  is good. The algorithm will terminate in  $O(|E|)$  iterations since in every iteration, we either fixed the value of some  $x_e$  to 1, or changed some  $B_v$  from a finite number to  $\infty$ .

### 2.3 Analysis of the Algorithm

We now begin to analyze the algorithm. As discussed, the algorithm will terminate with a subgraph which satisfies the connectivity requirements. To prove Theorem 5, we need to analyze the total cost and the  $\ell_p$ -norm of the degrees.

In Step 8, we say that we *round* the edge  $e$ . In Step 10, we say we *relax* the vertex  $v$ . At any time of the algorithm, we define a vector  $\bar{x} \in [0, 1]^E$  as follows. If  $e$  has not been rounded yet, then let  $\bar{x}_e = x_e$ . Otherwise, let  $\bar{x}_e$  be the value of  $x_e$  right before Step 8 in which we round  $e$ . Thus, from the moment,  $\bar{x}_e$  remains unchanged.

Let  $T$  be the number of iterations we run Loop 3; notice that this is a random variable. For every integer  $t \in [0, T]$ , we let  $x^t, \bar{x}^t, B^t$  to be the values of  $x, \bar{x}, B$  at the end of the  $t$ -th iteration of the Loop 3. So  $x^T$  is the output of the algorithm.

► **Observation 6.** *The following statements are true.*

- (6a) *During Loop 3, we always have  $\bar{x}_e \leq x_e \leq \alpha \bar{x}_e$  for every  $e \in E$ .*
- (6b) *Assume  $x^0(\delta(v)) < 1$  for a vertex  $v \in V$ . Then at the first moment when  $x(\delta(v)) \geq 1$  holds, we have  $\bar{x}(\delta(v)) \leq 1$ .*
- (6c)  *$\bar{x}(\delta(v))$  does not change from the first moment  $x(\delta(v)) \geq 1$  holds, until the moment  $v$  is relaxed, or the end of the algorithm if this does not happen.*

**Proof.**  $\bar{x}_e \leq x_e$  by the definition of  $\bar{x}_e$ . Moreover,  $x_e \leq \alpha \bar{x}_e$  as if  $x_e > \bar{x}_e$ , then  $x_e = 1$  and  $x_e \geq \frac{1}{\alpha}$ . So a holds.

To prove b, we consider two scenarios. In the first scenario, the moment is after Step 5 in some iteration. In this scenario,  $\bar{x}(\delta(v)) = x(\delta(v)) = 1$  since  $B_v = 1$  at the moment. In the second scenario, the moment is after we round some edge  $e \in \delta(v)$  in Step 8. In this case  $\bar{x}(\delta(v))$  is the same as  $x(\delta(v))$  before the step, which is strictly less than 1.

c holds since we maintained  $B_v = x(\delta(v))$  from the moment  $x(\delta(v))$  becomes at least 1. If  $\bar{x}_e \neq x_e$  at some time, it must be the case that  $x_e = 1$ . In this case, both  $x_e$  and  $\bar{x}_e$  will not change in the future. ◀

We can now analyze the expected cost of the algorithm. First, though, we will need a structural result.

► **Lemma 7.** *For every edge  $e \in E$ , the sequence  $\bar{x}_e^0, \bar{x}_e^1, \dots, \bar{x}_e^T$  is a martingale.*

**Proof.** Focus on an iteration  $t \geq 1$  and edge  $e \in E$ , and we fix the sequence  $\bar{x}_e^0, \bar{x}_e^1, \dots, \bar{x}_e^{t-1}$ . For simplicity we use  $\mathbb{E}'[\cdot]$  to denote  $\mathbb{E}[\cdot | \bar{x}_e^0, \bar{x}_e^1, \dots, \bar{x}_e^{t-1}]$ . We need to prove  $\mathbb{E}'[\bar{x}_e^t] = \bar{x}_e^{t-1}$ .

If we rounded  $e$  in iteration  $t$  or before, then  $\bar{x}_e^t = \bar{x}_e^{t-1}$  happens with probability 1. So, we can assume that  $e$  has not been rounded by the end of iteration  $t$ . In this case,  $\bar{x}_e^{t-1} = x_e^{t-1}$ .

So, in iteration  $t$ , either a happens for some  $e' \neq e$ , or b happens. In either case, we have  $\mathbb{E}'[\bar{x}_e^t] = \mathbb{E}'[x_e^t] = x_e^{t-1} = \bar{x}_e^{t-1}$  by the way we define the distribution for  $x'$  in Step 4. Therefore,  $\bar{x}_e^0, \bar{x}_e^1, \dots, \bar{x}_e^T$  is a martingale. ◀

► **Corollary 8.**  $\mathbb{E} \left[ \sum_{e \in E} c_e x_e^T \right] \leq \alpha \sum_{e \in E} c_e x_e^0$ .

**Proof.**

$$\mathbb{E} \left[ \sum_{e \in E} c_e x_e^T \right] \leq \alpha \mathbb{E} \left[ \sum_{e \in E} c_e \bar{x}_e^T \right] = \alpha \sum_{e \in E} c_e \bar{x}_e^0 = \alpha \sum_{e \in E} c_e x_e^0.$$

The inequality is by a and the first equality used Lemma 7.  $\blacktriangleleft$

Now that we understand the expected cost, it only remains to analyze the degree constraint. From now on we fix a vertex  $v \in V$ . We upper bound  $x^T(\delta(v))$ , which will in turn give an upper bound on  $\mathbb{E} [(x^T(\delta(v)))^p]$ . The main lemma we prove is

**► Lemma 9.** *For every  $v \in V$ , we have  $\mathbb{E} [(x^T(\delta(v)))^p] \leq \alpha(\alpha + \beta)^{p-1} \cdot f(x^0(\delta(v)))$ .*

**Proof.** We first consider the case  $x^0(\delta(v)) \geq 1$ . Let  $t$  be the iteration in which  $v$  is relaxed, or let  $t = T$  if  $v$  is not relaxed during the algorithm. By Property c,  $\bar{x}(\delta(v))$  does not change until the end of iteration  $t$ . Then, we have  $x^T(\delta(v)) \leq x^t(\delta(v)) + \beta \leq \alpha \bar{x}^t(\delta(v)) + \beta = \alpha \bar{x}^0(\delta(v)) + \beta = \alpha x^0(\delta(v)) + \beta$ . Notice that this happens with probability 1.

Notice that  $\mathbb{E}[x^T(\delta(v))] \leq \alpha \mathbb{E}[\bar{x}^T(\delta(v))] = \alpha \bar{x}^0(\delta(v)) = \alpha x^0(\delta(v))$  by Lemma 7. We have:

$$\begin{aligned} \mathbb{E} [(x^T(\delta(v)))^p] &\leq \frac{\alpha x^0(\delta(v))}{\alpha x^0(\delta(v)) + \beta} (\alpha x^0(\delta(v)) + \beta)^p = \alpha x^0(\delta(v)) (\alpha x^0(\delta(v)) + \beta)^{p-1}, \\ \frac{\mathbb{E} [(x^T(\delta(v)))^p]}{f(x^0(\delta(v)))} &\leq \frac{\alpha x^0(\delta(v)) (\alpha x^0(\delta(v)) + \beta)^{p-1}}{(x^0(\delta(v)))^p} = \alpha \left( \alpha + \frac{\beta}{x^0(\delta(v))} \right)^{p-1} \leq \alpha(\alpha + \beta)^{p-1}. \end{aligned}$$

Now we consider the second case:  $x^0(\delta(v)) < 1$ . We prove that with probability 1, we have  $x^T(\delta(v)) \leq \alpha + \beta$ . Assume  $x(\delta(v)) \geq 1$  happens at some time of the algorithm. By b, at the first moment when  $x(\delta(v)) \geq 1$ , we have  $\bar{x}(\delta(v)) \leq 1$ . By c, from the moment until the moment  $v$  becomes relaxed (or until the end of the algorithm if  $v$  is never relaxed),  $\bar{x}(\delta(v))$  does not change. Therefore, immediately after  $v$  becomes relaxed, we have  $\bar{x}(\delta(v)) \leq 1$ . Thus  $x^T(\delta(v))$  is at most the value of  $x(\delta(v)) + \beta$  at this moment, which is at most  $\alpha \bar{x}(\delta(v)) + \beta \leq \alpha + \beta$ . If  $x(\delta(v)) \geq 1$  never happens, then  $x^T(\delta(v)) < 1 \leq \alpha + \beta$ .

As in the first case, we have  $\mathbb{E}[x^T(\delta(v))] \leq \alpha x^0(\delta(v))$ . So

$$\begin{aligned} \mathbb{E} [(x^T(\delta(v)))^p] &\leq \frac{\alpha x^0(\delta(v))}{\alpha + \beta} (\alpha + \beta)^p = \alpha x^0(\delta(v)) (\alpha + \beta)^{p-1}, \\ \frac{\mathbb{E} [(x^T(\delta(v)))^p]}{f(x^0(\delta(v)))} &\leq \frac{\alpha x^0(\delta(v)) (\alpha + \beta)^{p-1}}{x^0(\delta(v))} = \alpha(\alpha + \beta)^{p-1}. \end{aligned}$$

So, we always have  $\mathbb{E} [(x^T(\delta(v)))^p] \leq \alpha(\alpha + \beta)^{p-1} f(x^0(\delta(v)))$ . This implies  $\mathbb{E} [\sum_v (x^T(\delta(v)))^p] \leq \alpha(\alpha + \beta)^{p-1} A^p$ .  $\blacktriangleleft$

Corollary 8 and Lemma 9 imply Theorem 5, which in turn implies Theorem 1.

### 3 A Tree Labeling Problem

In this section, we describe the tree labeling problem to which we reduce the Group Steiner Tree problem with degree bounds on bounded-treewidth graphs; the problem has served as a building block in many prior results [11, 12, 21]. We are given a full binary tree  $\mathbf{T} = (\mathbf{V}, \mathbf{E})$  rooted at  $\mathbf{r} \in \mathbf{V}$ .<sup>2</sup> For every vertex  $u \in \mathbf{V}$ , we are given a finite set  $L_u$  of labels for  $u$ ; we

<sup>2</sup> It is not important to require the binary tree to be full; our algorithm works when some internal nodes have only one child. Assuming every internal node have 2 children is only for notational convenience.

assume  $L_u$ 's are disjoint and let  $L := \bigcup_{u \in \mathbf{V}} L_u$ . The output is a labeling  $\vec{\ell} = (\ell_u \in L_u)_{u \in \mathbf{V}}$  of the vertices  $\mathbf{V}$ , that satisfies the constraints described below.

- **(consistency constraints)** For every internal node  $u$  of  $\mathbf{T}$  with two children  $v$  and  $v'$ , we are given a set  $\Gamma_u \subseteq L_u \times L_v \times L_{v'}$ . A valid labeling  $\vec{\ell}$  must satisfy  $(\ell_u, \ell_v, \ell_{v'}) \in \Gamma_u$ .
- **(covering constraints)** We are given  $k$  subsets  $S_1, S_2, \dots, S_k \subseteq L$ . A valid labeling  $\vec{\ell}$  needs to satisfy that for every  $t \in [k]$ ,  $\ell(\mathbf{V}) \cap S_t \neq \emptyset$ , where  $\ell(\mathbf{V})$  is defined as  $\{\ell_u : u \in \mathbf{V}\}$ . In words,  $\ell(\mathbf{V})$  needs to intersect every  $S_t$ .
- **(cost constraints)** We are given  $m \geq 0$  linear constraints defined by the costs  $(c_\ell^i \in [0, 1])_{i \in [m], \ell \in L}$ . For every  $i \in [m]$ , a valid labeling  $\vec{\ell}$  needs to satisfy  $\sum_{u \in \mathbf{V}} c_{\ell_u}^i \leq 1$ . In words, there are  $m$  types of resource, and we have 1 unit of each type. Setting the label of  $u$  to  $\ell$  will use  $c_\ell^i$  units of type  $i$ -resource.

We say a labeling  $\vec{\ell} = (\ell_u \in L_u)_{u \in \mathbf{V}}$  is *consistent* if it satisfies the consistency constraints. Given a consistent labeling  $\vec{\ell}$ , we say it covers group  $S_t$  if  $\ell(\mathbf{V}) \cap S_t \neq \emptyset$ . We define its type- $i$  cost to be  $\text{cost}^i(\vec{\ell}) := \sum_{u \in \mathbf{V}} c_{\ell_u}^i$ . So a valid labeling  $\vec{\ell}$  for the instance is a consistent one that covers all groups, and has  $\text{cost}^i(\vec{\ell}) \leq 1$  for every  $i \in [m]$ .

Given a label tree instance, we let  $n = |\mathbf{V}|$ ,  $D$  be the height of  $\mathbf{T}$  (the maximum number of edges in a root-to-leaf path in  $\mathbf{T}$ ) and  $\Delta = \max_{u \in \mathbf{V}} |L_u|$  be the maximum size of any  $L_u$ . The main theorem we prove is the following:

► **Theorem 10.** *Assume we are given a feasible label tree instance  $(\mathbf{T} = (\mathbf{V}, \mathbf{E}), \mathbf{r}, (L_u)_u, (\Gamma_u)_u, (S_t)_{t \in [k]}, A \in [0, 1]^{m \times L})$ , i.e., there is a valid labeling. There is a randomized algorithm that in time  $\text{poly}(n) \cdot \Delta^{O(D)}$  outputs a consistent labeling  $\vec{\ell}$  such that the following holds.*

**(10a)** *For every  $t \in [k]$ , we have  $\Pr[\vec{\ell} \text{ covers group } S_t] \geq \frac{1}{D}$ .*

**(10b)** *For every  $i \in [m]$ , we have  $\mathbb{E} \left[ \exp \left( \ln \left( 1 + \frac{1}{2D} \right) \cdot \text{cost}^i(\vec{\ell}) \right) \right] \leq 1 + \frac{1}{D}$ .*

Property b gives a tail concentration bound on  $\text{cost}^i(\vec{\ell})$ . The remaining part of this section is dedicated to the proof of Theorem 10.

### 3.1 Construction of a super-tree $T^\circ$

In this section, we construct a rooted tree  $T^\circ = (V^\circ, E^\circ)$  of size  $O(n)\Delta^{O(D)}$  such that a consistent labeling of  $\mathbf{T}$  corresponds to what we call a *consistent sub-tree*. So we can reduce the problem to finding the latter object. The root of  $T^\circ$  is  $r$ . Each internal node of  $T^\circ$  is either a *selector node*, or a *copier node*; their meanings will be clear soon. Each node  $p \in V^\circ$  is *associated with* a node  $u$  in  $\mathbf{T}$ . Each non-root selector node or leaf node is *associated with* a label  $\ell \in L_u$ . We shall use  $p$  and  $q$  and their variants to denote nodes in  $T^\circ$ , and  $u$  and  $v$  and their variants to denote nodes in  $\mathbf{T}$ .

The algorithm for constructing  $T^\circ$  is described in Algorithm 1, which calls the procedure `construct-tree` described in Algorithm 2. See Figure 2 for the illustration of the construction of  $T^\circ$  from  $\mathbf{T}$ . For a node  $p \in V^\circ$ , we use  $\Lambda(p)$  denotes the set of children of  $p$  in  $T^\circ$ , and  $\Lambda^*(p)$  denotes the set of descendants of  $p$  in  $T^\circ$ , including  $p$  itself.

■ **Algorithm 1** Main algorithm for the construction of  $T^\circ$ .

- 
- 1: create a node  $r$  associated with  $\mathbf{r}$  as the root of  $T^\circ$ , and let  $r$  be a *selector node*
  - 2: **for** every  $\ell \in L_{\mathbf{r}}$  **do**:
  - 3:     create a child  $p$  of  $r$ , associated with node  $\mathbf{r}$  and label  $\ell$
  - 4:     call `construct-tree`( $p, \mathbf{r}, \ell$ )
-

■ **Figure 2** An example for the construction of  $T^\circ$ . The tree on the left side is  $\mathbf{T}$ , and the tree on the right side is  $T^\circ$ . The labels of the nodes in  $\mathbf{T}$  are shown besides them. In  $T^\circ$ , selectors, copiers and leaves are denoted as empty circles, solid circles and empty squares respectively. The nodes in the two yellow polygons are associated with  $r$  and  $a$  respectively. The numbers in the circles and squares indicate the labels associated with the nodes. In the example, the triples in  $\Gamma_r$  with the first coordinate being 1 are  $(1, 4, 6)$ ,  $(1, 5, 6)$  and  $(1, 5, 7)$ . The triples in  $\Gamma_a$  with the first coordinate being 5 are  $(5, 9, 11)$ ,  $(5, 9, 12)$  and  $(5, 10, 11)$ .

■ **Algorithm 2**  $\text{construct-tree}(p, u, \ell)$ .  $\triangleright p \in V^\circ, u \in \mathbf{V}, \ell \in L_u$

- 
- 1: **if**  $u$  has no children **then return**  $\triangleright p$  is a leaf node.
  - 2: let  $p$  be a selector node, let  $v$  and  $v'$  be the two children of  $u$  in  $\mathbf{T}$
  - 3: **for every**  $\ell' \in L_v, \ell'' \in L_{v'}$  such that  $(\ell, \ell', \ell'') \in \Gamma_u$  **do**
  - 4:     create a child  $p'$  of  $p$ , associated with  $u$ , let  $p'$  be a copier node,
  - 5:     create two children  $q$  and  $q'$  of  $p'$ , associate  $q$  with node  $v$  and label  $\ell'$ , associate  $q'$  with node  $v'$  and label  $\ell''$
  - 6:     call  $\text{construct-tree}(q, v, \ell')$  and  $\text{construct-tree}(q', v', \ell'')$
- 

Now we can define consistent sub-trees of  $T^\circ$ :

► **Definition 11** (Consistent sub-trees). *Given a sub-tree  $T$  of  $T^\circ$  that contains  $r$ , we say  $T$  is consistent if the following conditions hold.*

- *Every selector node  $p$  in  $T$  has exactly one child in  $T$ .*
- *If  $p$  is a copier node in  $T$ , then both of its children in  $T^\circ$  are in  $T$ .*

The definition explains the names “selector” and “copier”: a selector node  $p$  in  $T$  needs to select one of its children in  $T^\circ$  and add it to  $T$ , and the children of a copier node  $p$  will follow the node  $p$  to enter  $T$ .

It is easy to see a one-to-one correspondence between consistent labelings  $\vec{\ell} = (\ell_u \in L_u)_{u \in \mathbf{V}}$  of  $\mathbf{T}$ , and consistent sub-trees  $T$  of  $T^\circ$ . Given the consistent labeling  $\vec{\ell}$ , the correspondent sub-tree  $T$  of  $T^\circ$  can be constructed as follows. First, we add  $r$  and its child  $p$  associated with label  $\ell_r$  to  $T$ . Then we grow the tree from  $p$  using a recursive procedure. Assume  $p$  is associated with node  $u$  in  $\mathbf{T}$  and label  $\ell \in L_u$ . If  $u$  is a leaf, we stop the procedure. Otherwise let  $v$  and  $v'$  be the two children of  $u$ , then we add the copier child  $p'$  of  $p$  that corresponds to the tuple  $(\ell_r, \ell_v, \ell_{v'})$  to  $T$ . We also add its two children  $q$  and  $q'$  to  $T$ . Then we run the procedure recursively over  $q$  and  $q'$ . Conversely, given a consistent sub-tree  $T$  of  $T^\circ$ , we can recover a consistent labeling  $\vec{\ell}$  of  $\mathbf{T}$ .

For convenience, we extend the costs  $(c_\ell^i)_{i \in [m], \ell \in L}$  to vertices in  $V^\circ$ : For every non-root selector node or leaf node  $p \in V^\circ$  associated with a label  $\ell$ , we define  $c_p^i = c_\ell^i$  for every  $i \in [m]$ . For the root or a copier node  $p$ , we define  $c_p^i = 0$ . For a consistent sub-tree  $T = (V, E)$  of  $T^\circ$ , and  $i \in [m]$ , we define its type- $i$  cost to be  $\text{cost}^i(T) = \sum_{p \in V} c_p^i$ . This will be the same as  $\text{cost}^i(\vec{\ell})$ , for the labeling  $\vec{\ell}$  correspondent to  $T$ .

We also extend the groups  $S_1, S_2, \dots, S_k$  to node sets in  $T^\circ$ : for every  $t \in [k]$ ,  $S'_t$  contains the set of nodes  $p \in V^\circ$  whose associated label is in  $S_t$ . Then, a consistent labeling  $\vec{\ell}$  covers a group  $S_t$  if and only if the correspondent sub-tree  $T = (V, E)$  covers  $S'_t$ , namely,  $V \cap S'_t \neq \emptyset$ .

Therefore, we are guaranteed that there is a consistent sub-tree  $T^*$  of  $T^\circ$  that covers all groups  $S'_1, S'_2, \dots, S'_k$ , and has  $\text{cost}^i(T^*) \leq 1$  for every  $i \in [m]$ . Our goal is to output a random consistent sub-tree  $T$  satisfying the conditions correspondent to a and b. This is done using an LP-based algorithm.

### 3.2 The LP relaxation for finding $T = (V, E)$

Now we describe the LP relaxation that we use to find  $T = (V, E)$ . For every vertex  $p \in V^\circ$ , we use  $x_p$  to indicate if  $p$  is in  $T$ , i.e.,  $p \in V$ . For every  $t \in [k]$  and  $q \in S'_t$ , we use  $y_q^t$  to indicate if  $q$  is the node in  $T$  we choose to cover  $S'_t$ . There might be multiple nodes in  $V \cap S'_t$ , and in this case, we only choose one node in the set to cover  $S'_t$ ; the choice can be arbitrary. The LP is as follows.

$$\begin{aligned}
 x_r &= 1 & (2) \quad & \sum_{q \in \Lambda^*(p) \cap S'_t} y_q^t \leq x_p, \forall p \in V^\circ, t \in [k] & (6) \\
 \sum_{q \in \Lambda(p)} x_q &= x_p, \forall \text{ selector } p \in V^\circ & (3) \quad & \sum_{q \in S'_t} y_q^t = 1, \forall t \in [k] & (7) \\
 x_q &= x_p, \forall \text{ copier } p \in V^\circ, q \in \Lambda(p) & (4) \quad & \sum_{q \in \Lambda^*(p)} c_q^i x_q \leq x_p, \forall p \in V^\circ, i \in [m] & (8) \\
 x_p &\geq 0, \forall p \in V^\circ & (5) \quad & & 
 \end{aligned}$$

Constraints (2)-(5) in the LP are for the consistency requirements. (2) says the root is always in  $T$ . (3) says if a selector node  $p$  is in  $T$ , then exactly one of its children is in  $T$ . (4) says if a copier node  $p$  is in  $T$ , and  $q$  is a child of  $p$ , then  $q$  is also in  $T$ . (5) is the non-negativity condition. (6) and (7) deal with the covering requirements. (6) says if  $p$  is in  $T$ , then we choose at most one descendant of  $p$  to cover the group  $S'_t$ ; notice that the constraint implies  $y_p^t \leq x_p$  if  $p \in S'_t$ . (7) says we choose exactly one node in  $T$  to cover  $S'_t$ . (8) handles the cost requirement: If  $p$  is included in  $T$ , then the type- $i$  cost of the descendants of  $p$  in  $T$  is at most 1.

### 3.3 The rounding algorithm

The rounding algorithm is based on [9]. We solve LP(2) to obtain a solution  $x \in [0, 1]^{V^\circ}$ . We add  $r$  to  $T$  and call `recursive-rounding`( $r$ ) to obtain a sub-tree  $T = (V, E)$ . The procedure is defined in Algorithm 3.

► **Observation 12.**  *$T$  is always consistent. For every  $p \in V^\circ$ , we have  $\Pr[p \in V] = x_p$ .*

**Proof.** For a selector node  $p$  in  $T$ , we always choose exactly one child of  $p$  and add it to  $T$ . For a copier node  $p$  added to  $T$  and one of its child  $q$ ,  $q$  is added to  $T$  with probability 1. By the probabilities we add nodes to  $T$ , we can see that  $\Pr[p \in V] = x_p$  for every  $p \in V^\circ$ . ◀

■ **Algorithm 3** recursive-rounding( $p$ ).

---

```

1: if  $p$  is a selector node then
2:   choose one vertex  $q \in \Lambda(p)$  randomly, so that  $q$  is chosen with probability  $\frac{x_q}{x_p}$ 
3:   add  $q$  to  $T$ , and call recursive-rounding( $q$ )
4: else ▷  $p$  is a copier or leaf node
5:   for every  $q \in \Lambda(p)$  do
6:     with probability  $\frac{x_q}{x_p} = 1$ : add  $q$  to  $T$ , and call recursive-rounding( $q$ )
    
```

---

**4** Analysis of probabilities of group coverage

We fix  $t \in [k]$  and analyze the probability that  $T$  covers the group  $S'_t$ ; or equivalently, the correspondent labeling covers the group  $S_t$ . This will prove Property a. For every vertex  $p \in V^\circ$ , we define  $z_p := \sum_{q \in \Lambda^*(p) \cap S'_t} y_q^t$ , which indicates whether  $S'_t$  is covered by vertices in the sub-tree rooted at  $p$ . By (6), we have  $z_p \leq x_p$ . By (7), we have  $z_r = 1 = x_r$ .

We define the height of a node  $p \in V^\circ$  to be the maximum number of copier nodes in a path from  $p$  to one of its descendant leaves. We prove in Appendix A the following lemma:

► **Lemma 13.** *Assume  $p \in V^\circ$  has height  $h$ . Then  $\Pr \left[ \Lambda^*(p) \cap V \cap S'_t \neq \emptyset \mid p \in V \right] \geq \frac{1}{h+1} \frac{z_p}{x_p}$ .*

Notice that the height of the root  $r$  of  $T^\circ$  is  $D - 1$ . Applying the above lemma with  $p = r$ , we have that  $T$  covers group  $S'_t$  with probability at least  $\frac{1}{D} \cdot \frac{z_r}{x_r} = \frac{1}{D}$ . So, the correspondent  $\vec{\ell}$  covers  $S_t$  with probability at least  $\frac{1}{D}$ , proving Property a.

### 4.1 Concentration bound on costs

In this section, we prove Property b. We fix an index  $i \in [m]$  and analyze the type- $i$  cost of  $T = (V, E)$ . For notation convenience, we use  $c_p$  to denote  $c_p^i$ , and cost for type- $i$  cost.

For every vertex  $p \in V^\circ$ , let  $w_p = \sum_{q \in \Lambda^*(p)} c_q x_q$  be the fractional cost incurred by the sub-tree of  $T^\circ$  rooted at  $p$ . By (8), we have  $w_p \leq x_p$ . Let  $W_p = \sum_{q \in \Lambda^*(p) \cap V} c_q$  be the cost of  $T$  incurred by descendants of  $p$ . So, we have  $\mathbb{E}[W_p] = w_p$ .

As is typical, we shall introduce a parameter  $s > 0$  and consider the expectation of the random exponential variables  $e^{sW_p}$ . Later we shall set  $s = \ln(1 + \frac{1}{2D})$ , but the main lemma holds for any  $s > 0$ . We define an  $\alpha_h$  for every integer  $h \geq 0$  as  $\alpha_0 = e^s$  and  $\alpha_h = e^{\alpha_{h-1}-1}, \forall h \geq 1$ . Notice that  $\alpha_0, \alpha_1, \dots$  is an increasing sequence.

In this section, we count selector nodes in the definition of heights: the height of a node  $p \in V^\circ$  is the maximum number of selector nodes in a path from  $p$  to its descendant leaf.

► **Lemma 14.** *For any node  $p$  in  $T^\circ$  of height  $h$ , we have  $\mathbb{E} \left[ e^{sW_p} \mid p \in V \right] \leq \alpha_h^{w_p/x_p}$ .*

**Proof.** We prove the lemma for nodes  $p$  from bottom to top of the tree  $T^\circ$ . Focus on a node  $p$  of height  $h$ . If  $p$  is a copier or leaf node, all children of  $p$  has height at most  $h$ . We have

$$\begin{aligned} \mathbb{E} \left[ e^{sW_p} \mid p \in V \right] &= e^{sc_p} \prod_{q \in \Lambda(p)} \mathbb{E} \left[ e^{sW_q} \mid q \in V \right] \\ &= \alpha_0^{c_p x_p / x_p} \prod_{q \in \Lambda(p)} \alpha_h^{w_q / x_p} \leq \alpha_h^{c_p x_p / x_p} \prod_{q \in \Lambda(p)} \alpha_h^{w_q / x_p} = \alpha_h^{w_p / x_p}. \end{aligned}$$

The last inequality used that  $\alpha_0 \leq \alpha_h$ , and the last equality used that  $w_p = c_p x_p + \sum_{q \in \Lambda(p)} w_q$ .

Now suppose  $p$  is a selector. Then all children of  $p$  have height at most  $h-1$ . Conditioned on  $p \in V$ , the rounding procedure adds exactly one child  $q$  of  $p$  to  $V$ . Then, we have

$$\begin{aligned} \mathbb{E} \left[ \mathbf{e}^{sW_p} \mid p \in V \right] &= \mathbf{e}^{sc_p} \cdot \sum_{q \in \Lambda(p)} \frac{x_q}{x_p} \mathbb{E} \left[ \mathbf{e}^{sW_q} \mid q \in V \right] = \mathbf{e}^{sc_p} \cdot \sum_{q \in \Lambda(p)} \frac{x_q}{x_p} \alpha_{h-1}^{w_q/x_q} \\ &\leq \mathbf{e}^{sc_p} \left( \left( \frac{w_p}{x_p} - c_p \right) \cdot \alpha_{h-1} + \left( 1 - \frac{w_p}{x_p} + c_p \right) \right) = \mathbf{e}^{sc_p} \left( 1 + \left( \frac{w_q}{x_q} - c_p \right) (\alpha_{h-1} - 1) \right) \\ &\leq \mathbf{e}^{sc_p} \cdot \exp \left( \left( \frac{w_p}{x_p} - c_p \right) (\alpha_{h-1} - 1) \right) = \mathbf{e}^{sc_p} \cdot \alpha_h^{w_p/x_p - c_p} \leq \alpha_h^{w_p/x_p}. \end{aligned}$$

To see the inequality in the second line, we notice the following four facts: (i)  $\alpha_{h-1}^\theta$  is a convex function of  $\theta$ , (ii)  $w_q/x_q \in [0, 1]$  for every  $q \in \Lambda(p)$ , (iii)  $\sum_{q \in \Lambda(p)} \frac{x_q}{x_p} = 1$  and (iv)  $\sum_{q \in \Lambda(p)} \frac{x_q}{x_p} \cdot \frac{w_q}{x_q} = \sum_{q \in \Lambda(p)} \frac{w_q}{x_p} = \frac{w_p}{x_p} - c_p$ . The equality in the last line is by the definition of  $\alpha_h$ . The last inequality used that  $\mathbf{e}^s = \alpha_0 \leq \alpha_h$ .  $\blacktriangleleft$

The height of the root  $r$  is  $D$ .<sup>3</sup> Now, we set  $s = \ln(1 + \frac{1}{2D})$ .

► **Lemma 15.** *For every  $h \in [0, D]$ , we have  $\alpha_h \leq 1 + \frac{1}{2D-h}$ .*

**Proof.** By definition,  $\alpha_0 = \mathbf{e}^s = 1 + \frac{1}{2D}$  and thus the statement holds for  $h = 0$ . Let  $h \in [1, D]$  and assume the statement holds for  $h-1$ . Then, we have

$$\begin{aligned} \alpha_h &= \mathbf{e}^{\alpha_{h-1}-1} \leq \mathbf{e}^{\frac{1}{2D-h+1}} \leq 1 + \frac{1}{2D-h+1} + \left( \frac{1}{2D-h+1} \right)^2 \\ &= 1 + \frac{2D-h+2}{(2D-h+1)^2} \leq 1 + \frac{1}{2D-h}. \end{aligned}$$

The first inequality used the induction hypothesis and the second one used that for every  $\theta \in [0, 1]$ , we have  $e^\theta \leq 1 + \theta + \theta^2$ .  $\blacktriangleleft$

To wrap up, we apply Lemma 14 on  $p = r$ . Notice that  $r \in V$  always happens, at  $W_r = \text{cost}^i(T)$ . We have  $\mathbb{E} \left[ \exp \left( \ln \left( 1 + \frac{1}{2D} \right) \cdot \text{cost}^i(T) \right) \right] \leq \alpha_D^{w_r/x_r} \leq 1 + \frac{1}{D}$  by Lemma 15 and that  $w_r \leq x_r = 1$ . Using the correspondence between sub-trees of  $T^\circ$  and labelings of  $\mathbf{T}$  proves Property b.

## A

 Proof of Lemma 13

We repeat the lemma below:

► **Lemma 13.** *Assume  $p \in V^\circ$  has height  $h$ . Then  $\Pr \left[ \Lambda^*(p) \cap V \cap S'_t \neq \emptyset \mid p \in V \right] \geq \frac{1}{h+1} \cdot \frac{z_p}{x_p}$ .*

**Proof.** If  $p \in S'_t$  then  $\Pr \left[ \Lambda^*(p) \cap V \cap S'_t \neq \emptyset \mid p \in V \right] = 1 \geq \frac{z_p}{x_p}$ . The inequality holds trivially. So, we can assume  $p \notin S'_t$ , and we prove the lemma for nodes  $p$  from bottom to top in the tree  $T^\circ$ . Suppose  $p$  is a leaf; then  $h = 0$ , and  $z_p = 0$  as we assumed  $p \notin S'_t$ . The inequality trivially holds.

So we can assume  $p$  to be a non-leaf node of height  $h$  and assume the lemma holds for every  $q \in \Lambda(p)$ . First, assume  $p$  is a selector node. Then all children of  $p$  have height at most  $h$ .

$$\Pr \left[ \Lambda^*(p) \cap V \cap S'_t \neq \emptyset \mid p \in V \right] \geq \sum_{q \in \Lambda(p)} \frac{x_q}{x_p} \cdot \frac{1}{h+1} \cdot \frac{z_q}{x_q} \geq \sum_{q \in \Lambda(p)} \frac{1}{h+1} \cdot \frac{z_q}{x_p} = \frac{1}{h+1} \cdot \frac{z_p}{x_p}.$$

Then consider the case that  $p$  is a copier node. All children of  $p$  have height at most  $h-1$ . Even though  $p$  has exactly two children, our analysis works if it has any number of children.

$$\begin{aligned} \Pr \left[ \Lambda^*(p) \cap V \cap S'_t \neq \emptyset \mid p \in V \right] &\geq 1 - \prod_{q \in \Lambda(p)} \left( 1 - \frac{1}{h} \cdot \frac{z_q}{x_q} \right) = 1 - \prod_{q \in \Lambda(p)} \exp \left( -\frac{1}{h} \cdot \frac{z_q}{x_p} \right) \\ &= 1 - \exp \left( -\frac{1}{h} \cdot \frac{z_p}{x_p} \right) \geq \frac{1}{h} \cdot \frac{z_p}{x_p} - \frac{1}{2} \left( \frac{1}{h} \cdot \frac{z_p}{x_p} \right)^2 \geq \frac{1}{h} \cdot \frac{z_p}{x_p} - \frac{1}{2} \left( \frac{1}{h} \right)^2 \frac{z_p}{x_p} \\ &= \left( \frac{2h-1}{2h^2} \right) \frac{z_p}{x_p} \geq \frac{1}{h+1} \cdot \frac{z_p}{x_p}. \end{aligned}$$

The first equality in the first line used that  $x_q = x_p$  for every  $q \in \Lambda(p)$ . The second equality used that  $z_p = \sum_{q \in \Lambda(p)} z_q$  as  $p \notin S'_t$ . The first inequality in the second line used that  $e^{-\theta} \leq 1 - \theta + \frac{\theta^2}{2}$  for every  $\theta \geq 0$ . The second inequality used that  $\frac{z_p}{x_p} \leq 1$ . ◀

## B

 Reduction of Degree-Bounded Group Steiner Tree on Bounded-Treewidth Graphs to Tree-Labeling Problem

In this section, we prove Theorem 2, by reducing Group Steiner Tree with degree bounds on bounded treewidth graphs to the tree labeling problem studied in Section 3. Recall the input of the problem contains a graph  $G = (V, E)$  with edge costs  $c \in R_{\geq 0}^E$ , a root  $r$ ,  $k$  groups  $S_1, S_2, \dots, S_k$  of vertices, and a degree bound  $\text{db}_v \in \mathbb{Z}_{>0}$  for every  $v \in V$ . Without loss of generality, we assume  $\{r\}, S_1, S_2, \dots, S_k$  are mutually disjoint. Again, we use  $\text{opt}$  to denote the minimum cost of a valid subgraph  $H$ .

Let  $\mathbf{T} = (B, \mathbf{E})$  be the tree decomposition of the graph  $G = (V, E)$ . Every  $b \in B$  is called a bag and let  $X_b \subseteq V$  be the set of vertices contained in the bag  $b$ . We can add the root  $r$  to all the bags, which increases the maximum size of a bag by at most 1. It was shown in [3] that we can assume  $\mathbf{T}$  is a rooted binary tree of depth  $O(\log n)$ , by sacrificing the bag size by an  $O(1)$  factor. We summarize the properties as follows:

- $\mathbf{T}$  is a full binary tree rooted at  $\mathbf{r}$ , with depth  $O(\log n)$ .
- $|X_b| \leq O(1) \cdot \text{tw}$  for every  $b \in B$ .
- For every edge  $(u, v) \in E$ , there is some  $b \in B$  with  $\{u, v\} \subseteq X_b$ .
- For every  $v \in V$ , the set of bags  $b$  with  $v \in X_b$  is connected in  $\mathbf{T}$ .

For every  $e \in E$ , let  $b_e$  be the highest node  $b$  such that  $X_b$  contains both end vertices of  $e$ . This is well-defined due to the last property in the above list. For every  $b \in B$ , we let  $E_b = \{e \in E : b_e = b\}$ . So,  $(E_b)_{b \in B}$  forms a partition of  $E$ .

**Notations on Partitions.** Given two partitions  $\Pi$  and  $\Pi'$  of a common set  $X$ , we say  $\Pi'$  refines  $\Pi$  if any two elements in  $X$  that are in the same set in  $\Pi'$  are also in the same set in  $\Pi$ . We use  $\Pi' \leq \Pi$  to denote that  $\Pi'$  refines  $\Pi$ . Given two partitions  $\Pi$  and  $\Pi'$  of  $X$ , we use  $\Pi \vee \Pi'$  to denote the join of  $\Pi$  and  $\Pi'$  w.r.t the relation  $\leq$ . That is, we define a graph where there is an edge between  $u$  and  $v$  if they are in the same set in  $\Pi$  or  $\Pi'$ . Then two vertices  $u$  and  $v$  are in the same set in the partition  $\Pi \vee \Pi'$  if and only if they are in the same connected component in the graph.

Abusing notations slightly, if an element  $v$  is not included in a partition  $\Pi$ , we treat  $\{v\}$  as a singleton set in  $\Pi$ . This allows us to extend the operators  $\leq$  and  $\vee$  to two partitions  $\Pi$  and  $\Pi'$  with different ground sets. Given a partition  $\Pi$  and a set  $X$ , we let  $\Pi[X]$  be the partition  $\Pi$  restricted to the ground set  $X$ : two elements  $u, v \in X$  are in the same set in  $\Pi[X]$  if and only if they are in the same set in  $\Pi$ .

For any set  $F \subseteq E$  of edges, we define  $CC(F)$  to be the partition of the vertices incident to  $F$ , such that  $u$  and  $v$  are in the same set in  $CC(F)$  if and only if they are in the same connected component in  $(V, F)$ .

**Construction of Labels and Consistency Triples.** The tree  $\mathbf{T}$  for the tree-labeling instance is the same as the decomposition tree  $\mathbf{T}$ . (This is the reason we use the same notion  $\mathbf{T}$ .) So we have  $\mathbf{V} = B$ . Now we fix a bag  $b \in B$  and define the set  $L_b$  of labels for  $b$ . To define the labels, we let  $H = (V_H, E_H)$  be any sub-graph of  $G$ , which we should think of as the output of the GST problem. Fix a bag  $b \in B$ , let  $\Lambda^*(b)$  be the set of descendants of  $b$  in  $\mathbf{T}$ , including  $b$  itself. We then make the following definitions:

- $F_b(H) := E_H \cap E_b$  is the set of edges from  $E_b$  that are included in  $H$ .
- $\Pi_b^\downarrow(H)$  is the partition of  $X_b$  so that two vertices  $u, v \in X_b$  is in the set in  $\Pi_b^\downarrow(H)$  if and only if they are connected in the graph  $(V_H, E_H \cap \bigcup_{b' \in \Lambda^*(b)} E_{b'})$ .
- $\Pi_b^\uparrow(H)$  is the partition of  $X_b$  so that two vertices  $u, v \in X_b$  is in the set in  $\Pi_b^\uparrow(H)$  if and only if they are connected in the graph  $(V_H, E_H \cap \bigcup_{b' \in B \setminus \Lambda^*(b) \cup \{b\}} E_{b'})$ .

In words,  $\Pi_b^\downarrow(H)$  and  $\Pi_b^\uparrow(H)$  respectively indicate the partition of  $X_b$  correspondent to the edges of  $H$  in bags below and above  $b$  respectively.

Without knowing  $H$ , we can define the label set  $L_b$  for  $b$  to be all tuples  $(F_b, \Pi_b^\downarrow, \Pi_b^\uparrow)$  such that  $(F_b, \Pi_b^\downarrow, \Pi_b^\uparrow) = (F_b(H), \Pi_b^\downarrow(H), \Pi_b^\uparrow(H))$  for some valid output graph  $H$ . We then define the consistency tuples  $\Gamma_b$ 's so that a consistent labeling gives a valid outputs sub-graph  $H$ .

Formally, let  $L_b$  be the set of all tuples  $(F_b, \Pi_b^\downarrow, \Pi_b^\uparrow)$  such that

- $F_b \subseteq E_b$  is a forest over  $X_b$ ,  $CC(F_b) \leq \Pi_b^\downarrow$  and  $CC(F_b) \leq \Pi_b^\uparrow$ ,
- if  $b = \mathbf{r}$ , then  $\Pi_b^\uparrow = CC(F_b)$ , and
- if  $b$  is a leaf, then  $\Pi_b^\downarrow = CC(F_b)$ .

Then we define the set  $\Gamma_b$  of triples, for an inner vertex  $b$  in  $\mathbf{T}$  with two children  $b'$  and  $b''$ . We have  $((F_b, \Pi_b^\downarrow, \Pi_b^\uparrow), (F_{b'}, \Pi_{b'}^\downarrow, \Pi_{b'}^\uparrow), (F_{b''}, \Pi_{b''}^\downarrow, \Pi_{b''}^\uparrow)) \in \Gamma_b$  if and only if

- $\Pi_b^\downarrow = (\Pi_{b'}^\downarrow \vee \Pi_{b''}^\downarrow \vee CC(F_b))[X_b]$ ,
- $\Pi_{b'}^\uparrow = (\Pi_b^\uparrow \vee \Pi_{b''}^\downarrow \vee CC(F_{b'}))[X_{b'}]$ , and
- $\Pi_{b''}^\uparrow = (\Pi_b^\uparrow \vee \Pi_{b'}^\downarrow \vee CC(F_{b''}))[X_{b''}]$ .

▷ **Claim 16.** Let  $\{(F_b, \Pi_b^\downarrow, \Pi_b^\uparrow)\}_{b \in B}$  be a consistent labeling of the tree  $\mathbf{T}$ . Let  $H = (V, \bigcup_{b \in B} F_b)$ . Then we have  $\Pi_b^\downarrow[H] = \Pi_b^\downarrow$  and  $\Pi_b^\uparrow[H] = \Pi_b^\uparrow$  for every  $b \in B$ .

The claim says that if the labels are consistent, then  $\Pi_b^\downarrow$  and  $\Pi_b^\uparrow$  represent their true values.

**Construction of Covering and Cost Constraints.** The requirement that all groups are connected to  $r$  can be captured by the covering constraint in the tree-labeling problem. For every  $t \in [k]$ , a label  $(F_b, \Pi_b^\downarrow, \Pi_b^\uparrow) \in L_b$  for some  $b \in B$  can satisfy the group  $S_t$  if for some  $s \in S_t$  we have  $(s, r)$  are in the same set in the partition  $\Pi_b^\downarrow \vee \Pi_b^\uparrow$ .

The edge costs and degree constraints can be captured by the cost constraints in the tree-labeling instance. Consider the costs first. Using binary search, we assume we know the optimum cost  $C^*$  for the instance. For every bag  $b \in B$  and every label  $(F_b, \Pi_b^\downarrow, \Pi_b^\uparrow)$ , the cost of the label is  $c(F_b) := \sum_{e \in F_b} c_e$ . We disallow this label by removing it if  $c(F_b) > C^*$ . Scaling all costs by  $C^*$  so that all costs are in  $[0, 1]$ . So, the cost being at most  $C^*$  in the group Steiner tree instance is equivalent to that the cost of all labels is at most 1.

Finally, we consider the degree constraints  $d_H(v) \leq \text{db}_v$  for every  $v \in V$ . For every  $v \in V$ , we define a cost constraint in the tree-labeling instance. For every bag  $b \in B$  with  $v \in X_b$ , and every label  $(F_b, \Pi_b^\downarrow, \Pi_b^\uparrow)$ , the cost of the label is  $|\delta(v) \cap F_b|$ , where  $\delta(v)$  is the incident edges of  $v$  in  $G$ . Again, we disallow the label if  $|\delta(v) \cap F_b| > \text{db}_v$ , and we scale the costs by  $\text{db}_v$  so that all costs are in  $[0, 1]$ . Then the degree constraint on  $v$  is reduced to this cost requirement in the tree labeling instance.

**Wrapping Up.** We then run the algorithm in Theorem 10 on the constructed tree-labeling instance. Let  $(F_b, \Pi_b^\downarrow, \Pi_b^\uparrow)$  be the label of a bag  $b$ , and let  $H = (V, \bigcup_{b \in B} F_b)$ . By Claim 16, the consistency constraints guarantee that the  $\Pi_b^\downarrow$  and  $\Pi_b^\uparrow$  truthfully represent the connectivity of the graph  $G$ . So, if the covering constraint for a group  $S_t$  is satisfied, then  $H$  indeed connects  $r$  and  $S_t$ . Recall that  $D = O(\log n)$  is the depth of the tree  $\mathbf{T}$ . By Properties a and b, we have

- For every  $t \in [k]$ ,  $H$  connects  $r$  and  $S_t$  with probability at least  $\frac{1}{D}$ .
- $\mathbb{E} \left[ \exp(\ln(1 + \frac{1}{2D}) \cdot \frac{c(H)}{C^*}) \right] \leq 1 + \frac{1}{D}$ .
- $\mathbb{E} \left[ \exp(\ln(1 + \frac{1}{2D}) \cdot \frac{d_H(v)}{\text{db}_v}) \right] \leq 1 + \frac{1}{D}$  for every  $v \in V$ .

We run the algorithm for  $M = \Theta(D \log n) = \Theta(\log^2 n)$  times, with a large hidden constant in the  $O(\cdot)$  notation, and output the union  $H$  of all sub-graphs constructed by the  $M$  times. With high probability, all groups are connected to  $r$  in  $H$ .  $\mathbb{E}[\exp(\ln(1 + \frac{1}{2D}) \cdot \frac{d_H(v)}{\text{db}_v})] \leq (1 + \frac{1}{D})^M = n^{O(1)}$ . Using Markov inequality, we have  $\exp(\ln(1 + \frac{1}{2D}) \cdot \frac{d_H(v)}{\text{db}_v}) \leq n^{O(1)}$  for every  $v \in V$  with high probability. That is,  $d_H(v) \leq O(\text{db}_v \log n \cdot D) = O(\log^2 n) \text{db}_v$  with high probability. Similarly, with high probability, we have  $c(H) \leq O(\log^2 n) C^*$ .

We then analyze the running time of the algorithm. The key parameter deciding the running time is  $\Delta$ , the maximum size of a label set  $L_b$ . As we assumed  $F_b$  is a forest over  $X_b$  and  $|X_b| \leq O(\text{tw})$ , there are  $\text{tw}^{O(\text{tw})}$  different possibilities for  $F_b$ . There are also  $\text{tw}^{O(\text{tw})}$  possibilities for each of  $\Pi_b^\downarrow$  and  $\Pi_b^\uparrow$ . So,  $|L_b| \leq \text{tw}^{O(\text{tw})}$  for every  $b \in B$ . Therefore, the running time of the algorithm is  $\text{poly}(n) \cdot \Delta^{O(D)} = \text{poly}(n) \cdot (\text{tw}^{O(\text{tw})})^{O(\log n)} = n^{O(\text{tw} \log \text{tw})}$ . This finishes the proof of Theorem 2.

# Hybrid $k$ -Clustering: Blending $k$ -Median and $k$ -Center

## Abstract

We propose a novel clustering model encompassing two well-known clustering models:  $k$ -center clustering and  $k$ -median clustering. In the HYBRID  $k$ -CLUSTERING problem, given a set  $P$  of points in  $\mathbb{R}^d$ , an integer  $k$ , and a non-negative real  $r$ , our objective is to position  $k$  closed balls of radius  $r$  to minimize the sum of distances from points not covered by the balls to their closest balls. Equivalently, we seek an optimal  $L_1$ -fitting of a union of  $k$  balls of radius  $r$  to a set of points in the Euclidean space. When  $r = 0$ , this corresponds to  $k$ -MEDIAN; when the minimum sum is zero, indicating complete coverage of all points, it is  $k$ -CENTER.

Our primary result is a bicriteria approximation algorithm that, for a given  $\varepsilon > 0$ , produces a hybrid  $k$ -clustering with balls of radius  $(1 + \varepsilon)r$ . This algorithm achieves a cost at most  $1 + \varepsilon$  of the optimum, and it operates in time  $2^{(kd/\varepsilon)^{O(1)}} \cdot n^{O(1)}$ . Notably, considering the established lower bounds on  $k$ -center and  $k$ -median, our bicriteria approximation stands as the best possible result for HYBRID  $k$ -CLUSTERING.

■ **Figure 1** Two disks of radius 2 cover all except four points that are colored red. The total sum of distances from these points to the yellow disks is  $2(1 + \sqrt{8} - 2)$ .

### 1 Introduction

Suppose we want to install a set of  $k$  access points (APs) at certain locations to provide wireless internet (Wi-Fi) coverage to a group of people belonging to a certain area. Each AP is capable of providing Wi-Fi within a circular-shaped region (i.e., a *disk*) of fixed radius  $r$ , and it may not be possible to cover the entire region with  $k$  such disks. Thus, after placing  $k$  APs, some people may be *outliers*, that lie outside any of the  $k$  disks and do not receive Wi-Fi coverage. We can model this scenario as the classical  $k$ -CENTER WITH OUTLIERS problem, which is a crude model since it only cares about the *number* of outliers. However, our scenario is more nuanced. All people that lie within any of the  $k$  disks of radius  $r$  already receive Wi-Fi, whereas a person lying outside all of the  $k$  disks must travel to the boundary of the nearest disk in order to receive coverage. Naturally, we would like to minimize the total distance traveled by people. Motivated by this and several other problems in computational geometry/clustering, we consider the following clustering problem, which encompasses two fundamental variants of clustering:  $k$ -CENTER and  $k$ -MEDIAN. Given a set  $P$  of points in some metric space and integer  $k$  and real  $r \geq 0$ , our objective is to position  $k$  closed balls of radius  $r$  in a way that minimizes the sum of distances from points uncovered by the balls to their closest balls. In Figure 1, we provide an example of such clustering with  $k = 2$  and  $r = 2$ .

To define the new clustering formally, we need some definitions. We consider Euclidean inputs, i.e., all points belong to  $\mathbb{R}^d$  for some  $d \geq 1$  and the distance function  $\text{dist}(\cdot, \cdot)$  is given by the Euclidean ( $\ell_2$ ) distance. For a point  $p \in P$  and a finite set of points  $Q \subset \mathbb{R}^d$ , we define  $\text{dist}(p, Q) := \min_{q \in Q} \text{dist}(p, q)$ . Further, for  $x, y \in P$ , and a real  $r \geq 0$ , we define the shorthand  $\text{dist}_r(x, y) := \max \{ \text{dist}(x, y) - r, 0 \}$ .

|   |     |
|---|-----|
| HYBRID $k$ -CLUSTERING  |     |
| <b>Input.</b> A set $P \subset \mathbb{R}^d$ of $n$ points, an integer $k \geq 1$ , and a real $r \geq 0$ . |     |
| <b>Task.</b> Find a set $F \subset \mathbb{R}^d$ of size at most $k$ , that minimizes:                      |     |
| $\text{cost}_r(P, F) := \sum_{p \in P} \text{dist}_r(p, F)$   | (1) |

We denote an instance of HYBRID  $k$ -CLUSTERING as  $\mathcal{I} = (P, k, r, d)$ , where  $d$  denotes the dimension. When  $r = 0$ , the optimal cost of HYBRID  $k$ -CLUSTERING equals the optimal  $k$ -MEDIAN clustering cost of the instance. Thus in this case, HYBRID  $k$ -CLUSTERING reduces to  $k$ -MEDIAN. However, when  $r > 0$ ,  $\text{dist}_r(\cdot, \cdot)$  does not form a metric, and hence we cannot simply reduce the problem to  $k$ -MEDIAN. On the other hand, the minimum value  $r$  that guarantees the cost of HYBRID  $k$ -CLUSTERING to be zero is equal to the optimal  $k$ -CENTER value. In this sense, HYBRID  $k$ -CLUSTERING reduces to  $k$ -CENTER.

■ **Figure 2** Left:  $k$ -CENTER clustering, a special case of HYBRID  $k$ -CLUSTERING with  $r = r^*$ . All points are covered by  $k$  balls of radius  $r^*$  and  $\text{OPT}_{r^*} = 0$ . Right:  $k$ -MEDIAN clustering, a special case of HYBRID  $k$ -CLUSTERING with  $r = 0$ , and every point contributes its distance to the closest center (some are shown as brown arrows). Middle: A general instance of HYBRID  $k$ -CLUSTERING lies somewhere *in between* the two cases, where points outside radius- $r$  balls contribute the distance to the boundary (shown in blue).

## 1.1 Our Result and Techniques

The main result of this paper is a bicriteria approximation algorithm for HYBRID  $k$ -CLUSTERING. An  $\alpha$ -approximation to an instance  $\mathcal{I} = (P, k, r, d)$  is a subset  $F \subset \mathbb{R}^d$  of size  $k$  with  $\text{cost}_r(P, F) \leq \alpha \cdot \text{OPT}_r$ , where  $\text{OPT}_r := \text{cost}_r(P, F^*)$  denotes the cost of an optimal solution  $F^* \subset \mathbb{R}^d$  of size at most  $k$ . Furthermore, an  $(\alpha, \beta)$ -bicriteria approximation is a solution  $F \subset \mathbb{R}^d$  with  $\text{cost}_{\beta r}(P, F) \leq \alpha \cdot \text{OPT}_r$ . Here,  $\text{cost}_{\beta r}(P, F) = \sum_{p \in P} \text{dist}_{\beta r}(p, F)$ .

Consider the special case of  $r = r^*$ , where  $r^*$  is the optimal radius for  $k$ -CENTER. Then,  $\text{OPT}_{r^*} = 0$ . Therefore, a  $(\alpha, 1)$ -bicriteria approximation would return a solution of cost  $\alpha \cdot \text{OPT}_{r^*} = 0$  using radius  $1 \cdot r^*$ , i.e., an optimal solution for  $k$ -CENTER. On the other hand, a  $(1, \beta)$ -bicriteria approximation, for the special case of  $r = 0$ , would return an optimal-cost solution using the radius of  $\beta r = 0$ . That is, such an algorithm would optimally solve  $k$ -MEDIAN. Combining these observations with the established lower bounds from the literature for  $k$ -MEDIAN and  $k$ -CENTER in Euclidean spaces, implies the following bounds for HYBRID  $k$ -CLUSTERING.

► **Proposition 1.** *The following holds for HYBRID  $k$ -CLUSTERING even when the input is from  $\mathbb{R}^2$ .*

- *For any  $\alpha \geq 1$ , there exists no FPT in  $k$  algorithm that returns an  $(\alpha, 1)$ -approximation, unless  $\text{FPT} = \text{W}[1]$  [27].*
- *For any finite  $\beta \geq 1$ , there exists no polynomial-time algorithm that returns a  $(1, \beta)$ -approximation unless  $\text{P} = \text{NP}$  [29].*

*Further, assuming the Exponential-Time Hypothesis (ETH), if the input is from  $\mathbb{R}^d$  with  $d \geq 4$ , then there exists no  $n^{o(k)}$  time algorithm that returns a  $(1, \beta)$ -approximation, for any finite  $\beta \geq 1$  [10].*

#### 4:4 Hybrid $k$ -Clustering: Blending $k$ -Median and $k$ -Center

Given these results, a natural question arises: *Can we achieve a  $(1+\varepsilon, 1+\varepsilon)$ -approximation for HYBRID  $k$ -CLUSTERING, running in time  $f(k, \varepsilon) \cdot n^{\mathcal{O}(1)}$ , particularly in low-dimensional Euclidean spaces?* Our main theorem answers this question.

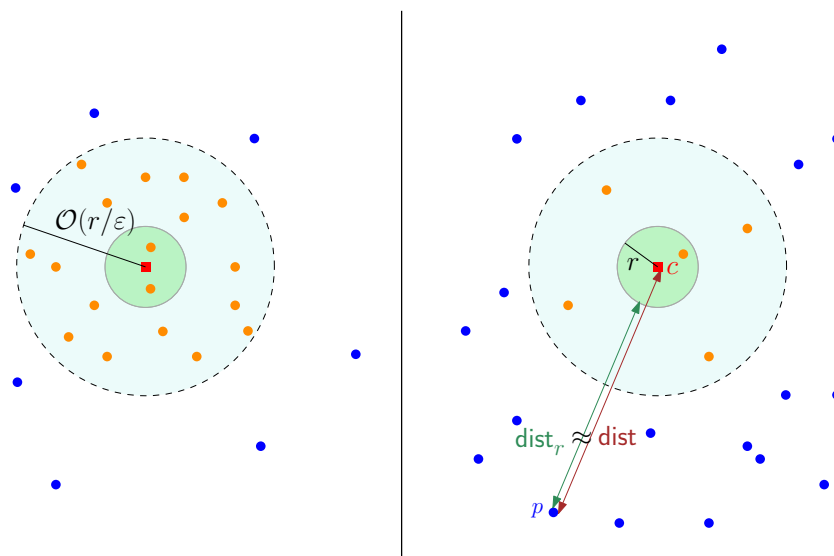

► **Theorem 2.** *Let  $0 < \varepsilon < 1$ . There exists a randomized algorithm that, given an instance of HYBRID  $k$ -CLUSTERING in  $\mathbb{R}^d$ , runs in time  $2^{\left(\frac{kd}{\varepsilon}\right)^{\mathcal{O}(1)}} \cdot n^{\mathcal{O}(1)}$ , and returns a  $(1 + \varepsilon, 1 + \varepsilon)$ -approximation with probability at least a positive constant.*

This randomized algorithm and the proof of correctness are described in Section 2. Here we discuss some of the main ideas. Recall that our objective, as the problem name suggests, is a “hybrid” of  $k$ -CENTER and  $k$ -MEDIAN. In our preprocessing steps, we first handle the inputs that behave *almost like* either of the two problems. Suppose we (approximately) know the optimal value of HYBRID  $k$ -CLUSTERING for the given set of points  $P$ , called  $\text{OPT}_r$ . First, in Lemma 4, if  $r > \text{OPT}_r$ , then we show that an approximate solution can be found using techniques used for approximating  $k$ -CENTER. Specifically, for each of the  $k$  centers in the optimal solution, we find a “nearby” center within distance  $\varepsilon r$  via overlaying a fine grid in the space. Thus, we can assume that  $r \leq \text{OPT}_r$ . Next, we consider the case when  $r$  is *too small* compared to  $\text{OPT}_r$ , namely, when  $r < \frac{\varepsilon \text{OPT}_r}{n}$ , and show that in this case, the input behaves like  $k$ -MEDIAN— an approximate  $k$ -MEDIAN solution is also an approximation for HYBRID  $k$ -CLUSTERING (Lemma 5). In this manner, we preprocess to handle inputs that resemble  $k$ -CENTER and  $k$ -MEDIAN, we obtain a relation between  $r$  and  $\text{OPT}_r$ , which can be used to discretize the distances, which can be used to bound the aspect ratio (i.e., the ratio of maximum to minimum positive distance) (Lemma 6).

After the preprocessing step, we obtain inputs that are not *immediately reducible* to  $k$ -CENTER/MEDIAN. To handle such inputs, we design an intricate recursive algorithm that, at each step, tries to simultaneously handle parts (i.e., clusters) of the input that can be handled by either of the two techniques. This algorithm is inspired by the sampling approach of Kumar, Sabharwal, and Sen [24, 25] (also Jaiswal, Kumar, and Sen [23]). In this approach, one first takes a large enough sample that can be used to pin down the location of the largest cluster center. Then, one removes enough points from the vicinity of this center, so that the next largest cluster becomes dominant, and hence a subsequent sample contains sufficiently many points from the second cluster, and so on.

However, our scenario is more intricate and challenging for several reasons due to the peculiar nature of the objective. Nevertheless, in principle, one can classify each cluster as either being more *1-center-like*, or more *1-median like* (see Figure 3 for an illustration). In a *1-center-like* cluster, a large fraction of points lie within a ball of radius  $\mathcal{O}(r/\varepsilon)$ . On the other hand, in a *1-median-like* cluster, a vast majority of points lie outside the  $\mathcal{O}(r/\varepsilon)$ -radius ball. Note that any such point loses very little due to the “ $-r$ ” term in the clustering cost, i.e., its  $\text{dist}_r$  and  $\text{dist}$  values are approximately equal. Hypothetically, if we knew the partition of the input points into  $k$  clusters, then we could use this classification to handle each type of cluster separately – an almost-optimal center of a *1-center-like* cluster can be found using a grid, whereas one can use an approximation for 1-median (as a black box) to handle a *1-median-like* cluster. However, the actual clusters are obviously unknown to the algorithm. Hence, the algorithm has to carefully navigate between the two types of clusters based on the random sample obtained, and must simultaneously handle both scenarios using branching (i.e., recursion). The analysis of the algorithm is also much more involved due to the various cases in which the distinction between two types of clusters is murkier. Nevertheless, we are able to show that the algorithm returns a  $(1 + \varepsilon, 1 + \varepsilon)$ -approximation in time  $2^{(kd/\varepsilon)^{\mathcal{O}(1)}} \cdot n^{\mathcal{O}(1)}$  with good probability. Note that we incur an exponential dependence on the dimension  $d$  due to “grid-arguments” used to handle *1-center-like* clusters, unlike the approach of [24]. However, such dependence seems unavoidable using our approach.

■ **Figure 3** Example of two different types of clusters. In each figure, we show the cluster center in red, a ball of radius  $r$  around the center in green, and a larger ball of radius  $\mathcal{O}(r/\epsilon)$  in cyan with a dashed outline. Left: A *1-center-like* cluster. Note that a large chunk of points lies within the radius  $\mathcal{O}(r/\epsilon)$  ball around the center. Right: A *1-median-like* cluster. Note that most of the points lie outside the  $\mathcal{O}(r/\epsilon)$  radius ball around  $c$ , and for any such point, e.g.,  $p$  that is outside the  $\mathcal{O}(r/\epsilon)$  radius ball,  $\text{dist}_r(p, c) \approx \text{dist}(p, c)$ .

## 1.2 Related Problems

**Euclidean Clustering.** An extensive body of literature exists on approximation algorithms for  $k$ -CENTER and  $k$ -MEDIAN in the Euclidean space. For  $k$ -MEDIAN in  $\mathbb{R}^d$ , Polynomial-Time Approximation Schemes (PTASes) with a running time of  $n^{f(\epsilon, d)}$  have been developed, leveraging local search techniques [18, 12]. Additionally, various Fixed-Parameter Tractable Approximation Schemes (FPT-AS) with a running time of  $f(k, d, \epsilon) \cdot n^{\mathcal{O}(1)}$  are known for this problem [11, 13, 25, 23]. The dependence on dimension  $d$  can be eliminated through dimensionality reduction techniques [26, 9].

For  $k$ -CENTER, an FPT-AS was introduced by Agarwal and Procopiuc in [4], with a runtime of  $\mathcal{O}(n \log k) + (k/\epsilon)^{\mathcal{O}(dk^{1-1/d})}$  in  $\mathbb{R}^d$ . Subsequent work by Badoiu, Har-Peled, and Indyk [5] improved the running time to  $2^{\mathcal{O}(k \log k)}/\epsilon^2$ .

In [30], Tamir introduces a common generalization of the two clustering problems, namely,  $\ell$ -CENTRUM. In this problem, one ignores  $\ell$  closest points from the cost. Notably,  $k$ -MEDIAN ignores 0 points, and  $k$ -CENTER ignores all but one point. While this problem is related to HYBRID  $k$ -CLUSTERING, their objectives differ. ORDERED  $k$ -MEDIAN, a further generalization of  $\ell$ -CENTRUM, also does not align with our objective. Approximation algorithms for this problem and some variants were developed in [2, 1, 6, 7].

**$k$ -center clustering with outliers.** In  $k$ -CENTER clustering, we are given sets  $P$  (clients) and  $\mathbb{F}$  (facilities) of points. Given an integer  $k$ , the task is to identify  $k$  centers  $F \subseteq \mathbb{F}$  minimizing the maximum distance of any point in  $P$  from its closest center. A popular variant of  $k$ -center is a formulation that considers outliers. For a selected parameter  $x$ , up to  $x$  points are allowed not to be allocated to any center. A plethora of approximation algorithms for this problem, and the related problems of covering points by disks and minimum enclosing balls

with outliers, exist in the literature [5, 14, 8, 19, 15, 16, 21, 28]. HYBRID  $k$ -CLUSTERING could be seen as a variant of  $k$ -CENTER with outliers, where we focus on the sum of distances to outliers rather than their numbers.

**Shape fitting.** A natural problem arising in machine learning, statistics, data-mining, and many other fields is to fit a shape  $\gamma$  to a set of points  $P$  in  $\mathbb{R}^d$ . Har-Peled in [20] introduces the following formalization of this problem. For a family of shapes  $\mathcal{F}$  (points, lines, hyperplanes, spheres, etc.) we seek for a shape  $\gamma \in \mathcal{F}$  with the best fit to  $P$ . The typical criteria for measuring how well a shape  $\gamma$  fits a set of points  $P$  could be the maximum distance between a point of  $P$  and its nearest point on  $\gamma$  ( $L_\infty$ -fitting), sum of the distances from  $P$  to  $\gamma$  ( $L_1$ -fitting) or the sum of the squares of the distances ( $L_2$ -fitting). In this setting, HYBRID  $k$ -CLUSTERING is the problem of  $L_1$ -fitting to a shape from  $\mathcal{F}$ , where  $\mathcal{F}$  is the family of shapes defined by unions (not necessarily disjoint) of  $k$  balls in  $\mathbb{R}^d$ . Some relevant work in this direction includes [3, 20, 22, 31].

## 2 Bicriteria FPT Approximation Scheme in Euclidean Spaces

We first set up some notation and define an important subroutine. For  $Y \subset \mathbb{R}^d$ , and  $y \in Y$ , let  $\text{cl}(y, Y) \subseteq P$  denote the subset of points of  $P$ , whose closest point in  $Y$  is  $y$ . Ties are broken arbitrarily. Note that  $\{\text{cl}(y, Y) : y \in Y\}$  forms a partition of  $P$ .

Let  $p \in \mathbb{R}^d$  be a point and  $\lambda \geq 0$ , let  $B(p, \lambda) = \{q \in \mathbb{R}^d : d(p, q) \leq \lambda\}$  denote the ball of radius  $\lambda$  centered at  $p$ . For  $0 \leq \tau \leq \lambda$ , let  $\text{Grid}(p, \lambda, \tau)$  be the outcome of the following procedure: we place a grid of sidelength  $\tau/\sqrt{d}$  (of arbitrary offset). From each grid cell  $L$  that (partially) intersects with  $B(p, \lambda)$  (i.e.,  $L$  contains a point  $q$  with  $d(p, q) \leq \lambda$ ), we pick an arbitrary point from  $L$  and add it to the set  $\text{Grid}(p, \lambda, \tau)$ . Note that  $\text{Grid}(p, \lambda, \tau)$  can be computed in time proportional to the size of the output. We have the following observations that follow from simple geometric arguments.

### ► Observation 3.

1.  $|\text{Grid}(p, \lambda, \tau)| \leq \mathcal{O}((\sqrt{d}\lambda/\tau)^d)$ , where  $d$  is the dimension.
2. For any  $q \in B(p, \lambda)$ , there exists some  $q' \in \text{Grid}(p, \lambda, \tau)$  such that  $d(q, q') \leq \tau$ .

## 2.1 Preprocessing

Suppose we know an estimate of  $\text{OPT}_r$  up to a constant factor – this can be done by an exponential search or by first finding a bicriteria (constant) approximation. For simplicity of exposition, we assume that we know  $\text{OPT}_r$  exactly.

**Step 1.** Obtaining  $\text{OPT}_r \geq r \geq \frac{\varepsilon \text{OPT}_r}{2n}$ .

First, in the following lemma, we handle  $k$ -center-like instances, which we can handle using “grid arguments”. If this is not applicable, we obtain that  $r \leq \text{OPT}_r$ .<sup>1</sup>

► **Lemma 4 (♠).** *If  $r > \text{OPT}_r$ , then in time  $(\frac{d}{\varepsilon})^{\mathcal{O}(dk)} \cdot n^{\mathcal{O}(1)}$  one can find a set  $F \subset \mathbb{R}^d$  of size  $k$ , such that,  $\text{cost}_{(1+\varepsilon)r}(P, F) \leq (1 + \varepsilon)\text{OPT}_r$ .*

<sup>1</sup> Due to space constraints, some proofs are omitted in this extended abstract. They can be found in the full version of the paper [17]. The statements with missing proofs are marked by ♠.

In the following lemma, we handle *k*-median-like instances, where  $r$  is very small compared to  $\text{OPT}_r$ . We directly reduce such instances to *k*-MEDIAN (where  $r = 0$ ). If this is not applicable, then we obtain that  $r$  is not “too small” compared to  $\text{OPT}_r$ .

► **Lemma 5** (♠). *Let  $0 < \varepsilon < 1$ . Suppose for an instance  $\mathcal{I}$ ,  $\text{OPT}_r \geq \frac{2nr}{\varepsilon}$ . Then,  $\text{OPT}_0 \leq (1 + \varepsilon/2) \cdot \text{OPT}_r \leq (1 + \varepsilon/2) \cdot \text{OPT}_0$ . Furthermore, if  $F \subset \mathbb{R}^d$  satisfies that  $\text{cost}_0(P, F) \leq (1 + \varepsilon/3) \cdot \text{OPT}_0$ . Then,  $\text{cost}_r(P, F) \leq (1 + \varepsilon) \cdot \text{OPT}_r$ . Such a set  $F$  can be found in time  $2^{(k/\varepsilon)^{\mathcal{O}(1)}} \cdot nd$ .*

For a given input  $P$ , we try the procedures from Lemma 4 and 5 and keep them as candidate solutions. However, if  $P$  does not satisfy the conditions required to apply these lemmas, then we must have that  $\frac{\varepsilon \text{OPT}_r}{2n} \leq r \leq \text{OPT}_r$ . In this case, we use the next step before proceeding to the main algorithm.

**Step 2.** Bounding the aspect ratio.

In this step, we suitably discretize the distances in order to bound the aspect ratio of the metric (i.e., the maximum ratio of inter-point distances) by  $\mathcal{O}(\frac{n^2}{\varepsilon})$ . This procedure preserves the cost of an optimal solution up to a factor of  $1 + \varepsilon$ .

► **Lemma 6** (♠). *Let  $P$  be a set of points satisfying  $\frac{\varepsilon \text{OPT}_r}{2n} \leq r \leq \text{OPT}_r$ . Then, in polynomial time we can obtain another (multi)set of points  $P'$  such that, for any solution  $F \subset \mathbb{R}^d$ ,  $\text{cost}_r(P', F) \in (1 \pm \varepsilon) \cdot \text{cost}_r(P, F)$ , and  $\frac{\max_{p,q \in P'} \text{dist}(p,q)}{\min_{p,q \in P': \text{dist}(p,q) \neq 0} \text{dist}(p,q)} \leq \frac{4n^2}{\varepsilon}$ .*

Bounding the aspect ratio by  $\mathcal{O}(\frac{n^2}{\varepsilon})$  means that an exponential search over distances has at most  $\log_2 \left( \frac{n^2}{\varepsilon} \right) = \mathcal{O} \left( \frac{\log(n)}{\varepsilon} \right)$  levels, which will be useful in our main algorithm. By slightly abusing the notation, we continue to use  $P$  for referring to the discretized (multi)set  $P'$  returned by Lemma 6. If there are any co-located points in  $P$ , we will treat them as separate points, and hence use set terminology instead of multiset terminology.

After the two preprocessing steps, we now proceed to the description of the main algorithm.

## 2.2 Main Algorithm

Our goal is to prove Theorem 2, that is, to design a randomized bicriteria FPT approximation for HYBRID *k*-CLUSTERING. We define some parameters. Let  $\delta := \frac{\varepsilon}{10k} < \frac{1}{2}$ ,  $\delta' := \frac{\delta}{3}$  and  $r' := (1 + \delta')r$ .

Algorithm 1 is a recursive algorithm, and is called `HybridClustering`. It takes three parameters  $F', k$ , and  $m$ .  $F' \subset \mathbb{R}^d$  is a subset of centers added to the solution so far and has size  $k - m$ . Further,  $k$  is the total size of the solution, and  $m$  is an upper bound on the remaining solution (since we have already added  $k - m$  centers). At a high (and imprecise) level, the goal of each recursive step is to find an *approximate replacement* for each center in an unknown optimal solution.

In line 2, we check whether  $m = 0$ , i.e., whether we have used our budget of  $k$  centers, and if so, we return the same set  $F'$  of centers built through the recursive process. Otherwise (line 4 onward), we assume that  $m > 0$ , i.e., we are yet to add a set of centers. Throughout this process (line 4 to 13, we will build a set  $R$  consisting of candidate centers, at least one of which will be an approximate replacement of an *unseen* center (i.e., one whose approximate replacement has not already been found) from an optimal solution. Finally, in line 15, we will make a recursive call by adding each candidate to the current solution  $F'$ . Now we discuss how we build the set  $R$ .

---

**Algorithm 1** HybridClustering( $F', k, m$ ).
 

---

$F' \subseteq \mathbb{R}^d$  is a subset of centers of size at most  $k - m$  added to the solution so far  
 $\beta = \frac{1}{\delta^{c'}} r$  as required in Proposition 13 and  $\beta' := \beta \cdot \frac{150k}{\delta^3}$ .

- 1: **if**  $m = 0$  **then**
- 2:     **return**  $F'$
- 3: **end if**
- 4:  $R \leftarrow \bigcup_{c' \in F'} \text{Grid}(c', 16r, \delta r)$
- 5: **for** each  $q$  of the form  $2^j$  in the range  $[8r, \text{dist}_{\max}]$  **do**
- 6:      $P_q := P \setminus (\bigcup_{c' \in F'} B(c', q))$
- 7:     Let  $S_q$  be a sample of size  $\beta'$  chosen uniformly at random from  $P_q$
- 8:      $R \leftarrow R \cup \bigcup_{p \in S_q} \text{Grid}(p, \frac{8r}{\delta}, \delta r)$
- 9:     **for** each  $S \subseteq S_q$  of size  $\beta$  **do**
- 10:          $c' \leftarrow \text{ApproxSolutionOnSample}(S, \delta/8)$       $\triangleright$  Algorithm from Proposition 13
- 11:          $R \leftarrow R \cup \{c'\}$
- 12:     **end for**
- 13: **end for**
- 14: **for** each  $c \in R \setminus F'$  **do**
- 15:     Call HybridClustering( $F' \cup \{c\}, k, m - 1$ )
- 16: **end for**
- 17: Call HybridClustering( $F', k, m - 1$ )
- 18: **return** solution  $\tilde{F}$  minimizing  $\text{cost}_{r'}(P, \tilde{F})$  over recursive calls made in lines 15 and 17

---

First, in line 4, for each center  $c' \in F'$  added so far, we add a set of “nearby” centers by placing a grid. This handles the case when an unseen optimal center is close to one of the already chosen centers in  $F'$ . Next, in the outer **for** loop (line 5 to 13), we handle the case when all new optimal centers are relatively far from the already chosen centers. In this **for** loop, we iterate over a range of values for the parameter  $q$  via exponential search. Parameter  $q$  tries to approximate half of the minimum distance between the already chosen and new optimal centers. Thus, for the “correct” value of  $q$ , the set of points  $C_q$  lying “far” from the centers of  $F'$  (line 6), leaves all of the  $m$  unseen optimal clusters untouched. At this point, we aim to use a sample of faraway size (chosen in line 7), to find an approximate replacement for one of these  $m$  unseen centers. We do this by using the sample in two different ways, to handle two different situations. First, if our sample happens to contain a point “nearby” an unseen center, say  $c^*$ , then the points chosen from the fine grid in line 8 will find such an approximate replacement for  $c^*$ . Otherwise, the idea is that, if we have removed a significant fraction of points from the “seen” clusters in line 6, by virtue of being close to  $F'$ , then the sample contains sufficiently many (i.e., at least  $\beta$ ) points from the largest unseen cluster, say  $C^*$ , with reasonable probability, and these points can be used to find an approximate replacement of the cluster center (using Proposition 13). However, *a priori* we do not know which subset of the sample comes from  $C^*$ . Therefore, we iterate over all subsets of size  $\beta$  in the inner **for** loop (lines 9 to 12) to find such a subset of size  $\beta$  that comes entirely from  $C^*$  and use a known subroutine, called **ApproxSolutionOnSample**, to find an approximate replacement. Finally, in 15, we make a recursive call by adding each center from  $R \setminus F'$ , and in line 17, we make a recursive call by not adding any new center (to handle a particular case). In line 18, we return the minimum-cost solution found over all recursive calls. This completes the description of the algorithm.

## 2.3 Analysis

The crux of the analysis is to establish that Algorithm 1 satisfies the following invariant.

### Invariant

Let  $0 \leq m \leq k$  and  $0 < \alpha < 1$  be a constant. Suppose for the given  $F'$  of size at most  $k - m$ , there exists some  $F = F' \uplus F_o \subset \mathbb{R}^d$ , such that

1.  $|F_o| \leq m$ , and
- 2.

$$\sum_{c \in F'} \text{cost}_{r'}(\text{cl}(c, F), c) + \sum_{c \in F_o} \text{cost}_r(\text{cl}(c, F), c) \leq (1 + \delta)^{k-m} \cdot \text{OPT}_r \quad (2)$$

Then, with probability at least  $\alpha^m$ , the algorithm returns a solution  $\tilde{F} \subset \mathbb{R}^d$ , such that

1.  $|\tilde{F}| \leq k$ ,
2.  $F' \subseteq \tilde{F}$ , and
- 3.

$$\sum_{c \in \tilde{F}} \text{cost}_{r'}(\text{cl}(c, F), c) \leq (1 + \delta)^k \cdot \text{OPT}_r. \quad (3)$$

### Proof of Correctness

The proof is by induction on  $m$ . For the base case, consider  $m = 0$ . In the base case (Algorithm 1), we return the same  $F' = F$  with probability one. In this case, the invariant tells us that  $\text{cost}_{r'}(P, F) \leq (1 + \delta)^k \cdot \text{OPT}_r$ , which is what we need to prove. Now we assume that the claim is true for some  $m - 1 \geq 0$  and we prove it for  $m$  by considering different cases.

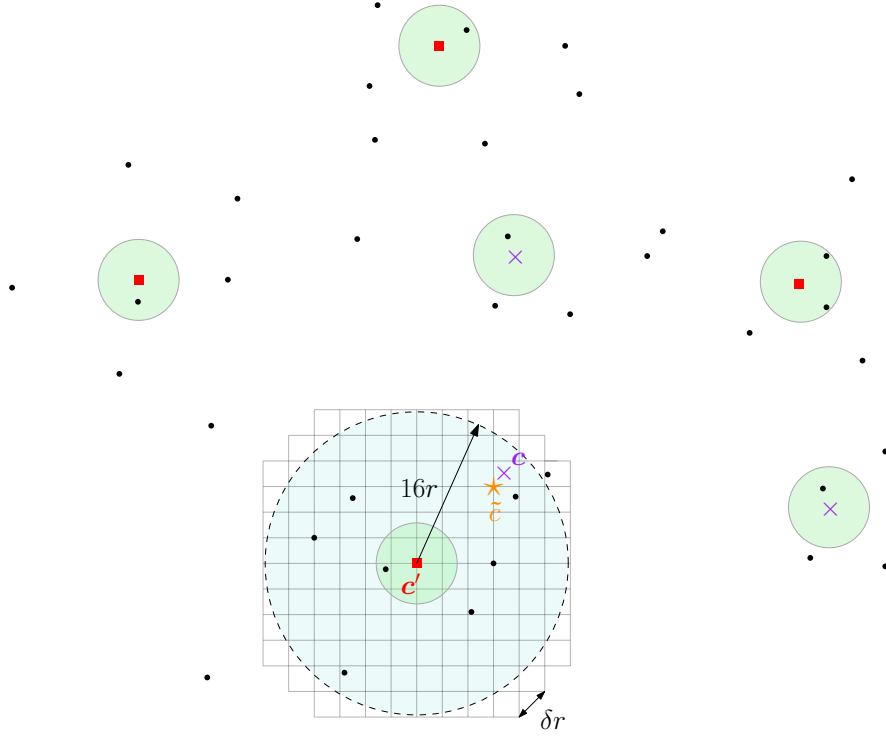

**Easy case:  $F = F'$ .** This is a much simpler case since we have already found the desired set. In this case, any solution  $\tilde{F}$  returned by a recursive call always contains  $F = F'$  as a subset. Then, in this case, we have that:

$$\text{cost}_{r'}(P, \tilde{F}) \leq \text{cost}_{r'}(P, F) \leq (1 + \delta)^{k-m} \cdot \text{OPT}_r \leq (1 + \delta)^k \cdot \text{OPT}_r$$

Here, the first inequality follows from the assumption that  $\tilde{F} \supseteq F = F'$ , and the second inequality follows from (2) of the invariant. Note that we do not need to rely on the induction here.

**Main case:  $F' \subsetneq F$ .** This is the case where we are yet to discover some subset (namely,  $F \setminus F'$ ) of centers. We will analyze this case by considering different scenarios based on the inter-center distances, as well as their relative sizes.

First, since  $F' \subsetneq F$ , there exists some  $c \in F \setminus F'$ . Now, let  $c \in F \setminus F'$  and  $c' \in F'$  be the pair of centers with the smallest distance, i.e.,  $(c, c')$  is a pair realizing  $\min_{c_1 \in F \setminus F', c_2 \in F'} \text{dist}(c_1, c_2)$ . Now we consider different cases depending on  $\text{dist}(c, c')$ , namely the closest distance between an already chosen center  $c' \in F'$ , and an “unseen center”  $c \in F \setminus F'$ .

■ **Figure 4** Illustration for Case 1. Centers in  $F'$  are shown as red squares and unseen centers of  $F \setminus F'$  are shown as purple crosses.  $c$  is the closest center to  $F'$  and  $\text{dist}(c, c') \leq 16r$ . Then, a nearby center  $\tilde{c}'$  can be found using a  $\delta r$  grid.

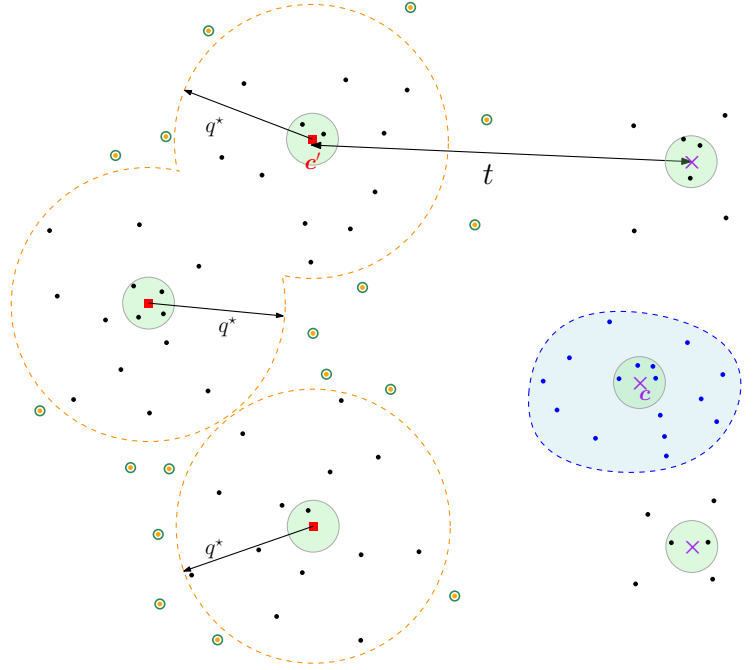

**Case 1. Nearby center:  $\text{dist}(c, c') \leq 16r$ .** In this case, via Observation 3, we conclude that there exists some  $\tilde{c} \in \text{Grid}(c', 16r, \delta r)$  with  $\text{dist}(\tilde{c}, c) \leq \delta r$ . Let  $\tilde{F} = F' \cup \{\tilde{c}\}$ . Then, the proof follows from the following claim (see Figure 4).

▷ **Claim 7.** Let  $c_1 \in F_o$  and let  $\tilde{c}_1 \in \mathbb{R}^d$  be such that  $\text{dist}(c_1, \tilde{c}_1) \leq \delta r$ . Then, with probability at least  $\alpha^{m-1}$ ,  $\text{HybridClustering}(F \cup \tilde{c}_1, k, m - 1)$  returns a solution  $\tilde{F}$  that satisfies the required properties.

*Proof.* Consider  $c_1, \tilde{c}_1$  as defined in the statement. Let  $A = \text{cl}(c_1, F)$ . For any point  $p \in A$ ,  $\text{dist}(p, \tilde{c}_1) \leq \text{dist}(p, c_1) + \text{dist}(c_1, \tilde{c}_1) \leq \text{dist}(p, c_1) + \delta r$ . This implies that,  $\text{dist}_{r'}(p, \tilde{c}_1) \leq \text{dist}_{r'}(p, c_1)$ . Define  $F_{\text{new}} := F'_{\text{new}} \uplus F'_o$ , where  $F'_{\text{new}} := F' \cup \{\tilde{c}_1\}$  and  $F'_o := F_o \setminus \{c_1\}$ . First, we show the following inequality.

$$\begin{aligned} \sum_{c \in F'_{\text{new}}} \text{cost}_{r'}(\text{cl}(c, F), c) + \sum_{c \in F'_o} \text{cost}_r(\text{cl}(c, F_{\text{new}}), c) \\ \leq \sum_{c \in F'} \text{cost}_{r'}(\text{cl}(c, F), c) + \sum_{c \in F_o} \text{cost}_r(\text{cl}(c, F), c) \end{aligned} \quad (4)$$

We construct an assignment of clients to the centers in  $F_{\text{new}}$ , where we may not assign a client to its closest center. To construct this assignment, we consider different cases. For  $c \in F' \cup F_o \setminus \{c_1\}$ , we assign all points  $p \in \text{cl}(c, F)$  to  $c$ . The contribution of all such points is the same as the right-hand side of (4). Finally, we assign all points in  $\text{cl}(c_1, F)$  to  $\tilde{c}_1$ . By the choice of  $\tilde{c}_1$ ,  $\text{cost}_{r'}(\text{cl}(c_1, F), \tilde{c}_1) \leq \text{cost}_r(\text{cl}(c_1, F), c_1)$ , which is the contribution of such points on the right-hand side. Since the cost on the left-hand side is no larger than the cost of the assignment thus constructed, it shows (4).

■ **Figure 5** Illustration for Case 2. Centers of  $F'$  are shown as red squares and unseen centers of  $F \setminus F'$  are shown as purple crosses. Balls of radius  $q^*$  around  $F'$  are shown in dashed orange.  $P'$  are the points lying outside these balls. Among the points of  $P'$ ,  $D$  is the set of points belonging to clusters around  $F'$ , and shown as green-orange filled dots. Finally, the cluster around  $c$  is the largest unseen cluster (marked in dashed blue shape),  $L$ . We analyze different cases depending on the relative sizes of  $L$  and  $D$ .

Note that the right-hand side of (4) is at most  $(1 + \delta)^{k-m} \cdot \text{OPT}_r$ , due to the invariant, and hence  $F_{\text{new}}$  satisfies the properties required to apply the inductive hypothesis for  $m - 1$ . This implies that with probability at least  $\alpha^{m-1}$  the recursive call  $\text{Recursive}(F' \cup \{\tilde{c}_1\}, k, m - 1)$  returns a solution  $\tilde{F}$  satisfying  $\text{cost}_{r'}(P, \tilde{F}) \leq (1 + \delta)^k \cdot \text{OPT}_r$ .  $\triangleleft$

**Case 2. Faraway center:**  $16r < \text{dist}(c, c') \leq \text{dist}_{\max}$ . Let  $t = \text{dist}(c, c')$  and  $q^*$  be the largest power of 2 that is at most  $t/2$ . Consider  $P_{q^*} = P \setminus (\bigcup_{c_1 \in F'} B(c_1, q^*))$ . Let  $c^* \in F \setminus F'$  denote the center of the maximum-size cluster, i.e.,  $c^* = \arg \max_{c_1 \in F \setminus F'} |\text{cl}(c_1, F)|$ , and  $L := \text{cl}(c^*, F)$  denote the largest cluster. Finally, let  $D := \bigcup_{c_{\text{old}} \in F'} \text{cl}(c_{\text{old}}, F) \cap P_{q^*}$  denote the set of clients that are distant from the respective centers in  $F'$ . Let us summarize some consequences of these definitions in the following observation (its proof is essentially discussed above). Also see Figure 5.

► **Observation 8.**

1.  $P_{q^*} = D \uplus \biguplus_{c_1 \in F \setminus F'} \text{cl}(c_1, F) \cap P_{q^*}$ .
2. In particular,  $\text{cl}(c, F), \text{cl}(c^*, F) \subseteq P_{q^*}$ .

We consider different sub-cases based on the relative sizes of  $L$  and  $D$ .

**Case 2.1. New cluster is tiny:**  $|L| \leq \delta^2/4 \cdot |D|$ . Let  $N := \text{cl}(c, F)$ . Note that the definition of  $c^*$ , combined with the case assumption, implies that  $|N| \leq |L| \leq \frac{\delta^2}{4} \cdot |D|$ . We summarize a few technical consequences of these definitions in the following claim.

## 4:12 Hybrid $k$ -Clustering: Blending $k$ -Median and $k$ -Center

▷ Claim 9.

$$\text{cost}_r(N, c') \leq \delta \cdot \text{cost}_r(D, F) + (1 + \delta) \cdot \text{cost}_r(N, c) \quad (5)$$

Proof. Note that for each  $p \in D$ ,  $\text{dist}(p, F) \geq \frac{t}{4}$ . Thus,  $\text{dist}_r(p, c') \geq \frac{t}{4} - r \geq \frac{3t}{16}$ , where the last inequality follows from the case assumption, namely  $t > 16r$ . Thus, each point  $p \in D$  contributes at least  $\frac{3t}{16}$  to  $\text{cost}_{r'}(P, F)$ , and their total contribution to  $\text{cost}_r(P, F)$  is

$$\text{cost}_r(D, F) := \sum_{p \in D} \text{dist}_r(p, c') \geq |D| \cdot \frac{3t}{16} \quad (6)$$

Now we upper bound the cost of assigning points of  $N$  to  $c'$ . To this end, we partition  $N = N_{\text{near}} \uplus N_{\text{far}}$ , where  $N_{\text{near}} := \{p \in A : \text{dist}(p, c) \leq 2r/\delta\}$  and  $N_{\text{far}} := \{p \in A : \text{dist}(p, c) > 2r/\delta\}$ . Note that, for each  $p \in N_{\text{far}}$ ,  $\text{dist}_r(p, c) = \text{dist}(p, c) - r \geq \text{dist}(p, c) - \frac{\delta}{2} \cdot \text{dist}(p, c)$ , which implies that, for each  $p \in N_{\text{far}}$ ,

$$\text{dist}(p, c) \leq \left( \frac{1}{1 - \frac{\delta}{2}} \right) \cdot \text{dist}_r(p, c) \leq (1 + \delta) \cdot \text{dist}_r(p, c) \quad (7)$$

Now consider,

$$\begin{aligned} \text{cost}_r(N, c') &\leq \sum_{p \in N} \text{dist}(p, c') && \text{(Since } \text{dist}_r(\cdot, \cdot) \leq \text{dist}(\cdot, \cdot)\text{)} \\ &\leq \sum_{p \in N} \text{dist}(p, c) + \text{dist}(c, c') && \text{(Triangle inequality)} \\ &= |N| \cdot \text{dist}(c, c') + \sum_{p \in N_{\text{near}}} \text{dist}(p, c) + \sum_{p \in N_{\text{far}}} \text{dist}(p, c) \\ &\leq \frac{\delta^2}{8} \cdot |D| \cdot t + \sum_{p \in N_{\text{near}}} \frac{4r}{\delta} + \sum_{p \in N_{\text{far}}} (1 + \delta) \cdot \text{dist}_r(p, c) \\ &&& \text{(From case assumption and (7))} \\ &= \frac{\delta^2}{4} \cdot |D| \cdot t + \frac{4r}{\delta} \cdot |N_{\text{near}}| + (1 + \delta) \cdot \text{cost}_r(N, c) \\ &\leq \frac{\delta^2}{4} \cdot |D| \cdot t + \delta \cdot |D| \cdot \frac{t}{16} + (1 + \delta) \cdot \text{cost}_r(N, c) \\ &&& (|N_{\text{near}}| \leq |N| \leq \frac{\delta^2}{4} \text{ and } t > 16r) \\ &\leq |D| \cdot \frac{3t}{16} \cdot \delta \cdot \left( \frac{4\delta}{3} + \frac{1}{3} \right) + (1 + \delta) \cdot \text{cost}_r(N, c) \\ &\leq \delta \cdot \text{cost}_r(D, F) + (1 + \delta) \cdot \text{cost}_r(N, c) \end{aligned} \quad (8)$$

Where the last inequality follows from (6) and  $\delta < 1/2$ . ◁

Thus, consider the solution  $F \setminus \{c\}$ . To upper bound  $\text{cost}_r(P, F \setminus \{c\})$ , we assign all points in  $N = \text{cl}(c, F)$  to  $c'$ . The cost of this solution can be upper bounded as follows

$$\begin{aligned} \text{cost}_r(P, F \setminus \{c\}) &\leq \text{cost}_r(P, F) - \text{cost}_r(N, c) + \text{cost}_r(N, c') \\ &\leq \text{cost}_r(P, F) + \delta \cdot \text{cost}_r(D, F) + \delta \cdot \text{cost}_r(N, c) && \text{(From (5))} \\ &\leq \text{cost}_r(P, F) + \delta \cdot \text{cost}_r(P, F) && \text{(Since } D \uplus N \subseteq P\text{)} \\ &\leq (1 + \delta)^{k-m+1} \cdot \text{OPT}_r \end{aligned} \quad (9)$$

Where the last inequality follows from the invariant. Further, observe that  $c \in F \setminus F'$ , which implies that  $|(F \setminus \{c\}) \setminus F'| \leq m - 1$ . This, combined with (9), shows that the solution  $F \setminus \{c\} = F' \uplus (F_o \setminus \{c\})$  satisfies the conditions of the invariant for  $m - 1$ . Then, by using inductive hypothesis,  $\text{HybridClustering}(F, k, m - 1)$ , with probability at least  $\alpha^{m-1} \geq \alpha^m$ , returns a solution  $\tilde{F}$  such that (a)  $|\tilde{F}| \leq k$ , (b)  $F \subseteq \tilde{F}$ , and (c)  $\text{cost}_{(1+\delta)r'}(F, \tilde{F}) \leq (1 + \delta)^k \cdot \text{OPT}_r$ , completing the induction.

**Case 2.2. New cluster is large enough:**  $|L| > \delta^2/4 \cdot |D|$ . That is, the largest “untouched” cluster is at least an  $\delta$  fraction of the remaining points. Since  $L = \text{cl}(c^*, F)$  is the largest “untouched” cluster,  $|L| \geq |\text{cl}(c_1, F)|$  for all  $c_1 \in F \setminus F'$ . Then, by Observation 8, we have that,

$$|P_{q^*}| = |D| + \sum_{c_1 \in F \setminus F'} |\text{cl}(c_1, F)| \leq |D| + |F \setminus F'| \cdot |L| \leq \frac{4}{\delta^2} \cdot |L| + k \cdot |L| \leq \frac{5k}{\delta^2} \cdot |L|$$

In other words,  $|L| \geq \frac{\delta^2}{5k} \cdot |P_{q^*}|$ .

In the next claim, we summarize some properties of the sample  $S$  chosen in line 7 of the algorithm, in the current case, i.e., when  $|L| \geq \frac{\delta^2}{5k} |C_{q^*}|$ .

▷ **Claim 10.** Consider the iteration of the **for** loop of Algorithm 1, when  $q = q^*$ , and the corresponding sample  $S_q$  obtained in Algorithm 1. The following statements hold.

1. With probability at least  $1/2$ ,  $S_q$  contains at least  $\beta$  points of  $L$ .
2.  $S_q \cap L$  has the same distribution as selecting  $|S_q \cap L|$  points uniformly at random from  $L$ .
3. Let  $L' \subseteq L$  be an arbitrary subset of size at least  $\frac{\delta}{10}|L|$ . Then, with probability at least  $1/2$ ,  $S_q$  contains at least 1 point from  $L$ , i.e.,  $S_q \cap L' \neq \emptyset$ .

*Proof.* Recall that  $\beta' = \beta \cdot \frac{150k}{\delta^3}$  and  $|L| \geq \frac{\delta^2}{5k} |C_{q^*}|$ . So, the first item follows, say, via Markov’s inequality<sup>2</sup>. The second item is an easy consequence of conditional distributions. The proof of the third item is analogous to the first item, combined with the bound on  $|L'|$ . ◁

Now we condition on the event that  $|S_{q^*} \cap L| \geq \beta$ , which, by Claim 10 happens with probability at least  $\frac{1}{2}$ . Then, let  $S' \subseteq S \cap L$  be such a subset of size  $\beta$ . Let  $L = L_{\text{near}} \uplus L_{\text{far}}$ , where  $L_{\text{near}} = \{p \in L : \text{dist}(p, c^*) \leq \frac{8r}{\delta}\}$  and  $L_{\text{far}} = \{p \in L : \text{dist}(p, c^*) > \frac{8r}{\delta}\}$ . We consider different cases depending on the relative sizes of  $L_{\text{near}}$  and  $L_{\text{far}}$ . In the first case below (2.2.1), when  $|L_{\text{near}}|$  is not very tiny compared to  $|L_{\text{far}}|$ , we show that our sample contains at least one point from  $L_{\text{near}}$  with good probability, and hence an  $\varepsilon r$  grid around that point will contain an approximate center. In the complementary case (2.2.2),  $|L_{\text{near}}|$  is very tiny compared to  $|L_{\text{far}}|$ , and in this case, we argue that, instead of finding an approximate HYBRID 1-MEDIAN, we can focus on finding an approximate 1-MEDIAN, which can be found using the sample. Now we formally analyze each of these cases.

**Case 2.2.1.**  $|L_{\text{near}}| > \frac{\delta}{8} \cdot |L_{\text{far}}|$ . In this case, letting  $L' \leftarrow L_{\text{near}}$  in Claim 10, we infer that with at least probability  $1/2$ ,  $S' \cap L_{\text{near}} \neq \emptyset$ . We condition on this event. Then, since  $\text{dist}(p, c^*) \leq \frac{8r}{\delta}$ , it follows that there exists a  $\tilde{c}^* \in \text{Grid}(p, \frac{8r}{\delta}, \delta r)$ , such that  $\text{dist}(\tilde{c}^*, c^*) \leq \delta r$ . Since we branch on each point in  $\bigcup_{p' \in S} \text{Grid}(p', \frac{8r}{\delta}, \delta r)$ , we will branch on  $\tilde{c}^*$  in particular. Then, by Claim 7,  $\text{HybridClustering}(F' \cup \{\tilde{c}^*\}, k, m - 1)$  returns a solution  $\tilde{F}$ , with probability at least  $1/2 \cdot \alpha^{m-1} \geq \alpha^m$ .

**Case 2.2.2.**  $|L_{\text{near}}| \leq \frac{\delta}{8} \cdot |L_{\text{far}}|$ . We prove two claims, namely Claim 11, and Claim 12. The latter essentially reduces the problem to finding an approximate solution to 1-median on  $L$ . Intuitively speaking, this follows from the following two reasons: (1) As we show in (10), a similar statement holds for the points in  $L_{\text{far}}$ . This essentially follows from the fact that, since each point of  $L_{\text{far}}$  has distance at least  $\frac{8r}{\delta}$  to  $c$ , the subtraction of  $r$  from their distances has little effect on the cost, and (2) Due to the case assumption, the points of  $L_{\text{far}}$  vastly outnumber the points of  $L_{\text{near}}$ . Hence, the preceding claim also translates to the points of  $L = L_{\text{far}} \cup L_{\text{near}}$ , at a further small approximation error.

<sup>2</sup> In fact, a closer inspection reveals that the probability is much closer to 1, but “at least  $1/2$ ” suffices for our purpose.

#### 4:14 Hybrid $k$ -Clustering: Blending $k$ -Median and $k$ -Center

▷ Claim 11.  $\sum_{p \in L} \text{dist}_r(p, c^*) \leq \sum_{p \in L} \text{dist}(p, c^*) \leq (1 + \frac{3\delta}{4}) \cdot \sum_{p \in L} \text{dist}_r(p, c^*)$ .

Proof. First, consider,

$$\sum_{p \in L_{\text{far}}} \text{dist}_r(p, c^*) = \sum_{p \in L_{\text{far}}} \text{dist}(p, c^*) - r \geq \sum_{p \in L_{\text{far}}} \text{dist}(p, c^*) - \frac{\delta}{8} \cdot \text{dist}(p, c^*)$$

(Since  $\text{dist}(p, c^*) \geq \frac{8r}{\delta} > r$ )

Then, the inequality between the first and the last term can be rewritten as,

$$\sum_{p \in L_{\text{far}}} \text{dist}(p, c^*) \leq \frac{1}{1 - \delta/8} \cdot \sum_{p \in L_{\text{far}}} \text{dist}_r(p, c^*) \leq (1 + \frac{\delta}{4}) \cdot \sum_{p \in L_{\text{far}}} \text{dist}_r(p, c^*) \quad (10)$$

The following inequality will be used later to show that the contribution of points of  $L_{\text{near}}$  is negligible to the overall cost.

$$\begin{aligned} \sum_{p \in L_{\text{far}}} \text{dist}(p, c^*) &\geq \sum_{p \in L_{\text{far}}} \text{dist}_r(p, c^*) \geq \sum_{p \in L_{\text{far}}} (1 - \frac{\delta}{8}) \cdot \text{dist}(p, c^*) && \text{(From (10))} \\ &\geq (1 - \frac{\delta}{8}) \cdot \frac{8r}{\delta} \cdot |L_{\text{far}}| && \text{(Definition of } L_{\text{far}}) \\ &\geq \frac{1}{2} \cdot \frac{8r}{\delta} \cdot \frac{8}{\delta} \cdot |L_{\text{near}}| && \text{(Case assumption: } |L_{\text{far}}| \geq \frac{8}{\delta} \cdot |L_{\text{near}}|) \\ &= \frac{4}{\delta} \cdot \frac{8r}{\delta} \cdot |L_{\text{near}}| \\ &\geq \frac{4}{\delta} \cdot \sum_{p \in L_{\text{near}}} \text{dist}_r(p, c^*) && (11) \end{aligned}$$

Where the last inequality follows from the definition of  $L_{\text{near}}$ .

The next sequence of inequalities shows a bound similar to (10), but when the sum is taken over all points of  $L$  (instead of only the points of  $L_{\text{far}}$ , as in Equation (10)).

$$\begin{aligned} \sum_{p \in L} \text{dist}_r(p, c^*) &\leq \sum_{p \in L} \text{dist}(p, c^*) = \sum_{p \in L_{\text{near}}} \text{dist}_r(p, c^*) + \sum_{p \in L_{\text{far}}} \text{dist}_r(p, c^*) \\ &= (1 + \frac{\delta}{4}) \cdot \sum_{p \in L_{\text{far}}} \text{dist}_r(p, c^*) && \text{(From (11))} \\ &\leq (1 + \frac{\delta}{4}) \cdot (1 + \frac{\delta}{4}) \cdot \sum_{p \in L_{\text{far}}} \text{dist}_r(p, c^*) && \text{(From (10))} \\ &\leq (1 + \frac{3\delta}{4}) \cdot \sum_{p \in L} \text{dist}_r(p, c^*) && (12) \end{aligned}$$

Where the last inequality follows from (i)  $(1 + \frac{\delta}{4}) \cdot (1 + \frac{\delta}{4}) \leq 1 + \frac{3\delta}{4}$  and (ii)  $L_{\text{far}} \subseteq L$ . This completes the proof of the claim.  $\triangleleft$

Using this claim, we prove the following claim, which shows that it is sufficient to find an approximate 1-median solution for  $L$ , which will also be a good approximation for HYBRID 1-MEDIAN for  $L$ . To this end, let  $\tilde{c}^* \in \mathbb{R}^d$  denote the optimal 1-median for  $L$ .

▷ Claim 12. Let  $c_1$  be an  $(1 + \frac{\delta}{8})$ -approximation for 1-MEDIAN for  $L$ , i.e.,  $\sum_{p \in L} \text{dist}(p, c_1) \leq (1 + \frac{\delta}{8}) \cdot \sum_{p \in L} \text{dist}(p, \tilde{c}^*)$ . Then, it is also a  $(1 + \delta)$ -approximation for HYBRID 1-MEDIAN for  $L$ , i.e.,

$$\sum_{p \in L} \text{dist}_r(p, c_1) \leq (1 + \delta) \cdot \sum_{p \in L} \text{dist}_r(p, c^*) \quad (13)$$

Proof. Let  $c_1, \tilde{c}^* \in \mathbb{R}^d$  as defined above. Then,

$$\begin{aligned}
\sum_{p \in L} \text{dist}_r(p, c_1) &\leq \sum_{p \in L} \text{dist}(p, c_1) \leq (1 + \frac{\delta}{8}) \cdot \sum_{p \in L} \text{dist}(p, \tilde{c}^*) && \text{(By definition of } c_1) \\
&\leq (1 + \frac{\delta}{8}) \cdot \sum_{p \in L} \text{dist}(p, c^*) \\
&\text{(Since } c_1 \in \mathbb{R}^d \text{ is an optimal 1-median and } c^* \in \mathbb{R}^d \text{ is a feasible median)} \\
&\leq (1 + \frac{\delta}{8}) \cdot (1 + \frac{3\delta}{4}) \cdot \sum_{p \in L} \text{dist}_r(p, c^*) && \text{(From Claim 11)} \\
&\leq (1 + \delta) \cdot \sum_{p \in L} \text{dist}_r(p, c^*) && \triangleleft
\end{aligned}$$

Thus, now the task reduces to finding a  $1 + \frac{\delta}{8}$ -approximate 1-MEDIAN solution for  $L$ . To this end, we have the following result from [24, 25].

► **Proposition 13** ([24, 25]). *Let  $X \subset \mathbb{R}^d$  be a set of  $n$  points and  $0 < \delta < 1$ . Let  $S \subseteq X$  be a uniform sample chosen from  $X$  of size  $\beta = (\frac{1}{\delta})^{c'}$ . Then, there exists an algorithm that runs in time  $2^{\mathcal{O}(1/\delta^c)d}$ , and with probability at least  $\alpha'$ , returns an  $(1 + \delta)$ -approximate 1-median for  $X$ . Here,  $c, c'$  are absolute constants independent of the dimension  $d$ .*

We combine the properties of the sample  $S_{q^*}$  proved in Claim 10 along with the previous proposition, to complete the proof. To this end, note that the first item of Claim 10 implies that, with probability at least  $1/2$ ,  $S_{q^*}$  contains at least  $\beta = \frac{1}{\delta^c}$  points from  $L$ . Then, we use the algorithm of Proposition 13, that returns with probability at least  $\alpha'$ , a  $(1 + \frac{\delta}{8})$ -approximate 1-median  $c_1 \in \mathbb{R}^d$  for  $L$ . It follows that,

$$\begin{aligned}
&\sum_{c \in F' \cup \{c_1\}} \text{cost}_{r'}(\text{cl}(c, F), c) + \sum_{c \in F_o \setminus \{c^*\}} \text{cost}_r(\text{cl}(c, F), c) \\
&\leq \sum_{c \in F'} \text{cost}_{r'}(\text{cl}(c, F), c) + \sum_{c \in F_o} \text{cost}_r(\text{cl}(c, F), c) - \text{cost}_r(\text{cl}(c^*, F), c^*) + \sum_{p \in L} \text{dist}_r(p, c_1) \\
&\leq \sum_{c \in F'} \text{cost}_{r'}(\text{cl}(c, F), c) + \sum_{c \in F_o} \text{cost}_r(\text{cl}(c, F), c) - \text{cost}_r(\text{cl}(c^*, F), c^*) \\
&\quad + \delta \cdot \sum_{c \in F_o} \text{cost}_r(\text{cl}(c, F), c) && \text{(From Claim 12)} \\
&\leq (1 + \delta) \cdot \left( \sum_{c \in F'} \text{cost}_{r'}(\text{cl}(c, F), c) + \sum_{c \in F_o} \text{cost}_r(\text{cl}(c, F), c) \right) \\
&\leq (1 + \delta)^{k-m+1} \cdot \text{OPT}_r && (14)
\end{aligned}$$

Then, by induction hypothesis,  $\text{HybridClustering}(F' \cup \{c_1\}, k, m - 1)$ , with probability at least  $\alpha^{m-1}$ , returns a solution  $\tilde{F}$  such that  $\text{cost}_{r'}(P, \tilde{F}) \leq (1 + \delta)^k \cdot \text{OPT}_r$ . The overall probability of this event is at least  $\frac{1}{2} \cdot \alpha' \cdot \alpha^{m-1} = \alpha^m$ , completing the induction.

This finishes the case analysis, and thus we have established the invariant using induction. Using the invariant, we can show the following key lemma.

► **Lemma 14.** *HybridClustering( $\emptyset, k, k$ ) returns a  $(1 + \varepsilon, 1 + \varepsilon)$ -bicriteria approximation solution to the given instance of HYBRID  $k$ -CLUSTERING with probability at least  $\alpha^k$  for some constant  $0 < \alpha < 1$ .*

## 4:16 Hybrid $k$ -Clustering: Blending $k$ -Median and $k$ -Center

**Proof.** We first show the following:

$$\triangleright \text{Claim 15. } |R| \leq \left(\frac{k\sqrt{d}}{\delta}\right)^{\mathcal{O}(d)} + \frac{k \log n}{\delta^{\mathcal{O}(1)}} \cdot \left( \left(\frac{\sqrt{d}}{\delta}\right)^{\mathcal{O}(d)} + \binom{\beta'}{\beta} \right) \leq (\log n) \cdot 2^{(kd/\delta)^{\mathcal{O}(1)}}.$$

**Proof.** First, in Algorithm 1, we add the points returned by  $\text{Grid}(c', 16r, \delta r)$  for each  $c' \in F'$ . The number of such points is  $\left(\frac{16r\sqrt{d}}{\delta r}\right)^d = \left(\frac{\sqrt{d}}{\delta}\right)^{\mathcal{O}(d)}$ . Next, there are at most  $\frac{\log n}{\delta^{\mathcal{O}(1)}}$  values for  $q$  (this follows from the second preprocessing step, cf. Lemma 6), corresponding to each iteration of the for loop. In each iteration, we take a sample  $S$  of size  $\beta' = \mathcal{O}\left(\frac{150k\beta}{\delta^3}\right)$ . Then, for each  $p \in S$ , we add to  $R$  the points of  $\text{Grid}(p, 8r/\delta, \delta r)$ , and the number of such points is at most  $\left(\frac{8\sqrt{d}}{\delta^2}\right)^d = \left(\frac{\sqrt{d}}{\delta^2}\right)^{\mathcal{O}(d)}$ . In addition, we iterate over each subset  $S' \subseteq S$  of size  $\beta$ , and the number of such subsets is  $\binom{\beta'}{\beta} \leq \left(\frac{\epsilon\beta'}{\beta}\right)^\beta = \left(\frac{k}{\delta^3 \cdot \beta}\right)^\beta = \left(\frac{k}{\delta^3}\right)^{(1/\delta)^{\mathcal{O}(1)}} = k^{1/\delta^{\mathcal{O}(1)}}$ . Thus, overall, the size of  $R$  is bounded by  $(\log n) \cdot 2^{(kd/\delta)^{\mathcal{O}(1)}}$ .  $\triangleleft$

To bound the running time of the algorithm, let  $T(m)$  denote an upper bound on  $\text{HybridClustering}(F', k, m)$  for any  $F' \subset \mathbb{R}^d$ . Note that we make a recursive call on each point in  $R$ . Further by Proposition 13, the time taken to compute a center in Algorithm 1 is at most  $2^{(1/\delta)^{\mathcal{O}(1)}}$ ; and this algorithm is used in each of the at most  $\frac{k \log n}{(1/\delta)^{\mathcal{O}(1)}} \cdot \binom{\beta'}{\beta} \leq (\log n) \cdot k^{(1/\delta)^{\mathcal{O}(1)}}$ . Thus,  $T(m)$  can be bounded by the following recurrence.

$$\begin{aligned} T(m) &\leq |R| \cdot T(m-1) + (\log n) \cdot k^{(1/\delta)^{\mathcal{O}(1)}} \cdot n^{\mathcal{O}(1)} \\ &\leq (\log n) \cdot 2^{\left(\frac{kd}{\delta}\right)^{\mathcal{O}(1)}} \cdot T(m-1) + k^{(1/\delta)^{\mathcal{O}(1)}} \cdot n^{\mathcal{O}(1)} \end{aligned}$$

It can be shown that this recurrence solves to  $T(m) \leq 2^{\left(\frac{kd}{\delta}\right)^{\mathcal{O}(1)}} \cdot n^{\mathcal{O}(1)}$  – here we use the standard argument that  $(\log n)^k \leq k^{\mathcal{O}(k)} \cdot n^{\mathcal{O}(1)}$ .

Finally, note that our first call to the recursive algorithm is  $\text{HybridClustering}(F' = \emptyset, k, k)$ . At this point, the precondition of the invariant is satisfying setting  $F_o \leftarrow F^*$ , an optimal solution satisfying  $\text{cost}_r(P, F^*) = \text{OPT}_r$ . Then, the correctness of the invariant implies that, with probability at least  $\alpha^k$ , the algorithm returns a solution  $\tilde{F}$  of size at most  $k$ , that is a  $(1 + \epsilon, 1 + \epsilon)$ -bicriteria approximation – here we use that  $\delta = \frac{\epsilon}{10k}$ , which implies that  $(1 + \delta)^k \leq (1 + \epsilon)$ .  $\blacktriangleleft$

We now conclude with the following theorem, which is restated for convenience.

**► Theorem 2.** *Let  $0 < \epsilon < 1$ . There exists a randomized algorithm that, given an instance of HYBRID  $k$ -CLUSTERING in  $\mathbb{R}^d$ , runs in time  $2^{\left(\frac{kd}{\epsilon}\right)^{\mathcal{O}(1)}} \cdot n^{\mathcal{O}(1)}$ , and returns a  $(1 + \epsilon, 1 + \epsilon)$ -approximation with probability at least a positive constant.*

**Proof.** From Lemma 14, the success probability of the algorithm is  $\alpha^k$  for some constant  $\alpha > 0$ . Thus, we need to repeat the algorithm  $\alpha^{-k}$  times to boost the probability to at least a positive constant, which gets absorbed in the  $2^{\left(\frac{kd}{\epsilon}\right)^{\mathcal{O}(1)}}$  factor.  $\blacktriangleleft$

### A Hybrid of $k$ -CENTER and $k$ -MEANS

We note that an almost identical algorithm also implies a  $(1 + \epsilon, 1 + \epsilon)$  bicriteria approximation for an analogous generalization of  $k$ -CENTER and  $k$ -MEANS. In this problem, the objective of (1) is replaced by the following:  $\text{cost}_r(C, F) := \sum_{p \in C} \text{dist}_r(p, C)^2$ . Let us refer to this problem as HYBRID  $(k, 2)$ -CLUSTERING – the “2” in the name refers to the squares of the

distance-thresholds that feature in the objective. Most of the analysis can be adapted to deal with the squares of the distances, by appropriately changing the sizes and distance-thresholds. The only significant change is that instead of Proposition 13, one needs to use an algorithm that computes an approximate 1-MEANS solution given a large enough uniform sample of the cluster – such an algorithm can also be found in [25]. Then, one obtains the following theorem.

► **Theorem 16.** *Let  $0 < \varepsilon < 1$ . There exists a randomized algorithm that, given an instance of HYBRID  $(k, 2)$ -CLUSTERING in  $\mathbb{R}^d$ , runs in time  $2^{(\frac{kd}{\varepsilon})^{\mathcal{O}(1)}} \cdot n^{\mathcal{O}(1)}$  and returns a  $(1 + \varepsilon, 1 + \varepsilon)$ -approximation with probability at least a positive constant.*

More generally, one can also define HYBRID  $(k, z)$ -CLUSTERING analogously, where the threshold-distances feature the  $z$ -th power of distances. Again, our approach easily extends to this problem, modulo a version of Proposition 13 for the vanilla  $(k, z)$ -CLUSTERING in Euclidean spaces. To the best of our knowledge, such an algorithm is not explicitly known in the literature; however, it may be possible to obtain such an algorithm using the approach of [23, 25].

### 3 Conclusion and Future Directions

In this paper, we proposed a novel clustering objective and defined a new problem, called HYBRID  $k$ -CLUSTERING, that generalizes both  $k$ -MEDIAN and  $k$ -CENTER. For  $d$ -dimensional euclidean inputs, we designed a randomized  $(1 + \varepsilon, 1 + \varepsilon)$ -bicriteria approximation scheme for HYBRID  $k$ -CLUSTERING running in time  $2^{(kd/\varepsilon)^{\mathcal{O}(1)}}$ , for any  $\varepsilon > 0$ . Further, essentially the same algorithm also generalizes for a hybrid objective of  $k$ -CENTER and  $k$ -MEANS. We remind that improving either of the two  $(1 + \varepsilon)$  factors to 1 would imply an exact FPT algorithm for  $k$ -CENTER/MEDIAN(/MEANS) in Euclidean spaces, which is unlikely to exist.

Our work opens up several interesting research directions. An immediate question is whether improving or removing the FPT dependence on the dimension  $d$  is possible, similar to the approach in [25] for  $k$ -MEDIAN/MEANS. One potential direction for achieving this could be the recent result that imports the famous Johnson-Lindenstrauss dimension reduction technique to  $k$ -clustering problems [26]. Another intriguing question is the design of coresets for HYBRID  $k$ -CLUSTERING, which could also have some implications for the previous problem via the approach of [9]. However, at a high level, designing coresets for HYBRID  $k$ -CLUSTERING appears to be challenging, since *a priori* we do not know which points belong inside the radius- $r$  balls (and thus contribute 0 to the cost), and which ones lie outside, and hence their cost needs to be approximately preserved.

Finally, considering HYBRID  $k$ -CLUSTERING with inputs from arbitrary metric spaces, a primal-dual algorithm from [7] can be adapted to obtain an  $(\alpha, \beta)$ -bicriteria approximation in polynomial time, for some constants  $\alpha$  and  $\beta$ <sup>3</sup>. Exploring the best possible constants in the bicriteria approximation would be an interesting avenue for future research.

## Abstract

We study information aggregation in networks when agents interact to learn a binary state of the world. Initially each agent privately observes an independent signal which is *correct* with probability  $\frac{1}{2} + \delta$  for some  $\delta > 0$ . At each round, a node is selected uniformly at random to update their public opinion to match the majority of their neighbours (breaking ties in favour of their initial private signal). Our main result shows that for sparse and connected binomial random graphs  $\mathcal{G}(n, p)$  the process stabilizes in a *correct* consensus in  $\mathcal{O}(n \log^2 n / \log \log n)$  steps with high probability. In fact, when  $\log n/n \ll p = o(1)$  the process terminates at time  $\hat{T} = (1 + o(1))n \log n$ , where  $\hat{T}$  is the first time when all nodes have been selected at least once. However, in dense binomial random graphs with  $p = \Omega(1)$ , there is an information cascade where the process terminates in the *incorrect* consensus with probability bounded away from zero.

## 1 Introduction

Our opinions and actions we take as individuals are often influenced by both our private knowledge of the world and the information we obtain through our interactions with others. For example, a voter deciding which candidate’s economics policies would decrease inflation, might have an initial belief based on her own past expenditure and later might be swayed by her friends’ opinions. Now more than ever, with the advent of social media and online platforms, our interactions have increased many folds and our social networks are massive. Hence, an important research question is to understand if and how the structure of the social network and the dynamics of the interactions impact the (mis)information propagated [35]. Do our social networks enable successful information aggregation and lead to social learning, or do they amplify incorrect beliefs leading to an information cascade?

There has been extensive work modeling these opinion dynamics formally to study the network effects on information aggregation; see Section 1.4. In this paper, we focus on the model of *asynchronous majority dynamics*, where agents in a network (asynchronously) update

their opinions to match the majority opinion amongst their neighbours. In particular, each agent initially has a private belief over a binary state of the world and no publicly announced opinion. At each time step, an agent is chosen uniformly at random to announce/update her opinion and she does so by simply copying the majority of the neighbours' current announced opinions, breaking ties with her initial belief. Majority dynamics is clearly a naïve learning model, as the agents do not reason about potential information redundancy due to interaction between one's neighbours. Such naïve learning (non-Bayesian) models are a more faithful abstraction of everyday interactions between agents with bounded rationality (e.g., voters and consumers), while Bayesian models are a better abstraction of rational agents or interactions about high-stakes information (e.g., traders and scientists). We consider asynchronous updates which are more suitable to capture human decision making. Moreover, asynchronous emergence of announcements also captures an initial information diffusion phase before conventional social learning starts.

In our model, there is a *correct* opinion (i.e., the true state of the world) and each agent's initial private belief is independently drawn and is biased towards being correct (with probability  $1/2 + \delta$ ). So initially, in a large network, there is enough information so that an omniscient central planner can infer the true state (with very high probability). However, agents in the network are updating their opinions based on local heuristics, so the network structure can crucially alter the final outcome of the dynamics. For example, in a complete graph, with a constant probability all the nodes converge to the wrong opinion. On the other hand, in a star graph with high probability all the nodes converge to the correct opinion. This brings us to the main question of interest:

*“What network structures enable efficient social learning, where the dynamics stabilizes with every agent in the network reaching the correct opinion?”*

Feldman et al. [20], who initiated the study of asynchronous majority dynamics, showed that when the network is sparse (has bounded degree) and expansive, a correct consensus is reached with high probability. More recently, Bahrani et al. [4] studied networks that have certain tree structures (like preferential attachment trees and balanced  $m$ -ary trees) and showed that the dynamics stabilizes in a correct majority. Both results heavily rely on these particular assumptions on the network. For example, to even establish that a *majority of the nodes* have the correct opinion *at some point* in the process, it is crucial that the network is either a bounded degree graph or is a tree. In this paper, our goal is to extend the guarantees of asynchronous majority dynamics beyond these assumptions and to develop techniques applicable to more general networks formed through random graph models.

## 1.1 The Model

Consider any undirected graph  $G = (V, E)$  on  $n = |V|$  nodes. Individuals initially have one of two private *beliefs* which we will refer to as “Correct” (or 1) and “Incorrect” (or 0). Formally, each  $v \in V(G)$  receives an independent private signal  $X(v) \in \{0, 1\}$ , and  $\Pr(X(v) = 1) = 1/2 + \delta$ , for some universal constant  $\delta \in (0, 1/2)$ . Individuals also have a publicly announced *opinion* which we will simply refer to as an announcement or opinion. We define  $C^t(v) \in \{\perp, 0, 1\}$  to be the public announcement of  $v \in V$  at time  $t$ . Initially, no announcement have been made, that is,  $C^0(v) = \perp$  for all  $v \in V$ . In each subsequent step, a single node  $v^t$  is chosen uniformly at random from  $V$ , independently from the history of the process. In particular, as in the classical coupon collector problem, some nodes will be chosen many times before others will get lucky to get chosen for the first time. In step  $t$ ,  $v^t$  updates her announcement using *majority dynamics*, while announcements of other nodes stay the same. To be specific, for any  $i \in \{\perp, 0, 1\}$  and  $v \in V$ , let  $N_i^t(v)$  denotes the number of neighbours of  $v$  that have opinion  $i$  at time  $t$ . Then,

$$C^t(v) = \begin{cases} 1 & \text{if } N_1^{t-1}(v) > N_0^{t-1}(v) \text{ and } v = v^t, \\ 0 & \text{if } N_1^{t-1}(v) < N_0^{t-1}(v) \text{ and } v = v^t, \\ X(v) & \text{if } N_1^{t-1}(v) = N_0^{t-1}(v) \text{ and } v = v^t, \\ C^{t-1}(v) & \text{if } v \neq v^t. \end{cases}$$

Finally, for any  $i \in \{\perp, 0, 1\}$ , let  $Y_i^t$  be the number of nodes that have opinion  $i$  at time  $t$ , that is,  $Y_i^t = |\{v \in V : C^t(v) = i\}|$ .

As shown in [20], it is easy to see that in any network this process stabilizes with high probability in  $\mathcal{O}(n^2)$  steps. In fact, the process stabilizes in  $\mathcal{O}(n \log n + n \cdot d(G))$  where  $d(G)$  is the diameter of the graph [4]. That is, the network reaches a state at some time  $T$  where no node will want to change its announcement and thus the process terminates. Our goal is to understand what fraction of nodes converges to the correct opinion, that is, what the value of  $Y_1^T/n$  is.

## 1.2 Our Results

The main contribution of this paper is the proof that the asynchronous majority dynamics on *binomial random graph*  $\mathcal{G}(n, p)$  converges to the correct opinion, provided that the graph is sparse (that is, the average degree  $np = o(n)$ ) and connected (that is,  $np - \log n \gg 1$ ). If  $np \gg \log n$ , then the process converges to the correct opinion as quickly as it potentially could.

► **Theorem 1.** *Let  $\delta \in (0, 1/10]$ . Let  $\omega' = \omega'(n) = o(\log n)$  be any function that tends to infinity as  $n \rightarrow \infty$ . Suppose that  $p = p(n) \ll 1$  and  $p \gg \log n/n$ , and consider the asynchronous majority dynamics on  $\mathcal{G}(n, p)$ .*

*Then, asymptotically almost surely (a.a.s.) after  $n(\log n + \omega') = (1 + o(1))n \log n$  rounds the process terminates with all nodes announcing the correct opinion. In fact, it happens exactly at time  $\hat{T}$ , where  $\hat{T}$  is the first time when all nodes are selected at least once.*

For sparser (but still connected) graphs, the process also converges to the correct opinion. In this case, we do not aim to show that it happens at time  $\hat{T}$  and we only provide an upper bound for the number of rounds. It remains an open problem to determine if the process terminates at time  $\hat{T}$  or it needs more time to converge.

► **Theorem 2.** *Let  $\delta \in (0, 1/10]$ . Let  $\omega' = \omega'(n) = o(\log n)$  be any function that tends to infinity as  $n \rightarrow \infty$ . Suppose that  $p = p(n) \leq \omega' \log n/n$  and  $p \geq (\log n + \omega')/n$ , and consider the asynchronous majority dynamics on  $\mathcal{G}(n, p)$ .*

*Then, a.a.s. after  $\mathcal{O}(n(\log n)^2/(\log \log n))$  rounds the process terminates with all nodes announcing the correct opinion.*

These results are best possible in the following sense. If  $p \leq (\log n - \omega')/n$ , then a.a.s.  $\mathcal{G}(n, p)$  is disconnected. In fact, a.a.s. there are at least  $\omega'$  isolated nodes which announce their own private beliefs. As a result, a.a.s. some nodes announce the correct opinion but some of them announce the incorrect one. Indeed, the probability that all isolated nodes converge to the same opinion is at most  $o(1) + (1/2 + \delta/2)^{\omega'} + (1/2 - \delta/2)^{\omega'} = o(1)$ . On the other hand, if  $p \in (0, 1]$  is a constant separated from zero, then with positive probability the process converges to the correct opinion and with positive probability it converges to the incorrect opinion.

► **Theorem 3.** *Let  $\delta \in (0, 1/2)$ . Let  $\omega' = \omega'(n) = o(\log n)$  be any function that tends to infinity as  $n \rightarrow \infty$ . Suppose that  $p \in (0, 1]$  is a constant, and consider the asynchronous majority dynamics on  $\mathcal{G}(n, p)$ .*

*Then, the following is true for  $i \in \{0, 1\}$ : with probability at least  $p_i$ , after  $n(\log n + \omega') = (1 + o(1))n \log n$  rounds the process terminates with all nodes announcing opinion  $i$ , where*

$$p_1 = (1/2 + \delta) \exp\left(-\log(1/p)(1/p)\right) > 0$$

$$p_0 = (1/2 - \delta) \exp\left(-\log(1/p)(1/p)\right) > 0.$$

Finally, let us mention that for some technical reason, in Theorems 1 and 2 it is assumed that  $\delta \leq 1/10$ . However, it is easy to couple the process with  $\delta \leq 1/10$  with the one with  $\delta \in (1/10, 1/2)$  to show that the result holds for any  $\delta \in (0, 1/2)$  – see Subsection 2.3 for more details.

### 1.3 Future Directions

Let us highlight a few potential directions one might want to consider.

- As already mentioned above, for very sparse graphs ( $np - \log n \rightarrow \infty$  and  $np = \mathcal{O}(\log n)$ ), it would be interesting to determine if the process terminates at time  $\hat{T}$  or it needs more time to converge to the correct opinion – see Theorem 2.
- Theorem 2 holds as long as  $pn = \log n + \omega$  for some  $\omega = \omega(n) \rightarrow \infty$  as  $n \rightarrow \infty$ . It is known that if  $pn = \log n + c$  for some constant  $c \in \mathbb{R}$ , then with probability bounded away from one and from zero the graph is disconnected. As a result, there is no hope to extend the result for this range of  $p$ . But it is plausible that a.a.s. it holds right at the time the random graph process creates a connected graph. This would be an optimal “hitting time” result.
- For disconnected graphs ( $np - \log n \rightarrow -\infty$ ), it would be interesting to investigate the process run on the giant component of  $\mathcal{G}(n, p)$ .
- For dense graphs, it is not true that a.a.s. all nodes converge to the correct opinion – see Theorem 3. Having said that, it is reasonable to expect that a.a.s. all nodes converge to the same opinion (for example, [21] show that a consensus is reached in this case in a synchronous setting). Is it true in our asynchronous setting? In any case, what is the asymptotic value of the probability that all nodes converge to the correct opinion?
- It would be interesting to investigate other random graph models that are able to generate graphs with power-law degree distributions as the Chung-Lu model [16] or the classical configuration model. More challenging, but an important and interesting, direction would be to understand the learning process on a network with a community structure such as the ABCD (Artificial Benchmark for Community Detection) model [30] which produces a random graph with community structure and power-law distribution for both degrees and community sizes. In this model, small communities might create echo chambers, environments in which participants encounter beliefs that amplify or reinforce their preexisting beliefs inside a community and insulated from rebuttal.

### 1.4 Related Work

In this section, we briefly discuss prior work on social learning mainly focusing on the setting with a binary state of the world and the agents initially have a correct opinion independently with probability  $1/2 + \delta$ . We refer to some recent surveys on social learning and opinion dynamics [37, 8, 11] for a more detailed literature review.

Majority dynamics falls under a wide class of naive or non-Bayesian models, where agents use a simple local heuristic to update their opinions, to capture simple behaviours exhibited by non-expert decision makers. Prior works have studied majority dynamics under a variety of modeling assumptions, to understand when a consensus is possible and when there is social learning – that is, the consensus (or the majority) is correct. These works study a variety of networks such as  $k$ -regular trees [28, 32, 4], bounded degree graphs [20], random regular graphs [23], “symmetric” graphs and expanders [39]. In [44], a different perspective on social learning asks when is it possible to “recover the correct opinion” at the end of the dynamics through any function (not just a consensus or majority vote). Prior work has also considered models with different notions of bias towards correct opinion, for example, each node updates to the correct opinion with some probability [3], or the initial configuration of the network has some  $n/2 + \delta$  correct opinions [45, 46].

Recently, there has been a series of work studying synchronous majority dynamics in binomial random graphs [10, 21, 15], with a focus to showing that 99% of the nodes converge to the same opinion (with high probability) for sparse random graphs, with  $p = \Omega(\log n/n^{3/5})$  being the best known lower bound for the average degree. Moreover, [47] showed that a correct consensus is reached with high probability for binomial random graphs with  $p = \Omega(\log n/n)$ . In contrast to these works, we focus on asynchronous dynamics and prove that a correct consensus is reached with high probability for  $p = \Omega(\log n/n)$  and  $p = o(1)$ . Binomial random graphs are also studied under label propagation [34] which is a special case of synchronous majority dynamics with non-binary opinion in  $[0, 1]$ .

Many of the works mentioned above focus on synchronous updates, where all agents update their opinions synchronously in each round. Majority dynamics with synchronous updates leads to a correct consensus for all networks that are sufficiently connected [39], whereas with asynchronous updates the network structure can have a huge impact on social learning. This is best illustrated by the complete graph. With asynchronous updates, once the first agent announces their opinion (which can be wrong with probability  $1/2 - \delta$ ) everyone will copy this. Hence, with a probability bounded away from zero all the nodes converge to the wrong opinion. In contrast, if all agents were to update synchronously, then the majority of the round one updates will be correct with high probability, so there will be a correct consensus in round two. Recent work [5], studies the DeGroot model with uninformed agents, to capture the different phases of information diffusion and social learning, which is a key phenomena that occurs in our asynchronous model.

Other non-Bayesian dynamics have also been extensively studied. In the Voter model, agents choose a random neighbour and copy their opinion [17, 27]. A similar dynamics called  $k$ -majority model are studied in the distributed computing literature, where agents choose  $k$ -neighbours at random and copy their majority [9, 25, 24, 18, 1]. In the DeGroot Model, an agent’s opinion lies in  $[0, 1]$  (as opposed to binary  $\{0, 1\}$ ) and agents update to the average of their neighbours [19, 26]. A key difference between these works and majority dynamics is that in these models a consensus is reached with probability 1 for any connected graphs. This is not the case in majority dynamics even with synchronous updates.

While our focus is in non-Bayesian dynamics, there has also been a long line of work studying Bayesian models, where agents update their beliefs rationally given their (local) observations exhibiting more sophisticated decision-making. Seminal works [7, 12] introduced the study of Bayesian dynamics and identified conditions that lead to information cascades. Here, the agents arrive sequentially and observe all the announcements (i.e., they form a complete graph), and many other subsequent works consider Bayesian dynamics under different assumptions and variations [43, 6, 14]. Bayesian dynamics in general social networks were first studied in [2]. There is also a long line of work studying Bayesian learning with repeated interactions [22, 42, 31, 41, 40, 38].

## 2 Preliminaries

### 2.1 Notation

Let us first precisely define the  $\mathcal{G}(n, p)$  binomial random graph.  $\mathcal{G}(n, p)$  is a distribution over the class of graphs with the set of nodes  $[n] := \{1, \dots, n\}$  in which every pair  $\{i, j\} \in \binom{[n]}{2}$  appears independently as an edge in  $G$  with probability  $p$ . Note that  $p = p(n)$  may (and usually does) tend to zero as  $n$  tends to infinity. We say that  $\mathcal{G}(n, p)$  has some property *asymptotically almost surely* or a.a.s. if the probability that  $\mathcal{G}(n, p)$  has this property tends to 1 as  $n$  goes to infinity. For more about this model see, for example, [13, 29, 33].

Given two functions  $f = f(n)$  and  $g = g(n)$ , we will write  $f(n) = \mathcal{O}(g(n))$  if there exists an absolute constant  $c \in \mathbb{R}_+$  such that  $|f(n)| \leq c|g(n)|$  for all  $n$ ,  $f(n) = \Omega(g(n))$  if  $g(n) = \mathcal{O}(f(n))$ ,  $f(n) = \Theta(g(n))$  if  $f(n) = \mathcal{O}(g(n))$  and  $f(n) = \Omega(g(n))$ , and we write  $f(n) = o(g(n))$  or  $f(n) \ll g(n)$  if  $\lim_{n \rightarrow \infty} f(n)/g(n) = 0$ . In addition, we write  $f(n) \gg g(n)$  if  $g(n) = o(f(n))$  and we write  $f(n) \sim g(n)$  if  $f(n) = (1 + o(1))g(n)$ , that is,  $\lim_{n \rightarrow \infty} f(n)/g(n) = 1$ .

### 2.2 Concentration Tools

In this section, we state a few specific instances of Chernoff's bound that we will find useful. Let  $(Z_1, \dots, Z_n)$  be a sequence of independent Bernoulli( $p$ ) random variables. For each  $j \in [n]$ , let  $X_j = \sum_{i=1}^j Z_i$ . In particular,  $X_n \in \text{Bin}(n, p)$  is a random variable distributed according to a Binomial distribution with parameters  $n$  and  $p$ . Then, a consequence of *Chernoff's bound* (see e.g. [29, Theorem 2.1]) is that for any  $t \geq 0$  we have

$$\mathbb{P}(X_n - \mathbb{E}[X_n] \geq t) \leq \exp\left(-\frac{t^2}{2(\mathbb{E}[X_n] + t/3)}\right) \quad (1)$$

$$\mathbb{P}(\mathbb{E}[X_n] - X_n \geq t) \leq \exp\left(-\frac{t^2}{2\mathbb{E}[X_n]}\right). \quad (2)$$

Moreover, let us mention that the above bounds hold in a more general setting as well, that is, for any sequence  $(Z_j)_{1 \leq j \leq n}$  of independent random variables such that for every  $j \in [n]$  we have  $Z_j \in \text{Bernoulli}(p_j)$  with (possibly) different  $p_j$ -s (again, see e.g. [29] for more details).

Finally, we note that  $X_n - \mathbb{E}[X_n]$  in (1) can be replaced with  $\max_{1 \leq j \leq n} (X_j - \mathbb{E}[X_j])$  and  $\mathbb{E}[X_n] - X_n$  in (2) can be replaced with  $\max_{1 \leq j \leq n} (\mathbb{E}[X_j] - X_j)$ . That is, we have

$$\mathbb{P}\left(\max_{1 \leq j \leq n} (X_j - \mathbb{E}[X_j]) \geq t\right) \leq \exp\left(-\frac{t^2}{2(\mathbb{E}[X_n] + t/3)}\right) \quad (3)$$

$$\mathbb{P}\left(\max_{1 \leq j \leq n} (\mathbb{E}[X_j] - X_j) \geq t\right) \leq \exp\left(-\frac{t^2}{2\mathbb{E}[X_n]}\right). \quad (4)$$

This is a consequence of a standard martingale bound (see e.g. [36] for more details).

### 2.3 Coupling

Suppose that at some point of the process, the public announcement is captured by  $C^t(v)$ ,  $v \in V$ . Let  $\hat{C}^t(v)$  be any sequence of opinions such that the following properties hold: (a) if  $\hat{C}^t(v) = 1$ , then  $C^t(v) = 1$ , (b) if  $\hat{C}^t(v) = 0$ , then  $C^t(v) \in \{0, 1, \perp\}$ , (c) if  $\hat{C}^t(v) = \perp$ , then  $C^t(v) = \perp$ . In other words, we get the auxiliary sequence  $\hat{C}^t(v)$  by modifying some of the opinions 1 and  $\perp$  in  $C^t(v)$  to 0. Hence, the process starting from  $C^t(v)$  can be coupled with the auxiliary process starting from  $\hat{C}^t(v)$  such that all the properties (a)–(c) are satisfied in

every step of the process. In particular, if the auxiliary process converges to all nodes having opinion 1, then so does the original process. This easy observation will turn out to be useful in analyzing the process.

Similarly, suppose private beliefs in the auxiliary process are dominated by private beliefs in the original process: for any  $v \in V$ ,  $\hat{X}(v) \leq X(v)$ . If the two processes are coupled, then properties (a)–(c) hold again. As before, if the auxiliary process converges to all nodes having opinion 1, then so does the original process. In particular, as mentioned above, the assumption that  $\delta \in (0, 1/10]$  in Theorems 1 and 2 can be relaxed to  $\delta \in (0, 1/2)$ .

### 3 Sparse Random Graphs

In this section, we consider sparse random graphs, that is, we will assume that  $p = o(1)$ . Let  $\omega = \omega(n)$  be a function that tends to infinity as  $n \rightarrow \infty$ , arbitrarily slowly. In particular, each time we refer to  $\omega$ , we will assume that  $\omega \ll pn$  and  $\omega \ll (1/p)^{1/2}$  so that  $1/p \gg 1/(p\omega) \gg 1/(p\omega^2) \gg 1$ .

We will consider a few phases. During the first phase (Subsection 3.1), most of the nodes that are chosen have not yet announced their opinions ( $C^{t-1}(v^t) = \perp$ ) and none of their neighbours have announced ( $N_1^{t-1}(v^t) = N_0^{t-1}(v^t) = 0$ ). Hence, the announcement of  $v^t$  will typically coincide with its private belief. Moreover, most of the nodes selected will not be chosen again during this phase. During the second phase (Subsection 3.2), it is still the case that most selected nodes are selected for the first time but this time they might have neighbours that announced their opinions. As a result, the argument is more involved but the conclusion is that at the end of the second phase more nodes have correct opinion than not.

The analysis of the first two phases can be applied for all sparse graphs, even below the threshold for connectivity. The analysis of the final steps of the process is slightly more involved. We first present an easy argument for not very sparse graphs (Subsection 3.3), that is, when the asymptotic expected degree satisfies  $pn \gg \log n$ . Very sparse graphs for which  $pn = \Theta(\log n)$  (but, of course, above the connectivity threshold) are considered in Subsection 3.4.

#### Overview

A key phenomena in asynchronous dynamics is that the process involves both information diffusion and conventional social learning. Intuitively, the process initially produces some independent beliefs/opinions pop up sporadically throughout the network. These opinions then diffuses in the network during the process as more nodes are selected to announce/update their opinion by learning from their neighbours. With this in mind, our analysis considers multiple phases of the process. We provide a brief description of the different phases below.

- **Phase 1.** In the first few time steps, most nodes that are selected to announce have not been selected earlier and, more importantly, do not have neighbours who have been selected before. So almost all of the opinions in the network at the end of phase one are just the independent private beliefs of the selected nodes. Since the private signals are biased towards being correct, a strict majority of the opinions are correct at the end of the first phase. In particular, we show that at time  $T_1 = \delta/2p$ , the number of nodes with opinion 1 is at least  $(1/2 + 3\delta/5)T_1$  and opinion 0 is represented at most  $(1/2 - 3\delta/5)T_1$  times. Moreover,  $T_1(1 - o(1))$  nodes have made some announcement in this phase, that is, very few nodes were selected more than once.

- **Phase 2.** In the second phase, again most nodes that are selected to announce have not been selected earlier. In particular, we show that at any time  $t$  during the second phase (i.e., after time  $T_1$  but before time  $T_2 = n/\omega$ ), the number of nodes that were selected twice before time  $t$  is  $o(t)$ . Moreover, since a *super majority* of the opinions at the end of the previous phase were correct, we prove that nodes that are selected to announce for the first time are more likely to learn the correct opinion even if we pretend that the few nodes that are selected *again* were to change their opinion to 0.
- **Phase 3 (a).** For not very sparse graphs, we are able to show all nodes which were not selected in the first two phases have more neighbours with opinion 1 than not. Again, very few nodes who were selected before are selected again before time  $T_3 = n/\sqrt{\omega}$ , so even if all of them announce 0 all nodes who make their first announcement between time  $T_2$  and time  $T_3$  announce the correct opinion. Finally, even if all the nodes that were selected before time  $T_2$  are to have opinion 0 and all nodes that were selected for the first time between time  $T_2$  and time  $T_3$  have opinion 1, we show that a.a.s. all announcements after time  $T_3$  are always correct.
- **Phase 3 (b).** For very sparse graphs, the proof of the last phase is more involved as there might be nodes whose degree is too small to guarantee that a majority of their neighbours have opinion 1, even though there is a super majority of opinion 1 in the network. However, we may bound the number of nodes with small degrees and show that no large degree node has more than one small degree neighbour. With this in hand, we show that after every batch of  $O(n \log n)$  many time steps the number of large degree nodes with opinion 0 shrinks by at least  $(\log \log n)^{1/4}$  factor. Hence, after  $o(\log n)$  many such batches all large nodes have opinion 1. Finally, we show that no two small degree nodes are adjacent to each other, and hence all the small degree nodes will also switch to opinion 1 by copying the opinions of their large degree neighbours.

We highlight a few simple techniques that help us in the analysis. Firstly, separating the randomness of the graph, the node selection process and the opinion formation. For example, we wait to reveal the edges adjacent to a node only when she is selected to announce for the first time. Second, considering an auxiliary dynamics that is coupled with the actual dynamics in order to ignore problematic but rare events such as the repeated nodes in the first two phases. Finally, finding independent sequences of random variables that stochastically dominate the opinion dynamics sequence in order to compute probability bounds more easily.

### 3.1 Phase 1: $T_1 = \delta/(2p)$

In the analysis of the process, it will be convenient to ignore opinions of a small fraction of nodes, and consider the following *auxiliary dynamics*. We will use  $D^t(v) \in \{\perp, ?, 0, 1\}$  to denote the *auxiliary announcement* of  $v \in V$  at time  $t$ . For any  $i \in \{\perp, ?, 0, 1\}$ , let  $Z_i^t$  be the number of nodes that have auxiliary opinion  $i$  at time  $t$ , that is,  $Z_i^t = |\{v \in V : D^t(v) = i\}|$ . We will explain how the values of  $D^t(v)$  are determined soon but the auxiliary dynamics will be coupled with the original one and, in particular, we will make sure that the following property holds.

► **Property 4.** *If  $D^t(v) = i$  for some  $i \in \{\perp, 0, 1\}$  and time  $t$ , then  $C^t(v) = D^t(v)$ . On the other hand, if  $D^t(v) = ?$ , then  $C^t(v) \in \{0, 1\}$ . As a result, for  $i \in \{0, 1\}$  and any time  $t$  during the first phase, we have*

$$Z_i^t \leq Y_i^t \leq Z_i^t + Z_?^t. \quad (5)$$

The first phase takes  $T_1 = \delta/(2p) = \Theta(1/p) \gg \omega^2 \gg 1$  rounds. In order to keep the analysis easy, we postpone exposing edges of  $\mathcal{G}(n, p)$  for as long as possible, and keep the following useful property.

► **Property 5.** *At any time  $t$ , only edges of  $\mathcal{G}(n, p)$  with both endpoints in the set  $\{v : D^t(v) \neq \perp\}$  are exposed.*

The auxiliary dynamics, coupled with the original one, that we aim to understand is defined as follows. Consider a node  $v^t$  chosen at time  $t$ . For all other nodes  $v \neq v^t$  we have  $D^t(v) = D^{t-1}(v)$ . For  $v^t$  we have,

$$D^t(v^t) = \begin{cases} ? & \text{if } D^{t-1}(v^t) \neq \perp, \\ ? & \text{if } \exists \text{ node } v \text{ such that } v \in N(v^t) \text{ and } D^{t-1}(v) \neq \perp, \\ X(v^t) & \text{otherwise.} \end{cases}$$

That is, if  $v^t$  had announced her opinion at least once before time  $t$  ( $D^{t-1}(v^t), C^{t-1}(v^t) \neq \perp$ ), then we fix  $D^t(v^t) = ?$ . On the other hand, if  $v^t$  has not announced her opinion yet (that is,  $D^{t-1}(v^t) = C^{t-1}(v^t) = \perp$ ), then we expose edges of  $\mathcal{G}(n, p)$  between  $v^t$  and the set  $\{v : D^{t-1}(v) \neq \perp\}$ . If no edge between  $v^t$  and the set  $\{v : D^{t-1}(v) \neq \perp\}$  is present, then no neighbour of  $v^t$  has an announced opinion and so  $D^t(v^t) = C^t(v^t) = X(v^t)$  is fixed to the private belief of  $v^t$ . Otherwise (that is, at least one edge is present), then we simply fix  $D^t(v^t) = ?$ . Let us note that, an alternative approach would be to investigate the value of  $C^t(v^t)$  and then fix  $D^t(v^t) = C^t(v^t)$ . However, we expect at most  $pt \leq pT_1 = \delta/2$  edges between  $v^t$  and  $\{v : D^{t-1}(v) \neq \perp\}$ , and so there will not be many nodes  $v^t$  of this type. As a result, we may simply ignore the announcements of such nodes, thus simplifying our analysis.

Moreover, a useful implication of this approach is that in order to estimate the values of  $Z_{\perp}^t$  and  $Z_{?}^t$  in this process, we do not need to uncover nodes' private beliefs ( $X(v)$ 's). Hence, we may postpone exposing private beliefs of nodes with  $D^t(v) \notin \{\perp, ?\}$  to the very end of this phase, and only then expose this information to determine how many nodes satisfy  $D^{T_1}(v) = 1$  and how many of them satisfy  $D^{T_1}(v) = 0$ . Finally, it is easy to see that Property 4 is satisfied at time  $T_1$  and Property 5 is satisfied in any point of the process.

Here is the main result of this subsection.

► **Proposition 6.** *Suppose that  $p = p(n) \ll 1$  and  $p \gg 1/n$ . Set  $T_1 = \delta/(2p)$ . Let  $\omega = \omega(n) \ll \min\{pn, (1/p)^{1/2}\}$  be any function that tends to infinity as  $n \rightarrow \infty$ . Then, a.a.s. the following holds:*

$$Z_{?}^{T_1} \leq \frac{\delta T_1}{4} (1 + \mathcal{O}(1/\omega)) \quad (6)$$

$$Z_{\perp}^{T_1} \geq (1/2 + 3\delta/5) T_1 \quad (7)$$

$$Z_{?}^{T_1} + Z_{\perp}^{T_1} + Z_0^{T_1} = T_1 (1 - \mathcal{O}(1/\omega)). \quad (8)$$

As a result, by Property 4,

$$Y_1^{T_1} \geq (1/2 + 3\delta/5) T_1$$

$$Y_0^{T_1} \leq (1/2 - 3\delta/5) T_1$$

$$Y_1^{T_1} + Y_0^{T_1} = T_1 (1 - \mathcal{O}(1/\omega)).$$

**Proof.** Let us start with investigating  $Z_{?}^{T_1}$ . Recall that in our auxiliary dynamics, there are two ways node  $v^t$  could change its state to  $D^t(v^t) = ?$  at time  $t$ . Let  $I_t$  be the indicator random variable that this happens because  $D^{t-1}(v^t) \neq \perp$ , and let  $I = \sum_{t=1}^{T_1} I_t$ . Similarly, let  $J_t$  be the indicator random variable that  $D^{t-1}(v^t) = \perp$  but there is an edge between  $v^t$  and the set  $\{v : D^{t-1}(v) \neq \perp\}$ . Let  $J = \sum_{t=1}^{T_1} J_t$ .

## 5:10 Asynchronous Majority Dynamics on Binomial Random Graphs

Note that, at most  $t - 1$  distinct nodes have made an announcement before round  $t$ . In particular, at most one node can change its state from  $D^{t-1}(v) = \perp$  to  $D^t(v) \neq \perp$ , deterministically, at any round  $t$  of the process. So, the number of nodes with  $D^{t-1}(v) \neq \perp$  is  $n - Z_{\perp}^{t-1} \leq t - 1$ . We get that

$$\Pr(I_t = 1) = \frac{n - Z_{\perp}^{t-1}}{n} \leq \frac{t-1}{n},$$

and so  $I$  can be stochastically upper bound by  $\hat{I} = \sum_{t=1}^{T_1} \hat{I}_t$  where  $(\hat{I}_t)_{1 \leq t \leq T_1}$  are independent variables and for every  $t \in [T_1]$  we have  $\hat{I}_t \in \text{Bernoulli}((t-1)/n)$ . Note that, since  $pn \gg \omega$ ,

$$\mathbb{E}[\hat{I}] = \sum_{t=1}^{T_1} \frac{t-1}{n} = \frac{(T_1-1)T_1}{2n} \sim \frac{\delta T_1}{4pn} \ll \frac{T_1}{\omega}. \quad (9)$$

It follows from Chernoff's bound (Eq. (1)) (and the comment right after it) applied with  $t = T_1/\omega = \Theta(1/(p\omega)) \gg \omega \gg 1$  that

$$\Pr(\hat{I} \geq \mathbb{E}[\hat{I}] + t) \leq \exp\left(-\frac{t^2}{(2/3 + o(1))t}\right) = \exp(-\Theta(t)) = o(1).$$

So a.a.s.  $I \leq \hat{I} = \mathcal{O}(T_1/\omega)$ . Similarly, since  $pt \leq pT_1 = \delta/2 < 1/4$ ,

$$\Pr(J_t = 1) = \frac{Z_{\perp}^{t-1}}{n} \left(1 - (1-p)^{n-Z_{\perp}^{t-1}}\right) \leq 1 - (1-p)^t = 1 - \left(1 - pt + p^2 \binom{t}{2} - \dots\right) \leq pt.$$

As before, we stochastically upper bound  $J$  by  $\hat{J} = \sum_{t=1}^{T_1} \hat{J}_t$ , where  $\hat{J}_t \in \text{Bernoulli}(pt)$ . We get that

$$\mathbb{E}[\hat{J}] = \sum_{t=1}^{T_1} pt = \frac{p(T_1+1)T_1}{2} = \frac{pT_1^2}{2} (1 + \mathcal{O}(1/T_1)) = \frac{\delta T_1}{4} (1 + \mathcal{O}(1/\omega)),$$

and Chernoff's bound (Eq. (1)) (applied with  $t = \mathbb{E}[\hat{J}]/\omega$ ) implies that

$$\Pr(\hat{J} \geq \mathbb{E}[\hat{J}] + t) \leq \exp\left(-\frac{\mathbb{E}[\hat{J}]}{(2 + o(1))\omega^2}\right) = \exp(-\Theta(T_1/\omega^2)) = \exp(-\Theta(1/(p\omega^2))) = o(1).$$

Hence, a.a.s.  $J \leq \hat{J} \leq \frac{\delta T_1}{4} (1 + \mathcal{O}(1/\omega))$  and so a.a.s.  $Z_7^{T_1} \leq I + J \leq \frac{\delta T_1}{4} (1 + \mathcal{O}(1/\omega))$ . This proves (6).

It remains to investigate  $Z_0^{T_1}$  and  $Z_1^{T_1}$ . Let us summarize the situation at time  $T_1$ . The number of rounds when nodes were not chosen for the first time is at most  $I = \mathcal{O}(T_1/\omega)$  a.a.s. Hence, a.a.s. the number of nodes that were chosen at least once is equal to  $T_1 - \mathcal{O}(T_1/\omega)$ . This proves (8). Moreover, it implies that a.a.s. the number of nodes with  $D^{T_1}(v) \notin \{\perp, ?\}$  is equal to

$$Z_1^{T_1} + Z_0^{T_1} = T_1 - \mathcal{O}(T_1/\omega) - Z_7^{T_1} \geq (1 - \delta/4)T_1 (1 + \mathcal{O}(1/\omega)).$$

More importantly, as mentioned above, in the analysis so far we did not use their opinions which are consistent with their private beliefs. We conveniently deferred this information up to now. After exposing this information, we get that  $Z_1^{T_1}$  is stochastically lower bounded by the random variable  $\hat{Z}_1 \in \text{Bin}((1 - \delta/4)T_1 - cT_1/\omega, 1/2 + \delta)$ , where  $c > 0$  is a large enough constant. After applying Chernoff's bound (Eq. (2)) (with  $t = T_1/\omega$ ) we get that

$$\begin{aligned} Z_1^{T_1} \geq \hat{Z}_1 &= (1/2 + \delta)(1 - \delta/4)T_1(1 + \mathcal{O}(1/\omega)) \\ &\geq (1/2 + \delta - \delta/4)T_1(1 + \mathcal{O}(1/\omega)) \\ &\geq (1/2 + 3\delta/5)T_1 \end{aligned}$$

with probability at least

$$1 - \exp(-\Theta(T_1/\omega^2)) = 1 - \exp(-\Theta(1/(p\omega^2))) = 1 - o(1).$$

This proves (7).

The conclusion for  $Y_1^{T_1}$  follows immediately from Property 4, and the bound for  $Y_0^{T_1}$  is a trivial implication of the fact that  $Y_1^{T_1} + Y_0^{T_1} \leq T_1$ . The proof of the proposition is finished.  $\blacktriangleleft$

### 3.2 Phase 2: $T_2 = T_2(n)$ such that $\omega/p \leq T_2 \leq n/\omega$

By Proposition 6, since we aim for a statement that holds a.a.s., we may assume that at the beginning of Phase 2,

$$\begin{aligned} Y_1^{T_1} &\geq (1/2 + 3\delta/5) T_1 \\ Y_0^{T_1} &\leq (1/2 - 3\delta/5) T_1 \\ Y_1^{T_1} + Y_0^{T_1} &= T_1 (1 + \mathcal{O}(1/\omega)). \end{aligned}$$

As in the previous phase, it will be convenient to ignore opinions of some problematic nodes and assign auxiliary announcements  $D^t(v) = ?$  to such nodes. We will continue using  $Z_i^t$  to denote the number of nodes that have auxiliary opinion  $i$  at time  $t$ . We fix  $D^{T_1}(v) = C^{T_1}(v)$  for all  $v$  so, initially, auxiliary announcements coincide with the truth announcements. However, this time we assign  $D^t(v^t) = ?$  only if  $D^{t-1}(v^t) \neq \perp$  (that is, the node chosen at time  $t$  has made an announcement in the past); otherwise, the auxiliary announcement  $D^t(v^t)$  is determined immediately pretending that all neighbours  $v$  of  $v^t$  with  $D^{t-1}(v) = ?$  announced 0. More formally, for each node  $v$  and  $i \in \{0, 1, \perp, ?\}$  let  $\hat{N}_i^t(v)$  denote the number of neighbours  $v'$  of  $v$  with auxiliary opinion  $D^t(v') = i$  at time  $t$ . Then we have,

$$D^t(v^t) = \begin{cases} ? & \text{if } D^{t-1}(v^t) \neq \perp, \\ 1 & \text{if } \hat{N}_1^{t-1}(v^t) > \hat{N}_0^{t-1}(v^t) + \hat{N}_?^{t-1}(v^t), \\ 0 & \text{if } \hat{N}_1^{t-1}(v^t) < \hat{N}_0^{t-1}(v^t) + \hat{N}_?^{t-1}(v^t), \\ X(v^t) & \text{if } \hat{N}_1^{t-1}(v^t) = \hat{N}_0^{t-1}(v^t) + \hat{N}_?^{t-1}(v^t). \end{cases}$$

As a consequence,  $D^t(v)$  and  $C^t(v)$  are coupled so that the following property is satisfied.

► **Property 7.** *If  $D^t(v) = i$  for some  $i \in \{\perp, 1\}$  and time  $t$ , then  $C^t(v) = D^t(v)$ . On the other hand, if  $D^t(v) = i$  for some  $i \in \{0, ?\}$ , then  $C^t(v) \in \{0, 1\}$ . As a result, for any time  $t$  during the second phase, we have  $Y_1^t \geq Z_1^t$ .*

As before, it is easy to see that Property 5 is also satisfied during this phase. Here is the main result of this subsection.

► **Proposition 8.** *Suppose that  $p = p(n) \ll 1$  and  $p \gg 1/n$ . Let  $\omega = \omega(n) \ll \min\{pn, (1/p)^{1/2}\}$  be any function that tends to infinity as  $n \rightarrow \infty$ . Set  $T_2 = T_2(n)$  such that  $\omega/p \leq T_2 \leq n/\omega$ . Then, a.a.s. the following holds:*

$$\begin{aligned} Z_?^{T_2} &= \mathcal{O}(T_2/\omega) \\ Z_1^{T_2} &\geq (1/2 + \delta/2) T_2 \\ Z_?^{T_2} + Z_1^{T_2} + Z_0^{T_2} &= T_2 (1 - \mathcal{O}(1/\omega)). \end{aligned}$$

## 5:12 Asynchronous Majority Dynamics on Binomial Random Graphs

As a result, by Property 7,

$$\begin{aligned} Y_1^{T_2} &\geq (1/2 + \delta/2) T_2 \\ Y_0^{T_2} &\leq (1/2 - \delta/2) T_2 \\ Y_1^{T_2} + Y_0^{T_2} &= T_2 (1 - \mathcal{O}(1/\omega)). \end{aligned}$$

Before we move to the proof of this proposition, let us make some simple but useful observations. First, note that only a negligible fraction of the nodes have opinion that we do not control. The proof is deferred to the full version.

► **Lemma 9.** *Suppose that  $p = p(n) \ll 1$  and  $p \gg 1/n$ . Let  $\omega = \omega(n) \ll \min\{pn, (1/p)^{1/2}\}$  be any function that tends to infinity as  $n \rightarrow \infty$ . Set  $T_2 = T_2(n)$  such that  $\omega/p \leq T_2 \leq n/\omega$ . Then, a.a.s., for any  $t$  such that  $T_1 \leq t \leq T_2$ ,  $Z_1^t \leq 2t/\omega$ .*

Let us fix  $k \in \mathbb{N}$  and consider random variable  $X_k \in \text{Bin}(k, 1/2 + \delta/2)$ . We will need to understand the following sequence of constants (the connection to our problem will become clear soon):

$$q_k := \mathbb{P}(X_k > k/2) + \mathbb{P}(X_k = k/2) \cdot (1/2 + \delta). \quad (10)$$

Clearly,  $q_0 = 1/2 + \delta$  and  $q_1 = 1/2 + \delta/2$ . For any other value of  $k \geq 2$ ,  $q_k \geq 1/2 + 51\delta/100$  as we show in the next technical lemma. The proof can be found in the full version.

► **Lemma 10.** *Fix  $k \in \mathbb{N}$  such that  $k \geq 2$ , and  $\delta \in (0, 1/10]$ . Then,*

$$q_k \geq \frac{1}{2} + \frac{51}{100}\delta.$$

Now, we are ready to go back to analyzing the behaviour of the process during the second phase.

**Proof of Proposition 8.** Our goal is to show that a.a.s. the following inequalities hold for any  $t$  such that  $T_1 \leq t \leq T_2$ :

$$\frac{Z_1^t}{Z_0^t + Z_1^t} \geq \frac{1/2 + \delta/2}{1/2 - \delta/2} \quad (11)$$

$$Z_1^t \leq 2t/\omega. \quad (12)$$

Formally, we define the stopping time  $S$  to be the minimum value of  $t \geq T_1$  such that either (11) fails, (12) fails or  $t = T_2$ . (A stopping time is any random variable  $S$  with values in  $\{T_1, T_1 + 1, \dots, T_2\}$  such that, for any time  $\hat{t}$ , it is determined whether  $S = \hat{t}$  from knowledge of the process up to and including time  $\hat{t}$ .)

Property (12) is trivially satisfied at the beginning of the second phase as  $Z_1^{T_1} = 0$ . By Proposition 6, since we aim for a statement that holds a.a.s., we may assume that (11) is satisfied at the beginning of the second phase. In fact,

$$\frac{Z_1^{T_1}}{Z_0^{T_1} + Z_1^{T_1}} = \frac{Y_1^{T_1}}{Y_0^{T_1} + 0} \geq \frac{1/2 + 101\delta/200}{1/2 - 101\delta/200} \geq \frac{1/2 + \delta/2}{1/2 - \delta/2}.$$

It will be convenient to define  $Z^t = Z_1^t + Z_0^t + Z_2^t$ ; that is,  $Z^t$  is the number of nodes that announced their opinions by time  $t$ . If (12) is satisfied, then only a negligible fraction of nodes were selected more than once and we get that  $Z^t = t(1 - \mathcal{O}(1/\omega)) \sim t$ .

Let us first show that if (11) and (12) are satisfied at time  $t$  and the node selected at time  $t + 1$  was not selected before (that is,  $D^t(v^{t+1}) = C^t(v^{t+1}) = \perp$ ), then the probability that  $v^{t+1}$  announces an auxiliary opinion 1 is at least  $1/2 + 101/200\delta$ .

We first expose edges from  $v^{t+1}$  to the set  $\{v : D^t(v) \neq \perp\}$  (see Property 5) and let us define  $p_k$  to be the probability that  $v^{t+1}$  has precisely  $k$  neighbours in that set. In particular, we have

$$\begin{aligned} p_1 &= Z^t p(1-p)^{Z^t-1} = \lambda(1-p)^{\lambda/p-1} \\ &\leq \lambda e^{-\lambda}/(1-p) \\ &\leq 1/e + o(1) < 1/2, \end{aligned} \tag{13}$$

where  $\lambda = pZ^t = pt(1 - \mathcal{O}(1/\omega))$  and the second inequality follows because  $xe^{-x} \leq e^{-1}$  and  $p = o(1)$ .

Now, condition on  $v^t$  having exactly  $k$  neighbours that already announced their opinion. Note that we did not expose the neighbours yet (only the number of them) so neighbours form a random set of cardinality  $k$  from the set  $\{v : D^{t-1}(v) \neq \perp\}$ . Let  $r_k$  to be the probability that  $v^t$  announces auxiliary opinion 1 in this conditional probability space. It happens if more than  $k/2$  neighbours of  $v^t$  have  $D^{t-1}(v) = 1$ . Moreover, if exactly  $k/2$  neighbours have this property, then  $v^t$  announces opinion 1 with probability  $1/2 + \delta$ , which is the probability that its private belief is 1. Since (11) holds,  $r_k$  can be lower bounded by  $q_k$  which we defined in (10). It follows that the probability that  $v^t$  announces 1 is asymptotic to

$$\begin{aligned} \sum_{k \geq 0} r_k \cdot p_k &\geq \sum_{k \geq 0} q_k \cdot p_k = q_1 p_1 + \sum_{k \geq 0, k \neq 1} q_k \cdot p_k \\ &\geq \left(\frac{1}{2} + \frac{\delta}{2}\right) p_1 + \left(\frac{1}{2} + \frac{51}{100}\delta\right) (1 - p_1) \\ &= \left(\frac{1}{2} + \frac{51}{100}\delta\right) - p_1 \left(\frac{1}{100}\delta\right) \\ &\geq \frac{1}{2} + \frac{101}{200}\delta, \end{aligned} \tag{14}$$

where the second inequality follows from Lemma 10 and the last one from (13).

Let  $s$  be the number of rounds  $t$  in the second phase in which  $v^t$  was not selected before, i.e.,  $D^{t-1}(v^t) = \perp$ , and let  $t_1, t_2, \dots, t_s$  denote such round. Clearly,  $s \leq T_2 - T_1 = T_2(1 - \mathcal{O}(1/\omega))$  but, in fact, a.a.s. we have  $s = T_2(1 - \mathcal{O}(1/\omega))$  by Lemma 9. For  $i \in [s]$ , let  $L_i$  be the indicator random variable for the event that  $v^{t_i}$  announced an auxiliary opinion 1, that is,  $L_i = Z_1^{t_i} - Z_1^{t_i-1}$ . If both (11) and (12) hold at time  $t_i - 1$ , then  $\mathbb{P}(L_i = 1) \geq 1/2 + 101\delta/200$  but, of course, we cannot condition on these two properties to hold. Instead, we will use a small trick and consider an auxiliary sequence of random variables after the stopping time  $S$  when one of the properties fails.

Fix  $\hat{p} = 1/2 + 101\delta/200$  and let  $M_1, \dots, M_s$  be a sequence of independent Bernoulli variables with parameter  $\hat{p}$ . For each  $i \in [s]$ , we define  $L'_i = L_i$  if both (11) and (12) hold at times  $t < t_i$  and otherwise  $L'_i = M_i$ . That is, the process “stops” at our stopping time  $S$  which, in our context, means that it simply follows part of the sequence  $(M_i)_{i=1}^s$  (namely,  $(M_i)_{i=S+1}^s$ ) from that point on, ignoring the behaviour of the original process. Thus, defining  $L'_{\leq j} = \sum_{i=1}^j L'_i$  and  $M_{\leq j} = \sum_{i=1}^j M_i$ , (14) implies that one can couple  $L'_{\leq j}$  and  $M_{\leq j}$  such that  $L'_{\leq j} \geq M_{\leq j}$  for all  $j \in [s]$ .

Note that  $\mathbb{E}[M_{\leq j}] = \hat{p}j = (1/2 + 101\delta/200)j$  for any  $j \in [s]$ . It follows from Chernoff’s bound (4),

$$\begin{aligned}
 & \mathbb{P}\left(\exists_{1 \leq j \leq s} \mathbb{E}[M_{\leq j}] - M_{\leq j} \geq \frac{\delta}{400}(T_1 + j)\right) \\
 & \leq \sum_{a \geq 1} \mathbb{P}\left(\max_{(2^{a-1}-1)T_1 < j \leq (2^a-1)T_1} (\mathbb{E}[M_{\leq j}] - M_{\leq j}) \geq 2^{a-1} \frac{\delta}{400} T_1\right) \\
 & \leq \sum_{a \geq 1} \exp(-\Theta(2^a T_1)) = \exp(-\Theta(T_1)) = o(1),
 \end{aligned}$$

since  $T_1 = \Theta(1/p) \rightarrow \infty$ . In other words, a.a.s. for any  $j \in [s]$ ,

$$L'_{\leq j} \geq M_{\leq j} \geq \left(\frac{1}{2} + \frac{101}{200}\delta\right)j - \frac{\delta}{400}(T_1 + j).$$

Since  $L_{\leq j} = L'_{\leq j}$  for any  $j \in [s]$  such that  $t_j < S$ , and  $Z_1^t$  can decrease by at most one in a single round, a.a.s.

$$\begin{aligned}
 Z_1^S & \geq Z_1^{S-1} - 1 \\
 & \geq Z_1^{T_1} + L_{\leq S-T_1-\mathcal{O}(S/\omega)} - \mathcal{O}(S/\omega) \\
 & \geq \left(\frac{1}{2} + \frac{101}{200}\delta\right)T_1 + \left(\frac{1}{2} + \frac{101}{200}\delta\right)(S - T_1 - \mathcal{O}(S/\omega)) - \frac{\delta}{400}(S - \mathcal{O}(S/\omega)) - \mathcal{O}(S/\omega) \\
 & \geq \left(\frac{1}{2} + \frac{201}{400}\delta\right)S - \mathcal{O}(S/\omega) \\
 & \geq \left(\frac{1}{2} + \frac{\delta}{2}\right)S,
 \end{aligned}$$

implying that (11) holds at time  $S$ . Indeed, there were  $Z_1^{T_1}$  nodes with auxiliary opinion 1 at the beginning of the second phase. By Lemma 9,  $S - T_1 - \mathcal{O}(S/\omega)$  nodes were selected for the first time before the stopping time and  $L_{\leq S-T_1-\mathcal{O}(S/\omega)}$  of them announced 1 at that time. Finally, at most  $\mathcal{O}(S/\omega)$  nodes that already announced their opinion were selected again. It implies that a.a.s. the process does not “stop” because of (11) failing. By Lemma 9, a.a.s. it also does not stop because of (12). Hence, a.a.s.  $S = T_2$  and the proof of the proposition is finished.  $\blacktriangleleft$

### 3.3 Not Very Sparse Random Graphs

In this subsection, we provide a relatively easy argument that works for random graphs with  $pn \gg \log n$ . In particular, we show that a.a.s. after round  $T_2$  but before round  $T_3 = n/\sqrt{\omega}$  all nodes that are selected for the first time announce 1. Moreover, after round  $T_3$  every node selected announces 1 a.a.s.

**Proof of Theorem 1.** Let  $\omega = \omega(n) \ll \min\{(pn/\log n)^{1/2}, pn, (1/p)^{1/2}\}$  be any function that tends to infinity as  $n \rightarrow \infty$ . In particular,  $pn \geq \omega^2 \log n$ . Fix  $T_2 = T_2(n) = n/\omega$ . It follows from Proposition 8 that a.a.s. at the end of the second phase, there are  $Y_1^{T_2} \geq (1/2 + \delta/2)T_2$  nodes that announced opinion 1, and so  $Y_0^{T_2} \leq (1/2 - \delta/2)T_2$  nodes announced opinion 0; moreover,  $Y_1^{T_2} + Y_0^{T_2} = T_2(1 + \mathcal{O}(1/\omega))$ .

Let  $V_i = \{v : C^t(v) = i\}$  be the set of nodes with opinion  $i \in \{0, 1\}$  at time  $T_2$ . Note that, by Property 5, we may assume that only edges within  $V_0 \cup V_1$  are exposed at that stage of the process. We will first show that a.a.s. all nodes  $v \notin V_0 \cup V_1$  have substantially more neighbours in  $V_1$  than in  $V_0$ . Indeed, this is a simple consequence of the Chernoff bounds (1) and (2): for any  $v \notin V_0 \cup V_1$ :

$$\begin{aligned}
& \mathbb{P}\left(|N(v) \cap V_1| \leq |N(v) \cap V_0| + \delta T_2 p / 2\right) \\
& \leq \Pr\left(|N(v) \cap V_1| \leq (1/2 - \delta/4)T_2 p + \delta T_2 p / 2 \text{ or } |N(v) \cap V_0| \geq (1/2 - \delta/4)T_2 p\right) \\
& \leq \mathbb{P}\left(|N(v) \cap V_1| \leq (1/2 + \delta/4)T_2 p\right) + \mathbb{P}\left(|N(v) \cap V_0| \geq (1/2 - \delta/4)T_2 p\right) \\
& = \mathbb{P}\left(\text{Bin}(|V_1|, p) \leq (1/2 + \delta/4)T_2 p\right) + \mathbb{P}\left(\text{Bin}(|V_0|, p) \geq (1/2 - \delta/4)T_2 p\right) \\
& \leq 2 \exp\left(-\Theta(T_2 p)\right) \\
& = 2 \exp\left(-\Omega\left(\frac{n}{\omega} \cdot \frac{\omega^2 \log n}{n}\right)\right) \\
& = \mathcal{O}(1/n^2),
\end{aligned}$$

where the first inequality follows simply by observing that  $|N(v) \cap V_1| > c + \delta T_2 p / 2$  and  $|N(v) \cap V_0| < c$  implies  $|N(v) \cap V_1| > |N(v) \cap V_0| + \delta T_2 p / 2$ . The final inequality follows since  $\mathbb{E}[\text{Bin}(|V_1|, p)] \geq (1/2 + \delta/2)T_2 p$  and  $\mathbb{E}[\text{Bin}(|V_0|, p)] \leq (1/2 - \delta/2)T_2 p$ . The desired property holds by the union bound over all nodes  $v \notin V_0 \cup V_1$ .

Fix  $T_3 = T_3(n) = n/\sqrt{\omega}$ . The third phase will last till time  $T_3$ . Let  $V'_1 \subseteq V_1$  be the set of nodes from  $V_1$  that were selected during the third phase. Note that each node from  $V_1$  is selected during the third phase with probability at most  $(T_3 - T_2)/n \leq 1/\sqrt{\omega}$ . Hence,  $\mathbb{E}[|V'_1|] \leq |V_1|/\sqrt{\omega}$  and so a.a.s.  $|V'_1| \leq |V_1|/\omega^{1/3}$  by Markov's inequality. A simple but important observation is that  $V'_1$  is determined exclusively by the selection process (coupon collector process); in particular, it does not depend on the random graph nor the opinion dynamics. Hence, we can use Chernoff's bound again to show that a.a.s. all nodes  $v \notin V_0 \cup V_1$  have very few neighbours in  $V'_1$ . Indeed, note that for any  $v \notin V_0 \cup V_1$ , the number of neighbours of  $n$  in  $V'_1$  can be stochastically upper bounded by  $\text{Bin}(|V_1|/\omega^{1/3}, p)$  with expectation  $|V_1|p/\omega^{1/3} = \Theta(np/\omega^{4/3}) = \Omega(n^{2/3} \log n) \gg \log n$ . Hence,  $|N(v) \cap V'_1| = \mathcal{O}(|V_1|p/\omega^{1/3}) = \mathcal{O}(T_2 p/\omega^{1/3}) = o(T_2 p)$  with probability  $1 - \mathcal{O}(1/n^2)$ , and so a.a.s. all nodes  $v \notin V_0 \cup V_1$  satisfy this property.

Combining the two properties together, we get that a.a.s. for all nodes  $v \notin V_0 \cup V_1$  we have

$$|N(v) \cap (V_1 \setminus V'_1)| > |N(v) \cap (V_0 \cup V'_1)|. \quad (15)$$

Let  $W_1$  be the set of nodes outside of  $V_0 \cup V_1$  that were selected during the third phase (possibly multiple times). If property (15) is satisfied, then (deterministically) all nodes in  $W_1$  announce 1 in this phase. Indeed, even if all nodes from  $V'_1$  changed their opinion to 0 in the meantime, nodes in  $V_1$  still have majority of their neighbours with opinion 1.

Let us summarize the situation at the beginning of the fourth (and the last) phase. Recall that  $W_1$  consists of nodes that were selected for the first time during the third phase. Let  $W_0 = V_0 \cup V_1$  be the set of nodes that were selected before the third phase (that is, during the first or the second phase). A.a.s. nodes in  $W_1$  have opinion 1 and  $|W_1| = (T_3 - T_2) + \mathcal{O}(T_3^2/n) \sim T_3$ . We may assume that nodes in  $W_0$  have opinion 0 and a.a.s.  $|W_0| = T_2(1 + \mathcal{O}(1/\omega)) \sim T_2 = o(T_3)$ . Again, it is important to notice that  $W_1$  and  $W_0$  are determined exclusively by the selection process. ( $V_1$  and  $V_0$  do not possess this property and that was the main reason we needed to consider the third phase.) We may then use Chernoff's bound again, on the number of neighbours in  $W_1$  and  $W_0$  of any given node, to show that a.a.s. all nodes (not only outside of  $W_1 \cup W_0$ !) have more neighbours in  $W_1$  than in  $W_0$ . It means that every node that is selected during this last phase announces opinion 1.

Since a.a.s. every node is selected at least once during the next  $n(\log n + \omega'/2)$  rounds, the process is over after at most that many rounds with everyone converging to opinion 1. Hence, a.a.s. the entire process takes at most  $T_3 + n(\log n + \omega'/2) \leq n(\log n + \omega')$  rounds. In fact, the expected number of nodes that were selected before the last phase but were not selected in the first  $T'_4 = n(\log n - \log \omega/4)$  rounds of the last phase is equal to

$$T_3 \left(1 - \frac{1}{n}\right)^{T'_4} \leq \frac{n}{\sqrt{\omega}} \exp(-\log n + \frac{1}{4} \log \omega) = \omega^{-1/4} = o(1),$$

and so a.a.s. all nodes selected before the last phase are selected again during the first  $T'_4$  rounds of the last phase. On the other hand, a.a.s. there are still some nodes not selected at all after  $T_3 + T'_4$  rounds. Indeed, this follows immediately from the well studied coupon collector concentration bound for  $\hat{T}$ :  $\mathbb{P}(\hat{T} < n \log n - cn) < e^{-c}$ . The conclusion is that a.a.s. all nodes are selected at least once between round  $T_3$  and  $\hat{T}$ , and the proof is finished.  $\blacktriangleleft$

### 3.4 Very Sparse Random Graphs

In this subsection, we investigate random graphs that are close to the threshold for connectivity but are still connected, that is, we assume that  $pn \leq \omega \log n$  and  $pn \geq \log n + \omega$  for some  $\omega = \omega(n) \rightarrow \infty$  as  $n \rightarrow \infty$ .

First, we will show that at time  $T_3 = T_3(n) = 2n \log n$ , every node announced its opinion at least once, and only at most  $n\omega/\log n = o(n)$  nodes have opinion 0. The proof is deferred to the full version.

**► Proposition 11.** *Let  $\omega = \omega(n) = o(\log n)$  be any function that tends to infinity (sufficiently slowly) as  $n \rightarrow \infty$ . Suppose that  $p = p(n) \leq \omega \log n/n$  and  $p \geq (\log n + \omega)/n$ . Set  $T_3 = T_3(n) = 2n \log n$  and  $s = s(n) = n\omega/\log n$ . Then, a.a.s. all nodes announced their opinion at time  $T_3$ , and at most  $s$  of them have opinion 0.*

We will call a node  $v$  to be of *small degree*, if its degree is at most  $k = 5 \log n / (\log \log n)^{1/2}$ . Nodes of degree larger than  $k$  will be called of *large degree*. Before we continue investigating the process, we need to show a well-known fact that small degree nodes are not too close to each other.

**► Lemma 12.** *Let  $\omega = \omega(n) = o(\log n)$  be any function that tends to infinity (sufficiently slowly) as  $n \rightarrow \infty$ . Suppose that  $p = p(n) \leq \omega \log n/n$  and  $p \geq (\log n + \omega)/n$ . Then, the following property holds a.a.s. in  $\mathcal{G}(n, p)$ : any two small degree nodes are at distance at least 2 from each other.*

**Proof.** Since  $np > \log n$  and  $k = o(\log n)$ ,  $\binom{n}{i} p^i$  is an increasing sequence for  $0 \leq i \leq k$  and hence we have

$$\mathbb{P}(\deg(v) \leq k) \leq \sum_{i=0}^k \binom{n}{i} p^i (1-p)^{n-i} \leq (k+1) \binom{n}{k} p^k (1-p)^{n-k}.$$

We obtain the following upper bound on the probability that a node  $v$  has small degree:

$$\begin{aligned} \mathbb{P}(\deg(v) \leq k) &\leq (k+1) \binom{n}{k} p^k (1-p)^{n-k} \\ &\leq (k+1) \left(\frac{en}{k} \cdot \frac{\omega \log n}{n}\right)^k \exp(-pn + pk) \\ &\leq (k+1) \left(\omega (\log \log n)^{1/2}\right)^k \exp(-\log n - \omega + o(1)) \\ &\leq (k+1) \exp\left(\frac{5 \log n}{(\log \log n)^{1/2}} \cdot \log \log \log n - \log n\right) \\ &= n^{-1+o(1)}. \end{aligned}$$

Hence, we expect  $n^{o(1)}$  small degree nodes and so a.a.s. we have only  $n^{o(1)}$  of them. More importantly, using similar computations one can show that the expected number of small degree nodes that are adjacent to each other is equal to

$$\binom{n}{2} \cdot p \cdot \left(n^{-1+o(1)}\right)^2 = n^{-1+o(1)} = o(1).$$

Similarly, the expected number of small degree nodes that are at distance two from each other is equal to

$$\binom{n}{2} \cdot n \cdot p^2 \cdot \left(n^{-1+o(1)}\right)^2 = n^{-1+o(1)} = o(1).$$

Hence, a.a.s. any two nodes of small degree are at distance at least two from each other, and the proof of the lemma is finished.  $\blacktriangleleft$

Our next observation is that the number of large degree nodes that have opinion 0 is decreasing. The proof is deferred to the full version.

► **Proposition 13.** *Let  $\omega = \omega(n) = o(\log n)$  be any function that tends to infinity (sufficiently slowly) as  $n \rightarrow \infty$ . Suppose that  $p = p(n) \leq \omega \log n/n$  and  $p \geq (\log n + \omega)/n$ . Then, the following property holds a.a.s. for all phases.*

*Suppose that at the beginning of a phase,  $s = (n\omega/\log n) \cdot (\log \log n)^{-(i-1)/4}$  large degree nodes have opinion 0 for some  $i \in \mathbb{N}$ . Then, after  $2n \log n$  rounds all nodes announced their opinion at least once more, and at most  $u = s/(\log \log n)^{1/4} = (n\omega/\log n) \cdot (\log \log n)^{-i/4}$  large degree nodes have opinion 0.*

Finally, we are ready to show that all nodes eventually converge to opinion 1.

**Proof of Theorem 2.** The proof is an easy consequence of Propositions 11, 13, and Lemma 12. Indeed, a.a.s. at time  $T_3 = T_3(n) = 2n \log n$ , all but at most  $s = s(n) = n\omega/\log n$  nodes have opinion 1 (Proposition 11). Most of them are of large degree but some of them may be of small degree. By Proposition 13, the number of large degree nodes that have opinion 0 decreases: a.a.s. at time  $2n \log n \cdot \mathcal{O}(\log n/\log \log n) = \mathcal{O}(n(\log n)^2/(\log \log n))$  no large degree node has opinion 0. There could possibly be still some nodes of small degree that have opinion 0 but everyone converges to opinion 1 after additional  $\mathcal{O}(n \log n)$  rounds. Indeed, every node is selected at least once during that time period a.a.s. Large degree nodes have many neighbours but at most one neighbour of small degree (Lemma 12). So they will not change their opinion and stay with opinion 1. On the other hand, by the same lemma, no small degree node has a neighbour of small degree. Hence, such nodes will switch to opinion 1 once they are selected again. This finishes the proof of the theorem.  $\blacktriangleleft$

## 4 Dense Random Graphs

In this section, we prove that for dense graphs (that is, when  $p \in (0, 1]$  is a constant) it is not true that all nodes converge to the correct opinion a.a.s. On the contrary, there maybe an information cascade where all the nodes converge to the wrong opinion with constant probability.

**Proof of Theorem 3.** Fix any  $p \in (0, 1)$ . We will consider the easy case  $p = 1$  at the end.

Trivially, the first node announces its private belief, that is, it announces opinion 1 with probability  $1/2 + \delta$ ; otherwise, it announces 0. Since nodes are selected by the process (“coupon collector”) independently of the graph, we may postpone exposing edges of the

random graph till the first time a node is selected. Each time this happens, we expose edges from  $v^t$  to all nodes that already announced their opinion. If every single time at least one edge is present, then all nodes are going to announce the opinion of the very first node. It follows that

$$p_1 \geq (1/2 + \delta) \prod_{i=1}^n (1 - (1-p)^i).$$

It is easy to see that for any  $x \in [0, 1-p]$ ,

$$f(x) = 1 - x \geq \exp\left(-\frac{\log(1/p)}{1-p}x\right) = g(x).$$

(Note that  $f(0) = g(0)$ ,  $f(1-p) = g(1-p)$ , and  $g(x)$  is convex.) Hence,

$$\begin{aligned} p_1 &\geq (1/2 + \delta) \exp\left(-\frac{\log(1/p)}{1-p} \sum_{i=1}^n (1-p)^i\right) \\ &\geq (1/2 + \delta) \exp\left(-\log(1/p) \sum_{i=0}^{\infty} (1-p)^i\right) \\ &= (1/2 + \delta) \exp\left(-\log(1/p)(1/p)\right). \end{aligned}$$

The same argument works for  $p_0$  with the only difference that the probability of the first node announcing 1 ( $1/2 + \delta$ ) needs to be replaced with the probability of announcing 0 ( $1/2 - \delta$ ).

Finally, note that if  $p = 1$ , then the graph is (deterministically) the complete graph and (again, deterministically) all nodes are going to adopt the opinion of the very first node. Thus, we immediately get  $p_1 = 1/2 + \delta$  and  $p_0 = 1/2 - \delta$  (which matches the general formula that works for  $p \in (0, 1]$ ). This finishes the proof of the theorem. ◀

## Abstract

In a disk graph, every vertex corresponds to a disk in  $\mathbb{R}^2$  and two vertices are connected by an edge whenever the two corresponding disks intersect. Disk graphs form an important class of geometric intersection graphs, which generalizes both planar graphs and unit-disk graphs. We study a fundamental optimization problem in algorithmic graph theory, BIPARTIZATION (also known as ODD CYCLE TRANSVERSAL), on the class of disk graphs. The goal of BIPARTIZATION is to delete a minimum number of vertices from the input graph such that the resulting graph is bipartite. A folklore (polynomial-time) 3-approximation algorithm for BIPARTIZATION on disk graphs follows from the classical framework of Goemans and Williamson [Combinatorica'98] for cycle-hitting problems. For over two decades, this result has remained the best known approximation for the problem (in fact, even for BIPARTIZATION on unit-disk graphs). In this paper, we achieve the first improvement upon this result, by giving a  $(3 - \alpha)$ -approximation algorithm for BIPARTIZATION on disk graphs, for some constant  $\alpha > 0$ . Our algorithm directly generalizes to the broader class of *pseudo-disk* graphs. Furthermore, our algorithm is *robust* in the sense that it does not require a geometric realization of the input graph to be given.

## 1 Introduction

Disk graphs refer to intersection graphs of disks in the plane  $\mathbb{R}^2$ . Formally, in a disk graph, every vertex corresponds to a disk in  $\mathbb{R}^2$  and two vertices are connected by an edge whenever the two corresponding disks intersect. As a rather general class of geometric intersection graphs, disk graphs simultaneously generalize two important graph classes, unit-disk graphs and planar graphs, both of which have been extensively studied over decades. Many central problems in algorithmic graph theory have been considered on disk graphs, including VERTEX COVER [8, 28, 41], INDEPENDENT SET [8], MAXIMUM CLIQUE [5], FEEDBACK VERTEX SET [26, 28], DOMINATING SET [13], etc.

In this paper, we investigate a fundamental optimization problem on the class of disk graphs, called BIPARTIZATION. In this problem, the input is a graph  $G$  and the goal is to delete a smallest number of vertices from  $G$  such that the resulting graph is bipartite. There has been a long line of work studying BIPARTIZATION (e.g., see [10, 20, 34, 36, 37] and citations therein). Observe that the edge counterpart of the BIPARTIZATION problem, EDGE BIPARTIZATION, where we need to find fewest edges whose deletion results in a bipartite graph, is equivalent to the classical MAXIMUM CUT problem (which has been studied for over five decades [14, 39]). It is known that EDGE BIPARTIZATION (and MAXIMUM CUT) reduces to BIPARTIZATION [42], and both problems find applications in computational biology [42, 38], VLSI chip design [18], genome sequence assembly [32], and more. BIPARTIZATION is of particular interest also due to the following observation: a graph is bipartite if and only if it does not contain any odd cycle. As such, it can be formulated as hitting all odd cycles in the graph (using fewest vertices). For this reason, the BIPARTIZATION problem is also known as ODD CYCLE TRANSVERSAL, and belongs to the family of *cycle-hitting* problems, one of the most well-studied topics in algorithmic graph theory. Besides BIPARTIZATION, other important cycle-hitting problems that have been studied on disk graphs include FEEDBACK VERTEX SET, TRIANGLE HITTING, SHORT CYCLE HITTING, etc.

There is no surprise that BIPARTIZATION is NP-complete. In fact, it is NP-complete even on graphs of maximum degree 3 and planar graphs of maximum degree 4 [6]. As such, the study of the problem is mainly in the context of approximation algorithms and parameterized algorithms. On the parameterized front, it was known that BIPARTIZATION can be solved in  $2^{O(k)} \cdot n^{O(1)}$  time where  $k$  is the solution size [20, 25, 35]. On planar graphs and unit-disk graphs, there exist improved algorithms with running time  $k^{O(\sqrt{k})} \cdot n^{O(1)}$  [2, 3, 29, 31], which are almost tight assuming the Exponential-Time Hypothesis (ETH). On disk graphs, it was not known whether BIPARTIZATION admits a subexponential-time parameterized algorithm, until very recently Lokshantov et al. gave a  $k^{O(k^{27/28})} \cdot n^{O(1)}$ -time algorithm [26].

From the perspective of approximation algorithms (which is the focus of this paper), BIPARTIZATION is one of the trickiest problems in the sense that no polynomial-time approximation scheme (PTAS) was known on any (nontrivial) graph classes, but at the same time no inapproximability results was known except for general graphs. On general graphs, BIPARTIZATION cannot admit any (polynomial-time) constant-approximation algorithm assuming the Unique Games Conjecture [4], and the best known approximation ratio is  $O(\sqrt{\log \text{opt}})$  due to Kratsch and Wahlström [24], improving the earlier bounds of  $O(\log n)$  [9] and  $O(\sqrt{\log n})$  [1]. It has been a long-standing open question whether BIPARTIZATION admits a PTAS on planar graphs or unit-disk graphs. On planar graphs, the currently best approximation for BIPARTIZATION is still the  $\frac{9}{4}$ -approximation algorithm given in the seminal work of Goemans and Williamson [15] more than two decades ago. This result immediately gives a 3-approximation algorithm for BIPARTIZATION on disk graphs (and in particular, unit-disk graphs) by the well-known fact that triangle-free disk graphs are planar [22].

► **Theorem 1** (folklore). *There exists a polynomial-time 3-approximation algorithm for BIPARTIZATION on the class of disk graphs.*

**Proof.** Let  $G$  be the input disk graph. We repeat the following step until  $G$  contains no triangles: find a triangle in  $G$ , add its three vertices to the solution, and remove them from  $G$ . Denote by  $S$  the set of vertices added to the solution and by  $G' = G - S$  the resulting triangle-free graph, which is planar [22]. Now apply the algorithm of Goemans and Williamson [15] on  $G'$  to obtain a  $\frac{9}{4}$ -approximation solution  $S'$ . Note that  $S \cup S'$  is a 3-approximation solution (for  $G$ ). Indeed, any solution of BIPARTIZATION must hit all triangles in  $G$  and thus contains at least  $|S|/3$  vertices in  $S$ . Also, it contains at least  $|S'|/4$  vertices in  $V(G')$ . So its size is at least  $|S|/3 + |S'|/4 \geq |S \cup S'|/3$ . ◀

For over two decades, this has remained the best approximation algorithm for BIPARTIZATION on disk graphs (in fact, even on unit-disk graphs). Thus, there is a natural question to be asked: can we achieve an approximation ratio better than 3 for the problem? Note that one cannot achieve this by improving the approximation ratio  $\frac{9}{4}$  for BIPARTIZATION on planar graphs. Indeed, even if we had a PTAS on planar graphs, the above argument still only gives us a 3-approximation algorithm on disk graphs. Therefore, the number 3 here is truly a bottleneck of the approximation ratio of the problem. In this paper, we break this bottleneck and answer the above question affirmatively by giving the first algorithm for BIPARTIZATION on disk graphs with an approximation ratio better than 3. Specifically, our main result is the following.

► **Theorem 2.** *There exists a polynomial-time  $(3 - \alpha)$ -approximation algorithm for BIPARTIZATION on the class of disk graphs, for some constant  $\alpha > 0$ .*

We remark that Theorem 2 should be viewed as a proof of concept, rather than the quantitative improvement. Our algorithm in Theorem 2 is *robust* in the sense that it does not require the geometric realization of the input disk graph to be given. Furthermore, our algorithm directly generalizes to the broader class of *pseudo-disk* graphs, which are the intersection graphs of topological disks in which the boundaries of every two of them intersect at most twice. (Note that the 3-approximation algorithm in Theorem 1 also works for pseudo-disk graphs as triangle-free pseudo-disk graphs are planar [22].) Again, this generalized algorithm is robust.

► **Theorem 3.** *There exists a polynomial-time  $(3 - \alpha)$ -approximation algorithm for BIPARTIZATION on the class of pseudo-disk graphs, for some constant  $\alpha > 0$ .*

Finally, we observe that our technique not only works for the BIPARTIZATION problem. In fact, it can be applied to a large category of vertex-deletion problems on (pseudo-)disk graphs, resulting in  $(3 - \alpha)$ -approximation algorithms. Although at this point it only yields interesting results for BIPARTIZATION (mainly because most well-studied problems in the category already have algorithms on disk graphs with approximation ratio better than 3), this demonstrates that our technique could possibly have further applications in the future. We shall briefly discuss this part in Section 4.

### Other related work

NP-complete optimization problems on disk graphs and other geometric intersection graphs have received considerable attention over years. Here we only summarize some recent work on this topic. The work of de Berg et al. [7] gave a framework for designing ETH-tight exact algorithms on (unit-)disk graphs or more generally (unit-)ball graphs, which works for a variety of classical optimization problems. Bonamy et al. [5] presented the first EPTAS and subexponential-time algorithm for MAXIMUM CLIQUE on disk graphs. Fomin et al. [11] designed almost ETH-tight parameterized algorithms for various cycle-packing and cycle-hitting problems on unit-disk graphs; in a follow-up paper [12], the same authors improved some of their algorithms to be ETH-tight. Recently, Lokshtanov et al. [26, 28] proposed frameworks for subexponential parameterized algorithms and EPTASes for various vertex-deletion problems on disk graphs (the framework for EPTASes does not work for BIPARTIZATION, while the one for subexponential parameterized algorithms works). A very recent work by the same authors [27] gave a 1.9999-approximation for VERTEX COVER on string graphs (i.e., intersection graphs of arbitrary connected geometric objects in the plane), which has the same flavor as this paper.

Besides the aforementioned algorithmic research on BIPARTIZATION, the problem was also studied in the context of kernelization complexity. The seminal work by Kratsch and Wahlström [23] showed that BIPARTIZATION admits a randomized polynomial kernel with respect to  $k$ . Later, for planar graphs, it was shown to admit a deterministic polynomial kernel by Jansen et al. [17]. Moreover, the kernelization complexity of BIPARTIZATION was studied also with respect to some structural parameterizations [16].

On a related note, we remark that structural properties of odd cycles in a graph has also received significant attention from various combinatorial points of view. While the survey of these results is beyond the scope of this paper, as an illustrative example, let us mention the study of Erdős–Pósa properties for odd cycles (see e.g., [10, 19, 33, 40]).

## 2 Preliminaries

Let  $G$  be a graph. We use  $V(G)$  and  $E(G)$  to denote the vertex set and edge set of  $G$ , respectively. For a subset  $V \subseteq V(G)$ , denote by  $G[V]$  the subgraph of  $G$  induced by  $V$ , and by  $G - V$  the subgraph of  $G$  induced by  $V(G) \setminus V$ . For a vertex  $v$ , we use  $N_G(v)$  to denote the set  $\{x \in V(G) \setminus \{v\} : (x, v) \in E(G)\}$ . For a vertex subset  $S$ , we use  $N_G(S)$  and  $N_G[S]$  to denote the sets  $\bigcup_{z \in S} N_G(z) \setminus S$  and  $S \cup N_G(S)$ , respectively. For a vertex  $v$  in  $G$ , we use  $d_G(v)$  to denote the degree of  $v$  (i.e.,  $|N_G(v)|$ ) in  $G$ . A vertex subset  $I \subseteq V(G)$  is a *distance- $d$  independent* set in  $G$ , if for any two distinct vertices  $x$  and  $y$  in  $I$ , the distance between  $x$  and  $y$  in  $G$  is strictly more than  $d$ . Here, the distance between two vertices is the number of edges in a shortest path between those vertices. Let  $\mathcal{S}$  be a collection of subsets of  $V(G)$ . A *packing* of  $\mathcal{S}$  is a sub-collection  $\mathcal{S}'$  such that  $S \cap S' = \emptyset$  for all  $S, S' \in \mathcal{S}'$  with  $S \neq S'$ . We say a packing  $\mathcal{S}' \subseteq \mathcal{S}$  is *maximal* if any  $\mathcal{S}'' \subseteq \mathcal{S}$  satisfying  $\mathcal{S}' \subsetneq \mathcal{S}''$  is not a packing of  $\mathcal{S}$ , and is *maximum* if any subset  $\mathcal{S}'' \subseteq \mathcal{S}$  satisfying  $|\mathcal{S}'| < |\mathcal{S}''|$  is not a packing of  $\mathcal{S}$ . Any maximum packing of  $\mathcal{S}$  has the same size.

An *odd cycle transversal* (or *OCT* for short) of  $G$  is a subset  $S \subseteq V(G)$  such that  $G - S$  is a bipartite graph. A *triangle* in  $G$  refers to a set  $T = \{u, v, w\}$  of three vertices of  $G$  such that  $(u, v), (v, w), (w, u) \in E(G)$ . We use  $\Delta(G)$  to denote the family of all triangles in  $G$ . For a set  $\mathcal{T}$  of triangles in  $G$ , we denote by  $V(\mathcal{T})$  the set of vertices of all triangles in  $\mathcal{T}$ , i.e.,  $V(\mathcal{T}) = \bigcup_{T \in \mathcal{T}} T$ . The notation  $\text{tri}(\mathcal{T})$  denotes the size of a maximum packing of  $\mathcal{T}$ .

## 3 Our algorithm

In this section, we present our approximation algorithm for BIPARTIZATION on disk graphs. Our algorithm first takes a simple preprocessing step, which reduces the general problem to the problem on  $K_4$ -free disk graphs (i.e., disk graphs without cliques of size 4). Then in the main part of our algorithm, we solve BIPARTIZATION on  $K_4$ -free disk graphs. For a cleaner exposition, we shall present a randomized version of our algorithm, as it is more intuitive and yields a better approximation ratio. The derandomization can be found in the full version of the paper.

### 3.1 Preprocessing: reducing to the $K_4$ -free case

For a graph  $G$ , let  $K_4(G)$  be the set of all  $K_4$ 's in  $G$ . The following lemma allows us to reduce the problem to BIPARTIZATION on  $K_4$ -free disk graphs.

► **Lemma 4.** *Let  $G$  be a graph and  $\mathcal{C}$  be a packing of  $K_4(G)$ . Let  $S$  be a  $\rho$ -approximation solution for BIPARTIZATION on  $G - V(\mathcal{C})$ . Then,  $S \cup V(\mathcal{C})$  is a  $\max\{2, \rho\}$ -approximation solution for BIPARTIZATION on  $G$ .*

**Proof.** First, it is clear that  $S \cup V(\mathcal{C})$  is an OCT of  $G$ , since  $G - S \cup V(\mathcal{C}) = (G - V(\mathcal{C})) - S$  contains no odd cycles. Let  $S^*$  be an optimal OCT of  $G$ . For every  $K_4$  in  $\mathcal{C}$ ,  $S^*$  must contain at least 2 vertices in the  $K_4$  (for otherwise  $G - S^*$  contains a triangle). Since the  $K_4$ 's in  $\mathcal{C}$  are disjoint, we have  $|S^* \cap V(\mathcal{C})| \geq 2|\mathcal{C}| = |V(\mathcal{C})|/2$ . Furthermore,  $S^* \cap (V(G) \setminus V(\mathcal{C}))$  is an OCT of  $G - V(\mathcal{C})$ , which implies  $|S^* \cap (V(G) \setminus V(\mathcal{C}))| \geq |S|/\rho$ . Therefore,

$$|S^*| = |S^* \cap V(\mathcal{C})| + |S^* \cap (V(G) \setminus V(\mathcal{C}))| \geq \frac{|V(\mathcal{C})|}{2} + \frac{|S|}{\rho} \geq \frac{|S| + |V(\mathcal{C})|}{\max\{2, \rho\}}.$$

As  $|S \cup V(\mathcal{C})| = |S| + |V(\mathcal{C})|$ , we have  $|S \cup V(\mathcal{C})| \leq \max\{2, \rho\} \cdot |S^*|$ .  $\blacktriangleleft$

One reason for why this reduction helps us is the degeneracy of a  $K_4$ -free disk graph. Recall that a graph  $G$  is  $c$ -degenerate if we can sort its vertices as  $v_1, \dots, v_n$  such that each  $v_i$  is neighboring to at most  $c$  vertices in  $\{v_1, \dots, v_{i-1}\}$ . A  $c$ -degenerate graph of  $n$  vertices has at most  $cn$  edges and thus has average degree at most  $2c$ . We prove that every  $K_4$ -free disk graph is 11-degenerate. To prove this we use the following known result.

► **Lemma 5** ([30]). *Let  $D$  be a disk of radius  $r$ . Let  $\mathcal{S}$  be a set of pairwise non-overlapping disks of radius  $r$  such that every disk in  $\mathcal{S}$  intersects with  $D$ . Then,  $|\mathcal{S}| \leq 5$ .*

► **Lemma 6.** *Every  $K_4$ -free disk graph is 11-degenerate.*

**Proof.** To prove the lemma, it is enough to prove that for any  $K_4$ -free disk graph, there is a vertex of degree at most 11. Let  $G$  be a  $K_4$ -free disk graph with a realization  $\mathcal{D}$ , and let  $D_v \in \mathcal{D}$  be the disk representing the vertex  $v \in V(G)$ . Let  $u$  be a vertex in  $G$  such that disk  $D_u$  has the smallest radius among the disks in  $\mathcal{D}$ . We will prove that  $d_G(u) \leq 11$ . Let  $r$  be the radius of  $D_u$ . Notice that for each  $v \in N_G(u)$ , the radius of  $D_v$  is at least  $r$ . Now we construct a graph  $H$  with vertex set  $N_G[u]$  such that  $H$  is a unit disk graph,  $H$  is a subgraph of  $G$  (and hence  $K_4$ -free), and  $d_G(u) = d_H(u)$ . The construction of  $H$  is as follows. For each  $v \in N_G(u)$ , construct a disk  $D'_v$  of radius  $r$  which is fully contained in the disk  $D_v$  and intersects  $D_u$ . The graph  $H$  is the geometric intersection graph of  $\mathcal{D}' = \{D_u\} \cup \{D'_v : v \in N_G(u)\}$ . It is easy to see that  $H$  is a unit disk graph,  $H$  is a subgraph of  $G$  and  $d_G(u) = d_H(u)$ . For each  $v \in V(H) \setminus \{u\}$ , let  $L_v$  be the line segment between the centers of  $D_u$  and  $D'_v$ . Let  $\{v_1, \dots, v_t\} = N_G(u)$  such that the line segments  $L_{v_1}, L_{v_2}, \dots, L_{v_t}$  are in the clockwise order. We claim that  $t \leq 11$ . For the sake of contradiction assume that  $t \geq 12$ . Suppose there exists two distinct  $i, j \in \{1, 3, 5, 7, 9, 11\}$  such that  $D'_{v_i}$  intersects with  $D'_{v_j}$ . This implies that  $D'_{v_{i+1}}$  or  $D'_{v_{j+1}}$  intersects both  $D'_{v_i}$  and  $D'_{v_j}$ . Let  $w \in \{v_{i+1}, v_{j+1}\}$  be the vertex such that  $D'_w$  intersects both  $D'_{v_i}$  and  $D'_{v_j}$ . Then,  $H[\{u, w, v_i, v_j\}]$  is a complete graph on 4 vertices, which is a contradiction because  $H$  is  $K_4$ -free. Then, the disks  $D'_{v_1}, D'_{v_3}, D'_{v_5}, D'_{v_7}, D'_{v_9}, D'_{v_{11}}$  are pairwise non-overlapping, which is a contradiction to Lemma 5. Thus, we proved that  $t \leq 11$  and hence  $d_H(v) = d_G(v) \leq 11$ . That is, the degeneracy of  $G$  is at most 11.  $\blacktriangleleft$

### 3.2 The main algorithm

Our main algorithm for BIPARTIZATION on  $K_4$ -free disk graphs is presented in Algorithm 1. At the beginning, it takes an arbitrary maximal triangle packing  $\mathcal{T}$  of  $G$  (line 1) and defines  $\mathcal{O}$  as the triangles in  $G$  that have at least one vertex outside  $V(\mathcal{T})$ . In a high-level, our algorithm computes three different solutions  $S_1, S_2, S_3$  and returns the best one.

The first solution  $S_1$  is computed in exactly the same way as the 3-approximation algorithm described in the introduction. Specifically, we include in  $S_1$  all vertices in the triangle packing  $\mathcal{T}$ , and an OCT  $X_1$  of  $G - V(\mathcal{T})$  computed by a sub-routine PLANARBIP (line 3), which is an algorithm for BIPARTIZATION on planar graphs.

## 6:6 Bipartizing (Pseudo-)Disk Graphs

The second solution  $S_2$  is constructed in a more involved way. First, in each triangle  $T \in \mathcal{T}$ , we randomly sample one vertex  $v_T \in T$  (line 6); here the function  $\text{random}(T)$  returns each vertex in  $T$  with probability  $\frac{1}{3}$  and different calls of  $\text{random}$  are independent. Let  $R$  be the vertices in  $V(\mathcal{T})$  not sampled (line 7). Then we include in  $S_2$  all vertices in  $R$ , all vertices in an arbitrary maximal triangle packing  $\mathcal{T}'$  of  $G - R$  (line 8), and an OCT  $X_2$  of  $G - (R \cup V(\mathcal{T}'))$  computed by PLANARBIP.

If  $\mathcal{O}$  is nonempty, we need to construct our third solution  $S_3$ . We take a maximal packing  $\mathcal{T}''$  of the triangles in  $\mathcal{O}$  (line 12). Then we include in  $S_3$  all vertices in  $V(\mathcal{T}'') \cap V(\mathcal{T})$  and an OCT  $X_3$  of  $G - (V(\mathcal{T}'') \cap V(\mathcal{T}))$  recursively computed by our algorithm (line 13).

Finally, we return the best one among  $S_1, S_2, S_3$  (line 15); here  $\min\{S_1, S_2, S_3\}$  returns the set of smallest size among  $S_1, S_2, S_3$ . If  $S_3$  is not computed, we simply return  $\min\{S_1, S_2\}$ . It is obvious that each of  $S_1, S_2, S_3$  is an OCT of  $G$  and thus the algorithm always returns a correct solution. The quality of the solution obtained will be analyzed in the next section. Also, one can easily see that Algorithm 1 runs in polynomial time. Indeed, except the recursive call of OCT in line 13, all the other steps can be done in polynomial time. Line 13 will only be executed when  $\mathcal{O} \neq \emptyset$ . In this case,  $\mathcal{T}'' \neq \emptyset$  and  $V(\mathcal{T}'') \neq \emptyset$ . Thus, the graph  $G - (V(\mathcal{T}'') \cap V(\mathcal{T}))$  has at most  $n - 1$  vertices where  $n = V(G)$ , and the running time of Algorithm 1 satisfies the recurrence  $T(n) \leq T(n - 1) + n^{O(1)}$  which solves to  $T(n) = n^{O(1)}$ .

```

1:  $\mathcal{T} \leftarrow$  a maximal packing of  $\Delta(G)$ 
2:  $\mathcal{O} \leftarrow \{T \in \Delta(G) : T \not\subseteq V(\mathcal{T})\}$ 
3:  $X_1 \leftarrow \text{PLANARBIP}(G - V(\mathcal{T}))$  ▷ construct the first solution  $S_1$ 
4:  $S_1 \leftarrow V(\mathcal{T}) \cup X_1$ 
5: for every  $T \in \mathcal{T}$  do ▷ construct the second solution  $S_2$ 
6:    $v_T \leftarrow \text{random}(T)$ 
7:    $R \leftarrow \bigcup_{T \in \mathcal{T}} (T \setminus \{v_T\})$ 
8:    $\mathcal{T}' \leftarrow$  a maximal packing of  $\Delta(G - R)$ 
9:    $X_2 \leftarrow \text{PLANARBIP}(G - (R \cup V(\mathcal{T}')))$ 
10:  $S_2 \leftarrow R \cup V(\mathcal{T}') \cup X_2$ 
11: if  $\mathcal{O} \neq \emptyset$  then ▷ construct the third solution  $S_3$ 
12:    $\mathcal{T}'' \leftarrow$  a maximal packing of  $\mathcal{O}$ 
13:    $X_3 \leftarrow \text{BIPARTIZATION}(G - (V(\mathcal{T}'') \cap V(\mathcal{T})))$ 
14:    $S_3 \leftarrow (V(\mathcal{T}'') \cap V(\mathcal{T})) \cup X_3$ 
15: return  $\min\{S_1, S_2, S_3\}$  ▷ if  $S_3$  is undefined, simply return  $\min\{S_1, S_2\}$ 

```

---

### 3.3 Analysis

In this section, we analyze the (expected) approximation ratio of Algorithm 1. We denote by  $\rho$  this ratio and aim to establish an upper bound for  $\rho$ . Consider a given disk graph  $G$  which is  $K_4$ -free. Let  $\text{opt}$  be the minimum size of an odd cycle transversal of  $G$ , and  $\mathcal{T}, \mathcal{O}$  be the two sets of triangles as in Algorithm 1. The output of Algorithm 1 is the best one among three OCT solutions  $S_1, S_2, S_3$ . Therefore, to analyze the approximation ratio of our algorithm, we have to consider the approximation ratios of  $S_1, S_2, S_3$ . It turns out that each solution  $S_i$  individually may be of size  $3\text{opt}$  or even larger in worst case. However, as we will see, the best one among them always admits an approximation ratio strictly smaller than 3.

In order to analyze the three solutions, we define two important parameters:  $a = |\mathcal{T}|/\text{opt}$  and  $b = \text{tri}(\mathcal{O})/\text{opt}$  (recall that  $\text{tri}(\mathcal{O})$  is the size of a *maximum* packing of  $\mathcal{O}$ ). Note that  $a, b \in [0, 1]$  because both  $|\mathcal{T}|$  and  $\text{tri}(\mathcal{O})$  are at most the size of a maximum triangle packing in  $G$ , which is smaller than or equal to  $\text{opt}$ . The analysis of  $S_1, S_2, S_3$  will be done in terms of  $a$  and  $b$ , that is, we shall represent the approximation ratios of  $S_1, S_2, S_3$  as functions of  $a$  and  $b$ . Roughly speaking, we shall show that  $S_1$  is good when  $a$  is small,  $S_2$  is good when  $b$  is small, and  $S_3$  is good when both  $a$  and  $b$  are large. For convenience, we use the notation  $\rho_0$  to denote the approximation ratio of the PLANARBIP sub-routine used in Algorithm 1.

### 3.3.1 The quality of $S_1$

The solution  $S_1$  is computed using exactly the 3-approximation algorithm described in the introduction. A more careful analysis shows that its approximation ratio is related to the parameter  $a$ : the smaller  $a$  is, the better  $S_1$  is.

► **Lemma 7.**  $|S_1| \leq (3a + \rho_0(1 - a)) \cdot \text{opt}$ .

**Proof.** Since  $a = |\mathcal{T}|/\text{opt}$ , and  $\mathcal{T}$  is a triangle packing, we get that  $|V(\mathcal{T})| = 3|\mathcal{T}| = 3a \cdot \text{opt}$ . Since  $\mathcal{T}$  is a triangle packing, any odd cycle transversal contains at least  $|\mathcal{T}|$  vertices from  $V(\mathcal{T})$ , the size of a minimum odd cycle transversal in  $G - V(\mathcal{T})$  is at most  $\text{opt} - |\mathcal{T}| = (1 - a)\text{opt}$ . Therefore,  $|S_1| = |V(\mathcal{T})| + |X_1| \leq (3a + \rho_0(1 - a)) \cdot \text{opt}$ . ◀

### 3.3.2 The quality of $S_2$

Figuring out the quality of  $S_2$  is the most involved part in our analysis. Basically, what we shall show is that whenever the parameter  $b$  is sufficiently small,  $S_2$  always gives us a better-than-3 approximation no matter what the value of  $a$  is. The analysis in this section shall explicitly use the fact that  $G$  is  $K_4$ -free. Let  $v_T, R$ , and  $\mathcal{T}'$  be as in Algorithm 1. We first need the following simple observation, which will allow us to bound the expected size of  $S_2$  using the expected size of  $\mathcal{T}'$ .

► **Observation 8.**  $\mathbb{E}[|R \cap S_{\text{opt}}|] \geq \frac{1}{3}|R|$  and  $|V(\mathcal{T}') \cap S_{\text{opt}}| \geq |\mathcal{T}'|$ .

**Proof.** Since  $S_{\text{opt}}$  is an OCT of  $G$ , it contains at least one vertex in every triangle  $T \in \mathcal{T}$ . Thus,  $\mathbb{E}[|(T \setminus \{v_T\}) \cap S_{\text{opt}}|] \geq \frac{2}{3}$ . By the linearity of expectation, we have

$$\mathbb{E}[|R \cap S_{\text{opt}}|] = \sum_{T \in \mathcal{T}} \mathbb{E}[|(T \setminus \{v_T\}) \cap S_{\text{opt}}|] \geq \frac{2}{3}|\mathcal{T}| = \frac{1}{3}|R|.$$

The fact  $|V(\mathcal{T}') \cap S_{\text{opt}}| \geq |\mathcal{T}'|$  follows from the fact that  $\mathcal{T}'$  is a triangle packing:  $S_{\text{opt}}$  contains at least one vertex in every triangle  $T \in \mathcal{T}'$ . ◀

The above observation implies that  $\mathbb{E}[|(R \cup V(\mathcal{T}') \cap S_{\text{opt}})|] \geq \frac{1}{3}|R| + \mathbb{E}[|\mathcal{T}'|]$ . Therefore, we have  $\mathbb{E}[|S_{\text{opt}} \setminus (R \cup V(\mathcal{T}'))|] \leq \text{opt} - \frac{1}{3}|R| - \mathbb{E}[|\mathcal{T}'|]$  and hence  $\mathbb{E}[|X_2|] \leq \rho_0 \cdot (\text{opt} - \frac{1}{3}|R| - \mathbb{E}[|\mathcal{T}'|])$ . It follows that

$$\begin{aligned} \mathbb{E}[|S_2|] &= |R| + \mathbb{E}[|V(\mathcal{T}')|] + \mathbb{E}[|X_2|] \\ &\leq |R| + 3 \cdot \mathbb{E}[|\mathcal{T}'|] + \rho_0 \cdot \left( \text{opt} - \frac{1}{3}|R| - \mathbb{E}[|\mathcal{T}'|] \right) \\ &= \left( 1 - \frac{\rho_0}{3} \right) \cdot |R| + \rho_0 \cdot \text{opt} + (3 - \rho_0) \cdot \mathbb{E}[|\mathcal{T}'|] \end{aligned} \tag{1}$$

## 6:8 Bipartizing (Pseudo-)Disk Graphs

We say a vertex  $v \in V(\mathcal{T})$  is *dead* if  $v \notin R$  and  $v$  is not contained in any triangle in  $G[V(\mathcal{T}) \setminus R]$ . Let  $D$  denote the set of all dead vertices, which is a random subset of  $V(\mathcal{T})$  as it depends on the random vertices  $v_T$ . For each  $v \in V(\mathcal{T})$ , let  $\deg(v)$  denote the degree of  $v$  in  $G[V(\mathcal{T})]$ . Recall that  $a = |\mathcal{T}|/\text{opt}$  and  $b = \text{tri}(\mathcal{O})/\text{opt}$ . It is easy to see the following relation between  $|\mathcal{T}'|$  and  $|D|$ .

► **Observation 9.**  $|\mathcal{T}'| \leq (a + b) \cdot \text{opt} - \frac{|R|}{3} - \frac{|D|}{3}$ .

**Proof.** Since  $\mathcal{T}'$  is a triangle packing, we have  $|\mathcal{T}' \cap \mathcal{O}| \leq \text{tri}(\mathcal{O}) = b \cdot \text{opt}$ . On the other hand, all elements in  $\mathcal{T}' \setminus \mathcal{O}$  are triangles in  $G[V(\mathcal{T}) \setminus R]$ . However, dead vertices cannot be the vertex of any triangle in  $G[V(\mathcal{T}) \setminus R]$ . Thus, the vertices of the triangles in  $\mathcal{T}' \setminus \mathcal{O}$  must lie in  $V(\mathcal{T}) \setminus (R \cup D)$ . We have  $|V(\mathcal{T}) \setminus (R \cup D)| = 3 \cdot |\mathcal{T}| - |R| - |D| = 3a \cdot \text{opt} - |R| - |D|$ , which implies  $|\mathcal{T}' \setminus \mathcal{O}| \leq a \cdot \text{opt} - \frac{|R|}{3} - \frac{|D|}{3}$ . Because  $|\mathcal{T}'| = |\mathcal{T}' \cap \mathcal{O}| + |\mathcal{T}' \setminus \mathcal{O}|$ , we have the inequality in the observation. ◀

Combining the above observation with Equation 1, we have

$$\begin{aligned} \mathbb{E}[|S_2|] &\leq \left(1 - \frac{\rho_0}{3}\right) \cdot |R| + \rho_0 \cdot \text{opt} + (3 - \rho_0) \cdot \mathbb{E}[|\mathcal{T}'|] \\ &= \left(1 - \frac{\rho_0}{3}\right) \cdot |R| + \rho_0 \cdot \text{opt} + (3 - \rho_0) \cdot \left((a + b) \cdot \text{opt} - \frac{|R|}{3} - \frac{\mathbb{E}[|D|]}{3}\right) \\ &= (\rho_0 + (3 - \rho_0)(a + b)) \cdot \text{opt} - (3 - \rho_0) \cdot \frac{\mathbb{E}[|D|]}{3}. \end{aligned} \quad (2)$$

To show that  $S_2$  has an approximation ratio below 3 when  $b$  is small, the crucial observation is that we have a large number of dead vertices in expectation.

► **Observation 10.**  $\Pr[v \text{ is dead}] \geq \left(\frac{1}{3}\right)^{\frac{3}{8}\deg(v) + \frac{1}{4}}$  for all  $v \in V(\mathcal{T})$ . Thus, we have  $\mathbb{E}[|D|] \geq \left(\frac{1}{3}\right)^{\frac{3}{8}d + \frac{1}{4}}(3a \cdot \text{opt})$ , where  $d$  is the average degree of  $G[V(\mathcal{T})]$ .

**Proof.** Let  $v \in V(\mathcal{T})$  and  $T_0 \in \mathcal{T}$  be the triangle containing  $v$ . Denote by  $N(v)$  the set of neighbors of  $v$  in  $V(\mathcal{T})$  (excluding  $v$  itself). We then have  $|N(v)| = \deg(v)$  and  $|N(v) \setminus T_0| = \deg(v) - 2$ . Observe that the graph  $G[N(v)]$  is triangle-free. Indeed, if  $G[N(v)]$  contains a triangle  $T$ , then  $T \cup \{v\}$  forms a clique in  $G$  of size 4, which contradicts with the fact that  $G$  is  $K_4$ -free. As  $G[N(v)]$  is triangle-free, it is planar. In particular,  $G[N(v) \setminus T_0]$  is planar. It was known that every  $n$ -vertex planar graph has a vertex cover of size at most  $\frac{3}{4}n$  (indeed, a planar graph is 4-colorable, so it has an independent set of size at least  $\frac{n}{4}$  and thus a vertex cover of size at most  $\frac{3}{4}n$ ). Thus,  $G[N(v) \setminus T_0]$  has a vertex cover  $C \subseteq N(v) \setminus T_0$  with  $|C| \leq \frac{3}{4}|N(v) \setminus T_0| = \frac{3}{4}(\deg(v) - 2)$ .

Next, we notice that if  $v \notin R$  and  $C \subseteq R$ , then  $v$  is a dead vertex. Indeed, if  $v$  is contained in a triangle  $\{v, u, w\}$  in  $G[V(\mathcal{T}) \setminus R]$ , then at least one of  $u$  and  $w$  must be in  $C$ , since  $C$  is a vertex cover of  $N(v) \setminus T_0$  (note that  $u, w \notin T_0$  for otherwise  $v \in R$ ). Let  $\mathcal{T}_1 \subseteq \mathcal{T}$  (resp.,  $\mathcal{T}_2 \subseteq \mathcal{T}$ ) consist of the triangles that contain one vertex (resp., two vertices) in  $C$ . Note that no triangle in  $\mathcal{T}$  can contain three vertices in  $C$  because  $G[C]$  is triangle-free. Therefore,  $C \subseteq R$  if and only if  $v_T \notin C$  for all  $T \in \mathcal{T}_1 \cup \mathcal{T}_2$ . The events  $v_T \notin C$  for all  $T \in \mathcal{T}_1 \cup \mathcal{T}_2$  are independent, and happen with probability  $\frac{2}{3}$  if  $T \in \mathcal{T}_1$  and with probability  $\frac{1}{3}$  if  $T \in \mathcal{T}_2$ . It follows that  $\Pr[C \subseteq R] = \left(\frac{2}{3}\right)^{|\mathcal{T}_1|} \cdot \left(\frac{1}{3}\right)^{|\mathcal{T}_2|}$ . We have the inequality  $|\mathcal{T}_1| + 2|\mathcal{T}_2| = |C| \leq \frac{3}{4}(\deg(v) - 2)$ . Subject to  $|\mathcal{T}_1| \geq 0$ ,  $|\mathcal{T}_2| \geq 0$ , and  $|\mathcal{T}_1| + 2|\mathcal{T}_2| \leq \frac{3}{4}(\deg(v) - 2)$ , the quantity  $\left(\frac{2}{3}\right)^{|\mathcal{T}_1|} \cdot \left(\frac{1}{3}\right)^{|\mathcal{T}_2|}$  is minimized when  $|\mathcal{T}_1| = 0$  and  $|\mathcal{T}_2| = \frac{3}{8}(\deg(v) - 2)$ , and is equal to  $\left(\frac{1}{3}\right)^{\frac{3}{8}(\deg(v) - 2)}$ . Thus, we have  $\Pr[C \subseteq R] \geq \left(\frac{1}{3}\right)^{\frac{3}{8}(\deg(v) - 2)}$ . Furthermore, the events  $v \notin R$  and  $C \subseteq R$  are independent because whether  $v \notin R$  happens only depends on the choice of  $v_{T_0} \in T_0$ . We have  $\Pr[v \notin R] = \frac{1}{3}$  and  $\Pr[C \subseteq R] \geq \left(\frac{1}{3}\right)^{\frac{3}{8}(\deg(v) - 2)}$ . Since  $v$  is a dead vertex if both  $v \notin R$  and  $C \subseteq R$  happen, we finally have  $\Pr[v \text{ is dead}] \geq \left(\frac{1}{3}\right)^{\frac{3}{8}\deg(v) + \frac{1}{4}}$ . By the linearity of expectation and the fact  $|V(\mathcal{T})| = 3|\mathcal{T}| = 3a \cdot \text{opt}$ , we then have

$$\mathbb{E}[|D|] = \sum_{v \in V(\mathcal{T})} \Pr[v \text{ is dead}] \geq \sum_{v \in V(\mathcal{T})} \left(\frac{1}{3}\right)^{\frac{3}{8}\deg(v) + \frac{1}{4}} \geq \left(\frac{1}{3}\right)^{\frac{3}{8}d + \frac{1}{4}} (3a \cdot \text{opt}).$$

where  $d = \sum_{v \in V(\mathcal{T})} \deg(v) / |V(\mathcal{T})|$ . ◀

At the end, we can establish the bound for  $\mathbb{E}[|S_2|]$ .

► **Lemma 11.**  $\mathbb{E}[|S_2|] \leq (\rho_0 + (1 - (\frac{1}{3})^{\frac{3}{8}d + \frac{1}{4}})(3 - \rho_0)a + (3 - \rho_0)b) \cdot \text{opt}$ , where  $d$  denotes the average degree of  $G[V(\mathcal{T})]$ .

**Proof.** Combining Observation 10 with Equation 2 completes the proof. ◀

According to Lemma 6, we have  $d \leq 22$ , and thus the above lemma gives us a good bound for  $\mathbb{E}[|S_2|]$ : as long as  $b$  is sufficiently small, no matter what  $a$  is, we can have that  $\mathbb{E}[|S_2|] \leq (3 - \alpha) \cdot \text{opt}$  for some constant  $\alpha > 0$ .

### 3.3.3 The quality of $S_3$

Finally, we analyze the quality of  $S_3$ . Given  $S_1$  is good when  $a$  is small and  $S_2$  is good when  $b$  is small, we clearly want  $S_3$  to be good when both  $a$  and  $b$  are large.

► **Lemma 12.** *If  $\rho \geq 2$ , then  $\mathbb{E}[|S_3|] \leq (\frac{2b}{3} + \rho(2 - a - \frac{b}{3})) \cdot \text{opt}$ .*

**Proof.** Let  $r = |\mathcal{T}''| / \text{opt}$ . Since  $\mathcal{T}''$  is a *maximal* packing in  $\mathcal{O}$ ,  $V(\mathcal{T}'')$  is a hitting set of  $\mathcal{O}$ , which implies  $3|\mathcal{T}''| = |V(\mathcal{T}'')| \geq \text{tri}(\mathcal{O})$  and thus  $r \geq \frac{\text{tri}(\mathcal{O})}{3 \cdot \text{opt}} = \frac{b}{3}$ .

▷ **Claim 13.**  $\mathbb{E}[|X_3|] \leq \rho(2 - a - r)\text{opt}$ .

**Proof.** Let  $S^*$  be an optimal OCT of  $G$ . So  $|S^*| = \text{opt}$ . We call a triangle  $T \in \mathcal{T}''$  *bad* if  $S^*$  contains a vertex from  $V(T) \setminus V(\mathcal{T})$ . Since  $\mathcal{T}$  is a triangle packing, we also know that  $|S^* \cap V(\mathcal{T})| \geq |\mathcal{T}| = a \cdot \text{opt}$ . Thus, the number of bad triangles in  $\mathcal{T}''$  is at most  $(1 - a)\text{opt}$ , because  $S^*$  contains at most  $(1 - a)\text{opt}$  vertices outside of  $V(\mathcal{T})$ , and any such vertex can be part of at most one triangle in  $\mathcal{T}''$ . That is, the number of *good* triangles in  $\mathcal{T}''$  is at least  $(r - (1 - a))\text{opt}$ . For each good triangle  $T \in \mathcal{T}''$ ,  $S^*$  contains a vertex from  $V(T) \cap V(\mathcal{T})$ . This implies that  $|S^* \cap (V(\mathcal{T}'') \cap V(\mathcal{T}))| \geq (r - (1 - a))\text{opt}$ , and hence  $|S^* \setminus (V(\mathcal{T}'') \cap V(\mathcal{T}))| \leq \text{opt} - (r - (1 - a))\text{opt} = (2 - a - r)\text{opt}$ . Also, notice that  $S^* \setminus (V(\mathcal{T}'') \cap V(\mathcal{T}))$  is an OCT of  $G - (V(\mathcal{T}'') \cap V(\mathcal{T}))$ . Thus, the size of an optimal OCT of  $G - (V(\mathcal{T}'') \cap V(\mathcal{T}))$  is at most  $(2 - a - r)\text{opt}$ , which implies  $\mathbb{E}[|X_3|] \leq \rho(2 - a - r)\text{opt}$ . ◀

Since each triangle  $T \in \mathcal{T}''$  is also in  $\mathcal{O}$ , we have  $|V(T) \cap V(\mathcal{T})| \leq 2$ . This implies that  $|V(\mathcal{T}'') \cap V(\mathcal{T})| \leq 2r \cdot \text{opt}$ . Now we are ready to deduce

$$\begin{aligned} \mathbb{E}[|S_3|] &= \mathbb{E}[|V(\mathcal{T}'') \cap V(\mathcal{T})| + |X_3|] \\ &= |V(\mathcal{T}'') \cap V(\mathcal{T})| + \mathbb{E}[|X_3|] \\ &\leq (2r \cdot \text{opt}) + \rho(2 - a - r)\text{opt} \quad (\text{By Claim 13 and } |V(\mathcal{T}'') \cap V(\mathcal{T})| \leq 2r \cdot \text{opt}) \\ &= (2 - \rho)r \cdot \text{opt} + \rho(2 - a)\text{opt} \\ &\leq (2 - \rho)\frac{b}{3}\text{opt} + \rho(2 - a)\text{opt} \quad (\text{Because } r \geq \frac{b}{3}, \text{ and } 2 - \rho < 0) \\ &\leq \left(\frac{2b}{3} + \rho\left(2 - a - \frac{b}{3}\right)\right) \cdot \text{opt}. \end{aligned}$$

This completes the proof of the lemma. ◀

### 3.3.4 Putting everything together

Given the analyses for  $S_1$ ,  $S_2$ , and  $S_3$  in the previous sections, we are ready to bound the (expected) approximation ratio  $\rho$  of the entire algorithm. Let  $\rho_1 = 3a + \rho_0(1 - a)$ ,  $\rho_2 = \rho_0 + (1 - (\frac{1}{3})^{\frac{3}{8}d + \frac{1}{4}})(3 - \rho_0)a + (3 - \rho_0)b$ ,  $\rho_3 = \frac{2b}{3} + \rho(2 - a - \frac{b}{3})$  be the approximation ratios of  $S_1, S_2, S_3$  given in Lemmas 7, 11, 12, respectively<sup>1</sup>. As the output is the best one among  $S_1, S_2, S_3$ , we have

$$\rho \leq \frac{\mathbb{E}[\min\{|S_1|, |S_2|, |S_3|\}]}{\text{opt}} \leq \frac{\min\{\mathbb{E}[|S_1|], \mathbb{E}[|S_2|], \mathbb{E}[|S_3|]\}}{\text{opt}} \leq \min\{\rho_1, \rho_2, \rho_3\}.$$

Note that  $\rho_1, \rho_2, \rho_3$  can be viewed as linear functions of  $a$  and  $b$ , when the other numbers  $d, \rho_0, \rho$  are all fixed. So we first figure out the values of  $a$  and  $b$  that maximizes  $\min\{\rho_1, \rho_2, \rho_3\}$ . With calculation, we have

$$\min\{\rho_1, \rho_2, \rho_3\} \leq \frac{(3 - \rho_0)(2\rho - \rho_0)}{(3 - \rho_0 + \rho) + (\rho - 2) \cdot 3^{-(\frac{3}{8}d + \frac{5}{4})}} + \rho_0, \quad (3)$$

and the upper bound is achieved when

$$a = \frac{(2\rho - \rho_0)}{(3 - \rho_0 + \rho) + (\rho - 2) \cdot 3^{-(\frac{3}{8}d + \frac{5}{4})}} \quad \text{and} \quad b = \frac{(2\rho - \rho_0) \cdot 3^{\frac{3}{8}d + \frac{1}{4}}}{(3 - \rho_0 + \rho) + (\rho - 2) \cdot 3^{-(\frac{3}{8}d + \frac{5}{4})}},$$

in which case  $\rho_1 = \rho_2 = \rho_3$ . Now combine Equation 3 with the inequality  $\rho \leq \min\{\rho_1, \rho_2, \rho_3\}$  and re-arrange the terms in the inequality, we deduce

$$(3^{-(\frac{3}{8}d + \frac{5}{4})} + 1) \cdot \rho^2 - ((2 + \rho_0) \cdot 3^{-(\frac{3}{8}d + \frac{5}{4})} + 3) \cdot \rho + (2\rho_0 \cdot 3^{-(\frac{3}{8}d + \frac{5}{4})}) \leq 0.$$

The left-hand side of the above inequality is a quadratic function of  $\rho$  in which the coefficient of the quadratic term is positive. Therefore, in order to make the quadratic function non-positive,  $\rho$  must be smaller than its larger root, i.e.,

$$\rho \leq \frac{((2 + \rho_0) \cdot 3^{-(\frac{3}{8}d + \frac{5}{4})} + 3) + \sqrt{((2 + \rho_0) \cdot 3^{-(\frac{3}{8}d + \frac{5}{4})} + 3)^2 - (3^{-(\frac{3}{8}d + \frac{5}{4})} + 1)(8\rho_0 \cdot 3^{-(\frac{3}{8}d + \frac{5}{4})})}}{2 \cdot (3^{-(\frac{3}{8}d + \frac{5}{4})} + 1)}.$$

By Lemma 6,  $G[V(\mathcal{T})]$  is 11-degenerate and thus  $d \leq 22$ . Furthermore, using the  $\frac{9}{4}$ -approximation algorithm [15] for planar bipartization, we can set  $\rho_0 = \frac{9}{4}$ . Plugging in these values to the above inequality, we have  $\rho \leq 2.99993033741$ .

Our entire algorithm first applies Lemma 4 with a maximal packing  $\mathcal{C}$  of  $K_4(G)$  to reduce the problem to  $G - V(\mathcal{C})$ , which is a  $K_4$ -free disk graph, and then applies Algorithm 1 on  $G - V(\mathcal{C})$ . By Lemma 4 and the above analysis, this algorithm solves BIPARTIZATION on disk graphs with an *expected* approximation ratio at most 2.99993033741. By repeating the algorithm polynomial number of times, we can also obtain a randomized algorithm that achieves the same approximation ratio with high probability.

► **Theorem 14.** *There exists a polynomial-time randomized algorithm for BIPARTIZATION on the class of disk graphs that gives a  $(3 - \alpha)$ -approximation solution with high probability, for some  $\alpha > 10^{-5}$ .*

<sup>1</sup> In Lemma 12, the bound for  $\mathbb{E}[|S_3|]$  has a condition  $\rho \geq 2$ . But we can assume this is always the case, for otherwise our algorithm is already a 2-approximation algorithm.

With some efforts, we can derandomize our algorithm to obtain a deterministic  $(3 - \alpha)$ -approximation algorithm for BIPARTIZATION on disk graphs. In fact, in Algorithm 1, only the construction of the set  $R$  is randomized. We show in the full version how to construct  $R$  deterministically while still guaranteeing the nice properties of  $R$  (the key point is to guarantee that there are many dead vertices). The approximation ratio of our deterministic algorithm is slightly worse than the randomized one (while it is still smaller than 3).

► **Theorem 2.** *There exists a polynomial-time  $(3 - \alpha)$ -approximation algorithm for BIPARTIZATION on the class of disk graphs, for some constant  $\alpha > 0$ .*

## 4 Generalizations

In this section, we discuss some generalizations of our result. First, we observe that our algorithm directly generalizes to *pseudo-disk graphs*. A set of geometric objects in the plane are called *pseudo-disks* if each of them is homeomorphic to a disk and the boundaries of any two objects intersect at most twice. A graph is a *pseudo-disk graph* if it can be represented as the intersection graph of a set of pseudo-disks.

In our BIPARTIZATION algorithm, we only exploit two properties of disk graphs: (i) triangle-free disk graphs are planar, and (ii)  $K_4$ -free disk graphs are  $c$ -degenerate for some constant  $c$ . In fact, pseudo-disk graphs also satisfy these two properties.

► **Fact 15** ([22]). *Triangle-free pseudo-disk graphs are planar.*

► **Fact 16.**  *$K_4$ -free pseudo-disk graphs are  $c$ -degenerate for some constant  $c$ .*

**Proof.** We show that any  $K_r$ -free pseudo-disk graph of  $n$  vertices only has  $O(rn)$  edges, which implies the fact. Let  $G$  be a  $K_r$ -free pseudo-disk graph realized by a set  $\mathcal{S}$  of pseudo-disks. We say an edge  $(S, S')$  of  $G$  is an *inclusion edge* if  $S \subseteq S'$  or  $S' \subseteq S$ . We first observe that  $G$  has  $O(rn)$  inclusion edges. Indeed, a pseudo-disk  $S \in \mathcal{S}$  cannot be contained in  $r - 1$  (or more) other pseudo-disks in  $\mathcal{S}$ , for otherwise there is a copy of  $K_r$  in  $G$ . Thus, if we charge every inclusion edge  $(S, S')$  to the smaller one of  $S$  and  $S'$ , every pseudo-disk is charged at most  $r - 2$  times. This implies that  $G$  has  $O(rn)$  inclusion edges. Now we bound the number of other edges in  $G$ . Note that if  $(S, S')$  is a non-inclusion edge in  $G$ , then the boundaries of  $S$  and  $S'$  intersect. So it suffices to bound the total number of intersection points of the boundaries of the pseudo-disks in  $\mathcal{S}$ . The depth of an intersection point  $x$  is the number of pseudo-disks in  $\mathcal{S}$  containing  $x$ . It is well-known that in a set of  $n$  pseudo-disks, the number of boundary intersection points of depth at most  $d$  is bounded by  $O(dn)$  [21]. Since  $G$  is  $K_r$ -free, every intersection point is of depth at most  $r$ . Thus, the total number of boundary intersection points is  $O(rn)$ , implying that  $G$  has  $O(rn)$  edges. ◀

Therefore, our algorithm directly generalizes to pseudo-disk graphs.

► **Theorem 3.** *There exists a polynomial-time  $(3 - \alpha)$ -approximation algorithm for BIPARTIZATION on the class of pseudo-disk graphs, for some constant  $\alpha > 0$ .*

Next, we observe that our techniques apply to not only the specific problem of BIPARTIZATION. In fact, it works for a wide class of vertex-deletion problems on (pseudo-)disk graphs. Recall that in a vertex-deletion problem, the goal is to delete a minimum set  $S$  of vertices from a graph  $G$  such that  $G - S$  satisfies some desired property  $\mathbf{P}$ . In BIPARTIZATION, the property  $\mathbf{P}$  is “being bipartite”. Our technique applies to any vertex-deletion problem that is (i) hereditary, i.e., if a graph satisfies  $\mathbf{P}$  then all its induced subgraphs also satisfy  $\mathbf{P}$ , and (ii) triangle-conflicting, i.e., a graph satisfies  $\mathbf{P}$  only if it is triangle-free.

► **Theorem 17.** *If a hereditary and triangle-conflicting vertex-deletion problem admits a  $(3 - \delta)$ -approximation algorithm on the class of planar graphs for some  $\delta > 0$ , then it admits a  $(3 - \alpha)$ -approximation algorithm on the class of (pseudo-)disk graphs for some  $\alpha > 0$ .*

**Proof.** We just replace the PLANARBIP sub-routine in Algorithm 1 with the  $(3 - \delta)$ -approximation algorithm for the problem on planar graphs. As one can easily verify, our analysis only depends on the fact that the vertex-deletion problem is hereditary and triangle-conflicting. Thus, the same analysis shows that this is a  $(3 - \alpha)$ -approximation algorithm for the problem on (pseudo-)disk graphs. ◀

Well-studied instances of hereditary and triangle-conflicting vertex-deletion problems (other than BIPARTIZATION) include VERTEX COVER, FEEDBACK VERTEX SET, TRIANGLE HITTING, etc. Most of these problems already have  $(3 - \delta)$ -approximation algorithms on disk graphs, and some of them do not have known  $(3 - \delta)$ -approximation algorithms on planar graphs. Thus, at this point, we can only obtain interesting results for BIPARTIZATION. However, we believe that this is not the full power of Theorem 17. To provide some evidences, let us consider a vertex-deletion problem, PLANARIZATION&BIPARTIZATION, in which the desired property  $\mathbf{P}$  is “being planar and bipartite”. This problem is clearly hereditary and triangle-conflicting. On planar graphs, it is equivalent to BIPARTIZATION and thus admits a  $(3 - \delta)$ -approximation algorithm. Therefore, Theorem 17 gives a  $(3 - \alpha)$ -approximation algorithm for PLANARIZATION&BIPARTIZATION on (pseudo-)disk graphs. Although this problem itself is somehow artificial and not well-studied, it reveals that Theorem 17 could possibly have further applications in the future.

---

## Abstract

A linearly ordered (LO)  $k$ -colouring of a hypergraph assigns to each vertex a colour from the set  $\{0, 1, \dots, k - 1\}$  in such a way that each hyperedge has a unique maximum element. Barto, Batistelli, and Berg conjectured that it is NP-hard to find an LO  $k$ -colouring of an LO 2-colourable 3-uniform hypergraph for any constant  $k \geq 2$  [STACS'21] but even the case  $k = 3$  is still open. Nakajima and Živný gave polynomial-time algorithms for finding, given an LO 2-colourable 3-uniform hypergraph, an LO colouring with  $O^*(\sqrt{n})$  colours [ICALP'22] and an LO colouring with  $O^*(\sqrt[3]{n})$  colours [ACM ToCT'23]. Very recently, Louis, Newman, and Ray gave an SDP-based algorithm with  $O^*(\sqrt[5]{n})$  colours. We present two simple polynomial-time algorithms that find an LO colouring with  $O(\log_2(n))$  colours, which is an exponential improvement.

## 1 Introduction

Given a graph  $G$ , the *graph  $k$ -colouring* problem asks to find a colouring of the vertices of  $G$  by colours from the set  $\{0, 1, \dots, k - 1\}$  in such a way that no edge is monochromatic. The *approximate graph colouring problem* asks, given a  $k$ -colourable graph  $G$ , to find an  $\ell$ -colouring of  $G$ , where  $\ell \geq k$ . For  $k = 3$ , the state-of-the-art results are NP-hardness of the case  $\ell = 5$  [2] and a polynomial-time algorithm for finding a colouring with  $\ell = O(n^{0.19747})$  colours, where  $n$  is the number of vertices of the input graph  $G$  [9]. For non-monochromatic

colourings of hypergraphs, it is known that finding an  $\ell$ -colouring of a  $k$ -colourable  $r$ -uniform hypergraph is NP-hard for any constant  $\ell \geq k \geq 2$  and  $r \geq 3$  [7], and also some positive results are known for colourings with super-constantly many colours, e.g. [11, 10, 6].

A new variant of hypergraph colourings was identified in [1]. Given a 3-uniform hypergraph  $H$ , a colouring of the vertices of  $H$  with colours from the set  $\{0, 1, \dots, k-1\}$  is called a *linearly ordered (LO)  $k$ -colouring* if every edge  $e$  of  $H$  satisfies the following: if two vertices of  $e$  have the same colour then the third colour is larger. More generally, a colouring of a hypergraph  $H$  is an LO colouring if every edge of  $H$  has a unique maximum colour. (Note that the two definitions coincide for 3-uniform hypergraphs.) Barto et al. conjectured that finding an LO  $\ell$ -colouring of a 3-uniform hypergraph that admits an LO  $k$ -colouring is NP-hard for every constant  $\ell \geq k \geq 2$  [1] but even the case  $k = 2$  and  $\ell = 3$  is open. Nakajima and Živný established NP-hardness for some regimes of the parameters  $k, \ell, r$  [13, 14] and, very recently, Filakovský et al. [8] showed NP-hardness of the case  $k = 3, \ell = 4, r = 3$ . More importantly for this paper, Nakajima and Živný also considered finding an LO  $f(n)$ -colouring of an LO 2-colourable 3-uniform hypergraph with  $n$  vertices and presented polynomial-time algorithms with  $f(n) = O(\sqrt{n \log \log n} / \log n)$  [13] and  $f(n) = O(\sqrt[3]{n \log \log n} / \log n)$  [14]. Very recently, Louis, Newman, and Ray [12] have given a polynomial-time SDP-based algorithm with  $f(n) = O^*(\sqrt[5]{n})$  colours.

As our main result, we improve their results by an exponential factor.

► **Theorem 1.** *There is an algorithm which, if given a 3-uniform hypergraph  $H$  with  $n \geq 4$  vertices and  $m$  edges that admits an LO 2-colouring, finds an LO  $\log_2(n)$ -colouring of  $H$  in time  $O(n^3 + nm)$ .*

In fact we present two different algorithms that return colourings using  $O(\log n)$  colours. Both are based on solving the natural system of linear equations implied by the existence of an LO 2-colouring. In one case, the system is solved modulo 2, and in the other case, the system is solved over the rationals.

While the  $H$  which we are given as input is 3-uniform, we will need the notion that follows in greater generality; hence we define it for general hypergraphs. For each edge  $\{x_1, \dots, x_r\}$  of  $H$ , we write an equation  $v_{x_1} + \dots + v_{x_r} = 1$  where we initially use equality modulo 2 but as stated above we later use the same system over the rational numbers. Let  $A$  be this set of equations, written as a matrix with  $m$  rows and  $n$  columns. (Note that  $A$  is the *incidence matrix* of  $H$ .) Thus  $v$  is a solution if and only if  $Av = 1^m$ . Clearly a valid LO 2-colouring gives one solution but in the general case, the system has a large dimensional affine space as its set of solutions and the desired solution is hard to find.

## 2 Algorithm based on equations modulo 2

In this section all linear equations are taken modulo 2. For the following, given a set  $S$  of positive integers, an  $S$ -uniform hypergraph is a hypergraph where all edges have sizes taken from  $S$ . We first prove the following subprocedure of the main algorithm.

► **Lemma 2.** *There is an algorithm which, if given a  $\{2, 3\}$ -uniform hypergraph  $H$  with  $n$  vertices and  $m$  edges that admits an LO 2-colouring and such that the implied linear system of equations  $Av = 1^m$  does not fix the value of any variable, outputs a subset  $T$  of vertices that intersects edges of size three in zero or two vertices and edges of size two in exactly one vertex. Moreover, we have  $|T| \geq n/2$ . The algorithm runs in  $O(n^3 + nm)$  time.*

**Proof.** We first describe a randomised version of our algorithm, and then derandomise it. The set of solutions to  $Av = 1^m$  is an affine space and hence a generic solution can be written as  $v = v^0 + \sum_{i=1}^r a_i v^i$  for a basic solution  $v^0$ , linearly independent solutions to the homogeneous system  $v^i$ , and field elements (in this case bits)  $a_i$ . The fact that no variable is fixed implies that for each vertex  $x$  there is some positive  $i$  such that  $v_x^i = 1$ .

For the randomised algorithm choose  $a_1, \dots, a_r$  to be independent identically distributed uniformly random bits, and set  $T$  to be the set of variables  $x$ , such that  $v_x = 0$ . Clearly  $T$  satisfies the conclusion of the lemma as in each edge we have an odd number of ones. Since for every vertex  $x$  there exists positive  $i$  such that  $v_x^i$ , due to the influence of  $a_i v_x^i$  we see that  $x$  is included in  $T$  with probability  $1/2$ . Thus, on average  $T$  contains half the vertices.

Now, we derandomise this algorithm using the method of conditional expectations. Go through the variables  $a_i$  in increasing order and fix its value once and for all. Fixing the value of  $a_i$  determines the value of some  $v_x$  while other values remain undetermined. For each value being determined  $v_x^i = 1$  and hence one value of  $a_i$  gives the final value 0 and the other gives final value 1. Set  $a_i$  such that at least half the determined values are 0. After we have fixed all  $a_i$  this way, we have a final solution with at least  $n/2$  zeroes.

The bottleneck of the running time of this algorithm is solving the linear system of equations. This can be done in the advertised running time since every equation has  $O(1)$  entries. ◀

**Proof of Theorem 1.** As a preliminary step, we eliminate any variable determined by the system  $Av = 1^m$ . Note that if the colour of a vertex is determined by the system  $Av = 1^m$ , then this vertex must have that same colour in *all* LO 2-colourings. Fix these variables once and for all and eliminate them from the equation system. For all vertices that have been given the colour 1, we set the colours of the two other vertices in all of its edges to be 0. This process of identifying fixed variables and eliminating them is then repeated until the system  $Av = 1^m$  contains no variables fixed to a constant. At any fixed point of this process, for every edge, either all vertices in that edge are fixed (and the edge has a unique maximum as required), or exactly one vertex in it is fixed to 0.

Now, remove all coloured vertices from the hypergraph  $H$ , shrinking the edges they belonged to. The remaining hypergraph will no longer be 3-uniform, but importantly it will still be LO 2-colourable. Our goal is still to LO colour the remaining hypergraph, since any edge partially coloured by the preliminary step above must have had exactly one vertex  $v$  fixed to 0; and hence, if we LO colour the edge that resulted from removing  $v$ , this leads to an LO colouring of the original hypergraph when  $v$  is assigned 0.

Consider the following algorithm, where  $i$  starts at 0.

1. If the hypergraph  $H$  has at most, say, 20 vertices, find an LO-colouring of  $H$  by brute force using colours  $i$  and  $i + 1$ . (It exists since  $H$  is LO 2-colourable.)
2. Otherwise, find the subset  $T$  guaranteed by Lemma 2.
3. Colour the vertices in  $T$  by colour  $i$ . Remove the vertices in  $T$  from  $H$ . Remove all edges that intersect  $T$  from  $H$ . Increment  $i$  by 1.
4. Repeat.

Note that  $|T| \geq n/2$  and thus within  $-4 + \log_2 n$  repetitions we reach the first case. Each step adds one colour and we get two additional colours from the final brute-force colouring for a total of at most  $\log_2 n$  colours. The output is correct as the first time some vertex in an edge is coloured, for edges with three vertices exactly one more vertex in the same edge is coloured at the same time, and for edges with two vertices only that vertex is coloured at that time. The remaining vertex is given a higher colour and hence the edge is correctly coloured. For the time complexity, we again note that it is dominated by the time needed to solve the linear system of equations. ◀

## 7:4 A Logarithmic Approximation of Linearly-Ordered Colourings

Note that the number 20 selected above can be increased to any number that is  $O(\log n)$  and the algorithm remains polynomial time (since we must compute the colouring for a subgraph of this size by brute force). If we stop the algorithm at  $B$  vertices, then we save  $\log B + \Theta(1)$  colours, since this is how many colours the algorithm would have used to colour the last  $B$  vertices. By setting  $B = \Theta(\log n)$ , we can thus save  $\Theta(1) + \log \log n$  colours while keeping run time of the algorithm polynomial in  $n$ .

A slight variant can be obtained by instead counting the number of remaining edges with no coloured vertex. Once we have no more such vertices, we colour all remaining vertices with the next colour. For such edge, a random solution  $v$  gives the four sets of values  $(0, 0, 1)$ ,  $(0, 1, 0)$ ,  $(1, 0, 0)$  and  $(1, 1, 1)$  with equal probabilities. Thus the number of edges decreases, on average, by a factor 4 for each iteration. (Note that all the edges of size 2 are solved in the first iteration, so there is no need to count them.) It is easy to achieve this deterministically by conditional expectations. We state the conclusion as a theorem.

► **Theorem 3.** *There is an algorithm which, if given a 3-uniform hypergraph  $H$  with  $n$  vertices and  $m \geq 1$  edges that admits an LO 2-colouring, finds an LO  $(2 + \frac{1}{2} \log_2(m))$ -colouring of  $H$  in time  $O(n^3 + nm)$ .*

► **Remark 4.** Our algorithm has some similarity with algorithms for *temporal* CSPs [3]. Note that an LO  $\omega$ -colouring (which means an LO-colouring, but with no restriction on the number of colours) is a temporal CSP; to solve it, one finds a subset that could be the smallest colour (by solving mod-2 equations as above), sets that colour, then continues recursively. The difference is that for an LO  $\omega$ -colouring one does not care about the number of colours, so one can find any nonempty set of vertices to set the lowest colour to, whereas in our problem we are trying to find a large set of this kind. We note that the algorithm of [14] also uses this approach when setting “small colours”.

► **Remark 5.** We remark that the subprocedure of our algorithm computes the exclusive or of two vectors of bits. Thus the algorithm runs very fast in practice – on most architectures hundreds of operations of this kind are done at one time by (i) packing the bits within a larger word and (ii) using SIMD instructions.

### 3 Algorithm using $\mathbb{Q}$

In this section we present a more complicated algorithm which uses more colours. This might seem pointless, and indeed it might be. On the other hand the ideas used are slightly different and hence there might be situations where the ideas of this section can turn out to be useful. It is also curious to see that we can use the same system of linear equations, now over the rationals, in a rather different way. The algorithm here is in fact essentially saying that we can always use the unbalanced case of [12]. As this eliminates many complications and in particular makes it possible to completely avoid any semi-definite programming, we state all facts needed in the current section rather than refer to the very similar statements in [12]. As already stated, all arithmetic in this section is over the rational numbers. In this situation, no variables can be determined as we can set  $v^0$  to have all coordinates equal to  $1/3$ .

We study the homogeneous system  $Av = 0$  and by the assumption of LO 2-colourability it has a solution,  $w$ , with coordinates either  $-\frac{1}{3}$  or  $\frac{2}{3}$ . Let us first show how solutions over the rational numbers can be used to find LO-colourings. This is the same lemma used in the unbalanced case of [12].

► **Lemma 6.** *Suppose we have a solution,  $u$ , to the homogeneous system where  $M$  is the maximal value of the absolute value of a coordinate and  $m > 0$  is the minimal absolute value. Then we can LO-colour with  $2 + \log_2(M/m)$  colours.*

**Proof.** For notational convenience let us instead require that the minimal colour in each edge should be unique. We can simply reverse the order of the colours at the end. By scaling we can assume  $M = 1$ . We use even colours for positive coordinates and we give  $x$  the colour  $2\ell$  if  $v_x$  is at most  $2^{-(2\ell-1)}$  and strictly larger than  $2^{-(2\ell+1)}$ . For negative coordinates we use  $2\ell + 1$  as the colour if  $v_x$  is between  $-2^{-2\ell}$  (inclusive) and  $-2^{-(2\ell+2)}$  (non-inclusive). Let us verify that this gives a correct colouring.

Take an edge  $(x, y, z)$  and suppose both  $x$  and  $y$  get the same colour  $2\ell$ . Then by the linear equation of the edge  $v_z < -2^{-2\ell}$  and thus  $z$  has a colour below  $2\ell$ . The case of two vertices of odd colour is similar and as the bound on the number of colours is immediate, the lemma follows. ◀

Let us choose the vectors  $(v^i)_{i=1}^r$  giving the solutions to the homogeneous system to be of unit length and orthogonal. Define  $u = \sum_{i=1}^r y_i v^i$  where  $y_i$  are independent normal variables with mean 0 and standard deviation 1. The length of  $u$  is very close to  $\sqrt{r}$  but to be crude we use that  $E[\|u\|^2] = r$  and hence with probability  $\frac{3}{4}$  the length of  $u$  is at most  $2\sqrt{r}$ .

Let  $c^j = (v_j^1, v_j^2, \dots, v_j^r)$  be the vector of dimension  $r$  given by the  $j$ th coordinates of each vector  $v^i$ . Using this notation we see that the  $j$ th coordinate of  $u$  is a normal variable with standard deviation  $\|c^j\|$ . Recall that  $w$  is our assumed solution to  $Av = 0$  with all coordinates either  $-\frac{1}{3}$  or  $\frac{2}{3}$ . We can write  $w = \sum_{i=1}^r a_i v^i$  for some numbers  $a_i$ , and by orthonormality  $\|a\| = \|w\|$  which is at most  $\frac{2}{3}\sqrt{n}$ . As

$$|w_j| = |(c^j, a)| \leq \|c^j\| \|a\|,$$

using that  $|w_j|$  is at least  $\frac{1}{3}$  we conclude that

$$\|c^j\| \geq 1/(2\sqrt{n}).$$

The probability that a normal variable with standard deviation  $\sigma$  is of absolute value at most  $\delta$  is at most  $2\delta/(\sqrt{2\pi}\sigma)$ . We conclude that for a suitable constant  $d$  the probability that  $|u_j|$  is below  $dn^{-3/2}$  is at most  $1/(2n)$ . Thus with probability at least  $1/2$  the absolute value of any coordinate of  $u$  is at least  $dn^{-3/2}$ . Thus with probability at least  $\frac{1}{4}$ , we can apply Lemma 6 with  $M = 2n^{1/2}$  and  $m = dn^{-3/2}$  and we conclude.

► **Theorem 7.** *Using the system of linear equations over the rational numbers we can find, with probability at least  $\frac{1}{4}$  and in polynomial time, an LO-colouring with  $O(1) + 2\log_2 n$  colours.*

This algorithm is less efficient compared to the algorithm of the previous section. The main computational cost is still solving a linear system but this is more complicated over the rational numbers as coefficients are likely to grow. Our bound for the number of colours is also worse. Heuristically one could hope to have the ratio of the smallest and largest coordinate of  $u$  to be  $\Theta(n)$  but not better. Thus it is possible that we could eliminate the multiplicative constant 2 in the theorem but to get substantially fewer than  $\log n$  colours by this method sounds unlikely.

As a final observation in this section let us note that defining a colouring by the sign of the vector  $u$  we get a standard (non-monochromatic) 2-colouring of the hypergraph. This gives an alternative algorithm to that of [5, 4].

#### 4 Concluding remarks

Our algorithms indicate that LO 2-colouring is quite different from many other colouring problems. The key property that we use in our algorithm is that the constraint implies a linear constraint. The analysis of the algorithms also heavily relies on the fact that we study 3-uniform hypergraphs.

It is tempting to think that the proposed methods would extend to other constraint satisfaction problems where we are guaranteed that a solution must satisfy a linear constraint. We have so far been unable to find an interesting such example.

## Abstract

Speed-robust scheduling is the following two-stage problem of scheduling  $n$  jobs on  $m$  uniformly related machines. In the first stage, the algorithm receives the value of  $m$  and the processing times of  $n$  jobs; it has to partition the jobs into  $b$  groups called bags. In the second stage, the machine speeds are revealed and the bags are assigned to the machines, i.e., the algorithm produces a schedule where all the jobs in the same bag are assigned to the same machine. The objective is to minimize the makespan (the length of the schedule). The algorithm is compared to the optimal schedule and it is called  $\rho$ -robust, if its makespan is always at most  $\rho$  times the optimal one.

Our main result is an improved bound for equal-size jobs for  $b = m$ . We give an upper bound of 1.6. This improves previous bound of 1.8 and it is almost tight in the light of previous lower bound of 1.58. Second, for infinitesimally small jobs, we give tight upper and lower bounds for the case when  $b \geq m$ . This generalizes and simplifies the previous bounds for  $b = m$ . Finally, we introduce a new special case with relatively small jobs for which we give an algorithm whose robustness is close to that of infinitesimal jobs and thus gives better than 2-robust for a large class of inputs.

## 1 Introduction

Speed-robust scheduling is a two-stage problem that was introduced by Eberle *et al.* [4]. The eventual goal is to schedule on  $m$  uniformly related machines, however their speeds are not known at the beginning. In the first stage, the algorithm receives the value of  $m$  and the processing times of  $n$  jobs; it has to partition the jobs into  $b$  groups called bags. In the second stage, the machine speeds are revealed and the bags are assigned to the machines, i.e., the algorithm produces a schedule where all the jobs in the same bag are assigned to the same machine. The objective is to minimize the makespan (the length of the schedule). The algorithm is compared to the optimal schedule of the jobs on the machines with known speeds; it is called  $\rho$ -robust, if its makespan is always at most  $\rho$  times the optimal one.

This problem is motivated by situations like the following one. Suppose that you have  $n$  computational tasks that you want to solve. You have a computational cluster available, but with unknown parameters. You only know that there will be (at most)  $m$  machines available on the cluster. You do not know anything about the performance of the machines – some of the machines might be faster than others; you only know that there will be (at most)  $m$

machines available on the cluster. Furthermore, you can submit at most  $b$  different tasks to the cluster. Hence you will have to partition your  $n$  tasks into at most  $b$  groups. One such group will then have to be executed on one machine. The cluster will then schedule the groups optimally, knowing the speeds of the machines, and minimize the makespan.

Studying uncertainty in scheduling has a long history. In the classical online scheduling [10], the machine environment is usually fixed and the uncertainty stems from job arrivals. Considering uncertainty in the machine environment is less frequent. One early example is the work of Csanád and Noga [7], where additional machines can be bought for a certain cost. A substantial body of research with changing machine speeds is the area of dynamic speed scaling, in particular in the context of minimizing the power consumption, see [1, 9]; however, note that here the changing speeds are not a part of the adversarial environment but used by the algorithm to its advantage. Another direction considers online scheduling with unavailability periods [3]. One-machine scheduling with adversarially changing machine speed was considered in [5] in the context of unreliable machines.

Completely reversing the scenario with all jobs known from the beginning but uncertain machine environment is a recent new model introduced by Stein and Zhong [11] and Eberle et al. [4], see Section 1.2.

### 1.1 Formal definitions

Formally, in the first stage, we receive three positive integers  $n, m, b$  and  $n$  non-negative real numbers  $p_1, \dots, p_n$  representing the processing times of  $n$  jobs. The total processing time is denoted  $P = \sum_{j=1}^n p_j$ . The output of our first-stage algorithm is a mapping  $B: \{1, \dots, n\} \rightarrow \{1, \dots, b\}$ , where  $B(j) = i$  represents the fact that the job  $j$  was assigned to the bag  $i$ . The sum of the processing times of all the jobs assigned to bag  $i$  the *size* of bag  $i$  and denoted  $a_i = \sum_{j: B(j)=i} p_j$ . The exact mapping  $B$  is not important for the second stage since the makespan depends only on the bag sizes.

In the second stage, we are given the bag sizes  $a_1, \dots, a_b$  and the previously unknown machine speeds  $s_1, \dots, s_m \geq 0$ , not all equal to 0. We partition the bag indices  $\{1, \dots, b\}$  into  $m$  sets  $M_1, \dots, M_m$ , representing the assignment to the  $m$  machines. Machine  $i$  then has a completion time  $C_i = (\sum_{j \in M_i} a_j) / s_i$ ; for  $s_i = 0$  we require  $M_i = \emptyset$  and set  $C_i = 0$ , i.e., machine of speed 0 does not accept any jobs. Finally,  $C_{\max} = \max_{i=1}^m C_i$  is the makespan, i.e., the length of the schedule.

Let  $C_{\max}^*$  denote the makespan of the adversary, who does not have to create bags and can assign jobs directly to machines. Alternatively and equivalently, the adversary also creates bags, but with the knowledge of the speeds already in the first stage.

We call a first stage algorithm  $\rho$ -robust if, for all possible inputs and for all possible choices of machine speeds, there exists a second-stage assignment of bags to machines such that  $C_{\max} \leq \rho \cdot C_{\max}^*$ . Intuitively, an algorithm is  $\rho$ -robust if it performs at most  $\rho$  times worse than the adversary.

The previous definition implicitly assumes that the second stage is solved optimally. This is reasonable, as the scheduling on uniformly related machines allows PTAS, see [6, 12], so the chosen (presumably optimal) second-stage solution can be replaced by an arbitrarily good approximation. Also, our proofs show that the second-stage algorithm can be implemented by efficient greedy algorithms without any loss of performance, once the optimal makespan or its approximation is known.

We call the special cases of the problem *sand*, *bricks*, *rocks* and *pebbles*. Sand, bricks, and rocks were introduced by Eberle et al. [4]. These words represent the types of jobs.

- Rocks can be any shape or size and represent jobs of arbitrary processing time. This is the most general setting.
- Bricks are all the same and represent jobs with equal processing times.
- Sand grains are very small and represent infinitesimally small processing times.
- Pebbles represent jobs that are relatively small compared to the average load of all machines. We call an instance of speed-robust scheduling  $q$ -pebbles if  $p_j \leq q \cdot \frac{P}{m}$  holds for all jobs  $j$ .

## 1.2 Previous results

The two-stage scheduling problem with uncertainty in the machine environment was introduced by Stein and Zhong [11]. They focused on the case of  $m$  identical machines where in the second stage some machine might fail and then do not process any tasks. This amounts to a special case of speed-robust scheduling where  $s_i \in \{0, 1\}$  for  $1 \leq i \leq m$ . They gave lower bounds of  $4/3$  for equal-size jobs (bricks) and  $(\sqrt{2} + 1)/2 \approx 1.207$  for infinitesimal jobs (sand). Their algorithms were later improved by Eberle *et al.* [4] to algorithms matching the lower bounds in both cases.

Our immediate predecessor, Eberle *et al.* [4], introduced the speed-robust scheduling for general speeds, i.e., on uniformly related machines. They studied mainly the case  $b = m$ , i.e., the case when the number of bags is equal to the number of machines. For this case they gave tight bounds for sand for every  $m$ , for large  $m$  the bound approaches  $e/(e - 1) \approx 1.58$ . For equal-size jobs (bricks), they have shown an upper bound of 1.8.

For the most general case of rocks, the strongest known result is the algorithm with the robustness factor at most  $1 + (m - 1)/b$ , which equals  $2 - 1/m$  for  $b = m$ , given also by Eberle *et al.* [4]. It remains an interesting open problem to improve this bound, in particular to give an upper bound  $2 - \varepsilon$  for rocks and  $b = m$ .

## 1.3 Our results

We now describe our results and compare them to the previous ones in each of the scenarios.

**Sand.** For sand, we give matching lower and upper bounds for any  $b$  and  $m$ . Namely, for  $b \geq m$  we give an optimal algorithm which is  $\bar{\rho}(m, b)$ -robust for

$$\bar{\rho}(m, b) = \frac{m^b}{m^b - (m - 1)^b} = \frac{1}{1 - \left(1 - \frac{1}{m}\right)^b}. \quad (1.1)$$

This matches the results of Eberle *et al.* [4] who gave an algorithm with the robustness factor equal to  $\bar{\rho}(m, b) \leq e/(e - 1) \approx 1.58$  for  $b = m$ , generalizes them to arbitrary  $b \geq m$  and significantly simplifies the proof.

An interesting case is when the number of bags is a constant multiple of  $m$ . For a fixed  $\alpha \geq 1$  and  $b = \alpha m$ , our bound approaches  $1/(1 - e^{-\alpha})$  from below for a large  $m$ . For example, doubling the number of bags to  $b = 2m$  decreases the robustness factor from 1.58 to 1.16.

If  $b < m$ , the second-stage algorithm uses only the  $b$  fastest machines, so we can decrease  $m$  to  $m' = b$  and tight results with robustness factor  $\bar{\rho}(m', b) = \bar{\rho}(b, b)$  follow already from [4].

**Pebbles.** For the new case of  $q$ -pebbles and  $b \geq m$ , we give a  $(\bar{\rho}(m, b) + q)$ -robust algorithm. For  $p < 0.42$ , this gives an algorithm with the robustness factor below 2, i.e., below the currently strongest known upper bound for rocks.

**Bricks.** As our main result, we give a 1.6-robust algorithm for bricks for  $b = m$ . This improves the bound of 1.8 from Eberle *et al.* [4].

Furthermore, as a direct application of our results for pebbles we give a  $(\bar{\rho}(m, b) + m/n)$ -robust algorithm for any  $n$  and  $b \geq m$ . This improves and generalizes the  $((1 + m/n)\bar{\rho}(m, m))$ -robust algorithm for  $b = m$  given by Eberle *et al.* [4]. Namely, we improve the multiplicative factor of  $(1 + m/n)$  to only an additive term of  $m/n$ .

**Structure of the paper.** We give some general preliminaries in Section 2. We give the results for sand and pebbles in Sections 3 and 4. We focus on our main result for bricks in Section 5. Some small cases need computer verification or tabulation of parameters, results of these are given in the full version of the paper on arXiv [8].

## 2 Preliminaries

We assume that the processing times, the machine speeds, and the bag sizes are always listed in a non-increasing order.

In the rest of this paper, we will make two assumptions below that restrict the speeds to particular special cases. This is without loss of generality, leveraging the fact that the algorithm must commit the bag sizes in the first phase without knowing the speeds.

- The optimal makespan is equal to 1. This implies that the robustness factor is equal to the makespan of the algorithm.

Scaling all the speeds does not change the ratio of the makespans of our algorithm and the adversary. Thus for every instance of the problem, there exists another instance with  $C_{\max}^* = 1$  that differs only in the speeds and the ratio of makespans of our algorithm and the adversary remains the same. It follows that any first-stage algorithm that is  $\rho$ -robust for instances with  $C_{\max}^* = 1$  is  $\rho$ -robust for general instances, too.

- The sum of the processing times of all jobs equals to the sum of the speeds of all the machines, i.e.,  $P = \sum_{i=1}^m p_i = \sum_{i=1}^m s_i$ . In other words, the adversary is fully utilizing all the machines, and the completion time of all the machines with non-zero speed is equal to 1, using the previous assumption.

If there is some machine  $i$  with  $s_i > 0$  and completion time  $C_i^* < 1$  in the optimal schedule, we change its speed to  $s'_i = C_i^* s_i$ . This does not change the optimal makespan of the adversary and the makespan of the algorithm can only increase. Once again, it follows that any first-stage algorithm that is  $\rho$ -robust for these special instances is also  $\rho$ -robust for general instances.

For the second stage, typically, we use a simple greedy algorithm for the second stage instead of analyzing the optimal schedule. Technically, for an algorithm we need to know the optimal makespan (to modify the speeds appropriately, according to the assumptions above). However note that first we can approximate the makespan and second the algorithm is only used as a tool in the analysis.

For sand and pebbles we use Algorithm GREEDYASSIGNMENT (see below), a variant of the well-known LPT algorithm. It is parameterized by  $\rho$ , the robustness factor to be achieved. At the beginning, every machine is assigned a capacity equal to its speed multiplied by  $\rho$ . The algorithm then goes through all the bags from large to small, assigns them on the machine with the largest capacity remaining, and decreases the capacity appropriately. If the capacities remain non-negative at the end, the makespan of the created assignment is at most  $\rho$  since machine  $i$  has been assigned jobs of total processing times at most  $\rho s_i$ .

We use this to formulate the following sufficient condition for  $\rho$ -robustness of an algorithm which is instrumental in proving the upper bounds for sand and pebbles.

■ **Algorithm** GREEDYASSIGNMENT.

---

**Input:** bag sizes  $a_1 \geq \dots \geq a_b$ ; machine speeds  $s_1 \geq \dots \geq s_m$ ; desired robustness factor  $\rho$

**for**  $i \leftarrow 1$  **to**  $m$  **do**

$c_i \leftarrow \rho s_i$  ▷ Initialize the capacities of all machines

$M_i = \emptyset$  ▷ Initialize the assignment

**for**  $k \leftarrow 1$  **to**  $b$  **do**

$i \leftarrow$  index of a machine with the largest  $c_i$

$M_i \leftarrow M_i \cup \{k\}$  ▷ Assign bag  $k$  to machine  $i$

$c_i \leftarrow c_i - a_k$  ▷ Decrease the remaining capacity of the selected machine

**return**  $M_1, \dots, M_m$

---

▶ **Theorem 2.1.** *If a first-stage algorithm always produces bag sizes satisfying inequalities  $a_k \leq \frac{\rho P - \sum_{j=1}^{k-1} a_j}{m}$ , for all  $k = 1, \dots, b$ , then the algorithm is  $\rho$ -robust.*

**Proof.** Recall that we assume  $\sum_{i=1}^m s_i = P$ . We claim that the second-stage algorithm GREEDYASSIGNMENT produces an assignment with makespan at most  $\rho$ . We only need to show that there is a machine with capacity at least  $a_k$  when assigning the  $k$ th bag. The initial total capacity was  $\rho P$  and was already decreased by  $\sum_{j=1}^{k-1} a_j$  at the time of assigning bag  $a_k$ . It follows that the remaining capacity is equal to  $\rho P - \sum_{j=1}^{k-1} a_j$  and thus there exists a machine with capacity at least  $(\rho P - \sum_{j=1}^{k-1} a_j)/m \geq a_k$ . ◀

**3 Sand**

Intuitively, the case of sand corresponds to the limit case where  $n$  is large and all the jobs are small and have equal sizes. One can view this as an infinite number of infinitesimal jobs.

More formally, we are given just  $m, b$ , and  $P$  as an input of the first stage. The result of the first stage are  $b$  non-negative reals  $a_1, \dots, a_b$  whose sum equals  $P$ . The formulation of the second stage remains the same.

The model of infinitesimally small jobs resembles preemptive scheduling. In the optimal algorithm for preemptive scheduling [2], one needs to maintain the loads of machines in a geometric sequence with common ratio  $m/(m-1)$  for  $m$  machines, roughly speaking. The proofs for sand show that here the same geometric sequence is also crucial, in particular it is used for the bag sizes in the algorithm. We now describe the sequence and state its properties useful both for the upper and lower bounds.

We define  $U = m^b$ ,  $L = m^b - (m-1)^b$  and  $t_j = m^{b-j}(m-1)^{j-1}$  for  $j \in \{1, \dots, b\}$ .

Observe that equation (1.1) defines  $\bar{\rho}$  as  $\bar{\rho}(m, b) = U/L$ .

▶ **Lemma 3.1.** *For all  $k = 1, \dots, b$ , it holds that  $\sum_{j=1}^k t_j = U - (m-1)t_k$ . In particular,  $\sum_{j=1}^b t_j = U - (m-1)^b = L$ .*

**Proof.** We proceed by induction on  $k$ . The lemma holds for  $k = 1$  since  $U = mt_1$  and thus  $t_1 = U - (m-1)t_1$ . Now suppose it holds for  $k$ . We can derive

$$\sum_{j=1}^{k+1} t_j = U - (m-1)t_k + t_{k+1} = U - m^{b-k}(m-1)^k + m^{b-k-1}(m-1)^k = U - (m-1)t_{k+1}$$

which completes the induction step. ◀

■ **Figure 3.1** An example of bag sizes chosen for  $m = 2$  and  $b = 4$ .

To get some intuition behind the algorithm for sand, it might be useful to consider the case  $m = 2$ , see Figure 3.1. Suppose that  $P = L = 2^b - 1$ , choose the bag sizes  $a_k = t_k = 2^{b-k}$ . For  $m = 2$  the sizes are powers of two, so it is easy to see that we can achieve the robustness ratio of  $1 + 1/(2^b - 1) = 2^b/(2^b - 1)$  as follows: The adversary chooses any speeds  $s_1, s_2$  such that  $s_1 + s_2 = P = 2^b - 1$ . The capacities of the machines (as in GREEDYASSIGNMENT) then satisfy  $c_1 + c_2 = 2^b$  and thus  $\lfloor c_1 \rfloor + \lfloor c_2 \rfloor \geq 2^b - 1$ . We can express  $\lfloor c_1 \rfloor$  in binary, assign the corresponding bags on the first machine and the remaining bags to the second machine.

### 3.1 Upper bound

We use a different approach than Eberle et al. [4] for the proof of the upper bound. We choose the same bag sizes (for  $b = m$ ) but we simplify the proof by use of Theorem 2.1. Algorithm SAND describes the bag sizes. Note that the sum of bag sizes produced by SAND is  $P$ , using Lemma 3.1.

■ **Algorithm** SAND.

---

**Input:** number of bags  $b$ ; number of machines  $m$ ; total amount of sand  $P$   
 $L \leftarrow m^b - (m - 1)^b$   
**for**  $j \leftarrow 1$  to  $b$  **do**  $a_j \leftarrow t_j \frac{P}{L}$   
**return**  $a_1, a_2, \dots, a_b$

---

► **Theorem 3.2.** *Algorithm SAND is  $\bar{\rho}(m, b)$ -robust for sand, for  $\bar{\rho}$  defined by (1.1).*

**Proof.** We assume  $P = L$  since it does not change the ratio of our makespan and the makespan of the adversary. Under this assumption, SAND produces bag sizes  $a_k = t_k$ .

It is sufficient to show that the bag sizes produced by SAND satisfy the condition of Theorem 2.1. Let us prove the  $k$ th inequality in the assumption of the theorem. We have

$$\bar{\rho}(m, b)P - \sum_{j=1}^{k-1} a_j = \frac{U}{L}L - \sum_{j=1}^{k-1} t_j = U - \sum_{j=1}^k t_j + t_k.$$

According to Lemma 3.1, we can simplify the right-hand side as follows.

$$U - \sum_{j=1}^k t_j + t_k = U - (U - (m - 1)t_k) + t_k = mt_k = ma_k.$$

The  $k$ th inequality in the assumption of Theorem 2.1 follows, in fact it holds with equality.

Theorem 2.1 now implies that there exists an assignment with makespan at most  $\bar{\rho}(m, b)$ . ◀

### 3.2 Lower bound

The following proof is a slightly modified and generalized version of the proof by Eberle et al. [4]. The main difference is that we do not require the number of bags and machines to be the same.

► **Theorem 3.3.** *No deterministic algorithm for sand may have a robustness factor smaller than  $\bar{\rho}(m, b)$ , for  $\bar{\rho}$  defined by (1.1).*

**Proof.** Let us without loss of generality assume  $P = U$  (be aware that we assumed  $P = L$  in the proof of the upper bound). Let us denote the chosen bag sizes by  $a_1 \geq \dots \geq a_b$ . We will restrict the adversary to  $b$  different speed configurations indexed by  $k$ , where

$$\mathcal{S}_k = \{s_1 = U - (m - 1)t_k, s_2 = t_k, s_3 = t_k, \dots, s_m = t_k\}.$$

See Figure 3.2 for an example. Note that the sum of machine speeds is equal to  $U$  in every configuration and hence the makespan of the adversary is indeed 1 as we always assume. In every speed configuration, there are  $m - 1$  slow machines and one fast machine, since

$$s_1 = U - (m - 1)t_k = \sum_{j=1}^k t_j \geq t_k.$$

■ **Figure 3.2** An example of speed configurations considered by the adversary for  $m = 2$  and  $b = 4$ .

Let  $k_{\max}$  be the largest index such that  $a_{k_{\max}} \geq \frac{U}{L}t_{k_{\max}}$ . This index must exist since

$$\sum_{j=1}^b a_j = U = \frac{U}{L}L = \frac{U}{L} \sum_{j=1}^b t_j.$$

Now let the adversary choose the speed configuration  $\mathcal{S}_{k_{\max}}$ . We distinguish two cases depending on the bag assignment in the second stage.

**Case 1.** At least one of the bags  $a_1, \dots, a_{k_{\max}}$  is assigned to a slow machine. The makespan is at least the completion time of this machine which is at least

$$\frac{a_j}{t_{k_{\max}}} \geq \frac{a_{k_{\max}}}{t_{k_{\max}}} \geq \frac{U}{L}.$$

## 8:8 Speed-Robust Scheduling Revisited

**Case 2.** All of the bags  $a_1, \dots, a_{k_{\max}}$  are assigned to the fast machine. Total size of the bags assigned to the fast machine is at least

$$\sum_{j=1}^{k_{\max}} a_j = U - \sum_{j=k_{\max}+1}^b a_j.$$

By definition of  $k_{\max}$  it holds that  $a_j < \frac{U}{L}t_j$  for  $j > k_{\max}$  and we can bound

$$U - \sum_{j=k_{\max}+1}^b a_j \geq U - \frac{U}{L} \sum_{j=k_{\max}+1}^b t_j.$$

Since  $\sum_{j=1}^b t_j = L$ , we can rearrange the right-hand side as follows

$$U - \frac{U}{L} \sum_{j=k_{\max}+1}^b t_j = U - \frac{U}{L} \left( L - \sum_{j=1}^{k_{\max}} t_j \right) = \frac{U}{L} \sum_{j=1}^{k_{\max}} t_j.$$

By Lemma 3.1 it holds that

$$\frac{U}{L} \sum_{j=1}^{k_{\max}} t_j = \frac{U}{L} (U - (m-1)t_{k_{\max}}) = \frac{U}{L} s_1$$

due to the choice of  $s_1$  in the configuration  $\mathcal{S}_{k_{\max}}$ . Thus the makespan would be at least  $U/L = \bar{\rho}(m, b)$ .

The makespan was at least  $U/L$  in both cases, hence the robustness factor is at least  $U/L = \bar{\rho}(m, b)$  and the theorem follows.  $\blacktriangleleft$

### 4 Pebbles

Recall that an instance of our problem is called  $q$ -pebbles if the processing times satisfy

$$p_j \leq q \cdot \frac{P}{m} = q \cdot \frac{\sum_{\ell=1}^n p_\ell}{m}.$$

This definition might seem a bit unnatural at the first glance, but there is a very intuitive formulation. The expression  $\frac{P}{m}$  represents the *average load of a machine*. The definition of pebbles says that the processing times are relatively small compared to the average load of all machines.

Without loss of generality we assume in this section that the sum of processing times is  $P = m$ . This transforms the condition for  $q$ -pebbles from the definition into

$$p_j \leq q,$$

which is easy to work with.

We use similar ideas as in the optimal algorithm for sand. Recall the condition of Theorem 2.1

$$a_k \leq \frac{\rho P - \sum_{j=1}^{k-1} a_j}{m}.$$

As we have already noticed in Section 3.1, the optimal bag sizes for sand not only satisfy the above inequality, they actually have equality there. The bag sizes for sand are given by the recurrence

$$a_k = \frac{\bar{\rho}(m, b)P - \sum_{j=1}^{k-1} a_j}{m}.$$

When we in addition assume  $P = m$ , as in the case of pebbles, we get

$$a_k = \bar{\rho}(m, b) - \frac{1}{m} \sum_{j=1}^{k-1} a_j. \quad (4.1)$$

Let  $a_1, \dots, a_b$  denote values given by the recurrence (4.1) for the rest of this section. Remember that the sum of  $a_1, \dots, a_b$  equals  $P$ . Let us denote the bag sizes we will be choosing for pebbles  $d_1, \dots, d_b$ . We again want to use Theorem 2.1. In other words, for the desired robustness factor  $\rho$ , we want the bag sizes to satisfy

$$d_k \leq \rho - \frac{1}{m} \sum_{j=1}^{k-1} d_j. \quad (4.2)$$

Consider the following algorithm. Place as many pebbles as you can into the first bag while it satisfies the inequality (4.2). Then do the same for the second bag and so on until the last bag (or until we run out of jobs). See PEBBLES for pseudocode.

■ **Algorithm** PEBBLES.

---

**Input:** processing times  $p_1 \geq \dots \geq p_m$ ; number of machines  $m$ ; number of bags  $b$ ; desired robustness factor  $\rho$   
 $B \leftarrow$  empty mapping  
**for**  $k \leftarrow 1$  to  $b$  **do**  $d_k \leftarrow 0$  ▷  $d_k$  represents the size of the  $k$ th bag  
 $k \leftarrow 1$  ▷  $k$  represents index of currently considered bag  
**for**  $j \leftarrow 1$  to  $n$  **do**  
    **while**  $k \leq b$  **and**  $d_k + p_j > \rho - \frac{1}{m} \sum_{\ell=1}^{k-1} d_\ell$  **do**  $k \leftarrow k + 1$   
    **if**  $k > b$  **then break**  
     $B[j] \leftarrow k$   
     $d_k \leftarrow d_k + p_j$   
**return**  $B$

---

► **Theorem 4.1.** *There exists a  $(\bar{\rho}(m, b) + q)$ -robust algorithm for  $q$ -pebbles, for  $\bar{\rho}$  defined by (1.1).*

**Proof.** We show that Algorithm PEBBLES puts every job in some bag for  $\rho = \bar{\rho}(m, b) + q$ .

Suppose for a contradiction that the algorithm does not use all the jobs. Then the bag sizes  $d_k$  at the end of the algorithm must satisfy

$$d_k + q > \rho - \frac{1}{m} \sum_{j=1}^{k-1} d_j.$$

Indeed, if for some  $k$  this inequality is not satisfied, adding one more job of size at most  $p$  to bag  $k$  would not violate the inequality (4.2) and the algorithm would have done so.

Plugging in the expression for  $\rho$  gives us

$$d_k > \bar{\rho}(m, b) - \frac{1}{m} \sum_{j=1}^{k-1} d_j. \quad (4.3)$$

We are going to show

$$\sum_{j=1}^k d_j \geq \sum_{j=1}^k a_j, \quad (4.4)$$

## 8:10 Speed-Robust Scheduling Revisited

for all  $k \in \{0, \dots, b\}$ . We prove this claim by induction. The case  $k = 0$  is trivial since the summations are empty and both sides are equal to 0. Let us now prove the induction step for  $k$  using the equation (4.1) and the inequality (4.3).

$$d_k - a_k \geq \left( \bar{\rho}(m, b) - \frac{1}{m} \sum_{j=1}^{k-1} d_j \right) - \left( \bar{\rho}(m, b) - \frac{1}{m} \sum_{j=1}^{k-1} a_j \right) = -\frac{1}{m} \left( \sum_{j=1}^{k-1} d_j - \sum_{j=1}^{k-1} a_j \right)$$

We can now easily finish the induction step. We simplify

$$\begin{aligned} \sum_{j=1}^k d_j - \sum_{j=1}^k a_j &= \left( \sum_{j=1}^{k-1} d_j - \sum_{j=1}^{k-1} a_j \right) + (d_k - a_k) \\ &\geq \left( \sum_{j=1}^{k-1} d_j - \sum_{j=1}^{k-1} a_j \right) - \frac{1}{m} \left( \sum_{j=1}^{k-1} d_j - \sum_{j=1}^{k-1} a_j \right) = \frac{m-1}{m} \left( \sum_{j=1}^{k-1} d_j - \sum_{j=1}^{k-1} a_j \right), \end{aligned}$$

which is non-negative by the induction hypothesis for  $k-1$  and thus the claim (4.4) holds.

Using the claim (4.4) for  $k = b$  gives us

$$\sum_{j=1}^b d_j \geq \sum_{j=1}^b a_j = P,$$

which is a contradiction with the assumption that we did not use all jobs.  $\blacktriangleleft$

It is interesting to take a look at the case  $b = m$ . Theorem 4.1 implies that there exists an algorithm with robustness factor at most

$$\frac{e}{e-1} + q \approx 1.58 + q.$$

The best known result for rocks gives robustness factor  $2 - 1/m$ . This gets arbitrarily close to 2 for large  $m$ . Hence we have obtained a stronger result for

$$q < 2 - \frac{e}{e-1} \approx 0.42.$$

## 5 Bricks

In this section, we study the case of jobs with equal processing times. An important parameter is the ratio of the number of jobs and the number of machines, which we denote  $\lambda = n/m$ . We can scale the instance so that  $p_j = 1$  for all  $j$ , which we assume from now on. Note that now  $P = n$  and the average load is  $P/m = n/m = \lambda$ .

Thus the instance satisfies the definition of  $p$ -pebbles for  $p = 1/\lambda$ . Theorem 4.1 immediately implies our first improved bound for bricks:

► **Theorem 5.1.** *There exists an algorithm with robustness factor at most  $\bar{\rho}(b, m) + m/n$  solving the problem for  $n$  bricks,  $m$  machines and  $b$  bags.*  $\blacktriangleleft$

In the rest of this section we focus on our main result, the 1.6-robust algorithm for bricks in case  $b = m$ . This will have the following ingredients:

- For  $\lambda \geq 60$  we have  $e/(e-1) + 1/60 < 1.6$ , so by Theorem 5.1 we can use Algorithm PEBBLES.
- For  $\lambda < 60$  we design a new algorithm BRICKS. We split the analysis into two cases.

- For  $m \geq 144$ , we modify its solution into a certain fractional solution, which is easier to analyze, and bound the difference between the two solutions.
  - For  $m < 144$ , we have a finite number of instances, which we verify using a computer.
- We stress that the analysis of instances for  $m < 144$  shows that Algorithm BRICKS works here without any changes, too, i.e., it does not lead to an algorithm with exploding number of cases tailored to specific inputs.

### 5.1 First stage algorithm BRICKS

Our assumptions on the optimal solution explained at the beginning of Section 2 imply that we can also restrict ourselves to instances with  $\sum_{i=1}^m s_i = n$  and furthermore the values of speeds  $s_i$  are integral, as in the optimal solution the machine loads are necessarily integral. (Recall that this is due to the fact that we can modify the speeds independently of the first-stage algorithm.)

The key ingredient of the improved algorithm is to observe that the integrality of speeds allows us to use the pigeonhole principle to create larger bags. Furthermore, with appropriate accounting we can use the pigeonhole principle iteratively.

Let us demonstrate this on an example. Let  $n = 13$ ,  $m = 10$  and  $\rho = 1.6$ . The total speed of 10 machines is 13, so one machine has speed at least 2. This means that one of the machines will have capacity  $2\rho = 3.2$  and we can create and assign a bag of size  $\lfloor 2\rho \rfloor = 3$ . Without integrality of the speeds, only a machine with speed 1.3 would be guaranteed, so the capacity would be just above 2.

To continue iteratively, we cannot reason about the capacity as in Algorithm GREEDYASSIGNMENT. Instead, for each bag we reserve some integral amount of speed on one of the machines. For this accounting, we represent the remaining unreserved total speed by *coins*.

In the example above, we pay 2 coins for a bag of size 3. This seems like an overpayment compared to Algorithm GREEDYASSIGNMENT, as the 2 coins correspond to capacity 3.2, so we waste a capacity of 0.2. However, after this step, we are left with 11 coins among the 10 machines, and using the integrality and the pigeonhole principle once more, we are guaranteed to have one machine with 2 coins (these coins may be on a different machine or they may be the ones remaining on the same machine). Thus we can create another bag of size 3. Now there are only 9 coins remaining and we can only create a bag of size 1 at cost 1. See Figure 5.1 for an illustration. Overall, the effect of integrality is more significant than the overpayment due to rounding, and thus we are able to obtain an improved algorithm.

■ **Figure 5.1** Graphical representation of the first three chosen bags for  $n = 13$ ,  $m = 10$ . The dots represent coins and the boxes represent chosen bags. The number of coins inside a box represent the cost of the bag. Vertical lines emphasize the multiples of  $m$ , which determine the bag costs.

Formally, we start Algorithm BRICKS with  $c = n$  coins. In each round we pay  $z = \lfloor c/m \rfloor$ , create a bag of size  $\lfloor z \cdot \rho \rfloor$  and continue with remaining coins on  $m$  machines. The *cost* of a bag is the number of coins we pay for it, i.e.,  $z$  in the algorithm.

If Algorithm BRICKS produces bags of total size at least  $n$ , we say it is *successful*. If the total sum of bag sizes exceeds  $n$ , we decrease the sizes of some bags to make the sum equal to  $n$ . E.g., we can remove some of the last small bags and then decrease size of the last non-empty bag as needed.

■ **Algorithm** BRICKS.

---

**Input:** number of bricks  $n$ ; number of machines  $m$ ; number of bags  $b$ ; desired robustness factor  $\rho$

$c \leftarrow n$  ▷ The initial number of coins is  $n$

**for**  $j \leftarrow 1$  to  $b$  **do**

$z \leftarrow \lceil c/m \rceil$  ▷ max guaranteed coins on a machine

$a_j \leftarrow \lfloor z \cdot \rho \rfloor$  ▷ max integer such that  $\text{cost}(a_j) = z$

$c \leftarrow c - z$

**return**  $a_1, a_2, \dots, a_b$

---

In Section 5.3 we show that this algorithm is sound, namely, we give a modification of the second stage algorithm algorithm GREEDYASSIGNMENT for which we show that a machine with unused speed  $z$  always exists and thus we can assign all bags.

For a general instance, there is always a machine of speed at least  $\lceil n/m \rceil = \lceil \lambda \rceil$ , and thus the cost of the first bag is chosen as  $\lceil \lambda \rceil$ . The cost will then decrease by 1 every time the number of coins decreases below a multiple of  $m$ . Figure 5.2 illustrates this.

■ **Figure 5.2** Graphical representation of the first chosen bag of size  $\lceil \lambda \rceil$ .

Note that the costs of the bags chosen by BRICKS do not depend on  $\rho$ . The sizes of the bags, however, do depend on  $\rho$ . See Figure 5.3 below for an example execution of BRICKS for  $n = 45$  and  $m = 9$ . This execution shows that BRICKS fails for  $\rho < 1.6$  but succeeds for  $\rho = 1.6$ .

## 5.2 Fractional solutions

In general, the cost of the first bag chosen will be  $\lceil \lambda \rceil$ . The cost will then decrease by 1 every time the number of coins decreases below a multiple of  $m$ . Roughly speaking, we use approximately  $m$  coins for bags of each size.

We need to show that the created  $b$  bags have total size at least  $n$ . If we would use exactly  $m/z$  bags for each cost  $z$ , the total size of bags is easy to compute. However, the integral number of bags of each cost causes rounding issues when the bag cost decreases and these complicate the calculations.

To structure our analysis, we first modify the solution obtained by BRICKS into a solution that uses possibly non-integral number of bags of each size. In such a solution, we can use fractions of bags (such as  $\frac{4}{5}$  of a bag of size 8 as in the Figure 5.4). We arrange the modification so that the total size of bags of cost  $z$  is exactly  $m$ , except for the smallest and largest bag costs. In the main part of our proof, we bound the rounding error, i.e., the difference between the sizes of the integral and fractional solution. To complete the proof, we calculate the total size of bags in the modified fractional solution, which is easy, and show that it is well above  $n$ .

For the fractional solutions, it is better to use an alternative representation of the bags by a function  $F$  that for each  $z$  gives the number  $F(z)$  of bags of cost  $z$ . The size of  $F$  is then defined as the total size of bags. Recall that a bag of cost  $z$  has size  $\lfloor z \cdot \rho \rfloor$ . Formally:

■ **Figure 5.3** Tabular and graphical representation of the execution of BRICKS for  $n = 45$ ,  $m = 9$  and  $\rho = 1.6$ . The numbers above bags represent their sizes. The sum of bag sizes is actually  $46 > n = 45$ , to solve this, we can for example replace one bag of size 3 with a bag of size 2.

■ **Figure 5.4** Fractional solution for  $n = 45$ ,  $m = 9$  and  $\rho = 1.6$  produced by BRICKSFRACT. Notice that we always use only one bag size (cost) between consecutive multiples of  $m$ . Compare this to Figure 5.3 where bag cost 5 “overflows” the line at  $4m$  coins.

► **Definition 5.2.** A fractional solution is a mapping  $F : \mathbb{N} \rightarrow \mathbb{R}_0^+$  satisfying  $\sum_{z=1}^{\infty} F(z) = b$ . The size of fractional solution  $F$  for robustness factor  $\rho$  is defined as

$$\text{size}(F, \rho) = \sum_{z=1}^{\infty} F(z) \cdot \lfloor z \cdot \rho \rfloor.$$

We will sometimes use only  $\text{size}(F)$  if  $\rho$  is clear from the context.

We start by reformulating BRICKS so that it produces the solution directly in the alternative representation, see Algorithm BRICKSALT below. It is easy to see that BRICKS and BRICKSALT are equivalent.

► **Observation 5.3.** BRICKS and BRICKSALT use each bag cost the same number of times.

**Proof.** One step of BRICKSALT corresponds to several steps of BRICKS. BRICKS chooses the bags one by one, and it may choose the same bag cost in several consecutive iterations. BRICKSALT in each step calculates how many bags of given cost would BRICKS use. The key observation is that the expression  $\lceil (c - m(z - 1))/z \rceil$  calculates how many bags of cost  $z$  are needed to have at most  $m(z - 1)$  coins remaining. In other words, it calculates how many bags of cost  $z$  BRICKS uses before it starts using bags of cost  $z - 1$  (or runs out of bags). Hence both BRICKS and BRICKSALT use the same number of bags of cost  $z$  for each  $z$ . ◀

Algorithm BRICKSFRACT (see below) is obtained from BRICKSALT by removing the rounding in the calculation of the number of bags  $x$ .

## 8:14 Speed-Robust Scheduling Revisited

### Algorithm BRICKSALT.

---

**Input:** number of bricks  $n$ ; number of machines  $m$ ; number of bags  $b$   
**Output:** Fractional solution  $I$

$r \leftarrow b$   $\triangleright r$  is the remaining number of bags (integral)  
 $c \leftarrow n$   $\triangleright c$  is the remaining number of coins (integral)  
 $I[z] \leftarrow 0$  for  $z \in \mathbb{N}$   
**while**  $r > 0$  **and**  $c > 0$  **do**  
     $z \leftarrow \lceil \frac{c}{m} \rceil$   $\triangleright z$  is the bag cost  
     $x \leftarrow \min\left(r, \lceil \frac{c-m(z-1)}{z} \rceil\right)$   $\triangleright x$  is the (integral) number of bags of cost  $z$   
     $r \leftarrow r - x$   
     $c \leftarrow c - x \cdot z$   
     $I[z] \leftarrow x$   
**return**  $I$

---

### Algorithm BRICKSFRACT.

---

**Input:** number of bricks  $n$ ; number of machines  $m$ ; number of bags  $b$   
**Output:** Fractional solution  $F$

$r \leftarrow b$   $\triangleright r$  is the remaining number of bags (fractional)  
 $c \leftarrow n$   $\triangleright c$  is the remaining number of coins (fractional)  
 $F[z] \leftarrow 0$  for  $z \in \mathbb{N}$   
**while**  $r > 0$  **and**  $c > 0$  **do**  
     $z \leftarrow \lceil \frac{c}{m} \rceil$   
     $x \leftarrow \min\left(r, \frac{c-m(z-1)}{z}\right)$   $\triangleright x$  is the fractional amount of bags of cost  $z$   
     $r \leftarrow r - x$   
     $c \leftarrow c - x \cdot z$   
     $F[z] \leftarrow x$   
**return**  $F$

---

The following observation says that the algorithm follows our initial intuition, namely that for bags of each cost we use exactly  $m$  coins, except for the first and last bag cost used.

► **Definition 5.4.** Let  $F$  be a fractional solution, then let  $z_{\min}$  and  $z_{\max}$  denote the smallest and largest integers such that  $F(z_{\min}) > 0$  and  $F(z_{\max}) > 0$ .

► **Observation 5.5.** Let  $F$  be a result BRICKSFRACT with input  $n$  and  $m$ . Then  $F(z) = m/z$  for every  $z$  such that  $z_{\min} < z < z_{\max}$ .

**Proof.** Observe that in every step of the algorithm, except the last one, it holds that  $x = (c - m(z - 1))/z$  and thus  $c - x \cdot z = m(z - 1)$ . It follows that in all the steps except for the first and last ones  $x = (mz - m(z - 1))/z = m/z$ . ◀

Next we observe that the result of BRICKSFRACT scales, i.e., essentially it depends only on  $\lambda$ . Note also that BRICKSFRACT is well defined even for non-integral  $m$  and  $n$ .

► **Observation 5.6.** Let  $\alpha \in \mathbb{R}^+$ . Suppose BRICKSFRACT produces solution  $F$  with  $n$  and  $m$  as an input and solution  $\bar{F}$  with inputs  $\alpha n$  and  $\alpha m$ . Then  $\bar{F}(z) = \alpha F(z)$  for all  $z$ . It follows that  $\text{size}(\bar{F}, \rho) = \alpha \cdot \text{size}(F, \rho)$ .

**Proof.** We go through the execution of BRICKSFRACT step by step. Suppose that we multiply both  $m$  and  $n$  by  $\alpha$ . Then in every iteration of the loop  $r$  is multiplied by  $\alpha$ ,  $c$  is multiplied by  $\alpha$ ,  $z$  stays the same, and  $x$  is multiplied by  $\alpha$ . ◀

Now we are ready to bound the difference between the solutions produced by BRICKSFRACT and BRICKSALT, i.e., the rounding error.

► **Lemma 5.7.** *Let  $F$  be the fractional solution produced by BRICKSFRACT and  $I$  the solution produced by BRICKSALT on the same input. Then*

- *for  $\lambda \leq 5$  it holds that  $\text{size}(I, 1.6) \geq \text{size}(F, 1.6)$  and*
- *for  $\lambda \leq 60$  it holds that  $\text{size}(I, 1.6) \geq \text{size}(F, 1.6) - 12$ .*

**Proof.** We give an algorithm which transforms  $F$  into a solution  $F'$  that is almost integral and very close to  $I$ . Set  $\bar{z}$  to be  $z_{\min}$  of the solution  $F$  and note that  $z_{\max} = \lceil \lambda \rceil$ .

We go through the bag costs, denoted by  $z$ , from  $\lceil \lambda \rceil$  down to  $\bar{z} + 1$ . For each  $z$ , if  $F$  uses non-integral amount of bags of cost  $z$ , round it up. This makes the number of bags of cost  $z$  equal to their number in the solution  $I$ . Then decrease the number of bags of cost  $z - 1$  so that the total cost of all bags remains the same. Finally, increase the number of bags of cost 1 so that the total number of bags stays equal to  $b$ . See Figure 5.5 for an illustration.

■ **Figure 5.5** Graphical representation of  $F$ ,  $F'$  and  $I$ . In the first step of the transformation from  $F$  to  $F'$ ,  $\frac{9}{5}$  is rounded up to 2 and the number of bags of cost 5 (and size 8) increases by  $\frac{1}{5}$ . In order to keep the total cost the same, number of bags of cost 4 (and size 6) is decreased by  $\frac{1}{4}$ . As a result, total number of bags decreased by  $\frac{1}{4} - \frac{1}{5} = \frac{1}{20}$ , hence we add  $\frac{1}{20}$  of a bag of cost 1 (and size 1). This is actually the only step in which something happens since number of used bags of cost 4 and 3 is already integral. We do not process the bags of cost 2, as  $\bar{z} = 2$ . Solution  $F'$  is almost identical to the solution  $I$ , but has  $\frac{1}{20}$  of bag of cost 1 instead of  $\frac{1}{20}$  of bag of cost 2.

For  $z = \bar{z} + 1$ , the previous procedure could lead to a negative value of  $F'(\bar{z})$ . In this special case we proceed slightly differently and instead of rounding  $G(z)$  up we only increase it so that  $F'(\bar{z}) = 0$ .

We now describe one step of the process formally and analyze it. Let  $G$  denote the current fractional solution and let  $H$  denote the result of one transformation step. Let  $z$  be the current cost of bags.

We set  $H(z) = \lceil G(z) \rceil$ , note that  $H(z) - G(z) < 1$ . We want the sum of costs of bags of costs  $z - 1$  and  $z$  to remain the same, hence we want

$$H(z) \cdot z + H(z - 1) \cdot (z - 1) = G(z) \cdot z + G(z - 1) \cdot (z - 1) \tag{5.1}$$

## 8:16 Speed-Robust Scheduling Revisited

to hold. Rearranging (5.1) to an equivalent equation leads to (5.2), so we set

$$H(z-1) = G(z-1) + (G(z) - H(z)) \cdot \frac{z}{z-1}. \quad (5.2)$$

We claim that  $H(z-1) > 0$  for  $z-1 > \bar{z}$ . Indeed, as  $m > 144$  and  $z \leq \lceil \lambda \rceil \leq 60$  in the considered case, we have  $G(z-1) = F(z-1) = m/(z-1) > 2$  (using also  $\bar{z} = z_{\min} < z-1 < z_{\max}$ ). As  $H(z) - G(z) < 1$ , we get  $H(z-1) > G(z-1) - 1 > 0$ .

Now we describe the modification in the special case when  $H(z-1)$  would become negative. We have shown above that this can happen only for  $z = \bar{z} + 1$ , i.e., in the last step. Then we set  $H(z-1) = 0$  and set

$$H(z) = G(z) + (G(z-1) - H(z-1)) \frac{z-1}{z}.$$

This equation is equivalent to (5.1), which is in turn equivalent to (5.2), which thus also holds. Furthermore, the fact that the previous procedure would lead to negative  $H(z-1)$  implies that now we have  $G(z) \leq H(z) \leq \lceil G(z) \rceil$  and thus  $H(z) - G(z) < 1$  holds again.

In both cases, the total number of bags has decreased by

$$(G(z) - H(z)) + (G(z-1) - H(z-1)) = \frac{1}{z-1} (H(z) - G(z)).$$

Thus we set

$$H(1) = G(1) + \frac{1}{z-1} (H(z) - G(z)).$$

Note that in the transformation step, both the total number of bags and their total cost remain constant.

Recall that the size of a bag of cost  $z$  is  $\lfloor z\rho \rfloor$ . It follows that

$$\begin{aligned} \text{size}(H) - \text{size}(G) &= (H(z) - G(z)) \cdot \lfloor z\rho \rfloor + (H(z-1) - G(z-1)) \cdot \lfloor (z-1)\rho \rfloor + (H(1) - G(1)) \cdot \lfloor \rho \rfloor \\ &= (H(z) - G(z)) \cdot \left( \lfloor z\rho \rfloor - \frac{z}{z-1} \lfloor (z-1)\rho \rfloor + \frac{1}{z-1} \lfloor \rho \rfloor \right) \end{aligned}$$

Note that the second factor in the expression above does not depend on the solution. We call it the transformation factor and for  $z$  we denote it by

$$f(z) = \left( \lfloor z\rho \rfloor - \frac{z}{z-1} \lfloor (z-1)\rho \rfloor + \frac{1}{z-1} \lfloor \rho \rfloor \right).$$

If  $f(z) \geq 0$ , the size of the solution could have only increased, as  $H(z) \geq G(z)$ , i.e., we have  $\text{size}(H) \geq \text{size}(G)$ . If  $f(z) < 0$ , the size of the solution might have decreased – those are the important (“bad”) cases we need to bound. We have  $H(z) - G(z) < 1$ , hence  $\text{size}(H) \geq \text{size}(G) + f(z)$  in case of negative  $f(z)$ .

Now we sum these bounds over all steps for  $z$  from  $\lceil \lambda \rceil$  to 2 and get

$$\text{size}(F') - \text{size}(F) \geq \sum_{z=2}^{\lceil \lambda \rceil} \min(0, f(z))$$

We give a list of values of  $f(z)$  for  $z$  from 2 to 60 and  $\rho = 1.6$  in the full version of the paper on arXiv [8]. For  $z \leq 5$  the values  $f(z)$  are non-negative, thus for  $\lambda \leq 5$  we get  $\text{size}(F') - \text{size}(F) \geq 0$ . It can be verified that the sum of all negative values of  $f(z)$  for  $z \leq 60$  is larger than  $-12$  and thus for  $\lambda \leq 60$  we get  $\text{size}(F') - \text{size}(F) > -12$ .

Examining the algorithms BRICKSALT and BRICKSFRACT that generate the solutions  $I$  and  $F$ , respectively, and the transformation process above shows that the solution  $F$  is step by step transformed towards  $I$ . In particular,  $I(z) = F'(z)$  for all values  $z \geq \bar{z}$  (if the special case does not apply) or  $(z \geq \bar{z} + 1$  if the special case applies). For the small values of  $z$ , the only possible difference is that solution  $F'$  might have some amount of bags of size 1 instead of some larger bags in solution  $I$ . (Note that the total number of bags does not change during the transformation.) This implies  $\text{size}(I) \geq \text{size}(F')$  and the lemma follows. ◀

To complete the proof we need to show that  $\text{size}(F)$  is sufficiently large so that  $\text{size}(I) \geq n$ . Actually, as the previous transformation possibly gives  $I$  with a slightly smaller size than  $F$ , we need to compensate for this difference which is at most 12. Precisely, we need to prove that  $\text{size}(F, 1.6) \geq n$  for  $\lambda \leq 5$  and  $\text{size}(F, 1.6) \geq n + 12$  for  $5 < \lambda \leq 60$  and  $m \geq 144$ .

Since the fractional solution  $F$  scales when  $m$  and  $n$  are scaled, see Observation 5.6, it is convenient to normalize by  $m$  and consider  $(\text{size}(F, 1.6) - n)/m$  in the following lemma. Let us call this crucial quantity *normalized brick surplus*, as it measures how many bricks we are able to put in the bags in the fractional solution in addition to  $n$  bricks, normalized by  $m$ .

► **Lemma 5.8.** *Let  $F$  be a fractional solution produced by BRICKSFRACT. Then*

- For  $\lambda \leq 4$  it holds that  $\text{size}(F, 1.6) \geq n$ .
- For  $4 \leq \lambda \leq 60$  it holds that  $\text{size}(F, 1.6) \geq n + \frac{1}{12}m$ .

**Proof.** By Observation 5.6, the normalized brick surplus  $(\text{size}(F, 1.6) - n)/m$  is uniquely determined by  $\lambda$ , i.e., multiplying both  $n$  and  $m$  by the same constant does not change it.

This means that the normalized brick surplus is a function of  $\lambda$ . Furthermore, we claim that the function is piece-wise linear. Suppose we slowly increase  $\lambda$ , for example fix  $m$  and increase  $n$  by  $\delta$ . Then  $F(z)$  remains constant for all  $z$  except  $z_{\min}$  and  $z_{\max}$  by Observation 5.5. The number of the largest bags  $F(z_{\max})$  increases by  $\delta/\lceil\lambda\rceil$  and  $F(z_{\min})$  decreases by the same amount; this amount is proportional to  $\delta$ . The function  $\text{size}(F)$  is linear in the values of  $F(z)$ . So the normalized brick surplus is piece-wise linear with possible breakpoints between the segments at the values of  $\lambda$  when one of the values of  $z_{\min}$  or  $z_{\max}$  changes.

The value of  $z_{\max}$  changes exactly when  $\lambda$  is an integer. The breakpoints where  $z_{\min}$  increases can be calculated in the following way: Execute BRICKSFRACT for all integer values of  $\lambda \leq 60$ . Let us denote one of such solutions  $F$ . Take a look at  $F(z_{\min})$ , if we now slowly increase  $\lambda$ ,  $F(z_{\min})$  will decrease linearly as described above. Calculate at which point it reaches 0; if it happens before  $\lambda$  increases above another integer, we found a point where  $z_{\min}$  changes. The first case of changing  $z_{\min}$  is at  $\lambda = \frac{11}{3}$  when we stop using bags of cost 1, see Figure 5.6.

■ **Figure 5.6** Example of solution produced by BRICKSFRACT for  $n = 11$ ,  $m = 3$  and  $\rho = 1.6$ . Size of this solution is 11.5 and normalized brick surplus is  $\frac{1}{6}$ . The solution does not use any bags of cost 1. However, if  $\lambda$  were smaller, the solution would use bags of size 1.

The computer-generated tables of values of the normalized brick surplus function are given in the full version of the paper on arXiv [8]. The plot of the values is given in Figures 5.7 and 5.8 below.

■ **Figure 5.7** Plot of normalized brick surplus for small  $\lambda$ .

■ **Figure 5.8** Plot of normalized brick surplus for large  $\lambda$ .

The lemma now follows, since the normalized brick surplus is always non-negative and it is at least  $1/12$  for  $\lambda \geq 5$ . (Note that it is a constant function equal to  $1/12$  for  $\lambda \in [4, 6]$ .) ◀

► **Theorem 5.9.** *For  $\rho = 1.6$  and  $\lambda \leq 60$ , Algorithm BRICKS always succeeds, i.e., outputs bags of total size at least  $n$ .*

**Proof.** For  $\lambda \leq 5$ , the first claims in Lemmata 5.8 and 5.7 together prove  $\text{size}(I, 1.6) \geq \text{size}(F, 1.6) \geq n$ .

For  $5 \leq \lambda \leq 60$  and  $m \geq 144$  the second claims in Lemmata 5.8 and 5.7 together prove  $\text{size}(I, 1.6) \geq \text{size}(F, 1.6) - 12 \geq n + m/12 - 12 \geq n + 144/12 - 12 = n$ .

For  $\lambda \leq 60$  and  $m \leq 144$  there are only a finitely many instances and we verify  $\text{size}(I, 1.6) \geq n$  for them by computer, see the full version of the paper on arXiv [8]. ◀

We note that our choice of the bounds in the previous two lemmata is somewhat arbitrary. The plots of the normalized brick surplus suggest that we could bound it by an appropriate linear function instead of a constant. Also, the bound on  $\text{size}(F) - \text{size}(I)$  can be made smaller for intermediate values of  $\lambda$ . These changes would decrease the number of cases we need to check by a computer program, but would not improve the robustness factor.

### 5.3 Second stage

We need to show that if BRICKS succeeds, in the second stage we can indeed achieve makespan  $\rho$ . To do this, we cannot use Algorithm GREEDYASSIGNMENT and Theorem 2.1. Instead we modify it to Algorithm INTEGRALASSIGNMENT below, which copies the coins accounting scheme from BRICKS and thus follows the intuition behind it.

■ **Algorithm** INTEGRALASSIGNMENT.

---

**Input:** bag sizes  $a_1 \geq \dots \geq a_b$ ; machine speeds  $s_1 \geq \dots \geq s_m$ ; desired robustness factor  $\rho$

**for**  $i \leftarrow 1$  to  $m$  **do**

$c_i \leftarrow s_i$  ▷ Machine  $i$  gets  $s_i$  coins at the beginning.

$M_i = \emptyset$  ▷ Initialize the assignment

**for**  $k \leftarrow 1$  to  $b$  **do**

$i \leftarrow$  index of the machine with the largest  $c_i$

$M_i \leftarrow M_i \cup \{k\}$  ▷ Assign bag  $k$  to machine  $i$

$c_i \leftarrow c_i - \lceil a_k/\rho \rceil$  ▷ Machine  $i$  pays for the bag  $k$

**return**  $M_1, \dots, M_m$

---

► **Theorem 5.10.** *Suppose the first-stage algorithm BRICKS succeeds, i.e., outputs bags of total size of at least  $n$ . Then INTEGRALASSIGNMENT in the second stage produces an assignment with makespan at most  $\rho$ .*

**Proof.** Imagine that BRICKS and INTEGRALASSIGNMENT are running in parallel. BRICKS chooses the size of one bag and INTEGRALASSIGNMENT assigns it to a machine. Note that the values of  $c_i$  remain integral during the entire execution.

We claim that during the execution the value  $c$  in BRICKS is at most  $\sum_{i=1}^m c_i$  for  $c_i$ 's in INTEGRALASSIGNMENT. At the beginning, the quantities are equal. Suppose that BRICKS creates a bag of cost  $z$  and thus decreases  $c$  by  $z$ . Then the bag has size  $a = \lfloor z \cdot \rho \rfloor \leq z\rho$ . Thus INTEGRALASSIGNMENT decreases  $c_i$  by  $\lceil a/\rho \rceil \leq \lceil z\rho/\rho \rceil = z$ . Thus the sum of  $c_i$ 's decreases by at most  $z$  and the claim follows.

The claim implies that in each step before creating/assigning a bag of cost  $z$ , there exists a machine with  $c_i \geq z$  in INTEGRALASSIGNMENT. Indeed, BRICKS chooses  $z = \lceil c/m \rceil$ , thus  $m(z - 1) < c \leq \sum_{i=1}^m c_i$  using the previous claim. Hence there exists a machine with  $c_i > z - 1$  and together with integrality of  $c_i$  we get  $c_i \geq z$ .

It follows that  $c_i$ 's remain non-negative during the execution. Thus INTEGRALASSIGNMENT assigned to machine  $i$  bags of the total size at most  $s_i \cdot \rho$ . It follows that the makespan is at most  $\rho$ . ◀

Theorems 5.1, 5.9, and 5.10 immediately imply our main result.

► **Theorem 5.11.** *There exists 1.6-robust algorithm for the case of bricks and  $b = m$ .* ◀

## Conclusions

Our main result still leaves a small gap in the bounds for bricks (equal-length jobs) and  $b = m$  between the lower bound of  $e/(e - 1) \approx 1.58$  and our upper bound of 1.6. Our algorithm BRICKS does not admit a smaller robustness factor than 1.6, as is shown for  $n = 45$  and  $m = 9$  in Figure 5.3. So a smaller upper bound would need some additional techniques or special handling of some cases. Eberle *et al.* [4] give an example that shows a lower bound for bricks that is larger than  $\bar{\rho}(m, m)$  for  $m = 6$ . Although the value of the bound is below the limit value  $e/(e - 1)$ , this may be taken as a weak evidence that matching the lower bound may be hard.

The main open problem in this model remains to find a  $(2 - \varepsilon)$ -robust algorithm for the general case and  $b = m$ .

## Abstract

Dense subgraph discovery is an important problem in graph mining and network analysis with several applications. Two canonical polynomial-time solvable problems here are to find a *maxcore* (subgraph of maximum min degree) and to find a *densest subgraph* (subgraph of maximum average degree). Both of these problems can be solved in polynomial time. Veldt, Benson, and Kleinberg [47] introduced the generalized  $p$ -mean densest subgraph problem which captures the maxcore problem when  $p = -\infty$  and the densest subgraph problem when  $p = 1$ . They observed that for  $p \geq 1$ , the objective function is supermodular and hence the problem can be solved in polynomial time. In this work, we focus on the  $p$ -mean densest subgraph problem for  $p \in (-\infty, 1)$ . We prove that for every  $p \in (-\infty, 1)$ , the problem is NP-hard, thus resolving an open question from [47]. We also show that for every  $p \in (0, 1)$ , the weighted version of the problem is APX-hard. On the algorithmic front, we describe two simple  $\frac{1}{2}$ -approximation algorithms for every  $p \in (-\infty, 1)$ . We complement the approximation algorithms by exhibiting non-trivial instances on which the algorithms simultaneously achieve an approximation factor of at most  $\frac{1}{2}$ .

## 1 Introduction

Dense subgraph discovery is an essential tool in graph mining and network analysis. The aim here is to find clusters in a graph which are denser than the entire graph. There are a number applications of dense subgraph discovery in biological settings [29, 20, 35, 4, 42], web mining [24, 14], social network analysis [34], real-time story identification [2], and finance

and fraud detection [15, 48, 31]. Motivated by the needs of applications and theoretical considerations, various density measures have been used and studied in the literature (see [18, 25, 37, 45, 36] for some surveys). Each density definition leads to a corresponding combinatorial optimization problem: given a graph  $G$ , find a subgraph of maximum density. Two of the most popular density measures in the literature are (i) the minimum degree of the subgraph and (ii) the average degree of the subgraph. These measures lead to the maxcore problem and densest subgraph problem respectively. They are both polynomial-time solvable and have been extensively studied. We briefly describe them before discussing a common generalization that will be the focus of this work.

In the maxcore problem (MAXCORE), the goal is to find a subgraph with maximum minimum degree. The optimum value of this problem is known as the *degeneracy* of the graph and the subgraph achieving the optimum is known as a *maxcore* of the graph. A *k-core* of a graph is a maximal connected subgraph in which all vertices have degree at least  $k$ . Min-degree is a popular measure of density, commonly finding use in what is known as the *k-core decomposition*, a nested sequence of subgraphs that captures *k*-cores for every  $k$ . One nice feature of a *k-core decomposition* is that there is a simple linear-time peeling algorithm to compute it. The peeling algorithm – denoted **Greedy** – produces an ordering of the vertices by repeatedly removing the vertex with least degree in the current graph. This ordering can in turn be used to solve MAXCORE. We refer the reader to [38] for a survey on *k-core decomposition* and applications.

In the densest subgraph problem (DSG), the goal is to find a subgraph of maximum average degree. DSG is widely used in graph mining applications. It is a well-studied problem in combinatorial optimization and is polynomial time solvable via a variety of techniques including network flow [40, 21], submodular function minimization (folklore), and linear programming [9]. Even though DSG can be solved exactly, the algorithms are slow and this has spurred the design of fast approximation algorithms [9, 5, 13, 8, 7, 10, 27]. Amongst these approximation algorithms is a peeling algorithm introduced by Asahiro, Iwama, Tamaki, and Tokuyama [3] which was shown to be a  $\frac{1}{2}$ -approximation by Charikar [9]. We note that the peeling order of this algorithm is the same as the one for computing a maxcore, namely **Greedy**; a second step of the algorithm returns the best subgraph induced by a suffix of the peeling order (best in terms of average degree). The specific density measure for DSG is used only in the second step. Charikar’s analysis has spurred the development and analysis of a variety of peeling algorithms for several variants of DSG in both graphs and hypergraphs [1, 46, 44, 30, 33, 47].

Veldt, Benson, and Kleinberg [47] introduced the generalized mean densest subgraph problem that unifies MAXCORE and DSG. The input here is a real value  $p \in \mathbb{R} \cup \{-\infty, \infty\}$  and an undirected graph  $G = (V, E)$ . For a subset  $S \subseteq V$  of vertices, the density of the subgraph  $G[S]$  induced by  $S$  is defined as:

$$M_p(S) := \left( \frac{1}{|S|} \sum_{v \in S} d_S(v)^p \right)^{1/p},$$

where  $d_S(v)$  is the degree of vertex  $v$  in the subgraph  $G[S]$ . We note that  $M_{-\infty}(S) = \min_{v \in S} d_S(v)$  is the minimum degree in the induced subgraph  $G[S]$ , while  $M_{\infty}(S) = \max_{v \in S} d_S(v)$  is the maximum degree. For  $p = 0$ , the density of the subgraph  $G[S]$  is  $M_0(S) = (\prod_{v \in S} d_S(v))^{1/|S|} = \exp(\frac{1}{|S|} \sum_{v \in S} \ln d_S(v))$ . The goal is to find a subset  $S$  of vertices with maximum  $M_p(S)$ . We refer to this problem as the  $p$ -mean densest subgraph problem ( $p$ -MEAN DSG). As  $p$  varies from  $-\infty$  to  $\infty$ ,  $M_p(S)$  prioritizes the smallest degree in  $S$  to the largest degree in  $S$  and consequently,  $p$ -MEAN DSG provides a smooth way to generate subgraphs with different density properties.

$p$ -MEAN DSG generalizes to weighted graphs in a natural manner. For a graph  $G = (V, E)$  with positive edge weights  $w : E \rightarrow \mathbb{R}_+$ , we define  $d_S(v)$  as the sum of the weight of edges that are incident to vertex  $v$  in  $G[S]$ . For a subset  $S \subseteq V$  of vertices, its  $p$ -mean density  $M_p(S)$  is defined using  $d_S(v)$  as it was for the unweighted case. The goal again is to find a subset  $S$  of vertices with maximum  $M_p(S)$ . We refer to this problem as WEIGHTED  $p$ -MEAN DSG.

Veldt, Benson, and Kleinberg made several contributions to  $p$ -MEAN DSG. They observed that 1-MEAN DSG is equivalent to DSG and that  $(-\infty)$ -MEAN DSG is equivalent MAXCORE. For  $p \geq 1$ , they observed that the set function  $f_p : 2^V \rightarrow \mathbb{R}_{\geq 0}$  defined by  $f_p(S) := \sum_{v \in S} d_S(v)^p$  is a supermodular set function<sup>1</sup>. This implies that one can solve  $p$ -MEAN DSG in polynomial time for all  $p \geq 1$  via a standard reduction to submodular set function minimization, a classical polynomial-time solvable problem in combinatorial optimization [41]. Motivated by the fact that exact algorithms are very slow in practice, they described a greedy peeling algorithm, denoted Greedy- $p$ , that runs in  $O(mn)$  time and achieves an approximation factor of  $1/(p+1)^{1/p}$  for  $p \geq 1$  (here  $m$  and  $n$  are the number of edges and nodes of the graph). The peeling order of their Greedy- $p$  algorithm is *not* the same as that of Greedy – in particular, the peeling order depends on  $p$ . They supplement these theoretical results with empirical evaluation, showing that Greedy- $p$  returns solutions with desirable characteristics for values of  $p$  in the range  $[1, 2]$ . We note that the function  $f_p(S)$  is *not* supermodular if  $p < 1$ , which partially stems from the fact that the univariate function  $g(x) := x^p$  is not convex if  $p < 1$ .

## 1.1 Our Results

We study the complexity and algorithmic status of  $p$ -MEAN DSG for  $p \in (-\infty, 1)$  which was mentioned as a compelling direction for future work by Veldt et al. [47]. It is intriguing that  $p$ -MEAN DSG is polynomial-time solvable for  $p = -\infty$  and  $p \geq 1$  while the status for  $p \in (-\infty, 1)$  is non-trivial to understand. Our work fills this gap.

### Hardness of $p$ -mean DSG for $p \in (-\infty, 1)$

We prove that  $p$ -MEAN DSG is NP-Hard for every  $p \in (-\infty, 1)$ . We also show that WEIGHTED  $p$ -MEAN DSG is APX-hard for every fixed constant  $p \in (0, 1)$ . The hardness results are the main contribution of this work. They are technically involved for two reasons. First, the objective function is non-linear and does not fall into a clean and known class of functions. Second, the problem is effectively an unconstrained problem. The initial inspiration for our reduction came from a high-level connection to submodularity due to the concavity of the univariate function  $x^p$  for  $p \in (0, 1)$ ; constrained versions of submodular optimization are NP-hard. However, the objective function for  $p$ -MEAN DSG is not a submodular function and there are no constraints. Nevertheless, we are able to model it via a gadget. Although the reduction is quite simple to describe, the proof of the reduction requires careful parameter setting and a detailed case analysis. The reduction/analysis for the weighted case is somewhat easier, however, we prove NP-Hardness for the unweighted case since it is of particular interest. We prove APX-hardness for the weighted case, and only for  $p \in (0, 1)$ , to mitigate the calculations. It may be possible to extend our APX-hardness proof to the unweighted case and also to the full range  $(-\infty, 1)$ .

<sup>1</sup> A real-valued set function  $f : 2^V \rightarrow \mathbb{R}$  is *supermodular* if  $f(A) + f(B) \leq f(A \cup B) + f(A \cap B)$  for all  $A, B \subseteq V$ . We recall that  $f$  is supermodular iff  $-f$  is *submodular*.

### Approximation algorithms for $p \in (-\infty, 1)$

The NP-Hardness result for  $p$ -MEAN DSG motivates the search for approximation algorithms for  $p \in (-\infty, 1)$ . We note that the peeling algorithm for  $p$ -MEAN DSG, namely Greedy- $p$ , given by Veldt, Benson, and Kleinberg [47] is well-defined only for  $p > 0$ . In the same paper, the authors show empirical results for Greedy- $p$  for  $p \in (0, 1)$  even though the corresponding function  $f_p$  is not supermodular; however, no approximation guarantee is known for Greedy- $p$  for  $p \in (0, 1)$ . We describe two different and simple algorithms for  $p$ -MEAN DSG— one based on simple greedy peeling and the other based on an exact solution to DSG. We show that both algorithms achieve a  $\frac{1}{2}$ -approximation for all  $p \in (-\infty, 1)$ . These are the first algorithms with approximation guarantees for  $p$  in the regime  $(-\infty, 1)$ . We complement the algorithms by exhibiting tight instances on which *both* algorithms exhibit an approximation factor of at most  $\frac{1}{2}$ , thus ruling out the possibility of improving the ratio by taking the best of the two algorithms.

This paper builds upon and extends an earlier version [11] by two of the authors. The previous version included results on faster algorithms for  $p$ -MEAN DSG for  $p > 1$  and empirical evaluation of several algorithms. A full version including those results will be made available in the future.

### Organization

We present the NP-hardness result in Section 2 and the APX-hardness result in Section 3. We present our algorithmic results in Section 4. All proofs that are omitted from the main body of the paper are given in the appendix.

### Notation

Let  $G = (V, E)$  be a graph. For a subset  $S \subseteq V$  of vertices and a vertex  $v \in S$ , we recall that  $d_S(v)$  is the (weighted) degree of  $v$  in the induced subgraph  $G[S]$ . Let  $S$  be a subset of vertices. We define  $f_p(S) := \sum_{v \in S} d_S(v)^p$  if  $p \in [-\infty, 0) \cup (0, \infty]$  and  $f_p(S) := \sum_{v \in S} \ln d_S(v)$  if  $p = 0$ . We also define  $\rho_p(S) := f_p(S)/|S|$  for all  $p$ . With these definitions, we have  $M_p(S) = \rho_p(S)^{1/p}$  for all  $p$ . Thus, finding a set  $S$  of vertices with maximum  $M_p(S)$  is equivalent to finding a set  $S$  of vertices with *maximum*  $\rho_p(S)$  if  $p \geq 0$ , and to finding a set  $S$  of vertices with *minimum*  $\rho_p(S)$  if  $p < 0$ .

## 1.2 Other Related Work

DSG and the subfield of dense subgraph discovery is large. We point the reader to a recent survey [36] and restrict our attention to discussing some closely related work, specifically on sequential models and approximability.

As we remarked, DSG is poly-time solvable by several techniques including via maximum flow. Although maximum flow now admits an almost-linear time algorithm [12], the existing exact algorithms for DSG are slow in practice for large graphs. Thus approximation algorithms have also been considered (especially before the recent developments on network flow). In particular, there has been a line of work that obtained a  $(1 - \epsilon)$ -approximation in  $\tilde{O}(m \cdot \text{poly}(\frac{1}{\epsilon}))$ -time [5, 8, 10]; in particular, the algorithm in [10] runs in time  $\tilde{O}(\frac{m}{\epsilon})$ . These faster approximation algorithms also have some limitations in practice for large graphs. Several simpler iterative algorithms based on continuous optimization methods have been developed – these include algorithms based on the Frank-Wolfe method [13], an algorithm based on iterating Greedy called Greedy++ [7], and the projected gradient descent method [27].

They are simple to implement and have been shown to converge quickly to near-optimal solutions on large graphs, both synthetic and real-world, even though the known worst-case theoretical convergence rates are fairly large.

We discuss some other measures of density considered in the literature. Given a graph  $G = (V, E)$  and a finite collection of pattern graphs  $\mathcal{F}$ , one can consider the problem of finding a set  $S$  that maximizes  $f(S)/|S|$  where  $f : 2^V \rightarrow \mathbb{Z}_+$  counts the number of occurrences of the patterns from  $\mathcal{F}$  in the induced subgraph  $G[S]$ . If we consider a single edge as the pattern, then we obtain DSG. [46] considered the special case where  $\mathcal{F}$  is a single triangle graph and [44] considered the special case where  $\mathcal{F}$  is a clique on  $k$  vertices. The densest subgraph problem under the general notion of patterns was considered in [17]. Densest subgraph has also been studied for hypergraphs with density of a set  $S$  of vertices being defined as  $|E(S)|/|S|$  where  $E(S)$  is the set of hyperedges with all vertices in  $S$  [30]. We can reduce the densest subgraph problem with pattern based densities to the densest subgraph problem in hypergraphs by introducing a hyperedge for each occurrence of the pattern in the input graph. Charikar's analysis of Greedy can be generalized to show an approximation factor of at least  $\frac{1}{r}$  in rank  $r$ -hypergraphs. Veldt, Benson, and Kleinberg [47] showed that Greedy is not a good worst-case algorithm for  $p$ -MEAN DSG when  $p > 1$ , and as we mentioned earlier, they developed a different peeling algorithm. Chekuri, Quanrud and Torres [10] unified several results by considering density measures of the form  $f(S)/|S|$  where  $f : 2^V \rightarrow \mathbb{R}_+$  is an arbitrary non-negative supermodular set function over a vertex set  $V$ . They showed that there is a natural peeling algorithm for each  $f$  and derived an approximation bound in terms of certain properties of  $f$ ; Greedy- $p$  from [47] and its approximation bound are derived as special cases. They also generalized Greedy++ to supermodular densities and showed that the resulting algorithm converges to an optimum solution, partially answering a conjecture from [7] (the conjecture has a strong convergence rate). See [27, 28] for additional insights. One can also consider density measures of the form  $f(S)/g(S)$  where  $g : 2^V \rightarrow \mathbb{R}_+$  is another set function such as a concave or convex function of  $|S|$ . We refer the reader to [36, 10] for results and pointers on this aspect.

Constrained versions of DSG such as the  $k$ -densest-subgraph (find a densest subgraph with at most  $k$  vertices) are well-studied in theoretical computer science.  $k$ -densest-subgraph is of particular importance due to its connection to various other problems, and due to the intriguing difficulty in understanding its approximability. Since there is a large literature on this problem and since constrained versions are not the focus of this paper, we point the reader to some relevant papers on algorithms and hardness [19, 6, 39].

## 2 NP-hardness

In this section, we prove the following theorem.

► **Theorem 1.**  *$p$ -MEAN DSG is NP-hard for all  $p \in (-\infty, 1)$ .*

We reduce from the Exact  $\ell$ -Cover problem.

► **Problem 1.** *EXACT  $\ell$ -COVER: the input is a finite ground set  $\mathcal{U} = \{e_1, e_2, \dots, e_{\ell n}\}$  of cardinality  $\ell n$  for some positive integers  $\ell$  and  $n$ , and a family of subsets  $\mathcal{S} \subseteq 2^{\mathcal{U}}$ , where each  $X \in \mathcal{S}$  has cardinality  $\ell$ . The goal is to determine whether there exist  $n$  disjoint sets  $S_{i_1}, S_{i_2}, \dots, S_{i_n} \in \mathcal{S}$  whose union is  $\mathcal{U}$ .*

We will say that the input instance  $(\mathcal{U}, \mathcal{S})$  of EXACT  $\ell$ -COVER has an exact  $\ell$ -cover if there exist  $n$  disjoint sets whose union is  $\mathcal{U}$ . EXACT 3-COVER is a well-known NP-complete problem [22]. A standard padding approach reduces EXACT 3-COVER to EXACT  $\ell$ -COVER for every  $\ell \geq 3$ .

► **Theorem 2.** *EXACT  $\ell$ -COVER is NP-complete for every integer  $\ell \geq 3$ .*

### 2.1 Reduction from exact $\ell$ -cover

We reduce EXACT  $\ell$ -COVER to  $p$ -MEAN DSG. Let  $\mathcal{U} = \{e_1, e_2, \dots, e_{\ell n}\}$  and  $\mathcal{S} = \{S_1, S_2, \dots, S_m\}$  with  $S_i \subseteq \mathcal{U}$  for every  $i \in [m]$  be the input instance of EXACT  $\ell$ -COVER. For a positive integer  $d$  (to be chosen later), we construct a graph  $G_d = (L \cup A, E)$ , where  $L := \{v_i : i \in [m]\}$  and  $A := \{u_j : j \in [\ell \cdot n]\}$ . For every  $1 \leq i \leq m$  and  $1 \leq j \leq \ell \cdot n$ , if the set  $S_i$  contains element  $e_j$ , then we add an edge between  $v_i$  and  $u_j$  in graph  $G_d$ . Further, we add edges between vertices in  $A$  to make  $G_d[A]$  to be a connected  $d$ -regular graph, where  $d$  will be chosen appropriately (we may assume that  $n$  is even so that such a connected  $d$ -regular graph always exists). See Figure 1. If  $p \neq 0$ , then we set  $\rho^* := \frac{\ell^p + \ell \cdot (d+1)^p}{\ell+1}$  and if  $p = 0$ , then we set  $\rho^* := \frac{\ln \ell + \ell \cdot \ln(d+1)}{\ell+1}$ . We will show that there exist positive integers  $\ell \geq 3$  and  $d$  such that the input instance admits an exact  $\ell$ -cover if and only if  $\max\{M_p(X) : X \subseteq V\} \geq (\rho^*)^{1/p}$ .

■ **Figure 1** Graph constructed in our reduction from EXACT  $\ell$ -COVER for  $\ell = 3$  and  $d = 5$ . The EXACT 3-COVER instance consists of the ground set  $\mathcal{U} := \{e_1, \dots, e_{3n}\}$  and the family  $\mathcal{S} := \{S_1, \dots, S_m\}$ .

Next, we prove the NP-hardness of  $p$ -MEAN DSG by casing on the value of  $p$  via the above mentioned reduction. We prove NP-hardness for  $p \in (0, 1)$  in Section 2.2 (see Theorem 7). The missing proofs are given in the appendix. The proofs for  $p \in (-\infty, 0]$  are given in the full version owing to space limitations.

### 2.2 NP-hardness for $p \in (0, 1)$

We recall that  $\rho_p(X) = M_p(X)^p$  for every subset  $X$  of vertices and hence, finding a set  $X$  of vertices that maximizes  $M_p(X)$  reduces to finding a set  $X$  of vertices that maximizes  $\rho_p(X)$  if  $p \in (0, 1)$ . We define  $\text{OPT}_{G_d} := \max_{X \subseteq V} \rho_p(X)$ . We observe that  $\text{OPT}_{G_d}$  is a maximization problem for  $p \geq 0$ . Hence, in order to show correctness of our reduction, we will need an upper bound on  $\rho_p(X)$  for  $p \geq 0$ . The following lemma gives an upper bound.

► **Lemma 3.** *Let  $G_d = (L \cup A, E)$  be the graph constructed in the reduction. Let  $S \subseteq L$  and  $A' \subseteq A$ . Then, for  $p > 0$ , we have that*

$$\rho_p(S \cup A') \leq \frac{\ell^p \cdot |S| + \sum_{v \in A'} (d + d_{S+v}(v))^p}{|S| + |A'|}.$$

Moreover, the inequality above is strict if  $|A'| < |A|$ .

**Proof.** For the case of  $p > 0$ , we note that

$$\begin{aligned}
\rho_p(S \cup A') &= \frac{f_p(S \cup A')}{|S \cup A'|} \\
&= \frac{\sum_{u \in S} d_{S \cup A'}(u)^p + \sum_{v \in A'} d_{S \cup A'}(v)^p}{|S| + |A'|} \\
&\leq \frac{\sum_{u \in S} d_{S \cup A}(u)^p + \sum_{v \in A'} d_{S \cup A}(v)^p}{|S| + |A'|} \quad (\text{since } p > 0) \\
&= \frac{\ell^p \cdot |S| + \sum_{v \in A'} d_{S \cup A}(v)^p}{|S| + |A'|} \quad (\text{since } d_{S \cup A}(u) = \ell) \\
&= \frac{\ell^p \cdot |S| + \sum_{v \in A'} (d + d_{S+v}(v))^p}{|S| + |A'|}. \quad (\text{since } G[A] \text{ is a } d\text{-regular graph})
\end{aligned}$$

If  $|A'| < |A|$ , then there exists a vertex  $u \in A'$  such that  $d_{A'}(u) < d_A(u) = d$  because  $G[A]$  is connected, which implies that the inequality above is strict.  $\blacktriangleleft$

We need the following technical lemma about the maximizer of a relevant function.

► **Lemma 4.** *Let  $c \in \mathbb{R}_{\geq 0}$ . Let  $f : \mathbb{R}_{\geq 0}^n \rightarrow \mathbb{R}$  be defined as  $f(x) := \sum_{i=1}^n (c + x_i)^p$ . For  $0 < p < 1$ , consider the following maximization problem parameterized by  $s \in \mathbb{N}$ :*

$$\text{maximize } \left\{ f(x) : x \in \mathbb{Z}^n, x \geq 0, \sum_{i=1}^n x_i \leq s \right\}.$$

*Every maximizer for the above problem has  $\mu$  coordinates set to  $\lceil s/n \rceil - 1$  and  $n - \mu$  coordinates set to  $\lceil s/n \rceil$ , where  $\mu = n \cdot \lceil s/n \rceil - s$ . If  $s$  is a multiple of  $n$ , then the maximizer has all coordinates set to  $s/n$ .*

**Proof.** Let  $x \in \mathbb{Z}^n$  and  $x \geq 0$  be a maximizer. If  $\sum_{i=1}^n x_i < s$ , then by setting  $x'_n = x_n + 1$  and  $x'_k = x_k$  for every  $k \in [n - 1]$ , we have  $f(x') > f(x)$ , a contradiction to optimality of  $f(x)$ .

Suppose that  $\sum_{i=1}^n x_i = s$ . We prove that all coordinates are in  $\{\lceil s/n \rceil, \lceil s/n \rceil - 1\}$ . Assume that  $x$  has at least one entry not in  $\{\lceil s/n \rceil, \lceil s/n \rceil - 1\}$ . Then, there exists some coordinate  $x_i$  that is strictly larger than  $\lceil s/n \rceil$  or smaller than  $\lceil s/n \rceil - 1$ . Without loss of generality, we assume that  $x_i > \lceil s/n \rceil$ . Consequently, there exists some index  $j \in [n]$  such that  $x_j < \lceil s/n \rceil$ . Since  $x_j < \lceil s/n \rceil < x_i$  and  $x_i, x_j$  are both integers, we have  $x_i - x_j \geq 2$ . Because  $(c + x)^p$  is a concave function of  $x$ ,  $(c + x_i)^p + (c + x_j)^p < (c + x_i - 1)^p + (c + x_j + 1)^p$ . By setting  $x'_i = x_i - 1$ ,  $x'_j = x_j + 1$ , and  $x'_k = x_k$  for every  $k \in [n] \setminus \{i, j\}$ , we have  $f(x') > f(x)$ , a contradiction to optimality of  $f(x)$ .

Hence, for every maximizer  $x \in \mathbb{Z}^n$ , we have  $\sum_{i=1}^n x_i = s$  and  $x_i \in \{\lceil s/n \rceil, \lceil s/n \rceil - 1\}$  for every  $i \in [n]$ . This implies that  $(n - \mu)$  coordinates are  $\lceil s/n \rceil$  and  $\mu$  coordinates are  $\lceil s/n \rceil - 1$ , where  $\mu = n \cdot \lceil s/n \rceil - s$ . When  $s$  is a multiple of  $n$ , by Jensen's inequality, we have  $x_i = s/n$  for every  $1 \leq i \leq n$ .  $\blacktriangleleft$

We will use the following lemma about the existence of an integer  $\ell$  that satisfies two inequalities simultaneously for every given  $p$ .

► **Lemma 5.** *For every  $p \in (0, 1)$ , there exists an integer  $\ell \geq 3$  s.t the following two inequalities hold:*

$$\left(1 - \frac{1}{2\ell}\right)^p < 1 - \frac{1 - 1/2^p}{\ell + 1} \quad \text{and} \quad \left(1 + \frac{1}{2\ell}\right)^p < 1 + \frac{1 - 1/2^p}{\ell + 1}. \quad (1)$$

We need the following lemma about NO-instances of EXACT  $\ell$ -COVER.

► **Lemma 6.** *Let  $p \in (0, 1)$  and  $\ell \geq 3$  be an integer that satisfies the two inequalities in (1). Consider an instance of EXACT  $\ell$ -COVER with ground set  $\mathcal{U}$  of size  $\ell n$  and family  $\mathcal{S} \subseteq 2^{\mathcal{U}}$ . Suppose that the instance has no exact  $\ell$ -cover. Then, for every non-negative integers  $s, a' \in \mathbb{Z}_{\geq 0}$  with  $s \leq |\mathcal{S}|$ ,  $a' \leq \ell n$ , and  $s + a' \geq 1$  and every non-negative integer vector  $X \in \mathbb{Z}_{\geq 0}^{a'}$  with  $\sum_{i=1}^{a'} X_i \leq \ell s$ , we have that*

$$\frac{\ell^p \cdot s + \sum_{i=1}^{a'} (2\ell - 1 + X_i)^p}{s + a'} \leq \frac{\ell^p + \ell \cdot (2\ell)^p}{\ell + 1}. \quad (2)$$

Moreover, if there exists  $i \in [a']$  such that  $X_i \neq \ell s/a'$ , then the above inequality is strict.

**Proof.** We case on the value of the ratio  $s/a'$ .

**Case 1.** Suppose  $\ell \cdot s = a'$ . Then, we have

$$\begin{aligned} \frac{\ell^p \cdot s + \sum_{i=1}^{a'} (2\ell - 1 + X_i)^p}{s + a'} &\leq \frac{\ell^p \cdot s + a' \cdot (2\ell - 1 + \frac{\ell \cdot s}{a'})^p}{s + a'} \quad (\text{by } \sum_{i=1}^{a'} X_i \leq \ell \cdot s \text{ and Lemma 4}) \\ &= \frac{\ell^p \cdot a'/\ell + a' \cdot (2\ell)^p}{a'/\ell + a'} \quad (\text{since } \ell \cdot s = a') \\ &= \frac{\ell^p + \ell \cdot (2\ell)^p}{\ell + 1}. \end{aligned}$$

By Lemma 4, if there exists  $i \in [a']$  such that  $X_i \neq \ell s/a'$ , then the above inequality is strict.

**Case 2.** Suppose  $\ell \cdot s = \beta \cdot a'$  for some  $0 \leq \beta < 1$ . Then, we have

$$\begin{aligned} \frac{\ell^p \cdot s + \sum_{i=1}^{a'} (2\ell - 1 + X_i)^p}{s + a'} &\leq \frac{\ell^p \cdot s + \beta a' \cdot (2\ell)^p + (1 - \beta)a' \cdot (2\ell - 1)^p}{s + a'} \\ &\quad (\text{by } \sum_{i=1}^{a'} X_i \leq \ell \cdot s \text{ and Lemma 4}) \\ &= \frac{\ell^p \cdot \beta + \ell \beta \cdot (2\ell)^p + \ell(1 - \beta) \cdot (2\ell - 1)^p}{\beta + \ell}. \quad (\text{since } \ell \cdot s = \beta \cdot a') \end{aligned}$$

We define  $h : [0, 1] \rightarrow \mathbb{R}$  as

$$h(\beta) := \frac{\ell^p \cdot \beta + \ell \beta \cdot (2\ell)^p + \ell(1 - \beta) \cdot (2\ell - 1)^p}{\beta + \ell},$$

which implies that the left hand side expression in the lemma is at most  $h(\beta)$ . By differentiating the function  $h$  with respect to  $\beta$ , we have

$$\begin{aligned} \frac{d}{d\beta} h(\beta) &= \frac{(\ell^p + \ell \cdot (2\ell)^p - \ell \cdot (2\ell - 1)^p)(\beta + \ell) - (\ell^p \cdot \beta + \ell \beta \cdot (2\ell)^p + \ell(1 - \beta) \cdot (2\ell - 1)^p)}{(\beta + \ell)^2} \\ &= \frac{\ell^{p+1} + \ell^2 \cdot (2\ell)^p - \ell^2 \cdot (2\ell - 1)^p - \ell \cdot (2\ell - 1)^p}{(\beta + \ell)^2} \\ &= \frac{\ell^{p+1} + \ell^2 \cdot (2\ell)^p - (\ell^2 + \ell) \cdot (2\ell - 1)^p}{(\beta + \ell)^2} \\ &> \frac{\ell^{p+1} + \ell^2 \cdot (2\ell)^p - (\ell^2 + \ell) \cdot (2\ell)^p \cdot (1 - \frac{1-2^{-p}}{\ell+1})}{(\beta + \ell)^2} \quad (\text{by inequality (1)}) \\ &= \frac{\ell^{p+1} + \ell^2 \cdot (2\ell)^p - \ell \cdot (2\ell)^p \cdot (\ell + 2^{-p})}{(\beta + \ell)^2} = 0. \end{aligned}$$

Hence, function  $h(\beta)$  is strictly increasing for  $\beta \in [0, 1]$ . Thus,

$$\frac{\ell^p \cdot s + \sum_{i=1}^{a'} (2\ell - 1 + X_i)^p}{s + a'} \leq h(\beta) < h(1) = \frac{\ell^p + \ell \cdot (2\ell)^p}{\ell + 1}.$$

**Case 3.** Suppose  $\ell \cdot s = \alpha \cdot a'$  for some  $\alpha > 1$ . Let  $\alpha = t + \beta$  where  $t \geq 1$  is an integer and  $0 < \beta \leq 1$ . Then, we have

$$\begin{aligned} \frac{\ell^p \cdot s + \sum_{i=1}^{a'} (2\ell - 1 + X_i)^p}{s + a'} &\leq \frac{\ell^p \cdot s + \beta a' \cdot (2\ell + t)^p + (1 - \beta) |A'| \cdot (2\ell - 1 + t)^p}{|S| + |A'|} \\ &\quad (\text{by } \sum_{i=1}^{a'} X_i \leq \ell \cdot s \text{ and Lemma 4}) \\ &= \frac{\ell^p \cdot (t + \beta) + \ell \beta \cdot (2\ell + t)^p + \ell(1 - \beta) \cdot (2\ell - 1 + t)^p}{t + \beta + \ell} \\ &\quad (\text{since } \ell \cdot s = (t + \beta) \cdot a'). \end{aligned}$$

We define  $g : [0, +\infty) \times [0, 1] \rightarrow \mathbb{R}$  as

$$g(t, \beta) := \frac{\ell^p \cdot (t + \beta) + \ell \beta \cdot (2\ell + t)^p + \ell(1 - \beta) \cdot (2\ell - 1 + t)^p}{t + \beta + \ell},$$

which implies that the left hand side expression in the lemma is at most  $g(t, \beta)$ . We note that  $g(t, 1) = g(t + 1, 0)$  for every  $t \geq 0$ .

By differentiating the function  $g$  with respect to  $\beta$ , we have

$$\begin{aligned} \frac{d}{d\beta} g(t, \beta) &= \frac{(\ell^p + \ell \cdot (2\ell + t)^p - \ell \cdot (2\ell - 1 + t)^p)(t + \beta + \ell) - (\ell^p \cdot (t + \beta) + \ell \beta \cdot (2\ell + t)^p + \ell(1 - \beta) \cdot (2\ell - 1 + t)^p)}{(t + \beta + \ell)^2} \\ &= \frac{\ell^{p+1} + (\ell^2 + t \cdot \ell) \cdot (2\ell + t)^p - (\ell^2 + (t + 1) \cdot \ell) \cdot (2\ell + t - 1)^p}{(t + \beta + \ell)^2}. \end{aligned}$$

Now, we note that

$$\begin{aligned} \frac{d}{dt} (\ell^{p+1} + (\ell^2 + t \cdot \ell) \cdot (2\ell + t)^p - (\ell^2 + (t + 1) \cdot \ell) \cdot (2\ell + t - 1)^p) &= p \cdot (\ell^2 + t \cdot \ell) \cdot (2\ell + t)^{p-1} + \ell \cdot (2\ell + t)^p - p \cdot (\ell^2 + (t + 1) \cdot \ell) \cdot (2\ell + t - 1)^{p-1} - \ell \cdot (2\ell + t - 1)^p \\ &\leq p \cdot (\ell^2 + t \cdot \ell) \cdot (2\ell + t)^{p-1} + \ell \cdot p \cdot (2\ell + t - 1)^{p-1} - p \cdot (\ell^2 + (t + 1) \cdot \ell) \cdot (2\ell + t - 1)^{p-1} \\ &\quad (\text{since } (x + 1)^p - x^p \leq p \cdot x^{p-1} \text{ for every } x > 0) \\ &= p \cdot (\ell^2 + t \cdot \ell) \cdot ((2\ell + t)^{p-1} - (2\ell + t - 1)^{p-1}) < 0. \end{aligned}$$

Thus,

$$\begin{aligned} \frac{d}{d\beta} g(t, \beta) &= \frac{\ell^{p+1} + (\ell^2 + t \cdot \ell) \cdot (2\ell + t)^p - (\ell^2 + (t + 1) \cdot \ell) \cdot (2\ell + t - 1)^p}{(t + \beta + \ell)^2} \\ &\leq \frac{\ell^{p+1} + (\ell^2 + \ell) \cdot (2\ell + 1)^p - (\ell^2 + 2\ell) \cdot (2\ell)^p}{(1 + \beta + \ell)^2} \quad (\text{since } t \geq 1) \\ &= \frac{(2\ell)^p \cdot (2^{-p} \cdot \ell + (\ell^2 + \ell) \cdot (1 + \frac{1}{2\ell})^p) - (\ell^2 + 2\ell)}{(1 + \beta + \ell)^2} \\ &< \frac{(2\ell)^p \cdot (2^{-p} \cdot \ell + (\ell^2 + \ell) \cdot (1 + \frac{1-2^{-p}}{\ell+1})) - (\ell^2 + 2\ell)}{(1 + \beta + \ell)^2} \quad (\text{by inequality (1)}) \\ &= \frac{(2\ell)^p \cdot (2^{-p} \cdot \ell + (\ell^2 + \ell) + (1 - 2^{-p}) \cdot \ell) - (\ell^2 + 2\ell)}{(1 + \beta + \ell)^2} = 0. \end{aligned}$$

## 9:10 On the Generalized Mean Densest Subgraph Problem: Complexity and Algorithms

Hence, function  $g(t, \beta)$  is strictly decreasing with respect to  $\beta$  for  $\beta \in [0, 1]$ . Thus,

$$\frac{\ell^p \cdot s + \sum_{i=1}^{a'} (2\ell - 1 + X_i)^p}{s + a'} \leq g(t, \beta) < g(t, 0).$$

For every positive integer  $r > 1$ , we have  $g(r, 0) = g(r - 1, 1) < g(r - 1, 0)$ . Thus,

$$\frac{\ell^p \cdot s + \sum_{i=1}^{a'} (2\ell - 1 + X_i)^p}{s + a'} < g(t, 0) < g(1, 0) = \frac{\ell^p + \ell \cdot (2\ell)^p}{\ell + 1}. \quad \blacktriangleleft$$

Now, we are ready to prove the NP-hardness of  $p$ -MEAN DSG for  $p \in (0, 1)$ . We recall that  $\text{OPT}_G := \max_{X \subseteq V} \rho_p(X)$ .

► **Theorem 7.** *For every  $p \in (0, 1)$ , there exist positive integers  $\ell \geq 3$  and  $d$  such that for an instance of EXACT  $\ell$ -COVER with ground set  $\mathcal{U}$  and family  $\mathcal{S} \subseteq 2^{\mathcal{U}}$ , there exists an exact  $\ell$ -cover iff  $\text{OPT}_G \geq \rho^* = \frac{\ell^p + \ell \cdot (d+1)^p}{\ell + 1}$ , where  $G = G_d$  is the graph constructed in the reduction above.*

**Proof.** By Corollary 5, we know that there exists a positive integer  $\ell \geq 3$  satisfying the two inequalities in (1). Fix such an  $\ell$ . Let  $\mathcal{U}$  be the ground set and  $\mathcal{S}$  be the collection of subsets of an instance of EXACT  $\ell$ -COVER. We set  $d = 2\ell - 1$  and consider the graph  $G = G_d$  constructed in the reduction in Section 2.1. We show that there exists an exact  $\ell$ -cover iff  $\text{OPT}_G \geq \rho^* = \frac{\ell^p + \ell \cdot (d+1)^p}{\ell + 1}$ .

Suppose  $\mathcal{S}$  contains an exact  $\ell$ -cover  $S_{i_1}, \dots, S_{i_n}$ . Let  $S = \{v_{i_1}, v_{i_2}, \dots, v_{i_n}\}$ . We note that  $|S| = n = \frac{|A|}{\ell}$ . Thus, we have

$$\text{OPT}_G \geq \rho_p(S \cup A) = \frac{f_p(S \cup A)}{|S \cup A|} = \frac{\ell^p \cdot |S| + (d+1)^p \cdot |A|}{|S| + |A|} = \frac{\ell^p \cdot |A|/\ell + (d+1)^p \cdot |A|}{|A|/\ell + |A|} = \rho^*.$$

Suppose  $\mathcal{S}$  does not contain an exact  $\ell$ -cover. Let  $S \subseteq L$  and  $A' \subseteq A$ . We note that  $\ell \cdot |S| = \sum_{v \in A} d_{S+v}(v) \geq \sum_{v \in A'} d_{S+v}(v)$ . Thus, we have

$$\begin{aligned} \rho_p(S \cup A') &= \frac{f_p(S \cup A')}{|S \cup A'|} \leq \frac{\ell^p \cdot |S| + \sum_{v \in A'} (d + d_{S+v}(v))^p}{|S| + |A'|} \quad (\text{by Lemma 3}) \\ &\leq \rho^*. \quad (\text{by Lemma 6}) \end{aligned}$$

We note that since  $S$  is not an exact  $\ell$ -cover, we have that either  $|A'| < |A|$  or there exists  $u, v \in A$  with  $d_{S+u}(u) \neq d_{S+v}(v)$ . This implies that either the first inequality or the second inequality above is strict according to the respective lemmas, that is,  $\rho_p(S \cup A') < \rho^*$ . ◀

### 3 APX-hardness for $p \in (0, 1)$

In this section, we adapt the NP-hardness proof from Section 2 to show that WEIGHTED  $p$ -MEAN DSG is APX-hard for every fixed constant  $p \in (0, 1)$ .

► **Theorem 8.** *For every fixed constant  $p \in (0, 1)$ , there exists a constant  $\delta_p > 0$  that depends only on  $p$  such that it is NP-hard to obtain a  $(1 - \delta_p)$ -approximation for WEIGHTED  $p$ -MEAN DSG.*

In order to prove Theorem 8, we will rely on the APX-hardness of EXACT  $\ell$ -COVER as stated below.

► **Theorem 9.** *There exists a constant  $\varepsilon \in (0, 1)$  such that for every integer  $\ell \geq 3$ , it is NP-hard to distinguish between the following two cases for a given finite ground set  $\mathcal{U}$  of size  $\ell n$  and a family  $\mathcal{S} \subseteq 2^{\mathcal{U}}$  of subsets each of cardinality  $\ell$ :*

- *YES-instance: There exists a collection of  $n$  sets in  $\mathcal{S}$  whose union is  $\mathcal{U}$ .*
- *NO-instance: The union of every collection of  $n \cdot (1 + \varepsilon)$  sets in  $\mathcal{S}$  has size at most  $\ell \cdot n \cdot (1 - \varepsilon)$ .*

Exact  $\ell$ -Cover is a special case of Set Cover. The hardness we seek requires a disjoint set cover in the YES case, and we also need the hardness to hold for every fixed integer  $\ell \geq 3$ . Related results have been proved in the literature [32, 43, 26, 23], however the precise version we need requires a formal argument. We provide the proof in the full version and also comment on the relation to previous work.

### Reduction from Exact $\ell$ -Cover to weighted $p$ -mean DSG

We reduce from the APX-hard variant of EXACT  $\ell$ -COVER, namely the problem mentioned in Theorem 9. Consider an instance of the problem mentioned in Theorem 9: namely, let  $\mathcal{U}$  be a ground set of size  $\ell n$  and let  $\mathcal{S} \subseteq 2^{\mathcal{U}}$  of subsets each of cardinality  $\ell$ . For a positive integer  $d$  (to be chosen later), we construct a graph  $G_d = (L \cup A, E)$  as follows: we define  $L := \{v_i : i \in [m]\}$  and  $A := \{u_j : j \in [\ell \cdot n]\}$ . For every  $i \in [m]$  and  $j \in [\ell \cdot n]$ , if set  $S_i$  contains element  $e_j$ , then we add an edge with unit weight between  $v_i$  and  $u_j$  in graph  $G$ . We add an edge between all pairs of vertices in  $A$  with weight  $\frac{d}{|A|-1}$ , where  $d$  will be chosen appropriately (instead of  $G[A]$  being a connected  $d$ -regular graph as used in the NP-hardness reduction in Section 2). We note that for every vertex  $v \in A$ , the sum of weight of edges incident to  $v$  in the induced subgraph  $G[A]$  is  $d$ . We define  $\text{OPT}_{G_d} := \max_{X \subseteq V} \rho_p(X)$  and set  $\rho^* := \frac{\ell^p + \ell \cdot (d+1)^p}{\ell+1}$ . We will prove that if the instance is a YES instance, then  $\text{OPT}_{G_d} \geq \rho^*$  and if the instance is a NO instance, then  $\text{OPT}_{G_d} < (1 - \delta_p) \cdot \rho^*$  for some constant  $\delta_p > 0$  that depends only on  $p$ . We now state the main theorem of the section below.

► **Theorem 10.** *For every  $p \in (0, 1)$ , there exist positive integers  $\ell \geq 3$  and  $d$  such that for an instance  $(\mathcal{U}, \mathcal{S})$  of the problem mentioned in Theorem 9, where the ground set  $\mathcal{U}$  has size  $\ell n$  and every set in  $\mathcal{S}$  has size  $\ell$ , the following two hold:*

- *if the instance is a YES-instance, then  $\text{OPT}_{G_d} \geq \rho^*$ , and*
- *if the instance is a NO-instance, then  $\text{OPT}_{G_d} < (1 - \delta_p) \cdot \rho^*$  for some constant  $\delta_p > 0$  that depends only on  $p$ .*

Here,  $G_d$  is the graph constructed in the reduction from Exact  $\ell$ -Cover for Weighted Version.

Theorem 8 follows from Theorem 10. We briefly outline our proof of Theorem 10 and refer to the full version for the full proof. It is easy to see that if the instance  $(\mathcal{U}, \mathcal{S})$  of the problem mentioned in Theorem 9 is a YES-instance, then  $\text{OPT}_{G_d} \geq \rho^*$  (similar to the proof of NP-hardness). We focus on showing that if the instance is a NO-instance, then  $\text{OPT}_{G_d} < (1 - \delta) \rho^*$ . Let  $S \subseteq L$  and  $A' \subseteq A$ . We need to show that  $\rho_p(S \cup A') < (1 - \delta) \rho^*$ . For this, we recall the proof of NP-hardness in Section 2.2. There, we showed that if the instance does not have an exact  $\ell$ -cover, then  $\rho_p(S \cup A') < \rho^*$ . For this, we proved that  $\rho_p(S \cup A')$  is maximized and is at most  $\rho^*$  if  $\ell|S|/|A'| = 1$ . That proof can be adapted in a straightforward fashion to show that  $\rho_p(S \cup A') < (1 - \delta) \rho^*$  if  $\ell|S|/|A'| \geq 1 + \varepsilon$  or if  $\ell|S|/|A'| \leq 1 - \varepsilon$  for some constants  $\delta, \varepsilon > 0$  (even for the graph  $G_d$  that appears in the reduction to unweighted  $p$ -MEAN DSG) – see cases 1 and 2 in the proof of Theorem 10. Thus, the non-trivial case to handle is if  $\ell|S|/|A'| \in (1 - \varepsilon, 1 + \varepsilon)$ . In this situation, we consider two cases: (i) Suppose that  $|A'| \leq (1 - \varepsilon)|A|$ . In this case, we exploit the clique in the weighted graph constructed in the reduction above to conclude that  $\rho_p(S \cup A') < (1 - \delta) \rho^*$  for some constant  $\delta > 0$  (see case 3 in the proof of Theorem 10). (ii) Suppose that  $|A'| > (1 - \varepsilon)|A|$ .

In this case, we rely on the APX-hardness of EXACT  $\ell$ -COVER (i.e., the instance  $(\mathcal{U}, \mathcal{S})$  is a NO-instance of the problem mentioned in Theorem 9) to conclude that  $\rho_p(S \cup A') < (1 - \delta)\rho^*$  for some constant  $\delta > 0$  (see case 4 in the proof of Theorem 10). We emphasize that the weighted clique over the set  $A$  of vertices in the reduction graph (as opposed to an unweighted  $d$ -regular graph over the set  $A$  of vertices) is useful in the first case. We also mention that the constant  $\delta_p$  in Theorem 10 is very small. We give an estimation of  $\delta_{1/2}$  in the full version.

## 4 Approximation Algorithms

We give two new approximation algorithms for  $p$ -MEAN DSG. Our algorithms achieve an approximation factor of  $\frac{1}{2}$  for all  $p \in (-\infty, 1)$ . Our algorithms rely on the fact that MAXCORE and DSG can be solved in polynomial time. First, we show that the peeling algorithm used to compute MAXCORE can be adapted to obtain a  $\frac{1}{2}$ -approximate solutions to  $p$ -MEAN DSG for every  $p \in (-\infty, 1)$ . Secondly, we show that an optimum solution to DSG is a  $\frac{1}{2}$ -approximate solution to  $p$ -MEAN DSG for every  $p \in (-\infty, 1)$ . We complement these results with a family of graphs for which both algorithms *simultaneously* achieve only a  $\frac{1}{2}$ -approximation.

Let  $G = (V, E)$  be the input graph. We let  $S_p^* := \arg \max_{S \subseteq V} M_p(S)$  and let  $M_p^* := M_p(S_p^*)$ . We need the following fact about the monotonicity of the objective.

► **Proposition 11.** *Let  $S \subseteq V$ . For every  $p \leq q$ , we have  $M_p(S) \leq M_q(S)$ .*

We have the following statement connecting different values of  $M_p^*$ .

► **Proposition 12.** *For every  $p \in [-\infty, 1]$ , we have  $M_{-\infty}^* \leq M_p^* \leq M_1^* \leq 2M_{-\infty}^*$ .*

The first two inequalities follow directly from Proposition 11 and the last inequality follows via a simple known argument connecting degeneracy to the maximum average degree of a subgraph (e.g., see [16]).

### $\frac{1}{2}$ -approximation via maxcore approach

Our first algorithm leverages the standard greedy peeling algorithm for the maxcore. Our algorithm, denoted Simple-Greedy- $p$ , is given in Figure 2. The algorithm for  $p = -\infty$  is the peeling algorithm used to compute maxcore and the algorithm for  $p = 1$  is Charikar's greedy peeling algorithm. We recall that Charikar showed that the algorithm achieves a  $\frac{1}{2}$ -approximation for 1-MEAN DSG.

■ **Figure 2**  $\frac{1}{2}$ -approximation via greedy peeling for  $p$ -MEAN DSG where  $p < 1$ .

► **Theorem 13.** *Let  $p \in [-\infty, 1]$  and let  $S$  be the output of Simple-Greedy- $p(G)$ . Then,  $M_p(S) \geq \frac{1}{2}M_p^*$ .*

**Proof.** The algorithm for  $p = -\infty$  is the peeling algorithm used to compute maxcore. In particular, it is well-known that there exists  $i \in [n]$  with  $M_{-\infty}(S_i) = M_{-\infty}^*$ . By Proposition 11,  $M_{-\infty}(S_i) \leq M_p(S_i)$  and by choice of  $S$ , we have  $M_p(S_i) \leq M_p(S)$ . Therefore,  $M_{-\infty}^* \leq M_p(S)$ . Finally, by Proposition 12, we have  $\frac{1}{2}M_p^* \leq M_{-\infty}^*$ . Combining these two statements, we get  $\frac{1}{2}M_p^* \leq M_p(S)$ . ◀

► **Remark 14.** Simple-Greedy- $p$  returns an optimum solution for  $p = \infty$ . Our results show that for  $p \in (-\infty, 1]$ , Simple-Greedy- $p$  returns a  $\frac{1}{2}$ -approximation. However, for  $p > 1$ , [47] showed that the approximation factor of Simple-Greedy- $p$  can be arbitrarily small.

### $\frac{1}{2}$ -approximation via 1-mean densest subgraph

Our second algorithm is to simply return a 1-mean densest subgraph. We recall that  $S_1^* = \arg \max_{S \subseteq V} M_1(S)$  and it can be computed in polynomial time. We analyze its approximation factor.

► **Theorem 15.** *Let  $p \in [-\infty, 1]$ . Then,  $M_p(S_1^*) \geq \frac{1}{2}M_p^*$ .*

**Proof.** We first prove that

$$M_{-\infty}(S_1^*) \geq \frac{1}{2}M_1^*. \quad (3)$$

It suffices to show that  $d_{S_1^*}(v) \geq \frac{|E(S_1^*)|}{|S_1^*|}$  for every  $v \in S_1^*$ . Suppose towards a contradiction that there exists  $v \in S_1^*$  such that  $d_{S_1^*}(v) < \frac{|E(S_1^*)|}{|S_1^*|}$ . Using this and observing  $|E(S_1^*)| - |E(S_1^* - v)| = d_{S_1^*}(v)$ , after rearranging, we have  $\frac{|E(S_1^* - v)|}{|S_1^* - v|} > \frac{|E(S_1^*)|}{|S_1^*|}$ . Multiplying through by 2, we obtain  $M_1(S_1^* - v) > M_1(S_1^*)$ , contradicting the optimality of  $S_1^*$ .

Thus, we have

$$M_p(S_1^*) \geq M_{-\infty}(S_1^*) \geq \frac{1}{2}M_1^* \geq \frac{1}{2}M_p^*$$

where the first and last inequality are by Proposition 11 and the second inequality is via (3). ◀

► **Remark 16.** We described two algorithms that achieve an approximation factor of  $\frac{1}{2}$ . Would returning the best among the sets returned by the two algorithms achieve a factor that is better than  $\frac{1}{2}$ ? In the full version, we construct a non-trivial family of instances on which both algorithms have an approximation factor of at most  $\frac{1}{2}$ . We emphasize that we seek non-trivial instances – in particular, instances in which the optimum value is arbitrary (i.e., grows) and is not a fixed constant.

## 5 Conclusion

MAXCORE and DSG are polynomial-time solvable densest subgraph problems with numerous applications.  $p$ -MEAN DSG, introduced by Veldt, Benson, and Kleinberg [47], captures both these special cases and provides a unified way to generate subgraphs with different density properties.  $p$ -MEAN DSG is polynomial-time solvable for  $p = -\infty$  and for  $p \geq 1$ . In this work, we addressed the complexity and algorithmic aspects of the problem for  $p \in (-\infty, 1)$ .

We showed that  $p$ -MEAN DSG is NP-hard for  $p \in (-\infty, 1)$  and WEIGHTED  $p$ -MEAN DSG is APX-hard for every fixed constant  $p \in (0, 1)$ . Our hardness results motivate the need for approximation algorithms for  $p \in (-\infty, 1)$ . We gave a simple  $1/2$ -approximation for  $p$ -MEAN DSG for all  $p \in (-\infty, 1)$ . Our approximation algorithms also extend to WEIGHTED  $p$ -MEAN DSG with the same approximation guarantee in a natural manner.

There are two interesting directions for future work. Firstly, is  $p$ -MEAN DSG (or WEIGHTED  $p$ -MEAN DSG) APX-hard for every  $p \in (-\infty, 1)$ ? Our APX-hardness results hold for every fixed constant  $p \in (0, 1)$ . Extending our approach to show APX-hardness for fixed constant  $p \in (-\infty, 0)$  requires extending the proof of Theorem 10 to  $p < 0$ . The technical barrier to extending is the third case in the proof. Secondly, can we improve the approximability of  $p$ -MEAN DSG for  $p \in (-\infty, 1)$ ? In contrast to the densest subgraph problem, the non-linearity of the objective function of  $p$ -MEAN DSG makes it difficult to develop mathematical programming relaxations. We leave it here as an interesting open problem.

---

## A Missing proofs for NP-hardness

We include the missing proofs for  $p \in (0, 1)$  from Section 2 here.

### A.1 Proof of Theorem 2

► **Theorem 2.** *EXACT  $\ell$ -COVER is NP-complete for every integer  $\ell \geq 3$ .*

**Proof.** We recall that EXACT 3-COVER is NP-complete [22]. We reduce EXACT  $\ell$ -COVER to EXACT  $(\ell+1)$ -COVER for  $\ell \geq 3$ . Consider an instance of EXACT  $\ell$ -COVER with ground set  $\mathcal{U}$  of cardinality  $\ell n$  and a family  $\mathcal{S} \subseteq 2^{\mathcal{U}}$  of subsets each of which has cardinality  $\ell$ . Let  $x_1, \dots, x_n$  be  $n$  new elements that are not in  $\mathcal{U}$ . We create an instance of EXACT  $(\ell+1)$ -COVER as follows:

- Let  $\mathcal{U}' := \mathcal{U} \cup \{x_1, \dots, x_n\}$  be the ground set. We have that  $|\mathcal{U}'| = |\mathcal{U}| + n = (\ell+1) \cdot n$ .
- Let  $\mathcal{S}' := \{S \cup \{x_i\} : S \in \mathcal{S}, 1 \leq i \leq n\}$ . Each set in  $\mathcal{S}'$  has cardinality  $\ell+1$ .

If there exists an exact  $\ell$ -cover  $\{S_{i_1}, S_{i_2}, \dots, S_{i_n}\}$  of  $\mathcal{U}$ , then  $\{S_{i_1} \cup \{x_1\}, S_{i_2} \cup \{x_2\}, \dots, S_{i_n} \cup \{x_n\}\}$  is an exact  $(\ell+1)$ -cover of  $\mathcal{U}$ . If an exact  $\ell$ -cover of  $\mathcal{U}$  does not exist, then an exact  $(\ell+1)$ -cover of  $\mathcal{U}'$  does not exist. Hence, NP-completeness of EXACT 3-COVER implies NP-completeness of EXACT  $\ell$ -COVER for every  $\ell \geq 3$ . ◀

### A.2 Technical Lemmas for Hardness Results

The following inequalities will be used when proving the hardness results.

► **Lemma 17.** *Let  $p, x \in (0, 1)$ . Then,*

1.  $(1-x)^p < 1 - px$ ,
2.  $(1-x)^p < 1 - px - \frac{p(1-p)}{2}x^2$ ,
3.  $(1+x)^p < 1 + px$ , and
4.  $(1+x)^p < 1 + px - \frac{p(1-p)}{2}x^2 + \frac{p(1-p)(2-p)}{6}x^3$ .

**Proof.** For the first inequality, let  $f_1(x) := (1-x)^p - (1-px)$ . Then,  $f_1'(x) = p \cdot (1 - (1-x)^{p-1}) < 0$ , which implies that  $f_1(x) < f_1(0) = 0$ .

For the second inequality, let  $f_2(x) := (1-x)^p - (1-px - \frac{p(1-p)}{2}x^2)$ . Then,  $f_2'(x) = p \cdot (1 + (1-p)x - (1-x)^{p-1})$  and  $f_2''(x) = p \cdot (1-p) \cdot (1 - (1-x)^{p-2}) < 0$ . Hence,  $f_2'(x) < f_2'(0) = 0$ , which implies that  $f_2(x) < f_2(0) = 0$ .

For the third inequality, let  $f_3(x) := (1+x)^p - (1+px)$ . Then,  $f_3'(x) = p \cdot ((1+x)^{p-1} - 1) < 0$ , which implies that  $f_3(x) < f_3(0) = 0$ .

For the fourth inequality, let  $f_4(x) := (1+x)^p - (1+px - \frac{p(1-p)}{2}x^2 + \frac{p(1-p)(2-p)}{6}x^3)$ . Then,  $f_4'(x) = p \cdot ((1+x)^{p-1} - (1 + (1-p)x + \frac{(1-p)(2-p)}{2}x^2))$ . Also,  $f_4''(x) = p \cdot (1-p) \cdot (1 - (2-p)x - (1+x)^{p-2})$  and  $f_4'''(x) = p(1-p)(2-p) \cdot ((1+x)^{p-3} - 1) < 0$ , which implies that  $f_4''(x) < f_4''(0) = 0$ . Thus,  $f_4'(x) < f_4'(0) = 0$  and  $f_4(x) < f_4(0) = 0$ . ◀

### A.3 Proof of Lemma 5

Lemma 5 follows from the following stronger lemma. The stronger version will be useful in proving APX-hardness.

► **Lemma 18.** *For every  $p \in (0, 1)$ , there exists a positive value  $\eta > 0$  and an integer  $\ell \geq 3$ , both of which depend only on  $p$ , such that the following two inequalities hold:*

$$\left(1 - \frac{1}{2\ell}\right)^p < 1 - \frac{1 - 1/2^p}{\ell + 1} - \eta \quad \text{and} \quad \left(1 + \frac{1}{2\ell}\right)^p < 1 + \frac{1 - 1/2^p}{\ell + 1} - \eta.$$

**9:18 On the Generalized Mean Densest Subgraph Problem: Complexity and Algorithms**

**Proof.** Set  $\ell_0 := \frac{p \cdot 2^{p-1}}{2^p - p \cdot 2^{p-1} - 1}$ . Then, we have  $\frac{p}{2\ell_0} = \frac{1-1/2^p}{\ell_0+1}$ . We note that

$$\ell_0 - \frac{5}{2} = \frac{p \cdot 2^{p-1}}{2^p - p \cdot 2^{p-1} - 1} - \frac{5}{2} = \frac{2^{1-p} + \frac{7}{5}p - 2}{2^p - p \cdot 2^{p-1} - 1} \cdot \frac{5}{2} \cdot 2^{p-1} = \frac{2^{1-p} - \frac{7}{5}(1-p) - \frac{3}{5}}{2^p - p \cdot 2^{p-1} - 1} \cdot \frac{5}{2} \cdot 2^{p-1} > 0.$$

The last inequality holds since  $2^x - \frac{7}{5}x - \frac{3}{5}$  is a convex function and evaluates to zero at  $x = 1$  with negative derivative. This implies that  $2^{1-p} - \frac{7}{5}(1-p) - \frac{3}{5} > 0$ . Consequently,

$$\ell_0 > \frac{5}{2}. \tag{4}$$

We also note that

$$\begin{aligned} 2 - (1-p)\ell_0 &= 2 - (1-p) \cdot \frac{p \cdot 2^{p-1}}{2^p - p \cdot 2^{p-1} - 1} \quad (\text{since } \ell_0 = \frac{p \cdot 2^{p-1}}{2^p - p \cdot 2^{p-1} - 1}) \\ &= \frac{2^p \cdot (2 - \frac{3}{2}p + \frac{1}{2}p^2 - 2^{1-p})}{2^p - p \cdot 2^{p-1} - 1} \\ &= \frac{2^p \cdot (1 + (1-p) + \frac{1}{2}(-p)(1-p) - 2^{1-p})}{2^p - p \cdot 2^{p-1} - 1} < 0. \end{aligned}$$

The last inequality above is because  $2^x > 1 + x + \frac{1}{2}x(x-1)$  for all  $x \in (0, 1)$ . This implies that

$$(1-p)\ell_0 > 2. \tag{5}$$

Hence, if we can prove that the two inequalities of the lemma hold for every  $\ell \in [\ell_0 - \frac{1}{2}, \ell_0 + \frac{1}{2}]$ , then it implies the lemma. We define two functions  $f_1 : (0, +\infty) \rightarrow \mathbb{R}$  and  $f_2 : (0, +\infty) \rightarrow \mathbb{R}$  as

$$f_1(\ell) = (1 - \frac{1}{2\ell})^p + \frac{1-1/2^p}{\ell+1} - 1 \quad \text{and} \quad f_2(\ell) = (1 + \frac{1}{2\ell})^p - \frac{1-1/2^p}{\ell+1} - 1.$$

By setting

$$\eta := \frac{1}{2} \cdot \min \left\{ \frac{\frac{1}{2}p \cdot (2\ell_0 + 3)}{\ell_0 \cdot (2\ell_0 + 3) \cdot (2\ell_0 + 1)^2} \cdot ((1-p)\ell_0 - 2), \frac{p}{2\ell_0 - 1} \cdot \frac{16\ell_0 - 16}{6\ell_0(2\ell_0 + 1)(2\ell_0 - 1)^2} \right\},$$

which is larger than 0 by inequalities (4) and (5), we will prove that  $f_1(\ell) < -\eta$  and  $f_2(\ell) < -\eta$  for every  $\ell \in [\ell_0 - \frac{1}{2}, \ell_0 + \frac{1}{2}]$ . We note that

$$\eta < \frac{\frac{1}{2}p \cdot (2\ell_0 + 3)}{\ell_0 \cdot (2\ell_0 + 3) \cdot (2\ell_0 + 1)^2} \cdot ((1-p)\ell_0 - 2) \quad \text{and} \tag{6}$$

$$\eta < \frac{p}{2\ell_0 - 1} \cdot \frac{16\ell_0 - 16}{6\ell_0(2\ell_0 + 1)(2\ell_0 - 1)^2}. \tag{7}$$

By differentiating  $f_1$  with respect to  $\ell$ , we have

$$\begin{aligned}
\frac{d}{d\ell} f_1(\ell) &= \frac{p}{2\ell^2 \cdot (1 - \frac{1}{2\ell})^{1-p}} - \frac{1 - 1/2^p}{(\ell + 1)^2} \\
&= \frac{p \cdot (\ell + 1)^2 - 2(1 - 1/2^p)\ell^2 \cdot (1 - \frac{1}{2\ell})^{1-p}}{2\ell^2 \cdot (1 - \frac{1}{2\ell})^{1-p} \cdot (\ell + 1)^2} \\
&= \frac{2(1 - 1/2^p) \cdot \ell^2}{2\ell^2 \cdot (1 - \frac{1}{2\ell})^{1-p} \cdot (\ell + 1)^2} \cdot \left( \frac{p}{2(1 - 1/2^p)} \cdot (1 + \frac{1}{\ell})^2 - (1 - \frac{1}{2\ell})^{1-p} \right) \\
&= \frac{2(1 - 1/2^p) \cdot \ell^2}{2\ell^2 \cdot (1 - \frac{1}{2\ell})^{1-p} \cdot (\ell + 1)^2} \cdot \left( \frac{\ell_0}{\ell_0 + 1} \cdot (1 + \frac{1}{\ell})^2 - (1 - \frac{1}{2\ell})^{1-p} \right) \\
&\quad (\text{since } \frac{p}{2\ell_0} = \frac{1 - 1/2^p}{\ell_0 + 1}) \\
&> \frac{2(1 - 1/2^p) \cdot \ell^2}{2\ell^2 \cdot (1 - \frac{1}{2\ell})^{1-p} \cdot (\ell + 1)^2} \cdot \left( \frac{\ell_0}{\ell_0 + 1} \cdot (1 + \frac{1}{\ell})^2 - (1 - \frac{1-p}{2\ell}) \right) \\
&\quad (\text{since } (1 - \frac{1}{2\ell})^{1-p} < 1 - \frac{1-p}{2\ell} \text{ according to Lemma 17}) \\
&= \frac{2(1 - 1/2^p) \cdot \ell^2}{2\ell^2 \cdot (1 - \frac{1}{2\ell})^{1-p} \cdot (\ell + 1)^2} \cdot \frac{\ell_0 \cdot (\ell + 1)^2 - (\ell_0 + 1) \cdot \ell^2 + \frac{1-p}{2}(\ell_0 + 1) \cdot \ell}{(\ell_0 + 1) \cdot \ell^2} \\
&> \frac{2(1 - 1/2^p) \cdot \ell^2}{2\ell^2 \cdot (1 - \frac{1}{2\ell})^{1-p} \cdot (\ell + 1)^2} \cdot \frac{\ell_0 \cdot (\ell + 1)^2 - (\ell_0 + 1) \cdot \ell^2}{(\ell_0 + 1) \cdot \ell^2} \\
&= \frac{2(1 - 1/2^p) \cdot \ell^2}{2\ell^2 \cdot (1 - \frac{1}{2\ell})^{1-p} \cdot (\ell + 1)^2} \cdot \frac{\ell_0(2\ell + 1) - \ell^2}{(\ell_0 + 1) \cdot \ell^2} \\
&\geq \frac{2(1 - 1/2^p) \cdot \ell^2}{2\ell^2 \cdot (1 - \frac{1}{2\ell})^{1-p} \cdot (\ell + 1)^2} \cdot \frac{(\ell - \frac{1}{2})(2\ell + 1) - \ell^2}{(\ell_0 + 1) \cdot \ell^2} \quad (\text{since } \ell_0 \geq \ell - \frac{1}{2}) \\
&= \frac{2(1 - 1/2^p) \cdot \ell^2}{2\ell^2 \cdot (1 - \frac{1}{2\ell})^{1-p} \cdot (\ell + 1)^2} \cdot \frac{\ell^2 - \frac{1}{2}}{(\ell_0 + 1) \cdot \ell^2} \\
&> 0. \quad (\text{since } \ell \geq \ell_0 - \frac{1}{2} > 2 \text{ according to inequality (4)})
\end{aligned}$$

Hence, the function  $f_1(\ell)$  is strictly increasing for  $\ell \in [\ell_0 - \frac{1}{2}, \ell_0 + \frac{1}{2}]$ . This implies that

$$\begin{aligned}
f_1(\ell) &\leq f_1(\ell_0 + \frac{1}{2}) = (1 - \frac{1}{2\ell_0 + 1})^p + \frac{1 - 1/2^p}{\ell_0 + \frac{3}{2}} - 1 \\
&= \frac{\frac{\ell_0 + 1}{2\ell_0} \cdot p}{\ell_0 + \frac{3}{2}} + (1 - \frac{1}{2\ell_0 + 1})^p - 1 \quad (\text{since } \frac{p}{2\ell_0} = \frac{1 - 1/2^p}{\ell_0 + 1}) \\
&< \frac{p \cdot (\ell_0 + 1)}{\ell_0 \cdot (2\ell_0 + 3)} - \frac{p}{2\ell_0 + 1} - \frac{p(1-p)}{2} \cdot \frac{1}{(2\ell_0 + 1)^2} \\
&\quad (\text{since } (1-x)^p < 1 - px - \frac{p(1-p)}{2}x^2 \text{ according to Lemma 17}) \\
&= p \cdot \frac{(\ell_0 + 1)(2\ell_0 + 1)^2 - \ell_0(2\ell_0 + 3)(2\ell_0 + 1) - \frac{1-p}{2}\ell_0(2\ell_0 + 3)}{\ell_0 \cdot (2\ell_0 + 3) \cdot (2\ell_0 + 1)^2} \\
&= p \cdot \frac{(2\ell_0 + 1) - \frac{1-p}{2}\ell_0(2\ell_0 + 3)}{\ell_0 \cdot (2\ell_0 + 3) \cdot (2\ell_0 + 1)^2} \\
&< \frac{\frac{1}{2}p \cdot (2\ell_0 + 3)}{\ell_0 \cdot (2\ell_0 + 3) \cdot (2\ell_0 + 1)^2} \cdot (2 - (1-p)\ell_0) \\
&< -\eta. \quad (\text{by inequality (6)})
\end{aligned}$$

By differentiating  $f_2$  with respect to  $\ell$ , we have

$$\begin{aligned}
 \frac{d}{d\ell} f_2(\ell) &= -\frac{p}{2\ell^2 \cdot (1 + \frac{1}{2\ell})^{1-p}} + \frac{1 - 1/2^p}{(\ell + 1)^2} \\
 &= \frac{-p \cdot (\ell + 1)^2 + 2(1 - 1/2^p)\ell^2 \cdot (1 + \frac{1}{2\ell})^{1-p}}{2\ell^2 \cdot (1 + \frac{1}{2\ell})^{1-p} \cdot (\ell + 1)^2} \\
 &= \frac{2(1 - 1/2^p) \cdot \ell^2}{2\ell^2 \cdot (1 + \frac{1}{2\ell})^{1-p} \cdot (\ell + 1)^2} \cdot \left( -\frac{p}{2(1 - 1/2^p)} \cdot (1 + \frac{1}{\ell})^2 + (1 + \frac{1}{2\ell})^{1-p} \right) \\
 &= \frac{2(1 - 1/2^p) \cdot \ell^2}{2\ell^2 \cdot (1 + \frac{1}{2\ell})^{1-p} \cdot (\ell + 1)^2} \cdot \left( -\frac{\ell_0}{\ell_0 + 1} \cdot (1 + \frac{1}{\ell})^2 + (1 + \frac{1}{2\ell})^{1-p} \right) \\
 &\quad \left( \text{since } \frac{p}{2\ell_0} = \frac{1 - 1/2^p}{\ell_0 + 1} \right) \\
 &< \frac{2(1 - 1/2^p) \cdot \ell^2}{2\ell^2 \cdot (1 + \frac{1}{2\ell})^{1-p} \cdot (\ell + 1)^2} \cdot \left( -\frac{\ell_0}{\ell_0 + 1} \cdot (1 + \frac{1}{\ell})^2 + (1 + \frac{1-p}{2\ell}) \right) \\
 &\quad \left( \text{since } (1 + \frac{1}{2\ell})^{1-p} < 1 + \frac{1-p}{2\ell} \text{ according to Lemma 17} \right) \\
 &= \frac{2(1 - 1/2^p) \cdot \ell^2}{2\ell^2 \cdot (1 + \frac{1}{2\ell})^{1-p} \cdot (\ell + 1)^2} \cdot \frac{(\ell_0 + 1) \cdot \ell^2 + \frac{1-p}{2}(\ell_0 + 1) \cdot \ell - \ell_0 \cdot (\ell + 1)^2}{(\ell_0 + 1) \cdot \ell^2} \\
 &< \frac{2(1 - 1/2^p) \cdot \ell^2}{2\ell^2 \cdot (1 + \frac{1}{2\ell})^{1-p} \cdot (\ell + 1)^2} \cdot \frac{(\ell_0 + 1) \cdot \ell^2 + \frac{1}{2}(\ell_0 + 1) \cdot \ell - \ell_0 \cdot (\ell + 1)^2}{(\ell_0 + 1) \cdot \ell^2} \\
 &= \frac{2(1 - 1/2^p) \cdot \ell^2}{2\ell^2 \cdot (1 + \frac{1}{2\ell})^{1-p} \cdot (\ell + 1)^2} \cdot \frac{\ell^2 - \frac{3}{2}\ell_0\ell + \frac{1}{2}\ell - \ell_0}{(\ell_0 + 1) \cdot \ell^2} \\
 &\leq \frac{2(1 - 1/2^p) \cdot \ell^2}{2\ell^2 \cdot (1 + \frac{1}{2\ell})^{1-p} \cdot (\ell + 1)^2} \cdot \frac{\ell(\ell_0 + \frac{1}{2}) - \frac{3}{2}\ell_0\ell + \frac{1}{2}\ell - \ell_0}{(\ell_0 + 1) \cdot \ell^2} \quad \left( \text{since } \ell \leq \ell_0 + \frac{1}{2} \right) \\
 &= \frac{2(1 - 1/2^p) \cdot \ell^2}{2\ell^2 \cdot (1 + \frac{1}{2\ell})^{1-p} \cdot (\ell + 1)^2} \cdot \frac{-\frac{1}{2}\ell_0\ell + \ell - \ell_0}{(\ell_0 + 1) \cdot \ell^2} \\
 &\leq \frac{2(1 - 1/2^p) \cdot \ell^2}{2\ell^2 \cdot (1 + \frac{1}{2\ell})^{1-p} \cdot (\ell + 1)^2} \cdot \frac{-\frac{1}{2}\ell_0\ell + \frac{1}{2}}{(\ell_0 + 1) \cdot \ell^2} \quad \left( \text{since } \ell \leq \ell_0 + \frac{1}{2} \right) \\
 &< 0. \quad \left( \text{since } \ell_0 > \frac{5}{2} \text{ and } \ell \geq \ell_0 - \frac{1}{2} > 2 \text{ according to inequality (4)} \right)
 \end{aligned}$$

Hence, function  $f_2(\ell)$  is strictly decreasing for  $\ell \in [\ell_0 - \frac{1}{2}, \ell_0 + \frac{1}{2}]$ . This implies that

$$\begin{aligned}
 f_2(\ell) &\leq f_2(\ell_0 - \frac{1}{2}) = \left(1 + \frac{1}{2\ell_0 - 1}\right)^p - \frac{1 - 1/2^p}{\ell_0 + \frac{1}{2}} - 1 \\
 &= -\frac{\frac{\ell_0+1}{2\ell_0} \cdot p}{\ell_0 + \frac{1}{2}} + \left(1 + \frac{1}{2\ell_0 - 1}\right)^p - 1 \quad \left( \text{since } \frac{p}{2\ell_0} = \frac{1 - 1/2^p}{\ell_0 + 1} \right) \\
 &< -\frac{\frac{\ell_0+1}{2\ell_0} \cdot p}{\ell_0 + \frac{1}{2}} + \left(1 + \frac{p}{2\ell_0 - 1} - \frac{p(1-p)}{2(2\ell_0 - 1)^2} + \frac{p(1-p)(2-p)}{6(2\ell_0 - 1)^3}\right) - 1 \\
 &\quad \left( \text{since } (1+x)^p < 1 + px - \frac{p(1-p)}{2}x^2 + \frac{p(1-p)(2-p)}{6}x^3 \right. \\
 &\quad \left. \text{according to Lemma 17} \right) \\
 &= \frac{p}{2\ell_0 - 1} \cdot \left( \frac{1}{\ell_0(2\ell_0 + 1)} - \frac{1-p}{2(2\ell_0 - 1)} + \frac{(1-p)(2-p)}{6(2\ell_0 - 1)^2} \right)
 \end{aligned}$$

$$\begin{aligned}
&< \frac{p}{2\ell_0 - 1} \cdot \left( \frac{1}{\ell_0(2\ell_0 + 1)} - \frac{1-p}{2(2\ell_0 - 1)} + \frac{1-p}{3(2\ell_0 - 1)^2} \right) \\
&= \frac{p}{2\ell_0 - 1} \cdot \frac{6(2\ell_0 - 1)^2 - (1-p) \cdot (3\ell_0(2\ell_0 + 1)(2\ell_0 - 1) - 2\ell_0(2\ell_0 + 1))}{6\ell_0(2\ell_0 + 1)(2\ell_0 - 1)^2} \\
&= \frac{p}{2\ell_0 - 1} \cdot \frac{6(2\ell_0 - 1)^2 - (1-p)\ell_0 \cdot (12\ell_0^2 - 4\ell_0 - 5)}{6\ell_0(2\ell_0 + 1)(2\ell_0 - 1)^2} \\
&< \frac{p}{2\ell_0 - 1} \cdot \frac{6(2\ell_0 - 1)^2 - 2 \cdot (12\ell_0^2 - 4\ell_0 - 5)}{6\ell_0(2\ell_0 + 1)(2\ell_0 - 1)^2} \\
&\quad \text{(since } (1-p)\ell_0 > 2 \text{ according to inequality (5)} \\
&\quad \text{and } 12\ell_0^2 - 4\ell_0 - 5 = (6\ell_0 - 5)(2\ell_0 + 1) > 0) \\
&= \frac{p}{2\ell_0 - 1} \cdot \frac{-16\ell_0 + 16}{6\ell_0(2\ell_0 + 1)(2\ell_0 - 1)^2} \\
&< -\eta. \quad \text{(by inequality (7))}
\end{aligned}$$

Thus, for every  $\ell \in [\ell_0 - \frac{1}{2}, \ell_0 + \frac{1}{2}]$ , we have  $f_1(\ell) < -\eta$  and  $f_2(\ell) < -\eta$ . ◀

# Improved Online Load Balancing with Known Makespan

## Abstract

We break the barrier of  $3/2$  for the problem of online load balancing with known makespan, also known as bin stretching. In this problem,  $m$  identical machines and the optimal makespan are given. The load of a machine is the total size of all the jobs assigned to it and the makespan is the maximum load of all the machines. Jobs arrive online and the goal is to assign each job to a machine while staying within a small factor (the competitive ratio) of the optimal makespan.

We present an algorithm that maintains a competitive ratio of  $139/93 < 1.495$  for sufficiently large values of  $m$ , improving the previous bound of  $3/2$ . The value  $3/2$  represents a natural bound for this problem: as long as the online bins are of size at least  $3/2$  of the offline bin, all items that fit at least two times in an offline bin have two nice properties. They fit three times in an online bin and a single such item can be packed together with an item of any size in an online bin. These properties are now both lost, which means that putting even one job on a wrong machine can leave some job unassigned at the end. It also makes it harder to determine good thresholds for the item types. This was one of the main technical issues in getting below  $3/2$ .

The analysis consists of an intricate mixture of size and weight arguments.

## 1 Introduction

ONLINE LOAD BALANCING WITH KNOWN MAKESPAN is an online problem defined as follows. At the start of the input, the number  $m$  of machines is revealed, followed by a sequence of jobs with sizes in  $[0, 1]$ , arriving one by one. Each job needs to be assigned to a machine,

and the load of a machine is the total size of the jobs assigned to it. The algorithm is guaranteed a priori that the entire sequence of jobs can be scheduled on  $m$  machines so that the makespan (the load of the most-loaded machine) is at most 1. The objective of the algorithm is to schedule the jobs on the machines as they arrive, minimizing the makespan  $R$  of the online schedule, which is allowed to be larger than 1. The value  $R$  is also known under the name *stretching factor*.

The problem was first introduced in 1998 by Azar and Regev [3, 4] under the name ONLINE BIN STRETCHING, and studied intensively since [8, 9, 15, 17, 21]. Among its given applications is container repacking [7] and reallocation during a server upgrade. This scheduling problem shares its terminology and some algorithmic ideas with ONLINE BIN PACKING. The overarching goal of the research of ONLINE BIN STRETCHING and other related problems over the last few decades is to learn how a small amount of additional knowledge ahead of time (such as knowledge of the makespan) impacts the best possible competitive ratio for the quintessential online problem ONLINE LOAD BALANCING [16].

To that end, another closely related problem is ONLINE LOAD BALANCING WITH KNOWN SUM OF PROCESSING TIMES, where we have a guarantee that the total volume of jobs is at most  $m$ , but the optimum can be larger than 1. (e.g., if jobs larger than 1 appear in the input sequence). For comparison in ONLINE BIN STRETCHING we have a guarantee on the makespan which is stronger, while in the classical ONLINE LOAD BALANCING problem we have no guarantee. Having information on the total volume of jobs or the makespan could be viewed as particular kinds of *advice* given to the online algorithm [10, 11, 24].

To answer the general question above quantitatively, the state of the art is the following. For ONLINE LOAD BALANCING, Fleischer and Wahl [13] presented a deterministic algorithm with competitive ratio approximately 1.92, and Rudin [25] showed that no deterministic algorithm can be better than 1.88-competitive. Kellerer et al. [18] showed that having a guarantee on the sum of processing times allows an approximately 1.585-competitive algorithm as  $m$  goes to infinity, matching the lower bound of Albers and Hellwig [2]. Finally, for ONLINE BIN STRETCHING, Böhm et al. [8] presented an algorithm with stretching factor  $3/2$ , and Azar and Regev [4] showed that no algorithm can have a stretching factor below  $4/3$ .

### Our contribution

We propose an online algorithm for ONLINE BIN STRETCHING that is able to surpass the  $3/2$  threshold:

► **Theorem 1.1.** *For  $m \geq 60000$  and for  $\varepsilon = 1/31$ , there exists an online algorithm for ONLINE BIN STRETCHING with stretching factor  $3/2 - \varepsilon/6 = 139/93 < 1.495$ .*

For  $\varepsilon = 1/62$  the algorithm works already for  $m \geq 3300$ . Our algorithm builds upon the main concepts of its immediate predecessors [15, 8], by keeping a portion of the bins empty until a later phase of the input, and by tracking combinatorial properties of the items using a *weight-based analysis*. Any feasible algorithm must follow this general structure. However, once the stretching factor is set below  $3/2$ , new types of items appear which require great care to pack efficiently. See Figure 1 and the full version. The level of complexity of our algorithm as well as its analysis significantly surpasses the previously best-known results. For instance, it now becomes necessary to use new item types when we start to fill up previously used bins later in the algorithm, as most of the initial item types do not fit well in the remaining space. Achieving a ratio below  $3/2$  for *all* values of  $m$  seems to be much harder still, as we often have constantly many bins which are only half-full; only when  $m$  is large is the number of such bins negligible.

## History and related work

The first results on ONLINE BIN STRETCHING have appeared even before the introductory paper of Azar and Regev in 1998; a year before, Kellerer et al. [19] already discovered the matching lower and upper bound of  $4/3$  for the case  $m = 2$ . Since the beginning, some research works focus on the stretching factor for general number of bins  $m$ , while others focus on the special cases for  $m$  small and fixed. One interesting property of ONLINE BIN STRETCHING with fixed  $m$  is that both the best-known lower bounds [21] and some algorithms [22] were designed using a computer-aided approach based on the *Minimax* algorithm, as initially proposed by Gabay et al. [14].

For any value  $m \geq 2$  a general lower bound of  $4/3$  comes from Azar and Regev [4]. For  $m = 3$ , the best-known algorithm is by Böhm et al. [7]. The remaining lower and upper bounds for the range  $3 \leq m \leq 8$ , listed in the table below, were designed by multiple variants of computer-aided search; the results are by Böhm and Simon [9], Lhomme et al. [21] and Lieskovský [23].

| $m$         | 3         | 4          | 5          | 6          | 7          | 8          | $\geq 9$        |

For general  $m$ , Böhm et al. [8] presented the so far best algorithm in 2017 which achieves stretching factor  $3/2$ ; this result was preceded by a long sequence of steady improvements on the algorithmic front, among others by Kellerer and Kotov [17] and Gabay et al. [15]. Recently in [20], Lhomme et al. give first results for randomized algorithms. They show that for  $m = 2$  there exists a  $5/4$ -competitive randomized algorithm that outperforms the optimal deterministic algorithm. Furthermore, they provide lower bounds for  $2 \leq m \leq 4$  on the competitive ratio of randomized algorithms.

For some small fixed values of  $m$ , especially  $m = 2$ , also specialized problems related to ONLINE BIN STRETCHING have been investigated previously; for example, Epstein [12] considered online bin stretching with two machines (bins) of uniformly related speed and Akaria and Epstein [1] considered online bin stretching on two bins with grade of service and migration.

## 2 Structure of the algorithm

From now on, as is common in the literature on ONLINE BIN STRETCHING and because we are dealing with a packing problem, we refer to bins, levels of bins and items instead of machines, loads of machines and jobs, respectively. Our initial setting is that the offline optimum bins have size 1 and the bins usable by our algorithm have size  $R = 3/2 - \varepsilon/6$ .

We assume that the number of bins  $m$  is at least 60000. We scale the sizes of the bins such that an offline bin has size 12 and an online bin has size  $18 - 2\varepsilon$ . (We use  $2\varepsilon$  here so that half of the size of an online bin is a more convenient value.) Our goal is to construct an algorithm which works for the largest possible value of  $\varepsilon$ . We will eventually set  $\varepsilon = 1/31$ , but for an easier understanding of the relationships between the various values we will mostly use symbolic calculations. Scaling the offline bin size to 12 allows us to work with near-integer type thresholds, which is convenient. After scaling, the total size of the jobs on input is at most  $12m$ .

Our algorithm uses the algorithms Best Fit and First Fit as subroutines. These algorithms work as follows. Both algorithms open a new bin if the item does not fit into any existing bin. Otherwise, Best Fit places an item in a bin where the item can still fit and that, after

## 10:4 Improved Online Load Balancing with Known Makespan

placement, leaves the least amount of remaining empty space in the bin. This means it uses the most-filled bin that can still accept the item. First Fit always places the item in the first bin in which it will fit, using the order in which it opened the bins. In this paper, we will sometimes fix the order in which the bins are to be used in advance, namely if these bins already contain some items. This means that we are applying First Fit to variable-sized “bins” (the empty spaces in the actual bins). We give a proof for the performance of First Fit on variable-sized bins which may be of independent interest.

► **Lemma 2.1.**<sup>1</sup> *Consider a set  $V$  of bins that is packed by First Fit of which at least the last  $|V| - 2$  bins contain at least  $k$  items. If  $|V| \geq 3$ , the total level of the bins in  $V$  is more than*

$$\frac{k|V|}{k+1}.$$

► **Lemma 2.2.** *For any set of  $v$  variable-sized bins that is packed using First Fit, the following property holds. If at least  $k < v/2$  items are packed into each bin, the total size of all the items packed into these bins is at least*

$$\frac{k}{k+1} \sum_{j=k}^{v-k} s(j),$$

where the size of the  $j$ -th bin is denoted by  $s(j)$ . This even holds if the number of bins increases while First Fit is running (in this case  $v$  is the final number of bins).

**Proof.** Let the bins be sorted by the order of First-Fit.

We look at an  $(k+1)$ -tuple  $(j, j+1, \dots, j+k)$  with  $1 \leq j \leq v-k$ . Let  $\alpha$  be the largest empty space of bins  $j, \dots, j+(k-1)$ . The items in bin  $j+k$  have size at least  $\alpha$ . Bins  $j, \dots, j+(k-1)$  on the other hand are filled to at least  $s(j) - \alpha, \dots, s(j+(k-1)) - \alpha$ . We know that at least  $k$  items of size at least  $\alpha$  are packed in bin  $j+k$ , so in these  $k+1$  bins we have an overall load of at least  $\sum_{i=j}^{j+(k-1)} s(i)$ . Applying this bound for  $j = 1, 2, \dots$  we find guarantees for First-Fit of at least  $\sum_{i=1}^k s(i) + \sum_{i=k+2}^{2k+1} s(i) + \dots, \sum_{i=2}^{k+1} s(i) + \sum_{i=k+3}^{2k+2} s(i) + \dots$ , etc. Adding all these bounds gives

$$(k+1) \cdot FF \geq \sum_{i=1}^{k-1} i \cdot s(i) + \sum_{i=k}^{v-k} k \cdot s(i) + \sum_{i=v-(k-1)}^{v-1} (v-i) s(i) > k \sum_{i=k}^{v-k} s(i). \quad \blacktriangleleft$$

### 2.1 Item types

Our algorithm initially uses the following item types; once we start filling up the bins in the fill-up phase, it will be necessary to use different types because of the amount of space that will be left. We group some item types into supertypes. There are two intervals for small items, as these items are packed the same way. The three weighting functions are related to the three types of items that fit only once in an offline bin. Having three separate such types is a consequence of the existence of quarter items (see Figure 1).

<sup>1</sup> The simple proof of this lemma can be found, e.g., in [5].

| Supertype                 | –                  |                    |                   | middle             |                    |                   | dominant            |     |
|---------------------------|--------------------|--------------------|-------------------|--------------------|--------------------|-------------------|---------------------|-----|
| Type                      | small              | quarter            | small             | nice               | half               | large             | big                 | top |
| Maximum size              | $3 - 3\varepsilon$ | $4 - 4\varepsilon$ | $5 + \varepsilon$ | $6 - 2\varepsilon$ | $6 + 2\varepsilon$ | $9 - \varepsilon$ | $10 + 6\varepsilon$ | 12  |
| Weight $w_{\text{top}}$   | 0                  | 1                  | 1                 | 2                  | 2                  | 2                 | 3                   | 4   |
| Weight $w_{\text{big}}$   | 0                  | 0                  | 0                 | 2                  | 2                  | 2                 | 4                   | 4   |
| Weight $w_{\text{large}}$ | 0                  | 0                  | 0                 | 0                  | 2                  | 4                 | 4                   | 4   |

We describe the ideas behind these type thresholds in detail in the full version of the paper. Here we describe some fundamental properties of the various (super-)types. See also Figure 1.

Dominant items fit only once in an online bin. Nice items fit twice in an offline bin and can be placed in an online bin while still leaving room for another item of any size. (These items are indeed in principle nice to pack, but we still need to be very careful with them.) Half and large items fit twice in an online bin, but a large item cannot be packed together with a half item in an offline bin (due to the thresholds  $6 - 2\varepsilon$  and  $6 + 2\varepsilon$ ), whereas two half items *may* fit together in an offline bin.

In our algorithm, we will pack small items only to a level of  $6 - 6\varepsilon$  at the beginning to leave room for one top item or two half items. As described above, using First Fit guarantees that more than  $4 - 4\varepsilon$  is packed in almost all bins that are packed like this. Of course we get the same guarantee for small items of size more than  $4 - 4\varepsilon$ , and this is what motivates the upper bound  $4 - 4\varepsilon$  for quarter items. It is also the same guarantee that we will achieve on average for (a certain subset of) the bins with quarter items (some bins will contain two quarter items). A big item fits in an online bin with two quarter items, and this is the reason that the dominant items are divided into two types.

► **Definition 2.3.** For a partial input  $I_{\text{partial}}$ , let the value  $\text{TOPTHREAT}$  (resp.,  $\text{BIGTHREAT}$ ,  $\text{LARGETHREAT}$ ) be the maximum number of top items (resp., big items, large items) in  $I_{\text{future}}$  so that  $I_{\text{partial}} \cup I_{\text{future}}$  can be packed in  $m$  bins of size 12, and let  $\text{TOPBLOCK}$  (resp.,  $\text{BIGBLOCK}$ ,  $\text{LARGEBLOCK}$ ) be the set of bins that contain more than  $6 - 2\varepsilon$  (resp.,  $18 - 2\varepsilon - (10 + 6\varepsilon) = 8 - 8\varepsilon, 9 - \varepsilon$ ).

For any packing of a partial input, we have  $\text{TOPTHREAT} \leq \text{BIGTHREAT} \leq \text{LARGETHREAT}$  and  $\text{LARGEBLOCK} \leq \text{BIGBLOCK} \leq \text{TOPBLOCK}$ .

► **Lemma 2.4.** For any feasible input  $I$  and weighting function  $w \in \{w_{\text{top}}, w_{\text{big}}, w_{\text{large}}\}$ , we have  $w(I) \leq 4m$ . For any  $k \geq 0$  and any partial input  $I_{\text{partial}}$ :

- if  $w_{\text{top}}(I_{\text{partial}}) \geq 4k$ , then  $\text{TOPTHREAT} \leq m - k$ ,
- if  $w_{\text{big}}(I_{\text{partial}}) \geq 4k$ , then  $\text{BIGTHREAT} \leq m - k$ ,
- if  $w_{\text{large}}(I_{\text{partial}}) \geq 4k$ , then  $\text{LARGETHREAT} \leq m - k$ .

**Proof.** The bound  $w_{\text{large}}(I) \leq 4m$  follows from the type thresholds (a large and a half item do not fit together in an offline bin). For the other two weighting functions, note that for an item  $i$  of type  $j$ , the weight  $w_{\text{top}}(i) = \lfloor \frac{5}{12}s_j \rfloor$  and  $w_{\text{big}}(i) = 2(\lfloor \frac{3}{12}s_j \rfloor)$ , where  $s_j$  is the infimum size of an item of type  $j$  (where the small items are split into two separate types for this calculation, one for each range of small items). Intuitively,  $w_{\text{top}}$  counts the number of items larger than  $\frac{12}{5}$ , that is, items that fit at most four times in an offline bin. Similarly,  $w_{\text{big}}$  counts items larger than  $\frac{12}{3}$ , and multiplies the result by two. The bounds  $w_{\text{top}}(I) \leq 4m$  and  $w_{\text{big}}(I) \leq 4m$  follow. ◀

The following invariant is a necessary property of any feasible algorithm and we will maintain it and other invariants throughout the processing of the input.

## 10:6 Improved Online Load Balancing with Known Makespan

■ **Figure 1** (Sketch, using  $\varepsilon = 1/6$ ) A comparison of the important thresholds for an algorithm with competitive ratio  $3/2$  (top) and an algorithm with competitive ratio strictly less than  $3/2$  (middle). The thresholds our algorithm uses are displayed at the bottom. The green box indicates (half) the difference between the online and offline bin size. In the top figure, 6 is also a point where the amounts that can be packed in a bin change, both online and offline.

We immediately see that in the middle figure items exist which did not exist before (red); for a competitive ratio of  $3/2$ , the online algorithm can pack more items per bin for *all* items smaller than 9. Moreover, items in the orange range can block some items of maximal size from being packed in the same bin, if we pack two such items in one bin. Finally, the fact that the red range exists means that items just larger than this (yellow) also need to be packed more carefully than before.

■ **Figure 2** An overview of the phases and states.

► **Invariant 2.5.** We have  $TOPTHREAT \leq m - TOPBLOCK$  and  $BIGTHREAT \leq m - BIGBLOCK$ .

We will *not* be able to maintain  $LARGETHREAT \leq m - LARGEBLOCK$  throughout the algorithm (not even in the starting phase). However, fortunately large items can be placed twice in an online bin. Since these items can have size up to  $9 - \varepsilon$ , a bin must be completely empty in order to guarantee that two large items may be packed in it.

### 2.2 Phases and states

In the starting phase, we use bins one by one, while staying below a level of  $6 - 2\varepsilon$  unless there is a very good reason not to do so. If many relatively large items arrive, we may reach a state where it is sufficient to use First Fit for all remaining items (Simple Fill-Up) or where we know by weight that all items can be packed (Weight-based packing). Otherwise, we will eventually go to the Fill-up phase, where we start filling up the bins that previously received less than  $6 - 2\varepsilon$  (or up to  $8 - 8\varepsilon$  in the case of bins with two quarter items). In this phase we will eventually also reach a state where we know that the remaining input can be packed, either by size or by a weight argument.

### The starting phase

From the lens of a single bin, our algorithm typically either packs items until a bin is full – which is typical for bins containing a single item type, such as the middle items – or it packs them only up to a level of  $6 - 6\epsilon$ , particularly for items of size at most  $6 - 6\epsilon$ .

However, as we have already seen, quarter items do not fit in this framework. On the one hand, we need to avoid packing many quarter items alone in bins (bad packing guarantee) while on the other hand, we also cannot pack too many quarter items in pairs in bins that do not yet contain anything else: that could block top items from being packed (Invariant 2.5 would be violated).

Ideally, we would like to pack items as follows:

- top items or pairs of half items with small items
- big items with quarter items
- large items in pairs
- nice items three per bin

In this way, all bins would have a weight of at least 4 in  $w_{\text{top}}$  and  $w_{\text{big}}$  and they would also all be more than 12 full (except for bins that contain one big item and one quarter item and bins that contain a top item/two half items smaller than 6 and not enough small items). There are several problems in using these methods, however:

- For bins that are planned to contain items of two different types, or two items of one type, it is not known whether the second type or item will ever arrive.
- Packing large items and smaller middle items into separate bins can easily lead to instances that cannot be packed (if there are two bins with single middle items that fit together in an offline bin, and then many top items arrive).

We can work around the first problem by changing our packing methods after a certain number of bins have received items of only one type, in particular if many small or quarter items arrive. Basically, our algorithm will first aim to reach the ideal packing described above. When sufficient volume has been packed, we go back and start filling up the already used bins. This is the fill-up phase of our algorithm.

The second problem requires us to be very careful with nice items in particular, since some nice items fit with some large items in an offline bin. Packing nice items three per bin in dedicated bins will be fine. However, we cannot afford to do this already starting from the very first bin with nice items, as there could also be a bin with one half item and another bin with one large item at the same time, blocking too many bins for top items so that the algorithm fails. Fortunately, a bin with only a nice item can still receive an item of any other type, so we will pack one nice item alone before starting to pack them three per bin from the second bin onwards. We still need to be very careful if both half and nice items arrive.

### Good situations and the fill-up phase

We may be fortunate and reach a situation where many bins are filled to (significantly) more than 12. In this case it will be sufficient to pack the remaining items by essentially using First Fit. This is one example of a *good situation*. This is our term for a configuration which ensures that all remaining items can be packed, usually by using a very simple algorithm. This one is called the **First Fit case**.

It may also happen that many relatively large items arrive early. In this case we may reach a state where we know that a small or quarter item will never need to be packed into an empty bin anymore, because they are packed in existing bins first and we would reach the

First Fit case before using an empty bin. To ensure that the algorithm does succeed in all cases, even if all bins receive items, we will always use Best Fit as last resort for any item (after exhausting all other rules and all empty bins). We call this the **Rule of last resort**.

If many bins contain items but not enough of them contain a total size of more than 12 or sufficiently large items, it becomes important whether there exist bins that contain only small items or only single quarter items. If that is the case, we will go to the fill-up phase, in which we start filling up the nonempty bins using different item types. Otherwise, we will remain in the starting phase and we will eventually reach a good situation or the input will end.

### The $(9 - \varepsilon)$ -guarantee

We need to determine when exactly it is safe to start filling up bins in which we have already packed some items, without failing for instance to the threat of top items. To be precise, once we start filling up bins, we need a guarantee that this *remains* feasible no matter what the remaining input is. This will certainly require us to pack a sufficient total size in each bin that we fill up, as we always need to maintain Invariant 2.5.

Our cutoff for starting to fill up bins will be the point at which we know for certain that the future number of *big* items is (and will remain!) strictly smaller than the number of bins in which big items can still be packed (so,  $\text{BIGTHREAT} < m - \text{BIGBLOCK}$ ). There are in principle two ways by which we can know this: by considering weight and by considering volume. The problem with using a weight-based guarantee is that for instance small items can start arriving, which do not have weight. If we start filling up bins using small items, we can soon reach a point where the weight-based bound for  $\text{BIGTHREAT}$  has not changed, but  $\text{BIGBLOCK}$  has increased and we fail when many big items arrive.

We therefore use a volume-based bound. We need to be careful also here. Suppose that already  $2m/3$  bins contain small items, and each such bin has a level in the range  $(4 - 4\varepsilon, 6 - 6\varepsilon]$ . Now suppose that many big items start arriving one by one. These big items do *not* bring us really closer to the point where we can safely start filling up the nonempty bins, because every time that we pack a big item  $\text{BIGTHREAT}$  decreases by 1 and  $m - \text{BIGBLOCK}$  decreases by 1. Similarly, top items bring us only slowly closer to this point (since they are slightly larger than big items).

We will start the fill-up phase once we know the so-called  **$(9 - \varepsilon)$ -guarantee** holds:

Whenever new items of total size  $9 - \varepsilon$  arrive,  $\text{BIGTHREAT}$  decreases by at least 1.

Having the  $(9 - \varepsilon)$ -guarantee essentially ensures that packing  $9 - \varepsilon$  per bin is sufficient to maintain Invariant 2.5, although the problem of  $m$  large items arriving remains and needs to be dealt with separately. Maintaining this average is not at all straightforward, since we also have to make sure not to use too many *empty* bins too early, in order to pack as many pairs of large items into them as possible.

We present a very careful method of filling the nonempty bins which takes care to use the remaining space in those bins as efficiently as possible, using new item types which are tailored to the remaining space. This method consists of several stages.

## 2.3 Bin types

During the execution of the algorithm, each bin in the instance will be assigned a specific type. Sets of bins of a certain (sub)type are denoted typically by script letters (possibly with an index). We define six main types of bins. We use the corresponding lower case letters to refer to numbers of bins of a type: for instance,  $\ell = |\mathcal{L}|$  and  $\delta = |\Delta|$ .

- $\mathcal{E}$  Empty bins.
- $\mathcal{L}$  Large-complete bins. This is a set of bins that reduce `LARGETHREAT`; more generally, they reduce the number of items with weight that can still arrive. Specifically, the number of large items that can still arrive will always be at most  $m - \ell$ , and the total weight that can still arrive will be at most  $4(m - \ell)$ . Since items without weight can still arrive however, and bins in  $\mathcal{L}$  do not necessarily contain at least 12, large-complete bins do still accept items. A formal definition of these bins follows below.
- $\mathcal{S}$  Bins with only *small* items. At most  $6 - 6\varepsilon$  of small items is packed in each such bin.
- $\Delta$  At most four bins that contain two nice items or a single middle item and maybe some other items. See below for more details.
- $\mathcal{Q}$  Bins that are not in  $\Delta$  in which the first item (or the second, if the bin was previously in  $\Delta$ ) is a quarter item and that are unmatched. (The algorithm sometimes matches some bins in  $\mathcal{Q}$ ; these bins are then moved to a special subset  $\mathcal{Q}_{\text{match}}$ .)
- $\mathcal{N}$  Bins in which the first two items are nice items and the third item is nice or half.

Bins started by nice items are filled to triples of nice items in the ideal packing and kept separate to achieve this; these bins can become large-complete upon receiving a dominant item. With this large-scale picture in mind, the large-complete bins are defined as follows. These bins require a careful definition because nice items may exist.

► **Definition 2.6.** *A bin is called large-complete if it satisfies all of the following conditions.*

- *it has  $w_{\text{big}} \geq 4$ ,*
- *it contains an item larger than 6 or two items larger than  $6 - 2\varepsilon$ ,*
- *the bin was never in  $\mathcal{Q}$ .*

It can be seen that each bin with  $w_{\text{big}} \geq 4$  has a big item or  $w_{\text{top}} \geq 4$ . A large-complete bin does not necessarily contain a large item or a dominant item. The first condition ensures that these bins contain as much weight as any offline bin. The second condition implies that `LARGETHREAT`  $\leq m - \ell$  at all times. Note that this does not follow from the first condition alone, as a bin could contain two nice items, and a nice and a large item may fit together in an offline bin.

The set  $\Delta$  contains at most four exceptional bins used for careful handling of middle items. Each of these bins will be created explicitly in our algorithm if they are needed. There are the following four kinds of bins in  $\Delta$ .

- $\Delta_{\text{large}}$  one bin that contains a single large item, nothing else.
- $\Delta_{\text{half}}$  one bin that contains a single half item and possibly small items of total size at most  $6 - 6\varepsilon$  (notation  $\Delta_{\text{half}}^S$ ) or a quarter item (notation  $\Delta_{\text{half}}^Q$ ), nothing else. If the bin contains *only* a half item we call it  $\bar{\Delta}_{\text{half}}$ , else  $\Delta_{\text{half}}^+$ .
- $\Delta_{\text{nice},1}$  at most two bins that contain one nice item and nothing else.
- $\Delta_{\text{nice},2}$  one bin that contains two nice items and nothing else.

Our algorithm will use the so-called **nice rule** as long as possible: do not pack nice items into  $\Delta_{\text{large}} \cup \Delta_{\text{half}}$  and do not pack half or large items into  $\Delta_{\text{nice},1}$ . This rule ensures that nice items get packed into dedicated bins as much as possible (three per bin) so that we gain on these items (both by weight and by packed size per bin) compared to the optimal packing. This in turn ensures that nice items will hardly occur in inputs that are important for our analysis; see the weighting function  $w_{\text{large}}$ .

► **Definition 2.7.** *A bin is in  $\mathcal{Q}$  if it satisfies the following properties:*

- *The first item is a quarter item,*
- *The bin is not in  $\Delta_{\text{half}}$ ,*
- *The bin has not been matched (see algorithm).*

## 10:10 Improved Online Load Balancing with Known Makespan

Additionally, a bin that was in  $\overline{\Delta}_{\text{half}}$  and then received a quarter item and finally another half or larger item is also in  $\mathcal{Q}$  as long as it has not been matched.

We define the subset of  $\mathcal{Q}$  of bins in which the first two items are quarter items by  $\mathcal{Q}_2$ , and  $\mathcal{Q}_1 := \mathcal{Q} \setminus \mathcal{Q}_2$ . A bin in  $\mathcal{Q}_1$  may leave  $\mathcal{Q}$  (and  $\mathcal{Q}_1$ ) by receiving a half item (it enters  $\Delta_{\text{half}}$ ); such a bin may later rejoin  $\mathcal{Q}$  by receiving a half or larger item. Bins in  $\mathcal{Q}$  may also leave  $\mathcal{Q}$  permanently by being matched (two bins in  $\mathcal{Q}_1$  to one bin in  $\mathcal{Q}_2$ ).

Instead of using the partition  $\mathcal{Q} = \mathcal{Q}_1 \cup \mathcal{Q}_2$ , we will also consider the useful partition of  $\mathcal{Q}$  in the table below. (Some of these subsets may be empty.)

| Bin type                     | Conditions on contents  |
|------------------------------|---|
| $\overline{\mathcal{Q}}_1$   | A single quarter item, nothing else   |
| $\overline{\mathcal{Q}}_2$   | Two quarter items, nothing else   |
| $\mathcal{Q}_{1,\text{big}}$ | First item is a quarter item, second item is big  |
| $\mathcal{Q}_5$              | First item is a quarter item, $w_{\text{big}} \geq 4$ , bin is not in $\mathcal{Q}_{1,\text{big}}$<br>Or: The first three items are (in this order) half, quarter, half or larger |

We let  $\overline{\mathcal{Q}} = \overline{\mathcal{Q}}_1 \cup \overline{\mathcal{Q}}_2$ . Bins in  $\mathcal{Q}_5$  can be in  $\mathcal{Q}_1$  (for instance, bins with a top item) or in  $\mathcal{Q}_2$ ; we keep track of their membership via the sets  $\mathcal{Q}_{1,5} := \mathcal{Q}_5 \cap \mathcal{Q}_1$  and  $\mathcal{Q}_{2,5} := \mathcal{Q}_5 \cap \mathcal{Q}_2$ . All bins in  $\mathcal{Q}_5$  will have  $w_{\text{top}}$ -weight 5 (or more), explaining the name  $\mathcal{Q}_5$ . For comparison, bins in  $\mathcal{Q}_1$  have  $w_{\text{top}}$ -weight at least 1 and bins in  $\mathcal{Q}_2$  have  $w_{\text{top}}$ -weight at least 2.

Bins in  $\mathcal{Q}_{1,\text{big}}$  may get matched (pairwise) to bins in  $\mathcal{Q}_{2,5}$ ; this is explained in the algorithm (Step 3). The set of matched bins is denoted by  $\mathcal{Q}_{\text{match}}$ .

Since the first two items in each bin in  $\mathcal{Q}_2$  are quarter items, we have  $\mathcal{Q}_2 \cap \mathcal{Q}_{1,\text{big}} = \emptyset$ . We use the membership of bins in  $\mathcal{Q}_1$  and  $\mathcal{Q}_2$  to keep track of the distribution of quarter items in the non-large-complete bins. In our proofs, we will assign weight from the quarter items in  $\mathcal{Q}_1$  to bins in  $\mathcal{Q}_2$  on the one hand (so we need sufficiently many bins in  $\mathcal{Q}_1$ ) and assign volume from bins in  $\mathcal{Q}_2$  to bins in  $\mathcal{Q}_1$  on the other hand (so we need sufficiently many bins in  $\mathcal{Q}_2$ ). The separation from large-complete bins and the separation of  $\mathcal{Q}_{1,5}$  and  $\mathcal{Q}_{2,5}$  will help us maintain an almost fixed ratio  $q_1 : q_2$ . Because of various half-full bins, we will need some additional bins in  $\mathcal{Q}_1$  (at most 15 in the fill-up phase) before starting to create bins in  $\mathcal{Q}_2$ . A bin in  $\overline{\mathcal{Q}}_1$  that receives a half item leaves  $\mathcal{Q}$  and enters  $\Delta_{\text{half}}$  (and  $\Delta_{\text{half}}^{\mathcal{Q}}$ ). If it later receives another half item or a large, it returns to  $\mathcal{Q}$ , namely  $\mathcal{Q}_{1,5}$ , or moves to  $\mathcal{L}$ . Summarizing, we have the following disjoint unions.

$$\mathcal{Q}_1 = \overline{\mathcal{Q}}_1 \cup \mathcal{Q}_{1,\text{big}} \cup \mathcal{Q}_{1,5} \tag{1}$$

$$\mathcal{Q}_2 = \overline{\mathcal{Q}}_2 \cup \mathcal{Q}_{2,5}. \tag{2}$$

We define the set of *complete* bins  $\mathcal{C}$  as the set of bins that from the point of view of the algorithm (and the analysis) do not need to receive any specific items, as follows:

$$\mathcal{C} := \mathcal{L} \cup \mathcal{Q}_5 \cup \mathcal{Q}_{\text{match}} \cup \mathcal{N}.$$

Into these bins, any item may be packed. Finally, the unmatched nonempty bins that are not large-complete are called *regular* (set  $\mathcal{R}$ ). We have

$$\mathcal{R} = \mathcal{S} \cup \mathcal{Q} \cup \mathcal{N} \cup \Delta = \mathcal{S} \cup \overline{\mathcal{Q}}_1 \cup \overline{\mathcal{Q}}_2 \cup \mathcal{Q}_{1,\text{big}} \cup \mathcal{Q}_5 \cup \mathcal{N} \cup \Delta. \tag{3}$$

At all times, each bin is in exactly one of the sets  $\mathcal{R}, \mathcal{Q}_{\text{match}}, \mathcal{L}, \mathcal{E}$ .

We will show eventually that in the starting phase, some bins remain empty or we can guarantee that all remaining items can be packed (possibly using different methods). However, the partitioning of the sets shown here remains valid even after we run out of empty bins

apart from the fact that some bins may contain some items that do not belong there; for instance, there could be some small items packed into  $\overline{Q}_2$ . Also, after we run out of empty bins the nice rule may be violated. We will maintain the following invariant.

► **Invariant 2.8.** *There is never a bin in  $\overline{Q}_1 \cup \overline{Q}_2$  at the same time as a bin with a big item as its only item with weight.*

► **Invariant 2.9.** *We have  $LARGETHREAT \leq m - (c - n)$  as long as the nice rule is followed.*

► **Lemma 2.10.** *Invariant 2.9 holds for any packing of items.*

**Proof.** As long as the nice rule is followed, all complete bins except for the ones in  $\mathcal{N}$  contain two half items or an item larger than 6 and have  $w_{\text{big}} \geq 4$ . ◀

From this bound it can be seen that the possible existence of bins in  $\mathcal{N}$  force us to keep bins empty for *pairs* of large items, since we cannot ensure  $LARGETHREAT \leq m - c$ .

## 2.4 Proof overview

The present version omits essentially all of the proofs. Here we merely give an overview. The proof begins with some initial observations regarding how many bins there can be of different types and how much they contain. We then focus on the set  $\mathcal{Q}$  and prove that up to an additive constant,  $2q_2 = q_1$  throughout the starting phase. The (almost) fixed ratio  $q_2 : q_1$  is used to help show Invariant 2.5 for top items and to show a packing guarantee for  $\mathcal{Q}$ . There will be constantly many bins that do not satisfy our packing guarantees, these bins will be in a set  $\mathcal{X}$ .

In the starting phase, either some bins remain empty,  $\overline{q}_2 > 0$ , or all items get packed. It turns out that Invariant 2.5 is maintained as long as we do not use the rule of last resort (essentially, as long as some bins are empty). There exist so-called good situations in which we can guarantee that all remaining items can be packed (possibly using a different algorithm). We show that Invariant 2.5 is maintained in the entire starting phase or we reach a good situation. More generally, the algorithm does not fail in the starting phase. We find that packing  $9 - \varepsilon$  additionally in each non-complete bin in the fill-up phase is enough to maintain Invariant 2.5 in the fill-up phase as well.

To analyze the fill-up phase, we first consider some simple cases (essentially, new good situations). We then continue by showing that the algorithm does not fail in the first three stages of the fill-up phase. Linear programs are used to show that the algorithm does not fail in the fill-up phase.

### 3 Algorithm in the starting phase

Whenever the algorithm uses or attempts to use a set  $A$  to pack an item in the following description, we use First Fit on the bins in  $A$ , unless otherwise stated. The notation  $A \rightarrow B$  means that a bin in the set  $A$  moves to  $B$  by receiving an item of the current type.

**Step 1: Using and creating complete bins** Try the following in this order.

- for half and large items:  $\Delta_{\text{nice},2} \rightarrow \mathcal{N} \subseteq \mathcal{C}$ ,
- for non-small items:  $\mathcal{Q}_{1,\text{big}} \rightarrow \mathcal{Q}_{1,5} \subseteq \mathcal{C}$
- use a complete bin (a bin in  $\mathcal{C} = \mathcal{L} \cup \mathcal{Q}_5 \cup \mathcal{Q}_{\text{match}} \cup \mathcal{N}$ ).

## 10:12 Improved Online Load Balancing with Known Makespan

- create a complete bin if this does not violate the nice rule (page 9).  
First try the bins  $\overline{Q}_2, \overline{Q}_1, \Delta_{\text{half}}^Q$  in this order. Among other bins, use Best Fit to create a bin in  $\mathcal{L}$ , but do not pack a half item into  $\Delta_{\text{large}}$  (yet).<sup>2</sup>

**Step 2: Packing rules for each item type** If an item is not packed yet, we apply the following rules depending on the item type.

**Small:** First Fit on bins in  $\mathcal{S} \cup \Delta_{\text{half}}^S$  while packing at most  $6 - 6\varepsilon$  of small items in each bin,  $\overline{\Delta}_{\text{half}} \rightarrow \Delta_{\text{half}}^S, \mathcal{E} \rightarrow \mathcal{S}$ .

**Quarter:** If  $|\mathcal{Q}_1| + \delta_{\text{half}}^Q \geq 2|\mathcal{Q}_2| + 15$  then  $\overline{Q}_1 \rightarrow \overline{Q}_2$ , else  $\overline{\Delta}_{\text{half}} \rightarrow \Delta_{\text{half}}^Q, \mathcal{E} \rightarrow \overline{Q}_1$ .

**Nice:**  $\Delta_{\text{nice},2} \rightarrow \mathcal{N}$ , if  $\delta_{\text{nice},1} = 2$  then  $\Delta_{\text{nice},1} \rightarrow \Delta_{\text{nice},2}, \mathcal{E} \rightarrow \Delta_{\text{nice},1}$ .

**Half:** Best Fit on bins in  $\mathcal{S} \cup \overline{Q}_1 \rightarrow \Delta_{\text{half}}, \Delta_{\text{large}} \rightarrow \mathcal{L}, \mathcal{E} \rightarrow \Delta_{\text{half}}$ .

**Large:**  $\mathcal{E} \rightarrow \Delta_{\text{large}}$ .

**Dominant:** Always packed in Step 1.

**Rule of last resort** If some item cannot be packed according to these rules, which can only happen after we run out of empty bins, we use Best Fit for this item, except that we still follow the nice rule as long as possible. If the nice rule has already been violated, we simply use Best Fit. For future items we still use the packing rules above first.

**Step 3: Matching rule** This step minimizes the number of bins in  $\mathcal{Q}_{1,\text{big}}$ .

If  $|\mathcal{Q}_{1,\text{big}}| \geq 2$  and there is a bin in  $\mathcal{Q}_{2,5}$ , two bins in  $\mathcal{Q}_{1,\text{big}}$  are matched to a bin in  $\mathcal{Q}_{2,5}$  and all three bins are moved from  $\mathcal{Q}$  to  $\mathcal{Q}_{\text{match}}$ .

**Step 4: Swapping rule** Each time that a new bin  $\bar{b}$  in  $\overline{Q}_1$  is created, if there exists a large-complete bin  $b$  with a big item but no other items with weight (such a bin must contain also other items, or we would not have created  $\bar{b}$ ), we virtually swap some items. That is, the bin  $\bar{b}$  is treated as a bin in  $\mathcal{S}$  from now on, and the bin  $b$  supposedly contains a big item and a quarter item. The quarter item is not considered to be the first item in  $b$ , so  $b$  is not in  $\mathcal{Q}$ . This ensures that Invariant 2.8 is maintained.

The swapping rule ensures that big items can be packed together with small items without violating Invariant 2.8 even if quarter items arrive later. Whenever the swapping rule is applied on two bins  $\bar{b} \in \overline{Q}_1$  and  $b \in \mathcal{L}$ , the total size packed into these bins is more than  $18 - 2\varepsilon$  at this point (else  $\bar{b}$  would not have been opened). If the bin  $\bar{b}$  contains less than  $4 - 4\varepsilon$  we reassign volume such that the bin  $\bar{b}$  ends up with exactly  $4 - 4\varepsilon$ . We see that more than  $18 - 2\varepsilon - (4 - 4\varepsilon) = 14 + 2\varepsilon$  remains for the bin  $b$ . This just means that  $\bar{b}$  possibly has slightly more space for additional items than the algorithm calculates with (because it views  $\bar{b}$  as containing the small items that were in  $b$ ).

The large-complete bins used by the swapping rule differ from the other bins in  $\mathcal{L}$  only in that they are not used to pack any future item. That is, we ignore such bins in Step 1 (this is not written explicitly in the algorithm; it seemed cleaner to explain this here).

### Transitioning to the fill-up phase

In general, the transition from the starting phase to the fill-up phase happens once the  $(9 - \varepsilon)$ -guarantee starts to hold. This is roughly speaking after packing an average of  $3 + \varepsilon$  on the (non-complete) regular and empty bins and 12 on the complete bins. More precisely

<sup>2</sup> If  $\mathcal{S} \cup \overline{Q}_1 \neq \emptyset$ , we prefer packing half items there rather than in  $\Delta_{\text{large}}$ , because this improves certain packing guarantees. (If  $\mathcal{S} \cup \overline{Q}_1 \neq \emptyset$ ,  $\Delta_{\text{half}}$  exists and a large item arrives, we will have that  $\Delta_{\text{half}} = \Delta_{\text{half}}^S$  which already improves the guarantee.)

after packing  $T_1 := (3 + \varepsilon)m + (9 - \varepsilon)(c + q_{1,\text{big}} + 14)$ . We can guarantee that the algorithm keeps at least roughly  $\mathcal{E}_0 := \frac{1-5\varepsilon}{4-4\varepsilon}(m - \ell - q_{\text{match}}) + \frac{2+8\varepsilon}{4-4\varepsilon}n + \frac{1-5\varepsilon}{4-4\varepsilon}q_{\text{match}} + \frac{4\varepsilon}{4-4\varepsilon}\ell - 48$  bins empty when reaching the packing threshold. For more details see the full version.

**Figure 3** (Sketch) Overview of bins in the starting phase. The three bins in  $\mathcal{Q}_{\text{match}}$  were moved there by the matching rule. The second quarter item in the rightmost bin in  $\mathcal{Q}_{\text{match}}$  arrived there when the bins were already in  $\mathcal{Q}_{\text{match}}$ . The swapping rule was applied to the rightmost bin in  $\mathcal{S}$  and the rightmost bin in  $\mathcal{L}$ . The small items on top of the big item in the rightmost bin arrived before the swapping rule was applied. For visual clarity we have left out a number of bins in  $\overline{\mathcal{Q}}_1$ .

## 4 The fill-up phase

### 4.1 Preliminaries

Once the fill-up phase is reached we refer to the bins by their type they had when the fill-up phase was started and no longer update these sets. E.g., a bin in  $\overline{\mathcal{Q}}_2$  at the start of the fill-up phase that receives a big item in the fill-up phase does not become a bin in  $\mathcal{Q}_{2,5}$  but is referred to as a bin in  $\overline{\mathcal{Q}}_2$  even after receiving the big item. We assume all bins in  $\mathcal{S}$  contain more than  $4 - 4\varepsilon$ , overestimating its total content by at most  $2 \cdot (4 - 4\varepsilon)$ . The bin in  $\Delta_{\text{large}}$  is assumed to contain a  $\text{large}^+$  item once we enter this phase, overestimating its content by at most  $3 + \varepsilon$ . The bin  $\Delta_{\text{half}}^+$  contains an easy item which matches the packing rules in the fill-up phase.

There are three possible states when entering the fill-up phase:

- $s + \overline{q}_1 > 0$
- $s + \overline{q}_1 + \overline{q}_2 = 0$
- $s + \overline{q}_1 = 0$  and  $\overline{q}_2 > 0$

The first case is what we will call the standard case where  $e \geq \mathcal{E}_0 = \Omega(m)$  holds, for which we can guarantee that when using our packing rules we will eventually end in a good situation or the input ends. For the second and third case we can guarantee that we are already in good situations that do not have requirements on  $e$  or  $r$ . For more details we refer to the full version.

► **Definition 4.1.** Let  $e_0$  be the number of empty bins at the start of the fill-up phase.

## 10:14 Improved Online Load Balancing with Known Makespan

For the fill-up phase, we introduce the set  $\mathcal{U}$  of *unused* bins. These are mostly bins that have not received items in the fill-up phase but that we do plan to use for items. At the start of the fill-up phase, these are the bins that are not in  $\mathcal{L} \cup \mathcal{Q}_{\text{match}}$ , so  $|\mathcal{U}| = m - \ell - q_{\text{match}} = r + e_0$ .

Bins in  $\mathcal{N}$  are also not used for items anymore, but are initially counted as part of  $\mathcal{U}$  so that  $\text{LARGETHREAT} \leq u$  (see Invariant 2.9). Bins in  $\mathcal{Q}_5$  are initially in  $\mathcal{U}$  to maintain the proper ratio  $q_1 : q_2$ . At the start of the fill-up phase, the bins in  $\mathcal{U}$  are sorted from left to right. We use the ordering<sup>3</sup>

$$\mathcal{N}, \mathcal{Q}_{2,5}, \overline{\mathcal{Q}}_2, \mathcal{S}, \mathcal{Q}_1, \mathcal{E}, \overline{\Delta}_{\text{half}} \cup \Delta_{\text{large}}$$

where the subsets  $\mathcal{S}$  and  $\mathcal{Q}_1$  are ordered by non-increasing levels and  $\Delta_{\text{half}}^+$  is placed among them if it exists. Indeed, the entire set  $\mathcal{U}$  is essentially sorted by the levels of small and quarter items at the start of the fill-up phase, so for instance bins in  $\mathcal{Q}_1$  (including bins in  $\mathcal{Q}_{1,5}$  and  $\mathcal{Q}_{1,\text{big}}$ ) have level at most  $4 - 4\varepsilon$  for the sorting. Throughout the fill-up phase, by the level of a bin in  $\mathcal{Q}$  we will always mean the total size of the quarter items in this bin at the end of the starting phase. Regarding  $\mathcal{N}$ , it is often convenient to divide the contents of these bins in a part of size at least  $6 - 6\varepsilon$  and a part of size exactly  $9 - \varepsilon$  (and this is why these bins are first in the ordering).

During the fill-up phase, we will maintain a set  $\mathcal{D}$  such that  $\text{TOPTHREAT} \leq u - d$  will hold throughout the fill-up phase. We define a specific initial set  $\mathcal{D}$  below and we will update this set throughout, using the following rules.

**Rule 1** Each bin that is used (in particular bins in  $\mathcal{D}$ ) will receive at least  $9 - \varepsilon$  (including parts assigned to a bin but not packed in it) to ensure  $\text{BIGTHREAT} \leq m - \text{BIGBLOCK}$  continues to hold. We already note that for bins that are empty at the start of the fill-up phase the bound of  $9 - \varepsilon$  can be reached simply by using Next Fit (it will hold for all but at most one bin at any time).

**Rule 2** Whenever some item cannot be packed into some bin in  $\mathcal{D}$  that already received items of the same type in the fill-up phase (types are defined below), that bin will leave  $\mathcal{D}$  and  $\mathcal{U}$ . Each time we pack and/or assign  $10 + 6\varepsilon$  to  $\mathcal{D}$  in the fill-up phase, a new bin is added to  $\mathcal{D}$ . (Sometimes we will assign parts of items packed into other bins to bins in  $\mathcal{D}$ .)

**Rule 3** Each bin that is not in  $\mathcal{D}$  will receive at least  $10 + 6\varepsilon$  on average to maintain  $\text{TOPTHREAT} \leq u - d$ .

### Reducing the unused bins

We begin the fill-up phase by removing the bins in  $\mathcal{N}$  and  $\mathcal{Q}_5$  from the unused bins. The contents of these bins were and remain counted. For some later calculations it will still be important that these bins may exist, which is why we include them initially and gave a specific ordering for them.

Recall that the initial value of  $u$  is  $m - \ell - q_{\text{match}}$ . By the transition of the starting phase to the fill-up phase,  $\text{TOPTHREAT} \leq \frac{9-\varepsilon}{10+6\varepsilon}(m - c - 14)$ . So at least

$$\begin{aligned} m - \frac{9 - \varepsilon}{10 + 6\varepsilon}(m - c - 14) &= \frac{1 + 7\varepsilon}{10 + 6\varepsilon}m + \frac{9 - \varepsilon}{10 + 6\varepsilon} \cdot (14 + c) \\ &= \frac{1 + 7\varepsilon}{10 + 6\varepsilon}(m - c) + \frac{9 - \varepsilon}{10 + 6\varepsilon} \cdot 14 + c \end{aligned}$$

<sup>3</sup> The at most two bins in  $\Delta_{\text{nice},1} \cup \Delta_{\text{nice},2}$  can be placed anywhere. However, they are ignored when determining  $\beta_0$  later.

bins will not receive top items in the fill-up phase (but  $c$  of those bins are unavailable for top items anyway). Then after removing  $\mathcal{N}$  and  $\mathcal{Q}_5$  from the unused bins, we have  $u = m - c$ , so at least

$$\frac{1 + 7\varepsilon}{10 + 6\varepsilon} \cdot u + \frac{9 - \varepsilon}{10 + 6\varepsilon} \cdot 14$$

unused bins will not receive top items. We will initially set  $d = \frac{1+7\varepsilon}{10+6\varepsilon} \cdot u + \frac{9-\varepsilon}{10+6\varepsilon} \cdot 14$ .

Analogously,  $\text{BIGTHREAT} \leq m - c - 14$ , so at least  $c + 14$  bins will not receive big items, meaning that at least 14 unused bins will not receive big items in the fill-up phase. While packing the input, at any time there will be *half-full* bins. These are bins which have received some items during the fill-up phase but have not yet received (or been counted for)  $9 - \varepsilon$  or, in the case of non- $\mathcal{D}$  bins,  $10 + 6\varepsilon$ . These half-full bins need to be taken into account to ensure that Invariant 2.5 is maintained. Denote their number by  $h$ .

► **Invariant 4.2.** *At any time, the number of bins in  $\mathcal{D}$  that have not yet received any item in the fill-up phase is at least  $\frac{1+7\varepsilon}{10+6\varepsilon} \cdot u + \frac{9-\varepsilon}{10+6\varepsilon} \cdot 14 - h$ , where  $u = m - c$  initially and  $u$  is updated according to Rule 2.*

► **Lemma 4.3.** *As long as we pack items according to Rule 1 and update  $\mathcal{D}$  and  $\mathcal{U}$  according to Rule 2 for all except at most 10 bins, or pack items according to Rule 3, and at most 13 bins are half-full at any time,  $\text{TOPTHREAT} \leq u - d$ ,  $\text{BIGTHREAT} \leq m - \text{BIGBLOCK}$  and Invariant 4.2 are maintained.*

**Proof.** If we pack items according to Rule 3, the claims follow from the fact that we pack at least  $10 + 6\varepsilon$  in every non- $\mathcal{D}$  bin, decreasing  $\text{TOPTHREAT}$  and  $\text{BIGTHREAT}$  by at least 1 while increasing  $\text{BIGBLOCK}$  by at most 1 and removing exactly 1 bin from  $\mathcal{U}$  when we start using a new bin. Hence  $u - d$  and  $\text{TOPTHREAT}$  both decrease by 1, and  $\text{BIGTHREAT}$  decreases by at least 1. In this case the ratio  $d : u$  increases.

Regarding items that get packed according to Rule 1, we pack at least  $9 - \varepsilon$  in every bin in  $\mathcal{D}$  (and then remove such bins from  $\mathcal{D}$  and  $\mathcal{U}$ ) and add a new bin to  $\mathcal{D}$  after packing  $10 + 6\varepsilon$ , which means that we add a bin on average after using  $\frac{10+6\varepsilon}{9-\varepsilon}$  bins in  $\mathcal{D}$ . The ratio  $d : u$  remains constant during this process apart from at most one bin.

The ratio can be seen as follows. After packing a total size of  $x$  into  $\mathcal{D}$ , we have removed at most  $x/(9 - \varepsilon)$  bins from  $\mathcal{D}$  (because we only remove a bin from  $\mathcal{D}$  once we start using the next one) and we have added  $\lfloor x/(10 + 6\varepsilon) \rfloor$  bins to  $\mathcal{D}$ . Ignoring the rounding, overall  $d$  has decreased by at most  $x(\frac{1}{9-\varepsilon} - \frac{1}{10+6\varepsilon})$  and  $u$  has decreased by at most  $x/(9 - \varepsilon)$ . The ratio is maintained. The rounding means that the set  $\mathcal{D}$  may be 1 smaller during processing. This together with the initial value  $d = \frac{1+7\varepsilon}{10+6\varepsilon} \cdot u + \frac{9-\varepsilon}{10+6\varepsilon} \cdot 14$  leaves 10 bins for which the rules do not need to be followed, since  $\frac{9-\varepsilon}{10+6\varepsilon} \cdot 14 > 11$ .

Finally, maintaining  $\text{BIGTHREAT} \leq m - \text{BIGBLOCK}$  given that initially  $\text{BIGTHREAT} \leq m - c - 14$  means that it is sufficient (due to the bin  $\Delta_{\text{nice},2}$ ) that at most 13 bins will be half-full at any time during the fill-up phase. ◀

A consequence of Invariant 4.2 is that the set  $\mathcal{D}$  does not become empty during the packing if we indeed maintain  $h \leq 13$ . Maintaining this invariant means that all remaining big and top items can be packed at any point during the fill-up phase. Note that if at some point indeed very many top items arrive, they can perhaps not all of them be packed outside of  $\mathcal{D}$ , as there can be various half-full bins outside of  $\mathcal{D}$ . However, by Invariant 4.2, as long as the total number of half-full bins is at most 13, all top items can indeed be packed.

**Item types**

Naturally, as we start filling up bins in the fill-up phase, new thresholds become important. Rather than leaving enough space for items that may arrive in the future as in the starting phase, we now want to use the remaining space efficiently. Bins in  $\mathcal{S}$  have at least  $(18 - 2\varepsilon) - (6 - 6\varepsilon) = 12 + 4\varepsilon$  space remaining and bins in  $\overline{\mathcal{Q}}_2$  leave at least  $(18 - 2\varepsilon) - 2(4 - 4\varepsilon) = 10 + 6\varepsilon$  space. If some item type fits at least three times on top of bins in  $\overline{\mathcal{Q}}_2$ , then First Fit gives a stronger bound on the packing and Rule 1 is satisfied. As there is at least  $10 + 6\varepsilon$  remaining space, we define small items to be of size at most  $\frac{10+6\varepsilon}{3}$ . Items of size more than  $\frac{9-\varepsilon}{2}$  that fit twice in this space are also small items. Apart from the range  $(5 + \varepsilon, 5 + 3\varepsilon]$ , these size ranges are a subset of what defined small items in the starting phase.

The next items are *quarter* items which may not fit three times on  $\overline{\mathcal{Q}}_2$  but at least three times on  $\mathcal{S}$ . For these we need to be slightly more careful; this is described below. *Small* items fit at least four times in an empty bin and at least two times on  $\mathcal{S} \cup \overline{\mathcal{Q}}_2$ . It can be seen that two items that are larger than small items satisfy Rule 1. To fill the remaining space well, the remaining items are split into *quarter*<sup>+</sup> and *quarter*<sup>++</sup> items. Analogously, *easy* items fit twice on  $\mathcal{S}$  and satisfy Rule 3, explaining the (unchanged) threshold  $6 + 2\varepsilon$ . These items have good sizes as well as large weights. To pack large items in the range  $(6 + 2\varepsilon, 9 - \varepsilon]$  efficiently we introduce a new threshold at  $\frac{18-2\varepsilon-\beta}{2}$  separating *large*<sup>-</sup> and *large*<sup>+</sup> items which will be explained later.

■ **Figure 4** (Sketch, using  $\varepsilon = 1/31, \beta = 5$ ) A comparison of the important thresholds for our algorithm in the starting phase (top) and in the fill-up phase (bottom). The small (green) items fit at least three times (resp. twice) in the remaining empty space in a  $\overline{\mathcal{Q}}_2$  bin ( $10 + 6\varepsilon$ ), the *easy*<sup>2</sup> (yellow) items fit at least twice in the remaining empty space in a  $\mathcal{S}$  bin ( $12 + 4\varepsilon$ ) and the *large*<sup>-</sup> (red) (resp. *quarter*<sup>+</sup> (purple)) items fit at least twice (resp. three times) in the remaining empty space in a bin filled to at most  $\beta$  ( $18 - 2\varepsilon - \beta$ ).

The value  $\beta$  will be defined later and will change during the fill-up phase; we will have  $\beta \in (3 - 3\varepsilon, 6 - 6\varepsilon]$ . There are ten size ranges, but the items in six ranges are straightforward to pack (see below). We call the *quarter*<sup>+</sup>, *quarter*<sup>++</sup>, *large*<sup>-</sup> and *large*<sup>+</sup> items *hard* items.

| Type                         | Max size                          | Type                      | Max size                          |
|------------------------------|-----------------------------------|---------------------------|-----------------------------------|
| small                        | $\frac{10+6\varepsilon}{3}$       | easy                      | $6 + 2\varepsilon$                |
| quarter                      | $4 + \varepsilon$                 | <i>large</i> <sup>-</sup> | $\frac{18-2\varepsilon-\beta}{2}$ |
| <i>quarter</i> <sup>+</sup>  | $\frac{18-2\varepsilon-\beta}{3}$ | <i>large</i> <sup>+</sup> | $9 - \varepsilon$                 |
| <i>quarter</i> <sup>++</sup> | $\frac{9-\varepsilon}{2}$         | big                       | $10 + 6\varepsilon$               |
| small                        | $5 + 3\varepsilon$                | top                       | 12                                |

We see that *quarter* items and small items may be slightly larger than in the starting phase. This does not decrease their weight. From the starting phase, we will only use the facts that bins in  $\overline{\mathcal{Q}}_2$  have level at most  $8 - 8\varepsilon$  and bins in  $\mathcal{S}$  have level at most  $6 - 6\varepsilon$ ; the old size thresholds play no further part in the analysis.

## 4.2 Packing methods for non-hard items

**small and big** These are items such that when packing them into  $\overline{Q}_2$  using First Fit (which are the fullest bins (ignoring  $\mathcal{X}$ ) that possibly still need to receive items in the fill-up phase), each bin (apart from constantly many) will receive at least  $9 - \varepsilon$  of items.

These items are always packed in the leftmost available bin that did not already receive items from another type in the fill-up phase. That is, we essentially use First Fit, but items of the three different size ranges are not packed together into bins. We only use bins in  $\mathcal{D}$ . This is feasible because new bins will enter the set  $\mathcal{D}$  as we pack items in it (Rule 2).

**easy and top** When packing easy or top items using First Fit into any bin that is not in  $\overline{Q}_2 \cup \Delta_{\text{large}} \cup \Delta_{\text{nice},1}$ , Rule 3 is automatically satisfied. (We have  $|\Delta_{\text{large}} \cup \Delta_{\text{nice},1}| \leq 2$ .) These items are packed exactly like the small items except that we skip the bins in  $\overline{Q}_2$ . We use First Fit for easy and top items (on the bins not in  $\overline{Q}_2$ ) separately.

**quarter** The quarter items are packed by First Fit, alternating between bins in  $\overline{Q}_2$  and bins not in  $\overline{Q}_2$ . If we run out of bins in  $\overline{Q}_2$  we use First Fit on dedicated bins not in  $\overline{Q}_2$ . If we run out of nonempty bins not in  $\overline{Q}_2$  we can always pack all remaining items as is shown in the full version.

**hard** These are the quarter<sup>+</sup>, quarter<sup>++</sup>, large<sup>-</sup> and large<sup>+</sup> items. These are the only types of items that we will sometimes (have to) pack into empty bins although nonempty bins that are not in  $\overline{Q}_2$  are still available. When packing hard items of one type using First Fit into empty bins, Rule 3 is satisfied *and* there is a surplus above the requirement of  $10 + 6\varepsilon$ . We use this surplus to pack as many items as possible into nonempty bins, which is necessary to succeed. See Section 4.3.

Once First Fit uses a new bin for an item, the bin previously considered (in which the item did not fit anymore) is removed from  $\mathcal{U}$ .

## 4.3 Hard (quarter<sup>+(+)</sup> and large) items

The above lemmas show that in the fill-up phase, all items except quarter<sup>+(+)</sup> and large items can be packed while following the rules – as long of course as quarter<sup>+(+)</sup> and large items are packed following the rules as well. We next consider quarter<sup>+(+)</sup> and large items separately. For this we first need to define some important sets.

### 4.3.1 Sets considered for packing hard items

#### The set $\mathcal{S}_{-L}$ and the parameter $\beta_0$

At the beginning of the fill-up phase, if there are  $e$  empty bins, then if we pack two large items in each empty bin, there will be  $e$  nonempty bins that will *not* be needed to pack large items that have not arrived yet, even if  $u$  of them arrive in total. In principle, we let  $\mathcal{S}_{-L}$  be the  $e$  *rightmost* nonempty bins. We only deviate from this if there are less than  $e$  nonempty bins. In that case  $\mathcal{S}_{-L}$  consists of all nonempty unused bins (after the removal of  $\mathcal{N} \cup Q_{2,5}$ ). We define  $\beta_0$  as the level of the leftmost bin in  $\mathcal{S}_{-L}$  unless all other nonempty bins are in  $\mathcal{N} \cup Q_{2,5}$ , in which case  $\beta_0$  is set to  $6 - 6\varepsilon$ . Of course, due to other items arriving, it may well be that some large items end up getting packed in  $\mathcal{S}_{-L}$  after all.

Since  $u = m - \ell - q_{\text{match}}$  at the start of the fill-up phase, it is not possible that more than  $u - q_5$  large items arrive in the fill-up phase. This holds because each bin counted in  $q_5 + q_{\text{match}}$  contains two items larger than  $6 - 2\varepsilon$  or a dominant item, and each bin counted in  $\ell$  contains two items larger than  $6 - 2\varepsilon$  or an item larger than 6. Moreover, as above, Invariant 4.2 is maintained by the  $(9 - \varepsilon)$ -guarantee. As soon as  $u$  starts to decrease in the fill-up phase, more than  $u - q_5$  large items may still arrive.

## 10:18 Improved Online Load Balancing with Known Makespan

### Construction of the set $\mathcal{D}$

We initially define  $\mathcal{D}$  as the leftmost  $\frac{1+7\varepsilon}{10+6\varepsilon} \cdot u + \frac{9-\varepsilon}{10+6\varepsilon} \cdot 14$  unused bins (where bins in  $\mathcal{Q}_5$  and  $\mathcal{N}$  have already been eliminated).

### Definition of the set $\mathcal{S}_L$

We define  $\mathcal{S}_L$  as the set of the remaining nonempty bins in  $\mathcal{U}$  (that is, all the unused bins that are not in  $\mathcal{D} \cup \mathcal{S}_{-L} \cup \mathcal{E}$ ). The set  $\mathcal{S}_L$  may be empty.

Note that the above construction is done only once. The sets  $\mathcal{S}_L$  and  $\mathcal{S}_{-L}$  do not increase and a bin leaves such a set only if the bin leaves  $\mathcal{U}$  or is added to  $\mathcal{D}$ . While packing items in the fill-up phase, bins will be added to  $\mathcal{D}$  from left to right. Hence entering  $\mathcal{D}$  will happen first to bins in  $\mathcal{S}_L$  and then (possibly) to  $\mathcal{S}_{-L}$  and  $\mathcal{E}$ . Such bins leave their original sets.

Bins in  $\mathcal{S}$  are filled to at most  $6 - 6\varepsilon$  and hence have at least  $12 + 4\varepsilon$  empty space. Easy<sup>2</sup> items fit at least twice. Bins in  $\mathcal{S}_{-L}$  are filled to at most  $\beta_0$  and hence have at least  $18 - 2\varepsilon - \beta_0$  empty space. Large<sup>-</sup> items therefore fit at least twice (explaining that threshold). Bins initially in  $\mathcal{D}$  are loaded to at most  $2(4 - 4\varepsilon)$  and hence have at least  $18 - 2\varepsilon - 2(4 - 4\varepsilon) = 10 + 6\varepsilon$  space.

### 4.3.2 Packing methods for hard items: Five stages

Hard items are packed as follows. There are five possible stages; depending on what the packing looks like when the fill-up phase starts, not all stages might be applicable. Generally, we start by taking advantage of any  $\mathcal{Q}_{1,5}$  bins that are available, then we start filling the nonempty bins from right to left, always trying to avoid using empty bins as much as possible.

Hard items are always distributed among several types of bins ( $\mathcal{D}, \mathcal{S}_L, \mathcal{S}_{-L}, \mathcal{E}$ ). One of the used types will always be  $\mathcal{D}$ . In several cases, we will specify that nonintegral numbers of bins need to be used for some items. This can be implemented as follows. We always start by using a bin that is not in  $\mathcal{D}$ . Then, we keep using bins in  $\mathcal{D}$  until we would exceed the desired ratio. At that point we use a bin that is not in  $\mathcal{D}$  again, and repeat the process. In the long term we get closer and closer to the desired ratio.

#### Stage 1

In this stage, as mentioned above we first exploit any bins in  $\mathcal{Q}_{1,5}$  that may exist. These bins can be intermixed with  $\overline{\mathcal{Q}}_1$  in the sorted order, but we use them first. To be more precise, these bins are not used to pack any new items (as they are already quite full) but rather to pack additional items into  $\mathcal{D}$ , as follows. Note that these bins are not in  $\mathcal{U}$ . For this stage we define the upper bound for quarter<sup>+</sup> items as  $\frac{9-\varepsilon}{2}$  and the upper bound for large<sup>-</sup> items as  $9 - \varepsilon$  and hence neither quarter<sup>++</sup> items nor large<sup>+</sup> items exist. This also means that the value of  $\beta$  (see table of item type thresholds for the fill-up phase) does not yet play a role.

**Quarter<sup>+(+)</sup>:** As long as there exist bins in  $\mathcal{Q}_{1,5}$  with partially uncounted contents, for packing quarter<sup>+(+)</sup> items such bins are considered to contain quarter<sup>+(+)</sup> items (of the size of the ignored items). Each such bin allows us to pack  $\frac{1+7\varepsilon}{1-3\varepsilon}$  bins in  $\mathcal{D}$  with two quarter<sup>+(+)</sup> items each. In these  $\frac{1+7\varepsilon}{1-3\varepsilon}$  bins we then pack (or count) more than  $2\frac{1+7\varepsilon}{1-3\varepsilon}(4 + \varepsilon) + (1 + 7\varepsilon) = \frac{1+7\varepsilon}{1-3\varepsilon} \cdot (9 - \varepsilon)$ , which includes the so far uncounted part of the bin in  $\mathcal{Q}_{1,5}$ .

**Large:** As long as there exist bins in  $\mathcal{Q}_{1,5}$  with partially uncounted contents, for packing large items such bins are considered to contain large items (of the size of the ignored items). Each such bin allows us to pack  $\frac{1+7\varepsilon}{3-3\varepsilon}$  bins in  $\mathcal{D}$  with one large item each. In these  $\frac{1+7\varepsilon}{3-3\varepsilon}$  bins we then pack (or count) more than  $\frac{1+7\varepsilon}{3-3\varepsilon}(6+2\varepsilon) + (1+7\varepsilon) = \frac{1+7\varepsilon}{3-3\varepsilon} \cdot (9-\varepsilon)$ , which includes the so far uncounted part of the bin in  $\mathcal{Q}_{1,5}$ .

It can be seen that by packing  $\text{quarter}^{+(+)}$  and large items this way, Rule 1 and Rule 3 are followed. Once we run out of bins in  $\mathcal{Q}_{1,5}$ , we start using the methods in the following table. The value of  $\beta$  will change over time and is set at the start of each of the following stages. Note here that for  $\beta \leq \frac{9-\varepsilon}{2}$  the upper bound for  $\text{quarter}^+$  items is at least the upper bound for  $\text{quarter}^{++}$  items and hence  $\text{quarter}^{++}$  items do not exist as long as  $\beta \leq \frac{9-\varepsilon}{2}$ .

| Item type             | Bin type   | Nr bins   | Per bin | Counted                              | Average                      |
|-----------------------|--|---|---------|--------------------------------------|------------------------------|
| $\text{quarter}^+$    | $\mathcal{D}$  | 3   | 2       | $2(4+\varepsilon)$                   | $9 + \frac{9}{4}\varepsilon$ |
|                       | $\overline{\mathcal{Q}}_1, \mathcal{S}_{-L}(\mathcal{S}_L), \mathcal{E}$ | 1   | 3       | $3(4+\varepsilon)$                   |                              |
| $\text{quarter}^{++}$ | $\mathcal{E}$  | 1   | 4       | $\frac{4}{3}(18-2\varepsilon-\beta)$ | $9-\varepsilon$              |
|                       | $\mathcal{D}$  | $\frac{45-4\beta-5\varepsilon}{2\beta-(9-\varepsilon)}$ | 2       | $\frac{2}{3}(18-2\varepsilon-\beta)$ |                              |
| $\text{large}^-$      | $\mathcal{D}$  | 1   | 1       | $6+2\varepsilon$                     | $9+3\varepsilon$             |
|                       | $\overline{\mathcal{Q}}_1, \mathcal{S}_{-L}(\mathcal{S}_L), \mathcal{E}$ | 1   | 2       | $12+4\varepsilon$                    |                              |
| $\text{large}^+$      | $\mathcal{D}$  | $\frac{18-2\varepsilon}{\beta} - 2$                     | 1       | $\frac{18-2\varepsilon-\beta}{2}$    | $9-\varepsilon$              |
|                       | $\mathcal{E}$  | 1   | 2       | $18-2\varepsilon-\beta$              |                              |

The third column indicates the number of bins used each time. The column “Average” contains the average amount counted over all bin types used for this item.

This table is implemented as follows. Items from these four types are packed into separate bins. For each type except  $\text{quarter}^{++}$  items, we first use a bin in  $\mathcal{D}$ . For  $\text{quarter}^{++}$  items, we use  $\mathcal{E}$  first to ensure that the average packed in the bins with these items is always greater than  $9-\varepsilon$ , apart from at most one bin: the bin currently being used. For all other types, we have this guarantee for all used bins up to and including the most recently filled bin in  $\mathcal{E}$ , which is all but at most four bins for each type.

For each bin used we pack items in it until we have packed the number of items in the column Per bin. We first use bins in  $\mathcal{D}$  until we have packed the number of items in the column Per bin and until we have used the number of bins in the column Nr bins, followed by one bin in  $\mathcal{E}$ . (If the number of bins supposed to be used in  $\mathcal{D}$  is not an integer, then the number of bins used in  $\mathcal{D}$  is always off by less than 1 compared to the desired ratio of  $\mathcal{D} : \mathcal{E}$  usage.) This procedure keeps repeating. Whenever we start using a new bin, the previous bin for this type is called *closed*. Once a bin is closed it is removed from  $\mathcal{U}$ .

In the following we will always check if bins with level at most  $\beta$  exist. While this is true we remain in the current stage. Else we update  $\beta$  to the next higher bound.

## Stage 2

We set  $\beta := \min(\beta_0, 4-4\varepsilon)$ . As long as there are bins with level at most  $\beta$  available, we use these bins (including bins in  $\mathcal{S}_L$  if needed) for packing  $\text{quarter}^+$  and  $\text{large}^-$  items. There are no  $\text{quarter}^{++}$  items and only  $\text{large}^+$  items are packed into empty bins.

## Stage 3

As Stage 2, but with  $\beta := \min(\beta_0, \frac{9-\varepsilon}{2})$ . Bins in  $\mathcal{S}_L$  with level at most  $\beta$  will still be used for  $\text{quarter}^+$  and  $\text{large}^-$  items. There are no  $\text{quarter}^{++}$  items and only  $\text{large}^+$  items are packed into empty bins.

**Stage 4**

This stage only exists if  $\beta_0 > \frac{9-\varepsilon}{2}$ . We set  $\beta := \beta_0$ .

Quarter<sup>++</sup> and large<sup>+</sup> items are packed into empty bins. All items are packed according to the table. Bins in  $\mathcal{S}_L$  are *not* used for quarter<sup>+</sup> items; we would go to Stage 5 instead. This is done to ensure that enough bins are left for large<sup>-</sup> items and that we do not waste bins on quarter<sup>+</sup> items.

**Stage 5**

Only bins in  $\mathcal{S}_L \cup \mathcal{D} \cup \mathcal{E}$  are left. At this point quarter<sup>+</sup> and large<sup>-</sup> items are also packed into empty bins.

Stage 6 would be the stage where all empty bins have been filled while some bins in  $\mathcal{S}_L \setminus \mathcal{D}$  remain. The case where all nonempty bins get filled first is discussed in the full version. We will show that Stage 6 is not reached or we are in a good situation.

As is in the starting phase, if some item cannot be packed according to the packing rules (including the case where we change the packing rules if we reach a good situation) we use the rule of last resort.

# On the NP-Hardness Approximation Curve for Max-2Lin(2)

Björn Martinsson  

KTH Royal Institute of Technology, Stockholm, Sweden

---

## Abstract

In the Max-2Lin(2) problem you are given a system of equations on the form  $x_i + x_j \equiv b \pmod{2}$ , and your objective is to find an assignment that satisfies as many equations as possible. Let  $c \in [0.5, 1]$  denote the maximum fraction of satisfiable equations. In this paper we construct a curve  $s(c)$  such that it is NP-hard to find a solution satisfying at least a fraction  $s$  of equations. This curve either matches or improves all of the previously known inapproximability NP-hardness results for Max-2Lin(2). In particular, we show that if  $c \geq 0.9232$  then  $\frac{1-s(c)}{1-c} > 1.48969$ , which improves the NP-hardness inapproximability constant for the min deletion version of Max-2Lin(2). Our work complements the work of O'Donnell and Wu that studied the same question assuming the Unique Games Conjecture.

Similar to earlier inapproximability results for Max-2Lin(2), we use a gadget reduction from the  $(2^k - 1)$ -ary Hadamard predicate. Previous works used  $k$  ranging from 2 to 4. Our main result is a procedure for taking a gadget for some fixed  $k$ , and use it as a building block to construct better and better gadgets as  $k$  tends to infinity. Our method can be used to boost the result of both smaller gadgets created by hand ( $k = 3$ ) or larger gadgets constructed using a computer ( $k = 4$ ).

## 1 Introduction

Maximum constraint satisfaction problems (Max-CSPs) form one of the most fundamental classes of problems studied in computational complexity theory. A Max-CSP is a type of problem where you are given a list of variables and a list of constraints, and your goal is to find an assignment that satisfies as many of the constraints as possible. Some common examples of Max-CSP are Max-Cut and Max-2Sat. Every Max-CSP also has a corresponding Min-CSP-deletion problem where your objective is deleting as few constraints as possible to make all of the remaining constraints satisfiable. The Min-CSP-deletion problem is fundamentally the same optimisation problem as its corresponding Max-CSP, however their objective values are different.

### 1.1 History of Max-Cut

The Max-Cut problem is arguably both the simplest Max-CSP as well as the simplest NP-hard problem. In the Max-Cut problem you are given an undirected graph, and your objective is to find a cut of the largest possible size. A cut of an undirected graph is a

partition of the vertices into two sets and the size of a cut is the fraction of edges that connect the two sets relative to the total number of edges. Solving Max-Cut exactly is difficult, but there are trivial approximation algorithms that get within a factor of  $\frac{1}{2}$  of the optimum. One such algorithm is randomly picking the cut by tossing one coin per vertex.

Knowing this, one natural question is, how close can a polynomial time algorithm get to the optimum? Goemans and Williamson partly answered this in a huge breakthrough in 1995 [8] by applying semi-definite programming (SDP) to create a polynomial time algorithm that finds a solution that is within a factor of  $\alpha_{\text{GW}} \approx 0.87856$  of the optimum. At the time, there was hope that Goemans and Williamson’s algorithm could be improved further to get even better approximation factors than 0.87856, but no such improvements were ever found. Instead, in 2004 Khot et al [11] proved using the Unique Games Conjecture (UGC), that approximating Max-Cut within a factor of  $\alpha_{\text{GW}} + \varepsilon$  is NP-hard for any  $\varepsilon > 0$ . This conjecture had been introduced by Khot two years prior [12]. This was possibly the first result establishing the close connection between UGC and SDP based algorithms.

To this day, UGC remains an open problem, and in particular no one has been able to find an approximation algorithm for Max-Cut with a better approximation ratio than  $\alpha_{\text{GW}}$ . In 2008 O’Donnell and Wu [14] were able to very precisely describe the tight connection between SDP based approximation algorithms for Max-Cut and UGC. They constructed a curve  $\text{Gap}_{\text{SDP}}(c) : [0.5, 1] \rightarrow [0.5, 1]$  with the following two properties:

1. It is UGC-hard to find a cut of size  $\text{Gap}_{\text{SDP}}(c) + \varepsilon$  given that the optimal cut has size  $c$  for any  $\varepsilon > 0$ . We here use *UGC-hard* as a short hand for “NP-hard under UGC”.
2. Within the RPR<sup>2</sup>-framework [7, 14], there are polynomial time algorithms that are guaranteed to find a cut of size at least  $\text{Gap}_{\text{SDP}}(c) - \varepsilon$  if the optimal cut has size  $c$ . The RPR<sup>2</sup>-framework is a generalisation of Goemans and Williamson’s algorithm.

This means that their work both describe the best known polynomial time approximation algorithms for Max-Cut, and also show that under UGC these approximation algorithms cannot be improved. It is important to note that their algorithmic results do not require UGC. We emphasize that one implication of their result is that giving efficient algorithms with a better performance would disprove UGC.

## 1.2 NP-hardness inapproximability of Max-2Lin(2)

Max-2Lin(2) is a Max-CSP that is very closely related to Max-Cut. An instance of Max-2Lin(2) is a system of linear equations on the form  $x_i + x_j \equiv b \pmod{2}$ , and the objective is to find an assignment that satisfies as many equations as possible. Max-Cut is the special case where we only allow equations with right hand side equal to 1. This implies that any hardness result for Max-Cut immediately yields the same hardness result for Max-2Lin(2). One example of this is the UGC-hardness of Max-Cut described by the  $\text{Gap}_{\text{SDP}}(c)$  curve by O’Donnell and Wu [14].

Furthermore, O’Donnell and Wu’s algorithmic results [14] also directly carries over to Max-2Lin(2). This is because the RPR<sup>2</sup>-framework that they relied on uses odd rounding functions, and therefore does not differentiate between Max-Cut and Max-2Lin(2).

The conclusion is that the  $\text{Gap}_{\text{SDP}}(c)$  describes a tight connection between the UGC-hardness of Max-2Lin(2) as well as the best known polynomial time approximation algorithms for Max-2Lin(2). On the other hand, the NP-hardness inapproximability of Max-2Lin(2) is not well understood. The strongest NP-hardness inapproximability results known for Max-2Lin(2) ([9], [16]) are still far off from the UGC-hardness described by the  $\text{Gap}_{\text{SDP}}(c)$  curve.

The aim of this paper is to improve the state of the art NP-hardness inapproximability of Max-2Lin(2) and also to give the full picture of the state of the art NP-hardness inapproximability of Max-2Lin(2). We do this by constructing a curve  $s(c) : [0.5, 1] \rightarrow [0.5, 1]$  such that it is NP-hard to distinguish between instances where the optimal assignment satisfies a fraction of  $c$  of the equations, and instances where all assignments satisfy at most a fraction of  $s(c)$  of the equations. Our curve either matches or improves all previously known NP-hardness inapproximability results for Max-2Lin(2). We construct the curve by solving a separate optimisation problem for each value of  $c$ , so our result covers the entire spectrum of  $c \in [0.5, 1]$ .

Our result complements the work by O’Donnell and Wu [14]. Our curve describes the state of the art NP-hardness inapproximability of Max-2Lin(2) while O’Donnell and Wu’s  $\text{Gap}_{\text{SDP}}(c)$  curve describes the UGC-hardness of Max-2Lin(2). It is worth noting that UGC is still an open problem that over the years has been the subject of much debate. There are results that indicate that UGC might be true, such as the proof of the closely related 2-to-2 Games Conjecture [13]. But on the other hand there are also results that indicate the UGC might be false, such as the existence of subexponential algorithms for Unique Games [2]. Currently there is no consensus for whether UGC is true or not. It is for this reason that it is important to study NP-hardness independent of UGC, especially for fundamental problems such as Max-2Lin(2).

### 1.3 Gadget reductions

Gadgets are the main tools used to create reductions from one Max-CSP  $\Phi$  to another Max-CSP  $\Psi$ . A gadget is a description of how to translate a specific constraint  $\varphi$  of  $\Phi$  into one or more constraints of  $\Psi$ . For example, if  $\Phi$  is Max-3Lin(2) and  $\Psi$  is Max-Cut, then a gadget from  $\varphi$  to  $\Psi$  is a graph. A gadget is allowed to use both the original variables in the constraint  $\varphi$ , which are called *primary variables*, and new variables specific to the gadget, which are called *auxiliary variables*.

The standard technique used to construct gadgets is to follow the “automated gadget” framework of Trevisan et al [15]. This framework describes how to construct a gadget by solving a linear program and also proves that the constructed gadget is optimal. This framework is mainly used to construct gadgets for small and simple Max-CSPs. This is because the number of variables in the gadget scales exponentially with the number of satisfying assignments of  $\varphi$ . Furthermore, the number of constraints in the LP scales exponentially with the number of variables, so it scales double exponentially with the number of satisfying assignment of  $\varphi$ .

As an example let us take the gadget from Max-3Lin(2) to Max-2Lin(2) used by Håstad [9], which was originally constructed by Trevisan et al [15]. A constraint in Max-3Lin(2) has 4 satisfiable assignments. Having 4 satisfiable assignments means that the gadget uses  $2^4 = 16$  variables. Furthermore, since Max-2Lin(2) allow negations, half of these variables can be removed because of negations. So the actual number of variables in the gadget is  $2^{4-1} = 8$ . This in turn implies that the number of constraints in the LP is  $2^8 = 256$ . This number is small enough that it is feasible for a computer to solve the LP. In this paper we are interested in constructing gadgets from generalisations of Max-3Lin(2), called the Hadamard Max-CSPs. These have significantly more satisfying assignments than Max-3Lin(2). It is easy to see that a simple-minded application of the “automated gadget” framework leads to an LP that is far too large to naively be solved by a computer. This means that we have to deviate from the “automated gadget” framework in order to construct our gadgets.

Gadgets have two important properties, called *soundness*  $s$  and *completeness*  $c$ . If a gadget is constructed using the “automated gadget” framework, then it is trivial to calculate the completeness of the gadget. On the other hand, calculating the soundness of a gadget from  $\Phi$  to  $\Psi$  involves solving instances of  $\Psi$ . In practice, calculating the soundness of a large gadget can be very difficult since  $\Psi$  is usually an NP-hard problem.

Gadgets can be constructed with different goals in mind. The case that we are interested in is finding the gadget with the largest soundness for a fixed completeness. This is what allows us to construct our curve  $s(c)$ . In general there are also other objectives that could be of interest when constructing gadgets. One such case is finding the gadget with the smallest ratio of  $\frac{s}{c}$ . This corresponds to finding the best lower bound for the approximation ratio of Max-2Lin(2). Another possibility is to maximise  $\frac{1-s}{1-c}$ . This corresponds to finding the best upper bound for the approximation ratio of Min-2Lin(2)-deletion. It is possible to use the “automated gadget” framework by Trevisan et al [15] to find the optimal gadgets for all of these scenarios.

## 1.4 The Hadamard Max-CSPs Max-Had $_k$

One of the earliest gadget reductions used to show NP-hardness inapproximability of Max-2Lin(2) is a gadget reduction from Max-3Lin(2) used by Håstad in his classical paper from 1997 [9], which was constructed by Trevisan et al [15]. More recently, NP-hardness inapproximability results for Max-2Lin(2) have used gadget reductions from a generalisation of Max-3Lin(2) called the Hadamard Max-CSPs [10, 16]. The  $(2^k - 1)$ -ary Hadamard Max-CSP,  $k \geq 2$ , is a constraint satisfaction problem where a clause is satisfied if and only if its literals form the truth table of a linear  $k$ -bit Boolean function. The  $(2^k - 1)$ -ary Hadamard CSP is denoted by Max-Had $_k$ . One special case is  $k = 2$ , where the number of literals of a clause is 3. It turns out that this case coincides with Max-3Lin(2). This means that Max-Had $_k$  can be seen as a generalisation of Max-3Lin(2).

There are mainly two reasons as to why Max-Had $_k$  is useful for gadget reductions. The first reason is that Max-Had $_k$  is a very sparse CSP. It being sparse refers to the number of satisfiable assignments of a clause being few in relation to the total number of possible assignments. The number of satisfying assignments of a clause is just  $2^k$ , one for each linear  $k$ -bit Boolean function, while the total number of possible assignments is  $2^{(2^k - 1)}$ .

The second reason is that Max-Had $_k$  is a *useless predicate* for any  $k \geq 2$ , which is an even stronger property than being approximation resistant. This was shown by Chan in 2013 [6]. Max-Had $_k$  being a useless predicate means that if you are given a nearly satisfiable instance of Max-Had $_k$ , then it is NP-hard to find an assignment such that the distribution over the  $(2^k - 1)$  long bit strings given by the literals of the clauses is discernibly different from the uniform distribution.

### 1.4.1 Historical overview of Had $_k$ -to-2Lin(2) gadgets

In 1996, Trevisan et al [15] constructed the optimal gadget from Max-Had $_2$  to Max-2Lin(2). They showed that the Max-Had $_2$  gadget that minimises  $\frac{s}{c}$  is the same gadget as the one that maximises  $\frac{1-s}{1-c}$ . Furthermore, since this gadget is very small, using only 8 variables, they were able to construct it using the “automated gadget” framework.

In 2015, Håstad et al. [10] constructed gadgets from Max-Had $_3$  to Max-2Lin(2). They showed that the Max-Had $_3$  gadget that minimises  $\frac{s}{c}$  is equivalent to the Max-Had $_2$  gadget. So using Max-Had $_3$  over Max-Had $_2$  does not give an improved hardness for the approximation ratio of Max-2Lin(2). However, the Max-Had $_3$  gadget that maximises  $\frac{1-s}{1-c}$  is notably better

than the Max-Had<sub>2</sub> gadget. This gadget is relatively small, only using 128 variables. This is too many variables for it to be possible to naively apply the “automated gadget” framework. However, Håstad et al. were still able to construct and analyse the optimal gadget by hand based on ideas from the “automated gadget” framework.

In 2018, Wiman [16] constructed gadgets from Max-Had<sub>4</sub> to Max-2Lin(2). Note that Max-Had<sub>4</sub> gadgets have  $2^{15}$  variables. Calculating the soundness of a such a gadget requires solving an instance of Max-2Lin(2) with  $2^{15}$  variables, which is infeasible to do by hand or even with a computer. Wiman initially followed the “automated gadget” framework. However, in order to be able to calculate the soundness of the gadget, Wiman relaxed the Max-2Lin(2) problem into a Max-Flow problem. This *relaxed soundness*  $rs$  is an upper bound of the true soundness. This relaxation made it possible for Wiman to use a computer to find the gadget that maximises  $\frac{1-rs}{1-c}$ . Wiman’s relaxation was successful, since by using it he was able to find a Max-Had<sub>4</sub> gadget that was better than the optimal Max-Had<sub>3</sub> gadget. Note, however, that by using a relaxation, it is uncertain whether Wiman found the optimal Max-Had<sub>4</sub> gadget or not.

### 1.4.2 Our Had<sub>k</sub>-to-2Lin(2) gadgets

In this paper, we construct gadgets from Max-Had<sub>k</sub> to Max-2Lin(2) for  $k$  approaching infinity. Recall that a gadget uses  $2^{2^k-1}$  variables, so using a computer to construct gadgets for  $k > 5$  is normally impossible. We get around this limitation by introducing a procedure for taking Max-Had<sub>k</sub> gadgets and transforming them to Max-Had<sub>k'</sub> gadgets, for  $k' > k$ . We refer to this procedure as the *lifting* of a Max-Had<sub>k</sub> gadget into a Max-Had<sub>k'</sub> gadget. Two of the properties of lifting is that the completeness stays the same and the soundness does not decrease.

To show NP-hardness of approximating Max-2Lin(2), we start by constructing Max-Had<sub>k</sub> to Max-2Lin(2) gadgets for  $k = 4$  using a computer. We then analytically prove an upper bound of Wiman’s relaxed soundness of the lifting of these gadgets as  $k' \rightarrow \infty$ .

The method we use to construct our gadgets is by solving an LP. This LP is similar to what Wiman could have used to construct his gadget. The difference is that the LP we use is made to minimise the soundness of the lifted gadget, instead of minimising the soundness of the gadget itself. If done naively, this LP would have roughly  $2^{3 \cdot (2^k-1)} = 2^{45}$  variables. But by making heavy use of symmetries of the LP, we are able to bring it down to a feasible size.

The main technical work of this paper is proving an upper bound on Wiman’s relaxed soundness of a lifted gadget as  $k' \rightarrow \infty$ . Recall that calculating Wiman’s relaxed soundness involves solving instances of Max-Flow. As  $k'$  tends to infinity, the size of these instances also tend to infinity. In order to lower bound the value of these Max-Flow problems, we introduce the concept of a type of infeasible flows which we call *leaky flows*. A leaky flow is a flow for which the conservation of flows constraint has been relaxed. This allows leaky flows to attain higher values compared to feasible flows. We then show that by randomly overlapping leaky flows onto the large Max-Flow instances, we are able to get closer and closer to a feasible flow as the size of the instances tend to infinity.

## 1.5 Our results and comparison to previous results

Using a gadget reductions from Max-Had<sub>k</sub> to Max-2Lin(2), we are able to construct a curve  $s(c) : [0.5, 1] \rightarrow [0.5, 1]$  such that it is NP-hard to distinguish between instances of Max-2Lin(2) where the optimal assignment satisfies a fraction of  $c$  of the equations and instances where all assignments satisfy at most a fraction of  $s(c)$  of the equations. This curve does not have an explicit formula. Instead, each point on the curve is defined as the solution to an LP, which we solve using a computer.

## 11:6 On the NP-Hardness Approximation Curve for Max-2Lin(2)

► **Theorem 1.1.** *Let  $s(c) : [0.5, 1] \rightarrow [0.5, 1]$  be the curve defined in Definition 4.1. Then for every sufficiently small  $\varepsilon > 0$ , it is NP-hard to distinguish between instances of Max-2Lin(2) such that*

**Completeness** *There exists an assignment that satisfies a fraction at least  $c - \varepsilon$  of the constraints.*

**Soundness** *All assignments satisfy at most a fraction  $s(c) + \varepsilon$  of the constraints.*

A notable point on the curve is  $c = \frac{590174949}{639271832} \approx 0.9232$  and  $s(c) = \frac{141533171}{159817958} \approx 0.8856$ . This is the point on the curve that gives the highest NP-hardness inapproximability factor  $\frac{1-s}{1-c}$  of Min-2Lin(2)-deletion.

► **Corollary 1.2.** *It is NP-hard to approximate Min-2Lin(2)-deletion within a factor of  $\frac{73139148}{49096883} + \varepsilon \approx 1.48969 + \varepsilon$ .*

In order to be able to compare our curve  $s(c)$  to prior results, we plot our curve together with O’Donnell and Wu’s  $\text{Gap}_{\text{SDP}}(c)$  curve [14], which, as discussed earlier, describes both the UGC-hardness of Max-2Lin(2), as well as the best known polynomial time approximation algorithms of Max-2Lin(2). Additionally, we also include historical NP-hardness inapproximability results as points in the diagram. We have also marked the point  $(c, s)$  where Goemans and Williamson’s algorithm achieves the approximation ratio of  $\frac{s}{c} = \alpha_{\text{GW}} \approx 0.87856$ . This point was shown to be UGC-hard by Khot et al. in 2004 [11].

The curve  $s(c)$  is plotted in three Figures. All three Figures contain the same exact same data, but the data is plotted in different ways. In Figure 1 the soundness  $s(c)$  is on the  $y$ -axis and the completeness  $c$  is on the  $x$ -axis. This plot has the disadvantage that to the eye, it is difficult to distinguish the exact shape of the curve  $s(c)$ . In the next plot, Figure 2,  $\frac{s(c)}{c}$  is on the  $y$ -axis and  $c$  is on the  $x$ -axis. This plot describes the approximation ratio of Max-2Lin(2). The third plot, in Figure 3, has  $\frac{1-s(c)}{1-c}$  on the  $y$  axis and  $c$  on the  $x$ -axis. This plot describes the approximation ratio of Min-2Lin(2)-deletion.

It is important to note that the curves in Figure 1 are convex functions since it is possible to take the convex combination of two hard instances using disjoint sets of variables. One implication from this is that it is possible to construct NP-hardness curves using any of the points  $(c, s)$  by drawing two lines, one from  $(0.5, 0.5)$  to  $(c, s)$  and one from  $(c, s)$  to  $(1, 1)$ . This means that all of the historical inapproximability results can also be described using convex curves.

In Figures 1-3 prior inapproximability results for Max-2Lin(2) are marked as dots. Bellare et al [5] was first to give an explicit NP-hardness result, which had  $c = 0.72$  and  $s = 0.71$ . In 2015, Håstad et al [10] used Chan’s result [6] to create a gadget reduction from Max-Had<sub>3</sub> which had  $c = \frac{7}{8}$  and  $s = \frac{53}{64}$ . This result became the new record for the upper bound of the approximation ratio of Min-2Lin(2)-deletion, as seen in Figure 3. Three years later, Wiman [16] further improved on this result by using Max-Had<sub>4</sub> instead of Max-Had<sub>3</sub>. Wiman’s Max-Had<sub>4</sub> gadget has  $c = \frac{15}{16}$  and  $s = \frac{3308625759}{3640066048} \approx 0.9089$ . This further improved the upper bound on the approximation ratio of Min-2Lin(2)-deletion.

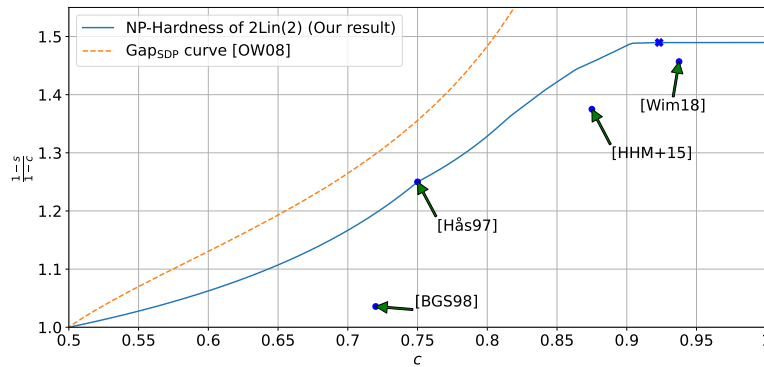

Similar to earlier results, the technique we use to construct our curve is also a gadget reduction from Max-Had <sub>$k$</sub>  to Max-2Lin(2). But instead of using a gadget reduction from Max-Had <sub>$k$</sub>  for a fixed  $k$ , we instead let  $k$  tend to infinity. This improves the quality of our gadget. One example of such an improvement is our upper bound on the approximation ratio of Min-2Lin(2)-deletion, which can be seen in Figure 3. The ratio  $\frac{1-s(c)}{1-c}$  is maximised on our curve at  $c = \frac{590174949}{639271832} \approx 0.9232$  and  $s = \frac{141533171}{159817958} \approx 0.8856$ , which is marked by a blue cross in Figure 3.

■ **Figure 1** The  $y$ -axis shows the soundness  $s$  and the  $x$ -axis the completeness  $c$ . The blue filled curve is our NP-hardness curve  $s(c)$ . The red dashed curve is the  $\text{Gap}_{\text{SDP}}(c)$  by O’Donnell and Wu’s [14]. The points marked with arrows are prior inapproximability results of Max-2Lin(2). The blue cross on the curve marks our best inapproximability result for Min-2Lin(2)-deletion, see Figure 3. Note that both of the curves in this figure are convex functions.

■ **Figure 2** The  $y$ -axis shows  $s/c$ , which corresponds to the approximation ratio of Max-2Lin(2). The point on the curve  $c(s)$  that minimises this ratio is  $c = 3/4$  and  $s(c) = 11/16$ , which exactly matches Håstad’s result from 1997 [9].

■ **Figure 3** The  $y$ -axis shows  $(1 - s)/(1 - c)$ , which corresponds to the approximation ratio of Min-2Lin(2)-deletion. This ratio reaches its maximum  $\frac{1-s(c)}{1-c} = \frac{73139148}{49096883} \approx 1.4896$  at  $c = \frac{590174949}{639271832}$ , which is marked by a blue cross. The curve stays constant after this point.

## 1.6 The limitations of $\text{Had}_k\text{-to-2Lin}(2)$ gadget reductions

In Figure 1, it is possible to see a clear gap between our  $s(c)$  curve and O’Donnell and Wu’s  $\text{Gap}_{\text{SDP}}(c)$  curve [14]. The gap is especially noticeable in Figure 3, since the behaviour of the two curves are completely different when  $c$  is close to 1. One natural question is, how close can a  $\text{Had}_k\text{-to-2Lin}(2)$  gadget reduction get to the  $\text{Gap}_{\text{SDP}}(c)$  curve?

Håstad et al [10] showed that any gadget reduction from a Hadamard Max-CSP to Max-2Lin(2) can never achieve an approximation ratio for Min-2Lin(2)-deletion better than  $\frac{1}{1-e^{-0.5}} \approx 2.54$ . In Appendix B we show that any gadget reduction from a Hadamard CSP to Max-2Lin(2) that uses Wiman’s soundness relaxation can never achieve an approximation ratio of Min-2Lin(2)-deletion better than 2. Both 2.54 and 2 are fairly large in comparison to the current best value of 1.48969 shown in Figure 3. So it is potentially possible to still improve our results in the future using a  $\text{Had}_k\text{-to-2Lin}(2)$  gadget reduction for some  $k \geq 4$ . However, these limitations means that it is impossible to make  $s(c)$  match the behaviour of  $\text{Gap}_{\text{SDP}}(c)$  when  $c$  is close to 1.

## 1.7 Outline of proof

Our result is based on  $\text{Had}_k\text{-to-2Lin}(2)$  gadget reduction for arbitrary large values of  $k$ . We start from the “automated gadget” framework by Trevisan et al [15]. In this framework, computing the soundness of a  $\text{Had}_k\text{-to-2Lin}(2)$  gadget involves solving a Max-2Lin(2) problem. Following the work of Wiman [16], we relax the soundness computation to a Max-Flow problem on the  $2^k$ -dimensional hypercube. Using symmetries, it is computationally feasible to construct  $\text{Had}_k\text{-to-2Lin}(2)$  gadgets that are optimal with respect to the relaxed soundness for  $k \leq 4$ .

In order to be able harness the power of arbitrarily large  $k$ , we define a procedure of embedding a  $\text{Had}_k\text{-to-2Lin}(2)$  gadget  $G$  inside a  $\text{Had}_{k'}\text{-to-2Lin}(2)$  gadget where  $k' > k$ . By overlapping multiple different embeddings of  $G$ , we construct a gadget  $G'$  for an arbitrarily large  $k'$ .

Recall that the relaxed soundness computation is a Max-Flow problem, which can be expressed as an LP. By carefully relaxing this LP, we are able to create an infeasible flow solution to  $\text{rs}(G)$ , such that if we lift it, it becomes an almost feasible flow of  $\text{rs}(G')$ . The underlying idea for this relaxation is based on leaky flows (flows where the flow entering a node can be different than the flow exiting the node). The “leaks” of a leaky flow are signed, so random overlap of leaky flows can result in a feasible flow. We show that this is actually the case for the solution to our relaxed LP using a second order moment analysis.

The final step is to construct the  $\text{Had}_k\text{-to-2Lin}(2)$  gadget  $G$  and its corresponding leaky flow for  $k = 4$  used in the embedding. This construction is naturally done using a rational LP solver to solve the relaxed LP.

## 1.8 Organisation of paper

Section 2 contain the preliminaries. It introduces Max-CSPs and the automated gadget framework. Section 3 introduces Wiman’s relaxed soundness and the infinity relaxed soundness in terms of an LP. This section also states our main Lemma, Lemma 3.11, relating the infinity relaxed soundness to the relaxed soundness. Appendix A is about Max-Flow, and it proves some general theorems about how symmetries can be used to simplify Max-Flow problems. Appendix B contain an analysis of relaxed soundness, and how it relates to the (true) soundness. Appendix C studies affine maps. These affine maps are used both to analyse the infinity relaxed soundness, and to describe the symmetries of the LPs. Appendix D

contains the proof of Lemma 3.11 using the affine maps. Appendix E describes the procedure we use for constructing and verifying the gadgets. Section 4 contains our numerical results. This includes both plots and tables of various  $\text{Had}_k\text{-to-2Lin}(2)$  gadgets. Finally, Appendix F contains a compact description of all gadgets that we construct.

## 2 Preliminaries

This section is split into three parts. In Subsection 2.1 we introduce some basic concepts and notations for Boolean functions  $\mathbb{F}_2^k \rightarrow \{1, -1\}$ . After that, in Subsection 2.2 we formally define the  $(2^k - 1)$ -ary Hadamard predicate. The last subsection, Subsection 2.3, introduces the “automated gadget” framework by Trevisan et al [15], and explains the classical result of how to construct reductions from the  $(2^k - 1)$ -ary Hadamard predicate to  $\text{Max-2Lin}(2)$ .

### 2.1 Boolean functions

A  $k$ -bit Boolean function is a function that takes in  $k$  bits and outputs one bit. The  $k$  input bits should be thought of as a vector in a  $k$ -dimensional vector field over  $\mathbb{F}_2$ . On the other hand, the output bit is a scalar. For convenience, we denote the vectors as being elements in  $\mathbb{F}_2^k$  and the scalars as elements in  $\mathbb{R}$ , where a scalar bit is represented as 1 (False) or  $-1$  (True).

► **Definition 2.1.** *The set of  $k$ -bit Boolean functions is denoted by  $\mathcal{F}_k = \{f : \mathbb{F}_2^k \rightarrow \{1, -1\}\}$ .*

One special type of Boolean functions that is of great importance is the set of linear Boolean functions. Each linear Boolean function in  $\mathbb{F}_2^k$  corresponds to an element  $\alpha \in \mathbb{F}_2^k$ , and is denoted by  $\chi_\alpha$ .

► **Definition 2.2.** *For  $\alpha \in \mathbb{F}_2^k$  let  $\chi_\alpha \in \mathcal{F}_k$  be denote the function*

$$\chi_\alpha(x) = (-1)^{(\alpha, x)}$$

where  $(\alpha, x) = \sum_{i=1}^k \alpha_i x_i \pmod{2}$ .

Any Boolean function can be represented as a sum of linear Boolean functions using the Fourier transform.

► **Proposition 2.3.** *Given  $f \in \mathcal{F}_k$ , then*

$$f(x) = \sum_{\alpha \in \mathbb{F}_2^k} \chi_\alpha(x) \hat{f}_\alpha,$$

where  $\hat{f}_\alpha$  denotes the Fourier transform of  $f$  at  $\alpha$ , defined as

$$\hat{f}_\alpha = \frac{1}{2^k} \sum_{x \in \mathbb{F}_2^k} \chi_\alpha(x) f(x), \quad \alpha \in \mathbb{F}_2^k.$$

The Fourier transform is used to define the supporting affine subspace of a Boolean function. This also gives a natural definition for the dimension of a Boolean function.

► **Definition 2.4.** *Given  $f \in \mathcal{F}_k$ , its supporting affine sub-space  $\text{affine}(f)$  is the affine span of  $\{\alpha \in \mathbb{F}_2^k : \hat{f}_\alpha \neq 0\}$ .*

► **Definition 2.5.** *Let  $\dim(f)$ ,  $f \in \mathcal{F}_k$ , denote the dimension of  $\text{affine}(f)$ .*

## 11:10 On the NP-Hardness Approximation Curve for Max-2Lin(2)

► Remark 2.6. Affine functions have dimension 0.

The distance between two Boolean function is given by the normalised Hamming distance.

► **Definition 2.7.** Let  $\text{dist} : \mathcal{F}_k \times \mathcal{F}_k \rightarrow \mathbb{R}$  be the normalised Hamming distance between two Boolean functions, i.e.

$$\text{dist}(f_1, f_2) = \frac{1}{2^k} \sum_{x \in \mathbb{F}_2^k} \frac{1 - f_1(x)f_2(x)}{2}.$$

## 2.2 Max-CSP

This section introduces Constraint Satisfaction Problems (CSP) and Max-CSP. The framework we use is that CSPs are defined by predicates, which describe which kind of constraints that can appear in the CSP.

► **Definition 2.8.** An  $m$ -ary predicate is a function  $\phi \in \mathcal{F}_m$ . The predicate is said to be satisfied by  $x \in \mathcal{F}_2^m$  if  $\phi(x) = -1$ . Otherwise  $x$  is said to violate  $\phi$ . The set of  $x \in \mathcal{F}_2^m$  that satisfies  $\phi$  is denoted by  $\text{Sat}(\phi)$ .

Given a set of Boolean variables  $V$  and a  $m$ -ary predicate  $\phi$ , a  $\phi$ -constraint  $\mathcal{C}$  is a tuple  $((x_1, b_1), \dots, (x_m, b_m))$  where  $x_i \in V, i = [m]$ , and  $b_i \in \mathbb{F}_2, i \in [m]$ , where all of the  $x_i$ 's are distinct. The constraint  $\mathcal{C}$  is said to be satisfied if

$$\phi(b_1 + x_1, \dots, b_m + x_m) = -1,$$

where  $+$  denotes the xor-operation. In other words, if  $b_i = 1$  then  $x_i$  is negated.

► **Definition 2.9.** Given a  $m$ -ary predicate  $\phi$ , an instance  $\mathcal{I}$  of the Max- $\phi$ -CSP is a variable set  $V$  and a distribution of  $\phi$ -constraints over  $V$ . The Max- $\phi$ -CSP optimisation problem is; given an instance  $\mathcal{I}$ , find the assignment  $A : V \rightarrow \mathbb{F}_2$  that maximises the fraction of satisfied constraints in  $\mathcal{I}$ . The optimum is called the value of  $\mathcal{I}$ .

The main Max-CSPs of interest in this paper are the Hadamard  $\text{Had}_k$  Max-CSP, and Max-2Lin(2) and Max-3Lin(2). These have the following predicates.

► **Definition 2.10.** The 2Lin(2) predicate is the function  $f(x, y) = (-1)^{x+y+1}$ . Similarly, the 3Lin(2) predicate is the function  $f(x, y, z) = (-1)^{x+y+z+1}$ .

► **Definition 2.11.** The Hadamard  $\text{Had}_k$  predicate for  $k \geq 2$  is a  $(2^k - 1)$ -ary predicate. There is one input variable per non-empty subset  $S \subseteq [k]$ . The  $\text{Had}_k$  predicate is satisfied by a binary input string  $\{x_S\}_{\emptyset \neq S \subseteq [k]}$  if and only if there exists some  $\beta \subseteq [k]$  such that

$$\chi_\beta(S) = (-1)^{x_S}$$

for all non-empty subset  $S \subseteq [k]$ . I.e. the  $\text{Had}_k$  predicate is satisfied if and only if the input string forms the truth table of a linear function.

► Remark 2.12. The 3Lin(2) predicate and the  $\text{Had}_2$  predicate are in fact identical. Thus the family of Hadamard Max-CSPs can be seen as a natural generalisation of Max-3Lin(2).

► Remark 2.13. The set  $\text{Sat}(\text{Had}_k \text{ predicate})$  can be expressed using a  $2^k$  dimensional Hadamard matrix. Let  $M_k$  be a  $2^k \times (2^k - 1)$  matrix, where the rows are index by subsets  $\beta \subseteq [k]$  and the columns are indexed by non-empty subsets  $S \subseteq [k]$ . Let

$$(M_k)_{\beta, S} = \begin{cases} 0 & \text{if } \chi_\beta(S) = 1, \\ 1 & \text{if } \chi_\beta(S) = -1. \end{cases}$$

$$\begin{pmatrix} 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 1 & 0 & 1 & 0 & 1 & 0 & 1 \\ 0 & 1 & 1 & 0 & 0 & 1 & 1 \\ 1 & 1 & 0 & 0 & 1 & 1 & 0 \\ 0 & 0 & 0 & 1 & 1 & 1 & 1 \\ 1 & 0 & 1 & 1 & 0 & 1 & 0 \\ 0 & 1 & 1 & 1 & 1 & 0 & 0 \\ 1 & 1 & 0 & 1 & 0 & 0 & 1 \end{pmatrix}$$

■ **Figure 4** The matrix  $M_k$  for  $k = 3$ . It is an  $8 \times 7$  matrix. Note that prepending a zero column to  $M_k$  and switching 0/1 to  $1/-1$  would make it into a Hadamard matrix, which is symmetric.

The matrix  $M_k$  is the set  $\text{Sat}(\text{Had}_k \text{ predicate})$  expressed on the form of a matrix, with one row per element. Note that  $M_k$  is almost the  $2^k$ -dimensional Hadamard matrix.  $M_k$  can be made into the Hadamard matrix by prepending an all 0 column to it, and then switching out 0/1 to  $1/-1$ . This connection between  $\text{Sat}(\text{Had}_k \text{ predicate})$  and Hadamard matrices is one of the reasons as to why this Max-CSP is called the Hadamard Max-CSP. An example of the matrix  $M_k$  can be found in Figure 4.

The Hadamard predicate has been shown to be a *useless predicate*. The concept of useless predicates was first introduced in [3]. This property of  $\text{Had}_k$  was originally proven by Austrin and Mossel using UGC [4], which relies on the fact that  $\text{Sat}(\text{Had}_k)$  admits a balanced pairwise independent set. Later on Chan was able to show that  $\text{Had}_k$  is a useless predicate without requiring UGC [6]. To state this result we first need two definitions.

► **Definition 2.14.** Given an instance  $\mathcal{I}$  of an  $m$ -ary Max-CSP and an assignment  $A$ , let  $\mathcal{D}(A, \mathcal{I})$  denote the distribution of binary strings  $\mathbb{F}_2^m$  generated by sampling  $((x_1, b_1), \dots, (x_m, b_m)) \sim \mathcal{I}$  and outputting the binary string  $((A(x_1) + b_1), \dots, (A(x_m) + b_m))$ .

► **Definition 2.15.** The total variation distance  $d_{\text{TV}}$  between two probability measures  $\mu_1$  and  $\mu_2$  over a finite set  $\Omega$  is defined as

$$d_{\text{TV}}(\mu_1, \mu_2) = \frac{1}{2} \sum_{\omega \in \Omega} |\mu_1(\omega) - \mu_2(\omega)|.$$

► **Theorem 2.16** ([6]). For every  $\varepsilon > 0$ , it is NP-hard to distinguish between instances  $\mathcal{I}$  of the  $\text{Had}_k$  Max-CSP such that

**Completeness** There exists an assignment  $A$  such that

$$d_{\text{TV}}(\mathcal{D}(A, \mathcal{I}), \text{uniform}(\{\text{Sat}\}(\text{Had}_k \text{ predicate}))) \leq \varepsilon.$$

**Soundness** For every assignment  $A$ ,

$$d_{\text{TV}}(\mathcal{D}(A, \mathcal{I}), \text{uniform}(\mathbb{F}_2^{2^k - 1})) \leq \varepsilon.$$

Here  $\text{uniform}(\text{Sat}(\text{Had}_k \text{ predicate}))$  denotes the uniform distribution over binary strings that satisfy the  $\text{Had}_k$  predicate. Similarly,  $\text{uniform}(\mathbb{F}_2^{2^k - 1})$  denotes the uniform distribution over all binary strings of length  $2^k - 1$ .

► **Remark 2.17.** The uniform distribution on satisfiable instances in the completeness case is a subtle detail. The result by [6] is not formulated like this. However, it is trivial to take the instances constructed by Chan and modify them to make the completeness case be uniformly

distributed over satisfied instances. The first time this was used was by [16]. However, this detail turns out to not actually matter in the end since all of the gadgets that we construct and all of the gadgets that Wiman construct are symmetric. So this uniform randomness assumption is only there because of convenience, and is not actually used in the end.

### 2.3 The automated gadget framework

The “automated gadget” framework by Trevisan et al [15] describes how to construct optimal gadgets when reducing from one predicate to another. Let us denote the starting predicate as  $\phi$  and the target predicate as  $\psi$ . A  $\phi$ -to- $\psi$ -gadget is a description for how to reduce a  $\phi$ -constraint to one or more  $\psi$ -constraints. As an example, let us take a gadget from 3SAT to 2Lin(2). In this case the gadget describes a system of linear equations that both involve the three original variables from the 3SAT constraint (called *primary variables*, denoted by  $\mathbb{X}$ ) as well as new extra variables (called *auxiliary variables*, denoted by  $\mathbb{Y}$ ).

Gadgets have two important properties, called *completeness* and *soundness*. These properties describe how closely the  $\psi$ -constraints are able to mimic the satisfiability of the original  $\phi$ -constraint. The completeness of a gadget is a value between 0 and 1 that describe how many of the  $\psi$ -constraints that can be satisfied under the restriction that  $\mathbb{X}$  satisfies the original  $\phi$ -constraint. In a similar fashion, the soundness of a gadget is a value between 0 and 1 that describes the case when  $\mathbb{X}$  does not satisfy the original  $\phi$ -constraint. When we construct our gadgets, we fix the completeness of the gadget, and then we find the gadget that minimises the soundness for this fixed completeness. A gadget that minimises the soundness for a given completeness is referred to as an *optimal gadget*.

There is no a priori upper bound on how many auxiliary variables that a  $\phi$ -to- $\psi$ -gadget can have. However, the “automated gadget” framework by Trevisan et al [15] proves that, under some reasonable assumptions, the number of variables  $|\mathbb{X} \cup \mathbb{Y}|$  in an optimal gadget can be assumed to be at most  $2^{|\text{Sat}(\phi)|}$ . Furthermore, if  $\psi$  allows the negations of variables, then this number drops to  $2^{|\text{Sat}(\phi)|-1}$ .

In the case of a Had<sub>k</sub>-to-2Lin(2) gadget, the number of satisfying assignments of Had<sub>k</sub> is  $2^k$ , and 2Lin(2) allow the negation of variables. This means that the total number of variables in the gadget is  $2^{2^k-1}$ . Out of these,  $2^k - 1$  variables are in  $\mathbb{X}$ , and  $2^{2^k-1} - (2^k - 1)$  variables are in  $\mathbb{Y}$ . Furthermore, the “automated gadget” framework gives a natural way to index these variables in terms of  $|\text{Sat}(\text{Had}_k)|$ -long bitstrings. According to the framework, each primary variable should be indexed by a bitstring describing that variable’s assignment to all of the satisfying assignments to Had<sub>k</sub>, meaning a column in the matrix shown in Figure 4. The auxiliary variables are indexed by the bitstrings that do not appear in the matrix.

Instead of using  $2^k$ -long bitstrings to index the variables, it is arguably more natural to index the variables using functions in  $\mathbb{F}_2^k$ . These representations are equivalent since every  $2^k$  long bitstring can be interpreted as a truth table of a function in  $\mathcal{F}_k$ , and vice versa. By indexing the set of variables using functions in  $\mathcal{F}_k$ , the set of primary variables are indexed by linear functions  $\{\chi_\alpha\}_{\emptyset \subset \alpha \subseteq [k]}$ , and the negations of linear functions  $\{-\chi_\alpha\}_{\emptyset \subset \alpha \subseteq [k]}$ . This gives us the following description of a Had<sub>k</sub>-to-2Lin(2) gadget.

► **Definition 2.18.** A Had<sub>k</sub>-to-2Lin(2) gadget is given by a tuple  $(G, \mathbb{X}_k, \mathbb{Y}_k)$ , where  $G$  is a probability distribution over  $\binom{\mathcal{F}_k}{2}$  where  $G(f_1, f_2) = 0$  if  $f_1 = -f_2$ .  $\mathbb{X}_k$  is the set of primary variables and  $\mathbb{Y}_k$  is the set of auxiliary variables. The set of variables  $\mathbb{X}_k \cup \mathbb{Y}_k$  are indexed by functions in  $\mathcal{F}_k$ , meaning  $\mathbb{X}_k \cup \mathbb{Y}_k = \{x_f : f \in \mathcal{F}_k\}$ . A variable  $x_f$  is a primary variable if and only if  $f$  is a linear function or  $-f$  is a linear function.

The reduction from a  $\text{Had}_k$  constraint  $\text{Had}_k(b_{\{1\}} + y_{\{1\}}, \dots, b_{\{k\}} + y_{\{k\}})$  to  $2\text{Lin}(2)$  is given by the distribution formed by

1. Sampling  $(f_1, f_2) \sim G$ ,
2. Outputting the constraint  $T(f_1) = T(f_2)$  where

$$T(f) = \begin{cases} x_f & \text{if } x_f \in \mathbb{Y}_k, \\ b_\alpha + y_\alpha & \text{if } f = \chi_\alpha \text{ for some } \alpha \in \mathbb{F}_2^k, \\ b_\alpha + y_\alpha + 1 & \text{if } f = -\chi_\alpha \text{ for some } \alpha \in \mathbb{F}_2^k. \end{cases}$$

Let us now precisely define the soundness and completeness of a  $\text{Had}_k$ -to- $2\text{Lin}(2)$  gadget  $(G, \mathbb{X}_k, \mathbb{Y}_k)$ . From Theorem 2.16 it follows that the natural definition of soundness is to uniformly at random assign the primary variables  $\mathbb{X}_k$  to  $\mathbb{F}_2$ , and then assign the rest of the variables in order to satisfy as many of the equations as possible.

► **Definition 2.19.** Given a set of Boolean variables  $\mathbb{X}$ . Let  $\mathcal{F}(\mathbb{X})$  denote the set of assignments  $\mathbb{X} \rightarrow \mathbb{F}_2$ . Let  $\mathcal{F}_{\text{fold}}(\mathbb{X})$  the set of all folded assignments, i.e. functions  $P : \mathbb{X} \rightarrow \mathbb{F}_2$  such that  $P(1+x) = 1 + P(x) \forall x \in \mathbb{X}$ . Here  $1+x$  denotes the negation of the variable  $x$ .

► **Definition 2.20.** The soundness of  $G$  is defined as

$$s(G) = \mathbb{E}_{P \in \mathcal{F}_{\text{fold}}(\mathbb{X}_k)} \max_{\substack{A \in \mathcal{F}_{\text{fold}}(\mathbb{X}_k \cup \mathbb{Y}_k), \\ A(x) = P(x), x \in \mathbb{X}_k}} \text{val}(A, G),$$

where

$$\text{val}(A, G) = \sum_{(f_1, f_2) \in \binom{\mathcal{F}_k}{2}} G(f_1, f_2)[A(x_{f_1}) = A(x_{f_2})].$$

The completeness of  $G$  is defined using dictator cuts. A *dictator cut*  $\delta_y$  of  $y \in \mathbb{F}_2^k$  is an assignment where  $(-1)^{\delta_y(x_f)} = f(y)$ . From Theorem 2.16 we see that the natural definition for completeness is the expectation over  $\text{val}(\delta_y, G)$ , where  $\delta_y$  is a random dictator cut.

► **Definition 2.21.** The completeness of  $G$  is defined as

$$c(G) = \mathbb{E}_{y \in \mathbb{F}_2^k} \text{val}(\delta_y, G) = 1 - \sum_{(f_1, f_2) \in \binom{\mathcal{F}_k}{2}} G(f_1, f_2) \text{dist}(f_1, f_2).$$

There is a result based on Theorem 2.16 that relates the soundness and completeness of  $\text{Had}_k$ -to- $2\text{Lin}(2)$  gadgets to NP-hardness results for  $\text{Max-2Lin}(2)$ .

► **Proposition 2.22** ([10, Proposition 2.17]). Given a  $\text{Had}_k$ -to- $2\text{Lin}(2)$  gadget  $(G, \mathbb{X}_k, \mathbb{Y}_k)$  with  $s = s(G)$  and  $c = c(G)$ , where  $c > s$ . Then for every sufficiently small  $\varepsilon > 0$ , it is NP-hard to distinguish between instances  $\mathcal{I}$  of  $\text{Max-2Lin}(2)$  such that

(Completeness) There exists an assignment that satisfies a fraction at least  $c - \varepsilon$  of the constraints.

(Soundness) All assignments satisfy at most a fraction  $s + \varepsilon$  of the constraints.

One particularly interesting case is the inapproximability of  $\text{Min-2Lin}(2)$ -deletion. From UGC it follows that it is NP-hard to approximate  $\text{Min-2Lin}(2)$ -deletion within any constant [14]. The following proposition from Håstad et al. [10] tells us that a  $\text{Had}_k$ -to- $2\text{Lin}(2)$  gadget reduction can never be used to show an inapproximability factor of  $\text{Min-2Lin}(2)$ -deletion better than 2.54. This means that any NP-hardness result for  $\text{Min-2Lin}(2)$ -deletion shown using a gadget reduction from  $\text{Had}_k$ -to- $2\text{Lin}(2)$  cannot match results obtained by UGC.

## 11:14 On the NP-Hardness Approximation Curve for Max-2Lin(2)

► **Proposition 2.23** ([10, Proposition 2.29 and Theorem 6.1]). *For any given  $\text{Had}_k\text{-to-2Lin}(2)$  gadget  $(G, \mathbb{X}_k, \mathbb{Y}_k)$ . There exists a  $\text{Had}_k\text{-to-2Lin}(2)$  gadget  $(\tilde{G}, \mathbb{X}_k, \mathbb{Y}_k)$  with completeness  $1 - 2^{-k}$  such that*

$$\frac{1 - s(G)}{1 - c(G)} \leq \frac{1 - s(\tilde{G})}{1 - c(\tilde{G})},$$

and

$$\frac{1 - s(\tilde{G})}{1 - c(\tilde{G})} \leq \frac{1}{1 - e^{-0.5}} \approx 2.54.$$

► **Remark 2.24.** A  $\text{Had}_k\text{-to-2Lin}(2)$  gadget having completeness  $1 - 2^{-k}$  implies that the gadget only have positive weight edges of length  $2^{-k}$ . So far fewer edges are used compared to the total number of possible edges.

► **Remark 2.25.** The upper limit of 2.54 shown by [10] is much more general than what is stated here. In fact, they show that the bound of 2.54 holds for any gadget reduction from a useless predicate  $\phi$  such that  $\text{Sat}(\phi)$  has a balanced pairwise independent subset.

### 3 Relaxed soundness and infinity relaxed soundness

The main difficulty when designing and analysing gadgets is that the soundness is difficult to compute. In the case of a gadget reduction from Max-Had $_k$  to Max-2Lin(2), computing the soundness of the gadget involves solving an instance of Max-2Lin(2). For  $k \leq 3$  this is computationally feasible, since the Max-2Lin(2) instance is rather small, but for  $k \geq 4$  the instances can become so large that, even using a computer, it is practically impossible to solve them.

To get around this issue, Wiman [16] proposed to relax the definition of the soundness by not requiring that the assignment  $A$  of the auxiliary variables  $\mathbb{Y}_k$  is folded. Note that the assignment  $A$  is still required to be folded on the primary variables  $\mathbb{X}_k$ , meaning  $A(x_f) = 1 + A(x_{-f}) \forall x_f \in \mathbb{X}_k$ . Removing the requirement that  $A$  is folded over  $\mathbb{Y}_k$  makes it significantly easier to compute the soundness.

► **Definition 3.1** ([16, Definition 3.3]). *Wiman's relaxed soundness*

$$\text{rs}(G) = \max_{\substack{P \in \mathcal{F}_{\text{fold}}(\mathbb{X}_k \cup \{x_1, x_{-1}\}) \\ A \in \mathcal{F}(\mathbb{X}_k \cup \mathbb{Y}_k), \\ A(x) = P(x), x \in \mathbb{X}_k \cup \{x_1, x_{-1}\}}} \mathbb{E} \text{val}(A, G),$$

where

$$\text{val}(A, G) = \sum_{(f_1, f_2) \in \binom{\mathcal{F}_k}{2}} G(f_1, f_2)[A(x_{f_1}) = A(x_{f_2})].$$

This relaxation fundamentally changes the soundness computation from being a Max-2Lin(2) problem to being an  $s$ - $t$  Min-Cut problem. This is because the computation of  $1 - \text{rs}(G)$  for a fixed  $P$  is a minimisation problem where the goal is to minimise the number of times that  $A(x_{f_1}) \neq A(x_{f_2})$ , which makes it a  $s$ - $t$  Min-Cut problem. According to the Max-Flow Min-Cut Theorem, this also means that  $\text{rs}(G)$  can be computed by solving a Max-Flow problem.

The conclusion from this is that  $1 - \text{rs}(G)$  can be interpreted as the average max flow on the fully connected  $2^k$ -dimensional hypercube, where the placement of sources and sinks is randomly distributed over nodes labeled by affine functions. The sources correspond to

primary variables  $x_f$  where  $P(x_f) = 1$  and the sink nodes correspond to primary variables  $x_f$  where  $P(x_f) = 0$ . The capacity of an edge  $\{x_{f_1}, x_{f_2}\}$  in the fully connected hypercube is given by  $G(f_1, f_2)$ . Note that the sum over capacities in the graph is equals to 1.

There are some significant benefits to using the relaxed soundness. Firstly, it is significantly simpler to solve a Max-Flow problem compared to a Max-2Lin(2) problem. The implication from this is that it is computationally simple to compute the relaxed soundness of Had<sub>4</sub>-to-2Lin(2) gadgets and even possible to compute relaxed soundness of Had<sub>5</sub>-to-2Lin(2) gadgets if given enough computational resources. Furthermore, the relaxed soundness allows us to analyse Had<sub>k</sub>-to-2Lin(2) gadgets even in the case where  $k$  is very large. The disadvantage to using relaxed soundness is that it is not guaranteed to be close to the true soundness.

### 3.1 Relaxed soundness described as an LP

Recall that  $1 - \text{rs}(G)$  can be expressed as the average max flow on a fully connected  $2^k$ -dimensional hypercube with randomised source/sink placements. This means that  $\text{rs}(G)$  can be stated as an LP. One reason for why it is preferable to express this Max-Flow problem as an LP is because it is possible to move the capacities (i.e. the ‘‘gadget variables’’) of the Max-Flow problem to the variable side of the LP. So the same LP can be used both to calculate the the relaxed soundness of a specific gadget and to construct new gadgets.

One additional step we use in the formulation of this LP is to use a function  $g \in \mathcal{F}_k$  to describe the source/sink placement instead of using the assignment  $P$ . A node  $v_{\chi_\alpha}$ ,  $\alpha \in \mathbb{F}_2^k$  is a sink node if  $g(\alpha) = 1$ , and a source node if  $g(\alpha) = -1$ . These two representations of the source/sink placement are equivalent, but using a Boolean function  $g$  is more helpful for understanding the symmetries of the LP, as done in Appendix C. The following is the LP reformulation of the relaxed soundness  $\text{rs}(G)$ .

► **Definition 3.2.** A flow  $w$  of a Had<sub>k</sub>-to-2Lin(2) gadget  $(G, \mathbb{X}_k, \mathbb{Y}_k)$  is a function  $\mathcal{F}_k^3 \rightarrow \mathbb{R}_{\geq 0}$ . The flow  $w$  is said to be feasible if and only if

$$w(f_1, f_2, g) + w(f_2, f_1, g) \leq G(f_1, f_2) \quad \forall f_1, f_2, g \in \mathcal{F}_k, \quad (1)$$

$$\text{out}_w(f, g) = \text{in}_w(f, g) \quad \forall f, g \in \mathcal{F}_k, \dim(f) \geq 1. \quad (2)$$

where  $\text{out}_w(f, g) = \sum_{f_2 \in \mathcal{F}_k} w(f, f_2, g)$  and  $\text{in}_w(f, g) = \sum_{f_2 \in \mathcal{F}_k} w(f_2, f, g)$ . The value of  $w$  for at a source/sink placement  $g \in \mathcal{F}_k$  is defined as

$$\text{val}_g(w) = \sum_{\alpha \in \mathbb{F}_2^k} \text{out}_w(g(\alpha)\chi_\alpha, g) - \text{in}_w(g(\alpha)\chi_\alpha, g).$$

► **Definition 3.3.** The relaxed soundness LP for a Had<sub>k</sub>-to-2Lin(2) gadget  $(G, \mathbb{X}_k, \mathbb{Y}_k)$ , denoted by  $\text{rsLP}(G)$ , is the following LP

$$\text{rs}(G) = 1 - \max_w \mathbb{E}_{g \in \mathcal{F}_k} \text{val}_g(w),$$

where the maximum is taken over feasible flows  $w$  of  $G$ .

► **Remark 3.4.** Recall that  $1 - \text{rs}(G)$  is the average of  $2^{2^k}$  independent Max-Flow problems. The different Max-Flow problems are indexed by the function  $g \in \mathcal{F}_k$ , which describes the placements of sinks and sources. The nodes in each Max-Flow problem are indexed by functions in  $\mathcal{F}_k$ . The sink nodes in the  $g$ -th Max-Flow problem are the nodes  $v_{g(\alpha)\chi_\alpha}$ ,  $\alpha \in \mathbb{F}_2^k$ , and the source nodes are the nodes  $v_{-g(\alpha)\chi_\alpha}$ ,  $\alpha \in \mathbb{F}_2^k$ . The flow from  $v_{f_1} \rightarrow v_{f_2}$  is  $w(f_1, f_2, g)$ , and the capacity of the undirected edge  $\{v_{f_1}, v_{f_2}\}$  is  $G(f_1, f_2)$ .

► **Remark 3.5.** Note that it is possible to modify the  $\text{rsLP}(G)$  to include the capacities of the graph (i.e. gadget  $G$ ) as variables. The implications of this is that the optimisation problem of finding a  $\text{Had}_k\text{-to-2Lin}(2)$  gadget with the maximum relaxed soundness for a fixed completeness can also be expressed as an LP.

► **Remark 3.6.** Note that the  $\text{rsLP}(G)$  has roughly  $|\mathcal{F}_k|^3 = 2^{3 \cdot 2^k}$  variables. This is a very large number, even for small values of  $k$ . So in order to be able to solve this LP, we have to make use of the symmetries of the LP in order to reduce the number of variables.

### 3.2 Introduction of infinity relaxed soundness

One natural question is, how small can one make the relaxed soundness if we fix the completeness of a  $\text{Had}_k\text{-to-2Lin}(2)$  gadget and let  $k \rightarrow \infty$ ? In practice, even just finding the gadget minimising the relaxed soundness when  $k = 5$  is a very daunting task, so cannot hope to calculate this limit directly from the  $\text{rsLP}(G)$ .

Our method to handle large values of  $k$  is to create a  $\text{Had}_k\text{-to-2Lin}(2)$  gadget for some small value of  $k$ , for example  $k = 4$ , and then introduce the concept of embedding a  $\text{Had}_k\text{-to-2Lin}(2)$  gadget  $G$  into a  $\text{Had}_{k'}\text{-to-2Lin}(2)$  gadget  $G'$ , where  $k' > k$ . It is also possible to embed the flow of the  $\text{rsLP}(G)$  onto the  $\text{rsLP}(G')$ . This embedding has the property that the completeness and the soundness of both gadgets are the same.

The key insight is that by using multiple overlapping embeddings of  $G$ , we can improve the soundness of  $G'$  without affecting its completeness. Our argument for why multiple overlapping embeddings improve the relaxed soundness is based on leaky flows. Note that the leaks of a leaky flow have signs. This means that it is possible that overlapping embeddings of leaky flows could become a feasible flow, since the overlap of the embeddings could cause the signed leaks to sum to 0. We use this type of argument to show an upper bound on  $\text{rs}(G')$  based on a leaky flow solution to the  $\text{rsLP}(G)$ .

The exact procedure for the embeddings is defined in Appendix C and analysed in detail in Appendix D using second moment analysis. The conclusion from that analysis is that the following relaxation of the  $\text{rsLP}(G)$ , which we call the *infinity relaxed soundness LP*, denoted by  $\text{rs}_\infty\text{LP}(G)$ , has the following two important properties. Firstly, the solution of  $\text{rs}_\infty\text{LP}(G)$  is a leaky flow of  $\text{rsLP}(G)$ , and secondly, overlapping embeddings of this leaky flow tends to a feasible flow of  $\text{rsLP}(G')$  as  $k' \rightarrow \infty$ .

► **Definition 3.7.** A flow  $\tilde{w}$  of a  $\text{Had}_k\text{-to-2Lin}(2)$  gadget  $(G, \mathbb{X}_k, \mathbb{Y}_k)$  is said to be a *infinity relaxed flow* if constraint (1) is satisfied and

$$\sum_{g'} \text{out}_w(f, g') = \sum_{g'} \text{in}_w(f, g') \quad \forall g, f \in \mathcal{F}_k : \dim(f) \geq 1, \quad (3)$$

where the sums are over functions  $g' \in \mathcal{F}'_k$  such that  $g'|_{\text{affine}(f)} = g|_{\text{affine}(f)}$ . The (signed) leak at  $(f, g)$ , where  $f, g \in \mathcal{F}_k, \dim(f) \geq 1$ , is defined as  $\text{leak}_{\tilde{w}}(f, g) = \text{in}_w(f, g) - \text{out}_w(f, g)$ .

► **Definition 3.8.** The *infinity relaxed soundness* of  $G$ , denoted by  $\text{rs}_\infty(G)$ , is the solution to the  $\text{rs}_\infty\text{LP}(G)$

$$\text{rs}_\infty(G) = 1 - \max_{\tilde{w}} \mathbb{E}_{g \in \mathcal{F}_k} \text{val}_g(\tilde{w}),$$

where the maximum is taken over all infinity relaxed flows  $\tilde{w}$  of  $G$ .

► **Remark 3.9.** The  $\text{rs}_\infty\text{LP}(G)$  is a constraint relaxation of the  $\text{rsLP}(G)$  where constraint (2) has been relaxed to constraint (3). So a solution of the  $\text{rs}_\infty\text{LP}(G)$  is a leaky flow in the  $\text{rsLP}(G)$ .

► **Remark 3.10.** Constraint (3) is used for a proof in Appendix D of Lemma D.5, which is a 2nd order moment analysis of the overlap of leaks from random embeddings. In the proof, constraint (3) is used to show that if  $w$  is an infinity relaxed flow then  $\forall g, f \in \mathcal{F}_k, \dim(f) \geq 1 : \sum_{g'} \text{leak}_w(f, g') = 0$ , where the sum is over  $g' \in \mathcal{F}_k$  such that  $g'|_{\text{affine}(f)} = g|_{\text{affine}(f)}$ .

The following lemma describes a relationship between the  $\text{rsLP}(G)$  and the  $\text{rs}_\infty\text{LP}(G)$ . This is the key Lemma, which is proven in Appendix D.

► **Lemma 3.11.** *Let  $(G, \mathbb{X}_k, \mathbb{Y}_k)$  be a  $\text{Had}_k\text{-to-2Lin}(2)$  gadget. For any  $\varepsilon > 0$  there exists a  $\text{Had}_{k'}\text{-to-2Lin}(2)$  gadget  $(G', \mathbb{X}_{k'}, \mathbb{Y}_{k'})$  for some  $k' > k$  such that  $c(G) = c(G')$  and  $\text{rs}(G') \leq \text{rs}_\infty(G) + \varepsilon$ .*

From this Lemma, it follows that  $\text{rs}_\infty(G) + \varepsilon$  is the upper bound of  $\text{rs}(G')$  for some gadget  $G'$ , which in turn is an upper bound of  $s(G')$ . This means that the NP-hardness result of  $\text{Max-2Lin}(2)$  stated in Proposition 2.22 for  $\text{rs}(G)$  also holds for  $\text{rs}_\infty(G)$ . This gives us our main result.

► **Theorem 3.12.** *Let  $(G, \mathbb{X}_k, \mathbb{Y}_k)$  be a  $\text{Had}_k\text{-to-2Lin}(2)$  gadget with  $s = \text{rs}_\infty(G)$  and  $c = c(G)$ , where  $c > s$ . Then for every sufficiently small  $\varepsilon > 0$ , it is NP-hard to distinguish between instances of  $\text{Max-2Lin}(2)$  such that*

**Completeness** *There exists an assignment that satisfies a fraction at least  $c - \varepsilon$  of the constraints.*

**Soundness** *All assignments satisfy at most a fraction  $s + \varepsilon$  of the constraints.*

## 4 Numerical results

This section contains a presentation of constructed  $\text{Had}_k\text{-to-2Lin}(2)$  gadgets. Recall that there are three different ways to measure the soundness of a  $\text{Had}_k\text{-to-2Lin}(2)$  gadget. There is the true soundness of a gadget, which can be used to show NP-hardness results for  $\text{Max-2Lin}(2)$ , see Proposition 2.22. Then there is the relaxed soundness, denoted by  $\text{rs}$ . This is an upper bound of the true soundness, see Proposition B.1. Finally there is the infinity relaxed soundness, denoted by  $\text{rs}_\infty$ , which according to our main result, Theorem 3.12, also imply NP-hardness results for  $\text{Max-2Lin}(2)$ .

We compute gadgets for  $k = 2, 3, 4$ , optimised either for  $\text{rs}$  or  $\text{rs}_\infty$ . The short rundown of the process of constructing a gadget is to first decide on the completeness of the gadget, and then call an LP-solver to find the gadget with that completeness that either minimises  $\text{rs}$  or  $\text{rs}_\infty$ , depending on which measure of soundness we want to optimise the gadget for.

### 4.1 Edges used/unused in constructed gadgets

The capacity  $G$  of a  $\text{Had}_k\text{-to-2Lin}(2)$  gadget  $(G, \mathbb{X}_k, \mathbb{Y}_k)$  is a probability distribution over (undirected) edges. Every gadget that we construct is symmetrical under the mappings of  $\mathcal{M}_{k \rightarrow k}$ , so edges from the same edge orbit share the same capacity. Tables 7–9 in Appendix F list all edge orbits that have non-zero weight in at least one of our constructed gadgets for  $k = 2, 3, 4$ . Note that as discussed in Appendix E.2.1, in the case of  $k = 4$  it is possible that the gadgets we construct are sub-optimal if  $c < 1 - 2^{-k}$ . This means that it is possible that the Table for  $k = 4$ , Table 9, could look slightly different had we constructed optimal gadgets.

## 11:18 On the NP-Hardness Approximation Curve for Max-2Lin(2)

■ **Table 1** The curve  $s(c)$  as shown in Figure 1. The values of  $s(c)$  in this table are rounded up to 4 decimals. This table has the same format as the table describing the  $\text{Gap}_{\text{SDP}}(c)$  curve, found in Appendix E of [14].

| $c$   | $s(c)$ | $c$   | $s(c)$ | $c$   | $s(c)$ | $c$   | $s(c)$ | $c$   | $s(c)$ |

## 4.2 Lists and plots of gadgets

Figures 5, 6 and 7 show  $\text{Had}_k\text{-to-2Lin}(2)$  gadgets with completeness on the  $x$ -axis, and either maximal  $\frac{1-\text{rs}(G)}{1-c(G)}$  or maximal  $\frac{1-\text{rs}_\infty(G)}{1-c(G)}$  on the  $y$ -axis. To create this plot, we construct one gadget for each completeness value from 0.5 to  $1 - 2^{-k}$  (inclusive), with a spacing of  $2^{-9}$ . The curve is constructed using interpolation by taking convex combinations of pairs of neighbouring gadgets.

### 4.2.1 The curve $s(c)$

The curve  $s(c)$  describes the infinity relaxed soundness of  $\text{Had}_4\text{-to-2Lin}(2)$  gadgets as a function of completeness, shown as the upper curve in Figure 7, as well as in Figures 1, 2 and 3. The data for this curve can be found in Table 1. It has the following formal definition.

► **Definition 4.1.** *The curve  $s(c) : [0.5, 1] \rightarrow [0.5, 1]$ ,  $k = 4$ , is for  $c \in [0.5, 1 - 2^{-k}]$  defined as the solution to the restricted compressed  $\text{rs}_\infty\text{LP}$ . For  $c \geq 1 - 2^{-k}$  the curve is defined as  $s(c) = 1 + 2^k(s(1 - 2^{-k}) - 1)(1 - c)$ , meaning  $\frac{1-s(c)}{1-c}$  is constant for all  $c \geq 1 - 2^{-k}$ .*

**Proof of Theorem 1.1.** For  $c \in [0.5, 1 - 2^{-k}]$ , the NP-hardness result follows directly from Theorem 3.12 since the solution of the restricted compressed  $\text{rs}_\infty\text{LP}(G)$  is an upper bound of the (non-restricted)  $\text{rs}_\infty\text{LP}(G)$ . For  $c \geq 1 - 2^{-k}$  the NP-hardness result follows from taking the convex combination of  $(c, s) = (1 - 2^{-k}, s(1 - 2^{-k}))$  and  $(c, s) = (1, 1)$ . Since it is possible to create a hard instance by taking the convex combination of two hard instances using separate variables. ◀

■ **Figure 5** This plot shows two types of Had<sub>2</sub>-to-2Lin(2) gadgets. The filled curve describes the minimisation of  $rs$  and the striped curve describes the minimisation of  $rs_\infty$ . The completeness value is on the  $x$ -axis, and either  $\frac{1-rs(G)}{1-c(G)}$  or  $\frac{1-rs_\infty(G)}{1-c(G)}$  on the  $y$ -axis. In this particular case, the case of  $k = 2$ , it turns out that these two curves are identical.

■ **Figure 6** This plot shows two types of Had<sub>3</sub>-to-2Lin(2) gadgets. The filled curve describes the minimisation of  $rs$  and the striped curve describes the minimisation of  $rs_\infty$ . The completeness value is on the  $x$ -axis, and either  $\frac{1-rs(G)}{1-c(G)}$  or  $\frac{1-rs_\infty(G)}{1-c(G)}$  on the  $y$ -axis.

■ **Figure 7** This plot shows two types of Had<sub>4</sub>-to-2Lin(2) gadgets. The filled curve describes the minimisation of  $rs$  and the striped curve describes the minimisation of  $rs_\infty$ . The completeness value is on the  $x$ -axis, and either  $\frac{1-rs(G)}{1-c(G)}$  or  $\frac{1-rs_\infty(G)}{1-c(G)}$  on the  $y$ -axis. The top part of both of these curves are perfectly flat, which is not the case in Figure 5 and Figure 6. The gadgets that mark the point where the curves become flat can be found in Tables 2 and 3, and are marked by crosses in the plot.

## 11:20 On the NP-Hardness Approximation Curve for Max-2Lin(2)

■ **Table 2** The Had<sub>4</sub>-to-2Lin(2) gadget  $G$  with minimal completeness among those that minimise  $\frac{1-\text{rs}(G)}{1-c(G)}$ . The completeness of  $G$  is  $c(G) = 9939/10768$  and relaxed soundness is  $\text{rs}(G) = 2623643487/2955083776$ . The right most column tells how much of the total capacity is contained in each edge orbit. This column sums up to 100%.

| $f_1$            | $f_2$            | length | $G(f_1, f_2)$    | % of total |
|------------------|------------------|--------|------------------|------------|
| 1100000000000000 | 1110000000000000 | 1      | 5461/969636864   | 30.3       |
| 1110000000000000 | 1111000000000000 | 1      | 17007/1616061440 | 18.9       |
| 1110000000000000 | 1110100000000000 | 1      | 437/404015360    | 23.2       |
| 1110100000000000 | 1110100010000000 | 1      | 19/92346368      | 4.4        |
| 0000000000000000 | 1100000000000000 | 2      | 13/215360        | 23.2       |

■ **Table 3** The Had<sub>4</sub>-to-2Lin(2) gadget  $G$  with minimal completeness among those that minimise  $\frac{1-\text{rs}_\infty(G)}{1-c(G)}$ . The completeness of  $G$  is  $c(G) = 590174949/639271832$  and the infinity relaxed soundness is  $\text{rs}_\infty(G) = 141533171/159817958$ . The right most column tells how much of the total capacity is contained in each edge orbit. This column sums up to 100%.

| $f_1$            | $f_2$            | length | $G(f_1, f_2)$        | % of total |

### 4.3 Notable gadgets

There are two gadgets that are of particular interest. These are the gadgets with minimal completeness among those that maximises either  $\frac{1-\text{rs}(G)}{1-c(G)}$  or  $\frac{1-\text{rs}_\infty(G)}{1-c(G)}$ . These gadgets are marked by crosses in Figure 7. The gadget with minimal completeness that maximises  $\frac{1-\text{rs}(G)}{1-c(G)}$  can be found in Table 2. The gadget with minimal completeness that maximises  $\frac{1-\text{rs}_\infty(G)}{1-c(G)}$  can be found in Table 3, and is also marked by a cross on the curve  $s(c)$  in Figures 1-3. The method used to construct such minimal completeness gadgets is slightly different compared to the construction of gadgets with fixed completeness. Propositions 2.23 and B.1 guarantees that gadgets with completeness  $1 - 2^{-k}$  can be used to maximise  $\frac{1-\text{rs}(G)}{1-c(G)}$  and  $\frac{1-\text{rs}_\infty(G)}{1-c(G)}$ . This means that the maximum values of  $\frac{1-\text{rs}(G)}{1-c(G)}$  and  $\frac{1-\text{rs}_\infty(G)}{1-c(G)}$  can be computed by fixing the completeness to  $c(G) = 1 - 2^{-k}$ . Using these maximums, it is possible to slightly modify the objective of the LP such that its solution is the gadget with minimal completeness that maximises either  $\frac{1-\text{rs}(G)}{1-c(G)}$  or  $\frac{1-\text{rs}_\infty(G)}{1-c(G)}$ .

## 5 Conclusions

In this work, we have introduced a procedure called lifting for taking a Had <sub>$k$</sub> -to-2Lin(2) gadget for a fixed  $k$  and using that gadget to construct better and better Had <sub>$k'$</sub> -to-2Lin(2) gadgets, as  $k'$  tends to infinity. In order to be able to analyse this, both numerically and analytically, we made use of a relaxation of the (true) soundness, first introduced by Wiman [16] in their analysis of the Had<sub>4</sub>-to-2Lin(2) gadget. This procedure allowed us to show new inapproximability results of Max-2Lin(2), and most notably using  $k = 4$ , we have shown that Min-2Lin(2)-deletion has an inapproximability factor of  $\frac{73139148}{49096883} \approx 1.48969$ .

Some open problems still remain. The most obvious one is that it is likely within reach to carry out the analysis we did for  $k = 4$  also for  $k = 5$ . The main bottleneck is to find or write a very efficient LP solver that is able to handle large instances and give consistent and stable results. The solvers available to us were not quite able to get trustworthy results. This being said, without substantial new ideas we do not see how to attack the  $k = 6$  case.

Another open problem is to understand the best possible gadget reduction from  $\text{Had}_k$ -to- $2\text{Lin}(2)$  as  $k \rightarrow \infty$ . More specifically, which is the best possible inapproximability factor of  $\text{Min-}2\text{Lin}(2)$ -deletion attainable using such a gadget reduction? We were able to show an inapproximability factor of  $\frac{73139148}{49096883} \approx 1.48969$  using relaxed soundness. We have also shown that by using relaxed soundness, it is impossible to go above 2 (see Proposition B.1). Furthermore, it is known from a previous work [10, Theorem 6.1] that by using (non-relaxed) soundness,  $\frac{1}{1-e^{-0.5}} \approx 2.54$  is an upper bound. This leaves us with a fairly large gap. So it would be of interest to close this gap.

In comparison, by assuming the Unique Games Conjecture (UGC), it is possible to show that the inapproximability factor of  $\text{Min-}2\text{Lin}(2)$ -deletion can be made arbitrarily large. The main open problem here is to show this without assuming UGC. This however, is not possible to do using a gadget reduction from  $\text{Had}_k$ -to- $2\text{Lin}(2)$ , and would instead require a completely new approach.

Finally, as a concluding remark, it would be interesting to see if our ideas of lifting small gadgets and analysing them using a relaxed version of the (true) soundness, could be used in other applications. Maybe there are other gadgets out there that could be improved using a similar procedure?

---

## A Max-Flow and symmetries

This section introduces the concepts of feasible flows and leaky flows, and show how to make use symmetries in a graph to more efficiently solve the Max-Flow problem. These Max-Flow techniques and concepts are used during the construction of gadgets. These techniques are very general, and become easier to explain without involving the intricacies of gadgets. Let us start by defining the Max-Flow problem as an LP.

► **Definition A.1.** A flow graph is a tuple  $G = (V, C, S, T)$ , where  $C(u, v) = C(v, u) \geq 0$  is the capacity of edge  $(u, v) \in V \times V$ , and  $S \subset V$  is a set of sources and  $T \subset V$  is a set of sinks, and  $S \cap T = \emptyset$ .

► **Definition A.2.** A flow  $w$  of a flow graph  $G = (V, C, S, T)$  is a function  $V \times V \rightarrow \mathbb{R}_{\geq 0}$ . The flow  $w$  is said to be feasible if and only if

$$w(v, u) + w(u, v) \leq C(u, v) \quad \forall v, u \in V, \tag{4}$$

$$\text{out}_w(v) = \text{in}_w(v) \quad \forall v \in V \setminus (S \cup T). \tag{5}$$

where

$$\text{out}_w(v) = \sum_{u \in V} w(v, u),$$

$$\text{in}_w(v) = \sum_{u \in V} w(u, v).$$

The value of a flow is defined as

$$\text{val}(w) = \sum_{s \in S} \text{out}_w(s) - \text{in}_w(s).$$

The value of the maximum flow of a flow graph  $G$  is denoted by  $\max\_flow(G)$ .

### A.1 Feasible flows and leaky flows

When solving a Max-Flow problem we normally require the flow to be conserved (constraint (5) above), meaning that the incoming flow into a node is equal to the outgoing flow. This is the definition of a feasible flow. However, to find an approximate solution to a Max-Flow problem, it can be helpful to relax the conservation of flows constraint, allowing for “leaks”. A flow that does not fulfil the conservation of flow constraint is called a *leaky flow*. This section aims to analyse the relation between leaky flows and feasible flows, with the goal of showing that if the leaks of a leaky flow are small, then there is a feasible flow with almost the same value as the leaky flow.

► **Definition A.3.** A flow  $\tilde{w}$  is said to be a leaky flow if constraint (4) is satisfied. The (signed) leak at node  $v$  be defined as  $\text{leak}_{\tilde{w}}(v) = \text{in}_{\tilde{w}}(v) - \text{out}_{\tilde{w}}(v)$  for  $v \in V \setminus (S \cup T)$ .

► **Remark A.4.** Note that a leaky flow  $\tilde{w}$  is also a feasible flow if and only if  $\text{leak}_{\tilde{w}}(v) = 0$  for all  $v \in V \setminus (S \cup T)$ .

The following theorem tells us that if the sum of absolute values of the leaks are small, then there is a feasible flow having almost the same value as the leaky flow. The implications from this is that we can use leaky flows to get an approximation of the true Max-Flow.

► **Theorem A.5.** Given a leaky flow  $\tilde{w}$  of a flow graph  $G = (V, C, S, T)$ , there exists a feasible flow  $w$  of  $G$  such that

$$\text{val}(w) \geq \text{val}(\tilde{w}) - \sum_{v \in V \setminus (S \cup T)} |\text{leak}_{\tilde{w}}(v)|.$$

**Proof.** Create a new graph  $\tilde{G} = (V \cup \{\tilde{s}, \tilde{t}\}, \tilde{C}, S \cup \{\tilde{s}\}, T \cup \{\tilde{t}\})$  with an additional new source node  $\tilde{s}$  and sink node  $\tilde{t}$ . We construct  $\tilde{C}$  using  $C$ . Firstly let  $\tilde{C}(u, v) = C(u, v)$  for all nodes  $u, v \in V$ . Secondly, for every  $v \in V \setminus (S \cup T)$  such that  $\text{leak}_{\tilde{w}}(v) > 0$ , let  $\tilde{C}(u, \tilde{t}) = \text{leak}_{\tilde{w}}(v)$ , and for every  $v \in V \setminus (S \cup T)$  such that  $\text{leak}_{\tilde{w}}(v) < 0$  let  $\tilde{C}(u, \tilde{s}) = -\text{leak}_{\tilde{w}}(v)$ . Finally let  $\tilde{C}$  be 0 in all other cases.

Note that for this new graph  $\tilde{G}$ , the leaky flow  $\tilde{w}$  can be extended into a feasible flow since all of the leaks can be routed to either  $\tilde{s}$  or  $\tilde{t}$  depending on the sign of the leakage. Furthermore, if we can show that

$$\max\_flow(\tilde{G}) \leq \max\_flow(G) + \sum_{v \in V \setminus (S \cup T)} |\text{leak}_{\tilde{w}}(v)|, \tag{6}$$

then that would imply the the Theorem.

To show (6) we use the Max-Flow Min-Cut Theorem. Note that any  $S$ - $T$  cut in  $\tilde{G}$  has a corresponding  $S$ - $T$  cut in  $G$  and vice versa since  $G$  and  $\tilde{G}$  share the same non-source/sink nodes. Additionally, note that the value of a  $S$ - $T$  cut in  $\tilde{G}$  can be bounded from above by the value of the corresponding cut in  $G$  plus the extra capacities in  $\tilde{G}$ . The conclusion from this is that

$$\begin{aligned} \max\_flow(\tilde{G}) &= \min\_cut(\tilde{G}) \\ &\leq \min\_cut(G) + \sum_{v \in V \setminus (S \cup T)} |\text{leak}_{\tilde{w}}(v)| \\ &= \max\_flow(G) + \sum_{v \in V \setminus (S \cup T)} |\text{leak}_{\tilde{w}}(v)|. \end{aligned} \quad \blacktriangleleft$$

## A.2 Symmetries of Max-Flow graphs

If a flow graph  $G = (V, C, S, T)$  has some kind of symmetry, then we can use them to more efficiently solve the Max-Flow problem. In our setting, the symmetries are described by a group  $H$  acting on  $V$  with the property that the capacities are invariant under the group action, meaning  $C(u, v) = C(h \cdot u, h \cdot v)$  for all  $h \in H$  and  $u, v \in V$ . Here  $h \cdot u$  denotes the group action of  $h$  on  $u$ .

► **Definition A.6.** *Given a flow graph  $G = (V, C, S, T)$  and a group  $H$  acting on  $V$ , then  $H$  is said to be a symmetry group of  $G$  if and only if  $\forall h \in H$ :*

1.  $h \cdot s \in S \forall s \in S$ ,
2.  $h \cdot t \in T \forall t \in T$ ,
3.  $C(u, v) = C(h \cdot u, h \cdot v) \forall h \in H$  and  $\forall u, v \in V$ .

Using  $G$  and the group  $H$  acting on  $V$ , we can create a new flow graph where the set of vertices is the quotient space  $V/H$ . This “compresses” the graph  $G$  into one vertex per orbit. Let the capacities between two orbits  $A, B \in V/H$  be the sum capacities over all pairs in  $A \times B$ .

► **Definition A.7.** *Given a flow graph  $G = (V, C, S, T)$  and a symmetry group  $H$  of  $G$ . Let the quotient flow graph  $G/H = (V/H, C/H, S/H, T/H)$  where  $V/H$  is the set of all orbits of  $V$  under the action of  $H$ , and similarly  $S/H$  is the set of orbits of  $S$  and  $T/H$  is the set of orbits of  $T$ . Let  $C/H$  be defined as a function  $V/H \times V/H \rightarrow \mathbb{R}$  such that*

$$(C/H)(A, B) = \sum_{u \in A} \sum_{v \in B} C(u, v)$$

for all  $A, B \in V/H$ .

What remains to show is that the original graph  $G$  and the compressed graph  $G/H$  has the same Max-Flow.

► **Theorem A.8.** *Given a flow graph  $G = (V, C, S, T)$  and a symmetry group  $H$  of  $G$ . Then  $\max\_flow(G) = \max\_flow(G/H)$ .*

**Proof.** First let us show that  $\max\_flow(G) \leq \max\_flow(G/H)$ . Let  $w$  be the max-flow of  $G$ . Now define  $w/H$  as a function from  $V/H \times V/H \rightarrow \mathbb{R}$  such that

$$(w/H)(A, B) = \sum_{a \in A} \sum_{b \in B} w(a, b).$$

What remains to show is that that  $w/H$  is a feasible flow of  $G/H$  and that  $\text{val}(w) = \text{val}(w/H)$  since those two properties would imply that  $\max\_flow(G) \leq \max\_flow(G/H)$ . Firstly, note that  $w/H$  fulfills (4) and (5) from Definition A.2 for the graph  $G/H$  since the constraints are linear. For example take constraint (4),

$$\begin{aligned} (w/H)(A, B) + (w/H)(B, A) &= \sum_{a \in A} \sum_{b \in B} w(a, b) + w(b, a) \\ &\leq \sum_{a \in A} \sum_{b \in B} C(a, b) \\ &= (C/H)(A, B). \end{aligned}$$

So  $w/H$  is a feasible flow of  $G/H$ . Secondly note that the value of  $w$  is the same as the value of  $w/H$  since

$$\begin{aligned} \text{val}(w/H) &= \sum_{A \in S/H} \text{out}_{w/H}(A) - \text{in}_{w/H}(A) \\ &= \sum_{A \in S/H} \sum_{s \in A} \text{out}_w(s) - \text{in}_w(s) \\ &= \sum_{s \in S} \text{out}_w(s) - \text{in}_w(s) \\ &= \text{val}(w). \end{aligned}$$

It remains to show that  $\max\_flow(G) \geq \max\_flow(G/H)$ . Let  $w'$  be a max-flow of  $G/H$ . Now define  $w : V \times V \rightarrow \mathbb{R}$  such that

$$w(a, b) = w'(H \cdot a, H \cdot b) \frac{C(a, b)}{(C/H)(H \cdot a, H \cdot b)}$$

where  $a, b \in V$  and  $H \cdot a$  is the orbit of  $a$  and  $H \cdot b$  is the orbit of  $b$ . What remains to show is that  $w(a, b)$  is a feasible flow of  $G$  and that the value of  $w$  is the same as the value of  $w'$ . Firstly, note that  $w/H$  fulfill constraints (4) and (5) from Definition A.2 for the graph  $G$  since the constraints are linear. For example take constraint (4),

$$\begin{aligned} w(a, b) + w(b, a) &= (w'(H \cdot a, H \cdot b) + w'(H \cdot b, H \cdot a)) \frac{C(a, b)}{(C/H)(H \cdot a, H \cdot b)} \\ &\leq (C/H)(H \cdot a, H \cdot b) \frac{C(a, b)}{(C/H)(H \cdot a, H \cdot b)} \\ &= C(a, b). \end{aligned}$$

Secondly note that the value of  $w$  is the same as  $w'$  since

$$\begin{aligned} \text{val}(w') &= \sum_{A \in S/H} \text{out}_{w'}(A) - \text{in}_{w'}(A) \\ &= \sum_{A \in S/H} \sum_{B \in V/H} w'(A, B) - w'(B, A) \\ &= \sum_{A \in S/H} \sum_{B \in V/H} (w'(A, B) - w'(B, A)) \left( \sum_{a \in A} \sum_{b \in B} \frac{C(a, b)}{(C/H)(A, B)} \right) \\ &= \sum_{A \in S/H} \sum_{B \in V/H} \sum_{a \in A} \sum_{b \in B} (w'(A, B) - w'(B, A)) \frac{C(a, b)}{(C/H)(A, B)} \\ &= \sum_{A \in S/H} \sum_{B \in V/H} \sum_{a \in A} \sum_{b \in B} w(a, b) - w(b, a) \\ &= \sum_{a \in S} \sum_{b \in V} w(a, b) - w(b, a) \\ &= \sum_{a \in S} \text{out}_w(a) - \text{in}_w(a) \\ &= \text{val}(w). \end{aligned}$$

So  $w$  is a feasible flow of  $G$  and  $\text{val}(w) = \text{val}(w')$ , so  $\max\_flow(G) \geq \max\_flow(G/H)$ . ◀

## B Properties of relaxed soundness

The relaxed soundness share many similarities with the (true) soundness. One example is the following Proposition, which is an analogue to Proposition 2.23 but for relaxed soundness.

► **Proposition B.1.** *For any  $\text{Had}_k\text{-to-2Lin}(2)$  gadget  $(G, \mathbb{X}_k, \mathbb{Y}_k)$*

(a)

$$s(G) \leq \text{rs}(G).$$

(b) *There exists a  $\text{Had}_k\text{-to-2Lin}(2)$  gadget  $(\tilde{G}, \mathbb{X}_k, \mathbb{Y}_k)$  with completeness  $1 - 2^{-k}$  such that*

$$\frac{1 - \text{rs}(G)}{1 - c(G)} \leq \frac{1 - \text{rs}(\tilde{G})}{1 - c(\tilde{G})},$$

(c) *and for any  $\text{Had}_k\text{-to-2Lin}(2)$  gadget  $(\tilde{G}, \mathbb{X}_k, \mathbb{Y}_k)$  with completeness  $1 - 2^{-k}$*

$$\frac{1 - \text{rs}(\tilde{G})}{1 - c(\tilde{G})} \leq 2.$$

**Proof.**

(a) Note that interpreting  $x_1$  and  $x_{-1}$  as being primary variables do not affect soundness, i.e.

$$s(G) = \max_{P \in \mathcal{F}_{\text{fold}}(\mathbb{X}_k \cup \{x_1, x_{-1}\})} \mathbb{E}_{A \in \mathcal{F}_{\text{fold}}(\mathbb{X}_k \cup \mathbb{Y}_k), A(x) = P(x), x \in \mathbb{X}_k \cup \{x_1, x_{-1}\}} \text{val}(A, G). \quad (7)$$

The reason for this is that there exists a degree of freedom in the choice of  $A$  since for any  $A$ ,  $\text{val}(A, G) = \text{val}(1 + A, G)$ . This means for example that we can add one extra constraint like  $A(x_1) = 1 + A(x_{-1}) = 1$  to the definition of  $s(G)$  without affecting its value.

Comparing (7) and the definition of relaxed soundness, we can clearly see that  $s(G) \leq \text{rs}(G)$  since the relaxed soundness is a less constrained maximisation problem compared to the right hand side of (7).

(b) This proof is analogous to the proof of [10, Proposition 2.29]. Note that by definition  $1 - c(\tilde{G})$  is the average length of edges  $(f_1, f_2)$  of the gadget  $\tilde{G}$ , weighted by  $\tilde{G}(f_1, f_2)$ . For  $\tilde{G}$  to have completeness  $1 - 2^{-k}$ , the edges in  $\tilde{G}$  need to have an average length of  $2^{-k}$ . Since there are no edges shorter than  $2^{-k}$ ,  $\tilde{G}$  can only put non-zero capacity on edges of length exactly  $2^{-k}$ .

Construct  $\tilde{G}$  using the following procedure. Start with  $G$ . Split up each edge  $(f_1, f_2)$  in  $G$  into an arbitrary path starting at  $f_1$ , ending at  $f_2$ , with edges of length  $2^{-k}$ , where the sum of lengths of edges in the path should be equal to the length of the original edge  $(f_1, f_2)$ . Remove the capacity of edge  $(f_1, f_2)$  and give each edge in the path the same capacity as the capacity of the original edge  $(f_1, f_2)$ . This will increase the total capacity of the graph by a factor of  $(1 - c(G))/2^k$ . As a final step, normalize the capacity by dividing the capacity of all edges by  $(1 - c(G))/2^k$ . Let the resulting graph be  $\tilde{G}$ . Note that  $\tilde{G}$  is a  $\text{Had}_k\text{-to-2Lin}(2)$  consisting only of edges of length  $2^{-k}$ , so its completeness is  $1 - 2^{-k}$ .

Recall that  $1 - \text{rs}(G)$  can be interpreted as the expected value of a Max-Flow problem on a fully connected  $2^k$ -dimensional hypercube, where the placements of sources and sinks have been randomised. Note that any feasible flow  $\omega$  of  $G$ , when scaled down by a factor of  $(1 - c(G))/2^{-k}$ , corresponds to a feasible flow of  $\tilde{G}$ . This implies that  $(1 - \text{rs}(G)) \leq (1 - \text{rs}(\tilde{G}))(1 - c(G))/2^{-k}$ .

The conclusion from this is that

$$\frac{1 - \text{rs}(\tilde{G})}{1 - c(\tilde{G})} = \frac{1 - \text{rs}(\tilde{G})}{2^{-k}} \geq \frac{1 - \text{rs}(G)}{1 - c(G)}.$$

- (c) Let  $\tilde{G}$  be the gadget from b). Recall that  $1 - \text{rs}(\tilde{G})$  can be interpreted as the expected value of a Max-Flow problem on a fully connected  $2^k$ -dimensional hypercube, where the placements of sources and sinks have been randomised. The capacities of this flow graph sum to 1.

Note that the sources and sinks correspond to affine functions, which have a normalised Hamming distance of at least  $1/2$ . Furthermore, since all edges in  $\tilde{G}$  has length  $2^{-k}$ , any path in  $\tilde{G}$  between a source and a sink must contain at least  $2^{k-1}$  edges.

For any flow graph, if all paths between sources and sinks contain at least  $2^{k-1}$  edges, and the sum of capacity over all edges in the graph is 1, then the maximum flow is at most  $2^{1-k}$ . So  $1 - \text{rs}(\tilde{G}) \leq 2^{1-k}$ , which implies that

$$\frac{1 - \text{rs}(\tilde{G})}{1 - c(\tilde{G})} \leq \frac{2^{1-k}}{2^{-k}} = 2. \quad \blacktriangleleft$$

► Remark B.2. Since the relaxed soundness is an upper bound of the true soundness, it follows that the NP-hardness result of Max-2Lin(2) as stated in Proposition 2.22 also holds for  $s = \text{rs}(G)$ .

## C Affine maps and lifts

Recall that the  $\text{rsLP}(G)$  can be interpreted as the expected value of a Max-Flow problem with a randomised source/sink placement over a fully connected  $2^k$ -dimensional hypercube, where the nodes are indexed by Boolean functions  $f \in \mathcal{F}_k$ . The source/sink nodes are indexed by affine Boolean functions. In order to be able to describe the symmetries of these graphs, we want to study mappings  $M : \mathcal{F}_k \rightarrow \mathcal{F}_k$  with the following properties:

1. Source and sink nodes map to source and sink nodes, i.e. if  $f$  is an affine function then  $M(f)$  is also an affine function.
2. The length of all edges  $\{v_{f_1}, v_{f_2}\}$  are preserved by the mapping, i.e.  $\text{dist}(M(f_1), M(f_2)) = \text{dist}(f_1, f_2)$ .

There is a natural choice of mappings from  $\mathcal{F}_k \rightarrow \mathcal{F}_k$  for which Property 1 and 2 hold. Additionally as a bonus, the same natural choice of mappings can also be extended to construct mappings from  $\mathcal{F}_k \rightarrow \mathcal{F}_{k'}$ ,  $k \leq k'$ , and still have that both Property 1 and 2 hold. This can then be used to embed the  $2^k$ -dimensional hypercube in the  $2^{k'}$ -dimensional hypercube.

► Definition C.1. Let  $M_{A,b,\beta,c} : \mathcal{F}_k \rightarrow \mathcal{F}_{k'}$  be defined as

$$M_{A,b,\beta,c}(f)(y) = f(Ay + b)(-1)^c \chi_\beta(y),$$

where  $k, k' \in \mathbb{Z}_{>0}$ ,  $k \leq k'$ ,  $y \in \mathbb{F}_2^{k'}$ ,  $A \in \mathbb{F}_2^{k \times k'}$  is a full rank matrix,  $b \in \mathbb{F}_2^k$ ,  $c \in \mathbb{F}_2$  and  $\beta \in \mathbb{F}_2^{k'}$ . Let  $\mathcal{M}_{k \rightarrow k'}$  denote the set of all maps  $M_{A,b,\beta,c}$  from  $\mathcal{F}_k \rightarrow \mathcal{F}_{k'}$ . For convenience, we often denote  $M_{A,b,\beta,c}$  by  $M$ , where the  $A, b, \beta, c$  are all implicit.

## 11:28 On the NP-Hardness Approximation Curve for Max-2Lin(2)

Since these mappings are reminiscent of affine maps from linear algebra, we call them *affine maps*. However, they are not affine maps in the classical sense.

The function  $M(f) \in \mathcal{F}_{k'}$  is called the *M-lift of f*. It is not hard to see that the *M-lift* of an affine function is an affine function. More generally, *M-lifts* always preserve the dimension of Boolean functions.

► **Proposition C.2.** *Given  $f \in \mathcal{F}_k$  and  $M \in \mathcal{M}_{k \rightarrow k'}$ ,  $k \leq k'$ , then  $\dim(M(f)) = \dim(f)$ .*

**Proof.** It follows from a direct calculation that

$$M_{A,b,\beta,c}(f)(y) = (-1)^c \sum_{\alpha \in \{0,1\}^k} \chi_{A^T \alpha + \beta}(y) \hat{f}_\alpha \chi_b(\alpha).$$

This shows that the affine mapping  $M$  moves  $\text{affine}(f)$  to  $\text{affine}(M(f)) = \{A^T \alpha + \beta : \alpha \in \text{affine}(f)\}$ . Furthermore, since  $A$  is a full rank matrix,  $\dim(f) = \dim(M(f))$ . ◀

Affine maps also preserve the (normalised Hamming) distance of affine functions.

► **Proposition C.3.** *Given  $f_1, f_2 \in \mathcal{F}_k$  and  $M \in \mathcal{M}_{k \rightarrow k'}$ ,  $k \leq k'$ , then  $\text{dist}(M(f_1), M(f_2)) = \text{dist}(f_1, f_2)$ .*

**Proof.** Let  $M = M_{A,b,\beta,c}$ . Note that  $\text{dist}(M(f_1), M(f_2))$  only depends on  $A$  and  $b$  since

$$\begin{aligned} \text{dist}(M(f_1), M(f_2)) &= \frac{1}{2^{k'}} \sum_{y \in \mathbb{F}_2^{k'}} \frac{1 - M(f_1)(y)M(f_2)(y)}{2} \\ &= \frac{1}{2^{k'}} \sum_{y \in \mathbb{F}_2^{k'}} \frac{1 - f_1(Ay + b)f_2(Ay + b)}{2}. \end{aligned}$$

Furthermore, since  $A$  is a full rank  $k \times k'$  Boolean matrix, the kernel of  $A$  has dimension  $k' - k$  and size  $2^{k'-k}$ , so

$$\sum_{y \in \{0,1\}^{k'}} f_1(Ay + b)f_2(Ay + b) = 2^{k'-k} \sum_{x \in \{0,1\}^k} f_1(x)f_2(x).$$

This shows that  $\text{dist}(M(f_1), M(f_2)) = \text{dist}(f_1, f_2)$ . ◀

The last notable property of the affine maps is that they form a group under composition. This property is needed to be able to apply the techniques from Appendix A.2 to the  $\text{rsLP}(G)$  and to the  $\text{rs}_\infty \text{LP}(G)$  in order to “compress” them.

► **Proposition C.4.**  *$\mathcal{M}_{k \rightarrow k}$  under composition forms a group.*

**Proof.** The composition of two affine maps  $M_{A',b',\beta',c'} \circ M_{A,b,\beta,c}$ , is an affine map  $M_{A'',b'',\beta'',c''}$ , where

$$\begin{aligned} A'' &= AA', \\ b'' &= Ab' + b, \\ \beta'' &= (A')^T \beta + \beta', \\ c'' &= (b', \beta) + c' + c. \end{aligned}$$

Furthermore, the left and right inverse of an affine map  $M_{A,b,\beta,c}$  is given by  $M_{A',b',\beta',c'}$  where

$$\begin{aligned} A' &= A^{-1}, \\ b' &= A^{-1}b, \\ \beta' &= (A^{-1})^T \beta, \\ c' &= c + (A^{-1}b, \beta). \end{aligned}$$

This shows that  $\mathcal{M}_{k \rightarrow k}$  forms a group under composition. ◀

### C.1 $M$ -lifts of sink and sources

Recall that the source/sink placements of the  $\text{rsLP}(G)$  and the  $\text{rs}_\infty\text{LP}(G)$  are described using a Boolean function  $g \in \mathcal{F}_k$ ,

$$g(\alpha) = \begin{cases} 1 & \text{iff } v_{\chi_\alpha} \text{ is a sink,} \\ -1 & \text{iff } v_{\chi_\alpha} \text{ is a source.} \end{cases}$$

Note that  $M$ -lifts move the sink and source nodes. If  $k = k'$ , then the  $M$ -lift permutes the sink and source nodes. If  $k < k'$ , then the  $M$ -lift “lifts” the sink and source nodes onto a higher dimensional hypercube. This means that there exists multiple different source/sink placements  $g' \in \mathcal{F}_{k'}$  that all match the lifted positions of the sinks and sources. The condition for when an  $M$ -lift of a source/sink placement  $g \in \mathcal{F}_k$  is described by a source/sink placement  $g' \in \mathcal{F}_{k'}$  is given by the following proposition.

► **Proposition C.5.** *An  $M$ -lift will map sink nodes in  $\mathcal{F}_k$  onto sink nodes of  $\mathcal{F}_{k'}$  and source nodes in  $\mathcal{F}_k$  onto source nodes in  $\mathcal{F}_{k'}$  if and only if*

$$M_{A^T, \beta, b, c}(g') = g.$$

**Proof.**

Note that the  $M_{A,b,\beta,c}$ -lift of  $\chi_\alpha$  is  $M_{A,b,\beta,c}(\chi_\alpha) = \chi_{A^T \alpha + \beta}(x)(-1)^c \chi_b(\alpha)$ . Using the source/sink placement  $g'$  we can tell whether a node  $v_{\chi_\alpha}$  is lifted onto a sink node or a source node,

$$g'(A^T \alpha + \beta)(-1)^c \chi_b(\alpha) = \begin{cases} 1 & \text{iff } v_{M_{A,b,\beta,c}(\chi_\alpha)} \text{ is a sink according to } g', \\ -1 & \text{iff } v_{M_{A,b,\beta,c}(\chi_\alpha)} \text{ is a source according to } g'. \end{cases}$$

This implies that the sufficient and necessary condition to make all sinks in  $\mathcal{F}_k$  to be  $M_{A,b,\beta,c}$ -lifted to sinks in  $\mathcal{F}_{k'}$  and all sources in  $\mathcal{F}_k$  to be  $M_{A,b,\beta,c}$ -lifted to sources in  $\mathcal{F}_{k'}$ , is that

$$g(\alpha) = g'(A^T \alpha + \beta)(-1)^c \chi_b(\alpha)$$

for all  $\alpha \in \mathbb{F}_2^k$ . This is identical to requiring that  $M_{A^T, \beta, b, c}(g') = g$ . ◀

► **Definition C.6.** *The operator  $M_{A^T, \beta, b, c}$  is denoted by  $M_{A,b,\beta,c}^\#$ .*

### C.2 Lifting gadgets and flows

It is possible to extend the definition of  $M$ -lifting to  $\text{Had}_k\text{-to-2Lin}(2)$  gadgets  $G$  by defining  $M \cdot G$  as

$$(M \cdot G)(f'_1, f'_2) = \sum_{\substack{f_1 \in M^{-1}(f'_1), \\ f_2 \in M^{-1}(f'_2)}} G(f_1, f_2).$$

## 11:30 On the NP-Hardness Approximation Curve for Max-2Lin(2)

This moves the capacity  $G(f_1, f_2)$  of edge  $\{v_{f_1}, v_{f_2}\}$  onto edge  $\{v_{M(f_1)}, v_{M(f_2)}\}$ . Furthermore, let the *full  $k \rightarrow k'$  lift* of  $G$  be defined as the average of all possible  $M$ -lifts, i.e.

$$\text{lift}_{k \rightarrow k'}(G) = \frac{1}{|\mathcal{M}_{k \rightarrow k'}|} \sum_{M \in \mathcal{M}_{k \rightarrow k'}} (M \cdot G).$$

Completely analogue to the definition of  $M$ -lifts of gadgets, let the  $M$ -lift of a flow  $w$  of the  $\text{rs}(G)$  LP be defined as

$$(M \cdot w)(f'_1, f'_2, g') = \sum_{\substack{f_1 \in M^{-1}(f'_1), \\ f_2 \in M^{-1}(f'_2)}} w(f_1, f_2, M^\#(g')),$$

and let the full  $k \rightarrow k'$  lift of  $w$  be defined as

$$\text{lift}_{k \rightarrow k'}(w) = \frac{1}{|\mathcal{M}_{k \rightarrow k'}|} \sum_{M \in \mathcal{M}_{k \rightarrow k'}} (M \cdot w).$$

By connecting these two concepts of lifting gadgets and flows, we can show the following proposition.

► **Proposition C.7.** *The full lift of  $G$  is a  $\text{Had}_k$ -to-2Lin(2) gadget  $G'$  where  $c(G') = c(G)$  and  $\text{rs}(G') \leq \text{rs}(G)$ .*

**Proof.** Let  $w$  be a feasible flow of  $G$  and let  $w' = \text{lift}_{k \rightarrow k'}(w)$ . Note that  $w'$  is a feasible flow of  $G'$  since the capacity of  $G$  is lifted together with the flow  $w$ . So constraints (1) and (2) are satisfied by  $w'$ . Additionally,

$$\mathbb{E}_{g \in \mathcal{F}_k} \text{val}_g(w) = \mathbb{E}_{g' \in \mathcal{F}_{k'}} \text{val}_{g'}(w').$$

since any lift preserves the amount of flow going in and out of sink nodes and source nodes. ◀

The final Proposition that we need for Appendix D is that the full lift of a leaky flow  $w$  of the  $\text{rsLP}(G)$  is a leaky flow of the  $\text{rsLP}(G')$ , and that the full lift does not affect the value of the flow. This is a fundamental property of lifts that is used in Appendix D to upper bound  $\text{rs}(G')$  when  $k' \rightarrow \infty$ .

► **Proposition C.8.** *Let  $G'$  be the full lift of  $G$ , and let  $w'$  be the full lift of a leaky flow  $w$  of the  $\text{rsLP}(G)$ . Then  $w'$  is a leaky flow of the  $\text{rsLP}(G')$ , and  $\mathbb{E}_{g \in \mathcal{F}_k} \text{val}_g(w) = \mathbb{E}_{g' \in \mathcal{F}_{k'}} \text{val}_{g'}(w')$ .*

**Proof.** Let  $w$  be a leaky flow of  $G$  and let  $w' = \text{lift}_{k \rightarrow k'}(w)$ . Note that constraint (1) is satisfied by  $w'$  since the capacity of  $G$  is lifted together with the flow  $w$ . So  $w'$  is a leaky flow. Additionally,

$$\mathbb{E}_{g \in \mathcal{F}_k} \text{val}_g(w) = \mathbb{E}_{g' \in \mathcal{F}_{k'}} \text{val}_{g'}(w').$$

since any lift preserves the amount of flow going in and out of sink nodes and source nodes. ◀

## D Proving that $\text{rs}_\infty(G)$ can be attained in the limit

The goal of this section is to prove Lemma 3.11, which relates the infinity relaxed soundness to the relaxed soundness. Let  $G$  be the  $\text{Had}_k$ -to-2Lin(2) gadget in Lemma 3.11 and let  $w$  be the optimal flow of the  $\text{rs}_\infty \text{LP}(G)$ , which implies that  $\text{rs}_\infty(G) = 1 - \mathbb{E}_{g \in \mathcal{F}_k} \text{val}_g(w)$ . Let  $k'$  be some integer greater than  $k$  and define  $G' = \text{lift}_{k \rightarrow k'}(G)$  and  $w' = \text{lift}_{k \rightarrow k'}(w)$ . According to Proposition C.7  $G'$  is a  $\text{Had}_k$ -to-2Lin(2) with  $c(G') = c(G)$  and according to Proposition C.8  $w'$  is a leaky flow of the  $\text{rsLP}(G')$  and  $\mathbb{E}_{g \in \mathcal{F}_k} \text{val}_g(w) = \mathbb{E}_{g' \in \mathcal{F}_{k'}} \text{val}_{g'}(w')$ . We prove that as  $k'$  tends to infinity the total leakage of  $G'$  converges to 0. After we have established this, Lemma 3.11 follows from Theorem A.5.

### D.1 Total leakage approaches 0 as $k' \rightarrow \infty$

Let us start by formally defining the leaks of  $w$  and  $w'$ , where  $w$  is a leaky flow of the rsLP( $G$ ) and  $w'$  is a leaky flow of the rsLP( $G'$ ). Recall that the rsLP( $G'$ ) describe the expectation of the maximum flow of a graph with a random source/sink placement  $g' \in \mathcal{F}_{k'}$ . It is for this reason that the total leakage of  $w'$  is defined as an expectation over  $g' \in \mathcal{F}_{k'}$  of the total leakage of the graph with source/sink placement given by  $g'$ .

► **Definition D.1.** Let  $L_{k'}$  denote the total leakage of  $w'$ ,

$$L_{k'} = \mathbb{E}_{g' \in \mathcal{F}_{k'}} \left( \sum_{\substack{f' \in \mathcal{F}_{k'} \\ \text{s.t. } \dim(f') > 0}} |\text{leak}_{w'}(f', g')| \right),$$

where

$$\begin{aligned} \text{leak}_{w'}(f', g') &= \text{out}_{w'}(f', g') - \text{in}_{w'}(f', g') \\ &= \frac{1}{|\mathcal{M}_{k \rightarrow k'}|} \sum_{M \in \mathcal{M}_{k \rightarrow k'}} \left( \sum_{\substack{f \in \mathcal{F}_k \\ \text{s.t. } M(f) = f'}} \text{leak}_w(f, M^\#(g')) \right). \end{aligned}$$

The aim of this subsection is to prove that  $L_{k'} \rightarrow 0$  as  $k' \rightarrow \infty$ . We do this by proving the following upper bound on  $L_{k'}$  through a second order moment analysis.

► **Proposition D.2.**

$$L_{k'} \leq \frac{2^{2k+k}}{\sqrt{2^{k'} - 2^k}}.$$

The proof of Proposition D.2 relies on the following Proposition describing the relationship between random pairs of affine maps  $M_1, M_2 \in \mathcal{M}_{k \rightarrow k'}$  such that  $M_1(f) = M_2(f)$  for some fixed  $f \in \mathcal{F}_k$ .

► **Definition D.3.** Given  $M_{A,b,\beta,c} \in \mathcal{M}_{k \rightarrow k'}$ , let  $T_M : \mathbb{F}_2^k \rightarrow \mathbb{F}_2^{k'}$  denote the affine map  $T_M(x) = Ax + \beta$ . Furthermore, let  $\text{affine}(M_{A,b,\beta,c})$  denote the affine subspace  $\{T_M(x) : x \in \mathbb{F}_2^k\} \subseteq \mathbb{R}^{k'}$ .

► **Proposition D.4.** Given  $f \in \mathcal{F}_k$  and  $f' \in \mathcal{F}_{k'}$  with  $\dim(f) = \dim(f') = d$ . Then

$$|\{(M_1, M_2) \in \mathcal{N}_{f \rightarrow f'} \times \mathcal{N}_{f \rightarrow f'} : \dim(\text{affine}(M_1) \cap \text{affine}(M_2)) > d\}| \leq |\mathcal{N}_{f \rightarrow f'}|^2 \frac{(2^k - 2^d)^2}{2^{k'} - 2^d},$$

where  $\mathcal{N}_{f \rightarrow f'} = \{M \in \mathcal{M}_{k \rightarrow k'} : M(f) = f'\}$  denotes the set of affine maps in  $\mathcal{M}_{k \rightarrow k'}$  that lifts  $f$  to  $f'$ .

**Proof.** Note that for any  $M_1, M_2 \in \mathcal{N}_{f \rightarrow f'}$ , the dimension of  $\text{affine}(M_1) \cap \text{affine}(M_2)$  is at least  $d$ , since according to the proof of Proposition C.2 both  $T_{M_1}$  and  $T_{M_2}$  must map  $\text{affine}(f)$  onto  $\text{affine}(f')$ , so  $\dim(\text{affine}(M_1) \cap \text{affine}(M_2) \cap \text{affine}(f')) = d$ . However, the two maps  $T_{M_1}$  and  $T_{M_2}$  can map the complement of  $\text{affine}(f)$  in different ways since there is no restriction to how they map the complement of  $\text{affine}(f)$ .

## 11:32 On the NP-Hardness Approximation Curve for Max-2Lin(2)

Fix  $M_1$  and uniformly at random pick  $M_2$  from  $\mathcal{N}_{f \rightarrow f'}$ . Given any fix  $x \notin \text{affine}(f)$ , the probability that  $T_{M_2}(x) \in \text{affine}(M_1)$  is  $(2^k - 2^d)/(2^{k'} - 2^d)$  since  $|\text{affine}(M_1) \setminus \text{affine}(f')| = 2^k - 2^d$  and  $T_{M_2}(x)$  is uniformly distributed over the complement of  $\text{affine}(f')$ . Taking a union bound over all  $x \notin \text{affine}(f)$  shows that

$$P_{M_2 \in \mathcal{N}_{f \rightarrow f'}}[\dim(\text{affine}(M_1) \cap \text{affine}(M_2)) > d] \leq \frac{(2^k - 2^d)^2}{2^{k'} - 2^d}.$$

Proposition D.4 follows directly from this inequality.  $\blacktriangleleft$

The takeaway from Proposition D.4 is that if  $M_1$  and  $M_2$  are two random affine maps such that  $M_1(f) = M_2(f)$  for some fixed  $f \in \mathcal{F}_k$ , then with high probability  $\text{affine}(M_1) \cap \text{affine}(M_2) = \text{affine}(f)$ . This allows us to create a bound on the second order moment of the terms that define  $L_{k'}$ .

**► Lemma D.5.** *Given  $f \in \mathcal{F}_k$ ,  $f' \in \mathcal{F}_{k'}$  and  $g' \in \mathcal{F}_{k'}$ , where  $\dim(f) = \dim(f') = d > 0$ , then*

$$\mathbb{E}_{g' \in \mathcal{F}_{k'}} \left( \left| \sum_{M \in \mathcal{N}_{f \rightarrow f'}} \text{leak}_w(f, M^\#(g')) \right|^2 \right) \leq |\mathcal{N}_{f \rightarrow f'}|^2 \frac{(2^k - 2^d)^2}{2^{k'} - 2^d}.$$

**Proof.** Expanding the square we need to prove that,

$$\sum_{M_1, M_2 \in \mathcal{N}_{f \rightarrow f'}} \mathbb{E}_{g' \in \mathcal{F}_{k'}} (\text{leak}_w(f, M_1^\#(g')) \text{leak}_w(f, M_2^\#(g'))) \leq |\mathcal{N}_{f \rightarrow f'}|^2 \frac{(2^k - 2^d)^2}{2^{k'} - 2^d}.$$

Split the terms up into two cases, either  $\dim(\text{affine}(M_1) \cap \text{affine}(M_2)) > d$  or  $\dim(\text{affine}(M_1) \cap \text{affine}(M_2)) = d$ . By Proposition D.4 the number of terms of the first type is at most  $|\mathcal{N}_{f \rightarrow f'}|^2 (2^k - 2^d)^2 / (2^{k'} - 2^d)$ . Each term is bounded by one since the sum of capacities in the rs( $G$ ) LP is equal to 1, so the absolute value of a leak is always smaller than or equal to 1 at any node and for any source/sink placement.

In the other case, when  $\dim(\text{affine}(M_1) \cap \text{affine}(M_2)) = d$ , then the two random functions  $M_1^\#(g')$  and  $M_2^\#(g')$  are equal on  $\text{affine}(f)$ , and independently uniformly random  $\{1, -1\}$  on the complement of  $\text{affine}(f)$ . This allows us to rewrite the expectation over  $g'$  as

$$\begin{aligned} & \mathbb{E}_{g' \in \mathcal{F}_{k'}} (\text{leak}_w(f, M_1^\#(g')) \text{leak}_w(f, M_2^\#(g'))) \\ &= \mathbb{E}_{g' \in \mathcal{F}_{k'}} \left( \text{leak}_w(f, M_1^\#(g')) \mathbb{E}_{\substack{g'_2 \in \mathcal{F}_{k'} \\ \text{s.t. } M_2^\#(g'_2)|_{\text{affine}(f)} = M_1^\#(g')|_{\text{affine}(f)}}} \text{leak}_w(f, M_2^\#(g'_2)) \right) \\ &= \mathbb{E}_{g \in \mathcal{F}_k} \left( \text{leak}_w(f, g) \mathbb{E}_{\substack{g_2 \in \mathcal{F}_k \\ \text{s.t. } g_2|_{\text{affine}(f)} = g|_{\text{affine}(f)}}} \text{leak}_w(f, g_2) \right). \end{aligned}$$

This is equal to 0, since for any infinity relaxed flow  $w$  (see Definition 3.7) the expectation of  $\text{leak}_w(f, g_2)$  over  $g_2$  given  $g$  is 0.  $\blacktriangleleft$

We are now at the point where we can prove Proposition D.2 using Lemma D.5.

**Proof of Proposition D.2.** A trivial upper bound of  $L_{k'}$  using the triangle inequality is

$$L_{k'} \leq \frac{1}{|\mathcal{M}_{k \rightarrow k'}|} \sum_{f \in \mathcal{F}_k} \sum_{\substack{f' \in \mathcal{F}_{k'} \\ s.t. \dim(f') > 0}} \mathbb{E}_{g' \in \mathcal{F}_{k'}} \left( \left| \sum_{M \in \mathcal{N}_{f \rightarrow f'}} \text{leak}_w(f, M^\#(g')) \right| \right).$$

Applying Jensen's inequality to the expectation over  $g' \in \mathcal{F}_{k'}$  gives

$$\mathbb{E}_{g' \in \mathcal{F}_{k'}} \left( \left| \sum_{M \in \mathcal{N}_{f \rightarrow f'}} \text{leak}_w(f, M^\#(g')) \right| \right) \leq \sqrt{\mathbb{E}_{g' \in \mathcal{F}_{k'}} \left( \left| \sum_{M \in \mathcal{N}_{f \rightarrow f'}} \text{leak}_w(f, M^\#(g')) \right|^2 \right)},$$

which according to Lemma D.5 can be further upper bounded by

$$\begin{aligned} \sqrt{\mathbb{E}_{g' \in \mathcal{F}_{k'}} \left( \left| \sum_{M \in \mathcal{N}_{f \rightarrow f'}} \text{leak}_w(f, M^\#(g')) \right|^2 \right)} &\leq \frac{2^k - 2^{\dim(f)}}{\sqrt{2^{k'} - 2^{\dim(f)}}} |\mathcal{N}_{f \rightarrow f'}| \\ &\leq \frac{2^k}{\sqrt{2^{k'} - 2^k}} |\mathcal{N}_{f \rightarrow f'}|. \end{aligned}$$

We have so far shown that

$$L_{k'} \leq \frac{2^k}{\sqrt{2^{k'} - 2^k}} \sum_{f \in \mathcal{F}_k} \sum_{\substack{f' \in \mathcal{F}_{k'} \\ s.t. \dim(f') > 0}} \frac{|\mathcal{N}_{f \rightarrow f'}|}{|\mathcal{M}_{k \rightarrow k'}|}.$$

Finally, note that  $\sum_{f' \in \mathcal{F}_{k'}} |\mathcal{N}_{f \rightarrow f'}| = |\mathcal{M}_{k \rightarrow k'}|$  since  $\mathcal{N}_{f \rightarrow f'}$  are disjoint subsets of  $\mathcal{M}_{k \rightarrow k'}$  for different  $f' \in \mathcal{F}_{k'}$  and their union over  $f' \in \mathcal{F}_{k'}$  is equal to  $\mathcal{M}_{k \rightarrow k'}$ . So

$$L_{k'} \leq \frac{2^k}{\sqrt{2^{k'} - 2^k}} \sum_{f \in \mathcal{F}_k} \sum_{\substack{f' \in \mathcal{F}_{k'} \\ s.t. \dim(f') > 0}} \frac{|\mathcal{N}_{f \rightarrow f'}|}{|\mathcal{M}_{k \rightarrow k'}|} \leq \frac{2^k}{\sqrt{2^{k'} - 2^k}} \sum_{f \in \mathcal{F}_k} 1 \leq \frac{2^{2k+k}}{\sqrt{2^{k'} - 2^k}}. \blacktriangleleft$$

## D.2 The proof of Lemma 3.11

All that remains is to tie up the loose ends by proving Lemma 3.11 using Proposition D.2 combined with Theorem A.5.

**Proof of Lemma 3.11.** Since  $w'$  is a leaky flow of the rsLP( $G'$ ), it follows from Theorem A.5 that there exists a feasible flow  $\tilde{w}'$  of the rsLP( $G'$ ) such that

$$\mathbb{E}_{g' \in \mathcal{F}_{k'}} \text{val}_{g'}(\tilde{w}') + L_{k'} \geq \mathbb{E}_{g' \in \mathcal{F}_{k'}} \text{val}_{g'}(w').$$

Note that  $\text{rs}(G') \geq 1 - \mathbb{E}_{g' \in \mathcal{F}_{k'}} \text{val}_{g'}(\tilde{w}')$  since  $\tilde{w}'$  is a feasible flow of the rsLP( $G'$ ). Furthermore, recall that  $\text{rs}_\infty(G) = 1 - \mathbb{E}_{g' \in \mathcal{F}_{k'}} \text{val}_{g'}(w')$ . So

$$\text{rs}(G') - L_{k'} \leq \text{rs}_\infty(G).$$

Proposition D.2 implies that  $L_{k'} \rightarrow 0$  as  $k' \rightarrow \infty$ , which proves that  $\forall \varepsilon > 0$  there exists a gadget  $G'$  with  $c(G') = c(G)$  such that  $\text{rs}(G') - \varepsilon \leq \text{rs}_\infty(G)$ .  $\blacktriangleleft$

## E Gadget construction and verification

This section contains the details for how to practically compute  $\text{Had}_k\text{-to-2Lin}(2)$  gadgets using the  $\text{rsLP}(G)$  and the  $\text{rs}_\infty\text{LP}(G)$ . These LPs have far too many variables and constraints to directly be solved by a computer when  $k \geq 4$ . The solution is to make use of the symmetries of the LP:s to construct smaller LP:s with the same optimum. This is done in two steps. Step 1 is to use Proposition C.7 to argue that best gadgets are the symmetrical gadgets. This means that we only need to take into account symmetrical gadgets when solving the  $\text{rsLP}(G)$  and the  $\text{rs}_\infty\text{LP}(G)$ . Step 2 is to use the fact that if  $G$  is symmetrical, then Theorem A.8 allows us to compress the LP, merging a huge number of variables into a single variable.

### E.1 Symmetrical $\text{Had}_k\text{-to-2Lin}(2)$ gadgets are optimal

The meaning of a  $\text{Had}_k\text{-to-2Lin}(2)$  gadget  $(G, \mathbb{X}, \mathbb{Y})$  being *optimal* is that there exists no  $\text{Had}_k\text{-to-2Lin}(2)$  gadget  $(\tilde{G}, \mathbb{X}, \mathbb{Y})$  such that  $c(G) = c(\tilde{G})$  and  $\text{rs}(G) > \text{rs}(\tilde{G})$ . The following Proposition states that symmetric gadgets are optimal. By symmetric, we refer to the property that the gadget  $G$  is invariant under  $M$ -lifts.

► **Proposition E.1.** *Given any  $\text{Had}_k\text{-to-2Lin}(2)$  gadget  $(G, \mathbb{X}, \mathbb{Y})$ , there exists a symmetric  $\text{Had}_k\text{-to-2Lin}(2)$  gadget  $(\tilde{G}, \mathbb{X}, \mathbb{Y})$  such that  $c(G) = c(\tilde{G})$  and  $\text{rs}(G) \geq \text{rs}(\tilde{G})$ .*

**Proof.** Let  $\tilde{G} = \text{lift}_{k \rightarrow k}(G)$ . According to Proposition C.7,  $c(G) = c(\tilde{G})$  and  $\text{rs}(G) \geq \text{rs}(\tilde{G})$ . Furthermore,  $\tilde{G}$  is a symmetric gadget since for any  $f_1, f_2 \in \mathcal{F}_k$  and  $M \in \mathcal{M}_{k \rightarrow k}$ ,

$$\begin{aligned} (M \cdot \tilde{G})(f_1, f_2) &= \frac{1}{|\mathcal{M}_{k \rightarrow k}|} \sum_{M_2 \in \mathcal{M}_{k \rightarrow k}} ((M \circ M_2) \cdot \tilde{G})(f_1, f_2) \\ &= \frac{1}{|\mathcal{M}_{k \rightarrow k}|} \sum_{M_2 \in M \circ \mathcal{M}_{k \rightarrow k}} (M_2 \cdot \tilde{G})(f_1, f_2). \end{aligned}$$

According to Proposition C.4,  $\mathcal{M}_{k \rightarrow k}$  forms a group, so  $M \circ \mathcal{M}_{k \rightarrow k} = \mathcal{M}_{k \rightarrow k}$ . We have shown that  $M \cdot \tilde{G} = \tilde{G}$  and thus  $\tilde{G}$  is a symmetric gadget. ◀

### E.2 Compressing the $\text{rsLP}(G)$ and $\text{rs}_\infty\text{LP}(G)$

As discussed earlier, both the  $\text{rsLP}(G)$  and the  $\text{rs}_\infty\text{LP}(G)$  can be interpreted as Max-Flow problems. Furthermore, if  $G$  is symmetric under  $M$ -lifts, then  $\mathcal{M}_{k \rightarrow k}$  is a symmetry group for both of these Max-Flow problems. This means that we can apply Theorem A.8 to compress the Max-Flow problems, giving us the *compressed*  $\text{rsLP}(G)$  and the *compressed*  $\text{rs}_\infty\text{LP}(G)$ .

One of the symmetries that the compression is able to capture is that many different source/sink placements are equivalent. In a sense, the source/sink placements of the compressed LPs consist of one representative source/sink placement from each set of equivalent source/sink placements. This symmetry turns out to be the main contributor as to why the compressed LP is significantly smaller than the original LP.

Without the compression, the LPs each have  $2^{3 \cdot 2^k}$  variables, which for  $k \geq 4$  is computationally infeasible. However, even with the compression, for  $k = 4$  the LPs are still large enough that it is computationally challenging to solve them.

#### E.2.1 Further restricting the compressed LPs

To further restrict the size of the LPs in the case of  $k = 4$ , we heuristically identify a list of beneficial gadget variables by solving the compressed LPs with floating point numbers

■ **Table 4** Sizes of the  $\text{rsLP}(G)$  and  $\text{rs}_\infty\text{LP}(G)$  for  $\text{Had}_2\text{-to-2Lin}(2)$  gadgets  $G$ . The three numbers are the number of linear constraints, number of variables and number of non-zero entries in the constraints. All variables have the implicit constraint of being non-negative.

|            | $\text{rsLP}(G)$ |     |     | $\text{rs}_\infty\text{LP}(G)$ |     |     |
|------------|------------------|-----|-----|--------------------------------|-----|-----|

| Compressed | 23               | 38  | 106 | 23                             | 38  | 106 |

■ **Table 5** Sizes of the  $\text{rsLP}(G)$  and  $\text{rs}_\infty\text{LP}(G)$  for  $\text{Had}_3\text{-to-2Lin}(2)$  gadgets  $G$ . The three numbers are the number of linear constraints, number of variables and number of non-zero entries in the constraints. All variables have the implicit constraint of being non-negative.

|            | $\text{rsLP}(G)$ |                |                | $\text{rs}_\infty\text{LP}(G)$ |                |                |
|------------|------------------|----------------|----------------|--------------------------------|----------------|----------------|
| Original   | $8 \cdot 10^6$   | $2 \cdot 10^7$ | $5 \cdot 10^7$ | $8 \cdot 10^6$                 | $2 \cdot 10^7$ | $5 \cdot 10^7$ |
| Compressed | 298              | 546            | 2330           | 243                            | 462            | 1987           |

using Gurobi. Any gadget variable that is given non-zero weight in at least one floating point solution is added to the list. Using this list, we define the *restricted compressed LP* as the compressed LP but with all other gadget variables that are not on the list, removed. The list we use can be found in Table 9 in Appendix F. Note that one possible drawback to restricting the LPs like this is that the restriction could lead to construction of sub-optimal gadgets.

Tables 4–6 show the sizes of the LPs depending on if compression or restriction is being applied. Note that the restricted and compressed LP:s have significantly fewer variables than the original LP:s.

There is a special case where we do not need the restrictions. If the completeness of a gadget is  $1 - 2^{-k}$ , then the gadget only has non-zero weight on edges of length  $2^{-k}$ . There are comparatively relatively few edges of length  $2^{-k}$ . This allows us to directly construct the gadget by solving the non-restricted LP. So in the case of completeness  $1 - 2^{-k}$ , the gadgets we construct are guaranteed to be optimal since we do not make use of any restrictions.

### E.3 Implementation details

The compressed  $\text{rsLP}(G)$  and compressed  $\text{rs}_\infty\text{LP}(G)$  are constructed using a Python script where all of the calculations are done using integer arithmetic. The script makes use of affine maps to efficiently compute the symmetries of the two LPs, in order to compress them. The time and memory complexities of the script are roughly  $O(2^{2 \cdot 2^k})$ , so the script is able to handle  $k = 2, 3$  and  $4$ . In theory it would be possible to also make the script support  $k = 5$ , but that would require both more powerful hardware, as well as improving the time complexity to roughly  $O(2^{2^k})$  time.

■ **Table 6** Sizes of the  $\text{rsLP}(G)$  and  $\text{rs}_\infty\text{LP}(G)$  for  $\text{Had}_4\text{-to-2Lin}(2)$ . The three numbers are the number of linear constraints, number of variables and number of non-zero entries in the constraints.

|                         | $\text{rsLP}(G)$  |                   |                   | $\text{rs}_\infty\text{LP}(G)$ |                   |                   |
|-------------------------|-------------------|-------------------|-------------------|--------------------------------|-------------------|-------------------|
| Original                | $1 \cdot 10^{14}$ | $3 \cdot 10^{14}$ | $4 \cdot 10^{14}$ | $1 \cdot 10^{14}$              | $3 \cdot 10^{14}$ | $4 \cdot 10^{14}$ |
| Restricted              | $2 \cdot 10^{11}$ | $4 \cdot 10^{11}$ | $6 \cdot 10^{11}$ | $2 \cdot 10^{11}$              | $4 \cdot 10^{11}$ | $6 \cdot 10^{11}$ |
| Compressed              | $4 \cdot 10^5$    | $7 \cdot 10^5$    | $1 \cdot 10^7$    | $3 \cdot 10^5$                 | $6 \cdot 10^5$    | $9 \cdot 10^6$    |
| Restricted & compressed | $3 \cdot 10^4$    | $6 \cdot 10^4$    | $2 \cdot 10^5$    | $3 \cdot 10^4$                 | $5 \cdot 10^4$    | $2 \cdot 10^5$    |

After having computed the compressed  $\text{rsLP}(G)$  and compressed  $\text{rs}_\infty\text{LP}(G)$ , the list of beneficial gadget variables found in Section 4.1 are used to construct the restricted compressed LPs. In order to solve the compressed LP we use the exact rational number LP solver `QSopt_ex`[1]. This results in a gadget described only using rational numbers, as well as an accompanying compressed flow, also described only using rational numbers.

#### E.4 Verification of $\text{rs}(G)$ and $\text{rs}_\infty(G)$

It is significantly simpler to verify the relaxed soundness and the infinity relaxed soundness of a gadget than it is to construct the gadget. The verification can be done almost directly on the original LPs, without needing the restricted compressed LPs or the compressed LPs.

The input to the verification program is a gadget  $G : \binom{\mathcal{F}_k}{2} \rightarrow [0, 1]$  together with a flow  $w_g : \mathcal{F}_k \times \mathcal{F}_k \rightarrow \mathbb{R}$ , for each source/sink placement equivalence class representative  $g$ . The flow acts as a witness for the relaxed soundness / infinity relaxed soundness of the gadget. In order to avoid floating point errors, we require both  $G$  and the  $w_g$  to be rational.

The verification process is done in five steps.

1. For each source/sink placement representative  $g$ , verify that the flow  $w_g$  satisfies the capacity constraints of the  $\text{rs}(G)$  LP /  $\text{rs}_\infty(G)$  LP, i.e. that  $w_g(f_1, f_2) + w_g(f_2, f_1) \leq G(f_1, f_2)$  for all  $f_1, f_2 \in \mathcal{F}_k$ .
2. Verify that the gadget  $G$  is symmetric under action by  $M \in \mathcal{M}_{k \rightarrow k}$ , meaning that for all functions  $f_1, f_2 \in \mathcal{F}_k$  and affine maps  $M \in \mathcal{M}_{k \rightarrow k}$ , it holds that  $G(f_1, f_2) = G(M(f_1), M(f_2))$ .
3. For each source/sink placement representative  $g$  and each function  $f \in \mathcal{F}_k$ , compute  $\text{in}(f, g)$  and  $\text{out}(f, g)$ . Now extend  $\text{in}$  and  $\text{out}$  to be defined for all  $f$  and  $g$  in  $\mathcal{F}_k$ . For any source/sink placements  $\tilde{g} \in \mathcal{F}_k$  that is not a representative, pick a map  $M \in \mathcal{M}_{k \rightarrow k}$  and representative  $g$  such that  $g = M^\#(\tilde{g})$ , and define  $\text{in}(f, \tilde{g})$  as  $\text{in}(M^{-1}(f), g)$  and  $\text{out}(f, \tilde{g})$  as  $\text{out}(M^{-1}(f), g)$ .
4. Verify the conservation of flow constraint in the  $\text{rsLP}(G)$  /  $\text{rs}_\infty\text{LP}(G)$  by iterating over all  $(f, g) \in \mathcal{F}_k \times \mathcal{F}_k$  that are not sinks or sources. For the  $\text{rsLP}(G)$  this just involves checking that  $\text{in}(f, g) = \text{out}(f, g)$ . For the  $\text{rs}_\infty\text{LP}(G)$  this involves checking that  $\sum_{g'} \text{in}(f, g') = \sum_{g'} \text{out}(f, g')$ , where the sum is over all  $g'$  such that  $g'|_{\text{affine}(f)} = g|_{\text{affine}(f)}$ .
5. Compute and output the completeness and  $\text{rs}$  /  $\text{rs}_\infty$  of the gadget using the extended inflow and outflow as a witness.

Note that the first step verifies the capacity constraints only for representatives of equivalent source/sink placements. The second step checks that the gadget  $G$  is symmetric, which combined with the first step implies that any extension of the flow to an arbitrary source/sink placement will fulfil the capacity constraints. The fourth step checks that the conservation of flow constraint is fulfilled, which in the case of the  $\text{rs}_\infty\text{LP}(G)$  involves computing the affine support of all possible source/sink placements.

The LP's we use and the gadgets we present in this paper can be found at <https://github.com/bjorn-martinsson/NP-hardness-of-Max-2Lin-2>, as well as a stand alone implementation of a verification script written in Python. As described in the verification process above, the verification requires a flow  $w_g$  as input. So on the Github, there is also a script used to generate this witness flow. This is done by solving the restricted compressed  $\text{rsLP}(G)$  /  $\text{rs}_\infty\text{LP}(G)$  using an integral Max-Flow solver, and then uncompressing the result.

**F** Edges used/unused in constructed gadgets

During the numerical analysis, we solve LPs to construct the gadgets. A gadget can be interpreted as a probability distribution over (undirected) edges. Tables 7–9 list all edges that have been given non-zero weight in at least one solution to an LP, for  $k = 2, 3, 4$ . Recall that every gadget that we construct is symmetrical under the mappings of  $\mathcal{M}_{k \rightarrow k}$ , so edges from the same edge orbit share the same capacity. More specifically, the tables contain a list of all edge orbits that are used in at least one constructed gadget.

## Abstract

---

The online joint replenishment problem (JRP) is a fundamental problem in the area of online problems with delay. Over the last decade, several works have studied generalizations of JRP with different cost functions for servicing requests. Most prior works on JRP and its generalizations have focused on the clairvoyant setting. Recently, Touitou [44] developed a non-clairvoyant framework that provided an  $O(\sqrt{n \log n})$  upper bound for a wide class of generalized JRP, where  $n$  is the number of request types.

We advance the study of non-clairvoyant algorithms by providing a simpler, modular framework that matches the competitive ratio established by Touitou for the same class of generalized JRP. Our key insight is to leverage universal algorithms for Set Cover to approximate arbitrary monotone subadditive functions using a simple class of functions termed *disjoint*. This allows us to reduce the problem to several independent instances of the TCP Acknowledgement problem, for which a simple 2-competitive non-clairvoyant algorithm is known. The modularity of our framework is a major advantage as it allows us to tailor the reduction to specific problems and obtain better competitive ratios. In particular, we obtain tight  $O(\sqrt{n})$ -competitive algorithms for two significant problems: Multi-Level Aggregation and Weighted Symmetric Subadditive Joint Replenishment. We also show that, in contrast, Touitou's algorithm is  $\Omega(\sqrt{n \log n})$ -competitive for both of these problems.

## 1 Introduction

Online problems with delay have received much attention in the last few years. An important family of online problems with delay consists of the Joint Replenishment Problem (JRP) and its variants. A typical instance consists of a sequence of requests that arrive over time. Each request can be one of  $n$  request types, and the cost of serving a set of requests is a subadditive<sup>1</sup> function of their types. We assume that the algorithm has oracle access to the service cost function. Requests do not need to be served on arrival but each request accumulates a delay cost while unserved. In particular, each request  $q$  has an associated delay cost function  $d_q$  and its delay cost is  $d_q(t)$  if it is served at time  $t$ . The goal of the problem is to serve all requests minimizing the total service cost and delay cost. An important special case is the deadline case; this is when requests do not incur delay cost but instead must be served by some given time. We call this family of problems *Subadditive JRP*.

These problems can be studied under the clairvoyant and non-clairvoyant settings. In the *clairvoyant* setting, when a request  $q$  arrives, the algorithm is given the entire delay cost function  $d_q$  (or its deadline in the case of deadlines). In contrast, in the *non-clairvoyant* setting, the algorithm only knows of the delay cost accumulated so far. In the case of deadlines, the algorithm only knows whether the request's deadline is now (and must be served immediately) or later.

Most previous works on Subadditive JRP have focused on the clairvoyant setting. Key problems within the family of Subadditive JRP include (in increasing order of generality): TCP Acknowledgement [36, 27, 20], Joint Replenishment Problem [21, 18, 14, 23], and Multi-Level Aggregation (MLA) [19, 7, 12, 11, 42]. For general subadditive service cost functions, deterministic  $O(\log N)$  (where  $N$  is the number of requests) and  $O(\log n)$  upper bounds are known ([22] and [8], respectively).

There is much less work in the non-clairvoyant setting. For a small number of problems, such as TCP Acknowledgement and Set Cover with Delay [3], clairvoyance is not required in the sense that the same competitive ratio can be attained in both the clairvoyant and non-clairvoyant settings. However, Azar et al. [5]'s lower bound for Online Service with Delay (a different family of online problems with delay) can be translated into an  $\Omega(\sqrt{n})$  lower bound against deterministic algorithms for JRP, and thus, MLA and Subadditive JRP. In contrast, clairvoyant Subadditive JRP has a  $O(\log n)$  competitive ratio [8]. Recently, Le et al. [39] showed that randomization does not help in breaking the  $\Omega(\sqrt{n})$  barrier and also developed algorithms for JRP and MLA with matching and nearly-matching upper bounds. Shortly after, Touitou [44] presented a general non-clairvoyant framework for Subadditive JRP with a deterministic  $O(\sqrt{n \log n})$  competitive ratio.

### 1.1 Our Results

Our main contribution is a simple, modular framework for non-clairvoyant Subadditive JRP that matches the current-best competitive ratio of  $O(\sqrt{n \log n})$ , and yields tight  $O(\sqrt{n})$  competitive ratios for the key problems of Multi-Level Aggregation and Weighted Symmetric Subadditive Joint Replenishment. We also show that the framework of Touitou [44] is  $\Omega(\sqrt{n \log n})$  for these problems. We now formally define these problems and state our results.

---

<sup>1</sup> A set function over a ground set  $U$  is *subadditive* if  $f(A) + f(B) \geq f(A \cup B)$  for every  $A, B \subseteq U$ .

### 1.1.1 General Framework for Subadditive JRP

**Subadditive JRP.** We have a set  $U$  of  $n$  request types and a monotone non-decreasing, subadditive *service function*  $f : 2^U \mapsto \mathbb{R}_{\geq 0}$  that satisfies  $f(\emptyset) = 0$ . Requests  $q$  arrive over time. Each request  $q$  has a type  $h_q \in U$ , an arrival time  $a_q$ , and a non-decreasing, continuous delay function  $d_q$ . At any point in time, the algorithm can serve a subset  $Q$  of the requests that have arrived and incur a service cost of  $f(S_Q)$  where  $S_Q = \{h_q : q \in Q\}$  is the set of types of  $Q$ . Let  $C_q$  be the time when request  $q$  was served. The *delay cost* of request  $q$  is  $d_q(C_q)$ .<sup>2</sup> The goal is to serve all requests while minimising the sum of the total service and delay costs.

**Approximating set functions.** The core idea underlying our framework is the following simple but powerful observation. Given two set functions  $f, g$  over the same ground set  $U$  of  $n$  elements, we say that  $g$  is an  $\alpha$ -*approximation* of  $f$  if  $f(S) \leq g(S) \leq \alpha f(S)$  for every  $S \subseteq U$ . Our observation is that for a given subadditive service function  $f$ , if we can  $\alpha$ -approximate  $f$  by a simpler service function  $g$ , then we can reduce any instance of Subadditive JRP with service function  $f$  to one with  $g$  instead. In fact, this leads us to the following simplification of the problem.

**Disjoint TCP Acknowledgement.** In Disjoint TCP Acknowledgement, we have a set  $U$  of  $n$  request types. We also have a partition of  $U$  into subsets  $S_1, \dots, S_k$  with costs  $c_1, \dots, c_k$ . For a subset  $S \subseteq U$ , we have  $f(S) = \sum_{i=1}^k c_i \cdot \mathbb{1}\{S_i \cap S \neq \emptyset\}$ . In other words, we pay  $c_i$  for every part  $S_i$  that intersects with  $S$ . Such a function is called a *disjoint service function*. Observe that when  $k = 1$ , this is equivalent to the TCP Acknowledgement problem; when  $k > 1$ , this corresponds to several independent instances of TCP Acknowledgement. The 2-competitive algorithm for TCP Acknowledgement of [27] can be easily extended to a 2-competitive algorithm for Disjoint TCP Acknowledgement (see Section 2.1).

We now state our main technical lemma.

► **Lemma 1.1** (Reduction Lemma). *If there exists a **disjoint** service function  $g$  that  $\alpha$ -approximates  $f$ , then there exists a non-clairvoyant algorithm that is  $2\alpha$ -competitive non-clairvoyant algorithm for every Subadditive JRP instance with service cost function  $f$ .*

A major advantage of our Reduction Lemma is that it reduces the task of designing and analyzing an online algorithm for a Subadditive JRP problem to the much cleaner task of showing that the corresponding service function  $f$  can be approximated by a disjoint service function well. In particular, this boils down to finding a partition of the set of request types  $U$  into subsets  $S_1, \dots, S_k$ , for some  $k$ , such that the following quantity is small

$$\max_{S \subseteq U} \frac{\sum_{i=1}^k f(S_i) \cdot \mathbb{1}\{S_i \cap S \neq \emptyset\}}{f(S)}.$$

For general Subadditive JRP, our key insight is that the problem of approximating an arbitrary service function  $f$  by a disjoint service function can be reformulated as the Universal Set Cover problem.

<sup>2</sup> We assume W.L.O.G. that  $d_q(a_q) = 0$ , i.e., serving a request immediately on arrival incurs no delay cost.

**Universal Set Cover (USC).** An instance of the Universal Set Cover (USC) problem consists of a universe  $U$  of  $n$  elements, a collection  $\mathcal{C}$  of subsets of  $U$ , and costs  $c(S)$  for each set  $S \in \mathcal{C}$ . A solution is an assignment  $a$  of each element  $e$  to a set  $a(e) \in \mathcal{C}$ . For any subset  $X \subseteq U$ , define  $a(X) = \{a(e) : e \in X\}$ . The *stretch* of the assignment  $a$  is  $\max_{X \subseteq U} c(a(X))/\text{OPT}(X)$  where  $\text{OPT}(X)$  is the cost of the optimal set cover of  $X$ .

Jia et al. [35] introduced the Universal Set Cover problem and showed that a  $O(\sqrt{n \log n})$ -stretch assignment can always be found efficiently. We show that this implies that any subadditive service function  $f$  can be approximated by a disjoint service function to within a factor of  $O(\sqrt{n \log n})$  (Lemma 2.2). Together with our Reduction Lemma, we get a deterministic  $O(\sqrt{n \log n})$ -competitive algorithm for Non-Clairvoyant Subadditive JRP, matching the current state-of-the-art [44].

### 1.1.2 MLA and Weighted Symmetric Subadditive JRP

One main technical contribution of the paper is to exploit the inherent structure of the MLA and Weighted Symmetric Subadditive JRP functions to show that they can be  $O(\sqrt{n})$ -approximated by disjoint service functions. We then employ the Reduction Lemma to prove tight  $O(\sqrt{n})$ -competitive ratios for the two corresponding problems.

**Multi-Level Aggregation.** In the Multi-Level Aggregation (MLA) problem, the service function  $f$  is defined by a rooted *aggregation tree*  $T$ , where each node corresponds to a different request type. Let  $r$  be the root of  $T$  and let  $c(v)$  be the cost of node  $v$  for each  $v \in T$ . For a subset  $V$  of nodes,  $f(V)$  is defined to be the total cost of the nodes in the minimal subtree connecting  $V$  to  $r$ .

► **Theorem 1.2.** *There exists an efficient deterministic  $O(\sqrt{n})$ -competitive algorithm for the Non-Clairvoyant Multi-Level Aggregation problem.*

To show the above result, given Lemma 1.1, our goal is to find a good partition  $P$  of the tree  $T$ 's nodes into subtrees and subforests (that we refer to as clusters). More precisely, let us use  $P$  to define a disjoint service function  $g$  where for each subset  $V$  of nodes of  $T$ ,  $g(V) = \sum_{C \in P: C \cap V \neq \emptyset} f(C)$ .

The crucial idea is to notice that since we aim for the gap of order at most  $\sqrt{n}$  between  $g$  and  $f$ , we can see it as  $g$  being assigned a budget of roughly  $\sqrt{n}f(V)$  to serve  $V$  for each subset  $V$  of  $T$ 's nodes. Since the cost that  $f$  incurred on a set  $V$  equals the cost of the minimal subtree connecting all the nodes in  $V$  to the root  $r$  of  $T$ , the value of  $g(V)$  cannot exceed  $\beta\sqrt{n}$  times this cost for some fixed  $\beta \in \mathbb{N}$ . To achieve this, we generate a partition consisting of two types of clusters. First are the subtrees rooted at “expensive” nodes. The intuition is that their cost alone multiplied by  $\alpha\sqrt{n}$  for some  $\alpha \in \mathbb{N}$  is enough to “cover” the cost of both their subtree and the path to  $r$ . The second type is the clusters that contain more than  $\sqrt{n}$  nodes, since there cannot be many of them.

**Weighted Symmetric Subadditive JRP.** In Weighted Symmetric Subadditive JRP, the service function  $f$  is a function of the total weight  $w(S) = \sum_{i \in S} w_i$  of the set of types being served. In particular,  $f$  is a monotone non-decreasing subadditive function with  $f(S) = f(w(S))$  and  $f(0) = 0$ , that satisfies that for every weights  $x, y$ ,  $f(x+y) \leq f(x) + f(y)$ . We refer to these functions as *weighted symmetric subadditive*.

► **Theorem 1.3.** *There exists an efficient deterministic  $O(\sqrt{n})$ -competitive algorithm for the Non-Clairvoyant Weighted Symmetric Subadditive Joint Replenishment problem.*

As in the MLA case, given Lemma 1.1, our goal is to devise a partitioning algorithm inducing a disjoint service function that  $O(\sqrt{n})$ -approximates the corresponding weighted symmetric subadditive service cost function. We first consider the special case where each weight equals 1. In this scenario, the service function  $f$  is symmetric and becomes a function of the cardinality of the set of types being served. Consequently, the partition of elements should ideally reflect this symmetry by ensuring equal-sized parts.

Determining the optimal size for each part involves striking a delicate balance. Larger sizes enable us to leverage the subadditivity of  $f$  but excessively large sizes incur higher costs for smaller sets. We demonstrate that selecting sets of size  $O(\sqrt{n})$  is the optimal tradeoff in worst-case scenarios. Notably, this partition remains effective across all symmetric subadditive functions simultaneously.

Extending this approach to the general case of weighted symmetric subadditive functions involves categorizing elements into weight classes based on powers of 2, ensuring approximate size equivalence, and then partitioning into sets of size  $\sqrt{n}$ . However, this approach risks generating an excessive number of sets. To address this issue, we devise a partitioning strategy that accommodates light-weight elements first. Then, for heavier-weight elements, we further partition by a factor of 2, provided it is feasible, to achieve a refined division.

### 1.1.3 Running time of Algorithms and Reductions

Regarding the running time of our algorithms, we stress that, in the case of Multi-Level Aggregation and Weighted Symmetric Subadditive JRP, the reductions are executed in polynomial time. However, the reduction for general subadditive functions is executed in exponential time, as we need to create a set for each subset of types.

### 1.1.4 Lower bounds on approximating subadditive service functions

Since Non-Clairvoyant MLA and Weighted Symmetric Subadditive JRP have a  $\Omega(\sqrt{n})$  lower bound [5, 39], the Reduction Lemma implies that MLA and Weighted Symmetric Subadditive JRP service functions do not admit  $o(\sqrt{n})$ -approximation by disjoint service functions. Nevertheless, we also give direct proofs in Sections 3 and 4, respectively. The latter provides a simpler alternative proof for the  $\Omega(\sqrt{n})$  lower bound for unweighted Universal Set Cover shown in [35]. We also show, in Proposition 5.1, that Jia et al.’s analysis of their Universal Set Cover algorithm [35] is tight. Thus, we need a different approach to  $o(\sqrt{n \log n})$ -approximate arbitrary subadditive service functions by disjoint service functions. Finally, in Proposition 5.2, we exhibit an MLA and Weighted Symmetric Subadditive JRP instance where Touitou’s algorithm [44] can only achieve an  $\Omega(\sqrt{n \log n})$ -approximation to the respective service cost functions.

## 1.2 Future Directions

Our work leaves several tantalizing open questions. The main open problem is whether subadditive service functions admit better than  $O(\sqrt{n \log n})$ -approximation by disjoint service functions. This would immediately improve the competitive ratio for general non-clairvoyant Subadditive JRP. It would also be interesting to find better approximations of other interesting subclasses such as XOS and submodular functions.

### 1.3 Further Related Work

**Network Design with Delay.** Network Design with Delay is very closely related to Subadditive JRP. In Network Design with Delay, we are given a universe of  $n$  request types and  $m$  items with costs. Each request type  $h$  has a corresponding upwards-closed collection  $\mathcal{C}_h$  of subsets of items that satisfy it. At any point in time, the algorithm can transmit a set of items. A request of type  $h$  is served by a transmission that contains some subset in  $\mathcal{C}_h$ . Some specific problems are Set Cover with Delay [22, 3, 43], Facility Location [7, 8, 13] and other network design problems [7, 8]. Network Design with Delay is equivalent to Subadditive JRP as the optimal cost of satisfying a subset of request types is subadditive, and Subadditive JRP can be formulated as Set Cover with Delay with exponentially many sets.

**Online problems with delay.** There has been a lot of work on other online problems with delay as well. In Online Service with Delay, we are given one or multiple servers on a metric space. Requests arrive on points of the metric space and are served when a server is moved to their location. In Online Matching with Delay, we are given an underlying metric space. Requests arrive on points of the metric space and are served when they are matched. Most of the work on Online Service with Delay [5, 33, 34, 17, 38, 45] and Online Matching with Delay [28, 2, 1, 16, 4, 15, 29, 6, 41, 24] has been in the clairvoyant setting. Nevertheless, non-clairvoyant algorithms have been designed for Online Service with Delay [38] and Online Matching with Delay [24].

**Approximating subadditive functions.** The approximation of subadditive functions has been a focal point of research, at least since the introduction of the complement-free hierarchy of functions introduced in [40]. This consists of the class of submodular function, which is strictly contained into the XOS class, which in turn is strictly contained in the general subadditive class.<sup>3</sup> As for approximation, it is known that XOS approximates subadditive within a factor of  $O(\log(n))$ , which is tight [25, 10]. The approximability gap between Submodular and XOS is  $\Theta(\sqrt{n})$  [9, 31]. In a similar vein, [26] prove that Gross-Substitute functions (first introduced in [37]) cannot approximate submodular set functions within a factor better than  $\Omega\left(\frac{\log(n)}{\log \log(n)}\right)$ . In the context of *symmetric* function approximation, [30] show that symmetric subadditive, symmetric XOS and symmetric submodular<sup>4</sup> functions are all 2-close to each other, which is tight.

## 2 Subadditive Joint Replenishment

In this section, we prove our Reduction Lemma (Lemma 1.1) and apply it to Subadditive JRP.

### 2.1 Reduction Lemma

We begin by showing that there is a simple deterministic 2-competitive algorithm for Disjoint TCP Acknowledgement via a straightforward extension of the classic algorithm for TCP Acknowledgement of [27].

<sup>3</sup> Several other classes within the submodular class have been considered (e.g. additive, unit-demand, Gross-Substitutes).

<sup>4</sup> We use the term symmetric submodular to indicate functions that are (monotone) concave in the size of the set.

In the following, we use  $\lambda$  to denote a service and  $Q_\lambda$  to be the set of request types transmitted by  $\lambda$ . We also use OPT to mean both the optimal solution and the cost of the optimal solution.

► **Lemma 2.1.** *There is a deterministic 2-competitive algorithm for Disjoint TCP Acknowledgement.*

**Proof.** Suppose there is a partition of  $H$  into subsets  $S_1, \dots, S_k$  with costs  $c_1, \dots, c_k$  and  $f(S) = \sum_{i=1}^k c_i \cdot \mathbb{1}\{S_i \cap S \neq \emptyset\}$ . Our algorithm works as follows: for each set  $S_i$ , transmit  $S_i$  whenever the pending requests in  $S_i$  have accumulated a total delay equal to  $c_i$ .

It is clear that the total service cost of the algorithm is at most its total delay cost. We now show that the latter is at most the cost of the optimal solution. To this end, let us consider the cost of the optimal solution. Suppose that the optimal solution makes a set of services  $\Lambda^*$ . Let  $\Lambda_i^*$  denote the subset of services that transmit a request type in  $S_i$ . The total service cost of the optimal solution is then

$$\sum_{\lambda \in \Lambda^*} f(Q_\lambda) = \sum_{\lambda \in \Lambda^*} \sum_{i=1}^k c_i \cdot \mathbb{1}\{S_i \cap Q_\lambda \neq \emptyset\} = \sum_{i=1}^k c_i \cdot |\Lambda_i^*|.$$

Define  $d_q^{\text{OPT}}$  and  $d_q^{\text{ALG}}$  to be the delay cost of  $q$  in the optimal solution and algorithm's solution, respectively. Let  $\text{OPT}_i = c_i \cdot |\Lambda_i^*| + \sum_{q: h_q \in S_i} d_q^{\text{OPT}}$ . This is the total cost that OPT incurs on requests on  $S_i$ . Observe that  $\text{OPT} = \sum_{i=1}^k \text{OPT}_i$ .

We now show that  $\sum_{q: h_q \in S_i} d_q^{\text{ALG}} \leq \text{OPT}_i$  for each set  $S_i$ . Suppose that the algorithm transmits  $S_i$  at times  $t_1, \dots, t_\ell$ . Since every request must be served eventually, no request with type in  $S_i$  arrives after  $t_\ell$ . Consider the intervals  $[0, t_1], (t_1, t_2], \dots, (t_{\ell-1}, t_\ell]$ . By construction, the delay cost of the algorithm is exactly  $\ell c_i$ . For each interval  $I$ , let  $Q(I)$  denote the requests with types in  $S_i$  that arrived during the interval. During  $I$ , the optimal solution either transmits a type in  $S_i$  or incurs a delay cost of  $c_i$  on the requests in  $Q(I)$ . Since the intervals are disjoint,  $\text{OPT}_i \geq \ell c_i$ , as desired.

The lemma now follows from the fact that the total service cost of the algorithm is exactly its delay cost, which in turn is at most OPT. ◀

We are now ready to prove the Reduction Lemma which we restate here.

► **Lemma 1.1 (Reduction Lemma).** *If there exists a **disjoint** service function  $g$  that  $\alpha$ -approximates  $f$ , then there exists a non-clairvoyant algorithm that is  $2\alpha$ -competitive non-clairvoyant algorithm for every Subadditive JRP instance with service cost function  $f$ .*

**Proof.** Lemma 2.1 implies that it suffices to reduce the Subadditive JRP instance to an instance of Disjoint TCP Acknowledgement losing at most a factor of  $\alpha$ . Let  $Q$  be the set of requests of the Subadditive JRP instance and let  $\text{OPT}^f$  denote the cost of the optimal solution. Our reduction creates an instance of Disjoint TCP Acknowledgement with the same set of requests but with service cost function  $g$ . Let  $\text{OPT}^g$  denote the cost of the optimal solution to the instance of Disjoint TCP Acknowledgement. We now show that  $\text{OPT}^f \leq \text{OPT}^g \leq \alpha \text{OPT}^f$ . Let  $\Lambda$  be a feasible solution to  $Q$ ,  $c^f(\Lambda)$  be its cost in the Subadditive JRP instance and  $c^g(\Lambda)$  be its cost in the Disjoint TCP Acknowledgement instance. The delay cost of  $\Lambda$  is the same in both instances. The service cost of  $\Lambda$  in the Subadditive JRP instance has cost  $\sum_{\lambda \in \Lambda} f(Q_\lambda)$  and in the Disjoint TCP Acknowledgement instance, it has cost  $\sum_{\lambda \in \Lambda} g(Q_\lambda)$ . Since  $g$   $\alpha$ -approximates  $f$ , we get that  $c^f(\Lambda) \leq c^g(\Lambda) \leq \alpha c^f(\Lambda)$ . This implies that  $\text{OPT}^f \leq \text{OPT}^g \leq \alpha \text{OPT}^f$ , as desired. ◀

## 2.2 Applying the Reduction Lemma to Subadditive JRP

We use the Reduction Lemma proved earlier to give a simple deterministic  $O(\sqrt{n \log n})$ -competitive algorithm for Non-Clairvoyant Subadditive JRP. The main insight is to reduce the problem of showing that an arbitrary service function  $f$  can be approximated by a disjoint service function to the Universal Set Cover problem.

► **Lemma 2.2.** *Suppose every instance of USC admits a  $\alpha$ -stretch assignment. Then every subadditive service function  $f$  can be  $\alpha$ -approximated by some disjoint service function  $g$ .*

**Proof.** We will construct an instance of USC and use the  $\alpha$ -stretch assignment to construct  $g$ . Consider the instance of USC with universe  $U = H$ ,  $\mathcal{C} = 2^H$ , and  $c(S) = f(S)$  for every  $S \in \mathcal{C}$ . Note that  $\text{OPT}(S) = f(S)$  since  $f$  is monotone non-decreasing and subadditive.

Let  $a$  be an  $\alpha$ -stretch assignment for this USC instance. Suppose  $a(U) = \{S_1, \dots, S_k\}$ . Since  $a$  maps each element to a set containing it, we have that  $a^{-1}(S_i) \subseteq S_i$ . Moreover,  $f$  is monotone non-decreasing, so we can assume W.L.O.G. that  $a^{-1}(S_i) = S_i$ ;<sup>5</sup> thus  $S_1, \dots, S_k$  are disjoint and partition  $H$ . Define the disjoint service function  $g$  with the partition  $\{S_1, \dots, S_k\}$  and costs  $c_1, \dots, c_k$  where  $c_i = f(S_i)$ . Observe that  $g(S) = c(a(S)) \geq \text{OPT}(S) = f(S)$ . Since  $a$  has  $\alpha$ -stretch, we get that for every  $S$ ,  $f(S) \leq g(S) \leq \alpha f(S)$ . ◀

Jia et al. [35] showed that every instance of USC has a  $O(\sqrt{n \log n})$ -stretch assignment. Together with the above lemma, we get the following theorem.

► **Theorem 2.3.** *For every subadditive service function  $f$ , there is a disjoint service function  $g$  that  $O(\sqrt{n \log n})$ -approximates  $f$ .*

Combining this with the Reduction Lemma yields the desired theorem.

► **Theorem 2.4.** *There is a deterministic  $O(\sqrt{n \log n})$ -competitive algorithm for Non-Clairvoyant Subadditive JRP.*

## 3 Multi-Level Aggregation

In this section, we consider the Multi-Level Aggregation (MLA) problem. Let  $T = (U, E)$  be a rooted tree defined over the universe  $U$  of  $n$  request types and let  $c : U \mapsto \mathbb{R}_{\geq 0}$  be a cost function assigning weights to the nodes. We recall that  $c$  determines the service function  $f : 2^U \mapsto \mathbb{R}_{\geq 0}$  for this problem as  $f$  assigns to each subset of nodes  $V \subseteq U$  the cost of the minimal subtree that connects all the nodes in  $V$  to the root  $r$ . Here, we prove that for every MLA service function  $f$ , there exists a disjoint service function  $g : 2^U \mapsto \mathbb{R}_{\geq 0}$  that  $O(\sqrt{n})$ -approximates  $f$ . In other words, we show that for every MLA instance  $(T, c)$ , there exists a partition  $P_1, \dots, P_k$  of nodes of  $T$  for some  $k$  (which defines  $g(X) = \sum_{i \in [k]} f(P_i) \cdot \mathbb{1}\{P_i \cap X \neq \emptyset\}$  for all  $X \subseteq U$ ), such that for all  $V \subseteq U$ , it holds that  $g(V)/f(V) \leq O(\sqrt{n})$ . Moreover, one can find such a partition in polynomial time.

### 3.1 Notation and Algorithm Overview

Throughout this section, we assume tree  $T$  is the current MLA instance that we work with and thus is known from the context. In what follows, we refer to the *maximal subtree* of  $T$  rooted at node  $v$  and to the *path* connecting  $v$  to the root  $r$  by simply writing  $T(v)$  and  $R(v)$ , respectively. Moreover, to denote these objects with node  $v$  excluded, we use  $T_o(v)$  and  $R_o(v)$ . Finally, we let  $C(v)$  be the set of  $v$ 's *children* in  $T$ .

<sup>5</sup> Otherwise, we can assign the elements in the preimage of  $S_i$  under  $a$ , i.e.,  $a^{-1}(S_i)$ , to the preimage itself.

■ **Figure 1** In the first three figures we show the costs of serving the orange nodes. The first figure corresponds to the cost of  $f$  on these nodes. The following two figures show the cost of  $g$  on these nodes, assuming that they belong to different clusters  $A$  and  $B$ . Fourth figure shows the set of active nodes in the tree (colored in green) after  $T(v)$  gets clustered. Fifth figure presents the setting in Proposition 3.7.

First, we present the idea behind our approach. Recall that our goal is to find a partition  $P_1, \dots, P_k$  of nodes of  $T$  such that the gap between the values  $f(V)$  and  $g(V)$  is at most of order  $\sqrt{n}$  for all the sets  $V \subseteq U$ . Here,  $f(V)$  is the cost of minimal subtree  $T_V$  of  $T$  that connects all the nodes in  $V$  to the root, as stated before. On the other hand,  $g(V)$  needs to cover the costs of all the parts in  $P$  that intersect with  $V$ . For instance, if  $V$  intersects exactly two parts  $A$  and  $B$  in  $P$ , then  $g(V) = f(A) + f(B)$ . Although these parts themselves are disjoint by the definition of partition  $P$ , as we pay for each of them separately in  $g$  (by paying for set  $A$ , we mean generating the cost of  $f(A)$ ), we incur not only the costs of their nodes  $c(A)$  and  $c(B)$  but also the costs of the paths that connect them to the root  $r$  (see Figure 1).

Note that this process can cause us to incur two types of additional costs with respect to the optimal value  $f(V)$ . First, both parts  $A$  and  $B$  may contain not only the nodes in  $V$  but also their neighbors, for which we need to pay as well. Second, as we pay for each part separately, we may be forced to pay for some nodes on the paths to the root multiple times (see Figure 1).

Since  $f(V)$  is equal to the cost of the nodes in  $T_V$  and we aim for  $g$  to be  $\sqrt{n}$ -approximation of  $f$ , the intuition is that  $g$  can afford to pay the cost of each node in  $T_V$  roughly  $\sqrt{n}$  times (as this gives the desired ratio). This observation provides the foundations for our algorithm. Let us remark that at the beginning, all the nodes in  $T$  are unpartitioned, i.e.,  $P = \emptyset$ . Our algorithm revolves around two procedures. The first one can be seen as assigning each node  $v$  in  $T$  a budget of  $\alpha\sqrt{n} \cdot c(v)$  for some  $\alpha \in \mathbb{N}$ . A vertex  $v$  may then use such a budget to create a new part  $K$  in the partition. We allow  $v$  to generate only one form of a *cluster*, i.e., a part to be included in  $P$ , that consists of all the unpartitioned nodes in its subtree  $T(v)$ . Furthermore, for such a part  $K$  to be added to  $P$ , it needs to hold that the costs of (the unpartitioned nodes in)  $T(v)$  and  $R(v)$  both fit into  $v$ 's budget. If we manage to add  $K$  to  $P$ , we call both node  $v$  and cluster  $K$  *heavy*.

Whenever the first procedure cannot be applied, i.e., there are no vertices that can generate heavy clusters from the unpartitioned nodes, we run the second procedure. The idea then is to find a subtree (or a family of subtrees) of size roughly  $\sqrt{n}$  (details to be presented later) and group them together into a new part in the partition. We call this part a *light cluster*. In case there are nodes that become heavy after this action (as their descendants got clustered), we go back to the first procedure, which starts a new iteration of the main algorithm.

Notice that the idea behind the second procedure is to upper bound the number of times we need to pay the cost of the paths connecting the clusters to the root  $r$ . Since  $T$  has  $n$  nodes and each light cluster is of size close to  $\sqrt{n}$ , we can only create roughly  $\sqrt{n}$  such clusters. Thus, even when  $V$  intersects all the light clusters, we pay for the nodes in  $T_V$  at most  $O(\sqrt{n})$  times, which we can afford. It remains to estimate the cluster costs, which follow in the next section.

### 3.2 MLA Partitioning Algorithm

**Heavy clusters.** Let us first present two definitions. Here, we assume that whenever we are given a partially created partition  $\tilde{P}$  of nodes of an MLA tree  $T$ , then the set of nodes it already partitioned, i.e.,  $V(\tilde{P}) = \bigcup \tilde{P}$ , does not disconnect  $T$ , i.e., tree  $T' = T \setminus \bigcup \tilde{P}$  is a subtree of  $T$ .

► **Definition 3.1.** Let  $T$  be a tree given in an MLA instance, denote the set of its nodes by  $U$ , and let  $\tilde{P}$  be a partially created partition of  $U$  (i.e.,  $V(\tilde{P}) = \bigcup \tilde{P}$  is a proper subset of  $U$ ). Then we call all the nodes that are not partitioned yet, i.e., belong to  $U \setminus V(\tilde{P})$ , active (see Figure 1). We use the notation of  $V|_{act}$  to restrict any subset  $V$  of nodes in  $T$  to the nodes that are active.

► **Definition 3.2.** Let  $(T, c)$  be an MLA instance, and let  $\tilde{P}$  be a partially created partition of  $T$ 's nodes. We say that an active node  $v$  is heavy if the costs of path  $R(v)$  and subtree  $T_{act}(v)$  are at most  $4\sqrt{n} \cdot c(v)$  each. If we extend  $\tilde{P}$  by adding  $T_{act}(v)$ , we call this new part a heavy cluster.

Now, we can prove a simple fact about heavy clusters.

► **Proposition 3.3.** Let  $(T, c)$  be an MLA instance. Take any partition  $P$  of nodes of  $T$  and let  $P_{h,1}, \dots, P_{h,s}$  be a sublist of all heavy clusters in  $P$ . We denote their roots by  $v_{h,1}, \dots, v_{h,s}$ , respectively, and the set containing them by  $V_h$ . Then, it holds that  $\sum_{i=1}^s f(P_{h,i}) \leq 8\sqrt{n} \cdot f(V_h)$ .

**Proof.** By Definition 3.2, we have that for each node  $v_{h,i}$  the following is satisfied:  $c(P_{h,i}) \leq 4\sqrt{n} \cdot c(v_{h,i})$  and  $c(R(v_{h,i})) \leq 4\sqrt{n} \cdot c(v_{h,i})$ . The first inequality here comes from the fact that cluster  $P_{h,i}$  was the set of all active nodes (Definition 3.1) contained in the subtree  $T(v_{h,i})$  at the moment it was created (i.e., it was  $T_{act}(v_{h,i})$ ). Hence, it holds that

$$\begin{aligned} f(P_{h,i}) &= c(P_{h,i}) + c(R(v_{h,i})) \leq c(P_{h,i}) + c(R(v_{h,i})) \\ &\leq 4\sqrt{n} \cdot c(v_{h,i}) + 4\sqrt{n} \cdot c(v_{h,i}) = 8\sqrt{n} \cdot c(v_{h,i}), \end{aligned} \quad (1)$$

where the first equality comes from the fact that  $P_{h,i}$  is a subtree, which means that the minimal tree containing all its nodes and the root  $r$  is only missing the path from  $v$  to  $r$  (with  $v$  excluded as we already counted it in the cluster). Moreover, let us notice that  $f(V_h) \geq \sum_{i=1}^s c(v_{h,i})$ , as it is the cost of the minimal tree containing all the nodes  $v_{h,i}$ . Thus, to obtain the desired inequality, we only need to sum (1) over all the heavy clusters and then apply the inequality above. ◀

**Light clusters.** Here, we present a procedure that generates a light cluster.

► **Definition 3.4.** Let  $(T, c)$  be an MLA instance, and let  $\tilde{P}$  be a partially created partition of  $T$ 's nodes. We say that a subset  $K$  of nodes of  $T_{act}$  is a light cluster if (1) its size fits into the range  $I(n) := [\sqrt{n}, 2\sqrt{n}]$ , (2) it is either a maximal subtree in  $T_{act}$  or a collection of maximal subtrees having the same parent, and (3)  $T_{act}$  does not contain any heavy nodes.<sup>6</sup> In case  $T_{act}$  is of size smaller than  $\sqrt{n}$ , and we set  $K = T_{act}$ , we drop the first condition and still call  $K$  a light cluster.

Given the definition above, we present Algorithm 1 that shows how to find such a cluster.

<sup>6</sup> This third condition is for analysis purposes only and the property giving the name to *light* clusters.

■ **Algorithm 1** MLA Light Cluster Search.

**Input:** MLA tree  $T$  with some nodes marked active ( $T_{act}$  is a subtree of  $T$  containing its root  $r$ )

**Output:** light cluster formed of the nodes in  $T_{act}$

---

```

1: if  $|T_{act}| \leq 2\sqrt{n}$ 
2:   return  $T_{act}$ 
3:  $u := r$ 
4: while there exist a node  $v \in C_{act}(u)$  such that  $|T_{act}(v)| > 2\sqrt{n}$ 
5:    $u := v$ 
6: if there exist a node  $v \in C_{act}(u)$  such that  $|T_{act}(v)| \geq \sqrt{n}$  then
7:   return  $T_{act}(v)$ 
8: else
9:   denote all the elements in  $C_{act}(u)$  by  $v_1, v_2, \dots, v_j$  for some  $j$ 
10:  set iterator  $i = 1$  and initialize a new cluster  $V$  with an empty set
11:  while  $|V| < \sqrt{n}$ 
12:    add  $T_{act}(v_i)$  to  $V$ 
13:    increment  $i$  by 1
14:  return  $V$ 

```

---

► **Proposition 3.5.** *If there are no heavy nodes in  $T_{act}$  (see condition (3) in Definition 3.4), then Algorithm 1 finds a light cluster in  $T_{act}$ .*

**Proof.** Notice that we start the search of a new cluster by checking whether the size of  $T_{act}$  (the subtree containing all the active nodes in  $T$ ) is smaller or equal to  $2\sqrt{n}$  (line 1). If so, we return the whole tree  $T_{act}$  since it fits into the description given in the last sentence of Definition 3.4. Otherwise, we set  $r$  to be the current node we are at, which we denote by  $u$  (line 3). Then, we go through the while loop from line 4 to 5, each time picking a child  $v$  of the current node  $u$  such that the subtree  $T_{act}(v)$  is of size greater than  $2\sqrt{n}$ . If such a node exists, we move to it, setting  $u = v$ , and we leave the while loop otherwise.

In the second case, we know that, as we go to line 6, two conditions are satisfied. First, the size of the subtree  $T_{act}(u)$  rooted at the current node  $u$  is at least  $2\sqrt{n}$ . Indeed, we either stayed at the root node, not satisfying the condition in the if statement in line 1, or we further went from  $r$  through a sequence of its descendants, each having a subtree of size greater than  $2\sqrt{n}$ . Second, none of  $u$ 's children has a subtree of size greater than  $2\sqrt{n}$ , as we already left the while loop.

Now, in line 6, we check whether there exists a child  $v$  of the current node, which subtree  $T_{act}(v)$  is of size at least  $\sqrt{n}$ . If so, we return  $T_{act}(v)$ , as it satisfies the conditions to be a light cluster. Otherwise (line 8), we iterate through  $u$ 's children  $v_i$  (line 11) and add the nodes contained in their subtrees  $T_{act}(v_i)$  to a set  $V$ . We stop at the moment when the size of  $V$  becomes at least  $\sqrt{n}$  and return  $V$  as a new cluster. It is easy to notice that in the while loop, we indeed need to pass the  $\sqrt{n}$  size threshold, as  $|T_{act}(u)| > 2\sqrt{n}$ . Moreover, we know that before we added the nodes of the last subtree  $T'$  to  $V$ ,  $V$  had a size smaller than  $\sqrt{n}$ . Since  $|T'| < \sqrt{n}$ , we have that the whole group is of size smaller than  $2\sqrt{n}$ . ◀

**Main algorithm.** Before we describe the partitioning algorithm, let us introduce a helper function. We define method `cluster(V)` to group all the elements of  $V$  together and include them as a new part in the partition. Let us also emphasize that after this call, all the elements in  $V$  become inactive. With the above notation, we can formalize our approach as presented in Algorithm 2.

---

**Algorithm 2** MLA Partitioning Algorithm.

---

**Input:** MLA instance  $(T, c)$ **Output:** partition  $P$  of the nodes of  $T$ 

```

1: initialize an empty partition  $P$ 
2: while  $T_{act}$  is not empty
3:   while there exist a heavy node  $v \in T_{act}$ 
4:     cluster $(T_{act}(v))$ 
5:   if  $T_{act}$  is empty
6:     break
7:   apply Algorithm 1 to find a light cluster  $V$  in  $T_{act}$ 
8:   cluster $(V)$ 
9: return  $P$ 

```

---

As mentioned in the first part of this section, the main partitioning algorithm runs heavy and light cluster searches in a loop. In the first step, it iteratively finds the heavy clusters in the tree  $T_{act}$  determined by the already created partition (lines 3 to 4). Then, if tree  $T$  is not yet partitioned (condition in line 5 does not hold), it goes to the second step that finds one light cluster and adds it to the partition (lines 7 to 8). After this point, it goes to the initial step and loops.

Let us emphasize that during the whole partitioning procedure, the set  $T_{act}$  of all active elements in  $T$  forms a proper subtree containing the root  $r$  of  $T$ . Indeed, in the beginning,  $T_{act} = T$  and all the **cluster** calls truncate one or more maximal subtrees from  $T_{act}$ . Now, given Algorithm 2, we go back to proving the properties of light clusters.

► **Proposition 3.6.** *Let  $T$  be an MLA tree rooted at some node  $r$  and let  $P$  be the partition of nodes of  $T$  created by Algorithm 2. We denote all the light clusters in  $P$  by  $P_{\ell,1}, P_{\ell,2}, \dots, P_{\ell,t}$  and require them to be listed in the creation order. Then, it holds that there are at most  $\sqrt{n} + 1$  parts  $P_{\ell,i}$ .*

**Proof.** Notice that by the definition, the only light cluster that can have a size smaller than  $\sqrt{n}$  is the one containing the root  $r$ . Thus, all the light clusters created before, i.e., at least  $t - 1$  of them, have the size at least  $\sqrt{n}$ . Since there are  $n$  nodes in tree  $T$ , we get that there are at most  $n/\sqrt{n} = \sqrt{n}$  such clusters. Thus,  $t \leq \sqrt{n} + 1$ , which concludes the proof. ◀

In the remaining part of this section, we refer to the clusters created in lines 2, 7 of Algorithm 2, i.e., the ones that consist of a single subtree, as the light clusters of type I. We call the light clusters consisting of forests (created in line 14) the light clusters of type II. We prove that the cost function  $c$  satisfies the following properties. Here, we overuse the notation of  $c$  and extend it to the subsets as well, i.e., for any  $V \subseteq U$  we set  $c(V) = \sum_{v \in V} c(v)$ .

► **Proposition 3.7.** *Let  $(T, c)$  be an MLA instance and let  $P$  be the partition obtained on it by Algorithm 2. Take any light cluster  $K$  in  $P$  and denote by  $r_K$  the root of  $K$  if it is a cluster of type I. Otherwise, if  $K$  is a cluster of type II, we use  $r_K$  to denote the parent node of the forest contained in  $K$ . Then it holds that  $c(P(r_K)) \geq c(K)$ .*

**Proof.** Without loss of generality, assume that  $K$  is of type I. Let  $w$  be the node in  $K$  that has the highest cost. By Definition 3.4, we know that  $|K| \leq 2\sqrt{n}$ . Hence, by an averaging argument, we have  $c(w) \geq c(K)/(2\sqrt{n})$ , which implies  $2\sqrt{n} \cdot c(w) \geq c(K)$ . Now, assume by contradiction that  $c(P(r(K))) < c(K)$ . Then, if we split the path from  $w$  to  $r$  into two parts by cutting it on the node  $r_K$ , we got  $c(P(w)) = c(P(w) \cap K) + c(P_o(r_K))$ . Since  $c(P(w) \cap K) \leq c(K)$  and  $c(P(r_K)) \leq c(K)$  by our assumption, we get that  $c(P(w)) \leq$

$2c(K) \leq 2 \cdot 2\sqrt{n} \cdot c(w) = 4\sqrt{n} \cdot c(w)$ . However, this means that  $w$  is a heavy node, which contradicts the initial assumption. Thus, it holds that  $c(P(r_K)) \geq c(K)$ . The proof for type II follows the same steps.  $\blacktriangleleft$

► **Corollary 3.8.** *Let us subsume the notation and the conditions of Proposition 3.7. Then, it holds that  $f(K) \leq 2f(r_K)$ .*

**Proof.** Notice that for type I cluster  $K$ ,  $f(K)$  consists of the cost of  $K$  and the cost of the path connecting it to the root  $r$  of  $T$  (to be precise, excluding  $r_K$  from this path, as we already count its cost in the cluster). Thus, the following holds

$$f(K) = c(K) + c(P_o(r_K)) \leq c(P(r_K)) + c(P_o(r_K)) \leq 2c(P(r_K)) = 2f(r_K),$$

where the first inequality is implied by Proposition 3.7, the second one from the fact that we added the cost of  $r_K$  to the right side, and the last inequality is by the definition of  $f$ .  $\blacktriangleleft$

Given the above, we can prove the main theorem of this section.

► **Theorem 3.9.** *For any MLA service function  $f$ , there exists a disjoint service function  $g$  that  $O(\sqrt{n})$ -approximates  $f$ . It can be found in time polynomial w.r.t. the MLA instance defining  $f$ .*

**Proof.** Let  $(T, c)$  be the MLA instance that defines  $f$ , and let  $U$  be the set of nodes in  $T$ . The idea is to prove that the partition  $P = \{P_1, P_2, \dots, P_k\}$  generated on  $T$  by Algorithm 2 induces a set function  $g(V) = \sum_{i \in [k]} f(P_i) \mathbb{1}\{P_i \cap V \neq \emptyset\}$  on all subsets  $V \subseteq U$  that is an  $O(\sqrt{n})$ -approximation to  $f$ . The function  $g$  is a disjoint service function by design.

For this purpose, we need to show that  $\max_{V \subseteq U} g(V)/f(V)$  is of order at most  $\sqrt{n}$ . Let us note that in our case,  $f(V)$  is just the cost of the minimal subtree connecting  $V$  to the root. Thus, for any subset  $V'$  of  $V$  it holds that  $f(V') \leq f(V)$ .

Let  $V \subseteq U$  be any subset of nodes and let  $P_{h,1}, \dots, P_{h,s}$  and  $P_{\ell,1}, P_{\ell,2}, \dots, P_{\ell,t}$  be the lists of all the heavy and light clusters that intersect  $V$ , respectively. We also denote the roots of the heavy clusters by  $v_{h,1}, \dots, v_{h,s}$ , respectively, and the set containing them by  $V_h$ . Similarly, we use the convention from Proposition 3.7 to define light cluster nodes. For  $P_{\ell,i}$ , we denote its root by  $r_{\ell,i}$ .

By Proposition 3.3, it holds that  $\sum_{i=1}^s f(P_{h,i}) \leq 8\sqrt{n} \cdot f(V_h)$ . Moreover, since  $V$  intersects all these heavy clusters, it either contains their roots or some nodes that are their descendants. Thus, the minimal subtree connecting  $V$  to the root  $r$  contains the minimal subtree connecting  $V_h$  to the root  $r$ . Hence,

$$\sum_{i=1}^s f(P_{h,i}) \leq 8\sqrt{n} \cdot f(V_h) \leq 8\sqrt{n} \cdot f(V). \quad (2)$$

Now, for each light cluster  $P_{\ell,i}$ , we notice that since  $V$  intersects it, the minimal tree connecting  $V$  to  $r$  contains the path from  $r_{\ell,i}$  to  $r$ . Thus,  $f(V) \geq f(r_{\ell,i})$  and by Proposition 3.3, we get that

$$f(P_{\ell,i}) \leq 2f(r_{\ell,i}) \leq 2f(V) \quad (3)$$

for each  $\ell \in [t]$ . Note that  $g(V) = \sum_{K \in P: V \cap K \neq \emptyset} f(K)$ . Combining inequalities 2 and 3, we obtain that

$$\begin{aligned} \frac{g(V)}{f(V)} &= \frac{\sum_{K \in P: V \cap K \neq \emptyset} f(K)}{f(V)} = \frac{\sum_{i=1}^s f(P_{h,i}) + \sum_{i=1}^t f(P_{\ell,i})}{f(V)} \leq \frac{8\sqrt{n} \cdot f(V) + \sum_{i=1}^t 2f(V)}{f(V)} \\ &\leq \frac{8\sqrt{n} \cdot f(V) + 2(\sqrt{n} + 1) \cdot f(V)}{f(V)} = 10\sqrt{n} + 2, \end{aligned}$$

with the last inequality implied by Proposition 3.6. This concludes the proof that  $g$  is an  $O(\sqrt{n})$ -approximation to  $f$ .

## 12:14 Universal Optimization for Non-Clairvoyant Subadditive Joint Replenishment

Finally, it is easy to notice that the algorithm runs in polynomial time. We can define a dynamic structure over the tree  $T$  that, for each node  $v$ , stores its subtree and path costs ( $c(T(v))$ ,  $c(P(v))$ ), together with the size  $|T(v)|$  of its subtree. Updates on such a structure take at most polynomial time in  $n$  (as we create a cluster, we go from the cluster root to the root of  $T$ , updating the data on all the nodes on the path, which is of length at most  $n$ ). With such a structure, checking whether a node is heavy or going through a path from  $r$  in search of a light cluster also takes at most linear time in  $n$ . ◀

Thus, by Lemma 1.1, we get Theorem 1.2. The result of Theorem 3.9 is tight:

► **Proposition 3.10.** *There exists a decreasing MLA instance  $T, c$  with  $n$  nodes, such that for every partition  $P_1, \dots, P_k$  of  $T$  for some  $k$ , there exists a non-empty set  $S \subseteq T$  such that*

$$\frac{\sum_{i \in [k]} f(P_i) \mathbb{1}\{S \cap P_i \neq \emptyset\}}{f(S)} = \Omega(\sqrt{n}).$$

**Proof.** Consider the tree  $T$  with a root  $r$  and  $n - 1$  children of  $r$  denoted by  $v_1, \dots, v_{n-1}$ . The cost  $c$  is such that  $c(r) = \sqrt{n}$ , while for all  $i \in [n - 1]$ ,  $c(v_i) = 1$ . Now, consider any partition  $P_1, \dots, P_k$ . If  $k > \sqrt{n}$ , then consider a set  $S$  that intersects each  $P_i$  exactly once. Thus,  $f(S) \leq \sqrt{n} + k \leq 2k$ , while  $\sum_{i \in [k]} f(P_i) \mathbb{1}\{S \cap P_i \neq \emptyset\} \geq k \cdot \sqrt{n}$ , which proves this case. Else ( $k \leq \sqrt{n}$ ), consider a set  $S$  that intersects  $P_i$  once if and only if  $|P_i| < \sqrt{n}/2$  (otherwise does not intersect at all). It holds that  $f(S) \leq 2\sqrt{n}$  because one has  $\sqrt{n}$  from  $r$  and  $\sqrt{n}$  intersections with  $P_i$ 's in the worst case, while

$$\sum_{i \in [k]} f(P_i) \mathbb{1}\{S \cap P_i \neq \emptyset\} \geq n - \sum_{i \in [k]} |P_i| \cdot \mathbb{1}\{S \cap P_i = \emptyset\} \geq n - k\sqrt{n}/2 \geq n/2,$$

which concludes the proof. ◀

## 4 Weighted Symmetric Subadditive Joint Replenishment

In this section, we study Weighted Symmetric Subadditive JRP. We have a set  $U$  of  $n$  request types with weights  $w(\{j\}) = w_j$  for each  $j \in U$ . Let  $f$  be the set function over  $U$ : In this setting, we have that the service cost of a set  $S$  only depends on the total weight of the elements belonging to  $S$ , as opposed to the identity of those elements. Formally,  $f(S) = f(w(S))$ , where function  $f$  is now intended as a monotone non-decreasing subadditive function of weights of a set with  $f(0) = 0$ , and for every two weights  $x, y$ , it holds that  $f(x + y) \leq f(x) + f(y)$ . For brevity, we call these functions *weighted symmetric subadditive*. Our goal is to show that for every weighted symmetric subadditive service function  $f$  on  $U$ , there exists a partition of  $U$  into sets  $S_1, \dots, S_k$  for some  $k$ , such that the disjoint service function  $g : U \rightarrow \mathbb{R}_{\geq 0}$  defined by this partition where  $g(S) = \sum_{i=1}^k f(S_i) \cdot \mathbb{1}[S \cap S_i \neq \emptyset]$  satisfies  $g(S) \leq O(\sqrt{n})f(S)$  for every  $S \subseteq U$ .

We begin, in Section 4.1, by analyzing a special case of unweighted symmetric subadditive service costs. Namely, where the weight of each element is 1, and thus,  $w(S) = |S|$ : These functions are simply referred to as *symmetric subadditive*. We achieve a tight  $\Theta(\sqrt{n})$ -stretch with a simple partitioning algorithm (partition into  $\sqrt{n}$  sets of size  $\sqrt{n}$  each), and this serves as a warm-up to the weighted symmetric subadditive case presented in Section 4.2, where we also achieve a tight  $\Theta(\sqrt{n})$ -stretch.

## 4.1 Symmetric Subadditive JRP

We first consider symmetric subadditive service functions. Observe that these functions are symmetric (i.e.,  $f(S) = f(S')$  for all sets  $S, S' \subseteq U$  such that  $|S| = |S'|$ ). For convenience, for a cardinality  $0 \leq s \leq |U|$ , we use  $f(s)$  as the value of sets of size  $s$ . We show that for symmetric subadditive  $f$ , one can construct a disjoint service function  $g$  that  $O(\sqrt{n})$ -approximates  $f$ . We then show that  $O(\sqrt{n})$  is tight even in the special case of  $f$  being a symmetric unweighted set cover function. This provides an alternative, simpler proof for the lower bound on USC of [35]. We first state the following simple but useful observation.

► **Observation 4.1.** *For all symmetric subadditive functions  $f : \mathbb{R}_+ \rightarrow \mathbb{R}_+$ , and all  $y \geq x > 0$ , it holds that  $f(y)/f(x) \leq \lceil y/x \rceil$ .*

**Proof.** Let  $k = \lceil y/x \rceil$ . Then,  $f(y) \leq f(kx) \leq f(x) + f((k-1)x) \leq f(x) + \dots + f(x) = k \cdot f(x)$ . The first inequality is by monotonicity, and the second and third by subadditivity. ◀

► **Lemma 4.2.** *For every symmetric subadditive service function  $f$ , there exists a disjoint service function  $g$  that  $O(\sqrt{n})$ -approximates it.*

**Proof.** Let us consider an arbitrary symmetric subadditive service function  $f$  on request types  $U$ . Let  $g$  be the disjoint service function that induces an arbitrary partition of the elements of  $U$  into sets  $\{X_1, \dots, X_k\}$ , where  $k = \lceil \sqrt{n} \rceil$ , each of cardinality  $|X_i| \leq \lceil \sqrt{n} \rceil$  (such a partition always exists). We now bound the following fraction for every  $S \subseteq U$ :

$$\begin{aligned} \frac{\sum_{i \in [k]} f(X_i) \cdot \mathbb{1}\{S \cap X_i \neq \emptyset\}}{f(S)} &\leq \frac{\sum_{i \in [k]} f(\lceil \sqrt{n} \rceil) \cdot \mathbb{1}\{S \cap X_i \neq \emptyset\}}{f\left(\sum_{i \in [k]} \mathbb{1}\{S \cap X_i \neq \emptyset\}\right)} \\ &\leq \left( \sum_{i \in [k]} \mathbb{1}\{S \cap X_i \neq \emptyset\} \right) \cdot \left[ \frac{\lceil \sqrt{n} \rceil}{\sum_{i \in [k]} \mathbb{1}\{S \cap X_i \neq \emptyset\}} \right] \\ &\leq 2\lceil \sqrt{n} \rceil. \end{aligned}$$

The first inequality is because  $|X_i| \leq \lceil \sqrt{n} \rceil$  and from the fact that, since  $X_i$ 's are disjoint, the size of  $S$  is at least the number of non-empty intersections with sets  $X_i$ 's. The second inequality follows from Observation 4.1, and the third inequality follows since  $\lceil \frac{a}{b} \rceil \leq 2 \cdot \frac{a}{b}$ , for every  $\frac{a}{b} \geq \frac{1}{2}$ , and the denominator  $\sum_{i \in [k]} \mathbb{1}\{S \cap X_i \neq \emptyset\} \leq \sqrt{n} + 1$ . ◀

Thus, by Lemma 1.1 and Lemma 4.2, the following holds:

► **Theorem 4.3.** *There exists a deterministic  $O(\sqrt{n})$ -competitive algorithm for the Non-Clairvoyant Symmetric Subadditive Joint Replenishment problem.*

We complement the above result by giving a tight instance:

► **Theorem 4.4.** *There exists a symmetric subadditive service function such that every disjoint service function is an  $\Omega(\sqrt{n})$ -approximation of it.*

**Proof.** Let  $U$  be the set of request types. For simplicity of the proof, we assume that  $n = |U|$  has an integer square root. Let us consider the service function  $f(S) = \left\lceil \frac{|S|}{\sqrt{n}} \right\rceil$ , which is symmetric and subadditive, let  $g$  be any disjoint service function, let  $\mathcal{S}$  be the collection of disjoint sets  $X_i$ 's that  $g$  generates, and let  $k$  be the number of parts in the partition  $\mathcal{S}$ .

## 12:16 Universal Optimization for Non-Clairvoyant Subadditive Joint Replenishment

Consider some  $X \subseteq U$  that intersects each  $X_i$  exactly once. We now analyze the cost of this induced partition on  $X$ :

$$\frac{\sum_{i=1}^k f(X_i)}{f(X)} = \frac{\sum_{i=1}^k \left\lceil \frac{|X_i|}{\sqrt{n}} \right\rceil}{\left\lceil \frac{k}{\sqrt{n}} \right\rceil} \geq \frac{\max\{k, \sqrt{n}\}}{\left\lceil \frac{k}{\sqrt{n}} \right\rceil},$$

where the inequality holds since it is a sum of  $k$  terms where each is at least 1, and since the sets  $X_1, \dots, X_k$  cover  $U$ , thus  $\sum_{i=1}^k |X_i| = n$ .

Now, if  $k \leq \sqrt{n}$  then

$$\frac{\max\{k, \sqrt{n}\}}{\left\lceil \frac{k}{\sqrt{n}} \right\rceil} = \sqrt{n}.$$

Otherwise,  $\frac{k}{\sqrt{n}} > 1$ , thus  $\left\lceil \frac{k}{\sqrt{n}} \right\rceil \leq 2\frac{k}{\sqrt{n}}$ , which implies that

$$\frac{\max\{k, \sqrt{n}\}}{\left\lceil \frac{k}{\sqrt{n}} \right\rceil} \geq \frac{k}{2k/\sqrt{n}} = \frac{\sqrt{n}}{2},$$

which concludes the proof.  $\blacktriangleleft$

### 4.2 Weighted Symmetric Subadditive JRP

We now relax the assumption of  $w(S) = |S|$  and provide a  $O(\sqrt{n})$ -approximation for every weighted subadditive function. We begin with some facts about weighted subadditive and symmetric concave functions. Every symmetric concave function is the pointwise infimum of a set of affine functions, and can be approximated by a set of affine functions with exponentially decreasing slopes. The next lemma combines this fact with the fact that every weighted subadditive function can be approximated by a symmetric concave function.

► **Lemma 4.5.** *Let  $g : \{0, 1, \dots, W\} \rightarrow \mathbb{R}_{\geq 0}$  be a monotone non-decreasing subadditive function. Then, there exists a finite set of affine functions  $\{g_1, \dots, g_p\}$  for some  $p \leq \log(W)$  where  $g_i(x) = \sigma_i + x \cdot \delta_i$  such that  $\sigma_{i+1} > 2\sigma_i$  and  $\delta_{i+1} < \delta_i/2$  for every  $i < p$ , and the function  $\hat{g}$  defined by  $\hat{g}(x) = \min_i g_i(x)$  satisfies that for every  $x \in \{0, \dots, W\}$ , it holds that:*

$$g(x) \leq \hat{g}(x) \leq 8g(x).$$

**Proof.** By [30], we know that there exists a concave function  $g' : \{0, \dots, W\} \rightarrow \mathbb{R}_{\geq 0}$  that approximates  $g$  within a factor of 2. Now, for every  $i = 2, \dots, \lceil \log(W) \rceil$  consider the affine function  $g'_i : \{0, \dots, W\} \rightarrow \mathbb{R}_{\geq 0}$  that interpolates between  $(2^{i-1}, g'(2^{i-1}))$  and  $(2^i, g'(2^i))$ , and  $g'_1(x)$  that interpolates between  $(0, g'(0))$  and  $(1, g'(1))$ . It holds that for every  $x \in \{0, \dots, W\}$  then

$$\frac{g'(x)}{2} \leq \min_{i=1, \dots, p} g'_i(x) \leq g'(x),$$

where the first inequality holds since

$$\begin{aligned} g'(x) &\leq g'(2^{\lceil \log(x) \rceil}) \leq 2g'(2^{\lfloor \log(x) \rfloor}) \\ &\leq 2g'_{2^{\lfloor \log(x) \rfloor}}(2^{\lfloor \log(x) \rfloor}) = 2 \min_{i=1, \dots, p} g'_i(2^{\lfloor \log(x) \rfloor}) \leq 2 \min_{i=1, \dots, p} g'_i(x), \end{aligned}$$

and the second inequality holds by concavity of  $g'$ . In [32], they present an algorithm that reduces the set of affine functions such that the coefficients and slopes satisfy the conditions of the lemma while losing a factor of 2, which, if applied to the set of affine functions  $2g'_i$ , concludes the proof.  $\blacktriangleleft$

Henceforth, we will denote by  $W = w(U)$ , and assume that  $f$  is defined on  $\{0, \dots, W\}$ , and is a pointwise infimum of  $p$  affine functions  $g_1, \dots, g_p$  where  $g_i(x) = \sigma_i + x \cdot \delta_i$  and the  $\sigma_i$ s and  $\delta_i$ s satisfy the properties stated in the lemma. Proving the theorem for  $f$  that satisfies the condition proves the same (with additional loss of a factor of 8) for general symmetric subadditive functions.

The following lemma will be useful to lower bound  $f(w(S))$  using the largest weight in  $S$ .

► **Lemma 4.6.** *For every  $k \in \{2, \dots, p\}$ , if  $x \geq \frac{\sigma_k}{\delta_{k-1}}$ , then  $f(x) \geq \sigma_k$ .*

**Proof.** Recall that  $f(x) = \min_{1 \leq i \leq p} \sigma_i + x\delta_i$ . For  $i < k$ , we have  $\sigma_i + x\delta_i \geq x\delta_{k-1} \geq \sigma_k$ . For  $i \geq k$ , we have  $\sigma_i + x\delta_i \geq \sigma_k$ . Thus,  $f(x) \geq \sigma_k$ . ◀

Henceforth, for brevity, we write  $f(S)$  to mean  $f(w(S))$ , for an arbitrary set  $S$ . In the following, we frequently use the fact that for any set  $H$ ,  $f(H) = \min_{1 \leq i' \leq p} \sigma_{i'} + w(S)\delta_{i'} \leq \sigma_i + w(H)\delta_i$  for every  $i$ .

**High-Level Overview.** Let  $S$  be a set chosen by an adversary, unknown to us. Suppose that  $f(S) = \min_{1 \leq i \leq p} \sigma_i + w(S)\delta_i = \sigma_\ell + w(S)\delta_\ell$ . The idea is to construct a partition such that some of the parts that intersect  $S$  can be charged to  $\sigma_\ell$ , and the remaining parts that intersect  $S$  can be charged to  $w(S)\delta_\ell$ . Towards this end, we first classify each type  $j$  as follows. We say that type  $j$  is *eligible* for class  $2 \leq k \leq p$  if  $w_j \geq \frac{\sigma_k}{\delta_{k-1}}$ . All types are eligible for class 1. Define the *class* of type  $j$  to be the largest class it is eligible for and  $X_k$  to be the set of class- $k$  types.

Next, we partition  $X_k$  into heavy and light types. The light part  $Z_k$  contains all types  $j \in X_k$  with  $w_j\delta_k \leq \sigma_k/\sqrt{n}$ . Since  $Z_k$  is light,  $f(Z_k) \leq \sigma_k + w(Z_k)\delta_k \leq O(\sqrt{n})\sigma_k$ . Also, if  $S \cap X_k \neq \emptyset$ , then Lemma 4.6 implies that  $f(S) \geq \sigma_k$ . We can then use the fact that  $\sigma_k$ 's are geometric to show that the total value of the parts  $Z_k$  that intersect  $S$  is at most  $O(\sqrt{n})f(S)$ .

Now, consider the heavy types in  $X_k$ , i.e. those types  $j$  with  $w_j\delta_k > \sigma_k/\sqrt{n}$ . We further partition these types according to their weights in powers of 2. Let  $R_{k,i} = \{j \in X_k \setminus Z_k : w_j \in [2^i, 2^{i+1})\}$ . For each weight class  $i$ , we greedily partition  $R_{k,i}$  into as many parts of size  $\lceil \sqrt{n} \rceil$  as we can. This produces a collection  $F_{k,i}$  of parts of size  $\lceil \sqrt{n} \rceil$  and at most one leftover part  $G_{k,i}$  of size less than  $\sqrt{n}$ . We say that a part is *nice* if it belongs to  $F_{k,i}$  and the part  $G_{k,i}$  a *leftover* part.

Observe that there are at most  $\lceil \sqrt{n} \rceil$  nice parts, each of size at most  $\lceil \sqrt{n} \rceil$  and contains types of roughly the same weight. Thus, we can use a similar argument as in the unweighted case to show that the total value of the nice parts that intersect  $S$  is at most  $O(\sqrt{n})f(S)$ . For the leftover parts, we charge the parts  $G_{k,i}$  that intersect  $S$  with  $k < \ell$  to  $w(S)\delta_\ell$  and those with  $k \geq \ell$  to  $\sigma_\ell$ .

■ **Algorithm 3** Weighted Symmetric Subadditive Partitioning Algorithm.

- 
- 1: **for**  $k = 1$  to  $p$  **do**
  - 2:   Create a part  $Z_k = \{j \in X_k : w_j\delta_k \leq \sigma_k/\sqrt{n}\}$
  - 3:   Let  $R_{k,i} = \{j \in X_k \setminus Z_k : w_j \in [2^i, 2^{i+1})\}$
  - 4:   **for each**  $i$  **do**
  - 5:     Greedly partition  $R_{k,i}$  into as many sets of size exactly  $\lceil \sqrt{n} \rceil$  as possible
  - 6:     Let  $F_{k,i}$  denote the sets of size of size  $\lceil \sqrt{n} \rceil$
  - 7:     Let  $G_{k,i}$  denote the remaining set of size less than  $\sqrt{n}$ , if it exists
  - 8:     Create a part for each set in  $F_{k,i}$  and a part for the set  $G_{k,i}$
-

We now give the detailed analysis below.

► **Theorem 4.7.** *For any weighted symmetric subadditive service function  $f$ , there exists a disjoint service function  $g$  that  $O(\sqrt{n})$ -approximates  $f$ . It can be found in time polynomial w.r.t. the weights defining  $f$ .*

**Proof.** Let  $S$  be an arbitrary set and suppose  $f(S) = \min_{1 \leq i \leq p} \sigma_i + w(S)\delta_i = \sigma_\ell + w(S)\delta_\ell$ . We now decompose  $w(S)$  using the partition produced by our algorithm. In particular, we have

$$f(S) = \sigma_\ell + \left( \sum_k w(Z_k \cap S) + \sum_{k,i} \sum_{T \in F'_{k,i}} w(T \cap S) + \sum_{k,i} w(G_{k,i} \cap S) \right) \cdot \delta_\ell.$$

Define  $F'_{k,i}$  as the subset of parts in  $F_{k,i}$  that intersects with  $S$ . We now show that the algorithm pays at most  $O(\sqrt{n})f(S)$ . In other words, we will prove that the total value of the parts that intersect  $S$  are upper bounded as follows:

$$\sum_{k: Z_k \cap S \neq \emptyset} f(Z_k) + \sum_{k,i} \sum_{T \in F'_{k,i}} f(T) + \sum_{k,i: G_{k,i} \cap S \neq \emptyset} f(G_{k,i}) \leq O(\sqrt{n})f(S).$$

We begin by bounding  $\sum_{k: Z_k \cap S \neq \emptyset} f(Z_k)$ . Let  $k_{\max}$  be the largest  $k$  such that  $Z_k \cap S \neq \emptyset$ . (If none exists, then we do not need to bound this term.) We have that  $w(S) \cdot \delta_{k_{\max}-1} \geq w(Z_k \cap S) \cdot \delta_{k_{\max}-1} \geq \sigma_{k_{\max}}$ . Thus, Lemma 4.6 implies that  $f(S) \geq \sigma_{k_{\max}}$ . On the other hand,

$$\sum_{k: Z_k \cap S \neq \emptyset} f(Z_k) \leq \sum_{k: Z_k \cap S \neq \emptyset} O(\sqrt{n})\sigma_k \leq O(\sqrt{n})\sigma_{k_{\max}} \leq O(\sqrt{n})f(S).$$

where the first inequality follows directly from the definition of  $Z_k$  in line 2 of Algorithm 3 and since there are at most  $n$  elements in  $Z_k$ , the second inequality is since the  $\sigma_k$ 's are geometrically increasing.

Next, we bound  $\sum_{k,i} \sum_{T \in F'_{k,i}} f(T)$ . Since every set  $T \in F'_{k,i}$  has size  $\lceil \sqrt{n} \rceil$ , we have  $\sum_{k,i} |F'_{k,i}| \leq \sqrt{n}$ . Moreover, every  $j \in T$  has  $w_j \in [2^i, 2^{i+1})$ , so  $w(T) \leq O(\sqrt{n})w(T \cap S)$ . Thus, we have

$$\begin{aligned} \sum_{k,i} \sum_{T \in F'_{k,i}} f(T) &\leq \sum_{k,i} \sum_{T \in F'_{k,i}} \sigma_\ell + w(T)\delta_\ell \\ &\leq \sum_{k,i} |F'_{k,i}| \sigma_\ell + O(\sqrt{n}) \sum_{k,i} \sum_{T \in F'_{k,i}} w(T \cap S)\delta_\ell \\ &\leq O(\sqrt{n}) \left( \sigma_\ell + \sum_{k,i} \sum_{T \in F'_{k,i}} w(T \cap S)\delta_\ell \right) \leq O(\sqrt{n})f(S). \end{aligned}$$

where the last inequality follows from the fact that all  $T \in F'_{k,i}$  are disjoint so we have that  $w(S) \geq \sum_{k,i} \sum_{T \in F'_{k,i}} w(T \cap S)$ .

We now turn to bounding  $\sum_{k,i: G_{k,i} \cap S \neq \emptyset} f(G_{k,i})$ . Consider a set  $G_{k,i}$  that intersects  $S$  for  $\ell \leq k \leq p$ . Since  $G_{k,i}$  is a subset of  $X_k \setminus Z_k$  and is at most of size  $\sqrt{n}$ , we have that

$$f(G_{k,i}) \leq \sigma_k + w(G_{k,i})\delta_k \leq O(\sqrt{n})w(G_{k,i} \cap S)\delta_k.$$

Since  $\delta_k \leq \delta_\ell$ , we get that

$$\sum_{k \geq \ell} \sum_{i: G_{k,i} \cap S \neq \emptyset} f(G_{k,i}) \leq \sum_{k \geq \ell} \sum_{i: G_{k,i} \cap S \neq \emptyset} O(\sqrt{n})w(G_{k,i} \cap S)\delta_\ell \leq O(\sqrt{n})f(S).$$

Finally, when  $\ell = 1$ , the argument is complete. Let us now consider the case when  $\ell > 1$ . Consider a set  $G_{k,i}$  that intersects  $S$  for  $1 \leq k < \ell$ . We have that  $f(G_{k,i}) \leq \sigma_k + w(G_{k,i})\delta_k \leq O(\sqrt{n})2^{i+1}\delta_k$ . Moreover, since every  $j \in X_k$  has  $w_j\delta_k < \sigma_{k+1}$ , we have that

$$\sum_{k < \ell} \sum_{i: G_{k,i} \cap S \neq \emptyset} f(G_{k,i}) \leq O(\sqrt{n}) \sum_{k < \ell} \sigma_{k+1} \leq O(\sqrt{n})\sigma_\ell \leq O(\sqrt{n})f(S).$$

Finally, it is not hard to see that, by design, Algorithm 3 can be implemented in polynomial time in the logarithm of the total weight,  $\log(w(U))$ . This concludes the proof. ◀

Thus, by Lemma 1.1, we get Theorem 1.3.

## 5 Tight Instances against Previous Algorithms

### 5.1 An $\Omega(\sqrt{n \log n})$ Tight Instance for the Algorithm of [35]

► **Proposition 5.1.** *There exists a weighted set cover instance for which the Universal Set Cover algorithm of [35] has stretch  $\Omega(\sqrt{n \log n})$ .*

**Proof.** The algorithm of [35] works as follows: while the set  $U$  of elements  $e$  for which  $f(e)$  is undefined is non-empty, pick the set  $S$  that minimizes  $\frac{c(S)}{\sqrt{|S \cap U|}}$  and for all  $e \in S \cap U$ , define  $f(e) = S$ .

The high-level idea is that [35]'s analysis uses the Cauchy-Schwarz inequality and the tight instance is created by looking at when the Cauchy-Schwarz inequality is tight.

Consider the following set system where we have sets  $S, S_1, \dots, S_k$  for some  $k$  that we will choose later. The set  $S$  contains  $k$  elements and set  $S_i$  contains  $\lfloor \frac{k}{k-(i-1)} \rfloor$  elements. The sets also satisfy that  $|S \cap S_i| = 1$  and  $S_i \cap S_j = \emptyset$  for  $1 \leq i < j \leq k$ . Moreover, the sets  $S_i$  form a partition of all the  $n$  elements. The costs of the sets are:  $c(S) = 1$ ,  $c(S_i) = \frac{\sqrt{|S_i|}}{\sqrt{k-(i-1)}}$ .

We now claim that in the  $i$ -th iteration, the algorithm chooses  $S_i$ . First observe that for  $1 \leq i < j \leq k$ , we have

$$\frac{c(S_i)}{\sqrt{|S_i|}} < \frac{c(S_j)}{\sqrt{|S_j|}}.$$

Thus, it suffices to show that in each iteration  $i$ , the algorithm chooses  $S_i$  over  $S$ . We do this by induction on  $i$ . When  $i = 1$ , we have that

$$\frac{c(S_1)}{\sqrt{|S_1|}} = \frac{1}{\sqrt{k}} = \frac{c(S)}{\sqrt{|S|}}.$$

Now consider  $i > 1$ . By induction, we have that  $|S \cap U| = k - (i - 1)$  and  $S_i \cap U = S_i$  (the latter is because the only set that intersects  $S_i$  is  $S$ ). Thus, we also have

$$\frac{c(S_i)}{\sqrt{|S_i|}} = \frac{1}{\sqrt{k - (i - 1)}} = \frac{c(S)}{\sqrt{|S \cap U|}}.$$

We conclude that in each iteration  $i$ , the algorithm chooses  $S_i$ .

■ **Figure 2** Tight instance for [44], where  $w = \frac{\sqrt{n \log n - 1}}{n-1}$ .

Thus, the competitive ratio of the algorithm is at least  $(\sum_{i=1}^k c(S_i))/c(S) = \sum_{i=1}^k c(S_i)$  since  $c(S) = 1$ . We have that

$$\sum_{i=1}^k c(S_i) = \sum_{i=1}^k \frac{\sqrt{\left\lfloor \frac{k}{k-(i-1)} \right\rfloor}}{\sqrt{k-(i-1)}} = \Omega(\sqrt{k} \log k). \quad (4)$$

It now remains to maximize  $k$ . The constraint on  $k$  is that  $\sum_{i=1}^k |S_i| = n$  since  $S_i$ s are disjoint. Now,  $\sum_{i=1}^k |S_i| = \sum_{i=1}^k \left\lfloor \frac{k}{k-(i-1)} \right\rfloor = \Theta(k \log k)$ . Thus, setting  $k = \Theta(n/\log n)$  satisfies the constraint on  $k$ . Plugging this into (4) yields the claim. ◀

## 5.2 An $\Omega(\sqrt{n \log n})$ Tight Instance for the Algorithm of [44]

We complement the  $O(\sqrt{n})$ -stretch achieved by Algorithm 2 and Algorithm 3 with a JRP instance such that the algorithm of [44] (Algorithm 2) must suffer a stretch of at least  $\Omega(\sqrt{n \log n})$ . Note that the instance we present in Figure 2 is both an MLA instance and a weighted concave one. This shows that for the specific case of MLA and weighted concave functions, not only is our algorithm optimal, but also that Touitou's algorithm cannot achieve the same guarantee. At a high level, whenever Touitou's algorithm decides to serve some requests, it issues up to two services (lines 9 and 12). One of them serves a subset of requests  $R$  for which delay and service costs are the same. At the same time, a second service with a budget of up to  $\sqrt{n \log n} \cdot c(R)$  can be issued to serve some pending requests in advance. The following example is one where the optimal algorithm rarely issues this second service.

► **Proposition 5.2.** *There exists an instance for which the algorithm of [44] has stretch  $\Omega(\sqrt{n \log n})$ . Moreover, this is an MLA and a weighted concave instance.*

**Proof.** Let us consider the JRP tree  $T$  in Figure 2, where  $w = \frac{\sqrt{n \log n - 1}}{n-1}$  and the delay cost functions on the nodes read

$$d_i(t) = \begin{cases} 2t, & \text{if } i = 1 \\ \varepsilon t, & \text{if } i \geq 2 \end{cases},$$

for  $\varepsilon \ll w$  to be set later. In particular, at each time step, there are  $n$  requests arriving on tree  $T$ , one per node.

Let us first observe that the optimum algorithm only serves the requests at  $v_1$ , paying a service cost of 1 at each time step. Moreover, it serves requests arriving at any  $v_i$  with  $i \geq 2$  once  $\varepsilon t = w$ , i.e., every  $w/\varepsilon$  time steps, and pays  $(n-1)w + 1 = \sqrt{n \log n}$ . Thus, letting  $\tau$  be the length of the requests sequence, the overall optimal cost is  $\text{OPT}(\tau) = \tau + \frac{\varepsilon \tau}{w} \sqrt{n \log n} \leq 2\tau$ , by setting  $\varepsilon = w/n$ .

Algorithm 2 in [44] (whose cost is referred to as ALG from now on) serves a request arriving at  $v_1$  (line 9) as soon as its accumulated delay equals its service cost (this is when the UPONCRITICAL event occurs). Once a request at  $v_1$  arrives, the algorithm waits until the time elapsed  $t$  is such that  $2t = 1$  to serve it. That is, when the  $j$ -th request located at  $v_1$  arrives, the algorithm serves it at time  $t_j = j + \frac{1}{2}$ . Right after, it issues a second service (line 12) to serve all other requests at  $v_2, \dots, v_n$ . Overall, the algorithm pays  $\text{ALG}(\tau) = \tau \cdot (1 + (n-1)w) = \tau\sqrt{n \log n}$ .

Hence,

$$\frac{\text{ALG}(\tau)}{\text{OPT}(\tau)} \geq \frac{\sqrt{n \log n}}{2},$$

for all  $\tau \geq 1$ . To conclude, the fact that the instance in Figure 2 is an MLA one comes directly from the fact that it is a depth 2 tree. Moreover, observe that no matter how we choose  $S \subseteq V$ ,  $f(S) = f(w(S))$ , and thus the instance in Figure 2 is also a weighted concave instance. ◀

---

## Abstract

We initiate the study of centralized algorithms for welfare-maximizing allocation of goods to buyers subject to *average-value constraints*. We show that this problem is NP-hard to approximate beyond a factor of  $\frac{e}{e-1}$ , and provide a  $\frac{4e}{e-1}$ -approximate offline algorithm. For the online setting, we show that no non-trivial approximations are achievable under adversarial arrivals. Under i.i.d. arrivals, we present a polytime online algorithm that provides a constant approximation of the optimal (computationally-unbounded) online algorithm. In contrast, we show that no constant approximation of the ex-post optimum is achievable by an online algorithm.

## 1 Introduction

Allocating goods to buyers so as to maximize social welfare is one of the most central problems in economics. This problem, even under linear utilities, is complicated by buyers’ various constraints and the manner in which items are revealed.

In this work we introduce the *average-value allocation* problem (AVA). Here, we wish to maximize social welfare (total value of allocated items), while guaranteeing for each buyer  $j$  an *average* value of allocated items of at least  $\rho_j$ . Formally, if the value of item  $i$  for buyer  $j$  is  $v_{ij}$ , and  $x_{ij} \in \{0, 1\}$  indicates whether item  $i$  is allocated to buyer  $j$ , we wish to maximize the social welfare  $\sum_{i,j} v_{ij} x_{ij}$ , subject to each item being allocated to at most one buyer (i.e.,  $\sum_j x_{ij} \leq 1$ ), and to the “average value” constraint:

---

## 13:2 The Average-Value Allocation Problem

$$\forall j, \quad \sum_i v_{ij} x_{ij} \geq \rho_j \cdot \left( \sum_i x_{ij} \right). \quad (1.1)$$

Average-value constraints arise naturally in numerous situations. E.g., consider settings when goods are to be distributed among “buyers”, and the (fixed) cost of distributing, receiving, or deploying each such good allocated is borne by the recipient. Each buyer wants their average value for their goods to be at least some parameter  $\rho_j$ . This parameter  $\rho_j$  allows to convert between units, and so this fixed cost for each buyer can be in money, time, labor, or any other unit. So, for example, for allocation and distribution of donations to a charitable organization, a certain value-per-item is required to justify the time contributed by volunteers, or the money spent by government in the form of subsidies. In other words, the amount of “benefit” per task allocated to an individual  $j$  should be above the threshold  $\rho_j$ , so that even if some of the tasks are individually less rewarding (i.e., they have benefit less than  $\rho_j$ , the total amount of happiness they get overall justifies their workload.

In addition to this average-value constraint on the allocation, we may also consider side-constraints (such as the well-studied budget constraints), but for now we defer their discussion and focus on on the novel constraint (1.1). At first glance, the AVA problem may seem similar to other packing problems in the literature, but there is a salient difference – it is not a packing problem at all! Indeed, if buyer  $i$  gets some subset  $S_i = \{j \mid x_{ij} = 1\}$  of items in some feasible allocation, it is possible that a subset  $S' \subseteq S_i$  of this allocation is no longer feasible, since its average value may be lower. Given that this packing (subset-closedness) property is crucial to many previous results on allocation problems, their techniques do not apply. Hence, we have to examine this problem afresh, and we ask: *how well can the average-value allocation be approximated?* We investigate this question, both in the offline and online settings.

### 1.1 Our Results and Techniques

Recall that the AVA problem seeks to maximize the social welfare  $\sum_{ij} v_{ij} x_{ij}$  subject to each item going to at most one buyer, and also the novel average-value constraint (1.1) above. Our first result rules out polynomial-time exact algorithms for AVA in an offline setting, or even a PTAS, showing that this problem is as hard to approximate as the MAX-COVERAGE problem:

► **Theorem 1 (Hardness of AVA).** *For any constant  $\varepsilon > 0$ , the AVA problem is NP-hard to  $(\frac{e}{e-1} - \varepsilon)$ -approximate.*

We then turn our attention to positive results, and give the following positive result for the problem:

► **Theorem 2 (Offline AVA).** *There exists a randomized polynomial-time algorithm for the AVA problem which achieves an approximation factor of  $\frac{4e}{e-1}$ .*

To prove Theorem 2, we would like to draw on techniques used for traditional packing problems, but the non-traditional nature of this problem means we need to investigate its structure carefully. A key property we prove and leverage throughout is the existence of approximately-optimal solutions of a very special kind: each buyer gets a collection of “bundles”, where a bundle for buyer  $j$  consists of a single item  $i$  with positive  $v_{ij} - \rho_j$  (i.e., contributing positively to the average-value constraint (1.1)) and some number of items  $i$  with

negative  $v_{ij} - \rho_j$ , such that they together satisfy the AVA constraint. Given this structure we can focus on partitioning items among bundles, and allocating bundles to buyers. Note that this partitioning and allocation have to happen simultaneously, since the values (i.e.,  $v_{ij}$ ) and whether it contributes positively or negatively (i.e.,  $v_{ij} - \rho_j$ ) depend on the buyer and bundle under consideration. We show how algorithms for GAP (generalized assignment problem) with matroid constraints [13] can be used.

**Relax-and-Round.** In order to extend our results from the offline to the online settings, and to add in side-constraints, we then consider linear programming (LP) based relax-and-round algorithms for the AVA problem. The LP relaxations take advantage of the structural properties above, as they try to capture the best bundling-based algorithms (and hence to approximate the optimal solution of any kind). Once we have fractional solutions to the LP, we can then round these in both offline and online settings to get our feasible allocations.

Our first rounding-based algorithm, given in §4, is in the offline setting, and yields another  $O(1)$ -approximate algorithm for AVA, qualitatively matching the result from Theorem 2. While the constants are weaker, the result illustrates our ideas, and allows us to support additional side-constraints (more on this in §1.1.1).

**Online Algorithms.** We then turn to online AVA, where items arrive over  $T$  timesteps, and must be allocated to buyers as soon as they arrive. We want to maintain feasible solutions to the AVA at all times. We show that under adversarial arrivals, only trivial  $O(T)$  approximations are possible. This forces us to focus our attention on i.i.d. arrivals. Our first result is a time-efficient approximation of the optimum (computationally-unbounded) online algorithm:

► **Theorem 3** (Online AVA: Approximating the Optimal Online IID Algorithm). *There exists a randomized polynomial-time online algorithm for the AVA problem which achieves a constant factor of the value achieved by the optimal (computationally-unbounded) online algorithm.*

To approximate the optimum online algorithm, we provide an LP capturing a constraint only applicable to online algorithms, inspired by such constraints from the secretary problem and prophet inequality literatures [12, 34]. We then provide a two-phase online algorithm achieving a constant approximation of this LP, analyzed via a coupling with an imaginary algorithm that may violate AVA constraints and allocate items to several buyers.

We then turn our attention to approximating the ex-post optimum (a.k.a., getting a competitive ratio for the observed sequence). In contrast, we show that when comparing with the ex-post optimum, no such constant approximation ratio is possible, but we give matching upper and lower bounds. (Due to lack of space, this is deferred to Appendix A.)

► **Theorem 4** (Online AVA: Ex-post Guarantees (Informal)). *There exist families of online i.i.d. AVA instances on which any online algorithm is  $\Omega\left(\frac{\log T}{\log \log T}\right)$ -competitive. In contrast, there exists an online algorithm matching this bound asymptotically (on all instances).*

The lower bound is proved by giving an example using a balls-and-bins process (and its anti-concentration). Then we formulate an LP capturing this kind of anti-concentration, using which we match the lower bound, under some mild technical conditions (see Appendix A for details).

### 1.1.1 Generalizations

There are many interesting generalizations of the basic problem. For example, there might exist “budgets” which limit the number of items any buyer can receive; or more generally we may have costs on items which must sum to at most the buyer’s budgets. These costs could be different for different buyers, and in different units than those captured by constraint (1.1). These constraints are the natural ones considered in packing problems; in general, we can consider the AVA constraint as being a non-packing constraint on the allocation that can be supplemented with other conventional packing constraints. As we show in §4.3, our relax-and-round algorithm extends seamlessly to accommodate such side constraints, provided any individual item has small cost compared to the relevant budgets.

Another natural generalization is *return-on-spend* (RoS) constraints, which have been central to much recent work on advertisement allocation (see [25, 20]) and §1.2). We call the problem *generalized AVA* (GenAVA) and define it as follows: the objective is to maximize social welfare, but now the average value is measured in a more general way. Indeed, the allocation of item  $i$  to buyer  $j$  can incur a different “cost”  $c_{ij}$ , and the average-value constraint becomes the following ROS constraint:

$$\forall j, \quad \sum_i v_{ij} x_{ij} \geq \rho_j \cdot \left( \sum_i c_{ij} x_{ij} \right). \quad (1.2)$$

In contrast to AVA, we show that allowing general costs  $c_{ij}$  in the generalized AVA problem in (1.2) makes it as hard as one of the hardest combinatorial problems – computing a maximum clique in a graph. In particular, we show that it is NP-hard to  $n^{1-\varepsilon}$ -approximate GenAVA with  $n$  buyers, for any constant  $\varepsilon > 0$ . In Appendix B we show that similar hardness persists even for stochastically generated inputs, and the problem remains hard even if we allow for bicriteria approximation.

## 1.2 Related Work

Resource allocation is one of the most widely-studied topics in theoretical computer science. Here we briefly discuss some relevant lines of work.

**Packing/Covering Allocation Problems.** The *budgeted allocation problem* or ADWORDS of [32] is NP-hard to approximate within some constant [14], and constant approximations are known even online [32, 11, 28]. The *generalized assignment problem (GAP)* [22] and its extension, the *separable assignment problem*, have constant approximations in both offline [23, 13] and (stochastic) online settings [30]. In both cases, arbitrarily-good approximations are impossible under adversarial online arrivals, even under structural assumptions allowing for an offline PTAS (e.g., “small” bids) [32]. However, assuming both small bids and *random-order* (or *i.i.d.*) arrivals allows us to achieve  $(1 - \varepsilon)$ -competitiveness [16, 18, 30, 26, 2]. Some such allocation problems are also considered with concave or convex utilities [17, 7]. As noted above, many results and techniques for (offline and online) packing and covering constraints are not applicable to our problem, which is neither a packing nor covering problem in the conventional sense.

**RoS constraints in online advertising.** Return-on-spend constraints as defined in (1.2) have received much attention in recent years in the context of online advertising. Several popular autobidding products allow advertisers to provide campaign-level RoS constraints with a goal to maximize their volume or value of conversions (sales) [25, 20]). Fittingly, there has been

much interest in understanding the RoS setting along various directions, including optimal bidding [1], mechanism design [8, 24], and on welfare properties at equilibrium [1, 15, 31]. In these results, distributed bidding based algorithms are shown to achieve a constant fraction of the optimal welfare. However, note that the per-item costs in the autobidding setting are *endogenous* (set via auction dynamics) whereas in our allocation problem there is no pricing mechanism and the costs are *exogenous*. Our results about the hardness of the generalized AVA show that under exogenous prices, such allocation problems do not admit constant (or even sublinear) approximation guarantees.

**Approximating the optimum online algorithm.** Our online i.i.d. results relate to a recent burgeoning line of work on approximation of the optimum online algorithm via restricted online algorithms. This includes restriction to polynomial-time algorithms (as in our case) [34, 33, 10, 3, 29], fair algorithms [5], order-unaware algorithms [19] and inflexible algorithms [4, 35], and more. These works drive home the message that approximating the optimum online algorithm using restricted algorithms is hard, but can often lead to better approximation than possible when comparing to the (unattainable) benchmark of the ex-post optimum. We echo this message, showing that for our problem under i.i.d. arrivals, a constant-approximation of the optimum online algorithm (using polytime algorithms) is possible, but is impossible when comparing to the optimum offline solution.

### 1.3 Problem Formulation

In the *average-value-constrained allocation problem (AVA)*, allocating item  $i$  to buyer  $j$  yields a value of  $v_{ij}$ . Each buyer  $j$  requires that the average value they obtain from allocated items be at least  $\rho_j$ . We wish to (approximately) maximize the total social welfare, or sum of values obtained by the buyers, captured by the following integer LP:

$$\begin{aligned}
 \max \quad & \sum_{(i,j) \in E} v_{ij} x_{ij} && \text{(AVA-ILP)} \\
 \text{s.t.} \quad & \sum_i v_{ij} x_{ij} \geq \rho_j \cdot \sum_i x_{ij} && \forall \text{ buyers } j \\
 & \sum_j x_{ij} \leq 1 && \forall \text{ items } i \\
 & x_{ij} \in \{0, 1\} && \forall \text{ items } i, \text{ buyers } j.
 \end{aligned}$$

An instance  $\mathcal{I}$  of AVA can be captured by a bipartite graph  $(I, J, E)$ , with a set  $I$  of items and set  $J$  of buyers, and edges  $E \subseteq I \times J$ , capturing all buyer-item pairs with non-zero value. For  $i \in I$  and  $j \in J$ , edge  $(i, j)$  has value  $v_{ij}$ . We say edge  $(i, j)$  is a *P-edge* (positive edge) if it has non-negative *excess*  $v_{ij} - \rho_j \geq 0$ , and an *N-edge* otherwise, in which case we refer to  $v_{ij} - \rho_j < 0$  as its *deficit*. An item  $i$  is a *P-item* if *all* its edges in  $E$  are *P-edges*, and an *N-item* if *all* its edges in  $E$  are *N-edges*: naturally, some items may be neither *P-items* or *N-items*. We will call an instance *unit- $\rho$*  if  $\rho_j = 1$  for all buyers.<sup>2</sup>

In the online setting, the  $n$  buyers and their  $\rho_j$  values are known a priori, but items  $i$  are revealed one at a time, together with their value  $v_{ij}$  for each buyer  $j$ , and an algorithm must decide what buyer to allocate an item to (if any), immediately and irrevocably on

<sup>2</sup> Such instances capture the core difficulty of the AVA problem, and our examples (except those for GenAVA in Section B) are unit- $\rho$  instances, so one can WLOG take  $\rho_j = 1$  in the first read.

arrival. In the online i.i.d. setting,  $T$  items are drawn (one after another) i.i.d. from a known distribution over  $m$  known item types, with type  $i$  drawn with probability  $q_i$ . We say an edge type  $(i, j)$  is an  $N$ -edge type or a  $P$ -edge type if  $v_{ij} - \rho_j < 0$  or  $v_{ij} - \rho_j \geq 0$ , respectively.

## 1.4 Paper Outline

We begin in §2 by proving some structural lemmas regarding AVA, including an unintuitive non-linear dependence of the welfare on the amount of supply. In §3 we present the improved algorithm for the offline setting giving Theorem 2. In §4 we present our LP-rounding algorithm for AVA in an offline setting. We also discuss the approach's extendability, allowing to incorporate additional constraints, in §4.3. Building on this offline rounding-based algorithm, in §5 we present a constant-approximation of the optimum online algorithm. In the interest of space, we defer the discussion of competitive ratio bounds to Appendix A, and our hardness results to Appendix B.

## 2 The Structure of Near-optimal Solutions for AVA

In this section, we show how to partition any feasible allocation of AVA instances into structured subsets (which we call *permissible bundles*). This bundling-based structure will prove useful for all of our algorithms.

► **Definition 5** (Bundling). *A set  $S$  of edges incident on buyer  $j$  is a permissible bundle if **nolistsep**  $S$  consists of a single  $P$ -edge  $(i^*, j)$  and zero or more  $N$ -edges  $(i, j)$ , and **nolistsep** the edges in  $S$  satisfy the average-value constraint, i.e.,  $\sum_{(i,j) \in S} v_{ij} \geq \rho_j \cdot |S|$ . A bundling-based solution is one that can be partitioned into a collection of permissible bundles.*

Clearly, no bundling-based solution can be better than the best unconstrained solution, but in the following lemma we show a converse, up to constant factors. (Throughout, we use the shorthand notation  $v \cdot x := \sum_{ij} v_{ij} x_{ij}$  for any vector  $x \in \mathbb{R}^E$ .)

► **Lemma 6** (Good Bundling-Based Solution). *Let  $x^*$  be a solution to an instance of AVA. Then, there exists a bundling-based solution  $\hat{x}$  of value at least  $v \cdot \hat{x} \geq \frac{1}{2} v \cdot x^*$ .*

As a corollary, the best bundling-based solution is a 2-approximation, and so we will strive to approximate such bundling-based solutions.

We prove a strengthening of Lemma 6 which also addresses online settings.

► **Definition 7** (Committed Bundling). *An online algorithm is a committed bundling-based algorithm if its solution consists of permissible bundles, and items can only be added to bundles; in particular, it commits to the allocation of each item to a particular bundle, and does not move items between permissible bundles.*

► **Lemma 8** (Online Bundling-Based Solution). *Let  $x^*$  be a solution to an instance of AVA, with  $x^*$  revealed online and (all interim partial solutions) satisfying the average-value constraints throughout. Then there exists a solution  $\hat{x}$  that is the output of a committed online bundling-based algorithm, of value at least  $v \cdot \hat{x} \geq \frac{1}{2} v \cdot x^*$ .*

**Proof.** For each buyer  $j$ , consider the edges  $S := \{(i, j) \mid x_{ij}^* = 1\}$  corresponding to items assigned to buyer  $j$  in solution  $x^*$ , in order of addition to the solution  $x^*$ , namely  $e_1, e_2, \dots, e_{|S|}$ , with  $e_k = (i_k, j)$ . We now show how a committed online algorithm can output a collection of permissible bundles of at least half the value from among the edges in  $S$ ; doing this for each buyer proves the result.

Consider  $i_k$ , i.e., the  $k$ -th item allocated to  $j$  by  $x^*$ , if  $e_k$  is a  $P$ -edge (i.e.  $v_{i_k,j} \geq \rho_j$ ), we denote  $p = i_k$ , open (create) a bundle  $B_p = \{(j,p)\}$  and allocate appropriately in the new solution  $\hat{x}$ . When  $e_k = (i_k,j)$  is an  $N$ -edge, if  $e_k$  can be added to some open bundle  $B_p$  of  $j$  while keeping it permissible, we add  $(i_k,j)$  to  $B_p$  in solution  $\hat{x}$ ; otherwise, we pick some open bundle  $B_p$  of  $j$  and mark it as closed (and never add more edges to this bundle). Since  $x^*$  is feasible throughout the online arrival, for any  $k \in [1, |S|]$  we have that  $\sum_{\ell \leq k} v_{i_\ell,j} \geq k \cdot \rho_j$ , and since we allocate all  $P$ -edges of  $x^*$  in  $\hat{x}$  and only allocate a subset of the  $N$ -edges, we find that there must always be some open bundle of  $j$  when considering an  $N$ -edge  $e_k$ . Therefore, the above (committed) bundling-based online algorithm is well-defined. Now, each bundle is closed by at most one  $N$ -edge  $(i,j)$ , and so we can charge the  $N$ -edges  $(i,j)$  allocated in  $x^*$  but not in  $\hat{x}$  to the  $P$ -edge  $(p,j)$  in the bundle  $B_p$  that they closed. But by definition of the  $P$ -edge and  $N$ -edge, we know  $v_{pj} \geq \rho_j \geq v_{ij}$ . Therefore, denoting by  $x_D^*$  the part of the solution  $x^*$  that is *discarded* in  $\hat{x}$  and by  $x_p^*$  and  $x_n^*$  the value of the  $P$ -edges and  $N$ -edges allocated by both  $x^*$  and the new solution  $\hat{x}$ , we have that  $v \cdot x_D^* \leq v \cdot x_p^*$ . Hence,

$$v \cdot x^* = v \cdot x_D^* + v \cdot (x^* - x_D^*) \leq 2v \cdot x_p^* + x_n^* \leq 2v \cdot (x_p^* + x_n^*). \quad (2.3)$$

That is, the obtained bundles of the solution  $\hat{x} = x_p^* + x_n^*$  constitute a 2-approximation. ◀

► **Remark 9.** This loss of a factor of two in the value is tight. To see this, consider a single-buyer unit- $\rho$  AVA instance. There are  $\frac{1}{\varepsilon}$   $N$ -edges each with value  $1 - \varepsilon$  and  $\frac{1}{\varepsilon(1-\varepsilon)}$   $P$ -edges each with value  $1 + \varepsilon(1 - \varepsilon)$ . It is feasible to allocate all items to the buyer, and (arbitrarily close to) half the value of this solution is given by  $N$ -edges, but any permissible bundle contains no  $N$ -edges as any single  $P$ -edge doesn't have enough excess to cover the deficit of any  $N$ -edge.

For our algorithms it will be convenient if each item is incident only on  $P$ -edges, or only on  $N$ -edges, thus removing the ambiguity about whether to use these as the single  $P$ -edge in a permissible bundle. Fittingly, we call such instances *unambiguous*. For example, when all buyers have the same average-value constraint (i.e.  $\forall j : \rho_j = \rho$ ), for any item  $i$  incident on a  $P$ -edge (i.e.,  $\exists j : v_{ij} \geq \rho$ ), we can trivially drop all  $N$ -edges of the item (i.e., drop  $(i,j')$  where  $v_{ij'} < \rho$ ) since there is no reason to allocate any  $N$ -edge instead of a  $P$ -edge of  $i$ , and so making such instances unambiguous comes with no cost. As we now show, any instance of AVA in general can be made unambiguous while still preserving a bundling-based allocation that is constant-approximate for the original instance.

► **Lemma 10 (Bundling Unambiguous Sub-Instances).** *Given an AVA instance  $\mathcal{I} = (I, J, E)$ , dropping all of the  $P$ -edges or all the  $N$ -edges of each item  $i \in I$  independently with probability  $1/2$  results in an unambiguous sub-instance  $\mathcal{I}' = (I, J, E')$  (where  $E' \subseteq E$ ), admitting a bundling-based solution  $x'$  which is 4-approximate for  $\mathcal{I}$ .*

**Proof.** Let  $x^*$  be an optimal solution for  $\mathcal{I}$ . If we denote by  $x_p^*$  and  $x_n^*$  the characteristic vector for  $P$ -edges and  $N$ -edges allocated by both  $x^*$  and  $\hat{x} = x_p^* + x_n^*$  as in the proof of Lemma 8, then, by the penultimate inequality of Equation (2.3), we have that  $v \cdot x^* \leq 2v \cdot x_p^* + v \cdot x_n^*$ . Now, consider the solution  $x'$  consisting of all  $P$ -edges allocated in  $\hat{x}$  that were not dropped and all non-dropped  $N$ -edges allocated in bundle  $S$  whose  $P$ -edge was also not dropped. We therefore have that this new solution has value precisely  $\frac{1}{2}v \cdot x_p^* + \frac{1}{4}v \cdot x_n^*$ , and so, by Equation (2.3), we have that  $x'$  is a 4-approximation, since

$$v \cdot x^* \leq 4 \cdot \left( \frac{1}{2}v \cdot x_p^* + \frac{1}{4}v \cdot x_n^* \right) = 4v \cdot x'. \quad \blacktriangleleft$$

We also provide an alternative, deterministic method to find such an unambiguous subinstance. However, since our algorithms are randomized, we defer discussion of this method to the full version. Note in unambiguous instances, every item is either a  $P$ -item or an  $N$ -item.

## 2.1 Welfare is non-linear in supply

In this section we provide a bound on the multiplicative gain in welfare in terms of increased supply. This will prove useful later. For now, it illustrates non-linearity of the AVA problem in its supply. (This is in contrast to other allocation problems where the welfare is at best linear in the supply.)

To motivate this bound, consider the outcome of creating  $k$  copies of each item in an AVA instance. Clearly, the welfare increases by a factor of at least  $k$ , as we can just repeat the optimal allocation for the original instance  $k$  times. However, as the following example illustrates, welfare can be *super-linear* in the supply size increase for AVA.

► **Example 11.** Consider a unit- $\rho$  instance of  $k$ -buyer AVA with a single  $P$ -item of value  $1 + k\varepsilon$  for all buyers and  $k$  many  $N$ -items, with the  $i$ -th  $N$ -items having value zero for all buyers except for one distinct buyer  $i$ , to whom it has value  $1 - \varepsilon$ . In this instance  $\text{OPT} \approx 2$ , since the  $P$ -item can only be allocated to a single buyer, who can then only be allocated one  $N$ -item, while in the instance obtained by creating  $k$  copies of each item we can allocate a  $P$ -item to each buyer together with  $k$  many  $N$ -items, and so for this instance  $\text{OPT} \approx k^2$ , i.e., increasing supply  $k$ -fold increases the welfare  $(k^2/2)$ -fold.

The following lemma shows that the above example is an extreme case, and for a  $k$ -fold increase in supply, an  $O(k^2)$ -fold increase in welfare is best possible.

► **Lemma 12 (Supply Lemma).** *Let  $\mathcal{I} = (I, J, E)$  be an AVA instance, and let  $\mathcal{I}' = (I', J, E')$  be an instance with the same buyer set and underlying costs and values obtained by copying each item in  $\mathcal{I}$  some  $k$  times.*

$$\text{OPT}(\mathcal{I}') \leq O(k^2) \cdot \text{OPT}(\mathcal{I}).$$

**Proof.** Since bundling-based solutions are nearly optimal up to a constant factor of 2, we can start with an optimal bundling-based allocation  $\mathcal{A}'$  for  $\mathcal{I}'$  and randomly (and independently) associate the items of  $\mathcal{I}$  with one of their  $k$  copies in  $\mathcal{I}'$ , allocating them as in  $\mathcal{A}'$ . Finally, we remove all non-permissible obtained bundles to obtain allocation  $\mathcal{A}$  for  $\mathcal{I}$ . For each copy  $i'$  of an item  $i$ , if  $i'$  is allocated in a  $P$ -edge in  $\mathcal{A}'$ , the probability that  $i$  is associated with  $i'$  (and thus assigned to the same buyer by  $\mathcal{A}$ ) is precisely  $1/k$ . In contrast, if  $i'$  is allocated in an  $N$ -edge by  $\mathcal{A}'$ , the probability that  $\mathcal{A}$  allocates  $i$  the same way as  $i'$  is precisely  $1/k^2$ , as this requires both  $i$  to be assigned to the same bundle (associated with the same copy) and the  $P$ -edge of this bundle to similarly be assigned to the same bundle. The lemma then follows by linearity of expectation. ◀

## 3 Offline Algorithm via Reduction to Matroid-Constrained GAP

In this section we provide an improved constant-approximation for AVA in the *offline* setting; we will show in Appendix B.1 that the problem is hard to approximate to better than  $\frac{e}{e-1}$ .

► **Theorem 13.** *There exists a  $(\frac{4e}{e-1} + o(1))$ -approximate randomized algorithm for AVA.*

The algorithm proceeds by reducing AVA to GAP with matroid constraints. Recall that an instance of the *generalized assignment problem* (GAP) consists of  $n$  elements that can be packed into  $m$  bins. Packing an element  $e$  into a bin  $b$  gives a value  $v_{eb}$  and uses up  $s_{eb}$  space in that bin. If we let  $y_{eb} \in \{0, 1\}$  denote the indicator for whether element  $e$  is assigned to

bin  $b$ , then naturally  $\sum_b y_{eb} \leq 1$ . Each bin has unit size, and so the size of elements assigned to bin  $b$  is at most 1: in other words,  $\sum_e s_{eb} y_{eb} \leq 1$ . The goal is to maximize the total value of the assignment  $\sum_{eb} v_{eb} y_{eb}$ . [23] gave a  $(1 - 1/e)$ -approximation for this problem. [13] gave the same approximation for an extension of the problem, where the opened subset of bins must be an independent set in some given matroid  $\mathcal{M}$ .

► **Theorem 14.** *There exists a randomized polynomial-time algorithm that, for any unambiguous AVA instance, outputs a solution with expected value at least  $(1 - 1/e - o(1))$  times the optimal bundling-based solution.*

**Proof.** Given an unambiguous AVA instance (i.e., one where each item is incident on only  $P$ -edges or only  $N$ -edges), we construct an instance of Matroid-Bin GAP as follows:

1. *Elements and bins:* For each  $P$ -item  $p$  and buyer  $j$ , construct a bin  $(p, j)$  in the GAP instance. The elements of the GAP instance are exactly the items of the AVA instance.
2. *Values/sizes of  $P$ -items:* Assigning a  $P$ -item  $p$  to bin  $(p, j)$  yields value  $v_{pj}$  and uses zero space; Assigning  $P$ -item  $p$  to a bin  $(p', j)$  with  $p \neq p'$  yields value zero and uses  $1 + \varepsilon$  space.
3. *Values/sizes of  $N$ -items:* Assigning  $N$ -item  $i$  to bin  $(p, j)$  yields value  $v_{ij}$  and uses  $\frac{\rho_j - v_{ij}}{v_{pj} - \rho_j}$  space.
4. *Matroid on the bins:* Finally, the matroid  $\mathcal{M}$  on the bins is a partition matroid, requiring that we choose at most one bin from  $\{(p, j) \mid j \in B\}$ , for each  $P$ -item  $p$ .

The construction above results in a value-preserving one-to-one correspondence between feasible GAP solutions which are *maximal*, i.e., where each  $P$ -item  $p$  is assigned to some bin, and permissible bundling-based solutions to the AVA instance. Indeed, for any feasible bundling-based solution to the AVA instance, fix a bundle  $(p, j)$  containing the item set  $S$ . The value of placing the items in  $S$  in the bin  $(p, j)$  is precisely  $\sum_{i \in S} v_{ij}$ . Summing over all bins, we find that both solutions (to the AVA and GAP instance) have the same value. On the other hand, the GAP solution is feasible since for each  $P$ -item  $p$  we open up at most one bin  $(p, j)$  (thus respecting the matroid constraint) and moreover each bin's size constraint is respected due to the per-bundle average-value constraint and the zero size of  $p$  in bin  $(p, j)$ , implying that  $\sum_{i \in S} s_{i,(p,j)} = \sum_{i \in S \setminus \{p\}} \frac{\rho_j - v_{ij}}{v_{pj} - \rho_j} \leq 1$ . Similarly, starting with a maximal solution to the GAP instance, the single bin  $(p, j)$  into which  $p$  is placed has its average-value constraint satisfied (note that  $p$  cannot be placed in a bin  $(p', j)$  for  $p' \neq p$ , where its size is  $1 + \varepsilon$ ), and the value of the bundles obtained this way is the same as the GAP solution's value. Now the  $(1 - 1/e - o(1))$ -approximation algorithm for GAP with matroid constraints [13] gives the same approximation for AVA on unambiguous instances. ◀

Theorem 14 combined with Lemma 10 completes the proof of Theorem 13.

## 4 An Offline Algorithm via Relax-and-Round

Let us now present an LP-rounding based algorithm for AVA. This more sophisticated algorithm yields another constant-approximate offline algorithm, which also allows to incorporate additional side constraints, see Section 4.3). Moreover, this section's algorithm also provides a template for our main *online* algorithms.

The natural starting point for an LP-rounding based algorithm, the LP relaxation obtained by dropping the integrality constraints of (AVA-ILP), turns out to be a dead end. This relaxation has an integrality gap of  $\Omega(n)$  on  $n$ -buyer instances,<sup>3</sup> even for unit- $\rho$ , as shown by the reinspecting the instance of Example 11.

<sup>3</sup> Recall that an LP relaxation's *integrality gap* is the difference in objective between its best fractional and integral solutions.

## 13:10 The Average-Value Allocation Problem

► **Example 15.** Consider an  $n$ -buyer unit- $\rho$  instance with a single  $P$ -item  $p$  of value  $1 + n\varepsilon$  for all buyers, and  $n$   $N$ -items, with the  $i$ -th  $N$ -item having zero value for all buyers except for buyer  $j_i$ , for whom its value is  $1 - \varepsilon$ . An assignment  $x_{pj} = \frac{1}{n}$  for all buyers  $j$  and  $x_{ij_i} = 1$  for every  $N$ -item  $i$  gives value  $n + 1$  for the LP relaxation of (AVA-ILP), while clearly the optimal integral solution has value  $\approx 2$ .

Therefore, to obtain any constant approximation via LP rounding, we need a tighter relaxation. To this end, we rely on Lemmas 6 and 10, and provide the following relaxation for *bundling-based* solutions for unambiguous AVA instances. This LP has decision variables  $x_{ijp}$  for ( $P$  or  $N$ )-item  $i$ , buyer  $j$  and  $P$ -item  $p$ . Informally, these correspond to the probability that  $i$  is allocated to  $j$  in the bundle with  $P$ -item  $p$ , which we denote by  $jp$ . (Note: this polynomially-sized LP is clearly poly-time solvable.)

$$\max \sum_{i,j,p} v_{ij} x_{ijp} \quad (\text{Bundle-LP})$$

$$\text{s.t.} \quad \sum_i (\rho_j - v_{ij}) x_{ijp} \leq 0 \quad \forall j, p \quad (4.4)$$

$$\sum_{j,p} x_{ijp} \leq 1 \quad \forall i \quad (4.5)$$

$$x_{ijp} \leq x_{pjp} \quad \forall i, j, p \quad (4.6)$$

$$x_{p'jp} = 0 \quad \forall j, P\text{-item } p' \neq p \quad (4.7)$$

$$x_{ijp} \geq 0 \quad \forall i, j, p$$

Intuitively, the bundling, and in particular Equation (4.6), will allow us to overcome the integrality gap example above. We formalize this intuition later by approximately rounding this LP, but first we show that (Bundle-LP) is a relaxation of bundling-based allocations for unambiguous AVA instances.

► **Lemma 16.** *For any unambiguous AVA instance, the value of (Bundle-LP) is at least as high as that of the optimal bundling-based allocation.*

**Proof.** Fix a (randomized) bundling-based allocation algorithm  $\mathcal{A}$ . Let  $Y_{ijp}$  be the indicator for  $\mathcal{A}$  having allocated item  $i$  in bundle  $jp$ . We argue that  $Y_{ijp}$  satisfy the constraints of (Bundle-LP), realization by realization. Consequently, by linearity of expectation, so do their marginals,  $\mathbb{E}[Y_{ijp}]$ . Constraint (4.4) holds since  $\mathcal{A}$  satisfies the average-value constraint for each bundle. Constraint (4.5) holds since each item is allocated at most once. Constraint (4.6) holds because bundle  $jp$  must be opened for  $i$  to be allocated in it. Constraint (4.7) holds since permissible bundles have a single  $P$ -item in them. Finally, non-negativity of  $\mathbf{Y}$  is trivial. We conclude that  $\mathbb{E}[\mathbf{Y}]$  is a feasible solution to the above LP, with objective precisely  $\sum_{i,j,p} v_{ij} \mathbb{E}[Y_{ijp}]$ . The lemma follows. ◀

We now turn to rounding this LP. To this end, we consider a two-phase algorithm, whose pseudo-code is given in Algorithm 1. In Phase I we *open bundles*, letting each  $P$ -item  $p$  pick a single buyer  $j$  with probability  $x_{pjp}$ ,<sup>4</sup> and opening the bundle  $jp$ . In Phase II we *enrich the bundles*, by adding  $N$ -items to them. Specifically, for each  $N$ -item  $i$ , we create a set  $S_i$  containing each open bundle  $jp$  independently with probability  $\alpha \cdot \frac{x_{ijp}}{x_{pjp}}$ , where  $\alpha \in [0, 1]$

<sup>4</sup> Since Constraint (4.5) is tight for every  $P$ -item in any optimal LP solution,  $\{x_{pjp}\}_j$  is a distribution over buyers.

is a parameter to be specified later. Then, if this set  $S_i$  contains a single bundle  $jp$  and adding  $i$  to this bundle would not violate the average-value constraint restricted to the bundle (denoted by  $\text{BundleAV}_{jp}$ ), i.e., this bundle would remain permissible, then we allocate  $i$  to the bundle  $jp$ . Otherwise, we leave  $i$  unallocated.

■ **Algorithm 1** Offline rounding of Bundle-LP.

---

```

1: Make the instance unambiguous as in Lemma 10
2: Let  $\mathbf{x}$  be an optimal solution to (Bundle-LP) for the obtained unambiguous instance
3: for each  $P$ -item  $p$  do ▷ Phase I
4:   Pick  $j$  according to distribution  $\{x_{pjp}\}_{j=1,\dots,n}$  and open bundle  $jp$ 
5: for each  $N$ -item  $i$  do ▷ Phase II
6:    $S_i \leftarrow \emptyset$ 
7:   for each bundle  $jp$ , with probability  $\alpha \cdot \frac{x_{ijp}}{x_{pjp}}$  do
8:     if  $jp$  was opened in Phase I then
9:        $S_i \leftarrow S_i \cup \{jp\}$ 
10:  if  $|S_i| = 1$  then
11:    if the only bundle  $jp \in S_i$  remains permissible after adding  $i$  to it then
12:      Allocate  $i$  to  $jp$ 

```

---

Algorithm 1 clearly outputs a feasible allocation, since it only allocates  $N$ -items  $i$  to a bundle  $jp$  if this would not violate the average-value constraint of the bundle, and hence by linearity the average-value constraint of the buyer remains satisfied. Moreover, the algorithm is well-defined; in particular, the probability spaces defined in lines 4 and 7 are valid, by constraints (4.5) for  $P$ -item  $p$ , and (4.6) for triple  $i, j, p$ , respectively. We turn to analyzing this algorithm's approximation ratio. For this, we will lower bound the probability of each item  $i$  to be allocated in bundle  $jp$  in terms of  $x_{ijp}$ .

By Section 4, each  $P$ -item  $p$  is assigned in bundle  $jp$  precisely with probability  $x_{pjp}$ . Consequently, the expected value Algorithm 1 obtains from  $P$ -items is precisely their contribution to the LP solution's value. It remains to understand what value we get from  $N$ -items.

#### 4.1 Allocation of $N$ -items

To bound the contribution of  $N$ -items, we consider any tuple of  $N$ -item  $i$ , buyer  $j$  and  $P$ -item  $p$ . Note that  $N$ -item  $i$  is assigned to bundle  $jp$  if and only if all the four following events occur:

1.  $\mathcal{E}_1$ : the event that bundle  $jp$  is open, which happens with probability  $x_{pjp}$ .
2.  $\mathcal{E}_2$ : the event that the Bernoulli( $\alpha \cdot \frac{x_{ijp}}{x_{pjp}}$ ) in Section 4 comes up heads for  $jp$ .
3.  $\mathcal{E}_3$ : the event that  $S_i \setminus \bigcup_{j'=1,\dots,n} \{j'p\} = \emptyset$ .
4.  $\mathcal{E}_4$ : the event that  $jp$  would remain permissible if we were to add  $i$  to bundle  $jp$ .

We note that events  $\mathcal{E}_1, \mathcal{E}_2, \mathcal{E}_3$  are all independent, as they depend on distinct (and independent) coin tosses. So, for example,  $\Pr[S_i \ni jp] = \Pr[\mathcal{E}_1 \wedge \mathcal{E}_2] = \Pr[\mathcal{E}_1] \cdot \Pr[\mathcal{E}_2] = \alpha \cdot x_{ijp}$ . Moreover, we have the following simple bound on  $\Pr[\mathcal{E}_3]$ .

► **Lemma 17.**  $\Pr\left[\bigwedge_{\ell=1}^3 \mathcal{E}_\ell\right] = \prod_{\ell=1}^3 \Pr[\mathcal{E}_\ell] \geq (1 - \alpha) \cdot \alpha \cdot x_{ijp}$ .

## 13:12 The Average-Value Allocation Problem

**Proof.** The first equality follows from independence of  $\mathcal{E}_1, \mathcal{E}_2, \mathcal{E}_3$ . We therefore turn to lower bounding  $\Pr[\mathcal{E}_3]$ . Since  $\Pr[X > 0] \leq \mathbb{E}[X]$  for any integer random variable  $X \geq 0$ , we know

$$\Pr[\overline{\mathcal{E}_3}] \leq \mathbb{E} \left[ \left| S_i \setminus \bigcup_{j'} \{j'p\} \right| \right] = \sum_{p' \neq p} \sum_{j'} \alpha \cdot x_{ij'p'} \leq \alpha,$$

where the equality follows from  $\Pr[S_i \ni j'p'] = \alpha \cdot x_{ij'p'}$  by the above, and the last inequality follows from Constraint (4.5). Since  $\Pr[\mathcal{E}_1] \cdot \Pr[\mathcal{E}_2] = \alpha \cdot x_{ijp}$ , the lemma follows.  $\blacktriangleleft$

**A challenge.** As noted above,  $\mathcal{E}_1, \mathcal{E}_2, \mathcal{E}_3$  are independent, resulting in a simple analysis for the probability  $\Pr[\bigwedge_{\ell=1}^3 \mathcal{E}_\ell] = \prod_{\ell=1}^3 \Pr[\mathcal{E}_\ell]$ . Unfortunately, lower bounding  $\Pr[\mathcal{E}_4 \mid \mathcal{E}_1 \wedge \mathcal{E}_2 \wedge \mathcal{E}_3]$  is more challenging, due to possible *negative correlations* between  $\mathcal{E}_4$  and  $\mathcal{E}_3$ . To see this, note that  $\mathcal{E}_3 \wedge \mathcal{E}_1$  implies  $S_i = \{jp\}$ , and this event can be positively correlated with previous  $N$ -items  $i'$  having  $S_{i'} = \{jp\}$ , thus making it more likely that  $jp$  won't be able to accommodate  $i$  under  $\text{BundleAV}_{jp}$ .

We can overcome this challenge of negative correlations, provided  $(i, j)$  has small deficit compared to  $(p, j)$ 's excess. (We address the large deficit case separately later.) Specifically, by coupling our algorithm with an algorithm that allocates more often and does not suffer from such correlations, we can lower bound this conditional probability as follows.

**► Lemma 18.** *Let  $\beta \in [0, 1]$ . If  $i, j, p$  are such that  $\rho_j - v_{ij} \leq \beta \cdot (v_{pj} - \rho_j)$ , then*

$$\Pr[\mathcal{E}_4 \mid \mathcal{E}_1 \wedge \mathcal{E}_2 \wedge \mathcal{E}_3] \geq 1 - \frac{\alpha}{1 - \beta}.$$

**Proof.** Consider an imaginary algorithm  $\mathcal{A}'$  that allocates every  $N$ -item  $i'$  into every bundle  $j'p' \in S_{i'}$ , even when  $|S_{i'}| > 1$  (so we may over-allocate) and even if this violates the  $\text{BundleAV}_{j'p'}$  constraint. Coupling  $\mathcal{A}'$  with Algorithm 1 by using the same randomness for both algorithms, we have that item  $i'$  is allocated to bin  $j'p'$  by  $\mathcal{A}'$  with probability precisely  $\Pr[S_{i'} \ni j'p'] = \alpha \cdot x_{i'j'p'}$ . In particular,  $\mathcal{A}'$  only allocates more items than Algorithm 1.

We denote by  $N'_{jp}$  the set of  $N$ -items allocated to bundle  $jp$  by  $\mathcal{A}'$ . Now, let  $\mathcal{E}'_4$  be the event that  $\sum_{i' \in N'_{jp} \setminus \{i\}} (\rho_j - v_{i'j}) \leq (1 - \beta) \cdot (v_{pj} - \rho_j)$ , that is, the deficit of  $N$ -items other than  $i$  that  $\mathcal{A}'$  allocated to the bundle  $jp$  together only consumes at most a  $(1 - \beta)$  fraction of  $p$ 's excess for  $j$ . By the small deficit assumption on  $i, j, p$ , we know that event  $\mathcal{E}'_4$  is sufficient for  $\text{BundleAV}_{jp}$  to be satisfied if Algorithm 1 were to add  $i$  to  $jp$ . Thus,  $\mathcal{E}'_4$  implies  $\mathcal{E}_4$  in any realization (of the randomness), since  $\mathcal{A}'$  only allocates more items to each bin than Algorithm 1. On the other hand, we also have that both  $\mathcal{E}'_4$  and  $\mathcal{E}_1$  are independent of both  $\mathcal{E}_2 \wedge \mathcal{E}_3$ , since the latter combined event depends on an independent random coin toss ( $\mathcal{E}_2$ ) and events concerning other bundles  $j'p'$ , which are both independent of the randomness concerning bundle  $jp$ . (Here we use that  $\mathcal{A}'$  allocates  $i$  to  $jp$  whenever  $S_i \ni jp$ , regardless of other bundles  $j'p'$  belonging to  $S_i$ .) Consequently, by standard applications of Bayes' Law, we obtain the following.

$$\Pr[\mathcal{E}'_4 \mid \mathcal{E}_1 \wedge \mathcal{E}_2 \wedge \mathcal{E}_3] = \Pr[\mathcal{E}'_4 \mid \mathcal{E}_1].$$

As the imaginary algorithm  $\mathcal{A}'$  assigns  $i'$  to  $jp$  (i.e.  $i' \in N'_{jp}$ ) iff  $S_{i'} \ni jp$ , we know that

$$\begin{aligned} \mathbb{E} \left[ \sum_{i' \in N'_{jp}} (\rho_j - v_{i'j}) \mid \mathcal{E}_1 \right] &= \sum_{i' \neq p} (\rho_j - v_{i'j}) \cdot \Pr[S_{i'} \ni jp \mid \mathcal{E}_1] \\ &= \alpha \cdot \sum_{i' \neq p} (\rho_j - v_{i'j}) \frac{x_{i'jp}}{x_{pjp}} \leq \alpha \cdot (v_{pj} - \rho_j). \end{aligned}$$

Above, the second equality follows from linearity and  $\Pr[S_{i'} \ni jp \mid \mathcal{E}_1] = \alpha \cdot \frac{x_{ij'p'}}{x_{pjp}}$ , and the inequality follows from the average-value constraint for bundle  $jp$  (i.e. Equation (4.4)) in our LP. Therefore, by Markov's inequality

$$\Pr \left[ \sum_{i' \in N'_{jp} \setminus \{i\}} (\rho_j - v_{i'j}) > (1 - \beta) \cdot (v_{pj} - \rho_j) \mid \mathcal{E}_1 \right] \leq \frac{\mathbb{E} \left[ \sum_{i' \in N'_{jp} \setminus \{i\}} (\rho_j - v_{i'j}) \mid \mathcal{E}_1 \right]}{(1 - \beta) \cdot (v_{pj} - \rho_j)} \leq \frac{\alpha}{1 - \beta},$$

and thus  $\Pr[\mathcal{E}'_4 \mid \mathcal{E}_1] \geq 1 - \frac{\alpha}{1 - \beta}$ . Recalling that  $\mathcal{E}'_4$  implies  $\mathcal{E}_4$  in any realization, we conclude with the desired bound, as follows.

$$\Pr[\mathcal{E}_4 \mid \mathcal{E}_1 \wedge \mathcal{E}_2 \wedge \mathcal{E}_3] \geq \Pr[\mathcal{E}'_4 \mid \mathcal{E}_1 \wedge \mathcal{E}_2 \wedge \mathcal{E}_3] = \Pr[\mathcal{E}'_4 \mid \mathcal{E}_1] \geq 1 - \frac{\alpha}{1 - \beta}. \quad \blacktriangleleft$$

Lemma 18 and the preceding discussion yield a lower bound on the probability of an  $N$ -item  $i$  being successfully allocated to a bundle  $jp$  when  $i$ 's deficit is small relative to the excess of the  $P$ -item  $p$ . For the large deficit case, no such bound holds. However, as we now observe (with proof deferred to the full version), large-deficit edges contribute a relative small portion of the allocation's value in the optimal LP solution.

► **Lemma 19.** *Let  $\beta \in [0, 1]$ . For any bundle  $jp$ , let  $L_{jp}^\beta$  denote the set of  $\beta$ -large deficit  $N$ -items for bundle  $jp$ , i.e.,  $N$ -item  $i$  with  $\rho_j - v_{ij} > \beta \cdot (v_{pj} - \rho_j)$ . Then,*

$$\sum_{j,p} \sum_{i \in L_{jp}^\beta} v_{ij} x_{ijp} \leq \frac{1}{\beta} \sum_{j,p} v_{pj} x_{pjp}.$$

## 4.2 Completing the analysis

We are now ready to bound the approximation ratio of Algorithm 1.

► **Theorem 20.** *Algorithm 1 with  $\alpha = 0.3$  is a 32-approximation for AVA.*

**Proof.** Let  $\beta \in [0, 1]$  be some constant to be determined and let  $\gamma = \gamma(\alpha, \beta) := \alpha \cdot (1 - \alpha) \cdot \left(1 - \frac{\alpha}{1 - \beta}\right)$ . Denote  $N_{jp}$  by the set of  $N$ -items allocated to bundle  $jp$  by the algorithm. By Lemmas 17 and 18 we have for bundle  $jp$  and  $N$ -item  $i \notin L_{jp}^\beta$  that

$$\Pr[i \in N_{jp}] = \Pr \left[ \mathcal{E}_4 \mid \bigwedge_{\ell=1}^3 \mathcal{E}_\ell \right] \Pr \left[ \bigwedge_{\ell=1}^3 \mathcal{E}_\ell \right] \geq \left(1 - \frac{\alpha}{1 - \beta}\right) \cdot \alpha \cdot (1 - \alpha) \cdot x_{ijp} = \gamma \cdot x_{ijp}.$$

Therefore, by linearity of expectation and Lemma 19, the expected value of the (feasible) random allocation of Algorithm 1 is at least

$$\begin{aligned} & \sum_{j,p} v_{pj} x_{pjp} + \gamma \sum_{i,j,p:i \neq p} v_{ij} x_{ijp} - \gamma \sum_{j,p} \sum_{i \in L_{jp}^\beta} v_{ij} x_{ijp} \\ & \geq \left(1 - \frac{\gamma}{\beta}\right) \sum_{j,p} v_{pj} x_{pjp} + \gamma \sum_{i,j,p:i \neq p} v_{ij} x_{ijp}. \end{aligned}$$

So, this algorithm's output has value at least a  $\min\{1 - \frac{\gamma}{\beta}, \gamma\}$  fraction of the optimal LP value; i.e., it is a  $1 / \min\{1 - \frac{\gamma}{\beta}, \gamma\}$ -approximation. Taking  $\alpha \approx 0.3$  and  $\beta \approx 0.156$  (optimized by an off-the-shelf numerical solver) yields a ratio of  $1/0.13 < 8$ . The theorem then follows from Lemma 16 and Lemma 10.  $\blacktriangleleft$

### 4.3 Extension: adding side constraints

Before moving on to our online algorithms, we note that the LP-based approach allows us to incorporate additional constraints seamlessly. For example, our LP and algorithm, with minor modifications, allow to approximate allocation problems with both the average-value constraint and  $O(1)$  many budget constraints (for every buyer), corresponding to different resources. More formally, for a cost function  $\ell$  (e.g., corresponding to storage, time, or other costs), each buyer  $j$  has some budget  $B_j^{(\ell)}$ , and the  $\ell$ -cost of allocation to buyer  $j$  must not exceed this budget. That is, for  $x_{ij} \in \{0, 1\}$  an indicator for item  $i$  being allocated to buyer  $j$ , we have

$$\forall j, \quad \ell\text{-cost}_j = \sum_i \ell_{ij} x_{ij} \leq B_j^{(\ell)}. \quad (4.8)$$

The *small-cost* assumption (a.k.a. the small-bids assumption for online AdWords [32]) stipulates that no particular item has high cost compared to the budget, i.e.  $\max_{ij} \ell_{ij}/B_j^{(\ell)} \leq \varepsilon \rightarrow 0$ .

► **Theorem 21.** *There exists a constant-approximate algorithm for AVA and any constant number of budget constraints (for every buyer) subject to the small-bids assumption.*

We defer the proof of the above result to the full version. The same arguments in this section extend to our online algorithms, but are omitted for brevity.

## 5 Online Algorithms: Approximating the Online Optimum

In this section and the next we study AVA in the online i.i.d. setting (see Section 1.3 for definition and notation). Specifically, in this section we provide a polynomial-time online algorithm which provides a constant approximation of the optimal online algorithm.

First, by Lemma 6, we have that the optimal online algorithm is approximated within a factor two by a bundling-based online algorithm which is *committed*. As we will show, the following LP provides a relaxation for the value of the best such online algorithm. Our LP consists of variables  $x_{ijp}$  for each item type  $i \in [m]$ , buyer  $j \in [n]$  and item type  $p$  such that  $(p, j)$  is a  $P$ -edge.

$$\max \sum_{i,j,p} v_{ij} x_{ijp} \quad (\text{OPTon-Bundle-LP})$$

$$\text{s.t.} \quad \sum_i (\rho_j - v_{ij}) x_{ijp} \leq 0 \quad \forall P\text{-edge type } (p, j) \quad (5.9)$$

$$\sum_{j,p} x_{ijp} \leq q_i \cdot T \quad \forall \text{ item type } i \quad (5.10)$$

$$x_{ijp} \leq x_{pjp} \cdot q_i \cdot T \quad \forall N\text{-edge type } (i, j), P\text{-edge type } (p, j) \quad (5.11)$$

$$x_{p'jp} = 0 \quad \forall P\text{-edge types } (p, j) \neq (p', j) \quad (5.12)$$

$$x_{ijp} \geq 0 \quad \forall \text{ item type } i, P\text{-edge type } (p, j)$$

► **Lemma 22.** *(OPTon-Bundle-LP) has value which is at least half the expected value of any online AVA algorithm under i.i.d. arrivals (from the same distribution used in the LP), where item type  $i$  is drawn with probability  $q_i$ .*

**Proof.** First, by the Online Bundling Lemma (Lemma 8), the best committed online bundling-based algorithm 2-approximates the best online algorithm. We therefore turn to showing that (OPTon-Bundle-LP) is a relaxation of the value of the best committed bundling-based online algorithm,  $\mathcal{A}$ . Let  $x_{ijp}$  be the average number of times a copy of item type  $i$  is allocated in a copy of bundle  $jp$  by  $\mathcal{A}$ . Constraint (5.9) follows by linearity of expectation, together with the fact that each opened copy of bundle  $jp$  must satisfy the average-value constraint. Constraint (5.10) simply asserts that  $i$  is allocated at most as many times as it arrives. Constraint (5.11) holds for a committed online algorithm (that guarantees feasibility with probability 1), for the following reason: for every copy of bundle  $jp$  opened, no items can be placed in that bundle before it is opened. But the expected number of copies of  $i$  to be assigned after any bundle  $jp$  is opened is at most the number of arrivals of  $i$  after this bundle is opened and is at most  $q_i \cdot T$ , which upper-bounds the ratio between  $x_{ijp}$  and  $x_{pjp}$ . All other constraints hold similarly to their counterparts in the proof of Lemma 16.  $\blacktriangleleft$

**Note.** Constraint (5.11) is reminiscent of constraints bounding the optimal online algorithm in the secretary problem literature [12] and prophet inequality literature [34].

The outline of our algorithm is similar to that of Algorithm 1, though as it does not have random access to the different items throughout, it first allocates  $P$ -edges in the first  $T/2$  arrivals, and only then allocates  $N$ -edges in the last  $T/2$  arrivals. To distinguish between bundles opened at different times, we now label copies of bundle type  $jp$  (i.e., items allocated to buyer  $j$  with single  $P$ -edge of type  $(p, j)$ ) opened at time  $t$  by  $jpt$ . The algorithm's pseudocode is given in Algorithm 2.

Note that in our online algorithms (here and in Appendix A), the LPs are based on distributions that can be ambiguous in the sense that each item type in the distribution can have both  $P$ -edges and  $N$ -edges, and we don't explicitly modify the distribution to make it unambiguous. However, our algorithm effectively makes each realized instance (of  $T$  sampled items) unambiguous, as we ignore all  $N$ -edges incident to the first  $T/2$  items and vice versa for the last  $T/2$  items.

■ **Algorithm 2** Online rounding of bundling-based LP.

---

```

1: Let  $\mathbf{x}$  be an optimal solution to Equation (OPTon-Bundle-LP)
2: for all arrivals  $t = 1, \dots, T/2$ , of type  $p$  do
3:   Pick a  $j$  according to the distribution  $\{\frac{x_{pjp}}{q_p \cdot T}\}_{j=1, \dots, n}$  and open bundle  $jpt$ 
4: for all arrival  $t^* = T/2 + 1, \dots, T$  of type  $i$  do
5:    $S_{it^*} \leftarrow \emptyset$ 
6:   for all bundles  $jpt$ , with probability  $\frac{\alpha \cdot x_{ijp}}{x_{pjp} \cdot q_i \cdot T}$  do
7:     if bundle  $jpt$  is open then
8:        $S_{it^*} \leftarrow S_{it^*} \cup \{jpt\}$ 
9:   if  $|S_{it^*}| = 1$  then
10:    if  $jpt \in S_{it^*}$  remains permissible after adding  $it^*$  to it then
11:      Allocate  $it^*$  to  $jpt$ 

```

---

## 5.1 Analysis

In what follows we provide a brief overview of the relevant events in the analysis of Algorithm 2, deferring proofs reminiscent of the analysis of Algorithm 1 to the full version.

## 13:16 The Average-Value Allocation Problem

First, the value obtained from  $P$ -edges by Algorithm 2 is clearly half that of the LP, by linearity of expectation. In particular, we create  $x_{pjp}/2$  copies of bundle  $jp$  in expectation. The crux of the analysis is in bounding our gain from  $N$ -edges.

To bound the contribution of  $N$ -edges, we note that a copy of item  $i$  at time  $t^* > T/2$ , which we denote by  $it^*$ , is assigned to bundle  $jpt$  if and only if all the five following events (overloading notation from Section 4) occur:

1.  $\mathcal{E}_0$ : the event that  $it^*$  is the realized item at time  $t^*$ , which happens with probability  $q_i$
2.  $\mathcal{E}_1$ : the event that bundle  $jpt$  is open, which happens with probability  $q_p \cdot \frac{x_{pjp}}{q_p \cdot T} = \frac{x_{pjp}}{T}$ .
3.  $\mathcal{E}_2$ : the event that the Bernoulli( $\frac{\alpha \cdot x_{ijp}}{x_{pjp} \cdot q_i \cdot T}$ ) in Section 5 comes up heads for  $jpt$ .
4.  $\mathcal{E}_3$ : the event that  $S_{it^*} \setminus \bigcup_{j'p'} \bigcup_{t' \neq t} \{j'p't'\} = \emptyset$ .
5.  $\mathcal{E}_4$ : the event that  $jpt$  would remain permissible if we were to add  $it^*$  to bundle  $jpt$ .

Similarly to the events we studied when analyzing our offline Algorithm 1, the events  $\mathcal{E}_0, \mathcal{E}_1, \mathcal{E}_2$  are independent, as are the events  $\mathcal{E}_1, \mathcal{E}_2, \mathcal{E}_3$ . However,  $\mathcal{E}_3$  is not independent of  $\mathcal{E}_0$  (in particular, it occurs trivially if  $\mathcal{E}_0$  does not). Nonetheless, bounding  $\Pr \left[ \bigwedge_{\ell=0}^3 \mathcal{E}_\ell \right]$  is not too hard. The following lemma, whose proof essentially mirrors that of Lemma 17, and is thus deferred to the full version, provides a bound on the probability of all first four events occurring.

► **Lemma 23.**  $\Pr[\mathcal{E}_0 \wedge \mathcal{E}_1 \wedge \mathcal{E}_2 \wedge \mathcal{E}_3] \geq \alpha \cdot (1 - \alpha/2) \cdot \frac{x_{ijp}}{T^2}$ .

As with our offline Algorithm 1, the challenge in the analysis is due to possible negative correlations between  $\mathcal{E}_4$  and  $\mathcal{E}_3$ . Similarly, we overcome this challenge of negative correlations, provided  $(i, j)$  has small deficit compared to  $(p, j)$ 's excess, by coupling with an algorithm with no such correlations. (We address large-deficit  $(i, j)$  later.) The obtained syntactic generalization of Lemma 18, whose proof is deferred to the full version, is the following.

► **Lemma 24.** *Let  $\beta \in [0, 1]$ . If  $i, j, p$  are such that  $\rho_j - v_{ij} \leq \beta \cdot (v_{pj} - \rho_j)$ , then*

$$\Pr[\mathcal{E}_4 \mid \mathcal{E}_0 \wedge \mathcal{E}_1 \wedge \mathcal{E}_2 \wedge \mathcal{E}_3] \geq 1 - \frac{\alpha}{2(1-\beta)}.$$

Lemma 24 and the preceding discussion yield a lower bound on the probability of a copy of item  $i$  be allocated to a bundle  $jpt$  at time  $t^*$  if  $i, j, p$  is in the small deficit case as the above lemma. For large-deficit items, no such bound holds. However, large-deficit edges contribute a small portion of the allocation's value. Specifically, Lemma 19, holds for (OPTon-Bundle-LP) as well, since the only constraint that this lemma's proof relied on was Constraint (4.4), which is identical to Constraint (5.9) in (OPTon-Bundle-LP).

We are now ready to bound the approximation ratio of Algorithm 1.

► **Theorem 25.** *Algorithm 1 with  $\alpha = 0.64$  is a polynomial-time algorithm achieving a 57-approximation of the optimal online algorithm for AVA under known i.i.d. arrivals.*

**Proof.** That the algorithm runs in polynomial time follows from its description, together with the LP (OPTon-Bundle-LP) having polynomial size (in the distribution size). The analysis is essentially identical to that of Theorem 20, with the following differences. First, we recall that the expected number of copies of bundle  $jp$  opened is  $\frac{T}{2} \cdot q_p \cdot \frac{x_{pjp}}{q_p \cdot T} = \frac{1}{2} x_{pjp}$ . Next, by Lemmas 23 and 24, the probability that copy  $it^*$  of small-deficit item  $i$  for bundle  $jpt$  is allocated to it is at least  $\gamma \cdot \frac{x_{ijp}}{T^2}$ , for  $\gamma = \gamma(\alpha, \beta) := \frac{\alpha}{2} \cdot (1 - \frac{\alpha}{2}) \cdot (1 - \frac{\alpha}{2(1-\beta)})$ . Again, linearity of expectation and summation over all  $(t, t^*) \in [T/2] \times (T/2, T]$  in combination with Lemma 19 implies that for any  $\beta \in [0, 1]$ , the gain of Algorithm 2 is at least

$$\begin{aligned} & \frac{1}{2} \left( \sum_{j,p} v_{pj} x_{pj} + \frac{\gamma}{4} \sum_{i,j,p:i \neq p} v_{ij} x_{ij} - \frac{\gamma}{4} \sum_{j,p} \sum_{i \in L_{jp}^\beta} v_{ij} x_{ij} \right) \\ & \geq \left( \left( \frac{1}{2} - \frac{\gamma}{4\beta} \right) \sum_{j,p} v_{pj} x_{pj} + \frac{\gamma}{4} \sum_{i,j,p:i \neq p} v_{ij} x_{ij} \right). \end{aligned}$$

Therefore, by Lemma 22, Algorithm 2 yields a  $2/\min\{\frac{1}{2} - \frac{\gamma}{4\beta}, \frac{\gamma}{4}\}$ -approximation. This expression is optimized by  $\alpha \approx 0.64$  and  $\beta \approx 0.0766$ , yielding a ratio of  $\approx \frac{2}{0.0355} < 57$ , as claimed.  $\blacktriangleleft$

## A Online Algorithms: Approximating the Offline Optimum

In this section we look at the lower and upper bounds of the competitive ratio for online algorithms, i.e. the approximation of the ex-post optimum allocation’s value, and we consider both the adversarial and i.i.d. cases.

**Adversarial arrival.** In this setting, we note that no online algorithm can be  $o(T)$ -competitive. To see this, consider the unit- $\rho$  instance where the first  $T - 1$  arriving items have value  $1 - \varepsilon$  for all  $n = T$  buyers, followed by a single item at the end with value  $1 + \varepsilon T$  for a single adversarially chosen buyer and value 0 for all other buyers. Any online algorithm cannot allocate any of the first  $T - 1$  items due to the average-value constraint, and thus can only get value  $1 + \varepsilon T$  from the last item. In contrast, the ex-post optimum can allocate all items to one buyer and collect value  $T + 1 - \varepsilon$ . On the other hand, a competitive ratio of  $T$  is trivial to achieve for online AVA, by simply allocating any item  $i$  with a  $P$ -edge  $(i, j)$  greedily to the buyer  $j$  yielding the highest value. This is a feasible allocation and has value equal to the highest-valued edge in the  $T$ -item instance, which is obviously at least a  $1/T$  fraction of the optimal allocation’s value.

The rest of this section will therefore be dedicated to AVA with i.i.d. arrivals, as in Section 5, but now focusing on approximating the ex-post optimum. We start with the following result lower bounding the competitive ratio.

► **Lemma 26.** *There exists a family of uniform online i.i.d. unambiguous unit- $\rho$  AVA instances with  $n = m = T \geq 2$  growing, on which every online algorithm’s approximation ratio of the ex-post optimum is at least  $\Omega\left(\frac{\ln n}{\ln \ln n}\right) = \Omega\left(\frac{\ln m}{\ln \ln m}\right) = \Omega\left(\frac{\ln T}{\ln \ln T}\right)$ .*

**Proof.** Let  $\varepsilon = \frac{1}{T}$ . Consider an instance with  $T$  buyers  $j_1, \dots, j_T$ , where all buyers have  $\rho = 1$ , and  $T$  item types. Each item type  $i \in [T - 1]$  is an  $N$ -item, with value  $1 - \varepsilon$  for buyer  $j_i$  and value zero for all others. (So, buyer  $j_T$  has zero value for all  $N$ -items.) The single  $P$ -item type  $T$  has value  $1 + \varepsilon T$  for all buyers. The  $T$  arrival types are drawn uniformly from these  $T$  types, and consequently there is a single arrival of each type in expectation. Now, an online algorithm (that guarantees average-value constraints in any outcome) can only allocate  $N$ -items to a buyer after the buyer was allocated a  $P$ -item. But since each  $N$ -item appears only once in expectation (and hence at most once after the arrival of a  $P$ -item type), each allocation of a  $P$ -item (and  $N$ -items) to a buyer yields expected value at most  $1 + \varepsilon T + 1 - \varepsilon = 3 - \varepsilon$  to an online algorithm. Since only one  $P$ -item arrives in expectation, an online algorithm accrues value at most  $3 - \varepsilon$  in expectation on this instance family.

In contrast, the event  $\mathcal{E}$  that a single  $P$ -item arrived satisfies  $\Pr[\mathcal{E}] = T \cdot \frac{1}{T} \cdot \left(1 - \frac{1}{T}\right)^{T-1} \geq \left(1 - \frac{1}{T}\right)^T \geq \frac{1}{4}$ . Conditioned on  $\mathcal{E}$ , we have a multi-nomial distribution for the number of arrivals  $A_i$ ’s of the  $N$ -item types. Therefore, by standard anti-concentration arguments for the classic balls and bins process [6], we have

$$\Pr\left[\max_i A_i \geq \frac{\ln T}{\ln \ln T} - 1 \mid \mathcal{E}\right] = 1 - o(1).$$

Consequently, the offline algorithm which, if event  $\mathcal{E}$  occurs, allocates the single  $P$ -item and all copies of  $i^* := \arg \max_i A_i$  to  $j_{i^*}$  yields expected value at least  $\mathbb{E}[\max_i A_i \mid \mathcal{E}] \cdot \Pr[\mathcal{E}] = \Omega\left(\frac{\ln T}{\ln \ln T}\right)$ . Consequently, this asymptotic ratio also lower bounds any online algorithm's approximation ratio of the ex-post optimum. The full lemma statement follows, since  $n = m = T$ .  $\blacktriangleleft$

### A.1 A matching algorithm assuming constant expected arrivals

Lemma 26 relied on anti-concentration. If the expected number of arrivals  $A_i$  of each item type  $i$  is at least some constant  $\Gamma > 0$ , namely  $\mathbb{E}[A_i] = q_i \cdot T \geq \Gamma$  (e.g., in Lemma 26 we had  $q_i \cdot T = 1$  for every  $i$ ), then this anti-concentration is tight. In particular, we have the following, by standard Chernoff bounds and union bound (see the full version for proof).

► **Observation 27.** *If  $\mathbb{E}[A_i] \geq \Gamma$  for all  $i \in [m]$  and  $\kappa := \frac{6}{\min(1, \Gamma)} \cdot \frac{\ln T}{\ln \ln T}$ , then*

$$\Pr\left[\max_i A_i \geq \kappa \cdot q_i \cdot T\right] \leq \frac{1}{T^2}.$$

We will show that if the distribution satisfies the assumption on all  $\mathbb{E}[A_i] \geq \Gamma = \Theta(1)$ , we can show an asymptotically matching upper-bound  $O\left(\frac{\ln T}{\ln \ln T}\right)$  of the competitive ratio.

Our first ingredient towards this proof will, naturally, be another LP, this time capturing possible anti-concentration of arrivals. Similar to (OPTon-Bundle-LP), the LP has one variable  $x_{ijp}$  for each item type  $i \in [m]$ , buyer  $j \in [n]$  and item type  $p$  such that  $(p, j)$  is a  $P$ -edge.

$$\max \sum_{i,j,p} v_{ij} x_{ijp} \quad (\text{OPToff-Bundle-LP})$$

$$\text{s.t.} \quad \sum_i (\rho_j - v_{ij}) x_{ijp} \leq 0 \quad \forall P\text{-edge type } (p, j) \quad (\text{A.13})$$

$$\sum_{jp} x_{ijp} \leq 2 \cdot \lceil q_i \cdot T \rceil \quad \forall \text{ item type } i \quad (\text{A.14})$$

$$x_{ijp} \leq x_{pjp} \cdot \lceil q_i \cdot T \cdot \kappa \rceil \quad \forall N\text{-edge type } (i, j), P\text{-edge type } (p, j) \quad (\text{A.15})$$

$$x_{p'jp} = 0 \quad \forall P\text{-edge types } (p, j) \neq (p', j) \quad (\text{A.16})$$

$$x_{ijp} \geq 0 \quad \forall \text{ item type } i, P\text{-edge type } (p, j)$$

► **Lemma 28.** *Fix an AVA instance with i.i.d. arrivals satisfying  $q_i \cdot T \geq \Gamma = \Theta(1)$  for all  $i \in [m]$ . Let OPT be the ex-post optimal value and let  $V[\text{OFF}]$  be the value of (OPToff-Bundle-LP). Then,*

$$\mathbb{E}[\text{OPT}] \leq O(V[\text{OFF}]).$$

**Proof.** By Lemma 16, we can restrict to the optimal ex-post bundling-based solution and just lose a factor of 2 in the approximation ratio. We start with a trivial upper-bound on the value of OPT in any outcome of the i.i.d. arrivals. Consider the instance with exactly one copy of each item type from the support of the distribution. The best bundling-based offline solution for this instance is upper-bounded by (Bundle-LP) (Lemma 16), and this value is clearly upper bounded by  $V[\text{OFF}]$  since the constraints for (Bundle-LP) are tighter than those of (OPToff-Bundle-LP). Under  $T$  i.i.d. arrivals, each item can appear at most  $T$  times, and thus by the Supply Lemma (Lemma 12) applied to the instance with a single occurrence per item type, we find that the following bound holds deterministically.

$$\text{OPT} \leq O(T^2) \cdot V[\text{OFF}].$$

Next, let  $\mathcal{E}$  be the event that no item type  $i$  has more than  $\lceil q_i \cdot T \cdot \kappa \rceil$  arrivals. By Observation 27,  $\Pr[\mathcal{E}] \geq 1 - \frac{1}{T^2}$ . Conditioned on  $\mathcal{E}$ , consider the expected number of times (over the randomness of the i.i.d. arrivals) that the ex-post optimal bundling-based solutions allocate an item of type  $i$  to a copy of bundle  $jp$ , and denote this value by  $x_{ijp}$ . We will argue that such  $x_{ijp}$ 's form a feasible solution for (OPToff-Bundle-LP). Since the expected value of the ex-post optimal bundling-based solution conditioned on  $\mathcal{E}$  is simply  $\sum_{i,j,p} v_{ij} x_{ijp}$ , this immediately gives that  $\mathbb{E}[\text{OPT} \mid \mathcal{E}] \leq 2 \cdot V[\text{OFF}]$ .

The proof that  $x_{ijp}$  constructed above is feasible follows essentially the same argument as Lemma 22. The average-value constraint (A.13) holds by linearity of expectation because the ex-post (bundling-based) optimum for any outcome satisfies the average-value constraint. Constraint (A.14) holds since the expected times we allocate items of type  $i$  cannot exceed  $i$ 's expected number of occurrences, which is bounded by  $\mathbb{E}[A_i \mid \mathcal{E}] \leq \frac{\mathbb{E}[A_i]}{\Pr[\mathcal{E}]} \leq \frac{q_i \cdot T}{1 - 1/T^2} \leq 2 \cdot q_i \cdot T \leq 2 \cdot \lceil q_i \cdot T \rceil$ . Constraint (A.15) holds since whenever a bundle  $jp$  is opened in the ex-post optimum for any outcome, conditioned on  $\mathcal{E}$  we have at most  $q_i \cdot T \cdot \kappa$  items of type  $i$ , which is a trivial upperbound on how many items of type  $i$  can be allocated to bundle  $jp$ , and thus cap the ratio between  $x_{ijp}$  and  $x_{pjp}$ .

Combining the above arguments together with linearity of expectation, the lemma follows.

$$\mathbb{E}[\text{OPT}] = \mathbb{E}[\text{OPT} \mid \mathcal{E}] \cdot \Pr[\mathcal{E}] + \mathbb{E}[\text{OPT} \mid \bar{\mathcal{E}}] \cdot \Pr[\bar{\mathcal{E}}] \leq O(V[\text{OFF}]). \quad \blacktriangleleft$$

We make the simple observation that (OPTon-Bundle-LP) and (OPToff-Bundle-LP) only differ at the RHS of the constraints, with the most crucial difference being in the constraints upper bounding  $x_{ijp}/x_{pjp}$ , where they differ by a factor of  $\frac{\lceil q_i \cdot T \cdot \kappa \rceil}{q_i \cdot T} = O(\kappa)$  (using that  $\Gamma = \Omega(1)$ ). As we prove in the full version, scaling down any feasible solution of the latter LP by  $O(\kappa)$  yields a feasible solution to the former LP, leading to the following observation.

► **Observation 29.** *Fix an AVA instance with i.i.d. arrivals, satisfying  $q_i \cdot T \geq \Gamma = \Theta(1)$  for all item type  $i$ . Then,  $V[\text{OFF}]$  and  $V[\text{ON}]$ , the values of (OPToff-Bundle-LP) and (OPTon-Bundle-LP) (respectively) satisfy  $V[\text{OFF}] \leq O\left(\frac{\ln T}{\ln \ln T}\right) \cdot V[\text{ON}]$*

In our proof of Theorem 25, we showed that Algorithm 2 achieves value at least  $\Omega(V[\text{ON}])$ . Consequently, Lemma 28 and Observation 29 imply the following result.

► **Theorem 30.** *Algorithm 2 is an  $O\left(\frac{\ln T}{\ln \ln T}\right)$ -competitive online algorithm for AVA under  $T$  known i.i.d. arrivals with each item type arriving an expected constant number of times.*

► **Remark 31.** Under the stronger assumption that  $\mathbb{E}[A_i] = q_i \cdot T = \Omega(\ln(mT)/\varepsilon^2)$  for each of the  $m$  item types  $i$  (e.g., if  $T$  grows while the distribution  $\{q_i\}$  remains fixed), the number of arrivals of each item is more concentrated: it is  $\mathbb{E}[A_i] \cdot (1 \pm \varepsilon)$  w.h.p. Consequently, natural extensions of the arguments above, with a smaller blow-up of the RHS of the constraints in (OPTon-Bundle-LP), imply that Algorithm 2's competitive ratio improves to  $O(1)$  in this case.

## **B** Hardness Results

In this section we provide hardness of approximation results for AVA and stark impossibility results for the generalization to GenAVA.

### **B.1** Max-Coverage hardness of AVA

Here we prove that AVA is as hard as the Max-Coverage problem, even if restricted to the unit- $\rho$  case.

## 13:22 The Average-Value Allocation Problem

► **Theorem 32** (Hardness of AVA). *For any constant  $\varepsilon > 0$ , it is NP-hard to approximate AVA to a factor better than  $(\frac{\varepsilon}{\varepsilon-1} + \varepsilon)$  even for unit- $\rho$  instances.*

**Proof.** We give a reduction from “balanced” instances of the MAX-COVERAGE problem. Such an instance consists of a set system with  $n$  elements and  $m$  sets, with each set containing  $n/k$  elements. A classic result of [21] shows that for each  $\delta > 0$ , there exist  $n$  and  $k \leq n\delta$ , such that it is NP-hard to distinguish between the following two cases: (a) there exists a perfect partition, i.e.,  $k$  sets in the set system that cover all  $n$  elements (YES-instances), and (b) no collection of  $k$  sets from the set system cover more than  $n(1 - 1/e + \delta)$  elements (NO-instances). We now define a unit- $\rho$  AVA instance consisting of:

1.  $m$  buyers, where each buyer  $i_S$  corresponds to a set  $S$  in the set system,
2.  $k$  identical *choice items*, which have value  $1 + (\varepsilon/2) \cdot n/k$  for every buyer, and
3.  $n$  distinct *element items*, one for each element  $e$ , which has value  $1 - (\varepsilon/2)$  for the buyers  $i_S$  such that set  $S$  contains element  $e$ , and value zero for the other buyers.

For a YES-instance of MAX-COVERAGE, there is a solution with value  $k + n$ : we can assign both the choice and element items to the buyers corresponding to the  $k$  sets in the perfect partition, thereby getting us value  $n + k$ . (The excess for each choice item can subsidize the deficit for the  $n/k$  element items assigned to that buyer.) On the other hand, for a NO-instance, the  $k$  buyers/sets selected by the choice items can give value  $k$  and also subsidize at most  $n(1 - 1/e + \delta)$  element items with deficit. (No other items with deficit can be chosen.) Setting  $\delta = \varepsilon/2$  means the NO-instances have value at most  $k + n(1 - 1/e + \delta) + n\varepsilon/2 \leq n(1 - 1/e + \varepsilon)$ . This gives a gap between instances with value at least  $n$  and at most  $n(1 - 1/e + \varepsilon)$ , proving the theorem. ◀

### B.2 Clique hardness of GenAVA

Next, we prove that approximating GenAVA defined in (1.2) is as hard as approximating the maximum independent set number in a graph. Recall that the objective in GenAVA is to maximize welfare  $\sum_{ij} v_{ij} x_{ij}$  subject to the more general return-on-spend (ROS) constraints:

$$\forall j, \quad \sum_i v_{ij} x_{ij} \geq \rho_j \cdot \left( \sum_i c_{ij} x_{ij} \right). \quad (\text{B.17})$$

Without loss of generality, we scale  $c_{ij}$  and ensure that all  $\rho_j = 1$ . We show the hardness even for the case where costs depend only on the items, i.e.,  $c_{ij} = c_i$  for each item  $i$ . (The case where  $c_{ij} = c_j$  for each buyer  $j$  is much easier – equivalent to the AVA problem – because we can just fold the  $c_j$  term into the  $\rho_j$  threshold.)

► **Theorem 33** (Hardness of GenAVA). *For any constant  $\varepsilon > 0$ , it is NP-hard to approximate GenAVA for  $n$ -buyer instances with  $\Omega(n^2)$  items to better than a factor of  $n^{1-\varepsilon}$ .*

The proof uses a reduction from the Maximum Independent Set problem. The reduction proceeds as follows: given a graph  $G = (V, E)$  with  $|V| = n$ , define  $M := 2|E|/n^\varepsilon$ , and construct the following GenAVA instance.

1. For each vertex  $v \in V$ , there is a buyer  $j_v$  with  $\rho_{j_v} = 1$ .
2. For each vertex  $v \in V$ , there is a *vertex item*  $i_v$  with item cost  $c_i := M + \deg(v)$ , where  $\deg(v)$  is  $v$ 's degree in  $G$ ; it has value  $M$  for the buyer  $j_v$ , and zero value for all other buyers.
3. For each edge  $e = (u, v) \in E$ , there is an *edge item*  $i_e$  having zero cost; it has value 1 for buyers  $j_u$  and  $j_v$ , and zero value for all others.

**Proof of Theorem 33.** If vertex item  $i_v$  is allocated to buyer  $j_v$ , then by the constraints above, all edge items  $j_e$  with  $e \ni v$  must be allocated to  $i_v$ . Thus, the set of vertices  $U \subseteq V$  whose buyers are sold their respective vertex item is an independent set in  $G$ . Conversely,  $U$  can be taken to be any independent set. Thus, the maximum value obtained by allocating vertex items is precisely  $M \cdot \alpha(G)$ . On the other hand, any optimal allocation must allocate all edge items, as this does not violate any of the ROS constraints. Combining the above, we have that  $OPT = \alpha(G) \cdot M + |E|$ , where  $\alpha(G)$  is the independence number of  $G$ , i.e., the size of the maximum independent set of  $G$ .

Finally, we use the result that for any constant  $\varepsilon > 0$ , it is NP-hard to distinguish between the following two scenarios for an  $n$ -node graph  $G$ : (a)  $G$  contains a clique on  $n^{1-\varepsilon}$  nodes (YES instances), and (b)  $G$  contains no clique on  $n^\varepsilon/2$  nodes (NO instances) [27, 36]. This means that it is NP-hard to distinguish between instances of GenAVA with value at least  $n^{1-\varepsilon} \cdot M$  (corresponding to YES instances) from those with value at most  $(n^\varepsilon/2) \cdot M + |E| = n^\varepsilon \cdot M$  corresponding to the NO instances, and hence proves the claim. ◀

The above hardness construction can, with small changes, show the following hardness results. We defer these additional results' proofs, as well as algorithms showing the (near) tightness of our lower bounds for general GenAVA, to the full version.

► **Theorem 34** (Hardness of i.i.d. GenAVA). *For any constant  $\varepsilon > 0$ , it is NP-hard to  $n^{1-\varepsilon}$ -approximate GenAVA in  $n$ -buyer instances with  $\text{poly}(n)$  items drawn i.i.d. from a known distribution.*

► **Theorem 35** (Hardness of Bicriteria GenAVA). *For any  $\varepsilon > 0$ , it is NP-hard to obtain a solution (which can even be infeasible) to GenAVA that achieves an objective value at least  $\tilde{\Omega}(\sqrt{\varepsilon})$  times the optimal value (i.e. an  $\tilde{O}(1/\sqrt{\varepsilon})$ -approximation), while guaranteeing the cost for each buyer is at most  $1 + \varepsilon$  times their total value, assuming the UGC.<sup>5</sup>*

## Abstract

We consider a new scheduling problem on parallel identical machines in which the number of machines is initially not known, but it follows a given probability distribution. Only after all jobs are assigned to a given number of bags, the actual number of machines is revealed. Subsequently, the jobs need to be assigned to the machines without splitting the bags. This is the stochastic version of a related problem introduced by Stein and Zhong [SODA 2018, TALG 2020] and it is, for example, motivated by bundling jobs that need to be scheduled by data centers. We present two PTASs for the stochastic setting, computing job-to-bag assignments that (i) minimize the expected maximum machine load and (ii) maximize the expected minimum machine load (like in the Santa Claus problem), respectively. The former result follows by careful enumeration combined with known PTASs. For the latter result, we introduce an intricate dynamic program that we apply to a suitably rounded instance.

## 1 Introduction

Stein and Zhong [20] recently introduced scheduling problems in which the number of the given (identical) machines is initially unknown. Specifically, all jobs must be assigned to a given number of bags before the actual number of machines is revealed. When that happens, the bags cannot be split anymore and they have to be assigned to the machines as whole bags, optimizing some objective function. Such problems arise, e.g., when “bundling” jobs to be scheduled in data centers, where the number of available machines depends on external factors such as momentary demand [4, 20].

The aforementioned work (as well as follow-up works [1, 5]) focused on the robustness of a job-to-bag assignment. Specifically, they assumed a worst-case number of machines and compared their solution with the in-hindsight optimum for the respective objective function,

i.e., a direct job-to-machine assignment without bags. In contrast to this information-theoretic question, we assume that a distribution of the number of machines is known (e.g., from historical data) and aim to *efficiently compute* a job-to-bag assignment that optimizes the objective function *in expectation* – a common formulation of the objective function for stochastic (scheduling) problems [4, 9, 10, 14, 15, 17, 18]. In other words, we use a “fairer” benchmark for our algorithms, allowing us to sidestep the strong lower bounds by [20]. We are the first to study this novel type of scheduling problem, already proposed in [20].

We consider two classic objective functions: minimizing the maximum machine load (makespan) and maximizing the minimum machine load (Santa Claus). Both objectives are well-studied in the deterministic setting, the special case of our problem with one-point distributions, i.e., the distributions in which only one event happens with positive probability. These problems are well understood from a classic approximation perspective: both are known to be strongly NP-hard [7] and both admit Polynomial-Time Approximation Schemes (PTASs) [11, 21], i.e., polynomial-time  $(1 + \varepsilon)$ -approximation algorithms for any  $\varepsilon > 0$ . In this paper, surprisingly, we recover the same state for the stochastic versions by designing a PTAS in both cases. In contrast to the deterministic setting, we require different techniques tailored to each objective function. For the makespan minimization objective, our main technical contribution is the application and analysis of techniques that have previously been used in approximation schemes for *deterministic* scheduling and packing problems. Our approach for the Santa Claus objective is technically much more intriguing and requires the careful set-up of a novel dynamic program (DP) in order to control its size.

Our results are in stark contrast to classic stochastic scheduling problems, where in some cases the currently best known approximation algorithms have distribution-dependent or even linear guarantees [14, 18]. Even for better-understood problems such as load balancing of stochastic jobs on deterministic machines, previous approaches [4, 9, 15] rely on concentration bounds which inherently prohibit approximation ratios of  $1 + \varepsilon$  for arbitrarily small  $\varepsilon > 0$ . Moreover, PTASs for stochastic load balancing on deterministic machines are only known for identical machines and Poisson distributed jobs [2, 13]. We hope that our positive results inspire research for other scheduling problems with a stochastic number of machines, even for (in the classic model with jobs with stochastic processing times) notoriously hard objective functions such as expected weighted sum of completion times.

## 1.1 Our Contribution and Techniques

Our first result is the following.

► **Theorem 1.** *There is a PTAS for the problem of computing the job-to-bag assignment that minimizes the expected maximum machine load.*

We first guess the bag sizes of the optimal solution up to a factor of  $1 + \varepsilon$ . For each guess, we check whether there is a corresponding assignment of the jobs to the bags (up to a factor of  $1 + \varepsilon$ ), using the PTAS for bin packing with variable sizes [12]. Among the guesses that fulfill this condition, we can select the (approximately) best guess using the PTAS for makespan minimization [11].

For this approach to yield a PTAS, we need to bound the number of guesses by a polynomial (in the input length). First note that it is straightforward to get down to a *quasi-polynomial* number of guesses (and thus a QPTAS). The approach is to disregard jobs of size  $(\varepsilon/n) \cdot p_{\max}$  where  $p_{\max}$  is the largest processing time; indeed, for any solution, such jobs make up at most an  $\varepsilon$ -fraction of the objective-function value. The resulting number of possible guesses for a single bag size is then logarithmic in  $n$ , leading to a quasi-polynomial

number of guesses for the (multi-)set of bag sizes. To get a *polynomial* bound (and thus a PTAS), we make the following crucial observation. Let  $C$  be an estimate for the largest *bag* size, up to a constant factor. While bags of size  $\mathcal{O}(\varepsilon C)$  cannot be disregarded, it is enough to know their *number* rather than approximate size. Intuitively, when computing a bag-to-machine assignment, these bags are treated like “sand”, i.e., as infinitesimal jobs of total volume equal to the total volume of those bags. The number of possible (rounded) bag sizes is hence constant, leading to a polynomial number of guesses for the (multi-)set of bag sizes.

Our second result is significantly harder to achieve.

► **Theorem 2.** *There is a PTAS for the problem of computing the job-to-bag assignment that maximizes the expected minimum machine load.*

One may be tempted to try a similar approach as for our first result. Even getting a QPTAS is, however, not possible in the same way as one cannot simply disregard jobs of size  $(\varepsilon/n) \cdot p_{\max}$ . Consider an instance in which the number of machines is deterministically  $M$  and in which there are one job of size 1 and  $M - 1$  jobs of size  $\varepsilon/(2M)$ . Here, ignoring the jobs of size  $\varepsilon/(2M)$  leads to  $M - 1$  empty bags, yielding an objective function value of 0 instead of the optimal value  $\varepsilon/(2M)$ .

Also, it is no longer true either that for bags of size  $\mathcal{O}(\varepsilon C)$  (where  $C$  is the size of a largest bag) it is enough to know their total number: Consider an instance with optimal objective-function value  $\text{OPT}$  and add one huge job of size  $\text{OPT}/\varepsilon^2$  to the set of jobs and one machine to each scenario. Clearly, this new instance has maximum bag size  $C \geq \text{OPT}/\varepsilon^2$  while the optimal objective-function value does not change since this huge job can safely be packed in its private bag and scheduled on its private machine. (However, crucially for the PTAS for makespan minimization, adding this huge job there would change the objective-function value.) In this example, the probability that scenarios with optimal objective-function value much smaller than  $\varepsilon C$  occur is 1. To obtain a  $(1 + \varepsilon)$ -approximation, however, one still has to compute a  $(1 + \varepsilon)$ -approximation for the original instance, for which the sizes of bags of size  $\mathcal{O}(\varepsilon C)$  are relevant. Of course, the issue with this particular instance could be avoided by removing the huge job in a pre-processing step. However, by concatenating the above original instance at super-constantly many different scales, one can create a new instance where one essentially has to identify the “relevant scales” in a preprocessing step.

In some sense, the first step of proving Theorem 2 is addressing precisely the problem of identifying the correct scales: We show that, at a loss of  $1 + \mathcal{O}(\varepsilon)$  in the approximation guarantee, the problem can be reduced to the case of polynomially bounded processing times that are all powers of  $1 + \varepsilon$ . To do so, we define suitable (non-trivial) subproblems and assemble them to a global solution with a dynamic program (DP). This approach can be seen as a simpler version of our approach for polynomially bounded processing times, which we focus on in the following.

Our general approach is to divide the range of possible bag sizes into intervals that contain  $\mathcal{O}_\varepsilon(1)$  possible approximate bag sizes each. For each such interval, it is then possible to guess the set of bags of the respective size in polynomial time. Considering the same range for sizes of *jobs*, rather than bags, we would also be able to guess the assignment of these jobs to these bags. Observe that a job may, of course, be assigned to a bag whose size lies in a different interval than the job’s size. However, we argue that the precise assignment is only relevant when these intervals are neighboring intervals and, hence, can be guessed in polynomial time. If this is not the case, i.e., if jobs are assigned to a bag whose size lies in a much larger interval, then such jobs are sufficiently small for us to only consider their total volume. The resulting parameters, such as number of bags created so far and the assignment of

smaller jobs to larger intervals, through which the subproblems corresponding to the intervals interact, are kept track of by a DP. While it is straightforward to keep track of all bags from larger intervals as well as the assignment of jobs from these intervals to the bags, it is not clear how to do this with a polynomial-time DP. In particular, when we consider bag sizes of one interval, we still need to remember previously defined bags of much larger sizes with a super-constant number of possibilities for these sizes. In fact, we show that it is sufficient to keep track of a constant number of parameters that capture all necessary information about larger intervals. Using that the processing times are polynomially bounded, we can bound the size of the DP table by a polynomial in the encoding of the input.

When considering a DP cell corresponding to some interval and guessing bag sizes along with the other parameters implied by the discussion above, we need to evaluate the quality of this guess. To do so, we guess additional parameters (also kept track of by the DP). The main observation is as follows. Suppose that, in addition to the aforementioned parameters, we know the relevant range of the number of machines and the bag sizes from the next-lower interval. For each number of machines in the aforementioned range, we assign each bag

- (i) from a higher interval to one machine each,
- (ii) from the two currently relevant intervals optimally, and
- (iii) from the lower intervals fractionally (the total volume of these bags can be approximated).

The reason we may do so is that the bags assigned in (i) are large enough to assign enough load to an entire machine and the bags assigned in (iii) are small enough to be considered fractional.

We remark that for both problems considered, a PTAS is the best possible approximation algorithm achievable when the number of bags (and machines) is part of the input, unless  $P = NP$ : Since their strongly NP-hard deterministic counterparts [8] are special cases of the stochastic problems, neither makespan minimization nor Santa Claus on stochastic machines admits fully polynomial time approximation schemes (FPTASs) unless  $P = NP$ . If, however, the number of bags (and machines) is not part of the input, i.e., a constant, a FPTAS can be designed by directly guessing the bag sizes approximately, i.e., up to a factor of  $1 + \varepsilon$ , in polynomial time and using known FPTASs to compute a job-to-bag assignment based on these bag sizes [6, 16].

Stein and Zhong [20] also considered a third objective function, minimizing the difference between the maximum and the minimum machine load. Any polynomial-time approximation algorithm (in the multiplicative sense) is, however, impossible here unless  $P = NP$ . Indeed, already in the deterministic case, it is strongly NP-hard to decide whether the optimal objective-function value is 0 (as can be seen, e.g., by a straightforward reduction from 3-Partition).

## 1.2 Further Related Work

We first review the literature on the aforementioned information-theoretic question in which one compares with the in-hindsight optimum. Since this benchmark is stronger than ours and the upper bounds are obtained through polynomial-time algorithms, the upper bounds carry over to our setting as guarantees of polynomial-time approximation algorithms. Specifically, for makespan, Stein and Zhong [20] showed how to compute for any  $\varepsilon > 0$  a job-to-bag assignment whose cost is guaranteed to be a factor of at most  $5/3 + \varepsilon$  away from the cost of the in-hindsight optimum. They also showed an impossibility of  $4/3$ . When all jobs have infinitesimal size, the best-possible guarantee is  $(1 + \sqrt{2})/2 \approx 1.207$  [5, 20]. For Santa Claus and infinitesimal jobs, the best-possible guarantee is  $2 \ln 2 \approx 1.386$  [20].

This model has been generalized in two directions. First, Eberle et al. [5] considered arbitrary machine *speeds* (rather than just 0 or 1) that are revealed after the bags have been created. They gave a guarantee of  $2 - 1/m$  with respect to the in-hindsight optimum and improved guarantees for special cases. Second, Balkanski et al. [1] considered the problem with arbitrary speeds in the algorithms-with-predictions framework.

In the majority of the scheduling literature, stochastic uncertainty refers to uncertainty in the processing times of the jobs (see [17] for a survey and [4, 9, 10] for some recent works). The literature on stochastic uncertainty, even uncertainty in general, in the machines is much more scattered. Stadje considered the unrecoverable breakdown on a single machine caused by stochastic jobs [19]. Temporary machine unavailability has also been studied in [3].

## 2 Preliminaries

Formally, we are given a job set  $J = [n] := \{1, \dots, n\}$ , where each job has a *processing time*  $p_j$ , and a maximum number of machines  $M$ . For each  $1 \leq m \leq M$ , we are given its *probability*  $q_m$ , where  $\sum_{m=1}^M q_m = 1$ . We want to find a partition of the job set  $J$  into  $M$  sets, called *bags*. We denote the set of bags by  $\mathcal{B}$ . For a bag  $B \in \mathcal{B}$ , let  $p(B) = \sum_{j \in B} p_j$  denote its *size*. We typically say for  $j \in B$  that  $j$  is *packed* in bag  $B$ .

Clearly, if  $M \geq n$ , we can pack every job in its own private bag, and the problem becomes trivial. Hence, we assume from now on that  $M < n$ .

We denote by  $\text{OPT}(\mathcal{B}, m)$  the optimal objective function value for a given set of bags  $\mathcal{B}$  and a scenario with  $m$  machines, that is,  $\text{OPT}(\mathcal{B}, m)$  denotes the maximum or minimum machine load of an optimal bag-to-machine assignment, or *schedule*, respectively. The objective is to find a partition or set of bags  $\mathcal{B}$  that optimizes  $\sum_{m=1}^M q_m \text{OPT}(\mathcal{B}, m)$ . We denote a fixed optimal set of bags by  $\mathcal{B}^*$  and its objective function value by  $\text{OPT} := \sum_{m=1}^M q_m \text{OPT}(\mathcal{B}^*, m)$ .

As discussed above, the problems we consider are generalizations of strongly NP-hard problems. Thus, unless  $P = NP$ , we cannot expect to find  $\mathcal{B}^*$  in polynomial time. Hence, we are interested in *polynomial-time approximation schemes* (PTASs), i.e., for each  $\varepsilon > 0$ , a polynomial-time  $(1 + \varepsilon)$ -*approximation algorithm*. Such an algorithm is required to return a partition of the job set  $J$  into  $M$  bags, denoted by  $\mathcal{B}$ , that satisfies  $\sum_{m=1}^M q_m \text{OPT}(\mathcal{B}, m) \leq (1 + \varepsilon) \text{OPT}$  for makespan, and  $\sum_{m=1}^M q_m \text{OPT}(\mathcal{B}, m) \geq \frac{1}{1 + \varepsilon} \text{OPT}$  for Santa Claus.

## 3 Minimizing the maximum machine load

In this section we design and analyze our polynomial-time approximation scheme for the setting of makespan minimization: For a given number of machines  $m$  and a set  $\mathcal{B}$  of bags, we want to find an assignment of bags to machines that minimizes the maximum total size of bags assigned to any machine.

### 3.1 Algorithm

Let  $\varepsilon > 0$ ; we will give a polynomial-time algorithm that achieves an approximation ratio of  $1 + \mathcal{O}(\varepsilon)$ . This algorithm finds a good estimate of the optimal bag sizes in  $\mathcal{B}^*$ . To this end, we show later that the maximum size of a bag in  $\mathcal{B}^*$  is at most  $4C$ , where

$$C := \sum_{m=1}^M q_m \max \left\{ \max_{j \in J} p_j, \frac{1}{m} \sum_{j \in J} p_j \right\}.$$

We say a bag  $B$  in  $\mathcal{B}^*$  is *regular* if its size is at least  $\varepsilon C$  or if there is at least one job of size at least  $\varepsilon^2 C$  packed in  $B$ . For  $\ell \in \mathcal{L} := \{\lfloor \log_{1+\varepsilon}(\varepsilon^2 C) \rfloor, \lfloor \log_{1+\varepsilon}(\varepsilon^2 C) \rfloor + 1, \dots, \lfloor \log_{1+\varepsilon}(4C) \rfloor\}$ , the algorithm *guesses* the number  $M_\ell$  of optimal bags with  $p(B) \in [(1+\varepsilon)^\ell, (1+\varepsilon)^{\ell+1})$ .

Further, it *enumerates* all possible numbers  $M_{\text{sand}}$  of bags of size at most  $(1+\varepsilon)\varepsilon C$ , called *sand bags*. These sand bags do not directly correspond to optimal bags, but instead can pack all jobs not packed in regular bags in OPT.

Clearly, a guess  $(M_\ell)_{\ell \in \mathcal{L}}$  combined with  $M_{\text{sand}}$  sand bags does not necessarily guarantee that it is *feasible*, i.e., that  $M_{\text{sand}} + \sum_{\ell \in \mathcal{L}} M_\ell \leq M$  and that there is a partition of  $J$  into bags such that there are at most  $M_\ell$  bags with sizes in  $[(1+\varepsilon)^\ell, (1+\varepsilon)^{\ell+1})$  and  $M_{\text{sand}}$  bags of size at most  $(1+\varepsilon)\varepsilon C$ . Thus, the algorithm ignores all combinations of  $(M_\ell)_{\ell \in \mathcal{L}}$  and  $M_{\text{sand}}$  with more than  $M$  bags. If the total number of bags is at most  $M$ , the algorithm uses the PTAS by Hochbaum and Shmoys [12] for bin packing with variable bin sizes to check if there is a feasible packing of jobs into the bags as follows: The input is  $\varepsilon$  as approximation parameter, an item of size  $p_j$  for each job  $j \in J$ ,  $M_\ell$  bins of size  $(1+\varepsilon)^{\ell+1}$  for any  $\ell \in \mathcal{L}$ , and  $M_{\text{sand}}$  bins of size  $(1+\varepsilon)\varepsilon C$ . If the guess is feasible, the PTAS is guaranteed to return an item-to-bin (here a job-to-bag) assignment that violates the bin sizes by at most a factor  $(1+\varepsilon)$ .

If all jobs can be packed by the above PTAS, the algorithm evaluates the current guess by computing a  $(1+\varepsilon)$ -approximation of  $\text{OPT}((M_\ell)_{\ell \in \mathcal{L} \cup \{\text{sand}\}}, m)$ , where we overload notation and let  $\text{OPT}((M_\ell)_{\ell \in \mathcal{L} \cup \{\text{sand}\}}, m)$  denote the minimum makespan for a set of bags consisting of  $M_\ell$  bags of size  $(1+\varepsilon)^{\ell+1}$ , for any  $\ell \in \mathcal{L}$ , and  $M_{\text{sand}}$  bags of size  $(1+\varepsilon)\varepsilon C$ . We denote the makespan of this  $(1+\varepsilon)$ -approximation by  $z((M_\ell)_{\ell \in \mathcal{L} \cup \{\text{sand}\}}, m)$  and compute it by running the PTAS by Hochbaum and Shmoys [11] for makespan minimization on identical machines with approximation parameter  $\varepsilon$ ,  $M_\ell$  jobs with processing time  $(1+\varepsilon)^{\ell+1}$ ,  $M_{\text{sand}}$  jobs with processing time  $(1+\varepsilon)\varepsilon C$ , and  $m$  machines.

The algorithm returns a feasible minimizer of  $\sum_{m=1}^M q_m z((M_\ell)_{\ell \in \mathcal{L} \cup \{\text{sand}\}}, m)$ .

### 3.2 Analysis

In this section, we analyze the algorithm designed in the previous section. We start by justifying our bound on the maximum bag size before we argue that there exists a guess that is similar to the optimal set  $\mathcal{B}^*$  in terms of the bag size and objective-function value. Last, we evaluate the running time of the algorithm and conclude with the proof of Theorem 1. For formal proofs we refer to the full version.

We begin by justifying our assumption to only consider bags of size at most  $4C = 4 \sum_{m=1}^M q_m \max \{ \max_{j \in J} p_j, \frac{1}{m} \sum_{j \in J} p_j \}$ : By [20],  $4C$  is an upper bound on OPT. As the largest bag size lower bounds  $\text{OPT}(\mathcal{B}, m)$  in scenario  $m$ , this implies the next lemma.

► **Lemma 3.** *No optimal solution uses bags of size greater than  $4C$ .*

Fix a set of bags  $\mathcal{B}^*$  with objective-function value OPT. By Lemma 3, the maximum bag size is at most  $4C$ . The algorithm guesses a set of bag sizes similar to the bag sizes in  $\mathcal{B}^*$ .

Based on  $\mathcal{B}^*$  we define a “good” guess  $(\hat{M}_\ell)_{\ell \in \mathcal{L} \cup \{\text{sand}\}}$ , i.e., a set of possible bag sizes, as follows: Let  $\mathcal{B}_R^*$  denote the set of regular bags, i.e., the set of bags in  $\mathcal{B}^*$  that pack at least one job of size at least  $\varepsilon^2 C$  or have size at least  $\varepsilon C$ .

- For  $\ell \in \mathcal{L}$ , let  $\hat{M}_\ell$  be the number of regular bags in  $\mathcal{B}_R^*$  with  $p(B) \in [(1+\varepsilon)^\ell, (1+\varepsilon)^{\ell+1})$ .
- Set  $\hat{M}_{\text{sand}} = \left\lceil \frac{\sum_{B \in \mathcal{B}^* \setminus \mathcal{B}_R^*} p(B)}{\varepsilon C} \right\rceil$ ; recall that sand bags have size at most  $(1+\varepsilon)\varepsilon C$ .

Since the sizes of regular bags are only rounded up, the bags in  $(\hat{M}_\ell)_{\ell \in \mathcal{L}}$  can pack the same subset of jobs as  $\mathcal{B}_R^*$ . Since the volume of any sand bag has been increased by a  $(1+\varepsilon)$ -factor as opposed to  $\varepsilon C$  and the size of any job not packed in a regular bag is at most  $\varepsilon^2 C$ , we show that the bag-size vector  $\hat{M} := (\hat{M}_\ell)_{\ell \in \mathcal{L} \cup \{\text{sand}\}}$  is a possible and feasible guess.

► **Lemma 4.** *The above defined vector  $\hat{\mathcal{M}}$  is a feasible guess of the algorithm. The jobs can be packed into a set of bags consisting of  $\hat{M}_\ell$  bags with size  $(1 + \varepsilon)^{\ell+1}$  for  $\ell \in \mathcal{L}$  and  $\hat{M}_{\text{sand}}$  bags with size  $(1 + \varepsilon)\varepsilon C$ .*

Combining this lemma with Theorem 2 of [12], we get the next corollary.

► **Corollary 5.** *The PTAS by [12] returns a packing of all jobs into a set of bags with  $M_\ell$  bags of size  $(1 + \varepsilon)^{\ell+2}$  for  $\ell \in \mathcal{L}$  and  $M_{\text{sand}}$  bags of size  $(1 + \varepsilon)^2\varepsilon C$ .*

To prove the next lemma, we first assign the regular bags in the same way as in the optimal solution and assign the sand bags one by one to the currently least loaded machine. For bounding the makespan in a given scenario  $m$ , we distinguish whether a regular bag determines the makespan (which increases the makespan by at most a factor  $(1 + \varepsilon)$  compared to  $\text{OPT}(\mathcal{B}^*, m)$ ) or whether a sand bag determines the makespan. In the latter case, we use a volume bound to upper bound this sand bag's starting time (losing at most a factor  $(1 + \varepsilon)$ ) and amortize its maximum size, i.e.,  $(1 + \varepsilon)\varepsilon C$ , over all scenarios, using that  $\sum_{m=1}^M q_m = 1$ .

► **Lemma 6.**  *$\hat{\mathcal{M}} = (\hat{M}_\ell)_{\ell \in \mathcal{L} \cup \{\text{sand}\}}$  satisfies  $\sum_{m=1}^M q_m \text{OPT}(\hat{\mathcal{M}}, m) \leq (1 + 5\varepsilon)\text{OPT}$ .*

**Proof of Theorem 1.** Using that we return the cheapest guess and that the number of distinct rounded sizes of regular bags is bounded by  $\mathcal{O}(\frac{1}{\varepsilon^2})$ , we can show the following two lemmas. Combined, they complete the proof of Theorem 1.

► **Lemma 7.** *The set of bags returned by the algorithm guarantees an objective function value of at most  $(1 + \mathcal{O}(\varepsilon))\text{OPT}$ .*

► **Lemma 8.** *For  $\varepsilon \in (0, \frac{1}{2})$ , the algorithm runs in time  $\mathcal{O}\left(\left(\frac{n}{\varepsilon}\right)^{\mathcal{O}(1/\varepsilon^2)}\right)$ .*

## 4 Maximizing the minimum machine load

In this section, we present our polynomial-time  $(1 + \varepsilon)$ -approximation algorithm for the setting in which we want to maximize the minimum machine load. We refer to the full version for the formal proofs for the results presented in this section.

### Polynomially bounded processing times

First, we show that we can reduce our problem to the case of polynomially bounded job processing times that are all essentially powers of  $1 + \varepsilon$ , while losing at most a factor of  $1 + \mathcal{O}(\varepsilon)$  in our approximation guarantee. The main concepts of the reduction can be summarized by the following three ideas.

The first idea is to disregard scenarios whose contribution to the expected objective function value is very small. W.l.o.g., assume that  $p_j \in \mathbb{N}$  and let  $d$  be an integer such that  $\text{OPT}(\mathcal{B}^*, m)$  falls in the interval  $[1, (\frac{n}{\varepsilon})^d]$  for every scenario  $m$ . Then, for some offset  $a \in \{0, 1, \dots, \frac{1}{\varepsilon} + 3\}$  we “split” the interval  $[1, (\frac{n}{\varepsilon})^d]$  into a polynomial number of pairwise disjoint intervals  $\tilde{I}_i = \left[ \left(\frac{n}{\varepsilon}\right)^{3i + \frac{i-1}{\varepsilon} + a}, \left(\frac{n}{\varepsilon}\right)^{3i + \frac{i}{\varepsilon} + a} \right)$ . Observe that any two consecutive intervals have a multiplicative gap of  $\left(\frac{n}{\varepsilon}\right)^3$ . Using probabilistic arguments, we show that there is an offset  $a$  such that the scenarios with  $\text{OPT}(\mathcal{B}^*, m)$  in the gaps contribute very little to the expected objective function value. Hence, such scenarios can be neglected by losing a factor of at most  $1 + \mathcal{O}(\varepsilon)$  in the approximation ratio. As there is only a polynomial number of possible offsets  $a$ , we may assume that we correctly choose such  $a$  by enumeration.

The second idea is to observe that the gaps enable us to actually *ignore* a carefully chosen subset of jobs. Let  $\tilde{I}_i^+ = \left[ \left(\frac{n}{\varepsilon}\right)^{3i + \frac{i-1}{\varepsilon} + a - 3}, \left(\frac{n}{\varepsilon}\right)^{3i + \frac{i-1}{\varepsilon} + a} \right) \cup \tilde{I}_i$  denote the extended interval obtained by the union of the interval  $\tilde{I}_i$  and the smaller of its adjacent gaps, and let  $m$  be a scenario such that  $\text{OPT}(\mathcal{B}^*, m) \in \tilde{I}_i$ . We show that, by losing a factor of at most  $1 + \mathcal{O}(\varepsilon)$  in the approximation ratio, we may assume that a machine with minimum load in the schedule that achieves  $\text{OPT}(\mathcal{B}^*, m)$  is assigned only bags with jobs whose processing time is in  $\tilde{I}_i^+$ . Then, based on this assumption, we show that we may assume that there are no jobs whose processing times fall in the gaps by losing at most another factor of  $1 + \mathcal{O}(\varepsilon)$  in the approximation ratio. Observe that we are now facing an instance where neither  $\text{OPT}(\mathcal{B}^*, m)$  nor  $p_j$  belong to the just created gaps in the interval  $\left[1, \left(\frac{n}{\varepsilon}\right)^d\right]$ .

The third idea is then to solve the problem restricted to the intervals  $\tilde{I}_i$  individually by using the fact that within each interval  $\tilde{I}_i$  the processing times are polynomially bounded and combine the obtained solutions into a single one with a dynamic program. We show that rounding up the processing times and solving each subproblem that arises in the dynamic program costs a factor of at most  $1 + \mathcal{O}(\varepsilon)$  in the approximation ratio. Formalizing this proof sketch proves Lemma 9.

► **Lemma 9.** *By losing a factor of at most  $1 + \mathcal{O}(\varepsilon)$  in the approximation ratio, we can assume for each job  $j \in J$  that  $p_j = \lceil (1 + \varepsilon)^{k_j} \rceil$  for some  $k_j \in \mathbb{N}_0$  and  $p_j \in [1, n^{c(\varepsilon)}]$  where  $c(\varepsilon)$  is some global constant.*

**Algorithmic overview.** Based on Lemma 9, we assume that each job  $j \in J$  satisfies  $p_j \in [1, n^{c(\varepsilon)}]$ . The high-level idea of our algorithm is to partition  $[1, n^{c(\varepsilon)}]$  into intervals of the form  $I_k := \left[\left(\frac{1}{\varepsilon}\right)^{3k}, \left(\frac{1}{\varepsilon}\right)^{3k+3}\right)$  for  $k \in \mathbb{N}$  and only consider bags, jobs, and scenarios relevant for a *single* interval. More precisely, we use these intervals to partition the processing times  $\{p_j\}_{j \in J}$ , the bag sizes in  $\mathcal{B}^*$  and in our solution as well as the values  $\{\text{OPT}(\mathcal{B}^*, m)\}_m$ . Let  $K$  such that  $\sum_{j \in J} p_j \in I_K$ ; we ignore intervals  $I_k$  with  $k > K$ . For  $k \in [K]$ , let  $J_k := \{j \in J : p_j \in I_k\}$ , let  $L_k := \{\ell \in \mathbb{N} : \lceil (1 + \varepsilon)^\ell \rceil \in I_k\}$ , and let  $\mathcal{B}_k^* := \{B \in \mathcal{B}^* : p(B) \in I_k\}$ .

Our algorithm recursively considers the intervals in the order  $I_K, I_{K-1}, \dots, I_1$  and, step by step, defines bags that correspond to  $\mathcal{B}_K^*, \mathcal{B}_{K-1}^*, \dots, \mathcal{B}_1^*$ . When considering interval  $I_k$ , the algorithm enumerates all possible bag sizes of bags in  $\mathcal{B}_k^*$  and all possible assignments of a subset of the jobs in  $J_k \cup J_{k-1}$  to those bags; the remaining jobs in  $J_k$  are implicitly assigned to bags in  $\bigcup_{k'=k+1}^K \mathcal{B}_{k'}^*$ . Here, we use the fact that by definition of our intervals only a constant number of jobs in  $J_k \cup J_{k-1}$  can be assigned to any bag in  $\mathcal{B}_k^*$  while jobs in  $J_k$  are tiny compared to bags in  $\bigcup_{k'=k+2}^K \mathcal{B}_{k'}^*$  (see Figure 1 for visualization) and, hence, the assignment of jobs  $J_k$  to bags  $\bigcup_{k'=k+2}^K \mathcal{B}_{k'}^*$  cannot be guessed in polynomial time. The remaining jobs in  $J_{k-1}$  will be assigned when interval  $I_{k-1}$  is considered. We embed this recursion into a polynomial-time dynamic program (DP). Since our DP is quite technical, we first describe the algorithmic steps that correspond to the root subproblem of the recursion, i.e.,  $I_K$ , before we define the DP cells and argue about their solution. Defining the DP cells and solving their corresponding subproblem involves enumerating all possible values of several quantities and storing an approximation of the objective-function value of the (approximately) best combination in the DP cell. When arguing about the correctness of our DP, we show that there is a chain of DP cells that represent some (fixed) optimal solution. Hence, we use  $X^*$  for some parameter  $X$  when referring to the correct value, i.e., the value of this parameter in this optimal solution. We refer to this process as *guessing*  $X^*$ . In general, we use  $\hat{X}$  to refer to an arbitrary guess.

■ **Figure 1** Visualization of relation between jobs in  $J_k$  and bags in  $\mathcal{B}_k^*$ ,  $\mathcal{B}_{k+1}^*$  and  $\bigcup_{k'=k+2}^K \mathcal{B}_{k'}^*$ .

## 4.1 Guessing initial quantities

In the following, we describe how to guess and evaluate initial parameters corresponding to a (partial) solution of our root subproblem. Intuitively, we construct a partial assignment of jobs to bags  $\mathcal{B}_K^*$  and the parameters representing this partial assignment define the DP cell corresponding to the remaining problem.

### 4.1.1 Algorithm

The algorithm to compute a partial solution to a root subproblem can be essentially split into two phases: (1) *guessing* key quantities and (2) *evaluating* these guesses.

**Guessing phase.** We start by guessing  $|\mathcal{B}_K^*|$  and  $|\mathcal{B}_{K-1}^*|$ , the number of bags in  $\mathcal{B}_K^*$  and in  $\mathcal{B}_{K-1}^*$ , before we guess  $(1 + \varepsilon)$ -approximations for the bags sizes in  $\mathcal{B}_K^* \cup \mathcal{B}_{K-1}^*$ . Formally, for each bag  $B \in \mathcal{B}_K^* \cup \mathcal{B}_{K-1}^*$  we guess a value  $\ell(B) \in \mathbb{N}$  such that  $p(B) \in [(1 + \varepsilon)^{\ell(B)}, (1 + \varepsilon)^{\ell(B)+1})$ ; we say that such a value  $\ell(B)$  is the *size-estimate* for  $B$ . Next, we guess an assignment of all jobs in  $J_K$  and a subset of the jobs in  $J_{K-1}$  to the bags  $\mathcal{B}_K^*$  and an assignment of the remaining jobs in  $J_{K-1}$  and of a subset of the jobs in  $J_{K-2}$  to the bags  $\mathcal{B}_{K-1}^*$ . Finally, we guess  $m_{\max}^{(K)}$  which we define to be the largest value  $m \in M$  for which  $\text{OPT}(\mathcal{B}^*, m) \in I_K$ .

**Evaluation phase.** In contrast to the previous section, maximizing the minimum machine load asks for “covering” a machine or, in our case, a bag. To this end, we potentially have to assign jobs from  $\bigcup_{k'=1}^{K-2} J_{k'}$  to the bags in  $\mathcal{B}_K^*$ . Formally, for  $B \in \mathcal{B}_K^*$  let  $p^+(B)$  be the total size of the jobs from  $J_K$  and  $J_{K-1}$  already assigned to  $B$ . We define  $S := \sum_{B \in \mathcal{B}_K^*} \max\{[(1 + \varepsilon)^{\ell(B)}] - p^+(B), 0\}$ . Our DP also stores this value in order to guarantee that, in the remainder, jobs from  $\bigcup_{k'=1}^{K-2} J_{k'}$  with total size  $S$  are assigned to bags in  $\mathcal{B}_K^*$ . Let  $J_{K-1}(\mathcal{B}_{K-1}^*)$  and  $J_{K-2}(\mathcal{B}_{K-1}^*)$  be the subsets of  $J_{K-1}$  and  $J_{K-2}$  already assigned to bags in  $\mathcal{B}_{K-1}^*$ . Then,  $\bar{S} := \sum_{B \in \mathcal{B}_{K-1}^*} [(1 + \varepsilon)^{\ell(B)}] - p(J_{K-1}(\mathcal{B}_{K-1}^*) \cup J_{K-2}(\mathcal{B}_{K-1}^*))$  is the total volume of bags in  $\mathcal{B}_{K-1}^*$  that needs to be covered with jobs from  $\bigcup_{k'=1}^{K-3} J_{k'}$ .

For evaluating our current guess, we fix some  $m \leq m_{\max}^{(K)}$  and create a set  $J_T$  of dummy jobs, each with processing time 1 and total size  $T := \sum_{k=1}^{K-2} \sum_{j \in J_k} p_j - S - \bar{S}$ . Now, we guess the assignment of the bags  $\mathcal{B}_K^* \cup \mathcal{B}_{K-1}^*$  to the machines. Based on the load guaranteed by these bags, we now greedily distribute these dummy jobs as follows. Assume w.l.o.g. that the machines are sorted non-decreasingly by their loads and consider the prefix of the machines which all have the smallest load. We assign to each of these machines the same

number of dummy jobs such that their new load is equal to the load of the machines with the second smallest load. We repeat this procedure until all dummy jobs in  $J_T$  are assigned. At the end, among all possibilities to assign the bags  $\mathcal{B}_K^* \cup \mathcal{B}_{K-1}^*$ , we choose the one which maximizes the minimum machine load after the distribution of  $J_T$ . We define  $\text{ALG}(m)$  as the load of the least loaded machine for this fixed candidate solution.

Among all guesses with the same set of bag sizes for bags in  $\mathcal{B}_K^* \cup \mathcal{B}_{K-1}^*$ , the same value  $m_{\max}^{(K)}$  and the same values  $S$  and  $\bar{S}$ , we keep the guess which maximizes our proxy for the (partial) objective function,  $\sum_{m=1}^{m_{\max}^{(K)}} q_m \cdot \text{ALG}(m)$ .

#### 4.1.2 Analysis

Observing that  $|\mathcal{B}_K^*| \leq M \leq n$  and  $|\mathcal{B}_{K-1}^*| \leq M \leq n$  implies that we can enumerate all possible combinations in time  $O(n^2)$ . Since the relative length, i.e., the ratio of the left interval border to the right interval border, of  $I_K \cup I_{K-1}$  is bounded by  $(\frac{1}{\varepsilon})^6$ , there are at most  $\mathcal{O}_\varepsilon(1)$  possibilities for each size-estimate  $\ell(B)$ . By guessing the number of bags with a given size estimate, we can guess the size-estimates of all bags in  $\mathcal{B}_K^* \cup \mathcal{B}_{K-1}^*$  in time  $n^{\mathcal{O}_\varepsilon(1)}$ . Further, each bag in  $\mathcal{B}_K^*$  can be assigned at most  $\mathcal{O}_\varepsilon(1)$  many jobs from  $J_K \cup J_{K-1}$  and, similarly, each bag in  $\mathcal{B}_{K-1}^*$  can be assigned at most  $\mathcal{O}_\varepsilon(1)$  many jobs from  $J_{K-1} \cup J_{K-2}$ . Hence, there is only a constant number of possible assignments for each bag, up to permutations of jobs with the same size. We formalize these observations in the next lemma.<sup>1</sup>

► **Lemma 10.** *In time  $n^{\mathcal{O}_\varepsilon(1)}$ , we can guess the size-estimate  $\ell(B)$  for each bag  $B \in \mathcal{B}_K^* \cup \mathcal{B}_{K-1}^*$  as well as the assignment of the jobs in  $J_K$  to the bags  $\mathcal{B}_K^*$ , of the jobs in  $J_{K-1}$  to the bags  $\mathcal{B}_K^* \cup \mathcal{B}_{K-1}^*$  and of a subset of jobs in  $J_{K-2}$  to the bags in  $\mathcal{B}_{K-1}^*$ , up to a permutation of bags.*

First, observe that for each bag  $B \in \mathcal{B}_K^*$ , the value  $\max\{[(1+\varepsilon)^{\ell(B)}] - p^+(B), 0\} \in \mathbb{N}_0$  since  $p_j \in \mathbb{N}$  for each  $j \in J$  by Lemma 9. Hence,  $S$  accurately captures the total volume missing to ensure that each  $B \in \mathcal{B}_K^*$  packs jobs with a total size of at least  $(1+\varepsilon)^{\ell(B)} \geq \frac{p(B)}{1+\varepsilon}$ . Using that each job in  $\bigcup_{k=1}^{K-2} J_k$  is very small compared to a bag in  $\mathcal{B}_K^*$ , we can argue that knowing  $S$  is actually sufficient to cover  $B \in \mathcal{B}_K^*$  with jobs of total size of at least  $\frac{p(B)}{(1+\varepsilon)^2}$ .

Similarly, for a bag in  $\mathcal{B}_{K-1}^*$ , each job in  $\bigcup_{k=1}^{K-3} J_k$  is very small compared to its size. Hence, we can again argue that knowing  $\bar{S} \in \mathbb{N}_0$  is sufficient to pack jobs of total size at least  $\frac{p(B)}{(1+\varepsilon)^2}$  into bag  $B \in \mathcal{B}_{K-1}^*$ .

Observing that no bag in  $\bigcup_{k=1}^{K-2} \mathcal{B}_k^*$  can pack a job from  $J_K \cup J_{K-1}$  by definition of their sizes, we conclude that  $T$  indeed represents the total volume of bags in  $\bigcup_{k=1}^{K-2} \mathcal{B}_k^*$ . In fact, we can show that for scenarios with  $m \leq m_{\max}^{(K)}$  machines *any* assignment of the remaining jobs in  $\bigcup_{k'=1}^{K-2} J_{k'}$  of total volume at most  $\frac{T}{1+\varepsilon}$  to at most  $M - |\mathcal{B}_K^*| - |\mathcal{B}_{K-1}^*|$  bags of size at most  $\varepsilon(\frac{1}{\varepsilon})^{3K}$  yields the same objective function value (up to a factor of  $1 + \mathcal{O}(\varepsilon)$ ). These observations are formalized in the next lemma where some jobs are set aside in bags  $B_S$  and  $B_{\bar{S}}$ , corresponding to the values  $S$  and  $\bar{S}$ .

Recall that we use  $\hat{X}$  to denote a possible guess for parameter  $X$  considered by our algorithm.

► **Lemma 11.** *Let the guessed quantities be as defined above. Let  $\mathcal{B}' \cup \{B_S, B_{\bar{S}}\}$  be a partition of the jobs  $\bigcup_{k'=1}^{K-2} J_{k'}$  into  $M - |\hat{\mathcal{B}}_K| - |\hat{\mathcal{B}}_{K-1}| + 2$  bags such that*

■ *for each bag  $B \in \mathcal{B}'$ ,  $p(B) \leq \varepsilon \cdot (\frac{1}{\varepsilon})^{3K}$ ,*

<sup>1</sup> For the initial guesses, one could give tighter bounds by observing that  $|\mathcal{B}_K^*| + |\mathcal{B}_{K-1}^*| = \mathcal{O}_\varepsilon(1)$ . However, we give polynomial bounds which are sufficient and of the same kind as the bounds we will use later in the DP.

- $p(B_S) \geq S$ ,
  - $p(B_{\bar{S}}) \geq \bar{S}$ , and
  - $p(\mathcal{B}') := \sum_{B \in \mathcal{B}'} p(B) \geq (1 + \varepsilon)^{-1} T$ .
- Suppose that  $B \in \hat{\mathcal{B}}_K \cup \hat{\mathcal{B}}_{K-1}$  has size in  $[(1 + \varepsilon)^{\ell(B)}, (1 + \varepsilon)^{\ell(B)+1}]$ . We can compute the vector  $(ALG(m))_{m=1}^{m_{\max}^{(K)}}$  in polynomial time and  $OPT(\mathcal{B}' \cup \hat{\mathcal{B}}_K \cup \hat{\mathcal{B}}_{K-1}, m) \in [(1 + \varepsilon)^{-5} ALG(m), (1 + \varepsilon) ALG(m)]$  for each  $m \leq m_{\max}^{(K)}$ .

Note that the lemma does not state anything about the relationship of  $OPT(\mathcal{B}^*, m)$  and  $OPT(\mathcal{B}' \cup \hat{\mathcal{B}}_K \cup \hat{\mathcal{B}}_{K-1}, m)$ ; it relates our proxy function  $ALG(m)$  and  $OPT(\mathcal{B}' \cup \hat{\mathcal{B}}_K \cup \hat{\mathcal{B}}_{K-1}, m)$ , the best possible assignment for  $\mathcal{B}' \cup \hat{\mathcal{B}}_K \cup \hat{\mathcal{B}}_{K-1}$ .

In the remaining problem it suffices to focus on scenarios in which we have  $m > m_{\max}^{(K)}$  machines and which hence satisfy  $OPT(\mathcal{B}^*, m) < (\frac{1}{\varepsilon})^{3K}$ . Note that for each bag  $B \in \mathcal{B}_K^*$  we have that  $p(B) \geq (\frac{1}{\varepsilon})^{3K}$ . Therefore, if we are given  $m > m_{\max}^{(K)}$  machines, it is optimal to assign each bag  $B \in \mathcal{B}_K^*$  to a separate machine without any further bags assigned to that machine. Hence, if  $m > m_{\max}^{(K)}$ , then the bags in  $\mathcal{B}_1^*, \dots, \mathcal{B}_{K-1}^*$  need to ensure only that the remaining  $m - |\mathcal{B}_K^*|$  machines get enough load. This insight and the above lemma allow us to decouple our decisions for scenarios with  $m \leq m_{\max}^{(K)}$  machines from scenarios with  $m > m_{\max}^{(K)}$  machines. This is the key idea for our DP.

## 4.2 Dynamic program

After our initial guesses above, it remains to

- pack the jobs in  $\bigcup_{k'=1}^{K-1} J_{k'}$  into the bags in  $\mathcal{B}_{K-1}^*$ ,
- compute the bag sizes in  $\mathcal{B}_1^*, \dots, \mathcal{B}_{K-2}^*$ , and
- select jobs from  $\bigcup_{k=1}^{K-2} J_k$  with total size at least  $S$  for filling  $\mathcal{B}_K^*$ .

For each  $m \geq m_{\min}^{(K-1)} := m_{\max}^{(K)} + 1$ , our goal is to obtain a value close enough to  $OPT(\mathcal{B}^*, m)$  so that, overall, we achieve a value of  $(1 - \mathcal{O}(\varepsilon))OPT$ .

To this end, we design a dynamic program (DP) that solves the remaining problem from above. Each DP cell corresponds to some subproblem. We show that for each possible guess of the initial quantities in Section 4.1 there is a DP cell corresponding to the remaining subproblem. In order to solve each subproblem, we guess similar quantities as in the previous section and reduce the resulting remaining problem to the subproblem of another DP cell.

### 4.2.1 Algorithm

Following the same idea as for the root subproblem, our dynamic program proceeds as follows: for each DP cell we first *guess* key quantities defining a partial solution as well as the transition to the next DP cell and then we *evaluate* this guessed partial solution.

**DP cell and its subproblem.** Formally, each DP cell  $\mathcal{C}$  is specified by

- $k \in \mathbb{N}$  with  $k < K$  specifying that we still need to define  $\mathcal{B}_1, \dots, \mathcal{B}_k$ ,
- $M_{k+1}, \dots, M_K \in \mathbb{N}$  counting the previously defined (large) bags  $\mathcal{B}_{k+1}, \dots, \mathcal{B}_K$ ,
- $M_k \in \mathbb{N}$  representing our decision  $|\mathcal{B}_k| = M_k$ ,
- $m_{\min}^{(k)} \in \mathbb{N}$  indicating the minimal number of machines we consider,
- $s_\ell \in \mathbb{N}$  for  $\ell \in L_k$  counting  $B \in \mathcal{B}_k$  with  $\ell(B) = \ell$ ,
- $a_\ell \in \mathbb{N}$  for  $\ell \in L_k$  counting the jobs  $j$  with  $p_j = \lceil (1 + \varepsilon)^\ell \rceil$  that are assigned to bags in  $\mathcal{B}_{k+1}$ ,

## 14:12 Scheduling on a Stochastic Number of Machines

- $S \in \mathbb{N}$ , defining the total size of jobs in  $\bigcup_{k'=1}^k J_{k'}$  that must not be assigned to bags  $\bigcup_{k'=1}^k \mathcal{B}_{k'}$  and that are neither assigned to bags in  $\mathcal{B}_{k+1}$  via the values  $a_\ell$ ; instead they will be assigned to  $\bigcup_{k'=k+1}^K \mathcal{B}_{k'}$ . (Note that we will make sure that even though jobs from  $J_k$  might contribute to  $S$ , such jobs will not be used to cover bags in  $\mathcal{B}_{k+1}$ .)

The goal of the subproblem of  $\mathcal{C}$  is to pack a subset of the jobs  $\bigcup_{k'=1}^k J_{k'}$  into the bags  $\bigcup_{k'=1}^k \mathcal{B}_{k'}$  and define a size-estimate  $\ell(B)$  for  $B \in \bigcup_{k'=1}^k \mathcal{B}_{k'}$  such that

- $|\mathcal{B}_k| = M_k$ ,
- $p(B) \in I_{k'}$  for each  $k' \in [k]$  and each  $B \in \mathcal{B}_{k'}$ ,
- $p(B) \in [(1 + \varepsilon)^{\ell(B)}, (1 + \varepsilon)^{\ell(B)+1}]$  for each  $B \in \bigcup_{k'=1}^k \mathcal{B}_{k'}$ ,
- there are  $s_\ell$  bags  $B \in \mathcal{B}_k$  with  $\ell(B) = \ell$  for each  $\ell \in L_k$ ,
- each job  $j \in J_{k'}$  for  $k' \in [k]$  is either assigned to some bag in  $\mathcal{B}_{k'} \cup \dots \cup \mathcal{B}_k$  or not at all,
- there are  $a_\ell$  jobs  $j$  with  $p_j = \lceil (1 + \varepsilon)^\ell \rceil$  that are not assigned to any bag for each  $\ell \in L_k$ ,
- the jobs in  $\bigcup_{k'=1}^k J_{k'}$  not packed in any bag have total size at least  $S$ .

For each DP cell  $\mathcal{C}$ , we compute a solution and a corresponding objective function value which we denote by  $\text{profit}(\mathcal{C})$ . This objective function corresponds to the expected profit from scenarios in  $\{m_{\min}^{(k)}, \dots, M\}$  that we achieve with the solution stored in the DP cell and  $M_{k+1}, \dots, M_K$  “large” bags, i.e., bags  $B$  with  $p(B) \in \bigcup_{k'=k+1}^K I_{k'}$ .

**Guessing phase.** By definition of the DP cell,  $|\mathcal{B}_k^*| = M_k$ . For each  $\ell \in L_k$ , there are  $s_\ell$  many bags  $B \in \mathcal{B}_k^*$  with  $\ell(B) = \ell$  (and hence with  $p(B) \in [(1 + \varepsilon)^\ell, (1 + \varepsilon)^{\ell+1}]$ ). We start by guessing the assignment of the jobs  $J_{k-1} \cup J_k$  to the bags in  $\mathcal{B}_k^*$ . We only consider guesses satisfying the values  $a_\ell$  and  $S$  of our current DP cell, i.e., for every possible processing time in  $I_k$  enough jobs are left to be assigned to  $\mathcal{B}_{k+1}^*$  and enough total volume of jobs in  $\bigcup_{k'=1}^k J_{k'}$  is left to be assigned to bags in  $\bigcup_{k'=k+1}^K \mathcal{B}_{k'}$ . Finally, we guess  $m_{\max}^{(k)}$  which is the largest value  $m$  for which  $\text{OPT}(\mathcal{B}^*, m) \in I_k$ .

**Evaluation phase.** In order to calculate the proxy objective function value  $\text{profit}(\mathcal{C})$ , we need to combine  $\mathcal{C}$  with a cell  $\hat{\mathcal{C}}$  corresponding to a DP cell for the remaining problem. To this end, let us define the parameters of this cell  $\hat{\mathcal{C}}$ . Clearly, we only need to define  $\mathcal{B}_1, \dots, \mathcal{B}_{k-1}$ . Hence, the first parameter of  $\hat{\mathcal{C}}$  is  $k - 1$ . Further, the total number of previously defined bags is given by  $\hat{M}_{k, \dots, K} = M_k + M_{k+1}, \dots, M_K$ . As we do not ignore scenarios, we choose  $m_{\min}^{(k-1)} := m_{\max}^{(k)} + 1$ . Since we have already guessed the assignment of jobs in  $J_{k-1}$  to bags in  $\mathcal{B}_k^*$ , we can simply calculate the values  $\hat{a}_\ell$  for  $\ell \in L_{k-1}$  that indicate the number of jobs  $j$  with  $p_j = \lceil (1 + \varepsilon)^\ell \rceil$  to be assigned to bags in  $\mathcal{B}_k^*$ .

It remains to calculate the value  $\bar{S} \in \mathbb{N}$ , the total size of jobs in  $\bigcup_{k'=1}^{k-1} J_{k'}$  assigned as very small jobs to bags in  $\bigcup_{k'=k}^K \mathcal{B}_{k'}$ . To this end, we calculate the total size of jobs from  $\bigcup_{k'=1}^{k-2} J_{k'}$  that need to be packed in  $\mathcal{B}_k^*$ . For each  $B \in \mathcal{B}_k^*$ , let  $p^+(B)$  be the total size of the jobs from  $J_{k-1} \cup J_k$  that  $B$  already packs. We define  $S_k := \sum_{B \in \mathcal{B}_k^*} \max\{\lceil (1 + \varepsilon)^{\ell(B)} \rceil - p^+(B), 0\}$ . Denote by  $J_k(\mathcal{B}_k^* \cup \mathcal{B}_{k+1}^*)$  the set of jobs from  $J_k$  assigned to bags  $\mathcal{B}_k^*$  and  $\mathcal{B}_{k+1}^*$ . Then,  $\bar{S}$  is defined as  $\bar{S} := S - \sum_{j \in J_k \setminus J_k(\mathcal{B}_k^* \cup \mathcal{B}_{k+1}^*)} p_j + S_k$ , where  $S$  is defined by the current DP cell  $\mathcal{C}$ . (Note that  $\bar{S}$  does not contain jobs from  $J_{k-1}$  to be assigned to  $\mathcal{B}_k^*$  as they are accounted for by  $\hat{a}_\ell$ .)

Hence, the remaining problem corresponds to some DP cell  $\hat{\mathcal{C}}$  satisfying

$$\hat{\mathcal{C}} = \left( k - 1, M_{k+1}, \dots, M_K + M_k, \hat{M}_{k-1}, m_{\max}^{(k)} + 1, \hat{S} \geq \bar{S}, (\hat{s}_\ell)_{\ell \in L_{k-1}}, (\hat{a}_\ell)_{\ell \in L_{k-1}} \right), \quad (1)$$

where  $\hat{s}_\ell$  is a possible number of bags with size-estimate  $\ell \in L_{k-1}$ , i.e., with size  $(1 + \varepsilon)^\ell$ , the number of bags  $|\mathcal{B}_{k-1}^*|$  is given by  $\hat{M}_{k-1} = \sum_{\ell \in L_{k-1}} \hat{s}_\ell$ , and we require that  $\hat{S}$  is at least  $\bar{S}$ .

Given  $\text{profit}(\hat{\mathcal{C}})$  for some  $\hat{\mathcal{C}}$ , we can now calculate  $\text{profit}(\mathcal{C})$  as follows: For each value  $m \in \{m_{\min}^{(k)}, \dots, m_{\max}^{(k)}\}$ , we compute an estimate  $\text{ALG}(m)$  of the objective value of an optimal bag-to-machines assignment of  $\bigcup_{k'=1}^k \hat{\mathcal{B}}_{k'}$  and  $M_{k+1}, \dots, K$  large bags to  $m$  machines. To this end, we use a variant of Lemma 11, which is explained in detail in the full version. Then, the profit of the candidate combination of  $\mathcal{C}$  with  $\hat{\mathcal{C}}$  is given by  $\sum_{m=m_{\min}^{(k)}}^{m_{\max}^{(k)}} q_m \text{ALG}(m) + \text{profit}(\hat{\mathcal{C}})$ . Among all these candidate combinations, we choose the one with the largest profit and set  $\text{profit}(\mathcal{C}) = \sum_{m=m_{\min}^{(k)}}^{m_{\max}^{(k)}} q_m \text{ALG}(m) + \text{profit}(\hat{\mathcal{C}})$ .

### 4.2.2 Analysis

Observe that there are at most  $\mathcal{O}_\varepsilon(1)$  many distinct processing times of jobs  $J_{k-1} \cup J_k$  and each bag  $B \in \mathcal{B}_k^*$  contains at most  $\mathcal{O}_\varepsilon(1)$  many jobs from each of these processing times because of the definition of  $\mathcal{B}_k^*$ ,  $J_{k-1}$ , and  $J_k$ .

We guess all possible assignments of jobs to a single bag of size at most  $(\frac{1}{\varepsilon})^{3k+3}$ ; typically such an assignment is called a *configuration*. There are at most  $\mathcal{O}_\varepsilon(1)$  such configurations. Then, for each configuration and each  $\ell$  with  $\lceil (1 + \varepsilon)^\ell \rceil \in I_k$ , we guess how often the configuration is assigned to a bag  $B$  with  $\ell(B) = \ell$ . Following this sketch, the next lemma proves that we can in fact guess the job-to-bag assignment in polynomial time.

► **Lemma 12.** *In time  $n^{\mathcal{O}_\varepsilon(1)}$  we can guess the assignment of jobs from  $J_{k-1}$  and  $J_k$  to the bags  $\mathcal{B}_k^*$  up to permuting jobs and bags.*

During the evaluation phase, we try all possible combinations of the current DP cell  $\mathcal{C}$  with  $\hat{\mathcal{C}}$  satisfying (1), i.e., DP cells corresponding to the remaining subproblems matching the parameters of  $\mathcal{C}$ . We now give a proof sketch of why our guesses combined  $\mathcal{C}$  indeed give a feasible solution to the subproblem for  $k$ . Let  $\hat{\mathcal{B}}_1, \dots, \hat{\mathcal{B}}_{k-1}$  be the bags given by the solution to  $\hat{\mathcal{C}}$  and  $\hat{\mathcal{B}}_k$  be the bags corresponding to our guess. (We do not change  $\bigcup_{k'=1}^{k-1} \hat{\mathcal{B}}_{k'}$ .)

We need to assign jobs from  $\bigcup_{k'=1}^{k-1} J_{k'}$  to  $\hat{\mathcal{B}}_k$  satisfying

- (i) for every bag  $B \in \hat{\mathcal{B}}_k$ ,  $p(B) \geq (1 + \varepsilon)^{\ell(B)-1}$  and
- (ii) the total processing time of
  - all jobs in  $\bigcup_{k'=1}^{k-1} J_{k'}$  not assigned to bags in  $\bigcup_{k'=1}^k \hat{\mathcal{B}}_{k'}$  and
  - all jobs in  $J_k$  neither assigned to  $\hat{\mathcal{B}}_k$  nor reserved by the values  $a_\ell$  for the bags with size in  $I_{k+1}$
is at least  $S$ .

Each  $B \in \hat{\mathcal{B}}_k$  has already jobs from  $J_k$  and  $J_{k-1}$  of total size  $p^+(B)$  assigned to it. Let  $p^-(B) := \max\{\lceil (1 + \varepsilon)^{\ell(B)} \rceil - p^+(B), 0\}$  be the missing volume in  $B$  to cover  $B$  to the desired level of  $\lceil (1 + \varepsilon)^{\ell(B)} \rceil$ . If  $p^-(B) = 0$ , no additional job from  $\bigcup_{k'=1}^{k-2} J_{k'}$  needs to be assigned to  $B$ . Otherwise, we greedily add jobs from  $\bigcup_{k'=1}^{k-2} J_{k'}$  not packed in  $\bigcup_{k'=1}^{k-1} \hat{\mathcal{B}}_{k'}$  until assigning the next job would exceed  $p^-(B)$ . Hence, the total size of jobs  $\bigcup_{k'=1}^{k-2} J_{k'}$  assigned to  $B$  by this routine is at least  $p^-(B) - (\frac{1}{\varepsilon})^{3k-6}$ . Thus,

$$p(B) \geq p^+(B) + p^-(B) - \left(\frac{1}{\varepsilon}\right)^{3k-6} = (1 + \varepsilon)^{\ell(B)} - \left(\frac{1}{\varepsilon}\right)^{3k-6} \geq (1 + \varepsilon)^{-1} (1 + \varepsilon)^{\ell(B)}$$

since by definition  $(1 + \varepsilon)^\ell \geq \frac{1}{\varepsilon} \cdot (\frac{1}{\varepsilon})^{3k-6}$  for all  $\ell \in L_k$ .

By choice of  $\hat{\mathcal{C}}$ , the total size  $\hat{S}$  of jobs in  $\bigcup_{k'=1}^{k-1} J_{k'}$  neither assigned to bags in  $\bigcup_{k'=1}^{k-1} \hat{\mathcal{B}}_{k'}$  nor reserved for  $\mathcal{B}_k$  via the values  $(\hat{a}_\ell)_{\ell \in L_{k-1}}$  is at least  $\bar{S}$ . With the definition of  $\bar{S}$ , we get

$$\hat{S} \geq \bar{S} = S - \sum_{j \in J_k \setminus J_k(\hat{\mathcal{B}}_k \cup \hat{\mathcal{B}}_{k+1})} p_j + S_k = S - \sum_{j \in J_k \setminus J_k(\hat{\mathcal{B}}_k \cup \hat{\mathcal{B}}_{k+1})} p_j + \sum_{B \in \hat{\mathcal{B}}_k} p^-(B).$$

We remark that the second term indeed corresponds to the contribution of jobs from  $J_k$  to filling bags with sizes in  $\bigcup_{k'=k+1}^K J_{k'}$  since such jobs cannot be packed into  $\bigcup_{k'=1}^{k-1} \hat{B}_k$  by definition of the corresponding sizes. Observe that the greedy procedure described above assigns jobs from  $\bigcup_{k'=1}^{k-2} J_{k'}$  with total volume *at most*  $p^-(B)$  to  $B \in \hat{B}_k$ . Hence, the combination of our guess  $\hat{B}_k$  (and the guessed partial assignment of  $J_{k-1} \cup J_k$  to  $\hat{B}_k$ ) and the solution for  $\hat{C}$  is indeed a feasible solution for  $\mathcal{C}$ .

Similar to the proof of Lemma 11, we show that for any candidate solution (consisting of a guess  $\hat{B}_k$ , a partial assignment of  $J_k \cup J_{k-1}$ , and any solution for  $\hat{C}$  as defined in (1)), we can calculate the values  $\text{ALG}(m)$  for  $m \in \{m_{\min}^{(k)}, \dots, m_{\max}^{(k)}\}$  in polynomial time such that  $\text{ALG}(m)$  is within a factor  $(1 + \mathcal{O}(\varepsilon))$  of the optimal assignment given the same set of bags. This is formalized in the next lemma.

► **Lemma 13.** *Let  $\hat{B}_k, m_{\max}^{(k)}$  and the job-to-bag assignment of  $J_k \cup J_{k-1}$  to  $\hat{B}_k$  be guesses as defined. Further, let  $\hat{C}$  satisfy (1) and suppose that the bag sizes in  $\hat{B}_{k-1}$  are given by  $(\hat{s}_\ell)_{\ell \in L_{k-1}}$ . Let  $\mathcal{B}' \cup \{B_{\hat{s}}\}$  be a partition of the jobs  $\bigcup_{k'=1}^{k-2} J_{k'}$  into  $M - M_{k+1, \dots, K} - |\hat{B}_k| - |\hat{B}_{k-1}| + 1$  bags such that*

- for each bag  $B \in \mathcal{B}'$  we have that  $p(B) \leq \varepsilon \cdot \left(\frac{1}{\varepsilon}\right)^{3k}$ ,
- $p(B_{\hat{s}}) \geq \hat{S}$ ,
- $p(\mathcal{B}') := \sum_{B \in \mathcal{B}'} p(B) \geq (1 + \varepsilon)^{-1} T$ .

*Suppose that each bag  $B \in \hat{B}_k \cup \hat{B}_{k-1}$  satisfies  $p(B) \in [(1 + \varepsilon)^{\ell(B)}, (1 + \varepsilon)^{\ell(B)+1}]$  and let  $\hat{B}_L$  contain  $M_{k+1, \dots, K}$  many large bags of size at least  $\left(\frac{1}{\varepsilon}\right)^{3k+3}$ . There is a polynomial-time algorithm that either asserts that our guess is incorrect and cannot be combined with  $\hat{C}$  or that computes a vector  $(\text{ALG}(m))_{m=m_{\min}^{(k)}}^{m_{\max}^{(k)}}$  such that  $\text{OPT}(\mathcal{B}_L \cup \hat{B}_k \cup \hat{B}_{k-1} \cup \mathcal{B}', m) \in [(1 + \varepsilon)^{-5} \text{ALG}(m), (1 + \varepsilon) \text{ALG}(m)]$  holds for each  $m \in \{m_{\min}^{(k)}, \dots, m_{\max}^{(k)}\}$  for which  $\text{OPT}(\mathcal{B}_L \cup \hat{B}_k \cup \hat{B}_{k-1} \cup \mathcal{B}', m) \geq (1 + \varepsilon)^{-1} \left(\frac{1}{\varepsilon}\right)^{3k}$ .*

*Further, we can find the best  $\hat{C}$  that satisfies (1) and can be combined with our guess in polynomial time.*

To compute the final solution, we combine the correct initial guesses with the solution stored in the DP cell corresponding to the remaining subproblem. This yields a global solution to the original problem. In order to prove the correctness of our DP, we observe that for each  $k \in [K - 1]$  there is a *special* DP cell for which  $k$  is the first parameter and whose other parameters correspond to the optimal solution (e.g., the assignment of jobs in  $J_k$  to bags in  $\mathcal{B}_{k+1}^*$ ). We then prove by induction that, for each  $k \in [K - 1]$ , the solution stored in the corresponding special DP cell yields a profit that is similar to the optimal profit restricted to scenarios with  $m \in \{1, \dots, m_{\max}^{(k)}\}$  machines, using Lemma 13.

## 5 Conclusion

In this paper, we continue the recent line of research on scheduling with uncertainty in the machine environment [1, 5, 20] by considering a stochastic machine environment in which the number of identical parallel machines is only known in terms of a distribution and the actual number is revealed once the jobs are assigned to bags which cannot be split anymore. Interestingly, we present polynomial time approximation schemes for minimizing the makespan as well as maximizing the minimum machine load, which matches their respective deterministic counterparts from the perspective of approximation algorithms. We believe that our insights open up many interesting questions for future research such as extending the current model to the setting with uniformly related machines in which the uncertainty is modeled in terms of machine speeds as done in [5] from a robustness point-of-view or to the setting with different (job-based) objectives such as sum of weighted completion times.

## Abstract

In this work we study the classic problem of online weighted paging with a probabilistic prediction model, in which we are given additional information about the input in the form of distributions over page requests, known as *distributional online paging* (DOP). This work continues a recent line of research on learning-augmented algorithms that incorporates machine-learning predictions in online algorithms, so as to go beyond traditional worst-case competitive analysis, thus circumventing known lower bounds for online paging. We first provide an efficient online algorithm that achieves a constant factor competitive ratio with respect to the best online algorithm (policy) for weighted DOP that follows from earlier work on the stochastic  $k$ -server problem.

Our main contribution concerns the question of whether distributional information over a limited horizon suffices for obtaining a constant competitive factor. To this end, we define in a natural way a new predictive model with limited horizon, which we call *Per-Request Stochastic Prediction* (PRSP). We show that we can obtain a constant factor competitive algorithm with respect to the optimal online algorithm for this model.

## 1 Introduction

In the weighted paging problem there is a universe of  $n$  pages, where each page has a weight<sup>2</sup>, and there is a cache that can hold up to  $k$  pages. At each time step a page is requested, and if the requested page is already in the cache then no cost is incurred, otherwise, the page must be loaded into the cache, incurring a cost equal to its weight. The goal is to minimize the total cost incurred.

Paging is one of the earliest and most extensively studied problems in online computation and competitive analysis [38, 22, 40, 42, 36, 7, 6, 1, 4, 11, 10, 27, 28, 29], including works on non-standard caching models, e.g., elastic caches [25], caching with time windows [26], caching with dynamic weights [21], and caching with machine learning predictions [35]. In fact, online paging has become a focal point for many of the recent developments in competitive analysis, e.g., the online primal-dual method, projections, and mirror descent [17, 16, 15].

---

<sup>1</sup> Work done while at the Technion before joining Amazon.

<sup>2</sup> In the unweighted version of the problem, all weights are equal (unit weights).

In their seminal paper, Sleator and Tarjan [38] showed that any deterministic online algorithm is at least  $k$ -competitive and that the LRU policy (Least Recently Used) is exactly  $k$ -competitive for unweighted paging. The  $k$ -competitive bound was later generalized to weighted paging as well [19, 41]. When randomization is allowed, Fiat et al. [22] gave the elegant randomized marking algorithm for unweighted paging, which is  $\Theta(\log k)$ -competitive against an oblivious adversary. Bansal et al. [7] gave a  $\Theta(\log k)$ -competitive randomized algorithm for weighted paging based on the online primal-dual framework [17].

Algorithms with predictions, or learning-augmented algorithms, is an emerging field of research lying at the intersection of machine learning and foundations of algorithms (e.g. [5]). The goal is to use machine-generated predictions, that can be either deterministic or probabilistic, so as to go beyond traditional worst-case competitive analysis, and relax the overly pessimistic assumption of not having any prior knowledge of the future. This is in line with recent momentum in deploying machine learning techniques for various applications, e.g., search, business processes, and health.

The study of online paging with predictions has been a catalyst for the development of this new field. In an influential paper, Lykouris et al. [35] studied a simple predictor that provides for each requested page the next time step in which it is requested again, called PRP (Per-Request Prediction). Clearly, for unweighted paging, PRP suffices for implementing Belady's algorithm. Lykouris et al. [35] analyzed the robustness of PRP.

Computationally, weighted paging is a very different problem from unweighted paging, since it requires more global information about the request sequence to obtain (near) optimal algorithms. For example, Belady's local rule suffices to define an optimal offline algorithm in the unweighted case, while a minimum cost flow procedure is needed for computing an optimal solution in the weighted case. This is also manifested in the online setting, where PRP does not improve on the competitive factor in the weighted case [31]. Even with precise PRP, any deterministic online algorithm remains  $\Omega(k)$ -competitive, and any randomized algorithm is  $\Omega(\log k)$ -competitive.

### Distributional Online Paging

We focus on probabilistic prediction models for online weighted paging. Suppose that an online algorithm is given *in advance*, for each time step  $t \in \{1, 2, \dots, T\}$ , a distribution over page requests at  $t$ . Thus, the request at time  $t$  is drawn according to  $D_t$ . The given distributions are assumed to be *independent* between different time steps and the distributions are not necessarily identical. This model is known in the literature as *distributional online paging*, or DOP [34], and it can be viewed as the probabilistic counterpart of PRP. DOP is also a special case of the stochastic uber problem studied by [20]. (See more about this problem in the sequel.)

Define the cost of an online algorithm (or policy) for DOP to be the expected cost taken over all possible request sequences, where the probability of a request sequence is determined by the distributions  $D_1, \dots, D_T$ . An optimal online algorithm minimizes the expected cost and is defined by a Markov Decision Process. It can be computed by either a dynamic program or a linear program. Unfortunately, the state space of the dynamic program, or the size of the linear program, is of exponential size in  $k$ , rendering it computationally impractical. The computational hardness of finding an optimal algorithm for DOP is still open to the best of our knowledge<sup>3</sup>.

---

<sup>3</sup> It is stated as an open problem in [13]. For general metrics (i.e., the  $k$ -server problem), [20] gives a simple reduction to prove hardness: the uniform distribution over the points in the metric is given at all times; thus, a solution to the  $k$ -median problem on the metric defines the placement of the servers in an optimal online algorithm.

For unweighted DOP, the work of Lund et al. [34] is seminal. They show that *full* information about the distributions in each time step is actually not needed in order to get a near-optimal online algorithm. Specifically, for general distributions over page requests, if the probability that  $p$  is requested before  $q$  is available for any pair of pages  $p$  and  $q$ , then this information can be leveraged to get an efficient and simple 4-competitive algorithm with respect to the best online algorithm. However, these ideas do not seem to generalize to the weighted setting, due to the more global nature of weighted paging, as indicated before.

## 1.1 Our Results

We study the weighted DOP problem. Our goal is to provide an *efficient* online algorithm that achieves a constant competitive factor with respect to the best online algorithm (policy) for weighted DOP. Our starting point is a linear program for DOP which is based on the work of [20] for the stochastic  $k$ -server problem. In the case of the paging problem, this linear program specifies to which cache slot a page is loaded. The linear program provides a lower bound on the cost of any non-adaptive algorithm for DOP. However, [20] show that an optimal non-adaptive algorithm can cost at most thrice the cost of an optimal online algorithm for DOP. In Section 3 we provide the details for rounding the  $k$ -server linear program, yielding a constant competitive algorithm for the weighted DOP problem.<sup>4</sup> This is summarized in the following theorem.

► **Theorem 1.** *There exists an efficient algorithm for weighted DOP with  $O(1)$ -competitive ratio.*

The constant competitive factor obtained in Theorem 1 strongly utilizes information about the page distributions over the *entire* time horizon. However, such distributional information may not always be available. Thus, a natural question is whether distributional information over a limited horizon suffices for obtaining a constant competitive factor. This is the main focus of our paper.

In [31], a new deterministic predictive model for online weighted paging is suggested, due to the weakness of PRP in the weighted setting, as indicated earlier. This model, called SPRP, assumes that when a page  $p$  is requested, the full request sequence up to the next request for  $p$  is revealed. It turns out that the SPRP predictive model is strong enough to obtain a 2-competitive algorithm for online weighted paging in the adversarial setting [31].

Our first contribution is a novel limited horizon distributional model which we call the *Per-Request Stochastic Prediction* (PRSP) model. In this model, at any point of time, the known horizon of (future) distributions guarantees that for each page  $p$  in the cache, the sum of the probabilities of requesting  $p$  (in the known horizon) is at least one. Interestingly, this model captures the property needed from a limited horizon distributional model in order to design a near-optimal online algorithm.

Note that in a deterministic setting,  $D_t$  is equal to zero for all pages, except for one page, for which it is equal to one. Thus, when PRSP is restricted to a deterministic setting, it is equivalent to the SPRP model of [31].

We show that any algorithm for (full horizon) weighted DOP can be used in a black-box manner in the PRSP model, while increasing the competitive factor only by a constant. We thus obtain the next theorem.

<sup>4</sup> It is interesting to note that a natural linear programming formulation for the weighted DOP problem that provides a lower bound on the best online algorithm has a large integrality gap which depends on the maximum page weight. Thus, the work of [20] manages to circumvent this gap by utilizing a stronger LP.

► **Theorem 2.** *If there exists an  $\alpha$ -competitive algorithm for weighted DOP, then there exists an  $O(\alpha)$ -competitive algorithm for weighted DOP under the PRSP model. I.e., there exists an efficient  $O(1)$ -competitive algorithm for weighted DOP under the PRSP model.*

To prove Theorem 2, we design an algorithm called Split-and-Solve. The algorithm is very natural and it splits the time horizon into phases, solving each one separately. Using the properties of the PRSP model, the phases are chosen such that at the beginning of the phase the distributions are known for all times in the phase. Therefore, each phase can be regarded as a weighted DOP instance. As the analysis of Split-and-Solve does not make any assumptions regarding the solutions of the phases, any algorithm for weighted DOP can be employed in a black-box manner (e.g., Theorem 1). However, as each phase commences, the cache is reset to be the final cache state of the optimal offline solution of the realization of the request sequence of the previous phase.

The difficulty with analyzing the Split-and-Solve algorithm is in stitching together the performance of the different phases. Even though the policy employed in each phase by itself may be optimal, note that the initial cache states (in each phase) may be very different from the corresponding cache states of the optimal online algorithm (which is familiar with the full horizon). In particular, since our caching problem is weighted, the gap (in terms of weight) between cache states can be arbitrarily large, and may also further lead to poor performance within the phase. However, the crucial ingredient for bounding the performance of each phase is the property of the PRSP model that guarantees that for each page in the cache the sum of the probabilities in the known horizon adds up to at least 1. Thus, the performance of each phase can be related to the performance of the optimal online algorithm in the phase with a multiplicative constant factor (together with an additive term). Using a global analysis that considers all phases, the loss incurred by the sum of the additive terms can be charged to the cost of the optimal online algorithm, yielding Theorem 2.

## 1.2 Related Work

The  $k$ -server problem generalizes the paging problem to arbitrary metric spaces. (In paging the underlying metric is a weighted star.) A natural generalization of DOP is distributional  $k$ -server, where in every time step there is a given distribution over the possible request point. This problem was studied by [20], who also introduced the stochastic Uber problem, where each request is defined by two points in the metric. The server satisfying a request must travel to the start point of the request and then to its end point, incurring a cost equal to the total distance traveled. [20] gave a constant competitive factor algorithm for the case where the metric is a line. For general metrics, they gave an  $O(\log n)$ -competitive algorithm, where  $n$  is the number of points in the metric.

Work on distributional paging goes back more than fifty years. Franaszek and Wagner [24] compared FIFO and LRU in a model where every request is drawn from a fixed probability distribution over time. Shedler and Tung [37] suggested a Markov model for generating requests. This model and its extensions were analyzed in [32]. They also showed a gap of  $\Omega(\log k)$  between optimal online and offline algorithms in the case of a uniform distribution.

Besides stochastic models, several paging models assuming partial knowledge of future requests have been studied. For example, [8] studied the PRP model of Lykouris et al. [35] (mentioned earlier) in the weighted setting. A very sophisticated algorithm is given in [8] for this model whose competitive factor is at most a logarithm of the number of weight classes. Other examples for models with predictions are paging with locality of reference [12, 23, 30], paging with lookahead [3, 14, 39] and interleaved paging [9, 18, 33].

## 2 Preliminaries

### 2.1 Distributional Online Paging

In the weighted paging problem there is a universe of  $n$  pages, denoted by  $P = \{p_1, p_2, \dots, p_n\}$ , and a cache of size  $k$ . The initial cache state is  $C_0 \subseteq P$ . Each page  $p$  is associated with a weight  $w_p$ , the cost of loading or evicting page  $p$  to the cache. For a sequence of requests  $\sigma_1, \sigma_2, \dots, \sigma_T$ , an algorithm  $\mathcal{A}$  determines a series of cache states  $C_1, \dots, C_T$ , such that  $\forall t : \sigma_t \in C_t$ . The cost of serving the request sequence by  $\mathcal{A}$  is  $\sum_{t=1}^T \sum_{p \in C_t \Delta C_{t-1}} w_p$ , which is equal to the sum of the loading costs and the eviction costs. Note that the sum of the eviction costs and the loading costs can differ by at most an additive constant depending only on the initial and final cache contents. For simplicity, we assume the initial cache and final cache are identical, i.e.,  $C_0 = C_T$ . This means that the loading costs are equal to the eviction costs.

We focus on *distributional* prediction models in this paper. Suppose that we are given *in advance* at time  $t = 0$ , for each (future) time step  $t \in \{1, 2, \dots, T\}$ , a distribution over page requests at  $t$ . The given distributions are not necessarily identical, yet assumed to be *independent* between different time steps. More formally, for every  $t \in [T]$ , a probability distribution  $D_t$  is given from which request  $\sigma_t$  is drawn at time  $t$ . This model is called *distributional online paging*, or DOP.

► **Definition 3.** For an algorithm  $\mathcal{A}$ , let  $E(\mathcal{A})$  denote the expected cost of  $\mathcal{A}$  over all realizations of input sequences generated according to distributions  $D_1, \dots, D_T$ .

Denote by  $O$  the best online algorithm (in expectation) for DOP, i.e., it minimizes  $E(O)$ . We emphasize that algorithm  $O$  is only familiar with the distributions  $D_1, \dots, D_t$ , but does not have prior knowledge of the actual realization of the requests. Let  $E(O) = OPT$ .

### 2.2 Limited Horizon

So far we have assumed that all distributions  $D_1, \dots, D_T$  are given as input at the beginning. This is, of course, unreasonable in many cases as  $T$  may be very large. We aspire to bound the horizon that an online algorithm needs to “see”, i.e., at any time  $t$ , how many distributions into the future are available to the algorithm.

In [31] it was shown that the per-request-prediction (PRP) model and the lookahead model are not sufficient to circumvent the known lower bounds for online paging. In [31] a constant competitive factor for deterministic online weighted paging is achieved only through a combination of two models which they call SPRP. Specifically, upon arrival of a page, the time of its next request  $t$  is given, as in PRP, as well as the full sequence of page requests up to  $t$ .

Here, we propose an extension of the above model for our stochastic setting called Per-Request Stochastic Prediction (PRSP). The PRSP model requires that at any time  $t$  a sequence of future distributions is revealed such that sufficient information is revealed for each page in the current cache, as follows.

► **Definition 4.** Given a cache  $C \subseteq P$  and time  $t$ , let  $N(C, t)$  be the earliest time  $t'$  that satisfies:

$$\forall p \in C : \sum_{\tau=t}^{t'} D_\tau(p) \geq 1.$$

## 15:6 Distributional Online Weighted Paging with Limited Horizon

Note that in the deterministic setting,  $D_t$  is equal to zero for all pages, except for one page, for which it is equal to one. Assuming all pages in  $C$  are there because they were previously requested, Definition 4, restricted to a deterministic setting, is equivalent to the SPRP model of [31].

Using the definition of  $N(C, t)$  we can now give a formal definition of the PRSP model.

► **Definition 5.** *In the PRSP model at each time step  $t$ , where the cache is  $C_t$ , the sequence of distributions  $(D_t, \dots, D_{N(C_t, t)})$  is revealed to the algorithm.*

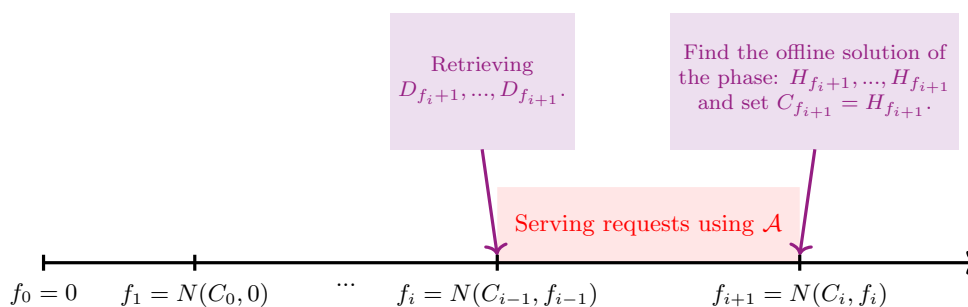

In a deterministic setting, at each time  $t$  it holds that there exists a single page  $p$  such that  $D_t(p) = 1$  and it is equal to zero for all other pages. Thus, in the PRSP model, when restricted to a deterministic setting, at any time  $t$ ,  $N(C_t, t)$  is equal to the latest time over the next arrivals of all pages in  $C_t$ . In reality, the distributions up to time  $N(C_t, t)$  were revealed earlier when the pages in  $C_t$  were requested and they were loaded to the cache. Thus, in the deterministic setting, we can interpret PRSP as SPRP since it reveals upon a request to a page the whole sequence of pages up to its next request.

### 3 Full Horizon

In this section we consider the weighted DOP problem when all the distributions are given in advance and provide a proof for Theorem 1. The proof essentially follows from the work of [20] on the stochastic  $k$ -server problem. Recall that weighted paging is the special case of  $k$ -server when the underlying metric is a weighted star. We show here that when applying the linear program for stochastic  $k$ -server to the special case of DOP, it can be rounded yielding a constant competitive algorithm. It is interesting to note that a natural linear programming formulation for the weighted DOP problem has a large gap compared to the best online algorithm, where the gap depends on the maximum page weight. Thus, the work of [20] manages to circumvent this gap by utilizing a stronger LP.

In [20], an algorithm  $\mathcal{A}$  for DOP is defined to be *non-adaptive* if it satisfies the following. First, algorithm  $\mathcal{A}$  pre-computes a sequence of cache configurations  $C_1, \dots, C_T$ ; then it serves the request sequence as follows. Upon arrival of request  $\sigma_t$  at time  $t$ : (i)  $\mathcal{A}$  changes the cache contents to configuration  $C_t$ ; (ii)  $\mathcal{A}$  replaces the lightest page in  $C_t$  with  $\sigma_t$ ; (iii)  $\mathcal{A}$  changes the cache contents back to the configuration that preceded the arrival of  $\sigma_t$ . The linear program for stochastic  $k$ -server suggested in [20] provides a lower bound on the cost of any non-adaptive algorithm. However, an online algorithm for the stochastic  $k$ -server problem does not necessarily imply a feasible solution for the latter linear program. It is shown in [20, Theorem 1.3] that an optimal non-adaptive online algorithm is a 3-approximation with respect to an optimal online algorithm for stochastic  $k$ -server. Thus, non-adaptive algorithms provide a useful tool for obtaining a competitive algorithm for stochastic  $k$ -server.

In what follows we describe the specialization of the linear program for the stochastic  $k$ -server problem [20] to DOP. Essentially, this means specifying to which cache slot is a page loaded. Thus, for each page  $p$ , there is a variable  $b_{t,p}$  that indicates the fraction of  $p$  that is not in the cache. For each page  $p$  and possible request  $q$ , variable  $x_{t,p,q}$  indicates whether  $q$  is served by replacing  $p$ .

■ **Figure 1** Algorithm *Split-and-Solve* splits the timeline into phases and separately solves each phase as DOP. As phase  $i$  begins at  $f_i$  the distributions till  $N(C_{f_i}, f_i)$  are revealed. The DOP black box  $\mathcal{A}$  serves the requests during the phase. As the phase terminates at  $N(C_{f_i}, f_i)$ , the optimal offline solution  $H_{f_{i+1}}, \dots, H_{f_{i+1}}$  is computed with the realization of the phase and  $H_{f_{i+1}}$  is loaded into  $C_{f_{i+1}}$ .

$$\begin{aligned}
 \min \quad & \sum_{p,q,t \geq 1} (w_p + w_q) \cdot D_t(q) \cdot x_{t,p,q} + \sum_{p,t \geq 1} w_p \cdot |b_{t,p} - b_{t-1,p}| \quad \text{s.t.} \\
 \forall t, q : \quad & \sum_{p \neq q} x_{t,p,q} \geq b_{t,q} \\
 \forall t, p, q : \quad & x_{t,p,q} \leq 1 - b_{t,p} \\
 \forall t : \quad & \sum_p b_{t,p} \geq n - k
 \end{aligned} \tag{31}$$

The cost function accounts for the weight of the pages that make two switches when serving a request. By doing so it forces the solution to be non-adaptive. Note that (31) gives us a lower bound only on the optimal non-adaptive algorithm. Thus, not every paging algorithm can be mapped into a solution for (31), only a non-adaptive one.

The details for rounding the LP solution so as to yield a 60-competitive algorithm are given in Appendix A.

## 4 The Split-and-Solve Algorithm

Section 3 provides us with a constant competitive factor algorithm, but requires that at time 0 all distributions  $D_1, \dots, D_T$  are known. In this section we present the Split-and-Solve algorithm that provides a constant-competitive factor for DOP in the PRSP model. The algorithm is very natural. It first splits the time horizon into phases: if a phase begins at time  $t$ , then it ends at time  $N(C_t, t)$ . As the horizon of the algorithm is at most  $\max\{N(C_{t'}, t') \mid t' \leq t\}$  for every time step  $t$ , the distributions  $D_{t+1}, \dots, D_{N(C_t, t)}$  can be retrieved by the properties of the PRSP model.

Each phase is solved independently using a (full horizon) DOP algorithm in a black-box manner. However, as each phase commences, the cache is reset to be the final cache state of the optimal offline solution of the realization of the request sequence of the previous phase. This cache state can be computed by running a min cost flow algorithm. This guarantees that the definition of phases is independent of the algorithm  $\mathcal{A}$ . The steps of the algorithm are depicted in Figure 1. We are now ready to give a formal definition of the Split-and-Solve algorithm.

---

**■ Algorithm 1 Split-and-Solve (SaS).**

---

**Input:** Instance  $\mathbf{I}$  of DOP and Algorithm  $\mathcal{A}$  for DOP.

- 1: Initialize  $i = 0, f_0 = 0, H_0 = C_0$ .
  - 2: **while**  $f_i < T$  **do**
  - 3:    Let  $f_{i+1} = N(C_{f_i}, f_i)$ .
  - 4:    Retrieve  $D_{f_{i+1}}, \dots, D_{f_{i+1}}$ .
  - 5:    Set  $C_{f_{i+1}}, \dots, C_{f_{i+1}}$  as the solution returned by  $\mathcal{A}$  for serving requests in time range  $[f_i, f_{i+1}]$  with initial cache  $H_{f_i}$ .
  - 6:    Let  $H_{f_{i+1}}, \dots, H_{f_{i+1}}$  be the optimal offline solution for time range  $[f_i, f_{i+1}]$  with initial cache  $C_{f_i}$ .
  - 7:    After serving  $\sigma_{f_{i+1}}$ , set  $C_{f_{i+1}} = H_{f_{i+1}}$  as the initial cache of the next phase.
  - 8:    Update  $i := i + 1$ .
- 

Before analyzing the algorithm, we need the following notation. We denote by  $F + 1$  the number of phases into which the time horizon is split. The optimal online algorithm is denoted by  $O_{on}$  and its caches are denoted by  $\{O_t\}_{t \in [T]}$ .

In the sequel we will show that given an  $\alpha$ -competitive algorithm for DOP, the Split-and-Solve (SaS) algorithm has an  $O(\alpha)$  competitive ratio, losing only an additional constant factor. To do so, we first bound in Lemma 7 the cost of our algorithm by the cost of the online algorithm when we also reset its cache at the beginning of each phase (i.e., similarly to Step 6, where at the beginning of each phase the cache is set to  $H_{f_i}$ ). Then, Lemma 8 bounds the cost of the online algorithm (with the cache reset) at phase  $i$  by the sum of three components:

1. The expected cost of  $O_{on}$  during the phase.
2. The total weight of  $H_{f_i} \setminus O_{f_i}$ .
3. The sum over pages in  $O_{f_i} \setminus H_{f_i}$  of the page weight times the probability it is requested in phase  $i$ .

Lemmas 9, 11 and 12 bound the last two components by a constant factor of the cost of  $O_{on}$ .

In the following definition we provide a notation for a partial solution.

► **Definition 6.** Let  $t_1, t_2 \in [T]$  such that  $t_1 < t_2$  and  $C \subseteq P$ . We denote the expected cost of an algorithm  $\mathcal{A}$  on the sub-range  $[t_1, t_2]$  with  $C_{t_1} = C$  as its initial cache by  $\mathcal{A}(C, t_1, t_2)$ .

From the definition of the optimal offline and online algorithms it is easy to see that for any  $t_1 < t_2$  and cache  $C$  it holds that  $O_{off}(C, t_1, t_2) \leq O_{on}(C, t_1, t_2)$ . The following lemma bounds the expected cost of phase  $i$  by  $2\alpha + 1$  times the expected cost of  $O$  during the phase when  $O$  begins the phase with the same cache.

► **Lemma 7.** Given an  $\alpha$ -competitive algorithm  $\mathcal{A}$  for DOP it holds that for every phase  $i$ :

$$\text{SaS}(H_{f_i}, f_i, f_{i+1}) \leq (2\alpha + 1) \cdot O_{on}(H_{f_i}, f_i, f_{i+1}).$$

**Proof.** At the beginning of each phase  $i$  we set the initial cache passed to algorithm  $\mathcal{A}$  in Step 5 to be the cache of the optimal offline solution  $H_{f_i}$ . For simplicity, we associate this cost with phase  $i - 1$  (note that for  $i = 0$  the cost is zero as  $H_0 = C_0$ ). Thus, in phase  $i$  we need to bound the cost of serving requests as well as the cost of loading cache  $H_{f_{i+1}}$  at the end of the phase.

The expected cost of serving requests in phase  $i$  is at most  $\alpha \cdot O_{on}(H_{f_i}, f_i, f_{i+1})$  due to the competitive ratio of  $\mathcal{A}$ . Next, loading  $H_{f_{i+1}}$  can be bounded by the cost of loading  $H_{f_i}$  and only then loading  $H_{f_{i+1}}$ . Loading  $H_{f_i}$  must cost less than the cost of SaS at this phase (as eviction and loading costs are symmetric). Afterwards, loading  $H_{f_{i+1}}$  is bounded by the cost of the optimal offline algorithm, but

$$O_{off}(H_{f_i}, f_i, f_{i+1}) \leq O_{on}(H_{f_i}, f_i, f_{i+1}).$$

Summarizing over the three cost components produces the desired bound.  $\blacktriangleleft$

The following lemma bounds  $O_{on}(H_{f_i}, f_i, f_{i+1})$  with the total cost of evicting  $H_{f_i} \setminus O_{f_i}$ , loading the requested pages from  $O_{f_i} \setminus H_{f_i}$  and then serving the requests as *on*.

► **Lemma 8.** *Let  $\gamma_{i,p}$  be the event that page  $p$  is requested in phase  $i$ , i.e.,  $\gamma_{i,p} = \mathbb{1}_p$  is requested in  $[f_i, f_{i+1}]$ . Then, it holds that:*

$$O_{on}(H_{f_i}, f_i, f_{i+1}) \leq O_{on}(O_{f_i}, f_i, f_{i+1}) + \sum_{p \in H_{f_i} \setminus O_{f_i}} w_p + \mathbb{E} \left[ \sum_{p \in O_{f_i} \setminus H_{f_i}} w_p \cdot \gamma_{i,p} \right].$$

**Proof.** Consider the following online algorithm for serving phase  $i$ . First, evict the pages in  $H_{f_i} \setminus O_{f_i}$ , incurring a cost of  $\sum_{p \in H_{f_i} \setminus O_{f_i}} w_p$ . Next, run the optimal online algorithm. A feasible solution for the online algorithm would be to act as if  $O_{f_i} \setminus H_{f_i}$  are in the cache, incurring a cost of  $O_{on}(O_{f_i}, f_i, f_{i+1})$ . Nonetheless, it might be that a page  $p \in O_{f_i} \setminus H_{f_i}$  is requested, incurring an additional cost of  $w_p$ , though this only happens with probability  $\mathbb{E}[\gamma_{i,p}]$ . Summing over the three terms produces the desired bound.  $\blacktriangleleft$

After bounding the cost at each phase, we will now evaluate the cost of all phases, bounding the cost of splitting the time horizon. To do so we must bound  $\sum_i \sum_{p \in H_{f_i} \setminus O_{f_i}} w_p$  and  $\sum_i \mathbb{E} \left[ \sum_{p \in O_{f_i} \setminus H_{f_i}} w_p \cdot \gamma_{i,p} \right]$ . The following lemma bounds the former term. It strongly uses the property of the PRSP model that for every page in cache the sum of the probabilities of requesting this page in the known horizon is at least 1.

► **Lemma 9.** *In each phase  $i \in [F]$  it holds that  $\sum_{p \in H_{f_i} \setminus O_{f_i}} w_p \leq \frac{e}{e-1} \cdot O_{on}(O_{f_i}, f_i, f_{i+1})$ .*

**Proof.** At the beginning of each phase we set  $f_{i+1} = N(H_{f_i}, f_i)$ . Thus from Definition 4 it holds that  $\sum_{t=f_i}^{f_{i+1}-1} D_t(p) \geq 1$  for each page  $p \in H_{f_i}$ . Using the inequality  $1 - x \leq e^{-x}$  for  $x \in [0, 1]$  we get that for  $p \in H_{f_i}$ :

$$\mathbb{E}[\gamma_{i,p}] = 1 - \prod_{t=f_i}^{f_{i+1}-1} (1 - D_t(p)) \geq 1 - \prod_{t=f_i}^{f_{i+1}-1} e^{-D_t(p)} = 1 - e^{-\sum_{t=f_i}^{f_{i+1}-1} D_t(p)} \geq 1 - e^{-1}. \quad (42)$$

Each page  $p \in H_{f_i} \setminus O_{f_i}$  must be loaded by  $O_{on}$  at phase  $i$  if it is requested. Thus from Equation (42) it follows that,

$$O_{on}(O_{f_i}, f_i, f_{i+1}) \geq \sum_{p \in H_{f_i} \setminus O_{f_i}} \mathbb{E}[\gamma_{i,p}] \cdot w_p \geq \sum_{p \in H_{f_i} \setminus O_{f_i}} (1 - e^{-1}) \cdot w_p.$$

Dividing by  $1 - e^{-1}$  completes the proof of the lemma.  $\blacktriangleleft$

The next corollary follows from lemmas 8 and 9.

► **Corollary 10.**

$$O_{on}(H_{f_i}, f_i, f_{i+1}) \leq \frac{2e-1}{e-1} O_{on}(O_{f_i}, f_i, f_{i+1}) + \mathbb{E} \left[ \sum_{p \in O_{f_i} \setminus H_{f_i}} w_p \cdot \gamma_{i,p} \right].$$

## 15:10 Distributional Online Weighted Paging with Limited Horizon

Next, we bound  $\sum_i \mathbb{E} \left[ \sum_{p \in O_{f_i} \setminus H_{f_i}} w_p \cdot \gamma_{i,p} \right]$ . To do so we need the following auxiliary lemma which bounds the expected eviction costs of  $O_{off}$ .

► **Lemma 11.** *Let  $Ev_{off}(H_{f_i}, f_i, f_{i+1})$  be the expected eviction costs of the optimal offline algorithm at phase  $i$  when initialized with cache  $H_{f_i}$ . It holds that,*

$$Ev_{off}(H_{f_i}, f_i, f_{i+1}) \leq \frac{2e-1}{e-1} O_{on}(O_{f_i}, f_i, f_{i+1}).$$

**Proof.** Due to the optimality of the offline algorithm,  $O_{off}(H_{f_i}, f_i, f_{i+1}) \leq O_{on}(H_{f_i}, f_i, f_{i+1})$ . So from Corollary 10 it follows that,

$$O_{off}(H_{f_i}, f_i, f_{i+1}) \leq \frac{2e-1}{e-1} O_{on}(O_{f_i}, f_i, f_{i+1}) + \mathbb{E} \left[ \sum_{p \in O_{f_i} \setminus H_{f_i}} W_p \cdot \gamma_{i,p} \right]. \quad (43)$$

In addition, the offline optimal algorithm must load any page  $p \notin H_{f_i}$  in phase  $i$  if it is requested. Thus, the expected loading costs of the offline optimal algorithm are at least  $\mathbb{E} \left[ \sum_{p \in O_{f_i} \setminus H_{f_i}} W_p \cdot \gamma_{i,p} \right]$ . By combining the bound on the loading costs and Equation (43) we get that,

$$\begin{aligned} Ev_{off}(H_{f_i}, f_i, f_{i+1}) + \mathbb{E} \left[ \sum_{p \in O_{f_i} \setminus H_{f_i}} W_p \cdot \gamma_{i,p} \right] &\leq O_{off}(H_{f_i}, f_i, f_{i+1}) \\ &\leq \frac{2e-1}{e-1} O_{on}(O_{f_i}, f_i, f_{i+1}) + \mathbb{E} \left[ \sum_{p \in O_{f_i} \setminus H_{f_i}} W_p \cdot \gamma_{i,p} \right]. \end{aligned}$$

Subtracting the last term from both sides proves the lemma. ◀

► **Lemma 12.**

$$\mathbb{E} \left[ \sum_{i \in [F]} \sum_{p \in O_{f_i} \setminus H_{f_i}} w_p \cdot \gamma_{i,p} \right] \leq \sum_{i \in [F]} \frac{2e-1}{e-1} O_{on}(O_{f_i}, f_i, f_{i+1}).$$

**Proof.** In Section 2.1 it is stated that we assume  $C_0 = C_T$ . If this was not the case, we can simply load  $C_T$  with only a constant additional cost. From this assumption it follows that the total eviction costs are equal to the total expected loading costs.

At each phase  $i$ ,  $O_{off}$  must load pages in  $O_{f_i} \setminus H_{f_i}$  if they are requested. Thus, in the event  $\gamma_{i,p}$  it will incur a loading cost of  $w_p$ . As the total expected eviction costs are equal to total expected loading costs we get that,

$$\mathbb{E} \left[ \sum_{i \in [F]} \sum_{p \in O_{f_i} \setminus H_{f_i}} w_p \cdot \gamma_{i,p} \right] \leq \sum_{i \in [F]} Ev_{off}(H_{f_i}, f_i, f_{i+1}).$$

Due to Lemma 11 it holds that

$$\mathbb{E} \left[ \sum_{i \in [F]} \sum_{p \in O_{f_i} \setminus H_{f_i}} w_p \cdot \gamma_{i,p} \right] \leq \sum_{i \in [F]} \frac{2e-1}{e-1} O_{on}(O_{f_i}, f_i, f_{i+1}). \quad \blacktriangleleft$$

The following lemma combines the above results to produce a bound on the competitive ratio of SaS.

► **Lemma 13.** *Given an  $\alpha$ -competitive algorithm  $\mathcal{A}$  for DOP, the Split-and-Solve algorithm is  $(2\alpha + 1) \cdot \frac{4e-2}{e-1}$ -competitive.*

**Proof.** From Lemma 7 the cost of the Split-and-Solve algorithm is at most

$$\sum_{i \in [F]} (2\alpha + 1) \cdot O_{on}(H_{f_i}, f_i, f_{i+1}).$$

Combining with Corollary 10 and Lemma 12 which provides a bound on  $\sum_{i \in [F]} O_{on}(H_{f_i}, f_i, f_{i+1})$ , we can bound the competitive ratio of the Split-and-Save algorithm by  $(2\alpha + 1) \cdot \frac{4e-2}{e-1}$ . ◀

Theorem 2 follows immediately from Lemma 13.

---

## A Rounding the LP

We show how to discretize to multiples of  $1/k$  a solution to the LP. We use techniques from [2] and transform each  $x_{t,p}$  to a multiple of  $\frac{1}{8k}$ . First, We set  $b'_{t,p} := \min\{1, 2 \cdot b_{t,p}\}$ . Assume  $a_{t,p} \in [8k]$  denote  $\lceil \frac{8k \cdot b'_{t,p}}{8k} \rceil = \frac{a_{t,p}}{8k}$ . For every  $p \in P$ , we do the following iterative process for  $t = 1 \dots T$ :

1. If  $a_{t,p}$  is even, set  $y_{t,p} := \frac{a_{t,p}}{8k}$ .
2. Else, if  $y_{t-1,p} > \frac{a_{t,p}}{8k}$ , set  $y_{t,p} := \frac{a_{t,p}+1}{8k}$ .
3. Otherwise, set  $y_{t,p} := \frac{a_{t,p}-1}{8k}$ .

► **Lemma 14.** *The following statements hold:*

## 15:14 Distributional Online Weighted Paging with Limited Horizon

1.  $\forall t, p : \text{if } b_{t,p} = 0 \text{ then } y_{t,p} = 0.$
2.  $\forall t, p : \text{if } b_{t,p} = 1 \text{ then } y_{t,p} = 1.$
3.  $\forall t, p : y_{t,p} \leq 4 \cdot b_{t,p}.$
4.  $\forall p : \sum_{t \in [1, T]} |y_{t,p} - y_{t-1,p}| \leq 4 \cdot \sum_{t \in [1, T]} |b_{t,p} - b_{t-1,p}|.$
5.  $\forall t : \sum_{p \in P} y_{t,p} \geq n - k.$

**Proof.**

1.  $b_{t,p} = 0 \rightarrow a_{t,p} = 0 \rightarrow y_{t,p} = 0.$
2.  $b_{t,p} = 1 \rightarrow a_{t,p} = 8k \rightarrow y_{t,p} = 1.$
3. If  $b_{t,p} < \frac{1}{16k}$ , then  $a_{t,p} = 0$  implying  $y_{t,p} = 0$ . Otherwise,  $y_{t,p} \leq 2b_{t,p} + \frac{1}{8k} \leq 4b_{t,p}.$
4. For a page  $p \in P$ , we prove the claim by induction on  $T$ .

**Basis:** for  $t = 0$  the claim holds trivially.

**Inductive step:** Assume the claim holds for every  $\tau' < t$ . We assume w.l.o.g that  $a_{t,p} \leq a_{t-1,p}$ . We split to cases:

- a. If  $a_{t,p} = a_{t-1,p}$  then also  $y_{t,p} = y_{t-1,p}.$
- b. If  $a_{t,p} = a_{t-1,p} - 2$  then  $|b'_{t,p} - b'_{t-1,p}| \geq \frac{1}{8k}$ , in addition note that  $|y_{t,p} - y_{t-1,p}| = \frac{1}{4k}.$  Overall,  $|y_{t,p} - y_{t-1,p}| = \frac{1}{4k} \leq 2|b'_{t,p} - b'_{t-1,p}| \leq 4|b_{t,p} - b_{t-1,p}|.$
- c. If  $a_{t,p} \leq a_{t-1,p} - 3$  then  $|b'_{t,p} - b'_{t-1,p}| \geq \frac{1}{4k}$ , in addition  $|y_{t,p} - y_{t-1,p}| \leq |b'_{t,p} - b'_{t-1,p}| - \frac{1}{4k}.$  Overall,  $|y_{t,p} - y_{t-1,p}| \leq |b'_{t,p} - b'_{t-1,p}| - \frac{1}{4k} \leq 2|b'_{t,p} - b'_{t-1,p}| \leq 4|b_{t,p} - b_{t-1,p}|.$
- d. Else,  $a_{t,p} = a_{t-1,p} - 1$ . In case that  $a_{t,p}$  is odd we that  $y_{t,p} = y_{t-1,p}.$  Otherwise, let  $t'$  be the last time before  $t-1$  such that  $a_{t',p} \neq a_{t-1,p}.$  It holds that  $a_{t',p} \leq a_{t,p} - 2$  and we get, similar to Cases 4b and 4c,  $\sum_{i=t'+1}^t |y_{i,p} - y_{i-1,p}| = |y_{t,p} - y_{t',p}| \leq 2|b_{t,p} - b_{t',p}|.$

We show that we can find  $t' < t$  such that:

$\sum_{\tau \in [t', t]} |y_{\tau,p} - y_{\tau-1,p}| \leq 4 \cdot \sum_{\tau \in [t', t]} |b_{\tau,p} - b_{\tau-1,p}|.$  Finally, we apply the inductive assumption for  $t'.$

5. For time  $t$  we note  $A = \{p | b_{t,p} < 0.5\}.$  It holds for every  $p$  that if  $p \in A$  then  $y_{t,p} \geq 2 \cdot b_{t,p} - \frac{1}{8k}$ , else  $y_{t,p} = 1.$  Therefore, if  $|A| \leq k$  we are done. Else,  $\sum_{p \in P} y_{t,p} = \sum_{p \in A} y_{t,p} + \sum_{p \in P \setminus A} y_{t,p} \geq \sum_{p \in A} (2 \cdot b_{t,p} - \frac{1}{8k}) + |P| - |A| \geq 2(|A| - k) - \frac{|A|}{8k} + |P| - |A| = |P| + |A| - \frac{|A|}{8k} - 2k.$  Now, note that if  $k + 1 \leq |A| \leq 2k$ , then  $|A| \geq k + \frac{|A|}{8k}$  so  $|P| + |A| - \frac{|A|}{8k} - 2k \geq n - k.$  Else,  $|A| > 2k$  and  $|P| + |A| - \frac{|A|}{8k} - 2k \geq n - k. \quad \blacktriangleleft$

A similar process is required for discretizing the value of the  $x$  variables. For simplicity we assume there is an additional page  $z$  with weight 0 such that

$y_z = \max \left\{ 0, \sum_p y_{t,p} - (n + 1 - k) \right\}.$  For time  $t$  and pages  $p, q \neq z$  in  $P$ : if  $x_{t,p,q} \geq 0.5$  then  $v_{t,p,q} = 1 - y_{t,p}$ , else  $v_{t,p,q} = \min \{ 1 - y_{t,p}, x_{t,p,q} \}.$  For  $z$ ,  $v_{t,z,q} = \max \left\{ 0, y_{t,z} - \sum_p v_{t,p,q} \right\}.$

► **Lemma 15.** *The following statements hold:*

1.  $\forall t, p, q : v_{t,p,q} \leq 1 - y_{t,p}.$
2.  $\forall t, q : \sum_p v_{t,p,q} = y_{t,q}.$
3.  $\sum_{p,q,t \geq 1} (w_p + w_q) \cdot v_{t,p,q} \leq 2 \cdot \sum_{p,q,t \geq 1} (w_p + w_q) \cdot x_{t,p,q}.$

**Proof.**

1. For every page  $p \neq z$  the statement holds by definition. For  $z$ , since  $(1 - b_{t,q}) + \sum_p x_{t,p,q} \geq 1$ , we can view it as a rounding of a cache with (at least) one slot. The value of  $v_{t,p,z}$  is the empty space in the cache, which is at most the empty space in the fractional cache  $Y$ , i.e.  $1 - y_{t,z}.$
2. Holds immediately following definition of  $v_{t,z,q}.$

3. We can rewrite the sum:  $\sum_{p,q,t \geq 1} w_p \cdot v_{t,p,q} + \sum_{p,q,t \geq 1} w_q \cdot v_{t,p,q}$ . Since  $\sum_q v_{t,p,q} = y_{t,p}$  and  $y_{t,p} \leq 2b_{t,p}$ , implying  $\sum_{p,q,t \geq 1} w_p \cdot v_{t,p,q} \leq 2 \cdot \sum_{p,q,t \geq 1} w_p \cdot x_{t,p,q}$ . In addition, for every page  $q$ ,  $v_{t,p,q} \leq 2 \cdot x_{t,p,q}$ . ◀

We use Lemma 7.3 from [17] that provides a method for transforming distributions over pages into distributions over cache states. It is immediate from the proof of this lemma that if every distribution over the pages is a multiple of  $\frac{1}{L}$ , for some  $L \in \mathbb{N}$ , then the size of the distribution is polynomial in  $L$ ,  $n$  and  $T$ .

► **Definition 16.** For a page  $p$  and a cache  $C$ ,  $W(C, p) = 0$  if  $p \in C$ , otherwise  $W(C, p) = \min \{w_q | w \in C\}$ .

We state here a lemma that summarizes the desired construction and its properties.

► **Lemma 17.** Given a solution  $(B, X)$  to the LP, a collection of random integral cache states  $R(B, X) = \{R_1, \dots, R_T\}$  can be constructed in polynomial time (in  $n$ ,  $k$ , and  $T$ ) such that:

1.  $\forall t, p$ : if  $b_{t,p} = 0$ , then  $p \in R_t$ ; if  $b_{t,p} = 1$ , then  $p \notin R_t$ .
2.  $\forall t, p$ :  $\Pr[p \notin R_t] \leq 4 \cdot b_{t,p}$ .
3.  $\mathbb{E} \left[ \sum_{t \in [1, T], p \in R_t \Delta R_{t-1}} w_p \right] \leq 20 \cdot \sum_{t \in [1, T]} |b_{t,p} - b_{t-1,p}| \cdot w_p$ .
4.  $\forall t, p$ :  $\mathbb{E}[W(R(t), p)] \leq 8 \sum_{p,q,t \geq 1} w_p \cdot x_{t,p,q}$ .

We use the construction in the above lemma as a black box. When  $X$  is obvious from the context, we replace  $R(X)$  with  $R$ . Thus, we get the following algorithm:

■ **Algorithm 2** DOP Algorithm.

---

**Input:** Fractional solution  $B$  to LP (31).

- 1: Initialize: let  $R(B) = \{R_1, \dots, R_T\}$  (see Lemma 17).
  - 2: **for** time  $t$  and request  $\sigma_t$  **do**
  - 3:   Set  $C_t = R_t$ .
  - 4:   **if**  $\sigma_t \notin R_t$  **then**
  - 5:     Evicts the lightest page in  $R_t$  and loads  $\sigma_t$  instead.
  - 6:   Set  $C_t = R_t$ .
- 

► **Lemma 18.** Algorithm 2 is 60-competitive.

**Proof.** The expected cost of Step 3 is  $20 \cdot \sum_{p,t \geq 1} w_p \cdot |B_{t,p} - B_{t-1,p}|$ . In Step 5 the cost is 0 if  $\sigma_t \in R_t$  and  $w_{\sigma_t}$  otherwise. Therefore the expected cost of Step 5 at time  $t$  is  $\sum_{t,p} y_{t,p} \cdot w_p$ . Now let us assume for time  $t$  that  $\sigma_t \notin R_t$ . In this case, the cost of Step 6 is equal to  $\min \{w_q | q \in R_t\} = W(\sigma_t, C_t)$ . Therefore the expected cost of this step is  $\mathbb{E}[W(\sigma_t, R(t))]$ . From the construction of  $R_t$  in [17], this value is at most  $8 \cdot \sum_q w_q \cdot v_{t,\sigma_t,q}$ . In total, the expected cost of the algorithm is at most 20 times the optimal value of the linear program (31), hence at most 20 times the cost of the best non-adaptive algorithm. With [20, Theorem 1.3] we get that the expected cost is at most  $60 \cdot OPT$ . ◀

Note that all the cache configurations during the execution of the algorithm contain at most  $k$  pages. In addition, for every time  $t$ , the request  $\sigma_t$  is loaded in case it is not part of  $C_t$ .

# Weighted Matching in the Random-Order Streaming and Robust Communication Models

## Abstract

We study the maximum weight matching problem in the random-order semi-streaming model and in the robust communication model. Unlike many other sublinear models, in these two frameworks, there is a large gap between the guarantees of the best known algorithms for the unweighted and weighted versions of the problem.

In the random-order semi-streaming setting, the edges of an  $n$ -vertex graph arrive in a stream in a random order. The goal is to compute an approximate maximum weight matching with a single pass over the stream using  $O(n \text{ polylog } n)$  space. Our main result is a  $(2/3 - \epsilon)$ -approximation algorithm for maximum weight matching in random-order streams, using space  $O(n \log n \log R)$ , where  $R$  is the ratio between the heaviest and the lightest edge in the graph. Our result nearly matches the best known unweighted  $(2/3 + \epsilon_0)$ -approximation (where  $\epsilon_0 \sim 10^{-14}$  is a small constant) achieved by Assadi and Behnezhad [6], and significantly improves upon previous weighted results. Our techniques also extend to the related robust communication model, in which the edges of a graph are partitioned randomly between Alice and Bob. Alice sends a single message of size  $O(n \text{ polylog } n)$  to Bob, who must compute an approximate maximum weight matching. We achieve a  $(5/6 - \epsilon)$ -approximation using  $O(n \log n \log R)$  words of communication, matching the results of Azarmehr and Behnezhad [20] for unweighted graphs.

## 1 Introduction

The maximum matching problem is a fundamental problem in graph algorithms. In the unweighted version of the problem, we are interested in computing a maximum *cardinality* matching, i.e. to maximize the total number of edges in the matching. In the weighted version, we are interested in computing a maximum *weight* matching, i.e. to maximize the sum of the edge weights in the matching.

In this paper, we study matchings in the semi-streaming model. The semi-streaming model, originally introduced in [42], is motivated by the rise of massive graphs where the data is too large to be stored in memory, and has received extensive attention (see among others

[69, 38, 48, 78, 58, 35, 73, 47, 59]). In this model, the edges of a graph arrive sequentially as a stream. The algorithm typically makes a single pass over the stream using space  $O(n \text{ polylog } n)$ , and must output an approximate maximum matching at the end of the stream. If the graph is unweighted, the greedy algorithm trivially gives a  $1/2$ -approximation, which is the best known for adversarially ordered streams. On the hardness side, it is known that a  $0.59$ -approximation is not possible [59] (see also [48, 58]). Closing the gap between these upper and lower bounds is one of the major open problems in the graph streaming literature. There has also been a long line of work on the weighted problem [42, 69, 38, 78, 35, 73, 47], culminating in a  $(1/2 - \epsilon)$ -approximation using space  $O(n)$  [73, 47].

Recently, there has been a wide interest in the random-order version of this problem, in which the arrival order of the edges is chosen uniformly at random. This problem has been extensively studied in the unweighted setting [64, 63, 5, 45, 41, 22, 6, 18]. Notably, Bernstein [22] gave a  $2/3$ -approximation, and Assadi and Behnezhad [6] improved it to  $(2/3 + \epsilon_0)$  for a small constant  $\epsilon_0 \sim 10^{-14}$ .

Progress on the weighted version of the problem lags behind. Gamlath et al. [45] broke the barrier of  $1/2$  in weighted graphs by obtaining a  $(1/2 + \delta)$ -approximation for a small constant  $\delta \sim 10^{-17}$ . More recently, Huang and Sellier [54] gave a  $\frac{1}{2-1/(2W)}$ -approximation under the assumption that the weights take integral values in  $[W]$ . This leaves a considerable gap between the best known results for the unweighted and weighted versions of the problem. In contrast, in other sublinear contexts, such as adversarially ordered streams or the dynamic graph setting, the weighted/unweighted gap has largely been closed [23]. The challenge of closing the gap in random-order streams remains an open problem, and has been highlighted explicitly in [22] and [23].

In this paper, we give a  $(\frac{2}{3} - \epsilon)$ -approximation algorithm for the weighted setting. Our result almost matches the best known  $(\frac{2}{3} + \epsilon_0)$ -guarantee for the unweighted setting, and improves significantly upon the previous results for the weighted setting.

► **Theorem 1.1.** *Given any constant  $\epsilon > 0$ , there exists a deterministic single-pass streaming algorithm that with high probability computes a  $(\frac{2}{3} - \epsilon)$ -approximate maximum weight matching if the edges arrive in a uniformly random order. The space usage of the algorithm is  $O(n \log n \log R)$ , where  $R$  is the ratio between the heaviest and the lightest edge weight in the graph.*

We also consider the two-player communication complexity model [77], and in particular the one-way communication complexity of matching, which was first studied in [48]. Here, the edge-set is partitioned between two parties Alice and Bob. Alice sends a single message to Bob, who must output an approximate maximum matching. Typically, we are interested in protocols with communication complexity  $O(n \text{ polylog } n)$ .

If the edges are partitioned adversarially between Alice and Bob, the right answer turns out to be  $2/3$ . A  $2/3$ -approximation can be achieved using  $O(n)$  communication for both bipartite unweighted [48], general unweighted [9] and general weighted [23] graphs. Going beyond a  $2/3$ -approximation requires  $n^{1+1/(\log \log n)} \gg n \text{ polylog } n$  communication even for unweighted bipartite graphs [48].

If instead the edges are partitioned randomly between the two parties, the answer is less clear. Recently, Azarmehr and Behnezhad [20] gave a  $5/6$ -approximation algorithm for unweighted graphs, improving upon a previous result of Assadi and Behnezhad [7]. To the best of our knowledge, prior to our work there were no results for weighted graphs (besides the  $2/3$ -approximation implied by adversarial protocols). We match the unweighted guarantees of Azarmehr and Behnezhad [20], thus closing weighted/unweighted gap in the robust communication complexity model.

► **Theorem 1.2.** *Given any constant  $\epsilon > 0$ , there exists a protocol that with high probability computes a  $(\frac{5}{6} - \epsilon)$ -approximate maximum weight matching in the two-party robust communication model using  $O(n \log n \log R)$  words of communication, where  $R$  is the ratio between the heaviest and the lightest edge weight in the graph.*

More generally, we match the results of Azarmehr and Behnezhad [20] for unweighted  $k$ -party robust communication, thus closing the unweighted/weighted gap also in this model.

► **Theorem 1.3.** *Given any  $k \geq 2$  and any constant  $\epsilon > 0$ , there exists a protocol that with high probability computes a  $(\frac{2}{3} + \frac{1}{3k} - \epsilon)$ -approximate maximum weight matching in the  $k$ -party one-way robust communication model using  $O(n \log n \log R)$  words of communication, where  $R$  is the ratio between the heaviest and the lightest edge weight in the graph.*

## 1.1 Related Work

The maximum matching problem is one of the most studied problems in the streaming setting, with numerous lines of work. This includes among others single-pass algorithms [42, 69, 38, 48, 78, 73, 47, 58, 35, 59, 8], multi-pass algorithms using 2 or 3 passes [64, 40, 56, 63, 65, 43, 3, 67, 66], and  $(1 - \epsilon)$ -approximation using a higher number of passes [69, 37, 1, 53, 2, 75, 45, 14, 10, 44, 18, 55, 4]. Garg et al. considered matching in a robust random-order streaming model with adversarial noise [46]. There are many results on dynamic streams, where edges can be deleted [33, 62, 12, 32, 11, 36, 17]. A different line of work considers estimating matching size, either in random-order streams [60, 28, 72, 61, 19] or in adversarially ordered streams [28, 70, 11, 34, 39, 71, 27, 13, 15]. Finally, there have also been several works on exact matching [42, 32, 53, 16, 30, 10].

## 2 Technical Overview

In this paper, we are interested in the random-order streaming model. The maximum cardinality matching problem has gained significant attention within this framework [64, 63, 45, 5, 41, 22, 6]. Bernstein [22] gave a  $2/3$ -approximation algorithm by adapting the “matching sparsifier” Edge-Degree Constrained Subgraph (EDCS) to the streaming context. Subsequent work by Assadi and Behnezhad [6] improved upon this, achieving a  $(2/3 + \epsilon_0)$ -approximation by simultaneously running Bernstein’s algorithm while identifying short augmenting paths. One of the motivations for studying the random-order setting, is that real-world data is rarely ordered adversarially. Rather, in most practical applications, it is reasonable to assume that the data is drawn from some distribution. However, assuming uniform randomness is often too strong of an assumption, since data correlations are prevalent in many real-world settings. This raises the question:

*How robust are random-order streaming algorithms to correlations in the arrival order?*

The robustness of random-order streaming algorithms to various types of adversarial distortions has already been studied previously, among others in the context of maximum matching and submodular maximization [46], rank selection [49, 50, 51], clustering problems [68] and component collection and counting [31]. In this paper, we focus on matchings. Our first contribution, is showing that existing algorithms for unweighted matching in random-order streams are in fact robust to correlations in the arrival order.

*Bernstein’s  $(\frac{2}{3} - \epsilon)$ -approximation algorithm is resilient to (limited) adversarial correlations in the arrival order.*

Surprisingly, this immediately gives a reduction from weighted matching in random-order streams.

In *adversarially* ordered streams, Bernstein, Dudeja and Langley [23] gave a reduction from maximum weight matching to maximum cardinality matching. Progress in *random-order streams* has been comparatively limited. Gamlath et al. [45] achieved a  $(1/2 + \delta)$ -approximation, where  $\delta \sim 10^{-17}$  is a small constant. More recently, Huang and Sellier [54] gave a  $\frac{1}{2-1/(2W)}$ -approximation under the assumption that the weights take integral values in  $[W]$ , improving upon the result of Gamlath et al. [45] for small weights. They generalized the definition of EDCS to weighted graphs, which enabled them to adapt Bernstein's algorithm [22] to weighted graphs. However, their generalized notion of EDCS has weaker guarantees compared to the unweighted version, resulting in a significant loss in the approximation ratio.

Our second contribution is to nearly close the gap between weighted and unweighted maximum matching in random-order streams. We show that the reduction of Bernstein, Dudeja and Langley can be applied to random-order streaming algorithms which are resilient to specific correlations in the arrival order. This, together with the fact that Bernstein's algorithm [22] is robust to the appropriate correlations, gives a  $2/3$ -approximation algorithm for weighted bipartite graphs. We are also able to extend the guarantees to non-bipartite graphs.

## 2.1 Reduction in Adversarial Streams

First, we review the reduction of Bernstein, Dudeja and Langley [23] for adversarial streams. It is based on a technique called graph unfolding by Kao, Lam, Sung and Ting [57].

► **Definition 2.1** (Graph Unfolding [57]). *Let  $G = (V, E, w)$  be a graph with non-negative integral edge weights. The unfolded graph  $\phi(G)$  is an unweighted graph created as follows. For each vertex  $u \in V$ , let  $W_u = \max_{e \ni u} w_e$  be the maximum edge weight incident on  $u$ . There are  $W_u$  copies of  $u$  in  $\phi(G)$ , denoted by  $u^1, \dots, u^{W_u}$ . For each edge  $e = (u, v)$  in  $G$ , there are  $w_e$  edges  $\{(u^i, v^{w_e - i + 1})\}_{i \in [w_e]}$  in  $\phi(G)$ . See Figure 1 for an illustration.*

■ **Figure 1** An example of a weighted graph  $G$  and its unfolding  $\phi(G)$ .

One can also do a reverse operation of unfolding to bring a subgraph back to  $G$ .

► **Definition 2.2** (Refolding [23]). *Let  $G = (V, E)$  be a weighted graph and let  $H \subseteq \phi(G)$ . The refolded graph  $\mathcal{R}(H)$  has vertex set  $V$  and edge set  $E(\mathcal{R}(H)) := \{e = (u, v) \in G : (u^i, v^{w_e - i + 1}) \in H \text{ for some } i \in [w_e]\}$ . See Figure 2 for an illustration.*

Figure 1 illustrates the unfolding operation and Figure 2 illustrates the refolding operation. The key property of refolding is that it preserves the matching size in bipartite graphs.

► **Lemma 2.3** (Refolding preserves matching size in bipartite graphs [23]). *Let  $G$  be a weighted bipartite graph, and let  $H \subseteq \phi(G)$  be a subgraph of its unfolding. Then  $\mu_w(\mathcal{R}(H)) \geq \mu(H)$ .*

■ **Figure 2** An example of a subgraph  $H \subseteq \phi(G)$  and its refolding  $\mathcal{R}(H) \subseteq G$ . In this example,  $H = \{(u^1, v^2)\}$ . Then  $\mathcal{R}(H) = \{(u, v)\}$ .

This leads to a reduction from maximum weight bipartite matching to maximum cardinality bipartite matching in *adversarially ordered streams*: Upon arrival of each weighted edge  $e \in G$ , unfold  $e$  and pass the corresponding unweighted edges  $\phi(e)$  into an unweighted streaming algorithm. At the end of the stream we obtain an unweighted matching in  $\phi(G)$ , which we can refold to obtain a weighted matching in  $G$ .

In *random-order streams*, this reduction breaks for the following reason: For each weighted edge  $e \in G$ , the unweighted edges  $\phi(e)$  will necessarily arrive together. This introduces correlations in the arrival order of the edges, so the guarantees of random-order streaming algorithms do not apply. To address this, we consider a new streaming model, the *b-batch random-order stream model*, which is similar to the hidden-batch model introduced in [31]. This model allows us to capture the edge-correlations that arise from graph unfolding.

► **Definition 2.4** (*b-batch random-order stream model*). *In the b-batch random-order stream model the edge set of the input graph  $G = (V, E)$  is presented as follows: An adversary partitions the edge set  $E$  into batches  $\mathcal{B} = \{B_1, \dots, B_q\}$  with  $|B_i| \leq b$  for all  $i$ . The arrival order of the batches  $(B_{i_1}, \dots, B_{i_q})$  is then chosen uniformly at random among all the permutations of  $\mathcal{B}$ . The edges in each batch arrive simultaneously.*

Graph unfolding gives a reduction from weighted bipartite random-order streams to unweighted bipartite *b-batch random-order streams*. Each batch corresponds to one weighted edge, so given a weighted graph  $G$ , we can simply run a *b-batch random-order stream* algorithm on  $\phi(G)$  with batches  $\mathcal{B} = \{\phi(e) : e \in G\}$ .

## 2.2 Bernstein's Algorithm for Unweighted Random-Order Streams

We now review Bernstein's algorithm for unweighted random-order streams [22]. The algorithm proceeds in two Phases. Let  $\beta = O(\text{poly}(\epsilon^{-1}))$  be a parameter. Phase 1 constructs a subgraph  $H$  such that for all  $(u, v) \in H$ ,

$$\deg_H(u) + \deg_H(v) \leq \beta. \quad (1)$$

Given a subgraph  $H$ , we will say that an edge  $(u, v) \in G$  is *underfull* if  $\deg_H(u) + \deg_H(v) \leq \beta - 2$ , otherwise say that  $(u, v)$  is non-underfull.

The algorithm constructs  $H$  by adding underfull edges in a greedy manner, and then removing any edges that violate Equation 1. Phase 1 terminates when  $\approx \text{poly}(\epsilon) \frac{m}{n}$  non-underfull edges arrive in a row, and the algorithm then moves on to Phase 2. Bernstein [22] showed that it is only possible to make at most  $n\beta^2$  modifications to  $H$ . Since Phase 1 terminates when we see  $\approx \text{poly}(\epsilon) \frac{m}{n}$  edges in a row without modifying  $H$ , the Phase must terminate within the first  $\approx n\beta^2 \cdot \text{poly}(\epsilon) \frac{m}{n} \approx \epsilon m$  edges. This argument also holds in the *b-batch random-order stream model*.

## 16:6 Weighted Matching in Random-Order Streams

Then, in Phase 2, the algorithm simply collects all underfull edges into a separate set  $U$  (without modifying the graph  $H$ ). Let  $G_{late}$  denote the edges that arrive in Phase 2. Bernstein [22] proved the following structural result about  $H \cup U$ , which holds regardless of the assumptions on the arrival order:

$$\mu(H \cup U) \geq \left(\frac{2}{3} - \epsilon\right) \mu(G_{late}). \quad (2)$$

Since Phase 2 contains at least a  $(1 - \epsilon)$  fraction of the edges, and since the stream is uniformly at random, it follows from the Chernoff bound that  $\mu(G_{late}) \geq (1 - 2\epsilon)\mu(G)$ . Consequently, by Equation 2, it holds that

$$\mu(H \cup U) \geq \left(\frac{2}{3} - 3\epsilon\right) \mu(G).$$

For the space analysis, observe that  $H$  contains at most  $n\beta = O(n)$  edges. Let us now consider  $U$ . Recall that  $U$  is the set of all underfull edges that arrive after the termination of Phase 1, and that Phase 1 terminates when we see  $\approx \frac{m}{n}$  non-underfull edges in a row. So the only way for  $U$  to become too large, is if we draw  $\approx \frac{m}{n}$  non-underfull edges in a row when there are more than  $C \cdot n \log n$  underfull edges left in the stream, for some constant  $C$ . The probability of this event can be upper-bounded by

$$\left(1 - \frac{C \cdot n \log n}{m}\right)^{m/n} \leq n^{-C},$$

so with high probability, the algorithm stores at most  $O(n \log n)$  edges. Note that the space analysis breaks down in the  $b$ -batch random-order stream model, due to the correlated arrival orders.

### 2.3 Applying the Algorithm to Batch Arrivals

We now sketch why Bernstein's algorithm can be adapted to work under batch arrivals. Let  $b$  denote the upper-bound on the batch-size, and let  $q$  denote the total number of batches in the stream. Recall that in the reduction from weighted random-order streams,  $b$  corresponds to the maximum weight in the graph and  $q$  corresponds to the number of edges in the weighted graph. We will now describe how to obtain an algorithm with a polynomial space dependence on  $b$ . We will later discuss how to remove this dependence in the reduction from weighted random-order streams.

We will say that a batch is *underfull* if it contains at least one underfull edge. Otherwise, if it does not contain any underfull edges, say that it is non-underfull.

We terminate Phase 1 when  $\approx \text{poly}(\epsilon) \frac{q}{bn}$  non-underfull batches arrive in a row. This ensures that Phase 1 terminates within the first  $\approx n\beta^2 \cdot \text{poly}(\epsilon) \frac{q}{bn} \approx \frac{\epsilon}{b} q$  batches. Since each batch contains at most  $b$  edges, and since the arrival order of the batches is uniformly at random, it follows from Chernoff bounds that

$$\mu(G_{late}) \geq (1 - 2\epsilon)\mu(G).$$

Combining with Equation 2 we obtain

$$\mu(H \cup U) \geq \left(\frac{2}{3} - 3\epsilon\right) \mu(G).$$

The only way for the space usage to become too large, is if  $\approx \text{poly}(\epsilon) \frac{q}{b \cdot n}$  non-underfull batches arrive in a row when there are more than  $C \cdot n \log n \text{poly}(\frac{b}{\epsilon})$  underfull batches left in the stream, for some large constant  $C$ . The probability of this event can be upper-bounded by

$$\left(1 - C \cdot \frac{n \log n}{q} \text{poly}\left(\frac{b}{\epsilon}\right)\right)^{\text{poly}(\epsilon/b)q/n} \leq n^{-C},$$

so with high probability, the algorithm stores at most  $O(n \log n \text{poly}(b))$  edges.

In our reduction, the parameter  $b$  corresponds to the maximum edge weight  $W$  in the graph. This means that we would incur a polynomial dependence on  $W$  in the space usage. However, a reduction due to Gupta and Peng [52] allows us to offset this space dependence. Gupta and Peng [52] devised a scheme for bucketing together edges according to their weight, which gives a reduction from general (possibly non-integral) weights, to integral bounded weights. Combining with this reduction, our algorithm uses space  $O(n \log n \log R)$ , where  $R$  is the ratio between the heaviest and the lightest edge in the graph, and it can handle any (possibly non-integral) edge weights. In particular, the space usage is  $O(n \text{polylog } n)$  as long as the weights are polynomial in  $n$ .

### 2.4 Non-bipartite graphs

In general, the reduction of Bernstein, Dudeja and Langley only holds for bipartite graphs. For non-bipartite graphs, it is no longer true that refolding preserves the matching size, since refolding a matching in  $\phi(G)$  can incur an additional  $2/3$  loss in the approximation ratio. Indeed, consider for example a weighted triangle with all edges of weight 2 (see Figure 3).

■ **Figure 3** Refolding does not in general preserve matching size in non-bipartite graphs. Consider for example the blue subgraph  $H = \{(x^1, z^2), (z^1, y^2), (y^1, x^2)\} \subseteq \phi(G)$  shown in the diagram. Then  $\mu(H) = 3$ , but  $\mu_w(\mathcal{R}(H)) = 2$ .

We prove that the subgraph  $H \cup U$  computed by Bernstein’s algorithm still satisfies  $\mu_w(\mathcal{R}(H \cup U)) \geq (2/3 - \epsilon)\mu_w(G)$ , even for non-bipartite graphs. This allows us to apply the unfolding reduction without any loss in the approximation ratio. We achieve this by reducing to the bipartite case: We show that for every weighted graph  $G$ , there exists a bipartite subgraph  $\tilde{G} \subseteq G$  such that  $\mu((H \cup U) \cap \phi(\tilde{G})) \geq (2/3 - \epsilon)\mu_w(G)$ . We can then apply Lemma 2.3 to the bipartite graph  $\tilde{G}$  to get the result.

In order to “bipartify” the graph, we use the following lemma from [23], which says that there exists a bipartite subgraph in which the degrees to  $H$  concentrate well (See Lemma 4.10 for the formal statement).

► **Lemma 2.5** (Informal version of Lemma 5.7 in [23]). *Let  $G$  be a weighted graph and let  $M^*$  be a maximum weight matching in  $G$ . Suppose that  $H \subseteq \phi(G)$  satisfies Equation 1. Then there exists a bipartite subgraph  $\tilde{G} \subseteq G$  such that  $\tilde{G}$  contains  $M^*$ , and, setting  $\tilde{H} := H \cap \tilde{G}$ , it holds that*

$$\deg_{\tilde{H}}(v) \approx \frac{\deg_H(v)}{2} \quad \forall v \in V.$$

Using this, we will show that  $(H \cup U) \cap \phi(\tilde{G})$  contains an EDCS, and therefore also contains a large matching.

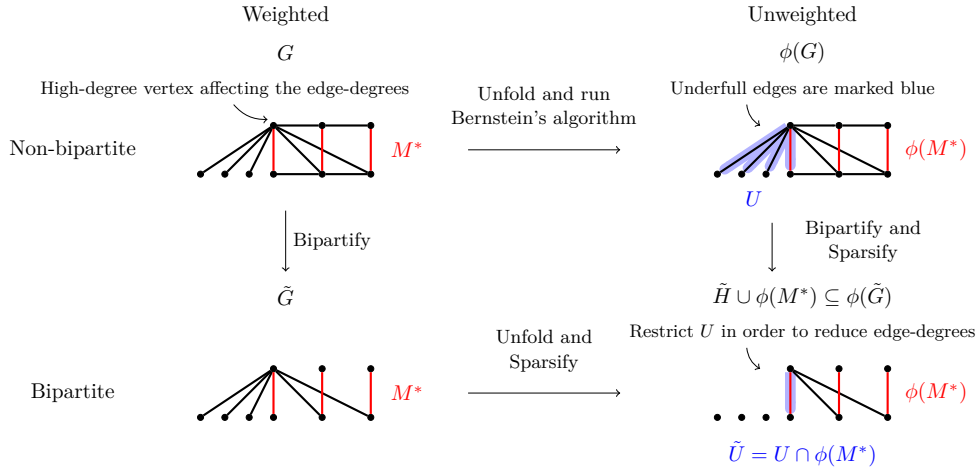

► **Definition 2.6** (EDCS [24]). *Let  $G = (V, E)$  be an unweighted graph, and  $H = (V, E_H)$  a subgraph of  $G$ . Given parameters  $\beta \geq 2$  and  $\lambda < 1$ , we say that  $H$  is a  $(\beta, \lambda)$ -EDCS of  $G$  if  $H$  satisfies the following properties:*

- (Property P1:) *For all edges  $(u, v) \in H$ , it holds that  $\deg_H(u) + \deg_H(v) \leq \beta$ .*
- (Property P2:) *For all edges  $(u, v) \in G \setminus H$ , it holds that  $\deg_H(u) + \deg_H(v) \geq \beta(1 - \lambda)$ .*

The crucial property of EDCS is that it contains a  $2/3$ -approximate maximum cardinality matching. This was first proved in [24] for bipartite graphs and in [25] for general graphs. See also Lemma 3.2 in [9] for a simpler proof with improved parameters.

► **Theorem 2.7** (EDCS contain a  $2/3$ -approximate matching [9]). *Let  $G$  be an unweighted graph and let  $\epsilon < 1/2$  be a parameter. Let  $\lambda, \beta$  be parameters with  $\lambda \leq \frac{\epsilon}{64}, \beta \geq 8\lambda^{-2} \log(1/\lambda)$ . Then, for any  $(\beta, \lambda)$ -EDCS  $H$  of  $G$ , we have that  $\mu(H) \geq (\frac{2}{3} - \epsilon)\mu(G)$ .*

Now consider the weighted input graph  $G$ . Fix a maximum weight matching  $M^*$  in  $G$  and let  $H$  be the graph computed by Phase 1 of Bernstein’s algorithm on input  $\phi(G)$ . Let  $\tilde{G} \subseteq G$  be the bipartite subgraph from Lemma 2.5. Ideally, we would like to show that  $(H \cup U) \cap \phi(\tilde{G})$  is an EDCS. However, this is not true in general, since the degrees to  $U$  can be arbitrarily large (consider for example the case when  $U$  is a star, see Figure 4 for an illustration), so  $\deg_{(H \cup U) \cap \phi(\tilde{G})}$  cannot be upper-bounded by a constant. Instead, we will sparsify  $U$ , so that its contribution to the degrees becomes insignificant. Let  $\tilde{H} = H \cap \phi(\tilde{G})$  and let  $\tilde{U} = U \cap \phi(M^*)$  (see Figure 4). This idea is similar to Bernstein’s original analysis [22], except that now we perform this sparsification in the unfolded and “bipartified” graph.

■ **Figure 4** Illustration of the reduction to the bipartite case. We show that  $\tilde{H} \cup \tilde{U}$  contains a matching of size at least  $(\frac{2}{3} - \epsilon)\mu_w(G)$ . Since  $\tilde{G}$  is bipartite, we can refold  $\tilde{H} \cup \tilde{U}$  without reducing the matching size.

Now  $\tilde{U}$  is a matching, so for all  $v \in V$ , we have  $\deg_{\tilde{H} \cup \tilde{U}}(v) \in \{\deg_{\tilde{H}}(v), \deg_{\tilde{H}}(v) + 1\}$ . So

$$\deg_{\tilde{H} \cup \tilde{U}}(v) \approx \deg_{\tilde{H}}(v) \approx \frac{1}{2} \deg_H(v).$$

In particular,

$$\forall (u, v) \in \tilde{H} \cup \tilde{U}, \quad \deg_{\tilde{H} \cup \tilde{U}}(u) + \deg_{\tilde{H} \cup \tilde{U}}(v) \approx \frac{1}{2} \deg_H(u) + \frac{1}{2} \deg_H(v) \leq \frac{\beta}{2},$$

and

$$\forall(u, v) \in \phi(M^*) \setminus (\tilde{H} \cup \tilde{U}), \quad \deg_{\tilde{H} \cup \tilde{U}}(u) + \deg_{\tilde{H} \cup \tilde{U}}(v) \approx \frac{1}{2} \deg_H(u) + \frac{1}{2} \deg_H(v) \geq \frac{\beta}{2} - 1.$$

Setting  $X = \tilde{H} \cup \tilde{U}$ ,  $\beta' \approx \frac{\beta}{2}$ , and  $\lambda'$  to be a sufficiently small constant, we can now apply Theorem 2.7 to the graph  $\tilde{H} \cup \phi(M^*)$ , and obtain

$$\mu(\tilde{H} \cup \tilde{U}) \geq (2/3 - \epsilon) \mu(\tilde{H} \cup \phi(M^*)) \geq (2/3 - \epsilon) \mu(\phi(M^*)).$$

Since  $\tilde{H} \cup \tilde{U} \subseteq \phi(\tilde{G})$  and since  $\tilde{G}$  is bipartite, we can apply Lemma 2.3 to get the required result

$$\mu_w(\mathcal{R}(H \cup U)) \geq \mu_w(\mathcal{R}(\tilde{H} \cup \tilde{U})) = \mu(\tilde{H} \cup \tilde{U}) \geq (2/3 - \epsilon) \mu(\phi(M^*)) = (2/3 - \epsilon) \mu_w(G).$$

In the rest of the paper, we will present the full analysis. In Section 4, we formally present the algorithm and analysis for random-order streams. In Section 5, we prove Theorem 1.2 and Theorem 1.3.

### 3 Notation and Preliminaries

Given a graph  $G = (V, E)$ , we will use  $n := |V|$  to denote the number of vertices and  $m := |E|$  to denote the number of edges in  $G$ . If  $G$  is weighted, then we will use  $w : E \rightarrow \mathbb{R}^+$  to denote the edge weights, and  $R := \max_{e \in E} w_e / \min_{e \in E} w_e$  to denote the ratio between the heaviest and the lightest edge in  $G$ . We use  $\mu(G)$  to denote the size of the maximum cardinality matching in  $G$ , and  $\mu_w(G)$  to denote the weight of the maximum weight matching in  $G$ .

Given  $\epsilon > 0$ , define  $\gamma_\epsilon := (4/\epsilon)^{\lceil 1/\epsilon \rceil}$ , a large constant which will be incurred in the space usage of our algorithms (instead of a dependence on the maximum weight of the graph). Note that for any fixed  $\epsilon$ , we have  $\gamma_\epsilon = O(1)$ .

#### 3.1 Models

**Random-order streams** In the random-order stream model, the weighted edges of the input graph arrive one-by-one in an order chosen uniformly at random from all possible orderings.

The algorithm makes a single pass over the stream and must output an approximate maximum weight matching at the end of the stream.

**Robust communication model** In the  $k$ -party one-way robust communication model, each weighted edge of the input graph is assigned independently and uniformly at random to one of the  $k$  parties. The  $i$ th party is supplied with its assigned edges and a message  $m_{i-1}$  from the  $(i-1)$ st party, and must send a message  $m_i$  to the  $(i+1)$ st party. The  $k$ th party must output a valid weighted matching of the input graph. The communication complexity of a protocol is defined to be  $\max_{1 \leq i \leq k} |m_i|$ , where  $|m_i|$  is the number of words in message  $m_i$ .

In the case of  $k = 2$ , we refer to the first party as Alice and to the second party as Bob.

#### 3.2 Graph Unfolding

In addition to the facts already stated in Section 2, we will need the following:

► **Theorem 3.1** (Unfolding preserves matching size in bipartite graphs [57]). *If  $G$  is a weighted bipartite graph, then  $\mu_w(G) = \mu(\phi(G))$ .*

► **Definition 3.2** (Refolding approximate [23]). *Let  $G$  be a weighted graph. A subgraph  $H \subseteq \phi(G)$  is  $\alpha$ -refolding-approximate if  $\mu_w(\mathcal{R}(H)) \geq \alpha \cdot \mu_w(G)$ .*

### 3.3 EDCS

We will use the following guarantee which holds for a relaxed notion of EDCS.

► **Definition 3.3** (Bounded edge-degree [22]). *We say that a graph  $H$  has bounded edge-degree  $\beta$  if for every edge  $(u, v) \in H$ , it holds that  $\deg_H(u) + \deg_H(v) \leq \beta$ .*

► **Definition 3.4** (Underfull edge [22]). *Let  $G$  be any unweighted graph, and let  $H$  be a subgraph of  $G$  with bounded edge-degree  $\beta$ . For any parameter  $\lambda < 1$ , we say that an edge  $(u, v) \in G \setminus H$  is  $(G, H, \beta, \lambda)$ -underfull if  $\deg_H(u) + \deg_H(v) < \beta(1 - \lambda)$ .*

► **Lemma 3.5** (Relaxed EDCS contain a 2/3-approximate matching [22]). *Let  $\epsilon < \frac{1}{2}$  be a parameter, and let  $\lambda, \beta$  be parameters with  $\lambda \leq \frac{\epsilon}{128}$ ,  $\beta \geq 16\lambda^{-2} \log(1/\lambda)$ . Consider any unweighted graph  $G$  and any subgraph  $H$  with bounded edge-degree  $\beta$ . Let  $U$  contain all edges in  $G \setminus H$  that are  $(G, H, \beta, \lambda)$ -underfull. Then  $\mu(H \cup U) \geq (2/3 - \epsilon)\mu(G)$ .*

### 3.4 Concentration Inequality

We will use the Chernoff bound for negatively associated random variables (see e.g. the primer in [76]).

► **Theorem 3.6.** *Let  $X_1, \dots, X_n$  be negatively associated random variables taking values in  $[0, 1]$ . Let  $X := \sum X_i$  and let  $\mu := \mathbb{E}[X]$ . Then, for any  $0 < \delta < 1$ , we have*

$$\Pr[X \leq \mu(1 - \delta)] \leq \exp\left(\frac{-\mu\delta^2}{2}\right).$$

## 4 2/3-Approximation in Random-Order Streams

In this section we prove Theorem 1.1. In Section 4.1, we formally describe the reduction from weighted random-order streams to unweighted  $b$ -batch random-order streams, and we prove its correctness. In Section 4.2, we show that Bernstein's 2/3-approximation algorithm [22] for random-order streams still works under batch-arrivals. Finally, in Section 4.3, we show that the obtained weighted random-order streaming algorithm still works for non-bipartite graphs, and we complete the proof of Theorem 1.1.

### 4.1 Reduction to Unweighted $b$ -batch Random-Order Streams

Gupta and Peng [52] gave a reduction which allows us to assume that the edge weights are integral and bounded above by a large constant. They originally proved the reduction for the dynamic graph model, however it also applies to the streaming and one-way communication models (See Theorem 6.1 and Theorem 6.2 in [23]).

► **Theorem 4.1** (Reduction to bounded integral weights [52, 23]). *If there is a random-order streaming algorithm  $\mathcal{A}$  to compute an  $\alpha$ -approximate maximum weight matching in graphs with edge weights in  $[W]$  and using space  $S(n, m, W, \alpha)$ , then there exists a random-order streaming algorithm  $\mathcal{A}'$  to compute a  $(1 - \epsilon)\alpha$ -approximate maximum weight matching with weights in graph with weights  $\mathbb{R}^+$  using space  $O(S(n, m, \gamma_\epsilon, \alpha) \log R)$ .*

*Similarly, if there is a one-way robust communication complexity protocol to compute an  $\alpha$ -approximate maximum weight matching for graphs with edge weights in  $[W]$  using  $C(n, m, W, \alpha)$  words of communication, then there exists a protocol to compute a  $(1 - \epsilon)\alpha$ -approximate maximum weight matching in graphs with weights in  $\mathbb{R}^+$  using  $O(C(n, m, \gamma_\epsilon, \alpha) \log R)$  words of communication.*

We would like to use the unfolding technique to reduce to the unweighted problem. As Bernstein, Dudeja and Langley [23] showed, in *adversarially ordered* streams, unfolding immediately gives a reduction for bipartite graphs: Whenever a weighted edge  $e \in G$  arrives, we can unfold it and pass the unweighted edges  $\phi(e)$  sequentially into an unweighted streaming algorithm while tracking the updates in the weighted stream. In *random-order* streams, there is a subtle issue with this approach. If the edges arrive uniformly at random in  $G$ , then the arrival order in  $\phi(G)$  will not be uniformly at random, but rather there will be batches of edges which necessarily arrive together. To overcome this issue, we consider the  $b$ -batch random-order stream model, restated below.

► **Definition 2.4** (*b*-batch random-order stream model). *In the  $b$ -batch random-order stream model the edge set of the input graph  $G = (V, E)$  is presented as follows: An adversary partitions the edge set  $E$  into batches  $\mathcal{B} = \{B_1, \dots, B_q\}$  with  $|B_i| \leq b$  for all  $i$ . The arrival order of the batches  $(B_{i_1}, \dots, B_{i_q})$  is then chosen uniformly at random among all the permutations of  $\mathcal{B}$ . The edges in each batch arrive simultaneously.*

Graph unfolding naturally gives a reduction from weighted random-order streams to unweighted  $b$ -batch random-order streams.

► **Theorem 4.2** (Reduction to the  $b$ -batch model). *If there exists an algorithm  $\mathcal{A}_B$  for the unweighted  $b$ -batch random-order stream model that computes an  $\alpha$ -approximate maximum cardinality matching in bipartite graphs using space  $S(n, m, b, \alpha)$ , then there exists an algorithm  $\mathcal{A}_w$  for weighted random-order streams (with weights in  $\mathbb{R}^+$ ) that computes a  $(1 - \epsilon)\alpha$ -approximate maximum weight matching in bipartite graphs using space  $O(S(n\gamma_\epsilon, m\gamma_\epsilon, \gamma_\epsilon, \alpha) \log R)$ .*

*Moreover, suppose that  $\mathcal{A}_B$  computes an  $\alpha$ -refolding approximate subgraph whenever the input graph is of the form  $\phi(G)$  for some weighted graph  $G$  with batches  $\mathcal{B} = \{\phi(e) : e \in G\}$ . Then the guarantees of  $\mathcal{A}_w$  also hold for non-bipartite graphs.*

**Proof.** Let  $\mathcal{A}_B$  be the unweighted  $b$ -batch random-order streaming algorithm using space  $S(n, m, b, \alpha)$ . By Theorem 4.1, it suffices to construct an algorithm  $\mathcal{A}_W$  that computes an  $\alpha$ -approximate maximum weight matching using space  $S(Wn, Wm, W, \alpha)$  when the edge weights are in  $[W]$ . We can obtain the required algorithm  $\mathcal{A}_W$  as follows:

Whenever an edge  $e$  arrives in the weighted stream, define a batch  $B_e := \phi(e)$  consisting of the unfolded edges of  $e$ . Feed the batch  $B_e$  as an update to the batch algorithm  $\mathcal{A}_B$ . In other words,  $\mathcal{A}_B$  is applied to the graph  $\phi(G)$  with batches  $\mathcal{B} = \{\phi(e) : e \in G\}$ . At the end of the stream,  $\mathcal{A}_B$  outputs an  $\alpha$ -approximate maximum cardinality matching  $M$  of  $\phi(G)$ . The algorithm  $\mathcal{A}_W$  outputs the maximum weight matching in  $\mathcal{R}(M)$  (which can easily be computed from  $M$ ). We have

$$\begin{aligned} \mu_w(\mathcal{R}(M)) &\geq \mu(M), && \text{by Lemma 2.3} \\ &\geq \alpha \cdot \mu(\phi(G)), && \text{by the assumption on } M \\ &= \alpha \cdot \mu_w(G), && \text{by Theorem 3.1} \end{aligned}$$

so  $\mathcal{A}_W$  outputs an  $\alpha$ -approximate maximum weight matching. Since the graph  $\phi(G)$  has at most  $Wn$  vertices and  $Wm$  edges, the space usage of  $\mathcal{A}_W$  is at most  $S(Wn, Wm, W, \alpha)$ , as required.

## 16:12 Weighted Matching in Random-Order Streams

For the “Moreover”-part, suppose that  $\mathcal{A}_B$  computes an  $\alpha$ -refolding approximate subgraph  $H$ . Define  $\mathcal{A}_W$  as before, except that now  $\mathcal{A}_W$  should output the maximum weight matching in  $\mathcal{R}(H)$ . Then

$$\mu_w(\mathcal{R}(H)) \geq \alpha \cdot \mu_w(G), \quad \text{by Definition 3.2,}$$

so the approximation ratio achieved by  $\mathcal{A}_W$  is still  $\alpha$ , even for non-bipartite graphs, as required.  $\blacktriangleleft$

► **Remark 4.3.** The argument can easily be adapted to the robust communication model. Consider a  $b$ -batch robust communication model, in which an adversary partitions the edges into batches of size at most  $b$ , and each batch gets assigned uniformly at random to each of the parties. Then any protocol for the  $b$ -batch robust communication model gives a protocol for the weighted robust communication model.

### 4.2 2/3-Approximation in $b$ -batch Random-Order Streams

In this section, we prove the following proposition.

► **Proposition 4.4.** *Given any unweighted graph  $G$  and any approximation parameter  $0 < \epsilon < 1$ , Bernstein’s algorithm (Algorithm 1) with high probability computes a  $(2/3 - \epsilon)$ -approximate maximum cardinality matching in the  $b$ -batch random-order stream model. The space complexity of the algorithm is  $O(nb^2 \log n \log b \text{ poly}(\epsilon^{-1}))$ , where  $b$  is the upper bound on batch-size.*

► **Definition 4.5 (Parameters).** *Let  $\epsilon < \frac{1}{2}$  be the final approximation parameter we are aiming for,  $\lambda = \frac{\epsilon}{512}$ ,  $\beta = 144\lambda^{-2} \log(2b/\lambda)$ ; note that  $\beta = O(\text{poly}(\epsilon^{-1}) \log b)$ . Set  $\alpha = \frac{\epsilon q}{b(n\beta^2 + 1)}$  and  $\gamma = 7 \log n \frac{q}{\alpha} = O(nb \log n \log b \text{ poly}(\epsilon^{-1}))$ .*

We now describe Bernstein’s algorithm [22] adapted to the  $b$ -batch model. The algorithm has two Phases. In Phase 1, it computes a subgraph  $H$  that is bounded edge-degree  $\beta$  (Definition 3.3). In Phase 2, it stores all the  $(G, H, \beta, \lambda)$ -underfull edges (Definition 3.4). That way, the algorithm computes a “relaxed” EDCS, which by Lemma 3.5 contains a  $(2/3 - \epsilon)$ -approximate maximum cardinality matching.

More concretely, the algorithm proceeds as follows: Initialize an empty subgraph  $H$  and start Phase 1. Phase 1 is split into epochs, each of which contains exactly  $\alpha$  batches. In each epoch, the algorithm processes the batches sequentially. For each edge  $(u, v)$  in the batch, if  $\deg_H(u) + \deg_H(v) < \beta(1 - \lambda)$ , then  $(u, v)$  is added to the subgraph  $H$  (note that the algorithm changes  $H$  over time, so  $\deg_H$  always refers to the degree of  $H$  at the time when the edge is examined). After adding an edge to  $H$ , the algorithm runs procedure REMOVEOVERFULLEDGES( $H$ ) to ensure that  $H$  is always bounded edge-degree  $\beta$ . In each epoch, the algorithm also has a boolean FOUNDUNDERFULL, which tracks whether at least one underfull edge arrived in the epoch. If FOUNDUNDERFULL is FALSE at the end of an epoch, then the algorithm terminates Phase 1 and moves on to Phase 2. Once Phase 1 terminates, the subgraph  $H$  becomes fixed and does not change anymore. Then, in Phase 2, the algorithm simply picks up all the underfull edges into a separate set  $U$ . For a formal description, see Algorithm 1. Note that the only difference between Algorithm 1 and Bernstein’s original algorithm (Algorithm 1 in [22]) is that the length of each epoch is now determined by the number of batches, rather than the number of edges.

► **Definition 4.6.** *Let  $\mathcal{B}_{\text{early}}$  denote the first  $\frac{\epsilon}{6}q$  batches in the stream and let  $\mathcal{B}_{\text{late}}$  denote the remaining batches. Let  $E_{\text{late}} := \{e \in E : e \in B \text{ for some } B \in \mathcal{B}_{\text{late}}\}$  be the set of edges that arrive as part of the late batches. More generally, let  $E_{>i}$  denote the the set of edges that arrive after the first  $i$  batches.*

■ **Algorithm 1** Bernstein’s Algorithm [22] adapted to the  $b$ -batch model.

---

```

1  $H \leftarrow \emptyset, U \leftarrow \emptyset$ 
2 Procedure PHASE 1
3   Do until termination

19     if  $\deg_H(u) + \deg_H(v) < \beta(1 - \lambda)$  then
20        $U \leftarrow U \cup \{(u, v)\}$ 
21   return the maximum matching in  $H \cup U$ 

```

---

First, we show that we don’t lose too many matching edges in the early part of the stream. To this end, we need to assume that the maximum cardinality matching is sufficiently large.

▷ **Claim 4.7.** We can assume that  $\mu(G) \geq 20b^2 \log n \epsilon^{-2}$ .

*Proof.* It is well known that every graph  $G$  satisfies  $m \leq 2n\mu(G)$ . Hence, if  $\mu(G) < 20b^2 \log n \epsilon^{-2}$ , then  $m = O(nb^2 \log n \epsilon^{-2})$ , so we can simply store all the edges. ◀

► **Lemma 4.8.** For  $\epsilon < b/2$ , it holds that  $\Pr[\mu(E_{\text{late}}) \geq (1 - 2\epsilon)\mu(G)] \geq 1 - n^{-5}$ .

*Proof.* Fix a maximum cardinality matching in  $M^*$  in  $G$ , and let  $B_1, \dots, B_k$  be the set of batches containing at least one matching edge from  $M^*$ . Each batch  $B_i$  contains at most  $b$  edges from  $M^*$ , so it suffices to show that at most  $\frac{2\epsilon\mu(G)}{b}$  of these batches arrive in the early part of the stream. For  $1 \leq i \leq k$ , let  $X_i$  be the indicator that  $B_i \in \mathcal{B}_{\text{late}}$ , and let  $X = \sum_{i=1}^k X_i$ . We will show that with high probability,  $X \geq k - \frac{2\epsilon\mu(G)}{b}$ . For  $1 \leq i \leq k$ , we have  $\mathbb{E}[X_i] = (1 - \frac{\epsilon}{b})$ , and so  $\mathbb{E}[X] = k(1 - \frac{\epsilon}{b})$ .

The  $X_i$ s are negatively associated, since these variables correspond to sampling  $(1 - \epsilon)q$  batches uniformly at random without replacement, which is known to be negatively associated (see the primer [76]). Applying Theorem 3.6 gives

$$\begin{aligned}
\Pr \left[ X \geq k - \frac{2\epsilon\mu(G)}{b} \right] &= 1 - \Pr \left[ X - \mathbb{E}[X] < - \left( \frac{2\epsilon\mu(G)}{b} - \frac{\epsilon k}{b} \right) \right] \\
&\geq 1 - \exp \left( \frac{-\epsilon^2(2\mu - k)^2}{4b^2k} \right) \\
&\geq 1 - n^{-5}.
\end{aligned}$$

The last inequality follows because  $\mu(G) \geq k$  and  $\mu(G) \geq 20b^2 \epsilon^{-2} \log n$ , by Claim 4.7. ◀

► **Lemma 4.9.** *Phase 1 satisfies the following properties:*

1. *Phase 1 terminates within the first  $\frac{\epsilon q}{b}$  batches of the stream.*
2. *Phase 1 constructs a subgraph  $H \subseteq G$  with bounded edge-degree  $\beta$ . As a corollary,  $H$  has at most  $O(n\beta)$  edges.*
3. *When Phase 1 terminates after processing some batch  $B_l$ , with probability at least  $1 - n^{-5}$ , the total number of  $(E_{>l}, H, \beta, \lambda)$ -underfull edges in  $E_{>l} \setminus H$  is at most  $b\gamma$ .*

The proof of Lemma 4.9 proceeds similarly to the proof of Lemma 4.1 in [22]. We will use the following result from the original analysis.

► **Lemma 4.10** ([22]). *Fix any parameter  $\beta > 2$ . Let  $H = (V, E_H)$  be a graph, with  $E_H$  initially empty. Say that an adversary adds and removes edges from  $H$  using an arbitrary sequence of two possible moves.*

- *(Deletion move) Remove an edge  $(u, v)$  from  $H$  for which  $\deg_H(u) + \deg_H(v) > \beta$ .*
- *(Insertion move) Add an edge  $(u, v)$  to  $H$  for some pair  $u, v \in V$  for which  $\deg_H(u) + \deg_H(v) < \beta - 1$ .*

*Then, after  $n\beta^2$  moves, no legal move remains.*

**Proof of Lemma 4.9.** *Property 1:* By Lemma 4.10, the algorithm can make at most  $n\beta^2$  changes to  $H$ . Since each epoch that does not terminate Phase 1 must make at least one change to  $H$ , there can be at most  $n\beta^2 + 1$  epochs in Phase 1. So overall, Phase 1 goes through at most  $\alpha(n\beta^2 + 1) = \frac{\epsilon q}{b}$  batches in Phase 1.

*Property 2:* Holds by construction of the algorithm, since the REMOVEOVERFULL procedure ensures that  $H$  is always bounded edge-degree  $\beta$ .

*Property 3:* Let  $l$  be the last batch processed in Phase 1. We will say that a batch  $B_j$  with  $j > l$  is *underfull* if it contains at least one  $(E_{>l}, H, \beta, \lambda)$ -underfull edge. We will show that with probability at least  $1 - n^{-5}$ , the number of underfull batches is at most  $\gamma$ . Since each underfull batch contains at most  $b$  underfull edges, this will give the result. The intuition is as follows: Phase 1 terminates only if there is an epoch without a single underfull batch. Since the stream is random, this means that there are relatively few underfull batches left in the stream. More formally, for each epoch  $0 \leq i \leq \frac{\epsilon q}{b}$ , say that a batch is *underfull* if it contains at least one  $(G, H_i, \beta, \lambda)$ -underfull edge, where  $H_i$  is the subgraph  $H$  constructed by the algorithm at the beginning of epoch  $i$ . Let  $\mathcal{E}_i$  be the event that no underfull batches appear in epoch  $i$ , and let  $\mathcal{F}_i$  be the event that there are more than  $\gamma$  underfull batches left in the stream when epoch  $i$  begins. Property 3 fails only if  $\mathcal{E}_i \wedge \mathcal{F}_i$  happens for some  $i$ , so we need to upper bound  $\Pr[\cup_{i=1}^{\epsilon q/b} \mathcal{E}_i \wedge \mathcal{F}_i]$ . Let  $\mathcal{B}_i^r$  denote the set of batches that have not yet appeared at the beginning of epoch  $i$  (r for remaining), let  $\mathcal{B}_i^e$  denote the set of batches that appear in epoch  $i$  (e for epoch) and let  $\mathcal{B}_i^u$  denote the set of underfull batches that remain in the stream (u for underfull). With these definitions, we can write  $\mathcal{E}_i \wedge \mathcal{F}_i$  as the event  $(\mathcal{B}_i^u \cap \mathcal{B}_i^e = \emptyset) \wedge (|\mathcal{B}_i^u| > \gamma)$ , since the event  $\mathcal{B}_i^u \cap \mathcal{B}_i^e = \emptyset$  ensures that the graph  $H$  does not change throughout the epoch. We have

$$\begin{aligned}
\Pr[\mathcal{E}_i \wedge \mathcal{F}_i] &= \Pr[(\mathcal{B}_i^u \cap \mathcal{B}_i^e = \emptyset) \wedge (|\mathcal{B}_i^u| > \gamma)] \\
&\leq \Pr[\mathcal{B}_i^u \cap \mathcal{B}_i^e = \emptyset \mid |\mathcal{B}_i^u| > \gamma] \\
&< \left(1 - \frac{\gamma}{q}\right)^\alpha \\
&= \left(1 - \frac{7 \log n}{\alpha}\right)^\alpha \\
&\leq n^{-7}.
\end{aligned}$$

Here the second inequality follows because  $\mathcal{B}_i^\epsilon$  is obtained by sampling  $\alpha$  batches from  $\mathcal{B}_i^r$  uniformly at random without replacement, and since  $|\mathcal{B}_i^u| > \gamma$  and  $|\mathcal{B}_i^r| \leq q$ . There are at most  $n^2$  epochs in total, so taking the union bound over all epochs gives the result.  $\blacktriangleleft$

Finally, we complete the proof of Proposition 4.4.

**Proof of Proposition 4.4.** Let us first show the approximation guarantee. By Part 2 of Proposition 4.9, Phase 1 computes a subgraph  $H$  which has bounded edge-degree  $\beta$ . Moreover, by Part 1 of Proposition 4.9, it holds that  $H \subseteq E_{late}$ . Phase 2 finds the set  $U$  of all  $(E_{late}, H, \beta, \lambda)$ -underfull edges. So by Lemma 3.5 applied to the graph  $E_{late}$ , the algorithm returns a matching of size at least

$$\begin{aligned} \mu(H \cup U) &\geq (2/3 - \epsilon)\mu(E_{late}) && \text{by Lemma 3.5} \\ &\geq (2/3 - \epsilon)(1 - 2\epsilon)\mu(G), && \text{by Lemma 4.8,} \end{aligned}$$

where the last inequality holds with probability at least  $1 - n^{-5}$ . Re-scaling  $\epsilon$  gives the approximation ratio.

For the space analysis: By Part 2 of Lemma 4.9, the space usage of Phase 1 is  $O(n\beta) = O(n \log b \text{poly}(\epsilon^{-1}))$ . By Part 3 of Lemma 4.9, with probability at least  $1 - n^{-5}$ , the space usage of Phase 2 is at most  $O(b\gamma) = O(nb^2 \log n \log b \text{poly}(\epsilon^{-1}))$ . So with probability at least  $1 - n^{-5}$ , the total space usage is at most  $O(nb^2 \log n \log b \text{poly}(\epsilon^{-1}))$ . By a union bound, the overall success probability of the algorithm is at least  $1 - 2n^{-5}$ .  $\blacktriangleleft$

### 4.3 Extension to Non-Bipartite Graphs

In this section, we show that the computed graph  $H \cup U$  is  $(2/3 - \epsilon)$ -refolding approximate. This, together with Proposition 4.4 and Theorem 4.2 will complete the proof of Theorem 1.1.

In [23], it was shown that EDCS are (almost)  $2/3$ -refolding approximate. However, since  $H \cup U$  is not actually an EDCS, but rather a relaxed version of an EDCS, this result cannot be applied directly. Instead, we need a more careful argument. We need the following lemma which was proved in [23].

► **Lemma 4.11** (Lemma 5.7 in [23]). *Let  $G$  be a weighted graph with weights in  $[W]$ . Let  $\delta \in (0, 1/2)$ , and let  $d \geq 36\delta^{-2} \log(W/\delta)$ . For any matching  $M$  in  $G$  and any subgraph  $H$  of  $\phi(G)$  with maximum degree at most  $d$ , there exists a bipartite subgraph  $\tilde{G} = \tilde{G}(M, H)$  of  $G$  such that, setting  $\tilde{H} := H \cap \phi(\tilde{G})$ , it holds that*

1.  $M \subseteq \tilde{G}$  and
2.  $|\deg_{\tilde{H}}(v) - \deg_H(v)/2| \leq \delta d$  for all vertices  $v \in V(H)$ .

► **Remark 4.12.** Bernstein, Dudeja and Langley [23] state the lemma for the special case when  $M$  is a maximum weight matching in  $G$ , however, without changing their argument, the same is true for any arbitrary matching  $M$ .

We now prove the main technical lemma, which shows that  $H \cup U$  is  $(2/3 - \epsilon)$ -refolding approximate.

► **Lemma 4.13.** *Let  $G$  be a (possibly non-bipartite) weighted graph with weights in  $[W]$ . Let  $\epsilon > 0$ ,  $\lambda \leq \frac{\epsilon}{512}$ ,  $\beta \geq \frac{144}{\lambda^2} \log(2W/\lambda)$ . Let  $G_S \subseteq G$  be any subgraph of  $G$ . Consider the unfolded graph  $\phi(G)$ . Let  $H$  be a subgraph of  $\phi(G)$  with bounded edge-degree  $\beta$ , and let  $U$  be the set of all edges in  $\phi(G_S) \setminus H$  that are  $(\phi(G_S), H, \beta, \lambda)$ -underfull. Then  $\mu_w(\mathcal{R}(H \cup U)) \geq (2/3 - \epsilon)\mu_w(G_S)$ .*

## 16:16 Weighted Matching in Random-Order Streams

**Proof.** Let  $\delta = \frac{\lambda}{2}$ . Fix a maximum-weight matching  $M^*$  of  $G_S$ , and let  $\tilde{G} = \tilde{G}(M^*, H)$  be the bipartite subgraph obtained from Lemma 4.11. Consider the subgraph  $\phi(\tilde{G}) \subseteq \phi(G)$ . Let  $\tilde{H} := H \cap \phi(\tilde{G})$  be the restriction of  $H$  to  $\phi(\tilde{G})$ , and let  $\tilde{U} := U \cap \phi(M^*)$  be the restriction of  $U$  to the matching  $\phi(M^*)$ . Note that  $\tilde{U}$  is a matching. By Lemma 4.11, we have  $\phi(M^*) \subseteq \phi(\tilde{G})$ , and therefore  $\tilde{H} \cup \tilde{U} \subseteq \phi(\tilde{G})$ . Therefore, we may now apply Lemma 2.3 to the bipartite graph  $\tilde{G}$  and the subgraph  $\tilde{H} \cup \tilde{U}$  of  $\phi(\tilde{G})$ .

$$\begin{aligned} \mu_w(\mathcal{R}(H \cup U)) &\geq \mu_w(\mathcal{R}(\tilde{H} \cup \tilde{U})), & \text{since } H \cup U \supseteq \tilde{H} \cup \tilde{U} \\ &\geq \mu(\tilde{H} \cup \tilde{U}), & \text{by Lemma 2.3.} \end{aligned} \quad (3)$$

Furthermore, recalling that  $M^*$  is a maximum weight matching in  $G_S$ , we have

$$\mu_w(G_S) = w(M^*) = |\phi(M^*)| \leq \mu(\tilde{H} \cup \phi(M^*)). \quad (4)$$

We will show that  $\mu(\tilde{H} \cup \tilde{U}) \geq (\frac{2}{3} - \epsilon)\mu(\tilde{H} \cup \phi(M^*))$ . To this end, we will show that  $\tilde{H} \cup \tilde{U}$  is an EDCS of  $\tilde{H} \cup \phi(M^*)$ .

▷ **Claim 4.14.**  $\tilde{H} \cup \tilde{U}$  is a  $(\beta', \lambda')$ -EDCS of  $\tilde{H} \cup \phi(M^*)$  for  $\beta' = \frac{\beta}{2} + \beta\lambda + 2$ ,  $\lambda' = 8\lambda$ .

*Proof.* Let us start by showing property P1 in Definition 2.6. First note that for all  $(u, v) \in \tilde{H} \cup \tilde{U}$ , it holds that  $\deg_H(u) + \deg_H(v) \leq \beta$ . Indeed, if  $(u, v) \in \tilde{H}$ , then  $(u, v) \in H$ , so  $\deg_H(u) + \deg_H(v) \leq \beta$  since  $H$  is bounded edge-degree  $\beta$ . If instead  $(u, v) \in \tilde{U}$ , then  $(u, v) \in U$ , so  $\deg_H(u) + \deg_H(v) \leq (1 - \lambda)\beta$ , since all elements of  $U$  are  $(\phi(G), H, \beta, \lambda)$ -underfull. Therefore, for all  $(u, v) \in \tilde{H} \cup \tilde{U}$ , it holds that

$$\begin{aligned} \deg_{\tilde{H} \cup \tilde{U}}(u) + \deg_{\tilde{H} \cup \tilde{U}}(v) &\leq \deg_{\tilde{H}}(u) + \deg_{\tilde{H}}(v) + \deg_{\tilde{U}}(u) + \deg_{\tilde{U}}(v) \\ &\leq \frac{\deg_H(u) + \deg_H(v)}{2} + 2\delta\beta + \deg_{\tilde{U}}(u) + \deg_{\tilde{U}}(v) \\ &\leq \frac{\beta}{2} + \beta\lambda + \deg_{\tilde{U}}(u) + \deg_{\tilde{U}}(v) \\ &\leq \frac{\beta}{2} + \beta\lambda + 2 \\ &= \beta'. \end{aligned}$$

The second inequality follows by Lemma 4.11, and the third inequality follows since  $\delta = \frac{\lambda}{2}$ .

We now show property P2 in Definition 2.6: If  $(u, v) \in (\tilde{H} \cup \phi(M^*)) \setminus (\tilde{H} \cup \tilde{U})$ , then  $(u, v) \in \phi(M^*) \setminus U$ , and in particular  $\deg_H(u) + \deg_H(v) > (1 - \lambda)\beta$  (by definition of  $U$ ). Thus,

$$\begin{aligned} \deg_{\tilde{H} \cup \tilde{U}}(u) + \deg_{\tilde{H} \cup \tilde{U}}(v) &\geq \deg_{\tilde{H}}(u) + \deg_{\tilde{H}}(v) \\ &\geq \frac{\deg_H(u) + \deg_H(v)}{2} - 2\delta\beta, & \text{by Lemma 4.11} \\ &\geq \frac{\beta(1 - \lambda)}{2} - \beta\lambda, & \text{since } \delta = \frac{\lambda}{2} \\ &\geq \left(\frac{\beta}{2} + \lambda\beta + 2\right)(1 - 8\lambda) \\ &= \beta'(1 - \lambda'). \end{aligned}$$

The last inequality follows from simple algebraic manipulations, using the fact that  $\lambda\beta \geq 2$ .

◁

By the choice of parameters, we have  $\lambda' \leq \frac{\epsilon}{64}$  and  $\beta' \geq 8\lambda'^{-2} \log(1/\lambda')$ , so Claim 4.14 together with Theorem 2.7 yields  $\mu(\tilde{H} \cup \tilde{U}) \geq (2/3 - \epsilon)\mu(\tilde{H} \cup \phi(M^*))$ . Combining everything, we get

$$\begin{aligned} \mu_w(\mathcal{R}(H \cup U)) &\geq \mu(\tilde{H} \cup \tilde{U}), && \text{by Equation 3} \\ &\geq (2/3 - \epsilon)\mu(\tilde{H} \cup \phi(M^*)) \\ &\geq (2/3 - \epsilon)\mu_w(G_S), && \text{by Equation 4.} \quad \blacktriangleleft \end{aligned}$$

Finally, we complete the proof of Theorem 1.1.

**Proof of Theorem 1.1.** We apply the reduction in Theorem 4.2 to Algorithm 1. By Proposition 4.4, Algorithm 1 computes a  $(2/3 - \epsilon)$ -approximate maximum cardinality matching using space  $O(n \log n \text{ poly}(b/\epsilon))$  in the  $b$ -batch random-order stream model. It remains to show that if the input graph is of the form  $\phi(G)$  for some weighted graph  $G$  with batches  $\mathcal{B} = \{\phi(e) : e \in G\}$ , then  $H \cup U$  is  $(2/3 - \epsilon)$ -refolding approximate. Let  $G_{late} \subseteq G$  denote the weighted edges corresponding to  $\mathcal{B}_{late}$ . An application of the Chernoff bound for negatively associated random variables (Theorem 3.6) shows that  $\Pr[\mu_w(G_{late}) \geq (1 - 2\epsilon)\mu_w(G)] \geq 1 - n^{-5}$  (the argument is similar to Lemma 4.8). Applying Lemma 4.13 to the graph  $G$  and the subgraph  $G_S := G_{late}$  yields

$$\begin{aligned} \mu_w(\mathcal{R}(H \cup U)) &\geq (2/3 - \epsilon)\mu_w(G_{late}), && \text{by Lemma 4.13} \\ &\geq (1 - 2\epsilon)(2/3 - \epsilon)\mu_w(G) \\ &\geq (2/3 - 3\epsilon)\mu_w(G), \end{aligned}$$

as required. Re-scaling  $\epsilon$  and applying Theorem 4.2 yields the result.  $\blacktriangleleft$

## 5 5/6-Approximation in the Robust Communication Model

In this section, we prove Theorem 1.2 and Theorem 1.3. By applying the results from the previous section, we can generalize the protocol of Azarmehr and Behnezhad [20] to the weighted case. By the reduction in Theorem 4.1, we can assume that the edge weights take integral values in  $[W]$ , for a large constant  $W$ . We will now describe the protocol for the two-party model.

Let  $\epsilon > 0$  be the final parameter we are aiming for, and let

$$\lambda = \frac{\epsilon}{2048}, \beta = 144\lambda^{-4} \log(2W/\lambda).$$

Let  $E_A$  denote the set of edges assigned to Alice and  $E_B$  the set of edges assigned to Bob. Alice simulates a random-order stream. She unfolds the edges and runs Algorithm 1 on the corresponding unweighted  $W$ -batch random-order stream. That way, she obtains a set  $H \subseteq \phi(E_A)$  with bounded edge degree  $\beta$  and a set  $U_A \subseteq \phi(E_A)$  consisting of all  $(\phi(E_A \setminus E_{early}), H, \beta, \lambda)$ -underfull edges, where  $E_{early} \subseteq E_A$  denotes the first  $\frac{\epsilon}{W}m$  weighted edges in her simulated stream. She communicates  $\mathcal{R}(H \cup U_A)$  to Bob. Bob outputs the maximum weight matching in  $\mathcal{R}(H \cup U_A) \cup E_B$ . See Algorithm 2 for a formal description.

The protocol for  $k$  parties is similar, only that now all of the first  $k - 1$  parties should simulate a random-order stream (we describe the protocol more formally in the proof of Theorem 1.3).

Assume that each edge is assigned to Bob with probability  $p \leq \frac{1}{2}$  (this will make the analysis applicable to the  $k$ -party setting). Let  $U_B$  be the set of all  $(\phi(E_B), H, \beta, \lambda)$ -underfull edges, i.e. the set of underfull edges assigned to Bob. Let  $U := U_A \cup U_B$  denote the set of all

## 16:18 Weighted Matching in Random-Order Streams

■ **Algorithm 2** Robust Communication Protocol for Weighted Graphs.

- 
1. Alice simulates a random-order stream by ordering the edges in  $E_A$  uniformly at random.
  2. Alice obtains  $H \cup U_A \subseteq \phi(E_A)$  by running Algorithm 1 on input  $\phi(E_A)$  with batches  $\mathcal{B} = \{\phi(e) : e \in E_A\}$ . She communicates  $\mathcal{R}(H \cup U_A)$  to Bob.
  3. Bob outputs the maximum weight matching in  $\mathcal{R}(H \cup U_A) \cup E_B$ .
- 

underfull edges. We will define an auxiliary fractional matching  $x$  on  $\mathcal{R}(H \cup U)$  of weight at least  $(2/3 - \epsilon)\mu_w(G)$ . We will then extend it to a fractional matching  $y$  on  $E_B \cup \mathcal{R}(H \cup U_A)$ , and show that due to the additional edges in  $E_B$ , the fractional matching  $y$  has weight at least  $(5/6 - \epsilon)\mu_w(G)$ .

Let  $E_{late} := E \setminus E_{early}$ . Fix a maximum weight matching  $M^*$  in  $E_{late}$ . Define a fractional matching  $x$  on  $\mathcal{R}(H \cup U)$  as follows:

- Start with  $H_1 = H$  and  $U_1 = U$ .
- For  $i = 1, \dots, \lambda\beta$ :
  - Let  $M_i$  be a maximum weight matching in  $\mathcal{R}(H_i \cup U_i)$ .
  - Let  $H_{i+1} = H_i \setminus \phi(M_i \setminus M^*)$  and  $U_{i+1} = U_i \setminus \phi(M_i \setminus M^*)$ .
- For every edge  $e$ , let  $x_e = \frac{|\{i: e \in M_i\}|}{\lambda\beta}$ .

In other words, we start with  $H \cup U$ , and then in each iteration, we find a maximum weight matching  $M_i$  in the refolding, and remove the edges in  $\phi(M_i \setminus M^*)$  from  $H \cup U$ .

► **Remark 5.1.** Note that this is a valid fractional matching, since

$$x_u = \sum_{e \ni u} x_e = \sum_{e \ni u} \frac{|\{i : e \in M_i\}|}{\lambda\beta} = \sum_i \frac{|\{e \ni u : e \in M_i\}|}{\lambda\beta} \leq 1.$$

Furthermore, note that  $x_e \leq \frac{1}{\lambda\beta}$  whenever  $e \notin M^*$ . This is because, if  $e \in M_i \setminus M^*$  for some  $i$ , then  $e \notin \mathcal{R}(H_j \cup U_j)$  for all  $j > i$ .

► **Lemma 5.2.** *It holds that  $\sum_e w_e x_e \geq (\frac{2}{3} - \epsilon)\mu_w(E_{late})$ .*

**Proof.** For each  $i$ , let  $G_i := E_{late} \setminus (\cup_{j < i} M_j \setminus M^*)$ . We will apply Lemma 4.13 to the graph  $G \setminus (\cup_{j < i} M_j \setminus M^*)$  and subgraph  $G_S = G_i$ . Recall that we obtain  $H_{i+1}$  from  $H_i$  by removing the edges in  $\phi(M_i \setminus M^*)$ . Since  $\phi(M_i \setminus M^*)$  is a matching, the degree of each edge in  $\phi(G)$  will decrease by at most two in each iteration. Therefore,  $U_i$  contains all the edges in  $G_i \setminus H_i$  that have  $H_i$  degree less than  $(1 - \lambda)\beta - 2(i - 1) \geq (1 - 3\lambda)\beta$ . By Lemma 4.13, we get

$$w(M_i) = \mu_w(\mathcal{R}(H_i \cup U_i)) \geq \left(\frac{2}{3} - \epsilon\right) \mu_w(G_i). \quad (5)$$

Also,  $G_i$  is constructed so that it always contains  $M^*$ , so

$$\mu_w(G_i) \geq w(M^*) = \mu_w(E_{late}). \quad (6)$$

Combining, we obtain

$$\begin{aligned}
\sum_{e \in \mathcal{R}(H \cup U)} w_e x_e &= \sum_{e \in \mathcal{R}(H \cup U)} w_e \frac{|\{i : e \in M_i\}|}{\lambda\beta} \\
&= \frac{1}{\lambda\beta} \sum_i \sum_{e \in \mathcal{R}(H \cup U)} w_e \mathbb{1}\{e \in M_i\} \\
&= \frac{1}{\lambda\beta} \sum_i w(M_i) \\
&\geq \frac{1}{\lambda\beta} \sum_i \left(\frac{2}{3} - \epsilon\right) \mu_w(G_i). && \text{by Equation 5} \\
&\geq \left(\frac{2}{3} - \epsilon\right) \mu_w(E_{late}), && \text{by Equation 6.} \quad \blacktriangleleft
\end{aligned}$$

Recall that the set of edges that Bob has access to is  $E_B \cup \mathcal{R}(H \cup U)$ . We need to show that  $\mu_w(E_B \cup \mathcal{R}(H \cup U)) \geq (\frac{5}{6} - \epsilon)\mu_w(G)$ . We will do this by extending the fractional matching  $x$  on  $\mathcal{R}(H \cup U)$  to a fractional matching  $y$  on  $E_B \cup \mathcal{R}(H \cup U)$ . In order to describe  $y$ , we will condition on the set of early edges  $E_{early}$ , thereby fixing  $\mathcal{R}(H \cup U)$  and  $x$ . For each edge  $e \in E_{late}$ , we have

$$\Pr[e \in E_B | e \in E_{late}] = \frac{\Pr[e \in E_B \wedge e \in E_{late}]}{\Pr[e \in E_{late}]} = \frac{p}{1 - \epsilon/W}.$$

and

$$\Pr[e \in E_A | e \in E_{late}] = 1 - \frac{p}{1 - \epsilon/W}.$$

Recall that  $M^*$  is a fixed maximum weight matching in  $E_{late}$ . Let  $M_{in} := M^* \cap \mathcal{R}(H \cup U)$  and let  $M_{out} := M^* \setminus \mathcal{R}(H \cup U)$ . After drawing  $E_B$ , define a random matching  $M' \subseteq M^*$  as follows:

- Include each edge  $e \in M_{in}$  independently with probability  $p$ .
- Include each edge  $e \in M_{out} \cap E_B$  independently with probability  $1 - \epsilon/W$ .

Conditioned on  $E_{early}$ , each edge in  $M_{out}$  ends up in  $M'$  independently with probability  $(1 - \epsilon/W) \cdot \frac{p}{1 - \epsilon/W} = p$ . Each edge in  $M_{in}$  also ends up in  $M'$  independently with probability  $p$ , so overall each edge in  $M^*$  ends up in  $M'$  independently with probability  $p$ .

For any edge  $e \notin M^*$ , let  $p_e$  denote the probability that  $e$  is *not* adjacent to any edge in  $M'$ . In other words,

$$p_e = \begin{cases} (1 - p) & \text{if } e \text{ has exactly one endpoint matched by } M^*, \\ (1 - p)^2 & \text{if both of the endpoints of } e \text{ are matched by } M^*. \end{cases}$$

We can now define  $\hat{y}$  on  $E_B \cup \mathcal{R}(H \cup U)$ .

$$\hat{y}_e = \begin{cases} 1 & \text{if } e \in M', \\ x_e & \text{if } e \in M^* \setminus M', \\ 0 & \text{if } e \notin M^* \text{ and } e \text{ is adjacent to at least one edge of } M' \\ (1 - p) \frac{x_e}{p_e} & \text{if } e \notin M^* \text{ and } e \text{ is not adjacent to } M'. \end{cases}$$

Finally, we scale down  $\hat{y}$  and zero out some of the entries in order to obtain a valid fractional matching  $y$ .

$$y_{(u,v)} = \begin{cases} 0 & \text{if } \hat{y}_u/(1 + \epsilon) > 1 \text{ or } \hat{y}_v/(1 + \epsilon) > 1 \\ \frac{\hat{y}_{(u,v)}}{1 + \epsilon} & \text{otherwise.} \end{cases}$$

► **Lemma 5.3.** *It holds that*

$$\mathbb{E} \left[ \sum_{e \in E} w_e y_e \right] \geq \left( \frac{2}{3} + \frac{p}{3} - 4\epsilon \right) \mu_w(G).$$

The proof is similar to Lemma 4.6 in [20], and is included in the full version of the paper. Next, we round  $y$  to an integral matching.

► **Lemma 5.4.** *There exists a matching of weight at least  $(1 - 3\epsilon) \sum_{e \in E} w_e y_e$  in  $E_B \cup \mathcal{R}(H \cup U_A)$ .*

The proof is similar to Lemma 4.7 in [20] and is included in the full version of the paper. Finally, we show that we have a large matching with high probability, and not just in expectation.

► **Lemma 5.5.** *With probability at least  $1 - n^{-5}$ , there exists a matching of weight at least  $(\frac{2}{3} + \frac{p}{3} - O(\epsilon)) \mu_w(G)$  in  $E_B \cup \mathcal{R}(H \cup U_A)$ .*

The proof is similar to Lemma 5.2 in [20], and is included in the full version of the paper. We now complete the proofs of Theorem 1.2 and Theorem 1.3.

**Proof of Theorem 1.2.** Suppose that the edge weights are in  $[W]$ . By Proposition 4.4, Protocol 2 uses  $O(n \log n \text{poly}(W/\epsilon))$  words of communication with high probability. By Lemma 5.5, the protocol achieves a  $(\frac{2}{3} + \frac{p}{3} - O(\epsilon))$ -approximation with high probability. So by Theorem 4.1, there exists a protocol that achieves a  $(\frac{2}{3} + \frac{p}{3} - O(\epsilon))(1 - \epsilon)$ -approximation using space  $O(n \log n \log R)$  when the edge weights are in  $\mathbb{R}^+$ . Letting  $p = \frac{1}{2}$  and re-scaling  $\epsilon$  proves the theorem. ◀

**Proof of Theorem 1.3.** Suppose that the edge weights are in  $[W]$ . We need to adjust the protocol to the  $k$ -party model. The first party simulates the start of a random-order stream by selecting an ordering of their edges uniformly at random. They unfold the edges and run Algorithm 1 on the corresponding unweighted  $W$ -batch random-order stream. They pass the memory state of the algorithm to the next party. Each of the next  $k - 2$  parties will continue to simulate the random-order stream that way. The  $(k - 1)$ st party communicates  $\mathcal{R}(H \cup U)$  to the last party, where  $H \cup U$  is the unweighted graph computed by Algorithm 1 on the unfolded  $W$ -batch stream. Finally, the last party will output the maximum weight matching in the graph consisting of all edges to which they have access. That way, we can set  $p = \frac{1}{k}$  and treat the first  $k - 1$  parties as Alice and the last party as Bob. By Proposition 4.4, the protocol uses  $O(n \log n \text{poly}(W/\epsilon))$  words of communication with high probability. By Lemma 5.5, the protocol achieves a  $(\frac{2}{3} + \frac{p}{3} - O(\epsilon))$ -approximation with high probability. So by Theorem 4.1, there exists a protocol that achieves a  $(\frac{2}{3} + \frac{p}{3} - O(\epsilon))(1 - \epsilon)$ -approximation using space  $O(n \log n \log R)$  when the weights are in  $\mathbb{R}^+$ . Re-scaling  $\epsilon$  proves the theorem. ◀

## Abstract

We study the two-sided stable matching problem with one-sided uncertainty for two sets of agents  $A$  and  $B$ , with equal cardinality. Initially, the preference lists of the agents in  $A$  are given but the preferences of the agents in  $B$  are unknown. An algorithm can make queries to reveal information about the preferences of the agents in  $B$ . We examine three query models: comparison queries, interviews, and set queries. Using competitive analysis, our aim is to design algorithms that minimize the number of queries required to solve the problem of finding a stable matching or verifying that a given matching is stable (or stable and optimal for the agents of one side). We present various upper and lower bounds on the best possible competitive ratio as well as results regarding the complexity of the offline problem of determining the optimal query set given full information.

## 1 Introduction

In the classical two-sided stable matching problem, we are given two disjoint sets  $A$  and  $B$  of agents (often referred to as men and women) of equal cardinality  $n$ . Each agent has a complete preference list over the agents of the other set. The task is to find a *stable* matching, i.e., a one-to-one allocation in which no two agents prefer to be matched to each other rather than to their current matching partners. This problem has applications in numerous allocation markets, e.g., university admission, residency markets, distributed

internet services, etc. Since its introduction by Gale and Shapley [13] this problem has been widely studied in different variants from both practical and theoretical perspectives; we refer to the books [15, 31, 25].

While the majority of the literature assumes full information about the preference lists, this may not be realistic in large matching markets. It might be impractical or too costly and not even necessary to gather the complete preferences. Hence, different models for uncertainty in the preferences have received attention in the past decade [1, 2, 6, 7, 9, 17, 16, 29, 30]. Many of these works rely on probabilistic models and guarantees. This may not be appropriate for applications in which no (correct) distributional information is available, e.g. in one-time markets. Further, one might ask for guaranteed properties such as stability and optimality instead of probabilistic ones.

A different way of handling uncertainty in the preferences is to allow an algorithm to make queries to learn about the unknown preferences. Various types of queries (in terms of both input and output) are conceivable, with one example being *interview queries* [6, 7, 29, 30]. Here one asks for a query sequence where a query corresponds to an interview between two potential matching partners and the outcome is the placement of the interview partners in each other's preference list among all other candidates that she has interviewed so far. Hence, if an agent has several such interviews then she finds out her preference order over all these candidates.

In this paper we investigate various query models for stable matching problems with *one-sided* uncertainty in the preferences. We assume that initially only the preference lists of one side,  $A$ , are known but the preference lists of the other side,  $B$ , are unknown. Applications include allocations between groups of different seniority or when preferences shall be kept private; see also [17, 16, 18]. For illustration consider, e.g., pairing new staff with mentors or new PhD students with supervisors as part of the onboarding. New staff can be asked to provide a full preference list of mentors based on information about the available mentors that can be made accessible with little effort, while requiring mentors to rank potential mentees might be considered too burdensome for senior staff due to other significant time commitments.

We consider three types of queries to gain information about the preferences, namely (i) *comparison queries* that reveal for an agent  $b \in B$  and a pair of agents from  $A$  which one  $b$  prefers, (ii) *set queries* that reveal for an agent  $b \in B$  and a subset  $S \subseteq A$  the agent in  $S$  that  $b$  prefers most, and (iii) *interview queries*.

We study basic problems regarding stability and optimality of matchings using these query models. A stable matching is called  $A$ -optimal (resp.  $B$ -optimal) if no agent in  $A$  (resp.  $B$ ) prefers a different stable matching over the current one. To our knowledge, most existing related work considers worst-case bounds on the absolute number of queries necessary to solve the respective problem; see Further Related Work below for a discussion. For many instances, however, executing such a worst-case number of queries might not be necessary. To also optimize the number of queries on these instances, we analyze our algorithms using *competitive analysis*. We say that an algorithm that makes queries until it can output a provably correct answer, e.g., a stable and  $A$ -optimal matching, is  $\rho$ -competitive (or  $\rho$ -query-competitive) if it makes at most  $\rho$  times as many queries as the minimum possible number of queries that also output a provably correct answer for the given instance. Note that this answer may differ from that of the algorithm, e.g., a different stable matching. In this paper, we design upper and lower bounds on the competitive ratios for the above mentioned problems and query models. Our results illustrate that worst-case instances regarding the competitive ratio are very different from the worst-case instances regarding the absolute number of queries. Thus,

our lower bounds on the competitive ratio use different instances and our algorithms are designed to optimize on different instances. Indeed, worst-case instances for the absolute number of queries turn out to be “easy” for competitive analysis as the optimal solution we compare against is very large.

Query-competitive algorithms are often associated with the field of “explorable uncertainty”. Most previous work considers queries revealing an originally uncertain *value* [4, 8, 10, 19, 20, 22, 26, 11], while in this work we query a *preference*.

**Our Contribution.** We study the stable matching problem with one-sided uncertainty in the preference lists and give the following main results. Note that we assume that the preferences of the  $B$  side are unknown, and  $|A| = |B| = n$ . We remark that our technically most involved main results are lower bounds on the competitive ratio and hardness results, so the results only get stronger by making these assumptions.

In Section 3 we focus on *comparison queries*. Firstly, we ask the question of how to verify that a given matching is stable. We show that the problem can be solved with a 1-competitive algorithm. Then we ask how to find a stable matching under one-sided uncertainty. We give a 1-competitive algorithm that finds a stable matching and, moreover, the solution is provably  $A$ -optimal. Essentially, we employ the well-known *deferred acceptance algorithm*, first analyzed by Gale and Shapley [13], and compare its number of queries carefully with the number of queries that any algorithm needs to verify a stable matching.

A substantially more challenging task is to find a  $B$ -optimal stable matching. Note that a trivial competitive ratio is  $O(n^2 \log n)$ , as it is possible to obtain the full preferences of each of the  $n$  elements in  $B$  using  $O(n \log n)$  queries, and the optimum total number of queries is at least 1. One of our main contributions is a tight bound of  $O(n)$ . To that end, we first show that every algorithm for verifying that a given matching is  $B$ -optimal and stable requires  $\Omega(n)$  queries. Then we give an  $O(n)$ -competitive algorithm for the problem of finding one. This is best possible up to constant factors, which we prove with a matching lower bound that also holds for verifying that a given matching is stable and  $B$ -optimal, even for randomized algorithms.

We complement these results by showing that the offline problem of determining the optimal number of queries for finding the  $B$ -optimal stable matching is NP-hard, and we give an  $O(\log n \log \log n)$ -approximation algorithm. Here, the *offline* version of a problem is to compute, given full information about the preferences of all agents, a smallest set of queries with the property that an algorithm making exactly those queries has sufficient information to solve the problem with one-sided uncertainty.

Section 4 discusses interview queries. We show that the bounds on the competitive ratio and hardness results for comparison queries translate to interview queries. We remark that some of these results for interview queries, e.g., a 1-competitive algorithm for finding an  $A$ -optimal stable matching, were already proven by Rastegari et al. [30] and discuss differences to their results in the corresponding section. Interestingly, we can use essentially the same techniques as for the comparison model. This may seem surprising, especially for the lower bounds, as interview queries seem to be more powerful. For instance,  $n$  interviews are sufficient to determine the precise preference order of an agent  $b \in B$ , while we need  $\Omega(n \log n)$  comparison queries to determine  $b$ 's preference order. On the other hand, an instance that can be solved with a single comparison query requires two interviews. In general, we can simulate a comparison query by using two interview queries.

In Section 5 we discuss the *set query* model. While some bounds remain the same as in the other models, e.g., 1-competitiveness for verifying the stability of a given matching, we show that some bounds change drastically. For example, we give an  $O(\log n)$ -competitive

algorithm for verifying that a given matching is  $B$ -optimal, which is in contrast to the lower bound of  $\Omega(n)$  in the other query models. It remains open whether  $\mathcal{O}(1)$ -competitive algorithms exist for the problems of finding a stable matching or verifying a  $B$ -optimal matching with set queries.

**Further Related Work.** In classical work on stable matching with queries, the preferences on both sides can only be accessed via queries, with a query usually either asking for the  $i$ th entry in a preference list or for the rank of a specific element within a preference list (cf. e.g. [27]). Note that two rank queries are sufficient to simulate a comparison query, but up to  $n - 1$  comparison queries are needed to obtain the information of a single rank query. Thus, existing lower bounds on the necessary number of rank queries in these query models translate to our setting (up to a constant factor), but upper bounds do not necessarily translate. Ng and Hirschberg [27] showed that  $\Theta(n^2)$  such queries are necessary to find or verify a stable matching in the worst case. The lower bound of  $\Omega(n^2)$  translates to any type of queries with boolean answers, including comparison queries [14]. Further work on interview queries includes empirical results [6, 7] and complexity results [29] on several decision problems under partial uncertainty. We discuss the latter in Section 4.

Our setting of one-sided uncertainty and querying uncertain preferences is also related to existing work on online algorithms for *eliciting partial preferences* [21, 28, 24]. These works also consider a setting where the preferences of agents in one of the sets are uncertain but can be determined by using different types of queries. In particular, [28] also considers the set query model. The main difference to our work is that these papers assume that the elements of one set do not have any preferences at all. As a consequence, they do not consider stability at all and instead aim at computing pareto-optimal or rank-maximal matchings.

## 2 Preliminaries

An instance of the *two-sided stable matching problem* consists of two disjoint sets  $A$  and  $B$  of size  $|A| = |B| = n$  and complete preference lists: The preference list for each agent  $a \in A$  is a total order  $\prec_a$  of  $B$ , the preference list of each agent  $b \in B$  is a total order  $\prec_b$  of  $A$ . Here,  $a_1 \prec_b a_2$  means that  $b$  prefers  $a_1$  to  $a_2$ . A matching is a bijection from  $A$  to  $B$ . For a matching  $M$ , we denote the element of  $B$  that is matched to  $a \in A$  by  $M(a)$ , and the element of  $A$  that is matched to  $b \in B$  by  $M(b)$ .

Given a matching  $M$ , a pair  $(a, b) \in A \times B$  is a *blocking pair* in  $M$  if  $a$  is not matched to  $b$  in  $M$ ,  $a$  prefers  $b$  to  $M(a)$ , and  $b$  prefers  $a$  to  $M(b)$ . A matching  $M$  is called a *stable matching* if there is no blocking pair in  $M$ .

In their influential paper, Gale and Shapley [13] showed that a stable matching always exists, and the *deferred acceptance algorithm* computes one in  $\mathcal{O}(n^2)$  time. In this algorithm, one group ( $A$  or  $B$ ) proposes matches and the other decides whether to accept or reject each proposal. The algorithm produces a stable matching that is best possible for the group  $X$  that proposes (we say  $X$ -optimal) and worst possible for the other group: Each element of the group that proposes gets matched to the highest-preference element to which it can be matched in any stable matching, and each element of the other group gets matched to the lowest-preference element to which it can be matched in any stable matching.

In this paper, we consider the setting of *one-sided uncertainty*, where initially only the preference lists of all agents in  $A$  are known, but the preference lists of  $b \in B$  are unknown. An algorithm can make queries to learn about the preferences of  $b \in B$ . We distinguish the following types of queries:

- *Comparison queries:* For agents  $b \in B$  and  $a_1, a_2 \in A$ , the query  $\text{prefer}(b, a_1, a_2)$  returns  $a_1$  if  $b$  prefers  $a_1$  to  $a_2$  and  $a_2$  otherwise. These queries can also be seen as Boolean queries that return true iff  $b$  prefers  $a_1$  to  $a_2$ .
- *Set queries:* For agents  $b \in B$  and any subset  $S \subseteq A$ , the query  $\text{top}(b, S)$  returns  $b$ 's most preferred element of  $S$ .
- *Interview queries:* For agents  $b \in B$  and  $a \in A$ , an interview query  $\text{intq}(b, a)$  reveals the total order of the subset  $\{a\} \cup P_b$  defined by  $\prec_b$ , where  $P_b$  is the set of all elements  $a' \in A$  for which a query  $\text{intq}(b, a')$  has already been executed before the query  $\text{intq}(b, a)$ .

A *stable matching instance with one-sided uncertainty* is given by two sets  $A$  and  $B$  of size  $n$  and, for each agent  $a \in A$ , a total order  $\prec_a$  of the agents in  $B$ . The preferences of the agents in  $B$  are initially unknown. For a given stable matching instance with one-sided uncertainty, we consider the following problems: *finding a stable matching*, *finding an  $A$ -optimal stable matching*, and *finding a  $B$ -optimal stable matching*. For a given stable matching instance with one-sided uncertainty and a matching  $M$ , we consider the following problems: *verifying that  $M$  is stable*, *verifying that  $M$  is stable and  $A$ -optimal*, and *verifying that  $M$  is stable and  $B$ -optimal*. All problems can be considered for each query model. For the verification problems, we consider the competitive ratio only for inputs where  $M$  is indeed a stable (and  $A$ - or  $B$ -optimal) matching. If this is not the case, the algorithm must detect this, but we do not compare the number of queries it makes to the optimum. This is because any algorithm may be required to make up to  $\Omega(n^2)$  comparison or interview queries to detect a blocking pair, while the optimum can prove its existence with a constant number of queries.

It is easy to see that for the optimum, the problem of verifying that a given matching  $M$  is stable and  $A$ -optimal ( $B$ -optimal) is the same as that of finding the  $A$ -optimal ( $B$ -optimal) stable matching. This implies that any lower bound on the number of queries required to verify that  $M$  is stable and  $A$ -optimal ( $B$ -optimal) also applies to the problem of finding the  $A$ -optimal ( $B$ -optimal) stable matching.

An important concept is the notion of *rotations*, which can be defined as follows (cf. [25]): Let a stable matching  $M$  be given. For an agent  $a_i \in A$ , let  $s_A(a_i)$  denote the most-preferred element  $b_j$  on  $a_i$ 's preference list such that  $b_j$  prefers  $a_i$  to her current partner  $M(b_j)$ . Note that  $s_A(a_i)$  must be lower than  $M(a_i)$  in  $a_i$ 's preference list as otherwise  $(a_i, s_A(a_i))$  would be a blocking pair. Let  $\text{next}_A(a_i) = M(s_A(a_i))$ . Then a rotation (exposed) in  $M$  is a sequence  $(a_{i_0}, b_{j_0}), \dots, (a_{i_{r-1}}, b_{j_{r-1}})$  of pairs such that, for each  $k$  ( $0 \leq k \leq r-1$ ),  $(a_{i_k}, b_{j_k}) \in M$  and  $a_{i_{k+1}} = \text{next}_A(a_{i_k})$ , where addition is modulo  $r$ . The rotation can be viewed as an alternating cycle consisting of the matched edges  $(a_{i_k}, b_{i_k})$  and the unmatched edges  $(a_{i_k}, b_{i_{k+1}})$  (for  $0 \leq k \leq r-1$ ). We refer to an edge  $(a, s_A(a))$  as a *rotation edge* or  *$r$ -edge* as it can potentially be part of a rotation. Note that every vertex  $a \in A$  is incident with at most one  $r$ -edge.

Given a rotation  $R$  in a stable matching  $M$ , we can construct a stable matching  $M'$  from  $M$  by removing all edges that are part of  $R$  and  $M$  and adding all  $r$ -edges that are part of  $R$ . We refer to this as *applying* a rotation. Observe that no agent in  $B$  is worse off in  $M'$  than in  $M$ , and some agents in  $B$  prefer  $M'$  to  $M$ . The following has been shown.

► **Lemma 1** (Lemma 2.5.3 in Gusfield and Irving [15]). *If  $M$  is any stable matching other than the  $B$ -optimal stable matching, then there is at least one rotation exposed in  $M$ .*

### 3 Stable Matching with Comparison Queries

In this section, we consider the comparison query model. We first discuss our results on the problems of verifying that a given matching is stable and finding an  $A$ -optimal matching, before moving on to our main results regarding the competitive ratio for finding/verifying a  $B$ -optimal matching.

### 3.1 Verifying That a Given Matching Is Stable

We consider the *verification problem* where we are given a matching  $M$  and our task is to verify that  $M$  is indeed stable. As argued in the previous section, we only care about the competitive ratio if the given matching  $M$  is indeed stable.

The following auxiliary lemma shows that exploiting transitivity cannot reduce the number of comparison queries to an agent  $b \in B$  if one needs to find out the preference relationship of  $k$  agents from  $A$  to one particular agent from  $A$  in  $b$ 's preference list.

► **Lemma 2.** *Consider two agents  $a \in A$ ,  $b \in B$  and assume that there are  $k$  agents  $a_1, \dots, a_k \in A \setminus \{a\}$  for each of which we want to know whether  $b$  prefers that agent to  $a$  or not. Then exactly  $k$  comparison queries to  $b$  are necessary and sufficient to obtain this knowledge.*

**Proof.** The  $k$  queries  $\text{prefer}(b, a, a_i)$  for  $i = 1, \dots, k$  are clearly sufficient. Assume that  $k'$  queries to  $b$ , for some  $k' < k$ , are sufficient to obtain the desired information. Consider the auxiliary graph  $H$  with vertex set  $V_H = A$  and an edge  $\{a', a''\}$  for each of those  $k'$  queries  $\text{prefer}(b, a', a'')$ . As the set  $A' = \{a, a_1, a_2, \dots, a_k\}$  has  $k+1$  vertices and  $H$  has fewer than  $k$  edges, the set  $A'$  intersects at least two different connected components of  $H$ . Let  $a_j$ , for some  $1 \leq j \leq k$ , be a vertex that does not lie in the same component as  $a$ . Then the  $k'$  queries do not show whether  $b$  prefers  $a_j$  to  $a$  or not, which contradicts  $k'$  queries being sufficient. ◀

If an algorithm obtains for agents  $x$  and  $y$  with  $y \neq M(x)$  the information that  $M(x) \prec_x y$  (either via a direct query or via transitivity), we say that the algorithm *relates*  $y$  to  $M(x)$  for  $x$ . By Lemma 2, if the optimum relates  $k$  different elements to  $M(x)$  for  $x$ , it needs to make  $k$  queries to  $x$ . A pair  $(x, y)$  with  $y \neq M(x)$  such that the optimum relates  $y$  to  $M(x)$  for  $x$  is called a *relationship pair* (for  $x$ ). Lemma 2 implies the following.

► **Corollary 3.** *The total number of relationship pairs (for all agents  $x$ ) is a lower bound on the number of comparison queries the optimum makes.*

► **Theorem 4.** *Given a stable matching instance with one-sided uncertainty and a stable matching  $M$ , there is a 1-competitive algorithm that uses  $\sum_{a \in A} |\{b \in B \mid b \prec_a M(a)\}|$  queries for verifying that  $M$  is stable in the comparison query model.*

**Proof.** Since the preferences of agents on the  $A$ -side are not uncertain, for each  $(a, b) \notin M$ , we already know whether  $M(a) \prec_a b$ . If  $M(a) \prec_a b$ , then we do not have to execute any queries to show that  $(a, b) \notin M$  is not a blocking pair. Otherwise, every feasible query set has to prove  $M(b) \prec_b a$ . Therefore, for each element  $b \in B$ , there is a uniquely determined number  $n_b$  of elements of  $A$  that any solution (including the optimum) must relate to  $M(b)$  for  $b$ . Let  $K = \sum_{b \in B} n_b$  be the resulting number of relationship pairs.

Our algorithm simply queries  $\text{prefer}(b, M(b), a)$  for every pair  $(a, b) \notin M$  for which  $b \prec_a M(a)$ . These are exactly  $K$  queries. As the total number of relationship pairs is  $K$ , the optimum must also make  $K$  queries (Corollary 3). Hence, our algorithm is 1-competitive. ◀

The proof of Theorem 4 implies that the stable matching that maximizes the number of queries that are required to prove stability is the  $B$ -optimal matching.

► **Corollary 5.** *The number of comparison queries needed to verify that the  $B$ -optimal matching is stable is  $\max_{M \text{ stable}} \sum_{a \in A} |\{b \in B \mid b \prec_a M(a)\}|$ .*

### 3.2 Finding an $A$ -Optimal Stable Matching

We obtain the following positive result by adapting the classical deferred acceptance algorithm [13] with  $A$  making the proposals.

► **Theorem 6.** *For a given stable matching instance with one-sided uncertainty, there is a 1-competitive algorithm for finding a stable matching in the comparison query model. The algorithm actually finds an  $A$ -optimal stable matching.*

**Proof.** We utilize the classical deferred acceptance algorithm [13] where  $A$  makes the proposals, and we assume the reader's familiarity with it. An unmatched agent  $a \in A$  makes a proposal to their preferred agent  $b \in B$  by whom it has never been rejected. If  $b$  is unmatched, then  $b$  accepts the proposal and  $a$  and  $b$  get matched. If  $b$  is currently matched to some  $a' \in A$ , the algorithm makes a query  $prefer(b, a, a')$ . If the query result is that  $b$  prefers  $a$  to  $a'$ , then  $b$  accepts  $a$ 's proposal and becomes matched to  $a$  while  $a'$  becomes unmatched. Otherwise,  $b$  rejects the proposal and remains matched to  $a'$ . The algorithm terminates if all agents in  $A$  are matched or if every unmatched agent in  $A$  has been declined by all agents in  $B$ .

We show that this algorithm makes the minimum possible number of comparison queries.

We execute the deferred acceptance algorithm with  $A$  as the proposers, so it produces an  $A$ -optimal stable matching. Consider an arbitrary agent  $b \in B$ . Assume that  $b$  gets matched to  $a \in A$  in the stable matching. Let  $A_b = \{a, a_1, a_2, \dots, a_{k_b}\}$  (for some  $0 \leq k_b < n$ ) be the set of agents of  $A$  that proposed to  $b$  during the execution of the algorithm. Note that  $|A_b| = k_b + 1$  and the algorithm has executed  $k_b$  queries to  $b$ , each for two agents of  $A_b$  (the first agent of  $A$  that proposed to  $b$  did not require a query). Observe that each of  $a_1, \dots, a_{k_b}$  gets matched with an agent of  $B$  that they rank strictly lower than  $b$  in the final matching.

We claim that no stable matching can be identified without making at least  $k_b$  queries to  $b$ . Let  $M'$  be an arbitrary stable matching. Note that  $b$  rates  $M'(b)$  at least as highly as  $a$ , because  $M$  is the worst possible matching for  $B$ . Furthermore, for each  $a_i$  with  $1 \leq i \leq k_b$ , we have that  $a_i$  rates  $b$  strictly higher than  $M'(a_i)$  because  $M$  is  $A$ -optimal and  $a_i$  rates  $M(a_i)$  strictly lower than  $b$ . Thus, for none of the pairs  $(a_i, b)$  for  $1 \leq i \leq k_b$  to be a blocking pair, the queries of any optimal query set must establish that  $b$  rates  $M'(b)$  more highly than every  $a_i$  for  $1 \leq i \leq k_b$ . This can only be achieved with at least  $k_b$  queries.

The same argument applies to each  $b \in B$ , so we have that both the optimal number of queries and the number of queries made by the algorithm are equal to  $\sum_{b \in B} k_b$ . ◀

The proof of Theorem 6 implies that, for the  $A$ -optimal stable matching  $M$ , the optimal number of queries to prove that  $M$  is stable equals the optimal number of queries to prove that  $M$  is stable and  $A$ -optimal. Hence, proving optimality comes in this case for free.

### 3.3 Finding a $B$ -Optimal Stable Matching

The problem of finding a  $B$ -optimal stable matching is substantially more challenging. While there still exists a 1-competitive algorithm in special cases, e.g., when all  $A$ -side preference lists are equivalent (see the full version [3]), this is not the case for arbitrary instances.

We first describe an algorithm that is  $\mathcal{O}(n)$ -competitive. Complementing this result, we then show that every (randomized) online algorithm has competitive ratio at least  $\Omega(n)$  for finding a  $B$ -optimal stable matching. Finally, we show that the offline problem of determining the optimal number of queries for computing a  $B$ -optimal stable matching is NP-hard and give an  $\mathcal{O}(\log n \log \log n)$ -approximation.

### 3.3.1 Algorithm for Computing a $B$ -Optimal Stable Matching

We first consider the problem of verifying that a given stable  $B$ -optimal matching is indeed stable and  $B$ -optimal. An algorithm for this problem needs to prove that  $M$  has no blocking pair and that no alternating cycle with respect to  $M$  is a rotation. For each potential blocking pair  $(a, b)$  that cannot be ruled out because of  $a$ 's preferences, such an algorithm has to prove that it is not a blocking pair using a suitable query to  $b$  as discussed in Section 3.1.

The more involved part is proving that  $M$  is  $B$ -optimal. By Lemma 1,  $M$  is  $B$ -optimal if and only if it does not expose a rotation. Based on the known  $A$ -side preferences, each edge  $(a, b)$  with  $M(a) \prec_a b$  could potentially be an  $r$ -edge. Thus, each cycle that alternates between such edges and edges in  $M$  could potentially be a rotation. An algorithm that proves  $B$ -optimality has to prove for each such alternating cycle that at least one non-matching edge  $(a, b)$  on that cycle is not an  $r$ -edge. By definition, there are two possible ways to prove that an edge  $(a, b)$  with  $M(a) \prec_a b$  is not an  $r$ -edge:

1. Query  $b$  and find out that  $b$  prefers  $M(b)$  to  $a$ . Then,  $b$  cannot be  $s_A(a)$  as  $b$  does not prefer  $a$  to  $M(b)$ .
2. Query one  $b'$  with  $M(a) \prec_a b' \prec_a b$  and find out that  $b'$  prefers  $a$  to  $M(b')$ . Then,  $b$  cannot be the most-preferred element in  $a$ 's list that prefers  $a$  to her current partner, as  $b'$  has that property and is preferred over  $b$ .

Corollary 5 gives the optimal number of queries to prove that the matching  $M$  is stable, which is a lower bound on the optimal number of queries necessary to prove that  $M$  is stable and  $B$ -optimal. Let  $Q(M)$  denote this number. However, there exist instances where  $Q(M) = 0$  and  $Q_B(M) > 0$  for the optimal number  $Q_B(M)$  of queries to prove that  $M$  is stable and  $B$ -optimal. Consider an instance where all elements of  $A$  have distinct first choices and let  $M$  denote the matching that matches all elements of  $A$  to their respective first choice. Then, there is a realization of  $B$ -side preference lists such that the matching  $M$  is also  $B$ -optimal. For this realization we have  $Q(M) = 0$  and  $Q_B(M) > 0$ . This implies that the lower bound of Corollary 5 is not strong enough for analyzing algorithms that verify  $B$ -optimality as we cannot prove that such an algorithm makes at most  $c \cdot Q(M)$  queries. We give another lower bound on the optimal number of queries.

► **Lemma 7.** *The optimal number of queries for verifying (and thus also for finding) the  $B$ -optimal stable matching is at least  $n - 1$  for every instance of the stable matching problem with one-sided uncertainty.*

**Proof.** Let  $M$  be the  $B$ -optimal stable matching for the given instance. For  $a \in A$ , call a query an  $a$ -query if it reveals for some  $b \in B$  with  $b \neq M(a)$  whether  $b$  prefers  $a$  to her current partner or not. We claim that an optimal algorithm needs to make at least one  $a$ -query for every  $a \in A$  with at most a single exception. Assume for a contradiction that the optimal algorithm makes neither an  $a$ -query nor an  $a'$ -query for two distinct elements  $a, a' \in A$ . If  $a$  prefers  $M(a)$  over  $M(a')$  and  $a'$  prefers  $M(a')$  over  $M(a)$ , then it is impossible to exclude the possibility that  $(a, M(a)), (a', M(a'))$  is a rotation exposed in  $M$ , because the only way to prove that  $(a, M(a'))$  is not an  $r$ -edge is via an  $a$ -query, and similarly for  $(a', M(a))$ . If  $a$  prefers  $M(a')$  over  $M(a)$ , then an  $a$ -query to  $M(a')$  is necessary to exclude that  $(a, M(a'))$  is a blocking pair. If  $a'$  prefers  $M(a)$  over  $M(a')$ , then an  $a'$ -query to  $M(a)$  is necessary for the analogous reason. Hence, the claim holds. We note that the  $n - 1$  queries whose existence is asserted by the claim are distinct: A query to some  $b \in B$  cannot be an  $a$ -query and at the same time an  $a'$ -query for some  $a' \neq a$ , as the query  $prefer(b, a, a')$  cannot yield previously unknown information about how both  $a$  and  $a'$  compare to  $M(b)$  in  $b$ 's preference list. ◀

■ **Algorithm 1** Algorithm to find the  $B$ -optimal stable matching using comparison queries.

---

**Input:** Instance of the stable matching problem with one-sided uncertainty.

```

1  $M \leftarrow A$ -optimal matching computed using Theorem 6 ;
2  $N \leftarrow \{a \in A \mid M(a) \text{ is last in } \prec_a\}$  ;          /* Elements without  $r$ -edge */
3  $\forall a \in A \setminus N: p(a) \leftarrow$  first element in  $\prec_a$  after  $M(a)$ ;
4  $\forall a \in A \setminus N: r(a) \leftarrow \top$  ;    /* known  $r$ -edges or  $\top$  if  $r$ -edge still unknown */
5 foreach  $a \in A \setminus N$  do
6   repeat
7      $t \leftarrow \text{prefer}(p(a), a, M(p(a)))$  ;
8     if  $t = M(p(a))$  then
9       if  $p(a)$  is the last element of  $\prec_a$  then  $N \leftarrow N \cup \{a\}$  ;
10      else  $p(a) \leftarrow$  direct successor of  $p(a)$  in  $\prec_a$  ;
11      else
12         $r(a) \leftarrow p(a)$ ;          /*  $r(a)$  and  $a$  form an  $r$ -edge */
13    until  $r(a) \neq \top$  or  $a \in N$ ;
14 if  $M$  exposes a rotation  $R$  then
15    $M \leftarrow$  stable matching constructed from  $M$  by applying  $R$ ;
16    $N \leftarrow N \cup \{a \in A \cap R \mid M(a) \text{ is last in } \prec_a\}$ ;
17    $\forall a \in (A \cap R) \setminus N: r(a) \leftarrow \top$  and  $p(a) \leftarrow$  first element in  $\prec_a$  after  $M(a)$ ;
18    $\forall a \in (A \setminus R) \setminus N: p(a) \leftarrow r(a)$  and  $r(a) \leftarrow \top$ ;
19   Jump to Line 5;
20 return  $M$ ;

```

---

Next, we give an  $\mathcal{O}(n)$ -competitive algorithm for finding a  $B$ -optimal matching and analyze it by exploiting the lower bounds on the optimal number of queries of Corollary 5 and Lemma 7. For pseudocode see Algorithm 1.

1. Find an  $A$ -optimal matching using the 1-competitive algorithm for  $A$ -optimal matchings.
2. Search for a rotation by asking, for every  $a \in A$ , the elements of  $B$  that are below  $M(a)$  in  $a$ 's preference list in order of  $\prec_a$  whether they prefer  $a$  to their current partner, until either an  $r$ -edge is found or we know that  $a$  has no  $r$ -edge.
3. If a rotation  $R$  is found, apply that rotation. The agents  $a \in A \cap R$  then no longer have a known  $r$ -edge as their previous  $r$ -edge is now their matching edge. However, the new  $r$ -edge partner of such an agent must be further down the preference list of  $a$  than the old one. The elements  $a \in A \setminus R$  that had an  $r$ -edge to an element  $b \in B \cap R$  can no longer be sure that their edge to  $b$  is an  $r$ -edge since  $b$  has a new matching partner  $M(b)$ , so  $b$  must be asked again whether it prefers the new partner over  $a$  when searching for the new  $r$ -edge of  $a$ . The algorithm then repeats Step 2 but starts the search for the new rotation edge of an agent  $a \in A$  at either the previous rotation edge (if  $a \in A \setminus R$ ) or at the direct successor of the new  $M(a)$  in  $\prec_a$  (if  $a \in A \cap R$ ).
4. When a state is reached where it is known for every  $a \in A$  what its  $r$ -edge is (or that it has no  $r$ -edge) but the  $r$ -edges do not form a rotation, the algorithm terminates and outputs  $M$ .

► **Theorem 8.** *Given a stable matching instance with one-sided uncertainty, the algorithm is  $\mathcal{O}(n)$ -competitive for finding a  $B$ -optimal stable matching using comparison queries.*

**Proof.** Let  $\text{OPT}$  denote the number of queries made by an optimal algorithm. Since finding any stable matching can never require more queries than finding a  $B$ -optimal stable matching, Theorem 6 implies that the algorithm makes at most  $\text{OPT}$  queries in the first step.

We analyze the queries executed *after* the first algorithm step. Call a query *good* if it is the first query involving a specific combination of an agent  $a \in A$  and an agent  $p(a) \in B$ , i.e., the first query of form  $\text{prefer}(p(a), a, M(p(a)))$  for that specific combination of  $p(a)$  and  $a$ . All other queries are *bad*. By definition of good queries, the algorithm makes at most  $n^2$  such queries since this is the maximum number of good queries that can exist. Since  $\text{OPT} \geq n - 1$  (Lemma 7), the number of good queries is  $\mathcal{O}(n) \cdot \text{OPT}$ .

Consider the bad queries and a fixed  $a \in A$ . In the second step of the algorithm, it repeatedly executes queries of the form  $\text{prefer}(p(a), a, M(p(a)))$  with  $p(a) \in B$  to find out if  $(a, p(a))$  is an  $r$ -edge, starting with the direct successor  $p(a)$  of  $M(a)$  in  $\prec_a$ . If  $(a, p(a))$  is not an  $r$ -edge, then the next query partner  $p(a)$  for  $a$  moves one spot down in the list  $\prec_a$ . This is repeated until the  $r$ -edge  $(a, r(a))$  of  $a$  is found or we know that  $a$  does not have an  $r$ -edge. Here,  $r(a)$  refers to the element that forms an  $r$ -edge with  $a$ .

If  $a$  does not have an  $r$ -edge, there will be no more queries for  $a$  again as all  $b \in B$  that are lower than  $M(a)$  in the preference list of  $a$  prefer their current partner  $M(b)$  over  $a$  and this partner will only improve during the execution of the algorithm. Otherwise,  $a$  will be considered again in the second step of the algorithm only if a rotation was found in the third step. If  $a$  is part of the rotation, then  $r(a) = p(a)$  will be the new matching partner of  $a$  and  $p(a)$  will be moved one spot down in  $\prec_a$ . Only if  $a$  is not part of the rotation,  $p(a) = r(a)$  remains unchanged by definition of the third step. In conclusion, the next query partner  $p(a)$  of  $a$  moves down one spot in  $\prec_a$  after each query for  $a$  unless a rotation is found that does not contain  $a$ . This means that a bad query for  $a$  can only occur as the first query for  $a$  after a new rotation that does not involve  $a$  is found. Thus, each rotation can cause at most  $|A| - 2$  bad queries (at least two members of  $A$  must be involved in the rotation). Thus, the number of bad queries is at most  $(n - 2) \cdot n_r$  for the number of applied rotations  $n_r$ .

For each applied rotation, at least two agents of  $A$  get re-matched to agents of  $B$  that are lower down on their preference lists than their previous matching partner. This increases the lower bound on the optimal number of queries to show stability (cf. Corollary 5) by at least 2. Thus, Corollary 5 implies  $\text{OPT} \geq 2 \cdot n_r$ . We can conclude that the number of bad queries is at most  $(n - 2) \cdot n_r \leq \mathcal{O}(n) \cdot \text{OPT}$ . ◀

### 3.3.2 Lower Bound for Computing a $B$ -Optimal Matching

We give a lower bound of  $\Omega(n)$  on the competitive ratio for finding a  $B$ -optimal stable matching with comparison queries. This implies that the result of Theorem 8 is, asymptotically, best-possible. Further, the lower bound also holds for verifying that a given matching is  $B$ -optimal.

► **Theorem 9.** *In the comparison query model, every deterministic or randomized online algorithm for finding a  $B$ -optimal stable matching in a stable matching instance with one-sided uncertainty has competitive ratio  $\Omega(n)$ .*

**Proof.** We show the statement for deterministic algorithms and refer to the full version [3] for the extension to randomized ones. The proof of the randomized lower bound exploits Yao's principle [5, 32] and uses a randomized version of the instance we describe here to show the statement. Consider the following instance (cf. Fig. 1) with two sets of agents  $A = \{a_0, \dots, a_{n-1}\}$  and  $B = \{b_0, \dots, b_{n-1}\}$ , and assume  $n/2$  to be even. If this is not the case, then the constant factor in the lower bound will be slightly worse.

■ **Figure 1** Example of the lower bound construction for finding  $B$ -optimal matchings. The solid edges represent the  $A$ -optimal matching  $M$  that needs to be shown to be also  $B$ -optimal using queries. The dashed edges represent rotation edges. Each of the agents in  $\{a_0, a_1, \dots, a_5\}$  also has a rotation edge to some agent in  $\{b_6, b_7, b_8, b_9, b_{10}, b_{11}\}$  that is not shown. An asterisk ( $*$ ) indicates that the remaining agents are placed in arbitrary order in the preference list. A diamond ( $\diamond$ ) indicates that the adversary decides in response to the queries made by the algorithm which of the agents in  $\{a_0, a_1, \dots, a_5\}$  are placed at the front of the preference list and which at the back.

We partition  $A$  into three subsets  $A_1 = \{a_0, \dots, a_{\frac{n}{2}-1}\}$ ,  $A_2 = \{a_{\frac{n}{2}}, \dots, a_{n-2}\}$  and  $A_3 = \{a_{n-1}\}$ , and  $B$  into two subsets,  $B_1 = \{b_0, \dots, b_{\frac{n}{2}-1}\}$  and  $B_2 = B \setminus B_1$ .

In the following, we first define the known  $A$ -side preferences and the adversarial strategy. Then we give bounds on the optimal number of queries and the number of queries made by any deterministic algorithm.

**A-side preferences.** Consider the following preference lists for  $A$ . For an agent  $a_i \in A_1$ , the preference list consists of three parts,  $P(a_i) = P_1(a_i)P_2(a_i)P_3(a_i)$ . The first part of the list is the corresponding  $i^{\text{th}}$  agent of  $B$ , i.e.,  $P_1(a_i) = (b_i)$ . The second part consists of the  $\frac{n}{2}$  agents of set  $B_2$  in increasing order, i.e.,  $P_2(a_i) = (b_{\frac{n}{2}}, b_{\frac{n}{2}+1}, \dots, b_{n-2}, b_{n-1})$ . The last part  $P_3(a_i)$  consists of the agents of  $B_1 \setminus \{b_i\}$  in an arbitrary order.

For an agent  $a_i \in A_2$ , the preference list starts with agent  $b_i$ , followed by the last agent  $b_{n-1}$  and finally an arbitrary order of the remaining agents in group  $B$ . For the single agent  $a_{n-1}$  in set  $A_3$ , the preference list starts with agent  $b_{n-1}$  followed by an arbitrary order of the remaining agents of set  $B$ .

**Adversarial strategy.** The preference lists of the agents in set  $B$  are unknown. The instance has the  $A$ -optimal matching  $M = \{(a_i, b_i) \mid 0 \leq i < n\}$ . The adversary will ensure that this matching is also  $B$ -optimal. Since each  $a_i$  is matched with its top choice, proving stability does not require any queries. To prove  $B$ -optimality of  $M$ , the executed queries must prove that there is no rotation.

The adversary will ensure that  $M$  can be shown to be a  $B$ -optimal matching with  $\mathcal{O}(n)$  queries while any deterministic algorithm is forced to make  $\Omega(n^2)$  queries.

To achieve this, the adversary sets the preferences of the agents of  $B_1$  independent of the algorithm's actions as follows. For each odd  $i \in \{1, 3, 5, \dots, (n/2) - 1\}$ , we let the preference list of  $b_i$  start with  $a_{i-1}$  followed by  $a_i$  and finally all remaining agents in  $A$  in an arbitrary order. The preference list of  $b_{i-1}$  starts with  $a_i$  followed by  $a_{i-1}$  and then the remaining

agents in  $A$  in an arbitrary order. Using these preferences, the sequences  $(a_{i-1}, b_{i-1}), (a_i, b_i)$  are potential rotations. To prove that such a sequence is not a rotation, an algorithm has to show that either  $(a_{i-1}, b_i)$  or  $(a_i, b_{i-1})$  is not an  $r$ -edge. The only way of showing this is to prove that either  $a_{i-1}$  or  $a_i$  instead has an  $r$ -edge to some agent of  $B_2$ .

Consider any deterministic algorithm. The adversary selects the preferences of the agents in  $B_2$  in such a way that the following properties hold:

- (P1) Agent  $a_{n-1}$  has no  $r$ -edge. Note that, by the definition of the preferences of  $B_1$  above,  $a_{n-1}$  already cannot have a rotation edge to an agent of  $B_1$ .
- (P2) Each agent in  $A_2$  has an  $r$ -edge to  $b_{n-1}$ .
- (P3) Each agent  $a_i$  in  $A_1$  has an  $r$ -edge to some agent  $b_{t(i)}$  of  $B_2$ . The choice of that agent  $b_{t(i)}$  depends on the queries made by the algorithm.

The properties (P1)–(P3) ensure that there is no rotation, as the alternating path starting at any  $a \in A \setminus \{a_{n-1}\}$  with the  $r$ -edge of that agent ends at  $a_{n-1}$ , which has no  $r$ -edge.

Let  $t(i)$  denote the index of the agent  $b_{t(i)}$  of  $B_2$  to which  $a_i \in A_1$  has an  $r$ -edge. This index is determined by the adversary in response to the queries made by the algorithm. Concretely, the adversary lets  $t(i)$  be the index of the *last agent*  $b_j \in B_2$  for which the algorithm makes a query of the form  $\text{prefer}(b_j, a_i, *)$ , where we use  $\text{prefer}(b_j, a_i, *)$  as a shorthand to refer to queries  $\text{prefer}(b_j, a_i, a_{i'})$  or  $\text{prefer}(b_j, a_{i'}, a_i)$  for some  $i'$ . If the algorithm doesn't make queries of this form for all  $b_j \in B_2$ , then let  $t(i)$  be an arbitrary  $j$  such that the algorithm does not make a query of this form for  $b_j \in B_2$ . The adversary sets the preferences of the agents in  $B_2$  in such a way that  $b_{t(i)}$  prefers  $a_i$  to her partner  $a_{t(i)}$  in the A-optimal matching  $M$  while all other  $b_j \in B_2$  prefer their partner in the A-optimal matching  $a_j$  to  $a_i$ . For example, if the algorithm was to make queries  $\text{prefer}(b_j, a_i, a_j)$  for all  $b_j \in B_2$  (which it might do in order to check whether  $a_i$  has an  $r$ -edge to one of these agents), the adversary would answer **false** to the first  $\frac{n}{2} - 1$  such queries and **true** to the final one.

To achieve the properties (P1)–(P3), the adversary sets the preferences of each agent  $b_j$  of  $B_2$  as follows:

- $b_j$  prefers  $a_i \in A_1$  to  $a_j$  if and only if  $j = t(i)$ .
- If  $j \neq n - 1$ ,  $b_j$  prefers  $a_j$  to  $a_{j'}$  for all  $j' \neq j, a_{j'} \in A_2$ .
- If  $j = n - 1$ ,  $b_j$  prefers  $a_{j'}$  to  $a_j$  for all  $j' \neq j, a_{j'} \in A_2$ .

This can be done by letting the preference list of  $b_j$  contain first the agents  $a_i \in A_1$  with  $j = t(i)$  in some order, then the agents of  $A_2$  in some order (only ensuring for  $b_j$  that  $a_j$  comes first among the agents of  $A_2$  if  $j \neq n - 1$  and that  $a_j$  comes last among the agents of  $A_2$  if  $j = n - 1$ ), and finally the agents  $a_i \in A_1$  with  $j \neq t(i)$  in some order.

**Upper bound on the optimal query cost.** An optimal solution for the instance can prove that matching  $M$  is  $B$ -optimal by verifying that the properties (P1)–(P3) indeed hold by using at most  $n - 1 + \frac{n}{2} - 1 + \frac{n}{2} = 2n - 2$  queries as follows:

- The  $n - 1$  queries  $\text{prefer}(b_i, a_{n-1}, a_i) = \text{false}$  for  $i \leq n - 2$  show that  $a_{n-1}$  has no  $r$ -edge.
- Each of the  $\frac{n}{2} - 1$  queries  $\text{prefer}(b_{n-1}, a_{\frac{n}{2}+i}, a_{n-1}) = \text{true}$  for  $0 \leq i \leq \frac{n}{2} - 2$  shows that  $a_{\frac{n}{2}+i}$  has an  $r$ -edge to  $b_{n-1}$ . This is because each agent of  $A_2$  has  $b_{n-1}$  in its preference list directly after its current matching partner. So if  $b_{n-1}$  prefers an agent of  $A_2$  over its current partner  $a_{n-1}$ , then this directly gives us an  $r$ -edge.
- Each of the  $\frac{n}{2}$  queries  $\text{prefer}(b_{t(i)}, a_i, a_{t(i)}) = \text{true}$  for  $0 \leq i \leq \frac{n}{2} - 1$  shows that  $a_i$  has a rotation edge to some agent in  $B_2$ . Based on the result of such a query,  $a_i$  must have an  $r$ -edge to either  $b_{t(i)}$  or to some other agent of  $B_2$  that is higher up in  $a_i$ 's preference list.

**Lower bound on the algorithm's query cost.** We provide to the algorithm the information that  $a_{n-1}$  has no  $r$ -edge, that each agent of  $A_2$  has an  $r$ -edge to  $b_{n-1}$ , and we reveal the full preference lists of all agents in  $B_1$ . Clearly, this extra information can only reduce the number of queries a deterministic algorithm may need as it could simply ignore the information.

For each agent  $a_i \in A_1$ , the algorithm will either make queries of the form  $prefer(b_j, a_i, *)$  for all  $b_j \in B_2$  or not. Call  $a_i$  *resolved* in the former case and *unresolved* otherwise. For any resolved agent, the algorithm may have determined that it has an  $r$ -edge to an agent of  $B_2$  and hence cannot be part of a rotation. For the unresolved agents, the algorithm cannot know whether they have an  $r$ -edge to an agent in  $B_2$ .

As argued above, for each odd  $i \in \{1, 3, 5, \dots, \frac{n}{2} - 1\}$ , the algorithm has to resolve either  $a_i$  or  $a_{i-1}$  to prove that  $(a_i, b_i), (a_{i-1}, b_{i-1})$  is not a rotation. Thus, it must resolve at least  $n/4$  agents. For each resolved agent, the algorithm has made queries of the form  $prefer(b_j, a_i, *)$  for each  $b_j \in B_2$ . This totals to at least  $\frac{n}{4} \cdot \frac{n}{2} \cdot \frac{1}{2} = \frac{n^2}{16} \in \Omega(n^2)$  queries. Note that we divide  $\frac{n}{4} \cdot \frac{n}{2}$  by two as a single query  $prefer(b_j, a_i, a_{i'})$  is of the form  $prefer(b_j, a_i, *)$  and also  $prefer(b_j, a_{i'}, *)$ . ◀

### 3.3.3 Offline Results for Computing $B$ -Optimal Stable Matchings

We show NP-hardness for the offline problem of verifying a given matching  $M$  to be stable and  $B$ -optimal. Recall that in the offline problem we assume full knowledge of the  $B$ -side preferences but still want to compute a query set of minimum size that a third party without knowledge of the  $B$ -side preferences could use to verify the  $B$ -optimality of  $M$ .

► **Theorem 10.** *The offline problem of computing an optimal set of comparison queries for finding (or verifying) the  $B$ -optimal stable matching in a stable matching instance with one-sided uncertainty is NP-hard.*

**Proof.** We give a reduction from the NP-hard *Minimum Feedback Arc Set (FAS)* problem. Given a directed graph  $G = (V, E)$ , a feedback arc set is a subset of edges  $E' \subseteq E$  which, if removed from  $G$ , leaves the remaining graph acyclic. The FAS problem is to decide for a given directed graph and some  $k \in \mathbb{Z}_+$ , whether there is a feedback arc set  $E'$  with  $|E'| \leq k$ .

Given an instance of FAS with  $G = (V, E)$  and some  $k$ , we construct a stable matching instance with one-sided uncertainty as follows. For each node  $v$  of  $G$ , introduce an agent  $v$  in  $A$  and an agent  $v'$  in  $B$ . Let  $N^+(v)$  denote the set of out-neighbors of  $v$  in  $G$ , and  $d^+(v) = |N^+(v)|$ . The preference list of  $v$  is such that it ends with  $v'$  followed by all  $u'$  for  $u \in N^+(v)$ . All other  $w'$  in  $B$  come before  $v'$ . Thus, the elements of  $B \setminus \{u' \mid u \in N^+(v)\}$  are the most preferred partners of  $v$ , followed by  $v'$  and finally the elements of  $\{u' \mid u \in N^+(v)\}$ . Let  $M$  be the matching that matches  $v$  to  $v'$ , for all  $v$ . The preference lists of  $b \in B$  are such that  $M$  is the  $B$ -optimal stable matching: Every  $v'$  has  $v$  as top preference, and the remaining agents of  $A$  follow in arbitrary order. By selecting the matching  $M$  this way, we have that, for every  $v \in A$ , all edges to elements of  $\{u' \mid u \in N^+(v)\}$  are potential  $r$ -edges. To prove that such an edge  $(v, u')$  is not an  $r$ -edge, an algorithm has to compare  $u$  and  $v$  from the perspective of  $u'$  to prove that  $u'$  prefers  $M(u') = u$  over  $v$ .

The number of queries  $Q(M)$  needed to verify the stability of  $M$  is determined by  $M$  and is polynomial-time computable by using Theorem 4. To prove  $B$ -optimality of  $M$ , we need to show that there is no rotation (Lemma 1). Indeed, there is a query strategy with  $k$  queries for verifying that there is no rotation if and only if there is a feedback arc set in  $G$  of size  $k$ . To see this, observe that every directed cycle in  $G$  corresponds to a potential rotation in the matching instance, and every query that excludes one of the edges of the potential rotation from being an  $r$ -edge corresponds to the removal of the corresponding arc in  $G$ .

Note that, for the constructed instance, all queries to verify the stability of  $M$  obtain information of the form  $M(b) \prec_b a$  for  $a \in A$  and  $b \in B$  with  $b \prec_a M(a)$ . On the other hand, all queries that help to verify the absence of a rotation obtain information of the form  $M(b) \prec_b a$  for  $a \in A$  and  $b \in B$  with  $M(a) \prec_a b$ . As these are disjoint query sets, we can conclude that there is a query strategy that proves  $M$  to be stable and  $B$ -optimal with at most  $Q(M) + k$  queries if and only if there is a feedback arc set in  $G$  of size at most  $k$ . ◀

We also prove the following approximation for the offline problem by exploiting an  $\mathcal{O}(\log n \log \log n)$ -approximation for weighted feedback arc set by Even et al. [12].

► **Theorem 11.** *The offline problem of computing an optimal set of comparison queries for finding the  $B$ -optimal stable matching in a stable matching instance with one-sided uncertainty can be approximated within ratio  $\mathcal{O}(\log n \log \log n)$ .*

**Proof.** Let  $M$  be the  $B$ -optimal matching. We give an algorithm that verifies  $M$  to be stable and  $B$ -optimal by executing at most  $\mathcal{O}(\log n \log \log n) \cdot \text{OPT}$  queries, where  $\text{OPT}$  is the optimal number of queries for the same instance. First, the algorithm proves that  $M$  is stable using Theorem 4. This leads to at most  $\text{OPT}$  queries.

After that, the algorithm has to prove  $B$ -optimality. First, for every  $a \in A$  that has an  $r$ -edge to an agent  $r(a) \in B$ , the algorithm queries  $\text{prefer}(r(a), a, M(r(a)))$ . Since  $(a, r(a))$  is an  $r$ -edge, this query must return that  $r(a)$  prefers  $a$  over  $M(r(a))$ . This leads to at most  $n \leq \text{OPT} + 1$  queries ( $n \leq \text{OPT} + 1$  holds by Lemma 7). Note that, for an  $a \in A$  with an  $r$ -edge, the query  $\text{prefer}(r(a), a, M(r(a)))$  proves that  $a$  has an  $r$ -edge but is not necessarily sufficient to prove that  $(a, r(a))$  is indeed the  $r$ -edge of  $a$ . If there is an agent  $b \in B$  with  $M(a) \prec_a b \prec_a r(a)$  for which we have not yet verified whether  $b$  prefers  $a$  over  $M(b)$ , then  $(a, b)$  could also still be the  $r$ -edge of  $a$ . We call such pairs  $(a, b)$  *potential  $r$ -edges* and let  $P$  denote the set of these edges.

It remains to consider the graph  $G$  defined by the matching edges, the  $r$ -edges  $R$ , and all potential  $r$ -edges  $P$ . If  $G$  has no cycle alternating between edges in  $M$  and edges in  $P \cup R$ , then we have shown that  $M$  does not expose a rotation and, thus, is  $B$ -optimal. Otherwise, the algorithm has to execute queries  $\text{prefer}(b, a, M(b))$  for edges  $(a, b) \in P$  to prove that they are not actually  $r$ -edges until it becomes clear that  $M$  has no rotation.

To select the edges  $(a, b) \in P$  for which the algorithm executes such queries, we exploit the  $\mathcal{O}(\log n \log \log n)$ -approximation for weighted feedback arc set by Even et al. [12]. To this end, we create an instance of the weighted feedback arc set problem by considering the vertices  $A \cup B$ , adding the edges  $M \cup R$  with weight  $\infty$  each and adding the edges  $P$  with weight 1 each. We orient all edges in  $M$  from the  $B$ -side vertex to the  $A$ -side vertex and all edges in  $R \cup P$  from the  $A$ -side vertex to the  $B$ -side vertex. The orientation ensures that all cycles in the graph alternate between  $M$ -edges and  $R \cup P$ -edges. Since the matching  $M$  is  $B$ -optimal by assumption, there cannot be an alternating cycle using only edges in  $M \cup R$ , so there must be a feedback arc set that only uses edges in  $P$ . The choice of the edge weights ensures that every approximation algorithm for weighted feedback arc set finds such a solution. We use the  $\mathcal{O}(\log n \log \log n)$ -approximation to find such a feedback arc set  $F \subseteq P$ . Since removing  $F$  from the instance yields an acyclic graph, querying  $\text{prefer}(b, a, M(b))$  for each  $(a, b) \in F$  proves that  $M$  does not expose a rotation. As the minimum weight feedback arc set is the cheapest way to prove that  $M$  does not have a rotation, we have  $|F| \leq \mathcal{O}(\log n \log \log n) \cdot \text{OPT}$ , which implies the theorem. ◀

## 4 Stable Matching with Interview Queries

In this section, we summarize our results for the interview query model. We refer to the full version [3] for formal proofs. Most of our results and proofs are quite similar to their counterparts for comparison queries. This might be surprising as interview and comparison queries are, in a sense, incomparable: While interview queries allow us to more efficiently determine full preference lists, a comparison between two agents can be done more efficiently via a single comparison query. As we show the same (asymptotic) bounds on the competitive ratio, the latter seems to be the deciding factor.

► **Theorem 12.** *In the interview query model, the best possible (randomized) competitive ratio for finding the  $B$ -optimal stable matching in an instance of stable matching with one-sided uncertainty is in  $\Theta(n)$ .*

For the offline problem of verifying a given  $B$ -optimal stable matching with interview queries, Rastegari et al. [30] show NP-hardness in a setting with partial uncertainty on both sides. As their proof exploits the possibility of giving partial information as part of the input, it does not directly translate to our setting with one-sided uncertainty.

► **Theorem 13.** *The offline problem of computing an optimal set of interview queries for finding the  $B$ -optimal stable matching in a stable matching instance with one-sided uncertainty is NP-hard.*

A 1-competitive algorithm for finding a stable matching and verifying a given stable matching with interview queries is implied by the results and arguments from [30] for a more general uncertainty setting.

## 5 Stable Matching with Set Queries

We consider the stable matching problem with one-sided uncertainty and set queries. Note that set queries are a natural generalization of comparison queries. For verifying any  $B$ -optimal matching, we show that the optimal number of set queries is at least  $n - 1$ . We also observe that there is an algorithm that makes at most  $n^2$  queries for finding the  $B$ -optimal matching (or an  $A$ -optimal matching if we want to), as one can sort all preference lists using  $n^2$  set queries. This implies an  $\mathcal{O}(n)$ -competitive algorithm for finding the  $B$ -optimal matching. For the subproblem of verifying that a given matching is  $B$ -optimal, we give an  $\mathcal{O}(\log n)$ -competitive algorithm by exploiting the additional power of set queries in an involved binary search algorithm. If we only have to verify stability for a given matching, we give a 1-competitive algorithm. Furthermore, we show that the offline problem of verifying that a given matching does not have a rotation is NP-hard.

### 5.1 Verifying That a Given Matching Is Stable

We start by characterizing the optimal number of queries (and query strategy) to verify that a given matching  $M$  is stable. The main difference to the comparison model is that, for a fixed  $b \in B$ , a single query  $\text{top}(b, \{a \mid b \prec_a M(a)\} \cup \{M(b)\})$  is sufficient to prove that  $b$  is not part of any blocking pair.

► **Theorem 14.** *Consider a stable matching instance with one-sided uncertainty and a stable matching  $M$ . The minimum number of set queries to verify that  $M$  is stable is  $|\{b \in B \mid \exists a \in A: b \prec_a M(a)\}| \leq n$ . Further, there is a 1-competitive algorithm to verify that  $M$  is stable.*

**Proof.** Consider an arbitrary  $b \in B$ . Let  $Z(b) = \{a \in A \mid b \prec_a M(a)\}$ , i.e.,  $Z(b)$  contains all  $a \in A$  that could potentially form a blocking pair with  $b$ . Thus,  $M$  can only be stable if  $M(b) \prec_b a$  holds for all  $b \in B$  and  $a \in Z(b)$ . If  $Z(b) \neq \emptyset$ , at least one query to  $b$  is necessary, and the query  $top(b, Z(b) \cup \{M(b)\})$  with answer  $M(b)$  reveals all the required information to prove that  $b$  is not part of any blocking pair. Thus, the minimum number of queries to confirm that  $M$  is stable is  $|\{b \in B \mid \exists a \in A: b \prec_a M(a)\}|$  as claimed. Furthermore, the algorithm that queries  $top(b, Z(b) \cup \{M(b)\})$  for all  $b \in B$  with  $Z(b) \neq \emptyset$  is 1-competitive.  $\blacktriangleleft$

## 5.2 Verifying That a Given Matching Is Stable and $B$ -Optimal

For the problem of confirming that a given matching is  $B$ -optimal by using set queries, we show that every algorithm needs to execute at least  $n - 1$  queries. This is analogous to the setting with comparison queries and uses a similar proof as Lemma 7. It implies that finding a  $B$ -optimal matching also requires at least  $n - 1$  queries.

► **Lemma 15.** *Consider an arbitrary stable matching instance with one-sided uncertainty and the  $B$ -optimal matching  $M$ . Every algorithm needs at least  $n - 1$  set queries to verify that  $M$  is indeed stable and  $B$ -optimal.*

**Proof.** For each  $b \in B$ , let  $Z(b) = \{a \in A \mid b \prec_a M(a)\}$  and let  $S = \{b \in B \mid Z(b) \neq \emptyset\}$ . By the proof of Theorem 14, every algorithm needs to execute at least one query of the form  $top(b, X)$  with  $X \subseteq A$  for all  $b \in S$  and this query has to return  $M(b)$  as the top choice. Since verifying  $B$ -optimality includes proving stability, this leads to at least  $|S|$  queries.

Consider an arbitrary algorithm that verifies  $M$  to be  $B$ -optimal and let  $A_1 \subseteq A$  denote the agents of  $A$  that are returned as the top choice by some query of the algorithm. Then  $|S| \leq |A_1|$  and  $\{a \in A \mid \exists b \in S: M(b) = a\} \subseteq A_1$  by the argumentation above.

If  $|A_1| \geq n - 1$ , then the statement follows immediately, so assume  $|A_1| < n - 1$  and let  $A_2 = A \setminus A_1$ . Since  $|A_1| < n - 1$ , the set  $A_2$  has at least two distinct members  $a_1$  and  $a_2$ . Furthermore, we must have  $M(a_1), M(a_2) \notin S$  as observed above. By definition of  $S$ , we have  $M(a_1) \prec_{a_1} M(a_2)$  and  $M(a_2) \prec_{a_2} M(a_1)$ . This means that  $(a_1, M(a_2))$  and  $(a_2, M(a_1))$ , based on the initially given information, could potentially be rotation edges. Thus,  $(a_1, M(a_1)), (a_2, M(a_2))$  could potentially be a rotation and the algorithm has to prove that this is not the case by showing that one of  $(a_1, M(a_2))$  and  $(a_2, M(a_1))$  is not an  $r$ -edge. To prove that  $(a_1, M(a_2))$  is not an  $r$ -edge, one has to either verify  $a_2 \prec_{M(a_2)} a_1$  or  $a_1 \prec_b M(b)$  for some  $b \in B$  with  $M(a_1) \prec_{a_1} b \prec_{a_1} M(a_2)$ . However, this requires at least one query that returns either  $a_1$  or  $a_2$  as the top choice, and there is a symmetric argument for proving that  $(a_2, M(a_1))$  is not an  $r$ -edge. Since  $a_1$  and  $a_2$  are never returned as the top choice by a query of the algorithm, this is a contradiction to the assumption that the algorithm verifies that  $M$  is  $B$ -optimal.  $\blacktriangleleft$

In contrast to the comparison model, there exists an offline algorithm that asymptotically matches the lower bound of Lemma 15.

► **Theorem 16.** *There exists a polynomial-time offline algorithm that, given an instance of stable matching with one-sided uncertainty and the  $B$ -optimal matching  $M$ , verifies that  $M$  is indeed stable and  $B$ -optimal by executing  $\mathcal{O}(n)$  set queries.*

**Proof.** By the proof of Theorem 14, an algorithm can prove  $M$  to be stable by executing at most  $n$  set queries, so it remains to prove that  $M$  is  $B$ -optimal by executing at most  $\mathcal{O}(n)$  set queries.

We do so by proving that  $M$  does not contain a rotation. First, for each  $b \in B$ , we compute the set  $P(b) = \{a \in A \mid M(a) \prec_a b \text{ and } M(b) \prec_b a\}$ . Each tuple  $(b, a)$  with  $b \in B$  and  $a \in P(b)$  could be a rotation edge based on  $\prec_a$  but is not a rotation edge as  $M(b) \prec_b a$ . An algorithm can prove that none of these edge are actually rotation edges by executing a query  $\text{top}(b, P(b) \cup \{M(b)\})$  for each  $b \in B$ . This leads to  $n$  additional queries.

If an  $a \in A$  does not have a rotation edge, then the previous queries prove that this is the case. Consider an  $a \in A$  that has a rotation edge. Then the second endpoint of that edge is the agent  $b \in B$  of highest preference according to  $\prec_a$  among those agents that satisfy  $M(a) \prec_a b$  and  $a \prec_b M(b)$ . Let  $b$  be that endpoint. To prove that  $(a, b)$  is indeed a rotation edge, an algorithm has to verify  $a \prec_b M(b)$  and  $M(b') \prec_{b'} a$  for all  $b'$  with  $M(a) \prec_a b' \prec_a b$ . The latter has already been verified by the previous  $n$  queries and the former can be proven by an additional query  $\text{top}(b, \{a, M(b)\})$ . Doing this for every  $a \in A$  that has a rotation edge leads to at most  $n$  further queries.

Executing these queries yields, for each  $a \in A$ , either the rotation edge of  $a$  or a proof that  $a$  does not have a rotation edge. Thus, it gives sufficient information to show that  $M$  does not have a rotation and is  $B$ -optimal.  $\blacktriangleleft$

Next, we give an online algorithm that decides whether a given matching  $M$  is  $B$ -optimal by executing at most  $\mathcal{O}(n \log n)$  set queries. In combination with Lemma 15, this yields an  $\mathcal{O}(\log n)$ -competitive algorithm for verifying that a given matching is  $B$ -optimal with set queries.

► **Theorem 17.** *There is an algorithm that decides if a given matching  $M$  in a stable matching instance with one-sided uncertainty is stable and  $B$ -optimal with  $\mathcal{O}(n \log n)$  set queries.*

**Proof.** First, we can use Theorem 14 and execute  $\mathcal{O}(n)$  queries to decide whether  $M$  is stable. If  $M$  turns out not to be stable, then we are done. Otherwise, we have to decide whether  $M$  is  $B$ -optimal by using at most  $\mathcal{O}(n \log n)$  set queries. We do so by giving an algorithm that, for each  $a \in A$ , either finds the rotation edge of  $a$  or proves that  $a$  does not have a rotation edge. After executing that algorithm we clearly have sufficient information to decide whether  $M$  exposes a rotation and, thus, whether it is  $B$ -optimal.

For each  $a \in A$ , we use  $R(a)$  to refer to the set of agents that could potentially form a rotation edge with  $a$ . Initially, we set  $R(a) = \{b \in B \mid M(a) \prec_a b\}$  as all agents with a lower priority than  $M(a)$  can potentially form a rotation edge with  $a$  based on the initially given information. During the course of our algorithm, we will update the set  $R(a)$  such that it always only contains the agents of  $B$  that, based on the information obtained by all previous queries, could still form a rotation edge with  $a$ . In particular, if we obtain the information that  $M(b) \prec_b a$  for some  $b \in R(a)$ , then  $(a, b)$  clearly cannot be a rotation edge and we can update  $R(a) = R(a) \setminus \{b\}$ . Similarly, if we obtain the information that  $a \prec_b M(b)$  for some  $b \in R(a)$ , then the agents  $b' \in R(a)$  with  $b \prec_a b'$  cannot form a rotation edge with  $a$  anymore and we can update  $R(a) = R(a) \setminus \{b' \in R(a) \mid b \prec_a b'\}$ . Given the current list  $R(a)$  of potential rotation edge partners, we use  $\bar{R}(a)$  to refer to the  $\left\lceil \frac{|R(a)|}{2} \right\rceil$  agents of  $R(a)$  with the highest priority in  $R(a)$  according to  $\prec_a$ .

Our algorithm, cf. Algorithm 2, proceeds in iterations that each execute at most  $\mathcal{O}(n)$  set queries. Let  $R_i(a)$ ,  $a \in A$ , denote the current sets of potential rotation edges at the beginning of iteration  $i$  and let  $\bar{R}_i(a)$  be as defined above. We define our algorithm in a way such that each iteration  $i$  decides for each  $a \in A$  whether it has a rotation edge to an agent of  $\bar{R}_i(a)$  or not. Then,  $|R_{i+1}(a)| \leq \frac{|R_i(a)|+1}{2}$  holds for each  $a \in A$  with  $|R_i(a)| > 1$  as we either get  $R_{i+1}(a) \subseteq \bar{R}_i(a)$  or  $R_{i+1}(a) \subseteq R_i(a) \setminus \bar{R}_i(a)$ . Furthermore, if  $|R_i(a)| = 1$ , then iteration  $i$  either identifies the rotation edge of  $a$  or proves that it does not have one. This means that

■ **Algorithm 2** Algorithm to decide whether a given matching is  $B$ -optimal using set queries.

---

**Input:** Stable matching instance with one-sided uncertainty and a matching  $M$ .

- 1 Decide whether  $M$  is stable using Theorem 14. If  $M$  is not stable, terminate;
- 2  $R(a) \leftarrow \{b \in B \mid M(a) \prec_a b\}$  for all  $a \in A$ ;
- 3 **while** *We did not decide yet whether  $M$  is  $B$ -optimal* **do**
- 4      $U \leftarrow \{a \in A \mid |\bar{R}(a)| \geq 1\}$ ;
- 5     **for**  $b \in B$  **do**
- 6          $U_b \leftarrow \{a \in U \mid b \in \bar{R}(a)\}$ ;
- 7         **repeat**
- 8              $t \leftarrow \text{top}(b, U_b \cup \{M(b)\})$ ;
- 9             **if**  $t = M(b)$  **then**  $R(a) \leftarrow R(a) \setminus b$  for all  $a \in U_b$ ;  $U_b \leftarrow \emptyset$  ;
- 10            **else**
- 11                 $U \leftarrow U \setminus \{t\}$ ;  $U_b \leftarrow U_b \setminus \{t\}$ ;
- 12                 $R(t) \leftarrow R(t) \setminus \{b' \in R(t) \mid b \prec_t b'\}$ ;
- 13         **until**  $U_b = \emptyset$ ;

---

after at most  $\mathcal{O}(\log n)$  such iterations, for each  $a \in A$ , we either found the rotation edge of  $a$  or verified that it does not have one. Since each iteration executes  $\mathcal{O}(n)$  set queries, we get an algorithm that executes  $\mathcal{O}(n \log n)$  set queries and decides whether  $M$  is  $B$ -optimal.

It remains to show that each iteration  $i$  indeed executes  $\mathcal{O}(n)$  set queries and decides, for each  $a \in A$ , whether  $a$  has a rotation edge to some agent of  $\bar{R}_i(a)$ . Lines 4 to 13 of Algorithm 2 show the pseudocode for such an iteration. In each iteration  $i$ , the algorithm considers the set  $U = \{a \in A \mid |\bar{R}_i(a)| \geq 1\}$ , i.e., the subset of  $A$  for which we do not yet know whether it has a rotation edge to some agent of  $\bar{R}_i(a)$ . Then, the algorithm iterates through the agents  $b$  of  $B$  and considers the set  $U_b = \{a \in U \mid b \in \bar{R}_i(a)\}$ . Note that, for each  $a \in U_b$ , it holds that if  $a \prec_b M(b)$ , then  $a$  has a rotation edge to some agent of  $\bar{R}_i(a)$  (not necessarily to  $b$ ). The algorithm executes the query  $\text{top}(b, U_b \cup \{M(b)\})$ . If this query returns  $M(b)$ , then we know for sure that  $b$  does not have a rotation edge to any agent of  $U_b$  and we can discard  $b$  for the rest of the iteration and also remove  $b$  from the current  $R(a)$  of all  $a \in U_b$ . On the other hand, if the query returns  $a \neq M(b)$ , then we know that  $a$  has a rotation edge to some agent of  $\bar{R}_i(a)$  and we do not need to consider  $a$  for the rest of the iteration anymore. Thus, after each query within the iteration we discard an agent of either  $A$  or  $B$ , which means that the iteration terminates after at most  $2n$  queries. At the end of the iteration, we know for each  $a \in A$  whether it has a rotation edge to some  $b \in \bar{R}_i(a)$ . ◀

For the offline problem, we show that computing the query set of minimum size that verifies that a given matching does not have a rotation is NP-hard. However, in the instances constructed by the reduction, verifying that the given matching does not have a rotation *and is stable* is trivial as we will discuss after the proof. This means that the following result does *not* imply NP-hardness for the offline variant of finding the  $B$ -optimal matching with set queries.

► **Theorem 18.** *In the set query model, the offline problem of computing an optimal set of queries for verifying that a given  $B$ -optimal stable matching  $M$  for a stable matching instance with one-sided uncertainty does not have a rotation is NP-hard.*

**Proof.** We show the statement by reduction from the NP-hard *feedback vertex set problem* [23]. In this problem, we are given a directed graph  $G = (V, E)$  and a parameter  $k \in \mathbb{N}$ . The goal is to decide whether there exists a subset  $F \subseteq V$  with  $|F| \leq k$  such that deleting  $F$  from  $G$  yields an acyclic graph.

We construct an instance of the stable matching problem with one-sided uncertainty and a matching  $M$  as follows:

1. For each  $v \in V$ , we add an agent  $a_v$  to set  $A$  and a matching partner  $M(a_v)$  to set  $B$ .
2. For each  $v \in V$  and  $u \in V \setminus \{v\}$ , we set  $M(a_v) \prec_{a_v} M(a_u)$  if  $(v, u) \in E$  and  $M(a_u) \prec_{a_v} M(a_v)$  otherwise.
3. For each  $v \in V$  and  $u \in V \setminus \{v\}$ , we set  $a_v \prec_{M(v)} a_u$ .

Based on the  $A$ -side preferences, each  $(a_v, M(a_u))$  with  $(v, u) \in E$  could be an  $r$ -edge and each  $(a_v, M(a_u))$  with  $(v, u) \notin E$  is not an  $r$ -edge. Consider the directed graph  $G' = (A \cup B, E')$  with  $E' = \{(M(a_v), a_v) \mid v \in V\} \cup \{(a_v, M(a_u)) \mid (v, u) \in E\}$ . Then, based on the  $A$ -side preferences, each cycle in  $G'$  could be a rotation. Furthermore, if we contract the edges  $\{(M(a_v), a_v) \mid v \in V\}$ , we arrive at the given graph  $G$ .

Assume that there is a set  $F \subseteq V$  with  $|F| \leq k$  such that deleting  $F$  from  $G$  yields an acyclic graph. Consider the queries  $\text{top}(M(a_v), A)$  for all  $v \in F$ . By the third step of the reduction, these queries prove that the agents  $M(a_v)$  with  $v \in F$  are not part of any rotation. This also means that the agents  $a_v$  with  $v \in F$  cannot be part of a rotation. Thus, the only edges that can still be part of a rotation are the matching edges  $(M(a_v), a_v)$  with  $v \notin F$  and the edges  $(a_v, M(a_u))$  with  $(v, u) \in E$  but  $v, u \notin F$ . If we consider the graph induced by these remaining edges and contract the matching edges, we arrive at the subgraph  $G[V \setminus F]$  of the given feedback vertex set instance. Since this graph by assumption does not contain a cycle, this implies that executing the queries proves that the constructed instance has no rotation.

Consider a query strategy that proves the constructed instance to not have a rotation by using at most  $k$  queries. Let  $A' \subseteq A$  denote the set of all agents that are returned as the top choice by at least one of those queries. Then, by construction, the alternative query strategy that queries  $\text{top}(M(a_v), A)$  for each  $a_v \in A'$  must also be feasible and uses at most  $k$  queries. This alternative strategy proves that there exists no rotation by proving that no  $a_v \in A'$  is part of any rotation. Thus, removing all vertices  $a_v$  and  $M(a_v)$  with  $a_v \in A'$  from the graph  $G'$  as defined above yields a graph without cycles. This also implies that removing  $F = \{v \in V \mid a_v \in A'\}$  from  $G$  yields a graph without cycles. Thus,  $F$  with  $|F| \leq k$  is feasible for the given feedback vertex set instance. ◀

In the instances constructed within the proof, querying  $\text{top}(M(a_v), A)$  for between  $n - 1$  and  $n$  agents  $a_v \in A$  proves that the given matching is stable and  $B$ -optimal. If  $n - 1$  queries suffice, then this is optimal by Lemma 15. Otherwise,  $n$  queries are optimal. We can decide whether  $n - 1$  queries suffice via enumeration over which agent  $M(a_v)$  does not receive a query  $\text{top}(M(a_v), A)$ . Thus, the NP-hardness for proving that no rotation exists does not directly translate to the offline problem of proving that a given matching has no rotation and is stable.

## 6 Open Problems

While we understand the comparison model quite rigorously, it remains open in the set query model what best possible competitive ratio can be achieved for finding a ( $A$ - or  $B$ -optimal) stable matching. Further, it would be interesting to investigate the two-sided stable matching problem with uncertainty in the preference lists on both sides. For verifying the stability of a given matching in this case, we give a best possible 2-competitive algorithm in the full version [3]. All other questions regarding finding a stable or stable and optimal matching remain open under two-sided uncertainty. It would also be interesting to investigate a generalized set query model in which a query to a set  $S \subseteq A$  for a  $b \in B$  reveals the top- $k$  partners of  $b$ , that is, the  $k$  partners in  $S$  that  $b$  prefers most.

# A Constant Factor Approximation for Directed Feedback Vertex Set in Graphs of Bounded Genus

Hao Sun   

University of Alberta, 116 St & 85 Ave, Edmonton, AB T6G 2R3, Canada

---

## Abstract

The minimum directed feedback vertex set problem consists in finding the minimum set of vertices that should be removed in order to make a directed graph acyclic. This is a well-known NP-hard optimization problem with applications in various fields, such as VLSI chip design, bioinformatics and transaction processing deadlock prevention and node-weighted network design. We show a constant factor approximation for the directed feedback vertex set problem in graphs of bounded genus.

## 1 Introduction

In the directed feedback vertex set problem (DFVS), we are given a (node-weighted) directed graph  $G = (V, E)$  with costs  $c_v \forall v \in V$  and wish to find a minimum cost set  $X$  for which  $G \setminus X$  is acyclic. DFVS is one of Karp's original 21 NP-hard problems [16]. The DFVS problem has many applications including deadlock resolution [10], VLSI chip design [19] and program verification [20].

A 2-approximation for (undirected) FVS is given in [2]. DFVS has a 2-approximation in tournaments [21] and bipartite tournaments [24], is polynomial-time solvable on graphs of bounded treewidth, has a 2.4-approximation in planar graphs [3] and has an  $O(\log n \log \log n)$ -approximation in general graphs [7]. DFVS does not have an  $O(1)$ -approximation under the unique games conjecture [13]. The genus of a graph is the minimal integer  $g$  such that the graph can be drawn without crossing itself on a sphere with  $g$  handles.

The following is the natural LP for DFVS and its dual, where  $\mathcal{C}$  is the set of directed cycles of our graph.

$$\begin{array}{lcl} \min & c^T x & (\text{P}_{\text{DFVS}}) \\ \text{s.t.} & x(C) \geq 1 \quad \forall C \in \mathcal{C} & (1) \\ & x \geq 0 & \end{array} \quad \left| \quad \begin{array}{lcl} \max & \mathbf{1}^T y & (\text{D}_{\text{DFVS}}) \\ \text{s.t.} & \sum_{C \in \mathcal{C}, v \in C} y_C \leq c_v \quad \forall v \in V(G) & \\ & y \geq 0 & . \end{array}$$

Given that constant approximations for DFVS exist for planar graphs, one naturally wonders if DFVS admits constant approximations in bounded genus graphs. We answer this question positively.

► **Theorem 1.** *For any fixed genus  $g$ , there is a polynomial-time  $O(g)$ -approximation for DFVS for graphs of genus  $g$ . Moreover, the algorithm returns a DFVS with cost  $O(g)$  times the optimum solution to  $(P_{DFVS})$ .*

From the proof of Theorem 1, it is clear that the algorithm in Theorem 1 runs in time  $O(g)\text{poly}(|V(G)|)$ .

For uniform costs, the dual LP  $(D_{DFVS})$  is the natural LP of the *dicycle packing problem*. The dicycle packing problem is the problem of finding the maximum number of vertex disjoint dicycles of a graph. Schlomberg et al. [23] show that the LP gap of the natural LP for dicycle packing is at most  $\Omega(\frac{1}{g^2 \log g})$  on any graph of genus  $g$ . Our result then also implies that the minimum size of a DFVS is at most  $O(g^3 \log g)$  the size of a maximum dicycle packing.

## 1.1 Our techniques

Informally speaking, for a (directed) graph embedded on a surface where each directed cycle bounds a region homeomorphic to the plane, one can apply the same primal-dual techniques in [12, 3] to obtain a constant factor primal-dual approximation.

In the other case, our algorithm will use the natural LP for DFVS to look for a “separator” [5, 8, 9]  $S \subset V$  of cost at most a constant times the optimal DFVS such that  $G \setminus S$  is of smaller genus. We obtain a directed cycle  $C$ , the removal of which results in a surface of one smaller genus. Traversing along the dicycle, we may define a “left” and “right” side of the dicycle. Like in [7], we solve the DFVS LP and use the LP values as distances.

If there is no short path leaving  $C$  from the left and entering  $C$  from the right and vice versa then there is a small separator  $S$  such that each dicycle of  $G \setminus S$  either does not use any “left arc” that is, an arc coming in or leaving  $C$  from the left, or does not use any “right arc” that is, an arc coming in or leaving  $C$  from the right.  $G$  with all left (resp. right) arcs deleted is of genus at least one less so inductively we can solve within a constant factor DFVS on  $G$  with all left (resp. right) arcs deleted. These two solutions together with  $S$  form a DFVS of constant times more than the optimum. If such short paths exist but all starting points of such paths and ending points of such paths are far apart the analysis is similar.

The final case is where there are short paths  $P_1, P_2$  leaving  $C$  from the left and entering  $C$  from the right (or vice versa) and the starting point of  $P_2$  is close to the endpoint of  $P_1$ . We show that  $P_1$  is “far” from  $P_2$  so to speak (we are using directed distances so this is not the same as  $P_2$  being far from  $P_1$ ) and compute a suitable separator. We show that the resulting strongly connected components are of smaller genus. We then combine approximations for different components to give an approximation for the original graph.

The presentation in this paper is focused on demonstrating linear dependence on the genus rather than optimizing the constant in Theorem 1.

## 2 Preliminaries

In our figures, we will use the representation of the torus by taking the unit square  $[0, 1] \times [0, 1]$  and identifying the two pairs of edges  $\{0\} \times [0, 1]$ ,  $\{1\} \times [0, 1]$  and  $[0, 1] \times \{0\}$ ,  $[0, 1] \times \{1\}$ , that is, the point  $(0, p)$  is identified with  $(1, p)$  and the point  $(q, 0)$  is identified with the point  $(q, 1)$ .

Throughout this paper, all surfaces are orientable and smooth and all curves are piecewise smooth. Distances on surfaces will refer to the geodesic (shortest path on the surface) distance. It is well known (see for instance [22]) that a smooth orientable surface  $Q$  is diffeomorphic to the  $g$ -genus torus for some  $g$ . For  $X \subset Q$ , denote  $\text{cl}(X)$  as the closure of  $X$  in  $Q$ . We henceforth assume our surface is a  $g$ -genus torus for some  $g$ .

Let us call a cycle of  $G$ , or a closed curve  $C$  embedded on a surface  $Q$  *facial* if it bounds a region  $\text{inside}(C)$  of the surface homeomorphic to the plane. If the genus of  $Q$  is greater than 0, call  $\text{inside}(C)$  the *inside region* of  $Q \setminus C$ . For any set  $F \subset V$ , define  $G^F$  to be the *residual graph*, that is, the subgraph of  $G$  induced by those vertices that lie in a dicycle of  $G \setminus F$ .

### 3 Hitting the facial cycles of a digraph

In general, given a (node-weighted) directed graph  $G = (V, E)$  with costs  $c_v \forall v \in V$  a set  $\mathcal{C}$  of cycles of a digraph  $G$ , we define the  $\mathcal{C}$ -hitting set problem as the problem of finding a minimum cost set  $X$  such that  $X \cap C \neq \emptyset \forall C \in \mathcal{C}$ . In this section, we are concerned with when  $\mathcal{C}$  is the set of facial cycles of our graph.

Given a digraph  $G$  embedded on a surface  $Q$ , we show how to obtain an  $O(g)$ -approximation for the problem of finding a minimal hitting set for the set of facial dicycles of a graph embedded on any surface  $Q$  of genus  $g$ .

► **Theorem 2.** *For a graph  $G$  embedded on a surface  $Q$  of genus  $g$ , there is a polynomial-time  $O(g)$ -approximation for the problem of hitting facial dicycles of  $G$ . Moreover, the algorithm returns a DFVS with cost  $O(g)$  times the optimum solution to  $(P_{\text{DFVS}})$  where  $\mathcal{C}$  is the set of facial dicycles.*

*Further, if  $G$  is embedded in a way such that there exist regions  $R_1, R_2$  of  $Q$  homeomorphic to the open disk, such that the inside region of any facial dicycle contains at least one of  $R_1, R_2$ , then there is an algorithm that returns the optimum solution to  $(P_{\text{DFVS}})$  where  $\mathcal{C}$  is the set of facial dicycles.*

**Proof.** We first show that DFVS has an  $O(g)$ -approximation. If  $C$  is a facial cycle bounding a face of  $G$ , call  $C$  *face minimal*. Note that if  $G$  contains a facial cycle, then it must contain a face minimal cycle by the following argument. Let  $C$  be a dicycle such that  $\text{inside}(C)$  is a minimal (by containment) region of  $Q$ . Recall that we removed all vertices of  $G$  not lying on a dicycle. In particular, any vertex  $w$  inside the region  $\text{inside}(C)$  must lie on a facial dicycle  $A_w$ .  $A_w$  cannot be contained entirely in  $\text{cl}(\text{inside}(C))$ , as then the region  $A_w$  would be strictly contained in  $\text{inside}(C)$ . Thus,  $\text{inside}(A_w)$  intersects  $C$  and there is a dipath  $P$  between two nodes  $u, v$  of  $C$ . If  $C$  is not a face, then either there is a vertex  $w$  inside the region  $R_C$  or there is an edge  $uv$  between two nodes  $u, v$  of  $C$  such that  $g(uv) \setminus (g(v) \cup g(u))$  lies in  $R_C$ . In either case, there is a dipath  $P$  between two nodes  $u, v$  of  $C$  then  $P$  together with either the  $u$ - $v$  or  $v$ - $u$  dipath in  $C$  forms a cycle bounding a smaller region of  $Q$ , which is a contradiction.

Our algorithm proceeds as follows. This is a primal-dual algorithm analogous to the technique of [12] for DFVS in planar graphs. Given a feasible dual solution  $y$  to  $(D_{\text{DFVS}})$ , let the *residual cost* of node  $v \in V$  be  $c_v - \sum_{C \in \mathcal{C}, v \in C} y_C$ . For  $\hat{S} \subset V(G)$ , recall  $G^{\hat{S}}$  denotes the subgraph of  $G$  induced by those vertices which are in a dicycle of  $G \setminus \hat{S}$ .

Our primal-dual method begins with a trivial feasible dual solution  $y = \mathbb{0}$ , and the empty, infeasible hitting set  $\hat{S} = \emptyset$ .

While  $G^{\hat{S}}$  contains a facial cycle, increment the dual variables  $y_C$  in  $P_{\text{DFVS}}$  of face minimal cycles  $C$  of  $G$ . When a node of  $G$  becomes tight add it to  $\hat{S}$ . When  $G^{\hat{S}}$  contains no facial cycles apply reverse deletion to  $\hat{S}$  with respect to the facial cycles of  $G^{\hat{S}}$ , that is, we consider

■ **Algorithm 3.1** MinWeightDirectedFVS ( $G, c$ ).

---

**Input** : A digraph  $G = (V, E)$  with non-negative node-costs  $c_v$ , for each  $v \in V$ .  
**Output** : A Directed FVS  $S$  of  $G$ .

```

1  $S = \emptyset$ 
2 while  $G^S$  contains a facial cycle do
3   | Increment all dual variables  $y_C$  for face minimal cycles of  $G^S$ . Add all nodes that
   |   became tight to  $S$ .
4 end while
5 Reverse-Deletion:
6   | Let  $s_1, s_2, \dots, s_l$  be nodes of  $S$  in the order they were added.
7   | for  $t = l$  downto 1 do
8   |   | if  $G^{S \setminus \{s_t\}}$  contains no facial cycle then
9   |   |   |  $S \leftarrow S \setminus \{s_t\}$ 
10  |   | end if
11  |   end for
12
13 return  $S$ 

```

---

each node  $v$  of  $\hat{S}$  in the order it was added and if  $G \setminus (\hat{S} \setminus \{v\})$  contains no facial cycles, delete  $v$  from  $\hat{S}$ . Denote by  $\bar{S}$  the set  $\hat{S}$  at the end of the algorithm. In other words, we apply the primal-dual method to solve the problem of hitting all facial dicycles of  $G$ .

Clearly,  $\bar{S}$  is a feasible hitting set for the set of facial dicycles of  $G$ , we claim it has cost  $O(g)OPT_{LP}$ . To do so we apply that standard analysis of primal-dual methods in [11, 12].

► **Theorem 3** ([11]). *Suppose  $S \subset V(G)$  and  $y$  is a solution to  $(D_{DFVS})$  output by our primal-dual algorithm such that the following holds.*

1.  $y$  is obtained starting with the initial feasible solution  $y := 0$  and incrementing some set of dual variables  $\{y_C : v \in C_t\}$  uniformly and maintaining feasibility of  $y$  for iterations  $t = 1, 2, \dots, l$  for some  $l \in \mathbb{N}$ .
2. For each iteration  $t \in \{1, 2, 3, \dots, l\}$ , the set  $\{y_C : C \in \mathcal{C}_t\}$  of incremented dual variables satisfies  $\sum_{C \in \mathcal{C}_t} |S \cap C| \leq \beta |\mathcal{C}_t|$ .
3.  $\forall v \in S, \sum_{C \in \mathcal{C}} y_C = c_v$ .

Then  $S$  has cost at most  $\beta \sum_{C \in \mathcal{C}} y_C$ , that is at most  $\beta$  times the LP value.

Using Theorem 3, it suffices to prove that during any iteration  $t$ , the face minimal cycles  $\mathcal{C}_t$  of  $G^{S_t}$ , where  $S_t$  is our current hitting set satisfies

$$\sum_{C \in \mathcal{C}_t} |\bar{S} \cap C| \leq O(g) |\mathcal{C}_t|. \quad (2)$$

Again we remove nodes of  $G$  that do not lie on any dicycle. Denote  $\bar{S}_t$  to be the nodes of  $\bar{S}$  that intersect a cycle of  $\mathcal{C}_t$ . So it suffices to show  $\sum_{C \in \mathcal{C}_t} |\bar{S}_t \cap C| \leq O(g) |\mathcal{C}_t|$ .

The following definition of crossing cycles was elementary to the approach by Goemans and Williamson [12].

► **Definition 4.** *Fix an embedding of a planar graph. Two cycles  $C_1, C_2$  cross if  $C_i$  contains an edge intersecting the interior of the region bounded by  $C_{3-i}$ , for  $i = 1, 2$ . That is, the plane curve corresponding to the embedding of the edge in the plane intersects the interior of the region of the plane bounded by  $C_{3-i}$ . A set of cycles  $\mathcal{C}$  is laminar if no two elements of  $\mathcal{C}$  cross.*

Denote  $\mathcal{C}'$  the set of facial cycles of  $\mathcal{C}$ . For a node  $v \in \bar{S}$ , call a cycle  $C \in \mathcal{C}'$  with  $C \cap \bar{S} = \{v\}$  a *witness* for  $v$ . Since we applied reverse deletion to  $\bar{S}$  at the end of the algorithm, each node of  $\bar{S}$  has a witness in  $\mathcal{C}'$  which is a cycle of  $G^S$ .

The following result about the structure of witness cycles was vital to the 3 and 2.4 approximations for DFVS in planar graphs by [12] and [3]. We observe that the proof in [12] which involves iteratively applying an ‘‘uncrossing’’ procedure to two witness cycles that cross yields the same result for facial cycles of graphs on surfaces.

► **Lemma 5** ([12]). *There exists a laminar family  $\mathcal{A} \subset \mathcal{C}'$  of witness cycles in  $G^{S_t}$  for  $\bar{S}_t$ .*

The laminar family  $\mathcal{A}$  can be represented by a forest where  $A_1$  is an ancestor of  $A_2$  if the inside region of  $A_1$  contains the inside region of  $A_2$ . Add a root node  $r$  to this forest, make it the parent of every maximal node of the forest and call the resulting tree  $T$ .

We assign each cycle  $C$  of  $\mathcal{C}_t$  to the smallest node of  $T$  containing  $C$ . Call the set of cycles assigned to  $w \in T$ ,  $\mathcal{C}_w$ . We assign the nodes that  $w$  and the children of  $w$  are witnesses of to  $w$  and call this set  $\bar{S}_w$ .

To bound  $\sum_{C \in \mathcal{C}_t} |\bar{S}_t \cap C|$ , we define the following bipartite graph.

► **Definition 6** ([12]). *The debit graph for  $\mathcal{C}_t$  and  $S$  is the bipartite graph  $\mathcal{D}_G = (\mathcal{R} \cup S, E)$  with edges  $E_{\mathcal{C}_t} = \{(C, s) \in \mathcal{C}_t \times S \mid s \in C\}$ .*

Since each  $C \in \mathcal{C}_t$  is incident to the vertices of  $\bar{S}_t$  on  $C$ ,  $|\bar{S}_t \cap C|$  is the degree of  $C$  in  $\mathcal{D}_G$ . Summing this equality over each  $C \in \mathcal{C}_t$  yields  $\sum_{C \in \mathcal{C}_t} |\bar{S}_t \cap C| = E(\mathcal{D}_G)$ . By placing the node of the debit graph corresponding to  $C$  inside the inside region of  $C$  we can see that the debit graph is also embedded on  $Q$ .

► **Proposition 7** (Corollary of Euler’s formula for graphs of genus  $g$ ). *A (simple) bipartite graph  $\bar{G}$  with at least three vertices embedded on a surface of genus  $g$  satisfies*

$$E(\bar{G}) \leq (2 + g)|V(\bar{G})| - 4$$

if  $\bar{G}$  has two vertices then

$$E(\bar{G}) \leq (2 + g)|V(\bar{G})| - 3$$

**Proof.** Euler’s formula (for instance see [17]) for graphs embedded on a surface of genus  $g$  yields  $2 - 2g = |V(\bar{G})| - |E(\bar{G})| + |F(\bar{G})|$ . Following the same method as the proof of Euler’s formula for bipartite planar graphs with at least 3 vertices, (for instance see Corollary 4.2.10 of [6]) we observe that each face of  $\bar{G}$  having at least 4 edges means  $|F(\bar{G})| \leq \frac{1}{2}|E(\bar{G})|$ . Thus, for  $|V(\bar{G})| \geq 3$ ,  $|E(\bar{G})| \leq 2|V(\bar{G})| - 4 + 4g \leq (2 + g)|V(\bar{G})| - 4$ . If  $|V(\bar{G})| \leq 2$  then  $|E(\bar{G})| \leq 1 \leq (2 + g)|V(\bar{G})| - 3$ . ◀

For a node  $w$  of  $T$  that is not a leaf or the root, the subgraph of  $\mathcal{D}_G$  induced by  $\mathcal{C}_w \cup \bar{S}_w$  is embedded on  $Q$  and further  $|\mathcal{C}_w \cup \bar{S}_w| \geq 3$ , thus by Proposition 7,

$$|E(\mathcal{D}_G(\mathcal{C}_w \cup \bar{S}_w))| \leq (2 + g)|\mathcal{C}_w| + (2 + g)|\bar{S}_w| - 4 = (2 + g)|\mathcal{C}_w| + (2 + g)(\deg_T(w) - 1) - 4. \quad (3)$$

For a leaf  $v$  of  $T$

$$|E(\mathcal{D}_G(\mathcal{C}_v \cup \bar{S}_v))| \leq (2 + g)|\mathcal{C}_v| + 2|\bar{S}_v| - 3 = (2 + g)|\mathcal{C}_v| + 2(\deg_T(v) - 1) - 3. \quad (4)$$

For the root  $r$  of  $T$

$$|E(\mathcal{D}_G(\mathcal{C}_r \cup \bar{S}_r))| \leq (2 + g)|\mathcal{C}_r| + 2|\bar{S}_r| = (2 + g)|\mathcal{C}_r| + 2(\deg_T(r) - 1). \quad (5)$$

Summing these up we get

$$\begin{aligned}
 |E(\mathcal{D}_G)| &= \sum_{v \in T} |E(\mathcal{D}_G(\mathcal{C}_v \cup \bar{S}_v))| \\
 &\leq (2+g)|\mathcal{C}| + \sum_{v \in T} (2+g) \deg_T(v) - 4|T| + l + 4 \\
 &\leq (2+g)|\mathcal{C}| + 2((2+g)|T| - 2) - 4|T| + l + 4 \\
 &\leq (2+g)|\mathcal{C}| + 2g|T| + l \\
 &\leq (3+3g)|\mathcal{C}|
 \end{aligned}$$

where  $l$  is the number of (non-root) leaves of  $T$ . Thus,  $\sum_{C \in \mathcal{C}_t} |\bar{S} \cap C| = |E(\mathcal{D}_G)| \leq (3+3g)|\mathcal{C}|$ .

This shows that  $\bar{S}$  has cost  $O(g)OPT_{LP}$  and hence our algorithm returns a solution of cost  $O(g)OPT_{LP}$ .

Now let us show that in the case  $G$  is embedded in a way such that there exist regions  $R_1, R_2$  of  $Q$  homeomorphic to the open disk, such that the inside region of any facial dicycle contains at least one of  $R_1, R_2$ , then Algorithm 3.1 is an 8-approximation.

The proof works exactly the same as the general case. The key here is to note that the inside regions of face minimal dicycles do not intersect. Thus,  $R_1$  lies in the inside region of at most one cycle in  $\mathcal{C}_t$ . Likewise,  $R_2$  lies in the inside region of at most one cycle in  $\mathcal{C}_t$ . Since inside region of any facial dicycle contains at least one of  $R_1, R_2$ ,  $|\mathcal{C}_t| \leq 2$ . Again Lemma 5 holds. For a facial dicycle  $A$ , denote  $\text{inside}_{\mathcal{C}_t}(A)$  the set of cycles of  $\mathcal{C}_t$  that lie in the closure of the inside region of  $A$ .

► **Lemma 8.** *There do not exist distinct  $A_1, A_2, A_3 \in \mathcal{A}$  such that  $\text{inside}_{\mathcal{C}_t}(A_1) = \text{inside}_{\mathcal{C}_t}(A_2) = \text{inside}_{\mathcal{C}_t}(A_3)$ .*

**Proof.** Suppose such  $A_1, A_2, A_3$  existed. Since they are laminar we may assume w.l.o.g that  $A_1$  is contained in the closure of the inside region of  $A_2$  and  $A_2$  is contained in the closure of the inside region of  $A_3$ . Let  $v_i$  be the hit node that  $A_i$  is the witness of. Note that  $v_2$  does not lie on  $A_1$ . Thus, as  $v_2$  lies outside  $\text{inside}(A_1)$ , it lies outside the closure  $\text{cl}(\text{inside}(A_1))$  of  $\text{inside}(A_1)$ . So  $v_2$  lies in  $Q \setminus \text{inside}(A_3)$ . Thus,  $v_2$  does not lie on any cycle of  $\text{inside}_{\mathcal{C}_t}(A_3)$ . Also  $v_2$  does not lie on  $A_3$ . Thus, as  $v_2$  lies inside  $\text{cl}(\text{inside}(A_3))$ , it lies inside  $\text{inside}(A_3)$ . Thus,  $v_2$  does not lie on any cycle of  $\mathcal{C}_t \setminus \text{inside}_{\mathcal{C}_t}(A_3)$ .

This implies that  $v_2$  does not lie on any cycle of  $\mathcal{C}_t$ , which is a contradiction. ◀

This implies that  $|\bar{S}_t| = |\mathcal{A}| \leq 2(2^{|\mathcal{C}_t|}) \leq 8$ . Thus,  $\sum_{C \in \mathcal{C}_t} |\bar{S}_t \cap C| \leq |\bar{S}_t| |\mathcal{C}_t| \leq 8|\mathcal{C}_t|$ . This shows Algorithm 3.1 is an 8-approximation. ◀

#### 4 Solving the case of no facial cycles

We now show the LP gap of the natural LP ( $P_{DFVS}$ ) for  $G$  has integrality gap  $O(g)$  in the case  $G$  contains no facial cycles. This will allow us to derive an  $O(g)$ -approximation for the general case by first using Theorem 2 to obtain a hitting set  $S$  for the set of facial cycles of cost at most  $O(g)OPT$  and then obtaining a hitting set  $\bar{S}$  for the remaining dicycles.

► **Lemma 9.** *Suppose  $G$  is a digraph embedded on a surface  $Q$  of some fixed genus  $g$  and there is no facial dicycle of  $G$ . Then the LP gap of the natural LP ( $P_{DFVS}$ ) for  $G$  has integrality gap  $O(g)$ .*

**Proof.** We prove the statement by induction on the genus  $g$ . The case  $g = 0$  is trivial because all cycles in planar graphs are facial. Suppose the statement is true for  $g = g'$ . Let  $Q$  be a surface of genus  $g$ , Let  $G$  be a digraph embedded on  $Q$ .

First, while the optimal solution  $\bar{x}$  to  $(P_{\text{DFVS}})$  has a vertex  $v$  with value  $\bar{x}_v \geq \frac{1}{24}$  add  $v$  to our temporary hitting set  $F$ . Formally initialize  $F = \emptyset$ . While the optimal solution  $\bar{x}$  to  $(P_{\text{DFVS}})$  for  $G^F$  contains a value  $\bar{x}_v$  which is  $\frac{1}{24}$  or more add  $v$  to  $F$ .

Let  $F$  denote the final set obtained. Let  $\hat{x}$  be an optimal extreme point solution for the DFVS LP  $(P_{\text{DFVS}})$  for  $G^F$ , so  $\hat{x}_v < \frac{1}{24} \forall v \in V(G^F)$ . Standard results in iterative rounding, see for instance page 14 of [18], show  $F$  has cost at most 24 times the optimal value of our LP.

We now seek to define (integral) distances on  $G^F$ . By standard LP theory,  $\hat{x}$  has rational coordinates. Let  $N \in \mathbb{Z}_{>0}$  be such that  $N\hat{x}$  and  $\frac{1}{12}N$  are integral, call  $N\hat{x}_v$ , the weight of  $v$ . Define the weighted distance of path  $P = v_0, v_1, \dots, v_l$ ,  $\omega(P)$  to be  $\omega(P) := \sum_{i=0}^{l-1} N\hat{x}_{v_i}$ . For a subgraph  $H$  of  $G^F$  define the weighted distance  $d_{\{\omega, H\}}(u, v)$  from  $u$  to  $v$  the minimum weight of a  $u$ - $v$  path in  $H$ . Define  $d_\omega := d_{\{\omega, G\}}$ . For  $U, W \subset V(G)$ , define  $d_{\omega, H}(U, W) := \min_{u \in U, w \in W} d_\omega(u, w)$ . Define  $d_\omega(U, W) = d_{\omega, G}(U, W)$ . Define the weighted distance of a closed walk  $P' = v_0, v_1, \dots, v_l v_0$ ,  $\omega(P')$  to be  $\omega(P') := \sum_{i=0}^l N\hat{x}_{v_i}$ . The results in this paper could also be shown by instead defining the weight of each vertex to be  $\hat{x}_v$  and instead defining the layers (see later) to be the vertices at distance a multiple of  $1/N$  from a given set of vertices. Since  $\hat{x}$  is feasible the following result holds.

► **Proposition 10.** *The weighted distance of any (directed) closed walk  $P'$  is at least  $N$ .*

Since  $\hat{x}$  is optimal, there exists a dicycle  $C^1 := v_1, v_2, \dots, v_{l'}$  such that  $\sum_{v \in C^1} \hat{x}_v = 1$ . The motivation of our definition of weighted distance comes from [7]. In [7], they also scale the LP values of  $(P_{\text{DFVS}})$  so that the resulting values are integer. For any vertex  $v$  with  $\hat{x}_v = 0$ , they “bypass” the vertex, that is, for each out neighbour  $u$  of  $v$  and in neighbour  $w$  of  $v$ , they add the edge  $wu$  to the graph and when they have done this for all neighbours, they delete  $v$  from the graph. For any vertex  $v$  with  $N\hat{x}_v > 1$  they replace  $v$  by a “chain” of  $N\hat{x}_v > 1$  vertices  $v_1 \rightarrow v_2 \rightarrow \dots \rightarrow v_{N\hat{x}_v}$ , that is, for  $i = 1, 2, \dots, N\hat{x}_v - 1$ ,  $v_i v_{i+1}$  is an edge.  $vv_1$  and  $v_{N\hat{x}_v}u$  are edges for each in neighbour  $w$  and out neighbour  $u$ . Call this graph  $H$ .

For any  $W \subset V(H)$  they define “layers”  $L_i = \{v \in H : d_H(W, v) = i\}$  the nodes at distance  $i$  from  $W$ . They show that the cost of all layers  $L_0, L_1, \dots$  is  $\sum_{v \in V(G)} N\hat{x}_v$ . This is very useful for us as we will use this to show that one layer in  $L_1, \dots, L_m$  has cost at most  $\frac{1}{m} \sum_{v \in V} N\hat{x}_v$ . However, the bypassing operation and replacing a node with a chain operation of [7] do not preserve the genus of the graph. We instead define the notion of weighted distance  $d_\omega$ . Denote the  $i$ -th layer from  $W$  as  $L_i := \{v \in V : i \geq d_\omega(W, v) > i - \omega(v)\}$  the set of nodes for which the distance from  $W$  to  $v$  is at most  $i$ , but for which the distance plus the weight of  $v$  is more than  $i$ . One can see that  $v$  lies in  $N\hat{x}_v$  different  $L_i$ , which is analogous to how  $H$  defined in [7] contains  $N\hat{x}_v$  copies of  $v$  each lying in different layers as well. In particular, a node of weight 0 does not lie in any  $L_i$ , which is analogous to how a vertex of weight 0 is bypassed in [7].

Consider the embedding of  $C^1$  on our surface. Given a subgraph  $W$  of  $G$ , denote by  $g(W)$  the subset of our surface occupied by a vertex or edge of  $W$ . We want to define a “small” neighbourhood around  $g(C^1)$ , not containing any vertices outside  $C^1$ , which we divide up into “left” of  $g(C^1)$  and “right” of  $g(C^1)$ , which we do using the following propositions. These are slightly informal statements of the exact propositions we require, the precise statements appear in Section 5.

► **Proposition 11** (Informal statement of Proposition 23 and Proposition 24). *Given a closed continuous non-self-intersecting curve  $C'$  embedded on an orientable surface  $Q$ , we may partition a small open neighbourhood about  $C'$  into a “left”  $L$  and “right”  $R$ . For any curve  $f : [0, 1] \rightarrow Q$  disjoint from  $C'$  except at  $f(1)$  the partition allows us to say that  $f$  “reaches”  $C'$  from either the left or right.*

■ **Figure 1**  $L$  and  $R$  from Proposition 11 in yellow and red respectively curve  $C'$  depicted in black. The curve  $h$  leaving  $C'$  from the left and entering from the right is depicted in dark green. The closed curve formed by  $h$  and the subcurve of  $C'$  between  $h(0)$  and  $h(1)$  depicted in light green forms a non-facial closed curve.

► **Proposition 12** (Informal statement of corollary of Proposition 26). *Let  $C'$  be a non-facial closed curve. If a curve  $h : [0, 1] \rightarrow Q$  “leaves”  $C'$  at a point  $h(0) \in C'$  from the left and reaches  $C'$  at a point  $h(1) \in C'$  from the right, then  $h([0, 1])$  together with a subcurve of  $C'$  from  $h(0)$  to  $h(1)$  is a non-facial closed curve.*

We defer the proofs of Proposition 11 and Proposition 12 for now. We apply Proposition 11 to  $g(C^1)$ . Let  $L, R$  be as in Proposition 11 so that each  $g(e)$  for  $e \in E(G) \setminus E(C^1)$  is disjoint from at least one of  $L, R$  and for each  $e \in E(G \setminus C^1)$ ,  $g(e)$  is disjoint from both  $L, R$ . For each arc  $uv$  of  $G^F$  with exactly one endpoint  $v$  on  $C^1$ ,  $g(uv)$  can be parameterized by a (continuous) curve  $f : [0, 1] \rightarrow g(uv)$  with  $f(0) = g(u)$ ,  $f(1) = g(v)$ . If  $f$  reaches  $g(C^1)$  from the left we say that  $uv$  reaches  $C^1$  from the left, otherwise, we say  $uv$  reaches  $C^1$  from the right.

Let  $u'_{i,1}, u'_{i,2}, \dots, u'_{i,l_i}$  be the out neighbours of  $v_i$  such that the edges  $u'_{i,t'}v_i$  reach  $v_i$  from the left, that is, the arc obtained from reversing the arc  $v_i u'_{i,t'}$  of our graph reaches  $v_i$  from the left. Let  $w'_{i,1}, w'_{i,2}, \dots, w'_{i,z_i}$  be the in neighbours of  $v_i$  such that the edges  $w'_{i,t'}v_i$  reach  $v_i$  from the right. Subdivide each edge  $v_i u'_{i,t}$  into a path  $v_i u_{i,t} u'_{i,t}$  and each edge  $w'_{j,t'} v_j$  into a path  $w'_{j,t'} w_{j,t'} v_j$  and give the new vertices  $w_{j,t'}, u_{i,t}$  infinite cost. There is a natural embedding of our new graph on our surface by placing each  $u_{i,t}$  where the midpoint of the curve  $g(v_i u'_{i,t})$  was embedded and likewise for  $w_{j,t'}$ . By abuse of notation, we continue to call our graph  $G$  and define  $\hat{x}_{u_{i,t}} = \hat{x}_{w_{j,t'}} = 0$  for all  $u_{i,t}, w_{j,t'}$ . Denote  $U := \cup_{i=1}^{l'} \{u_{i,1}, u_{i,2}, \dots, u_{i,l_i}\}$  and  $W := \cup_{i=1}^{l'} \{w_{i,1}, w_{i,2}, \dots, w_{i,z_i}\}$ . For  $X \subset [l']$ , denote  $U_X := \cup_{i \in X} \{u_{i,1}, u_{i,2}, \dots, u_{i,l_i}\}$ ,  $V_X = \{v_i : i \in X\}$  and  $W_X := \cup_{i \in X} \{w_{i,1}, w_{i,2}, \dots, w_{i,z_i}\}$ .

Let  $\tau_- := \{i \in [l'] : \exists w_{i,t'} \in W, \exists u_{j,t} \in U : d_{\omega, G^F \setminus C^1}(u_{j,t}, w_{i,t'}) < \frac{1}{12}N\}$  the first indices of the set of vertices of  $W$  of weighted distance at most  $\frac{1}{12}N$  from  $U$  in  $G^F \setminus C^1$ . Let  $\tau_+ := \{j \in [l'] : \exists u_{j,t} \in U, \exists w_{i,t'} \in W : d_{\omega, G^F \setminus C^1}(u_{j,t}, w_{i,t'}) < \frac{1}{12}N\}$  the first indices of the set of vertices of  $U$  that can reach  $W$  in  $G^F \setminus C^1$  with a path of weighted distance at most  $\frac{1}{12}N$ .

▷ **Claim 13.** If  $d_{\omega}(V_{\tau_-}, V_{\tau_+}) > \frac{1}{12}N$ , then we can find  $S \subset V$ ,  $c(S) = O(1)OPT_{LP}$ , where  $OPT_{LP} := \sum_{v \in V} c_v x_v$  is the value of the optimal fractional solution, such that any strongly connected component of  $G^F \setminus S$  does not contain a directed path from  $U$  to  $W$  in  $G \setminus C^1$ .

■ **Figure 2** Nodes of  $U_{\tau_+}$  and  $V_{\tau_-}$  shown in blue.

If  $d_\omega(V_{\tau_-}, V_{\tau_+}) \leq \frac{1}{12}N$ , then the LP gap of the natural LP (P<sub>DFVS</sub>) for  $G^F$  has integrality gap  $O(g)$ .

Proof. Suppose  $d_{\omega, G^F \setminus C^1}(V_{\tau_-}, V_{\tau_+}) > \frac{1}{12}N$ . For  $i = 0, \dots, \frac{1}{12}N$  let  $S_i := \{v \in V : i \geq d_{\omega, G^F \setminus C^1}(U \setminus U_{\tau_+}, v) > i - \omega(v)\}$  denote the set of vertices of  $V$  that are at weighted distance  $i$  from  $U \setminus U_{\tau_+}$  in  $G^F \setminus C^1$ . (see Figure 2). Since  $d_{\omega, G^F \setminus C^1}(U \setminus U_{\tau_+}, W) > \frac{1}{12}N$ , for  $i = 0, \dots, \frac{1}{12}N$ ,  $W \cap S_i = \emptyset$  and  $W$  is not reachable from  $U \setminus U_{\tau_+}$  in  $(G^F \setminus C^1) \setminus S_i$  for any  $i$ .

Since each  $v$  can lie in at most  $\omega(v)$   $S_i$ ,  $\sum_{i=0}^{\frac{1}{12}N} c(S_i) \leq N \cdot OPT_{LP}$ . Let  $S'$  be the  $S_i$  of minimum cost. For  $i = 0, \dots, \frac{1}{12}N$  let  $T_i := \{v \in V : i > d_{\omega, G^F \setminus C^1}(v, W \setminus W_{\tau_-}) - \omega(v), d_{\omega, G^F \setminus C^1}(v, W \setminus W_{\tau_-}) \geq i\}$ . Since for  $v \in U$ ,  $d_{\omega, G^F \setminus C^1}(v, W \setminus W_{\tau_-}) - \omega(v) = d_\omega(v, W \setminus W_{\tau_-}) > \frac{1}{12}N$ ,  $U \cap T_i = \emptyset$  for  $i = 0, \dots, \frac{1}{12}N$ . Hence  $W \setminus W_{\tau_-}$  is not reachable from  $U$  in  $(G^F \setminus C^1) \setminus T_i$  for any  $i$ . Let  $T'$  be the  $T_i$  of minimum cost.

Finally, let  $Y_i := \{v \in V : i \geq d_\omega(V_{\tau_-}, v) > i - \omega(v)\}$  the set of vertices of weighted distance  $i$  from  $V_{\tau_-}$ . By assumption  $d_\omega(V_{\tau_-}, V_{\tau_+}) > \frac{1}{12}N$  and hence  $V_{\tau_+}$  is not reachable from  $V_{\tau_-}$  in  $G^F \setminus Y_i$  for any  $i = 1, 2, \dots, \frac{1}{12}N$ . Let  $Y'$  be the  $Y_i$  of minimum cost.

Let  $S := S' \cup T' \cup Y'$ . We claim no strongly connected component  $K'$  of  $G^F \setminus S$  contains a directed path from  $U$  to  $W$  in  $G^F \setminus C^1$ . Suppose for a contradiction that some strongly connected component  $K'$  of  $G^F \setminus S$  contains a directed path from some  $u_{i,t} \in U$  to some  $w_{j,t'} \in W$ .

If  $j \notin \tau_-$ , then  $w_{j,t'}$  is not reachable from  $U$  in  $G^F \setminus S$ . If  $i \notin \tau_+$ , then  $W$  is not reachable from  $u_{i,t}$  in  $G^F \setminus S$ . Thus, if either  $j \notin \tau_-$  or  $i \notin \tau_+$  then there is no path from  $u_{i,t}$  to  $w_{j,t'}$  in  $G^F \setminus S$ . Thus,  $j \in \tau_-$  and  $i \in \tau_+$ . As  $K'$  is strongly connected, this implies that  $G^F \setminus S$  contains a path from  $V_{\tau_-}$  to  $V_{\tau_+}$ , which is not possible.

Now suppose that  $d_\omega(V_{\tau_-}, V_{\tau_+}) \leq \frac{1}{12}N$ . Let  $i \in \tau_-$  and  $j \in \tau_+$  be such that  $d_\omega(v_i, v_j) \leq \frac{1}{12}N$ . Let  $P_1, P_2, P_3$  be  $u_{a,t}v_i$ ,  $u_{j,t'}v_j$  and  $v_i v_j$  paths of weight at most  $\frac{1}{12}N$ , with the second last vertices of  $P_1, P_2$  being in  $W$ , for some  $a, b$ . Such paths exist as  $i \in \tau_-$  and  $j \in \tau_+$ . If  $a = i$ , then  $P_1 v_i u_{a,t}$  is a cycle for which  $\sum_{v \in P_1 v_i u_{a,t}} \hat{x}_v < 1$  which is a contradiction. So  $a \neq i$ , likewise  $b \neq j$ .

For  $i', j' \in \{1, 2, \dots, l'\}$ , let  $C_{(v_{i'}, v_{j'})}^1 := v_{i'}, v_{i'+1}, v_{i'+2}, \dots, v_{j'-1} v_{j'}$  (where  $v_t = v_{t \pmod{l'}}$ ) denote the directed path in  $C^1$  from  $v_{i'}$  to  $v_{j'}$ . Note that  $d_\omega(v_{i'}, v_{j'}) = \omega(C_{(v_{i'}, v_{j'})}^1)$ , for otherwise there is a  $v_{i'}v_{j'}$  path  $P'$  of weight less than  $d_\omega(v_{i'}, v_{j'})$ . Then  $C_{(v_{j'}, v_{i'})}^1 \cup P'$  is a directed closed walk of weight  $\omega(C^1) - \omega(C_{(v_{i'}, v_{j'})}^1) + d_\omega(v_{i'}, v_{j'}) < \omega(C^1)$ . Noting that

## 18:10 A Constant Factor Approximation for Directed Feedback Vertex Set

the weighted distance of a cycle is equal to  $N \sum_{v \in C^1} \hat{x}_v$ , we obtain  $N \sum_{v \in C^1_{(v_j, v_{i'})} \cup P'_{i'}} \hat{x}_v < \omega(C^1) = N$ , from which it follows the sum of the  $\hat{x}_v$  values along the closed walk  $C^1_{(v_j, v_{i'})} \cup P'_{i'}$ ,  $\sum_{v \in C^1_{(v_j, v_{i'})} \cup P'_{i'}} \hat{x}_v$  is strictly less than 1, which contradicts the feasibility of  $\hat{x}$ .

We claim  $\omega(C^1_{(v_a, v_i)}), \omega(C^1_{(v_j, v_b)}) \leq \frac{1}{12}N$ . Suppose for a contradiction that  $\omega(C^1_{(v_a, v_i)}) > \frac{1}{12}N$ . Since  $\omega(C^1) = N$ , this implies that  $\omega(C^1_{(v_{i+1}, v_{a-1})}) < N - \frac{1}{12}N$ . Then the cycle  $P_1 C^1_{(v_i, v_a)} v_a u_{a,t}$  satisfies  $\sum_{v \in V(P_1 C^1_{(v_i, v_a)} v_a u_{a,t})} \hat{x}_v < 1 - \frac{1}{12} + \frac{1}{12} = 1$  which is a contradiction. Likewise,  $\omega(v_j, v_b) \leq \frac{1}{12}N$ .

Let us show  $C^1_{(v_a, v_i)} \cap C^1_{(v_j, v_b)} = \{v_i\} \cap \{v_j\}$ , that is the paths  $C^1_{(v_a, v_i)}$  and  $C^1_{(v_j, v_b)}$  are disjoint except in the case  $i = j$  when their intersection is  $v_i$ . First, let us address the case  $i \neq j$ . Suppose for a contradiction that  $C^1_{(v_a, v_i)} \cap C^1_{(v_j, v_b)} \neq \emptyset$ . Let  $v \in C^1_{(v_a, v_i)} \cap C^1_{(v_j, v_b)}$ . Note  $v \neq v_i, v_j$  for otherwise  $C^1_{(v_j, v_i)} P_3$  is a closed walk of weight less than  $N$ . Let  $Q_1$  be a path from  $v$  to  $v_i$  in  $C^1_{(v_a, v_i)}$  and  $Q_2$  a path from  $v_j$  to  $v$  in  $C^1_{(v_j, v_b)}$ . Then  $Q_2 Q_1 P_3$  is a closed walk of weighted distance at most  $\frac{1}{4}N$  which is a contradiction.

Now suppose that  $i = j$ . Suppose for a contradiction that  $C^1_{(v_a, v_i)} \cap C^1_{(v_j, v_b)} \neq \{v_i\}$ . Let  $v \in (C^1_{(v_a, v_i)} \cap C^1_{(v_j, v_b)}) \setminus \{v_i\}$ . Let  $Q_1$  be a path from  $v$  to  $v_i$  in  $C^1_{(v_a, v_i)}$  and  $Q_2$  a path from  $v_i$  to  $v$  in  $C^1_{(v_i, v_b)}$ . Then  $Q_1 Q_2$  is a closed walk of weighted distance at most  $\frac{1}{6}N$ , which is a contradiction.

▷ **Claim 14.**  $d_\omega(P_2 \cup C^1_{(v_{j+1}, v_b)}, P_1 \cup C^1_{(v_a, v_i)}) \geq \frac{1}{6}N$ .

Proof. Suppose for a contradiction that  $d_\omega(P_2 \cup C^1_{(v_{j+1}, v_b)}, P_1 \cup C^1_{(v_a, v_i)}) < \frac{1}{6}N$ . Let  $s \in P_2 \cup C^1_{(v_{j+1}, v_b)}$  and  $q \in P_1 \cup C^1_{(v_a, v_i)}$  be such that  $d_\omega(s, q) < \frac{1}{6}N$ . Let  $P'_1$  be the directed path in  $P_1 \cup C^1_{(v_a, v_i)}$  from  $q$  to  $v_i$ .  $P'_2$  the directed path in  $P_2 \cup C^1_{(v_j, v_b)}$  from  $v_j$  to  $s$  and  $Q$  a path of weight at most  $\frac{1}{6}N$  from  $s$  to  $q$ . Then  $\bar{C} := v_j P'_2 Q P'_1 P_3$  is a closed walk such that  $\sum_{v \in \bar{C}} \hat{x}_v < 1$  which is a contradiction (see Figure 3).

Thus,  $d_\omega(P_2 \cup C^1_{(v_i, v_b)}, P_1 \cup C^1_{(v_a, v_i)}) \geq \frac{1}{6}N$ . Since  $d_\omega(u, v_i) \leq \frac{1}{12}N$  for any  $u \in C^1_{(v_a, v_i)}$ ,  $d_\omega(P_2, C^1_{(v_a, v_i)}) \geq \frac{1}{12}N$   $\triangleleft$

For  $i = 0, 1, \dots, \frac{1}{12}N$ , define  $R_i := \{v \in V : i \geq d_\omega(P_2 \cup C^1_{(v_{j+1}, v_b)}, v) > i - \omega(v)\}$ . Each vertex  $v \in V$  lies in at most  $\omega(v)$   $R_i$ . Let  $R'$  be the  $R_i$  of the smallest cost, so  $c(R') \leq 12OPT_{LP}$ . Since  $d_\omega(P_2 \cup C^1_{(v_{j+1}, v_b)}, P_1 \cup C^1_{(v_a, v_i)}) \geq \frac{1}{12}N$ , it follows that  $(P_1 \cup C^1_{(v_a, v_i)}) \setminus R_i$  is not reachable from  $(P_2 \cup C^1_{(v_{j+1}, v_b)}) \setminus R_i$  in  $G \setminus R_i$  for any  $i$ . Thus,  $(P_1 \cup C^1_{(v_a, v_i)}) \setminus R'$  is not reachable from  $(P_2 \cup C^1_{(v_{j+1}, v_b)}) \setminus R'$  in  $G \setminus R'$ .

Thus, any strongly connected component of  $G \setminus R'$  is either contained in  $G^F \setminus (P_1 \cup C^1_{(v_a, v_i)})$  or  $G^F \setminus (P_2 \cup C^1_{(v_{j+1}, v_b)})$ . For  $i = 1, 2, \dots, \frac{1}{12}N$  let  $K_i^+ := \{v \in V : i \geq d_\omega(v_j, v) > i - \omega(v)\}$  be the vertices of weighted distance  $i$  from  $v_j$ . Let  $K'^+$  denote the  $K_i^+$  of minimum cost.

▷ **Claim 15.**  $v_j$  is not contained in a cycle in  $G^F \setminus (R' \cup K'^+)$ .

Proof. Suppose that there is a cycle  $a_1, a_2, \dots, a_p v_j a_1$  in  $G^F \setminus (R' \cup K'^+)$ . If  $d_\omega(v_j, a_p) > \frac{1}{12}N$ , then  $a_p$  is not reachable from  $v_j$  in  $G^F \setminus (R' \cup K'^+)$ . Thus, there is a path  $P_a$  of weighted distance at most  $\frac{1}{12}N$  from  $v_j$  to  $a_p$ . Then the closed walk  $v_j P_a a_p v_j$  has weighted distance at most  $\omega(P_a) + \omega(a_p) \leq \frac{1}{12}N + \frac{1}{12}N < N$  which is a contradiction.  $\triangleleft$

Recall that any dicycle of  $G^F \setminus R'$  is contained in either  $G^F \setminus (P_1 \cup C^1_{(v_a, v_i)})$  or  $G^F \setminus (P_2 \cup C^1_{(v_{j+1}, v_b)})$ . Since  $v_j$  is not contained in any dicycle of  $G^F \setminus (R' \cup K'^+)$  it follows that any dicycle of  $G^F \setminus (R' \cup K'^+)$  is either contained in  $G \setminus (P_1 \cup C^1_{(v_a, v_i)})$  or in  $G \setminus (P_2 \cup C^1_{(v_j, v_b)})$ . By Proposition 12,  $g(P_1 \cup C^1_{(v_a, v_i)})$  and  $g(P_2 \cup C^1_{(v_j, v_b)})$  are nonfacial.

■ **Figure 3** On the left, there are  $u_{1,1}-v_2$  and  $u_{2,1}-v_3$  paths (green and blue vertices respectively) of weight at most  $\frac{1}{12}N$  and  $s-q$  path of length at most  $\frac{1}{12}N$ . The red cycle would then have weight at most  $N$ , which is a contradiction. On the right are the sets  $R_i$ , vertices at distance  $i$  from  $P_2 \cup C^1_{(v_{j+1}, v_b)}$ .

► **Definition 16** ([1, 14]). Given a simple closed curve  $f$  on a surface without boundary  $Q$ , not dividing the surface into 2 regions, we say  $Q'$  is obtained by doing surgery along  $f$  if  $Q'$  is obtained as follows. “Thicken”  $f$  to obtain a cylinder and remove this cylinder from  $Q$ , call this resulting surface  $Q''$ . The boundary of  $Q''$  consists of 2 circles we “glue” two cones  $N_1, N_2$  along these circles and call this final surface  $Q'$ .

► **Theorem 17** ([1] p.162). For a surface without boundary  $Q$  of genus  $g'$ ,  $Q'$  obtained by Definition 16 is a surface without boundary of genus at most  $g' - 1$ .

We apply the surgery of Definition 16 to  $g(P_1 \cup C^1_{(v_a, v_i)})$  to obtain a surface  $Q'$  of genus one less than  $Q$ . Let  $N'_1, N'_2$  denote the two cones glued to  $Q'$ . We also apply the surgery of Definition 16 to  $g(P_2 \cup C^1_{(v_j, v_b)})$  to obtain a surface  $\hat{Q}$  of genus one less than  $Q$ . Let  $\hat{N}_1, \hat{N}_2$  denote the two cones glued to  $\hat{Q}$ .

► **Lemma 18.** Let  $G$  be a graph embedded on a surface  $Q$  with no dicycles. Let  $h$  be a non-facial curve of  $Q \setminus G$ . Let  $Q'$  be the surface obtained by applying the surgery of Definition 16 to with respect to the curve  $h$  and surface  $Q$ . There is a natural embedding of  $G$  on  $Q'$  (by leaving each node of  $G$  where it was in  $Q$ ). Let  $N_1, N_2$  denote the two cones glued to  $Q'$  during the surgery process. Then each facial cycle of  $G$  with respect to its embedding in  $Q'$  contains either  $N_1$  or  $N_2$  in its inside region.

## 18:12 A Constant Factor Approximation for Directed Feedback Vertex Set

**Proof.** Let  $C$  be a facial cycle of  $G^F \setminus (P_1 \cup C_{(v_a, v_i)}^1)$  with respect to its embedding in  $Q'$ . If neither of the cones  $N_1, N_2$  are contained in the inside region of  $C$ , then  $C$  is a facial cycle of  $G$  with respect to its embedding in  $Q$ , which is a contradiction.  $\blacktriangleleft$

Thus, any facial cycle of  $G^F \setminus (P_1 \cup C_{(v_a, v_i)}^1)$  contains either  $N'_1$  or  $N'_2$  in its inside region.

Now let  $G_1, G_2, \dots, G_l$  be the strongly connected components of  $G^F \setminus (R' \cup K'^+)$ . Since any closed walk of  $G^F \setminus (R' \cup K'^+)$  is either contained in  $G \setminus (P_1 \cup C_{(v_a, v_i)}^1)$  or in  $G \setminus (P_2 \cup C_{(v_j, v_b)}^1)$  each strongly connected component is either contained in  $G \setminus (P_1 \cup C_{(v_a, v_i)}^1)$  or in  $G \setminus (P_2 \cup C_{(v_j, v_b)}^1)$ . If  $G_i$  is contained in  $G \setminus (P_1 \cup C_{(v_a, v_i)}^1)$ , then there is a natural embedding of  $G_i$  in  $Q'$  (obtained by leaving all nodes and edges where they are in the surgery for Definition 16). Likewise, if  $G_i$  is contained in  $G \setminus (P_2 \cup C_{(v_j, v_b)}^1)$ , then there is a natural embedding of  $G_i$  in  $\hat{Q}$ . Thus, for any  $G_i$  contained in  $G \setminus (P_1 \cup C_{(v_a, v_i)}^1)$  by Theorem 2, there is an 8-approximation for the problem of hitting the facial cycles of  $G_i$  (with respect to the natural embedding in  $Q'$ ). Likewise, for any  $G_i$  contained in  $G \setminus (P_2 \cup C_{(v_j, v_b)}^1)$  there is an 8-approximation for the problem of hitting the facial cycles of  $G_i$ . Let  $Z_i$  be a solution for the problem of hitting facial cycles of  $G_i$  of cost at most  $8OPT_{LP(G_i)}$  as guaranteed by Theorem 2.

Then each  $G_i \setminus Z_i$  is embedded in a surface of smaller genus with no facial cycles.

By induction, there are solutions  $A_i$  to  $G_i \setminus Z_i$  of cost  $c_{g-1}OPT_{LP(G_i \setminus Z_i)}$ , where  $c_g$  is the integrality gap of the DFVS LP for graphs of genus  $g$ .

Define  $\hat{x}^{G_i \setminus Z_i} \in \mathbb{R}^{V(G_i \setminus Z_i)}$  as  $\hat{x}^{G_i \setminus Z_i}(v) = \hat{x}_v$ , where  $\hat{x}$  is as in the proof of Lemma 9. Since graphs  $G_i$  are vertex disjoint,  $G_i \setminus Z_i$  are vertex disjoint, so  $\sum_{i=1}^l OPT_{LP(G_i)} \leq \sum_{i=1}^l \sum_{v \in V(G_i)} \hat{x}_v \leq \sum_{v \in V(G)} \hat{x}_v = OPT_{LP(G)}$ . Now  $F \cup R' \cup K'^+ \cup (\cup_{i=1}^l A_i) \cup (\cup_{i=1}^l Z_i)$  is a DFVS of cost  $(O(1) + c_{g-1})OPT_{LP(G)} = (O(1) + O(g-1))OPT_{LP(G)} = (O(g))OPT_{LP(G)}$ .  $\triangleleft$

Note that the argument in Claim 13 is symmetric with respect to left and right and we may swap right and left to get the following result. Let  $b'_{i,1}, b'_{i,2}, \dots, b'_{i,l'_i}$  be the in neighbours of  $v_i$  such that each edge  $b'_{i,t}v_i$  reaches  $v_i$  from the left and  $d'_{i,1}, d'_{i,2}, \dots, d'_{i,t'_i}$  be the out neighbours of  $v_i$  such that the edge  $d'_{i,t'}v_i$  reaches  $v_i$  from the right. Subdivide each edge  $b'_{j,t'}v_j$  into a path  $b'_{j,t'}b_{j,t'}v_j$  and each edge  $v_i d'_{i,t}$  into a path  $v_i d_{i,t} d'_{i,t}$  and give the new vertices  $d_{j,t'}, b_{i,t}$  infinite cost. There is a natural embedding of our new graph on our surface by placing each  $b_{i,t}$  where the midpoint of the curve  $g(v_i b'_{j,t'})$  was embedded and likewise for  $d_{j,t'}$ . By abuse of notation, we continue to call our graph  $G$  and define  $\hat{x}_{b_{i,t}} = \hat{x}_{d_{j,t'}} = 0$  for all  $b_{i,t}, d_{j,t'}$ .

Denote  $B := \cup_{i=1}^{l'} \{b_{i,1}, b_{i,2}, \dots, b_{i,l'_i}\}$ ,  $D = \cup_{i=1}^{l'} \{d_{i,1}, d_{i,2}, \dots, d_{i,t'_i}\}$ . Let  $\kappa_- : \{i \in [l'] : \exists b_{i,t'} \in B, \exists d_{j,t'} \in D : d_{\omega, G^F \setminus C^1}(d_{j,t'}, b_{i,t'}) < \frac{1}{12}N\}$  the first indices of the set of vertices of  $B$  of weighted distance at most  $\frac{1}{12}N$  from  $D$  in  $G^F \setminus C^1$ . Let  $\kappa_+ := \{j \in [l'] : \exists d_{j,t'} \in D, \exists b_{i,t'} \in B : d_{\omega, G^F \setminus C^1}(d_{j,t'}, b_{i,t'}) < \frac{1}{12}N\}$  the first indices of the set of vertices of  $D$  that can reach  $B$  with a path of weighted distance at most  $\frac{1}{12}N$  in  $G^F \setminus C^1$ . Similarly to how we proved Claim 13, we can show the following:

$\triangleright$  **Claim 19.** If  $d_{\omega}(V_{\kappa_-}, V_{\kappa_+}) > \frac{1}{12}N$ , then we can find  $T \subset V$ ,  $c(T) = O(1)OPT_{LP}$ , (recall  $OPT_{LP} := \sum_{v \in V} c_v x_v$  is the value of the optimal fractional solution), such that any strongly connected component of  $G^F \setminus T$  does not contain a directed path from  $D$  to  $B$  in  $G \setminus C^1$ .

If  $d_{\omega}(V_{\kappa_-}, V_{\kappa_+}) \leq \frac{1}{12}N$ , then the LP gap of the natural LP ( $P_{DFVS}$ ) for  $G$  has integrality gap  $O(1)$ .

We now construct a DFVS of cost at most  $O(g)OPT_{LP}$ . If either  $d_{\omega}(V_{\kappa_-}, V_{\kappa_+}) \leq \frac{1}{12}N$  or  $d_{\omega}(V_{\tau_-}, V_{\tau_+}) \leq \frac{1}{12}N$ . Then Claim 13 or Claim 19 respectively shows that the LP gap of the natural LP ( $P_{DFVS}$ ) for  $G$  has integrality gap  $O(g)$ .

Now assume both  $d_\omega(V_{\tau_-}, V_{\tau_+}), d_\omega(V_{\kappa_-}, V_{\kappa_+}) > \frac{1}{12}N$ . Then by Claim 13 and Claim 19, there are sets  $S, T$  such that any strongly connected component of  $G^F \setminus (S \cup T)$  does not contain a path from  $U$  to  $W$  or a path from  $D$  to  $B$  in  $G^F \setminus C^1$ .

For any digraph  $H$  define  $\text{un}(H)$  to be the underlying (undirected) graph of  $H$ . Let  $K$  be any strongly connected component of  $G^F \setminus (S \cup T)$ . We will prove  $\text{un}(K)$  does not contain any path from  $U \cup B$  to  $W \cup D$  in  $\text{un}(K) \setminus C^1$ .

► **Proposition 20.** *If there is a (undirected) path  $P = u_{i,t}q_1, q_2, \dots, q_t$  from some  $u_{i,t} \in U$  (resp  $u_{i,t} \in D$ ) in  $\text{un}(K) \setminus C^1$ , then there is a directed path from  $U$  (resp  $D$ ) to  $q_j$  in  $G^F \setminus (S \cup T \cup C^1)$  for any  $j = 1, 2, \dots, t$ .*

*If there is a (undirected) path  $P = q_1, q_2, \dots, q_t w_{i,t}$  from some  $w_{i,t} \in W$  (resp  $b_{i,t} \in B$ ) in  $\text{un}(K) \setminus C^1$ , then there is a directed path from  $q_j$  to  $W$  (resp  $B$ ) in  $G^F \setminus (S \cup T \cup C^1)$  for any  $j = 1, 2, \dots, t$ .*

**Proof.** Let  $P = u_{i,r}q_1, q_2, \dots, q_t$  be a path in  $\text{un}(K) \setminus C^1$  from some  $u_{i,r} \in U$  (resp  $u_{i,r} \in D$ ). We prove by induction  $t'$  on that there is a directed path from  $U$  to  $q_j$  in  $G^F \setminus (S \cup T \cup C^1)$  for any  $j = 1, 2, \dots, t'$ . The case  $t' = 1$  is clear as each  $u_{i,r} \in U$  (resp  $u_{i,r} \in D$ ) only has out-neighbours so the undirected edge  $\{u_{i,r}, q_1\}$  in  $\text{un}(K)$  is directed from  $u_{i,r}$  to  $q_1$ .

Now assume the statement true for  $t' = t''$ . For  $t' = t'' + 1$ , if the undirected edge  $\{q_{t'}, q_{t'+1}\}$  is directed from  $q_{t'}$  to  $q_{t'+1}$ , then there is a directed path from  $u_{i,r}$  to  $q_{t'+1}$  in  $G^F \setminus (S \cup T \cup C^1)$ .

Otherwise  $\{q_{t'}, q_{t'+1}\}$  is directed from  $q_{t'+1}$  to  $q_{t'}$ . By strong connectedness of  $K$ , there is a directed path  $P'$  from  $q_{t'}$  to  $q_{t'+1}$  in  $K \setminus (S \cup T)$ . If  $P'$  does not intersect  $C$  then there is a directed path from  $u_{i,r}$  to  $q_{t'+1}$  in  $G^F \setminus (S \cup T \cup C^1)$ . So, assume  $P'$  intersects  $W$  or  $B$ . Let  $P''$  denote the subpath of  $P'$  from  $q_{t'}$  to when  $P'$  first intersects  $U$  or  $B$ . By construction  $P''$  lies in  $G^F \setminus (S \cup T \cup C^1)$ . As  $u_{i,r}$  lies in  $U$  (resp  $D$ )  $P''$  does not intersect  $W$  (resp.  $B$ ), as then we would have a  $U$ - $W$  (resp.  $D$ - $B$ ) path in  $G^F \setminus (S \cup T \cup C^1)$ . Thus,  $P''$  is a  $q_{t'}$ - $B$  (resp.  $q_{t'}$ - $W$ ) path. Consider the subpath  $Q$  of the reversal of  $P'$  starting from  $q_{t'+1}$  to when the reversal of  $P'$  first intersects  $D$  or  $U$ . Let  $\text{rev}(Q)$  denote the reversal of  $Q$ . Note  $\text{rev}(Q)$  lies in  $G^F \setminus (S \cup T \cup C^1)$ . If the starting vertex of  $\text{rev}(Q)$  is in  $D$  (resp.  $U$ ), then  $\text{rev}(Q) \cup \{q_{t'+1}q_{t'}\} \cup P''$  is a  $D$ - $B$  (resp.  $U$ - $W$ ) path in  $G^F \setminus (S \cup T \cup C^1)$ . This contradicts Claim 19. Thus, the starting vertex of  $\text{rev}(Q)$  is in  $U$  (resp.  $D$ ). This implies there is a path from  $U$  (resp.  $D$ ) to  $q_{t'+1}$  completing the induction. The proof of the second part is similar. ◀

► **Proposition 21.** *There is no (undirected) path from  $W \cup D$  to  $U \cup B$  in  $\text{un}(K) \setminus C^1$ .*

**Proof.** If we have a  $U$ - $W$  path  $P = u_{i,t}q_1, q_2, \dots, q_t w_{j,t'}$  in  $\text{un}(K) \setminus C^1$ , then by Proposition 20, there are directed  $U$ - $q_1$  and  $q_1$ - $W$  paths  $P_1$  and  $P_2$  in  $\text{un}(K) \setminus C^1$ . Then  $P_1 \cup P_2$  is a directed  $U$ - $W$  path in  $K \setminus C^1$  which contradicts Claim 19. Thus, we do not have a  $U$ - $W$  path  $P = u_{i,t}q_1, q_2, \dots, q_t w_{j,t'}$  in  $K \setminus C^1$ . Likewise, we do not have a  $D$ - $B$  path  $P = u_{i,t}q_1, q_2, \dots, q_t w_{j,t'}$  in  $K \setminus C^1$ .

Suppose we have a  $U$ - $D$  path  $P = u_{i,t}q_1, q_2, \dots, q_t d_{j,t'}$  in  $\text{un}(K) \setminus C^1$ . By Proposition 20, there are directed  $U$ - $q_1$  and  $D$ - $q_1$  paths  $P_1$  and  $P_2$  in  $K \setminus C^1$ . Recall  $U$  has no in-neighbours of in  $G \setminus C^1$ , so the edge  $\{u_{i,t}, q_1\}$  in  $K$  is directed from  $u_{i,t}$  to  $q_1$ . By 2 connectedness of  $K$ , there is a path  $P_3$  from  $q_1$  to  $u_{i,t}$ . The only in-neighbours of  $u_{i,t}$  are in  $C^1$ , thus  $P_3$  intersects  $W \cup B$ . Let  $P'_3$  be the subpath of  $P_3$  from  $q_1$  to when it the path first intersects  $W \cup B$ . If the endpoint of  $P'_3$  is in  $W$ , then  $P_1 \cup P'_3$  is a  $U$ - $W$  path in  $K \setminus C^1$ . Otherwise, if the endpoint of  $P'_3$  is in  $B$ , then  $P_2 \cup P'_3$  is a  $D$ - $B$  path in  $K \setminus C^1$ . Either way this contradicts Claim 19. ◀

► **Proposition 22** ([15, 25]). *Suppose  $G$  is a graph embedded on a surface  $Q$ . Let  $C$  be a cycle of  $G$  that does not divide  $Q$  into two separate regions such that there is no edge between vertices of  $C$  that is not part of  $C$ . Define a “left” and “right” as in Proposition 11. Let  $\hat{L}, \hat{R}$  denote the neighbours of  $C$  that are “left” or “right” of  $C$ . Suppose each connected component of  $G \setminus C$  only contains nodes of  $\hat{L}$  or  $\hat{R}$  but not both. There is a non-facial closed curve  $h$  in  $Q \setminus G$ .*

Applying Proposition 21, we get that  $G^F$  satisfies Proposition 22 with respect to  $C^1$ . Thus, there is a non-facial closed curve  $h$  in  $Q \setminus G^F$ . We apply the surgery of Definition 16 with respect to the closed curve  $h$  and surface  $Q$  to obtain a surface  $Q'$  of lower genus. Let  $G_1, G_2, \dots, G_l$  be the strongly connected components of  $G^F \setminus (S \cup T)$ , so each  $G_i$  is embeddable on  $Q'$ . By Lemma 18 each facial dicycle of  $G_i$  contains one of the cones of  $Q'$ . Hence there is an algorithm that returns a hitting set  $Z_i$  to the set of facial cycles of  $G_i$  of cost at most  $8OPT_{LP(G_i)}$ . By induction, there are solutions  $A_i$  to  $G_i \setminus Z_i$  of cost  $c_{g-1}OPT_{LP(G_i)}$ , where  $c_g$  is the integrality gap of the DFVS LP for graphs of genus  $g$ . Define  $\hat{x}_i^G \in \mathbb{R}^{V(G_i)}$  as  $\hat{x}_i^G(v) = \hat{x}_v$ , where  $\hat{x}$  is as in the proof of Lemma 9. Since graphs  $G_i$  are vertex disjoint,  $\sum_{i=1}^l OPT_{LP(G_i)} \leq \sum_{i=1}^l \sum_{v \in V(G_i)} \hat{x}_i^G(v) \leq \sum_{v \in V(G)} \hat{x} = OPT_{LP(G)}$ . Then  $S \cup T \cup F \cup (\cup_{i=1}^l A_i) \cup (\cup_{i=1}^l Z_i)$  is a DFVS of cost  $(O(1) + c_{g-1})OPT_{LP(G)} = (O(1) + O(g-1))OPT_{LP(G)} = (O(g))OPT_{LP(G)}$ . ◀

As observed in [7],  $(P_{DFVS})$  can be solved in polynomial-time via the ellipsoid method. Hence Lemma 9 yields a polynomial time  $O(g)$ -approximation algorithm for DFVS in graphs of genus  $g$  with no facial cycle.

## 5 Statement and proofs of topological results we use

First let us prove Proposition 22.

**Proof.** Suppose each connected component of  $G \setminus C$  only contains nodes of  $\hat{L}$  or  $\hat{R}$  but not both. Let  $G_L$  and  $G_R$  be the unions of the components of  $G - C$  that only contain nodes from  $\hat{L}$  and  $\hat{R}$  respectively. Assume that  $Q \setminus G$  contains no non-facial curve  $h$ .

Case 1: At least one of  $G_L$  or  $G_R$  is empty.

Suppose, without loss of generality, that  $G_L$  is empty. Consider the face of  $G$  that contains  $C$  and intersects the left of  $C$ . But,  $C$  is not contractible (else it would separate the surface  $Q$  into two components). Hence, a small leftward shift of  $C$  which will lie in the face  $f$  will produce a non-facial curve  $h$ .

Case 2: Both  $G_L$  and  $G_R$  are nonempty.

We claim that if a face contains vertices of  $G_L, G_R$  and of  $C$  then there is a non-facial curve in  $Q \setminus G$ . Let  $f$  be such a face of degree  $d$ . Let  $\partial f = v_0 \cdots v_{d-1}$  be the boundary cycle of  $f$ , where  $i \in \mathbb{Z}/d\mathbb{Z}$ . Without loss of generality, assume that  $v_0 \in \hat{L}$  and for some  $q$   $v_1, v_2, \dots, v_q \in C$ , and  $v_{q+1} \in \hat{R}$ . There are points  $p_L$  on the edge  $v_0 v_1$  in the interior of  $L$  and  $p_R$  on the edge  $v_q v_{q+r}$  in the interior of  $R$ . Let  $h : [0, 1] \rightarrow Q$  be a non-self-intersecting curve in  $f$  from  $p_R$  to  $p_L$ . Let  $r_L, r_R > 0$  be such that  $B_Q(p_L, r_L) \subset L$ ,  $B_Q(p_R, r_R) \subset R$ . Let  $h^L, h^R$  be non-self-intersecting curves in  $B_Q(p_L, r_L)$  and  $B_Q(p_R, r_R)$  from  $p_L$  to  $v_1$  and  $p_R$  to  $v_q$  respectively not intersecting  $h$ . Then  $h \cup h^L \cup h^R$  satisfies the conditions of Proposition 12. Thus,  $h \cup h^L \cup h^R \cup g(p_L v_0, v_1, \dots, v_{q+1} p_R)$  does not bound a region of the closure of  $f$ . As this curve lies in the closure of  $f$ , this implies that  $f$  is not homeomorphic to an open disk. By the classification theorem for orientable surfaces (see for instance page 87 of [17]),  $cl(f)$  is homeomorphic to a  $m$ -torus  $T_m$  with a finite number of open disks removed. Since  $f$  is not homeomorphic to an open disk,  $f$  contains a non-facial closed curve  $h$  in its interior.

If there is a face  $f$  of  $G$  whose boundary contains vertices of  $G_L$  and of  $G_R$  (but not of  $C$ ), then as there is no edge between  $G_L$  and  $G_R$ , the boundary of  $f$  is not connected and so  $f$  is not homeomorphic to an open disk. Just as before this implies  $f$  contains a non-facial closed curve  $h$ .

Now, consider the subsets  $Q_L$  and  $Q_R$  of  $Q$  obtained by taking the union of all the vertices, edges and faces induced by  $G_L \cup C$  and  $G_R \cup C$ , respectively. By assumption 3, every component of  $G - C$  is in  $G_L$  or  $G_R$ , so every vertex and edge of  $G$  belongs to  $Q_L$  or  $Q_R$ . By the subcases eliminated above under Case 2, every face of  $G$  also belongs to  $Q_L$  or  $Q_R$  (but not both). Then,  $Q = Q_L \cup Q_R = (Q_L - C) \sqcup (Q_R - C) \sqcup C$ . This means that  $C$  separates  $Q$  into two components, which contradicts assumption 1. ◀

It is well known (see for instance [1] page 15) that smooth surfaces  $Q$  have the property that for each  $v \in Q$  there is an open ball  $B_Q(v, r_0)$  of some small radius  $r_0 > 0$  in  $Q$  and a diffeomorphism  $\psi$  from  $B_Q(v, r_0)$  to the open disk  $B_{\mathbb{R}^2}(0, r_0)$  of radius  $r_0$  about the origin in the two-dimensional plane such that  $\psi(v) = (0, 0)$  and  $\psi$  preserves distances from  $v$ , that is  $\text{dist}_Q(v, x) = \|\psi(v) - \psi(x)\|$ , where  $\text{dist}_Q(v, x)$  is the geodesic distance from  $v$  to  $x$  in  $Q$ . For  $p \in Q$ ,  $r > 0$ , denote by  $B(p, r)$  the open ball of radius  $r$  about  $p$ . We now formally state and prove what Proposition 11 and Proposition 12 informally say.

► **Proposition 23.** *Given a closed continuous non-self-intersecting curve  $C'$  embedded on an orientable surface  $Q$ . There exist some radius  $r > 0$  and disjoint subsets  $L, R$  “on each side” of  $C'$  such that the set  $\{B(v, r) : v \in C'\}$  (where  $B(v, r)$  is the open ball around  $v$  of radius  $r$  in  $Q$ ) is contained in the union  $L \cup R \cup C'$ , and for each  $v \in C'$ ,  $r' \leq r$ ,  $L \cap B(v, r')$  and  $R \cap B(v, r')$  are the two connected components of  $B(v, r') \setminus C'$ . There is a diffeomorphism  $\phi$  from  $L \cup C' \cup R$  to a connected open neighbourhood of  $C' \times \{0\}$  in  $C' \times \mathbb{R}$  and small  $q > 0$  with  $C' \times (-q, 0) \subset \phi(L) \subset C' \times (-\infty, 0)$ ,  $C' \times (0, q) \subset \phi(R) \subset C' \times (0, \infty)$  and  $\phi(C') = C' \times \{0\}$ . Further for any (piecewise smooth) curve  $f : [0, 1] \rightarrow Q$  such that  $f(x) \notin C'$  for any  $x \in [0, 1)$ ,  $f(1) \in C'$  satisfies that for some  $\beta \in (0, 1)$ , either  $f((\beta, 1)) \in L$ , that is the curve “reaches  $C'$  from the left”  $L$  or  $f((\beta, 1)) \in R$ , that is the curve “reaches  $C'$  from the right”  $R$ .*

► **Proposition 24.** *For a finite set of curves  $f_1, f_2, f_3, \dots, f_{t'}, h_1, h_2, \dots, h_{t'} : [0, 1] \rightarrow Q$  such that for each  $i$ ,  $f_i(x) \notin C'$  for any  $x \in [0, 1)$  and  $h_i(x) \notin C'$  for any  $x \in [0, 1]$  we may choose  $L, R, r$  above so that each curve  $f_i([0, 1))$  is disjoint from at least one of  $L, R$  and each curve  $h_i([0, 1])$  is disjoint from both  $L, R$ . We refer to  $L$  and  $R$  as the left and right of  $C'$  respectively.*

Further, there are curves  $f_L : [0, 1] \rightarrow L$ ,  $f_R : [0, 1] \rightarrow R$  which are homotopic to  $C'$ . Informally speaking, these are obtained by “slightly shifting”  $f$  “left” and “right” respectively.

► **Proposition 25.** *Lastly let  $h : [0, 1] \rightarrow Q$  be any curve that reaches  $C'$  from the right at a point  $c_2 = h(1)$  on  $C'$ , leaves  $C'$  from the left at  $c_1 = h(0)$ , that is the curve  $\bar{\psi}(t) = h(1 - t)$  reaches  $C'$  at  $c_1$  from the left and  $h$  is otherwise disjoint from  $C'$ . Assume  $c_1 \neq c_2$  and let  $C'_{c_1, c_2}$  be a subcurve of  $C'$  with endpoints  $c_1$  and  $c_2$ . Then there is a curve  $\hat{h} : [0, 2] \rightarrow Q$  that reaches  $C'$  from the right at  $c_1 = \hat{h}(1)$  and leaves  $C'$  at a point  $c_1 = \hat{h}(0)$   $\hat{h}$  is otherwise disjoint from  $C'$ , and there is a homeomorphism of  $Q$  that maps  $\hat{h}$  to the concatenation of  $h$  and  $C'_{c_1, c_2}$ .*

► **Proposition 26.** *Let  $Q$  be an orientable surface and  $\phi : [0, 1] \rightarrow Q$  a closed curve not dividing  $Q$  into 2 regions with disjoint subsets  $L, R$  “on each side” of  $\phi$  as in Proposition 23. Let  $c_1, c_2 \in [0, 1)$ , with  $c_2 \geq c_1$ . Suppose that  $\phi_1 : [0, 1] \rightarrow Q$  is a curve with  $\phi_1(0) = \phi(c_1)$   $\phi_1(1) = \phi(c_2)$ ,  $\phi_1([0, 1])$  is disjoint from  $\phi([0, 1])$  and the curve  $\phi_1([0, 0.5])$  approaches  $\phi([0, 1])$  from the left  $L$  and  $\phi_1([0.5, 1])$  approaches  $\phi([0, 1])$  from the right  $R$ .*

## 18:16 A Constant Factor Approximation for Directed Feedback Vertex Set

Then the curve  $\phi_2 : [0, 1] \rightarrow Q$ ,  $\phi_2(x) = \phi(c_2 - x)$  if  $x \leq c_2 - c_1$  and  $\phi_2(x) = \phi_1(\frac{1}{c_2 - c_1}(x - c_2 + c_1))$  for  $x > c_2 - c_1$ , that is the curve obtained by joining the portion of  $\phi$  from  $c_1$  to  $c_2$  to  $\phi_1([0, 1])$  does not divide  $Q$  into 2 regions.

**Proof.** We prove Proposition 23, Proposition 24, and Proposition 25. We use the following corollary of the tubular neighbourhood theorem (see for instance [4]).

► **Proposition 27** (corollary of tubular neighbourhood theorem [4]). *Given a curve  $C'$  embedded in a surface  $Q$  there is an open neighbourhood  $U$  of  $C'$  and an open set  $V$  in  $C' \times \mathbb{R}$  such that there is a diffeomorphism  $\phi : U \rightarrow V$  with  $\phi(C') = C' \times \{0\}$ .*

Let  $w : [0, 1] \rightarrow C'$  with  $w(0) = w(1)$ ,  $w(0.5) = c_2$  be a parameterization of  $C'$ . We define distance on  $C' \times \mathbb{R}$  by  $\text{dist}((a_1, b_1), (a_2, b_2)) := (\text{dist}_Q(a_1, a_2)^2 + |b_1 - b_2|^2)^{\frac{1}{2}}$ , where  $\text{dist}_Q(a_1, a_2)$  is the geodesic distance between  $a_1$  and  $a_2$  in  $Q$ . For each  $v \in C'$  let  $q_v$  be the minimum of 1 and  $\sup\{q' : B(v, q') \subset V\}$ .  $q_v$  is continuous in  $v$  and  $q_v > 0 \forall v \in C'$ . By compactness of  $C'$ ,  $q := \min_{v \in C'} q_v$  exists and is positive. Now define  $L' = \phi^{-1}(C' \times (-q, 0))$ ,  $R' = \phi^{-1}(C' \times (0, q))$ .

Define  $U' = L' \cup C' \cup R'$ . Let  $f : [0, 1] \rightarrow Q$  be a curve with  $f(x) \notin C'$  for any  $x \in [0, 1]$ . By continuity of  $f$  there is some  $\beta \in (0, 1)$  for which  $f((\beta, 1]) \subset U'$ . We claim  $f((\beta, 1]) \subset L'$  or  $f((\beta, 1]) \subset R'$ . If  $\phi(f((\beta, 1)))$  contains a point in  $C' \times (-\infty, 0)$  and a point in  $\phi^{-1}(C' \times (0, \infty))$  then by continuity  $\phi(f((\beta, 1)))$  contains a point in  $C' \times \{0\}$  and hence  $f((\beta, 1))$  contains a point in  $C'$  which is a contradiction. Thus, either  $\phi(f((\beta, 1))) \subset C' \times (-\infty, 0)$  or  $\phi(f((\beta, 1))) \subset C' \times (0, \infty)$ . If  $\phi(f((\beta, 1))) \subset C' \times (-\infty, 0)$ , then  $f((\beta, 1)) \subset L'$ . If  $\phi(f((\beta, 1))) \subset C' \times (0, \infty)$ , then  $f((\beta, 1)) \subset R'$ .

For each  $f_i$  there exists  $\beta_i$  for which  $f((\beta_i, 1]) \in L'$  or  $f((\beta_i, 1]) \in R'$ . For each  $x \in C'$  define  $r'_x$  to be the supremum of all radius  $r''_x$  for which the ball  $B(x, r''_x)$  of radius  $r''_x$  is entirely contained in  $U'$  and for which  $B(x, r''_x)$  is disjoint from  $f_1([0, \beta_1]), f_2([0, \beta_2]), f_3([0, \beta_3]), \dots, f_{l'}([0, \beta_{l'}]), h_1([0, 1]), h_2([0, 1]), \dots, h_{l'}([0, 1])$ . If the supremum does not exist, set  $r'_x = \infty$ . Define  $r_x = \min\{1, r'_x\}$ . Again  $r_x > 0$  for all  $x \in C'$  and is continuous in  $x$ . Since  $C'$  is a compact set,  $r := \min_{x \in C'} r_x$  exists and is positive. Note each curve  $f_i([0, 1])$  is disjoint from at least one of  $L' \cap \{B(x, r) : x \in C'\}, R' \cap \{B(x, r) : x \in C'\}$  and each curve  $h_i([0, 1])$  is disjoint from both  $L' \cap \{B(x, r) : x \in C'\}, R' \cap \{B(x, r) : x \in C'\}$ .

Let us show that by making  $r$  smaller if necessary  $B(v, r) \setminus C'$  contains two connected components.

► **Proposition 28.** *Given a (piece-wise smooth non-self-intersecting) curve  $f : [0, 1] \rightarrow \mathbb{R}^2$  with  $t_0 \in (0, 1)$  there exists  $r > 0$  for which  $B(f(t_0), r) \setminus f([0, 1])$  contains exactly two components.*

**Proof.** Let  $[t_0, t_1]$  be an interval in which  $f$  is smooth.

Let  $f(t) = f(t_0) + (t - t_0)\nabla f(t_0) + g(t - t_0)$ . By smoothness of  $f$ ,  $\nabla g(t - t_0)$  is bounded for  $t \in [t_0, t_1]$  and  $g(t - t_0) = o(t - t_0)$ . Differentiating  $\|f(t) - f(t_0)\|^2 = \|(t - t_0)\nabla f(t_0) + g(t - t_0)\|^2$  we obtain

$$\begin{aligned} \frac{d}{dt} \|f(t) - f(t_0)\|^2 &= 2(\nabla f(t_0) + \nabla g(t - t_0))^t ((t - t_0)\nabla f(t_0) + g(t - t_0)) \\ &= 2(\nabla f(t_0) + o(1))^t ((t - t_0)\nabla f(t_0) + o(t - t_0)) \\ &= 2(\nabla f(t_0) + o(1))^t (t - t_0)\nabla f(t_0) + o(t - t_0) \end{aligned}$$

For  $t$  close enough to  $t_0$  the last line is positive. This implies that for some  $t_2 > t_0$ ,  $\|f(t) - f(t_0)\|^2$  is increasing on  $[t_0, t_2]$ . Likewise, for some  $t_3 < t_0$ ,  $\|f(t) - f(t_0)\|^2$  is decreasing on  $[t_3, t_0]$ .

Let  $r > 0$  be such that  $\|f(t_0) - f(t)\| \geq 2r$  for all  $t \in [0, 1] \setminus \text{frac}([t_3, t_2])$ , where  $\text{frac}(x)$  is the fractional part of  $x$ . Then  $\|f(t_0) - f(t_2)\|, \|f(t_0) - f(t_3)\| \geq 2r$ . Then since  $\|f(t_0) - f(t)\|$  is increasing on  $[t_0, t_2]$  there is exactly one  $t_4 \in [t_0, t_2]$  with  $\|f(t_0) - f(t_4)\| = r$ . Likewise, there is exactly one  $t_5 \in [t_3, t_0]$  with  $\|f(t_0) - f(t_5)\| = r$ . So  $f([t_5, t_4])$  forms a simple curve in the closed ball  $\bar{B}(f(t_0), r)$  with endpoints on the boundary and  $f((t_5, t_4))$  lying in the interior. It follows from the Jordan curve theorem that  $B(f(t_0), r) \setminus f([0, 1]) = B(f(t_0), r) \setminus f((t_5, t_4))$  contains exactly two connected components.  $\blacktriangleleft$

Let  $v \in C'$ . For small enough  $r_0$ ,  $B(v, r_0)$  is diffeomorphic to the open disk  $B(0, r_0)$  in  $\mathbb{R}^2$  via some diffeomorphism  $\psi$  with  $\psi(v) = (0, 0)$ . Let  $w$  be a parameterization of  $C'$  with  $w(0.5) = v$ . Let  $t_1 := \inf\{t : w([t, 0.5]) \subset B(v, r_0)\}$  and  $t_2 := \sup\{t : w([0.5, t]) \subset B(v, r_0)\}$  that is  $[t_1, t_2]$  is a maximal interval for which  $w([t_1, t_2]) \subset B(v, r_0)$  by continuity  $t_1 < 0.5 < t_2$ . Choose  $r_1 > 0$  less than the distance from  $v$  to  $C' \setminus w((t_1, t_2))$  and  $r_1 < \text{dist}_Q(v, w(t_1)), \text{dist}_Q(v, w(t_2))$ . From the previous proposition there exists  $r_2 > 0$  such that  $B_{\mathbb{R}^2}(\psi(v), r_2) \setminus \psi(w([t_1, t_2]))$  contains exactly two connected components. By making  $r$  smaller than  $r_1$  and  $r_2$  if necessary we get that for any  $0 < \hat{r} \leq r$ ,  $B_{\mathbb{R}^2}(\psi(v), \hat{r}) \setminus \psi(C')$  contains exactly two connected components. Thus,  $B(v, \hat{r}) \setminus C'$  contains exactly two connected components.

Define  $L = L' \cap \{B(x, r) : x \in C'\}$ ,  $R = R' \cap \{B(x, r) : x \in C'\}$ . Each curve  $f : [0, 1] \rightarrow Q$  with  $f(x) \notin C'$  for any  $x \in [0, 1]$  satisfies  $f((\beta, 1)) \subset L$  or  $f((\beta, 1)) \subset R$ . Each curve  $f_i([0, 1])$  is disjoint from at least one of  $L, R$  and each curve  $h_i([0, 1])$  is disjoint from both  $L, R$ .

Since  $\phi(v) = \{v\} \times \{0\}$ ,  $\phi(B(v, \hat{r}))$  intersects both  $\{v\} \times (-\infty, 0)$  and  $\{v\} \times (0, \infty)$ . Recall  $B(v, \hat{r}) \subset L \cup R \cup C'$ , so  $B(v, \hat{r})$  intersects both  $L$  and  $R$ . Since there is no path from  $L$  to  $R$  in  $L \cup R \cup C'$  one component of  $B(v, \hat{r}) \setminus C'$  is contained in  $L$  and the other is contained in  $R$ .

For each  $v \in C'$  let  $y_v$  be the supremum of  $\{y'_v \geq 0 : \{v\} \times (-y'_v, y'_v) \subset \phi(B(v, r))\}$ . Again  $y_v$  is positive and continuous in  $v$  so  $y := \min_{v \in C'} y_v$  exists and is positive. Then  $C' \times (-y, 0) \subset \phi(L)$  and  $C' \times (0, y) \subset \phi(R)$ . Define the curves  $f_L, f_R$  to be parameterizations of  $\phi^{-1}(C' \times \{-\frac{y}{2}\})$  and  $\phi^{-1}(C' \times \{\frac{y}{2}\})$  respectively.

Lastly given a curve  $h : [0, 1] \rightarrow Q$  be any curve that reaches  $C'$  from the right at a point  $c_2 = h(1)$  on  $C'$ , leaves  $C'$  from the left at  $c_1 = h(0)$  and  $C'_{c_1, c_2}$  be a subcurve of  $C'$  with endpoints  $c_1$  and  $c_2$ . Let  $j : [0, 1] \rightarrow C'_{c_1, c_2}$  be a parameterization of  $C'_{c_1, c_2}$  and denote  $\bar{j} : [0, 2] \rightarrow Q$  by  $\bar{j}(t) = h(t)$  for  $t \in [0, 1]$  and  $\bar{j}(t) = j(t - 1)$  for  $t > 1$ . Informally speaking, we “slightly shift” all points in  $L \cup C' \cup R$  to the right while keeping  $h([0, 1]) \cap L$  to the left of  $C'$ . Let  $\phi(x) = (\phi_1(x), \phi_2(x))$ ,  $\phi^{-1}(x) = (\phi_1^{-1}(x), \phi_2^{-1}(x))$ .

Let  $\gamma : C' \rightarrow (-y, 0)$  be any continuous function such that  $\gamma(c_2) = 0$  and for any  $t \in [0, 1]$  for which  $\phi(h(t)) \in C' \times (-y, 0)$ ,  $(\phi(h(t))_2) < \gamma(\phi(h(t))_1) < 0$ . Informally  $\gamma$  is a curve lying to the right of  $\phi(h([0, 1])) \cap C' \times (-y, 0)$  and to the left of  $[0, 1] \times \{0\}$ . Such  $\gamma$  exists for instance define  $-\gamma(t)$  to be half of the minimum of the distance from the point  $(t, 0)$  to  $\phi(h([0, 1])) \cap C' \times (-y, 0)$  and  $y$ .

Define  $\bar{\gamma} : C' \times (-y, y) \rightarrow C' \times (-y, y)$  as follows. For  $(a, b) \in C' \times (-y, y)$  if  $b < \frac{\gamma(a)}{4}$  define  $\bar{\gamma}(a, b) = (a, b)$ . If  $\frac{\gamma(a)}{4} \leq b < 0$ , define  $\bar{\gamma}(a, b) = (a, \frac{\gamma(a)}{4} + 2(b - \frac{\gamma(a)}{4}))$ . If  $0 \leq b \leq \frac{-\gamma(a)}{2}$ , define  $\bar{\gamma}(a, b) = (a, \frac{-\gamma(a)}{4} + \frac{b}{2})$ . If  $b \geq \frac{-\gamma(a)}{2}$   $\bar{\gamma}(a, b) = (a, b)$ . Informally,  $\bar{\gamma}$  shifts  $C' \times (-y, y)$  to the right while keeping  $\phi(h([0, 1])) \cap C' \times (-y, 0)$  left of  $C' \times \{0\}$ .

Define  $\hat{\gamma} : Q \rightarrow Q$  by  $\hat{\gamma}(v) = v$  if  $v \notin \phi^{-1}(C' \times (-y, y))$  and  $\hat{\gamma}(v) = \phi^{-1}\bar{\gamma}(\phi(v))$  if  $v \in \phi^{-1}(C' \times (-y, y))$ . Note  $\hat{\gamma}$  is a homeomorphism from  $\phi^{-1}(C' \times (-y, y))$  to  $\phi^{-1}(C' \times (-y, y))$  and from  $Q \setminus \phi^{-1}(C' \times (-y, y))$  to  $Q \setminus \phi^{-1}(C' \times (-y, y))$ . Further,  $\hat{\gamma}$  agrees on the boundary of  $\phi^{-1}(C' \times (-y, y))$  and  $Q \setminus \phi^{-1}(C' \times (-y, y))$ , that is for sequence  $\{a_i\}_{i=1}^\infty$  converging to a boundary point  $a$  of  $\phi^{-1}(C' \times (-y, y))$  (resp  $Q \setminus \phi^{-1}(C' \times (-y, y))$ ) the sequence  $\{\hat{\gamma}(a_i)\}_{i=1}^\infty$  converges to  $\hat{\gamma}(a)$ . Thus,  $\hat{\gamma}$  is a homeomorphism on  $Q$ , in fact, it turns out to be a continuous deformation.

## 18:18 A Constant Factor Approximation for Directed Feedback Vertex Set

Define  $\hat{h} : [0, 2] \rightarrow Q$  by  $\hat{h}(t) = \hat{\gamma}(\bar{j}(t))$ . Then  $\hat{\gamma}$  is a homeomorphism mapping  $\hat{h}([0, 2])$  to  $\bar{j}([0, 2])$ .  $\blacktriangleleft$

The actual statement of the tubular neighbourhood theorem involves first defining the normal fibre  $N_x$  as the quotient  $T_x Q / T_x C$  where  $T_x Q$  and  $T_x C$  are the tangent plane and tangent to the curve  $C$  at  $x$  and the normal bundle  $NX$  as  $\{(x, v) : x \in C, v \in N_x\}$ .

► **Theorem 29** (tubular neighbourhood theorem). *There are open sets  $U$  in  $Q$  containing  $C$  and  $V$  in  $NX$  such that there is a diffeomorphism  $\gamma : U \rightarrow V$ .*

Let us quickly show how the version of the tubular neighbourhood theorem in Proposition 27 follows from the tubular neighbourhood theorem.

By orientability each point  $x \in Q$  has a normal vector  $n(x)$  and  $n$  is continuous. We may parameterize  $C'$  with a function  $\psi : [0, \beta] \rightarrow C'$  with derivative  $\psi'(x) = 1$  for some  $\beta$ . Define  $v(x)$  to be of unit norm and positively orthogonal to  $n(x)$ ,  $\phi'(x)$  that is  $n(x)^t v(x) = (\phi'(x))^t v(x) = 0$  and  $[n(x) \ \psi'(x) \ v(x)]$  has determinant 1. By the inverse function theorem,  $v(x)$  is continuous.  $n(x), \psi'(x), v(x)$  is a basis for  $\mathbb{R}^3$  known as the Darboux frame. Since  $v(x)$  is orthogonal to  $n(x)$  it lies in the tangent plane  $T_x Q$  since  $v(x)$  is orthogonal to  $\phi'(x)$ ,  $v(x), \phi'(x)$  is a basis for  $T_x Q$ . Thus,  $N_x = T_x Q / T_x C$  is diffeomorphic to  $\{av(x) : a \in \mathbb{R}\}$  which is diffeomorphic to  $\mathbb{R}$ . Thus,  $NX$  is diffeomorphic to  $C' \times \mathbb{R}$ .

To prove Proposition 26, we first prove the following special case.

► **Proposition 30.** *Let  $Q$  be an orientable surface and  $\phi : [0, 1] \rightarrow Q$  a closed curve not dividing  $Q$  into 2 regions with disjoint subsets  $L, R$  “on each side” of  $\phi$  as in Proposition 23. Let  $c \in [0, 1]$ , with  $c_2 \geq c_1$ . Suppose that  $\phi_1 : [0, 1] \rightarrow Q$  is a curve with  $\phi_1(0) = \phi(c)$ ,  $\phi_1(1) = \phi(c)$ ,  $\phi_1((0, 1))$  is disjoint from  $\phi([0, 1])$  and the curve  $\phi_1([0, 0.5])$  approaches  $\phi([0, 1])$  from the left  $L$  and  $\phi_1([0.5, 1])$  approaches  $\phi([0, 1])$  from the right  $R$ .*

*Then  $\phi_1$  does not divide  $Q$  into 2 regions.*

**Proof.** Suppose for a contradiction that  $\phi_1$  divides  $Q$  into 2 regions. It's a well-known result that one of the regions  $Q_1$  must be homeomorphic to an open disk. Let  $Q_2$  be the other region.

There exists a small radius  $r_1$  for which the ball  $B(\phi(c), r)$  of radius  $r_1$  about  $\phi(c)$  such that  $B(\phi(c), r_1)$  is homeomorphic to an open disk. Let  $r$  be as in Proposition 23 and define  $r_2 = \min\{r, r_1\}$ .

► **Definition 31.** *Given 2 curves  $f_1, f_2 : [0, 1] \rightarrow Q$  on a surface  $Q$ , with  $f_1(0.5) = f_2(0.5)$  and  $f_1(x) \neq f_2(y) \ \forall x, y \in ([0, 1] \setminus \{0.5\})$ , that is they intersect only at  $f_1(0.5)$ , we say that  $f_1$  crosses  $f_2$  at  $f_1(0.5)$  if there exists  $r_0 > 0$  such that for all  $r \leq r_0$  such that  $f_2$  intersects both regions of  $B(f_1(0.5), r) \setminus f_1([0, 1])$ , where  $B(p, r)$  is the open ball around  $p$  of radius  $r$ .*

► **Lemma 32.** *For two curves  $f_1, f_2$  on a surface  $Q$  and  $p$  a point on both curves,  $f_1$  crosses  $f_2$  at  $p$  if and only if  $f_2$  crosses  $f_1$  at  $p$ .*

**Proof.** Let  $f_1(b_1) = p = f_2(b_2)$ . Let  $L_1, R_1$  and  $r_1$  (resp  $L_2, R_2$  and  $r_2$ ) be the left, right and radius respectively for  $f_1$  (resp.  $f_2$ ) as guaranteed by Proposition 23. Define  $r = \min\{r_1, r_2\}$ .

▷ **Claim 33.**  $f_1$  crosses  $f_2$  at  $p$  if and only if for all  $r \geq r_0 > 0$  none of  $L_1 \cap B(p, r_0)$ ,  $R_1 \cap B(p, r_0)$ ,  $L_2 \cap B(p, r_0)$ ,  $R_2 \cap B(p, r_0)$  is contained in another.

Proof. Suppose that  $f_1$  crosses  $f_2$ . Let  $r \geq r_0 > 0$ . Let  $t_L, t_R \in \mathbb{R}$  be such that  $f_2(t_L) \in L_1 \cap B(p, r_0)$ ,  $f_2(t_R) \in R_1 \cap B(p, r_0)$ . Since  $R_1 \cap B(p, r_0), L_1 \cap B(p, r_0)$  are open, there exists  $r_L, r_R$  be such that  $B(f_2(t_L), r_L) \subset L_1 \cap B(p, r_0)$  and  $B(f_2(t_R), r_R) \subset R_1 \cap B(p, r_0)$ . Since  $B(f_2(t_L), r_L) \cap L_2, B(f_2(t_L), r_L) \cap R_2, B(f_2(t_R), r_R) \cap L_2, B(f_2(t_R), r_R) \cap R_2 \neq \emptyset$ , none of  $L_1 \cap B(p, r_0), R_1 \cap B(p, r_0), L_2 \cap B(p, r_0), R_2 \cap B(p, r_0)$  is contained in another.

Conversely, suppose that for any  $0 < r_0 \leq r$  none of  $L_1 \cap B(p, r_0), R_1 \cap B(p, r_0), L_2 \cap B(p, r_0), R_2 \cap B(p, r_0)$  is contained in another. Then for any  $0 < r_0 \leq r$ , if  $f_2$  does not intersect  $L_1 \cap B(p, r_0)$ , then  $L_1 \cap B(p, r_0)$  is connected in  $B(p, r_0) \setminus f_2$ , that is  $L_1 \cap B(p, r_0)$  is contained in one of the two components  $L_2 \cap B(p, r_0), R_2 \cap B(p, r_0)$  of  $B(p, r_0) \setminus f_2$ . Hence  $f_2$  intersects  $L_1 \cap B(p, r_0)$ , likewise  $f_2$  intersects  $R_1 \cap B(p, r_0)$ . Hence  $f_2$  crosses  $f_1$ .  $\triangleleft$

From the previous claim it's clear that crossing is a symmetric relation.  $\blacktriangleleft$

Define  $\phi_2(x) = \phi(\text{frac}(x - 0.5 + c))$ , where  $\text{frac}(x) = x - \lfloor x \rfloor$  is the fractional value of  $x$  and  $\phi_3(x) = \phi_1(\text{frac}(x - 0.5))$ , that is,  $\phi_2, \phi_3$  are reparameterized versions of  $\phi$  and  $\phi_1$ . For some  $0 < \beta_1 < \beta_2 < 1$   $\phi_1(x) \in L$  for  $x \in (0, \beta_1)$  and  $\phi_1(x) \in R$  for  $x \in (\beta_2, 1)$ .

Define  $\beta'_1 = \min\{\beta_1, 0.5\} + 0.5$   $\beta'_2 = \max\{\beta_2, 0.5\}$ . Then  $\phi_3((0.5, \beta'_1)) \subset L$  and  $\phi_3((\beta'_2, 0.5)) \subset R$ . Since  $L \cup R$  covers  $\bar{B}(\phi(c), r) \setminus \phi([0, 1])$ , this implies that  $\phi_3$  crosses  $\phi_2$ .

By Lemma 32  $\phi_2$  crosses  $\phi_3$ . Let  $L_{\phi_3}, R_{\phi_3}$  be the left and right of  $\phi_3$  as in Proposition 23. Since  $L_{\phi_3}, R_{\phi_3}$  are connected,  $L_{\phi_3}, R_{\phi_3}$  belong to different regions of  $Q \setminus \phi_3$ . Since  $\phi_2$  crosses  $\phi_3$ , there exists  $t_0$  for which  $\phi(t_0) \in Q_1$  and  $t_1$  for which  $\phi(t_1) \in Q_2$ . Let  $t_2 = \inf\{a \in [0, 1] : \exists b \in (a, 1] \text{ s.t. } \phi((a, b)) \subset Q_1\}$ ,  $t_3 = \sup\{b \in [t_2, 1] : \text{s.t. } \phi((t_2, b)) \subset Q_1\}$ , that is  $[t_2, t_3]$  is a maximal interval for which  $\phi([t_2, t_3]) \subset Q_1$ . It follows  $\phi(t_2), \phi(t_3)$  lie on the boundary of  $Q_1$ , that is on  $\phi_1$ . This implies  $t_2, t_3 \in \{0, 1\}$ . Since  $t_2 < t_3$   $t_2 = 0$  and  $t_3 = 1$ . This implies that  $\phi([0, 1])$  lies in  $Q_1 \cup \{\phi(0)\}$  contradicting that there exists  $t_1$  for which  $\phi(t_1) \in Q_2$ .  $\blacktriangleleft$

**Proof.** (of Proposition 26) Let  $f : [0, 1] \rightarrow C'$  be a parameterization of  $C'$  and let  $c = f^{-1}(c_1)$ . Note that by Proposition 25 the curve  $\phi_2$  is homeomorphic to a curve  $\phi_3$  that enters  $\phi$  from the right and leaves  $\phi$  from the left at the same point  $f(c)$ . By Proposition 30,  $\phi_3$  does not divide  $Q$  into 2 regions. Thus,  $\phi_2$  does not divide  $Q$  into 2 regions.  $\blacktriangleleft$

## Abstract

---

We expand on recent exciting work of Debris-Alazard, Ducas, and van Woerden [Transactions on Information Theory, 2022], which introduced the notion of *basis reduction for codes*, in analogy with the extremely successful paradigm of basis reduction for lattices. We generalize DDvW’s LLL algorithm and size-reduction algorithm from codes over  $\mathbb{F}_2$  to codes over  $\mathbb{F}_q$ , and we further develop the theory of proper bases. We then show how to instantiate for codes the BKZ and slide-reduction algorithms, which are the two most important generalizations of the LLL algorithm for lattices.

Perhaps most importantly, we show a new and very efficient basis-reduction algorithm for codes, called *full backward reduction*. This algorithm is quite specific to codes and seems to have no analogue in the lattice setting. We prove that this algorithm finds vectors as short as LLL does in the worst case (i.e., within the Griesmer bound) and does so in less time. We also provide both heuristic and empirical evidence that it outperforms LLL in practice, and we give a variant of the algorithm that provably outperforms LLL (in some sense) for random codes.

Finally, we explore the promise and limitations of basis reduction for codes. In particular, we show upper and lower bounds on how “good” of a basis a code can have, and we show two additional illustrative algorithms that demonstrate some of the promise and the limitations of basis reduction for codes.

## 1 Introduction

### 1.1 Codes and lattices

A *linear code*  $\mathcal{C} \subseteq \mathbb{F}_q^n$  is a subspace of the vector space  $\mathbb{F}_q^n$  over the finite field  $\mathbb{F}_q$ , i.e., it is the set of all  $\mathbb{F}_q$ -linear combinations of a linearly independent list of vectors  $\mathbf{B} := (\mathbf{b}_1; \dots; \mathbf{b}_k)$ ,

$$\mathcal{C} := \mathcal{C}(\mathbf{B}) := \{z_1 \mathbf{b}_1 + \dots + z_k \mathbf{b}_k : z_i \in \mathbb{F}_q\}.$$

We call  $\mathbf{b}_1, \dots, \mathbf{b}_k$  a *basis* for the code and  $k$  the *dimension* of the code. We are interested in the geometry of the code induced by the Hamming weight  $|\mathbf{c}|$  for  $\mathbf{c} \in \mathbb{F}_q^n$ , which is simply the number of coordinates of  $\mathbf{c}$  that are non-zero. For example, it is natural to ask about a

## 19:2 More Basis Reduction for Linear Codes

code's *minimum distance*, which is the minimal Hamming weight of a non-zero codeword, i.e.,

$$d_{\min}(\mathcal{C}) := \min_{\mathbf{c} \in \mathcal{C}_{\neq \mathbf{0}}} |\mathbf{c}|.$$

At a high level, there are two fundamental computational problems associated with linear codes. In the first, the goal is to find a short non-zero codeword – i.e., given a basis for a code  $\mathcal{C}$ , the goal is to find a non-zero codeword  $\mathbf{c} \in \mathcal{C}_{\neq \mathbf{0}}$  with relatively small Hamming weight  $|\mathbf{c}|$ . In the second, the goal is to find a codeword that is close to some target vector  $\mathbf{t} \in \mathbb{F}_q^n$  – i.e., given a basis for a code  $\mathcal{C}$  and a target vector  $\mathbf{t} \in \mathbb{F}_q^n$ , the goal is to find a codeword  $\mathbf{c} \in \mathcal{C}$  such that  $|\mathbf{c} - \mathbf{t}|$  is relatively small. (Here, we are being deliberately vague about what we mean by “relatively small.”)

We now describe another class of mathematical objects, which are also ubiquitous in computer science. Notice the striking similarity between the two descriptions.

A *lattice*  $\mathcal{L} \subset \mathbb{Q}^n$  is the set of all *integer* linear combinations of linearly independent basis vectors  $\mathbf{A} := (\mathbf{a}_1; \dots; \mathbf{a}_k) \in \mathbb{Q}^n$ , i.e.,

$$\mathcal{L} := \mathcal{L}(\mathbf{A}) := \{z_1 \mathbf{a}_1 + \dots + z_k \mathbf{a}_k : z_i \in \mathbb{Z}\}.$$

We are interested in the geometry of the lattice induced by the Euclidean norm  $\|\mathbf{a}\| := (a_1^2 + \dots + a_n^2)^{1/2}$ . In particular, it is natural to ask about a lattice's *minimum distance*, which is simply the minimal Euclidean norm of a non-zero lattice vector, i.e.,

$$\lambda_1(\mathcal{L}) := \min_{\mathbf{y} \in \mathcal{L}_{\neq \mathbf{0}}} \|\mathbf{y}\|.$$

At a high level, there are two fundamental computational problems associated with lattices. In the first, the goal is to find a short non-zero lattice vector – i.e., given a basis for a lattice  $\mathcal{L}$ , the goal is to find a non-zero lattice vector  $\mathbf{y} \in \mathcal{L}_{\neq \mathbf{0}}$  with relatively small Euclidean norm  $\|\mathbf{y}\|$ . In the second, the goal is to find a lattice vector that is close to some target vector  $\mathbf{t} \in \mathbb{Q}^n$  – i.e., given a basis for a lattice  $\mathcal{L}$  and a target vector  $\mathbf{t} \in \mathbb{Z}^n$ , the goal is to find a lattice vector  $\mathbf{y} \in \mathcal{L}$  such that  $\|\mathbf{y} - \mathbf{t}\|$  is relatively small. (Again, we are being deliberately vague here.)

Clearly, there is a strong analogy between linear codes and lattices, where to move from codes to lattices, one more-or-less just replaces a finite field  $\mathbb{F}_q$  with the integers  $\mathbb{Z}$  and the Hamming weight  $|\cdot|$  with the Euclidean norm  $\|\cdot\|$ . It is therefore no surprise that this analogy extends to many applications. For example, lattices and codes are both used for decoding noisy channels. They are both used for cryptography (see, e.g., [26, 3, 5, 23, 7, 30]; in fact, both are used specifically for *post-quantum* cryptography). And, many complexity-theoretic hardness results were proven simultaneously or nearly simultaneously for coding problems and for lattice problems, often with similar or even identical techniques.<sup>1</sup>

### 1.2 Basis reduction for lattices

However, the analogy between lattices and codes has been much less fruitful for algorithms. Of course, there are many algorithmic techniques for finding short or close codewords and many algorithmic techniques for finding short or close lattice vectors. But, in many parameter regimes of interest, the best algorithms for lattices are quite different from the best algorithms for codes.

---

<sup>1</sup> For example, similar results that came in separate works in the two settings include [15] and [14], [4] and [33], [27] and [19], [13, 2] and [32], etc. Works that simultaneously published the same results in the two settings include [9] and [18].

In the present work, we are interested in *basis reduction*, a ubiquitous algorithmic framework in the lattice literature. At a very high level, given a basis  $\mathbf{A} := (\mathbf{a}_1; \dots; \mathbf{a}_k)$  for a lattice  $\mathcal{L}$ , basis reduction algorithms work by attempting to find a “good” basis of  $\mathcal{L}$  (and in particular, a basis whose first vector  $\mathbf{a}_1$  is short) by repeatedly making “local changes” to the basis. Specifically, such algorithms manipulate the Gram-Schmidt vectors  $\tilde{\mathbf{a}}_1 := \mathbf{a}_1, \tilde{\mathbf{a}}_2 := \pi_{\{\mathbf{a}_1\}}^\perp(\mathbf{a}_2), \dots, \tilde{\mathbf{a}}_k := \pi_{\{\mathbf{a}_1, \dots, \mathbf{a}_{k-1}\}}^\perp(\mathbf{a}_k)$ . Here,  $\pi_{\{\mathbf{a}_1, \dots, \mathbf{a}_{i-1}\}}^\perp$  represents orthogonal projection onto the subspace orthogonal to  $\mathbf{a}_1, \dots, \mathbf{a}_{i-1}$ . Notice that we can view the Gram-Schmidt vector  $\tilde{\mathbf{a}}_i$  as a lattice vector in the lower-dimensional lattice generated by the *projected block*  $\mathbf{A}_{[i,j]} := \pi_{\{\mathbf{a}_1, \dots, \mathbf{a}_{i-1}\}}^\perp(\mathbf{a}_i; \dots; \mathbf{a}_j)$ . Basis reduction algorithms work by making many “local changes” to  $\mathbf{A}$ , i.e., changes to the block  $\mathbf{A}_{[i,j]}$  that leave the lattice  $\mathcal{L}(\mathbf{A}_{[i,j]})$  unchanged. The goal is to use such local changes to make earlier Gram-Schmidt vectors shorter. (In particular,  $\tilde{\mathbf{a}}_1 = \mathbf{a}_1$  is a non-zero lattice vector. So, if we can make the first Gram-Schmidt vector short, then we will have found a short non-zero lattice vector.) One accomplishes this, e.g., by finding a short non-zero vector  $\mathbf{y}$  in  $\mathcal{L}(\mathbf{A}_{[i,j]})$  and essentially replacing the first vector in the block with this vector  $\mathbf{y}$ . (Here, we are ignoring how exactly one does this replacement.)

This paradigm was introduced in the celebrated work of Lenstra, Lenstra, and Lovász [25], which described the polynomial-time LLL algorithm. Specifically, (ignoring important details that are not relevant to the present work) the LLL algorithm works by repeatedly replacing Gram-Schmidt vectors  $\tilde{\mathbf{a}}_i$  with a shortest non-zero vector in the lattice generated by the dimension-two block  $\mathbf{A}_{[i,i+1]}$ . The LLL algorithm itself has innumerable applications. (See, e.g., [29].) Furthermore, generalizations of LLL yield the most efficient algorithms for finding short non-zero lattice vectors in a wide range of parameter regimes, including those relevant to cryptography.

Specifically, the Block-Korkine-Zolotarev basis-reduction algorithm (BKZ), originally due to Schnorr [31], is a generalization of the LLL algorithm that works with larger blocks. It works by repeatedly modifying blocks  $\mathbf{A}_{[i,i+\beta-1]}$  of a lattice basis  $\mathbf{A} := (\mathbf{a}_1; \dots; \mathbf{a}_k)$  in order to ensure that the Gram-Schmidt vector  $\tilde{\mathbf{a}}_i$  is a shortest non-zero vector in the lattice generated by the block. Here, the parameter  $\beta \geq 2$  is called the *block size*, and the case  $\beta = 2$  corresponds to the LLL algorithm (ignoring some technical details). Larger block size  $\beta$  yields better bases consisting of shorter lattice vectors. But, to run the algorithm with block size  $\beta$ , we must find shortest non-zero vectors in a  $\beta$ -dimensional lattice, which requires running time  $2^{O(\beta)}$  with the best-known algorithms [6, 1, 12]. So, BKZ yields a tradeoff between the quality of the output basis and the running time of the algorithm. (Alternatively, one can view BKZ as a reduction from an approximate lattice problem in high dimensions to an exact lattice problem in lower dimensions, with the approximation factor depending on how much lower the resulting dimension is.)

BKZ is the fastest known algorithm in practice for the problems relevant to cryptography. However, BKZ is notoriously difficult to understand. Indeed, we still do not have a proof that the BKZ algorithm makes at most polynomially many calls to its  $\beta$ -dimensional oracle, nor do we have a tight bound on the quality of the bases output by BKZ, despite much effort. (See, e.g., [34]. However, for both the running time and the output quality of the basis, we now have a very good *heuristic* understanding [16, 11].)

Gama and Nguyen’s slide-reduction algorithm is an elegant alternative to BKZ that is far easier to analyze [20]. In particular, it outputs a basis whose quality (e.g., the length of the first vector) essentially matches our heuristic understanding of the behavior of BKZ, and it provably does so with polynomially many calls to a  $\beta$ -dimensional oracle for finding a shortest non-zero lattice vector. Indeed, for a wide range of parameters (including those relevant to cryptography), [20] yields the fastest algorithm with proven correctness for finding short non-zero lattice vectors.

### Dual reduction, and some foreshadowing

One of the key ideas used in Gama and Nguyen’s slide-reduction algorithm (as well as in other work, such as [28]) is the notion of a *dual-reduced block*  $\mathbf{A}_{[i,j]}$ . The motivation behind dual-reduced blocks starts with the observation that the product  $\|\tilde{\mathbf{a}}_i\| \cdots \|\tilde{\mathbf{a}}_j\|$  does not change if the lattice  $\mathcal{L}(\mathbf{A}_{[i,j]})$  is not changed. Formally, this quantity is the determinant of the lattice  $\mathcal{L}(\mathbf{A}_{[i,j]})$ , which is a lattice invariant. So, while it is perhaps more natural to think of basis reduction in terms of making earlier Gram-Schmidt vectors in a block shorter, with the ultimate goal of making  $\mathbf{a}_1$  short, one can more-or-less equivalently think of basis reduction in terms of making *later* Gram-Schmidt vectors *longer*.

One therefore defines a *dual-reduced* block as a block  $\mathbf{A}_{[i,j]}$  such that the last Gram-Schmidt vector  $\tilde{\mathbf{a}}_j$  is as *long* as it can be without changing the associated lattice  $\mathcal{L}(\mathbf{A}_{[i,j]})$ . When  $\beta := j - i + 1 > 2$ , a dual-reduced block is not the same as a block whose first Gram-Schmidt vector is as short as possible. However, there is still some pleasing symmetry here. In particular, it is not hard to show that the last Gram-Schmidt vector  $\tilde{\mathbf{a}}_j$  corresponds precisely to a non-zero (primitive) vector in the *dual* lattice of  $\mathcal{L}(\mathbf{A}_{[i,j]})$  with length  $1/\|\tilde{\mathbf{a}}_j\|$ . This of course explains the terminology. It also means that making the last Gram-Schmidt vector  $\tilde{\mathbf{a}}_j$  as long as possible corresponds to finding a shortest non-zero vector in the dual of  $\mathcal{L}(\mathbf{A}_{[i,j]})$ , while making the first Gram-Schmidt vector  $\tilde{\mathbf{a}}_i$  as short as possible of course corresponds to finding a shortest non-zero vector in  $\mathcal{L}(\mathbf{A}_{[i,j]})$  itself. Either way, this amounts to finding a shortest non-zero vector in a  $\beta$ -dimensional lattice, which takes time that is exponential in the block size  $\beta$ .

## 1.3 Basis reduction for codes!

As far as the authors are aware, until very recently there was no work attempting to use the ideas from basis reduction in the setting of linear codes. This changed with the recent exciting work of Debris-Alazard, Ducas, and van Woerden, who in particular showed a simple and elegant analogue of the LLL algorithm for codes [17].

Debris-Alazard, Ducas, and van Woerden provide a “dictionary” ([17, Table 1]) for translating important concepts in basis reduction from the setting of lattices to the setting of codes, and it is the starting point of our work. Below, we describe some of the dictionary from [17], as well as some of the barriers that one encounters when attempting to make basis reduction work for codes.

### 1.3.1 Projection, epipodal vectors, and proper bases

Recall that when one performs basis reduction on lattices, one works with the Gram-Schmidt vectors  $\tilde{\mathbf{a}}_i := \pi_{\{\mathbf{a}_1, \dots, \mathbf{a}_{i-1}\}}^\perp(\mathbf{a}_i)$  and the projected blocks  $\mathbf{A}_{[i,j]} := \pi_{\{\mathbf{a}_1, \dots, \mathbf{a}_{i-1}\}}^\perp(\mathbf{a}_i; \dots; \mathbf{a}_j)$ , i.e., the *orthogonal projection* of  $\mathbf{a}_i, \dots, \mathbf{a}_j$  onto the subspace  $\{\mathbf{a}_1, \dots, \mathbf{a}_{i-1}\}^\perp$  orthogonal to  $\mathbf{a}_1, \dots, \mathbf{a}_{i-1}$ .

So, if we wish to adapt basis reduction to the setting of linear codes (and we do!), it is natural to first ask what the analogue of *projection* is in the setting of codes. [17] gave a very nice answer to this question.<sup>2</sup> In particular, for a vector  $\mathbf{x} = (x_1, \dots, x_n) \in \mathbb{F}_q^n$  we call the set of indices  $i$  such that  $x_i$  is non-zero the *support* of  $\mathbf{x}$ , i.e.,

<sup>2</sup> [17] formally worked with the case  $q = 2$  everywhere. Rather than specialize our discussion here to  $\mathbb{F}_2$ , we will largely ignore this distinction in this part of the introduction. While the more general definitions that we provide here for arbitrary  $\mathbb{F}_q$  are new to the present work, when generalizing to  $\mathbb{F}_q$  is straightforward, we will not emphasize this in the introduction.

$$\text{Supp}(\mathbf{x}) := \{i \in [n] : x_i \neq 0\}.$$

Then, [17] define  $\mathbf{z} := \pi_{\{\mathbf{x}_1, \dots, \mathbf{x}_\ell\}}^\perp(\mathbf{y})$  as follows. If  $i \in \bigcup_j \text{Supp}(\mathbf{x}_j)$ , then  $z_i = 0$ . Otherwise,  $z_i = y_i$ . In other words, the projection simply “zeros out the coordinates in the supports of the  $\mathbf{x}_j$ .” This notion of projection shares many (but certainly not all) of the features of orthogonal projection in  $\mathbb{R}^n$ , e.g., it is a linear contraction mapping that is idempotent.

Armed with this notion of projection, [17] then defined the *epipodal vectors* associated with a basis  $\mathbf{b}_1, \dots, \mathbf{b}_n$  as  $\mathbf{b}_1^+ := \mathbf{b}_1, \mathbf{b}_2^+ := \pi_{\{\mathbf{b}_1\}}^\perp(\mathbf{b}_2), \dots, \mathbf{b}_n^+ := \pi_{\{\mathbf{b}_1, \dots, \mathbf{b}_{n-1}\}}^\perp(\mathbf{b}_n)$ , in analogy with the Gram-Schmidt vectors. In this work, we go a bit further and define

$$\mathbf{B}_{[i,j]} := \pi_{\{\mathbf{b}_1, \dots, \mathbf{b}_{i-1}\}}^\perp(\mathbf{b}_i; \dots; \mathbf{b}_j),$$

in analogy with the notation in the literature on *lattice* basis reduction.

Here, [17] already encounters a bit of a roadblock. Namely, the epipodal vectors  $\mathbf{b}_i^+$  can be zero! E.g., if  $\mathbf{b}_1 = (1, 1, \dots, 1)$  is the all-ones vector, then  $\mathbf{b}_i^+$  will be zero for all  $i > 1$ <sup>3</sup>. This is rather troublesome and could lead to many issues down the road. For example, we might even encounter entire blocks  $\mathbf{B}_{[i,j]}$  that are zero! Fortunately, [17] shows how to get around this issue by defining *proper* bases, which are simply bases for which all the epipodal vectors are non-zero. They then observe that proper bases exist and are easy to compute. (In Section 4, we further develop the theory of proper bases.) So, this particular roadblock is manageable, but it already illustrates that the analogy between projection over  $\mathbb{F}_q^n$  and projection over  $\mathbb{R}^n$  is rather brittle.

The LLL algorithm for codes then follows elegantly from these definitions. In particular, a basis  $\mathbf{B} = (\mathbf{b}_1; \dots; \mathbf{b}_k)$  is *LLL-reduced* if it is proper and if  $\mathbf{b}_i^+$  is a shortest non-zero codeword in the dimension-two code generated by  $\mathbf{B}_{[i,i+1]}$  for all  $i = 1, \dots, k-1$ . [17] then show a simple algorithm that computes an LLL-reduced basis in polynomial time. Specifically, the algorithm repeatedly makes simple local changes to any block  $\mathbf{B}_{[i,i+1]}$  for which this condition is not satisfied until the basis is reduced.

In some ways, this new coding-theoretic algorithm is even more natural and elegant than the original LLL algorithm for lattices. For example, the original LLL algorithm had to worry about numerical blowup of the basis entries. And, the original LLL algorithm seems to require an additional slack factor  $\delta$  in order to avoid the situation in which the algorithm makes a large number of minuscule changes to the basis. Both of these issues do not arise over finite fields, where all vectors considered by the algorithm have entries in  $\mathbb{F}_q$  and integer lengths between 1 and  $n$ .

### 1.3.2 What’s a good basis and what is it good for?

Given the incredible importance of the LLL algorithm for lattices, it is a major achievement just to show that one can make sense of the notion of “LLL for codes.” But, once [17] have defined an LLL-reduced basis for codes and shown how to compute one efficiently, an obvious next question emerges: what can one do with such a basis?

In the case of lattices, the LLL algorithm is useful for many things, but primarily for the two most important computational lattice problems: finding short non-zero lattice vectors and finding close lattice vectors to a target. In particular, the first vector  $\mathbf{a}_1$  of an LLL-reduced basis is guaranteed to  $\|\mathbf{a}_1\| \leq 2^{k-1} \lambda_1(\mathcal{L})$ . This has proven to be incredibly useful, despite the apparently large approximation factor.

<sup>3</sup> Of course, similar issues do not occur over  $\mathbb{R}^n$ , because if  $\mathbf{a}_1, \dots, \mathbf{a}_k \in \mathbb{R}^n$  are linearly independent, then  $\pi_{\{\mathbf{a}_1, \dots, \mathbf{a}_{k-1}\}}^\perp(\mathbf{a}_k)$  cannot be zero.

For codes over  $\mathbb{F}_2$ , [17] show that the same is true, namely that if  $\mathbf{B} = (\mathbf{b}_1; \dots; \mathbf{b}_k)$  is an LLL-reduced basis for  $\mathcal{C} \subseteq \mathbb{F}_2^n$ , then  $|\mathbf{b}_1| \leq 2^{k-1}d_{\min}(\mathcal{C})$ . They prove this by showing that if  $\mathbf{b}_i^+$  has minimal length among the non-zero codewords in  $\mathcal{C}(\mathbf{B}_{[i,i+1]})$ , then  $|\mathbf{b}_i^+| \leq 2|\mathbf{b}_{i+1}^+|$ . It follows in particular that  $|\mathbf{b}_1| = |\mathbf{b}_1^+| \leq 2^{i-1}|\mathbf{b}_i^+|$  for all  $i$ . One can easily see that  $d_{\min}(\mathcal{C}) \geq \min_i |\mathbf{b}_i^+|$ , from which one immediately concludes that  $|\mathbf{b}_1^+| \leq 2^{k-1}d_{\min}(\mathcal{C})$ . A simple generalization of this argument shows that over  $\mathbb{F}_q$ , we have  $|\mathbf{b}_1^+| \leq q^{k-1}d_{\min}(\mathcal{C})$ . (We prove something more general and slightly stronger in the full version [21].)

However, notice that all codewords have length at most  $n$  and  $d_{\min}(\mathcal{C})$  is always at least 1. Therefore, an approximation factor of  $q^{k-1}$  is non-trivial only if  $n > q^{k-1}$ . Otherwise, literally any non-zero codeword has length less than  $q^{k-1}d_{\min}(\mathcal{C})$ ! On the other hand, if  $n > q^{k-1}$ , then we can anyway find an exact shortest vector in time roughly  $q^k n \lesssim n^2$  by simply enumerating all codewords. (The typical parameter regime of interest is when  $n = O(k)$ .)

In some sense, the issue here is that the space  $\mathbb{F}_q^n$  that codes live in is too “cramped.” While lattices are infinite sets that live in a space  $\mathbb{Q}^n$  with arbitrarily long and arbitrarily short non-zero vectors, codes are finite sets that live in a space  $\mathbb{F}_q^n$  in which all non-zero vectors have integer lengths between 1 and  $n$ . So, while for lattices, any approximation factor between one and, say,  $2^k$  is very interesting, for codes the region of interest is simply more narrow.

[17] go on to observe that because  $|\mathbf{b}_{i+1}^+|$  is an integer, for codes over  $\mathbb{F}_2$  an LLL-reduced basis must actually satisfy

$$|\mathbf{b}_{i+1}^+| \geq \left\lceil \frac{|\mathbf{b}_i^+|}{2} \right\rceil .$$

With this slightly stronger inequality together with the fact that  $\sum |\mathbf{b}_i^+| \leq n$ , they are able to show that  $\mathbf{b}_1$  of an LLL-reduced basis will meet the Griesmer bound [22],

$$\sum_{i=1}^k \left\lceil \frac{|\mathbf{b}_1|}{2^{i-1}} \right\rceil \leq n , \tag{1}$$

which is non-trivial. E.g., as long as  $k \geq \log n$ , it follows that

$$|\mathbf{b}_1| - \frac{\lceil \log |\mathbf{b}_1| \rceil}{2} \leq \frac{n - k}{2} + 1 \tag{2}$$

(We generalize this in the full version [21] to show that the appropriate generalization of LLL-reduced bases to codes over  $\mathbb{F}_q$  also meet the  $q$ -ary Griesmer bound.)

### 1.3.2.1 Finding close codewords and size reduction

For lattices, Babai also showed how to use an LLL-reduced basis to efficiently find *close* lattice vectors to a given target vector [10], and like the LLL algorithm itself, Babai’s algorithm too has innumerable applications. More generally, Babai’s algorithm tends to obtain closer lattice vectors if given a “better” basis, in a certain precise sense. [17] showed an analogous “size-reduction” algorithm that finds close codewords to a given target vector, with better performance given a “better” basis. Here, the notion of “better” is a bit subtle, but essentially a basis is “better” if the epipodal vectors tend to have similar lengths. (Notice that  $\sum_i |\mathbf{b}_i^+| = |\text{Supp}(\mathcal{C})|$ , so we cannot hope for all of the epipodal vectors to be short.)

The resulting size-reduction algorithm finds relatively close codewords remarkably quickly. (Indeed, in nearly linear time.) Furthermore, [17] showed how to use their size-reduction algorithm combined with techniques from information set decoding to speed up some

information set decoding algorithms for finding short codewords or close codewords to a target, without significantly affecting the quality of the output. For this, their key observation was the fact that typically most epipodal vectors actually have length one (particularly the later epipodal vectors, as one would expect given that later epipodal vectors by definition have more coordinates “zeroed out” by projection orthogonal to the earlier basis vectors) and that their size-reduction algorithm derives most of its advantage from how it treats the epipodal vectors with length greater than one. They therefore essentially run information set decoding on the code projected onto the support of the epipodal vectors with length one and then “lift” the result to a close codeword using their size-reduction algorithm.

They call the resulting algorithm Lee-Brickell-Babai because it is a hybrid of Babai-style size reduction and the Lee-Brickell algorithm [24]. The running time of this hybrid algorithm is dominated by the cost of running information set decoding on a code with dimension  $k - k_1$ , where

$$k_1 := |\{i : |\mathbf{b}_i^+| > 1\}|$$

is the number of epipodal vectors that do not have length 1. Indeed, the (heuristic) running time of this algorithm is better than Lee-Brickell by a factor that is exponential in  $k_1$ , so that even a small difference in  $k_1$  can make a large difference in the running time. They then show that LLL-reduced bases have  $k_1 \gtrsim \log n$  (for random codes) and show that this reduction in dimension can offer significant savings in the running time of information set decoding.

Indeed, though the details are not yet public, the current record in the coding problem challenges [8] was obtained by Ducas and Stevens, apparently using such techniques.

## 1.4 Our contribution

In this work, we continue the study of basis reduction for codes, expanding on and generalizing the results of [17] in many ways, and beginning to uncover a rich landscape of algorithms.

### 1.4.1 Expanding on the work of [17]

#### 1.4.1.1 Generalization to $\mathbb{F}_q$

Our first set of (perhaps relatively minor) contributions are generalizations of many of the ideas in [17] from  $\mathbb{F}_2$  to  $\mathbb{F}_q$ , a direction proposed in that work. In fact, they quite accurately anticipated this direction. So, we quote directly from [17, Section 1.3]:

In principle, the definitions, theorems and algorithms of this article should be generalizable to codes over  $\mathbb{F}_q$  endowed with the Hamming metric. . . Some algorithms may see their complexity grow by a factor  $\Theta(q)$ , meaning that the algorithms remains polynomial-time only for  $q = n^{O(1)}$ . It is natural to hope that such a generalised LLL would still match [the] Griesmer bound for  $q > 2$ . However, we expect that the analysis of the fundamental domain [which is necessary for understanding size reduction]. . . would become significantly harder to carry out.

In Section 3, we generalize from  $\mathbb{F}_2$  to  $\mathbb{F}_q$  the definitions of projection, epipodal vectors, and proper bases; the definition of an LLL-reduced bases and the LLL algorithm;<sup>4</sup> and the size-reduction algorithm and its associated fundamental domain. Some of this is admittedly

<sup>4</sup> We actually describe the LLL algorithm as a special case of the more general algorithms that we describe below. See the full version [21].

quite straightforward – e.g., given the definitions in [17] of projection, epipodal vectors, and proper bases for codes over  $\mathbb{F}_2$ , the corresponding definitions for codes over  $\mathbb{F}_q$  are immediate (and we have already presented them in this introduction). And, the definition of an LLL-reduced basis and of size reduction follow more-or-less immediately from these definitions. In particular, we do in fact confirm that LLL over  $\mathbb{F}_q$  achieves the Griesmer bound.

As [17] anticipated, the most difficult challenge that we encounter here is in the analysis of the fundamental domain that one obtains when one runs size reduction with a particular basis  $\mathbf{B}$ . We refer the reader to the full version [21] for the details.

(We do not encounter the running time issue described in the quote above – except for our algorithm computing the number of vectors of a given length in  $\mathcal{F}(\mathbf{B}^+)$ . In particular, our versions of the LLL algorithm and the size-reduction algorithm – and even our generalizations like slide reduction – run in time that is proportional to a small polynomial in  $\log q$ .)

Along the way, we make some modest improvements to the work of [17], even in the case of  $\mathbb{F}_2$ . In particular, using more careful analysis, we shave a factor of roughly  $n$  from the proven running time of LLL. (See the full version [21].)

#### 1.4.1.2 More on the theory of proper bases

In order to develop the basis-reduction algorithms that we will describe next, we found that it was first necessary to develop (in Section 4) some additional tools for understanding and working with *proper bases*, which might be of independent interest. Specifically, we define the concept of a *primitive codeword*, which is a non-zero codeword  $\mathbf{c}$  such that  $\text{Supp}(\mathbf{c})$  does not strictly contain the support of any other non-zero codeword. We then show that primitive codewords are closely related to proper bases. For example, we show that  $\mathbf{c}$  is the first vector in some proper basis if and only if  $\mathbf{c}$  is primitive, and that a basis is proper if and only if the epipodal vectors are primitive vectors in their respective projections.

We find this perspective to be quite useful for thinking about proper bases and basis reduction in general. In particular, we use this perspective to develop algorithms that perform basic operations on proper bases, such as inserting a primitive codeword into the first entry of a basis without affecting properness. The resulting algorithmic tools seem to be necessary for the larger-block-size versions of basis reduction that we describe below, in which our algorithms must make more complicated changes to a basis.

#### 1.4.2 Backward reduction and redundant sets

Our next contribution is the notion of *backward reduction*, described in Section 5. Recall that in the context of lattices, a key idea is the notion of a *dual-reduced* block  $\mathbf{A}_{[i,j]}$ , in which the *last* Gram-Schmidt vector  $\tilde{\mathbf{a}}_j$  is as *long* possible, while keeping  $\mathcal{L}(\mathbf{A}_{[i,j]})$  fixed.

Backward-reduced blocks are what we call the analogous notion for codes. Specifically, we say that a block  $\mathbf{B}_{[i,j]}$  is *backward reduced* if the last epipodal vector  $\mathbf{b}_j^+$  is as *long* as possible, while keeping  $\mathcal{C}(\mathbf{B}_{[i,j]})$  fixed. Just like in the case of lattices, this idea is motivated by an invariant. Here, the invariant is  $|\mathbf{b}_i^+| + \cdots + |\mathbf{b}_j^+|$ , which is precisely the support of the code  $\mathcal{C}(\mathbf{B}_{[i,j]})$ . So, if one wishes to make earlier epipodal vectors shorter (and we do!), then one will necessarily make later epipodal vectors longer, and vice versa. In particular, in the case of LLL, when the block size  $\beta := j - i + 1$  is equal to 2, there is no difference between minimizing the length of the first epipodal vector and maximizing the length of the second epipodal vector. So, if one wishes, one can describe the LLL algorithm in [17] as working by repeatedly backward reducing blocks  $\mathbf{B}_{[i,i+1]}$ .

The above definition of course leads naturally to two questions. First of all, how do we produce a backward-reduced block (for block size larger than 2)? And, second, what can we say about them? Specifically, what can we say about the length  $|\mathbf{b}_j^+|$  of the last epipodal vector in a backward-reduced block  $\mathbf{B}_{[i,j]}$ ?

One might get discouraged here, as one quickly discovers that long last epipodal vectors *do not* correspond to short non-zero codewords in the dual code. So, the beautiful duality that arises in the setting of lattices simply fails in our new context. (The *only* exception is that last epipodal vectors with length *exactly* two correspond to dual vectors with length *exactly* two.) This is why we use the terminology “backward reduced” rather than “dual reduced.” One might fear that the absence of this correspondence would make backward-reduced blocks very difficult to work with.

Instead, we show that long last epipodal vectors  $\mathbf{b}_j^+$  in a block  $\mathbf{B}_{[i,j]}$  have a simple interpretation. They correspond precisely to large *redundant sets of coordinates* of the code  $\mathcal{C}(\mathbf{B}_{[i,j]})$ . In the special case when  $q = 2$ , a redundant set  $S \subseteq [n]$  of coordinates is simply a set of coordinates in the support of the code such that for every  $a, b \in S$  and every codeword  $\mathbf{c}$ ,  $c_a = c_b$ . For larger  $q$ , we instead have the guarantee that  $c_a = z c_b$  for fixed non-zero scalar  $z \in \mathbb{F}_q^*$  depending only on  $a$  and  $b$ . In particular, maximal redundant sets correspond precisely to the non-zero coordinates in a last epipodal vector. (See Lemma 8.)

This characterization immediately yields an algorithm for backward reducing a block. (See Algorithm 2.) In fact, finding a backward-reduced block boils down to finding a set of most common elements in a list of at most  $n$  non-zero columns, each consisting of  $\beta := j - i + 1$  elements from  $\mathbb{F}_q$ . One quite surprising consequence of this is that one can actually find backward-reduced blocks efficiently, even for large  $\beta$ ! (Compare this to the case of lattices, where finding a dual-reduced block for large  $\beta$  is equivalent to the NP-hard problem of finding a shortest non-zero vector in a lattice of dimension  $\beta$ .)

Furthermore, this simple combinatorial characterization of backward-reduced blocks makes it quite easy to prove a simple tight lower bound on the length of  $\mathbf{b}_j^+$  in a backward-reduced block  $\mathbf{B}_{[i,j]}$ . (See the full version [21].) Indeed, such a proof follows immediately from the pigeonhole principle. This makes backward-reduced blocks quite easy to analyze. In contrast, as we will see below, *forward-reduced* blocks, in which the first epipodal vector  $\mathbf{b}_i^+$  is as short as possible, are rather difficult to analyze for  $\beta > 2$ .

### 1.4.3 Fully backward-reduced bases

With this new characterization of backward-reduced blocks and the realization that we can backward reduce a block quite efficiently, we go on to define the notion of a *fully backward-reduced basis*. We say that a basis is *fully backward reduced* if *all* of the prefixes  $\mathbf{B}_{[1,j]}$  are backward reduced for all  $1 \leq j \leq k$ .<sup>5</sup> In fact, we are slightly more general than this, and consider bases that satisfy this requirement for all  $j$  up to some threshold  $\tau \leq k$ .

We show that a fully backward-reduced basis achieves the Griesmer bound (Equation (1) for  $q = 2$ ), just like an LLL-reduced basis. This is actually unsurprising, since it is not difficult to see that when the threshold  $\tau = k$  is maximal, a fully backward-reduced basis is also LLL reduced. However, even when  $\tau = \log_q n$ , we still show that a backward-reduced basis achieves the Griesmer bound. (See Theorem 16.)

<sup>5</sup> Notice that this implies that  $\mathbf{B}_{[i,j]}$  is also backward reduced for any  $1 \leq i < j$ . So, such bases really are *fully* backward reduced.

We then show a very simple and very efficient algorithm for computing fully backward-reduced bases. In particular, if the algorithm is given as input a *proper* basis, then it will convert it into a fully backward-reduced basis up to threshold  $\tau$  in time  $O(\tau^2 n \text{polylog}(n, q))$ . Notice that this is *extremely* efficient when  $\tau \leq \text{poly}(\log_q n)$ .<sup>6</sup> Indeed, for most parameters of interest, this running time is in fact less than the time  $O(nk \log q)$  needed simply to read the input basis  $\mathbf{B} \in \mathbb{F}_q^{k \times n}$ . (Of course, this is possible because the algorithm only looks at the first  $\tau$  rows of the input basis.) So, if one already has a proper basis, one can convert it into a fully backward-reduced basis nearly for free.<sup>7</sup>

In contrast, the LLL algorithm runs in time  $O(kn^2 \log^2 q)$ . One *can* perform a similar “threshold” trick and run the LLL algorithm only on the first  $\tau$  basis vectors for  $\tau = \lceil \log_q n \rceil$  (which would still imply that  $|\mathbf{b}_1|$  must be bounded by the Griesmer bound). But, this would still yield a running time of  $\Omega(\tau n^2 \log^2 q)$  in the worst case. The speedup that we achieve from fully backward reduction comes from the combination of this threshold trick together with the fact that fully backward reduction runs in time proportional to  $\tau^2 n$ , rather than  $\tau n^2$ .

Furthermore, we show empirically that the resulting algorithm tends to produce better bases than LLL in practice. (See the full version [21].)

(It seems unlikely that any similar algorithm exists for lattices for two reasons. First, in the setting of lattices, computing a dual-reduced basis for large block sizes is computationally infeasible. Second, while for codes it is not unreasonable to look for a short non-zero codeword in the subcode generated by the first  $\tau$  basis vectors, for lattices the lattice generated by the first  $k - 1$  basis vectors often contains no shorter non-zero vectors than the basis vectors themselves, even when the full lattice contains much shorter vectors.)

### 1.4.3.1 Heuristic analysis of full backward reduction

We also provide heuristic analysis of full backward reduction, providing a compelling heuristic explanation for why its performance in practice seems to be much better than what worst-case analysis suggests. In particular, recall that we essentially characterize the length of the last epipodal vector of a backward-reduced block  $\mathbf{B}_{[i,j]}$  in terms of the maximal number of times that a column in  $\mathbf{B}_{[i,j]}$  repeats. We then naturally use the pigeonhole principle to argue that for suitable parameters there must be a column that repeats many times.

E.g., for  $q = 2$ , there must be at least one repeated non-zero column if the number of non-zero columns  $s$  is larger than the number of possible non-zero columns  $2^\beta - 1$ , where  $\beta := j - i + 1$  is the length of a column. This analysis is of course tight in the worst case. However, in the average case, we know from the birthday paradox that we should expect to see a repeated column even if  $s$  is roughly  $2^{\beta/2}$ , rather than  $2^\beta$ .

So, under the (mild but unproven) heuristic that the blocks  $\mathbf{B}_{[1,j]}$  in a fully backward-reduced basis behave like a random matrices for all  $j$  (in terms of the number of redundant coordinates), it is easy to see that  $k_1 \gtrsim 2 \log_q n$ , which is significantly better than what LLL achieves (both in the worst case and empirically).

This heuristic argument is backed up by experiments. (See the full version [21].) We also show (in the full the version [21]) a less natural variant of this algorithm that provably achieves  $k_1 \gtrsim 2 \log_q n$  when its input is a random matrix. This variant works by carefully

<sup>6</sup> We argue (in the full version [21]) that there is not much point in taking  $\tau$  significantly greater than  $\log_q^2(n)$ .

<sup>7</sup> Computing a proper basis seems to require time  $O(nk^2 \log^2 q)$  (without using fast matrix multiplication algorithms), but in many contexts the input basis is in systematic form and is therefore proper.

“choosing which coordinates to look at” for each block, in order to maintain independence. We view this as an additional heuristic explanation for full backward reduction’s practical performance, since one expects an algorithm that “looks at all coordinates” to do better than one that does not.

This result about  $k_1$  for backward-reduced bases also compares favorably with the study of the LLL algorithm in [17]. In particular, in [17], they proved that LLL achieves  $k_1 \gtrsim \log n$  for a random code for  $q = 2$ , but in their experiments they observed that LLL combined with a preprocessing step called EpiSort actually seems to achieve  $k_1 \approx c \log n$  for some constant  $1 < c \leq 2$ . However, the behavior of LLL and EpiSort seems to be much more subtle than the behavior of full backwards reduction. We therefore still have no decent explanation (even a heuristic one) for why LLL and EpiSort seem to achieve  $k_1 \approx c \log n$  or for what the value of this constant  $c$  actually is.

#### 1.4.4 BKZ and slide reduction for codes

Our next set of contributions are adaptations of the celebrated BKZ and slide-reduction algorithms to the setting of codes.

##### 1.4.4.1 BKZ for codes

Our analogue of the BKZ algorithm for codes is quite natural.<sup>8</sup> Specifically, our algorithm works by repeatedly checking whether the epipodal vector  $\mathbf{b}_i^+$  is a shortest non-zero codeword in the code generated by the block  $\mathbf{B}_{[i, i+\beta-1]}$ . If not, it updates the basis so that this is the case (using the tools that we have developed to maintain properness). The algorithm does this repeatedly until no further updates are possible. At least intuitively, a larger choice of  $\beta$  here requires a slower algorithm because the resulting algorithm will have to find shortest non-zero codewords in  $\beta$ -dimensional codes. But, larger  $\beta$  will result in a better basis.

As we mentioned above, in the setting of lattices, the BKZ algorithm is considered to be the best performing basis-reduction algorithm in most parameter regimes, but it is notoriously difficult to analyze. We encounter a roughly similar phenomenon in the setting of linear codes. In particular, we run experiments that show that the algorithm performs quite well in practice. (Though it requires significantly more running time than full backward reduction to achieve a similar profile. See the full version [21].) However, we are unable to prove that it terminates efficiently, except in the special case of  $\beta = 2$ , in which case we recover the LLL algorithm of [17]. For  $\beta > 2$ , we offer only an extremely weak bound on the running time. As in the case of lattices, the fundamental issue is that it is difficult to control the effect that changing  $\mathbf{b}_i^+$  can have on the other epipodal vectors  $\mathbf{b}_{i+1}^+, \dots, \mathbf{b}_{i+\beta-1}^+$  in the block.

Here, we encounter an additional issue as well. In the case of lattices, there is a relatively simple tight bound on the minimum distance of the lattice generated by the block  $\mathbf{A}_{[i, i+\beta-1]}$  to the lengths of the Gram-Schmidt vectors  $\|\tilde{\mathbf{a}}_i\|, \dots, \|\tilde{\mathbf{a}}_{i+\beta-1}\|$  in the block. In particular, Minkowski’s celebrated theorem tells us that  $\lambda_1(\mathcal{L}(\mathbf{A}_{[i, i+\beta-1]})) \leq C\sqrt{\beta}(\|\tilde{\mathbf{a}}_i\| \cdots \|\tilde{\mathbf{a}}_{i+\beta-1}\|)^{1/\beta}$  for some constant  $C > 0$ , and one applies this inequality repeatedly with different  $i$  to understand the behavior of basis reduction for lattices.

<sup>8</sup> We note that the name “BKZ algorithm for codes” is perhaps a bit misleading. In the case of lattices, the BKZ algorithm is named after Korkine and Zolotarev due to their work on Korkine-Zolotarev-reduced bases (which can be thought of as BKZ-reduced bases with maximal block size  $\beta = k$ , and is sometimes also called a *Hermite*-Korkine-Zolotarev-reduced basis). A *Block*-Korkine-Zolotarev-reduced basis is (unsurprisingly) a basis in which each block  $\mathbf{B}_{[i, i+\beta-1]}$  is a Korkine-Zolotarev-reduced basis. For codes, the analogous notion of a Korkine-Zolotarev-reduced basis was called a Griesmer-reduced basis in [17]. So, we should perhaps call our notion “Block-Griesmer-reduced bases” and the associated algorithm “the block-Griesmer algorithm.” However, the authors decided to use the term “BKZ” here in an attempt to keep terminology more consistent between lattices and codes.

However, in the case of codes, there is no analogous simple tight bound on  $d_{\min}(\mathcal{C}(\mathbf{B}_{[i, i+\beta-1]}))$  in terms of the lengths of the epipodal vectors  $|\mathbf{b}_i^+|, \dots, |\mathbf{b}_{i+\beta-1}^+|$ , *except* in the special case when  $\beta = 2$ . Instead, there are many known incomparable upper bounds on  $d_{\min}$  in terms of the dimension  $\beta$  and the support size  $s := |\mathbf{b}_i^+| + \dots + |\mathbf{b}_{i+\beta-1}^+|$  (and, of course, the alphabet size  $q$ ). Each of these bounds is tight or nearly tight for some support sizes  $s$  (for fixed  $\beta$ ) but rather loose in other regimes. The nature of our basis-reduction algorithms is such that different blocks have very different support sizes  $s$ , so that we cannot use a single simple bound that will be useful in all regimes. And, due to the relatively “cramped” nature of  $\mathbb{F}_q^n$ , applying loose bounds on  $d_{\min}$  can easily yield trivial results, or results that do offer no improvement over the  $\beta = 2$  case. As a result, the bound that we obtain on the length of  $\mathbf{b}_1$  for a BKZ-reduced basis does not have a simple closed form. (Since the special case of  $\beta = 2$  yields a very simple tight bound  $d_{\min} \leq (1 - 1/q)s$ , this is not an issue in the analysis of the LLL algorithm in [17].)

In fact, we do not even know if the worst-case bound on  $|\mathbf{b}_1|$  for a BKZ-reduced basis is efficiently computable, even if one knows the optimal minimum distance of  $\beta$ -dimensional codes for all support sizes. However, we do show an efficiently computable bound that is nearly as good. And, we show empirically that in practice it produces quite a good basis. (See the full version [21].)

#### 1.4.4.2 Slide reduction for codes

Given our difficulties analyzing the BKZ algorithm, it is natural to try to adapt Gama and Nguyen’s slide-reduction algorithm [20] from lattices to codes. In particular, recall that in the case of lattices, the slide-reduction algorithm has the benefit that (unlike BKZ) it is relatively easy to prove that it terminates efficiently.

In fact, recall that the idea for backward-reduced bases was inspired by dual-reduced bases for lattices, which are a key component of slide reduction. We therefore define slide-reduced bases for codes by essentially just substituting backward-reduced blocks for dual-reduced blocks in Gama and Nguyen’s definition for lattices. Our slide-reduction algorithm (i.e., an algorithm that produces slide-reduced bases) follows similarly.

We then give a quite simple proof that this algorithm terminates efficiently. Indeed, our proof is a direct translation of Gama and Nguyen’s elegant potential-based argument from the case of lattices to the case of codes. (Gama and Nguyen’s proof is itself a clever variant of the beautiful original proof for the case when  $\beta = 2$  in [25].)

Finally, we give an efficiently computable upper bound on  $|\mathbf{b}_1|$  for a slide-reduced basis in a similar spirit to our upper bound on BKZ. Here, we again benefit from our analysis of backward-reduced blocks described above. Indeed, the behavior of the epipodal vectors in our backward-reduced blocks is quite easy to analyze. However, our bound does not have a simple closed form because the behavior of the forward-reduced blocks still depends on the subtle relationship between the minimal distance of a code and the parameters  $n$  and  $k$ , as we described in the context of BKZ above.

In our experiments (in the full version [21]), slide reduction is far faster than BKZ but does not find bases that are as good.

#### 1.4.5 Two illustrative algorithms

In the full version [21], we show yet two more basis-reduction algorithms for codes. We think of the importance of these algorithms as being less about their actual usefulness and more about what they show about the potential and limitations of basis reduction for codes. We explain below.

### 1.4.5.1 One-block reduction

The one-block-reduction algorithm is quite simple. It finds a short non-zero codeword in a code  $\mathcal{C}$  generated by some basis  $\mathbf{B}$  by first ensuring that  $\mathbf{B}$  is proper, and then by simply finding a shortest non-zero codeword in the subcode  $\mathcal{C}(\mathbf{B}_{[1,\beta]})$  generated by the prefix basis  $\mathbf{B}_{[1,\beta]}$ . Notice that if  $\beta \leq O(\log_q n)$ , then this algorithm runs in polynomial time. In particular, enumerating all codewords in the subcode can be done in time roughly  $O(nq^\beta \log q)$ .

Furthermore, it is not hard to see that when  $\beta = \lceil \log_q n \rceil$ , this simple algorithm actually meets the Griesmer bound! (See the full version [21].) At a high level, this is because (1) the worst case in the Griesmer bound has  $|\mathbf{b}_i^+| = 1$  for all  $i \geq \beta$ ; and (2) the resulting bound is certainly not better than the minimum distance of a code with dimension  $\beta$  and support size  $n - (k - \beta)$ . Here, the  $k - \beta$  term comes from the fact that  $\text{Supp}(\mathbf{B}_{[1,\beta]}) = n - |\mathbf{b}_{\beta+1}^+| - \dots - |\mathbf{b}_k^+|$ . (Similar logic explains why full backward reduction achieves the Griesmer bound with  $\tau \approx \log_q n$ .)

More generally, it seems unlikely that a basis-reduction algorithm will be able to find  $\mathbf{b}_1$  that is shorter than what is achieved by this simple approach if we take  $\beta \geq \max\{k_1^*, \beta'\}$ , where  $\beta'$  is the size of the largest block in the basis reduction algorithm and  $k_1^*$  is the maximal index of an epipodal vector that has length larger than one. (In practice,  $k_1^*$  is almost never much larger than  $k_1$ .) In particular, for a basis reduction algorithm to do better than this, it must manage to produce a block  $\mathbf{B}_{[1,\beta]}$  that has minimum distance less than what one would expect given its support size.

We therefore think of this algorithm as illustrating two points.

First, the existence of this algorithm further emphasizes the importance of the parameter  $k_1^*$  (and the closely related parameter  $k_1$ ) as a sort of “measure of non-triviality.” If an algorithm achieves large  $k_1^*$ , then the above argument becomes weaker, since we must take  $\beta \geq k_1^*$ . Indeed, if  $\beta$  is significantly larger than  $2 \log_q k$ , then the running time of one-block reduction (if implemented by simple enumeration) becomes significantly slower.

Second, the existence of the one-block-reduction algorithm illustrates that we should be careful not to judge basis-reduction algorithms *entirely* based on  $|\mathbf{b}_1|$ . We certainly think that  $|\mathbf{b}_1|$  is an important measure of study, and indeed it is the main way that we analyze the quality of our bases in this work. However, the fact that one-block-reduction exists shows that this should not be viewed as the only purpose of a basis-reduction algorithm.

Of course, the algorithms that we have discussed thus far are in fact non-trivial, because they (1) find short non-zero codewords *faster* than one-block reduction; and (2) find whole reduced bases and not just a single short non-zero codeword. Such reduced bases have already found exciting applications in [17] and [8], and we expect them to find more.

### 1.4.5.2 Approximate Griesmer reduction

Recall that [17] calls a basis  $\mathbf{B} \in \mathbb{F}_q^{k \times n}$  *Griesmer reduced* if  $\mathbf{b}_i^+$  is a shortest non-zero codeword in  $\mathcal{C}(\mathbf{B}_{[i,k]})$  for all  $i$ . And, notice that, if one is willing to spend the time to find shortest non-zero codewords in codes with dimension at most  $k$ , then one can compute a Griesmer-reduced basis iteratively, by first setting  $\mathbf{b}_1$  to be a shortest non-zero codeword in the whole code, then projecting orthogonal to  $\mathbf{b}_1$  and building the rest of the basis recursively. (Griesmer-reduced bases are the analogue of Korkine-Zolotarev bases for lattices. We discuss Griesmer-reduced bases more below.)

Our approximate-Griesmer-reduction algorithm is a simple variant of this idea. In particular, it is really a family of algorithms parameterized by a subprocedure that finds short (but not necessarily shortest) non-zero codewords in a code. Given such a subprocedure, the

algorithm first finds a short non-zero codeword  $\mathbf{b}_1$  in the input code  $\mathcal{C}$ . It then projects the code orthogonally to  $\mathbf{b}_1$  and builds the rest of the basis recursively. (To make sure that we end up with a proper basis, care must be taken to assure that  $\mathbf{b}_1$  is primitive. We ignore this in the introduction. See the full version [21].)

The running time of this algorithm and the quality of the basis produced of course depends on the choice of subprocedure. Given the large number of algorithms for finding short non-zero codewords with a large variety of performance guarantees for different parameters (some heuristic and some proven), we do not attempt here to study this algorithm in full generality. We instead simply instantiate it with the Lee-Brickell-Babai algorithm from [17] (an algorithm which itself uses [17]’s LLL algorithm as a subroutine). Perhaps unsurprisingly, we find that this produces significantly better basis profiles (e.g., smaller  $|\mathbf{b}_1|$  and larger  $k_1$  and  $k_1^*$ ) than all of the algorithms that we designed here. The price for this is, of course, that the subprocedure itself must run in enough time to find non-zero short codewords in dimension  $k$  codes.

We view this algorithm as a proof of concept, showing that at least in principle one can combine basis-reduction techniques with other algorithms for finding short codewords to obtain bases with very good parameters. This meshes naturally with the Lee-Brickell-Babai algorithm in [17], which shows how good bases can be combined with other algorithmic techniques to find short non-zero codewords. Perhaps one can merge these techniques more in order to show a way to use a good basis to find a better basis, which itself can be used to find a better basis, etc?

#### 1.4.6 On “the best possible bases”

Finally, in the full version [21], we prove bounds on “the best possible bases” in terms of the parameters  $k_1$  and  $k_1^*$ . Indeed, recall that the (heuristic) running time of [17]’s Lee-Brickell-Babai algorithm beats Lee-Brickell by a factor that is exponential in  $k_1$ . And, we argued above that  $k_1^*$  can be viewed as a measure of the “non-triviality” of a basis reduction algorithm. So, it is natural to ask how large  $k_1$  and  $k_1^*$  can be in principle.

In the full version [21], we show that *any* code over  $\mathbb{F}_2$  has a basis with  $k_1^* \geq \Omega(\log k^2)$ , even if the support size is as small as  $n = k + \sqrt{k}$ . For this, we use Griesmer-reduced bases (not to be confused with the approximate-Griesmer-reduced bases described above; note in particular that it is NP-hard to compute a Griesmer-reduced basis). Notice that this is a factor of  $\Omega(\log k)$  better than the logarithmic  $k_1^*$  achieved by all known efficient basis-reduction algorithms.

Here, we use the parameter  $k_1^*$  and not  $k_1$  because it is easy to see that in the worst case a code can have arbitrarily large support but still have no proper basis with  $k_1 > 1$ .<sup>9</sup> Typically, of course, one expects  $k_1^*$  and  $k_1$  to be very closely related, so that one can view this as heuristic evidence that typical codes have bases with  $k_1 \geq \Omega(\log^2 k)$ .

In the full version [21], we argue under a mild heuristic assumption that any basis for a random code over  $\mathbb{F}_2$  has  $k_1 \leq k_1^* \leq O(\log^2 k)$ , even if the support size  $n$  is a large polynomial in the dimension  $k$ .

Taken together, these results suggest that the best possible bases that we should expect to find in practice should have  $k_1 \approx k_1^* = \Theta(\log^2 k)$  for typical settings of parameters. Such a basis would (heuristically) yield a savings of  $k^{\Theta(\log k)}$  in [17]’s Lee-Brickell-Babai algorithm. So, it would be very exciting to find an efficient algorithm that found such a basis.

<sup>9</sup> For example, take that code  $\mathbb{F}_2^{k-1} \cup (\mathbb{F}_2^{k-1} + \mathbf{c})$  where  $\mathbf{c} := (1, 1, \dots, 1) \in \mathbb{F}_2^n$ . Any proper basis of this code must have  $k - 1$  vectors with length one and therefore must have  $k_1 = 1$ .

On the other hand, our (heuristic) upper bound on  $k_1$  suggests a limitation of basis reduction for codes. In particular, we should not expect any improvement better than  $k^{\Theta(\log k)}$  in Lee-Brickell-Babai. And, the upper bound also suggests that basis-reduction algorithms are unlikely to outperform the simple one-block-reduction algorithm for block sizes larger than  $\Omega(\log^2 k)$ .

## 2 Preliminaries

### 2.1 Some notation

Logarithms are base two unless otherwise specified, i.e.,  $\log(2^x) = x$ . We write  $\mathbf{I}_m$  for the  $m \times m$  identity matrix.

If  $\mathbf{b}_1, \dots, \mathbf{b}_k \in \mathbb{F}_q^n$ , then  $(\mathbf{b}_1, \dots, \mathbf{b}_k) \in \mathbb{F}_q^{n \times k}$  denotes the matrix where each  $\mathbf{b}_i$  is a column and  $(\mathbf{b}_1; \dots; \mathbf{b}_k) \in \mathbb{F}_q^{k \times n}$  denotes the matrix where each  $\mathbf{b}_i$  is row  $i$  of  $\mathbf{B}$ .

We say that a matrix  $\mathbf{B} \in \mathbb{F}_q^{k \times n}$  is *in systematic form* if  $\mathbf{A} = (\mathbf{I}_k, \mathbf{X})\mathbf{P}$ , where  $\mathbf{P}$  is a permutation matrix (i.e., if  $k$  contains the columns  $\mathbf{e}_1^T, \dots, \mathbf{e}_k^T$ ).

For any basis  $\mathbf{B} \in \mathbb{F}_q^{k \times n}$  and any subset  $S \subseteq [n]$  with  $|S| = k$  such that  $\mathbf{B}_S$  has full rank, we call the process of replacing  $\mathbf{B}$  by  $(\mathbf{B}|_S)^{-1}$  *systematizing  $\mathbf{B}$  with respect to  $S$* . When the set  $S$  is not important, we simply call this *systematizing  $\mathbf{B}$* . This procedure is useful at least in part because it results in a proper basis.

We define two notions of the support of a vector. Specifically, we write

$$\text{Supp}(\mathbf{x}) := \{i \in [1, n] : x_i \neq 0\},$$

and similarly

$$\overrightarrow{\text{Supp}}(\mathbf{x})_i := \begin{cases} 0 & x_i = 0 \\ 1 & x_i \neq 0. \end{cases}$$

We can also define the support of an  $[n, k]_q$  code  $\mathcal{C}$  by extending the definitions of  $\text{Supp}$  and  $\overrightarrow{\text{Supp}}$ ,

$$\text{Supp}(\mathcal{C}) \triangleq \bigcup_{c \in \mathcal{C}} \text{Supp}(c) \quad \overrightarrow{\text{Supp}}(\mathcal{C}) = \bigvee_{c \in \mathcal{C}} \overrightarrow{\text{Supp}}(c),$$

and we define the support of a matrix  $\mathbf{B} \in \mathbb{F}_q^{k \times n}$  as the support of the code generated by the matrix.

If  $\mathbf{A} \in \mathbb{F}_q^{m \times n}$ ,  $\mathbf{B} \in \mathbb{F}_q^{r \times s}$ , then the direct sum of  $\mathbf{A}$  and  $\mathbf{B}$ , denoted  $\mathbf{A} \oplus \mathbf{B} \in \mathbb{F}_q^{(m+r) \times (n+s)}$ , is

$$\mathbf{A} \oplus \mathbf{B} = \begin{pmatrix} \mathbf{A} & \mathbf{0}_{m \times s} \\ \mathbf{0}_{n \times r} & \mathbf{B} \end{pmatrix}$$

We will often use the following important property regarding matrix direct sums. If  $\mathbf{A} \in \mathbb{F}_q^{m \times n}$ ,  $\mathbf{B} \in \mathbb{F}_q^{r \times s}$ ,  $\mathbf{x} \in \mathbb{F}_q^n$ ,  $\mathbf{y} \in \mathbb{F}_q^s$ , then

$$(\mathbf{A} \oplus \mathbf{B}) \begin{pmatrix} \mathbf{x} \\ \mathbf{y} \end{pmatrix} = \begin{pmatrix} \mathbf{A}\mathbf{x} \\ \mathbf{B}\mathbf{y} \end{pmatrix}.$$

### 3 Generalizing epipodal vectors, size reduction, and the fundamental domain to $\mathbb{F}_q$

In this section, we generalize many of the fundamental concepts in [17] from codes over  $\mathbb{F}_2$  to codes over  $\mathbb{F}_q$ . Specifically, we generalize the notions of projection, epipodal matrices, and the size-reduction algorithm. We then study the geometry of the fundamental domain that one obtains by running the size-reduction algorithm on a given input basis.

Much of this generalization is straightforward (once one knows the theory developed for  $\mathbb{F}_2$  in [17]). So, one might read much of this section as essentially an extension of the preliminaries. The most difficult part, in the full version [21], is the analysis of the fundamental domain (which is not used in the rest of the paper).

#### 3.1 Projection and epipodal vectors

The notions of projection and epipodal vectors extend naturally to  $\mathbb{F}_q$  from the notions outlined in [17]. However, to ensure that this work is as self-contained as possible, we will now explicitly outline how some of those notions extend to  $\mathbb{F}_q$ . Notice that these operations are roughly analogous to orthogonal projection maps over  $\mathbb{R}^n$ .

► **Definition 1.** If  $\mathbf{x}_1 = (x_{1,1}, \dots, x_{1,n}), \dots, \mathbf{x}_k = (x_{k,1}, \dots, x_{k,n}) \in \mathbb{F}_q^n$ , the function  $\pi_{\{\mathbf{x}_1, \dots, \mathbf{x}_k\}} : \mathbb{F}_q^n \rightarrow \mathbb{F}_q^n$  is defined as follows:

$$\pi_{\{\mathbf{x}_1, \dots, \mathbf{x}_k\}}(\mathbf{y})_i = \begin{cases} y_i & x_{1,i} \neq 0 \vee \dots \vee x_{k,i} \neq 0 \\ 0 & \text{otherwise.} \end{cases}$$

We call this “projection onto the support of  $\mathbf{x}_1, \dots, \mathbf{x}_k$ .”

► **Definition 2.** If  $\mathbf{x}_1 = (x_{1,1}, \dots, x_{1,n}), \dots, \mathbf{x}_k = (x_{k,1}, \dots, x_{k,n}) \in \mathbb{F}_q^n$ , the function  $\pi_{\{\mathbf{x}_1, \dots, \mathbf{x}_k\}}^\perp : \mathbb{F}_q^n \rightarrow \mathbb{F}_q^n$  is defined as follows:

$$\pi_{\{\mathbf{x}_1, \dots, \mathbf{x}_k\}}^\perp(\mathbf{y})_i = \begin{cases} y_i & x_{1,i} = 0 \wedge \dots \wedge x_{k,i} = 0 \\ 0 & \text{otherwise.} \end{cases}$$

We call this “projection orthogonal to  $\mathbf{x}_1, \dots, \mathbf{x}_k$ .”

We will often simply write  $\pi_{\mathbf{x}}$  to denote  $\pi_{\{\mathbf{x}\}}$  and  $\pi_{\mathbf{x}}^\perp$  to denote  $\pi_{\{\mathbf{x}\}}^\perp$ .

We now define the epipodal matrix of a basis for a code, which is the analogue of the Gram–Schmidt matrix.

► **Definition 3.** Let  $\mathbf{B} = (\mathbf{b}_1; \dots; \mathbf{b}_k) \in \mathbb{F}_q^{k \times n}$  be a matrix with elements from  $\mathbb{F}_q$ . The  $i$ th projection associated to the matrix  $\mathbf{B}$  is defined as  $\pi_i := \pi_{\{\mathbf{b}_1, \dots, \mathbf{b}_{i-1}\}}^\perp$ , where  $\pi_1$  denotes the identity.

The  $i$ th epipodal vector is defined as  $\mathbf{b}_i^+ := \pi_i(\mathbf{b}_i)$ . The matrix  $\mathbf{B}^+ := (\mathbf{b}_1^+; \dots; \mathbf{b}_k^+) \in \mathbb{F}_q^{k \times n}$  is called the epipodal matrix of  $\mathbf{B}$ .

The following notation for a projected block will be helpful in defining our reduction algorithms. (The same notation is used in the lattice literature.)

► **Definition 4.** For a basis  $\mathbf{B} = (\mathbf{b}_1; \dots; \mathbf{b}_k) \in \mathbb{F}_q^{k \times n}$  and  $i, j \in [1, k]$  where  $i \leq j$ , we use the notation  $\mathbf{B}_{[i,j]}$  as shorthand for  $(\pi_i(\mathbf{b}_i); \dots; \pi_i(\mathbf{b}_j))$ . Furthermore, for  $i \in [1, k]$  and  $j > k$ , we define  $\mathbf{B}_{[i,j]} = \mathbf{B}_{[i,k]}$  for all  $j > k$ .

We will often write  $\ell_i$  to denote  $|\mathbf{b}_i^+|$  when the basis  $\mathbf{B} = (\mathbf{b}_1; \dots; \mathbf{b}_k)$  is clear from context.

See the full version [21].

## 3.2 Size reduction and its fundamental domain

See the full version [21].

## 4 Proper bases and primitivity

We will primarily be interested in bases that are *proper* in the sense that the epipodal vectors should all be non-zero.

► **Definition 5.** *A basis is said to be proper if all its epipodal vectors  $\mathbf{b}_i^+$  are non-zero.*

[17] observed that, given an arbitrary basis  $\mathbf{B} \in \mathbb{F}_q^{k \times n}$  for a code, we can efficiently compute a proper basis  $\mathbf{B}'$  for the same code by systematizing  $\mathbf{B}$ . In particular, let  $\mathbf{A} \in \mathbb{F}_q^{k \times k}$  be an invertible matrix formed from  $k$  columns of  $\mathbf{B}$  (which must exist because  $\mathbf{B}$  is a full-rank matrix). Then,  $\mathbf{B}' := \mathbf{A}^{-1}\mathbf{B}$  is a proper basis for the code generated by  $\mathbf{B}$ . In particular, every code has a proper basis. From this, we derive the following simple but useful fact.

See the full version [21].

## 5 Redundant sets of coordinates, the last epipodal vector, and backward reduction

We are now ready to develop the theory behind backward-reduced bases. A backward-reduced basis is one in which the last epipodal vector  $\mathbf{b}_k^+$  is as *long* as possible. In the context of lattices, such bases are called dual-reduced bases and the maximal length of the last Gram-Schmidt vector has a simple characterization in terms of  $\lambda_1$  of the dual lattice. For codes, the maximal length of the last epipodal vector behaves rather differently, as we will explain below. In particular, we will see how to find a backward-reduced basis quite efficiently. In contrast, finding a dual-reduced basis is equivalent to finding a shortest non-zero vector in a lattice and is therefore NP-hard.

On our way to defining backward reduction, we first define the notion of *redundant* coordinates. Notice that we only consider coordinates in the support of  $\mathcal{C}$ .

► **Definition 6.** *For a code  $\mathcal{C} \subseteq \mathbb{F}_q^n$ , we say that a set  $S \subseteq [n]$  of coordinates is redundant for  $\mathcal{C}$  if  $S \subseteq \text{Supp}(\mathcal{C})$  and for every  $\mathbf{c} \in \mathcal{C}$  and all  $i, j \in S$ ,  $c_i = 0$  if and only if  $c_j = 0$ .*

The following simple claim explains the name “redundant.” In particular, for any codeword  $\mathbf{c} \in \mathcal{C}$ , if we know  $c_i$  for some  $i \in S$ , then we also know  $c_j$  for any  $j \in S$ .

▷ **Claim 7.** For a code  $\mathcal{C} \subseteq \mathbb{F}_q^n$ , a set  $S \subseteq \text{Supp}(\mathcal{C})$  is redundant for  $\mathcal{C}$  if and only if for every  $i, j \in S$ , there exists a non-zero scalar  $a \in \mathbb{F}_q^*$  such that for all  $\mathbf{c} \in \mathcal{C}$ ,  $c_j = ac_i$ .

Furthermore, to determine whether  $S$  is a set of redundant coordinates, it suffices to check whether the latter property holds for all  $\mathbf{c} := \mathbf{b}_i$  in a basis  $(\mathbf{b}_1; \dots; \mathbf{b}_k)$  of  $\mathcal{C}$ .

Proof. See the full version [21].

◁

Next, we show that redundancy is closely connected with the last epipodal vector in a basis.

## 19:18 More Basis Reduction for Linear Codes

► **Lemma 8.** For a code  $\mathcal{C} \subseteq \mathbb{F}_q^n$  with dimension  $k$  and  $S \subseteq [n]$ , there exists a basis  $\mathbf{B} := (\mathbf{b}_1; \dots; \mathbf{b}_k)$  of  $\mathcal{C}$  with  $S \subseteq \text{Supp}(\mathbf{b}_k^+)$  if and only if  $S$  is redundant.

Furthermore, if  $S$  is redundant, then there exists a proper basis with this property.

**Proof.** See the full version [21]. ◀

The above motivates the following definition.

► **Definition 9.** For a code  $\mathcal{C} \subseteq \mathbb{F}_q^n$ , the repetition number of  $\mathcal{C}$ , written  $\eta(\mathcal{C})$ , is the maximal size of a redundant set  $S \subseteq \text{Supp}(\mathcal{C})$ .

In particular, notice that by Lemma 8,  $\eta(\mathcal{C})$  is also the maximum of  $|\mathbf{b}_k^+|$  over all bases  $(\mathbf{b}_1; \dots; \mathbf{b}_k)$  and this maximum is achieved by a proper basis. The next lemma gives a lower bound on  $\eta(\mathcal{C})$ , therefore showing that codes with sufficiently large support and sufficiently low rank must have bases whose last epipodal vector is long.

► **Lemma 10.** For any code  $\mathcal{C} \subseteq \mathbb{F}_q^n$  with dimension  $k$ ,

$$\eta(\mathcal{C}) \geq \left\lceil \frac{q-1}{q^k-1} \cdot |\text{Supp}(\mathcal{C})| \right\rceil.$$

**Proof.** See the full version [21]. ◀

We present in Algorithm 1 a simple algorithm that finds the largest redundant set of a code  $\mathcal{C}$ . (The algorithm itself can be viewed as a constructive version of the proof of Lemma 10.)

■ **Algorithm 1** Max Redundant Set.

---

**Input:** A basis  $\mathbf{B} = (\mathbf{b}_1; \dots; \mathbf{b}_k) \in \mathbb{F}_q^{k \times n}$  for  $\mathcal{C}$

**Output:** A redundant set  $S$  for  $\mathcal{C}$  with  $|S| = \eta(\mathcal{C})$

**for**  $j \in [n]$  **do**

  |  $a_j \leftarrow B_{i,j}^{-1}$ , where  $i \in [k]$  is minimal such that  $B_{i,j} \neq 0$ .

**end**

Find  $S \subseteq \text{Supp}(\mathcal{C})$  with maximal size such that for all  $j_1, j_2 \in S$  and all  $i$ ,

$a_{j_1} B_{i,j_1} = a_{j_2} B_{i,j_2}$ .

**return**  $S$

---

▷ **Claim 11.** Algorithm 1 outputs a redundant set  $S$  for  $\mathcal{C}$  with  $|S| = \eta(\mathcal{C})$ . Furthermore, Algorithm 1 runs in time  $O(kn \log(q) \log(qn))$  (when implemented appropriately).

**Proof.** See the full version [21]. ◀

### 5.1 Backward reduction

We are now ready to present our definition of backward-reduced bases.

► **Definition 12.** Let  $\mathbf{B} = (\mathbf{b}_1; \dots; \mathbf{b}_k) \in \mathbb{F}_q^{k \times n}$  be a basis of a code  $\mathcal{C}$ . We say that  $\mathbf{B}$  is backward reduced if it is proper and  $|\mathbf{b}_k^+| = \eta(\mathcal{C}(\mathbf{B}))$ .

Finally, we give an algorithm that finds a backward-reduced basis. See Algorithm 2.

▷ **Claim 13.** On input a proper basis  $\mathbf{B}$ , Algorithm 2 correctly outputs an invertible matrix  $\mathbf{A}$  such that  $\mathbf{A}\mathbf{B}$  is backward reduced. Furthermore, Algorithm 2 runs in time  $O(nk \log(q) \log(qn))$ .

**Proof.** See the full version [21]. ◀

■ **Algorithm 2** Backward Reduction.

---

**Input:** A proper basis  $\mathbf{B} = (\mathbf{b}_1; \dots; \mathbf{b}_k) \in \mathbb{F}_q^{k \times n}$  for  $\mathcal{C}$   
**Output:** An invertible matrix  $\mathbf{A} \in \mathbb{F}_q^{k \times k}$  such that  $\mathbf{A}\mathbf{B}$  is backward reduced.  
 $\{j_1, \dots, j_t\} \leftarrow \text{MaxRedundantSet}(\mathbf{B})$   
Let  $m$  be minimal such that  $B_{m,j_1} \neq 0$ .  
**for**  $i \in [m+1, k]$  **do**  
  |  $\mathbf{b}_i \leftarrow \mathbf{b}_i - B_{m,j_1}^{-1} B_{i,j_1} \mathbf{b}_m$   
**end**  
 $(\mathbf{b}_1; \dots; \mathbf{b}_k) \leftarrow (\mathbf{b}_1; \dots; \mathbf{b}_{m-1}; \mathbf{b}_{m+1}; \dots; \mathbf{b}_k; \mathbf{b}_m)$   
**return** the matrix corresponding to the linear transformation done to  $\mathbf{B}$ .

---

## 5.2 Full backward reduction

Since backward reduction can be done efficiently, it is natural to ask what happens when we backward reduce many prefixes  $\mathbf{B}_{[1,i]}$  of a basis. We could simply do this for all  $i \in [k]$ , but it is natural to be slightly more fine-grained and instead only do this for  $i \leq \tau$  for some threshold  $\tau$ . In particular, since the last  $k - \text{poly}(\log n)$  epipodal vectors tend to have length one even in very good bases (see the full version [21] to understand why), it is natural to take  $\tau \leq \text{poly}(\log n)$  to be quite small, which leads to very efficient algorithms. This suggests the following definition.

► **Definition 14.** For some threshold  $\tau \leq k$ , a basis  $\mathbf{B} \in \mathbb{F}_q^{k \times n}$  is fully backward reduced up to  $\tau$  if it is proper and  $\mathbf{B}_{[1,i]}$  is backward reduced for all  $1 \leq i \leq \tau$ .

We now show how to easily and efficiently compute a fully backward-reduced basis, using the backward-reduction algorithm (Algorithm 2) that we developed above. We present the algorithm in Algorithm 3 and then prove its correctness and efficiency. Notice in particular that the algorithm only changes each prefix  $\mathbf{B}_{[1,i]}$  (at most) once.

■ **Algorithm 3** Full Backward Reduction.

---

**Input:** A proper basis  $\mathbf{B} := (\mathbf{b}_1; \dots; \mathbf{b}_k) \in \mathbb{F}_q^{k \times n}$  for a code  $\mathcal{C}$  and a threshold  $\tau \in [1, k]$   
**Output:** A basis for  $\mathcal{C}$  that is totally backward reduced up to  $\tau$ .  
**for**  $i = \tau, \dots, 1$  **do**  
  |  $\mathbf{A} \leftarrow \text{BackwardReduction}(\mathbf{B}_{[1,i]})$   
  |  $\mathbf{B} \leftarrow (\mathbf{A} \oplus \mathbf{I}_{k-i})\mathbf{B}$   
**end**  
**return**  $\mathbf{B}$

---

► **Theorem 15.** On input a proper basis  $\mathbf{B} := (\mathbf{b}_1; \dots; \mathbf{b}_k) \in \mathbb{F}_q^{k \times n}$  for a code  $\mathcal{C}$  and a threshold  $\tau \in [1, k]$ , Algorithm 3 correctly outputs a basis  $\mathbf{B}' \in \mathbb{F}_q^{k \times n}$  for  $\mathcal{C}$  that is fully backward reduced up to  $\tau$ . Furthermore, the algorithm runs in time  $O(\tau^2 n \log(q) \log(qn))$ .

**Proof.** See the full version [21]. ◀

We next bound  $|\mathbf{b}_1|$  of a fully backward-reduced basis. In fact, when  $\tau \geq \lceil \log_q n \rceil$ , this bound matches the Griesmer bound. In fact, it is not hard to see that with  $\tau = k$ , a fully backward-reduced basis is in fact LLL-reduced as well. But, the below theorem shows that we do not need to go all the way to  $\tau = k$  to achieve the Griesmer bound. This is because in the worst case,  $|\mathbf{b}_i^+| = 1$  for all  $i \geq \log_q n$  anyway.

► **Theorem 16.** *For any positive integers  $k$ ,  $n \geq k$ , and  $\tau \leq k$ , a basis  $\mathbf{B} \in \mathbb{F}_q^{k \times n}$  of a code  $\mathcal{C}$  that is fully backward reduced up to  $\tau$  satisfies*

$$\sum_{i=1}^{\tau} \left\lceil \frac{|\mathbf{b}_i|}{q^{i-1}} \right\rceil \leq n - k + \tau .$$

**Proof.** See the full version [21]. ◀

### 5.3 Heuristic analysis suggesting better performance in practice

Recall that our analysis of backward-reduced bases in Section 5 relied crucially on the repetition number  $\eta(\mathcal{C})$ , which is the maximum over all bases of  $\mathcal{C}$  of the last epipodal vector. We showed that  $\eta(\mathcal{C})$  can be equivalently thought of as the maximal set of redundant coordinates. E.g., when  $q = 2$ ,  $\eta(\mathcal{C})$  is precisely the number of repeated columns in the basis  $\mathbf{B}$  for  $\mathcal{C}$ .

Our analysis of fully backward-reduced bases then relies on the lower bound on  $\eta(\mathcal{C})$  in Lemma 10. The proof of Lemma 10 simply applies the pigeonhole principle to the (normalized, non-zero) columns of a basis  $\mathbf{B}$  for  $\mathcal{C}$  to argue that, if there are enough columns, then one of them must be repeated many times. Of course, the pigeonhole principle is tight in general and it is therefore easy to see that this argument is tight in the worst case.

However, in the average case, this argument is not tight. For example, if the number  $n$  of (non-zero) columns in our basis  $\mathbf{B} \in \mathbb{F}_2^{k \times n}$  is smaller than the number of possible (non-zero) columns  $2^k - 1$ , then it is certainly possible that no two columns will be identical. But, the birthday paradox tells us that even with just  $n \approx 2^{k/2}$ , a random matrix  $\mathbf{B} \in \mathbb{F}_2^{k \times n}$  will typically have a repeated column. More generally, if a code  $\mathcal{C}$  is generated by a random basis  $\mathbf{B} \in \mathbb{F}_q^{k \times n}$ , then we expect to have  $\eta(\mathcal{C}) > 1$  with probability at least  $1 - 1/\text{poly}(n)$ , provided that, say,  $n \geq 10 \log(n)q^{k/2}$ , or equivalently, provided that

$$k \leq 2(\log_q n - \log_q(10 \log(n))) .$$

We could now make a heuristic assumption that amounts to saying that the prefixes  $\mathbf{B}_{[1,i]}$  behave like random matrices with suitable parameters (in terms of the presence of repeated non-zero columns). We could then use such a heuristic to show that we expect the output of Algorithm 3 to achieve

$$k_1 > (2 - o(1)) \log_q n .$$

We choose instead to present in the full version [21] a variant of Algorithm 3 that provably achieves the above. This variant is identical to Algorithm 3 except that instead of looking at all of  $\mathbf{B}_{[1,i]}$  and choosing the largest set of redundant coordinates in order to properly backward reduce  $\mathbf{B}_{[1,i]}$ , the modified algorithm chooses the largest set of redundant coordinates *from some small subset* of all of the coordinates. In other words, the modified algorithm ignores information. Because the algorithm ignores this information, we are able to rigorously prove that the algorithm achieves  $k_1 \gtrsim 2 \log_q n$  when its input is a random matrix (by arguing that at each step the algorithm has sufficiently many fresh independent random coordinates to work with).

We think it is quite likely that Algorithm 3 performs better (and certainly not much worse) than this information-ignoring variant. We therefore view this as strong heuristic evidence that Algorithm 3 itself achieves  $k_1 \gtrsim 2 \log_q n$ . (This heuristic is also confirmed by experiment. See the full version [21].)

### 5.3.1 Backward reducing without all of the columns

## Abstract

We consider the problem in which  $n$  points arrive online over time, and upon arrival must be irrevocably assigned to one of  $k$  clusters where the objective is the standard  $k$ -median objective. Lower-bound instances show that for this problem no online algorithm can achieve a competitive ratio bounded by *any* function of  $n$ . Thus we turn to a beyond worst-case analysis approach, namely we assume that the online algorithm is a priori provided with a predicted budget  $B$  that is an upper bound to the optimal objective value (e.g., obtained from past instances). Our main result is an online algorithm whose competitive ratio (measured against  $B$ ) is solely a function of  $k$ . We also give a lower bound showing that the competitive ratio of every algorithm must depend on  $k$ .

## 1 Introduction

Clustering problems, such as  $k$ -means clustering and  $k$ -median clustering, are a classic genre of learning / data mining problems [5]. Typically the input consists of a collection  $X = \{x_1, \dots, x_n\}$  of points in some metric space  $\mathcal{M}$  (typically  $\mathbb{R}^d$  with the 1-norm or 2-norm) and a positive integer  $k$ . Typically  $k$  is a small constant [2, 5]. The output for a **center-based clustering problem** is a collection  $c_1, \dots, c_k$  of  $k$  points from  $X$ , called centers, that succinctly summarize the data points. The implicit cluster  $C_i$  corresponding to the center  $c_i$  is the collection of points in  $X$  whose closest center is  $c_i$ , that is  $C_i = \{x_j \mid \arg \min_{h \in [k]} d(x_j, c_h) = i\}$ , where  $d(\cdot, \cdot)$  is the distance function for the metric space. The output for a **cluster-based clustering problem** is a partition  $C_1, \dots, C_k$  of  $X$  into  $k$  parts, called clusters. The implicit center of each cluster  $C_i$  is then  $c_i = \arg \min_{x_h \in C_i} \sum_{x_j \in C_i} d(x_h, x_j)$ . For both center-based clustering and cluster-based clustering, the objective is to minimize the cost of the clustering. This paper considers the  $k$ -median objective which is the aggregate distance from each point to the center of its cluster, that is  $\sum_{i=1}^k \sum_{x_j \in C_i} d(x_j, c_i)$ .

Leibniz International Proceedings in Informatics

Schloss Dagstuhl – Leibniz-Zentrum für Informatik, Dagstuhl Publishing, Germany

Here we consider applications where the data points in  $X$  arrive online over time. In an **online center-based clustering problem**, the online algorithm maintains a collection of centers. In a **online cluster-based clustering problem**, the online algorithm needs to assign the data points to a cluster when they arrive, that is each point  $x_j$  needs to be assigned a label  $\ell_j \in [k]$  when  $x_j$  arrives. In either case, these choices should (ideally) be irrevocable.

An application of online clustering given by [16] is the task of clustering news articles that arrive online, e.g., at Yahoo news or Google news. We refer to these outlets as the news providers. The news provider selects some (approximately) fixed number  $k$  of articles to feature on the news homepage, and has a “view complete coverage” link next to each article to see all the news stories on this topic. The problem of selecting the best  $k$  articles that summarize all current news articles is better modeled as a center-based clustering. The problem of partitioning all news articles into clusters of similar articles is better modeled as a cluster-based clustering. Other applications can be found in [17, 14], but we will use the news story clustering application as our running canonical example.

A line of research [12, 11, 14, 17] within online clustering goes by moniker of consistent clustering. Research on consistent clustering studies the tradeoffs between the following objectives:

- **Maximizing the Quality of the Clustering:** One seeks a clustering of small cost. The most common metric to measure the quality of a solution is the ratio of the cost of this solution to cost of the optimal solution. The most common metric to measure the quality of an online algorithm is the competitive ratio, which is the maximum (over all inputs) of the ratio of the cost of the online algorithm’s solution to the optimal cost.
- **Maximizing Consistency:** Ideally one would like the centers in a center-based problem, or the clusters (labels of points) in a cluster-based problem, to be consistent over time. That is, they should change as little as possible. E.g., the news provider does not want the clusters to completely change every time a new news article is written.

## 1.1 Prior Work on Consistent Clustering

$k$ -median clustering is NP-hard, but constant-factor approximation algorithms are known [9, 13, 1, 15, 6].

All prior algorithmic research on consistent clustering that we are aware of [12, 11, 14, 17, 4] is center-based. That is, the online algorithm explicitly maintains a collection of centers, and the clustering is implicit; each point is associated with the closest center, but there are no restrictions on how often points’ associated centers can change.

In the first paper in this line of research, Liberty et al. [17] gave a lower bound that showed that one cannot simultaneously have both high quality and maximum consistency. That is, they showed that if a center cannot be changed once it is established, then there is no algorithm whose competitive ratio can be bounded by any function of  $n$  and  $k$ . Thus various “beyond worst-case analysis” (see [21]) approaches have been used in the literature to attempt to circumvent the obstacle presented by this lower bound. One approach is to use bi-criteria analysis or *resource augmentation* analysis. This analysis allows the online algorithm to use more than  $k$  centers, and then compares the cost of the algorithm’s clustering to the optimal one using  $k$  centers [17]. A second approach is to allow the algorithm *recourse*, which in this setting means allowing the algorithm to change the centers (or clusters) a small number of times [14, 11, 12].

**Resource Augmentation.** Liberty et al. [17] give a randomized algorithm for  $k$ -means clustering and analyzes this algorithm using *resource augmentation* analysis. They show that the expected number of clusters/centers used by their algorithm is  $O(k \log n \log(n\Delta))$  and at all times the expected cost of the clustering using these centers is at most  $O(\log n)$  times the optimal cost using  $k$  clusters. Here  $\Delta$  is the aspect ratio of the data points, which is the ratio between the distance between the furthest pair of points and the distance between the closest pair of points. The algorithm leverages a randomized online algorithm for facility location of Meyerson [18] to decide whether to create a new center at a newly arriving data point. Once a center is established, it is maintained throughout the course of the algorithm. Finally, they give a randomized algorithm that requires a priori knowledge of  $n$  and a lower bound on the optimal with  $k$  centers, and that maintains a collection of  $O(k \log n \log \alpha)$  centers in expectation that has expected cost  $O(1)$  times the optimal cost with  $k$  centers. Here  $\alpha$  is the ratio between the actual optimal cost with  $k$  centers and the lower bound provided a priori to the algorithm.

**Recourse.** Lattanzi and Vassilvitskii [14] give a randomized algorithm for  $k$ -median clustering that uses *recourse*. It maintains the invariant that the cost of the current centers is always  $O(1)$ -competitive with the optimal clustering of the data points seen *to date*. To maintain this invariant, the expected number of cluster center changes used is  $O(k^2 \log^4(n\Delta))$ . They show a similar lower bound, that is they show that every algorithm requires  $\Omega(k \log_c \frac{\Delta}{k})$  center changes to maintain  $O(c)$ -competitiveness. Further, they show that it possible to maintain  $O(1)$ -competitiveness with  $O(k \log^2(n\Delta))$  center changes, but this is given as an existential result. In a follow-up paper, Fichtenberger et al. [11] gave a randomized algorithm that is  $O(1)$ -competitive with  $O(k \text{polylog}(n\Delta))$  cluster center changes. In both papers, the result of Meyerson [18] is again a key subroutine. The results of Lattanzi and Vassilvitskii [14] were extended to  $k$ -median clustering with outliers (so one could opt to not cluster a pre-specified number of points) by Guo et al. [12]. Lattanzi and Vassilvitskii [14] also observe that for  $k$ -center clustering an algorithm of Charikar et al. [8] yields an  $O(1)$ -competitive clustering with  $O(k \log(n\Delta))$  center changes.

While not directly germane to the work in this paper, there is also research on online clustering in the streaming setting, where the emphasis is more on the algorithm using a small amount of memory, or quickly responding to the arrival of a new data point (e.g. [7, 10, 3]).

## 1.2 Our Contribution

Our research investigates consistent clustering for cluster-based problems (recall that all the past algorithmic consistent clustering publications that we are aware of focus on center-based clustering). We are interested in applications where the focus is on explicitly maintaining consistent clusters (and not necessarily on maintaining consistent centers). The application where Google or Yahoo news is trying to maintain collections of similar news articles is an example of such an application. Note that even the algorithms from [17] that are perfectly consistent from a center perspective, in that once a center is established it persists until the end of the algorithm, are not necessarily consistent from a cluster perspective in that a data point could change clusters every time a new center is established. All one can say (at least naively) about the cluster consistency of the algorithms from [17] is that no data point changes clusters more than  $O(k \log n \log(n\Delta))$  times.

► **Problem 1** ((Online) cluster-based clustering). *The points  $X = \{x_1, \dots, x_n\}$  from a metric space arrive online in this (adversarial) order. Each point must be given an irrevocable label from  $\{1, \dots, k\}$  (i.e., irrevocably assigned a cluster) upon arrival. (The number of points  $n$  is not known.) The goal is to minimize the  $k$ -median objective.*

**Beyond Worst-Case Model.** We first observe that the lower bound from [17] extends to the cluster-based setting, so no online algorithm can achieve a competitive ratio bounded by *any* function of  $n$ . Thus we turn to a learning-augmented approach, namely we assume that the algorithm is provided a priori with an estimated upper bound  $B$  on the cost  $\text{OPT}$  of the final optimal clustering; recourse and resource augmentation are **not** allowed. This approach is both natural and appealing, as the a priori information provided to the algorithm is *minimal*. Moreover, it finds motivation in the Google/Yahoo news application, where presumably the final objective values for prior instances could be used as a basis to obtain a reasonable estimate for  $B$ . Thus we then seek algorithms that will maintain a clustering of low cost relative to  $B$  (not the current optimal cost for the points that have arrived to date). We say an algorithm is  $c$ -competitive with respect to  $B$  if the algorithm's cost is at most  $c \cdot B$  on instances where the optimal cost is at most  $B$  (after all points have arrived).

We first show that any deterministic algorithm must have dependence on  $k$  in the competitive ratio. The proof is deferred to the full version.

► **Proposition 1.** *Any deterministic algorithm for cluster-based clustering is  $\Omega(k)$ -competitive with respect to  $B$ .*

In almost all applications,  $k$  is a small constant [2, 5]. Thus, we ask if an algorithm can have performance only depending on  $k$  and not on the large parameters  $\Delta$  and  $n$ .

*Does there exist an online algorithm for Problem 1 that, given a priori knowledge of an upper bound  $B$  on  $\text{OPT}$ , achieves competitiveness independent of  $n$  and  $\Delta$ ?*

### 1.3 Results

Our main question is whether there exists an algorithm with competitiveness depending only on  $k$  (and not  $n$  or  $\Delta$ ). We answer this constructively:

► **Theorem 2.** *There is a poly-time algorithm for cluster-based clustering that is  $O(k^5 3^k)$ -competitive with respect to  $B$ .*

Intuitively, our algorithm uses the value of  $B$  to determine a scale for which costs are cheap (namely that are small relative to  $B$ ) and which are expensive (namely that are large relative to  $B$ ). Thus, one upshot of our results is that this minimal scaling information is all that the online algorithm needs to overcome the strong lower bound. Moreover, existing algorithms/subroutines in the recourse and resource augmentation settings do not seem to translate to guarantees in our setting. Thus, our setting requires novel techniques and structural insights, which we turn to next.

## 2 Technical Overview

As our algorithm is fairly detailed, we begin with a technical overview to build the case for our design decisions.

To understand the motivation for the learning-augmented approach, let us consider the lower bound instance from [17]. It is sufficient to assume  $k = 2$ . The first point  $x_1$  arrives and is assigned some irrevocable label. Then assume the second data point  $x_2$  arrives a unit

distance from  $x_1$ . If the online algorithm assigns  $x_2$  the same label as  $x_1$ , then the cost of the algorithm's clustering is 1, and the optimal cost is 0 (which is the cost if each of these data points were given a different label). This results in the algorithm having unbounded competitiveness. In contrast, if the algorithm gave  $x_2$  a different label from  $x_1$  then the third data point  $x_3$  could arrive very far away. In which case, the algorithm's clustering would necessarily have very high cost (as  $x_3$ 's label would have to be either the same as  $x_1$ 's or the same as  $x_2$ 's). However, the optimal clustering would have cost 1 (by giving  $x_1$  and  $x_2$  the same label and giving  $x_3$  the remaining label). Again, this results in competitiveness that can only be bounded by  $\Delta$  (which may be much larger than  $n$  or  $k$ ).

Intuitively, the dilemma faced by the algorithm when  $x_2$  arrives is that it does not know whether the distance between  $x_1$  and  $x_2$  is small or large. Equipped with an estimate of the optimal cost  $B$ , the algorithm could resolve the dilemma in this case by giving  $x_2$  a different label than  $x_1$  if their distance is larger than  $B$  and the same label otherwise.

## 2.1 Properties of competitive algorithms

To better understand our algorithm design it is useful to understand some instances that illustrate some properties that a competitive algorithm must have.

A simple first observation is that any reasonably competitive algorithm can never use  $t + 1$  labels if it is the case that the points to date could be clustered with cost at most  $B$  using at most  $t$  labels. If the algorithm ever allowed this to happen, it could be that the next  $k - t$  data points could arrive very far from the previous data points, and very far from each other. Thus after these data points arrive, the algorithm's cost would increase by an amount depending on the diameter of the metric space, while there would still be a clustering of cost at most  $B$ , since the clustering that used  $t$  labels could be extended with no additional cost by giving each of the new  $k - t$  data points a new label.

**Natural greedy algorithm fails.** In light of this last observation, a natural greedy algorithm would maintain the invariant that the number of labels it uses is always equal to the minimum number of labels necessary for a clustering of cost at most  $B$ , and then give each new data point the label that minimizes the increase in cost. To see why such an algorithm (and other similar algorithms) can have unbounded cost even when  $k = 2$ , and the metric space is the real line, consider the following instance (see Figure 1). Let  $\alpha$  be an arbitrarily large positive integer. We construct an example in which the budget  $B = 2$ . The first point arrives at location  $-2$ . Say the algorithm gives this point the label blue. The next point arrives at location 1. Now, we know that any offline clustering with cost at most 2 must use at least 2 clusters. So the greedy algorithm would give this new point a second label, say green, as that would minimize the increase in the objective. Then a total of  $\alpha$  additional points arrive at location 1. The algorithm labels these points green. Then  $\alpha$  points arrive at the origin 0. It is still the case that only 2 clusters are required in order to have cost at most 2, since we may place the points at location  $-2$  and the origin in one cluster, and the points at location 1 in the other cluster. However the algorithm would assign each point arriving at the origin the label green, since this increases the objective by at most 1 while assigning such a point the label blue increases the objective by 2. Yet, this results in a solution for the algorithm in which the contribution of green points towards the objective is  $\alpha$ .

■ **Figure 1** An example in which the natural greedy algorithm fails.

Upon reflection of this lower bound instance for the natural greedy algorithm, there appear to us to be two natural hypotheses as to the “mistake” that this algorithm is making, and correspondingly two natural paths towards a remedy:

- One hypothesis is that greedy assignment is a mistake, and then the natural remedy is some label assignment rule more sophisticated than greedy.
- Another is that the algorithm was too hasty in using a new label. Thus the natural remedy would be to delay using a new label until it is more clear as to a region where arriving data points should be given this new label. Note in the example in Figure 1 that if the algorithm had waited until some reasonable number of data points had arrived at the origin before using the second label, then the algorithm might have been able to see that the right choice was to give the remaining points arriving at the origin the second label of green.

## 2.2 Techniques

Here we primarily adopt the second remedy/approach (while also considering an alternate greedy assignment policy). To apply this remedy we must address the following:

- Under what conditions can the algorithm justify the use of an additional label, increasing from  $t - 1$  labels to  $t$  labels?
- When this can be justified, how should we modify our prior partition of space into  $t - 1$  parts to a partition into  $t$  parts? We would like to greedily assign each point to its “closest” part.

**Well-separated points.** At a high level our answer to the first question is that we do not use  $t$  labels until there exist  $t$  well-separated points  $x_{\alpha(1)}, \dots, x_{\alpha(t)}$ . We will say that a collection of points  $x_{\alpha(1)}, \dots, x_{\alpha(t)}$  from a collection  $S$  of points is  **$\beta$ -well-separated with respect to  $w_S$**  (for some  $\beta > 0$ ) if for all  $i, j \in [t], i \neq j$

$$\min\{w_S(x_{\alpha(i)}), w_S(x_{\alpha(j)})\} \cdot d(x_{\alpha(i)}, x_{\alpha(j)}) \geq \beta \cdot B \tag{*}$$

Here  $w_S(x_h)$  is what we call the **natural weight** of point  $x_h$  in  $S$ , which is the maximum number of points in  $S$  whose distances to  $x_h$  sum to at most  $2B$ :

$$w_S(x_h) := \max\{|S'| : S' \subseteq S, \sum_{s \in S'} d(s, x_h) \leq 2B\}.$$

The condition (\*) states that every pair of these  $t$  points is far apart – according to a weighted notion of distance. In turn, the weights used in this notion of distance are the so-called natural weight of each point, which captures the density of its nearby points. Intuitively, if we have  $t$  well-separated points, then not only must any near-optimal solution use  $t$  labels, but such a solution cannot combine the points near  $x_{\alpha(i)}$  and the points near  $x_{\alpha(j)}$  into a single cluster.

**Pivots.** The algorithm is divided into at most  $k$  **phases**. For each phase  $t$ , the algorithm maintains a collection of points  $p_1, \dots, p_t$  from the online stream  $X$  which we call *pivots*. The pivots  $p_1, \dots, p_t$  stay fixed during phase  $t$ . The key property they should satisfy is that they

are well-separated with respect to the points seen so far. Between phases, we increase the number of pivots, thus allowing the algorithm to use more labels. The pivot  $p_i$  is associated with the label  $i$ . Thus, during phase  $t$ , there are  $t$  clusters (i.e.,  $t$  labels in use). When a new point arrives, it is assigned the label  $i$  of the pivot  $p_i$  nearest to it (so we maintain a greedy labelling rule). Importantly, though, the *location* of the pivot  $p_i$  for label  $i$  may change over time. Roughly speaking, this occurs when there is a better representative for cluster  $i$ .

**Pivots vs. centers.** While one might reasonably think that the pivots are intuitively (low-cost) centers for the clusters, this intuition is only partially correct. Part of the subtlety of the algorithm design is that there are in fact scenarios where some pivots are poor centers for the corresponding clusters, but still good representatives for making cluster assignment decisions. What is critical is that the pivots are located so as to guarantee that using greedy assignment in the future results in a relatively low cost assignment; so pivots serve to recruit points to the right clusters. Our algorithm evinces a distinction between a good representative for a cluster in the long-term (a pivot) and a good center at a single moment.

**Invariants.** In order for our cost analysis to be tractable, the algorithm should maintain the following invariants:

- Each pivot  $p_i$  is located in a region where it would not be too costly to assign points arriving there the label  $i$ .
- The pivots  $p_1, \dots, p_t$  for phase  $t$  are well-separated (for some appropriate choice of  $\beta$ ) during phase  $t$ .<sup>1</sup>
- There is no other point that is well-separated from the pivots during a phase. (Otherwise, this indicates that another label can and should be in use.)
- The locations of the pivots should not move very often.

Note that some of these invariants can intuitively be in opposition to each other, which requires that the algorithm design be a bit detailed, as there are several different cases where maintaining this invariant requires different updates to the pivots. We now give an overview of how the algorithm maintains these invariants, highlighting representative cases.

## 2.3 Preliminaries

**Assumptions.** We state our results assuming  $B = \text{OPT}$ , but all still hold by replacing  $\text{OPT}$  with  $B$ .

**Terminology.** Recall from above the *natural weights*  $w_S(\cdot)$ . We will always take  $S$  to be some prefix of the online stream  $X$ . Note  $w_S(p)$  can only increase over time as  $S$  enlarges.

Other terms related to well-separation are: A pair of points  $x_i, x_j$  are  **$\beta$ -attached** with respect to  $w_S$  if  $\min\{w_S(x_i), w_S(x_j)\} \cdot d(x_i, x_j) < \beta \cdot B$ , i.e., the well-separated condition does *not* hold for this pair. A useful way of viewing attachment is that we may move a certain number of points lying near  $x_{\alpha_j}$  to  $x_{\alpha_i}$  at bounded cost (but perhaps not in the reverse direction). We say  $p$  is  **$\beta$ -well-separated from** a set of points  $\{x_{\alpha(1)}, \dots, x_{\alpha(m)}\}$  with respect to  $w_S$  if  $\min\{w_S(p), w_S(x_{\alpha(i)})\} \cdot d(p, x_{\alpha(i)}) \geq \beta \cdot B, \forall i \in [m]$ .

<sup>1</sup>  $\beta$  must be initialized sufficiently large and also decrease as the number of pivots increases.

**Figure notation.** In all figures below, dashed lines indicate well-separation. Solid lines indicate attachment; where included, arrows on solid lines specify the direction of attachment, i.e., point from smaller to larger natural weights (see previous paragraph). Colors except black correspond to cluster labels. Small circles drawn near a larger circle indicate the points attaining the natural weight of the larger point (the maximizing set  $S'$  in the definition of  $w_S$ ).

### 2.4 Subroutines

There are two subroutines used to enlarge the set of pivots from phase  $t$  to phase  $t + 1$ , the **Add Operation** and the **Exchange Operation**. There are subtleties to the execution of these operations that require we also keep track of good centers for the clusters built so far, called **estimated centers**.

**Estimated Centers.** As the pivots are not necessarily good centers (for example, pivot  $p_1$  at location  $-2$  as the points arrive at location  $1$  in Figure 1), the algorithm also maintains a collection  $c_1, \dots, c_T$  of estimated centers for the  $T$  labels<sup>2</sup> that have been used to date. The estimated centers are updated at the end of some phases, and satisfy the invariant that  $c_j$  is a center for label  $j$ 's current cluster with bounded cost. Consider Figure 2. At the start of phase  $T$ ,  $c_j^{\text{old}}$  is the estimated center for points in cluster  $j$ . Points arriving in phase  $T$  that are closer to  $p_j$  than to other pivots are given label  $j$  (by our greedy assignment rule). However, these new points may be concentrated around, for instance,  $y_2$ , so that  $p_j$  is not actually a good center for cluster  $j$  at the end of phase  $T$  (even though it is fine for labelling purposes).

■ **Figure 2** Updating the estimated centers at the end of a phase.

Thus, when it comes time to reset the pivots at the end of phase  $T$ , we might need to move  $p_j$  to the new estimated center  $y_2 = c_j^{\text{new}}$  or to a nearby point. So, estimated centers are not only used in the cost analysis, but critically are used algorithmically to update the locations of pivots. The computation of the estimated centers will involve running an offline approximation algorithm on the points seen to date.

**Add Operation.** An Add Operation is applicable when there is a point  $x_\alpha$  that is well-separated from the current pivots. Intuitively, this means a new label (cluster) can be justified, but the implementation requires the consideration of several possible scenarios. In the simplest scenario  $x_\alpha$  is near a cluster of new points that are all far from previous points, and the pivot  $p_{t+1}$  for the new label  $(t + 1)$  is set to  $x_\alpha$ . In some scenarios an old pivot  $p_i$  ( $i \leq t$ ) is set to  $x_\alpha$  and  $p_{t+1}$  is set to  $p_i$  (so the new pivot location inherits the old label  $i$  and an old pivot location gets the new label  $t + 1$ ). Intuitively, this occurs when the estimated

<sup>2</sup> We use  $T$  instead of  $t$  here to distinguish that this subroutine is only executed at the end of certain phases; see Section 3.

center  $c_i$  for cluster  $i$  is at or near the location of  $x_\alpha$ . See Figure 3 (left); take  $i = 2$ ,  $t = 4$ , and  $x_\alpha = c_2$ . Finally, there are scenarios where  $x_\alpha$  is close to two different clusters; in this case  $x_\alpha$  is never made a pivot and instead *two* pivots are added at the estimated centers of these clusters (so we skip straight to phase  $t + 2$ ). See Figure 3 (right). One must show that this move maintains the well-separation invariant.

■ **Figure 3** Two cases of the Add Operation.

**Exchange Operation.** An Exchange Operation is applicable when there are two points  $x_\alpha$  and  $x_\gamma$  near a pivot  $p_j$  that are well-separated from each other and the other pivots (besides  $p_j$ ). See Figure 4 (left); take  $j = 3$ . So intuitively the cluster of points labeled  $j$  appear to be splitting into two clusters. In the simplest scenario the location of pivot  $p_j$  is set to the location of one of  $x_\alpha$  or  $x_\gamma$ , and the location of the new pivot  $p_{t+1}$  is set to the other. See Figure 4 (right); set  $j = 3$ ,  $t = 4$ .

■ **Figure 4** A case of the Exchange Operation.

This scenario occurs in the instance depicted in Figure 1. The first pivot  $p_1$  is initially set to location  $-2$ . The points arriving at location 1 would all be assigned the label 1 (blue) as there is no point well-separated from  $p_1$  (the points located at 1 are not separated from  $p_1$  because the points at  $p_1$  can be cheaply moved to location 1). When enough points have arrived at the origin, then the points  $x_\alpha = 0$  and at  $x_\gamma = 1$  are near  $p_1$  (because the point at  $p_1$  can be cheaply moved to either  $x_\alpha$  or  $x_\gamma$ ), but are well-separated from each other and the pivots other than  $p_1$ . Thus our algorithm would locate  $p_1$  at 1 and  $p_2$  at the origin. While this gives intuition, there are other more subtle scenarios.

### 3 Algorithm Description

The algorithm sees an online sequence  $X = \{x_1, x_2, \dots, x_n\}$  of points. Let  $X_i = \{x_1, x_2, \dots, x_i\}$ . Let  $w_i$  be shorthand for  $w_{X_i}$ . During any phase  $t$ , the algorithm maintains:

- a collection of previously arriving points  $p_1, \dots, p_t$  that have been designated as *pivots*, where  $t$  is the number of labels used by the algorithm to date and pivot  $p_j$  is associated with label  $j$ ,
- a separation parameter  $\beta_t = 8 \cdot 3^{k-t+2}$ , and
- a collection of previously arriving points  $c_1, \dots, c_s$  ( $s \leq t$ ) that have been designated as estimated centers.

**Phase  $t$**  is the set of time steps when there are  $t$  pivots. Phase 1 is initialized as follows: the first point  $x_1$  is given the label 1, the first pivot  $p_1$  is set to  $x_1$ , and the collection of estimated centers is empty. Let  $T$  be the current phase. The algorithm handles the arrival

of each subsequent point  $x_i$  as follows. It checks whether there is an applicable Add or Exchange Operation, both of which will increase the number of pivots. If so, phase  $T$  ends. First estimated centers  $c_1, \dots, c_T$  are computed, and then, using these, the algorithm carries out consecutive Add and Exchange Operations (giving preference to Add Operations for technical reasons) until there are none left. With each operation, the phase increases and the pivots are reset. Call the last phase in this sequence of consecutive operations  $T^+$ . (Note that  $T^+ \geq T + 1$ .) The point  $x_i$  is the first point labelled during phase  $T^+$  (it is *not* labelled during phase  $T$ ). In summary:

1. **If** there is an applicable Add or Exchange Operation upon the arrival of  $x_i$  **then** compute new Estimated Centers  $c_1, \dots, c_T$ .
  - a. **Repeat** while there is an applicable Add Operation or Exchange Operation.
    - i. **If** there is an applicable Add Operation **then** apply an arbitrary applicable one.
    - ii. **Else** apply an arbitrary applicable Exchange Operation.
2. Give  $x_i$  label  $j$ , where  $p_j$  is the nearest pivot (among  $p_1, \dots, p_{T^+}$ ) to  $x_i$

We then repeat the above steps upon the arrival of  $x_{i+1}$ . Note that if there is  $t$  such that  $T < t < T^+$ , then no points are labelled during phase  $t$ . We call such phases  $t$  during which no points are labelled **intermediate**. During each other phase, at least one point is labelled, and we call such phases **non-intermediate**. So for a non-intermediate phase  $T$ ,  $T^+$  is the first non-intermediate phase after  $T$ , and we will also use  $T^-$  to refer to the last intermediate phase before  $T$ . We now describe the three subroutines.

### 3.1 The Estimated Center Subroutine

This subroutine computes  $T$  new estimated centers  $c_1, \dots, c_T$  from pivots  $p_1, \dots, p_T$ , the points  $X_{i-1}$  that have arrived before  $x_i$ , and estimated centers  $c_1, \dots, c_{T-}$ .

Choose  $y_1, \dots, y_k \in X_{i-1}$  to be an (offline) optimal collection of  $k$  centers<sup>3</sup> for the points in  $X_{i-1}$ . For each **offline optimal center**  $y_h$ ,  $h \in [k]$ , define  $p(y_h)$  to be the pivot with the minimum weighted distance to  $y_h$ , that is,

$$p(y_h) = \arg \min_{p_j} (\min\{w_{i-1}(p_j), w_{i-1}(y_h)\} \cdot d(p_j, y_h)) \quad (\dagger)$$

Say that  $y_h$  is *assigned to*  $p_j$  if  $p(y_h) = p_j$ . For each pivot  $p_j$ , we define the set  $\delta(p_j)$  to contain a subset of the offline optimal centers that are assigned to  $p_j$ , and possibly  $c_j$  as well; the points in  $\delta(p_j)$  are “close” to  $p_j$  in some sense. In particular,  $y_h \in \delta(p_j)$  if  $p(y_h) = p_j$  and  $w_{i-1}(y_h) > w_{i-1}(p(y_h))$ . Also,  $c_j$  is in  $\delta(p_j)$  if  $w_{i-1}(c_j) > w_{i-1}(p_j)$  and  $c_j$  is  $\beta_{t+1}$ -attached to  $p_j$  w.r.t.  $w_{i-1}$ .

As an example, see **Figure 2**. Here,  $\delta(p_j) = \{y_1, y_2\}$ , so  $c_j$  (denoted  $c_j^{\text{old}}$ ) is not in  $\delta(p_j)$ , because the arrow from  $c_j^{\text{old}}$  to  $p_j$  (representing attachment) points in the wrong direction.

For each  $j \in [T]$ , we now define the new **estimated center**  $c_j$ : If  $w_{i-1}(p_j) \geq \max_{p \in \delta(p_j)} w_{i-1}(p)$  then  $c_j = p_j$ , else

$$c_j = \arg \max_{p \in \delta(p_j)} w_{i-1}(p) \quad (\ddagger)$$

So in **Figure 2**,  $c_j$  is updated to  $y_2$  (denoted  $c_j^{\text{new}}$ ), because  $y_2$  has the largest weight in  $\delta(p_j)$ . Intuitively, this means that  $c_j^{\text{new}}$  is now a better center for cluster  $j$  than, say,  $c_j^{\text{old}}$ .

<sup>3</sup> To run in poly-time, replace with any constant approximation algorithm. This algorithm’s cost will change by a constant factor.

### 3.2 The Add Operation Subroutine

Let  $t \geq T$  be the number of pivots when an Add Operation is called (during an execution of (i) above). The Add Operation applies if there is a point  $x_\alpha \in X_i$  such that  $x_\alpha$  is  $\beta_{t+1}$ -well-separated from the current pivots  $p_1, \dots, p_t$  with respect to the weights  $w_i$ . (**E.g., Figure 3, left, with  $t = 4$ .**) The Add Operation depends on  $x_\alpha$ ,  $X_i$ , the current pivots  $p_1, \dots, p_t$ , and estimated centers  $c_1, \dots, c_T$ . In most cases, the Add Operation adds  $x_\alpha$  to the set of pivots, and changes the location of up to two previous pivots (**Figure 3**).

Define  $w_t := w_{i-1}$  if  $t = T$  and  $w_t := w_i$  if  $t > T$ .<sup>4</sup>

1. **If** there is an estimated center  $c_j$  that is  $\beta_{t+1}$ -well-separated from  $p_1, \dots, p_t$  w.r.t.  $w_i$  then set  $p_{t+1} = p_j$  and set  $p_j = c_j$ . (**Figure 3, left**)
2. **Else if** it is the case that for every estimated center  $c_j$  that is  $\beta_{t+2}$ -attached to  $x_\alpha$  w.r.t.  $w_i$  it is also the case that  $w_t(c_j) < w_t(p_j)$ , then set  $p_{t+1} = x_\alpha$ .
3. **Else if** there exists a unique estimated center  $c_j$  is  $\beta_{t+2}$ -attached to  $x_\alpha$  w.r.t.  $w_i$  and  $w_t(c_j) \geq w_t(p_j)$  then set  $p_{t+1} = p_j$  and  $p_j = x_\alpha$ .
4. **Else** Let  $c_f$  and  $c_g$  be estimated centers such that each is  $\beta_{t+2}$ -attached to  $x_\alpha$  w.r.t.  $w_i$ ,  $w_t(c_f) \geq w_t(p_f)$ , and  $w_t(c_g) \geq w_t(p_g)$ . Set  $p_{t+1} = p_f$ ,  $p_{t+2} = p_g$ ,  $p_f = c_f$ , and  $p_g = c_g$ . (**Figure 3, right**)

Note in the last case that we skip to phase  $t + 2$ .

### 3.3 The Exchange Operation Subroutine

The Exchange Operation subroutine is applicable if there exists two points  $x_\alpha$  and  $x_\gamma$  in  $X_i$ , and a pivot  $p_j$  such that:

- $x_\alpha$  and  $x_\gamma$  are each  $\beta_{t+1}$ -attached to  $p_j$  w.r.t.  $w_i$ ,
- $w_i(p_j) \leq w_i(x_\alpha)$ ,
- $w_i(p_j) \leq w_i(x_\gamma)$ , and
- The collection of the  $t + 1$  points, consisting of  $x_\alpha$ ,  $x_\gamma$ , and the pivots other than  $p_j$ , are  $\beta_{t+1}$ -well-separated w.r.t.  $w_i$ . (**E.g., Figure 4, left, with  $t = 4$ .**)

The Exchange Operation depends on  $x_\alpha$ ,  $x_\gamma$ ,  $X_i$ , the current pivots  $p_1, \dots, p_t$ , and estimated centers  $c_1, \dots, c_T$ . In most cases, the Exchange Operation adds  $x_\alpha$  and  $x_\gamma$  to and deletes  $p_j$  from the set of pivots, and possibly changes the location of one previous pivot.

1. **If**  $j > T$  then set  $p_j = x_\alpha$  and  $p_{t+1} = x_\gamma$ .
2. **Else if**  $w_i(c_j) < w_i(p_j)$  then set  $p_j = x_\alpha$  and  $p_{t+1} = x_\gamma$ .
3. **Else if**  $c_j$  is  $\beta_{t+2}$ -attached to  $x_\alpha$  w.r.t.  $w_i$  then set  $p_j = x_\alpha$  and  $p_{t+1} = x_\gamma$ . (**Figure 4, right**)
4. **Else if**  $c_j$  is  $\beta_{t+2}$ -attached to  $x_\gamma$  w.r.t.  $w_i$  then set  $p_j = x_\gamma$  and  $p_{t+1} = x_\alpha$ .
5. **Else** set  $p_{t+1} = x_\alpha$ ,  $p_{t+2} = x_\gamma$ , and  $p_j = c_j$ .

## 4 Algorithm Invariants and Analysis

In this section, we state the key technical lemmas. We defer full proofs to the Appendix.

► **Theorem 3.** *The algorithm uses at most  $k$  labels.*

► **Theorem 4.** *The algorithm's cost is  $O(k^5 \cdot 3^k \cdot OPT)$ .*

<sup>4</sup> We are overloading subscripts here for ease. We could instead write  $v_t$ , but we retain  $w$  to recall weights.

## 4.1 Notation

- $p_1^t, \dots, p_t^t$  denote the pivots for labels 1 through  $t$ , respectively, during phase  $t$ .
- $w^t$  are the natural weights at the end of phase  $t$ .
- $X(t)$  is the set of points assigned a label before or during phase  $t$ .
- For  $j \in [t]$ ,  $C_j^t$  is the set of points labelled  $j$  in phases 1 through  $t$ .
- For  $j \in [T]$ ,  $c_j^T$  is the estimated center (‡) computed at end of non-intermediate phase  $T$ .
- $y_1^T, \dots, y_k^T$  are the offline optimal centers computed at the end of phase  $T$  in The Estimated Center Subroutine.
- $P_T = \{p_1^T, \dots, p_T^T, y_1^T, \dots, y_k^T\}$
- $\text{cost}(S; c) = \sum_{p \in S} d(p, c)$  for  $S \subseteq X$  and  $c \in X$ .

## 4.2 Invariants

In the next two lemmas, we show that our algorithm maintains two key invariants. The full proofs are deferred to the full version, although we give a proof sketch of Lemma 5 in the appendix.

► **Lemma 5.** *Let  $t \in [k]$ . The algorithm maintains the invariant that  $p_1^t, \dots, p_t^t$  are  $\beta_t$ -well-separated w.r.t. the natural weights at the start of phase  $t$  (and after).*

Lemma 5 directly implies Theorem 3 once we show that there can be no more than  $k$  well-separated points in  $X$  and note that we have set  $\beta_1$  sufficiently large.

Next is a key technical lemma. It states that the estimated center  $c_j^{T^-}$  for the points given label  $j$  *before* phase  $T$  is close, in a weighted sense, to the pivot for label  $j$  in phase  $T$ . This is key to showing that points in cluster  $j$  that are labelled *before* phase  $T$  can be combined with those that are labelled *during* phase  $T$  at bounded cost. This lemma is in tension with the prior one because a pivot must be placed in a location where it is both well-separated from other pivots and is close to previously arriving points in its cluster.

► **Lemma 6.** *Let  $T$  be a non-intermediate phase and let  $j \in [T]$ . If  $T > 1$ , at least one of the following holds:*

- (a)  $w^{T^-}(c_j^{T^-}) \leq w^T(p_j^T)$  and  $w^{T^-}(c_j^{T^-}) \cdot d(c_j^{T^-}, p_j^T) \leq \beta_{T^-}(T - T^-) \cdot \text{OPT}$ .
- (b)  $c_j^{T^-}$  is  $\beta_{T+1}$ -attached to  $p_j^T$  w.r.t.  $w^T$ .

## 5 Bounding Cost

We show by induction that the estimated center  $c_j^T$  is good for *all* points given label  $j$  by the end of phase  $T$ . Taking  $T$  to be the last phase gives our main result. We follow Figure 5. By definition of attached, a certain number of points sitting at the head (equal to the head's natural weight) of an arc can be moved to the tail at bounded cost. First we address the cost of  $C_1^{T^-}$ , the points given label 1 before phase  $T$ . We inductively assume these can be moved to  $c_1^{T^-}$  at bounded cost. From there, we need to move them to  $c_1^T$  at bounded cost. This can be done by showing that (1)  $|C_1^{T^-}|$  is a bounded factor away from the natural weight of  $c_1^{T^-}$  (Lemma 8), and (2)  $c_1^T$  is “close” to  $p_1^T$  (Lemma 8). Together these imply that we can move the points in  $C_1^{T^-}$  along the arc from  $c_1^{T^-}$  to  $p_1^T$  at bounded cost.

Next we show that the points given label 1 *during* phase  $T$ , call them  $C_1$ , can also be moved to  $c_1^T$  at bounded cost. This is where we use the set of offline optimal centers  $y_1^T, \dots, y_k^T$  computed during the Estimated Centers Subroutine. Importantly, since during a phase every point is attached to at least one pivot (otherwise we execute an Add Operation

and leave the phase), each offline center  $y_i^T$  is attached to a pivot. We partition the points in  $C_1$  based on which center  $y_i^T$  they are assigned to in the *offline* optimal solution. The set of points in  $C_1$  that are assigned to centers attached to the pivot for label 1,  $p_1^T$ , is called  $S_{near,1}$ . In Figure 5, these are points assigned to  $y_1^T$  and  $y_2^T$ . One can show, using that during a phase no Exchange Operation occurs, that these can be moved to  $c_1^T$  at bounded cost. The set of points that are assigned to centers that are attached to a pivot for a different label, say label 2, is called  $S_{far,1}$ . These points are misclassified in the sense that the online and offline algorithms classify them differently. However, we show their cost is still controlled. Specifically, the well-separated invariant implies that (1) these points can be moved to  $p_1^T$  at bounded cost, and (2) the number of them is a bounded factor away from the natural weight of  $p_1^T$  (Lemma 7). These two properties imply we can move the points in  $S_{far,1}$  to  $p_1^T$ , and then to  $c_1^T$ , at bounded cost.

■ **Figure 5** The points given label 1 (blue) before or during phase  $T$  are partitioned as in the text.

► **Lemma 7.** *Let  $T$  be a non-intermediate phase. For any  $j \in [T]$ , let  $C_j$  be the points given label  $j$  during phase  $T$ , i.e.,  $C_j = C_j^T \setminus C_j^{T-}$ . Define  $S_{ji}$  to be the set of elements in  $C_j$  assigned to  $y_i$  in the clustering of  $X(T) \setminus X(T^-)$  induced by  $P_T$ . Define  $S_{far,j} = \bigcup_{i:p(y_i) \neq p_j^T} S_{ji}$ . Then*

1.  $cost(S_{far,j}; p_j^T) \leq k \cdot (\beta_{T+1} + 2) \cdot OPT$ , and
2.  $|S_{far,j}| \leq k \cdot w^T(p_j^T)$ , where  $w^T$  denotes the natural weights at the end of phase  $T$ .

► **Lemma 8.** *Let  $T$  be a non-intermediate phase and  $j \in [T]$ . Let  $w^T(c_j^T)$  be the natural weight of  $c_j^T$  at the end of phase  $T$  and  $C_j^T$  be the set of points in cluster  $j$  by the end of phase  $T$ . Then  $|C_j^T| \leq (2k + 1) \cdot T \cdot w^T(c_j^T)$ .*

The final lemma below shows that the cost of our algorithm's solution at the end of phase  $T$  is bounded against  $OPT$ . Taking  $T$  to be the last phase gives Theorem 4.

► **Lemma 9.** *Let  $T$  be a non-intermediate phase and  $j \in [T]$ . Then  $cost(C_j^T)$  is bounded against center  $c_j^T$ , i.e.,  $\sum_{x \in C_j^T} d(x, c_j^T) \leq g(T, k) \cdot OPT$ , where*

$$g(T, k) = T \cdot g(k) \quad \text{and} \quad g(k) = \beta_1(2k^3 + 3k^2 + 5k + 1) + 2k + 4.$$

## 6 Conclusion

This paper gives the first online algorithm for **cluster-based**  $k$ -median clustering, with competitive ratio independent of  $n$  and  $\Delta$ , that does not recluster or use additional centers. We take a learning-augmented approach, assuming minimal a priori information in the form of an upper bound  $B$  on the optimal cost. Prior to this work, it was not known that any algorithm could have bounded worst-case guarantees. Interestingly, we remark that if the algorithm does not know  $B$  and reclustering is allowed, our results imply an algorithm that maintains a solution competitive against the optimal solution on the points that have arrived *so far*. Reclustering an  $O(\log(n\Delta))$  number of times, the algorithm is always  $O(1)$ -competitive when  $k$  is a constant at each point in time. This matches the number of reclusterings used in prior work for the consistent center case.

The Appendix is organized as follows. In Appendix A, we introduce some additional terminology and notation. In Appendix B, we introduce a few propositions that will be useful for proving the main lemmas. In Appendix C, we prove Lemma 5, the well-separation invariant; this is a rather involved proof, so we include both a proof sketch with the high-level ideas, and defer the full proof to the full version. Then, in Appendix D, we show how Lemma 5 swiftly implies Theorem 3. In the remaining appendices, we prove the lemmas in Section 5. The last lemma, Lemma 9, directly implies Theorem 4.

## A Terminology

Throughout this appendix, we take  $B = \text{OPT}$  for simplicity. Our results still hold as long as  $B \geq \text{OPT}$ . Below is some additional terminology used in the proofs.

- Let  $y_1^T, \dots, y_k^T$  be the optimal collection of  $k$  centers computed at the end of phase  $T$  in The Estimated Center Subroutine. Let  $P_T = \{p_1^T, \dots, p_T^T, y_1^T, \dots, y_k^T\}$  and call this set the **offline centers** for phase  $T$ . When the context is clear, we may omit the superscript  $T$  in  $y_i^T$ .
- The **attachment digraph**  $D(T)$  is a bipartite digraph with vertex set  $P_T$ , plus  $\{c_j^{T-} \mid j \leq T-1\}$  if  $T > 1$ , partitioned as  $(\{p_1^T, \dots, p_T^T\}, \{y_1, \dots, y_k, c_1^{T-}, \dots, c_{T-1}^{T-}\})$ . There is a directed arc  $(y_i, p(y_i))$  if  $w^T(y_i) \leq w^T(p(y_i))$  and a directed arc  $(y_i, p(y_i))$  otherwise. If  $c_j^{T-}$  and  $p_j^T$  are  $\beta_{T+1}$ -attached w.r.t.  $w^T$ , add the arc  $(c_j^{T-}, p_j^T)$  if  $w^T(c_j^{T-}) \leq w^T(p_j^T)$  and the arc  $(p_j^T, c_j^{T-})$  otherwise.  $\delta^+(p_j^T)$  and  $\delta^-(p_j^T)$  denote the out- and in-degree of  $p_j^T$ . See Figure 6.

■ **Figure 6** The attachment digraph  $D(T)$ . Arrows represent attached pairs, and arrows point from smaller to larger natural weights. So we may move a certain number of points near the head, to the tail at bounded cost.

## B Helper Propositions

In this section, we present a few short propositions that will be useful in the remaining proofs. All excluded proofs are deferred to the full version.

The following fact justifies that the offline optimal centers  $y_1^T, \dots, y_k^T$  have cost at most  $2\text{OPT}$  on the points that arrive during phase  $T$ . This is used at various points in the analysis.

► **Fact 10** (Fact 2.1 in [19]). *Let  $N$  be a set of points, with  $S \subseteq N$ . Let  $k$  be an integer with  $0 \leq k \leq n$ . Let  $K \subseteq S$  be the  $k$ -element subset of  $S$  minimizing  $\sum_{x \in S} d(x, K)$  where  $d(\cdot, \cdot)$  is the distance function on  $N$ , and  $d(x, K)$  denotes  $\min_{m \in K} d(x, m)$ . Then if  $K'$  is a  $k$ -element subset of  $N$ ,  $\sum_{x \in S} d(x, K) \leq 2 \sum_{x \in S} d(x, K')$ .*

The following proposition is a weighted version of the triangle inequality.

► **Proposition 11.** *Let  $x, y, p$  be three points in some set  $S$ , and let  $w : S \rightarrow \mathbb{Z}_+$  be a weight function on  $S$ . Assume that  $\beta, \beta_x, \beta_y, B > 0$ . Suppose that  $w(x) \leq w(p)$  and that  $x$  and  $y$  are  $\beta$ -well-separated w.r.t.  $w$ . If  $x$  and  $p$  are  $\beta_x$ -attached w.r.t.  $w$ , and  $y$  and  $p$  are  $\beta_y$ -attached w.r.t.  $w$ , then  $\beta < \beta_x + \beta_y$ .*

Next, we show that a point set cannot contain more than  $k$  pairwise  $\beta$ -well-separated points for  $\beta$  a sufficiently large constant. This allows us to bound the number of labels used.

► **Proposition 12.** *Let  $X$  be a set of points whose optimal  $k$ -median cost using  $k$  centers is  $OPT$ . Let  $\{x_1, \dots, x_l\}$  be a set of points in  $X$ , and let  $w_X$  denote their natural weights in  $X$ . Let  $\beta > 8$ . If  $\{x_1, \dots, x_l\}$  is  $\beta$ -well-separated w.r.t.  $w_X$ , then  $l \leq k$ .*

The next two propositions will be used to aid the proofs of Lemmas 5 and 6. Recall that for each non-intermediate phase  $T$ , we defined a set of offline centers  $P_T$  that has cost at most  $2OPT$  on  $X(T)$  (Appendix A and Fact 10). In order to compare the (low-cost) offline clustering induced by  $P_T$  to our online algorithm's clustering, we relate the offline set of centers  $P_T$  (which we *know* have bounded cost on  $X(T)$ ) to the pivots in phase  $T$  (which are used to make the greedy online choices) in the next proposition.

► **Proposition 13.** *Let  $P_T = \{p_1^T, \dots, p_T^T, y_1, \dots, y_k\}$  be as in Appendix A. Then  $y_i$  and  $p(y_i)$  are  $\beta_{T+1}$ -attached w.r.t. the natural weights  $w^T$  at the end of phase  $T$ .*

Each attached pair in Proposition 13 is encoded in the digraph  $D(T)$  by a directed arc. So, we can now think of this directed arc as representing the direction in which we could move a certain number of points sitting near one endpoint to the other at bounded cost.

Next we show that the estimated center for a cluster at the end of a phase is attached to the pivot for that cluster in that phase. Thus, while the pivot itself may not be a good center for the cluster, the pivot is close to the estimated center (in at least one direction, in a weighted sense).

► **Proposition 14.** *The estimated center  $c_j^T$  is  $\beta_{T+1}$ -attached to  $p_j^T$  w.r.t. the natural weights  $w^T$  at the end of phase  $T$ . Further,  $w^T(c_j^T) \geq w^T(p_j^T)$ , with equality if and only if  $c_j^T = p_j^T$ .*

## C Proof of Lemma 5

As the proof of Lemma 5 is a rather involved double induction, we provide a proof sketch which pulls out the hard cases. In the full version, we give the full proof.

**Proof sketch of Lemma 5.** The proof is by induction. However, we need to couple the induction with a statement about the relative position of the estimated center for a cluster (which stays fixed between intermediate phases) to that cluster's pivot, which may change often as we consecutively reset the pivots between intermediate phases. Roughly, we prove below that if the estimated center for cluster  $j$  has not separated entirely from the present set of pivots, then it must be close (in a weighted sense) to the present pivot for label  $j$ .

▷ **Claim 1.** Let  $w_{i-1}$ ,  $w_i$ , and  $w_t$  be as Section 3.2. For each  $j \in [T]$  and  $t \in [T, T^+]$  such that  $p_1^t, \dots, p_t^t$  are defined,<sup>5</sup>

$$p_1^t, \dots, p_t^t \text{ are } \beta_t\text{-well-separated w.r.t. } w_t. \quad (\diamond)$$

Moreover, at least one of the following properties holds:

- (a)  $c_j^T$  is  $\beta_{t+1}$ -well-separated from  $p_1^t, \dots, p_t^t$  w.r.t.  $w_i$ .
- (b)  $c_j^T$  is  $\beta_{t+1}$ -attached to  $p_j^t$  w.r.t.  $w_t$ .
- (c)  $c_j^T$  is  $f(t, T)$ -attached to  $p_j^t$  w.r.t.  $w_t$  and  $w_t(c_j^T) < w_t(p_j^t)$ , where  $f(t, T) = \beta_T \cdot (t - T)$ .

<sup>5</sup> Recall in Case 4 of the Add Operation and Case 5 of the Exchange Operation, we go directly from  $t$  to  $t + 2$  pivots, skipping phase  $t + 1$ .

■ **Figure 7** Cases (i) –(iii) in the proof sketch of Lemma 5. Dashed lines indicate well-separation and solid lines indicate attachment, labelled with the appropriate parameters. Arrows go from smaller to larger natural weights.

For the proof sketch we focus on Case 4 of the Add Operation, which will give a flavor of the arguments. This is a concerning case a priori; for, if we were to add  $x_\alpha$  to the set of pivots as in Cases 2 and 3, it is ambiguous as to whether  $x_\alpha$  should be associated with label  $f$  or  $g$ , as both  $c_f^T$  and  $c_g^T$  are close to  $x_\alpha$ . We maneuver around the issue by making  $c_f^T$  and  $c_g^T$  new pivots and excluding  $x_\alpha$ . However, it is not immediately clear that such a step will preserve the desired invariants. To give intuition, we suppress the separation parameters and the precise weights used, though emphasize both are brittle (e.g., the arguments rely heavily on  $\beta_t$  decreasing with  $t$ ). The directions of attachment between points (arrows in Figure 7) are also crucial. We will also see why we need to couple the induction with (a) –(c).

To prove the inductive step for  $(\diamond)$  when Case 4 of the Add Operation is performed, we need to show (i)  $c_f^T$  and  $c_g^T$  are well-separated, (ii), WLOG,  $c_f^T$  is well-separated from  $p_f^t$ , and (iii), WLOG,  $c_f^T$  is well-separated from  $p_l^t$ ,  $l \neq f$ . See Figure 7. When we say “close” or “far” below, we always mean in a weighted sense. For (i), because  $p_f^T$  is close to  $c_f^T$  (Proposition 14) and likewise for  $p_g^T, c_g^T$ , then  $c_f^T$  and  $c_g^T$  cannot be close, since this would violate that  $p_f^T$  and  $p_g^T$  are (inductively) far. To prove (ii), note  $x_\alpha$  is far from  $p_f^t$  by assumption of the Add Operation, and  $c_f^T$  is close to  $x_\alpha$  by assumption of Case 4, so  $p_f^t$  and  $c_f^T$  must be far. Finally for (iii), one can (inductively) deduce that (b) must hold when  $j = f$ , so  $c_f^T$  and  $p_f^t$  are close; but, since  $p_f^t$  and  $p_l^t$  are (inductively) far,  $c_f^T$  and  $p_l^t$  must be far.

Proving the inductive step for (a) –(c) involves detailed casework. The Add and Exchange Operations are engineered so that, loosely speaking, an estimated center is either attached to the corresponding present pivot, or else breaks off to form its own pivot. A main subtlety is the direction and strength of attachment, e.g., property (c). Another is the sequence of operations, specifically, the Add Operation taking precedence over the Exchange Operation. ◀

## D Proof of Theorem 3

**Proof of Theorem 3.** The number of labels used by the algorithm is the number of pivots in the last phase. By Lemma 5, we maintain the invariant that pivots  $p_1^t, \dots, p_k^t$  are  $\beta_t$ -well-separated w.r.t. the natural weights at every time step in phase  $t$ . Suppose to the contrary that the final number of pivots is strictly more than  $k$ . Then at some point there are  $t = k + 1$  or  $t = k + 2$  pivots<sup>6</sup> that are  $\beta_t$ -well-separated w.r.t. the natural weights throughout phase  $t$ . But  $\beta_{k+2} = 8$ , and it is impossible for  $k + 2$  points to be 8-well-separated, by Proposition 12. We conclude the final number of pivots is at most  $k$ . ◀

<sup>6</sup> The algorithm may skip a phase, hence we consider both cases.

## E Proof of Lemma 7

**Proof of Lemma 7.** WLOG, let  $j = T$ . For  $c \in P_T$ , let  $m(c)$  be the number of points assigned to  $c$  in the clustering of  $X(T) \setminus X(T^-)$  induced by the centers  $P_T$ , i.e., in this clustering every point is assigned to the *nearest* point in  $P_T$ . For shorthand, let  $w$  denote the natural weights  $w^T$  of points at the end of phase  $T$ .

► **Observation 2.** For  $c \in P_T$ ,  $w(c) \geq m(c)$ .

This follows from the definition of  $w(c)$  and the fact that there are  $m(c)$  points whose movement cost to  $c$  is at most  $2\text{OPT}$ , by construction of  $P_T$ .

► **Observation 3.** If  $(p(y_i), y_i)$  is a directed edge in  $D(T)$ , then  $w(p(y_i)) \cdot d(p(y_i), y_i) < \beta_{T+1} \cdot \text{OPT}$ . Likewise, if  $(y_i, p(y_i))$  is a directed edge in  $D(T)$ , then  $w(y_i) \cdot d(p(y_i), y_i) < \beta_{T+1} \cdot \text{OPT}$ .

This follows from the definition of  $D(T)$  and Proposition 13.

Call the points in  $S_{far,T}$  far points. In the claims below, we show that the far points can be moved to  $p_T^T$  at bounded cost (Claims 1 and 2), and that there are not too many far points relative to the weight of  $p_T^T$  (Claim 3). In turn, we will be able to *charge* the cost of the far points to  $p_T^T$ .

▷ **Claim 1.** Let  $p(y_i) \neq p_T^T$ . Suppose  $w(y_i) > w(p(y_i))$ . Then  $\text{cost}(S_{T_i}; p_T^T) \leq (\beta_{T+1} + 2)\text{OPT}$ .

Proof. WLOG, let  $p(y_i) = p_1^T$ . We consider two cases.

► **Case 1.**  $|S_{T_i}| \geq w(p_1^T)$ . We will show this case cannot happen.

We know that  $w(y_i) \geq m(y_i) \geq |S_{T_i}| \geq w(p_1^T)$ , and by Observation 3, that  $w(p_1^T) \cdot d(p_1^T, y_i) < \beta_{T+1} \cdot \text{OPT}$ . By Proposition 11, this implies  $w(p_1^T) \cdot d(y_i, p_1^T) \geq 2\beta_{T+1} \cdot \text{OPT}$ .

Since  $|S_{T_i}| \geq w(p_1^T)$ , there exists  $S'_{T_i} \subseteq S_{T_i}$  such that  $|S'_{T_i}| = w(p_1^T)$ . In turn,  $\text{cost}(S'_{T_i}; p_1^T) \leq \text{cost}(S'_{T_i}; y_i) + w(p_1^T) \cdot d(y_i, p_1^T) < (\beta_{T+1} + 2) \cdot \text{OPT}$ , since  $P_T$  is a clustering with cost at most  $2\text{OPT}$ . On the other hand,

$$\text{cost}(S'_{T_i}; p_1^T) \geq \sum_{p \in S'_{T_i}} d(y_i, p_1^T) - \sum_{p \in S'_{T_i}} d(p, y_i) = w(p_1^T) \cdot d(y_i, p_1^T) - \sum_{p \in S'_{T_i}} d(p, y_i) \geq (2\beta_{T+1} - 2)\text{OPT}.$$

Since  $\beta_{T+1} \geq 4$ ,  $\beta_{T+1} + 2 \leq 2\beta_{T+1} - 2$ , so  $\text{cost}(S'_{T_i}; p_1^T) < \text{cost}(S'_{T_i}; p_1^T)$ , which violates that  $T = \arg \min_{j \in [T]} d(p, p_j^T)$  for all  $p \in S'_{T_i} \subseteq C_T$ .

► **Case 2.**  $|S_{T_i}| \leq w_t(p_1^T)$ .

In this case, we know that since  $w(p_1^T) \cdot d(y_i, p_1^T) < \beta_{T+1} \cdot \text{OPT}$ , we also have  $|S_{T_i}| \cdot d(y_i, p_1^T) < \beta_{T+1} \cdot \text{OPT}$ . By the triangle inequality,

$$\text{cost}(S_{T_i}; p_1^T) \leq \text{cost}(S_{T_i}; y_i) + |S_{T_i}| \cdot d(y_i, p_1^T) \leq 2\text{OPT} + \beta_{T+1} \cdot \text{OPT}.$$

Since  $\text{cost}(S_{T_i}; p_T^T) \leq \text{cost}(S_{T_i}; p_1^T)$  by the greedy procedure, this proves Claim 1. ◁

▷ **Claim 2.** Let  $p(y_i) \neq p_T^T$ . Suppose that  $w(y_i) \leq w(p(y_i))$ . Then  $\text{cost}(S_{T_i}; p_T^T) \leq (\beta_{T+1} + 1)\text{OPT}$ .

Proof. WLOG, let  $p(y_i) = p_1^T$ . By Observation 3,  $w(y_i) \cdot d(y_i, p_1^T) < \beta_{T+1} \cdot \text{OPT}$ . Further,  $|S_{T_i}| \leq m(y_i) \leq w(y_i)$ , so  $|S_{T_i}| \cdot d(y_i, p_1^T) < \beta_{T+1} \cdot \text{OPT}$ . So:

$$\text{cost}(S_{T_i}; p_T^T) \leq \text{cost}(S_{T_i}; p_1^T) \leq \text{cost}(S_{T_i}; y_i) + |S_{T_i}| \cdot d(y_i, p_1^T) \leq 2\text{OPT} + \beta_{T+1} \cdot \text{OPT}. \triangleleft$$

▷ **Claim 3.** Let  $p(y_i) \neq p_T^T$ . Then  $|S_{T_i}| \leq w(p_T^T)$ .

Proof. As before, assume WLOG that  $p(y_i) = p_1^T$ .

► **Case 1.**  $w(y_i) > w(p_1^T)$ .

We know from the proof of Claim 1, Case 1 that this implies  $|S_{T_i}| < w(p_1^T)$ . We have

$$\begin{aligned} |S_{T_i}| \cdot d(p_T^T, y_i) &= \sum_{p \in S_{T_i}} d(y_i, p_T^T) \leq \sum_{p \in S_{T_i}} d(p, p_T^T) + \sum_{p \in S_{T_i}} d(p, y_i) \\ &\leq (\beta_{T+1} + 2)\text{OPT} + 2\text{OPT} && \text{(Claim 1)} \\ &\leq 2\beta_{T+1} \cdot \text{OPT} \leq w(p_T^T) \cdot d(p_T^T, y_i) \end{aligned}$$

where in the last line we have applied Proposition 11, using that  $w(y_i) > w(p_1^T)$ , Observation 3, and  $p_1^T$  and  $p_T^T$  are  $\beta_T$ -well-separated w.r.t.  $w$ . Finally, dividing both ends of the chain of inequalities by  $d(p_T^T, y_i)$  gives  $|S_{T_i}| \leq w(p_T^T)$ , as desired.

► **Case 2.**  $w(y_i) \leq w(p_1^T)$ .

Consider when  $w(p_T^T) \geq w(y_i)$ . Then  $w(p_T^T) \geq w(y_i) \geq m(y_i) \geq |S_{T_i}|$ , so the claim follows.

So the last case to consider is when  $w(p_T^T) < w(y_i)$ . It suffices to show that  $w(p_T^T) \cdot d(p_T^T, y_i) \geq 2\beta_{T+1} \cdot \text{OPT}$ ; then, we can just apply the argument in Case 1. Suppose to the contrary that  $w(p_T^T) \cdot d(p_T^T, y_i) < 2\beta_{T+1} \cdot \text{OPT}$ . Then

$$\begin{aligned} \beta_T \cdot \text{OPT} &\leq w(p_T^T) \cdot d(p_T^T, p_1^T) \leq w(p_T^T) \cdot d(p_T^T, y_i) + w(p_T^T) \cdot d(y_i, p_1^T) \\ &\leq 2\beta_{T+1} \cdot \text{OPT} + w(p_T^T) \cdot d(y_i, p_1^T) \\ &< 2\beta_{T+1} \cdot \text{OPT} + w(y_i) \cdot d(y_i, p_1^T) \\ &< 2\beta_{T+1} \cdot \text{OPT} + \beta_{T+1} \cdot \text{OPT} = \beta_T \cdot \text{OPT} \end{aligned}$$

where the second-to-last line follows from Observation 3. The left-hand and right-hand sides give a contradiction, concluding the proof of the case and the claim. ◁

▷ **Claim 4.**  $\text{cost}(S_{far,T}; p_T^T) \leq k \cdot (\beta_{T+1} + 2)\text{OPT}$  and  $|S_{far,T}| \leq k \cdot w(p_T^T)$ .

Proof. By Claims 1 and 2,

$$\text{cost}(S_{far,T}; p_T^T) = \sum_{i:p(y_i) \neq p_T^T} \text{cost}(S_{T_i}; p_T^T) \leq k \cdot (\beta_{T+1} + 2)\text{OPT}$$

By Claim 3,

$$|S_{far,T}| = \sum_{i:p(y_i) \neq p_T^T} |S_{T_i}| \leq k \cdot w(p_T^T). \quad \triangleleft$$

This concludes the proof of the claim, thus also of the lemma. ◀

## F Proof of Lemma 8

**Proof of Lemma 8.** As in Lemma 7, let  $C_j = C_j^T \setminus C_j^{T^-}$  and let  $S_{j_i}$  be the set of elements in  $C_j$  assigned to  $y_i$  in the clustering of  $X(T) \setminus X(T^-)$  induced by  $P_T$ . Let  $S_{far,j} = \bigcup_{i:p(y_i) \neq p_j^T} S_{j_i}$ ,  $S_{near,j} = \bigcup_{i:p(y_i) = p_j^T} S_{j_i}$ , and  $S_j$  be the elements in  $C_j$  that are assigned to  $p_j^T$  in the clustering of  $X(T) \setminus X(T^-)$  induced by  $P_T$ .

## 20:20 Online $k$ -Median with Consistent Clusters

The proof is by induction. We have that

$$|C_j^T| = |C_j^{T-}| + |C_j| = |C_j^{T-}| + |S_{far,j}| + |S_{near,j}| + |S_j| \quad (1)$$

(Note we use that there are no points in  $C_j$  that are assigned to  $p_{j'}^T$ ,  $j' \neq j$ , in the offline clustering induced by  $P_T$ , due to the greedy labelling rule. This is true as long as in the offline clustering induced by  $P_T$  we break ties consistent with how the online algorithm breaks ties.)

First, we bound the last three terms. Let  $w^t$  denote the natural weights at the end of phase  $t$ .

$$|S_{far,j}| \leq k \cdot w^T(p_j^T) \leq k \cdot w^T(c_j^T) \quad (2)$$

where the first inequality follows from Lemma 7 and the second inequality follows from the definition (‡) of estimated center. Next,

$$|S_{near,j}| = \sum_{i:p(y_i)=p_j^T} |S_{ji}| \leq \sum_{i:p(y_i)=p_j^T} w^T(y_i) \leq k \cdot w^T(c_j^T) \quad (3)$$

where the second inequality follows from the definition of  $w^T$ . The third inequality follows from the definitions of attachment digraph and estimated center: If  $y_i \in \delta^-(p_j^T)$ , then  $w^T(y_i) \leq w^T(p_j^T)$  by construction of the attachment digraph  $D(T)$ . Otherwise,  $y_i \in \delta^+(p_j^T)$ , so by (‡),  $w^T(c_j^T) \geq w^T(y_i)$ . Finally,

$$|S_j| \leq w^T(p_j^T) \leq w^T(c_j^T) \quad (4)$$

where the first inequality is by the definition of  $w^T$  and the second inequality from (‡).

For simplicity, let  $h(t, k) = (2k + 1)t$ . Now we need to bound  $|C_j^{T-}|$  in terms of  $w^T(c_j^T)$ . If  $j \notin [T^-]$ , then  $|C_j^{T-}| = 0$ . So assume  $j \in [T^-]$ . Inductively, we have that

$$|C_j^{T-}| \leq h(T^-, k) \cdot w^{T-}(c_j^{T-}).$$

We will prove that

$$|C_j^{T-}| \leq h(T^-, k) \cdot w^T(c_j^T). \quad (5)$$

There are two cases to consider.

► **Case 1.** (a) holds in Lemma 6.

$$|C_j^{T-}| \leq h(T^-, k) \cdot w^{T-}(c_j^{T-}) \leq h(T^-, k) \cdot w^T(p_j^T) \leq h(T^-, k) \cdot w^T(c_j^T).$$

► **Case 2.** (b) holds in Lemma 6.

This means that  $c_j^{T-}$  is  $\beta_{T+1}$ -attached to  $p_j^T$  w.r.t.  $w^T$ . If  $w^T(c_j^{T-}) \leq w^T(p_j^T)$ , then  $w^T(c_j^{T-}) \leq w^T(c_j^T)$ . Otherwise,  $w^T(c_j^{T-}) > w^T(p_j^T)$ , so  $c_j^{T-} \in \delta^+(p_j^T)$ . By (‡),  $w^T(c_j^{T-}) \leq w^T(c_j^T)$ . In both cases we have  $w^T(c_j^{T-}) \leq w^T(c_j^T)$ , so building from the inductive assumption,

$$|C_j^{T-}| \leq h(T^-, k) \cdot w^{T-}(c_j^{T-}) \leq h(T^-, k) \cdot w^T(c_j^{T-}) \leq h(T^-, k) \cdot w^T(c_j^T)$$

which concludes the case. Putting equations (1), (2), (3), (4), (5) together gives

$$|C_j^T| \leq (h(T^-, k) + 2k + 1) \cdot w^T(c_j^T) \leq h(T, k) \cdot w^T(c_j^T) = (2k + 1) \cdot T \cdot w^T(c_j^T)$$

as desired. ◀

## G Proof of Lemma 9

**Proof of Lemma 9.** The proof is by induction. Let  $C_j$ ,  $S_{ji}$ , and  $S_{far,j}$  be as in Lemma 7. Define  $S_{near,j} = \bigcup_{i:p(y_i)=p_j^T} S_{ji}$  and  $S_j$  to be the elements in  $C_j$  that are assigned to  $p_j^T$  in the clustering of  $X(T) \setminus X(T^-)$  induced by  $P_T$ . Let  $w^t$  denote the natural weights at the end of phase  $t$ . First we need the following key claim.

▷ **Claim 1.** For any  $x, y \in \delta^+(p_j^T) \cup \delta^-(p_j^T) \cup \{p_j^T\}$ ,  $x$  and  $y$  are  $2\beta_{T+1}$ -attached w.r.t.  $w^T$ .

*Proof of Claim 1.* If  $x$  or  $y$  is  $p_j^T$ , then the claim automatically holds by Proposition 13. There are two other cases. The first case is, WLOG,  $x \in \delta^-(p_j^T)$ . Regardless of whether  $y$  is in  $\delta^-(p_j^T)$  or  $\delta^+(p_j^T)$ , the claim holds by Propositions 13 and 11. The second case is that  $x, y \in \delta^+(p_j^T)$ . We prove the stronger statement that  $x$  and  $y$  are  $\beta_{T+1}$ -attached w.r.t.  $w^T$ . Suppose to the contrary that  $x$  and  $y$  are  $\beta_{T+1}$ -well-separated. We claim that this implies

$$\{p_1^T, \dots, p_T^T\} \cup \{x, y\} \setminus \{p_j^T\} \quad (6)$$

is  $\beta_{T+1}$ -well-separated w.r.t.  $w^T$ ; this would give a contradiction, since if an Exchange Operation were available, it would have been executed. Now suppose that (6) does not hold. Then WLOG  $p_{j'}^T$  and  $x$  are  $\beta_{T+1}$ -attached w.r.t.  $w^T$ , for some  $j' \neq j$ . Since  $x \in \delta^+(p_j^T)$  and since  $x$  and  $p_{j'}^T$  are  $\beta_{T+1}$ -attached w.r.t.  $w^T$ , by Proposition 11,  $p_j^T$  and  $p_{j'}^T$  are  $2\beta_{T+1}$ -attached w.r.t.  $w^T$ . This contradicts that  $p_j^T$  and  $p_{j'}^T$  are  $\beta_T$ -well-separated w.r.t.  $w^T$ , since  $2\beta_{T+1} < \beta_T$ . This concludes the proof of the case and the claim. ◁

To bound the cost contribution of  $C_j^{T-}$ , we case on which statement holds in Lemma 6.

▶ **Case 1.**  $c_j^{T-}$  is  $\beta_{T+1}$ -attached to  $p_j^T$  w.r.t.  $w^T$  (i.e., (b) holds in Lemma 6).

Since in Case 1,  $c_j^{T-}$  is  $\beta_{T+1}$ -attached to  $p_j^T$  w.r.t.  $w^T$ ,  $c_j^{T-} \in \delta^+(p_j^T) \cup \delta^-(p_j^T)$ . Also,  $c_j^T$  by definition is in  $\delta^+(p_j^T) \cup \{p_j^T\}$ . So by Claim 1,  $c_j^{T-}$  is  $2\beta_{T+1}$ -attached to  $c_j^T$  w.r.t.  $w^T$ . Using this, we bound  $\text{cost}(C_j^{T-}; c_j^T)$ :

$$\begin{aligned} \text{cost}(C_j^{T-}; c_j^T) &\leq \text{cost}(C_j^{T-}; c_j^{T-}) + |C_j^{T-}| \cdot d(c_j^{T-}, c_j^T) \\ &\leq g(T^-, k) \cdot \text{OPT} + |C_j^{T-}| \cdot d(c_j^{T-}, c_j^T) \\ &\leq g(T^-, k) \cdot \text{OPT} + (2k+1) \cdot T^- \cdot w^{T-}(c_j^{T-}) \cdot d(c_j^{T-}, c_j^T) \\ &\leq g(T^-, k) \cdot \text{OPT} + (2k+1) \cdot T^- \cdot w^T(c_j^{T-}) \cdot d(c_j^{T-}, c_j^T) \\ &\leq g(T^-, k) \cdot \text{OPT} + (2k+1) \cdot T^- \cdot 2\beta_{T+1} \cdot \text{OPT} \end{aligned} \quad (7)$$

where the third inequality is due to Lemma 8.

▶ **Case 2.** (b) does not hold in Lemma 6, so (a) holds, i.e.,  $w^{T-}(c_j^{T-}) \leq w^T(p_j^T)$  and  $w^{T-}(c_j^{T-}) \cdot d(c_j^{T-}, p_j^T) \leq \beta_{T-}(T - T^-) \cdot \text{OPT}$ .

We bound  $\text{cost}(C_j^{T-}; c_j^T)$ :

$$\begin{aligned} \text{cost}(C_j^{T-}; c_j^T) &\leq \text{cost}(C_j^{T-}; c_j^{T-}) + |C_j^{T-}| \cdot d(c_j^{T-}, c_j^T) \\ &\leq g(T^-, k) \cdot \text{OPT} + |C_j^{T-}| \cdot d(c_j^{T-}, p_j^T) + |C_j^{T-}| \cdot d(p_j^T, c_j^T) \end{aligned} \quad (8)$$

and now we use the assumptions of the case to continue bounding from (8):

$$\begin{aligned} |C_j^{T-}| \cdot d(c_j^{T-}, p_j^T) &\leq (2k+1) \cdot T^- \cdot w^{T-}(c_j^{T-}) \cdot d(c_j^{T-}, p_j^T) \\ &\leq (2k+1) \cdot T^- \cdot \beta_{T-}(T - T^-) \cdot \text{OPT} \end{aligned} \quad (9)$$

## 20:22 Online $k$ -Median with Consistent Clusters

where the first inequality is due to Lemma 8. Next,

$$\begin{aligned} |C_j^{T^-}| \cdot d(p_j^T, c_j^T) &\leq (2k+1)T^- \cdot w^{T^-}(c_j^{T^-}) \cdot d(p_j^T, c_j^T) \leq (2k+1)T^- \cdot w^T(p_j^T) \cdot d(p_j^T, c_j^T) \\ &\leq (2k+1)T^- \cdot \beta_{T+1} \cdot \text{OPT} \end{aligned} \quad (10)$$

where the first inequality is due to Lemma 8 and the last inequality is due to Proposition 14. So combining (8), (9), (10) gives

$$\text{cost}(C_j^{T^-}; c_j^T) \leq g(T^-, k) \cdot \text{OPT} + (2k+1) \cdot T^- \cdot (\beta_{T^-}(T - T^-) + \beta_{T+1}) \cdot \text{OPT}. \quad (11)$$

Now we have bounds (7) and (11) for  $\text{cost}(C_j^{T^-}; c_j^T)$ . Recall that  $C_j^T = C_j^{T^-} \cup S_{far,j} \cup S_{near,j} \cup S_j$ . The following bounds will hold regardless of whether we are in Case 1 or 2. We have

$$\text{cost}(S_j; c_j^T) \leq \text{cost}(S_j; p_j^T) + |S_j| \cdot d(p_j^T, c_j^T) \leq 2\text{OPT} + w^T(p_j^T) \cdot d(p_j^T, c_j^T) \leq (2 + \beta_{T+1})\text{OPT} \quad (12)$$

$$\begin{aligned} \text{cost}(S_{near,j}; c_j^T) &= \sum_{i:p(y_i)=p_j^T} \text{cost}(S_{ji}; c_j^T) \leq \sum_{i:p(y_i)=p_j^T} \sum_{p \in S_{ji}} d(p, c_j^T) \\ &\leq 2\text{OPT} + \sum_{i:p(y_i)=p_j^T} w^T(y_i) \cdot d(y_i, c_j^T) \leq (2k\beta_{T+1} + 2)\text{OPT} \end{aligned} \quad (13)$$

where we have used Claim 1 and that  $|S_{ji}| \leq w^T(y_i)$ . Finally, by Lemma 7,

$$\text{cost}(S_{far,j}; c_j^T) \leq \text{cost}(S_{far,j}; p_j^T) + |S_{far,j}| \cdot d(p_j^T, c_j^T) \leq k(2\beta_{T+1} + 2)\text{OPT} \quad (14)$$

Combining (12), (13), (14) with (7) or (11) gives the sought bound:

$$\text{cost}(C_j^T; c_j^T) \leq [g(T^-, k) + g(k)]\text{OPT} \leq g(T, k) \cdot \text{OPT}. \quad \blacktriangleleft$$

# The Telephone $k$ -Multicast Problem

## Abstract

We consider minimum time multicasting problems in directed and undirected graphs: given a root node and a subset of  $t$  terminal nodes, multicasting seeks to find the minimum number of rounds within which all terminals can be informed with a message originating at the root. In each round, the telephone model we study allows the information to move via a matching from the informed nodes to the uninformed nodes.

Since minimum time multicasting in digraphs is poorly understood compared to the undirected variant, we study an intermediate problem in undirected graphs that specifies a target  $k < t$ , and requires the only  $k$  of the terminals be informed in the minimum number of rounds. For this problem, we improve implications of prior results and obtain an  $\tilde{O}(t^{1/3})$  multiplicative approximation. For the directed version, we obtain an *additive*  $\tilde{O}(k^{1/2})$  approximation algorithm (with a poly-logarithmic multiplicative factor). Our algorithms are based on reductions to the related problems of finding  $k$ -trees of minimum poise (sum of maximum degree and diameter) and applying a combination of greedy network decomposition techniques and set covering under partition matroid constraints.

## 1 Introduction

We study an information spreading problem that captures applications in distributed computing [16] and keeping distributed copies of databases synchronized [2]. A given graph models a synchronous network of processors that exchange information in rounds. There are several models describing how information may be exchanged between processors in the graph. In this work, we focus on the classic *Telephone Model* [8]: during a round, each vertex that knows the message can send the message to at most one of its neighbors.

In the **Minimum Time Telephone Multicast** (MTM) problem, we are given a network, modeled by a directed or undirected graph  $G(V, E)$ , a root vertex  $r$  that knows a message, and a set  $S$  of terminals. The message must be transmitted from  $r$  to  $S$  under the telephone model. In every round, there is a set of vertices  $K \subseteq V$  that know the message (initially  $K = \{r\}$ ), and the communication in a given round is described by a matching  $\{(k_1, v_1), \dots, (k_\ell, v_\ell)\}$  between some pairs of vertices  $k_i \in K$  and  $v_i \notin K$  for which  $k_i v_i \in E$ . In the directed setting, edge  $k_i v_i$  must be directed from  $k_i$  to  $v_i$ . Following this round, all of the matched vertices  $\{v_i\}$  are added to  $K$ . When  $S = V$  this problem is called **The Minimum Time Broadcast** (MTB) problem.

## 21:2 The Telephone $k$ -Multicast Problem

The best-known approximation ratio for the MTM problem on an undirected graph is  $O(\log t / \log \log t)$  [5], where  $t = |S|$ . In [4], it is shown that unless  $P = NP$ , the MTB problem admits no  $3 - \epsilon$  approximation for any constant  $\epsilon$ . For directed graphs, the Minimum Time Broadcast problem admits an  $O(\log n)$  approximation [4] in an  $n$ -node graph. The same paper shows that unless  $P = Quasi(P)$  the problem admits no better than  $\Omega(\sqrt{\log n})$  approximation.

However, for the directed case the multicast problem *seems* harder to approximate. The best-known approximation ratio for this problem is an additive  $O(\sqrt{t})$  guarantee (with poly-logarithmic multiplicative factor) [3]. This leaves a wide gap between the current best approximation algorithms for undirected versus directed multicast problems. In this work, we make progress toward closing that gap by studying an intermediate problem, the **Minimum Time Telephone  $k$ -Multicast** problem ( $k$ -MTM), defined below.

**Input:** A directed or undirected graph  $G(V, E)$  with root  $r$ , a collection of terminals  $S \subseteq V$  and a number  $k \leq |S|$ .  
**Required:** Send the message originating at  $r$  to *any*  $k$  terminals of  $S$  in the telephone model in a minimum number of rounds.

In terms of approximability, the undirected  $k$ -MTM problem lies between the undirected and directed MTM problems. Specifically, in [11] it is shown<sup>1</sup> that a  $\rho$ -approximation for directed MTM implies an  $O(\text{polylog } k)$ -approximation for undirected  $k$ -MTM, while it is immediate that any approximation for undirected  $k$ -MTM gives the same factor approximation for undirected MTM.

On the other hand, the directed version of the  $k$ -MTM problem generalizes all of the aforementioned problems.

**Applications.** Broadcast and multicast problems find numerous applications in distributed settings. For example, in the Network Aggregation problem, each user sends its data to a chosen central vertex  $r$ . This is equivalent to broadcasting in the local model for distributed computation (see [9]). Broadcasting is also crucial in Sensor Networks [13]. Another application is ensuring that the maximum information delay in vector clocks problems is minimized [12, 17].

One application of multicasting is to keep information across copies of replicated databases consistent, by broadcasting from the changed copy to the others [7, 14, 15]. If we are given a large set of  $t$  terminals of which we only want to keep replicated copies in some  $k$  of them, finding the best  $k$  to minimize the maximum synchronization time among these terminals corresponds to the  $k$ -MTM problem.

**Minimum Poise Trees.** Any telephone multicast schedule defines a tree rooted at  $r$ , spanning all terminals. The parent of a vertex  $u \neq r$  is defined to be the unique vertex that sends the message to  $u$ . Let  $T^*$  be the tree defined by the optimal schedule. The height of  $T^*$  (the largest distance in  $T^*$  from the root) is denoted by  $D^*$ . The largest out-degree<sup>2</sup> in  $T^*$  is denoted by  $B^*$ . The *poise* of  $T^*$  is defined as  $p^* = B^* + D^*$  [18]. Denote by OPT the number of rounds used by the optimal schedule. Since at every round, each informed vertex can send

---

<sup>1</sup> [11] deals with the degree-bounded versions of these problems, but their proof works as well for poise problems. See below for the connection between poise and  $k$ -MTM.

<sup>2</sup> For simplicity, we say degree instead of out-degree for the rest of the paper when discussing directed graphs.

the message to at most one neighbor,  $\text{OPT} \geq B^*$  and  $\text{OPT} \geq D^*$ . Hence, in general we have  $\text{OPT} \geq p^*/2$ . A partial converse is shown in [18]. A  $\rho$  approximation for the **Minimum Poise Steiner Tree** implies an  $O(\log t) \cdot \rho / \log \log t$  approximation for the MTM problem.

Following [18], approximating the  $k$ -MTM problem is equivalent (up to logarithmic factors in  $k$ ) to approximating the following **Minimum Poise Steiner  $k$ -Tree** problem:

**Input:** A directed or undirected graph  $G(V, E)$  with root  $r$ , a collection  $S \subseteq V$  of terminals, and a number  $k$ .  
**Required:** A  $k$ -tree rooted at  $r$ , namely a tree  $T'(V, E)$  containing paths from  $r$  to  $k$  of the terminals, with minimum poise.

In [11], they show that the approximability of minimum degree Steiner  $k$ -tree reduces to minimum degree group Steiner tree (which is a special case of minimum degree directed Steiner tree). Their reduction immediately extends to the minimum poise versions of these problems. Hence, the approximability of the undirected Minimum Poise Steiner  $k$ -Tree problem lies between the undirected Minimum Poise Steiner Tree problem and the directed Minimum Poise Steiner Tree problem (up to  $\log k$  factors). This implies the aforementioned analogous statement about the relationship between undirected  $k$ -MTM and the undirected/directed MTM problems.

We focus on approximating these poise problems.

► **Definition 1.1.** *A  $O(f(k))$ -additive approximation for the Minimum Poise Steiner  $k$ -Tree problem returns a tree  $T$  with  $k$  terminals, with maximum degree<sup>3</sup>  $\tilde{O}(B^*) + O(f(k))$  and height  $O(D^*)$ .*

## 1.1 Our results

We give an  $O(\sqrt{k})$ -additive approximation for the directed versions.

► **Theorem 1.2.** *Minimum Poise Steiner  $k$ -tree problem on directed graphs admits a polynomial time  $\tilde{O}(k^{1/2})$ -additive approximation. This implies the same approximation for the Minimum Time Telephone  $k$ -multicast problem.*

The second part of the statement follows from [18].

In [10], a multiplicative  $O(\sqrt{k})$ -approximation is given for the directed Min-Max Degree  $k$ -Tree problem, which asks to find a tree spanning  $k$  terminals while minimizing the maximum degree. Their algorithm iteratively finds trees containing  $\sqrt{k} \cdot B^*$  terminals, and uses flows to connect them to the root. Our directed result is more general than that of [10] in that it can handle both degree bounds and height bounds. Moreover, our approximation for degree is stronger, since we get an additive  $O(\sqrt{k})$  approximation. Therefore, it may be better than the approximation of [10] in the case that  $B^*$  is large. Our approximation ratio for the diameter is constant.

Our result is also more general than the  $O(\sqrt{t})$ -additive approximation for directed MTM of [3], as it handles the  $k$ -tree version of the problem, and recovers the same  $O(\sqrt{t})$ -additive approximation in the case  $k = t$  (up to logarithmic factors). In [3], the so-called *multiple set-cover* problem is used, a variant of set cover, while our result uses max coverage subject to a matroid constraint.

---

<sup>3</sup> The  $\tilde{O}$  notation hides poly-logarithmic factors in  $k$

For undirected graphs, we give an  $\tilde{O}(t^{1/3})$  approximation, which is a better ratio in the worst case if  $k$  is close to  $t$ . This represents progress toward closing the gap between the approximability of undirected and directed MTM, since in [11] it is shown that the undirected  $k$ -MTM problem lies between undirected and directed MTM in terms of approximability.

► **Theorem 1.3.** *The Minimum Poise Steiner  $k$ -tree problem on undirected graphs admits a polynomial time  $\tilde{O}(t^{1/3})$  approximation, and therefore the Minimum Time Telephone  $k$ -multicast problem admits the same approximation.*

The  $O(\sqrt{k})$  additive ratio can be as bad as  $\Omega(\sqrt{t})$  multiplicative ratio, if  $B^*$  is constant and  $k = \Omega(t)$ . Therefore, in the worst case, an  $\tilde{O}(t^{1/3})$  approximation is a better ratio. In addition, if  $B^* = o(t^{1/6})$  and  $k = \Omega(t)$ , the multiplicative ratio gives a better additive ratio.

## 1.2 Technical Overview

For the directed case, our techniques are based on [3]. However, our problem is harder since it is not clear which  $k$  terminals to choose. An important difference is that we use an approximation algorithm for maximizing set coverage (a submodular function) under matroid constraints [1]. The multiplicative approximation for the undirected case builds on this, and requires several graph decomposition techniques to be carefully combined.

For both results, we denote the maximum degree as  $B^*$  and height as  $D^*$  of an optimal minimum poise tree  $T^*$ . It can be assumed that  $D^*$  and  $B^*$  are known by trying all possibilities, as there are only polynomially many. Moreover, since  $D^*$  is known, all vertices of distance greater than  $D^*$  from the root may be removed.

**Directed Min-Poise Steiner  $k$ -Tree.** In order to get an  $O(\sqrt{k})$  additive approximation for the directed min-poise Steiner  $k$ -tree problem, we employ a greedy strategy. We iteratively find a collection of vertex-disjoint trees, each covering (i.e., containing) exactly  $\sqrt{k}$  terminals and of height at most  $D^*$ , until no more can be found. We call these *good trees*.

In the case that at least  $\sqrt{k}$  many good trees are found, an additive  $O(\sqrt{k})$ -approximation follows by taking any  $\sqrt{k}$  of the good trees along with shortest paths from the root  $r$  to the roots of each of these trees. This yields a subgraph (not necessarily a tree, since the shortest paths may not be disjoint from the good trees) with maximum out-degree at most  $2\sqrt{k}$ , and radius (maximum distance from  $r$ ) at most  $2 \cdot D^*$ . Moreover, the subgraph contains  $k$  terminals. Now the non-disjointness may be overcome by returning a shortest path tree spanning this subgraph. This gives the desired approximation.

In the other case that fewer than  $\sqrt{k}$  good trees are found, we may still connect them to the root via shortest paths. This gives a subgraph of low poise, but does not yet cover  $k$  terminals. If  $k_1 < k$  terminals are covered, we must determine how to cover  $k - k_1$  additional terminals without inducing high degree or height.

This is the main technical contribution of the directed result: we can recast the covering of  $k - k_1$  additional terminals as a set cover instance, and the desired poise guarantees can be obtained by imposing a partition matroid constraint on the sets in the instance. Then, an algorithm for approximating submodular function maximization subject to a matroid constraint [1] is applied. To the authors' knowledge, partition matroid constrained set coverage has not previously been used for multicasting problems.

**Partition Matroid Set Coverage Procedure.** Suppose we are given a partition of the graph into  $A \cup C = V$  with  $r \in A$ , such that all of  $A$  is reachable with low poise and contains  $k_1$  terminals. We want to cover at least  $k - k_1$  terminals in  $C$  with low poise, and we know that there exists a tree  $T^*$  rooted at  $r$  which does so.

Say that a node  $c \in C$  covers all the terminals in  $C$  that it can reach within distance  $D^*$ . In this way, we define a set cover instance over the ground set of terminals in  $C$  in which each set is identified by an edge  $(a, c)$  between a node  $a \in A$  and a node  $c \in C$ . The set corresponding to  $(a, c)$  contains all terminals covered by  $c$ . Defining the sets this way allows us to enforce degree constraints on the nodes in  $A$ , since the sets can be partitioned by their member in  $A$ . That is, we form a partition with the parts  $X(a) = \{(a, c) : c \in C, ac \in E\}$  for each  $a \in A$ . We now impose the constraint that at most  $B^*$  sets may be chosen from any part  $X(a)$ , reflecting the desired degree constraint. A *partition matroid* captures choosing at most a certain number of elements from each part of a partitioned set. Hence we have described a set cover instance with a partition matroid constraint and a coverage requirement of  $k - k_1$ .

The problem of selecting sets to maximize the number of terminals covered subject to the matroid constraint is a special case of submodular function maximization subject to a matroid constraint. Moreover,  $T^*$  provides a certificate that there exists a collection of sets satisfying the matroid constraint and covering at least  $k - k_1$  terminals in  $C$ . Hence, we may apply the  $(1 - \frac{1}{e})$ -approximation for this problem [1] (the simple greedy strategy giving a  $\frac{1}{2}$ -approximation [6] would also suffice here) to find a collection of sets satisfying the matroid constraint and covering at least  $(1 - \frac{1}{e}) \cdot (k - k_1)$  terminals in  $C$ .

Given the choice of sets  $(a, c)$  by the algorithm, we identify a set of edges that may be added to extend our subgraph to cover these terminals. These newly covered terminals are then removed, and the process repeated. In each round, we can cover a constant fraction of the desired number of terminals, so we need only  $O(\log k)$  rounds. Moreover, any given round induces additional degree of only  $B^*$  on nodes in  $A$ . The degree induced on nodes in  $C$  depends on the size of the parts  $X(a)$ , and this can be bounded in our applications (e.g., by  $\sqrt{k}$  in the directed setting described above, since the greedy strategy ensures that all nodes in  $c$  can reach at most  $\sqrt{k}$  terminals within distance  $D^*$ ). Finally, the distance from the root of any node added is  $O(D^*)$ , so in total the poise of the subgraph remains low. In the end, we again output a shortest path tree spanning this subgraph.

**Improvement in Undirected Graphs.** In the undirected setting, the result can be improved by taking advantage of the fact that if a good (low-poise) tree covering many terminals is found, then we need only cover *any* node in that tree in order to cover all of those terminals with low poise (as opposed to the directed case where we would have to cover the *root* of that tree). Essentially, we may contract the tree and treat the contracted node as containing many terminals.

Specifically, we will maintain a set  $R$  of nodes that we have covered so far with low poise (by contracting, we can think of this simply as the root  $r$ ). We first group the terminals in the remaining graph  $C = V \setminus R$  as before by greedily finding disjoint trees of low poise, now each containing  $t^{1/3}$  terminals, called *small trees*. Note that some terminals may not lie in any small tree. If the algorithm finds fewer than  $t^{1/3}$  small trees, then the same matroid-constrained covering procedure from above can be applied to immediately get an *additive*  $O(t^{1/3})$ -approximation.

On the other hand, if there are many small trees, we show that progress can be made by either covering or discarding a large number of terminals at once. If we are able to aggregate  $t^{1/3}$  small trees into a single tree within a distance  $D^*$ , we have covered  $t^{2/3}$  terminals and hence made sufficient progress in coverage: we can repeat this at most  $t^{1/3}$  times to finish, inducing at most  $t^{1/3}$  degree at the root to reach these trees. However, we may have the additional complexity of the optimal tree containing terminals that are not in one of

these small trees we computed in  $C$ . We handle this case by using the matroid-constrained coverage procedure to extract as many terminals as any optimal solution might cover from the small trees while staying within the degree and height bounds, and then discarding all the terminals from *all* of the unused small trees. Since the number of small trees (each with  $t^{1/3}$  terminals) is  $\Omega(t^{1/3})$ , this allows us to bound the number of such discarding iterations by  $O(t^{1/3})$ . In summary, we employ  $O(t^{1/3})$  iterations of either covering or discarding  $t^{2/3}$  terminals in the algorithm leading to the claimed  $O(t^{1/3})$  multiplicative guarantee. Over the course of these iterations, the total degree accumulated by any node will be at most  $\tilde{O}(t^{1/3}) \cdot B^*$  (Note this guarantee is now multiplicative, since a node can gain  $\tilde{O}(B^*)$  degree in each of the  $t^{1/3}$  covering iterations).

Finally, we remark that the improved guarantee in this setting is in terms of  $t$ , the total number of terminals, rather than  $k$ . This is because our algorithm relies on removing a large number of terminals from the entire set of  $t$  terminals, without necessarily covering all of them.

## 2 Preliminaries

Let  $\text{dist}(u, v)$  denote the number of edges in the shortest path from  $u$  to  $v$  in  $G$ . We denote by  $G[U]$  the graph induced by  $U$ , and by  $\text{dist}_{G[U]}(u, v)$  the distance from  $u$  to  $v$  in the graph  $G[U]$ . Recall that we denote the minimum poise tree by  $T^*$ , its maximum degree by  $B^*$ , and its height by  $D^*$ .

► **Assumption 2.1.** *Removing vertices of distance more than  $D^*$  from the root  $r$  in  $G$  does not change the optimal solution. Hence, we will assume for the rest of the paper that  $G$  only contains vertices of distance at most  $D^*$  from  $r$ .*

► **Remark 2.2.** For the rest of the paper, we assume that quantities such as  $\sqrt{k}$  are integral. Making the algorithm precise requires using  $\lceil \sqrt{k} \rceil$ . However, the changes are minimal and elementary.

For simplicity, we assume that every terminal has in-degree 1 and out-degree 0, by attaching new terminal vertices to every terminal (this only increases the poise by at most an additive constant). For undirected graphs, we assume that terminals have degree 1. Therefore, removing terminals can't turn a connected graph into a disconnected graph.

The input for the Set Cover problem is a universe  $\mathcal{U}$  and a collection  $\mathcal{S}$  of sets  $S_i \subseteq \mathcal{U}$ . We say that a set  $S_i$  covers all the elements that belong to this set. The goal is to find a sub-collection of sets  $\mathcal{S}' \subseteq \mathcal{S}$  of minimum size that covers all elements, namely,  $\bigcup_{S_i \in \mathcal{S}'} S_i = \mathcal{U}$ . The Set Coverage problem under matroid constraints has the input of Set Cover, and in addition, a matroid  $\mathcal{M}$  defined over the sets  $\mathcal{S}$ . The goal is to select an independent set  $\mathcal{I}$  in the Matroid so that  $|\bigcup_{S_i \in \mathcal{I}} S_i|$  is maximum. A partition matroid instance divides  $\mathcal{S}$  into pairwise disjoint collections of sets  $\mathcal{S}_i$ , whose union is all of  $\mathcal{S}$ . For every collection  $\mathcal{S}_i$ , there is a bound  $p_i$  on the number of sets that can be selected from  $\mathcal{S}_i$ . A collection of sets containing at most  $p_i$  sets from each  $\mathcal{S}_i$  is precisely an independent set in the partition matroid. The goal is to find an independent set in the partition matroid that covers the largest number of elements. This problem is a special case of maximizing a submodular function under matroid constraints. The greedy algorithm achieves a  $1/2$ -approximation for this problem [6], and is sufficient for our purposes. It is also known that the problem admits a polynomial time  $1 - 1/e$ -approximation [1], which may be used for improved constants. The procedure of [1] is one of the main tools in our algorithm. We called this procedure the **Matroid procedure**.

### 3 The Partition Matroid Cover Algorithm

In the next two sections, our algorithms for both the directed and undirected cases define a disjoint partition of the graph vertices into  $A \cup C = V$ . The root  $r$  always belongs to  $A$ , and we will ensure that all of  $A$  can be covered by a low poise tree rooted at  $r$ . In this section, we discuss how to cover sufficiently many terminals from  $C$  with low poise by connecting them to the root through  $A$ . We do this by defining an instance of the Set Coverage problem under a partition matroid constraint<sup>4</sup>.

► **Definition 3.1.** *Define a Set Coverage instance as follows.*

- *The items are  $S \cap C$  (the terminals in  $C$ ).*
- *The sets (also called pairs) are  $\mathcal{S} = \{(a, c) \mid a \in A, c \in C, \text{ and } ac \in E\}$  where  $(a, c)$  covers a terminal  $t \in S \cap C$  if  $\text{dist}_{G[C]}(c, t) \leq D^*$ .*

The partition matroid is defined as follows.

► **Definition 3.2.**  *$\mathcal{S}$  is partitioned into collections*

$$X(a) = \{(a, c) \mid c \in C \text{ and } ac \in E\}$$

for every  $a \in A$ . The bound on the number of sets to be chosen from  $X(a)$  is  $B^*$ .

By definition, the partition is disjoint and therefore, we have a valid partition matroid. Recall that  $r \in A$ . See Algorithm 1 for a description of the Procedure **PMCover**.

■ **Algorithm 1** **PMCover**.

---

**input** : Graph  $G(V, E)$  with terminals  $S$  and  $V$  partitioned into  $A \cup C$ , and a number  $k$ .

**output** : A collection of pairs of the form  $(a, c)$  with  $a \in A$  and  $c \in C$ .

- 1  $\mathcal{E}' \leftarrow \emptyset, S' \leftarrow S \cap C$ .
- 2 **while**  $k > 0$  **do**
- 3     Define the partition matroid Set Coverage instance from  $A, C, S'$  as above with sets  $\mathcal{S}'$  and apply Procedure **Matroid** of [1] to find an independent set of approximately maximum coverage. Let  $\mathcal{I}$  be the independent set it returns.
- 4      $\mathcal{E}' \leftarrow \mathcal{E}' \cup \mathcal{I}$ .
- 5     Decrease  $k$  by the number of terminals covered by  $\mathcal{I}$ .
- 6     Remove the terminals covered by  $\mathcal{I}$  from  $S'$ .
- 7 **return**  $\mathcal{E}'$ .

---

### Analysis

We will show that for every  $a \in A$ ,  $|X(a) \cap \mathcal{E}'| \leq O(\log k) \cdot B^*$ . This will be used to argue that if  $(a, c) \in \mathcal{E}'$ , we later may make  $a$  the parent of  $c$  in the tree we build without incurring high degree.

<sup>4</sup> Note that the parameter  $k$  represents the *remaining* number of terminals we need to cover. Given a partition  $A, C$  we will assume that all terminals in  $A$  have been spanned, and thus we need to cover  $k$  terminals in  $C$ . That is, if  $A$  has  $k_1$  terminals for some  $k_1 < k$ , we will set  $k \leftarrow k - k_1$ . Note that we are guaranteed that  $C \cap T^*$  contains at least  $k - k_1$  terminals supplying a feasible solution.

► **Definition 3.3.** Define a mapping from terminals in  $T^* \cap C$  to  $\mathcal{S}'$  as follows. For a terminal  $t$ , let  $a = a_t$  be the vertex  $a \in A$  that is an ancestor of  $t$  in  $T^*$  and among them  $\text{dist}_{T^*}(a, t)$  is minimum. This vertex is well defined since  $r \in A$  is the root of  $T^*$ . Let  $c = c_t$  be the child of  $a$  in  $T^*$  that is an ancestor of  $t$ . Define  $f(t) = (a, c)$ .

▷ **Claim 3.4.** There exists an independent set  $\mathcal{I}^*$  in the partition matroid that covers at least  $k$  terminals in  $C \cap S$ .

*Proof.* We show that every terminal in  $t \in T^* \cap C$  is covered by some set. Let  $a = a_t$  and let  $c = c_t$ . Since  $a$  has minimum distance to  $t$  from all vertices in  $A$ , the path from  $c$  to  $t$  belongs to  $G[C]$ . The number of edges in the path between  $c$  and  $t$  is at most  $D^* - 1$ . This implies that the set  $(a, c)$  covers  $t$ . Create a set  $\mathcal{I}^* = \{f(t) \mid t \in T^* \cap S \cap C\}$ . We note that  $f(t) = f(t') = (a, c)$  may hold for two different terminals, but  $\mathcal{I}^*$  includes every such pair  $(a, c)$  once (namely,  $\mathcal{I}^*$  is a set and not a multiset). For any  $a \in A$ , the number of different pairs of the form  $(a, c_1), (a, c_2), \dots$  in  $\mathcal{I}^*$  can't be more than  $B^*$ , because every such pair increases  $a$ 's degree in  $T^*$  by 1. Thus,  $\mathcal{I}^*$  is independent in the partition matroid. Since all terminals in  $T^* \cap C$  are covered,  $k$  terminals are covered. ◁

▷ **Claim 3.5.** Procedure `PMCover` returns a collection of pairs  $\mathcal{E}'$  so that for every  $a \in A$ ,  $X(a) \cap \mathcal{E}' = O(\log k) \cdot B^*$  and  $\mathcal{E}'$  covers  $k$  terminals. Thus if in some tree, vertex  $a \in A$  is made the parent of all  $c$  for which  $(a, c) \in \mathcal{E}'$ , the degree of  $a$  will be bounded by  $O(\log k) \cdot B^*$ .

*Proof.* Since Procedure `Matroid` returns an independent set in the partition matroid, at every iteration we have  $|X(a) \cap \mathcal{I}| \leq B^*$ . Claim 3.4 and the guarantee of Procedure `Matroid` by [1] imply that  $(1 - 1/e)k$  terminals are covered. Let  $k_{\text{or}} \leq k$  be the original number of terminals to be covered and  $k_{\text{new}}$  the number of terminals to be covered in a given iteration. Then in the next iteration,

$$k_{\text{new}} \leftarrow k_{\text{new}} - (1 - 1/e)k_{\text{new}} = \frac{k_{\text{new}}}{e}.$$

Therefore, after  $i$  iterations,  $k_{\text{or}}/e^i$  terminals remain to be covered. Hence, the number of iterations is  $O(\log k)$ . The claim follows. ◁

## 4 Approximating the poise for directed graphs

Our algorithm maintains a set  $A$  (initialized with the root  $r$ ) containing the terminals covered with low poise so far, and  $C = V \setminus A$ . Consider a set  $C$  and the graph  $G[C]$  induced by  $C$ .

► **Definition 4.1.** Denote by  $T(c)$  the coverage tree of  $c$  in  $G[C]$  formed by taking a shortest path from  $c$  to every terminal within distance  $D^*$ . A vertex  $c \in C$  is called  $\rho$ -good (with respect to  $C$ ) if there are at least  $\rho$  terminals in  $T(c)$ . A  $\rho$ -good tree is a tree rooted at some  $c$  (not necessarily  $T(c)$ ) with exactly  $\rho$  terminals and height at most  $D^*$ .

By assumption, the out-degree of terminals is 0. Therefore all terminals are leaves. Since we may discard non-terminal leaves, a  $\rho$ -good trees contains exactly  $\sqrt{k}$  leaf terminals.

► **Definition 4.2.** A set  $C$  of vertices, is a  $\rho$ -packing if there is no  $\rho$ -good vertex in  $C$ .

► **Definition 4.3.** Let  $\{T_i\}$  be a collection of vertex disjoint trees and let  $A$  be the set of vertices in  $\bigcup_i T_i$ . Let  $C = V - A$ . Then  $A, C$  is a  $\rho$ -additive partition if:

1. The trees  $T_i$  are  $\rho$ -good with respect to  $V$ , and are all vertex-disjoint.
2. There are at most  $\rho$  trees  $T_i$ .
3.  $C$  is a  $\rho$ -packing.

Let  $q_i$  be the root of  $T_i$ . Intuitively, since there are at most  $\rho$  trees  $T_i$ , we can add a shortest path  $P_i$  from the root  $r$  to each  $q_i$ , giving a tree rooted at  $r$  with low poise covering terminals in  $A$ . In addition, since  $C$  is a  $\rho$ -packing, at least  $k$  (meaning the number of *remaining* terminals to cover after covering those in  $A$ ) of  $C$ 's terminals can be covered with some collection of low poise trees. In particular, since every  $c \in C$  is not  $\rho$ -good, all of the coverage trees  $T(c)$  have max degree at most  $\rho$ .

The algorithm attempts to find a  $\rho$ -additive partition. It greedily finds  $\rho$ -good trees, and removes them until the set  $C$  that remains is a  $\rho$ -packing. Then the procedure **PMCover** can be used to connect the low poise trees covering  $A$  and  $C$ . However, there may be too many  $\rho$ -good trees in  $A$  for  $(A, C)$  to be a  $\rho$ -additive partition. In this case, it simply connects the root to any  $\rho$  of the trees  $T_i$ . By choosing  $\rho = \sqrt{k}$ , this ensures enough terminals are covered. See Algorithm 2 for a precise description of the Procedure **Directed**.

■ **Algorithm 2** **Directed**.

---

```

input : Graph  $G(V, E)$  with terminals  $S$ , and a number  $k$ .
output: A Steiner  $k$ -tree of  $G$ .

1 Set  $\rho = \sqrt{k}$ .
  /* Greedy Packing */
2 Let  $A = \{r\}$ , and  $C = V - \{r\}$ .
3 while  $C$  is not a  $\rho$ -packing do
4   Find a  $\rho$ -good tree  $T$  in  $G[C]$ .
5   Remove the vertices of  $T$  from  $C$  and add them to  $A$ .
6 Let  $\{T_i\}$  denote the set of  $\rho$ -good trees found.
  /* Many Trees */
7 if the number of  $\rho$ -good trees found is at least  $\rho$ , then
8   Choose any  $\rho$  of the trees  $\{T_i\}$  in  $A$ , and form the subgraph  $H \subseteq G$  by including
   the root  $r$ , the chosen trees, and a shortest path from  $r$  to the root  $q_i$  of each
   chosen tree  $T_i$ .
9   return a shortest path tree of  $H$  rooted at  $r$ .
  /* Few Trees */
10 else
11   The number of  $\rho$ -good trees found is at most  $\rho$ , so  $(A, C)$  is a  $\rho$ -additive partition.
   Apply the Procedure Complete on  $(A, C)$ , and return the resulting tree.

```

---

In the case that a  $\rho$ -additive partition  $(A, C)$  is found, we use the Procedure **Complete**, described in Algorithm 3. See Figure 1 for a depiction of the algorithm at this step.

## Analysis

For a directed tree,  $T$ , let  $\deg_T(v)$  be the (out-)degree of the vertex in  $T$ . Now say that we run step *Greedy Packing* of **Directed** with  $\rho = \sqrt{k}$ .

▷ **Claim 4.4.** If Procedure **Directed** finds at least  $\rho$   $\rho$ -good trees, then step *Many Trees* of Procedure **Directed** returns a tree with at least  $k$  terminals, maximum degree  $O(\sqrt{k})$ , and height  $O(D^*)$

*Proof.* Since each tree  $T_i$  is  $\sqrt{k}$ -good, it contains  $\sqrt{k}$  terminals. Hence, the graph  $H$  contains at least  $k$  terminals, each of which can be reached by a path from the root. So the returned shortest path tree of  $H$  has at least  $k$  terminals, as desired

## 21:10 The Telephone $k$ -Multicast Problem

■ **Algorithm 3** Complete.

- 
- input** : Graph  $G(V, E)$  with terminals  $S$ , a  $\rho$ -additive partition  $(A, C)$ , and a number  $k$ .
- output** : A Steiner  $k$ -tree of  $G$ .
- 1 Apply the procedure **PMCover** with partition  $(A, C)$  to get  $\mathcal{E}'$ .
  - 2 Let  $\mathcal{E} = \{ac : (a, c) \in \mathcal{E}'\}$ , the set of arcs corresponding to sets in  $\mathcal{E}'$ .
  - 3 Form the graph  $H_C$  on vertex set  $C \cup \{r'\}$ , where  $r'$  is a new node. For each  $c \in C$  appearing in some  $ac \in \mathcal{E}$ , include in  $H_C$  the arc  $(r', c)$  and the coverage tree  $T(c)$ . Take a shortest path tree on  $H_C$  rooted at  $r'$ , and let  $T_C$  be all of the edges from this tree in  $G[C]$ .
  - 4 Form the subgraph  $H \subseteq G$  by including the root  $r$ , each  $\rho$ -good tree  $T_i$  from  $A$  and a shortest path from  $r$  to its root  $q_i$ , the edges from  $\mathcal{E}$ , and the edges from  $T_C$ .
  - 5 **return** a shortest path tree of  $H$  rooted at  $r$ .
- 

■ **Figure 1** A depiction of the algorithm in the case that a  $\rho$ -additive partition is found. The set  $A$  includes the root  $r$  and all  $\sqrt{k}$ -good trees found, while  $C$  contains the remaining vertices. Terminals are depicted in blue. Short paths from  $r$  to the roots of the good trees are added (in red). Since  $C$  is a  $\sqrt{k}$ -packing, each vertex  $c \in C$  can reach less than  $\sqrt{k}$  terminals within distance  $D^*$ . Hence, we can run the **PMCover** procedure, with each iteration enforcing a degree constraint of  $B^*$  on each node in  $A$ , as shown.

To bound the degrees in the returned tree, we just bound the degrees in  $H$ . The good trees  $T_i$  are disjoint, and each have maximum degree at most  $\sqrt{k}$ . Moreover, there are  $\sqrt{k}$  of them, so there are only  $\sqrt{k}$  shortest paths to their roots. Therefore, the degree contributed to any node  $v \in H$  is at most  $\sqrt{k}$  from the  $T_i$ , and at most 1 for each shortest path, for a total of  $\deg_H(v) \leq 2\sqrt{k}$ . Finally, each tree  $T_i$  in  $H$  has height at most  $D^*$ , while each shortest path from the root to some  $q_i$  has length at most  $D^*$  (by Assumption 2.1), so the returned shortest path tree has height at most  $2 \cdot D^*$ .  $\triangleleft$

▷ **Claim 4.5.** If Procedure **Directed** finds less than  $\rho$   $\rho$ -good trees, then Procedure **Complete** finds a tree rooted at  $r$  with maximum degree  $O(\log k) \cdot B^* + O(\sqrt{k})$ , and height  $O(D^*)$  that contains at least  $k$  terminals of  $C \cap S$ .

*Proof.* First, observe that  $H$  contains all terminals in  $A$ , as well as those terminals in  $C$  covered by procedure **PMCover**. In particular, by Claim 3.5,  $H$  contains at least  $k$  terminals, so the returned shortest path tree does as well.

Now we bound the degrees of nodes in the returned tree. The  $T_i$  making up  $A$  are disjoint  $\sqrt{k}$ -good trees each having maximum degree at most  $\sqrt{k}$ . And there are less than  $\sqrt{k}$  of them, so we add at most  $\sqrt{k}$  shortest paths to their roots  $q_i$ . Hence, for each node  $v \in A$ , the contribution to the degree  $\deg_H(v)$  is at most  $\sqrt{k}$  from the  $T_i$ , at most 1 for each shortest path, plus the contribution from  $\mathcal{E}$ . By Claim 3.5, the edges of  $\mathcal{E}$  increase the degree of vertices in  $A$  by  $O(\log k) \cdot B^*$ , so in total  $\deg_H(v) \leq O(\log k) \cdot B^* + 2\sqrt{k}$  for each  $v \in A$ .

All other vertices in  $H$  lie in  $C$ , and so their degree comes only from the  $\sqrt{k}$  shortest paths (contributing at most 1 each), and the edges from  $T_C$ . Every coverage tree  $T(c)$  has depth at most  $D^*$  by definition. In particular, for any vertex  $c \in C$ , we must have  $\deg_{T_C}(c) \leq \sqrt{k}$ , since otherwise the subtree of  $T_C$  rooted at  $c$  has more than  $\sqrt{k}$  leaves, which can all be assumed to be terminals. But this means that  $c$  has more than  $\rho = \sqrt{k}$  terminals in  $C$  of distance at most  $D^*$ , contradicting that  $c$  is not  $\rho$ -good. Hence,  $\deg_H(c) \leq 2\sqrt{k}$  for every  $c \in C$ .

Finally, the height of the output tree is at most  $3 \cdot D^* + 1$ , because we get height  $D^*$ , from the trees  $T_i$ , height  $D^*$  from the shortest paths, height  $D^*$  from  $T_C$ , and an additional edge from  $\mathcal{E}$ . ◁

Therefore, in either case we return a tree with at least  $k$  terminals with maximum degree  $O(\log k) \cdot B^* + O(\sqrt{k})$  and height  $O(D^*)$ . This implies Theorem 1.2.

The following corollary is useful as it applies in case that the *Greedy Packing* step of Procedure **Directed** finds a  $\rho$ -additive partition (i.e., step *Few Trees* is executed) with some  $\rho$  that may be smaller than  $\sqrt{k}$ .

▶ **Corollary 4.6.** *If Procedure **Directed** finds a  $\rho$ -additive partition  $A, C$ , then there exists polynomial time  $\rho$ -additive approximation for the corresponding min poise  $k$ -tree problem.*

## 5 The undirected case

In this section, we provide our  $\tilde{O}(t^{1/3})$ -approximation algorithm for the Minimum Time Telephone  $k$ -multicast problem on undirected graphs with  $t$  terminals, proving Theorem 1.3.

**Preliminaries.** We assume (for convenience) that the root  $r$  is a non-leaf node in  $T^*$ . Recall that we assume that all terminals have degree 1. We can now assume that after rooting  $T^*$  at  $r$ , the set of leaves in  $T^*$  and the set of terminals in  $T^*$  is the same set. Also recall that the height of the tree  $T^*$  rooted at  $r$  is at most  $D^*$ , since the diameter of  $T^*$  is at most  $D^*$ .

**Algorithm outline.** The idea in the undirected case is that if a low-poise tree covering many terminals is found, then we need only cover *any* node in that tree in order to cover all of those terminals with low poise (as opposed to the directed case where we would have to cover the *root* of that tree). Essentially, we may contract the tree and treat the contracted node as containing many terminals.

Specifically, we will maintain a set  $R$  of nodes we have covered with low poise (by contracting, we can think of this simply as the root  $r$ ). We first partition the remaining graph  $C = V \setminus R$  as before by greedily finding small trees.

## 21:12 The Telephone $k$ -Multicast Problem

► **Definition 5.1.** We say that a tree is small size if it contains exactly  $t^{1/3}$  terminals. We say that a tree is large if it contains exactly  $t^{2/3}$  terminals

If this procedure succeeds in finding a  $t^{1/3}$ -additive partition, then we are done by Corollary 4.6. On the other hand, if we fail, we contract these small trees and show how to cover a sufficiently large number of them by either finding a single large tree reaching  $t^{1/3}$  of these small trees, or by applying the procedure **PMCover**. In either case, we may then remove *all* of the terminals from these small trees, contract the newly covered nodes into  $R$ , and iterate the entire process to cover the remaining terminals. In each iteration, we show the total number of terminals discarded is large, so there cannot be too many iterations, and hence not too much additional degree is incurred.

We first give a simple algorithm, Procedure **Small**, that finds trees  $\{T_i\}$  each with exactly  $t^{1/3}$  terminals (leaves).

■ **Algorithm 4** **Small**.

---

**input** : Graph  $G(V, E)$  with  $t$  terminals  $S$ , and a number  $k$ .

**output** : A collection of subtrees  $\{T_i\}$ , each with exactly  $t^{1/3}$  terminals, or a Steiner  $k$ -tree.

- 1 Apply step *Greedy Packing* from Procedure **Directed** on  $G$  with  $\rho = t^{1/3}$ . Denote the resulting trees as  $\{T_i\}$ .
  - 2 If the procedure succeeds in finding a  $t^{1/3}$ -additive partition, apply Procedure **Complete** on  $A, C$ , and **return** the resulting tree.
  - 3 Else, **return**  $\{T_i\}$
- 

In case that step *Greedy Packing* from Procedure **Directed** finds a  $t^{1/3}$ -additive partition  $A, C$ , we are guaranteed a  $t^{1/3}$ -additive ratio from Corollary 4.6. Hence, from now on we assume that step *Greedy Packing* from Procedure **Directed** gives more than  $t^{1/3}$  small trees  $T_i$ .

We will proceed to contract each of these small trees into super-terminals. The trees  $T_i$  that we compute, are built by step *Greedy Packing* from Procedure **Directed** with  $\rho = t^{1/3}$ . Hence, they have exactly  $t^{1/3}$  terminals/leaves. We contract the terminals of every  $T_i$  into a single super-terminal  $q_i$ . Denote by  $S(T_i)$  the terminals contained in  $T_i$  (i.e., those corresponding to  $q_i$ ). As mentioned in the outline, we have the possibility that the terminals of an optimal tree may only intersect with a few of these super-terminals. We capture this in the following definitions.

► **Definition 5.2.** We say that  $q_i$  is a true terminal if  $S(T_i) \cap T^* \neq \emptyset$ .

► **Definition 5.3.** Denote by  $k'$  the number of terminals in  $(\bigcup_i T_i) \cap T^*$ . Let  $\mu = \lceil k'/t^{1/3} \rceil$ .

From the definitions, we can see that  $T^*$  overlaps with at least  $\mu$  true terminals.

In the graph where the small trees have been contracted to super-terminals, we will attempt to find a  $t^{1/3}$ -packing of these super-terminals. For this, we generalize the definition of a  $t^{1/3}$ -packing in the set  $C$  with respect to the super-terminals.

► **Definition 5.4.** We say that  $c \in C$  is a  $t^{1/3}$ -good vertex with respect to the super-terminals  $\{q_i\}$  if there are at least  $t^{1/3}$  terminals  $q_i$  of distance at most  $D^*$  from  $c$ , in  $G[C]$ . If there are no  $t^{1/3}$ -good vertices in  $C$ ,  $C$  is called a  $t^{1/3}$ -packing with respect to  $\{q_i\}$ . If  $C$  is a  $t^{1/3}$ -packing, then  $R, C$  is called a  $t^{1/3}$ -additive partition with respect to  $\{q_i\}$ .

We can now describe the details of the rest of the undirected algorithm. Specifically, if Procedure **Small** fails to find a  $t^{1/3}$ -additive partition, then there are two possibilities. Either  $C = V \setminus R$  is a  $t^{1/3}$  packing with respect to the  $q_i$ , or otherwise there is a  $t^{1/3}$ -good vertex in  $C$ .

If  $C$  is a  $t^{1/3}$ -packing we apply Procedure **PMCover** on  $R, C$  with terminals  $\{q_i\}$  since  $R, C$  is a  $t^{1/3}$ -additive partition. The goal is covering  $\mu$  super-terminals. We know that  $T^*$  covers at least  $\mu$  true terminals  $q_i$ , so these can be reached with height  $D^*$  and maximum degree  $B^*$ . Therefore, our Procedure **PMCover** covers at least  $\mu$  super-terminals. Note that the number of original terminals we actually cover is  $\mu \cdot t^{1/3} \geq k'$ . This follows because each  $q_i$  represents a tree  $T_i$  that contains  $t^{1/3}$  terminals. We now discard all the terminals of  $\bigcup_i T_i$ . Since the number of  $T_i$  is at least  $t^{1/3}$ , the total number of discarded terminals is  $t^{2/3}$ .

The other case is that  $C$  is not a  $t^{1/3}$ -packing with respect to  $\{q_i\}$ . Let  $v \in C$  be a  $t^{1/3}$ -good vertex and let  $Q_v$  be the corresponding tree. Note that  $Q_v$  is a large tree since it spans  $t^{1/3}$  of the  $q_i$ , each representing  $t^{1/3}$  terminals. We connect  $r$  to  $Q_v$  via a shortest path  $P$  from  $r$  to  $Q_v$ , and contract  $r \cup P \cup Q_v$  into  $r$ . Then we discard the terminals of  $Q_v$ . Since  $Q_v$  is a large tree, the number of terminals discarded is  $t^{2/3}$ .

In summary, in both cases  $t^{2/3}$  terminals are discarded. Therefore the number of iterations in our algorithm is at most  $t^{1/3}$ .

The degree of vertices in  $R$  increases by  $O(\log k) \cdot B^*$  every time **PMCover** is applied. Alternatively, a large tree  $Q_v$  is created and we only need a path  $P$  from  $r$  to  $Q_v$ . This increases the degree of some vertices in  $R$  by exactly 2. This gives a total degree of  $2 \cdot t^{1/3}$  because of the bound on the number of iterations.

## The main procedure

Here we describe the precise algorithm for the undirected problem, Procedure **Undirected** in Algorithm 5.

### Analysis

▷ **Claim 5.5.**  $T^*$  contains at least  $\mu$  true terminals.

Proof. If the number of true terminals is at most  $\mu - 1$ , the number of terminals in  $\bigcup_i T_i$  is at most  $(\mu - 1) \cdot t^{1/3} < k'$  and this is a contradiction. ◁

▷ **Claim 5.6.** The number of iterations in Procedure **Undirected** is at most  $t^{1/3}$ .

Proof. If a tree  $Q_v$  is found, then it is a large tree hence it contains at least  $t^{2/3}$  terminals. These terminals are discarded in the iteration. Else, the terminals of  $S \cap \bigcup_i T_i$  are discarded and this, again, this removes  $t^{2/3}$  terminals, since we have at least  $t^{1/3}$  different small  $T_i$ 's (because procedure **Small** failed). Since in either case  $t^{2/3}$  terminals are discarded and the total number of terminals is  $t$ , the number of iterations is at most  $t^{1/3}$ . ◁

▷ **Claim 5.7.** Let  $v$  be a vertex so that  $v \notin R$ . A single iteration of Procedure **Undirected** increases  $v$ 's degree by at most  $2 \cdot t^{1/3} + 2$ . Moreover, if  $v$ 's degree increases,  $v$  is contracted into  $r$  in that iteration.

Proof. The degree of a vertex increases only if it belongs to a large tree  $Q_v$  (or its path  $P$  from  $r$ ), or it belongs to the subgraph  $Q$  computed by Procedure **PMCover**. In the first case, the degree increases by at most  $t^{1/3}$  from any one of the  $T_i$ 's in  $Q_v$ , at most  $t^{1/3}$  more for the paths from  $v$  to these  $T_i$ 's, and at most 2 more for the path  $P$  from  $r$  to  $Q_v$ , for a total of at

---

**Algorithm 5** Undirected.

---

**input** : Graph  $G(V, E)$  with  $t$  terminals  $S$ , and a number  $k$ .  
**output** : A Steiner  $k$ -tree

- 1  $R \leftarrow \{r\}$ ,  $S' \leftarrow S$ .
- 2 **while**  $k > 0$  **do**
- 3     Apply Procedure **Small** with  $\rho = t^{1/3}$  on  $C = V \setminus R$ . If it succeeds, return the resulting tree.
- 4     If **Small** fails, contract the terminals from each  $T_i$  in the resulting packing into a corresponding super-terminal  $q_i$ .
- 5     **if**  $C = V \setminus R$  is not a  $t^{1/3}$ -packing with respect to  $\{q_i\}$  **then**
- 6         Find a large tree  $Q_v$  inside  $G[C]$ .
- 7         Compute a shortest path  $P$  from  $r$  to  $Q_v$ .
- 8          $R \leftarrow R \cup P \cup Q_v$ .
- 9         Remove from  $S'$  all the terminals of  $Q_v$  and update  $k$ .
- 10    **else** *//  $C = V \setminus R$  is a  $t^{1/3}$ -packing.*
- 11
- 12     Apply Procedure **PMCover** with  $A = R$  and  $C = V - R$  with the goal of covering super-terminals.
- 13     Let  $\mathcal{E}$  be the edges corresponding to the returned sets  $(a, c) \in \mathcal{E}'$ , and  $T_C$  the shortest path tree on the corresponding trees  $T(c)$  (as in line 3 of **Complete**). Write  $Q = \mathcal{E} \cup T_C$ .
- 14      $R \leftarrow R \cup Q$ .
- 15     Remove from  $S'$  all the terminals  $\bigcup_i T_i$  and update  $k$ .

16 **return** the tree induced by  $R$

---

most  $2 \cdot t^{1/3} + 2$ . In the second case, the degree increases by at most  $t^{1/3}$  from  $T_C$  and 1 from  $\mathcal{E}$ , by an identical argument to Claim 4.5 (the proof of correctness of Procedure **Complete**).

In both cases, the vertex is immediately contracted into  $r$ .  $\triangleleft$

$\triangleright$  **Claim 5.8.** At every iteration, the degree of vertices in  $R$  is increased by at most  $O(\log k) \cdot B^*$ .

*Proof.* If a large tree  $Q_v$  is found, a shortest path from  $r$  to  $Q_v$  is computed. This increases the degree of any vertex by at most 2. Otherwise, Procedure **PMCover** is applied. This increases the degree of vertices of  $R$  by  $O(\log k) \cdot B^*$ . The claim follows.  $\triangleleft$

$\triangleright$  **Claim 5.9.** The returned tree contains  $k$  terminals, has maximum degree  $\tilde{O}(t^{1/3}) \cdot B^*$  and diameter  $O(D^*)$

*Proof.* By Claim 5.7, an iteration of Procedure **Undirected** increases the degree of a vertex  $v \notin R$  by at most  $O(t^{1/3})$ , any  $v$  whose degree increases immediately joins  $R$ . Now we bound the degree added to a vertex in  $R$ . By Claim 5.8 at every iteration the degree of  $v \in R$  can increase by  $O(\log k) \cdot B^*$ . By Claim 5.6, the number of iterations of Procedure **Undirected** is bounded by  $t^{1/3}$ . Therefore the total degree of a vertex is at most

$$O(t^{1/3}) + O(\log k) \cdot B^* \cdot t^{1/3} = O(\log k) \cdot t^{1/3} \cdot B^*.$$

In addition, the diameter of every  $Q_v$  or  $Q$  found, is  $O(D^*)$ . The distance of  $r$  to any  $Q$  or  $Q_v$  is at most  $D^*$  as well. This assures that the diameter is  $O(D^*)$ .

Finally, we argue that  $k$  terminals are covered. Fix a particular iteration of the algorithm. If Procedure `Small` succeeds in finding a  $t^{1/3}$ -additive partition, then we immediately cover the remaining number of terminals necessary by applying the Procedure `Complete`. Otherwise, we argue that among the terminals discarded in this iteration, the algorithm covers at least as many as  $T^*$  covers. Indeed, if  $C$  is not a  $t^{1/3}$ -packing with respect to  $\{q_i\}$ , then all terminals discarded are covered. On the other hand, if  $C$  is a  $t^{1/3}$ -packing, then by applying Procedure `PMCover`, Claim 5.5 ensures that at least  $\mu$  super-terminals are covered. Hence at least  $\mu \cdot t^{1/3} \geq k'$  terminals are covered, which is precisely the number of terminals covered by  $T^*$  among those discarded.  $\triangleleft$

Using [18] we get the following corollary that proves Theorem 1.3.

► **Corollary 5.10.** *The Minimum Time Telephone  $k$ -Multicast problem on undirected graphs admits a polynomial time,  $\tilde{O}(t^{1/3})$ -approximation algorithm.*

## Abstract

Motivated by modern architectures allowing for the partitioning of a GPU into hardware separated instances, we initiate the study of scheduling splittable jobs on configurable machines. We consider machines that can be configured into smaller instances, which we call blocks, in multiple ways, each of which is referred to as a configuration. We introduce the Configurable Machine Scheduling (CMS) problem, where we are given  $n$  jobs and a set  $C$  of configurations. A schedule consists of a set of machines, each assigned some configuration in  $C$  with each block in the configuration assigned to process one job. The amount of a job's demand that is satisfied by a block is given by an arbitrary function of the job and block. The objective is to construct a schedule using as few machines as possible. We provide a tight logarithmic factor approximation algorithm for this problem in the general setting, a factor  $(3 + \varepsilon)$  approximation algorithm for arbitrary  $\varepsilon > 0$  when there are  $O(1)$  input configurations, and a polynomial time approximation scheme when both the number and size of configurations are  $O(1)$ . Finally, we utilize a technique for finding conic integer combinations in fixed dimension to develop an optimal polynomial time algorithm in the case with  $O(1)$  jobs,  $O(1)$  blocks, and every configuration up to a given size.

## 1 Introduction

As the size of Deep Neural Network (DNN) models (particularly Large Language Models) continue to increase, there is a growing need to more efficiently allocate computational resources to these models at inference time. One challenge in efficiently allocating resources is that certain large models may require powerful GPUs, while other smaller models would greatly underutilize the power of such GPUs. To combat this issue, modern GPUs (e.g.,

NVIDIA A30, A100, H100) include a new hardware feature called Multi-Instance GPU (MIG). MIG enables a GPU to be partitioned into smaller hardware isolated GPU instances, each with their own processors, memory, L2 cache, and bus bandwidth.

While MIG theoretically allows GPUs to avoid wasting resources, the feature raises the problem of efficiently scheduling on MIG-enabled GPUs. The problem presents two main challenges which must be considered simultaneously, and so compound the complexity of finding a solution. The first challenge is to partition the GPU into a configuration of smaller, variably sized GPU instances that can be used to execute DNN models. The second challenge is to assign models to these instances based on their resource demands. The problem is further complicated by the facts that (a) different configurations of GPU instances may have varying levels of computational and memory resources, (b) the resources are non-fungible for DNN models in the sense that increasing the size of a GPU instance may not linearly increase its performance [17], and (c) due to hardware constraints, some partitions of the GPU may not be available [13].

No prior work has provided algorithms with provable performance guarantees in the presence of (a-c), and currently deployed scheduling algorithms ignore either (b) [14], or (c) [16], or all three [19]. While this problem has gained much attention [17, 10, 11], these investigations primarily rely on heuristics with no formal guarantees. This paper is the first to establish theoretical bounds for scheduling on MIG-enabled GPUs.

We provide a natural formalization of the above problem, initiating a systematic theoretical study of scheduling splittable jobs in configurable machines. We call this problem *Configurable Machine Scheduling* or CMS. We consider machines that can be partitioned into multiple *configurations* of smaller instances, which we call *blocks*. We consider jobs that have certain demands that need to be satisfied by allocating blocks to it. Each job also has a corresponding table that specifies how much of the job’s demand is satisfied by a given block type. A *schedule* specifies each machine’s configuration and which job each of the machine’s blocks is to execute. Our goal is to construct a schedule that satisfies all job demands using as few machines as possible.

**Configurable Machine Scheduling (CMS).** A CMS instance is defined by a set  $C$  of *machine configurations* and a set  $J$  of *jobs*, as well as an integer  $k$  indicating the number of available *block types*.

- Each machine configuration  $\sigma \in C$  is a multiset of blocks represented as a length  $k$  vector. For  $i \in [k] = \{1, \dots, k\}$ , we let  $\sigma_i \in \mathbb{Z}_{\geq 0}$  indicate the number of blocks of type  $i$  in  $\sigma$ .
- For each job  $j \in J$ , there is an associated *demand*  $d_j$  as well as a length  $k$  *throughput table*  $f_j$ . For a job  $j \in J$  and block type  $i \in [k]$ , the value of  $f_j(i)$  denotes the amount of  $j$ ’s demand satisfied when it is executed on a single block of type  $i$ .

The goal is to satisfy all job demands on as few *machines* as possible. A machine  $\mu$  specifies how each block is allocated for each job. Specifically,  $\mu(i, j)$  represents the number of blocks of type  $i$  on which machine  $\mu$  executes job  $j$ , with the constraint that, there exists a configuration  $\sigma$  such that  $\sum_j \mu(i, j) \leq \sigma_i$ , for each  $i \in [k]$ . That is, each machine has an implicit configuration, and the total number of blocks of type  $i$  used by machine  $\mu$  cannot exceed the number of blocks of type  $i$  included in  $\mu$ ’s configuration.

A *schedule* consists of a multiset  $M$  of machines, with  $M_\mu$  indicating the number of instances of machine  $\mu$  in  $M$ . In any schedule, all job demands must be completely satisfied, i.e. for any schedule  $M$ , we require  $\sum_{\mu \in M} \sum_{i \in [k]} M_\mu \cdot \mu(i, j) \cdot f_j(i) \geq d_j$  for each job  $j$ . The formal objective is, then, to construct a schedule  $M$  that minimizes the total number of machine instances, given by  $\sum_{\mu} M_\mu$ . (See Figure 1 for an example.)

**Figure 1** Example CMS instance (a) with schedule (b). The instance has  $k = 3$  block types,  $|C| = 2$  configurations, and  $|J| = 3$  jobs. Configuration  $\sigma$  has three type 1 blocks, and one type 3 block. Configuration  $\tau$  has two type 2 blocks. Job  $j_1$  had demand 11, with throughput  $f_{j_1}(1) = 2$ ,  $f_{j_1}(2) = 4$ , and  $f_{j_1}(3) = 5$ . Job  $j_2$  had demand 14, with throughput  $f_{j_2}(1) = 8$ ,  $f_{j_2}(2) = 1$ , and  $f_{j_2}(3) = 3$ . Job  $j_3$  had demand 29, with throughput  $f_{j_3}(1) = 5$ ,  $f_{j_3}(2) = 3$ , and  $f_{j_3}(3) = 5$ . The schedule uses six machines: two instances of  $\mu$ , one instance of  $\mu'$ , and three instances of  $\mu^*$ .  $\mu$  and  $\mu'$  have configuration  $\sigma$ .  $\mu$  executes  $j_1$  on three type 1 blocks and  $j_3$  on one type 3 block.  $\mu'$  executes  $j_2$  on one type 1 block and one type 3 block, and  $j_3$  on two type 1 blocks. Machine  $\mu^*$  has configuration  $\tau$  and executes  $j_2$  on one type 2 block and  $j_3$  on the other. Summing the throughput over all machines is sufficient to satisfy all job demands.

In any CMS instance, we assume that, for all  $j$ ,  $f_j$  maps to  $\{\ell \in \mathbb{N} : \ell \leq d_j\}$ , which we can ensure with only a polynomial increase in the length of the input, and no loss in the value of the optimal solution. The *size* of a configuration  $\sigma$ , denoted  $|\sigma|$ , is the number of blocks in the configuration, i.e.  $|\sigma| = \sum_{i \in [k]} \sigma_i$ . Furthermore, for convenience, some of our algorithms output the schedule as a multiset of configurations, one for each machine in the output schedule, and a multiset of blocks for each job. In the appendix, we prove that this format of the output is without loss of generality, since it can be efficiently transformed to a schedule as formally defined above.

## 1.1 Our results

Our CMS problem formulation yields a rich landscape of optimization problems, which vary depending on the properties of block types, configurations, and the job demand tables. In this paper, we explore the general CMS problem and three restricted versions of the problem. We obtain near-tight approximations or optimal results for the associated problems (see Table 1).

**Table 1** Results for Configurable Machine Scheduling.  $n$  is the number of jobs,  $k$  is the number of block types, and  $c = \max_{\sigma \in C} \{|\sigma|\}$  is the maximum size of any configuration. All results are proved in this paper. The hardness of CMS with  $O(1)$  jobs and  $O(1)$  configuration size is unknown.

| Problem  | Algorithm                                     | Approximation  | Hardness          |
|--|---|--|-------------------|
| General  | LP+ Greedy                                    | $O(\log cnk)$  | $\Omega(\log nk)$ |
| $O(1)$ configurations  | Extreme-Point LP Rounding                     | $(2 + \varepsilon)\text{OPT} +  C $<br>$3 + \varepsilon$ | 2                 |
| $O(1)$ configurations of $O(1)$ size   | Small/Large Job LP                            | $1 + \varepsilon$  | ?                 |
| $O(1)$ number of jobs and blocks, with all configurations up to a given size | Conic Integer Combinations in Fixed Dimension | 1  | -                 |

**General CMS (Section 2).** Using a reduction from minimum multiset multicover [15], we first observe that CMS is hard to approximate to within a factor of  $\Omega(\log nk)$ , where  $n$  is the number of jobs and  $k$  the number of blocks. We then present a factor  $O(\log(cnk))$  approximation algorithm, where  $n$  is the number of jobs,  $k$  the number of blocks, and  $c$  is the size of the largest configuration, which is essentially tight given the above hardness result. Our algorithm constructs a schedule by greedily selecting the highest throughput configuration on the basis of a linear programming relaxation.

The logarithmic-hardness result for the general problem motivates us to consider restricted versions with a constant number of configurations, which are also of practical interest.

**CMS with a constant number of configurations (Section 3).** Using a reduction from Partition, we observe that CMS, *even with one configuration and two jobs*, is hard to approximate to within a factor of 2. Our main result is an algorithm that, for any instance of CMS with a constant number of configurations  $C$  and arbitrary  $\varepsilon > 0$ , uses at most  $(2 + \varepsilon)\text{OPT} + |C|$  machines where OPT is the number of machines needed in the optimal solution, asymptotically almost matching the hardness result for a constant number of configurations. We also show that our algorithm always returns a  $3 + \varepsilon$  approximation. Our algorithm builds on the seminal LP rounding technique of [9] and exploits the structure of extreme-point solutions to iteratively and carefully round the LP variables.

To find more tractable cases, we study a further restriction of the problem that bounds the size of configurations.

**CMS with a constant number of configurations of constant size (Section 4).** We next consider CMS with a constant number of configurations, each of constant size (i.e., having a constant number of blocks). We show that the problem is solvable in pseudo-polynomial time; our main result here is a PTAS based on rounding a novel LP relaxation for the problem.

Our LP based approximations require the number of configurations given in the input to be constant. Our final result explores nontrivial tractable models where the number of jobs is constant while the number and size of configurations are not constant.

**CMS with a constant number of jobs and blocks, with all configurations up to a given size (Section 5).** We consider CMS with a constant number of jobs, a constant number of block types, and where every configuration up to a given size is available. We give an algorithm that solves this problem optimally in polynomial time. Our algorithm uses a technique for finding conic integer combinations in fixed dimension, which was developed by Goemans and Rothvoss in their study of bin packing with constant number of job types [5]. We also show that this technique extends to a more general setting where configurations are defined by a constant number of rational polytopes.

## 1.2 Our Techniques

**General CMS.** The logarithmic factor approximation algorithm for the most general case uses two algorithmic approaches, each of which faces challenges on its own. The first approach uses the natural heuristic of greedily allocating machines to execute as much total throughput as possible. When each job can be fully executed on at most one block of each type, we

show that this algorithm achieves a logarithmic approximation ratio. However, in general the algorithm's approximation ratio is  $\Omega(n)$ . The second approach is based on an LP relaxation that uses job-block variables to indicate how many blocks of a given type are used to execute a job. When the job-block variables are large enough (greater than 1) they can be rounded and scheduled using a multi-set multi-cover algorithm to achieve a logarithmic approximation ratio. On the other hand, variables with low values cannot be rounded up without a large loss in the approximation ratio, and cannot be rounded down because even a small fractional block allocation may represent a significant amount of *throughput*. Our solution is to marry these approaches. We first solve the LP relaxation and use a multi-set multi-cover algorithm to schedule those job-block pairs with large variable values. For any jobs with remaining demand, we show that they can be fully executed on at most one block of each type, and ensure that the maximum ratio of execution function values is at most the number of block types  $k$ . Executing the greedy algorithm on these remaining jobs yields an algorithm with a logarithmic approximation ratio.

**Constant number of configurations.** In this case, we use essentially the same LP as for the general problem, simplifying it to use only variables that represent how many of each block type are allocated to a job. We then build a graph with nodes representing the block types and jobs, and insert an edge between a job and block type if the corresponding variable in the LP is nonzero. We leverage extreme point properties to prove that the graph is a pseudo-forest; i.e., each component is either a tree or a tree with a cycle. Our key technical contribution is to carefully round the LP solution by exploiting this tree structure and the constraints on the possible LP values mandated by the fact that, by our construction, no block can satisfy more demand than the job requires. This algorithm returns a  $(2 + \varepsilon)\text{OPT} + |C|$  approximation. We extend this result to a  $(3 + \varepsilon)\text{OPT}$  approximation (which is better for  $\text{OPT} < |C|$ ) by running the above algorithm on each subset of the input configurations, and then returning the best solution.

**Constant number of configurations of constant size.** The LP used in the preceding two variants of the problem has an integrality gap of 2. This holds even for simple instances with one configuration of constant size and two jobs. To obtain a PTAS for a constant number of configurations of constant size, we first divide the jobs into small and large jobs based on whether the number of machines needed to serve their demand exceeds a constant threshold (based on a parameter  $\varepsilon$ ). We then formulate a new LP that imposes different constraints for the small jobs taking into account that there is a bounded number of ways their demands can be allocated. Through a careful rounding of the LP, we derive a  $(1 + \varepsilon)$ -approximation algorithm for the problem.

**Constant number of jobs and blocks, and all configurations up to a given size.** In this setting neither the number of configurations nor the size of any configuration is constant, and so any approach based on our LP relaxations faces the obstacle that either the program has an integrality gap of at least 2, or is intractable. Therefore, in order to solve this problem optimally, more sophisticated techniques are required. The approach we develop is based on a technique for finding conic integer combinations in fixed dimension which was developed by Goemans and Rothvoss in their study of bin packing with constant job types [5]. The challenges of this approach lie in formulating the problem to appropriately leverage the power of the apparatus. In our case, this involves providing a rational representation of the problem on an individual machine that yields a complete solution when combined with the

representations of other machines. In the general case, the nonlinear relationship of blocks to job throughput *and* to configuration size renders the problem extremely difficult, even when jobs and blocks are constant. However, when all configurations up to a given size are available, a configuration can be represented as a linear combination of block allocations, making the problem tractable. In fact, as long as the number of jobs and blocks types is constant, the general technique for finding conic integer combinations allows us to devise an optimal polynomial time algorithm whenever the set of configurations can be represented using a constant number of rational polytopes.

### 1.3 Related work

Configurable machine scheduling has connections to many well-studied problems in combinatorial optimization, including bin-packing, knapsack, multiset multicover, and max-min fair allocation. General CMS generalizes the multiset multicover problem [8, 6, 15], for which the best approximation factor achievable in polynomial time is  $O(\log m)$  where  $m$  is the sum of the sizes of the multisets [15, 18]. The hardness of approximating the problem to within an  $O(\log n)$  factor follows from the result for set cover [4].

As we note above, CMS is NP-complete even for the case of one configuration and two jobs. The single configuration version can be viewed as a fair allocation problem with each block representing an item and each job representing a player that has a value for each item (given by the demand table) and a desired total demand. The objective is to minimize the maximum number of copies we need of each block so that they can be distributed among the players satisfying their demands. In contrast, the Santa Claus problem in fair allocation [1] (also studied under a different name in algorithmic game theory [12]) aims to maximize the minimum demand that can be satisfied with the available set of blocks. The best result for the Santa Claus problem is a quasi-polynomial  $O(n^\varepsilon)$ -approximation algorithm, where  $\varepsilon = O(\log \log n / \log n)$  [2], though factor  $O(1)$  approximation algorithms are known for special cases (e.g., see [3]).

### 1.4 Discussion and Open Problems

Our study has focused on a *combinatorial* version of CMS in which each machine can be configured as a collection of abstract blocks. It is also natural to consider a *numerical* version of CMS in which each block type is an item of a certain size, and each configuration has a certain capacity and can only fit blocks whose sizes add up exactly to its capacity. Note that instances of numerical CMS can be presented more compactly than general instances of CMS since the allowable configurations can be captured by configuration capacities and block sizes. The approximation ratios established for CMS apply to numerical CMS as well; however, it is not certain that there is also a logarithmic hardness for numerical CMS. Thus, an intriguing open problem is whether numerical CMS admits an approximation factor significantly better than the logarithmic factor established in Section 2. Also of interest is a numerical CMS variant where all capacity-bounded configurations are allowed, for which we believe techniques from unbounded knapsack [7] and polytope structure results of the kind we show in Section 5 would be useful.

Our results indicate several directions for future research. One open problem is to devise approximation algorithms that leverage structure in the set of available configurations. In practice, the configuration sets associated with multi-instancing GPUs might not be arbitrary sets, e.g. the blocks of Nvidia's A100 GPU are structured as a tree and every valid configuration is a set of blocks with no ancestor-descendant relations [17]. Showing improved bounds for such cases seems to be a challenging, but potentially fruitful area of research.

Another open problem lies in shrinking the gap between our upper and lower bounds. The hard instance for CMS with a constant number of configurations has a constant-size solution, showing for instance that it is NP-hard to distinguish a problem with solution size 1 from one with solution size 2. These lower bounds are sufficient to show hardness of approximation, but do not rule out the possibility of asymptotic PTAS (even additive constant approximations). Furthermore, we have not been able to show any hardness for CMS with a constant number of configurations of constant size, and this is an important and interesting open problem.

Finally, our focus has been on the objective of minimizing the number of machines, which aims to meet all demands using minimum resources. Our results can be extended to minimizing makespan, given a constant number of machines. However, approximations for other objectives such as completion time or flow time, in both offline and online settings, are important directions for further research.

## 2 General CMS logarithmic approximation

In this section, we consider the most general model of CMS with an arbitrary configuration set  $C$  over  $k$  block types, and  $n$  jobs in  $J$ . Our first lemma presents an approximation-preserving reduction from multiset multicover to CMS. We thus obtain that no polynomial time algorithm can achieve an approximation ratio better than  $\Omega(\log nk)$  (assuming  $P \neq NP$ ). The lemma also implies that an improvement to our approximation ratio would yield an improvement to the best known approximation for multiset multicover.

► **Lemma 1.** *There is an approximation-preserving reduction from the multiset multicover problem to CMS.*

**Proof.** Consider an arbitrary instance  $I$  of multiset multicover. Let  $\mathcal{U}$  denote the set of elements and  $\mathcal{C}$  the collection of multisets in the set cover instance. Let  $r_e$  denote the coverage requirement for element  $e$ . We can assume without loss of generality that there do not exist two multisets  $S$  and  $S'$  with  $S \subseteq S'$ , since we can eliminate  $S$  from the set collection otherwise. We construct an instance of CMS where each multiset  $S$  is a configuration and each element  $e$  is both a block type and a job. The job  $e$  has demand  $r_e$ , which can only be satisfied by  $r_e$  blocks of type  $e$ .

Any multiset multicover solution, given by a collection  $M$  of multisets, corresponds to a solution for CMS: each multiset  $S$  in  $M$  is a machine configured according to  $S$ . Therefore, the number of multisets in  $M$  is the same as the number of machines in the CMS solution. Furthermore, since each element  $e$  is covered  $r_e$  times in  $M$ , it follows that each job  $e$  has  $r_e$  occurrences of block type  $e$  included in CMS solution, thus satisfying the demand for  $e$ . Similarly, every CMS solution with  $m$  machines is a collection of  $m$  multisets, with each multiset corresponding to the configuration of a machine. Since the objective function value achieved by each of the two solutions is identical, the reduction is approximation-preserving. ◀

The main result of this section is Algorithm 1, an  $O(\log(\max_{\sigma \in C} \{|\sigma|\} \cdot n \cdot k))$ -approximation algorithm for CMS. The first step of Algorithm 1 solves a linear relaxation of CMS, which minimizes  $\sum_{\sigma} y_{\sigma}$  subject to:

$$\sum_j x_{i,j} \leq \sum_{\sigma \in C} y_{\sigma} \cdot \sigma_i \quad i \in [k] \tag{1}$$

$$\sum_i f_j(i) \cdot x_{i,j} \geq d_j \quad j \in J \tag{2}$$

$$x_{i,j} \geq 0 \quad i \in [k] \text{ and } j \in J \tag{3}$$

$$y_{\sigma} \geq 0 \quad \sigma \in C \tag{4}$$

**Terms and Constraints.** Each variable  $x_{i,j}$  indicates the number of blocks of type  $i$  that are assigned to execute job  $j$ . Each variable  $y_\sigma$  indicates the number of machines that use configuration  $\sigma$ . Constraint 1 ensures a schedule cannot use more blocks of a given type than appear across all allocated machines. Constraint 2 states that the total number of blocks executing a job must be sufficient to satisfy its demand. It is easy to verify that this program relaxes CMS and is solvable in polynomial time.

Let  $(x^*, y^*)$  be variable assignments that yield an optimal solution to (1-4). For the second step of Algorithm 1, we separate the integer from the fractional components of the  $x$ -variables. We define  $\bar{x}_{i,j} = \lfloor x_{i,j}^* \rfloor$ .

We define  $\hat{x}_{i,j} = 0$  if either (i)  $(x_{i,j}^* - \lfloor x_{i,j}^* \rfloor) < \frac{1}{2k}$  or (ii)  $f_j(i) \cdot (x_{i,j}^* - \lfloor x_{i,j}^* \rfloor) < \max_{i'} \{f_j(i') \cdot (x_{i',j}^* - \lfloor x_{i',j}^* \rfloor)\} / k$ , otherwise  $\hat{x}_{i,j} = x_{i,j}^* - \lfloor x_{i,j}^* \rfloor$ . The second step of Algorithm 1 then calls Algorithm 2 to provide a schedule for the problem  $(C, \bar{J}, k)$  with modified demands  $\bar{d}_j = \min\{d_j, \sum_i f_j(i) \cdot \bar{x}_{i,j}\}$ .

**Algorithm 2.** We define the set  $A = \{(\sum_j \lfloor x_{i,j} \rfloor, i) : i \in [k]\}$ . We construct schedule  $S$  by using the greedy multiset multicover algorithm given in [15] on the instance  $(A, C)$ .

Step three of Algorithm 1 then constructs a schedule  $S'$  to satisfy any remaining demand given by the fractional components  $\hat{x}$  via Algorithm 3, which greedily allocates the highest throughput machines until all demands are met. Finally, Algorithm 1 outputs the schedule  $S^*$  such that,  $S_\mu^* = 2(S_\mu + S'_\mu)$  for each  $\mu$ .

**Algorithm 3.** For each  $j \in J$  and  $i \in [k]$ , we initialize  $\hat{f}_j(i) = f_j(i)$ . While there is some job that hasn't been fully executed, do the following. Compute a machine  $\mu_{\max}$  by iterating over all configurations  $\sigma$  and greedily allocating each block of  $\sigma$  to the job with the highest throughput for that block (accounting for demand already satisfied). Of these machines, greedily set  $\mu_{\max}$  to be the one with highest total throughput. Allocate enough instances of  $\mu$  such that some job's remaining demand becomes less than  $\hat{f}_j(i)$  for some  $i$ . Then, for each  $j, i$ , update  $\hat{f}_j(i) \leftarrow \min\{\hat{f}_j(i), D_j\}$  where  $D_j$  is the job's remaining demand. Then repeat.

In the remainder of the section, we provide analysis of Algorithm 1. The following lemmas establish bounds on the lengths of the schedules produced by Algorithm 3. We note that there exist instances for which Algorithm 3 produces schedules with length  $\Omega(n)$ , and so it cannot be used to solve CMS without some additional processing (which, for us, involves reducing the instance via Algorithm 2).

► **Lemma 2.** *If  $d_j \leq \sum_i f_j(i)$  for all  $i$  (i.e. each job can be executed on at most one block of each type) then Algorithm 3 returns an  $O(\log(\max_{\sigma \in C}\{|\sigma|\} \cdot nk\rho))$  approximation, where  $\rho = \max_{i,i',j}\{f_j(i)/f_j(i')\}$ .*

**Proof.** Consider the following integer program formulation of CMS, which minimizes  $\sum_{t,\sigma} w_{t,\sigma}$  subject to:  $\sum_{t,\sigma,i} z_{t,i,j} \cdot f_j(i) \geq d_j$ ,  $j \in J$  and  $\sum_j z_{t,i,j} \leq w_{t,\sigma} \cdot \sigma_i$ ,  $t \in \mathbb{N}$ ,  $\sigma \in C$ ,  $i \in [k]$  and  $\sum_{\sigma} w_{t,\sigma} \leq 1$ ,  $t \in \mathbb{N}$  and  $w_{t,\sigma}, z_{t,\sigma,i,j} \in \mathbb{N}$ ,  $t \in \mathbb{N}$ ,  $\sigma \in C$ ,  $i \in [k]$ ,  $j \in J$ . In this program,  $w_{t,\sigma} = 1$  if the  $t$ th machine instance has configuration  $\sigma$  (0 otherwise),  $z_{t,i,j}$  = the number of blocks of type  $i$  that the  $t$ th machine uses to execute job  $j$ . It is easy to see that the program relaxes CMS.

Let  $(w^*, z^*)$  be a variable assignment that minimizes the objective with value  $\eta$ . Then

$$\sum_j d_j \leq \sum_{\mu \in S} \mu(i,j) \cdot f_{\mu(i)}(i) \leq \eta \cdot k \cdot \max_{\sigma \in C} \{|\sigma|\} \cdot \max_{i,j} \{f_j(i)\}$$

The fact that  $d_j \leq \sum_i f_j(i)$  for all  $j$  implies that  $\eta \leq nk$  since, in the worst case, each block is executed on its own machine. So we can infer that  $\log(\sum_j d_j) \leq 2 \cdot \log(nk \cdot \max_{\sigma \in C} \{|\sigma|\} \cdot \max_{i,j} \{f_j(i)\})$ . In the remainder of the proof, we show that the greedy algorithm has an approximation ratio of  $\log(\sum_j d_j)$ .

Let  $(\bar{w}, \bar{z})$  be the variable assignment given by schedule produced by Algorithm 3. Let  $\bar{u}_t = \sum_{\sigma,i,j} \bar{z}_{t,\sigma,i,j}$  for every  $t$ . We define  $u_t^*$  and  $v_t^*$  to be any values that satisfy the following equalities:  $u_t^* + v_t^* = \sum_{\sigma,i,j} f_j(i) z_{t,\sigma,i,j}^*$ ,  $t \in \mathbb{N}$  and  $\sum_t v_t^* = \sum_j d_j - \sum_{t \leq \eta} \sum_{\sigma,i,j} f_j(i) \bar{z}_{t,\sigma,i,j}$  and  $\sum_t u_t^* = \sum_j d_j - \sum_t v_t^*$ . Informally,  $\bar{u}_t$  is amount of throughput achieved by machine instance  $t$  of  $(\bar{w}, \bar{z})$ .  $u_t^*$  is the amount of throughput achieved by machine instance  $t$  of  $(w^*, z^*)$  that is also satisfied by one of the first  $\eta$  machines in  $(\bar{w}, \bar{z})$ .  $v_t^*$  is the remaining demand satisfied by machine instance  $t$  of  $(w^*, z^*)$ . It is easy to see that,  $\sum_{t \leq \eta} \bar{u}_t = \sum_t u_t^*$ . We show that  $2 \sum_{t \leq \eta} \bar{u}_t \geq \sum_{t \leq \eta} v_t^*$ . Suppose, for the sake of contradiction, that the claim is false. Then for some  $t$ ,  $2\bar{z}_{\tau+1,\sigma,i,j} < v_t^*$ . However, since  $v^*$  represents demand not satisfied by  $(\bar{w}, \bar{z})$  in the first  $\eta$  machines, and since the machine  $\mu_{\max}$  in Algorithm 3 has throughput at least half of the maximum (proved below), in this case the throughput of  $\mu_{\max}$  would be at least  $v_t^*$ . This is a contradiction.

We now show that, when Algorithm 3 constructs  $\mu_{\max}$ , its throughput is at least half the throughput of the highest throughput machine possible. Let  $\sigma$  be the configuration used by  $\mu_{\max}$ . We show that the maximum throughput machine  $\mu^*$  over  $\sigma$  has throughput no more than twice that of  $\mu_{\max}$ . We consider an integer program formulation of the problem of finding the maximum throughput machine:  $w_j \leq d_j$ ,  $j \in J$  and  $w_j \leq \sum_i z_{i,j} f_j(i)$ ,  $j \in J$  and  $\sum_j z_{i,j} \leq \sigma_i$ ,  $i \in B$ .

The set  $B$  includes all block instances in  $\sigma$ . Let  $(w^*, z^*)$  represent the solution to this program given by the optimal machine  $\mu^*$ . Let  $(\bar{w}, \bar{z})$  represent the solution to this program given by  $\mu_{\max}$ . For each block  $i$ , we set  $u_i$  and  $v_i$  to be any values that satisfy the following equations.  $u_i + v_i = \sum_j z_{i,j}^* f_j(i)$ ,  $i \in [k]$  and  $\sum_i v_i = \sum_j w_j^* - \sum_{i,j} \bar{z}_{i,j} f_j(i)$  and  $\sum_i u_i = \sum_j w_j^* - \sum_i v_i$ . Informally,  $u_i$  is the amount of demand satisfied by block  $i$  of  $\mu^*$  that is also satisfied by  $\mu_{\max}$ , and  $v_i$  is the amount of demand satisfied by block  $i$  of  $\mu^*$  that is not satisfied by  $\mu_{\max}$ . For any block  $i$ , it is easy to see that  $\sum_j \bar{z}_{i,j} \geq u_i$ . We can also infer that  $\sum_j \bar{z}_{i,j} \geq v_i$  because, otherwise, the greedy algorithm would have chosen to execute the same job as  $\mu$  on block  $i$ . This proves the result.

Since  $\sum_{t \leq \eta} \bar{u}_t = \sum_t u_t^*$  and  $4 \sum_{t \leq \eta} \bar{u}_t \geq \sum_t v_t^*$ , the total demand satisfied by  $(\bar{w}, \bar{z})$  is at least 1/4 the total demand. It is straightforward to generalize this reasoning to show that every  $\eta$  machine instances of  $(\bar{w}, \bar{z})$ , reduce the total demand by a factor of 1/4, which proves our claim. ◀

## 22:10 Scheduling Splittable Jobs on Configurable Machines

► **Theorem 3.** *Algorithm 1 returns an  $O(\log(\max_{\sigma \in C}\{|\sigma|\} \cdot n \cdot k))$  approximation to the CMS problem.*

**Proof.** Let  $S$  and  $S'$  represent the schedules produced by Algorithm 2 and Algorithm 3, respectively. We first argue that  $S$  has length  $O(\log(\max_{\sigma}\{|\sigma|\} \cdot n)) \cdot \text{OPT}$ . Algorithm 2 reduces scheduling the integer components of the variables to an instance of multi-set multi-cover in which there are  $n$  elements and the largest covering multi-set has size  $\max_{\sigma}\{|\sigma|\}$ . The claim follows directly from Theorem 5.1 in [15].

We now show that  $S'$  has length  $O(\log(\max_{\sigma}\{|\sigma|\} \cdot nk)) \cdot \text{OPT}$ . By Lemma 2, we need only to show that  $d_j \leq \sum_i f_j(i)$  and that  $\max_{j,i,i'}\{f_j(i)/f_j(i')\} = O(k)$ . We can infer  $d_j \leq \sum_i f_j(i)$  because  $(C, J, k)$  with modified demand tables and demands  $\hat{f}, \hat{d}$  is defined over  $\hat{x}$ , so each job can be completely executed by one block of each type. Also, the definition of  $\hat{x}$  entails that for each  $j$ , every nonzero value of  $\hat{x}_{i,j}$  (resp.  $\hat{f}_j(i) \cdot \hat{x}_{i,j}$ ) is within a factor of  $2k$  (resp.  $k$ ) of every other.

Finally, in defining  $\hat{x}$ , we rounded down  $x_{i,j}^*$  if (i)  $z_{i,j}^* < 1/2k$  or if (ii)  $z_{i,j}^* \cdot f_j(i) < \max_{i'}\{z_{i',j}^* \cdot f_j(i')\}/k$ . Job  $j$ 's total reduction in demand from (i) is no more than  $d_j \sum_i x_{i,j}^* - \bar{x}_{i,j} \leq d_j/2$ , which is accounted for by doubling  $S_1$  and  $S_2$  in the output. Job  $j$ 's total reduction in demand due to (ii) is at most  $\max_{i'}\{z_{i',j}^* \cdot f_j(i')\}$  which is accounted for in setting  $\hat{x}_{i,j} = 2z_{i,j}^*$  for all remaining  $i$ 's. Each doubles our approximation ratio. ◀

### 3 CMS with a constant number of configurations

We consider CMS with  $n$  jobs and a set  $C$  of  $O(1)$  configurations, each of arbitrary size. We first observe that the problem is NP-hard to approximate to within a factor of two.

► **Lemma 4.** *CMS with a constant number of configurations is hard to approximate to within a factor of 2.*

**Proof.** We present a reduction from Partition to combinatorial CMS. Given an instance of Partition with a set  $S$  of  $n$  elements  $0 < a_1 < a_2 < \dots < a_n$ , we construct the following instance. We consider one configuration that contains  $n$  blocks all of a different type, labeled  $1, \dots, n$ . We have two jobs  $j_1, j_2$ , both with the demand function given by  $f(i) = a_i$ . The demand for each job is  $\frac{1}{2} \sum_i a_i$ .

We claim that the number of machines needed for scheduling the job is one if and only if the Partition instance has a yes answer. If the Partition instance has a yes answer, then there exists a way to split the  $n$  blocks into two parts so that each part's value adds up to  $\sum_i a_i/2$ . We use one machine, and assign the blocks to each job according to the Partition solution. The demand function ensures that the demand of the job is satisfied. Conversely, if the demand of the two jobs is satisfied by one machine, then each job has at least  $\sum_i a_i/2$  demand satisfied. According to the demand function  $f$ ,  $\sum_i a_i$  is the maximum amount of demand that can be satisfied by this configuration. Thus each job has exactly  $\sum_i a_i/2$  demand satisfied, and so there is some partition of  $S$  into two parts such that each part sums to  $\sum_i a_i/2$ . ◀

Our main result in this section is a polynomial time algorithm that returns a solution with cost the minimum of  $(2 + \epsilon)\text{OPT} + |C|$  and  $(3 + \epsilon)\text{OPT}$ , for arbitrary  $\epsilon > 0$ , where OPT is optimal cost. Our algorithm, detailed in Algorithm 4, guesses the number of each configuration used in an optimal solution, to within a factor of  $1 + \epsilon$  (see line 3), and then builds on the paradigm of [9] by carefully rounding an extreme-point optimal solution for a suitable instantiation of LP(1-4) (given in line 5).

■ **Algorithm 4** Schedule for CMS with  $O(1)$  configurations.

---

Using extreme-point properties, we establish Lemma 5, the proof of which closely follows [9].

► **Lemma 5.** *Every component in graph  $G$  of line 7 has at most one cycle.*

**Proof.** This proof follows a similar structure as the proof of Lemma 17.6 in [18]. We will use a proof by contradiction. First, consider a component in  $G$ , called  $G_c$ . Then consider the restriction of the LP,  $LP_c$ , to only the jobs and block types present in the component. Also let  $x_c$  be the restriction of  $x$  to those jobs and blocks present in the component. Let  $x_{\bar{c}}$  be the rest of  $x$ . Note that  $x_c$  is a feasible solution to  $LP_c$  since all the blocks that satisfy demand for jobs in  $G_c$  are connected to those jobs in the original graph  $G$  and thus are also included in  $G_c$ , so we continue to satisfy all the demand for these jobs. Now assume for contradiction that  $x_c$  is not an extreme point in  $LP_c$ . Then  $\exists x_1, x_2, \lambda$  where  $x_1$  and  $x_2$  are feasible solutions to  $LP_c$  and  $\lambda \in (0, 1)$  such that we have  $x_c = \lambda \cdot x_1 + (1 - \lambda) \cdot x_2$ .

Now we show that  $x_1 + x_{\bar{c}}$  and  $x_2 + x_{\bar{c}}$  are feasible solutions to the LP. First, consider that  $x_1, x_2$  have disjoint jobs and block types from  $x_{\bar{c}}$ . Thus, we can consider their corresponding constraints separately. Furthermore, together,  $x_1, x_2$ , and  $x_c$  cover all the constraints (since they cover all jobs and block types). Thus we need only verify that  $x_1, x_2$  satisfy their

## 22:12 Scheduling Splittable Jobs on Configurable Machines

constraints, and  $x_{\bar{c}}$  satisfies its constraints. Since  $x_1, x_2$  are feasible solutions to  $LP_c$  we know they satisfy the constraints in  $LP$  relevant to them. And since  $x_{\bar{c}}$  is part of the feasible solution  $x$ , it must also satisfy the constraints relevant to it. Between the two, all the constraints of the  $LP$  are satisfied, since together they cover all jobs and blocks.

But then since  $x = \lambda \cdot (x_1 + x_{\bar{c}}) + (1 - \lambda) \cdot (x_2 + x_{\bar{c}})$  we can say that  $x$  is a convex combination of two other solutions. Thus,  $x$  is not an extreme point solution. But, since  $x$  is an extreme point solution, we reach a contradiction.

Therefore,  $x_c$  must be an extreme point solution in  $LP_c$ . We know that the number of tight constraints in an extreme point solution is at least as many as the number of variables. Thus at most  $|B_c^*| + |J_c|$  constraints can be not tight (coming from constraints 1' and 2). Since we create an edge only if an  $x$  variable is nonzero, or equivalently, its nonzero constraint is not tight, we know that the number of edges in  $G_c$  must be at most the number of blocks + jobs in  $G_c$ . In other words, the number of edges is at most the number of nodes. Since  $C$  was chosen arbitrarily, we conclude that every component in  $G$  has at most one cycle. ◀

► **Lemma 6.** *Algorithm 4 returns a feasible integer solution to LP(1-4).*

**Proof.** Since the algorithm returns the least cost rounded solution over all iterations, we need to show that  $(x^*, y^*)$  is a feasible integer solution to LP(1-4). By our rounding,  $x_{i,j}^*$  and  $y_{\sigma}^*$  are integers for each  $i, j, \sigma$ . It remains to show that  $(x^*, y^*)$  is feasible in LP(1-4). Constraints 3 and 4 are true by definition of  $x^*, y^*$ .

We now consider constraint 1. If a block type  $i$  is not in  $B^*$ , then this constraint is satisfied because  $x_{i,j} = 0$  for all  $j$ , and thus  $x_{i,j}^* = 0$  for all  $j$ . Now we consider blocks that are in  $B^*$ . By Lemma 5, each component of  $G$  has at most one cycle. In the algorithm we remove an edge from each of these cycles, so the resulting graph is a forest. Thus each block type  $i$  has one parent and so is a child of one job. This means that all  $x_{i,j}$  variables associated with block  $i$  are rounded as  $\lfloor 2x_{i,j} \rfloor$ , except for the parent of  $i$ ,  $p_i$ . So

$$\begin{aligned} \sum_j x_{i,j}^* &= \sum_{j \neq p_i} \lfloor 2x_{i,j} \rfloor + \lceil 2x_{i,p_i} \rceil \leq \sum_j 2x_{i,j} + 1 \leq \sum_{\sigma \in C^*} 2m_{\sigma} \cdot \sigma_i + 1 \\ &\leq \sum_{\sigma \in C^*} (2m_{\sigma} + 1) \cdot \sigma_i \leq \sum_{\sigma \in C} y_{\sigma}^* \cdot \sigma_i \end{aligned}$$

The third inequality follows from constraint 1' since  $x$  satisfies  $LP_f$ , and the fourth inequality holds since  $i \in B^*$  implying that there is at least one  $\sigma \in C^*$  with  $\sigma_i \geq 1$ . Thus, constraint 1 is satisfied.

Now, we consider constraint 2. First, we consider some job  $j$  whose edge was not removed. Then, since  $G$  becomes a forest after pruning edges we obtain that either the children or the parent of  $j$  satisfy at least half of its demand. If its children satisfy at least half of its demand then we have  $\sum_{\text{children of } j} f_j(i) \cdot x_{i,j} \geq \frac{1}{2}d_j$  and thus we obtain

$$\sum_i f_j(i) \cdot x_{i,j}^* \geq \sum_{\text{children of } j} f_j(i) \cdot \lfloor 2x_{i,j} \rfloor \geq 2 \sum_{\text{children of } j} f_j(i) \cdot x_{i,j} \geq d_j,$$

Therefore, the constraint is satisfied. Otherwise, its parent  $p$  satisfies at least half of its demand implying that  $x_{p,j} \geq \frac{1}{2}$  since we have  $f_j(p) \leq d_j$  by our assumption on the input. Then,  $x_{p,j}^* = \lfloor 2x_{p,j} \rfloor > x_{p,j}$ , yielding  $\sum_i x_{i,j}^* \cdot f_j(i) \geq \sum_i x_{i,j} \cdot f_j(i) \geq d_j$  since  $x$  is a feasible solution to  $LP_f$ . So the constraint is satisfied.

Finally, we consider any job  $j$  that had an edge removed in the cycle. Assume without loss of generality that  $(b_2, j)$  was removed from the graph. Since  $j$  is the root of the tree it is in (by line 11), all of its neighboring blocks are its children. Then, we have

$$\begin{aligned} \sum_i x_{i,j}^* \cdot f_j(i) &= \sum_{i \neq b_2} \lceil 2x_{i,j} \rceil \cdot f_j(i) \geq x_{b_1,j} \cdot f_j(b_1) + x_{b_2,j} \cdot f_j(b_2) + \sum_{i \neq b_1, b_2} 2x_{i,j} \cdot f_j(i) \\ &\geq \sum_i x_{i,j} \cdot f_j(i) \geq d_j. \end{aligned}$$

The second inequality comes as a consequence of line 10 and the fact  $(b_2, j)$  was removed from the graph, which implies that  $2x_{b_1,j} \cdot f_j(b_1) \geq x_{b_1,j} \cdot f_j(b_1) + x_{b_2,j} \cdot f_j(b_2)$ . So the constraint is satisfied in all cases. Thus  $(x^*, y^*)$  is a feasible integer solution to LP(1-4). ◀

► **Theorem 7.** *Algorithm 4 returns a  $\min\{(3 + \varepsilon)\text{OPT}, (2 + \varepsilon)\text{OPT} + |C|\}$  approximation to the CMS problem in polynomial time if the number of configurations is constant.*

**Proof.** We show that the algorithm returns a solution with the stated approximation factor. Consider the iteration where  $C^* = C^{\text{OPT}}$  where  $C^{\text{OPT}}$  is the set of configurations used by an optimal integer solution. The algorithm will iterate through potential counts  $m_\sigma$  for each  $\sigma$  in  $C^*$ , round and return a schedule the first time  $LP_f$  has a feasible solution; let  $m$  be the vector of how many configurations are used in this iteration. By Lemma 6, the solution returned is feasible.

We now bound the cost by first arguing that  $\sum_\sigma m_\sigma \leq (1 + \varepsilon)\text{OPT}$ . Observe that the  $y$  values in the optimal integer solution to LP(1-4) would yield a feasible solution to  $LP_f$  if they equalled the corresponding  $m$  values in  $LP_f$  (namely by setting the  $x$  variables in  $LP_f$  to the  $x$  values in the optimal integer solution to LP(1-4)). For each such  $y_i$  value, consider  $p_i$ , the first power of  $1 + \varepsilon$  that is at least  $y_i$ . Then, we have  $y_i \leq \lfloor p_i \rfloor \leq (1 + \varepsilon)y_i$ . By definition of  $L$ , we will set values for  $m_\sigma$  such that they are greater than and within a factor of  $(1 + \varepsilon)$  of the  $y$  values from the optimal integer solution. Thus they will be feasible, since they use at least as many of each configuration and  $\sum_\sigma m_\sigma \leq (1 + \varepsilon)\text{OPT}$ . Since we iterate through the  $m$  values in increasing order of  $\sum_\sigma m_\sigma$ , the first feasible solution will use at most this many configurations.

Now consider that the rounded solution  $y^*$  has  $\sum_\sigma y_\sigma^* \leq \sum_\sigma (2m_\sigma + 1) = 2\sum_\sigma m_\sigma + |C^{\text{OPT}}| \leq 2(1 + \varepsilon)\text{OPT} + |C^{\text{OPT}}|$ . Since the optimal integer solution uses at least 1 of each configuration in  $C^{\text{OPT}}$ , we have that  $\sum_\sigma y_\sigma^* \leq (3 + \varepsilon)\text{OPT}$  and also that  $\sum_\sigma y_\sigma^* \leq (2 + \varepsilon)\text{OPT} + |C|$ .

Finally, we prove that the runtime of algorithm 4 is polynomial if  $|C| = O(1)$ . The first for loop in the algorithm ranges over  $2^{|C|}$  values. The inner for loop ranges over  $(\log L)^{|C^*|}$  values. Remember that  $L = \sum_j d_j$ . But then  $L \leq n \cdot \max_j d_j$ . Thus the inner loop ranges over  $\leq (\log(n \cdot \max_j d_j))^{|C^*|} \leq (\log n + \log \max_j d_j)^{|C|}$  values. Since  $d_j$  is specified as a number, it is specified using  $\log d_j$  bits. Thus the inner loop runs a number of times polynomial in the input, except for the number of configurations. Lastly we analyze the body of the inner for loop. The size of the LP is polynomial in the size of the input, and thus constructing and solving it takes time polynomial in the size of the input. Constructing the graph takes time polynomial in the size of the LP, as does rounding using the graph. Thus overall the runtime of the algorithm is polynomial in the size of the input, except for it being exponential in the number of configurations. So if  $|C| = O(1)$ , the algorithm is polynomial. ◀

#### 4 CMS with a constant number of configurations of constant size

In this section, we consider CMS with  $n$  jobs, a set  $C$  of a constant number of configurations with the additional constraint that each configuration has at most a constant number  $b$  of blocks. Let  $k$  be the total number of block types. Since  $|C|$  and  $b$  are both constant,  $k \leq b|C|$  is a constant. In Section 4.2, we present our main result of this section, a PTAS for the problem. As a warmup, in Section 4.1, we present an optimal dynamic programming algorithm for the problem, which takes time  $(nbd_{\max})^{O(k+|C|)}$ ; this is pseudo-polynomial time for constant  $k$  and  $|C|$ .

##### 4.1 A pseudo-polynomial time algorithm

We present an optimal dynamic programming algorithm that takes time polynomial in  $n$  and the maximum demand. Recall that  $C$  denotes the set of configurations, and  $|C|$  is constant. Let  $N$  denote the total number of machines. Then, there are  $\binom{N+|C|-1}{|C|-1}$  ways of distributing the  $N$  machines among these configurations. Each way yields a specific number of blocks of each type. For given  $n_i$ ,  $1 \leq i \leq k$ , let  $S(j, n_1, n_2, \dots, n_k)$  be True if the demand of jobs 1 through  $j$  can be satisfied using  $n_i$  blocks of type  $i$ , for each  $i$ . Then, we have

$$S(j, n_1, n_2, \dots, n_k) = \bigvee_{m_i \leq n_i, \forall i} (S(j-1, n_1 - m_1, n_2 - m_2, \dots, n_k - m_k) \wedge T(j, m_1, m_2, \dots, m_k))$$

where  $T(j, m_1, m_2, \dots, m_k)$  is true if and only if  $d_j$  can be satisfied using  $m_i$  blocks of type  $i$ , for each  $i$ . Note that  $T(j, m_1, m_2, \dots, m_k)$  can be computed easily by inspecting the demand table of job  $j$  and  $d_j$ .

The algorithm computes  $S(j, n_1, n_2, \dots, n_k)$  for  $1 \leq j \leq n$ ,  $n_i \leq Nb$ ; the number of different tuples equals  $n(Nb)^k$ . The time taken to compute a given  $S(j, n_1, n_2, \dots, n_k)$ , given  $S(j-1, n_1 - m_1, n_2 - m_2, \dots, n_k - m_k)$  for all choices of  $m_i$ 's, is proportional to the number of different choices of  $m_i$ 's, which is bounded by  $\binom{N+|C|-1}{|C|-1}$ . We thus obtain that  $S$  can be computed in  $n(Nb)^{O(k+|C|)}$ . This computation, coupled with a binary search over possible values of  $N$ , yields the desired algorithm. Since  $N$  is bounded by  $n$  times the maximum demand, we obtain a pseudopolynomial time optimal algorithm if  $|C|$  and  $k$  are bounded.

##### 4.2 A polynomial-time approximation scheme

*Blocks and patterns.* Abusing notation slightly, we use  $f_j(\sigma)$  to denote the total demand of  $j$  satisfied if every block in configuration  $\sigma$  is assigned to  $j$ . We partition the set  $J$  of jobs into two groups: the *large* jobs  $L$  and *small* jobs  $S$ . A job  $j$  is small if there exists a configuration  $\sigma$  such that  $f_j(\sigma) \geq \varepsilon d_j$ ; otherwise,  $j$  is large.

Let  $\varepsilon > 0$  be a given constant parameter, and let  $\lambda = \varepsilon/(2b)$ . We define a *pattern*  $\pi$  to be a size  $k$  list of integers  $\pi_1$  through  $\pi_k$  that sum to no more than  $b/\lambda^2$ ;  $\pi_i$  denotes the number of blocks  $i$  in pattern  $\pi$ . Let  $W$  be the set of all possible patterns. So,  $|W| \leq (b/\lambda^2)^k$ . We assign each small job a *type*. Job  $j$  is of type  $t \in 2^W$  if each pattern  $\pi \in t$  is such that the demand of  $j$  is satisfied if  $j$  is allocated  $\pi_i$  blocks  $i$  for  $1 \leq i \leq k$ . So, the number of job types is at most  $2^{(b/\lambda^2)^k}$ . Define constant  $\gamma = 2^{(b/\lambda^2)^k}$ .

*The linear program.* We define a linear program PTAS-LP using the following notation. In PTAS-LP,  $\sigma$  ranges over all configurations in  $C$ ,  $p \in \{1, \dots, k\}$  ranges over types of blocks,  $x_{j,p}$  is the number of  $p$ -blocks dedicated to processing a large job  $j$ ,  $y_\sigma$  is the number of

machines we use with configuration  $\sigma$ ,  $\sigma_p$  is the number of  $p$ -blocks in  $\sigma$ ,  $z_{t,\pi}$  is the number of small jobs of type  $t$  that are distributed according to pattern  $\pi$ , and  $n_t$  is the number of small jobs of type  $t$ . Recall that  $\pi_p$  is the  $p$ th entry of  $\pi$ . PTAS-LP minimizes  $\sum_{\sigma \in C} y_\sigma$  subject to the following constraints

$$\sum_{j \in L} x_{i,j} + \sum_{t \in 2^W} \sum_{\pi \in W} (z_{t,\pi} \cdot \pi_i) \leq \sum_{\sigma} y_\sigma \cdot \sigma_i \quad i \in [k] \quad (5)$$

$$\sum_{i \in [k]} f_j(p) \cdot x_{i,j} \geq d_j \quad j \in L \quad (6)$$

$$\sum_{\pi} z_{t,\pi} \geq n_t \quad t \in 2^W \quad (7)$$

$$x_{i,j}, y_\sigma, z_{t,\pi} \geq 0 \quad j \in L, i \in [k], \sigma, t \in 2^W, \pi \in W \quad (8)$$

**Constraints.** Constraint 5 guarantees that the number of blocks  $i$  that are used to execute jobs is at most the number of available blocks  $i$ . Constraint 6 ensures that each large job is fully executed, and constraint 7 guarantees that each small job is fully executed. Constraint 8 ensures non-negativity.

Lemma 8 proves that it is sufficient to consider schedules in which small jobs are executed by a bounded number of blocks. Lemma 9 uses Lemma 8 and shows PTAS-LP is an approximate relaxation for the problem.

► **Lemma 8.** *For any schedule with  $m$  machines, there exists a schedule with  $m(1 + b\lambda)$  machines in which each small job is executed by at most  $b/\lambda^2$  blocks.*

**Proof.** Consider any placement  $P$  that uses  $m$  machines. Suppose a small job  $j$  is in more than  $b/\varepsilon^2$  blocks in  $P$ . Since each configuration is of size at most  $b$ , it follows that  $j$  is placed in at least  $1/\lambda^2$  machines. Since  $j$  is small, there exists a configuration  $\sigma$  such that  $f_j(\sigma) \geq \lambda d_j$ . We remove  $j$  from each machine to which it is assigned in  $P$  and place it in  $1/\lambda$  additional machines, each with configuration  $\sigma$ , guaranteeing that the demand of  $j$  is satisfied. Since each machine can hold at most  $k$  small jobs, this modification of  $P$  results in the increase in the number of machines by a factor of at most  $(1 + b\lambda)$ , yielding the desired claim. ◀

► **Lemma 9.** *The value of PTAS-LP is at most  $(1 + b\lambda)\text{OPT}$ .*

**Proof.** Let  $A$  be an optimal placement of the jobs on  $m$  machines. Using Lemma 8, we first compute a new placement  $B$  using at most  $m(1 + b\lambda)$  machines in which each small job is placed in at most  $1/\lambda^2$  machines.

We now define variable assignments so that the value of PTAS-LP is no more than  $(1 + b\lambda)m$ . For each large job  $j$  and each block  $i$ , set  $x_{i,j}$  to be the number of blocks  $i$  on which  $B$  executes  $j$ . For each small job type  $t$  and each pattern  $\pi$ , set  $z_{t,\pi}$  to be the number of small jobs that are executed in pattern  $\pi$  according to  $B$ . Note that since each small job is placed in at most  $1/\lambda^2$  machines, and hence at most  $b/\lambda^2$  blocks, the placement of each small job follows one of the patterns in  $W$ . Set  $y_\sigma$  equal to the number of machines with configuration  $\sigma$  according to  $A$ .

It is easy to see that constraints (6 - 8) are satisfied. To see that constraint 5 is satisfied, observe that each machine used by  $B$  either has some block executing a large job (in which case it contributes toward the first term of 5) or it has some block executing a small job (in which case it contributes toward the second term). Therefore, the left hand side of 5 counts the total number of blocks needed to complete all the jobs, while the right hand side computes the total number of blocks supplied by the machines. ◀

■ **Algorithm 5** Schedule for  $O(1)$  configurations of  $O(1)$  size.

---

**Input:**  $(C, J, k)$

- 1 Solve PTAS-LP; let  $(x, y, z)$  be the solution computed.
- 2 **if**  $n \leq b(|C| + \gamma)/\lambda$  **then**
- 3    └ Compute and return an optimal solution using enumeration
- 4 **foreach** large job  $j$  and block  $i$  **do**
- 5    └  $\hat{x}_{i,j} = \lceil x_{i,j} \rceil$ ; Assign  $\lceil x_{i,j} \rceil$  blocks  $i$  to job  $j$
- 6 **foreach** job type  $t$  and pattern  $\pi$  **do**
- 7    └ Assign blocks per pattern  $\pi$  to each job in  $\lceil z_{t,\pi} \rceil$  small jobs of type  $t$
- 8 **foreach** configuration  $\sigma$  **do**
- 9    └ Use  $\lceil y_\sigma \rceil$  machines with configuration  $\sigma$

---

► **Theorem 10.** *Algorithm 5 returns a  $(1+\varepsilon)$  approximation to the CMS problem in polynomial time if the number of configurations is constant and they are of constant size.*

**Proof.** First, if  $n \leq b(|C| + \gamma)/\lambda$ , then the algorithm returns an optimal solution. Otherwise, since each machine has at most  $b$  blocks, we obtain that  $\text{OPT} \geq (|C| + \gamma)/\lambda$ . We will show that the number of machines used is at most  $(1 + b\lambda)\text{OPT} + \lambda^2 b\text{OPT} + |C| + \gamma$ , which is at most  $(1 + 2b\lambda)\text{OPT} = (1 + \varepsilon)\text{OPT}$ .

Rounding up the  $x$  variables increases the number of blocks by at most the number of large jobs times the number of block types. Since each large job requires at least  $1/\lambda^2$  machines, this increase in the number of blocks is at most  $\lambda^2 b\text{OPT}$ . Rounding up the  $z$  variables adds at most  $1/\lambda^2$  blocks per small job type assigned to a given pattern, increasing the number of blocks by at most  $\gamma$ . Rounding up the  $y$  variables increases the number of machines by  $|C|$ . Taken together with the above increase in the number of blocks, each of which requires at most one machine, the total increase is bounded by  $\lambda^2 b\text{OPT} + \gamma + |C|$ . By Lemma 9, the LP optimal is at most  $(1 + b\lambda)\text{OPT}$ , yielding the desired claim.

The linear program PTAS-LP has at most  $nk + |C| + \gamma \log \gamma$  variables and  $k + n + \gamma$  linear constraints (other than the non-negativity ones), and can be solved in polynomial time. The enumeration for  $n \leq b(|C| + \gamma)/\lambda$  is constant time, while the rest of the algorithm is linear in the number of variables. The hidden constant, however, is doubly exponential in  $|C|$  and the configuration size bound  $b$ , and exponential in  $1/\varepsilon$ . ◀

## 5 CMS with $O(1)$ number jobs and block types, and all configurations up to a given size

In this section, we consider models for which we are able to obtain optimal solutions in polynomial time. For models with a constant number of jobs, blocks, and configurations, the linear program (1-4) has constant size and so can be solved as an integer program. Many models, however, do not fit this framework and require more sophisticated methods. Consider a setting where the number  $n$  of jobs is constant, as well as the number  $k$  of block types. We also assume that there exists an integer  $K$  such that the set of available configurations  $C$  includes all configurations up to size  $K$ . For example, with  $k = 2$  block types  $\{1, 2\}$  and  $K = 3$ , the set of available configurations  $C = \{\{1, 1, 1\}, \{1, 1, 2\}, \{1, 2, 2\}, \{2, 2, 2\}\}$ . In this section, we show that a class of problems, including this model, is polynomial time solvable using methods developed by Goemans and Rothvoss [5] to optimally solve bin packing with a constant number of job types.

Consistent with our initial description of the CMS model, we assume all configurations are given as input. However, the input can be reduced exponentially if configurations are given as a single parameter  $K$  indicating the size of all valid configurations. The algorithm described in this section is polynomial time in either case – that is, the algorithm’s runtime is polynomial in  $\log K$  and  $\log \max_{i,j} \{d_j/f_j(i)\}$  (assuming  $n$  and  $k$  are constant). We note that there is an easy reduction from bin packing with constant job types to this problem (when configurations are not listed individually).

Let  $P$  be the set of vectors:

$$\begin{array}{l} \left[ \begin{array}{c} u_{1,1} \\ \vdots \\ u_{k,n} \\ v_1 \\ \vdots \\ v_n \\ 1 \end{array} \right] \text{ subject to} \\ \sum_{j=1}^n \sum_{i=1}^b u_{i,j} \leq K \quad (9) \\ v_j = \sum_{i=1}^k u_{i,j} \cdot f_j(i) \quad j \in J \quad (10) \\ u_{i,j} \geq 0 \quad i \in [k], j \in J \quad (11) \\ v_j \geq 0 \quad j \in J \quad (12) \end{array}$$

Let  $Q_H$  be the set of vectors

$$\begin{array}{l} \left[ \begin{array}{c} z_{1,1} \\ \vdots \\ z_{b,n} \\ w_1 \\ \vdots \\ w_n \\ h \end{array} \right] \text{ subject to,} \\ 0 \leq h \leq H \quad (13) \\ w_j \geq d_j \quad j \in J \quad (14) \\ z_{i,j} \geq 0 \quad i \in [k], j \in J \quad (15) \end{array}$$

► **Lemma 11** (Theorem 2.2 in [5]). *Let  $N = nk + n + 1$ . Given rational polyhedra  $P, Q \in \mathbb{R}^N$  where  $P$  is bounded, one can find a vector  $y \in \text{int.cone}(P \cap \mathbb{Z}^N) \cap Q$  and a vector  $\lambda \in \mathbb{Z}_{\geq 0}^{|P \cap \mathbb{Z}^N|}$  such that  $y = \sum_{x \in P \cap \mathbb{Z}^N} \lambda_x x$  in time  $\text{enc}(P)^{2^{O(N)}} \cdot \text{enc}(Q)$ , or decide that no such  $y$  exists. Moreover, the support of  $\lambda$  is bounded by  $2^{2N+1}$ .*

► **Lemma 12.** *Given  $P$  and  $Q_H$ , the algorithm of Lemma 11 returns a vector  $\lambda$  iff there exists a solution using at most  $H$  machines. Moreover, a returned vector  $\lambda$  provides a solution that uses at most  $H$  machines.*

**Proof.** As in the lemma, let  $N = nk + n + 1$ . We first show that, if there exists a valid solution using at most  $H$  machines then  $\text{int.cone}(P \cap \mathbb{Z}^N) \cap Q_H \neq \emptyset$ . Suppose there exists a valid solution to the problem using at most  $H$  machines. We argue that each machine  $\mu$  corresponds to an integer valued vector in  $P$ . Consider an arbitrary machine  $\mu$  in the given solution. Recall that  $\mu(i, j)$  is the number of blocks of type  $i$  on which  $\mu$  executes job  $j$ . This implies that  $\sum_j \sum_i \mu(i, j) \leq K$ . Setting  $v_j = \sum_i \mu(i, j) \cdot f_j(i)$  ensures that the vector  $(v_1 \dots v_n \ 1 \ u_{1,1} \dots u_{b,n}) \in P$ . Let  $p_\mu$  be the vector in  $P$  corresponding to machine  $\mu$ . Let  $\lambda = (\lambda_\mu)$ , where  $\lambda_\mu$  is the multiplicity of machine  $\mu$  in the given solution. Then  $\sum_\mu \lambda_\mu \cdot p_\mu$  yields integer vector  $q = (z_{1,1} \dots z_{b,n} \ w_1 \dots w_n \ h)$ . Since every job is fully executed, we can infer that  $w_j \geq d_j$ . Since the solution uses at most  $H$  machines, we can infer that  $0 \leq h \leq H$ . Therefore,  $q \in Q$ , which implies that  $\text{int.cone}(P \cap \mathbb{Z}^N) \cap Q \neq \emptyset$ .

We now show that, if  $\text{int.cone}(P \cap \mathbb{Z}^N) \cap Q_H \neq \emptyset$ , then there exists a solution to the problem using at most  $H$  machines. Suppose there exists a vector  $q \in \text{int.cone}(P \cap \mathbb{Z}^N) \cap Q_H$ . Define  $\lambda = (\lambda_x)_{x \in P \cap \mathbb{Z}^N}$  such that  $\sum_{x \in P \cap \mathbb{Z}^N} x \cdot \lambda_x = q$ . As above, we treat each element  $x \in P \cap \mathbb{Z}^N$  as corresponding to a machine, and  $\lambda_x$  as the multiplicity of that machine in our final schedule. Similar reasoning shows that  $\lambda$  yields a valid solution, which completes the proof of the lemma. ◀

► **Theorem 13.** *Given an instance of CMS with  $O(1)$  jobs and  $O(1)$  block types, and where all configurations of size at most  $K$  are available, there exists an algorithm that computes an optimal solution in  $\text{poly}(\log K, \log \max_{i,j} \{d_j/f_j(i)\})$  time.*

**Proof.** The maximum number of machines needed in any solution is  $m = n \cdot \max_{i,j} \{d_j/f_j(i)\}$ . We binary search in the range  $[0, m]$  to find the minimum integer value of  $H$  for which the algorithm of Lemma 11, given  $P$  and  $Q_H$ , returns a vector  $\lambda$ . By Lemma 12 this provides an optimal solution. ◀

We have shown the existence of an algorithm that computes an optimal solution to CMS with  $O(1)$  number of jobs and block types, and with all configurations up to a given size. However, the Goemans-Rothvoss framework generalizes to a constant number of polytopes (Theorem 6.2 in [5]) which entails the following stronger claim.

► **Lemma 14.** *Suppose an instance of CMS has a constant number of jobs and blocks, and the set of all configurations can be specified using a set  $T$  of rational polytopes with  $|T| = O(1)$ . Then there exists an algorithm that computes an optimal solution in time polynomial in  $\log K$  and  $\log \max_{i,j} \{d_j/f_j(i)\}$ .*

To prove Lemma 14, we use the following result from Goemans and Rothvoss.

► **Lemma 15** (Theorem 6.2 in [5]). *Given rational polytopes  $\{P_t \subseteq \mathbb{R}^{nk+n+1} : t \in T\}$  and rational polyhedron  $Q \subseteq \mathbb{R}^{n+1}$ , define  $X_t := \{x \in \mathbb{Z}^{n+1} : \exists y \in \mathbb{Z}^{nb}, (x, y) \in P_t\}$ . Then there is an algorithm that decides correctly whether  $\text{int.cone}(\bigcup_{t \in T} X_t) \cap Q \neq \emptyset$  in time  $(\text{enc}(P))^{2^{O(nk+n+1+|T|)}} \cdot \text{enc}(Q)^{O(1)}$ . In the affirmative case, the algorithm provides a vector  $\lambda = (\lambda_{t,x})_{t \in T, x \in X}$  with  $\lambda_{t,x} \in \mathbb{Z}_{\geq 0}$  and  $(\sum_{t \in T} \sum_{x \in X} \lambda_x \cdot x) \in Q$ . Moreover, the size of the support of  $\lambda$  is bounded by  $2^{2(nk+n+1+|T|)+1}$ .*

**Proof of Lemma 14.** For each  $t \in T$ , we specify  $P_t$  as an  $nk + n + 1$  length vector as above, except the polytope is defined by arbitrary rational constraints specific to  $P_t$ .  $Q_H$  is defined as above. As in Lemma 12, we argue the following claim: given  $\{P_t\}_{t \in T}$  and  $Q_H$ , the algorithm of Lemma 15 returns a vector  $\lambda$  iff there exists a solution using at most  $H$  machines. Moreover, a returned vector  $\lambda$  provides a solution that uses at most  $H$  machines. The reasoning is similar to that used in Lemma 12.

Let  $X_t$  be defined as in the lemma, for all  $t \in T$ . If there is a valid solution then for each machine  $\mu$  there is some  $t$  such that  $\mu$  can be represented as an element  $p$  of  $P_t$ . Also, we define  $\lambda = (\lambda_{t,p})_{t \in T, p \in X}$  such that  $\lambda_{t,p}$  provides the multiplicity of the machine corresponding to  $p$  in the solution. The fact that we begin with a valid solution on at most  $H$  machines ensures that  $\sum_{t \in T} \sum_{x \in X} x \cdot \lambda_{t,x} \in Q_H$ . In the other direction, we show that if the algorithm returns a vector  $\lambda$ , then  $\lambda$  provides a solution to the problem. As above, we can interpret  $\lambda_{t,x}$  as providing the multiplicity of the machine corresponding to  $x \in X$  in our solution – since there exists  $y$  such that  $(x, y) \in P_t$ , we can infer that  $x$  is a valid machine. By the constraints on  $Q_H$ , we can infer that the derived solution completes all jobs and uses at most  $H$  machines. This proves the lemma. ◀

## A Constructing Schedules of Polynomial Size

For any schedule  $S$  with  $m$  machine instances, there exists a multiset of configurations  $T$  used in  $S$  and, for each job  $j$ , a multiset of blocks  $T_j$  used in  $S$ . Note both  $\text{enc}(T)$  and  $\text{enc}(T_j)$ , for every  $j$ , are polynomial in  $|C|$ ,  $|J|$ , and  $k$ , where  $\text{enc}(A)$  denotes the binary encoding length of a multiset  $A$ .

► **Lemma 16.** *Given a multiset of configurations  $T$  and, for each job  $j$ , a multiset of blocks  $T_j$ , we can output a schedule  $M$  such that (i) the number of block instances across all machines instances in  $M$  is at least the number of block instances in  $T$ , (ii) the multiset of blocks assigned to each job  $j$  across all machine instances in  $M$  is identical to  $T_j$ , and (iii) the description of  $M$  has length polynomial in  $\text{unique}(T) + \sum_j \text{unique}(T_j)$ , where  $\text{unique}(A)$  denotes the number of distinct elements in multiset  $A$ .*

**Proof.** We construct  $M$  via Algorithm 6. We show that the number of different machines in the schedule produced by Algorithm 6 is polynomial in  $|T| + \sum_j |T_j|$ . A new machine is constructed in each iteration of the while-loop. In a single iteration of the while-loop, machines are allocated until condition (i) or condition (ii) holds. By the line 10 and 11 updates, the number of times these conditions can be met is at most  $\text{unique}(T) + \sum_j \text{unique}(T_j)$ . This proves the claim. ◀

## Abstract

We generalize the classical nuts and bolts problem to a setting where the input is a collection of  $n$  nuts and  $m$  bolts, and there is no promise of any matching pairs. It is not allowed to compare a nut directly with a nut or a bolt directly with a bolt, and the goal is to perform the fewest nut-bolt comparisons to discover the partial order between the nuts and bolts. We term this problem *bipartite sorting*.

We show that instances of bipartite sorting of the same size exhibit a wide range of complexity, and propose to perform a fine-grained analysis for this problem. We rule out straightforward notions of instance-optimality as being too stringent, and adopt a *neighborhood-based* definition. Our definition may be of independent interest as a unifying lens for instance-optimal algorithms for other static problems existing in literature. This includes problems like sorting (Estivill-Castro and Woods, ACM Comput. Surv. 1992), convex hull (Afshani, Barbay and Chan, JACM 2017), adaptive joins (Demaine, López-Ortiz and Munro, SODA 2000), and the recent concept of universal optimality for graphs (Haeupler, Hladík, Rozhoň, Tarjan and Tětek, 2023).

As our main result on bipartite sorting, we give a randomized algorithm that is within a factor of  $O(\log^3(n+m))$  of being instance-optimal w.h.p., with respect to the neighborhood-based definition.

As our second contribution, we generalize bipartite sorting to DAG sorting, when the underlying DAG is not necessarily bipartite. As an unexpected consequence of a simple algorithm for DAG sorting, we rule out a potential lower bound on the widely-studied problem of *sorting with priced information*, posed by (Charikar, Fagin, Guruswami, Kleinberg, Raghavan and Sahai, STOC 2000). In this problem, comparing keys  $i$  and  $j$  has a known cost  $c_{ij} \in \mathbb{R}^+ \cup \{\infty\}$ , and the goal is to sort the keys in an instance-optimal way, by keeping the total cost of an algorithm as close as possible to  $\sum_{i=1}^{n-1} c_{x(i)x(i+1)}$ . Here  $x(1) < \dots < x(n)$  is the sorted order. While several special cases of cost functions have received a lot of attention in the community, no progress on the general version with arbitrary costs has been reported so far. One reason for this lack of progress seems to be a widely-cited  $\Omega(n)$  lower bound on the competitive ratio for *finding the maximum*. This  $\Omega(n)$  lower bound by (Gupta and Kumar, FOCS 2000) uses costs in  $\{0, 1, n, \infty\}$ , and although not extended to sorting, this barrier seems to have stalled any progress on the general cost case.

We rule out such a potential lower bound by showing the existence of an algorithm with a  $\tilde{O}(n^{3/4})$  competitive ratio for the  $\{0, 1, n, \infty\}$  cost version. This generalizes the setting of *generalized sorting* proposed by (Huang, Kannan and Khanna, FOCS 2011), where the costs are either 1 or infinity, and the cost of the cheapest proof is always  $n-1$ .

## 1 Introduction

The classic nuts-and-bolts problem, originally mentioned as an exercise in [27], asks: a disorganized carpenter has  $n$  nuts and  $n$  bolts, and there is (perfect) matching bolt for every nut. The only allowed comparison is between a nut and a bolt, and the result of such a comparison is either  $<$ ,  $=$  or  $>$ . The goal is to find the matching without comparing two nuts or two bolts to each other. A simple Quicksort type algorithm can be shown to solve this problem in optimal  $O(n \log n)$  comparisons with high probability: Pick a random nut, compare to all bolts, find the matching bolt, and compare that bolt to all nuts. The problem is now partitioned into two subproblems with the match at the boundary; recurse. In a later work [3], Alon, Blum, Fiat, Kannan, Naor and Ostrovsky developed a deterministic Quicksort-type algorithm that uses expanders and performs  $O(n \text{ polylog } n)$  comparisons. This was later improved to an optimal  $O(n \log n)$  comparisons by Komlós, Ma, Szémeredi [24], by performing substantial modifications on AKS sorting.

Our starting point is a remark by Komlós, Ma and Szémeredi: “In particular, the fact that we can sort the nuts and bolts at all relies on the fact that there is a match between them.” Indeed, if there is no matching (all comparisons come out  $<$  or  $>$ ), one realizes that the above randomized Quicksort based algorithm fails, as there is no partitioning into subproblems. The only case where sorting without a matching is possible is when nuts and bolts alternate in the final sorted order. Call this the perfectly interleaved case. Komlós, Ma and Szémeredi observed (in a private communication with Aumann) that their AKS sorting-based algorithm sorts the nuts and bolts using  $O(n \log n)$  comparisons in this setting<sup>1</sup>. However, a general instance may not be perfectly interleaved, and this setting was left open.

**Generalized Nuts and Bolts.** We focus on the problem alluded to by Komlós, Ma, and Szémeredi: what if the carpenter is completely disorganized, and has an unequal collection of nuts and bolts, without any matching pairs<sup>2</sup>? That is, assume the carpenter has a set  $R$  of  $n$  nuts and a set  $B$  of  $m$  bolts, and is only allowed to compare a nut to a bolt, and the result is either  $<$ , or  $>$ . Unless  $m = n$  and we are in the perfectly interleaved case, sorting  $R \cup B$  is not possible: there could be two (or more) nuts (resp. bolts) that compare the same way to all the bolts (resp. nuts). A natural goal for the carpenter now is to “sort as much as you can”, i.e., partition the set of nuts  $R$  into subsets  $R_1, R_2, \dots$  such that for any  $r, r' \in R_i$  and any  $b \in B$ ,  $r$  and  $r'$  have the same order with  $b$  (either both are smaller, or both are larger), and vice-versa (see figure 1). We term this generalization of nuts and bolts as *bipartite sorting*: given the complete bipartite graph  $G = (R \cup B, E)$ , the goal is to discover the orientation<sup>3</sup> on all the edges in  $E$  by querying as few of them as possible.

**The need for fine-grained analysis.** If all nuts are smaller than all bolts, it is clear that  $nm$  comparisons are needed by any algorithm, and obviously this number of comparisons suffices for any instance. Recall that the perfectly interleaved case can be solved (in fact

<sup>1</sup> For a simple randomized algorithm that does the same, see Appendix A.1 of full version [15].

<sup>2</sup> It can be observed that having some matchings in the input only makes it easier to solve.

<sup>3</sup> An edge  $e = (u, v)$  in  $G$  is oriented as  $u\bar{v}$  if  $u < v$  in the underlying DAG.

■ **Figure 1** An example output to an instance of the bipartite sorting problem. Continuous runs of incomparable nuts and bolts are called “stripes”.

completely sorted) much faster with only  $O(n \log n)$  comparisons. Assuming for simplicity that  $m = \Theta(n)$ , the inherent complexities of instances range in  $[\tilde{O}(n), \Omega(n^2)]$ . Is there a way to define instance-optimality for bipartite sorting that captures its variety of underlying instances, and is there a good instance-optimal algorithm?

It is worthwhile to imagine the DAGs for the above two instances: if all nuts are smaller than all bolts, the DAG  $\vec{G} = (V = R \cup B, \vec{E})$  will have all edges oriented from  $R$  to  $B$ , whereas the DAG in the perfectly interleaved case will be the transitive closure of the oriented edges in the *directed Hamiltonian path corresponding to the sorted order of the nuts and the bolts*. A *transitive reduction* of a DAG is the fewest number of oriented edges that by transitivity imply all other orientations. For the first instance, the transitive reduction has size  $nm$ , whereas for the second case, it has size  $n - 1$ , and therefore if we ignore  $\log^{O(1)} n$  factors, for both instances, the sizes of their transitive reductions matches their complexity. This immediately suggests a parametrization similar to an output-sensitive setting: the number of comparisons of a good algorithm should be close to (say, within log factors of) the size of the transitive reduction of the underlying DAG.

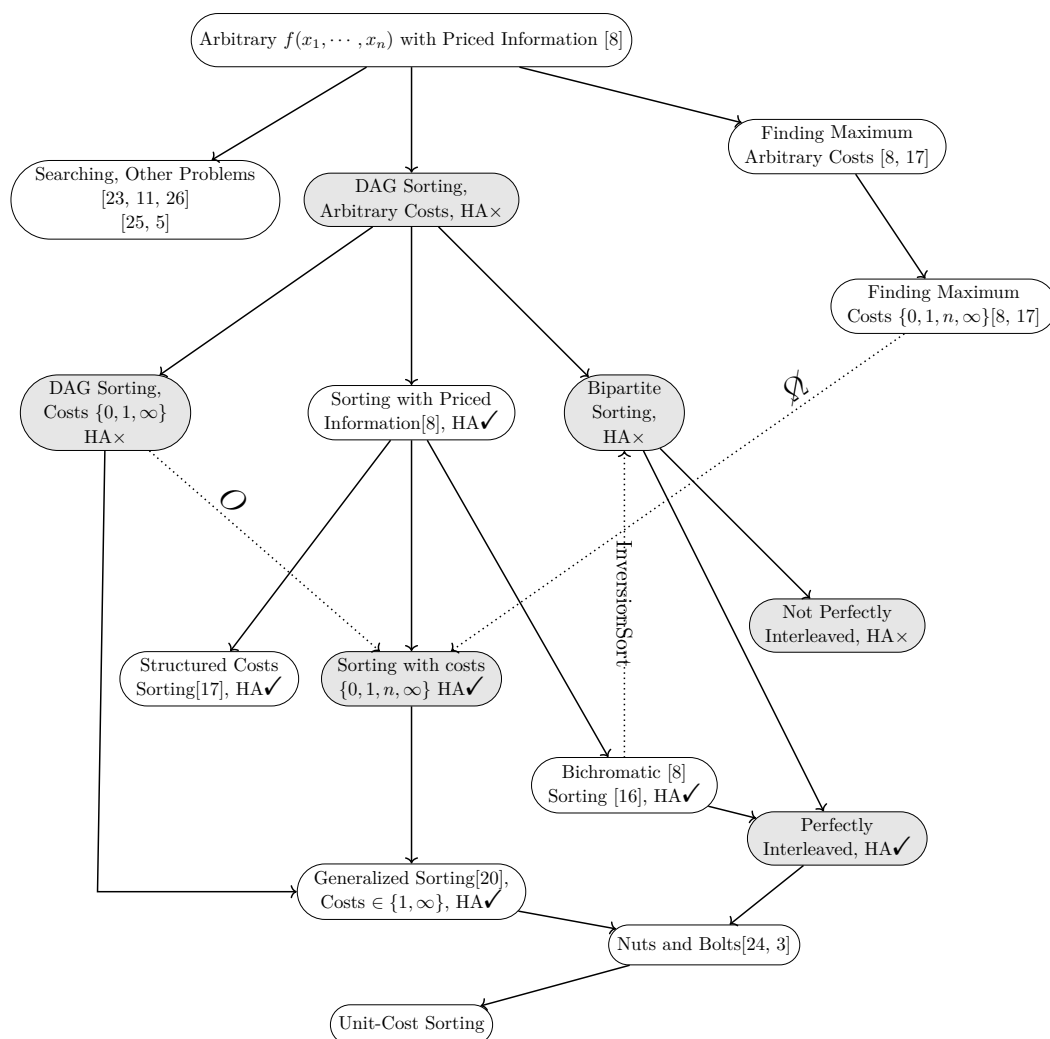

However, the following instance dashes all hopes of an algorithm that performs only roughly as many queries as there are edges in the transitive reduction:  $n - 1$  nuts are all smaller than a special bolt  $b$ , which is smaller than a special nut  $r$ , which is smaller than all other  $n - 1$  bolts. We call this the “*one-inversion*” instance. Even though the transitive reduction here has size  $2n - 1$ , any algorithm must perform  $n^2$  comparisons to find the hidden special pair  $(r, b)$ . Thus the gap between the transitive reduction and the inherent complexity of this instance is  $\Omega(n)$ , which is as large as the gap between the complexity of any two instances. Observe that the DAG for this instance is in some sense just “one-flip-away” from the all-nuts-smaller-than-all-bolts DAG, a phenomenon that will be important later. Given that the transitive reduction fails to capture the instances, we ask:

*Is there another meaningful way to define instance-optimality for bipartite sorting that captures its variety of underlying instances, and is there a good instance-optimal algorithm?*

## 2 Our Results and Technical Overview

In this paper, we answer the above question in the affirmative, and in the process of doing so, make unexpected progress on a widely-studied problem called generalized sorting (Huang, Kannan and Khanna [20]), which in turn is a special case of the sorting with priced information problem introduced by Charikar et al. [8]. We explain this connection first before stating our results.

**DAG Sorting.** One can generalize bipartite sorting to DAG sorting where the set of allowed comparisons is represented by an arbitrary (not necessarily bipartite) graph  $G = (V, E)$ . The goal is still to discover all orientations in the underlying DAG  $\vec{G} = (V, \vec{E})$  or equivalently, its transitive reduction, by querying as few edges of  $G$  as possible, where a query of an edge  $(u, v) \in E$  returns  $<$  or  $>$ . Edges not present in  $E$  cannot be queried.

■ **Figure 2** The landscape of sorting with priced information. Solid arrows go from a problem to its special case. HA✓ indicates that the Hamiltonian path is assumed to exist and HA× indicates that a Hamiltonian path may not exist. Problems shaded in gray are introduced or studied in this paper for the first time. Dotted arrows highlight our results, arrows with *O* show algorithms carrying over from one problem to another, and *Q* show lower bounds not carrying over.

It turns out that under the promise that  $\vec{G} = (V, \vec{E})$  has a directed Hamiltonian path, DAG sorting is exactly equivalent to generalized sorting. Thus both bipartite sorting<sup>4</sup> and generalized sorting can be viewed as special cases of DAG sorting. In fact, one can go a step further and assign non-negative costs to the edges in  $E$  in DAG sorting, and now ask for algorithms that find the transitive reduction with the cheapest cost. If the underlying DAG has a Hamiltonian path, this is exactly the problem of sorting with priced information.

<sup>4</sup> And by transitivity, sorting nuts and bolts when perfectly interleaved, matching nuts and bolts, and classical sorting.

## 2.1 Bipartite Sorting

As our main result, we define a meaningful notion of *instance optimality* for bipartite sorting, and give an algorithm that is instance optimal up to a factor of  $O(\log^3(n))$ . We found this (definition, algorithm) result surprising because it shows that in some sense, the “one-flip” phenomenon (recall the “one-inversion” instance) mentioned in the introduction is the *only* obstruction to achieving (almost) instance optimality. We believe our definition may be of independent interest as it unifies several previously-studied notions of instance optimality.

### 2.1.1 Defining Instance-Optimality

The transitive reduction of  $\vec{G}$ , denoted as  $\vec{T}$ , can be thought of as the “cheapest proof” of the underlying DAG being  $\vec{G}$ . Such a comparison to the cheapest proof has historically been very useful in defining instance optimality. Indeed, for the problems of generalized sorting and sorting with priced information, when the transitive reduction equals the directed Hamiltonian path, the cost of this directed Hamiltonian path is the measure of instance-optimality (and the factor by which an algorithm exceeds it is called *competitive ratio* in the original work by Charikar et al.[8]). The cheapest proof appears again in the work by Demaine, López-Ortiz and Munro [10], who study the problems of comparison-based set unions, intersections and differences. However in our setting, as the one-inversion instance shows, the size of the transitive reduction  $|\vec{T}|$  is *too strong a benchmark* to compare the performance of an algorithm to.

An important work on instance optimality deviating from a comparison to cheapest proof is by [Afshani, Barbay and Chan,[1]] which studies instance optimal algorithms for the convex hull problem. This was also adopted by [Cardinal, Dallant and Iacono [6]], who studied bichromatic rectangular visibility. When  $x$  is an input sequence of points, [1] and [6] define  $OPT(x)$  to be the runtime of an algorithm that is *order-oblivious*, i.e., OPT’s code can depend on the set of elements in  $x$ , but not on their order. The fact that *some* restriction on OPT is needed (at least for static problems) follows because comparing the runtime of an algorithm  $A$  on an input  $x$  to an algorithm (OPT) that is “tailor-made” for an input  $x$  is too strong: if OPT’s code can depend on  $x$ ,  $OPT(x)$  can be very small compared to  $A(x)$ . In the convex hull problem  $OPT(x)$  would just be  $O(n)$  as OPT only needs to read the input<sup>5</sup>, and for DAG/bipartite sorting if OPT knows the underlying DAG  $\vec{G}$  then (since we only count query complexity) OPT equals zero!

We posit a “*neighborhood-based*” approach to defining notions of instance optimality. In a nutshell, we observe that most definitions for instance optimality boil down to choosing the “right” neighborhood. The smaller the neighborhood is, the stronger the notion of instance-optimality, and the harder it is to attain. If the neighborhood is the set of all instances, we are back to worst-case analysis. Thus the art is in choosing the smallest meaningful neighborhood that still allows for instance optimal algorithms. This general step-by-step process of increasing the neighborhood until one sees hope for instance-optimality reveals quite a bit about the fine-grained nature of a problem. Perhaps this way of looking at instance-optimality was already known, but since we have not seen it in print, we show (see Appendix C of the full version of this paper [15]) how most of the existing works on instance-

<sup>5</sup> [Afshani, Barbay and Chan [1]] state: “For example, consider the 2D convex hull problem, which has  $\Theta(n \log n)$  worst-case complexity in the algebraic computation tree model: for every input sequence of  $n$  points, one can easily design an algorithm  $A$  (with its code depending on the input sequence) that runs in  $O(n)$  time on that particular sequence, thus ruling out the existence of an instance-optimal algorithm.”

optimality, ranging from the classical works on adaptive sorting and presortedness [13], to later works by Demaine et al. [10] and Afshani et al. [1], and including the very recent work on universal optimality [18], all agree with this paradigm.

We define a neighborhood of the underlying DAG  $\vec{G}$ , denoted as  $\mathcal{N}(\vec{G})$ . See Definition 8 for a precise definition but intuitively, this is the set of all DAGs that are either isomorphic, or “one-flip” away from  $\vec{G}$ . Define the runtime  $T_A(\vec{G})$  of a randomized algorithm  $A$  on an instance  $\vec{G}$  as its expected comparison-cost on instance  $\vec{G}$ . Let  $\mathcal{C}(\vec{G})$  be the set of randomized (Las Vegas) algorithms that are correct for all instances in  $\mathcal{N}(\vec{G})$ . Now define

$$\text{OPT}(\vec{G}) = \inf_{A \in \mathcal{C}(\vec{G})} \max_{\vec{G}' \in \mathcal{N}(\vec{G})} T_A(\vec{G}').$$

For  $\alpha \geq 1$ , we say an algorithm  $A$  is  $\alpha$ -instance optimal if for every instance  $\vec{G}$ ,  $T_A(\vec{G}) \leq \alpha \text{OPT}(\vec{G})$ . Does there exist an algorithm achieving  $\alpha = O(1)$ , or  $\alpha = \log^{O(1)} n$ ?

### 2.1.2 InversionSort: An Almost Instance Optimal Algorithm

The algorithm we investigate for bipartite sorting is a variant of an algorithm InversionSort that was recently presented by us (Goswami and Jacob [16]) for the version when there is a sorted order on the nuts and bolts, and nuts can be compared to nuts (at a cost  $\alpha > 1$ ) and bolts can be compared to bolts (at a cost  $\beta > 1$ ). In bipartite sorting, two nuts (or two bolts) cannot be compared to each other, i.e.,  $\alpha = \beta = \infty$ , but due to the similarity to the previous algorithm we call the algorithm for bipartite sorting InversionSort too. Note that in [16] the previous algorithm was compared to the cost of the Hamiltonian, whereas now not only may the Hamiltonian cease to exist, its natural counterpart (the transitive reduction) is a weak lower bound.

As a first try, let us see what goes wrong when we apply the simple randomized QuickSort algorithm for nuts and bolts to bipartite sorting. We pick a random nut  $r$  and use it to pivot the bolts obtaining two sets  $B_{<r}$  and  $B_{>r}$ . Since no match was obtained, in the alternating step we can select a random bolt  $b$ , say from  $B_{>r}$ , and pivot the nuts, obtaining  $R_{<b}$  (containing  $r$ ) and  $R_{>b}$ . Instead of the two perfectly-partitioned subproblems obtained in nuts and bolts, we unfortunately now have three subproblems:  $(R_{<b}, B_{<r})$ ,  $(R_{<b}, B_{>r})$ , and  $(R_{>b}, B_{>r})$ .

If the nuts and bolts were perfectly interleaved, we show (see Appendix A.1 of the full version of this paper [15]) that a BFS-style Quicksort algorithm that we call BackboneSort sorts using  $O(n \log n)$  comparisons. BackboneSort works in a sequence of alternating phases, a nut-phase and a bolt-phase. In a nut phase it tries to refine the nut subproblems and makes progress over the three subproblems above in a round-robin fashion: for example, to make progress in  $(R_{<b}, B_{<r})$ , it would select a random bolt in  $B_{<r}$  and pivot  $R_{<b}$ , and vice-versa in a bolt-phase.

Unfortunately, in a general instance of bipartite sorting the nuts and bolts are not perfectly interleaved everywhere, and it turns out that BackboneSort can perform badly (see Theorem 29 of full version [15]). The reason for this behavior arises from selecting a “random” pivot in the subproblem: for the perfectly interleaved instance, its sub-instances are also perfectly interleaved (in particular all three subproblems  $(R_{<b}, B_{<r})$ ,  $(R_{<b}, B_{>r})$ , and  $(R_{>b}, B_{>r})$  can be shown to be roughly a constant fraction of the original problem with good probability), and then such a random pivot is guaranteed to be good, just like in randomized Quicksort. However, if the underlying instance is lop-sided (think of many nuts in  $R_{<b}$  sandwiched between two bolts in  $B_{<r}$ ), a random bolt is not a good pivot. To add to this complication, an instance may be lop-sided in one region and perfectly interleaved in another, and an instance-optimal algorithm should ideally be able to detect such a situation.

InversionSort proceeds similarly to BackboneSort, but instead of selecting random pivots, it performs a random comparison: when trying to make progress in  $(R_{<b}, B_{<r})$ , it will look for “inversions”, defined as a pair  $(r, b) \in R_{<b} \times B_{<r}$  such that  $b < r$ . When it finds such a pair, it uses them as pivots. The intuition is that regions having “easy” subinstances (like perfectly interleaved ones) will resolve fast, whereas those that are lop-sided, like all nuts less than all bolts, will take longer, but this is a necessary task in this sub-region.

The following theorem quantifies the performance of InversionSort. Here,  $N = n + m$  and Definition 8 is our precise definition of instance optimality, sketched in the previous section.

► **Theorem 1** (Instance Optimality of InversionSort). *There exists a constant  $c > 0$ , such that for every instance  $\mathcal{I}$ , the cost of InversionSort on  $\mathcal{I}$  is, with probability at least  $1 - 1/N$ , at most  $c(\log N)^3 \text{OPT}(\mathcal{I})$ , where  $\text{OPT}(\mathcal{I})$  is as in Definition 8.*

Thus InversionSort is  $O(\log^3 N)$ -instance optimal, with respect to a natural notion of instance-optimality that accounts for the one-flip neighborhood of the underlying DAG. We conjecture that InversionSort is actually  $O(1)$ -instance optimal with this notion<sup>6</sup>.

## 2.2 Unexpected Result: Generalized Sorting and Sorting with Priced Information

While Theorem 1 gives an algorithm for bipartite sorting that is instance-optimal, what can we say for DAG sorting? Unfortunately proving a polylog-instance optimality guarantee seems out of reach for now. The reason is that even the “sortable” case of DAG sorting, where the DAG has a directed Hamiltonian path, has a current best bound of  $\tilde{O}(n^{1.5})$  comparisons, or in other words, is a factor  $\tilde{O}(\sqrt{n})$  away from the Hamiltonian cost (which is  $n - 1$ ). This results from an interesting randomized algorithm by Huang, Kannan and Khanna [20] that uses the work by Kahn and Linial [22] on balancing extensions via the Brunn-Minkowski theorem.

For a DAG that is not sortable, we extend the algorithm of Huang, Kannan and Khanna to give an algorithm that performs  $\tilde{O}(\min(w n^{1.5}, n^2))$  comparisons and outputs the transitive reduction of  $\vec{G}$  (see Theorem 20). Here  $w$  denotes the width of the DAG, which is the size of its largest antichain (a set of incomparable elements). We now point out an unexpected consequence of this result.

The problem of *sorting with priced information* introduced by Charikar, Fagin, Guruswami, Kleinberg, Raghavan and Sahai, [8], is a generalization of the classical, unit-cost, comparison-based sorting, defined as follows. The input is a weighted undirected graph  $G$  on  $n$  vertices, with the cost  $c_{ij} \in \mathbb{R}_{\geq 0}$  on the edge  $e_{ij}$  indicating the cost to compare keys (represented by vertices)  $v_i$  and  $v_j$ . As before, edges not in  $G$  have cost  $\infty$  and cannot be queried, and a query on an edge  $e_{ij}$  reveals if  $v_i < v_j$  (indicated as  $\vec{e}_{ij}$ ) or  $v_i > v_j$  (indicated as  $\bar{e}_{ij}$ ).

Since the hidden Hamiltonian path  $\mathcal{H}$  is the cheapest proof, its cost which equals  $\sum_{i=1}^{n-1} c_{x(i)x(i+1)}$  is a lower bound. Here  $x(1) < \dots < x(n)$  is the sorted order. [8] propose finding algorithms that come as close to the cost of  $\mathcal{H}$  as possible. The *competitive ratio* is defined as the ratio of the cost of the algorithm to the cost of  $\mathcal{H}$ , and the goal is to find an algorithm with small competitive ratio.

Several special cases of cost functions have been studied, but for arbitrary costs, almost nothing is known about the above problem. Note that the  $\tilde{O}(n^{1.5})$  result by Huang, Kannan and Khanna [20] works when all costs are either 1 or  $\infty$ . What about the version with

<sup>6</sup> As evidence, we prove in Theorem 28 in Appendix A.2 of full version [15] that InversionSort solves the perfectly interleaved instance in an optimal  $O(n \log n)$  comparisons.

arbitrary costs? Many works state that the general-cost version is “arbitrarily bad” (Huang, Kannan and Khanna [20]), “bleak” or “hopeless” (Gupta and Kumar [17]). The only evidence for this is an  $\Omega(n)$  lower bound on the competitive ratio of any algorithm that *finds the maximum*. There is an example where the costs are either 0, 1,  $n$  or  $\infty$ , and one can show that any algorithm that finds the maximum element  $m$  must have cost  $\Omega(n)$  times that of the cheapest proof (of  $m$  being the maximum) (Charikar et al. [8], Hartline et al. [19], Gupta and Kumar [17]). While it certainly provided intuition, the  $\Omega(n)$  lower bound for maximum (with costs in  $\{0, 1, n, \infty\}$ ) was never extended to sorting.

This makes the  $\{0, 1, n, \infty\}$  version interesting due to three reasons:

- do instances in this cost regime contain an  $\Omega(n)$  lower bound for sorting too?
- it is the natural step-up from generalized sorting with costs in  $\{1, \infty\}$ , and
- this is the first instance with forbidden comparisons that requires an *instance-specific analysis* for the competitive ratio. For generalized sorting and for stochastic sorting<sup>7</sup>, the cost of the Hamiltonian is always  $n - 1$ , so one only has to bound the cost of an algorithm, without worrying about the underlying instance. However, when costs are in  $\{0, 1, n, \infty\}$  the cost of the Hamiltonian can range from 0 to  $n(n - 1)$ , and so an algorithm must adapt to the underlying instance.

Our second theorem addresses this cost version of sorting with priced information, showing that it cannot be the  $\{0, 1, n, \infty\}$  version that makes sorting hopeless!

► **Theorem 2.** *Consider the problem of sorting when every comparison has a cost in  $\{0, 1, F, \infty\}$ , for any  $F \geq n^{3/4}$ . There exists a polynomial time randomized algorithm whose competitive ratio is  $\tilde{O}(n^{3/4})$ , with high probability.*

The main ingredient in the proof of this theorem is the aforementioned  $\tilde{O}(\min(wn^{1.5}, n^2))$  comparisons algorithm for DAG sorting. Even though DAG sorting does not promise a Hamiltonian, it turns out to be useful because it can be used as a subroutine in a “greedy” algorithm for the  $\{0, 1, n, \infty\}$  cost version: obtain with cheapest cost the partial DAG formed by all costs 0 and 1 comparisons.

**Organization.** We state our problems precisely in Section 3. This is followed by our result on bipartite sorting (Theorem 1) in Section 4, and our result on sorting with priced information (Theorem 2) in Section 5.

### 3 Problem Definitions

We formally define the problem of bipartite sorting first, and then the problems of DAG sorting and sorting with priced information. We invite the reader to see Figure 2 for the landscape of these problems, their relations to each other, and how our results fit in this landscape.

► **Definition 3 (Bipartite Sorting).** *Input: A complete bipartite undirected graph  $G$  of unit costs on  $V = R \cup B$ . Only edges in  $G$  can be queried (at unit cost), and querying an undirected edge  $(u, v)$  has one of two outcomes,  $u < v$  (implying  $\vec{uv} \in \vec{G}$ ) or  $u > v$  (implying  $\vec{vu} \in \vec{G}$ ).  $N := |V|$ .*

<sup>7</sup> Also initiated by Huang, Kannan and Khanna [20], this is the version where the input graph  $G$  is random

The instance of bipartite sorting is defined by a partition of  $R$  (reds) and  $B$  (blues) into stripes  $(S_1, \dots, S_k)$  (Figure 1), i.e., by the relative order<sup>8</sup> between the reds and the blues. Note that  $S_i$ s are unordered sets. The DAG  $\vec{G}$  has, for all  $1 \leq i \leq k-1$ , an edge from every element in  $S_i$  to every element of the other color greater than it, i.e., to every element in  $\cup_{\ell \geq 0} S_{i+(2\ell+1)}$ .

*Output:* The sequence of stripes  $(S_1, \dots, S_k)$  (see figure 1). Equivalently, the transitive reduction of  $\vec{G}$ .

**DAG Sorting.** Let  $\mathcal{P}$  denote a partial order on a set of  $n$  elements, and let  $\vec{P}$  denote the transitively closed DAG on  $V = \{v_1, \dots, v_n\}$  indicating all order relations in  $\mathcal{P}$ . That is, the vertex  $v_i$  is identified with element  $i$ , the edge  $\vec{e}_{ij}$  between vertices  $i$  and  $j$  exists if  $v_i < v_j$ , the edge  $\overleftarrow{e}_{ij}$  exists if  $v_i > v_j$ , and no edge between  $v_i$  and  $v_j$  exists if elements  $i$  and  $j$  are incomparable. For convenience, let  $P$  denote the set of (undirected) edges in  $\vec{P}$  without their directions. Let  $w$  denote the width of  $\vec{P}$ .

► **Definition 4** (Implied and essential edge, transitive reduction [2]). *Given a DAG  $\vec{G} = (V, \vec{E})$ , an edge  $(u, v) \in \vec{E}$  is implied, if there is a directed path in  $\vec{G}$  from  $u$  to  $v$ . Otherwise,  $(u, v)$  is essential. The set of essential edges is called the transitive reduction of  $\vec{G}$ .*

Note that for every implied edge  $(u, v) \in \vec{E}$ , there is a directed  $u$  to  $v$  path of essential edges in  $\vec{G}$ . It turns out that the transitive reduction of a DAG is unique [2]. Let  $\vec{T}$  denote the transitive reduction of  $\vec{P}$ . Let  $\mathcal{T}$  denote the undirected version of  $\vec{T}$ .

► **Definition 5** (DAG Sorting, arbitrary costs). *Input: An undirected graph  $G = (V, E \subset P)$  with costs  $c_{ij} \in \mathbb{R}_{\geq 0}$  on edges. An oracle that answers, given an undirected edge  $e_{ij}$  of  $G$ , its orientation in  $\vec{P}$ .*

*Promise:*  $\mathcal{T} \subset E$ . That is, the queryable edges contain the edges of the transitive reduction.

*Output:*  $\vec{T}$ .

*Cost of an algorithm  $\mathcal{A}$ :* The total cost of the edges queried by  $\mathcal{A}$  on the instance  $\vec{P}$ . This will be denoted by  $\text{cost}(\mathcal{A}, \vec{G})$ , where  $\vec{G}$  is the directed version of  $G$  (also referred to as the instance from now on), and contains all the information about  $\vec{P}$ .

When  $c_{ij} = 1$  for all  $i, j$ , we call the problem simply DAG Sorting.

We will only care about the query cost of the algorithm, and while there may be a compact representation of  $\vec{T}$ , we ask the algorithm to output  $\vec{T}$  in its entirety for simplicity.

DAG sorting generalizes sorting with priced information, which we describe next. This problem was introduced by [8] in the broader context of querying with priced information, where one wants to compute a function  $f$  of  $n$  inputs, and querying an input has a certain cost associated to it. The competitive ratio is defined as the (worst case) ratio of the cost of the query strategy to the *cost of the cheapest proof of  $f$* . This work initiated a multitude of papers on priced information, studying problems like learning with attribute costs [23], stochastic boolean function evaluation [11], searching on trees [26, 25], and priced information in external memory [5].

► **Definition 6** (Sorting with Priced Information [8]). *Sorting with priced information is a special case of DAG sorting, when the partial order  $\mathcal{P}$  is a total order. In this case,  $\vec{P}$  is a tournament and therefore  $P$  is a complete graph.  $\vec{T}$  is simply a directed Hamiltonian path*

<sup>8</sup>  $S_1$  is the set of all sources in the DAG  $\vec{G}$ ; since red and blue elements can be compared with unit-cost,  $S_1$  must necessarily be of one color.  $S_i$  can be iteratively defined as the set of sources in  $\vec{G}$  after all stripes 1 to  $i-1$  have been deleted.

$\mathcal{H}$  in  $\vec{P}$ . The input  $G$  is any graph on  $n$  vertices containing the edges of  $\mathcal{H}$  without their directions, and the output is  $\mathcal{H}$ . The total cost of the edges queried by an algorithm  $\mathcal{A}$  on the instance  $\vec{G}$  will be denoted by  $\text{cost}(\mathcal{A}, \vec{G})$ .

**Competitive ratio for sorting with priced information.** The **competitive ratio** of  $\mathcal{A}$  (as defined in [8]) is  $\rho(\mathcal{A}, n) = \max_{\vec{G}} \text{cost}(\mathcal{A}, \vec{G}) / \text{cost}(\mathcal{H})$ , where the maximum is taken over all instances  $\vec{G}$  of  $n$  vertices with a total order. The goal is to find sorting algorithms with small competitive ratio. Here  $\text{cost}(\mathcal{H})$  is considered as a proxy for the complexity of the instance  $\vec{G}$ , as it is the cheapest proof. It certainly is a valid lower bound, for the edges on the Hamiltonian *must* be queried by any algorithm.

For example, when  $G$  is the complete unit-cost graph, MergeSort or QuickSort achieve a competitive ratio of  $\Theta(\log n)$  (the latter w.h.p. if randomized). Similarly, when  $G$  is unit-cost but not complete, the  $\tilde{O}(n^{1.5})$  cost algorithm algorithm by Huang, Kannan and Khanna [20] has a competitive ratio of  $\tilde{O}(\sqrt{n})$ . As mentioned, very little is known about the case when  $G$  has arbitrary costs.

We end with the remark that DAG sorting is closely related to a line of work initiated by Faigle and Turán,[14] called sorting a partial ordered set, or identifying a poset. This was followed up by several works such as [9] and [12]. For a survey on this line of work that also includes generalized sorting, we refer the reader to [7].

## 4 Results on Bipartite Sorting

This section is divided into three subsections. In Section 4.1 we formally state our definition of instance-optimality. In Section 4.2 we derive some lower bounds on OPT stemming from the definition of instance-optimality. Finally, in Section 4.3 we define InversionSort, and prove that it comes close to achieving instance-optimality (Theorem 1) by charging the comparisons performed by InversionSort to the derived lower bounds.

### 4.1 Defining Instance-Optimality

As mentioned in the introduction, the following instance of bipartite sorting shows that comparing the cost of an algorithm to the transitive reduction is hopeless.

► **Definition 7 (One-inversion Instance).** Let  $G = (R, B, E)$  be the undirected complete bipartite graph on  $|R| = |B| = n/2$ . Pick an arbitrary  $r \in R$ ,  $b \in B$ , let  $R_{-r} = R \setminus \{r\}$  and  $B_{-b} = B \setminus \{b\}$ . Define a DAG  $\vec{G}$  via its transitive reduction as follows.

$$TR(\vec{G}) = \{\vec{x}b : x \in R_{-r}\} \cup \{\vec{b}r\} \cup \{\vec{r}y : y \in B_{-b}\}.$$

The transitive reduction has size  $O(n)$ , but any algorithm must spend  $\Omega(n^2)$  comparisons to identify  $r$  and  $b$ . Thus the “cheapest proof” is too strong a benchmark. We now present our neighborhood-based approach for bipartite sorting. This approach is general, and in the Appendix C of the full version [15], we show how this neighborhood-based approach fits several works on instance-optimal algorithms for static problems, namely the works on adaptive sorting [13], on set intersection, union and difference [10], and the recent work on universal optimality [18].

We start with small neighborhoods and gradually increase them until there is no immediate obstruction to instance-optimality. Define  $\mathcal{N}_{\mathcal{A}}(\vec{G})$  as the set of DAGs (Automorphic) isomorphic to  $\vec{G}$  if all edges in  $\vec{G}$  are unit-cost, and cost-isomorphic<sup>9</sup> otherwise. Next, define

<sup>9</sup> Meaning there exists an isomorphism between the DAGs that preserves the costs.

the runtime of an algorithm on an instance  $\vec{G}$  as its maximum comparison-cost on any instance in  $\mathcal{N}_{\mathcal{A}}(\vec{G})$ . Define  $OPT_{\mathcal{A}}(\vec{G})$  as the smallest comparison-cost of any algorithm.

For unit-cost sorting,  $\vec{G}$  is a complete DAG, and  $|\mathcal{N}_{\mathcal{A}}(\vec{G})| = n!$ . It is easily seen that now  $OPT(\vec{G}) = \Omega(n \log n)$ , and the unnecessary  $\log n$  gap arising from comparing to the cheapest proof vanishes. This is also consistent with the fact that any  $O(n \log n)$  algorithm that ignores the sequence of keys and only treats them as a set is  $O(1)$  instance optimal in the order-oblivious setting.<sup>10</sup>

Moving on to the case when  $\vec{G}$  is not complete, we see that the above definition is not sufficient by the following observation. Consider the case when  $\vec{G}$  is a complete bipartite graph, with all edges going in the same direction, i.e., from one partition  $R$  to the other  $B$ . Now  $|\mathcal{N}_{\mathcal{A}}(\vec{G})| = 1$ , and any algorithm that knows that it is operating on  $\vec{G}$  has zero comparison cost<sup>11</sup>. However, any instance-unaware algorithm needs  $\Omega(|R||B|)$  comparisons to verify that the instance is indeed  $\vec{G}$ . This suggests that we need a larger neighborhood than just  $\mathcal{N}_{\mathcal{A}}(\vec{G})$ .

Let  $\vec{E}$  denote the set of edges in the transitive reduction of  $\vec{G}$ , also called essential edges (Definition 4). Define  $\mathcal{N}_E(\vec{G})$  as the set of DAGs that differ from  $\vec{G}$  in exactly one essential edge being flipped, and any other changes it may imply. Again, define the runtime of an algorithm on an instance  $\vec{G}$  as its maximum comparison-cost on any instance in  $\mathcal{N}_E(\vec{G})$ , and define  $OPT_{\mathcal{A}}(\vec{G})$  as the smallest comparison-cost of any algorithm. It is straightforward now to observe that if  $\vec{G}$  is sortable,  $OPT(S) \geq \text{cost}(\mathcal{H})$  and if  $\vec{G}$  is not sortable,  $OPT(S) \geq \text{cost}(TR(\vec{G}))$ . Thus, we recover both definitions of competitive ratio by considering this one-flip neighborhood.

The algorithms we consider here are randomized, and we hence want a definition of instance optimality that allows for randomization. The notion of “instance optimal in the random-order setting” of [1], based on Yao’s principle, compares implicitly to the optimal expected running time of a correct randomized algorithm (Las Vegas style). Our following definition does this directly:

► **Definition 8** ( $\alpha$ -Instance Optimality). Let  $\mathcal{N}(\vec{G}) = \mathcal{N}_E(\vec{G}) \cup \mathcal{N}_{\mathcal{A}}(\vec{G})$ . Define the runtime  $T_A(\vec{G})$  of a randomized algorithm  $A$  on an instance  $\vec{G}$  as its expected comparison-cost on instance  $\vec{G}$ . Let  $\mathcal{C}(\vec{G})$  be the set of randomized (Las Vegas) algorithms that are correct for all instances in  $\mathcal{N}(\vec{G})$ . Define  $OPT(\vec{G}) = \inf_{A \in \mathcal{C}(\vec{G})} \max_{\vec{G}' \in \mathcal{N}(\vec{G})} T_A(\vec{G}')$ . For some  $\alpha \geq 1$ , an algorithm  $A$  is called  $\alpha$ -instance optimal if for every instance  $\vec{G}$ ,  $T_A(\vec{G}) \leq \alpha OPT(\vec{G})$ .

## 4.2 Lower Bounds on OPT

We first refine our notion of instance-optimality to make it more amenable to deriving lower bounds.

► **Definition 9** (Instance Optimality Distribution). Let  $\mathcal{C}'(\vec{G})$  be the set of deterministic algorithms that are correct for all instances in  $\mathcal{N}(\vec{G})$ . Let  $\mathcal{D}(\vec{G})$  be the uniform distribution over  $\mathcal{N}_{\mathcal{A}}(\vec{G})$ . Define  $OPT(\vec{G}) = \inf_{A \in \mathcal{C}'(\vec{G})} \mathbb{E}_{\vec{G}' \sim \mathcal{D}(\vec{G})} T_A(\vec{G}')$ .

An application of Yao’s principle [28] shows that for any  $\vec{G}$ :  $OPT_D(\vec{G}) \leq OPT(\vec{G})$ . Note that the optimal algorithm is allowed to depend on  $\mathcal{I}$ . We remark that while the following lower bounds would be easy to prove for algorithms unaware of  $\mathcal{I}$  using adversary arguments, we prove this for  $OPT$  (Definition 9), which requires some extra care.

<sup>10</sup> All algorithms that exploit certain presortedness in the input necessarily exploit the input sequence of keys. This corresponds to a smaller neighborhood than the  $n!$  size automorphism neighborhood.

<sup>11</sup> Recall that we do not charge to write down the transitive reduction which has size  $O(|R||B|)$ , only the query cost.

## 23:12 Instance-Optimal Algorithm and Sorting

► **Lemma 10** (Transitive Reduction or Verification lower bound). *Let  $\mathcal{I}$  be an instance of bipartite sorting, let  $K \subset \vec{E}_{\mathcal{I}}$  be its transitive reduction, and define  $C_V = |K|$ . Then, any algorithm that is correct for all inputs from  $\mathcal{N}(\mathcal{I})$  must perform at least  $C_V$  comparisons.*

**Proof.** Assume there exists an algorithm  $\mathcal{A}$  that is correct for all instances in  $\mathcal{N}(\mathcal{I})$  simultaneously that performs at most  $C_V - 1$  comparisons on input  $I$ . This means that there must exist an edge  $e$  on the transitive reduction that is not verified by  $\mathcal{A}$ . As  $\mathcal{A}$  is deterministic, it would report  $\mathcal{I}$  as output even when the input had  $e$  flipped because all other edges have the same direction as in  $\mathcal{I}$ , as we will argue now: If this (non-flipped) edge is between two stripes of size one, the two endpoints merge into two other stripes, but no edges changes direction. If this edge is between two stripes and both of them have size at least 2, then we create one additional inversion without changing other directions. If one stripe has size one and the other has size at least two, one element is moved from the size-at-least-two stripe to a neighboring stripe. Again, no bichromatic edges (implied or not) change their direction. ◀

While the above lower bound is natural as it is the cheapest proof, Definition 9 now allows for the following lower bound that captures the complexity of instances where transitive reduction is too weak a measure (recall the instance in Definition 7).

► **Lemma 11** (Inversion finding lower bound). *Let  $\mathcal{I}$  be an instance of bipartite sorting with  $n \geq 2$  red and  $m \geq 2$  blue elements, where not all comparisons come out the same, and define*

$$C_I = \frac{nm}{\min(|\{(r, b) \in R \times B \mid r < b\}|, |\{(r, b) \in R \times B \mid r > b\}|)}.$$

*Under the distribution of Definition 9, any deterministic algorithm  $\mathcal{A}$  that does at most  $C_I/2$  comparisons must fail with probability (at least)  $1/8$ .*

**Proof.** Let  $\mathcal{D}$  be the uniform distribution over  $\mathcal{N}_A(\mathcal{I})$ . Remember that  $\mathcal{N}_A(\mathcal{I})$  contains all instances where the stripes are internally arbitrarily permuted. Observe  $|\mathcal{N}_A(\mathcal{I})| \geq 4$  by the bounds on  $n$  and  $m$ . W.l.o.g., assume  $|\{(r, b) \in R \times B \mid r < b\}| < |\{(r, b) \in R \times B \mid b < r\}|$ , i.e., the usual outcome of a comparison is  $b < r$  and the inversion is  $r < b$ . Let  $p = 1/C_I = |\{(r, b) \in R \times B \mid r < b\}|/nm \leq 1/2$  be the probability that a randomly chosen pair of elements is an inversion. By Yao's principle, let  $\mathcal{A}$  be a deterministic algorithm and think of it as a decision tree  $\mathcal{T}$  where nodes are red-blue comparisons and non-inversion go to the left, inversions go to the right. Each leaf of the tree is marked with an output (that declares which instance was represented by the input), or a failure output.

**Claim.** Let  $v_k$  be the node  $v$  that is reached by  $k$  comparisons returning “non-inversion” (i.e. the leftmost node of  $\mathcal{T}$  at depth  $k$ ). When input is drawn from  $\mathcal{D}$ , the node  $v_k$  is reached with probability at least  $1 - kp$ .

**Proof of Claim.** An input reaches  $v_k$  if  $k$  (potentially dependent) random experiments all came out as “non-inversion”, each having a probability  $1 - p$ . The claim follows from a union bound over the fail events. ◀

From the claim it follows that if  $v_k$  is a leaf for  $k \leq C_I/2$ , the algorithm must fail with probability at least  $1/4$ : Then  $kp \leq C_I/2 \cdot 1/C_I = 1/2$  and  $1 - kp \geq 1/2$ , so half of the inputs reach  $v_k$ . Because there are at least four inputs, at least two reach  $v_k$ , but it can only be labeled with one, the other(s), which stand for at least  $1/4$  of the inputs in  $\mathcal{N}_A(I)$ , make the algorithm fail. ◀

Finally, we will need to combine various lower bounds from different subproblems. Let  $\mathcal{I}$  be an instance and  $(S_1, \dots, S_k)$  its stripes (see Figure 1). Consider pairs of indices  $(a_1, b_1), \dots, (a_\ell, b_\ell)$ , where for all  $1 \leq j \leq \ell$ ,  $a_j$  and  $b_j$  both belong to  $\{1, \dots, k\}$ , and  $a_j < b_j < a_{j+1} < b_{j+1}$  for all  $j < \ell$ . For  $1 \leq j \leq \ell$  define the subinstance  $\mathcal{I}_j$  by the subgraph of  $\vec{G}_{\mathcal{I}}$  on the vertices  $V_j = \bigcup_{i=a_j}^{b_j} S_i$ .

► **Lemma 12** (Decomposition into Lower Bounds for Subproblems). *For  $1 \leq j \leq \ell$ , let  $\mathcal{I}_j$  be a subinstances of  $\mathcal{I}$  as above. Then  $\text{OPT}_D(\mathcal{I}) \geq \sum_{j=1}^{\ell} \text{OPT}_D(\mathcal{I}_j)$ .*

**Proof.** As we are working with Definition 9, we first have to check that an algorithm that is correct on  $\mathcal{N}(\mathcal{I})$  is actually correct on each  $\mathcal{N}(\mathcal{I}_j)$ . To this end observe that every edge flip in  $\mathcal{I}_j$  is also an edge flip in  $\mathcal{I}$ , and that any permutation of the labels/names in  $\mathcal{I}_j$  is also a permutation in  $\mathcal{I}$ .

Run the algorithm  $A$  on an instance  $\mathcal{I}'$  drawn from  $\mathcal{D}(\mathcal{I})$ , and let  $X$  be the random variable describing the number of comparisons of  $A$ . Define the random variables  $X_j$  to be the number of comparisons between vertices in subproblem  $\mathcal{I}'_j$ . Then  $\sum X_j \leq X$ .

Let's conceptually draw  $\mathcal{I}'$  from  $\mathcal{D}(\mathcal{I})$  by first finding a position in the input list (name) for all vertices not in  $\mathcal{I}_j$  and finally draw names for the vertices in  $\mathcal{I}_j$ . Now we can think of  $A$  as deterministic algorithm for  $\mathcal{I}_j$  by considering all comparisons not in  $\mathcal{I}_j$  as fixed, and we get  $E[X_j] \geq \text{OPT}_D(\mathcal{I}_j)$ . The statement of the lemma follows by linearity of expectation. ◀

### 4.3 InversionSort and its $O(\log^3 n)$ instance-optimal guarantee

A generic state of InversionSort will be defined using a *backbone*, which is a sequence of elements of alternating colors, called *representatives* or *pivots*. Each representative will be assigned a *bucket*, which is a set of elements of the same color that lie between the two neighboring representatives of the other color on the backbone.

InversionSort makes progress from one state to the next by performing three steps: a) finding an *inversion* (which is defined soon) between neighboring representatives on the backbone, b) inserting this inversion on the backbone, and c) pivoting with these two elements, thereby refining the buckets.

#### 4.3.1 Description of InversionSort

► **Definition 13** (Backbone, Representatives, and Buckets). *The backbone consists of a totally ordered, alternating list of representatives  $(u_0, u_1, u_2, \dots, u_{2k}, u_{2k+1}) = (r_0, b_1, r_2, \dots, r_{2k}, b_{2k+1})$ , where  $r_{2i} \in R$  and  $b_{2j+1} \in B$  with  $r_i < b_{i+1}$  and  $b_i < r_{i+1}$ . Here,  $r_0$  is an artificial red element that is smaller than all elements, and the last element  $b_{2k+1}$  is an artificial blue element that is larger than all elements. The representatives define the buckets  $(X_0, X_1, X_2, \dots, X_{2k}, X_{2k+1}) = (R_0, B_1, R_2, \dots, R_{2k}, B_{2k+1})$  by  $R_i = \{x \in R \mid b_{i-1} < x < b_{i+1}\} \setminus \{r_i\}$  and  $B_i = \{x \in B \mid r_{i-1} < x < r_{i+1}\} \setminus \{b_i\}$ . Here, as a convention, the representative is not included in the bucket. Again,  $R_0 = \{x \in R \mid x < b_1\}$  and  $B_{2k+1} = \{x \in B \mid r_{2k} < x\}$  are special cases.*

► **Definition 14** (active subproblems and buckets). *As long InversionSort did not create a certificate that there are no further inversions between  $x_i$  and  $x_{i+1}$ , the subproblem defined by the buckets  $X_i$  and  $X_{i+1}$  is called active, and so are  $X_i$  and  $X_{i+1}$ .*

Our previous work [16] now defines an *inversion*, which gives the algorithm its name. Consider adjacent representatives  $u_i$  and  $u_{i+1}$ , their corresponding adjacent buckets  $X_i$  and  $X_{i+1}$ , and a bichromatic pair  $(x, y)$  of elements  $x \in X_i$  and  $y \in X_{i+1}$ . Observe that  $x$  and

---

$y$  are not ordered by transitivity of the backbone. Because  $x$  and  $y$  are of different color, they can be compared. If  $y < x$ , the pair is called an *inversion*. This allows one to extend the backbone: we get  $u_i < y < x < u_{i+1}$ , which is a chain of actual comparisons between elements of alternating color.

*The only way to find an inversion in a bipartite setting (this is where the bichromatic setting is different) is to uniformly at random, from all pairs in  $X_i$  and  $X_{i+1}$ , pick  $x$  and  $y$ .* If the fraction of inversions is  $p$ , then the probability of finding an inversion is  $p$  and the expected number of trials to find one is  $1/p$ .

InversionSort starts by (trivially) having the backbone consist only of the artificial smallest red element  $r_0$  and largest blue element  $b_1$ , and  $R_0 = R$  and  $B_1 = B$ . For a given backbone  $(u_0, u_1, u_2, \dots, u_{2k}, u_{2k+1}) = (r_0, b_1, r_2, \dots, r_{2k}, b_{2k+1})$ , InversionSort first, for each pair  $X_i, X_{i+1}$  of adjacent buckets that have not yet found an inversion or a proof that there is no further inversion (i.e., reached the adjacent-stripe verification bound), in a round-robin manner, does one round of inversion-searching by randomly comparing pairs of elements in adjacent buckets. If this leads to an inversion, the inverted pair is saved and the algorithm moves to the next pair of adjacent buckets. At the end of the round, all identified inversions are considered and used to extend the backbone. Then InversionSort splits existing buckets by pivoting with new elements on the backbone. Because there is at most one pair of inversions between each two neighboring representatives on the backbone, each element is compared to at most two new representatives in each round.

This reestablishes the backbone and creates some new pairs of neighboring buckets, for which InversionSort initializes the inversion finding procedures. The algorithm stops once all neighboring pairs of buckets are shown to not have an inversion, i.e., the comparisons in the verification bound between neighboring stripes have been performed.

**Analysis.** [16] visualizes a run of InversionSort as a ternary (refinement) tree, where nodes correspond to subproblems. For an internal node  $v$ , there is a corresponding subinterval on the backbone defined by two consecutive pivots, say a blue pivot followed by a red pivot,  $b_v < r_v$ . If InversionSort finds an inversion  $y < x$  ( $x$  is blue and  $y$  is red) between  $b_v$  and  $r_v$ , then  $v$  has three children with the respective pivots  $(b_v, y)$ ,  $(y, x)$ ,  $(x, r_v)$ .

The random nature of the inversion searching of InversionSort, is made precise in Lemma 11 in [16]. However, a stronger version of this lemma applies for bipartite setting with the same proof.

► **Lemma 15** (Randomness in Inversion Finding, Stronger Version of [16, Lemma 11, p11]). *At any stage of the InversionSort, consider a successful inversion finding procedure, which finds an inversion  $y < x$  between representatives  $u_i < y < x < u_{i+1}$ . Say, w.l.o.g., that  $u_i$  is red and  $u_{i+1}$  is blue, and hence  $x$  is red and  $y$  is blue.*

1. *for any  $y \in X_{i+1}$ , conditioned on  $y$  being in the inversion,  $x$  is uniformly distributed among all the red elements in  $R_y = \{x \in X_i \mid y < x < u_{i+1}\}$ , and.*
2. *for any  $x \in X_i$ , conditioned on  $x$  being in the inversion,  $y$  is uniformly distributed in  $B_x = \{y \in X_{i+1} \mid u_i < y < x\}$ .*

This gives a bound on the height of the tree.

► **Lemma 16** (Height of the refinement tree [16, Theorem 5, p11]). *Let  $\mathcal{T}$  be the refinement tree of running InversionSort on an instance  $\mathcal{I}$  with  $N = n + m$  elements. With high probability in  $N$ , the height of  $\mathcal{T}$  is  $O(\log N)$ .*

**Handling Overlaps.** Because of the overlapping nature of the problem, InversionSort cannot easily focus on elements between neighboring representatives. For example, for the child indicated by pivots  $(y, x)$ , instead of only getting the reds and blues that actually lie in this range as input, InversionSort instead has to also work with the red elements contained in  $(b_v, y)$  and the blue elements inside  $(x, r_v)$ . This “spill-in” from the neighboring subintervals on the backbone needs to be analyzed.

As is argued in [16], the cost of bichromatic inversion search procedure of InversionSort is justified by the subinstance (part of the Hamiltonian) between the neighboring elements on the backbone. In Section 4.3.2, we will analyse this in the bipartite setting using the notion of instance optimality. However, if the spill-in for this subproblem is too large, inversion search is too costly. Hence, [16] identify subproblems that do not have too much spill-in from their neighbors, and call these subproblems *unaffected*. Inversion search in unaffected subproblems can be charged to their subinstance. More precisely, [16] show that at any time, with high probability, at least roughly a  $1/(\log N)^2$  fraction of all current problems are unaffected. Accounting over the whole tree, including the pivoting, introduces another  $\log N$  factor corresponding to the depth of the tree.

### 4.3.2 Putting everything together: Proof of Theorem 1

We now complete the proof of our main result for bipartite sorting, restated here for convenience.

► **Theorem 1** (Instance Optimality of InversionSort). *There exists a constant  $c > 0$ , such that for every instance  $\mathcal{I}$ , the cost of InversionSort on  $\mathcal{I}$  is, with probability at least  $1 - 1/N$ , at most  $c(\log N)^3 \text{OPT}(\mathcal{I})$ , where  $\text{OPT}(\mathcal{I})$  is as in Definition 8.*

We will show how to charge the comparisons performed by InversionSort to the lower bounds presented in Section 4.2. First, Lemma 15 and Lemma 16 imply that the refinement tree height  $h = O(\log n)$  and hence the pivoting cost is  $O(n \log n)$ . Second, the considerations about unaffected subproblems remains valid, there are at most  $O(\log^2 n)$  affected subproblems per unaffected subproblem. The inversion searching cost in each unaffected subproblem is justified by Lemma 11 if an inversion is found, otherwise by Lemma 10. Adding the extra  $O(\log N)$  factor (height of the tree), the next lemma completes the proof of Theorem 1.

► **Lemma 17.** *Let  $\mathcal{T}$  be the refinement tree of height  $h$  for a run of *InversionSort* on instance  $\mathcal{I}$ , and let  $V_{\mathcal{T}}$  be the set of nodes of  $\mathcal{T}$ . Then*

$$\sum_{v \in V_{\mathcal{T}}} \text{OPT}(\mathcal{I}_v) \leq 2h \text{OPT}(\mathcal{I})$$

**Proof.** It suffices to show that for each level  $\mathcal{L}$  of  $\mathcal{T}$  the inequality  $\sum_{v \in \mathcal{L}} \text{OPT}(\mathcal{I}_v) \leq 2 \text{OPT}(\mathcal{I})$  holds. Note that the subinstances  $\mathcal{I}_v$  of the same polarity in any  $\mathcal{L}$  do not share vertices. Hence the decomposition Lemma 12 is applicable and the lemma follows because there are two polarities. ◀

## 5 Result on Sorting with Priced Information: Lower bound does not extend

Recall that there exists an instance demonstrating the lower bound of  $\Omega(n)$  on the competitive ratio of any algorithm that finds the **maximum** of a set of  $n$  elements. Announced in the original paper by Charikar et al.[8], this was spelled out one year later by Gupta and Kumar [17]. The instance is simple to describe (see Appendix B of the full version [15]), and all comparisons in it have costs in  $\{0, 1, n, \infty\}$ . Although this example was never formally stated for sorting, its discovery seems to have dampened efforts to study (either better algorithms, or lower bounds for) the general version of sorting with priced information in the past 20 years.

In this section, we prove Theorem 2, that shows that the  $\Omega(n)$  lower bound for maximum with costs in  $\{0, 1, n, \infty\}$  cannot extend to sorting.

► **Theorem 2.** *Consider the problem of sorting when every comparison has a cost in  $\{0, 1, F, \infty\}$ , for any  $F \geq n^{3/4}$ . There exists a polynomial time randomized algorithm whose competitive ratio is  $\tilde{O}(n^{3/4})$ , with high probability.*

While counterintuitive at a first glance (after all, the cost to sort is at least the cost to find the maximum), the simple explanation is that the cheapest proof for sorting is also more expensive than that of the maximum. This opens up the problem of arbitrary-cost sorting once again - is there a  $\Omega(n)$  lower bound for sorting with arbitrary costs, or can our  $\tilde{O}(n^{3/4})$  algorithm be extended to an  $o(n)$  competitive algorithm for arbitrary costs?

Theorem 2 is achieved by *first developing an algorithm for DAG sorting*. Why consider the case of an unsortable DAG, when the DAG we have is sortable? Here is the reasoning. If we consider greedy algorithms for sorting with priced information, it is natural to try to discover as much of  $\vec{G}$  as possible with low-cost edges<sup>12</sup>. However, note that the sub-DAG  $\vec{G}_{\leq w}$  consisting of edges with cost at most  $w$  in  $\vec{G}$  may not be sortable, which is exactly the problem of DAG sorting.

We set up some notation first. Given an undirected complete graph  $G$  with costs in  $\{0, 1, F, \infty\}$ , let  $\vec{G}$  denote the underlying DAG that contains a directed Hamiltonian path. Define  $\vec{G}_0$  as the DAG obtained by revealing all cost 0 edges, observe that it may not have

<sup>12</sup>We remark that some time after we first uploaded a version of Theorem 2 to Arxiv, a preprint by [Jiang, Wang, Zhang and Zhang, Arxiv [21]] was uploaded, where the authors also use an algorithm for DAG sorting (they call it GPSC) parameterized by  $w$  and extend our  $\tilde{O}(n^{3/4})$  algorithm to obtain a  $\tilde{O}(n^{1-1/2W})$  competitive algorithm for sorting with priced comparisons with at most  $W$  distinct costs. For our setting when  $W = 4$  they re-derive our result separately as their main theorem would give a  $n^{7/8}$ -competitive ratio.

a Hamiltonian path, and let  $w_0$  be the width of  $\vec{G}_0$ . Similarly, denote by  $\vec{G}_{01}$  the DAG obtained by revealing all cost 0 and 1 edges;  $\vec{G}_{01}$  may not have a Hamiltonian path either, and let  $w_{01}$  be the width of  $\vec{G}_{01}$ . Finally, let  $k_1$  and  $k_F$  be the number of cost 1 and cost  $F$  edges on the Hamiltonian path in  $\vec{G}$ .

## 5.1 Algorithm details

The following is our proposed algorithm for the  $0, 1, F, \infty$  cost version of sorting with priced information. Below, we will abbreviate the algorithm by Huang, Kannan and Khanna [20] for the  $1, \infty$  setting, by HKK.

■ **Algorithm 2** Algorithm for  $0, 1, F, \infty$  cost.

---

**Require:** undirected graph  $G = (V, E, c)$  with costs  $c(e) \in \{0, 1, F, \infty\}$

**Ensure:** the total order (directed Hamiltonian)

Probe all cost zero edges

Run the following 4 algorithms in parallel, performing one comparison from each. If any of them discover the Hamiltonian, report the edges in the Hamiltonian path, and abort the other algorithms

- Set  $F = \infty$ . Run the HKK algorithm on the cost 1 edges, starting from  $\vec{G}_0$
  - Set  $F = 1$ . Run the HKK algorithm on the cost 1 edges, starting from  $\vec{G}_0$
  - Run Algorithm 3 on the cost 1 edges, starting from  $\vec{G}_0$
  - Find the 0-1 DAG using Theorem 20, use Algorithm 3 with cost  $F$  edges on it.
- 

The running time of the final algorithm will then be a minimum of four running times. We briefly explain the first two algorithms, and then explain in detail the last two. Recall that HKK algorithm runs when costs are 1 or  $\infty$ . On an input with costs in  $\{0, 1, F, \infty\}$ , the first algorithm pretends that cost  $F$  edges are forbidden too, i.e.,  $F = \infty$ , and probes whatever edges HKK would have probed from the cost 1 edges. Clearly, this will not find the Hamiltonian if it contains cost  $F$  edges, as they aren't queried. However, in the case that the Hamiltonian does not contain cost  $F$  edges, it will sort the input, and stops. The second algorithm does the opposite: it does not differentiate between cost  $F$  and cost 1 edges, and probes them if they would have been probed by the HKK algorithm. If run for long enough, this will find the Hamiltonian, and is stopped once it does so.

### 5.1.1 Algorithm 3 : Hamiltonian By Predecessors

The third algorithm in Algorithm 2 is Algorithm 3, which is also used as the second half of the fourth algorithm in Algorithm 2. This algorithm finds a Hamiltonian path in a partially revealed DAG. It utilizes Lemma 18, that generalizes binary search to searching for predecessors of a vertex in a DAG of width  $w$ . For two DAGs  $D'$  and  $D$  on the same set of vertices, we will write  $D' \subset D$  if all the directed edges in  $D'$  are also contained in  $D$ .

► **Lemma 18** (Hamiltonian by predecessor search). *Let  $D' \subset D$  be two DAGs on the vertex set  $V$  and assume that  $D$  contains a Hamiltonian path. Assume that the Hamiltonian path in  $D$  contains a set  $\vec{S}$  of  $k$  edges that are not in  $D'$ , and let  $S$  be the undirected version of  $\vec{S}$ . Let  $E$  be a set of edges that can be queried and assume  $S \subset E$ . Let  $w$  be the width of  $D'$ . Then,  $k + 1 \geq w$  and the Hamiltonian in  $D$  can be found with  $O(wk \log n)$  queries on edges in  $E$ .*

Below is the pseudocode for Algorithm 3. It uses in turn a predecessor searching subroutine that is captured by the following simple lemma. Lemma 18.

## 23:18 Instance-Optimal Algorithm and Sorting

► **Lemma 19** (Predecessor search in DAG). *Given a DAG  $D' = (V, E')$  of width  $w$ , and a vertex  $v \in V$ ,  $|V| = n$ , let  $D$  be the DAG obtained by extending  $D'$  by probing all edges involving  $v$ . Define  $P_v = \{u \mid (u, v) \text{ is in the transitive reduction of } D\}$ . There exists an algorithm that computes  $P_v$  with  $O(w \log n)$  queries, and runs in  $O(n^2)$  time.*

**Proof.** Observe that any chain in  $D'$  can contain at most one element of  $P_v$ , and hence  $|P_v| \leq w$ . Indeed, we can run one binary search on each of the  $w$  chains in  $D'$ , leading to at most  $w$  candidate predecessors. The number of queries is easily seen to be  $O(w \log n)$  after computing an optimal partitioning into chains in polynomial time. ◀

**Proof of Lemma 18.** By Dilworth's Theorem,  $D'$  can be partitioned into  $w$  chains. To show  $k + 1 \geq w$ , assume otherwise,  $w > k + 1$ , and let  $A$  be  $k + 2$  non-comparable vertices in  $D'$ . By the pigeonhole principle, there must be two vertices of  $A$  in the same of the  $k + 1$  stretches of cost 0 edges on the Hamiltonian, a contradiction to them being incomparable.

To prove that Algorithm 3 performs at most  $O(kw \log n)$  queries, observe that adding edges to  $D'$  does not increase its width. In the while loop, as long as  $D'$  is not the Hamiltonian path, let  $S$  be the first layer of a BFS traversal of the transitive reduction of  $D'$  with  $|S| \geq 2$ , and observe that  $S$  is an antichain and hence  $|S| \leq w$ . All vertices of  $S$  but one have their incoming edge on the directed Hamiltonian not yet revealed / queried: Assume there are two vertices  $b \neq d \in S$  and their predecessors  $a \prec b$  and  $c \prec d$  are both already in  $D$ . Then,  $b$  and  $d$  are not sources in  $D$ , and hence  $S$  must be the set of successors of a vertex  $v$ . Additionally, there is only a single source  $s$  in  $D$ , and the set  $\{x \mid x \prec v\}$  forms a chain in the transitive reduction of  $D$  starting in  $s$ . This means  $w \leq a < b$  and  $w \leq c < d$  contradicting them being different.

By the above arguments,  $D$  contains the Hamiltonian with only  $k - |S| + 1$  unrevealed edges missing. We used  $O(|S|w \log n)$  queries to reduce the number of unrevealed edges by  $|S| - 1$  for  $|S| \geq 2$ , hence each search creating a missing edge of the Hamiltonian, and this search must justify at most one additional such search. Hence, the total number of queries to arrive at the Hamiltonian is  $O(wk \log n)$ .

Binary searching for a vertex  $v$  into one of the  $w$  chains takes  $O(\log n)$  probes, and in  $O(w \log n)$  probes one is sure to have at least discovered one edge from the Hamiltonian, namely the incoming edge to  $v$ . This can then be repeated  $k$  times, revealing the Hamiltonian.

■ **Algorithm 3** Hamiltonian By Predecessors.

---

**Require:** undirected  $G = (V, E)$  defining which comparisons are allowed

**Require:** DAG  $D$  of already probed edges (initially the cost 0 edges)

**Ensure:** The updated  $D$  contains a directed Hamiltonian

create (and maintain) a chain decomposition  $C$  of the transitive reduction of  $D$

**while**  $D$  has width  $w > 1$ , i.e. is not the intended result **do**

**if** The transitive reduction of  $D$  has several sources **then**

    Let  $S$  be the set of these sources

**else**

    Let  $v$  be the lowest vertex with more than 1 successors

    Let  $S$  be the set of successors of  $v$

**for** each  $u$  in  $S$  **do**

    Find all predecessors of  $u$  in  $D$  (Lemma 19), adding answers to  $D$

    \\ there are at most  $w$  such predecessors

---

### 5.1.2 The fourth algorithm in Algorithm 2

We will develop another algorithm, that proceeds in two steps: a) compute only the 0-1 DAG,  $\vec{G}_{01}$ , and b) find the cost  $F$  edges ( $k_F$ -many of them) on the Hamiltonian path. Step b) is performed using Algorithm 3. If  $k_F = 0$ , step a) recovers the complete Hamiltonian path. Before we state the DAG sorting algorithm for step a), we note that it only needs to output the transitive reduction of  $\vec{G}_{01}$ .

► **Theorem 20.** *There is a poly-time randomized algorithm that w.h.p. solves DAG sorting for an instance  $\vec{G}$  with edge costs in  $\{0, 1, \infty\}$ , using  $O(\min(w n^{3/2} \log n, n^2))$  comparisons, where  $w$  is the width of  $\vec{G}$ .*

We defer the proof of Theorem 20 for now and analyze our algorithm assuming it.

## 5.2 Analysis of Algorithm 2

► **Lemma 21.** *Algorithm 2 incurs the following costs*

$$\begin{cases} O(\min(n^{1.5} \log n, w_0 k_1 \log n)) & \text{if } k_F = 0 \\ O(\min(F n^{1.5} \log n, w_{01} n^{1.5} \log n + F w_{01} k_F \log n)) & \text{if } k_F > 0 \end{cases}$$

**Proof.** If  $k_F = 0$ , the first algorithm that ignores cost  $F$  edges by setting  $F = \infty$  never probes a cost  $F$  edge, and finishes in  $O(n^{1.5} \log n)$  comparisons (this is the cost of the algorithm by Huang, Kannan and Khanna [20]). Since the DAG formed by cost 0 edges has width  $w_0$  and  $k_F = 0$ ,  $w_0 \leq k_1 + 1$ . The third step running Algorithm 3 finishes after at most  $O(w_0 k_1 \log n)$  comparisons, by Lemma 18.

If  $k_F > 0$ , the first term comes from running HKK after setting  $F = 1$ : the true cost of probing an edge is at most a factor  $F$  larger. Finally, step 4 of Algorithm 2 runs the algorithm in Theorem 20 first, incurring at most  $w_{01} n^{1.5} \log n$  many comparisons. With the 0-1 DAG obtained using Theorem 20, Algorithm 3 now inserts at most  $k_F$  many edges in the Hamiltonian, probing at most  $w_{01} \log n$  many edges for each. Every probe costs  $F$ , for a total of  $w_{01} n^{1.5} \log n + F w_{01} k_F \log n$ . ◀

### 5.2.1 Proof of $\tilde{O}(n^{3/4})$ competitive ratio of Algorithm 2

We claim that the competitive ratio is always bounded by  $O(n^{3/4} \log n)$ . Observe that the cost of the Hamiltonian is  $k_1 + F k_F$ . If  $k_1 = k_F = 0$ , the Hamiltonian has a cost of 0 and our algorithm finds it at cost 0. From now on, we assume not both of  $k_1$  and  $k_F$  are 0.

Consider the case  $k_F = 0$  first. Note that this implies that the width  $w_{01}$  of  $\vec{G}_{01}$  is 1. First consider the subcase when  $w_0 \leq n^{3/4}$ . In this case, the competitive ratio is bounded above by  $O(w_0 k_1 \log n) / k_1 = O(w_0 \log n) \leq O(n^{3/4} \log n)$ . In the subcase when  $w_0 > n^{3/4}$ , observe that this implies that  $k_1 \geq n^{3/4}$  which implies that the competitive ratio is bounded above by  $O(n^{1.5} \log n) / k_1 \leq O(n^{3/4} \log n)$ .

Next, consider the case  $k_F \geq 1$ , and the cost of the Hamiltonian is at least  $F k_F$ . Since  $w_{01} \leq k_F + 1$ , the cost of the algorithm is at most  $O(w_{01} n^{1.5} \log n + F w_{01} k_F \log n) < O(k_F n^{1.5} \log n + F w_{01} k_F \log n)$ , and dividing by  $F k_F$  (the lower bound on the cost of the Hamiltonian), we get a competitive ratio of at most  $O((n^{1.5}/F + w_{01}) \log n)$ . Since  $F \geq n^{3/4}$ , this ratio is  $O(n^{3/4} \log n)$  as long as  $w_{01} \leq n^{3/4}$ . Else if  $w_{01} > n^{3/4}$ , we observe that  $k_F \geq n^{3/4}$ , and then the  $F n^{1.5} \log n$  query cost gives us a competitive ratio of at most  $F n^{1.5} \log n / F k_F \leq n^{3/4} \log n$ . Thus Theorem 2 is proved. ◀

It remains to prove Theorem 20, which is the topic of the next subsection.

### 5.3 Proof of Theorem 20

First, observe that if the width of  $\vec{G}$  is at least  $\sqrt{n}/4$ , the statement of Theorem 20 is easy to achieve by probing all edges. Hence, let us assume the width is at most  $\sqrt{n}/4$ . We will show that there is an algorithm that computes  $\vec{G}_{01}$  with cost at most  $O(w_{01}n^{1.5} \log n)$ . This algorithm will only probe cost 0 and 1 edges, and will be a generalization of the algorithm in [20]. Note that while the algorithm in [20] works on a cost  $\{1, \infty\}$  setting under the promise of a Hamiltonian path in the true graph, our algorithm finds the transitive reduction of the DAG  $\vec{G}_{01}$  of width  $w_{01}$ . We first address the challenges posed in extending the work by Huang Kannan and Khanna [20].

**Challenges in extending the results of Huang, Kannan and Khanna [20].** At a high level, the algorithm in [20] alternates between three ways of making progress:

1. Finding and probing balanced edges, defined as those that reduce the number of possible linear extensions of the current DAG by a  $1 - (1/(e\sqrt{n}))$  factor. Finding such edges requires approximating the average rank of vertices under all possible linear extensions at all stages of the algorithm.
2. After estimating the indegree of vertices upto an additive error of  $\tilde{O}(\sqrt{n})$  by an  $\tilde{O}(n^{1.5})$  sampling procedure, the algorithm probes free edges, defined as the set of edges  $(u, v)$  where the average rank of  $u$  is smaller than the average rank of  $v$ , and  $v$  has most  $\tilde{O}(\sqrt{n})$  unprobed incoming edges. Free edges that are balanced again reduce the number of linear extensions by a constant factor. Otherwise, they can contribute at most  $\tilde{O}(n^{1.5})$  to the total cost.
3. Binary Search - When there are no free edges, there must exist a set of  $\sqrt{n}$  vertices with known total order (Lemma 3.5 in [20]). The other vertices can perform binary search into these  $\sqrt{n}$  vertices at a cost of  $O(n \log n)$ , and doing so removes these  $\sqrt{n}$  vertices from the picture. The total cost of binary search is therefore  $\tilde{O}(n^{1.5})$ .

*The third step of the algorithm is the step that guarantees a reduction in the problem size. However, the third step of this algorithm no longer works for DAG sorting: the existence of a set of  $\sqrt{n}$  vertices with known total order crucially relies upon the existence of the Hamiltonian path.*

**Proof of Theorem 20.** All of the definitions, algorithms, and accounting to estimate the in-degree of a vertex in [20] remain valid and unchanged. Observe that any topological sorting of the underlying directed graph, together with the undirected graph, reveal the directed graph. Define the **average rank of a vertex** as the average rank over all linear extensions of the true underlying directed graph. The following result implies that the average rank  $r$  on a path in (the transitive reduction of) a DAG is increasing by at least one per edge.

► **Lemma 22.** *Let  $D = (V, E)$  be a DAG and  $r: V \rightarrow \mathbb{Q}^{\geq 0}$  be the average rank. Then for  $(u, v) \in E$  we have  $r(u) + 1 \leq r(v)$ .*

**Proof.** Let  $\Pi$  be the set of all linear extensions that are compatible with  $D$ , such that  $r(x)|\Pi| = \sum_{\pi \in \Pi} \pi(x)$ . Then  $|\Pi|(r(v) - r(u)) = \sum_{\pi \in \Pi} \pi(v) - \pi(u) \geq |\Pi| \cdot 1$ . ◀

► **Definition 23** (Convex vertex subset). *In a DAG  $G = (V, E)$ , a subset of vertices  $S \subseteq V$  is convex if for every pair of vertices  $u, v \in S$ , every vertex  $w$  on any directed path from  $u$  to  $v$  in  $G$  is also in  $S$ .<sup>13</sup>*

Hence, considering a subset of the vertices by an upper and a lower bound on the average rank, leads to a convex subset. Next, a vertex is **live** if there is an unprobed edge incident to it, otherwise it is **exhausted**. The **assumed graph** is the same directed graph as in [20]. An **active vertex** is one that has at most  $4\sqrt{n} \log n$  unprobed in-edges in the assumed graph. A **free edge** is an unprobed edge  $(u, v)$  where the endpoint  $v$  is active. The proof of the next lemma is identical to that in [20].

► **Lemma 24** (Generalization of Lemma 3.5 in [20]). *The  $\sqrt{n}$  live vertices with smallest average rank are all active.*

► **Lemma 25** (Generalization of Lemma 3.6 in [20]). *If there are no free edges, and the width of the underlying  $\vec{G}$  is at most  $\sqrt{n}/4$ , then there exists a set  $S$  of at least  $(3/4)\sqrt{n}$  live vertices with known partial order who form a DAG of width at most  $\sqrt{n}/4$ .*

**Proof.** Consider the set  $S$  of at most  $\sqrt{n}$  live vertices with smallest average rank. More precisely, we chose the largest upper bound on the average rank such that  $|S| \leq \sqrt{n}$ . By Lemma 22, at most  $\sqrt{n}/4$  vertices can have the same average rank, such that  $|S| \geq 3/4\sqrt{n}$ . By Lemma 24, all vertices of  $S$  are active. Let  $u, v \in S$  be a pair of vertices that have a directed path  $P$  from  $u$  to  $v$  in  $\vec{G}$ . Then, all of this path  $P$  is in  $S$ , and all live vertices of  $P$  are in  $S$ . Hence, because there are no free edges, and all vertices of  $P$  not in  $S$  are exhausted, all edges of  $P$  must be probed. Hence,  $S$  is convex. The statement on the width follows from a chain decomposition of  $\vec{G}$  remaining a chain decomposition for a convex subset of vertices. ◀

Note that Lemma 25 does not imply that the algorithm can, or should, identify precisely this set  $S$  defined in the proof. Hence, the algorithm is going to approximate the smallest width subset of at least  $3/4\sqrt{n}$  vertices among the live vertices. More precisely, starting from an empty  $S$ , it is going to iteratively find the longest (outside  $S$ ) chain among the live vertices (also using edges that are implied by transitivity via edges in  $S$ ). It stops once  $S$  contains at least  $3/4\sqrt{n}$  vertices, and uses it as the DAG of small width in the setting of Lemma 19, and determine for every remaining live vertex its predecessors in  $S$ , with  $O(w \log n)$  queries each, compared to the  $O(\log n)$  queries if there is a Hamiltonian. Hence, the total number of queries increases from  $O(n^{3/2} \log n)$  to  $O(w n^{3/2} \log n)$ , as claimed in Theorem 20, completing the proof.

## Abstract

---

We study the Maximum Independent Set (MIS) problem on general graphs within the framework of learning-augmented algorithms. The MIS problem is known to be NP-hard and is also NP-hard to approximate to within a factor of  $n^{1-\delta}$  for any  $\delta > 0$ . We show that we can break this barrier in the presence of an oracle obtained through predictions from a machine learning model that answers vertex membership queries for a fixed MIS with probability  $1/2 + \varepsilon$ . In the first setting we consider, the oracle can be queried once per vertex to know if a vertex belongs to a fixed MIS, and the oracle returns the correct answer with probability  $1/2 + \varepsilon$ . Under this setting, we show an algorithm that obtains an  $\tilde{O}(\sqrt{\Delta}/\varepsilon)^1$ -approximation in  $O(m)$  time where  $\Delta$  is the maximum degree of the graph. In the second setting, we allow multiple queries to the oracle for a vertex, each of which is correct with probability  $1/2 + \varepsilon$ . For this setting, we show an  $O(1)$ -approximation algorithm using  $O(n/\varepsilon^2)$  total queries and  $\tilde{O}(m)$  runtime. <sup>2</sup>

## 1 Introduction

We consider learning-augmented *maximum independent set* (MIS) in this paper. Given a (unweighted, undirected) graph  $G = (V, E)$ , an independent set is a set of vertices  $I \subseteq V$ , such that for any  $u, v \in I$ ,  $(u, v) \notin E$ , i.e., there is *no* edge between  $u$  and  $v$ . The maximum independent set problem asks to find the independent set with the largest size in  $G$ .

---

<sup>1</sup> Throughout we use  $\tilde{O}(\cdot)$  to hide polylog( $n$ ) factors.

<sup>2</sup> A full version appears on arxiv under the same title.

Finding the maximum independent set is one of the classical NP-hard problems [42]. Furthermore, the seminal work of [36, 60] demonstrates the NP-hardness of approximating the size of the MIS to within a factor of  $n^{1-\delta}$  for any  $\delta > 0$ . In contrast, outputting any single vertex gives an  $n$ -approximation trivially. [10] gave a non-trivial  $O(n/\log^2 n)$ -approximation to MIS and this was later improved by [29]. These results indicate that the problem is quite hard in its general form and thus, many research efforts have been devoted to approximation algorithms in special settings, e.g., planar graphs [3, 47], rectangle-intersection graphs [16, 22, 32], and exponential-time algorithms [51, 31, 59, 12].

On the other hand, heuristic algorithms, despite their bad worst-case guarantees, often exhibit commendable performance on real-world graphs [4, 24, 57]. For instance, the greedy algorithm only offers an approximation guarantee of  $O(\Delta)$ , where  $\Delta$  is the *maximum degree* of  $G$ . However, it frequently yields satisfactory empirical results. The gap between the worst-case hardness and practical efficiency motivates us to study the MIS problem through the lens of beyond worst-case analysis [11, 52]. In particular, under the modern context, we ask the question of finding the maximum independent set with *learning-augmented oracles*.

### Learning-augmented algorithms

Learning-augmented algorithms, also known as algorithms with predictions, have attracted considerable attention in recent years (see, e.g. [50, 38, 46, 21, 56, 7, 9, 1, 37, 13, 53], and references therein). This paradigm of beyond worst-case analysis has been successful in surmounting classical thresholds and bridging the gap between the worst-case hardness and practical efficiency (see, e.g., [48], for an excellent summary). Typically, in learning-augmented algorithms, we assume the access to an oracle that gives part of the “right answer” to the problem, and fails with some small but non-negligible probability. Conceptually, these algorithms aim to take advantage of modern machine learning models, which are fairly accurate on predictive tasks yet make random mistakes in an inconsistent fashion. Learning-augmented algorithms provide a great way to analyze algorithms beyond the worst case, and these algorithms usually have immediate implications in practice (see the empirical results in, e.g., [20, 38, 26, 56, 1]). Inspired by the recent work in utilizing machine learning-based techniques for the maximum independent set [2, 49, 14], we consider the MIS problem through the lens of learning-augmented algorithms.

The advantage of the learning-augmented algorithms has inspired a flurry of work that studies *graph problems* within this framework [8, 30, 17, 18, 39, 5, 45, 6, 23, 33]. In a very recent work, [23] considered the Max-cut problem, in which the oracle model is closely related to our setting for the MIS problem. Under the Unique Game Conjecture (UCG), it is known that getting anything better than  $\alpha \approx 0.878$  approximation for max-cut is NP-hard ([43]). In contrast, [23] showed that with a learning-augmented oracle, we could achieve better approximation than the  $\alpha$  threshold in polynomial time. In another closely related work, [33] studied the more general constraint satisfaction problems (CSPs) through the lens of the learning-augmented algorithms. There, they obtain results for both the Max-cut and the Max 2-Lin problem. Although [23, 33] defines more general learning-augmented oracles, they, unfortunately, fall short of capturing the MIS-type of CSP problems, and their results do not have direct implications on the MIS problem.

From the above discussion, we can see that *a)* studying the maximum independent set problem in the framework of learning-augmented algorithms has great potential; and *b)* to this end, the existing models and algorithms are not yet sufficient. In light of this, we ask the following question:

*Under the framework of learning-augmented algorithms, what efficient algorithms can we get for the maximum independent set problem?*

## 1.1 Our models and contributions

In what follows, we will define the learning-augmented oracle model we consider and present our main results.

### Our oracle model

We consider the following natural learning-augmented oracle: for a fixed maximum independent set  $I^*$ , the oracle answers whether a vertex  $v \in I^*$  correctly with probability  $1/2 + \varepsilon$ , and incorrectly with probability  $1/2 - \varepsilon$ . In addition, the randomness is *independent* across the vertices. We denote by  $\text{ORC}_{G,I^*}(v)$  the answer the oracle gives when queried for vertex  $v$ .

We study approximation algorithms for MIS with the learning-augmented oracle in two settings: the *persistent noise* setting and the *non-persistent noise* setting. We discuss the settings and the results, respectively, as follows.

- The **persistent noise** setting. In the persistent noise setting, the randomness of  $\text{ORC}_{G,I^*}$  is drawn exactly *once*. Therefore, the answer for a vertex will remain the same no matter how many times you query the oracle. Another way to think about this is that the oracle can be queried at most once for a vertex. This setting is the most standard in the learning-augmented literature, and graph problems are often studied under persistent noise (see, e.g. [30, 17, 18, 58, 39, 5, 23, 33] and references therein). Our main result in this setting is a randomized algorithm that with high probability<sup>3</sup> achieves an  $\tilde{O}(\sqrt{\Delta})$  (multiplicative) approximation to the MIS in  $O(m)$  time (Theorem 1).
- The **non-persistent noise** settings. In this setting, for each vertex  $v$ , we allow  $\text{ORC}_{G,I^*}(v)$  to use *fresh randomness* for different queries. If we are allowed to make  $O(n \log n)$  queries to the oracle in total, then we can trivially recover the entire set  $I^*$  with high probability by querying each vertex  $O(\log n)$  times. The interesting case is when we are allowed to make only  $O(n)$  queries, i.e., a number that is *asymptotically the same* as the persistent noise setting. Although the non-persistent noise setting is less frequently studied in the learning-augmented algorithm literature, it has recently sparked considerable interest in various problems [34, 35, 44]. In Appendix B of the full version, we show that it is easy to get an  $O(\log n)$ -approximation with  $O(n)$  queries. Our main result considerably improved on the approximation factor: we show that we can indeed obtain an  $O(1)$  approximation with  $O(n)$  queries and  $\tilde{O}(m)$  runtime (Theorem 5).

Our results in the persistent noise setting hold assuming full independence, but it can be easily extended to the setting where oracle queries are assumed to use  $k$ -wise independent hash function for  $k = O(\log n)$ . Extending it to the pair-wise independent case is challenging as the failure probabilities in the concentration bounds are not enough for the application of a union bound.

## 1.2 Technical overview

The biggest challenge in leveraging the oracle information is distinguishing the case where  $\text{ORC}_{G,I^*}(v)$  is indeed correct. In what follows, we give a high-level overview of our techniques describing how we can use the neighborhood information for this purpose. For the simplicity of the discussion, we always assume  $\varepsilon = \Theta(1)$  in the technical overview.

<sup>3</sup> As standard in the literature, we use “with high probability” to denote a success probability of  $1 - 1/\text{poly}(n)$ .

### Persistent noise setting

A natural approach in this setting would be to figure out the conditions in which a “yes” signal for a vertex  $v$  from the oracle implies  $v \in I^*$ , by aggregating signals from  $N(v)$ . However, such an idea is hard in the following sense. For a vertex  $v$  whose oracle query  $\text{ORC}_{G,I^*}(v) = 1$ , if there are many  $u \in N(v)$  such that  $\text{ORC}_{G,I^*}(u) = 1$ , we can determine that  $v$  should *not* be in the MIS. However, the converse is not true: if a vertex  $v$  is *not* in  $I^*$ , it does *not* necessarily have many neighbors in  $I^*$ . As a result, simply aggregating neighborhood information might not be enough to determine the membership of a vertex in the MIS.

The key idea here is, instead of looking at the oracle answer for vertex  $v$  ( $\text{ORC}_{G,I^*}(v)$ ), we look at what the oracle says for the *neighborhood* of the vertex  $v$ . This turns out to be a good enough signal to eliminate vertices that have *many* edges to the MIS  $I^*$ . Specifically, we can show that if  $v$  has  $\tilde{\Omega}(\sqrt{\deg(v)})$  edges to  $I^*$ , then the oracle queries for  $N(v)$  contain enough information to identify such a vertex  $v$ . Upon removal of such vertices, the remaining vertices have a small degree ( $\tilde{O}(\sqrt{\Delta})$ ) to  $I^*$ , and a greedy independent set on the residual vertices gives a good approximation.

### Non-persistent noise setting

Our algorithm for this setting is a bit more nuanced as we aim to minimize the query complexity to the oracle while aiming to achieve a good approximation. The starting point of our algorithm is from the viewpoint of the classical *pure exploration* algorithms in *multi-armed bandits (MABs)*. If we ignore the nature of MIS in our oracle, we can reduce to the following MABs problem: given  $n$  arms with mean rewards as either  $\frac{2}{3}$  or  $\frac{1}{3}$ , find *all* the arms with mean reward  $\frac{2}{3}$  with  $O(n)$  arm pulls. It is well-known that one can find a *single* best arm with high constant probability in  $O(n)$  queries. The question is, can we solve the problem by resorting to purely MABs algorithms, and simply ignoring the nature of the MIS?

It turns out that the above plan is not generally feasible. In particular, we note that returning the set of *all* arms with the higher reward is very similar to finding the *top- $k$  arms* in the MABs literature (see, e.g. [40, 41, 15, 19, 55]). In general, it would require  $\Omega(n \log k)$  arm pulls to obtain top- $k$  arms with high constant probability ([41, 55]). In Appendix C of the full version, we provide lower bound results, showing that to find even  $O(1)$  fraction of the high-reward arms in the instance distribution requires  $\omega(n)$  queries. The lower bounds teach us that to obtain the desired query efficiency and approximation guarantee, we have to exploit the structure of the MIS.

To better understand the hardness and the insights of MABs algorithms on our problem, let us look at the elimination-based algorithm as in the classical algorithm of [27, 28]. The first idea we can try is to adapt the elimination algorithm to our problem. To this end, a natural idea is to perform elimination based on whether the mean empirical reward of an arm is more than  $\frac{1}{2}$ . More concretely, we maintain a pool  $\tilde{I}$  of surviving vertices and use  $s_r$  as the number of queries to each vertex in round  $r$  with  $s_1 = O(1)$ . In round  $r$ , we can query  $\text{ORC}_{G,I^*}(v)$  for  $s_r$  time for each  $v \in \tilde{I}$ . We then eliminate all vertices  $v \in \tilde{I}$  whose number of “yes” answers is less than  $s_r/2$ , and recurse on the new  $\tilde{I}$  to round  $r + 1$ , for which we set  $s_{r+1} = 1.5s_r$ .

Since the probability for any  $v \notin I^*$  to survive decreases doubly-exponentially with the number of rounds, we can show that *all* vertices  $v \notin I^*$  are eliminated after  $O(\log \log n)$  rounds, and the total sample complexity on the *non-MIS* vertices is at most  $O(n)$ . Furthermore, the probability of losing any  $v \in I^*$  decreases exponentially, we can argue that in the end,  $\tilde{I}$

contains at least  $\Omega(1)$  fraction of the vertices in  $I^*$ . Unfortunately, due to this fact, for each vertex  $v \in I^* \cap \tilde{I}$ , i.e., the vertices in the MIS that survive till the end, we need to pay for  $2^{O(\log \log n)} = \text{polylog } n$  on the sample complexity. Therefore, this pure exploration algorithm only works when the size of  $I^*$  is upper-bounded by  $n/\text{polylog } n$ , and its worst-case guarantee is only a  $\text{polylog } n$  approximation.

Note that a  $\text{polylog } n$  approximation is far from what we want: after all, there is a trivial algorithm that achieves  $O(\log n)$  approximation with  $O(n)$  samples (see Appendix B of full version for details). Nevertheless, the existence of such an algorithm teaches us that the problematic case is when the MIS size is large and, in particular, *comparable* to the size of the non-MIS vertices. As such, a natural idea is to design an algorithm that handles the case when the numbers of the MIS and the non-MIS vertices are comparable, and fuse this algorithm with the elimination-based MABs procedure we discussed above.

The above idea is quite close to the final strategy we adapt, albeit we proceed differently for the roles of the two components. In particular, we use the pure exploration MABs algorithm not to output a set with vertex set  $\tilde{I} \subseteq I^*$ , but to output a set of vertex set  $\tilde{I}$  whose *majority (but not necessarily all)* of vertices are in  $I^*$ . To this end, we use a more *conservative* elimination strategy than the ones in the line of [27, 28]: instead of increasing the number of samples by a multiplicative factor, we increase the number of samples in each round by an *additive* factor. In this way, we cannot guarantee that all the “wrong” arms are eliminated; however, we can argue that, since the probability for the non-MIS vertices to survive decreases exponentially, we have *i)* the number of samples used on the vertices in  $I^*$  is bounded by  $O(n)$  *before* the size of  $\tilde{I} \setminus I^*$  reduces to the size of  $\tilde{I} \cap I^*$ ; and *ii)* the number of vertices in  $\tilde{I} \cap I^*$  only decreases by a constant fraction. In this way, we can design an efficient procedure that eliminates the “surplus” non-MIS vertices to always create cases when the number of non-MIS vertices is smaller.

The final missing piece is the MIS algorithm that deals with the case when the number of MIS vertices takes the majority of the vertex set. Our algorithm to handle this case is to compute an *approximate vertex cover* of the graph and the remaining vertices will form an approximate independent set. It is a well-known fact that if we compute a *maximal matching* and take *all* their endpoints, it forms a 2-approximate vertex cover that covers all edges in the graph. Furthermore, since the size of the non-MIS vertices is small, there can be only a *limited number* of vertices  $v \in I^*$  that can be counted in the vertex cover. As such, we can simply *remove* these vertices from the graph. The rest of the graph would form an independent set, and since we remove at most a constant fraction of vertices from  $I^*$  throughout the two phases, we get an  $O(1)$  approximation.

## 2 Preliminaries

### Notation

For a graph  $G = (V, E)$ , we use  $\deg(v)$  and  $N(v)$  for each vertex  $v \in V$  to denote the degree and neighborhood of  $v$ , respectively. We use  $G[U]$  for any set  $U$  of vertices to denote the induced subgraph of  $G$  on  $U$ .

We let  $I^*$  denote a fixed maximum independent set of the graph  $G$ . We let  $N_{I^*}(v) = N(v) \cap I^*$  be the set of neighbors of the vertex  $v$  in the independent set and let  $\deg_{I^*}(v) := |N_{I^*}(v)|$  be its size. Furthermore, we let  $\tilde{N}_{I^*}(v)$  be the set of neighbors of the vertex  $v$  that are claimed to be in the independent set by the oracle and let  $\tilde{\deg}_{I^*}(v)$  be its size.

For the purpose of conciseness, we defer the technical preliminaries to Appendix A.

### 3 An Algorithm in the Persistent Noise Setting

In this section we present an algorithm for the learning-augmented MIS problem with persistent noise. Formally we prove the following

► **Theorem 1.** *There exists a randomized algorithm that given*

- i) *an input graph  $G = (V, E)$  with maximum degree  $\Delta$  and*
- ii) *an MIS oracle  $\text{ORC}_{G, I^*}$  with persistent noise for an unknown maximum independent set  $I^*$ ,*

*in  $O(m)$  time outputs an independent set  $I$  such that  $|I| \geq \frac{\varepsilon}{12} \cdot (\Delta \ln n)^{-0.5} \cdot |I^*|$  with high probability.*

We dedicate the remainder of this section to the proof of Theorem 1. We start with the assumption that  $\varepsilon \leq 1/4$  (we can do this for any constant  $> 0$ ). This assumption is needed for technical reasons. If  $\varepsilon > 1/4$ , then it is easy to simulate an oracle with  $\varepsilon = 1/4$  by flipping the oracle answer with probability  $p = \frac{\varepsilon - 1/4}{1/2 + \varepsilon}$  ( $p \geq 0$  since  $\varepsilon > 1/4$ ). If we do this then the probability that the oracle gives the incorrect answer is  $(1/2 - \varepsilon) + p \cdot (1/2 + \varepsilon) = 1/4$  which is exactly what we wanted. Note that the final bound we get on the approximation factor now changes by a factor of at most 2. This is because when  $\varepsilon > 1/4$  we are replacing it with an oracle for  $\varepsilon = 1/4$  and the approximation factor linearly depends on  $\varepsilon$ .

#### The algorithm and analysis

We now state our algorithm.

■ **Algorithm 1** An algorithm for MIS in persistent noise setting.

---

**Input:** A graph  $G = (V, E)$  with maximum degree  $\Delta$  that contains an unknown maximum independent set  $I^*$ ; an MIS oracle  $\text{ORC}_{G, I^*}$  in the persistent noise setting

**Output:** A set of vertices  $I$  such that  $I$  forms an independent set and  $|I| \geq \frac{\varepsilon}{3} \cdot (\Delta \ln n)^{-0.5} \cdot |I^*|$ .

**Parameters:**  $s_v := (1/2 - \varepsilon) \deg(v) + 6\sqrt{\ln n} \cdot (1/2 - \varepsilon) \sqrt{\deg(v)}$ .

1. Calculate  $\widetilde{\deg}_{I^*}(v)$  for all vertices  $v \in V$ .
  2. Let  $L$  be the set of vertices where  $\widetilde{\deg}(v) \leq 36 \ln n$  for  $v \in V$ .
  3. Let  $S$  be the set of vertices where  $\widetilde{\deg}_{I^*}(v) \leq s_v$  for  $v \in V \setminus L$ .
  4. Output the greedy MIS  $I$  on  $G[S \cup L]$ .
- 

We first show that if  $v \in I^*$ , the number of “yes” answers in  $N(v)$  cannot be too high.

▷ **Claim 2.** If  $v \in I^* \setminus L$  then with high probability,  $\widetilde{\deg}_{I^*}(v) \leq (1/2 - \varepsilon) \deg(v) + 6\sqrt{\ln n} \cdot (1/2 - \varepsilon) \sqrt{\deg(v)}$ .

*Proof.* If  $v \in I^*$  then  $\deg_{I^*}(v) = 0$  which means that the expected size of  $\widetilde{\deg}_{I^*}(v)$  is  $(1/2 - \varepsilon) \deg(v)$ . Since we assume complete independence for the oracle we can use the Chernoff bound to get concentration.

Let  $X_i = 1$  if  $i^{\text{th}}$  neighbor is claimed to be in  $I^*$  by the oracle where  $i \in [\deg(v)]$ . Observe that  $\widetilde{\deg}_{I^*}(v) = \sum_i X_i$  is the number of neighbors that claim to be in  $I^*$ . We know  $\mu = \mathbb{E}[\widetilde{\deg}_{I^*}(v)] = (1/2 - \varepsilon) \deg(v)$ . Using the Chernoff (Proposition 12) bound with  $\delta_v = 6 \left( \frac{\ln n}{\deg(v)} \right)^{0.5} \leq 1$ :

$$\Pr \left( \widetilde{\deg}_{I^*}(v) > (1 + \delta_v) \mu \right) \leq \exp \left( -\frac{\delta_v^2 \cdot \mu}{3} \right) \leq n^{-3}. \quad (\text{since } \varepsilon \leq 1/4)$$

Notice that as  $\deg(v)$  gets larger we get better concentration. ◁

Note that Claim 2 does *not* rule out the case that a vertex  $v \in V \setminus I^*$  and has very few neighbors in  $I^*$ . Nevertheless, it tells us that if we simply eliminate the vertices that “block” a large number of neighbors in  $I^*$ , we will not mistakenly drop vertices in  $I^*$ .

Next, we show that if a vertex  $v$  has many neighbors in  $I^*$  i.e.  $\deg_{I^*}(v)$  is large then  $\widetilde{\deg}_{I^*}(v)$  should also be large and hence we should be able to detect such a vertex  $v \notin I^*$ .

▷ **Claim 3.** If  $v \notin I^*$  and  $\deg_{I^*}(v) \geq (3/\varepsilon)\sqrt{\ln n}\sqrt{\deg(v)}$  then with high probability,  $\widetilde{\deg}_{I^*}(v) > (1/2 - \varepsilon)\deg(v) + 6\sqrt{\ln n} \cdot (1/2 - \varepsilon)\sqrt{\deg(v)}$ .

Proof. If  $v \notin I^*$  and  $\deg_{I^*}(v) = k$  then the expected size of  $\widetilde{\deg}_{I^*}(v)$  is

$$\mu = \mathbb{E} \left[ \widetilde{\deg}_{I^*}(v) \right] = k(1/2 + \varepsilon) + (\deg(v) - k)(1/2 - \varepsilon) = (1/2 - \varepsilon)\deg(v) + 2\varepsilon k.$$

We now use the Chernoff bound (Proposition 11) with  $t = \varepsilon k$  to get concentration:

$$\begin{aligned} \Pr \left( \widetilde{\deg}_{I^*}(v) < \mu - t \right) &\leq \exp(-2t^2 / \deg(v)) \\ &= \exp(-2\varepsilon^2 k^2 / \deg(v)) \\ &\leq n^{-3}. \end{aligned} \quad (\text{using the lower bound on } k)$$

Thus, with high probability we have:

$$\begin{aligned} \widetilde{\deg}_{I^*}(v) &\geq \mu - \varepsilon k \\ &= (1/2 - \varepsilon)\deg(v) + \varepsilon k \\ &= (1/2 - \varepsilon)\deg(v) + 3\sqrt{\ln n}\sqrt{\deg(v)} \\ &> (1/2 - \varepsilon)\deg(v) + 6\sqrt{\ln n} \cdot (1/2 - \varepsilon)\sqrt{\deg(v)}. \end{aligned} \quad \triangleleft$$

We can conclude that the events in Claim 2 and Claim 3 happen with high probability by a union bound over all vertices.

**Finalizing the proof of Theorem 1.** Calculating  $\widetilde{\deg}_{I^*}(v)$  for all vertices  $v \in V$  and finding set  $S$  takes  $O(m)$  time. The greedy MIS can also be computed in  $O(m)$  time.

We first condition on the events in Claim 2 and Claim 3 for all vertices (this happens with high probability). Notice that for all vertices in  $v \in S$  we have  $\widetilde{\deg}_{I^*}(v) \leq s_v$ . By Claim 2 all vertices in  $I^*$  are in  $S$ . By Claim 3 we know that any non-MIS vertices  $v$  that are in  $S$  have  $\deg_{I^*}(v) \leq (3/\varepsilon)\sqrt{\ln n}\sqrt{\deg(v)} \leq (6/\varepsilon)\sqrt{\Delta \ln n}$ . Also, vertices in  $L$  have  $\deg_{I^*}(v) \leq \deg(v) = \sqrt{\deg(v)} \cdot \sqrt{\deg(v)} \leq \sqrt{\Delta}\sqrt{36 \ln n} \leq (6/\varepsilon)\sqrt{\Delta \ln n}$ .

This means that when we run the greedy MIS algorithm and pick a non-MIS vertex, we eliminate at most  $(6/\varepsilon)\sqrt{\Delta \ln n}$  vertices in  $I^*$ . Thus, we have  $|I| \geq \frac{\varepsilon}{6} \cdot (\Delta \ln n)^{-0.5} \cdot |I^*|$ . Finally, because of the assumption on  $\varepsilon$  ( $\varepsilon \leq 1/4$ ), we lose a factor of at most 2 in the approximation, giving us the final bound  $|I| \geq \frac{\varepsilon}{12} \cdot (\Delta \ln n)^{-0.5} \cdot |I^*|$ . ◀

▶ **Remark 4.** We assume that we have complete independence between the oracle queries for the vertices. But we can get essentially the same result (up to constants) when the oracle answers the queries using a  $k$ -wise independent hash function instead of a completely random function for  $k = O(\log n)$ .

This holds because we use Proposition 13 with  $k = O(\log n)$  instead of the Chernoff bound (Proposition 12). The min in the exponent always picks the second term because  $k$  is large enough and so we get something very similar to the Chernoff bound in Proposition 12 where the exponent only differs by some constants. Thus, the approximation we get will be a small constant factor worse but will remain the same asymptotically.

#### 4 An Algorithm in the Non-persistent Noise Setting

In this section, we consider algorithms in the *non-persistent noise setting* (*MABs setting*) of the MIS oracle, i.e., the algorithm can access the learning-augmented MIS oracle with *fresh randomness* for each query of a vertex  $v$ . The formal statement of our main result in this setting is as follows.

► **Theorem 5.** *There exists a randomized algorithm that given a parameter  $\delta \in (0, 1)$  and*

- i) *an input graph  $G = (V, E)$  with a maximum independent set  $I^*$ ; and*
- ii) *an MIS oracle  $\text{ORC}_{G, I^*}$  in the non-persistent noise setting,*

*with probability at least  $(1 - \delta)$ , in  $O(m \log n)$  time and  $\frac{30n}{\varepsilon^2} \cdot \log \frac{1}{\delta}$  total queries to  $\text{ORC}_{G, I^*}$ , computes a set  $I$  such that  $|I| \geq \frac{48}{50} \cdot |I^*|$ .*

We dedicate the remainder of this section to the proof of Theorem 5.

#### The algorithm

As we have discussed in our high-level overview, our algorithm proceeds in two phases. In the first phase, our algorithm focuses on eliminating most of the vertices in the non-MIS vertex set. Then, in the second phase, we show that a good approximation to vertex cover is enough to get a good approximation to the independent set. We can easily find a 2-approximate vertex cover in  $O(m)$  time by computing a maximal matching and picking all its endpoints. The detailed description of the algorithm is as follows.

■ **Algorithm 2** An algorithm for MIS in non-persistent noise setting.

---

**Input:** A graph  $G = (V, E)$  that contains an unknown maximum independent set  $I^*$ ; an MIS oracle  $\text{ORC}_{G, I^*}$  in the multi-armed bandit setting; a confidence parameter  $\delta \in (0, 1)$ .

**Output:** A set of vertices  $I$  such that  $I$  forms an independent set and  $|I| = O(|I^*|)$ .

**Parameters:**  $q_r = \frac{4}{\varepsilon^2} \cdot (r + \log \frac{1}{\delta})$ .

- Maintain a set of  $V_r$  with the initialization  $V_0 \leftarrow V$ .
  - For  $r = 1$  to  $\infty$ , do the following:
    1. **Elimination phase:**
      - For each vertex  $v \in V_{r-1}$ :
        - a. Query  $v$  for  $q_r$  times.
        - b. Remove  $v$  from  $V_{r-1}$  if the number of 1 returned by  $\text{ORC}_{G, I^*}(v)$  (“yes” answers) is less than  $q_r/2$ .
      - Let the updated vertex set be  $V_r$ , i.e.,  $V_r$  is a subset of vertices of  $V_{r-1}$  that gets at least  $q_r/2$  “yes” answers from  $\text{ORC}_{G, I^*}(v)$ .
    2. **Vertex Cover phase:**
      - a. Compute a 2-approximate vertex cover  $U_r$  of the induced subgraph  $G[V_r]$ .
      - b. Let  $I_r \leftarrow V_r \setminus U_r$ .
    3. Maintain the set  $I$  with the maximum size among all  $I_r$ 's, i.e., let  $I \leftarrow I_r$  if  $I_r$  is larger than  $I$  and keep  $I$  unchanged otherwise.
    4. If the total number of  $\text{ORC}_{G, I^*}$  queries is more than  $30 \cdot \frac{n}{\varepsilon^2} \cdot \log \frac{1}{\delta}$  then terminate and return the currently maintained  $I$ .
- 

Note that since we do *not* necessarily know the actual size of  $I^*$ , we compute a vertex cover after every elimination phase and simply output the independent set with the largest size throughout the process.

### The analysis

We now proceed to the analysis of the algorithm. Before diving into the main lemmas, we first show some straightforward technical claims that characterize the behavior of the MIS and non-MIS vertices in the elimination phase. We first show that the probabilities of an MIS vertex being eliminated and a non-MIS vertex surviving in round  $r$  are both small.

▷ **Claim 6.** The following statements are true:

1. Let  $v \in V_{r-1} \cap I^*$ ; then, the probability that  $v$  is removed from  $V_r$  is at most  $\frac{1}{100} \cdot \frac{\delta}{4^r}$ .
2. Let  $v \in V_{r-1} \setminus I^*$ ; then, the probability that  $v$  is *not* removed from  $V_r$  is at most  $\frac{1}{100} \cdot \frac{\delta}{4^r}$ .

*Proof.* We prove this claim by applying the Chernoff bound in Proposition 11. For any vertex  $v \in I^*$ , let the random variable  $X_v^i = 1$  if the  $i^{\text{th}}$  query for vertex  $v$  is a “yes” and  $X_v^i = 0$  otherwise for  $i \in [q_r]$ . Observe that  $X_v = \sum_i X_v^i$  is the number of “yes” answers returned by  $\text{ORC}_{G, I^*}(v)$  out of the  $q_r$  queries. Clearly, we have that  $\mathbb{E}[X_v] = (1/2 + \varepsilon) \cdot q_r$ , and  $X_v$  is a summation of the independent indicator random variables so, we can apply Proposition 11 to show that

$$\begin{aligned}
 \Pr\left(X_v < \frac{q_r}{2}\right) &= \Pr(X_v - \mathbb{E}[X_v] \leq -\varepsilon \cdot q_r) \\
 &\leq \exp(-2 \cdot \varepsilon^2 \cdot q_r) && \text{(applying Proposition 11)} \\
 &= \exp\left(-8r - 8 \log \frac{1}{\delta}\right) && \text{(by the definition of } q_r) \\
 &\leq \exp(-6) \cdot \exp(-2r) \cdot \exp\left(-8 \log \frac{1}{\delta}\right) \\
 &\leq \frac{1}{100} \cdot \frac{\delta}{4^r}.
 \end{aligned}$$

Note that the vertices in  $v \in I^* \cap V_{r-1}$  are in  $I^*$ . Therefore, we can get the desired statement for  $v \in I^* \cap V_{r-1}$ .

We can similarly define  $Y_v$  for the number of “yes” answers returned by  $\text{ORC}_{G, I^*}(v)$  with  $q_r$  queries for a vertex  $v \in V \setminus I^*$ . Here, we have that  $\mathbb{E}[Y_v] = (1/2 - \varepsilon)q_r$ . As such, we have that

$$\begin{aligned}
 \Pr\left(Y_v \geq \frac{q_r}{2}\right) &= \Pr(Y_v - \mathbb{E}[Y_v] \geq \varepsilon \cdot q_r) \\
 &\leq \exp(-2 \cdot \varepsilon^2 \cdot q_r) && \text{(applying Proposition 11)} \\
 &= \exp\left(-8r - 8 \log \frac{1}{\delta}\right) && \text{(by the definition of } q_r) \\
 &\leq \exp(-6) \cdot \exp(-2r) \cdot \exp\left(-8 \log \frac{1}{\delta}\right) \\
 &\leq \frac{1}{100} \cdot \frac{\delta}{4^r}.
 \end{aligned}$$

This gives us the desired statement for  $v \in V_{r-1} \setminus I^*$  as well. ◁

We now prove the main technical lemma of our algorithm that helps eventually prove Theorem 5. In what follows, we will denote the size of  $I^*$  as  $\alpha n$  for some  $\alpha \in (0, 1)$ . Our main lemma for the elimination phase is as follows.

► **Lemma 7.** *Let  $|I^*| = \alpha n$  for some  $\alpha \in (0, 1)$  and  $\tilde{r} = 1 + \log \frac{1}{\alpha}$ . With probability at least  $1 - \delta$ , the following statements about Algorithm 2 are true:*

- 1) *The number of vertices in  $V_{\tilde{r}}$  that are not in  $I^*$  is at most  $\alpha n/100$ , i.e.,*

$$|V_{\tilde{r}} \setminus I^*| \leq \frac{\alpha n}{100}.$$

## 24:10 Learning-Augmented Maximum Independent Set

II) The number of vertices in  $V_{\tilde{r}}$  that are in  $I^*$  is at least  $49/50 \cdot \alpha n$ , i.e.,

$$|V_{\tilde{r}} \cap I^*| \geq \frac{49}{50} \cdot \alpha n.$$

III) The total number of  $ORC_{G,I^*}$  queries in the first  $\tilde{r}$  rounds is at most  $30n/\varepsilon^2 \cdot \log 1/\delta$ , i.e.,

$$\sum_{r=1}^{\tilde{r}} |V_{r-1}| \cdot q_r \leq 30 \cdot \frac{n}{\varepsilon^2} \cdot \log \frac{1}{\delta}.$$

Note that in the above,  $|V_{r-1}| \cdot q_r$  is exactly the number of queries used in round  $r$ .

**Proof.** We prove the statements in order.

**Proof of i).** Note that by Claim 6, the probability that a vertex in  $V \setminus I^*$  survives round  $r$  is at most  $\frac{1}{100} \cdot \frac{\delta}{4^r}$ . As such, we have that

$$\begin{aligned} \mathbb{E}[|V_{\tilde{r}} \setminus I^*|] &= \sum_{v \in V_{\tilde{r}-1} \setminus I^*} \Pr(v \text{ survives round } \tilde{r}) \\ &= \sum_{v \in V \setminus I^*} \Pr(v \text{ survives all rounds till } \tilde{r}) \\ &= \sum_{v \in V \setminus I^*} \prod_{i=1}^{\tilde{r}} \Pr(v \text{ survives round } i \mid v \text{ survives all rounds till } i-1) \\ &\hspace{15em} \text{(All rounds are independent)} \\ &\leq \sum_{v \in V \setminus I^*} \prod_{i=1}^{\tilde{r}} \frac{\delta}{100} \cdot \frac{1}{4^i} \\ &\leq n \cdot \left(\frac{\delta}{100}\right)^{\tilde{r}} \cdot \left(\frac{1}{4}\right)^{\binom{\tilde{r}}{2}} \\ &\leq \frac{\delta n}{100} \cdot \left(\frac{1}{4}\right)^{\tilde{r}} \\ &\leq \frac{\alpha \cdot n \cdot \delta}{400}. \hspace{10em} \text{(using } \alpha \in (0, 1)) \end{aligned}$$

Therefore, by Markov inequality, we have

$$\Pr\left(|V_{\tilde{r}} \setminus I^*| > \frac{\alpha n}{100}\right) \leq \frac{\delta}{4}$$

as desired.

**Proof of ii).** By Claim 6, the probability that a vertex  $v$  is eliminated in round  $r$  is at most  $\frac{\delta}{100} \cdot \frac{1}{4^r}$ . We analyze the number of vertices in  $I^*$  that are eliminated by round  $r$ . We can show that the expected value is

$$\begin{aligned} \mathbb{E}[|I^* \setminus V_{\tilde{r}}|] &= \sum_{v \in I^*} \Pr(v \text{ is eliminated by round } \tilde{r}) \\ &\leq \sum_{v \in I^*} \sum_{i=1}^{\tilde{r}} \Pr(v \text{ is eliminated in round } i) \hspace{5em} \text{(Union Bound)} \\ &\leq \sum_{v \in I^*} \sum_{i=1}^{\tilde{r}} \frac{\delta}{100} \cdot \frac{1}{4^i} \\ &\leq (\alpha n) \cdot \frac{\delta}{100} \cdot \frac{1}{3}. \hspace{10em} \text{(Geometric Sum)} \end{aligned}$$

Therefore, by a simple Markov bound, we have that

$$\Pr\left(|I^* \setminus V_r| > \frac{\alpha n}{50}\right) \leq \frac{\delta}{6}.$$

Thus, with probability at least  $1 - \delta/6$  we have  $|I^* \cap V_{\tilde{r}}| \geq \frac{49}{50} \cdot \alpha n$ .

**Proof of iii).** Note that we are proving this bound holds even if we remove the termination condition from the algorithm. This will show that we will reach round  $\tilde{r}$  with high probability. We first condition on the events in the proofs of *i*) and *ii*). Note that, unlike the standard analysis of elimination-based algorithms, here, we cannot directly upper-bound the total number of queries each round. Instead, we separately analyze the number of queries induced by the vertices in  $I^*$  and  $V \setminus I^*$ .

We first analyze the number of queries induced by the vertices in  $V \setminus I^*$ . Let us define  $X_{-I^*}$  as the total number of queries induced by the non-MIS vertices. Similarly, we can define  $X_{-I^*}^r$  as the queries induced by the non-MIS vertices at round  $r$ . Thus, we have that

$$\begin{aligned} \mathbb{E}[X_{-I^*}] &= \sum_{v \in V - I^*} \sum_{i=1}^{\tilde{r}} \Pr(v \text{ survives till round } i) \cdot q_i \\ &\leq n \sum_{i=1}^{\tilde{r}} q_i \prod_{j=1}^i \Pr(v \text{ survives round } j \mid v \text{ survives till round } j-1) \\ &\leq n \sum_{i=1}^{\tilde{r}} q_i \prod_{j=1}^i \frac{\delta}{100} \cdot \frac{1}{4^j} && \text{(Claim 6)} \\ &\leq n \sum_{i=1}^{\tilde{r}} \left(\frac{\delta}{100}\right)^i \cdot \left(\frac{1}{4}\right)^{\binom{i}{2}} \cdot q_i \\ &= n \sum_{i=1}^{\tilde{r}} \left(\frac{\delta}{100}\right)^i \cdot \left(\frac{1}{4}\right)^{\binom{i}{2}} \cdot \frac{4}{\varepsilon^2} \cdot (i + \log 1/\delta) \\ &\leq \frac{4\delta n}{100\varepsilon^2} \sum_{i=1}^{\tilde{r}} \left(\frac{1}{4}\right)^i \cdot (i + \log 1/\delta) && \text{(Since } \delta \leq 1) \\ &\leq \frac{4\delta n}{100\varepsilon^2} (1 + \log 1/\delta). && \text{(using properties of geometric sums)} \end{aligned}$$

Therefore, by Markov inequality, we can show that

$$\Pr\left(X_{-I^*} > \frac{2n}{5\varepsilon^2} \log 1/\delta\right) \leq \delta/5.$$

We now analyze the queries induced by the vertices in  $I^*$ . Similar to the case of the non-MIS analysis, let us define  $X_{I^*}$  as the total number of queries induced by the MIS vertices. We will trivially upper bound  $X_{I^*}$  in the following way:

$$\begin{aligned} X_{I^*} &\leq \alpha n \sum_{i=1}^{\tilde{r}} q_i \\ &= \alpha n \sum_{i=1}^{\tilde{r}} \frac{4}{\varepsilon^2} \cdot \left(i + \log \frac{1}{\delta}\right) \end{aligned}$$

## 24:12 Learning-Augmented Maximum Independent Set

$$\begin{aligned}
&\leq \frac{4\alpha n}{\varepsilon^2} \cdot \left( \tilde{r}^2 + \tilde{r} \cdot \log \frac{1}{\delta} \right) \\
&\leq \frac{4\alpha n}{\varepsilon^2} \cdot \left( 1 + (\log 1/\alpha)^2 + \lg 1/\alpha \cdot (2 + \log 1/\delta) + \log 1/\delta \right) \\
&\leq \frac{4n}{\varepsilon^2} \cdot (5 + 2 \log 1/\delta) \quad (\text{using } \alpha \cdot \lg \frac{1}{\alpha} \leq 1 \text{ and } \alpha \cdot \lg^2 \frac{1}{\alpha} \leq 2 \text{ for any } \alpha \in (0, 1))
\end{aligned}$$

We can then add the number of queries used by  $X_{\neg I^*}$  and  $X_{I^*}$  to get the desired sample complexity bound of  $\frac{30n}{\varepsilon^2} \cdot \log 1/\delta$ .

Finally, we can apply a union bound over the failure probabilities of the events in the proofs of *i*), *ii*), and *iii*) to argue that with probability at least  $1 - \delta$ , all the statements hold.

Lemma 7 ◀

We now proceed to show the guarantee of the matching and MIS phase. Our main lemma for this part is as follows.

► **Lemma 8.** *Let  $V_r \subseteq V$  be any subset of vertices in Algorithm 2. Furthermore, assume that the number of MIS vertices in  $V_r$  is at least 50 times the number of non-MIS vertices in  $V_r$ , i.e.,*

$$|V_r \cap I^*| \geq 50 \cdot |V_r \setminus I^*|.$$

Then, the set  $I_r$  returned by Algorithm 2 is a valid independent set, and we have

$$|I_r| \geq \frac{49}{50} \cdot |V_r \cap I^*|.$$

**Proof.** Recall that we compute a 2-approximate vertex cover  $U_r$  in the vertex cover phase. We know that the complement  $I_r \leftarrow V_r \setminus U_r$  is an independent set. This is because all edges of the graph are incident on the vertex cover so the remaining vertices form an independent set.

We know that  $V_r \setminus I^*$  is a vertex cover since  $V_r \cap I^*$  is an independent set. Thus, we have

$$\begin{aligned}
|I_r| &= |V_r| - |U_r| && (\text{by definition}) \\
&\geq |V_r \cap I^*| + |V_r \setminus I^*| - 2|V_r \setminus I^*| && (\text{since } U_r \text{ is a 2-approximation}) \\
&\geq |V_r \cap I^*| - \frac{1}{50} \cdot |V_r \cap I^*| && (\text{using the assumption}) \\
&= \frac{49}{50} \cdot |V_r \cap I^*|
\end{aligned}$$

Lemma 8 ◀

The final missing piece is the *efficiency* of the algorithm. We now prove that the algorithm is efficient both in time and the number of  $\text{ORC}_{G, I^*}$  oracle queries.

► **Lemma 9.** *Algorithm 2 runs in  $O(m \log n)$  time and uses at most  $\frac{30n}{\varepsilon^2} \cdot \log \frac{1}{\delta}$  queries on  $\text{ORC}_{G, I^*}$ .*

**Proof.** The query complexity is by the design of the algorithm as we terminate upon using more than  $30 \cdot \frac{n}{\varepsilon^2} \cdot \log \frac{1}{\delta}$  queries.

For the running time, note that in each iteration of  $r$ , we only need to: *i*). take the majority for all queried vertices, which can be maintained in  $O(n)$  time; and *ii*). compute a greedy matching and remove the vertices, which takes  $O(m)$  time. By Lemma 7, the process terminates in  $O(\log \frac{1}{\alpha}) = O(\log n)$  time ( $\alpha \geq \frac{1}{n}$  since there has to be at least one vertex in  $I^*$ ). Therefore, the entire algorithm takes  $O(m \log n)$  time in total. ◀

**Finalizing the proof of Theorem 5.** The query efficiency is by the design of the algorithm, and the running time simply follows from Lemma 9. For the approximation guarantee, note that by Lemma 7, we will proceed to round  $\tilde{r} = 10 \log \frac{1}{\alpha}$ , at which point we will have  $|V_{\tilde{r}} \cap I^*| \geq \frac{49}{50} \cdot \alpha n$  and  $|V_r \cap I^*| \geq 50 \cdot |V_r \setminus I^*|$ . Therefore, by Lemma 8, the returned  $I_{\tilde{r}}$  is of size at least

$$|I_{\tilde{r}}| \geq \frac{49}{50} \cdot |V_{\tilde{r}} \cap I^*| \geq \frac{49}{50} \cdot \frac{49}{50} \cdot \alpha n,$$

which gives us the desired  $48/50$  approximation.  $\blacktriangleleft$

► **Remark 10.** We aim to get the  $O(1)$  approximation in our algorithm and analysis. However, we remark that we can get both non-asymptotic and asymptotic trade-offs between the number of queries and the approximation factor. For the non-asymptotic trade-off (i.e., using more queries to get a better constant approximation), we can increase the leading constant on the sample complexity, and obtain the approximation with a larger constant. For the asymptotic trade-off, we can perform the simple trick by sampling  $k$  vertices uniformly at random and running Algorithm 2 on the sampled vertices. This will give us an  $O(\frac{k}{n})$ -approximation algorithm with  $O(\frac{k}{\varepsilon^2} \cdot \log \frac{1}{\delta})$  queries as long as  $\alpha k = \Omega(\log n)$ .

## 5 Discussion and Open Problems

We discussed learning-augmented algorithms for the Maximum Independent Set problem in this paper. Our main results include algorithms for both persistent and non-persistent noise settings, demonstrating that a learning-augmented oracle could lead to MIS algorithms with considerably better efficiency. There are several intriguing open problems following our work.

- For the **persistent noise** setting, the main open question is whether we could beat the  $\tilde{\Theta}(\sqrt{\Delta}/\varepsilon)$  approximation bound with the same oracle. We do not have any lower bounds for the persistent noise setting in this paper, and it is unclear what type of techniques could be used to prove lower bounds for learning-augmented algorithms.
- For the **non-persistent noise** setting, our algorithm matches the *asymptotically* optimal approximation factor using  $O(n)$  queries. In Appendix C of full version, we also proved that we cannot obtain the same results by only querying the oracle (and *not* looking into the graph). An open problem here is that if we want to recover a  $1 - o(1)$  fraction of the MIS vertices, how many queries do we need? We suspect there is a lower bound on the number of queries (e.g.,  $\omega(n)$ ), but it is not immediately clear how to prove it.
- We can also ask about **sublinear** number of queries on the oracle  $\text{ORC}_{G, I^*}$ , i.e., if we make  $o(n)$  queries on the oracle, what is the best we can do for both persistent and non-persistent noise settings? Currently, our algorithms in both settings require  $\Omega(n)$  queries to the oracle.
- Finally, for the **practical** aspect of the algorithms, we believe the oracles are possible to implement in practice. For instance, if we have features on the nodes, it is possible to use forward-pass graph convolution networks (GCNs), and simply run greedy in each “cluster” of nodes whose final features are sufficiently similar. Exploring practical oracles for this purpose would also be an interesting problem to resolve.

---

## A Technical Preliminaries

We use the following standard forms of Chernoff bound.

► **Proposition 11** (Chernoff-Hoeffding bound). *Let  $X_1, \dots, X_m$  be  $m$  independent random variables with support in  $[0, 1]$ . Define  $X := \sum_{i=1}^m X_i$ . Then, for every  $t > 0$ ,*

$$\Pr(X - \mathbb{E}[X] \geq t) \leq \exp\left(-\frac{2t^2}{m}\right)$$

$$\Pr(X - \mathbb{E}[X] \leq -t) \leq \exp\left(-\frac{2t^2}{m}\right).$$

► **Proposition 12** (Chernoff bound; c.f. [25]). *Suppose  $X_1, \dots, X_m$  are  $m$  independent random variables with range  $[0, 1]$  each. Let  $X := \sum_{i=1}^m X_i$  and  $\mu_L \leq \mathbb{E}[X] \leq \mu_H$ . Then, for any  $\delta \in [0, 1]$ ,*

$$\Pr(X > (1 + \delta) \cdot \mu_H) \leq \exp\left(-\frac{\delta^2 \cdot \mu_H}{3 + \delta}\right) \quad \text{and} \quad \Pr(X < (1 - \delta) \cdot \mu_L) \leq \exp\left(-\frac{\delta^2 \cdot \mu_L}{2 + \delta}\right).$$

We also consider limited independence hash functions. Roughly speaking, a  $k$ -wise independent hash function behaves like a totally random function when considering at most  $k$  elements. Formally, a family of hash functions  $H = \{h : [n] \rightarrow [m]\}$  is  $k$ -wise independent if for any  $x_1, x_2, \dots, x_k \in [n]$  and  $y_1, y_2, \dots, y_k \in [m]$  the following holds:

$$\Pr_{h \in_R H}(h(x_1) = y_1 \wedge h(x_2) = y_2 \wedge \dots \wedge h(x_k) = y_k) = m^{-k}.$$

We shall use the following concentration result on an extension of Chernoff-Hoeffding bounds for limited independence hash function.

► **Proposition 13** ([54]). *Suppose  $h$  is a  $k$ -wise independent hash function and  $X_1, \dots, X_m$  are  $m$  random variables in  $\{0, 1\}$  where  $X_i = 1$  iff  $h(i) = 1$ . Let  $X := \sum_{i=1}^m X_i$ . Then, for any  $\delta > 0$ ,*

$$\Pr(|X - \mathbb{E}[X]| \geq \delta \cdot \mathbb{E}[X]) \leq \exp\left(-\min\left\{\frac{k}{2}, \frac{\delta^2}{4 + 2\delta} \cdot \mathbb{E}[X]\right\}\right).$$

# Maximum Unique Coverage on Streams: Improved FPT Approximation Scheme and Tighter Space Lower Bound

## Abstract

We consider the Max Unique Coverage problem, including applications to the data stream model. The input is a universe of  $n$  elements, a collection of  $m$  subsets of this universe, and a cardinality constraint,  $k$ . The goal is to select a subcollection of at most  $k$  sets that maximizes unique coverage, i.e., the number of elements contained in exactly one of the selected sets. The Max Unique Coverage problem has applications in wireless networks, radio broadcast, and envy-free pricing.

Our first main result is a fixed-parameter tractable approximation scheme (FPT-AS) for Max Unique Coverage, parameterized by  $k$  and the maximum element frequency,  $r$ , which can be implemented on a data stream. Our FPT-AS finds a  $(1 - \varepsilon)$ -approximation while maintaining a kernel of size  $\tilde{O}(kr/\varepsilon)$ , which can be combined with subsampling to use  $\tilde{O}(k^2r/\varepsilon^3)$  space overall. This significantly improves on the previous-best FPT-AS with the same approximation, but a kernel of size  $\tilde{O}(k^2r/\varepsilon^2)$ . In order to achieve our first result, we show upper bounds on the ratio of a collection's coverage to the unique coverage of a maximizing subcollection; this is by constructing explicit algorithms that find a subcollection with unique coverage at least a logarithmic ratio of the collection's coverage. We complement our algorithms with our second main result, showing that  $\Omega(m/k^2)$  space is necessary to achieve a  $(1.5 + o(1))/(\ln k - 1)$ -approximation in the data stream. This dramatically improves the previous-best lower bound showing that  $\Omega(m/k^2)$  is necessary to achieve better than a  $e^{-1+1/k}$ -approximation.

## 1 Introduction

We study the **Max Unique Coverage** problem, where we are given a universe of  $n$  elements, a collection of  $m$  subsets of the universe, and an integer  $k \in \{1, \dots, m\}$ . The goal is to select a collection of at most  $k$  subsets that maximizes the number of elements covered by *exactly* one set in the collection. This problem is a natural variant of the classic **Max Coverage** problem, where the goal is to select a collection of  $k$  subsets that maximizes the number of elements covered by *at least* one set in the collection.

A weighted version of **Max Unique Coverage** was first formally studied by Demaine et al. [9]. In their motivating scenario, a number of wireless base stations, each with an associated cost, must be placed to maximize the number of mobile clients served. However, due to interference, if covered by more than one base station, a client receives bad service. Demaine et al. point out further applications to radio broadcast and envy-free pricing. They then showed an offline polynomial-time  $\Omega(1/\log m)$ -approximation algorithm for their problem, which easily translates to a  $\Omega(1/\log k)$ -approximation for our problem.<sup>1</sup> Under various complexity assumptions, they showed (semi-)logarithmic inapproximability for polynomial-time algorithms; Guruswami and Lee [11] later proved nearly logarithmic inapproximability, assuming NP does not admit quasipolynomial-time algorithms.

**Streaming.** Our work emphasizes solving **Max Unique Coverage** approximately in the data stream model. All previous works, except McGregor et al. [15], only consider this problem in the offline model. In the data stream model, we focus on *set-streaming*: each set in the stream is fully specified before the next; this setting is assumed in related works [18, 2, 22, 16, 15]. We also constrain the space, measured in bits, to be  $o(mn)$ , i.e., sublinear in both the number of sets,  $m$ , and the size of the universe,  $n$ . Thus, we define the **Max Unique Coverage** problem to include the cardinality constraint,  $k$ . Previous works often formulate this problem without a cardinality constraint, simply referring to it as the “Unique Coverage” problem; this is equivalent to our formulation when  $k = m$ .

We are particularly interested in **Max Unique Coverage** when parameterized by  $k$  and the *maximum frequency*,  $r$ , defined as the maximum number of sets that an element belongs to; we also consider the *maximum set size*  $d$  to a lesser extent. This parameterization has received considerable attention in studying fixed-parameter tractable approximation schemes (FPT-AS) for classic coverage problems [21, 4, 20, 14, 15, 13, 19], but not as much for the **Max Unique Coverage** problem [15]. Note that an FPT exact algorithm for this parameterization is unlikely to exist because, when  $r = 2$ , **Max Unique Coverage** is equivalent to Capacitated Max Cut, which was shown by Misra et al. [17] to be W[1]-hard when parameterized by the capacity constraint.<sup>2</sup>

A central idea in achieving both FPT space and running time bounds is *kernelization*. We transform a problem instance,  $\mathcal{I}$ , into a smaller problem instance,  $\mathcal{I}'$ , called the (*approximate*) *kernel*, such that  $|\mathcal{I}'| \leq g(\gamma)$ , where  $g$  is a computable function in terms of problem parameters  $\gamma$ , while  $\mathcal{I}'$  (approximately) preserves the optimal solution value of  $\mathcal{I}$ ; a good solution can be found by brute-force search within  $\mathcal{I}'$ . Consistent with other works [8, 7, 6, 15], we further require an FPT streaming algorithm to use  $g(\gamma)$  polylog  $|\mathcal{I}|$  space.

<sup>1</sup> This is by assuming that all sets have unit cost and that the budget is  $k$ .

<sup>2</sup> Although Misra et al. [17] prove W[1]-hardness for Budgeted Max Cut when parameterized by the budget, their hardness proof only requires each vertex (corresponding to a set in our formulation) to have unit cost.

## 1.1 Our Contributions

Our first main result is an FPT-AS for **Max Unique Coverage** with strong space, running time, and approximation bounds, that is applicable to the data stream model. A crucial step in achieving such bounds is showing improved upper bounds on a key parameter of a collection  $\mathcal{C}$ . The *unique coverage ratio* is the ratio between the coverage of  $\mathcal{C}$  and the maximum unique coverage over all subcollections  $\mathcal{Q} \subseteq \mathcal{C}$ . We let  $\phi$  denote an *upper bound* on the unique coverage ratio: we define performance bounds of our FPT-AS in terms of  $\phi$ .

**Main Result 1: FPT Approximation Scheme.** We propose the FPT-AS `UNIQUETOPSETS`, parameterized by the cardinality constraint,  $k$ , and the maximum frequency,  $r$ , which can be easily implemented in the data stream model. It achieves a  $(1 - \varepsilon)$ -approximation using a kernel of size  $\lceil kr(\phi + 1)/\varepsilon \rceil$ . We formally present this algorithm in Theorem 3.6.

`UNIQUETOPSETS` is a refined version of the FPT-AS in Theorem 12 of McGregor et al. [15], in that our algorithm achieves a  $(1 - \varepsilon)$  rather than a  $(1/2 - \varepsilon)$ -approximation using only an extra logarithmic factor of  $(\phi + 1)$  in the kernel size. Further, our algorithm improves on the FPT-AS in Theorem 10 of McGregor et al. [15] by saving a factor of  $O(k/\varepsilon)$  in the kernel size, and therefore a factor of  $[O(k/\varepsilon)]^k$  in the running time, while achieving the same approximation factor. See Table 1 for a comparison of our FPT-AS with others.

■ **Table 1** Comparison of FPT-AS for **Max Unique Coverage**, parameterized by cardinality constraint,  $k$ , and maximum frequency,  $r$ . Note that the running time of each algorithm below is implied by its kernel size. Each finds a solution of size at most  $k$  by brute-force search in the kernel. Below, we can assign  $\phi = \min(\ln k + 1, 2 \ln r + o(\log r), 2 \ln d + o(\log d))$ .

| Reference  | Approx.             | Kernel Size                              |
|--|---------------------|--|
| [15, Theorem 10]                                 | $1 - \varepsilon$   | $O(k^2 r \log m / \varepsilon^2)$        |
| [15, Theorem 12]                                 | $1/2 - \varepsilon$ | $\lceil kr/\varepsilon \rceil$           |
| Ours, Theorem 3.6 ( <code>UNIQUETOPSETS</code> ) | $1 - \varepsilon$   | $\lceil kr(\phi + 1)/\varepsilon \rceil$ |

**Unique Coverage Algorithms.** In order to show good values for  $\phi$ , we propose a number of offline polynomial-time algorithms that, given an arbitrary  $\mathcal{C}$ , explicitly return a  $\mathcal{B} \subseteq \mathcal{C}$  whose unique coverage is at least a logarithmic ratio of  $\mathcal{C}$ 's coverage. We refer to them as *unique coverage algorithms*; in fact, they can be thought as approximation algorithms for the unconstrained Unique Coverage problem on an input instance of  $\mathcal{C}$ .

Our three offline polynomial-time algorithms, `UNIQUEGREEDY`, `UNIQUEGREEDYFREQ`, and `UNIQUEGREEDYSIZE`, each take a collection of sets,  $\mathcal{C}$ , and return a collection,  $\mathcal{B} \subseteq \mathcal{C}$ , whose unique coverage is at least a  $1/(\ln \ell + 1)$ ,  $1/(2 \ln r + o(\log r))$ , and  $1/(2 \ln d + o(\log d))$  proportion of  $\mathcal{C}$ 's coverage respectively; in this context,  $\ell = |\mathcal{C}|$ ,  $r$  is the maximum frequency in  $\mathcal{C}$ , and  $d$  is the maximum set size in  $\mathcal{C}$ . We formally present these algorithms in Theorem 4.1, Theorem 4.4, and in Theorem 4.8, respectively. See Table 2 for a comparison of our algorithms with those of Demaine et al. [9] along with their implied bounds,  $\phi$ , albeit weaker than ours.

■ **Table 2** Polynomial-time algorithms for **Max Unique Coverage**. Compared to others, our methods imply constant-factor improvements in the unique coverage ratio bound,  $\phi$ .

| Parameter                                  | Reference                               | (Implied) $\phi$      |
|--|---|-----------------------|
| $\ell =$ collection size                   | [9, Theorem 4.1]                        | $10.66 \ln(\ell + 1)$ |
|  | Ours, Theorem 4.1<br>(UNIQUEGREEDY)     | $\ln \ell + 1$        |
| $r =$ maximum frequency<br>in a collection | [9, Theorem 4.1]                        | $10.66 \ln(r + 1)$    |
|  | Ours, Theorem 4.4<br>(UNIQUEGREEDYFREQ) | $2 \ln r + o(\log r)$ |
| $d =$ maximum set size<br>in a collection  | [9, Theorem 4.2]                        | $21.32 \ln(d + 1)$    |
|  | Ours, Theorem 4.8<br>(UNIQUEGREEDYSIZE) | $2 \ln d + o(\log d)$ |

**Implication for FPT Approximation Scheme.** The bound on the unique coverage ratio,  $\phi$ , affects the kernel size and therefore the brute-force running time of UNIQUETOPSETS. In particular, when  $r = \Omega(\sqrt{k})$ , the bound of  $\phi$  implied by UNIQUEGREEDY is 10.66 times smaller than implied by Demaine et al. [9]; whereas when  $r = o(\sqrt{k})$ , the bound of  $\phi$  implied by UNIQUEGREEDYFREQ is almost 5.33 smaller than implied by Demaine et al. This means, by using our implied bounds rather than those implied by Demaine et al., we save a factor of  $10.66^k$  in UNIQUETOPSETS’s running-time when  $r = \Omega(\sqrt{k})$ , and a factor of almost  $5.33^k$  when  $r = o(\sqrt{k})$ .

**Improvements in Polynomial-Time Approximation.** As a separate contribution, each of our three unique coverage algorithms finds a logarithmic approximation to **Max Unique Coverage**, both offline and in the data stream. We first find a solution  $\mathcal{C}$  to **Max Coverage** in polynomial time, and then run one of our above algorithms on  $\mathcal{C}$  to return the subcollection  $\mathcal{B} \subseteq \mathcal{C}$ . For this purpose, our algorithms UNIQUEGREEDY, UNIQUEGREEDYFREQ, and UNIQUEGREEDYSIZE improve the approximation factor due to Demaine et al. [9] by a factor of 10.66, 5.33, and 10.66, respectively. Following the above approach, we propose a single-pass streaming algorithm for **Max Unique Coverage** that achieves a  $(1/(2\phi) - \varepsilon)$ -approximation using  $\tilde{O}(k^2/\varepsilon^3)$  space, where we can assign  $\phi = \min(\ln k + 1, 2 \ln r + o(\log r), 2 \ln d + o(\log d))$ . We formally state this in Theorem 3.8.

**Main Result 2: Streaming Lower Bound.** Our second main result is a significantly improved streaming lower bound for **Max Unique Coverage**. In the data stream model, we prove that any randomized algorithm that achieves a  $(1.5 + o(1))/(\ln k - 1)$ -approximation for **Max Unique Coverage** w.h.p. requires  $\Omega(m/k^2)$  space. We formally state this in Theorem 5.1. Our lower bound improves on the lower bound by McGregor et al. [15], which shows a similar result, but achieves w.h.p. a  $e^{-1+1/k} \geq 1/e$ -approximation. Interestingly, our approximation threshold is close to 3 times larger than the approximation (in terms of  $k$ ) achieved by our  $\tilde{O}(k^2/\varepsilon^3)$  space algorithm in Theorem 3.8, indicating that a dramatic increase in space is needed to bridge this approximation gap.

■ **Table 3** Comparison of space lower bounds for **Max Unique Coverage** in the data stream. Note that the lower bound by Assadi [1] was shown for **Max Coverage** with constant  $k = 2$ , but it is not difficult to adapt it for **Max Unique Coverage** because, in the hard instance constructed for the lower bound, the unique coverage of any pair of sets behaves similarly to its coverage.

## 1.2 Technical Overview

**FPT Approximation Scheme.** `UNIQUETOPSETS` refines the technique used in the FPT-AS for **Max Unique Coverage** in Theorem 12 of McGregor et al. [15], which is to construct an approximate kernel by storing a number of the largest sets by individual size, and then to find a subcollection of the kernel with maximum unique coverage by brute-force search. Similar techniques have been used in FPT-AS approaches for Max Vertex Cover [14, 13] and **Max Coverage** [21, 20, 15, 19]. Our novelty is providing a stronger analysis of the approximation factor preserved by the kernel, allowing us to achieve a  $(1 - \varepsilon)$ -approximation while only increasing the kernel size by a logarithmic factor in  $k$ ,  $r$ , or  $d$ .

**Unique Coverage Algorithms.** All of our unique coverage algorithms are combinatorial in design. Our first two, `UNIQUEGREEDY` and `UNIQUEGREEDYFREQ`, are novel algorithms that each, in some sense, use a greedy approach, noting that `UNIQUEGREEDY` is used as subroutine of `UNIQUEGREEDYFREQ`. Our third algorithm, `UNIQUEGREEDYSIZE`, is easily derived by combining `UNIQUEGREEDYFREQ` with the approach by Demaine et al. [9] for sets with maximum cost  $d$  (maximum size in our case).

**Streaming Lower Bound.** Our streaming lower bound relies on a novel reduction from  $k$ -player Set Disjointness in the one-way communication model to **Max Unique Coverage** in the data stream. In the hard instance of **Max Unique Coverage** thus constructed, either all collections of  $\ell \leq k$  sets have a unique coverage of  $ak^2(1.5 + o(1))$  w.h.p. or there exists a single collection of  $k$  sets whose unique coverage is at least  $ak^2(\ln k - 1)$ , where  $a = \Omega(k \log m)$ . By a standard argument, we show that distinguishing between these instances of **Max Unique Coverage** with a streaming algorithm is as hard as solving Set Disjointness, implying the required space lower bound.

## 1.3 Paper Structure

After preliminaries in Section 2, Section 3 presents our FPT-AS `UNIQUETOPSETS` and a polynomial-time algorithm, both applicable to the data stream. In Section 4, we present our component algorithms for bounding the unique coverage ratio. In Section 5, we present a space lower bound for achieving a  $(1.5 + o(1))/(\ln k - 1)$ -approximation for **Max Unique Coverage**. We conclude in Section 7. Claims whose proofs are found in the full version of this paper are marked thus: (\*).

## 2 Preliminaries

**Notation.** For convenience, we hence let  $[n]$  denote the set of integers  $\{1, 2, \dots, n\}$ . Likewise,  $U = [n]$  denotes a universe of  $n$  elements, while  $\mathcal{V}$  denotes a collection of  $m$  subsets of  $U$ .

Given a collection  $\mathcal{C}$  of sets, the *unique cover* of  $\mathcal{C}$  is the subset of the universe covered by exactly one set in  $\mathcal{C}$ , formally,  $\tilde{\psi}(\mathcal{C}) := (\bigcup_{S \in \mathcal{C}} S) \setminus (\bigcup_{S \neq T \in \mathcal{C}} S \cap T)$ , and the *unique coverage* of  $\mathcal{C}$  is  $|\tilde{\psi}(\mathcal{C})|$ . For convenience, the *cover* of  $\mathcal{C}$  is the union of the sets in  $\mathcal{C}$ , formally  $\psi(\mathcal{C}) := \bigcup_{S \in \mathcal{C}} S$ , and the *coverage* of  $\mathcal{C}$  is  $|\psi(\mathcal{C})|$ . Further, the *non-unique cover* of  $\mathcal{C}$  is the subset of the universe covered by at least two sets from  $\mathcal{C}$ , formally  $\psi_{\geq 2}(\mathcal{C}) = \bigcup_{S \neq T \in \mathcal{C}} S \cap T$  – or equivalently  $\psi_{\geq 2}(\mathcal{C}) = \psi(\mathcal{C}) \setminus \tilde{\psi}(\mathcal{C})$  – and the *non-unique coverage* of  $\mathcal{C}$  is  $|\psi_{\geq 2}(\mathcal{C})|$ . The *maximum unique coverage* of  $\mathcal{C}$  is the largest unique coverage of a subcollection of  $\mathcal{C}$ . The *unique coverage ratio* of  $\mathcal{C}$  is the ratio between its coverage and maximum unique coverage. In other words, if  $\mathcal{Q}$  is the subcollection of  $\mathcal{C}$  that has maximum unique coverage, then the unique coverage ratio of  $\mathcal{C}$  is  $|\psi(\mathcal{C})|/|\tilde{\psi}(\mathcal{Q})|$ .

Given an element  $x \in U$  and a collection  $\mathcal{C}$  of sets, the *frequency* of  $x$  in  $\mathcal{C}$  is defined as  $\text{freq}_{\mathcal{C}}(x) := |\{S \in \mathcal{C} : x \in S\}|$ , i.e., the number of sets in  $\mathcal{C}$  that contain  $x$ ; and the *maximum frequency* is defined as  $r := \max_{x \in U} \text{freq}_{\mathcal{C}}(x)$ . Also, the *maximum set size* is defined as  $d := \max_{S \in \mathcal{C}} |S|$ . We often use  $r$  and  $d$  to refer to the maximum frequency and set size, respectively, in  $\mathcal{C} = \mathcal{V}$  unless stated otherwise. Note that  $r \leq |\mathcal{C}|$  holds for every  $\mathcal{C}$ . We let  $H_z := \sum_{t=1}^z 1/t$  denote the  $z^{\text{th}}$  harmonic number, a term that appears several times.

**Formal Problem Definition.** An instance of **Max Unique Coverage** consists of an element universe  $U$ , a collection  $\mathcal{V}$  of  $m$  subsets of  $U$ , and an integer  $k \in [m]$ ; when the context is clear, we represent an instance with just  $\mathcal{V}$  for simplicity. The goal of **Max Unique Coverage** is to return a subcollection  $\mathcal{B} \subseteq \mathcal{V}$  (more precisely, a collection of IDs of sets), with  $|\mathcal{B}| \leq k$ , that maximizes  $|\tilde{\psi}(\mathcal{B})|$ . We let  $\mathcal{O}$  denote an optimal solution to this **Max Unique Coverage** problem, and  $\text{OPT} := |\tilde{\psi}(\mathcal{O})|$  as the maximum unique coverage.

**Subsampling for the Data Stream Model.** The universe subsampling technique has been widely successful in the development of streaming algorithms for coverage problems [10, 12, 3, 16]. In this work, we follow the approach of McGregor and Vu [16], and sample the universe so that each set has size  $O(k \log m / \varepsilon^2)$ . We assume that  $k \in o(mn)$ , and also that  $k$  is known prior to reading the stream. The main result is given in the following lemma, with a proof sketch of the subsampling approach in Section 6.

► **Lemma 2.1** (Subsampling Approach [15]). *Let  $\varepsilon \in (0, 1)$  be the subsampling error parameter. Given an instance of **Max Unique Coverage** and an  $\alpha$ -approximation streaming algorithm, we can run the algorithm on  $\lceil \log_2 n \rceil$  parallel subsampled instances and select one of them such that the algorithm's solution corresponds to a  $(\alpha - 2\varepsilon)$ -approximation for the original instance with probability  $1 - 1/\text{poly}(m)$ . Moreover, if the streaming algorithm stores at most  $s$  sets in every subsampled instance, then the total space complexity of the subsampling approach is bounded by  $\lceil \log_2 n \rceil \cdot s \cdot O(k \log m \log n / \varepsilon^2)$ .*

## 3 Streaming FPT-AS and Polynomial-Time Algorithms

In Section 3.1, we prove a kernelization lemma. Then, we use it to obtain an FPT-AS and a parameterized streaming algorithm in Section 3.2. Finally, we show how to use a bound on the unique coverage ratio to obtain a polynomial-time streaming algorithm in Section 3.3.

### 3.1 Kernelization Lemma

Our Kernelization Lemma below, as well as its proof, is a refinement of Lemma 11 by McGregor et al. [15]. We first provide some intuition on why our kernel preserves a  $(1 - \varepsilon)$ -approximation for **Max Unique Coverage**.

**Intuition of Kernelization Lemma.** For convenience, let  $\varepsilon'$  be an intermediate error parameter and define the kernel  $\mathcal{A}$  as the collection of the  $\lceil kr/\varepsilon' \rceil$  largest sets in instance  $\mathcal{V}$  by individual size. Given the optimal solution for **Max Unique Coverage**,  $\mathcal{O}$ , let  $\mathcal{O}^{\text{in}}$  and  $\mathcal{O}^{\text{out}}$  be the collections of optimal sets found and not found in  $\mathcal{A}$  respectively.

One main step in proving our Kernelization Lemma is showing that, in expectation, a collection of  $|\mathcal{O}^{\text{out}}|$  sets sampled without replacement from  $\mathcal{A}$ , denoted by  $\mathcal{Z}$ , can be appended to  $\mathcal{O}^{\text{in}}$  with little overlap in their unique covers. In particular, we can prove that  $\mathbb{E}[|\tilde{\psi}(\mathcal{O}^{\text{in}} \cup \mathcal{Z})|] \geq (1 - \varepsilon')|\tilde{\psi}(\mathcal{O})| - \varepsilon'|\psi(\mathcal{O})|$ .

However, due to the  $\varepsilon'|\psi(\mathcal{O})|$  term, this is not enough to achieve the required approximation factor. This term reflects the fact that, even if the unique cover of  $\mathcal{O}^{\text{in}}$  has little overlap with the unique cover of  $\mathcal{Z}$ , the *entire* cover of  $\mathcal{O}^{\text{in}}$  could be more extensive and, thus, overlap significantly with the unique cover of  $\mathcal{Z}$ . To address this, in Claim 3.4, we show  $\phi|\tilde{\psi}(\mathcal{O})| \geq |\psi(\mathcal{O})|$ , where  $\phi$  upper bounds the unique coverage ratio. Substituting this into the lower bound for  $\mathbb{E}[|\tilde{\psi}(\mathcal{O}^{\text{in}} \cup \mathcal{Z})|]$ , and assigning  $\varepsilon' = \varepsilon/(\phi + 1)$ , we obtain  $\mathbb{E}[|\tilde{\psi}(\mathcal{O}^{\text{in}} \cup \mathcal{Z})|] \geq (1 - \varepsilon)|\tilde{\psi}(\mathcal{O})|$ , implying the existence of a  $(1 - \varepsilon)$ -approximate subcollection of  $\mathcal{A}$ . Lastly, the final kernel size of  $|\mathcal{A}| = \lceil kr(\phi + 1)/\varepsilon \rceil$  follows from the assignment of  $\varepsilon'$ .

► **Lemma 3.1 (Kernelization Lemma).** *Suppose that every collection of sets has unique coverage ratio at most  $\phi$ . Let  $\mathcal{V}$  denote a collection of sets. Then, for every  $\varepsilon \in (0, 1)$ , the subcollection,  $\mathcal{A}$ , of the  $\lceil kr(\phi + 1)/\varepsilon \rceil$ -largest sets of  $\mathcal{V}$  (by size) contains a subcollection of at most  $k$  sets with unique coverage at least  $(1 - \varepsilon)\text{OPT}$ .*

**Proof.** Assume that  $|\mathcal{V}| \geq \lceil kr(\phi + 1)/\varepsilon \rceil$ : otherwise,  $\mathcal{A}$  would contain every set in  $\mathcal{V}$  and so would trivially have  $\mathcal{O}$  as a subcollection. Let  $\mathcal{O}^{\text{in}} = \mathcal{O} \cap \mathcal{A}$  and  $\mathcal{O}^{\text{out}} = \mathcal{O} \setminus \mathcal{A}$ . Let  $\mathcal{Z}$  be a uniform random sample of  $|\mathcal{O}^{\text{out}}|$  sets chosen from  $\mathcal{A}$  without replacement. The main goal is to prove Claim 3.5, below. Since  $\mathcal{O}^{\text{in}}$  and  $\mathcal{Z}$  are subsets of  $\mathcal{A}$ , this implies the existence of subcollection  $\mathcal{B} \subseteq \mathcal{A}$  as required by the lemma.

We start with the following lower bound on the expected unique coverage of  $\mathcal{O}^{\text{in}} \cup \mathcal{Z}$ , as shown in inequality (1) below. Then we lower bound each of the RHS terms separately and simplify afterwards. By definition,

$$|\tilde{\psi}(\mathcal{O}^{\text{in}} \cup \mathcal{Z})| \geq |\tilde{\psi}(\mathcal{O}^{\text{in}})| + |\tilde{\psi}(\mathcal{Z})| - (|\tilde{\psi}(\mathcal{O}^{\text{in}}) \cap \psi(\mathcal{Z})| + |\psi(\mathcal{O}^{\text{in}}) \cap \tilde{\psi}(\mathcal{Z})|),$$

hence, by linearity of expectation,

$$\mathbb{E}[|\tilde{\psi}(\mathcal{O}^{\text{in}} \cup \mathcal{Z})|] \geq |\tilde{\psi}(\mathcal{O}^{\text{in}})| + \mathbb{E}[|\tilde{\psi}(\mathcal{Z})|] - \mathbb{E}[|\tilde{\psi}(\mathcal{O}^{\text{in}}) \cap \psi(\mathcal{Z})|] - \mathbb{E}[|\psi(\mathcal{O}^{\text{in}}) \cap \tilde{\psi}(\mathcal{Z})|]. \quad (1)$$

Define an intermediate error parameter,  $\varepsilon' = \varepsilon/(\phi + 1)$ , meaning  $|\mathcal{A}| = \lceil kr/\varepsilon' \rceil$ . The probability of a set  $S \in \mathcal{A}$  being selected in  $\mathcal{Z}$  is  $p := |\mathcal{O}^{\text{out}}|/|\mathcal{A}| \leq k/(kr/\varepsilon') = \varepsilon'/r$ . Now Claim 3.2, below, is easily derived from the proof of Lemma 11 in by McGregor et al. [15].

► **Claim 3.2.** It holds that  $\mathbb{E}[|\tilde{\psi}(\mathcal{Z})|] \geq (1 - \varepsilon')|\tilde{\psi}(\mathcal{O}^{\text{out}})|$ .

**Proof.** Quantity  $|\tilde{\psi}(\mathcal{Z})|$  can be lower bounded by summing, over every  $S \in \mathcal{Z}$ , the number of elements in  $S$  not contained in any other  $T \in \mathcal{Z} \setminus \{S\}$ . From there, we prove inequality (3.2), below. We let  $[\mathcal{E}]$  denote the indicator variable for event  $\mathcal{E}$ .

$$\begin{aligned}
 |\tilde{\psi}(\mathcal{Z})| &\geq \sum_{S \in \mathcal{Z}} \left( |S| - \sum_{T \in \mathcal{Z} \setminus \{S\}} |S \cap T| \right), \text{ hence,} \\
 \mathbb{E}[|\tilde{\psi}(\mathcal{Z})|] &\geq \mathbb{E} \left[ \sum_{S \in \mathcal{A}} \left( |S| \mathbb{1}[S \in \mathcal{Z}] - \sum_{T \in \mathcal{A} \setminus \{S\}} |S \cap T| \mathbb{1}[S \in \mathcal{Z} \wedge T \in \mathcal{Z}] \right) \right] \\
 &\geq \sum_{S \in \mathcal{A}} \left( |S|p - \sum_{T \in \mathcal{A} \setminus \{S\}} |S \cap T|p^2 \right) && \Pr[S \in \mathcal{Z} \wedge T \in \mathcal{Z}] \leq p^2 \\
 &\geq \sum_{S \in \mathcal{A}} (|S|p - |S|p^2(r-1)) \geq p(1-pr) \sum_{S \in \mathcal{A}} |S| && \begin{array}{l} \text{each } x \in S \text{ intersects} \\ \leq r-1 \text{ other sets} \end{array} \\
 &\geq p(1-\varepsilon') \sum_{S \in \mathcal{A}} |S| && p \leq \frac{\varepsilon'}{r} \\
 &\geq p(1-\varepsilon') |\mathcal{A}| \frac{\sum_{Y \in \mathcal{O}^{\text{out}}} |Y|}{|\mathcal{O}^{\text{out}}|} && \begin{array}{l} \text{for all } S \in \mathcal{A} \text{ and all} \\ Y \in \mathcal{O}^{\text{out}}: |S| \geq |Y| \end{array} \\
 &\geq p(1-\varepsilon') |\mathcal{A}| \frac{|\tilde{\psi}(\mathcal{O}^{\text{out}})|}{|\mathcal{O}^{\text{out}}|} && \text{subadditivity of } \tilde{\psi} \\
 &= p(1-\varepsilon') \frac{|\tilde{\psi}(\mathcal{O}^{\text{out}})|}{p} = (1-\varepsilon') |\tilde{\psi}(\mathcal{O}^{\text{out}})|. && \triangleleft
 \end{aligned}$$

Claim 3.3 upper bounds the expected size of the overlap between  $\tilde{\psi}(\mathcal{O}^{\text{in}})$  and  $\psi(\mathcal{Z})$  and the expected size of the overlap between  $\tilde{\psi}(\mathcal{Z})$  and  $\psi(\mathcal{O}^{\text{in}})$ .

▷ **Claim 3.3.**  $\mathbb{E}[|\tilde{\psi}(\mathcal{O}^{\text{in}}) \cap \psi(\mathcal{Z})|] \leq \varepsilon' |\tilde{\psi}(\mathcal{O}^{\text{in}})|$  and  $\mathbb{E}[|\psi(\mathcal{O}^{\text{in}}) \cap \tilde{\psi}(\mathcal{Z})|] \leq \varepsilon' |\psi(\mathcal{O}^{\text{in}})|$ .

*Proof.* To prove the first inequality,

$$\mathbb{E}[|\tilde{\psi}(\mathcal{O}^{\text{in}}) \cap \psi(\mathcal{Z})|] \leq \sum_{x \in \tilde{\psi}(\mathcal{O}^{\text{in}})} \sum_{S \in \mathcal{A}: x \in S} \Pr[S \in \mathcal{Z}] \leq \sum_{x \in \tilde{\psi}(\mathcal{O}^{\text{in}})} rp \leq \varepsilon' |\tilde{\psi}(\mathcal{O}^{\text{in}})|.$$

To prove the second inequality, it is clear that  $\tilde{\psi}(\mathcal{Z}) \subseteq \psi(\mathcal{Z})$  for all  $\mathcal{Z}$ , so we have  $\mathbb{E}[|\psi(\mathcal{O}^{\text{in}}) \cap \tilde{\psi}(\mathcal{Z})|] \leq \mathbb{E}[|\psi(\mathcal{O}^{\text{in}}) \cap \psi(\mathcal{Z})|]$ . Then substituting  $\psi(\mathcal{O}^{\text{in}})$  for  $\tilde{\psi}(\mathcal{O}^{\text{in}})$  in the argument for the first inequality, we see that  $\mathbb{E}[|\psi(\mathcal{O}^{\text{in}}) \cap \psi(\mathcal{Z})|] \leq \varepsilon' |\psi(\mathcal{O}^{\text{in}})|$ .  $\triangleleft$

We now turn to a property of the optimal solution for **Max Unique Coverage**,  $\mathcal{O}$ .

▷ **Claim 3.4.**  $\phi |\tilde{\psi}(\mathcal{O})| \geq |\psi(\mathcal{O})|$ .

*Proof.* Recall that we assumed that every collection of sets has unique coverage ratio at most  $\phi$ . In particular,  $\mathcal{O}$  has a subcollection,  $\mathcal{Q}$ , of at most  $k$  sets with  $\phi |\tilde{\psi}(\mathcal{Q})| \geq |\psi(\mathcal{O})|$ . By optimality,  $\mathcal{O}$ 's unique coverage is at least that of  $\mathcal{Q}$ . Thus, we get the desired inequality.  $\triangleleft$

Starting from Ineq. (1), we can now lower bound  $\mathbb{E}[|\tilde{\psi}(\mathcal{O}^{\text{in}} \cup \mathcal{Z})|]$ , thus proving the lemma.

▷ **Claim 3.5.** We have the lower bound  $\mathbb{E}[|\tilde{\psi}(\mathcal{O}^{\text{in}} \cup \mathcal{Z})|] \geq (1-\varepsilon) |\tilde{\psi}(\mathcal{O})|$ .

Proof.

$$\begin{aligned}
& \mathbb{E}[|\tilde{\psi}(\mathcal{O}^{\text{in}} \cup \mathcal{Z})|] \\
& \geq |\tilde{\psi}(\mathcal{O}^{\text{in}})| + \mathbb{E}[|\tilde{\psi}(\mathcal{Z})|] - \mathbb{E}[|\tilde{\psi}(\mathcal{O}^{\text{in}}) \cap \psi(\mathcal{Z})|] - \mathbb{E}[|\psi(\mathcal{O}^{\text{in}}) \cap \tilde{\psi}(\mathcal{Z})|] && \text{Ineq. (1)} \\
& \geq |\tilde{\psi}(\mathcal{O}^{\text{in}})| + (1 - \varepsilon')|\tilde{\psi}(\mathcal{O}^{\text{out}})| - \varepsilon'|\tilde{\psi}(\mathcal{O}^{\text{in}})| - \varepsilon'|\psi(\mathcal{O}^{\text{in}})| && \text{Claims 3.2 and 3.3} \\
& = (1 - \varepsilon')(|\tilde{\psi}(\mathcal{O}^{\text{in}})| + |\tilde{\psi}(\mathcal{O}^{\text{out}})|) - \varepsilon'|\psi(\mathcal{O}^{\text{in}})| \\
& \geq (1 - \varepsilon')|\tilde{\psi}(\mathcal{O})| - \varepsilon'|\psi(\mathcal{O}^{\text{in}})| && \text{subadditivity of } \tilde{\psi} \\
& \geq (1 - \varepsilon')|\tilde{\psi}(\mathcal{O})| - \varepsilon'|\psi(\mathcal{O})| && \text{monotonicity of } \psi \\
& \geq (1 - \varepsilon')|\tilde{\psi}(\mathcal{O})| - \varepsilon'\phi|\tilde{\psi}(\mathcal{O})| && \text{Claim 3.4} \\
& = (1 - \varepsilon'(1 + \phi))|\tilde{\psi}(\mathcal{O})| \\
& = (1 - \varepsilon)|\tilde{\psi}(\mathcal{O})|. && \triangleleft
\end{aligned}$$

### 3.2 Applications of the Kernelization Lemma

We now apply the Kernelization Lemma to prove the following theorem.

► **Theorem 3.6.** *Suppose that every collection of sets has unique coverage ratio at most  $\phi$ . Let  $\mathcal{V}$  denote a collection of sets,  $k \geq 2$  denote the cardinality constraint,  $r \geq 2$  denote the maximum frequency in  $\mathcal{V}$ , and  $\varepsilon \in (0, 1)$  denote an error parameter. Then, there exists*

1. *an FPT-AS that finds a  $(1 - \varepsilon)$ -approximation for **Max Unique Coverage** and has a running time of  $(er(\phi + 1)/\varepsilon)^k \text{poly}(m, n, 1/\varepsilon)$ ; and*
2. *a streaming algorithm that finds a  $(1 - 3\varepsilon)$ -approximation for **Max Unique Coverage** with probability  $1 - 1/\text{poly}(m)$  and uses  $\tilde{O}(\phi k^2 r/\varepsilon^3)$  space.*

Our algorithm, **UNIQUE TOPSETS**, takes a collection of sets  $\mathcal{V}$  with maximum frequency  $r \geq 2$ , a cardinality constraint  $k$ , and an error parameter  $\varepsilon \in (0, 1)$ , and returns a  $(1 - \varepsilon)$ -approximation for **Max Unique Coverage**. It also takes parameter  $\phi$ , an upper bound on the unique coverage ratio of every subcollection. **UNIQUE TOPSETS** first finds  $\mathcal{A}$ , the  $\lceil kr(\phi + 1)/\varepsilon \rceil$ -largest sets  $S \in \mathcal{V}$  by size  $|S|$ . Then, it brute-forces over  $\mathcal{A}$ , i.e., it finds the subcollection of  $\mathcal{A}$  containing at most  $k$  sets and has the maximum unique coverage.

**FPT-AS.** Let us first see how **UNIQUE TOPSETS** has the properties of the FPT-AS claimed in Theorem 3.6. The Kernelization Lemma (Lemma 3.1) immediately implies that the solution returned by **UNIQUE TOPSETS** is a  $(1 - \varepsilon)$ -approximation. The running time bound follows by bounding the number of subcollections of  $\mathcal{A}$  containing at most  $k$  sets.

► **Lemma 3.7.** ***UNIQUE TOPSETS** has running time in  $(er(\phi + 1)/\varepsilon)^k \text{poly}(m, n, 1/\varepsilon)$ .*

**Proof.** **UNIQUE TOPSETS** considers every possible collection of  $\ell \in [k]$  sets from  $\mathcal{A}$  and outputs the one with the best unique coverage. Below, the second inequality holds since replacing  $\ell$  with  $k$  makes each binomial coefficient larger, as  $\ell \leq k \leq kr/2$  due to  $r \geq 2$ ; the equality holds since  $\binom{z+1}{k} = \binom{z}{k}(z+1)/(z+1-k)$ ; and the final inequality holds since  $\binom{z}{k} \leq (ez/k)^k$ . Thus, the running time is bounded as follows.

$$\begin{aligned}
& \sum_{\ell=1}^k \binom{|\mathcal{A}|}{\ell} \text{poly}(m, n) \leq \text{poly}(m, n) \sum_{\ell=1}^k \left( \frac{kr(\phi+1)}{\varepsilon} \frac{1}{\ell} + 1 \right) \leq \text{poly}(m, n) k \left( \frac{kr(\phi+1)}{\varepsilon} \frac{1}{k} + 1 \right) \\
& = \text{poly}(m, n, 1/\varepsilon) \left( \frac{kr(\phi+1)}{\varepsilon} \right) \leq \text{poly}(m, n, 1/\varepsilon) \left( \frac{er(\phi+1)}{\varepsilon} \right)^k. && \triangleleft
\end{aligned}$$

**Streaming Algorithm.** UNIQUETOPSETS can also be run on a data stream using the subsampling approach from Lemma 2.1. UNIQUETOPSETS returns a  $(1 - \varepsilon)$ -approximation in each subsampled instance by Lemma 3.1, implying a  $(1 - 3\varepsilon)$ -approximation for the original instance,  $\mathcal{V}$ , with probability  $1 - 1/\text{poly}(m)$ . Further, it stores  $|\mathcal{A}| \leq \lceil kr(\phi + 1)/\varepsilon \rceil$  sets in each subsampled instance, implying an overall space complexity of  $\lceil \log_2 n \rceil \cdot |\mathcal{A}| \cdot \tilde{O}(k/\varepsilon^2) = \tilde{O}(\phi k^2 r / \varepsilon^3)$ .

### 3.3 Polynomial-Time Streaming Algorithm

Here we present a single-pass streaming algorithm that returns a  $(1/(2\phi) - \varepsilon)$ -approximation for **Max Unique Coverage**, given a bound on the unique coverage ratio,  $\phi$ . We present the algorithm in Theorem 3.8 below.

In the theorem statement, we assume we can use an offline polynomial-time algorithm, ALG, that takes a collection  $\mathcal{C}$  and returns a subcollection  $\mathcal{B} \subseteq \mathcal{C}$  such that  $|\psi(\mathcal{B})| \geq |\psi(\mathcal{C})|/\phi$  for a ratio  $\phi$  depending on  $|\mathcal{C}| \leq k$ , the maximum frequency  $r$ , and the maximum set size  $d$ . ALG can be substituted with a procedure that runs all of our unique coverage algorithms from Section 4 on  $\mathcal{C}$  and returns the solution with the best unique coverage.

► **Theorem 3.8.** *Let  $\mathcal{V}$  denote a data stream of  $m$  sets,  $k \geq 2$  denote a cardinality constraint,  $r \geq 2$  denote the maximum frequency in  $\mathcal{V}$ ,  $d \geq 2$  denote the maximum set size in  $\mathcal{V}$ , and  $\varepsilon \in (0, 1)$  denote an error parameter. Further, assume we have a polynomial-time algorithm ALG with unique coverage ratio  $\phi$  depending on  $k, r$ , and  $d$ . Then we can find a  $(1/(2\phi) - 3\varepsilon)$ -approximation for **Max Unique Coverage** with probability  $1 - 1/\text{poly}(m)$ , using one pass,  $\tilde{O}(k^2/\varepsilon^3)$  space, and in polynomial-time.*

**Proof.** We use the subsampling approach from Lemma 2.1. In each subsampled instance, we use an existing polynomial-time streaming algorithm [16] to find a  $(1/2 - \varepsilon)$ -approximation,  $\mathcal{C}$ , for **Max Coverage** in one pass while storing  $\tilde{O}(k/\varepsilon)$  sets; the sets in  $\mathcal{C}$  must be stored explicitly so that we can run ALG on  $\mathcal{C}$ . Running ALG on  $\mathcal{C}$  returns a  $\mathcal{B} \subseteq \mathcal{C}$  that is a  $(1/(2\phi) - \varepsilon)$ -approximation for the subsampled instance of **Max Unique Coverage**. This implies a  $(1/(2\phi) - 3\varepsilon)$ -approximation for the original instance,  $\mathcal{V}$ , with probability  $1 - 1/\text{poly}(m)$ . Further, explicitly storing  $\tilde{O}(k/\varepsilon)$  sets in each subsampled instance implies an overall space complexity of  $\lceil \log_2 n \rceil \cdot \tilde{O}(k/\varepsilon) \cdot \tilde{O}(k/\varepsilon^2) = \tilde{O}(k^2/\varepsilon^3)$ . ◀

## 4 Algorithms for Bounding the Unique Coverage Ratio

We here present algorithms that run in polynomial time. Given a collection,  $\mathcal{C}$ , each returns a subcollection  $\mathcal{B} \subseteq \mathcal{C}$  such that  $\mathcal{B}$ 's unique coverage is within a logarithmic ratio of  $\mathcal{C}$ 's coverage. We hence call this the *unique coverage ratio* of an algorithm. Our algorithms UNIQUEGREEDY (Section 4.1), UNIQUEGREEDYFREQ (Section 4.2), and UNIQUEGREEDYSIZE (Section 4.3) have unique coverage ratios that are logarithmic in  $\ell = |\mathcal{C}|$ ,  $r$ , and  $d$ , respectively.

### 4.1 UniqueGreedy

We present and analyze our algorithm UNIQUEGREEDY, with pseudocode in Algorithm 1. Its purpose is to take a collection  $\mathcal{C}$  of  $\ell$  sets and return a collection  $\mathcal{B} \subseteq \mathcal{C}$  whose *unique coverage* is at least a  $1/H_\ell$  factor of  $\mathcal{C}$ 's coverage. We formally state this in Theorem 4.1.

**UniqueGreedy Overview.** UNIQUEGREEDY first checks whether  $\mathcal{C}$ 's unique coverage is at least  $1/H_\ell$  of its own coverage. If so, then it immediately returns  $\mathcal{C}$  as the solution, which of course occurs if  $\ell = 1$ . If not, then the idea is to discard the set  $T \in \mathcal{C}$  with the smallest

contribution to  $\mathcal{C}$ 's unique coverage. It follows that the total loss in coverage from  $\mathcal{C}$  to  $\mathcal{C} \setminus \{T\}$  is only  $1/\ell$  of  $\mathcal{C}$ 's unique coverage. Observe that  $T$  contributes at most  $1/\ell$  to  $\mathcal{C}$ 's unique coverage, and any elements in  $T$  that are also in  $\mathcal{C}$ 's non-unique cover must remain in  $\mathcal{C} \setminus \{T\}$ 's cover. We then apply `UNIQUEGREEDY` recursively, to  $\mathcal{C} \setminus \{T\}$ . As we show in Theorem 4.1, since the performance of `UNIQUEGREEDY` relates unique coverage to coverage,  $\mathcal{C} \setminus \{T\}$  has sufficient coverage so that the recursive solution from `UNIQUEGREEDY`( $\mathcal{C} \setminus \{T\}$ ) has a unique coverage of at least  $1/H_\ell$  of  $\mathcal{C}$ 's coverage.

■ **Algorithm 1** `UNIQUEGREEDY`.

---

**Input:**  $\mathcal{C}$ : collection of  $\ell$  sets.

**Output:**  $\mathcal{B} \subseteq \mathcal{C}$ : subcollection satisfying  $|\tilde{\psi}(\mathcal{B})| \geq |\psi(\mathcal{C})|/H_\ell$ .

```

1 if  $|\tilde{\psi}(\mathcal{C})| \geq |\psi(\mathcal{C})|/H_\ell$  then
2    $\mathcal{B} \leftarrow \mathcal{C}$ 
3 else
4    $T \leftarrow \arg \min_{S \in \mathcal{C}} |S \cap \tilde{\psi}(\mathcal{C})|$ 
5    $\mathcal{B} \leftarrow \text{UNIQUEGREEDY}(\mathcal{C} \setminus \{T\})$ 
6 return  $\mathcal{B}$ 

```

---

► **Theorem 4.1.** *Given a collection of  $\ell$  sets,  $\mathcal{C}$ , `UNIQUEGREEDY` returns a collection  $\mathcal{B} \subseteq \mathcal{C}$  satisfying*

$$|\tilde{\psi}(\mathcal{B})| \geq \frac{|\psi(\mathcal{C})|}{H_\ell}. \quad (2)$$

**Proof.** We prove Theorem 4.1 by induction on  $\ell = |\mathcal{C}|$ .

**Base Case.** If  $\ell = 1$ , then  $|\tilde{\psi}(\mathcal{C})| = |\psi(\mathcal{C})|$  and  $\mathcal{B} = \mathcal{C}$ , so we are done.

**Inductive Case.** Consider the case  $\ell \geq 2$ , and assume that Theorem 4.1 holds for  $\ell - 1$ . Then one of two subcases must hold: (i)  $|\tilde{\psi}(\mathcal{C})| \geq |\psi(\mathcal{C})|/H_\ell$ ; or (ii) the negation,  $|\tilde{\psi}(\mathcal{C})| < |\psi(\mathcal{C})|/H_\ell$ . In subcase (i), the Line 1 condition succeeds and `UNIQUEGREEDY` returns the subcollection  $\mathcal{B} = \mathcal{C}$ , which clearly satisfies Ineq. (2).

So, we focus on subcase (ii); since  $|\tilde{\psi}(\mathcal{C})| < |\psi(\mathcal{C})|/H_\ell$ , the Line 1 condition fails, thus Line 5 assigns to  $\mathcal{B}$  the solution from the recursive call on  $\mathcal{C} \setminus \{T\}$ . Claim 4.3 lower bounds the coverage of this subcollection,  $|\psi(\mathcal{C} \setminus \{T\})|$ . Prior to that, we prove a handy claim.

► **Claim 4.2.**  $|\psi(\mathcal{C} \setminus \{T\})| = |\psi_{\geq 2}(\mathcal{C})| + |\tilde{\psi}(\mathcal{C}) \setminus T|$ .

**Proof.** Observe that  $\psi_{\geq 2}(\mathcal{C})$  and  $\tilde{\psi}(\mathcal{C}) \setminus T$  are disjoint; so it suffices to show that  $\psi(\mathcal{C} \setminus \{T\}) = \psi_{\geq 2}(\mathcal{C}) \cup (\tilde{\psi}(\mathcal{C}) \setminus T)$ . We first show that RHS is a subset of LHS. Each element covered at least twice in  $\mathcal{C}$  remains covered in  $\mathcal{C} \setminus \{T\}$ ; while each element uniquely covered in  $\mathcal{C}$  that is not in  $T$  remains covered in  $\mathcal{C} \setminus \{T\}$ . Going the other way, consider an element that is in neither  $\psi_{\geq 2}(\mathcal{C})$  nor  $\tilde{\psi}(\mathcal{C}) \setminus T$ : then the only set it was in was  $T$ , and hence it is not in  $\mathcal{C} \setminus \{T\}$ .  $\triangleleft$

► **Claim 4.3.** Subcollection  $\mathcal{C} \setminus \{T\}$  satisfies

$$|\psi(\mathcal{C} \setminus \{T\})| \geq \left(1 - \frac{1}{\ell H_\ell}\right) |\psi(\mathcal{C})|.$$

## 25:12 Maximum Unique Coverage on Streams

Proof. First, observe that the contribution of each  $S \in \mathcal{C}$  to  $\tilde{\psi}(\mathcal{C})$ , i.e.,  $|S \cap \tilde{\psi}(\mathcal{C})|$ , is disjoint from the contributions of all other sets in  $\mathcal{C}$ : each element in  $\tilde{\psi}(\mathcal{C})$  is covered by exactly one set. Therefore, the set  $T = \arg \min_{S \in \mathcal{C}} |S \cap \tilde{\psi}(\mathcal{C})|$  in Line 4 satisfies

$$|T \cap \tilde{\psi}(\mathcal{C})| \leq \frac{|\tilde{\psi}(\mathcal{C})|}{\ell}. \quad (3)$$

With Claim 4.2, we now prove Claim 4.3.

$$\begin{aligned} |\psi(\mathcal{C} \setminus \{T\})| &= |\psi_{\geq 2}(\mathcal{C})| + |\tilde{\psi}(\mathcal{C}) \setminus T| \\ &= |\psi(\mathcal{C})| - |\tilde{\psi}(\mathcal{C})| + |\tilde{\psi}(\mathcal{C})| - |T \cap \tilde{\psi}(\mathcal{C})| \\ &= |\psi(\mathcal{C})| - |T \cap \tilde{\psi}(\mathcal{C})| \\ &\geq |\psi(\mathcal{C})| - \frac{|\tilde{\psi}(\mathcal{C})|}{\ell} && \text{Ineq. (3)} \\ &> |\psi(\mathcal{C})| - \frac{|\psi(\mathcal{C})|}{\ell H_\ell} && \text{subcase (ii)} \\ &= \left(1 - \frac{1}{\ell H_\ell}\right) |\psi(\mathcal{C})|. && \triangleleft \end{aligned}$$

Recall that in subcase (ii), Line 5 assigns to  $\mathcal{B}$  the solution from the recursive call on  $\mathcal{C} \setminus \{T\}$ . Since  $|\mathcal{C} \setminus \{T\}| = \ell - 1$ , we apply the inductive assumption to prove that  $\mathcal{B}$  satisfies Ineq. (2).

$$\begin{aligned} |\tilde{\psi}(\mathcal{B})| &\geq \frac{|\psi(\mathcal{C} \setminus \{T\})|}{H_{\ell-1}} && \text{inductive assumption} \\ &\geq \frac{1}{H_{\ell-1}} \left(1 - \frac{1}{\ell H_\ell}\right) |\psi(\mathcal{C})| && \text{Claim 4.3} \\ &= \frac{1}{H_{\ell-1}} \frac{\ell H_\ell - 1}{\ell H_\ell} |\psi(\mathcal{C})| \\ &= \frac{1}{H_{\ell-1}} \frac{H_\ell - \frac{1}{\ell}}{H_\ell} |\psi(\mathcal{C})| \\ &= \frac{|\psi(\mathcal{C})|}{H_\ell}. && H_\ell - \frac{1}{\ell} = H_{\ell-1}, \text{ for } \ell \geq 2 \end{aligned}$$

We have proven that  $\mathcal{B}$  satisfies Ineq. (2) in the base case and the inductive case, proving Theorem 4.1.  $\blacktriangleleft$

## 4.2 UniqueGreedyFreq

In this section, we present and analyze our algorithm UNIQUEGREEDYFREQ, with pseudocode in Algorithm 2. The purpose of this algorithm is to take a collection  $\mathcal{C}$  with maximum frequency  $r \leq |\mathcal{C}|$ , and an error parameter  $\varepsilon_r \in (0, 1)$ , and return a collection  $\mathcal{B} \subseteq \mathcal{C}$  whose unique coverage is at least a  $(1/H_{\lceil r(r-1)/\varepsilon_r \rceil} - \varepsilon_r)$  factor of  $\mathcal{C}$ 's coverage. By an appropriate choice of  $\varepsilon_r$  depending on  $r$ , this factor can be simplified to  $1/(2 \ln r + o(\log r))$ .

**UniqueGreedyFreq Overview.** The idea of UNIQUEGREEDYFREQ is to group all of the sets from  $\mathcal{C}$  into  $\hat{\ell}$  disjoint collections,  $\mathcal{G}_1, \dots, \mathcal{G}_{\hat{\ell}}$ , so that the sets must be selected into the solution  $\mathcal{B}$  in these groups, i.e., for each  $i \in [\hat{\ell}]$ , either all of the sets in  $\mathcal{G}_i$ , or none of the sets in  $\mathcal{G}_i$ , must be selected into  $\mathcal{B}$ . Then, letting  $\hat{\mathcal{C}}$  be the collection of the covers of  $\mathcal{G}_1, \dots, \mathcal{G}_{\hat{\ell}}$ , we can call UNIQUEGREEDY on  $\hat{\mathcal{C}}$  to find a selection of these covers, namely  $\hat{\mathcal{B}}$ . The returned solution,  $\mathcal{B}$ , is constructed by merging each  $\mathcal{G}_i$  whose cover was selected into  $\hat{\mathcal{B}}$ , which ensures that the sets are selected in groups.

It can be seen that, by calling UNIQUEGREEDY on  $\hat{\mathcal{C}}$  and by Theorem 4.1, the unique coverage of  $\hat{\mathcal{B}}$  is at least  $1/H_{\hat{\ell}}$  of  $\hat{\mathcal{C}}$ 's coverage, and therefore at least  $1/H_{\hat{\ell}}$  of  $\mathcal{C}$ 's coverage since  $\hat{\mathcal{C}}$  and  $\mathcal{C}$  have the same cover. The issue now is that sets from the same  $\mathcal{G}_i$  can overlap after being selected as a group into  $\mathcal{B}$ , which would make  $\mathcal{B}$ 's unique coverage smaller than  $\hat{\mathcal{B}}$ 's unique coverage. This is addressed by setting the number of groups to be  $\hat{\ell} = \lceil r(r-1)/\varepsilon_r \rceil$ , and by the way UNIQUEGREEDYFREQ allocates the sets into these groups: it allocates each  $S \in \mathcal{C}$  to the group  $\mathcal{G}_i$  whose unique coverage intersects the least with  $S$ . In this way, the total unique coverage that is lost due to overlapping sets in the same  $\mathcal{G}_i$  can be bounded by  $\varepsilon_r |\psi(\mathcal{C})|$ . Thus,  $\mathcal{B}$ 's unique coverage is at least  $(1/H_{\hat{\ell}} - \varepsilon_r) = (1/H_{\lceil r(r-1)/\varepsilon_r \rceil} - \varepsilon_r)$  of  $\mathcal{C}$ 's coverage. Details are given in the proof of Theorem 4.4.

■ **Algorithm 2** UNIQUEGREEDYFREQ.

---

**Input:**  $\mathcal{C}$ : collection with maximum frequency  $r \geq 2$ ,  $\varepsilon_r \in (0, 1)$ : error parameter.  
**Output:**  $\mathcal{B} \subseteq \mathcal{C}$ : collection satisfying  $|\tilde{\psi}(\mathcal{B})| \geq (1/H_{\lceil r(r-1)/\varepsilon_r \rceil} - \varepsilon_r) |\psi(\mathcal{C})|$ .

```

1  $\hat{\ell} \leftarrow \lceil r(r-1)/\varepsilon_r \rceil$ 
2 for  $i \in [\hat{\ell}]$  do // Initialize empty groups
3    $\mathcal{G}_i \leftarrow \emptyset$ 
4 for  $S \in \mathcal{C}$  do // Allocate sets to groups
5    $i \leftarrow \arg \min_{j \in [\hat{\ell}]} |\tilde{\psi}(\mathcal{G}_j) \cap S|$ 
6    $\mathcal{G}_i \leftarrow \mathcal{G}_i \cup \{S\}$ 
7  $\hat{\mathcal{C}} \leftarrow \{\psi(\mathcal{G}_1), \dots, \psi(\mathcal{G}_{\hat{\ell}})\}$  // Define collection of groups' covers
8  $\hat{\mathcal{B}} \leftarrow \text{UNIQUEGREEDY}(\hat{\mathcal{C}})$ 
9  $\mathcal{B} \leftarrow \emptyset$ 
10 for  $\psi(\mathcal{G}_i) \in \hat{\mathcal{B}}$  do // Construct returned solution
11    $\mathcal{B} \leftarrow \mathcal{B} \cup \mathcal{G}_i$ 
12 return  $\mathcal{B}$ 

```

---

► **Theorem 4.4.** *Given  $\mathcal{C}$  with maximum frequency  $r \geq 2$ , and error parameter  $\varepsilon_r \in (0, 1)$ , algorithm UNIQUEGREEDYFREQ returns a collection  $\mathcal{B} \subseteq \mathcal{C}$  satisfying*

$$|\tilde{\psi}(\mathcal{B})| \geq \left( \frac{1}{H_{\lceil r(r-1)/\varepsilon_r \rceil}} - \varepsilon_r \right) |\psi(\mathcal{C})|. \quad (4)$$

Moreover, setting  $\varepsilon_r = (9.27 \ln r)^{-1} (2 \ln r + 2 \ln \ln r + 5.61)^{-1}$ , we obtain

$$|\tilde{\psi}(\mathcal{B})| \geq \left( \frac{1 - 1/(9.27 \ln r)}{2 \ln r + 2 \ln \ln r + 5.61} \right) |\psi(\mathcal{C})| \geq \frac{1}{2 \ln r + o(\log r)} |\psi(\mathcal{C})|. \quad (5)$$

**Proof.** We first prove Ineq. (4), starting with the following claim.

► **Claim 4.5.**  $\tilde{\psi}(\mathcal{B}) = \tilde{\psi}(\hat{\mathcal{B}}) \setminus \bigcup_{i: \psi(\mathcal{G}_i) \in \hat{\mathcal{B}}} \psi_{\geq 2}(\mathcal{G}_i)$ .

**Proof.** Consider an element  $x$  that is in exactly one set in  $\mathcal{B}$ . This means that  $x$  is in exactly one set from exactly one group, say  $\mathcal{G}_y$ , chosen in  $\mathcal{B}$ . Focusing on  $\hat{\mathcal{B}}$ , element  $x$  is clearly in  $\psi(\mathcal{G}_y)$  only, but might occur more than once in  $\mathcal{G}_y$ . Excluding elements that are in  $\psi_{\geq 2}(\mathcal{G}_i)$  for every  $i$ , we thus have the claim statement. ◁

With Claim 4.5, we prove Claim 4.6.

► **Claim 4.6.** The solution  $\mathcal{B}$  satisfies  $|\tilde{\psi}(\mathcal{B})| \geq |\tilde{\psi}(\hat{\mathcal{B}})| - \varepsilon_r |\psi(\mathcal{C})|$ .

## 25:14 Maximum Unique Coverage on Streams

Proof. Given Claim 4.5,  $\mathcal{B}$  satisfies Ineq. (6),

$$\begin{aligned} |\tilde{\psi}(\mathcal{B})| &\geq |\tilde{\psi}(\hat{\mathcal{B}})| - \sum_{i: \psi(\mathcal{G}_i) \in \hat{\mathcal{B}}} |\psi_{\geq 2}(\mathcal{G}_i)| \\ &\geq |\tilde{\psi}(\hat{\mathcal{B}})| - \sum_{i \in [\hat{\ell}]} |\psi_{\geq 2}(\mathcal{G}_i)|. \end{aligned} \quad (6)$$

We upper bound  $\sum_{i \in [\hat{\ell}]} |\psi_{\geq 2}(\mathcal{G}_i)|$  in Ineq. (6). Let  $S_t$  be the  $t^{\text{th}}$  set allocated in the Line 4 loop, let  $\mathcal{G}_{i,0} = \emptyset$ , and let  $\mathcal{G}_{i,t}$  be the subcollection  $\mathcal{G}_i$  just after allocating  $S_t$ .

Upon inserting  $S_t$  into  $\mathcal{G}_i$ , every element in  $\tilde{\psi}(\mathcal{G}_{i,t-1})$  that becomes non-uniquely covered is accounted for by  $\tilde{\psi}(\mathcal{G}_{i,t-1}) \cap S_t$ . So it holds that  $|\psi_{\geq 2}(\mathcal{G}_{i,t})| - |\psi_{\geq 2}(\mathcal{G}_{i,t-1})| = |\tilde{\psi}(\mathcal{G}_{i,t-1}) \cap S_t|$ . Thus,  $|\psi_{\geq 2}(\mathcal{G}_i)|$  can be expressed by Equation (7) below, observing that for  $S_t$  the relevant difference term is zero.

$$\begin{aligned} |\psi_{\geq 2}(\mathcal{G}_i)| &= \sum_{S_t \in \mathcal{G}_i} (|\psi_{\geq 2}(\mathcal{G}_{i,t})| - |\psi_{\geq 2}(\mathcal{G}_{i,t-1})|) && \text{telescoping series} \\ &= \sum_{S_t \in \mathcal{G}_i} |\tilde{\psi}(\mathcal{G}_{i,t-1}) \cap S_t|. \end{aligned} \quad (7)$$

For each  $i \in [\hat{\ell}]$  and each  $S_t \in \mathcal{G}_i$ , we want to show an upper bound of  $|\tilde{\psi}(\mathcal{G}_{i,t-1}) \cap S_t| \leq (r-1)|S_t|/\hat{\ell}$ . To see this, since the maximum frequency is  $r$ , each element  $x \in S_t$  is covered by at most  $r-1$  other sets, each possibly in a different group. Therefore, we have that

$$\begin{aligned} \sum_{j \in [\hat{\ell}]} |\tilde{\psi}(\mathcal{G}_{j,t-1}) \cap \{x\}| &\leq r-1, \\ \sum_{x \in S_t} \sum_{j \in [\hat{\ell}]} |\tilde{\psi}(\mathcal{G}_{j,t-1}) \cap \{x\}| &\leq \sum_{x \in S_t} (r-1), \\ \sum_{j \in [\hat{\ell}]} |\tilde{\psi}(\mathcal{G}_{j,t-1}) \cap S_t| &\leq (r-1)|S_t|. \end{aligned}$$

Recall that  $S_t$  was allocated to the group  $\mathcal{G}_i = \arg \min_{j \in [\hat{\ell}]} |\tilde{\psi}(\mathcal{G}_{j,t-1}) \cap S_t|$  in Lines 5–6. Therefore, by averaging on the above inequality, we have that for each  $i \in [\hat{\ell}]$  and each  $S_t$  that ends up in  $\mathcal{G}_i$ ,

$$|\tilde{\psi}(\mathcal{G}_{i,t-1}) \cap S_t| \leq \frac{r-1}{\hat{\ell}} |S_t|. \quad (8)$$

Now we upper bound  $\sum_{i \in [\hat{\ell}]} |\psi_{\geq 2}(\mathcal{G}_i)|$ .

$$\begin{aligned} \sum_{i \in [\hat{\ell}]} |\psi_{\geq 2}(\mathcal{G}_i)| &= \sum_{i \in [\hat{\ell}]} \sum_{S_t \in \mathcal{G}_i} |\tilde{\psi}(\mathcal{G}_{i,t-1}) \cap S_t| && \text{Equation (7)} \\ &\leq \frac{r-1}{\hat{\ell}} \sum_{i \in [\hat{\ell}]} \sum_{S_t \in \mathcal{G}_i} |S_t| && \text{Ineq. (8)} \\ &= \frac{r-1}{\hat{\ell}} \sum_{S \in \mathcal{C}} |S| && \mathcal{G}_1, \dots, \mathcal{G}_{\hat{\ell}} \text{ partitions } \mathcal{C} \\ &\leq \frac{r-1}{\hat{\ell}} r |\psi(\mathcal{C})| && \text{for all } x \in \psi(\mathcal{C}): \text{freq}_{\mathcal{C}}(x) \leq r \\ &= \frac{r(r-1)}{\lceil r(r-1)/\varepsilon_r \rceil} |\psi(\mathcal{C})| && \text{value of } \hat{\ell} \text{ (Line 1)} \end{aligned}$$

$$\begin{aligned} &\leq \frac{r(r-1)}{r(r-1)/\varepsilon_r} |\psi(\mathcal{C})| \\ &\leq \varepsilon_r |\psi(\mathcal{C})|. \end{aligned}$$

Applying the above upper bound to Ineq. (6) completes the proof of the claim.  $\triangleleft$

To prove Ineq. (4), it remains to lower bound  $|\tilde{\psi}(\hat{\mathcal{B}})|$ , in the inequality of Claim 4.6, in terms of  $|\psi(\mathcal{C})|$ . Below,  $|\psi(\hat{\mathcal{C}})| = |\psi(\mathcal{C})|$  holds since every  $S \in \mathcal{C}$  is allocated to some  $\mathcal{G}_i \in \hat{\mathcal{C}}$ .

$$\begin{aligned} |\tilde{\psi}(\mathcal{B})| &\geq |\tilde{\psi}(\hat{\mathcal{B}})| - \varepsilon_r |\psi(\mathcal{C})| && \text{Claim 4.6} \\ &\geq \frac{|\psi(\hat{\mathcal{C}})|}{H_{\hat{\ell}}} - \varepsilon_r |\psi(\mathcal{C})| && \text{Line 8 and Theorem 4.1} \\ &= \frac{|\psi(\hat{\mathcal{C}})|}{H_{\lceil r(r-1)/\varepsilon_r \rceil}} - \varepsilon_r |\psi(\mathcal{C})| && \text{value of } \hat{\ell} \text{ (Line 1)} \\ &= \frac{|\psi(\mathcal{C})|}{H_{\lceil r(r-1)/\varepsilon_r \rceil}} - \varepsilon_r |\psi(\mathcal{C})| && |\psi(\hat{\mathcal{C}})| = |\psi(\mathcal{C})| \\ &= \left( \frac{1}{H_{\lceil r(r-1)/\varepsilon_r \rceil}} - \varepsilon_r \right) |\psi(\mathcal{C})|. \end{aligned}$$

**Ineq. (5).** It remains to show that there exists a choice of  $\varepsilon_r$  that implies Ineq. (5).

$\triangleright$  **Claim 4.7 (\*).** Setting  $\varepsilon_r = (9.27 \ln r)^{-1} (2 \ln r + 2 \ln \ln r + 5.61)^{-1}$  implies Ineq. (5).

This completes the proof of Theorem 4.4.  $\blacktriangleleft$

### 4.3 UniqueGreedySize

In this section, we present `UNIQUEGREEDYSIZE`, with pseudocode in Algorithm 3, derived by combining `UNIQUEGREEDYFREQ` with the approach in Theorem 4.2 of Demaine et al. [9]. The purpose of this algorithm is to take a collection,  $\mathcal{C}$ , with maximum set size  $d$ , an error parameter,  $\varepsilon_d \in (0, 1)$ , and another error parameter,  $\hat{\varepsilon}_d \in (0, 1)$ , and return a  $\mathcal{B} \subseteq \mathcal{C}$  whose unique coverage is at least a logarithmic factor of  $\mathcal{C}$ 's coverage, where the factor depends on  $d$ ,  $\varepsilon_d$ , and  $\hat{\varepsilon}_d$ . We state this formally in Theorem 4.8 and give the proof for completeness; in fact, our proof slightly generalizes the proof of Theorem 4.2 of Demaine et al. [9], by allowing an arbitrary  $\varepsilon_d$  rather than fixing  $\varepsilon_d = 1/2$ .

**UniqueGreedySize Overview.** `UNIQUEGREEDYSIZE` first modifies  $\mathcal{C}$  into a “minimal” collection by discarding each set  $T$  that uniquely covers no element. Then it checks if  $\mathcal{C}$ 's size is at least an  $\varepsilon_d$  factor of its own coverage. If so, then it assigns  $\mathcal{C}$  to the solution  $\mathcal{B}$ . Otherwise, it constructs a sub-instance on those elements of frequency at most  $d$  and calls `UNIQUEGREEDYFREQ` on the sub-instance with error  $\hat{\varepsilon}_d$  to get  $\hat{\mathcal{B}}$ . Returned solution  $\mathcal{B}$  comprises each set  $S \in \mathcal{C}$  whose intersection with  $\hat{U}$  was selected into  $\hat{\mathcal{B}}$ .

$\blacktriangleright$  **Theorem 4.8.** *Let  $\mathcal{C}$  denote a collection of sets,  $d$  denote the maximum size of a set in  $\mathcal{C}$ ,  $\varepsilon_d \in (0, 1)$  denote an error parameter, and  $\hat{\varepsilon}_d \in (0, 1)$  denote an error parameter passed to `UNIQUEGREEDYFREQ`. Then `UNIQUEGREEDYSIZE` returns a collection  $\mathcal{B} \subseteq \mathcal{C}$  satisfying*

$$|\tilde{\psi}(\mathcal{B})| \geq \min(\varepsilon_d, (1 - \varepsilon_d)\beta(d, \hat{\varepsilon}_d)) |\psi(\mathcal{C})|, \quad (9)$$

■ **Algorithm 3** UNIQUEGREEDYSIZE.

---

**Input:**  $\mathcal{C}$ : collection with maximum set size  $d$ ,  $\varepsilon_d \in (0, 1)$ : error parameter,  
 $\hat{\varepsilon}_d \in (0, 1)$ : error parameter used in UNIQUEGREEDYFREQ.  
**Output:**  $\mathcal{B} \subseteq \mathcal{C}$ : subcollection satisfying  $|\tilde{\psi}(\mathcal{B})| \geq \min(\varepsilon_d, (1 - \varepsilon_d)\beta(d, \hat{\varepsilon}_d))|\psi(\mathcal{C})|$   
 where  $\beta(d, \hat{\varepsilon}_d) = 1/H_{\lceil d(d-1)/\hat{\varepsilon}_d \rceil} - \hat{\varepsilon}_d$ .

```

1 while  $T \leftarrow \arg \min_{S \in \mathcal{C}} |S \cap \tilde{\psi}(\mathcal{C})|$  satisfies  $|T \cap \tilde{\psi}(\mathcal{C})| = 0$  do // Make  $\mathcal{C}$  minimal
2    $\mathcal{C} \leftarrow \mathcal{C} \setminus \{T\}$ 
3 if  $|\mathcal{C}| \geq \varepsilon_d |\psi(\mathcal{C})|$  then
4    $\mathcal{B} \leftarrow \mathcal{C}$ 
5 else // Define instance on elements with freq.  $\leq d$ 
6    $\hat{U} \leftarrow \{x \in \psi(\mathcal{C}) : \text{freq}_{\mathcal{C}}(x) \leq d\}$ 
7    $\hat{\mathcal{C}} \leftarrow \{S \cap \hat{U} : S \in \mathcal{C}\}$ 
8    $\hat{\mathcal{B}} \leftarrow \text{UNIQUEGREEDYFREQ}(\hat{\mathcal{C}}, \hat{\varepsilon}_d)$ 
9    $\mathcal{B} \leftarrow \emptyset$ 
10  for  $S \cap \hat{U} \in \hat{\mathcal{B}}$  do // Construct returned solution
11     $\mathcal{B} \leftarrow \mathcal{B} \cup \{S\}$ 
12 return  $\mathcal{B}$ 
    
```

---

where  $\beta(d, \hat{\varepsilon}_d) = 1/(H_{\lceil d(d-1)/\hat{\varepsilon}_d \rceil}) - \hat{\varepsilon}_d$  denotes the unique coverage ratio of UNIQUEGREEDYFREQ. Moreover, by assigning  $\varepsilon_d = (1/\beta(d, \hat{\varepsilon}_d) + 1)^{-1}$ ,  $\hat{\varepsilon}_d = (c_1 \ln d)^{-1} (2 \ln d + 2 \ln \ln d + c_2)^{-1}$ , and appropriate constants to  $c_1$  and  $c_2$ , we derive from Ineq. (9) the simpler inequality below.

$$|\tilde{\psi}(\mathcal{B})| \geq \frac{1}{2 \ln d + o(\log d)} |\psi(\mathcal{C})|. \quad (10)$$

**Proof.** We begin by proving Ineq. (9). Discarding sets from  $\mathcal{C}$  that uniquely cover no elements, as in Lines 1–2, does not affect  $\psi(\mathcal{C})$ . So assume that  $\mathcal{C}$  is minimal, i.e., every  $S \in \mathcal{C}$  uniquely covers at least one element. This means that  $|\tilde{\psi}(\mathcal{C})| \geq |\mathcal{C}|$ .

Now one of two cases must hold: (i)  $|\mathcal{C}| \geq \varepsilon_d |\psi(\mathcal{C})|$ ; or (ii)  $|\mathcal{C}| < \varepsilon_d |\psi(\mathcal{C})|$ . The final ratio in Ineq. (9) is the minimum ratio achieved out of these two cases.

In case (i), UNIQUEGREEDYSIZE returns the solution  $\mathcal{B} = \mathcal{C}$ , by the success of the condition in Line 3. Further,  $|\tilde{\psi}(\mathcal{B})| = |\tilde{\psi}(\mathcal{C})| \geq |\mathcal{C}| \geq \varepsilon_d |\psi(\mathcal{C})|$  holds by the minimality of  $\mathcal{C}$ . Thus,  $\mathcal{B}$  satisfies Ineq. (9) in case (i).

In case (ii), we show that the set  $\hat{U}$  of elements  $x \in \psi(\mathcal{C})$  with  $\text{freq}_{\mathcal{C}}(x) \leq d$ , as in Line 6, satisfies  $|\hat{U}| \geq (1 - \varepsilon_d) |\psi(\mathcal{C})|$ . We have

$$\begin{aligned}
 |U \setminus \hat{U}| &< \frac{1}{d} \sum_{S \in \mathcal{C}} |S| && \text{for all } x \in U \setminus \hat{U}: \text{freq}_{\mathcal{C}}(x) > d \\
 &\leq |\mathcal{C}| && \text{max. set size is } d \\
 &< \varepsilon_d |\psi(\mathcal{C})|, && \text{case (ii)} \\
 |\hat{U}| &> (1 - \varepsilon_d) |\psi(\mathcal{C})|.
 \end{aligned}$$

By the Line 7 definition,  $\psi(\hat{\mathcal{C}}) = \hat{U}$ , so  $|\psi(\hat{\mathcal{C}})| \geq (1 - \varepsilon_d) |\psi(\mathcal{C})|$ . Therefore, calling UNIQUEGREEDYFREQ on  $\hat{\mathcal{C}}$  with maximum frequency  $d$  and error  $\hat{\varepsilon}_d$ , as in Line 8, gives a collection  $\hat{\mathcal{B}}$  satisfying  $|\tilde{\psi}(\hat{\mathcal{B}})| \geq \beta(d, \hat{\varepsilon}_d) |\psi(\hat{\mathcal{C}})| \geq \beta(d, \hat{\varepsilon}_d) (1 - \varepsilon_d) |\psi(\mathcal{C})|$ . Likewise, by definition, in Lines 9–11,  $|\tilde{\psi}(\mathcal{B})| \geq |\tilde{\psi}(\hat{\mathcal{B}})|$ . Thus,  $\mathcal{B}$  satisfies Ineq. (9) in case (2), proving Theorem 4.8.

**Ineq. (10).** We first maximize  $\min(\varepsilon_d, (1 - \varepsilon_d)\beta(d, \hat{\varepsilon}_d))$  with respect to  $\varepsilon_d$  by setting the two arguments as equal; this makes the RHS of Ineq. (9) equal to  $\varepsilon_d = (1/\beta(d, \hat{\varepsilon}_d) + 1)^{-1}$ . Then, by assigning  $\hat{\varepsilon}_d = (c_1 \ln d)^{-1}(2 \ln d + 2 \ln \ln d + c_2)^{-1}$  and appropriate constants to  $c_1$  and  $c_2$ , **UNIQUEGREEDYFREQ**'s unique coverage ratio satisfies  $\beta(d, \hat{\varepsilon}_d) \geq 1/(2 \ln d + o(\log d))$  as in Theorem 4.4. Further substituting this into the RHS of Ineq. (9) proves Ineq. (10). This completes the proof of Theorem 4.8. ◀

## 5 Space Lower Bound for a $(1.5 + o(1)) / (\ln k - 1)$ -Approximation

In this section, we prove the following theorem:

► **Theorem 5.1.** *Let  $e^{2.5} \leq k \leq m$ ,  $a = k \ln m + \ln(k/0.05)$ , and assume the universe size to be  $n = k(k-1) \sum_{t=1}^k \lceil a/t \rceil$ . Then every constant-pass randomized streaming algorithm for **Max Unique Coverage** that, with probability at least 0.95, has an approximation factor of  $(3/2 + 3/\sqrt{2k}) / (H_k - 1)$ , requires  $\Omega(m/k^2)$  space.*

### 5.1 High-Level Ideas of the Reduction

Similar to other approaches [16, 15], we prove our space lower bound by reducing the problem of  $k$ -player Set Disjointness (with the unique intersection promise) in the one-way communication model, denoted by **Disj**, to **Max Unique Coverage** in the stream model.

**Set Disjointness in the One-Way Communication Model.** In the one-way communication model, players must take turns in some fixed order to send a message to the player next in order, i.e., the  $j^{\text{th}}$  player can only send a message to the  $(j+1)^{\text{th}}$  player. There can be  $p \geq 1$  rounds of communication, where a single round is completed once every player has taken their turn. The last player can send a message back to the 1<sup>st</sup> player at the end of a round if there is a next round.

In an instance of **Disj**, each player  $j \in [k]$  is given a set of integers  $D_j \subseteq [m]$ . Moreover, it is promised that only two kinds of instances can occur:

**NO instance.** All sets  $D_j$  are pairwise disjoint.

**YES instance.** There is a unique integer  $i^* \in [m]$  such that, for all  $j \in [k]$ ,  $i^* \in D_j$ .

The goal then is for the  $k^{\text{th}}$  player (in the final round) to correctly answer, with probability at least 0.9, whether the given sets form a YES or NO instance.

The communication complexity of **Disj** in the  $p$ -round one-way communication model is  $\Omega(m/k)$ , even for randomized protocols and even when the players can use public randomness [5]. Thus, as there are  $\leq pk$  messages, every (randomized) protocol for **Disj** must have at least one message of size  $\Omega(m/(pk^2))$  in the worst case.

**Reduction Overview.** Given an instance of **Disj**, the main goal of the reduction, with parameter  $a$ , is for the players to construct an instance of **Max Unique Coverage** in a stream such that if they were given a NO instance of **Disj**, the optimal unique coverage is less than  $ak^2(1.5 + o(1))$  (with high probability); whereas if the players were given a YES instance of **Disj**, the optimal unique coverage is at least  $ak^2(H_k - 1)$ . The ratio of these optimal unique coverages is less than  $(1.5 + o(1)) / (H_k - 1)$ , so the players can use a  $(1.5 + o(1)) / (H_k - 1)$ -approximation streaming algorithm on the **Max Unique Coverage** instance to distinguish between a NO and YES instance. By a standard argument, this implies a protocol for **Disj** which involves each player sending the memory of the streaming algorithm in a message to

the next player. A constant-pass  $O(s)$ -space streaming algorithm implies a protocol with a maximum message size of  $O(s)$  in constant rounds of communication where each pass of the streaming algorithm takes one round. Thus, a  $(1.5 + o(1))/(H_k - 1)$ -approximation streaming algorithm for **Max Unique Coverage** requires  $\Omega(m/k^2)$  space.

**Intuition of Max Unique Coverage Construction.** Here, we give the intuition for constructing the streaming instance of **Max Unique Coverage** that achieves the optimal unique coverages above, with details in the proof of Theorem 5.1.

Let the universe of the **Max Unique Coverage** instance be  $U = U_1 \cup \dots \cup U_k$ , where  $U_1, \dots, U_k$  are  $k$  disjoint sub-universes such that  $|U_t| = k(k-1)\lceil a/t \rceil$  (for a sufficiently large  $a$  as in Theorem 5.1). Then, for each  $i \in [m]$ , each player  $j$  constructs  $S_j^i \subseteq U$  such that  $S_1^i, \dots, S_k^i$  satisfy the following properties:

1. Each set  $S_j^i$  covers  $t/k$  proportion of  $U_t$  for all  $t$ .
2. For each  $t \in [k]$ , the sets  $S_1^i, \dots, S_k^i$  partition a proportion,  $q_t \in [0, 1]$ , of  $U_t$  while having a common intersection in the remaining  $(1 - q_t)$  proportion of  $U_t$ . I.e., sets with identical  $i$  form a “sunflower”, with their overlap concentrated in the sunflower’s “kernel”.
3. The choice of elements to be covered by  $S_j^i$  are independent and uniform random with respect to  $i \in [m]$ .

The above construction ensures that (with high probability) every collection of  $\ell \in [k]$  sets,  $S_{j_1}^{i_1}, \dots, S_{j_\ell}^{i_\ell}$ , with distinct  $i_1, \dots, i_\ell$  has a unique coverage less than  $ak^2(1.5 + o(1))$  (with high probability); whereas a collection of  $\ell = k$  sets with identical  $i_1, \dots, i_\ell$  has a unique coverage of at least  $ak^2(H_k - 1)$ . Observe that  $k \geq e^{2.5}$  ensures that  $H_k - 1 > 1.5 + o(1)$ .

Finally, to construct the streaming instance of **Max Unique Coverage**, each player  $j$  inserts  $S_j^i$  into the stream iff  $i \in D_j$ . This means that, given a NO instance, every set  $S_j^i$  in the stream has a distinct  $i$ ; whereas given a YES instance, there exists a collection of  $\ell = k$  sets in the stream all indexed by  $i^*$ , the unique integer contained in all  $D_1, \dots, D_k$ . This results in the optimal unique coverages for the NO and YES instances as required.

## 5.2 Proof of Theorem 5.1

We show a reduction from **Disj** to **Max Unique Coverage**. Assume without loss of generality that the sets  $D_j$  are padded so that  $|D_1 \cup \dots \cup D_k| \geq m/4 \geq m/k^2$  holds for  $k \geq 2$ .

**Construction of Max Unique Coverage Instance.** First, the players define the **Max Unique Coverage** universe as  $U = U_1 \cup \dots \cup U_k$ , where  $U_1, \dots, U_k$  are  $k$  disjoint sub-universes such that  $|U_t| = k(k-1)\lceil a/t \rceil$ . Observe that, as per the assumption in Theorem 5.1, we have  $n = |U| = \sum_{t=1}^k |U_t| = k(k-1) \sum_{t=1}^k \lceil a/t \rceil$ .

The players now construct the **Max Unique Coverage** sets so that they satisfy the properties given in the overview. For each  $i \in [m]$  and  $t \in [k]$ , the players define  $\tilde{U}_t^i \subseteq U_t$  as an independent and uniformly chosen random subset of size  $q_t = (k-t)/(k-1)$  proportion of  $U_t$ ; they then independently and uniformly-at-random partition  $\tilde{U}_t^i$  into  $k$  equally sized sets,  $P_{t,1}^i, \dots, P_{t,k}^i$ ; the players agree on all of these choices using public randomness. For example, the players obtain a common random permutation of  $U_t$  and pick the corresponding parts in order. Note that  $\tilde{U}_t^i$  can be divided into  $k$  equal sets since  $|\tilde{U}_t^i|/k$  is an integer, viz.

$$\frac{|\tilde{U}_t^i|}{k} = \frac{q_t |U_t|}{k} = \frac{(k-t)k(k-1)}{k(k-1)} \left\lceil \frac{a}{t} \right\rceil = (k-t) \left\lceil \frac{a}{t} \right\rceil.$$

Then, for each  $i \in [m]$ , each player  $j$  defines their set  $S_j^i$  such that, for each  $t \in [k]$ , it covers the  $j^{\text{th}}$  set in the partition of  $\tilde{U}_t^i$ , namely  $P_{t,j}^i$ ; and it covers all of  $U_t \setminus \tilde{U}_t^i$ . More precisely,

$$S_j^i = \bigcup_{t=1}^k [P_{t,j}^i \cup (U_t \setminus \tilde{U}_t^i)].$$

Observe Claim 5.2, which we use in Claim 5.4 later.

▷ **Claim 5.2.** For each  $i \in [m]$ ,  $j \in [k]$ , and  $t \in [k]$ ,  $S_j^i$  covers  $t/k$  proportion of  $U_t$ .

Proof. The proportion of  $U_t$  that  $S_j^i$  covers is  $|S_j^i \cap U_t|/|U_t|$ , which we prove to be  $t/k$  below.

$$\begin{aligned} \frac{|S_j^i \cap U_t|}{|U_t|} &= \frac{|P_{t,j}^i|}{|U_t|} + \frac{|U_t \setminus \tilde{U}_t^i|}{|U_t|} = \frac{|\tilde{U}_t^i|}{k|U_t|} + \frac{|U_t \setminus \tilde{U}_t^i|}{|U_t|} = \frac{q_t}{k} + 1 - q_t \\ &= \frac{k-t}{k(k-1)} + 1 - \frac{k-t}{k-1} = \frac{k-t}{k(k-1)} + \frac{t-1}{k-1} \\ &= \frac{k-t+kt-k}{k(k-1)} = \frac{kt-t}{k(k-1)} = \frac{t(k-1)}{k(k-1)} = \frac{t}{k}. \quad \triangleleft \end{aligned}$$

To complete the construction, each player  $j$  inserts set  $S_j^i$  into the stream iff  $i \in D_j$ . There are  $\Theta(m)$  sets inserted into the stream since  $m/4 \leq |D_1 \cup \dots \cup D_k| \leq m$ .

**Upper Bound on Optimal Unique Coverage in a NO Instance.** Next, we prove Lemma 5.3, which implies the required upper bound on the optimal unique coverage in a NO instance. We say that a collection  $\mathcal{L}_{\text{di}} = \{S_{j_1}^{i_1}, \dots, S_{j_\ell}^{i_\ell}\}$  with distinct  $i_1, \dots, i_\ell$  is a *player-distinct collection*; we also say that  $\mathcal{L}_{\text{di}}$  is *feasible* if it contains at most  $k$  sets. Note that in the **Max Unique Coverage** instance generated from a NO instance of **Disj**, every feasible solution is a player-distinct collection. Thus, it suffices to upper bound the unique coverage of every feasible player-distinct collection.

► **Lemma 5.3.** *With probability at least 0.95, every feasible player-distinct collection  $\mathcal{L}_{\text{di}}$  satisfies  $|\tilde{\psi}(\mathcal{L}_{\text{di}})| < ak^2(3/2 + 3/\sqrt{2k})$ .*

**Proof.** First, we upper bound  $\mathbb{E}[|\tilde{\psi}(\mathcal{L}_{\text{di}}) \cap U_t|]$  for every feasible player-distinct collection,  $\mathcal{L}_{\text{di}}$ , and for every sub-universe  $U_t$  (Claim 5.4), then we use Hoeffding's inequality to prove an upper bound on  $|\tilde{\psi}(\mathcal{L}_{\text{di}}) \cap U_t|$  that with high probability, holds simultaneously for every  $\mathcal{L}_{\text{di}}$  and  $U_t$  (Claim 5.5). Summing the bound in Claim 5.5 over all  $k$  sub-universes suffices.

For a feasible player-distinct collection  $\mathcal{L}_{\text{di}}$ , let  $X_{x, \mathcal{L}_{\text{di}}}$  be the random variable such that  $X_{x, \mathcal{L}_{\text{di}}} = 1$  if element  $x \in \tilde{\psi}(\mathcal{L}_{\text{di}})$ , and  $X_{x, \mathcal{L}_{\text{di}}} = 0$  otherwise. This means that for each sub-universe  $U_t$ , we have

$$|\tilde{\psi}(\mathcal{L}_{\text{di}}) \cap U_t| = \sum_{x \in U_t} X_{x, \mathcal{L}_{\text{di}}}; \text{ and so } |\tilde{\psi}(\mathcal{L}_{\text{di}})| = \sum_{t=1}^k \sum_{x \in U_t} X_{x, \mathcal{L}_{\text{di}}}. \quad (11)$$

▷ **Claim 5.4 (\*)**. For each feasible player-distinct  $\mathcal{L}_{\text{di}}$  of  $\ell \in [k]$  sets and each sub-universe  $U_t$ , it holds that  $\mathbb{E}[|\tilde{\psi}(\mathcal{L}_{\text{di}}) \cap U_t|] \leq k(a+t)\ell(1-t/k)^{\ell-1}$ .

▷ **Claim 5.5 (\*)**. With probability at least 0.95, for every feasible player-distinct  $\mathcal{L}_{\text{di}}$  of  $\ell \in [k]$  sets and every sub-universe  $U_t$ , it holds that

$$|\tilde{\psi}(\mathcal{L}_{\text{di}}) \cap U_t| < k(a+t)\ell \left(1 - \frac{t}{k}\right)^{\ell-1} + \frac{k(a+t)}{(2t)^{1/2}}.$$

## 25:20 Maximum Unique Coverage on Streams

Finally, summing the inequality of Claim 5.5 over the  $k$  sub-universes gives an upper bound on  $|\tilde{\psi}(\mathcal{L}_{\text{di}})|$  that holds simultaneously for every feasible player-distinct collection  $\mathcal{L}_{\text{di}}$  with high probability. We finalize the proof of Lemma 5.3 in Claim 5.6.

▷ Claim 5.6 (\*). With probability at least 0.95,  $|\tilde{\psi}(\mathcal{L}_{\text{di}})| < ak^2(3/2 + 3/\sqrt{2k})$ . ◀

**Lower Bound on Optimal Unique Coverage in a YES Instance.** Lemma 5.7 supports the required lower bound on the optimal unique coverage in a YES instance.

► **Lemma 5.7.** For all  $i$ , collection  $\mathcal{L}_{\text{id}} = \{S_1^i, \dots, S_k^i\}$  satisfies  $|\tilde{\psi}(\mathcal{L}_{\text{id}})| \geq ak^2(H_k - 1)$ .

**Proof.** For each  $t \in [k]$ ,  $\mathcal{L}_{\text{id}}$  uniquely covers  $|\tilde{U}_t^i|$  by construction. Below, the inequality holds since  $|U_t| = k(k-1)\lceil a/t \rceil \geq ak(k-1)/t$ .

$$\begin{aligned} |\tilde{\psi}(\mathcal{L}_{\text{id}})| &= \sum_{t=1}^k |\tilde{U}_t^i| = \sum_{t=1}^k q_t |U_t| \geq \sum_{t=1}^k \frac{k-t}{k-1} \frac{ak(k-1)}{t} = \sum_{t=1}^k \frac{k-t}{t} ak \\ &= ak \sum_{t=1}^k \left( \frac{k}{t} - 1 \right) = ak \left( k \sum_{t=1}^k \frac{1}{t} - k \right) = ak^2(H_k - 1). \end{aligned} \quad \blacktriangleleft$$

To conclude, when the players reduce from a NO instance of **Disj**, with probability at least 0.95, the optimal unique coverage is less than  $ak^2(3/2 + 3/\sqrt{2k})$ , since the streamed sets are player distinct and by Lemma 5.3; whereas when they reduce from a YES instance, the optimal unique coverage is at least  $ak^2(H_k - 1)$  since the sets  $S_1^{i^*}, \dots, S_k^{i^*}$  are in the stream and by Lemma 5.7. The required optimal unique coverage in a NO instance fails with probability at most 0.05. Let  $\alpha = (3/2 + 3/\sqrt{2k})/(H_k - 1)$ . Given a randomized  $O(s)$ -space  $\alpha$ -approximation streaming algorithm with failure probability at most 0.05, the players can run this algorithm on the **Max Unique Coverage** instance to distinguish between a NO or YES instance with failure probability at most 0.1. This implies a protocol for **Disj** with maximum message size  $O(s)$ . Thus, a constant-pass randomized  $\alpha$ -approximation streaming algorithm with success probability at least 0.95 requires  $\Omega(m/k^2)$  space.

## 6 Subsampling for the Data Stream

Here we outline the subsampling approach from [15]. Given a data stream instance of **Max Unique Coverage**, it is possible to construct a number of *subsamped* instances by sampling the universe  $U$  at varying rates. By running an algorithm on these subsampled instances in parallel, we lose only a small error in approximation w.h.p. while only needing to store sets of size  $O(k \log m/\varepsilon^2)$ . We summarize the overall approach in Lemma 2.1 and give a proof sketch.

**Proof Sketch of Lemma 2.1.** Given an instance of **Max Unique Coverage** with universe  $U$  and collection of sets  $\mathcal{V}$ , let  $v$  be a guess of the optimal solution value; each subsampled instance corresponds to some value of  $v$  (we calculate these guesses shortly). Let  $h : U \rightarrow \{0, 1\}$  be a hash function that is  $\Omega(k \log m/\varepsilon^2)$ -wise independent such that

$$\Pr[h(x) = 1] = p = \frac{ck \log m}{\varepsilon^2 v},$$

where  $c$  is a sufficiently large constant. Let  $U' = \{x \in U : h(x) = 1\}$  be the subsampled universe,  $S' = S \cap U'$ ,  $\mathcal{V}' = \{S' : S \in \mathcal{V}\}$  be the subsampled subsets, and  $\text{OPT}'$  be the optimal unique coverage in the subsampled instance. Further, let  $\mathcal{B}'$  be a solution from  $\mathcal{V}'$

and  $\mathcal{B}$  be the corresponding solution from the original collection  $\mathcal{V}$ . Then Lemma 6.1 below (a restatement of [15, Lemma 23]) shows that, in a subsampled instance where  $v \leq \text{OPT}$ , w.h.p., the loss in approximation is at most  $2\varepsilon$ .

► **Lemma 6.1** ([15, Lemma 23]). *If  $v \leq \text{OPT}$ , then with probability at least  $1 - 1/\text{poly}(m)$ , we have that*

$$(1 + \varepsilon)p\text{OPT} \geq \text{OPT}' \geq (1 - \varepsilon)p\text{OPT}.$$

Furthermore, for some  $\alpha \in (0, 1)$ , if  $\mathcal{B}' \subseteq \mathcal{V}'$  satisfies  $|\tilde{\psi}(\mathcal{B}')| \geq \alpha(1 - \varepsilon)p\text{OPT}$ , then  $|\tilde{\psi}(\mathcal{B})| \geq (\alpha - 2\varepsilon)\text{OPT}$ .

We guess  $v = 2^i$  for each  $i \in [\lceil \log_2 n \rceil]$  and construct a subsampled instance for each  $v$  in parallel. Then, in the particular subsampled instance where  $\text{OPT}/2 \leq v \leq \text{OPT}$ , Lemma 6.1 implies the following upper bound on every set size  $|S'|$  with probability  $1 - 1/\text{poly}(m)$ .

$$|S'| \leq \text{OPT}' \leq (1 + \varepsilon)p\text{OPT} = (1 + \varepsilon) \frac{ck \log m}{\varepsilon^2 v} \text{OPT} \leq (1 + \varepsilon) \frac{2ck \log m}{\varepsilon^2} = O\left(\frac{k \log m}{\varepsilon^2}\right).$$

To ensure that we only ever store sets of size  $O(k \log m / \varepsilon^2)$ , we terminate every subsampled instance that contains a set  $S'$  with  $|S'| > (2ck \log m / \varepsilon^2)(1 + \varepsilon)$ . W.h.p., this does not terminate the subsampled instance where  $\text{OPT}/2 \leq v \leq \text{OPT}$  by the above upper bound on  $|S'|$  for every  $S'$  in this particular instance.

This means that, out of the nonterminated subsampled instances, we should select the one with the smallest  $v$  and return the corresponding solution, giving an  $(\alpha - 2\varepsilon)$ -approximation for the original instance w.h.p. (this works even if the smallest nonterminated guess satisfies  $v < \text{OPT}/2$  since Lemma 6.1 holds for all  $v \leq \text{OPT}$ ).

The overall space complexity,  $\lceil \log_2 n \rceil \cdot s \cdot O(k \log m \log n / \varepsilon^2)$ , follows from the number of guesses of  $v$  and, for each guess, the algorithm storing at most  $s$  sets of size  $O(k \log m / \varepsilon^2)$  and using  $O(\log n)$  bits to store each element. ◀

## 7 Conclusions

We are pleased to present a suite of algorithms, and a streaming lower bound, for **Max Unique Coverage**. The component algorithms that build a solution to **Max Unique Coverage** from a solution to **Max Coverage** serve to support a fixed-parameter tractable approximation scheme (FPT-AS). The lower bound shows that  $\Omega(m/k^2)$  space is required even to get within a  $(1.5 + o(1))/(\ln k - 1)$  factor of optimal.

A plausible future direction would be to reduce, or indeed eliminate, the role of the upper bound on the unique coverage ratio,  $\phi$ , in the kernel size in a FPT-AS. This would match the kernel size used in existing FPT-ASs for **Max Coverage**, but may not be possible due to the inherent hardness of **Max Unique Coverage**. Another direction would be proving a streaming lower bound with a tighter approximation threshold. This may require a reduction from a different communication problem, rather than the renowned  $k$ -player Set Disjointness.

## Abstract

Estimating the size of the union of a stream of sets  $S_1, S_2, \dots, S_M$  where each set is a subset of a known universe  $\Omega$  is a fundamental problem in data streaming. This problem naturally generalizes the well-studied  $F_0$  estimation problem in the streaming literature, where each set contains a single element from the universe. We consider the general case when the sets  $S_i$  can be succinctly represented and allow efficient membership, cardinality, and sampling queries (called a Delphic family of sets). A notable example in this framework is the Klee’s Measure Problem (KMP), where every set  $S_i$  is an axis-parallel rectangle in  $d$ -dimensional spaces ( $\Omega = [\Delta]^d$  where  $[\Delta] := \{1, \dots, \Delta\}$  and  $\Delta \in \mathbb{N}$ ). Recently, Meel, Chakraborty, and Vinodchandran (PODS-21, PODS-22) designed a streaming algorithm for  $(\epsilon, \delta)$ -estimation of the size of the union of set streams over Delphic family with space and update time complexity  $O\left(\frac{\log^3 |\Omega|}{\epsilon^2} \cdot \log \frac{1}{\delta}\right)$  and  $\tilde{O}\left(\frac{\log^4 |\Omega|}{\epsilon^2} \cdot \log \frac{1}{\delta}\right)$ , respectively.

This work presents a new, sampling-based algorithm for estimating the size of the union of Delphic sets that has space and update time complexity  $\tilde{O}\left(\frac{\log^2 |\Omega|}{\epsilon^2} \cdot \log \frac{1}{\delta}\right)$ . This improves the space complexity bound by a  $\log |\Omega|$  factor and update time complexity bound by a  $\log^2 |\Omega|$  factor.

A critical question is whether quadratic dependence of  $\log |\Omega|$  on space and update time complexities is necessary. Specifically, can we design a streaming algorithm for estimating the size of the union of sets over Delphic family with space and complexity linear in  $\log |\Omega|$  and update time  $\text{poly}(\log |\Omega|)$ ? While this appears technically challenging, we show that establishing a lower bound of  $\omega(\log |\Omega|)$  with  $\text{poly}(\log |\Omega|)$  update time is beyond the reach of current techniques. Specifically, we show that under certain hard-to-prove computational complexity hypothesis, there is a streaming algorithm for the problem with optimal space complexity  $O(\log |\Omega|)$  and update time  $\text{poly}(\log(|\Omega|))$ . Thus, establishing a space lower bound of  $\omega(\log |\Omega|)$  will lead to break-through complexity class separation results.

## 1 Introduction

The past three decades bear witness to significant developments in the field of data streaming. The widespread adoption of computing systems has led to the era of big data, wherein the ubiquity of sensors has allowed the collection of a large amount of data. Consequently, the data streaming model and the design of algorithms that balance time and space efficiency in this model are of significant interest to theoreticians and practitioners alike.

In this paper, we focus on one of the fundamental problems in data streaming: Given a stream of sets  $S_1, S_2, \dots, S_M$  where each  $S_i$  is a subset of a universe  $\Omega$ , output an  $(\varepsilon, \delta)$ -estimate (see the Definition 5) of the size of the union of the sets, that is,  $|\bigcup_i S_i|$ . Note that when sets are singletons, the problem boils down to the estimation of the zeroth frequency moment ( $F_0$ ) of the stream of items and is well-studied in streaming literature. In particular, a long line of work culminated in the development of algorithms for  $F_0$ -estimation with optimal space complexity  $O(\log |\Omega| + \frac{1}{\varepsilon^2})$  and  $O(1)$  update time complexity [16] (for a constant error probability  $\delta$ ). In this work, we will focus on the Delphic family of sets which is a general framework for computational problems over abstract sets.

► **Definition 1** (Delphic family). *Let  $\Omega$  be a discrete universe. A set  $S \subseteq \Omega$  belongs to a Delphic family<sup>1</sup> if the following queries can be done in  $O(\log |\Omega|)$  time: (1) Membership: Given any  $x \in \Omega$  check if  $x \in S$ , (2) Cardinality: Determine the size of  $S$ , that is  $|S|$ , (3) Sampling: Draw a uniform random sample from  $S$ .*

The notion of the Delphic family is general enough to capture several well-known problems, such as Klee’s Measure Problem (KMP) [23, 25], test coverage estimation, and DNF counting. For example, the streaming version of Klee’s Measure Problem (KMP) refers to the case where the sets in a stream are represented by an axis-parallel rectangle in  $[\Delta]^d$  where  $\Delta$  is a natural number. KMP is a naturally occurring and fundamental topic that has been extensively researched in computational geometry [4, 6, 8, 10, 9, 12, 14, 17, 21]. While *Delphic Sets* was coined in [19], the notion has been implicit in prior work stretching to the early 1980’s. We are interested in designing streaming algorithms for estimating the size of the union of sets over a Delphic family. We also call this problem  $F_0$  estimation problem over Delphic sets.

► **Problem 2.** *Given a stream  $\mathcal{S} = \langle S_1, S_2, \dots, S_M \rangle$  wherein each  $S_i \subseteq \Omega$  belongs to a Delphic family, and  $0 < \varepsilon < 1$  output an  $(\varepsilon, 1/3)^2$  approximation of  $F_0(\mathcal{S}) := \left| \bigcup_{i=1}^M S_i \right|$ .*

<sup>1</sup> As observed in [18], every Delphic set can be represented by a circuit of size  $O(\log |\Omega| \log \log |\Omega|)$ .

<sup>2</sup>  $c$  is  $(\varepsilon, 1/3)$  approximation of  $F_0(\mathcal{S})$  if  $\Pr[F_0(\mathcal{S})(1 - \varepsilon) \leq c \leq F_0(\mathcal{S})(1 + \varepsilon)] \geq 2/3$ . Note that the choice of  $1/3$  is arbitrary. The probability  $1/3$  can be boosted to an arbitrary  $\delta$  by using standard boosting technique.

■ **Table 1** In the table  $n := \log |\Omega|$ ,  $m := \log M$  and  $c := O(1)$ . The Big-Oh notation ( $O$ ) in the above comparison table shows only dependency on  $n$  and  $m$  and hides the  $\text{poly}(1/\varepsilon, 1/\delta)$  factors on  $\varepsilon$  and  $\delta$ .

The design goal is to optimize the algorithm’s update time and space complexity, wherein the update time complexity refers to the amount of time spent processing an item (a set in our case) of the stream.

## 1.1 Prior Work and Technical Challenges

Since the work of Alon, Matias, and Szegedy [1], streaming algorithms gained considerable interest from algorithm design community. However, the problem of estimating distinct elements in a stream of items has been investigated prior to the work of [1]. In particular, the seminal work of Flajolet and Martin [11] pioneered a sketching-based framework for streaming algorithms for the case wherein every element of the stream is a singleton. The sketching-based techniques crucially rely on the use of pairwise independent hash functions. In the early 2000s, the sketching-based approach emerged as a principal technical tool in the design of streaming algorithms. Particularly for  $F_0$  estimation of single-item streams, a series of hash-function-based algorithms led to the development of both space-efficient and update-time optimal algorithms [16, 5].

$F_0$  estimation over set streams has garnered interest from researchers due to the natural extension from singletons to sets. Notably, Pavan and Tirthapura [22] and Sun and Poon [24] explored range-efficient  $F_0$  estimation, which addresses a specific case of the KMP in one dimension. For the broader KMP, Tirthapura and Woodruff [25] developed an algorithm with optimal space complexity. However, the update time for their algorithm was  $O(|\Omega|)$ , which is exponential in terms of set representation. Subsequently, Pavan, Vinodchandran, Bhattacharyya, and Meel [23] proposed an alternative technique, yet it similarly faced an update time complexity of  $O(|\Omega|)$ .

All the above-mentioned algorithms employed hash function based approaches and failed to yield an algorithm with update time complexity polynomial in representation of sets for the general case of Delphic sets. The primary technical barrier to such approaches arises from the fact that sketching-based techniques crucially rely on checking whether for a function  $h$ , randomly chosen from a pairwise independent hash family, there exists an element  $x \in S_i$  such that  $h(x) = 0$ . Nevertheless, whether a pairwise independent hash family exists that supports such checking in time  $\text{poly}(\log |\Omega|)$  is unknown.

In [19], the authors introduced a sampling-based technique for  $F_0$  estimation that eschews traditional hash functions. Their method involves maintaining a bucket  $\mathcal{X}$ , where each stream element is selected independently with probability  $p$ . To handle element repetitions, new elements from a set  $S_i$  replace those in  $\mathcal{X}$ , with all elements in  $S_i$  sampled independently

at the same probability  $p$ . To manage the bucket's size, elements are discarded with a probability of  $1/2$  once a threshold based on  $\varepsilon^{-1}$  is reached, halving  $p$  simultaneously. This approach yields a space complexity of  $\tilde{O}\left(\frac{\log |\Omega| \cdot \log M}{\varepsilon^2}\right)$ , with a logarithmic dependence on the stream size  $M$ . In a subsequent work [18], the authors modified this approach by allowing  $p$  to vary, not just decrease. Each tuple in  $\mathcal{X}$  then included the element and its sampling probability at arrival. This adjustment removed the dependency on  $M$ , leading to space complexity of  $\tilde{O}\left(\frac{\log^3 |\Omega|}{\varepsilon^2}\right)$  and update time complexity of  $\tilde{O}\left(\frac{\log^4 |\Omega|}{\varepsilon^2}\right)$ . This contrasts with the optimal algorithm for singleton sets  $S_i$  by Kane, Nelson, and Woodruff, which has a space complexity of  $O(\log |\Omega| + \frac{1}{\varepsilon^2})$ .

The above-mentioned line of research leads to the following significant open question:

*Can we design algorithm for  $F_0$  estimation over Delphic sets with space complexity  $O(\log |\Omega|)$  and update-time complexity  $\text{poly}(\log |\Omega|)$  (ignoring dependency on  $\varepsilon$  and  $\delta$ )?*

*Remark:* We note that if we have no restriction on the update time complexity, then the problem over Delphic sets reduces to  $F_0$  estimation of singleton streams: when a set  $S_i$  arrives, we can cycle through all elements in the universe  $\Omega$  and use membership testing only to stream elements of  $S_i$ . This leads to an algorithm with optimal space complexity of  $O(\log(|\Omega|) + \varepsilon^{-2})$  but with update time that depends linearly on  $|\Omega|$ . An asymptotic lower bound of  $\Omega(\log(|\Omega|) + \varepsilon^{-2})$  is known for the space complexity [15, 1].

It is worth observing that if we were to follow the approach suggested in [19, 18], then ensuring that the value of  $p$  at least  $\frac{1}{\varepsilon^2 \cdot F_0(S)}$  with sufficiently high probability does entail the space complexity of  $\tilde{O}\left(\frac{\log^3 |\Omega|}{\varepsilon^2}\right)$ . Therefore, an improvement in space complexity must require a new approach.

## 1.2 Our Results

As our first contribution, we report progress towards the above question. In particular, we establish the following:

► **Theorem 3 (Main Theorem).** *There is a streaming algorithm that given a stream  $S = \langle S_1, S_2, \dots, S_M \rangle$  wherein each  $S_i$  belongs to Delphic family, and  $0 < \varepsilon < 1$  outputs an  $(\varepsilon, 1/3)$ -estimation of  $\left| \bigcup_{i=1}^M S_i \right|$  with space complexity  $O\left(\frac{\log^2 |\Omega|}{\varepsilon^2} \cdot \log \frac{1}{\varepsilon}\right)$  and update time complexity  $O\left(\frac{\log^2 |\Omega|}{\varepsilon^2} \cdot \log^3 \frac{1}{\varepsilon}\right)$ .*

The above theorem improves the space complexity by a factor of  $\log |\Omega|$  and the update time complexity by a factor of  $\log^2 |\Omega|$ . We note that for special cases such as KMP, we can bring the update time complexity factor of  $\log^3 \frac{1}{\varepsilon}$  to  $\log \frac{1}{\varepsilon}$ , resulting in update time complexity of  $O\left(\frac{d^2 \log^2 \Delta}{\varepsilon^2} \cdot \log \frac{1}{\varepsilon}\right)$  where  $\Omega = [\Delta]^d$ .

Theorem 3 leads to the natural question of whether further improvement is possible towards solving the open question of designing a streaming algorithm for  $F_0$  estimation over Delphic sets with space complexity  $O(\log |\Omega|)$  (ignoring the dependence on  $\varepsilon$  and  $\delta$ ) and update time complexity significantly smaller than  $|\Omega|$ . This seems hard and will require new techniques: since storing a single element takes  $O(\log |\Omega|)$  space implies that one can only store a constant number of elements at any point of time. This appears to be a major technical restriction for sampling-based approaches like our algorithm in Theorem 3 and we even conjecture that  $\omega(\log |\Omega|)$  space is required if we restrict the update time to be  $\text{poly}(\log |\Omega|)$ . Unfortunately, establishing such a lower bound has a major computational

complexity bottleneck. In particular, we show that establishing a lower bound on space other than the lower bound known for computing  $F_0$  for singleton streams will lead to major separation result in computational complexity.

$\text{NTISP}(\text{poly}, \text{Linspace})$  is the class of language accepted by non-deterministic Turing machines in polynomial time and linear space simultaneously. Likely,  $\text{DTISP}(\text{poly}, \text{Linspace})$  is the class of languages accepted by deterministic Turing machines in polynomial time and linear space simultaneously. Whether or not  $\text{NTISP}(\text{poly}, \text{Linspace}) = \text{DTISP}(\text{poly}, \text{Linspace})$  is an open problem in complexity theory. If  $\text{NTISP}(\text{poly}, \text{Linspace}) = \text{DTISP}(\text{poly}, \text{Linspace})$  then  $P=NP$ . The other implication is yet to be discovered. However, separating  $\text{NTISP}(\text{poly}, \text{Linspace})$  from  $\text{DTISP}(\text{poly}, \text{Linspace})$  is a hard open question. The best-known lower bound for time-space complexity classes is that SAT (which is in  $\text{NTISP}(\text{poly}, \text{Linspace})$ ) cannot be solved in  $\text{DTISP}(n^{1.8}, o(n))$  [26]. Any improvement on this will be a major result in complexity theory. We show the following:

► **Theorem 4.** *There is a streaming algorithm,  $\text{DelphicWithNP}$ , that given, a stream  $\mathcal{S} = \langle S_1, \dots, S_M \rangle$ , where each set  $S_i \subseteq \Omega$  is a member of a Delphic family,  $0 < \varepsilon$ , and an oracle access to a language belonging to  $\text{NTISP}(\text{poly}, \text{Linspace})$ , computes a  $(\varepsilon, 1/3)$ -approximation of  $F_0(\mathcal{S})$ . Moreover,  $\text{DelphicWithNP}$  has the following properties:*

- (1) *it takes  $O(\log |\Omega| \cdot \varepsilon^{-2})$  space and  $\text{poly}(\log |\Omega|, \frac{1}{\varepsilon})$  update time,*
- (2) *the queries it makes to the oracle are of size  $O(\log |\Omega| \cdot \varepsilon^{-2})$ .*

*Thus, if  $\text{NTISP}(\text{poly}, \text{Linspace}) = \text{DTISP}(\text{poly}, \text{Linspace})$ , there is an algorithm (without oracle calls) for  $(\varepsilon, 1/3)$ -estimation of  $F_0$  of a set stream over Delphic family with  $O(\log |\Omega| \cdot \varepsilon^{-2})$  space and  $\text{poly}(\log |\Omega|, 1/\varepsilon)$  update time.*

Thus, for constant  $\varepsilon$ , we get a space optimal algorithm for estimating  $F_0$  over Delphic set streams as  $\log |\Omega|$  space is required even in the singleton case. In fact, the above theorem is true for a very relaxed version of Delphic sets where we only require one of the conditions for membership in Delphic sets to be decided in time linear in the representation of the set. Theorem 4 implies that establishing a space lower bound of  $\omega(\log |\Omega|)$  for estimating  $F_0(\mathcal{S})$  of Delphic set streams with  $\text{poly}(\log |\Omega|)$  will lead to proving  $\text{NTISP}(\text{poly}, \text{Linspace}) \neq \text{DTISP}(\text{poly}, \text{Linspace})$ , thus resolving a significant lower bound in complexity theory.

Our work leaves a tantalizing open question:

*What is the optimal space complexity for  $F_0$  estimation of set streams over Delphic family with  $\text{poly}(\log |\Omega|)$  update time complexity?*

### 1.3 Technical Overview

#### Key Ideas for Theorem 3

The high-level idea is to maintain a bucket for every level  $k \in \{1, \dots, \log |\Omega|\}$  such that the bucket,  $\mathcal{X}^{(k)}$ , at level  $k$  consists of elements from  $\bigcup_i S_i$  that were independently selected with a probability of  $2^{-k}$ . To handle repetitions, i.e., when a new set  $S_i$  arrives, we remove all the elements of  $\mathcal{X}^{(k)}$  that are present in  $S_i$ . This process ensures that the event of an element  $s$  being in  $\mathcal{X}^{(k)}$  at the end of the stream depends only on whether  $s$  was independently chosen from the set  $S_i$ , where  $S_i$  is the last set containing  $s$ , and there is no  $S_j$  with  $j > i$  such that  $s \in S_j$ .

To bound the space complexity, we establish a threshold, denoted by  $\text{thresh}$ , limiting the maximum size of the bucket. Whenever  $|\mathcal{X}^{(k)}| = \text{thresh}$ , no additional elements can be added to  $\mathcal{X}^{(k)}$  (i.e., we must wait until some elements are removed from  $\mathcal{X}^{(k)}$ ). We set  $\text{thresh} := O\left(\frac{1}{\varepsilon^2}\right)$ . Note that storing any element requires  $O(\log |\Omega|)$  space, and thus storing  $\text{thresh} \log |\Omega|$  elements necessitates  $O\left(\frac{\log^2 |\Omega|}{\varepsilon^2}\right)$  space.

The key technical insight from [19] is that if  $\text{thresh} = O\left(\frac{\log M}{\varepsilon^2}\right)$ , it can be demonstrated that, with sufficiently high probability and for  $k > \log(F_0(\mathcal{S}))$ ,  $\mathcal{X}^{(k)}$  would not be full (i.e.,  $|\mathcal{X}^{(k)}| < \text{thresh}$ ) at all times. Furthermore, in [18], it was observed that  $\text{thresh} = O\left(\frac{\log |\Omega|}{\varepsilon^2}\right)$ , then it can be demonstrated that, with sufficiently high probability and for  $k > \log(F_0(\mathcal{S}))$ ,  $\mathcal{X}^{(k)}$  would not be full (i.e.,  $|\mathcal{X}^{(k)}| < \text{thresh}$ ) when an element  $s \in \bigcup_i S_i$  appears for the last time in a stream.

The major technical advancement in our analysis hinges on a crucial observation: while it is plausible for  $\mathcal{X}^{(k)}$  to be full when an element  $s$  makes its final appearance in the stream, the resulting relative error of our estimator  $|\mathcal{X}^{(k)}| \cdot 2^k$  remains manageable even when  $k$  is approximately logarithmic in the order of magnitude of the size of the stream, that is  $k \sim \log(F_0(\mathcal{S}))$ . The ensuing technical analysis is complex due to its dependence on a meticulous formulation of significant events and the construction of a sum of products of random variables. We introduce two sets of random variables, denoted as  $X_{i,r}^{(k)}$  and  $Y_{i,r}^{(k)}$ . The random variable  $X_{i,r}^{(k)}$  indicates whether an element is sampled from the  $j$ -th set  $S_j$  in the stream. The random variables  $Y_{i,r}^{(k)}$  indicate whether a set of sampled elements is included in the buckets. We then define a series of random variables  $Z_r^{(k)}$ , dependent on the aforementioned random variables  $X_{i,r}^{(k)}$  and  $Y_{i,r}^{(k)}$ . To leverage concentration inequalities effectively, we maintain a collection of  $O(1/\varepsilon^2)$  buckets at each level  $k$ . Additionally, we set the size of each bucket to be  $O(\log(1/\varepsilon))$ . At the end of the stream, for each level  $k$ , we calculate the average number of elements in the buckets at that level, denoted as  $\bar{Z}^{(k)}$ .

Finally, it is important to note that our technical analysis only ensures that the relative error is small for  $k \approx \log(F_0(\mathcal{S}))$ . Since  $F_0(\mathcal{S})$  is unknown a priori, we must identify a method to choose an optimal  $k^*$  for returning the final estimate  $\bar{Z}^{(k^*)} \cdot 2^{k^*}$ . A key observation is that  $\bar{Z}^{(k)}$  is less than 1 for  $k \gg \log(F_0(\mathcal{S}))$ . Therefore, finding the largest  $k$  for which  $\bar{Z}^{(k)}$  exceeds 1 should suffice.

## Key Ideas for Theorem 4

The main idea is to adapt one of the standard hashing-based algorithms (e.g., Gibbons and Tirthapura's algorithm) for  $F_0$  estimation for singleton streams that takes  $O(\log |\Omega| \cdot \frac{1}{\varepsilon^2})$  space. The algorithm starts with picking a hash function  $h$  from a pairwise independent family and keeps a bucket  $\mathcal{X}$  which is initially set to empty and has a capacity of  $O(\frac{1}{\varepsilon^2})$ . The computational challenge is to implement the update step. For this, when a new set  $S$  comes, we need to add all elements  $x \in S$  so that the first  $m$  bits of  $h(x)$  are all 0s for a variable  $m$  that the algorithm keeps. If the addition of these elements makes the bucket  $\mathcal{X}$  overflow,  $m$  is incremented and deletes all elements  $\mathcal{X}$  with  $m + 1$ st bit of hash value is non-zero. The main computational challenge is to implement this step. However, we show how this step can be implemented by making linear size queries to disjoint union of two languages in NTISP(poly,LINSPACE). Thus if NTISP(poly,LINSPACE) = DTISP(poly,LINSPACE), then queries to this language can be simulated in space  $O(\log |\Omega| \cdot \frac{1}{\varepsilon^2})$  and update time  $\text{poly}(\log |\Omega|, \varepsilon^{-1})$ .

## 1.4 Paper Organization

The remainder of this paper is structured as follows. Section 2 introduces key notations and fundamental concepts. In Section 3, we present our primary Algorithm 2 for Delphic sets with WOR sampling, along with its correctness analysis. Subsequently, in subsection 3.2, we

present the algorithm for the general Delphic set. Section 4 contains the proof of Theorem 4. The appendix is divided as follows: Section A presents the concentration bounds used in the correctness analysis; Section B provides the missing proofs for Proposition 15; Section C details the algorithm for KMP along with its correctness analysis; and finally, Section D offers some basic probability results.

## 2 Preliminaries

### 2.1 $F_0$ -Estimator and Klee's Measure Problem

For a stream of sets,  $\mathcal{S} := \langle S_1, S_2, \dots, S_M \rangle$  where each set in the stream is a subset of  $\Omega$ , recall that we denote by  $F_0(\mathcal{S})$  the size of the union of the sets:  $F_0(\mathcal{S}) = \left| \bigcup_{j=1}^M S_j \right|$

► **Definition 5.** *A random variable  $X$  is an  $(\varepsilon, \delta)$ -approximation of  $c$  if  $\Pr[(1 - \varepsilon)c \leq X \leq (1 + \varepsilon)c] \geq (1 - \delta)$ . We also simply write the event  $(1 - \varepsilon)c \leq X \leq (1 + \varepsilon)c$  as  $X = (1 \pm \varepsilon)c$  (or  $X \neq (1 \pm \varepsilon)c$  to denote the complement event).*

Finally an  $F_0$ -estimator is a streaming algorithm that on input  $\varepsilon, \delta \in (0, 1)$  and access to a stream of set  $\mathcal{S} := \langle S_1, S_2, \dots, S_M \rangle$  outputs an  $(\varepsilon, \delta)$  approximation of  $F_0(\mathcal{S})$ .

There are two main complexity measures that we are interested about an  $F_0$ -estimator - space complexity and update time complexity. The space complexity is the amount of work space needed by the algorithm. The update time complexity is the amount of time spent by the algorithm for processing a single set in the stream. The goal is to design an  $F_0$ -estimator while trying to minimize both the space complexity and the update time complexity of the algorithm.

The notion of Delphic sets captures several well-known problems, such as Klee's Measure Problem, which we define below.

Let  $\Delta$  be a natural number, consider the following set  $[\Delta] = \{1, 2, \dots, \Delta\}$ . A  $d$ -dimensional axis-aligned rectangle  $\mathbf{r}$  over  $[\Delta]^d$  is a subset of  $[\Delta]^d$ , succinctly represented by the tuple  $(a_1, b_1, \dots, a_d, b_d)$ , and contains all the tuples  $\{(x_1, \dots, x_d)\}$  where  $a_i \leq x_i \leq b_i$  and  $x_i \in [\Delta]$ . Formally, we write  $\mathbf{r} = \{(x_1, x_2, \dots, x_d) : a_i \leq x_i \leq b_i, x_i \in [\Delta] \text{ for all } i \in [d]\}$

► **Definition 6** (Klee's Measure Problem (KMP) in Streaming Setting). *Given a stream  $\mathcal{R}$  of size  $M$  such that  $\mathcal{R} = \langle \mathbf{r}_1, \mathbf{r}_2, \dots, \mathbf{r}_M \rangle$ , where each item  $\mathbf{r}_i$  is a  $d$ -dimensional rectangle, compute a  $(\varepsilon, \delta)$ -approximation of  $\left| \bigcup_{i=1}^M \mathbf{r}_i \right|$ .*

Note that KMP is a special case of Problem 2 since set of  $d$ -dimensional axis-aligned rectangles over  $[\Delta]^d$  forms a Delphic family.

### 2.2 Notations

For any positive integer  $k$ , we write  $[k] = \{1, 2, \dots, k\}$ . In the rest of this paper, we will assume that  $\mathcal{S} := \langle S_1, S_2, \dots, S_M \rangle$  is a stream of sets, where each set is a subset of universe  $\Omega$ , i.e.,  $S_j \subseteq \Omega$  for all  $j \in [M]$ . We denote by  $s_j := |S_1| + \dots + |S_j|$  for all  $j \in [M]$  and  $s_0 := 0$ . We write  $s := s_M$  to denote the total number of elements counting with repetition that appeared in the stream  $\mathcal{S}$ . For  $j \in [M]$ , let  $\mathcal{I}_j = \{s_{j-1} + 1, s_{j-1} + 2, \dots, s_j\}$ , the set  $\mathcal{I}_j$  denotes the indices of elements in the set  $S_j$ . Note that  $\mathcal{I}_j$ 's are disjoint and  $\bigcup_{j=1}^M \mathcal{I}_j = [s]$ . Clearly, for every  $i \in [s]$ , we can assign a *streaming-index*  $j := j(i)$  (which is unique) such that  $i \in \mathcal{I}_j$ .

Although, total order of the elements on  $\Omega$  is not needed for our algorithms, we will assume an ordering of the elements of  $\Omega$ ; this will help us in the presentation of the correctness proofs of the algorithm. We can open the set stream into element streams and write a sequence  $\langle x_1, \dots, x_s \rangle$ , where  $S_j = \{x_i : i \in \mathcal{I}_j\}$ ,  $x_{s_{j-1}+1} < \dots < x_{s_j} \forall j \in [M]$ . For any  $k \in [|S_j|]$  we will denote by  $S_j[k]$  to the element  $x_{s_{j-1}+k}$ .

At any point, say after the sets  $S_1, \dots, S_j$  have arrived in the stream and for any element  $x$  in the stream  $\langle x_1, \dots, x_{s_j} \rangle$ , that is, the stream we have seen till now, we will be interested in the last time the element appeared in the stream. The set of indices in  $[s_{j-1}]$  that contains the last appearance of any element is called the set of *final indices with respect to  $j$ th set  $S_j$*  and is denoted by  $\mathcal{F}_j$ .

More formally, let  $j \in [M]$  be a stream index. We call  $i \leq s_{j-1}$  a *final index with respect to  $j$ th set  $S_j$*  if  $x_i \notin \{x_{i+1}, \dots, x_{s_j}\}$ . Let

$$\mathcal{F}_j = \{i \leq s_{j-1} : i \text{ is a final indices w.r.t. } j\text{th set } S_j\}.$$

When  $j = 1$ , the set  $\mathcal{F}_1 = \emptyset$ .

Now we make the following simple but valuable observations:

► **Observation 7.**

1. For all  $j \in [M]$ , (i)  $\mathcal{F}_j$  and  $\mathcal{I}_j$  are disjoint i.e.,  $\mathcal{F}_j \cap \mathcal{I}_j = \emptyset$  and (ii)  $\{x_i : i \in \mathcal{F}_j\}$  is disjoint from  $S_j$ .
2.  $\{x_i : i \in \mathcal{F}_j\} \sqcup S_j \subseteq S$ . The equality occurs for  $j = M$ , i.e.,  $\{x_i : i \in \mathcal{F}\} = S$  where  $\mathcal{F} = \mathcal{F}_M \sqcup \mathcal{I}_M$ . Note,  $|\mathcal{F}| = F_0(S)$ .
3. For all  $j \in [M - 1]$ ,  $\mathcal{F}_{j+1} \subseteq \mathcal{F}_j \sqcup \mathcal{I}_j$ .

## 2.3 Delphic Family with WOR Sampling

The definition of Delphic Sets (Definition 1) allows one to draw a uniform random sample from a Delphic Set  $S$ . However, if one needs to uniformly draw a set of  $k$  distinct samples from  $S$ , the only option is to draw independent samples from  $S$  until one gets  $k$  distinct samples. One can use the coupon collector theorem to ensure that with high probability, one has to draw at most  $O(k \log k)$  samples. Nevertheless, this “high probability” statement may not be sufficient if one has to repeat this process multiple times - a slightly more involved calculation may be necessary.

One way of dealing with this issue is assuming one is allowed to draw samples “without replacement (WOR)”. Formally, we define a Delphic family with WOR sampling as follows:

► **Definition 8** (Delphic family with WOR sampling). *A set  $S \subseteq \Omega$  belongs to the Delphic family with WOR sampling if the following queries can be done:*

- (1) know the size of the set  $S$ , in  $O(\log |\Omega|)$  time
- (2) given any  $x$  check if  $x \in S$ , in  $O(\log |\Omega|)$  time
- (3) for any  $k \leq |S|$ , we can draw in  $O(k \log |\Omega|)$  time a uniformly random subset  $S'$  of size  $k$ .

Note that, in contrast to Definition 8, the original Delphic family (Definition 1) can be called “Delphic family with WR sampling”, where WR stands for “with replacement”.

## 2.4 Random Processes and Distributions

We will be drawing samples according to different distributions. All the distributions are standard in the literature. The following are the distributions we will be using in this paper.

► **Definition 9** (Binomial Distribution). *Given any  $n \in \mathbb{N}$  and any  $p \in [0, 1]$  the Binomial Distribution over the set of integers  $\{0, 1, 2, \dots, n\}$  is denoted as  $\text{Bin}(n, p)$  where probability of a number  $0 \leq k \leq n$  is  $\binom{n}{k} p^k (1 - p)^{n-k}$ .*

► **Definition 10** (Bernoulli Process). *Given any finite set  $S$  and any  $p \in [0, 1]$ , a Bernoulli sample of probability  $p$  for the set  $S$  is denoted as  $\text{Ber}(S, p)$  such that every element  $x \in S$  is picked with probability  $p$ . If  $X$  denotes the sampled subset of  $S$  with probability  $p$  then for any set  $T \subseteq S$ ,  $\Pr(X = T) = p^{|T|} (1 - p)^{|S| - |T|}$ .*

*By abuse of notation, we will use  $\text{Ber}(p)$  to denote the distribution over  $\{0, 1\}$  where the probability of 1 is  $p$ . So, the Bernoulli process is nothing but independent copies of the Bernoulli distribution where 1 (or 0) represents that the element is picked (or not picked respectively).*

Clearly, if  $X \sim \text{Ber}(S, p)$  then  $|X| \sim \text{Bin}(|S|, p)$ . We now describe how to sample the Bernoulli process. We first sample  $d \sim \text{Bin}(|S|, p)$ , then we sample  $d$  many elements, denoted as  $T$ , in a without replacement (WOR) manner. Then,  $T \sim \text{Ber}(S, p)$ . One can sample WOR through with replacement (WR) sampling (this is well-known as the coupon collection problem). We have the following lemma using the coupon collector theorem (see Appendix D).

► **Lemma 11.**  $\text{WRSample}(S, r, t)$  (Algorithm 1) outputs a subset  $L$  of the set  $S$  with the following guarantee

- With probability  $\geq \left(1 - r^{-\frac{t}{r \log r} + 1}\right)$  the algorithm outputs a set of size  $r$  distinct samples, each drawn uniformly from the set  $S$ .
- With the remaining probability at most  $r^{-\frac{t}{r \log r} + 1}$  the algorithm outputs an empty set.
- The maximum number of samples drawn from  $S$  is  $t$ .

■ **Algorithm 1**  $\text{WRSample}(S, r, t)$ .

---

```

1: Input Set  $S$   $t, r \in \mathbb{N}$ 
2: Initialize  $L = \emptyset$ ;
3: for  $1 \leq i \leq t$  do
4:   if  $|L| < r$  then
5:     Draw a random sample  $x$  from  $S$  (with replacement)
6:     if  $x \notin L$  then  $L = L \cup \{x\}$ 
7: if  $|L| \neq r$  then  $L = \emptyset$ 
8: Output  $L$ 

```

---

**3 F<sub>0</sub>-Estimator for Delphic sets**

In this section, we prove Theorem 3. We prove it in two steps. In Section 3.1, we present Algorithm 2 and prove that it is an  $F_0$ -estimator for Delphic Sets with WOR sampling. Then, in Section 3.2, we show how the Algorithm 2 can be modified to obtain an  $F_0$ -estimator for general Delphic Sets and hence prove Theorem 3.

**3.1 Handling Delphic Sets with WOR sampling**

In this section, we will prove the following theorem:

► **Theorem 12.** *If  $\mathcal{S}$  is a stream of Delphic Sets with WOR sampling, then the Algorithm 2 is an  $(\varepsilon, 1/3)$ - $F_0$ -estimator. Also, the space and update time complexity of Algorithm 2 is  $O\left(\frac{\log^2 |\Omega|}{\varepsilon^2} \cdot \log \varepsilon^{-1}\right)$ .*

Before we present the proof of the correctness of the algorithm and the analysis of its complexities (in Section 3.1.1 and Section 3.1.2 respectively), we will give a brief description of the algorithm.

### Description of the Algorithm

Let  $0 < \varepsilon \leq 1/2$ , and we set  $\text{thresh} := \max\{18, \lceil \log \frac{2}{\varepsilon} \rceil\}$  and  $\text{Reps} = 90/\varepsilon^2$ . We will now give an efficient  $F_0$ -estimator for Delphic sets. At each level  $k$ , where  $k \in \{1, \dots, \log |\Omega|\}$ , there is a collection of  $\text{Reps}$  many buckets  $\mathcal{X}_r^{(k)}$  with  $r \in \{1, \dots, \text{Reps}\}$ . Each bucket  $\mathcal{X}_r^{(k)}$  can contain at most  $\text{thresh}$  many samples from the universe  $[n]$ . At the beginning of the algorithm, all the  $\text{Reps}$  many buckets in each level  $k$  is an empty set. Let the input stream  $S$  of Delphic sets be the following:  $\mathcal{S} := \langle S_1, \dots, S_M \rangle$ , where  $S_j \subseteq \Omega$  for all  $j \in [M]$ . Note that we want to estimate the size of the set  $S = \bigcup_{j=1}^M S_j$ . Suppose that our algorithm has already processed

the  $S_1, \dots, S_i$  from the stream and the buckets  $\mathcal{X}_r^{(k)}$  in each level  $k$  contains a sample of elements from the set  $S$ . Now, our algorithm receives a new set  $S_{i+1}$  over the data stream. Our algorithm will perform the following steps to process the new set  $S_{i+1}$ :

**Step 1:** For each buckets  $\mathcal{X}_r^{(k)}$ , where  $k \in [\log |\Omega|]$  and  $r \in [\text{Reps}]$ , we will first begin by removing all the elements in  $\mathcal{X}_r^{(k)}$  that are also present in the new set  $S_{i+1}$ , see **lines** 6 to 9 from the Algorithm 2. Observe that the time complexity for this step will be  $O(\text{Reps thresh} \log^2 |\Omega|)$

**Step 2:** Ideally, we would like to add an element from  $S_{i+1}$  independently with probability  $2^{-k}$  to each bucket  $\mathcal{X}_r^{(k)}$ , but this may not be possible as the size of each bucket is  $\text{thresh}$ . To work around this problem, for each  $k \in [\log |\Omega|]$  and  $r \in [\text{Reps}]$ , we will first sample  $d_r^{(k)} \sim \text{Bin}(|S_{i+1}|, 2^{-k})$ . By slight abuse of notation, we will denote by  $|\mathcal{X}_r^{(k)}|$  the current size of the bucket  $\mathcal{X}_r^{(k)}$ . If  $d_r^{(k)} \geq \text{thresh} - |\mathcal{X}_r^{(k)}|$  then we will keep  $\mathcal{X}_r^{(k)}$  unchanged. Otherwise, as  $S_{i+1}$  is a Delphic set with WOR sampling, we will sample without replacement  $d_r^{(k)}$  many samples from  $S_{i+1}$  and add them to  $\mathcal{X}_r^{(k)}$ . See **lines** 10 to 13 from the Algorithm 2.

Once we have processed the whole stream  $\mathcal{S} = \langle S_1, \dots, S_M \rangle$ , for all  $k \in [\log |\Omega|]$ , we will calculate the average size  $\bar{Z}^{(k)}$  of the buckets in each level  $k$ , (See **lines** 14 to 15 from Algorithm 2) that is,

$$\bar{Z}^{(k)} = \frac{1}{\text{Reps}} \sum_{r=1}^{\text{Reps}} |\mathcal{X}_r^{(k)}|$$

Once all the averages have been computed for each level  $k \in [\log |\Omega|]$  the algorithm computes the maximum  $k$ , let us call it  $k^*$  for which  $\bar{Z}^{(k^*)} \geq 1$ . Finally, the algorithm outputs  $2^{k^*} \cdot \bar{Z}^{(k^*)}$ . See **lines** 16 to 17 from Algorithm 2.

### 3.1.1 Correctness of Algorithm 2 for Delphic Sets with WOR sampling

If we replace the **lines** 10-13 in Algorithm 2 by the following lines, then it is easy to see that it functionally behaves identically.

10: Draw  $d_r^{(k)}$  from  $\text{Bin}(|S_j|, 1/2^k)$

■ **Algorithm 2** [ $F_0$ -Estimator for Delphic Sets with WOR sampling.]

---

```

1: Input Stream =  $\langle S_1, S_2, \dots, S_M \rangle$ ,  $\varepsilon$ ,  $\delta$ 
2: Initialize
3:  $p \leftarrow 1$ ; thresh  $\leftarrow \max\{\lceil \log 2/\varepsilon \rceil, 18\}$ ; Reps  $\leftarrow \lceil 90/\varepsilon^2 \rceil$ ;
4: for ( $1 \leq k \leq \log |\Omega|$ ) and ( $1 \leq r \leq \text{Reps}$ ) do
5:    $\mathcal{X}_r^{(k)} \leftarrow \emptyset$ ;

   STREAMING PHASE:
6: for  $j = 1$  to  $M$  do.
7:   for ( $1 \leq k \leq \log |\Omega|$ ) and ( $1 \leq r \leq \text{Reps}$ ). do
8:     for all  $s \in \mathcal{X}_r^{(k)}$  do
9:       if  $s \in S_j$  then remove  $s$  from  $\mathcal{X}_r^{(k)}$ 
10:    Draw  $d_r^{(k)}$  from  $\text{Bin}(|S_j|, 1/2^k)$ 
11:    if  $|\mathcal{X}_r^{(k)}| + d_r^{(k)} \leq \text{thresh}$  then
12:       $\mathcal{L}_r^{(k)}$  is a set of  $d_r^{(k)}$  samples drawn from  $S_j$  WOR
13:       $\mathcal{X}_r^{(k)} = \mathcal{X}_r^{(k)} \cup \mathcal{L}_r^{(k)}$ 

   POST-STREAMING PHASE:
14: for  $1 \leq k \leq \log |\Omega|$  do.
15:    $\bar{Z}^{(k)} = \frac{1}{\text{Reps}} \sum_{r=1}^{\text{Reps}} |\mathcal{X}_r^{(k)}|$ 
16:  $k^* = \max\{k \in [\log n] : \bar{Z}^{(k)} \geq 1\}$ 
17: Output  $\bar{Z}^{(k^*)} \cdot 2^{k^*}$ 

```

---

```

11:  $\mathcal{L}_r^{(k)}$  is a set of  $d_r^{(k)}$  samples drawn  $S_j$  WOR
12: if  $|\mathcal{X}_r^{(k)}| + d_r^{(k)} \leq \text{thresh}$  then
13:    $\mathcal{X}_r^{(k)} = \mathcal{X}_r^{(k)} \cup \mathcal{L}_r^{(k)}$ 

```

Note that the differences between the above lines and the lines in the Algorithm 2 is that in the Algorithm 2 we do not sample the set  $\mathcal{L}_r^{(k)}$  unless we are sure that we will use the set  $\mathcal{L}_r^{(k)}$ , that is the condition  $|\mathcal{X}_r^{(k)}| + d_r^{(k)} \leq \text{thresh}$  is satisfied. We do this in the actual algorithm (more like a “lazy sampling”) to have better control on the worst-case update time complexity. But, for the presentation of the proof of correctness of the theorem it is useful to use the above three lines (instead of **lines** 10-13 in Algorithm 2) where we first sample  $\mathcal{L}_r^{(k)}$  and then decide whether to use it.

Let us consider the  $j$ th round of the streaming phase of the algorithm. That is when the set  $S_j$  arrives in the stream. By the construction of the set  $\mathcal{L}_r^{(k)}$  it follows that all elements of  $S_j$ 's are chosen in  $\mathcal{L}_r^{(k)}$  independently with probability  $2^{-k}$ . For the sake of presentation, let  $\mathcal{L}_{j,r}^{(k)}$  denote the set  $\mathcal{L}_r^{(k)}$  during the  $j$ th round of the streaming phase of the algorithm<sup>3</sup>. Recall that the elements in the set  $S_j$ , that is, the elements  $x_{s_{j-1}+1}, \dots, x_{s_j}$  and for any  $i \in [s_j]$  we denote by  $j(i)$  the stream index such that  $i \in \{s_{j(i)-1} + 1, \dots, s_{j(i)}\}$  (refer to the notations in the Section 2.2). For any  $i \in [s_j]$  let us denote by  $X_{i,r}^{(k)}$  the random variable that takes value 1 if  $x_i$  is included in  $\mathcal{L}_{j(i),r}^{(k)}$  and 0 otherwise, that is, the element  $x_i$  is in the set  $\mathcal{L}_r^{(k)}$  during the  $j$ th round of the streaming phase of the algorithm. Clearly, for any  $i, r, k$   $X_{i,r}^{(k)} \stackrel{i.i.d.}{\sim} \text{Ber}(2^{-k})$ .

---

<sup>3</sup> We ignore the streaming index  $j$  in the Algorithm 2 as we use the same state to update the random set over different indices  $j$ .

However, the random set is actually included in  $\mathcal{X}_r^{(k)}$  provided  $|\mathcal{X}_r^{(k)}| + d_r^{(k)} \leq \text{thresh}$ . To indicate whether an element is actually included in  $\mathcal{X}_r^{(k)}$  we define the random variable  $Y_{i,r}^{(k)}$ , for any  $i \in [s_j]$ . We define the random variable  $Y_{i,r}^{(k)}$  as  $Y_{i,r}^{(k)} = 1$  if  $|\mathcal{X}_r^{(k)}| + d_r^{(k)} \leq \text{thresh}$ , 0 otherwise (i.e.,  $x_i$  is eventually included in  $\mathcal{X}_r^{(k)}$  if  $X_{i,r}^{(k)} Y_{i,r}^{(k)} = 1$ ).

Formally, the random variable  $Y_{i,r}^{(k)}$  can be defined recursively. First we note that since in **lines** 8-9 (of Algorithm 2) we remove all the elements in  $\mathcal{X}_r^{(k)}$  that are in  $S_j$ , so at that time (after **line** 9)

$$\mathcal{X}_r^{(k)} \subseteq \left( \cup_{k=1}^{j-1} S_k \right) \setminus S_j = \{x_i : i \in \mathcal{F}_j\}.$$

Thus the size of  $\mathcal{X}_r^{(k)}$  after **line** 9 is  $\sum_{a \in \mathcal{F}_j} X_{a,r}^{(k)} Y_{a,r}^{(k)}$ . Thus,

$$Y_{i,r}^{(k)} = \begin{cases} 0 & \text{if } \sum_{a \in \mathcal{F}_j(i)} X_{a,r}^{(k)} Y_{a,r}^{(k)} + \sum_{a \in \mathcal{I}_j(i)} X_{a,r}^{(k)} > \text{thresh} \\ 1 & \text{otherwise.} \end{cases}$$

Now, in the post-streaming phase, we set

$$Z_r^{(k)} = \sum_{i \in \mathcal{F}} X_{i,r}^{(k)} Y_{i,r}^{(k)}, \forall r \in [\text{Reps}], \quad \bar{Z}^{(k)} = \frac{Z_1^{(k)} + \dots + Z_{\text{Reps}}^{(k)}}{\text{Reps}}.$$

Note that  $\mathcal{F}$  denote the set of all final indices of the elements of  $S$ . Thus,  $Z_r^{(k)}$ 's are the sizes of the sets  $\mathcal{X}_r^{(k)}$  after processing the stream. Moreover, these are independent for all  $r$  and  $k$ .

► **Lemma 13.** For any  $k$  such that  $\text{thresh} \geq 6c$  where  $c := \frac{F_0(S)}{2^k}$ .

$$c(1 - 2^{-\text{thresh}}) \leq \mathbb{E}(Z_r^{(k)}) \leq c \tag{1}$$

$$\text{Var}(Z_r^{(k)}) \leq c(1 + 2^{-\text{thresh}})c. \tag{2}$$

**Proof.** The upper bound of expectation directly follows from the linearity of expectation. For the lower bound, we first note that

$$\begin{aligned} \Pr(Y_{i,r}^{(k)} = 0 \mid X_{i,r}^{(k)} = 1) &\leq \Pr \left( \sum_{a \in \mathcal{F}_j} X_{a,r}^{(k)} Y_{a,r}^{(k)} + \sum_{a \in \mathcal{I}_j} X_{a,r}^{(k)} \geq \text{thresh} + 1 \mid X_{i,r}^{(k)} = 1 \right) \\ &\leq \Pr(\text{Bin}(F_0(S) - 1, p) \geq \text{thresh}) \leq 2^{-\text{thresh}}. \end{aligned}$$

Note that the last inequality follows from Lemma 20. Thus,  $\mathbb{E}(X_{i,r}^{(k)} Y_{i,r}^{(k)}) = \Pr(X_{i,r}^{(k)} = 1, Y_{i,r}^{(k)} = 1) \geq p(1 - 2^{-\text{thresh}})$  for all  $i$ . Hence, the lower bound is established by linearity of expectation. To bound the variance, we first bound the second moment:

$$\mathbb{E}((Z_r^{(k)})^2) = \mathbb{E}(Z_r^{(k)}) + \sum_{i \neq j} \mathbb{E}(X_{i,r}^{(k)} Y_{i,r}^{(k)} X_{j,r}^{(k)} Y_{j,r}^{(k)}) \leq \mathbb{E}(Z_r^{(k)}) + F_0(S)^2 p^2.$$

Hence we obtain,

$$\begin{aligned} \text{Var}(Z_r^{(k)}) &\leq \mathbb{E}(Z_r^{(k)})(1 - \mathbb{E}(Z_r^{(k)}) + F_0(S)^2 p^2) \\ &\leq c(1 - (1 - 2^{-\text{thresh}})c) + c^2 \leq c + c^2 2^{-\text{thresh}} \end{aligned} \quad \blacktriangleleft$$

Before we complete the proof of the correctness of our Algorithm 2, we first state a core result based on bucket-load random variables (defined below) that would be used.

► **Definition 14** (Bucket-load). *A  $(c, \alpha)$ -bucket-load is a nonnegative random variable  $Z$  such that the first and second moments of  $Z$  satisfy the following relations:*

$$c(1 - \alpha) \leq \text{Ex}(Z) \leq c \quad \text{AND} \quad \text{Var}(Z) \leq c + \alpha c^2.$$

From Lemma 13 we note that for any  $k$  with  $\text{thresh} \geq 6F_0(\mathcal{S})/2^k$ ,  $Z_r^{(k)}$ 's are  $(c, \alpha)$ -bucket-load random variables for  $c = F_0(\mathcal{S})/2^k$  and  $\alpha = 2^{-\text{thresh}} \leq \min\{\varepsilon/2, 2^{-18}\}$ . Due to independence of the random variables  $Z_1^{(k)}, \dots, Z_{\text{Reps}}^{(k)}$ , the random variable  $\bar{Z}^{(k)}$  has mean approximately  $c$  and variance  $O(c/\text{Reps})$ . Thus, for an appropriately large  $\text{Reps}$ , we can apply Chebyshev's inequality to show that  $\bar{Z}^{(k)}$  is indeed very close to  $c$  with high probability. The following proposition makes this intuition formal. Let  $k_0$  be the unique negative power of 2 such that

$$\frac{3}{4} < c_0 = \frac{F_0(\mathcal{S})}{2^{k_0}} \leq \frac{3}{2} \quad (3)$$

► **Proposition 15.** *Let  $\text{Reps} = \lceil 90/\varepsilon^2 \rceil$  and let  $k_0$  be the number defined in Equation 3. For every  $k \geq k_0 - 1$ , let  $Z_1^{(k)}, \dots, Z_{\text{Reps}}^{(k)}$  be the  $\text{Reps}$  many independent  $(F_0(\mathcal{S})/2^k, \varepsilon/2)$ -bucket load random variables. Then,*

1.  $\bar{Z}^{(k_0)}$  and  $\bar{Z}^{(k_0-1)}$  are  $(\varepsilon, 1/24)$ -approximation of  $c_0$  and  $2c_0$  respectively. Hence,  $2^{k_0} \cdot \bar{Z}^{(k_0)}$  and  $2^{k_0-1} \cdot \bar{Z}^{(k_0-1)}$  are  $(\varepsilon, 1/24)$ -approximations of  $F_0(\mathcal{S})$ .
2.  $\Pr(\bar{Z}^{(k_0-1)} < 1) + \sum_{i \geq 1} \Pr(\bar{Z}^{(k_0+i)} \geq 1) \leq 1/4$ .

We postpone the proof of Proposition 15 to the Appendix B.

Item 2 of the Proposition 15 proves that  $k^* \in \{k_0, k_0 - 1\}$  with probability at least  $3/4$  (where  $k^*$  is defined in **line 16**). The first part proves that  $\bar{Z}^{(k_0)} \cdot 2^{k_0}$  and  $\bar{Z}^{(k_0-1)} \cdot 2^{k_0-1}$  are  $(\varepsilon, 1/24)$ -approximations of  $F_0(\mathcal{S})$ . Hence, we observe that  $\bar{Z}^{(k^*)} 2^{k^*}$  is an  $(\varepsilon, 1/3)$ -approximation of  $F_0(\mathcal{S})$  (as this can fail either when  $k^* \notin \{k_0, k_0 - 1\}$ , or  $\bar{Z}^{(k_0)} \cdot 2^{k_0}$  or  $\bar{Z}^{(k_0-1)} \cdot 2^{k_0-1}$  fails to approximate  $F_0(\mathcal{S})$ , the probability of any one of these can happen with probability at most  $1/3$ ). This proves that the Algorithm 2 is an  $F_0$ -estimator for Delphic Sets with WOR sampling.

### 3.1.2 Complexity of the Algorithm 2

The space complexity and the update time complexity are clear from the pseudo-code of the algorithm. The size of  $\mathcal{X}_r^{(k)}$  is upper bounded by  $\text{thresh}$ . And since  $r$  ranges from 1 to  $\text{Reps}$  and  $k$  ranges from 1 to  $\log |\Omega|$ , so the maximum number of elements of  $\Omega$  stored is  $O\left(\frac{\log |\Omega|}{\varepsilon^2}\right)$ . Nevertheless to store an element of  $\Omega$ , one needs  $O(\log |\Omega|)$  bits. So the total space required is  $O\left(\frac{\log^2 |\Omega|}{\varepsilon^2} \cdot \log \varepsilon^{-1}\right)$ . The additional space required for bookkeeping is  $O(\log |\Omega|)$ .

By the definition of Delphic Sets with WOR sampling, knowing the size of a set  $S_j$  and checking if an element is in  $S_j$  can be done in  $O(\log |\Omega|)$  time. So the for any  $j, r$  and  $k$  the **lines 8 to 9** can be done is at most  $O(|\mathcal{X}_r^{(k)}| \log(|\Omega|)) = O(\text{thresh} \log(|\Omega|))$  step. The number of samples drawn from any set  $S_j$  (in **line 12** is at most  $\text{thresh}$ . So the time taken in **line 12** is also  $O(\text{thresh} \log(|\Omega|))$ . We should note here that we assume **line 10** that is drawing a sample from  $\text{Bin}(|S_j|, 1/2^k)$  can be done in order  $O(\text{thresh} \log(|\Omega|))$  steps, since  $|S_j| \leq |\Omega|$  and  $k \leq \log |\Omega|$ . We have to do these steps for all  $k$  and  $r$ . Thus in total the update time complexity is  $O(\text{thresh} \log(|\Omega|) \cdot (\log |\Omega|) \cdot \text{Reps}) = O\left(\frac{\log^2 |\Omega|}{\varepsilon^2} \cdot \log \varepsilon^{-1}\right)$ .

Thus, we have the Theorem 12.

### 3.2 $F_0$ - Estimator for General Delphic Sets

Algorithm 2 in **line** 12 uses the ability to sample from the sets in the stream with WOR sampling. This property is not available in general Delphic Sets. However, with a little modification to Algorithm 2, we can also have an  $F_0$ -estimator for general Delphic Sets, which is what Theorem 3 states.

**Proof of Theorem 3.** To have an  $F_0$ -estimator for general Delphic sets, we need to make two important changes to Algorithm 2. Firstly, we set the **thresh** to be  $\max\{\lceil \log 4/\varepsilon \rceil, 18\}$  (instead of  $\max\{\lceil \log 2/\varepsilon \rceil, 18\}$ ). Secondly, we change the **line** 12 to the following:

$$12: \mathcal{L}_r^{(k)} = \text{WRSample}(S, d_r^{(k)}, d_r^{(k)} \log d_r^{(k)} \log(\frac{4}{\varepsilon}))$$

While in Algorithm 2 in **line** 12 the set  $|\mathcal{L}_r^{(k)}| = d_r^{(k)}$  with probability 1, in the modified algorithm this is not the case. In other words, if we try to prove the correctness of the modified algorithm in the same line as the proof of Algorithm 2 we note that the random variable  $Y_{i,r}^{(k)}$  takes value slightly differently.

The random variable  $Y_{i,r}^{(k)}$  can take value 1 for two possible cases.

1. Due to the overflow of the bucket, which can now happen with probability at most  $2^{-\text{thresh}} \leq \varepsilon/4$  (This is due to the modified setting of **thresh** so that  $2^{-\text{thresh}} \leq \varepsilon/4$ ).
2. Due to **WRSample** returning an empty set. By Lemma 11 and by the setting of the inputs of **WRSample** this can happen also with probability at most  $\varepsilon/4$ .

Thus we can prove a lemma corresponding to Lemma 13 and hence,  $Z_r^{(k)}$  is  $(c, \alpha)$ -bucket-load where  $\alpha = \min\{2^{-18}, \varepsilon/2\}$ . Now, we can apply our core Proposition 15 to conclude the correctness of the algorithm.

It is easy to see that the space and time complexity of the modified algorithm is  $O\left(\frac{\log^2 |\Omega|}{\varepsilon^2} \cdot \log \varepsilon^{-1}\right)$  and  $O\left(\frac{\log^2 |\Omega|}{\varepsilon^2} \cdot \log^3 \varepsilon^{-1}\right)$  respectively.  $\blacktriangleleft$

## 4 Space Optimal Algorithm with an Oracle in NTISP(poly, LINSPEACE)

In this section, we give a sketch of the proof of Theorem 4. We will implement the  $F_0$ -estimation algorithm by Gibbons and Tirthapura [13] for singleton streams as described in [2]. The proof that the algorithm gives the correct estimation follows from their proof and is hence omitted. The algorithm picks a random hash function  $h$  from a pairwise-independent family and keeps a bucket  $\mathcal{X}$  of hash values of a subset of elements in the stream and a number  $z$  of leading zeros of all the elements in the bucket. The size of the bucket is bounded by  $O(\frac{1}{\varepsilon^2})$ . When a new item  $x$  comes, if the number of leading zeros of  $h(x) \geq z$ , the algorithm updates the bucket to  $\mathcal{X} \cup \{h(x)\}$ . If the bucket overflows, then  $z$  is updated to  $z + 1$ , and all elements from  $\mathcal{X}$  with leading zeros  $\leq z$  are removed. At the end of the stream, the algorithm outputs  $|\mathcal{X}| \cdot 2^z$  as the estimate. In adapting their algorithm for the case of set streams, the computational challenge is implementing the update. The central intuition is that this can be accomplished by querying a language in NTISP(poly, LINSPEACE) with query size  $O(\log |\Omega| \cdot \frac{1}{\varepsilon^2})$ . Thus if NTISP(poly, LINSPEACE) = DTISP(poly, LINSPEACE), then queries to the language can be simulated in space  $O(\log |\Omega| \cdot \frac{1}{\varepsilon^2})$  and time  $\text{poly}(\log |\Omega|, \varepsilon^{-1})$ .

We will use  $n$  to denote  $\log |\Omega|$ , the length of the representation of any element in the universe  $\Omega$ . For any binary string  $y$ ,  $\text{Zero}(y)$  denotes the number of leading zeros of  $y$ . We will use the standard Toeplitz family of pairwise-independent hash functions denoted by  $H_{\text{Teop}}(n, k)$  (see Appendix D for details). Let  $h$  be a hash function. For every  $m \in \{1, \dots, n\}$ ,

## 26:14 Improved Streaming Algorithm for the Klee's Measure Problem and Generalizations

the  $m^{\text{th}}$  prefix-slice of  $h$ , denoted  $h_m$ , is a map from  $\{0, 1\}^n$  to  $\{0, 1\}^m$ , where  $h_m(y)$  is the first  $m$  bits of  $h(y)$ . If  $h$  is from  $\mathbf{H}_{\text{Teop}}(n, k)$ , both  $h$  and  $h_m$  are efficiently computable and take linear space to represent.

For a member  $S \subseteq \Omega$  of the Delphic set, we will assume a representation of size  $O(|\Omega|)$  and denote it by  $r_S$ . This is required for computational purposes, and all the Delphic families discussed in earlier works have such representations (e.g., rectangles in KMP). We use the notation  $x \in r_S$  to mean  $x \in S$ . Note that since  $S$  is a Delphic set, membership can be checked in time and space linear in the representation.

### Oracle Languages

We will define two languages,  $L$  and  $L_{\text{pref}}$ , and show that they are in  $\text{NTISP}(\text{poly}, \text{LINSPEACE})$ . We use these languages to implement Gibbons and Tirthapura algorithms. The first language,  $L$ , checks whether the bucket overflows by adding new elements from the current set  $S$  with the current value of the leading zeros count.

$$L = \{ \langle r_S, h, \mathcal{X}, \ell, m, 1^{\ell \log n} \rangle \mid \exists x_1 < x_2 < \dots < x_k \text{ such that } x_i \in r_S \\ \& \forall i (h_m(x_i) = 0^m) \& |\{h(x_1), \dots, h(x_k)\} \cup \mathcal{X}| > \ell \}.$$

The following language is (close to) the *prefix language* of  $L$  that can be used to construct witnesses  $x_1, \dots, x_k \in r_S$  if adding new elements does not result in an overflow of  $\mathcal{X}$ .

$$L_{\text{pref}} = \{ \langle r_S, h, \mathcal{X}, \ell, m, 1^{\ell \log n}, i, j \rangle \mid \exists x_1 < x_2 < \dots < x_k \text{ such that} \\ x_i \in r_S \& \forall i (h_m(x_i) = 0^m) \& |\{h(x_1), \dots, h(x_k)\} \cup \mathcal{X}| \leq \ell \& i^{\text{th}} \text{ bit of } x_j \text{ is } 1 \}.$$

To implement the algorithm, we must update  $\mathcal{X}$  with new elements from  $S$  (represented by  $r_S$ ), the current set in the stream. For this, the algorithm uses a subroutine **Construct** that in turn uses  $L_{\text{pref}}$  to search for a set of  $\leq l$  the elements  $x_i$ s in  $S$  so that  $h_m(x_i) = 0^m$ . We will ensure that we will use **Construct** only when we are guaranteed that adding the hash values on these elements will not make  $\mathcal{X}$  overflow. For this, we will use membership in  $L$ . The Algorithm 3 is described below. Theorem 4 follows from Claim 16, Claim 17, and the guarantee of Gibbons and Tirthapura's algorithm.

#### ■ Algorithm 3 DelphicWithNP( $S, \varepsilon$ ).

---

```

1:  $h \xleftarrow{R} \mathbf{H}_{\text{Teop}}(n, n)$ 
2:  $\mathcal{X} \leftarrow \phi$ ,  $\text{Const} \leftarrow \frac{100}{\varepsilon^2}$ ,  $m \leftarrow 0$ 
3: while not End-of-Stream do
4:   On item  $r_S$ 
5:   while  $\langle r_S, h, \mathcal{X}, \text{Const}, m, 1^{\text{Const} \cdot \log n} \rangle \notin L$  do
6:     Remove all  $y$ s from  $\mathcal{X}$  for which  $\text{Zero}(y) = m$ 
7:      $m \leftarrow m + 1$ 
8:    $\mathcal{X} \leftarrow \mathcal{X} \cup \text{Construct}(\langle r_S, h, \mathcal{X}, \text{Const}, 1^{\text{Const} \cdot \log n} \rangle)$ 
9: Output  $|\mathcal{X}|2^m$ 

```

---

▷ Claim 16. Both  $L$  and  $L_{\text{pref}}$  are in  $\text{NTISP}(\text{poly}, \text{LINSPEACE})$ .

Proof. We show membership of  $L$  in  $\text{NTISP}(\text{poly}, \text{LINSPEACE})$ . The proof of membership of  $L_{\text{pref}}$  is similar. Consider the following non-deterministic machine  $M_L$ .  $M_L$  on input  $\langle r_S, h, \mathcal{X}, 1^\ell, m \rangle$  first guesses a number  $1 \leq k \leq l$  and  $x_1 < x_2 < \dots < x_k$  in  $\Omega$ . Then it

verifies the following: (1)  $\forall i x_i \in r_S$ , (2)  $\forall i h_m(x_i) = 0^m$ , (3)  $|\{h(x_1), \dots, h(x_k)\} \cup \mathcal{X}| > \ell$ . The input size is  $O(|\mathcal{X}| + \ell \cdot \log n)$ . Since all the steps: guessing and verification (1), (2), and (3), can be done in time polynomial in the input length,  $M_L$  runs in polynomial time. The critical observation is that  $M_L$  can write down all the guesses in space linear in the input (at most  $\ell$   $x_i$ s from  $\Omega$  that takes  $O(\ell \log n)$  bits to store). Thus, the overall space used is linear in the input length.  $\triangleleft$

Let  $k$  be the maximum value of  $|\{h(x_1), \dots, h(x_t)\} \cup \mathcal{X}|$  so that the following property  $\mathcal{P}$  holds:

1.  $\exists x_1 < x_2 < \dots < x_t$  such that  $x_i \in r_S$
2.  $\forall i (h_m(x_i) = 0^m)$ .

$\triangleright$  **Claim 17.** There is a deterministic algorithm **Construct**, takes  $\langle r_S, h, \mathcal{X}, \text{Const}, 1^{\text{Const} \cdot \log n} \rangle$  as input and  $L$  and  $L_{\text{pref}}$  as oracles and if  $k \leq \text{Const}$ , it returns a set  $\{h(x_1), \dots, h(x_k)\}$  (if non-empty) so that  $\forall i (h_m(x_i) = 0^m)$  and  $x_i \in r_S$ . **Construct** runs in time polynomial and space linear in the input length and makes only queries that are linear in the input length.

**Proof (Sketch).** **Construct** first queries  $L$  to check  $k > \text{Const}$ . If  $k > \text{Const}$ , it rejects. Otherwise, it first finds  $k$  and uses  $k \log n$  queries to  $L_{\text{pref}}$  to construct all  $x_i$ s in  $S$  with the property  $\mathcal{P}$ . The complexity bounds are clear from the language's description and definition.  $\triangleleft$

## 5 Conclusion

In this paper, we present a new elegant algorithm that improves both the space and update time complexities for the computation of the size of the union of Delphic sets. The space and time complexities of our algorithm are  $\tilde{O}\left(\log^2(|\Omega|) \cdot \frac{\log(1/\delta)}{\varepsilon^2}\right)$ . To complement our algorithm, we also show that, given access to  $\text{NTISP}(\text{poly}, \text{Linspace})$  oracle, there exists a *hashing* based algorithm for approximating the size of the union of Delphic sets with space complexity  $O(\log(|\Omega|) \cdot \varepsilon^{-2} \cdot \delta^{-1})$  and  $\text{poly}(\log(|\Omega|), \varepsilon^{-1}, \log \frac{1}{\delta})$  update time complexity. Note  $\Omega(\log(|\Omega|))$  lower bound for our problem follows directly from the lower bound of  $F_0$ -estimation problem, but the above result implies that if the complexity of our problem is  $\omega(\log(|\Omega|))$ , then we should not expect this to be proved soon.

## A Concentration Bounds

► **Lemma 18.** *Let  $Z$  be a random variable with  $c(1 - \varepsilon/2) \leq \text{Ex}(Z) \leq c$  for some  $c > 0$  and  $0 \leq \varepsilon < 1$ . Then,*

$$\Pr(Z \neq (1 \pm \varepsilon)c) \leq \frac{4 \text{Var}(Z)}{c^2 \varepsilon^2}.$$

Note that the lower tail event  $Z \leq c - c\varepsilon$  implies  $Z - \text{Ex}(Z) \leq c\varepsilon/2$ . Thus,  $|Z - c| > c\varepsilon$  implies that  $|Z - \text{Ex}(Z)| > c\varepsilon/2$ . Thus, the above result follows from the Chebyshev's inequality. The following lemma directly follows from Chebyshev's inequality.

► **Lemma 19.**

1. *Let  $Z$  be a random variable with  $\text{Ex}(Z) \geq \mu$ . Then,*

$$\Pr(Z \leq \mu - t) \leq \frac{\text{Var}(Z)}{t^2}.$$

2. *Let  $Z$  be a random variable with  $\text{Ex}(Z) \leq \mu$ . Then,*

$$\Pr(Z \geq \mu + t) \leq \frac{\text{Var}(Z)}{t^2}.$$

We will also need the following Chernoff bound.

► **Lemma 20** (See Theorem 4.4 from [20]). *Suppose  $T \sim \text{Bin}(n, p)$  and  $L \geq 6np$  then*

$$\Pr(T \geq L) \leq 2^{-L}.$$

## B Proof of Proposition 15

We first observe the simple properties of the first and second moments of averages of the independent bucket-loads.

► **Lemma 21.** *Let  $c_0$  and  $k_0$  be defined as in Equation 3. Then,*

- $c_0(1 - \varepsilon/2) \leq \mathbb{E}(\bar{Z}^{(k_0)}) \leq c_0$ ,
- $\text{Var}(\bar{Z}^{(k_0)}) \leq V_0 := \frac{c_0 + c_0^2 2^{-18}}{\text{Reps}} \leq \frac{1}{80}$ .
- $\text{Var}(\bar{Z}^{(k_0-1)}) \leq V_{-1} := \frac{2c_0 + 4c_0^2 \varepsilon/8}{\text{Reps}} \leq 2V_0 \leq \frac{1}{40}$ .
- For all  $i \geq 1$ ,

$$\text{Var}(\bar{Z}^{(k_0+i)}) \leq V_i := \frac{2^{-i} \cdot c_0 + 2^{-2i} c_0^2 \varepsilon/2}{\text{Reps}} \leq V_0/2^i$$

The above follows directly from Lemma 13 along with the choice of  $\text{Reps} = 99/\varepsilon^2$  and  $\varepsilon \leq 0.5$ . Now, by using Lemma 18,

$$\Pr(\bar{Z}^{(k_0)} \neq (1 \pm \varepsilon)c_0) \leq \frac{4\text{Var}(\bar{Z}^{(k_0)})}{c_0^2 \varepsilon^2} \leq \frac{2}{\varepsilon^2 \text{Reps}} \left( \frac{2}{c_0} + \varepsilon \right) \leq \frac{(8/3) + 2\varepsilon}{\varepsilon^2 \text{Reps}} \leq 1/24.$$

The last inequality follows from the choice of  $\text{Reps} = 90/\varepsilon^2$  and we assume that  $\varepsilon \leq 0.5$ . So,  $\bar{Z}^{(k_0)}$  is an  $(\varepsilon, 1/24)$ -approximation of  $c_0$ . Similarly, by using Lemma 18,  $\bar{Z}^{(k_0-1)}$  is an  $(\varepsilon, 1/24)$ -approximation of  $2c_0$ . This completes the proof of Item 1 in Proposition 15.

Now we prove the Item 2 of Proposition 15.

## 26:18 Improved Streaming Algorithm for the Klee's Measure Problem and Generalizations

We start by bounding  $\Pr(\bar{Z}^{(k_0-1)} < 1)$ . Note that  $\mathbb{E}(\bar{Z}^{(k_0-1)}) \geq 2c_0(1 - 2^{-\text{thresh}}) \geq 3/2 \times (1 - 2^{-18}) \geq 3/2 - \beta$ , where  $\beta$  is a negligible real number such that  $3/2^{19} \leq \beta \leq 2^{-17}$ . Now it is easy to see that there exists some  $\alpha \in \mathbb{R}$  with  $2^{-16} \leq \alpha \leq 2^{-15}$  and  $\alpha^2 + 4\alpha < 1$  such that  $\frac{1}{2+\alpha} \leq 1/2 - \beta$ . By using Lemma 19,

$$\Pr(\bar{Z}^{(k_0-1)} < 1) \leq (2 + \alpha)^2 \text{Var}(\bar{Z}^{(k_0-1)}) = (4 + 4\alpha + \alpha^2) V_{-1} \leq 5V_{-1} = 10V_0 \quad (4)$$

Now let us bound  $\Pr(\bar{Z}^{(k_0+i)} \geq 1)$  for every  $i \geq 1$ . Note that  $\mathbb{E}(\bar{Z}^{(k_0+i)}) \leq c_0/2 \leq 3/4$ . So, by Lemma 19 we obtain

$$\Pr(\bar{Z}^{(k_0+i)} \geq 1) \leq 16V_1 = 8V_0 \quad (5)$$

Note that for  $i \geq 2$  we have  $\mathbb{E}(\bar{Z}^{(k_0+i)}) \leq c_0/2^i \leq 1/2$ . Applying Lemma 19 working out in detail we obtain,

$$\Pr(\bar{Z}^{(k_0+i)} > 1) \leq 4\text{Var}(\bar{Z}^{(k_0+i)}) \leq 2^{-i+2}V_0$$

Thus using the infinite geometric sum we obtain

$$\sum_{i \geq 2} \Pr(\bar{Z}^{(k_0+i)} \geq 1) \leq 2V_0 \quad (6)$$

Hence from the inequalities 5 and 6 we obtain

$$\sum_{i \geq 1} \Pr(\bar{Z}^{(k_0+i)} \geq 1) \leq 10V_0 \quad (7)$$

Finally, combining the inequalities 4 and 7 we conclude

$$\Pr(\bar{Z}^{(k_0-1)} < 1) + \sum_{i \geq 1} \Pr(\bar{Z}^{(k_0+i)} \geq 1) \leq 1/4$$

This completes the proof of Item 2 of Proposition 15.  $\blacktriangleleft$

## C Further Improvements for Klee's Measure Problem

Recall, every  $d$ -dimensional rectangle is a Delphic set with  $\Omega = [\Delta]^d$ . Therefore, Theorem 3 provides an algorithm that has space complexity  $O\left(\frac{d^2 \log^2 \Delta}{\varepsilon^2} \cdot \log \varepsilon^{-1}\right)$  and has update time complexity  $O\left(\frac{d^2 \log^2 \Delta}{\varepsilon^2} \cdot \log^3 \varepsilon^{-1}\right)$  for Klee's Measure Problem. We now discuss how we can further improve the dependence on  $\varepsilon$ . The key idea behind such an improvement is to observe that we can avoid the overhead due to WOR by replacing with sampling from Geometric distribution. Such a replacement is possible only because there exists a total ordering for all the elements in  $\Omega = [\Delta]^d$  such that we can access  $i$ -th element in time  $\log(|\Omega|)$ . Interestingly, all the known classes of Delphic sets satisfy the above property and therefore, we formalize such a family below:

► **Definition 22.** *A set  $S \subseteq \Omega$  belongs to Ordered Delphic family if there exists a total ordering  $\leq$  for all the elements in the  $\Omega$  and the following queries can be done in  $O(\log |\Omega|)$  time.*

1. Know the size of the set  $S$ ,
2. For any  $1 \leq i \leq |S|$  the  $i$ th element of the set  $S$  can be obtained,
3. Given any  $x$  check if  $x \in S$ .

In Section 2.4 we discussed how one can sample a Bernoulli process from a Delphic Set by using the coupon collector theorem. There is an alternate way to sample a Bernoulli process if the set is a Ordered Delphic Set. The set  $L$  returned by the algorithm  $Sample(S, p)$  follows  $Ber(S, p)$ . Since there is an order to the elements in a Ordered Delphic set, the process is basically same as sampling a Bernoulli process from  $[|S|]$ . This is a well known result in probability theory and details can be found in [3].

■ **Algorithm 4**  $GeometricSample(n, p)$ .

---

```

1: Input Set  $n$   $p \in [0, 1]$ .
2: Initialize  $L = \emptyset$ ;  $t = 0$ 
3: for  $t \leq |S|$  do
4:   Sample  $g$  from  $Geo(p)$ 
5:    $t = t + g$ 
6:   if  $t \leq n$  then  $L = L \cup \{t\}$ 
7: Output  $L$ 

```

---

► **Lemma 23.** *The subroutine  $GeometricSample(n, p)$  outputs a subset of  $[n]$  according to the Bernoulli process. More precisely, if we set  $I_j = 1$  if  $j \in L$ , 0 otherwise then  $I_1, \dots, I_n$  follow identically and independently distributed to  $Ber(p)$ .*

Using the subroutine  $GeometricSample$  we can now present the improved algorithm (Algorithm 5) for the Ordered Delphic Sets.

■ **Algorithm 5** [F<sub>0</sub>-Estimator for Ordered Delphic Sets.]

---

```

1: Input Stream =  $\langle S_1, S_2, \dots, S_M \rangle$ ,  $\varepsilon, \delta$ 
2: Initialize
3:  $p \leftarrow 1$ ; thresh  $\leftarrow \max\{\lceil \log 2/\varepsilon \rceil, 18\}$ ; Reprs  $\leftarrow \lceil 90/\varepsilon^2 \rceil$ ;
4: for  $(1 \leq k \leq \log n)$  and  $(1 \leq r \leq \text{Reprs})$  do
5:    $\mathcal{X}_r^{(k)} \leftarrow \emptyset$ ;

   STREAMING PHASE:
6: for  $j = 1$  to  $M$  do
7:   for  $(1 \leq k \leq \log n)$  and  $(1 \leq r \leq \text{Reprs})$  do
8:     for all  $s \in \mathcal{X}_r^{(k)}$  do
9:       if  $s \in S_j$  then remove  $s$  from  $\mathcal{X}_r^{(k)}$ 
10:    Draw  $D_r^{(k)}$  from  $GeometricSample(|S_j|, 1/2^k)$ 
11:    if  $|\mathcal{X}_r^{(k)}| + |D_r^{(k)}| \leq \text{thresh}$  then
12:       $\mathcal{L}_r^{(k)} = \{S_j[\ell] \mid \ell \in D_r^{(k)}\}$ 
13:       $\mathcal{X}_r^{(k)} = \mathcal{X}_r^{(k)} \cup \mathcal{L}_r^{(k)}$ 

   POST-STREAMING PHASE:
14: for  $1 \leq k \leq \log n$  do
15:    $\bar{z}^{(k)} = \frac{1}{\text{Reprs}} \sum_{r=1}^{\text{Reprs}} |\mathcal{X}_r^{(k)}|$ 
16:  $k^* = \max\{k \in [1, \log n] : \bar{z}^{(k)} \geq 1\}$ 
17: Output  $\bar{z}^{(k^*)} 2^{k^*}$ 

```

---

Algorithm 5 is the streaming algorithm for the Ordered Delphic Sets. For proving the correctness of Algorithm 5, we have the following theorem:

► **Theorem 24** (correctness theorem of Algorithm 5). *If  $\mathcal{S}$  is a stream of Ordered Delphic Set the Algorithm 5 is an  $(\varepsilon, 1/3)$ - $F_0$ -estimator. Also, the space and update time complexity of Algorithm 5 is  $O\left(\frac{\log^2 |\Omega|}{\varepsilon^2} \cdot \log \varepsilon^{-1}\right)$ .*

**Proof of Theorem 24.** Note that, the only difference between Algorithm 5 and Algorithm 2 is in **lines** 10, 11 and 12. Also note that the Algorithm 5 behaves identically if **lines** 10 to 13 is replaced by

- 10: Draw  $D_r^{(k)}$  from  $\text{GeometricSample}(|S_j|, 1/2^k)$
- 11:  $\mathcal{L}_r^{(k)} = \{S_j[\ell] \mid \ell \in D_r^{(k)}\}$
- 12: **if**  $|\mathcal{X}_r^{(k)}| + |D_r^{(k)}| \leq \text{thresh}$  **then**
- 13:      $\mathcal{X}_r^{(k)} = \mathcal{X}_r^{(k)} \cup \mathcal{L}_r^{(k)}$

By Lemma 23 the size of  $D_r^{(k)}$  is distributed according to the binomial distribution  $\text{Bin}(|S_k|, 1/2^k)$ , that is the distribution of  $d_r^{(k)}$  in Algorithm 2 is same as the distribution of  $|D_r^{(k)}|$  in Algorithm 5. Thus,  $L_r^{(k)}$  is distributed according to  $\text{Ber}(S_j, 1/2^k)$  which is also the same distribution if  $|D_r^{(k)}|$  samples are drawn from  $S_j$  using WOR sampling.

Thus the correctness of the Algorithm 5 follows from the correctness of Algorithm 2. The complexities of Algorithm 5 is also identical to that of Algorithm 2. ◀

Recall that every  $d$ -dimensional rectangle can be viewed as an Ordered Delphic set, therefore, Theorem 24 implies the following result in the context of Klee's Measure Problem.

► **Corollary 25** (Improved Algorithm for KMP). *There is a streaming algorithm for the Klee's Measure Problem with space and update time complexity  $O\left(\frac{d^2 \log^2 \Delta}{\varepsilon^2} \cdot \log \frac{1}{\varepsilon}\right)$ .*

## D Basic Probability Results

► **Definition 26** (Geometric Distribution). *Given any  $p \in (0, 1]$  the Geometric Distribution over the set of positive integers  $\{1, 2, 3, \dots\}$  is denoted as  $\text{Geo}(p)$  where probability of a positive integer  $k$  is  $(1 - p)^{k-1}p$ .*

► **Theorem 27** (Coupon Collection Problem). *Given access to uniform random samples from a set  $T$  and a number  $r \leq |T|$ , let  $W_r$  be a random variable that stand for the number of independent uniform random samples from  $T$  needed before we get  $r$  distinct samples from  $T$ . Then  $\Pr(W_r > \beta r \log r) \leq r^{-\beta+1}$ .*

► **Remark 28** (Pairwise Independent Hash Function). We will use pairwise independent hash functions. For an integer  $n, k$  and  $\mathcal{H}(n, k) \triangleq \{h : \{0, 1\}^n \rightarrow \{0, 1\}^k\}$  be a family of hash functions mapping  $\{0, 1\}^n$  to  $\{0, 1\}^k$ . We use  $h \xleftarrow{R} \mathcal{H}(n, k)$  to denote the probability space obtained by choosing a function  $h$  uniformly at random from  $\mathcal{H}(n, k)$ . A family of hash functions  $\mathcal{H}(n, k)$  is 2-wise independent if  $\forall \alpha_1, \alpha_2 \in \{0, 1\}^k$ , distinct  $x_1, x_2 \in \{0, 1\}^n$ ,  $h \xleftarrow{R} \mathcal{H}(n, k)$ ,  $\Pr[(h(x_1) = \alpha_1) \wedge (h(x_2) = \alpha_2)] = \frac{1}{2^{2k}}$ . Several families of 2-wise independent hash functions are known. We will use  $\text{H}_{\text{Teop}}(n, k)$ , which is known to be 2-wise independent [7]. The family is defined as follows:  $\text{H}_{\text{Teop}}(n, k) \triangleq \{h : \{0, 1\}^n \rightarrow \{0, 1\}^k\}$  is the family of functions of the form  $h(x) = Ax + b$  with  $A \in \mathbb{F}_2^{k \times n}$  and  $b \in \mathbb{F}_2^{k \times 1}$  where  $A$  is a uniformly randomly chosen Toeplitz matrix of size  $k \times n$  while  $b$  is uniformly randomly matrix of size  $k \times 1$ . It is worth noticing that  $\text{H}_{\text{Teop}}$  can be represented with  $\Theta(n)$ -bits and hash value of any element  $x \in \{0, 1\}^n$  can be computed in  $O(nk)$  time.

# An EPTAS for Cardinality Constrained Multiple Knapsack via Iterative Randomized Rounding

## Abstract

In [Math. Oper. Res., 2011], Fleischer et al. introduced a powerful technique for solving the generic class of *separable assignment problems* (SAP), in which a set of items of given values and weights needs to be packed into a set of bins subject to separable assignment constraints, so as to maximize the total value. The approach of Fleischer et al. relies on solving a configuration LP and sampling a configuration for each bin independently based on the LP solution. While there is a SAP variant for which this approach yields the best possible approximation ratio, for various special cases, there are discrepancies between the approximation ratios obtained using the above approach and the state-of-the-art approximations. This raises the following natural question: Can we do better by *iteratively* solving the configuration LP and sampling a few bins at a time?

To assess the potential of the iterative approach we consider a specific SAP variant as a case-study, UNIFORM CARDINALITY CONSTRAINED MULTIPLE KNAPSACK, for which we answer this question affirmatively. The input is a set of items, each has a value and a weight, and a set of uniform capacity bins. The goal is to assign a subset of the items of maximum total value to the bins such that (i) the capacity of any bin is not exceeded, and (ii) the number of items assigned to each bin satisfies a given *cardinality* constraint. While the technique of Fleischer et al. yields a  $(1 - \frac{1}{e})$ -approximation for the problem, we show that iterative randomized rounding leads to *efficient polynomial time approximation scheme* (EPTAS), thus essentially resolving the complexity status of the problem. Our analysis of iterative randomized rounding may be useful for solving other SAP variants.

## 1 Introduction

We consider problems in the class of maximizing assignment problems with packing constraints, also known as SEPARABLE ASSIGNMENT PROBLEMS (SAP). A general problem in this class is defined by a set of bins and a set of items to be packed in the bins. There is a *value*  $v_{ij}$  (also called *profit* sometimes) associated with assigning item  $i$  to bin  $j$ . We are also given a separate packing constraint for each bin  $j$ . The goal is to find an assignment of a subset of the items to the bins which maximizes the total value accrued. This class includes several well studied problems such as the GENERALIZED ASSIGNMENT PROBLEM (GAP).

In [12], Fleischer et al. introduced a powerful technique for solving SAP and its variants. The technique relies on first solving a configuration linear programming (configuration-LP) relaxation of the problem. Subsequently, configurations (i.e., feasible subsets of items for a single bin) are sampled independently according to a distribution specified by the LP solution to obtain an integral solution for the given instance. For many SAP variants, such as GAP, the approximation guarantee of the resulting algorithm is  $(1 - 1/e)$ .

Intuitively, we can do better using the following iterative randomized rounding approach: Iteratively solve a configuration LP relaxation of the problem for the remaining items and bins and sample a *few* configurations based on the distribution specified by the LP solution, until all bins are used. We note that if the LP is solved only once and all of the bins are packed based on the solution, then we have exactly the algorithm of Fleischer et al. [12]. This raises the following question:

Can iterative randomized rounding improve the approximation ratio of [12]?

As shown in [12], under standard complexity assumptions, there is a SAP variant for which their approximation ratio of  $(1 - 1/e)$  is the best possible. However, for various special cases (such as MULTIPLE KNAPSACK and GAP), there are discrepancies between the approximation guarantee obtained using the algorithm of [12] and the state-of-the-art approximations. This indicates that the iterative approach may potentially lead to improved approximation for some variants (compared to [12]). Hence, to assess the potential of the iterative approach we focus as a case study on one interesting SAP variant, namely, UNIFORM CARDINALITY CONSTRAINED MULTIPLE KNAPSACK (CMK). Specifically, we show that iterative randomized rounding is superior to the technique of [12] and use it to essentially resolve the complexity status of this problem.

An input for CMK consists of a set of items, each has a value and a weight, and a set of uniform capacity bins. The goal is to assign a subset of the items of maximum total value to the bins such that (i) the total weight of items in each bin does not exceed its capacity, and (ii) the number of items assigned to each bin satisfies a given cardinality constraint.<sup>1</sup> CMK has real-world applications in cloud computing, as well as in manufacturing systems and radio networks (see the full version of the paper [9]).

## 1.1 Related Work

Iterative randomized rounding of configuration-LPs has been recently used for obtaining the current state-of-the-art approximation for *vector bin packing* in [17]. In this problem, the goal is to pack a set of items, each given by a  $d$ -dimensional size vector for some  $d > 1$ , in a minimum number of  $d$ -dimensional bins, where a subset of items fits in a bin if it adheres to the capacity constraints in all dimensions. We are not aware of an application of iterative randomized rounding of configuration-LPs for *maximization* problems.

The MULTIPLE KNAPSACK WITH UNIFORM CAPACITIES (UMK) problem is the special case of CMK with no cardinality constraint, or equivalently, where the cardinality constraint is larger than the total number of items. In the more general MULTIPLE KNAPSACK (MK) problem, the capacity of the bins may be arbitrary. In terms of approximation algorithms, UMK and MK are well understood. A *polynomial time approximation scheme* PTAS for

---

<sup>1</sup> See a more formal definition in Section 1.3.

UMK was given by Kellerer [16]. Later, Chekuri and Khanna [5] developed the first PTAS for MK and ruled out the existence of a *fully* PTAS (FPTAS), already for UMK with only two bins. Jansen designed more involved *efficient* PTAS (EPTAS) for MK [13, 14], thus resolving the complexity status of the problem.<sup>2</sup>

For CMK, a randomized  $(1 - 1/e)$ -approximation follows from the previously mentioned results of Fleischer et al. [12] for SAP. More specifically, the authors present a randomized algorithm for SAP whose approximation guarantee is  $((1 - 1/e) \cdot \beta)$ , where  $\beta$  is the best approximation ratio for the single bin subproblem.<sup>3</sup> A slightly more efficient approximation ratio for CMK follows from a recent result of Cohen et al. [7] who give a randomized  $(1 - \ln(2)/2 - \varepsilon) \approx 0.653$ -approximation for *uniform 2-dimensional vector multiple knapsack*. In this problem, the cardinality constraint of CMK is generalized to a second knapsack constraint.
