Resolving one conjecture of Carlson, Davies, Kolla, and Perkins and disproving another (part (i) and (ii) respectively of [12, Conjecture 1]), we establish thresholds in the mean magnetization for fast and slow mixing of the Kawasaki dynamics on  $\mathcal{G}_\Delta$ .

► **Theorem 1.** *For the Kawasaki dynamics, the following two statements hold:*

- (1) *If  $0 \leq \beta < \beta_u$  or if  $\beta > \beta_u$  and  $|\eta| > \eta_a$ , then the Kawasaki dynamics for  $\hat{\mu}_{G, \beta, \eta}$  have mixing time  $O(|V(G)|^2)$  for all  $G \in \mathcal{G}_\Delta$ .*
- (2) *There exists a sequence of graphs  $G_n \in \mathcal{G}_\Delta$  with  $|V(G_n)| \rightarrow \infty$  such that for  $\beta > \beta_u$  and  $|\eta| < \eta_u$ , the Kawasaki dynamics for  $\hat{\mu}_{G, \beta, \eta}$  have mixing time  $\exp(\Omega(|V(G_n)|))$  on  $G$ .*

Fast mixing of the dynamics for all  $\eta$  when  $\beta < \beta_u$  was conjectured in [12]. The slow mixing for some  $\eta > \eta_c$  disproves the conjecture from [12] asserting the coincidence of the algorithmic and dynamical thresholds. If it were established that  $\lambda_a(\Delta, \beta) = \lambda_u(\Delta, \beta)$  then Theorem 1 would give the sharp dynamical threshold for the fixed-magnetization model. It is an interesting question to understand the dynamical threshold in both the Ising model and fixed-magnetization Ising model if instead it holds that  $\lambda_u < \lambda_a$ .

■ **Figure 1** Sketch of the phase space for the fixed-magnetization model on  $\mathcal{G}_\Delta$  when  $\Delta = 4$ , where  $\bar{\eta}_a = \eta_{\Delta, \beta, \bar{\lambda}_a}$ .

A diagram of the computational and dynamical thresholds for the fixed-magnetization Ising model is given in Figure 1.

Towards the proof of Theorem 1,(2), we establish that the Glauber dynamics for the Ising model on the random  $\Delta$ -regular graph takes exponential time to mix when  $\beta > \beta_u$  and  $\lambda$  is in the non-uniqueness regime for  $\mathbb{T}_\Delta$ .

► **Theorem 2.** Fix  $\Delta \geq 3$ ,  $\beta > \beta_u(\Delta)$ , and  $|\log \lambda| < \log \lambda_u(\Delta, \beta)$ . Let  $G$  be a uniformly random  $\Delta$ -regular graph on  $n$  vertices. Then with high probability as  $n \rightarrow \infty$ , the mixing time of the Glauber dynamics for the Ising model on  $G$  is  $e^{\Theta(n)}$ .

This theorem complements the result of Can, van der Hofstad, and Kumagai [8] showing that when  $|\log \lambda| > \log \lambda_u$ , with high probability over the random regular graph the mixing time of the Glauber dynamics is  $O(n \log n)$ ; they conjectured that the mixing time is exponential when  $|\log \lambda| < \log \lambda_u$ , which Theorem 2 confirms.

Theorem 2 also fills in more of the picture for dynamical thresholds in the Ising model on graphs in  $\mathcal{G}_\Delta$ ; see Figure 2.

■ **Figure 2** Sketch of the phase space for the Ising model Glauber dynamics on  $\mathcal{G}_\Delta$  when  $\Delta = 4$ .

Before we give an overview of our proof techniques, we state some open questions. Our first question is concerned with the relation between the analytic threshold and the uniqueness threshold for the Ising model.

► **Question 3.** Does  $\lambda_a(\Delta, \beta) = \lambda_u(\Delta, \beta)$ ?

If the answer is yes, then by the results above we would have a complete characterization of the dynamical thresholds in the Ising and fixed magnetization Ising models on  $\mathcal{G}_\Delta$ .

Next we conjecture the following improvement of part (1) of Theorem 1.

► **Conjecture 4.** If  $0 \leq \beta < \beta_u$  or if  $\beta > \beta_u$  and  $|\eta| > \eta_a$ , then the Kawasaki dynamics for  $\hat{\mu}_{G,\beta,\eta}$  are optimally mixing: the mixing time is in  $O(|V(G)| \cdot \log(|V(G)|))$  for all  $G \in \mathcal{G}_\Delta$ .

The analogous statement for independent sets is proved in [33] by proving a log-Sobolev inequality for the down-up walk with constant  $\Omega(1/n)$ .

While we focus on global Kawasaki dynamics in this paper, we suggest that our results also apply to the local dynamics. Note that for studying local Kawasaki dynamics, it makes sense to assume that  $G$  is connected. In this case, we believe that a Markov chain comparison argument as in [26] can be used to show that the mixing times of the local and global

dynamics only differ by a polynomial factor. While our slow mixing result for the global dynamics uses identical copies of disjoint random graphs, our arguments should still apply if they are connected with a sparse set of edges. As a consequence, both slow and rapid mixing from Theorem 1 would carry over. A full proof of this is left for future work.

## 1.1 Overview of Techniques

The proofs of Theorems 1 and 2 involve several different ingredients, including local central limit theorems, spectral independence, and first- and second-moment methods for spin models on random graph. We give an overview of the techniques here.

### 1.1.1 Fast Mixing

At a high level, the proof of Theorem 1, (1) follows the strategy used by Jain, Michelen, Pham, and Vuong [33] to show fast mixing for the down-up walk on independent sets of density less than  $\alpha_c(\Delta)$ .

In order to derive an upper bound on the mixing time of the Kawasaki dynamics for the fixed-magnetization Ising model, we prove that the spectral gap of the associated transition matrix is bounded below by  $\Omega(1/n)$ . To achieve this, we study a related down-up Ising walk on  $\Omega_k$  while arguing that the respective spectral gaps of the Kawasaki dynamics and the down-up walk are within a constant factor of each other. This allows us to make use of recent literature that relates the spectral gap of a down-up walk to spectral independence [1, 2, 14].

Informally speaking, spectral independence captures the idea that for most pairs of vertices  $v, w \in V$ , the spins assigned to  $v$  and  $w$  by a random configuration from  $\hat{\mu}_{G,\beta,\eta}$  are almost independent. While spectral independence for the Ising model has been studied before by Chen, Liu, and Vigoda [17], no comparable result exists for the fixed-magnetization model. To derive the required spectral independence property, we follow an approach introduced in [33] to analyze the down-up walk for fixed-size independent sets. The idea is to choose  $\lambda$  such that a random configuration from  $\mu_{G,\beta,\lambda}$  has expected magnetization per vertex close to  $\eta$ . We then view  $\hat{\mu}_{G,\beta,\eta}$  as  $\mu_{G,\beta,\lambda}$  conditioned on the desired magnetization.

We use this perspective to show that  $\hat{\mu}_{G,\beta,\eta}$  satisfies  $\ell_\infty$ -independence as follows:

- (1) An extremal combinatorics result on the magnetization of the Ising model from [12] shows that for any  $G \in \mathcal{G}_\Delta$ , the value of  $\lambda$  that achieves expected magnetization  $\eta$  satisfies  $|\log \lambda| > \log \lambda_a$  if  $|\eta| > \eta_a$ . This allows us to use an approach by Chen, Liu, and Vigoda [16] to derive  $O(1)$ - $\ell_\infty$ -independence for the Ising model for all such  $\lambda$  based on our zero-freeness assumption.
- (2) We next show that the probability under  $\mu_{G,\beta,\lambda}$  of drawing a configuration with exactly the correct magnetization is sufficiently large, and that this probability does not change significantly after conditioning on the spin of a vertex. For the former, a lower bound of  $\Theta(1/\sqrt{n})$  can be derived from existing local central limit theorems for the expected number of  $+1$  spins [12]. For the latter, we perform a similar analysis to [33] and use an Edgeworth expansion to prove that conditioning on the spin of a vertex changes this probability by at most  $O(n^{-3/2})$ . For both results it is crucial that the Ising model satisfies sufficiently strong zero-freeness assumptions for all considered  $\lambda$ .

The above discussion indicates how we obtain spectral independence for  $\hat{\mu}_{G,\beta,\eta}$ . The bulk of our work comes from leveraging this to derive a lower bound on the spectral gap of the down-up walk. This requires us to prove that spectral independence also holds when an arbitrary vertex set  $U \subset V$  with  $|U| < k$  is fixed (or *pinned*) to have spin  $+1$ . Such pinning interfere with the proof strategy above for several reasons. First of all, pinning vertices to  $+1$

decreases the  $\lambda$  that we need to choose to obtain the desired magnetization  $\eta$ . In particular, if we aim for  $\eta > \eta_a$ , this might cause the required value of  $\lambda$  to leave the regime in which zero-freeness (and  $\ell_\infty$ -independence) for the Ising model is guaranteed. We circumvent this by observing that the Kawasaki dynamics is symmetric under swapping  $+1$  and  $-1$  spins. Hence, it suffices to consider  $\eta < -\eta_a$ , and an application of the FKG inequality ensures that we only need to consider  $\lambda < 1/\lambda_a(\Delta, \beta)$  for all relevant pinnings.

The second difficulty is that once the number of free vertices  $k - |U|$  becomes sub-linear in  $n$ , both the local central limit theorem and the Edgeworth expansion can fail. Similar to [33], we solve this issue by using the localization framework by Chen and Eldan [14], which allows us to factorize the spectral gap of the down-up walk into the spectral gaps of two Markov chains that are easier to analyze. The first chain is a generalization of the down-up walk that updates  $\Theta(n)$  vertices in each step, and we can analyze its spectral gap based on the spectral independence result described above using the local-to-global framework for local spectral expanders [1, 2, 15, 17]. The second walk is a simple down-up walk but with a set of vertices  $U \subset V$  pinned to  $+1$ . In particular, we need to show that there is some  $\alpha > 0$  (depending on  $\beta$  and  $\Delta$ ) such that for  $k - |U| \leq \alpha n$ , the spectral gap of such a pinned down-up walk is bounded below by  $\Omega(1/n)$ .

For bounding the spectral gap of the pinned walk, we use a coupling argument. Specifically, we construct a suitable metric on the state space such that the distance between two coupled copies of the Markov chain contracts in expectation in each step. For the independent set model studied in [33], such a contracting coupling is well known, appearing in the original “path coupling” paper of Bubley and Dyer [7]. In contrast, for the fixed-magnetization Ising model, no such result exists, and the default choice of coupling (sometimes called the identity coupling) and metric (the number of vertices on which both configurations differ) does not exhibit the desired contraction. Roughly speaking, this is because the ferromagnetism can cause certain types of disagreements to increase the probability that new disagreements are created. We overcome this problem by studying a refined metric, which assigns different weights to “good” and “bad” disagreements in a way that guarantees that distances under this new metric decrease in expectation under the coupling, thus establishing the desired bound on the spectral gap.

### 1.1.2 Slow Mixing

For the slow mixing results, we leverage the connection between the Ising model on the infinite tree  $\mathbb{T}_\Delta$  and the behavior of the model on a uniformly random  $\Delta$ -regular graph. In the relevant range of parameters ( $\beta > \beta_u$ ,  $1 < \lambda < \lambda_u$ ) there are two distinct Ising Gibbs measures on  $\mathbb{T}_\Delta$ , the “plus measure” and the “minus measure.” On the random graph these two Gibbs measures manifest themselves as a dominant and subdominant metastable state: sets of configurations for which the Glauber dynamics take exponential time to escape from. The existence of multiple metastable states immediately shows slow mixing of the Glauber dynamics (Theorem 2), and we then use this to construct a graph on which the Kawasaki dynamics is slow mixing, proving Theorem 1,(2).

To do this, we exhibit the existence of a bottleneck in the state space of the model on a  $\Delta$ -regular graph  $H$  constructed as the disjoint union of several copies of a random  $\Delta$ -regular graph. We define two different subsets of configurations of the fixed-magnetization Ising model on  $H$ : in the set of configurations  $S_1$ , each copy of the random graph comprising  $H$  has magnetization  $\eta$ ; in the set  $S_2$ , some copies have magnetization approximately  $\eta_+ > \eta$  and some copies have magnetization approximately  $\eta_- < \eta$  (chosen in such a way that their average is  $\eta$ ). We then show that a third set  $S_3$  separates  $S_1$  and  $S_2$  (under single-step

updates of the Kawasaki dynamics) and carries exponentially less probability mass in the fixed-magnetization Ising model than either  $S_1$  or  $S_2$ . Via a standard conductance argument this proves exponentially slow mixing of the Kawasaki dynamics.

Bounds on the weights of the sets  $S_1, S_2$ , and  $S_3$  will follow from the existence of the metastable states on the random graph. One metastable state consists of configurations with magnetization close to  $\eta_{\Delta, \beta, \lambda}^+$  and the other consists of configurations with magnetization close to  $\eta_{\Delta, \beta, \lambda}^-$ . That is, the two metastable states are in correspondence with the two distinct extremal Gibbs measures on  $\mathbb{T}_\Delta$  (which is why  $\lambda < \lambda_u$  is crucial).

Identifying the metastable states follows from determining which states (organized according to their magnetizations) contribute significantly to the partition function  $Z_G(\beta, \lambda)$  of the Ising model on the random  $\Delta$ -regular graph. A first guess about how much each state contributes to  $Z_G(\beta, \lambda)$  would be to take the expected contribution. The exponential order of this expectation is captured by a function  $f_{\Delta, \beta, \lambda}(\eta)$ . From [29], we know that the critical points of this function correspond to fixed points of a recursion on  $\mathbb{T}_\Delta$ , and that the second-moment method can be used to lower bound the contribution of the state with magnetization  $\eta$ , where  $\eta$  is the maximum of  $f_{\Delta, \beta, \lambda}(\eta)$ . This suffices to determine the dominant state of the Ising model on the random graph (as was done in much greater generality by Dembo and Montanari in [23]).

To identify subdominant metastable states, however, we need to analyze the contribution of states with magnetization  $\eta$  when  $\eta$  is a local maximum of  $f_{\Delta, \beta, \lambda}(\eta)$ . For this we follow the approach of [19] utilizing non-reconstruction in planted models. While their setting is the  $q$ -state Potts model for  $q \geq 3$ , many of their results can be translated to our context of the external-field Ising model. We discuss their techniques in greater detail in Section 3.2 and in the full paper [36].

When we construct the graph  $H$  as the union of random graphs, we also must understand how the behavior of the fixed-magnetization Ising model relates to that of the Ising model. To do this, we give a new and simple argument in Section 3.2 to bound the probability of hitting a given magnetization in the Ising model.

Interestingly, while the graph on which we show slow mixing is the union of random regular graphs, the behavior of the Kawasaki dynamics on a single copy of the random regular graph can be very different. Recently, Bauerschmidt, Bodineau, and Dagallier [4] (see also [5]) showed that the local Kawasaki dynamics for the fixed-magnetization Ising model mixes in time  $O(n \log^6 n)$  on random  $\Delta$ -regular graphs at all magnetizations when  $\beta < 1/(8\sqrt{\Delta-1})$ . In particular, when  $\Delta$  is sufficiently large this regime of fast mixing includes parameters outside the tree uniqueness phase, i.e. inside the range of parameters for which we prove exponentially-slow mixing in the worst case over graphs in  $\mathcal{G}_\Delta$ .

## 1.2 Outline

In Section 2, we collect preliminary results that will be used in our proofs. In Section 3 we give a more detailed overview on our main steps for proving Theorem 1 and Theorem 2. In particular, in Section 3.1, we discuss our fast-mixing result, Theorem 1,(1), and in Section 3.2 we discuss our slow-mixing results, Theorem 1,(2) and Theorem 2. All proofs and more details can be found in the full version of the paper [36].

## 2 Preliminaries

Throughout the paper and unless otherwise stated, we will make the following assumptions:  $\Delta \geq 3$  is fixed,  $\beta \geq 0$ ,  $G = (V, E) \in \mathcal{G}_\Delta$ , and  $n = |V|$ .

We will often switch between notation of  $\eta$  for the magnetization per vertex and  $k = \lfloor \frac{\eta+1}{2} n \rfloor$  for the number of  $+1$  spins in such a configuration. We will thus abuse notation and write  $\hat{\mu}_{G,\beta,k}$  for  $\hat{\mu}_{G,\beta,\eta}$  and  $\hat{Z}_{G,k}(\beta)$  for  $\hat{Z}_{G,\eta}(\beta)$  when it makes things more clear. We will also on occasion drop  $G$  and  $\beta$  from the subscripts of our Gibbs measure notation as well as the subscripts and argument of our partition function notation when  $G$  and  $\beta$  do not play a role in the proofs.

## 2.1 Ising Model on the Infinite Tree

Let  $\mathbb{T}_\Delta$  denote the infinite  $\Delta$ -regular tree. Since it has infinitely many vertices, one cannot define the Ising model on  $\mathbb{T}_\Delta$  via (1). Instead, the Dobrushin-Lanford-Ruelle equations can be used to define “infinite-volume Gibbs measures” for the Ising model and other spin models on infinite graphs. This approach says that a probability measure  $\mu$  on  $\{\pm 1\}^{V(\mathbb{T}_\Delta)}$  is a Gibbs measure for the Ising model at inverse temperature  $\beta$  and external field  $\lambda$  if the conditional measure on any finite set of vertices given a configuration on the complement is the Ising model defined by (1) with the appropriate boundary conditions. See [30] for more details.

A main question about Gibbs measures on infinite graphs is whether for a given specification of parameters (i.e.  $\beta$  and  $\lambda$  in the Ising case) and a given infinite graph  $G$  there is a unique Gibbs measure or multiple distinct Gibbs measures. The transition between uniqueness and non-uniqueness as a parameter varies marks a phase transition.

Understanding uniqueness and non-uniqueness of the Ising model on  $\mathbb{T}_\Delta$  is relatively simple because of monotonicity and the FKG inequality. There are two extreme infinite-volume Gibbs measures in the sense of maximizing or minimizing the probability that a fixed vertex of  $\mathbb{T}_\Delta$  gets a  $+1$  spin: the “ $+$  measure” on  $\mathbb{T}_\Delta$  is the Gibbs measure realized by taking a weak limit of finite-volume Gibbs measures on depth  $N$  truncations of  $\mathbb{T}_\Delta$  with boundary vertices assigned  $+1$  spins; the “ $-$  measure” is the weak limit of finite-volume measures with boundary vertices receiving  $-1$  spins.

The quantities  $\eta_{\Delta,\beta,\lambda}^+$  and  $\eta_{\Delta,\beta,\lambda}^-$  are the respective expectations of  $\sigma_v$  (for any fixed  $v$  in  $\mathbb{T}_\Delta$ ) under these two Gibbs measures. The quantities can be calculated as solutions to fixed point equations (see e.g. [6]), giving

$$\eta_{\Delta,\beta,\lambda}^+ = \tanh(L^* + \operatorname{artanh}(\tanh(L^*) \tanh(\beta/2)))$$

where  $L^*$  is the largest solution to

$$L = \log(\lambda) + (\Delta - 1)\operatorname{artanh}(\tanh(L) \tanh(\beta/2)).$$

The following proposition summarizes information about  $\eta_{\Delta,\beta,\lambda}^+$ ,  $\eta_{\Delta,\beta,\lambda}^-$  and Gibbs uniqueness that we will use (all follow from the results in [6]).

► **Proposition 5.** *Fix  $\Delta \geq 3$ .*

- *There is uniqueness of Gibbs measure for the Ising model with parameters  $\beta, \lambda$  on  $\mathbb{T}_\Delta$  if and only if  $\eta_{\Delta,\beta,\lambda}^+ = \eta_{\Delta,\beta,\lambda}^-$ .*
- *For  $\beta \leq \beta_u(\Delta) = \ln\left(\frac{\Delta}{\Delta-2}\right)$ , there is uniqueness for all  $\lambda$ .*
- *For  $\beta > \beta_u(\Delta)$  there is  $\lambda_u > 1$  so that there is uniqueness if and only if  $|\log \lambda| > \log \lambda_u$ .*
- *$\eta_{\Delta,\beta,\lambda}^+$  is continuous and strictly increasing in  $\lambda$  on the interval  $[1, \infty)$ . In particular, recall that  $\eta_c(\Delta, \beta) = \eta_{\Delta,\beta,1}^+$  and  $\eta_u(\Delta, \beta) = \eta_{\Delta,\beta,\lambda_u}^+$ ; then for every  $\eta \in [\eta_c, \eta_u]$  there is  $\lambda \in [1, \lambda_u]$  so that  $\eta_{\Delta,\beta,\lambda}^+ = \eta$ .*

Finally, it will be important to bound the expected magnetization in the Ising model for given  $\beta, \lambda$  and any  $G \in \mathcal{G}_\Delta$ . The bound is an extremal result proved in [12].

► **Theorem 6** ([12, Theorem 3]). For  $G \in \mathcal{G}_\Delta$ ,  $\lambda \geq 1$ , and  $\beta \geq 0$ ,

$$\mathbb{E}_{\sigma \sim \mu_{G,\beta,\lambda}}[\eta(\sigma)] \leq \eta_{\Delta,\beta,\lambda}^+.$$

## 2.2 Pinned Models

For the fast-mixing argument, we will frequently consider pinned versions of our models, meaning conditioned on some subset of vertices having been assigned a particular spin. For  $U \subset V$ , we call a function  $\tau_U : U \rightarrow \{+1, -1\}$  a *pinning* on  $U$ . We write  $\Omega^{\tau_U} = \{\sigma \in \Omega \mid \forall u \in U : \sigma(u) = \tau_U(u)\}$  for the set of Ising configurations on  $G$  that agree with  $\tau_U$  on  $U$ . The *Ising partition function with pinning*  $\tau_U$  is defined as

$$Z_G^{\tau_U}(\beta, \lambda) = \sum_{\sigma \in \Omega^{\tau_U}} \lambda^{|\sigma|^+} e^{\beta m_G(\sigma)},$$

and the *Ising model under pinning*  $\tau_U$  is defined by Gibbs measure

$$\mu_{G,\beta,\lambda}^{\tau_U}(\sigma) = \frac{\mathbb{1}_{\sigma \in \Omega^{\tau_U}} \lambda^{|\sigma|^+} e^{\beta m_G(\sigma)}}{Z_G^{\tau_U}(\beta, \lambda)}.$$

Note that for  $\lambda > 0$ , it holds that  $\mu_{\beta,\lambda}^{\tau_U}$  is a well-defined probability distribution with support  $\Omega^{\tau_U}$ . We allow for the case  $U = \emptyset$ , which is equivalent to the unpinned Ising model. Often,  $\tau_U$  will be the constant  $+1$  function on  $U$ , in which case we write  $\Omega^U$ ,  $Z_G^U$  and  $\mu_{\beta,\lambda}^U$ .

Analogously to the Ising model, we will also impose pinnings on the fixed-magnetization model. To this end, set  $\Omega_k^{\tau_U} = \{\sigma \in \Omega_k : \forall u \in U : \sigma(u) = \tau_U(u)\}$  and define the *fixed-magnetization partition function with pinning*  $\tau_U$  as

$$\hat{Z}_{G,k}^{\tau_U}(\beta) = \sum_{\sigma \in \Omega_k^{\tau_U}} e^{\beta m_G(\sigma)}.$$

The *fixed-magnetization Ising model under pinning*  $\tau_U$  is a probability measure with support  $\Omega_k^{\tau_U}$  defined by

$$\hat{\mu}_{G,\beta,k}^{\tau_U}(\sigma) = \frac{\mathbb{1}_{\sigma \in \Omega_k^{\tau_U}} e^{\beta m_G(\sigma)}}{\hat{Z}_{G,k}^{\tau_U}(\beta)}.$$

Throughout the paper, we assume  $|\tau_U|^+ \leq k$  so that the expression above is well-defined. As with the Ising model, we write  $\Omega_k^U$ ,  $\hat{Z}_{G,k}^U$  and  $\hat{\mu}_{G,\beta,k}^U$  when  $\tau_U$  is the constant  $+1$  function.

## 2.3 Kawasaki Dynamics, Down-up Walk, and Glauber Dynamics

Here we formally define the three Markov chains that we will analyze. Our main object of study is the Kawasaki dynamics for the fixed-magnetization Ising model. For this, we fix a size  $k$  where  $1 \leq k \leq |V| - 1$ .

► **Definition 7** (Kawasaki dynamics). The *Kawasaki dynamics* on  $\Omega_k$  is a Markov chain  $\mathcal{K}_{\beta,k} = (X_t)_{t \geq 0}$  given by the following update rule:

1. Pick  $u \in X_t^{-1}(+1)$  and  $w \in X_t^{-1}(-1)$  uniformly at random, and set  $X \in \Omega_k$  such that  $X(v) = X_t(v)$ ,  $X(w) = X_t(w)$ , and  $X(u) = X_t(u)$  for  $u \neq v, w$ .
2. Set  $X_{t+1} = X$  with probability  $\min \left\{ 1, \frac{\hat{\mu}_{G,\beta,k}(X)}{\hat{\mu}_{G,\beta,k}(X_t)} \right\}$ , and set  $X_{t+1} = X_t$  otherwise.

## 56:12 Fast and Slow Mixing of the Kawasaki Dynamics

In other words, the Kawasaki dynamics chooses two vertices with opposite spins and swaps their spins with probability proportional to the change in monochromatic edges.

For proving fast mixing of the Kawasaki dynamics, we use the down-up walk on the  $+1$  spins as a proxy for our analysis. Here we will also need to consider the Markov chain under plus pinnings.

► **Definition 8** (Down-up walk with plus pinnings). For  $U \subset V$  and with  $|U| < k$  we define the  $+1$ -down-up walk on  $\Omega_k^U$  as a Markov chain  $\mathcal{P}_{\beta,k}^U = (Y_t)_{t \geq 0}$ , given by the following update rule:

1. Pick  $v \in Y_t^{-1}(+1) \setminus U$  uniformly at random and set  $W = Y_t^{-1}(+1) \setminus \{v\}$ .

2. Draw  $Y_{t+1}$  from  $\hat{\mu}_{G,\beta,k}^W$ .

We write  $\mathcal{P}_{\beta,k}$  if  $U = \emptyset$ .

The following observation is easy to check.

► **Observation 9.**  $\mathcal{K}_{\beta,k}$  and  $\mathcal{P}_{\beta,k}$  are ergodic and reversible with respect to  $\hat{\mu}_{\beta,k}$ . Moreover, there is a constant  $C \geq 1$  that only depends on  $\Delta$  and  $\beta$  such that for all  $\sigma_1 \neq \sigma_2$

$$\frac{1}{C} \cdot \mathcal{P}_{\beta,k}(\sigma_1, \sigma_2) \leq \mathcal{K}_{\beta,k}(\sigma_1, \sigma_2) \leq C \cdot \mathcal{P}_{\beta,k}(\sigma_1, \sigma_2).$$

Lastly, we also consider the Glauber dynamics for the Ising model.

► **Definition 10** (Glauber dynamics). The Glauber dynamics on  $\Omega$  is a Markov chain  $(X_t)_{t \geq 0}$ , given by the following update rule:

1. Pick  $v \in V(G)$  uniformly at random.

2. For  $u \neq v$ , set  $X_{t+1}(u) = X_t(u)$ , and sample  $X_{t+1}(v)$  from the marginal distribution at  $v$  conditioned on  $X_{t+1}(N(v))$ .

## 2.4 Mixing Times

Our goal in analyzing the Kawasaki dynamics is to understand the *mixing time* of this Markov chain. Given two probability distributions  $\mu$  and  $\nu$  on probability space  $(\Omega, \mathcal{A})$ , let

$$\|\mu - \nu\|_{\text{TV}} := \sup_{A \in \mathcal{A}} |\mu(A) - \nu(A)|$$

be the *total variation distance* between  $\mu$  and  $\nu$ . For a Markov chain on  $\Omega$  with transition matrix  $P$  and unique stationary distribution  $\pi$ , we may then define

$$d(t) := \max_{x \in \Omega} \|P^t(x, \cdot) - \pi\|_{\text{TV}}.$$

► **Definition 11.** The mixing time is

$$\tau_{\text{mix}} = \inf \left\{ t : d(t) \leq \frac{1}{4} \right\}.$$

See, e.g., [37] for background on Markov chains and mixing times. We use several different techniques to analyze the mixing time of the Kawasaki dynamics, which we now describe.

### 2.4.1 Upper Bounds on Mixing Time

A common way to upper-bound the mixing time of a reversible Markov chain  $P$  is by lower-bounding its spectral gap, which can be defined via the following variational characterization.

► **Definition 12.** Let  $P$  be a transition matrix that is reversible with respect to  $\pi$ . We denote by  $\mathbf{gap}(P)$  the spectral gap (or Poincaré constant) of  $P$ , which is defined as the largest constant  $\gamma$  such that  $\gamma \text{Var}_\pi(f) \leq \mathcal{E}_P(f, f)$  for any function  $f : \Omega \rightarrow \mathbb{R}$ , where  $\text{Var}_\pi(f)$  is the variance of  $f$  with respect to  $\pi$  and  $\mathcal{E}_P$  is the Dirichlet form of  $P$ , given by

$$\mathcal{E}_P(f, g) = \frac{1}{2} \sum_{x, y \in \Omega} (f(x) - f(y))(g(x) - g(y))P(x, y)\pi(x) \quad f, g : \Omega \rightarrow \mathbb{R}.$$

Using this characterization of the spectral gap, we have the following observation.

► **Observation 13.** Suppose  $P_1$  and  $P_2$  are transition matrices that are both reversible with respect to  $\pi$ . If there are constants  $\alpha_1, \alpha_2 > 0$  such that  $\alpha_1 \cdot P_1(x, y) \leq P_2(x, y) \leq \alpha_2 \cdot P_1(x, y)$  for all  $x \neq y$ , then  $\alpha_1 \cdot \mathbf{gap}(P_1) \leq \mathbf{gap}(P_2) \leq \alpha_2 \cdot \mathbf{gap}(P_1)$ .

On account of Observation 9, this allows us to study the spectral gap of the down-up walk  $\mathcal{P}_{\beta, k}$  instead of the Kawasaki dynamics  $\mathcal{K}_{\beta, k}$ .

An upper bound on the mixing time of an ergodic, reversible Markov chain with transition matrix  $P$  can be obtained from its spectral gap via the following standard relationship (see [37, Theorem 12.4]):

$$\tau_{\text{mix}} \leq \mathbf{gap}(P)^{-1} \cdot \log \left( \frac{4}{\min_{x \in \Omega} \pi(x)} \right).$$

There are various ways to obtain bounds on the spectral gap of a Markov chain, one of which is to construct a contracting coupling. For a transition matrix  $P$ , we say that a Markov chain  $(X_t, Y_t)_{t \geq 0}$  on  $\Omega \times \Omega$  is a *coupling* of  $P$  with itself if each of the marginal processes  $(X_t)_{t \geq 0}$  and  $(Y_t)_{t \geq 0}$  is a Markov chain with transition matrix  $P$ . We use this notion to bound the spectral gap.

► **Theorem 14** ([37, Theorem 13.1]). Suppose  $\Omega$  is finite and let  $(X_t, Y_t)_{t \geq 0}$  be a coupling of  $P$  with itself. If there is a constant  $c > 0$  and a function  $\rho : \Omega \times \Omega \rightarrow \mathbb{R}_{\geq 0}$  such that  $\rho(x, y) = 0$  if and only if  $x = y$ , and for all  $t \in \mathbb{Z}_{\geq 0}$  it holds that

$$\mathbb{E}[\rho(X_{t+1}, Y_{t+1}) \mid X_t, Y_t] \leq (1 - c)\rho(X_t, Y_t),$$

then the spectral gap of  $P$  is at least  $c$ .

We will use Theorem 14 to show that the down-up walk  $\mathcal{P}_{\beta, k}^U$  has a spectral gap of  $\Omega(1/k)$  whenever  $k - |U| \leq \alpha n$  for some  $\alpha$  depending on  $\Delta$  and  $\beta$ . In particular, by the symmetry of the Kawasaki dynamics under swapping all spins, this proves a spectral gap of  $\Omega(1/k)$  for  $\mathcal{K}_{\beta, k}$  if  $k \leq \alpha n$  or  $k \geq (1 - \alpha)n$ , but it does not cover the full regime of Theorem 1, (1).

To prove the full result of Theorem 1, (1), we prove that  $\hat{\mu}_{\beta, k}^U$  satisfies spectral independence for suitable  $k \in \mathbb{N}$  and sets  $U \subset V$ . Spectral independence is a property of the stationary distribution  $\pi$  of a Markov chain, and it was recently used to bound the spectral gap and prove rapid mixing of various chains [1, 2, 14, 15, 17, 33]. For the following discussion of spectral independence, we restrict ourselves to distributions on  $\Omega = 2^V$  where  $V$  is some finite set (e.g., the vertices of a graph). Note that this encompasses both the fixed-magnetization Ising

## 56:14 Fast and Slow Mixing of the Kawasaki Dynamics

model as well as the Ising model, by associating  $S \in \Omega$  with the Ising configuration that maps all vertices in  $S$  to  $+1$ . In this setting, we adopt the following notation: for a distribution  $\pi$  on  $\Omega$ , a subset  $S$  drawn from  $\pi$ , and  $v \in V$ , we write  $\pi(v)$  for the probability that  $v \in S$  and  $\pi(\bar{v})$  for the probability that  $v \notin S$ . We extend this to conditional probabilities, writing for example  $\pi(v | \bar{u})$  for the probability that  $v \in S$  given  $u \notin S$ .

► **Definition 15.** *The influence matrix of a distribution  $\pi$  on  $2^V$  is the matrix  $M_\pi \in \mathbb{R}^{n \times n}$  with entries*

$$M_\pi[u, v] = \begin{cases} 0 & \text{if } \pi(u) = 0 \\ \pi(v | u) - \pi(v) & \text{otherwise} \end{cases}$$

Using this definition of  $M_\pi$ , the definition of spectral independence of  $\pi$  is as follows.

► **Definition 16.** *A probability distribution  $\pi$  on  $2^V$  is called  $C$ -spectrally independent (for  $C \geq 0$ ) if the largest eigenvalue of  $M_\pi$  is at most  $C$ .*

Since directly bounding the largest eigenvalue of  $M_\pi$  is usually challenging, a common approach is to bound the  $\ell_\infty$ -norm of  $M_\pi$  instead. This leads to the stronger notion of  $\ell_\infty$ -independence.

► **Definition 17.** *A probability distribution  $\pi$  on  $2^V$  is  $C$ - $\ell_\infty$ -independent (for  $C \geq 0$ ) if*

$$\|M_\pi\|_\infty := \max_{u \in V} \sum_{v \in V} |M_\pi[u, v]|$$

*is at most  $C$ .*

► **Remark 18.** There are various definitions of the pairwise influence matrix in the literature [2, 15, 17]. For spin systems with two possible states for each vertex (such as the Ising model), pairwise influence is commonly defined as  $M_\pi[u, v] = \pi(v | u) - \pi(v | \bar{u})$ . However, note that switching between the two definitions only changes the spectral radius by some constant factor, provided that  $\pi(v)$  is uniformly bounded away from 0 and 1. Since this is the case for the Ising model, given that  $\lambda > 0$ , existing spectral independence results such as [17] carry over to our definition. Moreover, Definition 15 is arguably more natural for canonical ensembles, such as the fixed-magnetization Ising model, as it relates more directly to local spectral expansion of the associated simplicial complex (see [36] for details).

There are different ways to derive bounds on the spectral gap of a Markov chain from spectral independence. The most popular approach is the use of *local-to-global theorems*, which are applicable whenever the Markov chain in question can be represented as a down-up walk on a suitable weighted simplicial complex [1, 2, 15, 17]. Local-to-global theorems allow us to express the spectral gap of the down-up walk in terms of spectral gaps of local walks on the complex, which can then be related to the spectrum of the pairwise influence matrix.

A more recent framework was introduced by Chen and Eldan [14] and uses *localization schemes*. A localization scheme maps a probability distribution  $\pi$  on  $\Omega$  to a localization process – a random sequence of probability measures that interpolates between  $\pi$  and a random Dirac measure. Via the localization process, a localization scheme gives rise to a Markov chain with stationary distribution  $\pi$ . Provided that the localization process exhibits a property called “approximate conservation of variance,” this can be used to bound the spectral gap of the associated Markov chain. For a broad class of localization schemes, approximate conservation of variance follows if all measures along the localization process exhibit spectral independence. Since we are studying the fixed-magnetization Ising model, we

are particularly concerned with distributions  $\pi$  on  $\Omega_k$ . In this setting, the canonical choice for a localization scheme is the subset simplicial-complex localization (see [14, Example 5]), and the natural associated Markov chain is the down-up walk  $\mathcal{P}_{\beta,k}$ .

The main difficulty in applying the above frameworks in our setting is that they usually assume  $O(1)$ -spectral independence of the pinned distributions  $\hat{\mu}_{\beta,k}^U$  for all  $U \subset V$  with  $0 \leq |U| \leq k - 1$ . Unfortunately, we will not be able to derive spectral independence for all such  $U$ . Moreover, for the localization framework, it is not clear if the subset simplicial-complex localization allows us to derive approximate conservation of variance from spectral independence. To overcome these difficulties, we use an argument similar to that of Jain, Michelen, Pham and Vuong [33]. We combine the techniques above as follows: first, we use a localization scheme to show that for any  $\ell \leq k - 1$ , the spectral gap of  $\mathcal{P}_{\beta,k}$  is bounded below by the product of the spectral gap of the pinned down-up walk  $\mathcal{P}_{\beta,k}^U$  for any  $U \subset V$  with  $|U| = \ell$  and the spectral gap of the  $(k, \ell)$ -down-up walk, a modified version of  $\mathcal{P}_{\beta,k}$  that resamples  $k - \ell$  plus spins in each step. Choosing  $\ell$  such that  $k - \ell \leq \alpha n$  for some suitable  $\alpha > 0$ , we can use a coupling argument as discussed before to show that  $\text{gap}(\mathcal{P}_{\beta,k}^U) \in \Omega(1/k)$  for every  $U \subset V$  with  $|U| = \ell$ . To lower-bound the spectral gap of the  $(k, \ell)$ -down-up walk, we use a local-to-global theorem by Chen, Liu and Vigoda [15]. This only requires us to show that  $\hat{\mu}_{\beta,k}^W$  satisfies  $O(1)$ -spectral independence for all  $W \subset V$  with  $k - |W| \geq \alpha' n$  for some  $0 < \alpha' < \alpha$ . The range of  $k$  for which we can show this  $O(1)$ -spectral independence leads to the magnetization range given in Theorem 1,(1).

### 2.4.2 Lower Bounds on Mixing Time

To prove slow mixing, we exhibit the existence of a bottleneck in the state space, a set of configurations which separates two parts of the state space and carries an exponentially smaller probability in the stationary distribution than either of the two parts. The following lemma captures a simple form of this argument, often phrased in terms of *conductance*, for proving lower bounds on the mixing times of Markov chains.

► **Lemma 19.** *Let  $(X_t)_{t \geq 0}$  be a Markov chain on the state space  $\Omega$  with stationary distribution  $\pi$ . Suppose there exists disjoint sets  $S_1, S_2, S_3 \subset \Omega$  so that the following hold:*

- *For the chain to pass from  $S_2$  to  $S_1$  it must pass through  $S_3$ ;*
- $\pi(S_1) \geq \pi(S_2)$
- $\pi(S_3) \leq e^{-\Omega(n)} \pi(S_2)$ .

*Then the mixing time of the chain  $(X_t)$  is  $\exp(\Omega(n))$ .*

The statement is an immediate corollary of, e.g., [25, Claim 2.3].

To prove Theorem 2, we define  $S_1, S_2, S_3$  to be sets of configurations with certain magnetizations.  $S_1$  will be those configurations whose magnetization per vertex is close to that of the plus measure on  $\mathbb{T}_\Delta$  (when  $\lambda > 1$ );  $S_2$  will be those whose magnetization per vertex is close to that of the minus measure; and  $S_3$  will be configurations whose magnetization is just larger than that of  $S_2$ .

To prove Theorem 1,(2), we consider a graph  $H$  made up of disjoint copies of a random regular graph. We define  $S_1$  to be the set of configurations with magnetization  $\eta$  on each copy;  $S_2$  will be a set of configurations with magnetization  $\eta_+$  on some copies and  $\eta_-$  on others, for  $\eta_- < \eta < \eta_+$ , such that the overall magnetization is  $\eta$ . Again  $S_3$  will be a neighborhood of  $S_2$ . In both cases, the main work will be in verifying the conditions of Lemma 19.

### 2.5 Thresholds for Zero-Freeness and Spectral Independence

The definition of  $\lambda_a(\Delta, \beta)$  is based on viewing the Ising partition function as a polynomial in the (complex) variable  $\lambda$ . We write  $\mathcal{N}(z, \delta)$  for the open ball of radius  $\delta > 0$  around  $z \in \mathbb{C}$ .

► **Definition 20** (Absolute zero-freeness). *Given  $\beta \geq 0$ ,  $\Delta \in \mathbb{N}$ ,  $\lambda > 0$  and  $\delta > 0$ , we say that the Ising model is absolutely  $\delta$ -zero-free at activity  $\lambda$  if for all graphs  $G \in \mathcal{G}_\Delta$ , all pinnings  $\tau_U$  with  $U \subseteq V$  and all  $\lambda' \in \mathcal{N}(\lambda, \delta)$  it holds that  $Z_G^{\tau_U}(\beta, \lambda') \neq 0$ .*

We now define  $\lambda_a(\Delta, \beta)$  as follows.

► **Definition 21.** *For  $\Delta \in \mathbb{N}$  and  $\beta \geq \beta_u(\Delta)$  we set  $\lambda_a(\Delta, \beta)$  to be the smallest  $\lambda_a \geq 1$  such that for every compact set  $D \subset (\lambda_a, \infty)$  there is some  $\delta > 0$  such that for all  $\lambda \in D$  the Ising model is absolutely  $\delta$ -zero-free at  $\lambda$ .*

An important implication of absolute zero-freeness is given in the following theorem. Its proof follows a similar argument to those in [16] while using the ferromagnetism of the model and Montel’s theorem (see [49]) to avoid the requirement of multivariate zero-freeness. The proof can be found in the full version of the paper [36].

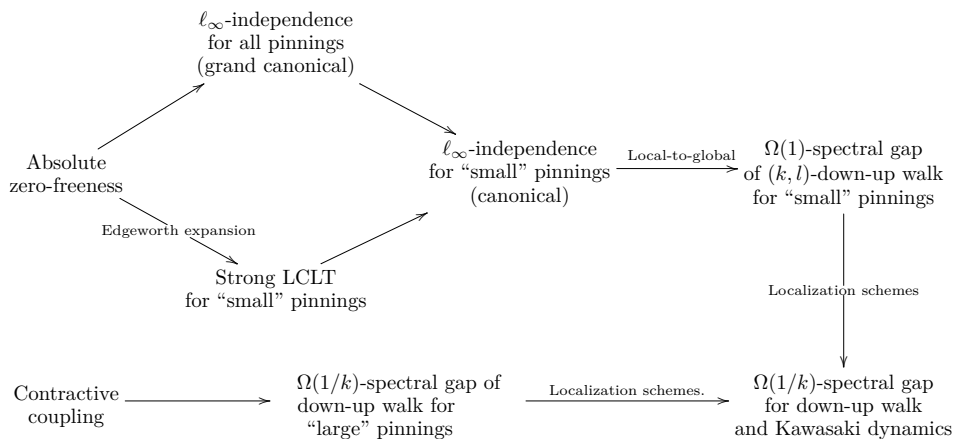

► **Theorem 22.** *Fix  $\beta \geq 0$  and  $\Delta \in \mathbb{N}$ . Let  $D \subset \mathbb{R}_{>0}$  be compact and assume there is some  $\delta > 0$  such that the ferromagnetic Ising model is absolutely  $\delta$ -zero-free at every  $\lambda \in D$ . Then, there is some constant  $C > 0$ , only depending on  $D$ ,  $\lambda$ ,  $\beta$  and  $\Delta$ , such that for all  $\lambda \in D$ ,  $G \in \mathcal{G}_\Delta$  and all pinnings  $\tau_U$  it holds that  $\hat{\mu}_{G, \beta, \lambda}^{\tau_U}$  is  $C$ - $\ell_\infty$ -independent.*

## 3 Main Statements and Proof Structure

We briefly state the most important steps for showing Theorem 1. All proofs and intermediate steps are omitted and can be found in the full version of the paper [36].

### 3.1 Rapid Mixing

We start with discussing our proof of the rapid mixing result in part (1) of Theorem 1. The structure of the entire proof is illustrated in Figure 3.

■ **Figure 3** The structure of the rapid mixing proof.

All results in this subsection are given in the context of the following assumptions.

► **Condition 23.**

1. Let  $\beta \geq 0$ , and let  $D \subset \mathbb{R}_{>0}$  be compact such that there is some  $\delta > 0$  for which the Ising model is absolutely  $\delta$ -zero-free for all  $\lambda \in D$ . Further, let  $\lambda \in D$ .
2. Let  $\alpha \in [0, 1)$ , let  $U \subset V$  with  $|U| \leq \alpha n$  and let  $\tau_U$  be a pinning of  $U$ .
3. Let  $\sigma \sim \mu_{\beta, \lambda}^{\tau_U}$  and let  $X = |\sigma|^+$ .

Our first step is to show that zero-freeness implies a strengthened version of a local central limit theorem for  $X$  via Edgeworth expansion. Using similar arguments as Jain, Michelen, Pham and Vuong [33] for the hard-core model, we obtain the following result.

► **Theorem 24.** *Suppose Condition 23 holds. Let  $d \in \mathbb{N}$  and let  $\ell \in \mathbb{R}$  such that  $\mathbb{E}[X] + \ell \in \mathbb{Z}_{\geq 0}$ . Set  $s = \sqrt{\text{Var}(X)}$  and  $\beta_j = \frac{\kappa_j(X)}{j!s^j}$  for all  $j \in \mathbb{N}$ , and write  $H_k(\cdot)$  for the  $k^{\text{th}}$  Hermite polynomial. It holds that*

$$\mu_{\beta, \lambda}^{\tau_U}(X - \mathbb{E}[X] = \ell) = \frac{e^{-\frac{\ell^2}{2s^2}}}{\sqrt{2\pi s}} \left( 1 + \sum_{r \geq 3} H_r(\ell/s) \sum_{k_3, \dots, k_{2d+1}} \prod_{j=3}^{2d+1} \frac{\beta_j^{k_j}}{k_j!} \right) + O(n^{-d})$$

where the inner sum is over tuples  $k_3, \dots, k_{2d+1} \in \mathbb{Z}_{\geq 0}$  such that  $\sum_j k_j \cdot j = r$  and  $\sum_j k_j \cdot \frac{j-2}{2} \leq d$ , and the implied constants depend only on  $\Delta, \beta, \delta, D, d$  and  $\alpha$ .

Our next ingredient is to use zero-freeness to obtain a stability result for the cumulants of  $X$  under adding vertices to the pinning. Writing  $\kappa_j(X)$  for the  $j$ th cumulant of  $X$ , we have the following statement.

► **Lemma 25.** *Suppose Condition 23 holds. Let  $v \in V \setminus U$ , and let  $\tau_U, +_v$  denote the pinning on  $U \cup \{v\}$  that maps  $v$  to  $+1$  and all other vertices  $u \in U$  to  $\tau_U(u)$ . Let  $X^+ = |\sigma'|^+$  for  $\sigma' \sim \mu_{\beta, \lambda}^{\tau_U, +_v}$ . For all  $j \in \mathbb{N}$  it holds that  $|\kappa_j(X^+) - \kappa_j(X)| = O(1)$  with implied constants only depending on  $\Delta, \beta, \delta, D$  and  $j$ .*

The analog of Lemma 25 for the hard-core model was proven in [33]. However, their arguments are tailored to the hard-core model and do not apply in our setting. Instead, we provide a more general argument based on an application of Montel’s theorem that is inspired by [43].

Using Theorem 24 and Lemma 25, we get the following stability result for the probability of having exactly  $k$  vertices assigned to  $+1$ .

► **Lemma 26.** *Suppose Condition 23 holds and assume further that  $|U| + 1 \leq \alpha n$ . Let  $k \in \mathbb{Z}_{\geq 0}$  be such that  $|\mathbb{E}[X] - k| \leq L$  for some  $L \in \mathbb{R}_{\geq 0}$ . For all  $v \in V \setminus U$  it holds that*

$$\mu_{\beta, \lambda}^{\tau_U}(X = k) = \Theta(n^{-1/2}), \tag{3}$$

$$\left| \mu_{\beta, \lambda}^{\tau_U}(X = k) - \mu_{\beta, \lambda}^{\tau_U}(X = k \mid \sigma(v) = +1) \right| = O(n^{-3/2}) \tag{4}$$

with implied constants depending only on  $\Delta, \beta, \delta, D, L$  and  $\alpha$ .

Next, recall that by Theorem 22 zero-freeness implies  $\ell_\infty$ -independence for the ferromagnetic Ising model. Combining this with Lemma 26 for a suitable  $\lambda$ , we get the following  $\ell_\infty$ -independence result for the fixed magnetization model.

► **Theorem 27.** *Assume  $0 \leq \beta < \beta_u(\Delta)$  and  $\gamma \in (0, 1/2]$ , or  $\beta \geq \beta_u(\Delta)$  and  $\gamma \in (0, \frac{1-\eta_a}{2})$  for  $\eta_a = \eta_a(\Delta, \beta)$ . For all  $k := \gamma n \in \mathbb{N}$ , all  $\alpha \in [0, \gamma)$  and  $U \subset V$  with  $|U| \leq \alpha n$  it holds that  $\hat{\mu}_{\beta, k}^U$  is  $C$ - $\ell_\infty$ -independent for a constant  $C$  depending only on  $\Delta, \beta, \gamma$  and  $\alpha$ .*

Using Theorem 27, we can apply a local-to-global theorem from [15] to show that for every  $k - \ell \in \Theta(n)$  the spectral gap of the  $(k, \ell)$ -down-up walk is in  $\Omega(1)$ . However, to get the desired spectral gap for  $\mathcal{P}_{\beta,k}$  (and  $\mathcal{K}_{\beta,k}$ ), we require one last ingredient, which is to show that the spectral gap of the pinned down-up walk  $\mathcal{P}_{\beta,k}^U$  is in  $\Omega(1/n)$  whenever  $k = \gamma n$  and  $U \subset V$  are such that  $k - |U|$  is small enough.

In the setting of fixed-size independent sets studied in [33], such a result was previously known due to Theorem 14 and a path coupling by Buble and Dyer [7]. In contrast, a straightforward application of path coupling with the Hamming metric does not work in our setting. Instead, we introduce a modified metric on the state space that takes into account how likely a disagreement is to spread, which allows us to prove the following result.

► **Lemma 28.** *Let  $G \in \mathcal{G}_\Delta$  with  $n$  sufficiently large. There exists some  $\alpha = \alpha(\Delta, \beta) > 0$  such that for all  $0 < k \leq n/2$  and all  $U \subset V$  with  $0 < k - |U| \leq \alpha n$  it holds that  $\mathcal{P}_{\beta,k}^U$  has spectral gap  $\Omega(1/k)$  with constants depending on  $\beta$  and  $\Delta$ .*

We can now proceed to sketch our proof of the rapid mixing part of Theorem 1. We first note that the Kawasaki dynamics Markov chain is invariant under swapping all spins (i.e. the mapping  $\sigma \mapsto -\sigma$ ), allowing us to focus on  $k \leq n/2$  (or equivalently the magnetization regime  $\eta \leq 0$ ). Moreover, by Observation 9 it suffices to prove the desired spectral gap for the down-up walk  $\mathcal{P}_{\beta,k}$  for the respective values of  $k$ . Using a localization scheme, we argue that the spectral gap of  $\mathcal{P}_{\beta,k}$  is bounded below by the product of  $\inf_{U \in \binom{V}{\ell}} \text{gap}(\mathcal{P}_{\beta,k}^U)$  and the spectral gap of the  $(k, \ell)$ -down-up walk. By Lemma 28, we know that  $\inf_{U \in \binom{V}{\ell}} \text{gap}(\mathcal{P}_{\beta,k}^U) \in \Omega(1/k)$  whenever  $\ell$  is such that  $k - \ell \leq \alpha n$  for some  $\alpha = \alpha(\Delta, \beta) > 0$ . Moreover, by Theorem 27 and a local-to-global theorem from [15], we can derive a  $\Omega(1)$  spectral gap for the  $(k, \ell)$ -down-up walk. Combining both concludes our rapid mixing proof.

### 3.2 Metastability and Slow Mixing

In this section we prove slow-mixing results for both the Ising Glauber dynamics and fixed magnetization Kawasaki dynamics when  $\beta > \beta_u(\Delta)$  and  $|\log \lambda| < \log \lambda_u$  and  $|\eta| < \eta_u$  respectively. The structure of the proof is illustrated below in Figure 4.

■ **Figure 4** The structure of the slow mixing proof.

**Note.** As in the previous section, both perspectives of fixed magnetization per vertex  $\eta$  and fixed size  $k$  will be useful in our arguments. We will use  $Z_{G,\eta}(\beta, \lambda)$  (where we sometimes drop the parameters  $\beta$  and  $\lambda$  for convenience) to denote the contribution to the Ising model partition function  $Z_G(\beta, \lambda)$  from configurations of magnetization  $\eta$ . The notation  $Z_{G,k}(\beta, \lambda)$  will mean the contributions to  $Z_G(\beta, \lambda)$  from configurations of size  $k$ . When  $k = \lfloor n^{\frac{\eta+1}{2}} \rfloor$ , we have  $Z_{G,\eta} = Z_{G,k}$  and will use the notations interchangeably.

Our goal is to understand how configurations of different magnetizations typically contribute to the partition function  $Z_G(\beta, \lambda)$  when  $G$  is a random  $\Delta$ -regular graph. To start, we shift to a slightly different model called the *configuration model*, which we will denote  $\mathbf{G}$ . To generate a graph from this model for a given  $\Delta$  and  $n$ , take  $\Delta$  copies of  $[n]$  and a uniformly random perfect matching on the  $\Delta n$  vertices, and then identify the copies corresponding to the same vertex. This gives a random  $\Delta$ -regular multigraph, and it is well-known that properties holding with high probability for the configuration model also hold with high probability for the uniform random  $\Delta$ -regular graph when  $\Delta$  is constant [34].

We say the model has multiple *metastable states* if the function  $\lim_{n \rightarrow \infty} \frac{1}{n} \mathbb{E} \log Z_{G,\eta}(\beta, \lambda)$  has more than one local maximum as  $\eta$  varies. A first attempt at understanding this phenomenon would be to look at the first moment, and understand the local maxima of

$$f_{\Delta,\beta,\lambda}(\eta) := \lim_{n \rightarrow \infty} \frac{1}{n} \log \mathbb{E} Z_{G,\eta}(\beta, \lambda) \tag{5}$$

as a function of  $\eta$  (with the crucial distinction between the two functions being the interchange of the expectation and logarithm).

Using computations similar to those found in [18, 19, 29], we can derive an expression for  $f_{\Delta,\beta,\lambda}(\eta)$ . We then proceed by studying the the maxima of  $f_{\Delta,\beta,\lambda}(\eta)$  as a one-variable function with respect to  $\eta$ . By a result in [29] (following [27, 41]), we know that the critical points of  $f_{\Delta,\beta,\lambda}(\eta)$  correspond exactly to fixed points of the *tree recursion* for the Ising model on  $\mathbb{T}_\Delta$ , which are the solutions to the equation

$$R = \frac{\lambda(Re^\beta + 1)^{\Delta-1}}{(R + e^\beta)^{\Delta-1}}. \tag{6}$$

► **Theorem 29** ([29, Theorem 9, Lemma 11]). *There is a 1-to-1 correspondence between the fixed points of the tree recursion given in (6) and the critical points of  $f_{\Delta,\beta,\lambda}(\eta)$ . Moreover, the stable fixed points of the tree recursion given in (6) are in 1-to-1 correspondence with Hessian local maxima of  $f_{\Delta,\beta,\lambda}(\eta)$ .*

Recall that a fixed point is *stable* if the absolute value of the derivative at that point is less than 1. A local maximum is a *Hessian local maximum* if the Hessian is negative definite at that point. In particular, as our functions are univariate (after fixing  $\Delta, \beta, \lambda$ ), this is simply saying that the second derivative is negative which implies the existence of a local maximum.

For the above theorem to be useful, we need to understand the solutions of (6).

► **Proposition 30.** *For  $\beta > \beta_u$ , the following hold:*

- (1) *If  $|\log \lambda| > \log \lambda_u$ , then (6) has a unique fixed point. It is stable and hence corresponds to the global maximizer of  $f_{\Delta,\beta,\lambda}$ . This maximizer is  $\eta_{\Delta,\beta,\lambda}^+ = \eta_{\Delta,\beta,\lambda}^-$ .*
- (2) *If  $|\log \lambda| = \log \lambda_u$ , then (6) has two distinct fixed points, one of which is stable and corresponds to the global maximizer of  $f_{\Delta,\beta,\lambda}$ . The other corresponds to an inflection point of  $f_{\Delta,\beta,\lambda}$ .*
- (3) *If  $|\log \lambda| < \log \lambda_u$ , then (6) has three distinct fixed points. The largest and the smallest are both stable, corresponding to the only two local maxima of  $f_{\Delta,\beta,\lambda}$ . When  $\lambda > 1$ ,  $\eta_{\Delta,\beta,\lambda}^+$  is the unique global maximizer; when  $\lambda < 1$ ,  $\eta_{\Delta,\beta,\lambda}^-$  is the unique global maximizer; when  $\lambda = 1$  then  $\eta_{\Delta,\beta,\lambda}^+, \eta_{\Delta,\beta,\lambda}^-$  are both global maximizers.*

Portions of this statement have been shown in, for example, [29, 30, 32], and we give a complete proof in [36]. An illustration of  $f_{\Delta,\beta,\lambda}(\eta)$  is given in Figure 5; the left plot appears for  $\lambda > \lambda_u$  (Case 1 above) and the right plot appears for  $1 < \lambda < \lambda_u$  (Case 3 above).

■ **Figure 5** Sketch of the function  $f_{\Delta,\beta,\lambda}(\eta)$  for  $\Delta = 4$ ,  $\beta = \ln(2) + 0.1$ , and (left)  $\lambda = 1.08$ , (right)  $\lambda = 1.01$ .

While the behavior described in part (3) suggests metastability, Proposition 30 is only about the expected partition function, and we will need to show that multiple local maxima exist with high probability over the random graph. This will involve showing a lower bound on the partition function at the two local maxima and an upper bound everywhere else.

Via Markov's inequality, the next statement gives a high probability approximate upper bound on  $Z_{G,\eta}(\lambda)$ .

► **Lemma 31.** *Fix  $\beta \geq 0, \lambda > 0$ . With probability  $1 - o(1)$  over the random  $\Delta$ -regular graph  $G$  on  $n$  vertices, it holds for every  $\eta$  that*

$$Z_{G,\eta}(\lambda) \leq n^2 \cdot \mathbb{E}Z_{G,\eta}(\lambda).$$

We further prove lower bounds on  $Z_{G,\eta}$  for values of  $\eta$  which are local maxima. For a global maximum, this was proved in [29] via the second moment method.

► **Theorem 32** ([29, Theorem 8]). *Fix  $\lambda > 0$  and suppose that  $\eta$  is a global maximizer of  $f_{\Delta,\beta,\lambda}$ . With probability  $1 - o(1)$  over the random  $\Delta$ -regular graph  $G$  on  $n$  vertices,*

$$Z_{G,\eta}(\lambda) \geq \frac{1}{n} \mathbb{E}Z_{G,\eta}(\lambda).$$

We prove the following corresponding statement for the local maximizers.

► **Proposition 33.** *Fix  $\lambda > 0$  and suppose that  $\eta$  is a local maximizer of  $f_{\Delta,\beta,\lambda}$ . For any  $\zeta > 0$ , with probability  $1 - o(1)$  over the random  $\Delta$ -regular graph  $G$  on  $n$  vertices,*

$$Z_{G,\eta}(\lambda) \geq e^{-\zeta n} \mathbb{E}[Z_{G,\eta}(\lambda)].$$

The proof of Proposition 33 follows the template of Coja-Oghlan, Galanis, Goldberg, Ravelomanana, Štefankovič, and Vigoda [19] in proving metastability in the zero-field ferromagnetic Potts model (which in turn used ideas from [3,21]). The argument involves various techniques such as studying the *planted model*, *Nishimori identities* [20], and *non-reconstruction of broadcasting processes* [19,29,39], and it is presented in the full paper [36]. We can now sketch the proofs of our slow mixing results.

### Slow mixing of Glauber Dynamics

We start with sketching our proof of Theorem 2. Let  $\beta > \beta_u(\Delta)$ ,  $\lambda \in [1, \lambda_u)$ , and  $G \sim \mathbf{G}$ . Let  $\eta = \eta_{\Delta,\beta,\lambda}^+$ , the mean magnetization of the root of  $\mathbb{T}_\Delta$  under the  $+$  boundary conditions with external field  $\lambda$ , and let  $\eta_- = \eta_{\Delta,\beta,\lambda}^-$ , the same but under the  $-$  boundary conditions.

As  $\eta$  and  $\eta_-$  are global and local maximizers of  $f_{\Delta,\beta,\lambda}$ , there are  $\epsilon > 0$  and  $\delta > 0$  so that:

1.  $\mathbb{E}[Z_{G,\eta'}(\lambda)] \leq e^{-\delta n} \mathbb{E}[Z_{G,\eta}(\lambda)]$  for all  $\eta'$  such that  $|\eta' - \eta| > \epsilon$ .
2.  $\mathbb{E}[Z_{G,\eta'}(\lambda)] \leq e^{-\delta n} \mathbb{E}[Z_{G,\eta_-}(\lambda)]$  for all  $\eta'$  such that  $|\eta' - \eta_-| \in (\epsilon, 2\epsilon)$ .

Next, we sketch how we construct the configuration sets  $S_1, S_2, S_3$  for applying Lemma 19, where we assume here for simplicity that the magnetization  $\eta$  can actually be realized on  $G$ . For  $\epsilon > 0$  as above, we set:

$S_1$ : configurations with magnetization  $\eta$

$S_2$ : configurations with magnetization in  $[\eta_- - \epsilon, \eta_- + \epsilon]$

$S_3$ : configurations with magnetization in  $[\eta_- - 2\epsilon, \eta_- - \epsilon] \cup (\eta_- + \epsilon, \eta_- + 2\epsilon]$ .

First, note that the Glauber dynamics starting in  $S_2$  must pass through  $S_3$  to reach  $S_1$ . Abbreviating  $\mu_{G,\beta,\lambda}$  as  $\mu$ , we can use Lemma 31, Theorem 32 and Property 1 from above to show that  $\mu(S_2) < \mu(S_1)$  a.a.s. over  $G$ . Similarly, using Proposition 30, Property 2 and Proposition 33 yields  $\mu(S_3) \leq e^{-\Omega(n)} \mu(S_2)$  a.a.s. Hence, applying Lemma 19, we conclude that the mixing time of Glauber dynamics on  $G$  is  $\exp(\Omega(n))$ .

### Slow Mixing of the Kawasaki Dynamics

We proceed with sketching the proof of part (2) of Theorem 1. Let  $\beta > \beta_u(\Delta)$ . We consider a graph  $H$  consisting of  $m$  identical copies  $G_1, G_2, \dots, G_m$  of a random  $\Delta$ -regular graph  $G$  from  $\mathbf{G}$ , where  $m$  is determined later based on  $\eta$ . We will separately consider the cases of  $|\eta| \in (\eta_c, \eta_u)$  and  $|\eta| \leq \eta_c$ , and assume without loss of generality that  $\eta > 0$ .

We start with the case  $\eta \in (\eta_c, \eta_u)$ . By Proposition 5, there exists  $\lambda_\eta \in (1, \lambda_u)$  such that  $\eta = \eta_{\Delta,\beta,\lambda_\eta}^+$ . For  $\lambda_+ \in (\lambda_\eta, \lambda_u)$ , set  $\eta_+ = \eta_{\Delta,\beta,\lambda_+}^+$  and  $\eta_- = \eta_{\Delta,\beta,\lambda_+}^-$ . In particular, note that we may choose  $\lambda_+$  such that there are  $m, \ell \in \mathbb{N}$  with  $\ell < m$  and  $m\eta = \ell\eta_+ + (m - \ell)\eta_-$ , where  $m$  is used for constructing  $H$ . Further, observe that  $\eta$  is the global maximizer of  $f_{\Delta,\beta,\lambda_\eta}$  and that  $\eta_+$  and  $\eta_-$  are the global and local maximizers of  $f_{\Delta,\beta,\lambda_+}$ . Hence, there are  $\epsilon > 0$  and  $\delta > 0$  so that:

1.  $\mathbb{E}[Z_{G,\eta'}(\lambda_\eta)] \leq e^{-\delta n} \mathbb{E}[Z_{G,\eta}(\lambda_\eta)]$  for all  $\eta'$  such that  $|\eta' - \eta| > \epsilon$ .
2.  $\mathbb{E}[Z_{G,\eta'}(\lambda_+)] \leq e^{-\delta n} \mathbb{E}[Z_{G,\eta_+}(\lambda_+)]$  for all  $\eta'$  such that  $|\eta' - \eta_+| \in (\epsilon, 2\epsilon)$ .
3.  $\mathbb{E}[Z_{G,\eta'}(\lambda_+)] \leq e^{-\delta n} \mathbb{E}[Z_{G,\eta_-}(\lambda_+)]$  for all  $\eta'$  such that  $|\eta' - \eta_-| \in (\epsilon, 2\epsilon)$ .

As for proving slow mixing of Glauber dynamics, we aim for applying Lemma 19. To sketch the construction of  $S_1, S_2, S_3$ , we again assume here for simplicity that a magnetization of  $\eta$  can be realized on each subgraph  $G_i$ . Given a configuration, we write  $\eta_{G_i}$  for the magnetization on subgraph  $G_i$ . We then take the following subsets of configurations on  $H$  with overall magnetization  $\eta$ :

$S_1$ :  $\eta_{G_i} = \eta$  for all  $1 \leq i \leq m$ ,

$S_2$ :  $\eta_{G_i} \in [\eta_+ - \epsilon, \eta_+ + \epsilon]$  for all  $i \leq \ell$  and  $\eta_{G_i} \in [\eta_- - \epsilon, \eta_- + \epsilon]$  for all  $i > \ell$ ,

$S_3$ :  $\eta_{G_i} \in [\eta_+ - 2\epsilon, \eta_+ + \epsilon]$  for all  $i \leq \ell$  and  $\eta_{G_i} \in [\eta_- - \epsilon, \eta_- + 2\epsilon]$  for all  $i > \ell$ , and there exists  $i \leq \ell$  with  $\eta_{G_i} \in [\eta_+ - 2\epsilon, \eta_+ - \epsilon]$  or  $i > \ell$  with  $\eta_{G_i} \in [\eta_- + \epsilon, \eta_- + 2\epsilon]$ .

Note that the Kawasaki dynamics have to pass through  $S_3$  to get from  $S_2$  to  $S_1$ . Moreover, abbreviating  $\hat{\mu}_{H,\beta,k}$  as  $\hat{\mu}$ , we can use Theorem 32, Lemma 31 and Property 1 to show that  $\hat{\mu}(S_1) \geq \hat{\mu}(S_2)$ , and we can use Lemma 31, Properties 2 and 3, Theorem 32 and Proposition 33 to show that  $\hat{\mu}(S_3) \leq e^{-\Theta(n)} \hat{\mu}(S_2)$  a.s. Hence, applying Lemma 19, we conclude that the mixing time of Kawasaki dynamics on  $H$  is  $\exp(\Omega(n))$ .

In the case that  $0 < \eta \leq \eta_c$ , we require a slightly different argument since we cannot apply Proposition 5 to  $\eta$ . Instead, we argue that for all  $\eta \in (0, \eta_c]$  we can choose  $\delta' > 0$  sufficiently small such that for all  $\eta_+ \in (\eta_c, \eta_c + \delta')$  and  $\eta_- = \eta_{\Delta, \beta, \lambda_{\eta_+}}^-$  it holds that  $\eta_- < \eta < \eta_+$ . In particular, we may choose  $\eta_+$  such that  $m\eta = \ell\eta_+ + (m - \ell)\eta_-$  for some  $m, \ell \in \mathbb{N}, \ell < m$ . We then define  $S_1, S_2, S_3$  (again with some slight simplification here) by

$$\begin{aligned} S_1: \eta_{G_i} &\in [\eta_- - \epsilon, \eta_- + \epsilon] \text{ for all } i \leq m - \ell \text{ and } \eta_{G_i} \in [\eta_+ - \epsilon, \eta_+ + \epsilon] \text{ else,} \\ S_2: \eta_{G_i} &\in [\eta_+ - \epsilon, \eta_+ + \epsilon] \text{ for all } i \leq \ell \text{ and } \eta_{G_i} \in [\eta_- - \epsilon, \eta_- + \epsilon] \text{ else,} \\ S_3: \eta_{G_i} &\in [\eta_+ - 2\epsilon, \eta_+ + \epsilon] \text{ for all } i \leq \ell \text{ and } \eta_{G_i} \in [\eta_- - \epsilon, \eta_- + 2\epsilon] \text{ else, and there} \\ &\text{exists } i \leq \ell \text{ with } \eta_{G_i} \in [\eta_+ - 2\epsilon, \eta_+ - \epsilon] \text{ or } i > \ell \text{ with } \eta_{G_i} \in [\eta_- + \epsilon, \eta_- + 2\epsilon]. \end{aligned}$$

By symmetry, we have  $\hat{\mu}(S_1) = \hat{\mu}(S_2)$  and by the same arguments as before it holds that  $\hat{\mu}(S_3) \leq e^{-\Theta(n)} \hat{\mu}(S_2)$ . Applying Lemma 19 then gives the desired result.

## Abstract

We introduce a novel concept termed “stochastic distance” for property testing. Diverging from the traditional definition of distance, where a distance  $t$  implies that there exist  $t$  edges that can be added to ensure a graph possesses a certain property (such as  $k$ -edge-connectivity), our new notion implies that there is a *high probability* that adding  $t$  *random* edges will endow the graph with the desired property. While formulating testers based on this new distance proves challenging in a sequential environment, it is much easier in a distributed setting. Taking  $k$ -edge-connectivity as a case study, we design ultra-fast testing algorithms in the CONGEST model. Our introduction of stochastic distance offers a more natural fit for the distributed setting, providing a promising avenue for future research in emerging models of computation.

## 1 Introduction

Property testing has become a major focus in computational research over the years. One of the main goals in this field is to quickly determine if a given structure has a specific property or is far from having it. Traditionally, this “distance” from a property has been defined using the Hamming distance, which counts the number of changes needed to give the structure the desired property. But a question arises: Is this the best way to measure distance in all situations, especially in emerging models of computation?

Consider the following motivating example. Distributed dynamic systems, such as peer-to-peer networks, frequently experience changes in their structure as nodes (clients) join or depart and edges may experience failures. For the sake of resilience against failures, it is imperative for these systems to maintain a topology with certain advantageous features, like  $k$ -edge-connectivity<sup>1</sup>. However, maintaining this throughout the evolution of the network

---

<sup>1</sup> Going forward we simply write  $k$ -connectivity.

may require resource-intensive corrections, which ideally should be minimized. Still, it might be the case that some topologies are “easy” to correct, in the sense that simply adding a small number of random edges to the graph will make the network topology  $k$ -connected. This can be seen as a “low-cost” fixing operation, compared to executing an elaborate algorithm that guarantees  $k$ -connectivity for *every* topology. A question arises: can we detect these easy-to-fix topologies *fast*?

We take a first step in addressing the above and introduce a new distance measure which we call *stochastic distance*. That is, we say that a graph  $G = (V, E)$  is  $t$ -stochastically-close to a property  $\mathcal{P}$  if it holds with high probability (w.h.p.)<sup>2</sup> that adding (roughly)  $t$  random edges to  $G$  will make it have property  $\mathcal{P}$ . Intuitively, the Hamming distance metric can be seen as asking whether the input graph is close to *at least one* graph instance that has a desired property, while our new distance measure asks whether the graph is close to *many instances* that have the property.

To exemplify the usefulness of our new distance measure, we take the property of  $k$ -connectivity as a case study. This is an extremely desirable graph property in the distributed setting, as it guarantees that the system remains connected even under several edge failures. In Section 3 we note that the simple case of connectivity already becomes hard to test in the sequential setting. However, using the distributed power of the system we can design extremely fast distributed testers for both connectivity and  $k$ -connectivity.

## 1.1 Our model and results

In the distributed setting, a network of nodes, which is represented by a communication graph  $G = (V, E)$ , aims to solve some graph problem with respect to  $G$ . Every node in  $G$  has unique ID of  $O(\log n)$  bits. Computation proceeds in synchronous rounds, in each of which every vertex can send a message to each of its neighbors. The running time of the algorithm is measured as the number of communication rounds it takes to finish. Our results hold for the CONGEST model of distributed computation, where messages are limited to  $O(\log n)$  bits (where  $n = |V|$ ).

A distributed 1-sided tester [5] for a property  $\mathcal{P}$  (or simply a tester) has the following guarantee. If the graph  $G$  has the property, then all nodes accept. If the graph is  $\epsilon$ -far from having the property, then with probability larger than  $2/3$  *at least* one node rejects. This definition remains the same for both the Hamming distance metric and our stochastic distance measure.

Note that  $\epsilon \in (0, 1)$  indicates the distance from the property relative to the number of edges in the graph (i.e.,  $\epsilon|E|$  in the general model) or to the possible number of edges in the graph (i.e.,  $\epsilon \binom{n}{2}$  in the dense model). In our model every non-edge is added with probability  $t/(\binom{n}{2} - |E|)$  (see Section 2 for an exact definition), therefore it is more natural to use  $t \in \mathbb{N}$  as the distance parameter rather than  $\epsilon$ . That is, our testers decide whether the graph has a certain property or if it is  $t$ -far from it. We state and prove the following two theorems<sup>3</sup>:

► **Theorem 1.** *There exists a deterministic algorithm in the CONGEST model, that for a parameter  $s \in \mathbb{N}$  runs in  $O(s)$  rounds and distinguishes whether the graph  $G$  is connected, or is  $\Omega((n \log n)/s)$ -stochastically-far.*

<sup>2</sup> With probability at least  $1 - n^{-c}$  for some constant  $c > 1$ . The choice of  $c$  does not affect the asymptotics of our results.

<sup>3</sup> Where  $\tilde{O}$  subsumes factors logarithmic in  $n$ .

► **Theorem 2.** *There exists a randomized algorithm in the CONGEST model, that for a parameter  $s \in \mathbb{N}$  runs in  $\tilde{O}(s^4)$  rounds and distinguishes w.h.p whether the graph  $G$  is  $k$ -connected, or is  $\Omega((kn \log n)/s)$ -stochastically-far from being one.*

Intuitively, the above states that the more random edges are added the easier it is to check if the graph will become  $k$ -connected or not. That is, if  $s \approx kn \log n$  then checking whether a constant number of random edges will make the graph  $k$ -connected is as hard as checking if the graph is connected, which requires traversing the entire graph. If  $s = O(1)$ , then so many edges are added that the graph almost surely becomes  $k$ -connected. Our results provide a smooth transition between these two cases.

## Related work

In (non-distributed) property testing, the objective is to devise algorithms that can distinguish between graphs satisfying a property  $\mathcal{P}$  and graphs that are  $\epsilon$ -far from having the property with a high probability. Testing connectivity properties in the bounded-degree model, where we have query access to the input graph via a list of incidence lists, has been extensively studied, including  $k$ -connectivity [13, 21, 17],  $k$ -vertex-connectivity [22, 17],  $(k, l)$ -sparsity [14] and supermodular-cut conditions [19].

The first distributed property testing algorithm was due to [3]. A thorough study of distributed property testing was initiated in [5]. This was followed by a long line of work, presenting new and improved testers for various properties [1, 9, 12, 11, 16, 10]. All of these works consider the Hamming distance handed down from the sequential testing model.

$k$ -connectivity received a large amount of attention in the distributed literature [20, 4, 8, 7, 6, 18, 2]. There is a large body of work that aims to find *sparse connectivity certificates* – for a  $k$ -connected graph the goal is to find a  $k$ -connected subgraph that has  $O(kn)$  edges. Another related problem is computing a  $k$ -edge-connected spanning subgraph ( $k$ -ECSS) – for a  $k$ -connected graph the goal is to find the *sparsest possible*  $k$ -connected subgraph. We note that both these problems assume that the input graph is  $k$ -connected, and are therefore inherently different than the problem we consider.

## 2 Preliminaries

### Distance from a property

We identify simple graphs  $G = (V = [n], E)$  with the  $\binom{n}{2}$ -dimensional characteristic vector of their edge set  $E \subseteq \binom{V}{2}$ , and use the Hamming metric over these vectors, defined by  $d_{\text{HAM}}(G, G') = \left| \{i \in \binom{V}{2} : G(i) \neq G'(i)\} \right|$ , where  $G(i)$  is the  $i^{\text{th}}$  entry in the vector  $G$ .

By extension, the distance of a graph  $G$  from a family of graphs  $\mathcal{G}$  is:

$$d_{\text{HAM}}(G, \mathcal{G}) = \min_{G' \in \mathcal{G}} d_{\text{HAM}}(G, G').$$

A property  $\mathcal{P}$  is formally a family of graphs (e.g., all connected graphs). Given positive integers  $n$  and  $t$ , we define the YES case of the corresponding testing problem to be all graphs  $G = (V, E)$  in  $\mathcal{P}$  over  $n$  vertices:

$$\text{YES} := \{G \in \{0, 1\}^{\binom{V}{2}} : G \in \mathcal{P}\}$$

We define the NO case, denoted  $\text{NO}'_t$ , to be all graphs  $G = (V, E)$  over  $n$  vertices with Hamming distance at least  $t$  from YES:

$$\text{NO}'_t := \{G \in \{0, 1\}^{\binom{V}{2}} : d_{\text{HAM}}(G, \text{YES}) \geq t\}$$

Motivated by connectivity, in the following we only consider monotone non-decreasing properties, for which it is easy to see that only additions count towards the distance from the property (note that many properties in the literature are monotone non-increasing instead. For these, one can replace additions with deletions). Formally, if  $\mathcal{P}$  is a monotone non-decreasing property, and  $G \notin \mathcal{P}$  is a graph that does not satisfy it, then for any  $H \in \mathcal{P}$  with  $d_{\text{HAM}}(G, H) = d_{\text{HAM}}(G, \mathcal{P})$ , we have  $E_G \subseteq E_H$  (or alternatively,  $d_{\text{HAM}}(G, H) = \left| \{i \in \binom{V}{2} : G(i) = 0 \wedge H(i) = 1\} \right|$ ).

### Stochastic distance

We define *stochastic closeness* to a property as follows:

► **Definition 3** (Random addition of edges). *For a graph  $G = (V, E)$ , we choose a random subset  $E'$  of the edge set  $\bar{E} = \binom{V}{2} \setminus E$ , by adding each edge with probability  $t/|\bar{E}|$  independently, for parameter  $t \in [0, |\bar{E}|]$ . We define the random graph  $\text{Add}(G, t) := (V, E \cup E')$ . We say that  $G' = \text{Add}(G, t)$  is created from  $G$  by a random addition of edges with parameter  $t$ .*

The parameter  $t$  should be understood intuitively as the (expected) number of random edges required to make the graph have the property  $\mathcal{P}$  w.h.p. Per our motivation, and in accordance with previous results for testing connectivity, we allow ourselves the mild assumption that  $|\bar{E}| = \Omega(n^2)$  which clearly holds for any input relevant to our setting. The amount of edges we aim to add, however, is always significantly smaller,  $t = o(n^2)$ . In particular it is always the case that  $t \leq |\bar{E}|$ , as desired.

► **Definition 4** (Stochastic closeness to a monotone property). *For a monotone property  $\mathcal{P}$ , a graph  $G \notin \mathcal{P}$  over  $n$  vertices is said to be  $t$ -stochastically-close to satisfying  $\mathcal{P}$  if the graph  $G' = \text{Add}(G, t)$  satisfies*

$$\Pr[G' \notin \mathcal{P}] \leq n^{-c}$$

for some global constant  $c > 1$ . As shown in Appendix A, the constant  $c$  can be chosen arbitrarily without affecting stochastic closeness by more than a constant factor.

We are now able to define the alternative set of NO instances:

$$\text{NO}_t := \{G \in \{0, 1\}^{\binom{V}{2}} : G \notin \text{YES and } G \text{ is not } t\text{-stochastically-close to } \mathcal{P}\}$$

In this text our main focus is solving promise problems of type  $(\text{YES}, \text{NO}_t)$ , rather than  $(\text{YES}, \text{NO}'_t)$ .

### Comparing the two notions of distance

As an illustrative example, consider two  $n$ -node graphs, both with exactly two connected components: in  $G_1$  a constant-size component is disconnected from the rest of the graph, while in  $G_2$  there are two components of the same size,  $n/2$ . While both graphs are exactly one edge away from being connected (i.e., both have hamming distance 1). The situation is quite different if edges are added randomly, instead of being handpicked, leading to different *stochastic* distance. While a small number of edges ( $\sim \log n$ ) are already likely to connect  $G_2$ , the same amount has only probability  $o(1)$  to connect  $G_1$ .

### 3 Warm-up: Connectivity with Stochastic Distance

In this section we deal with the graph connectivity property for a network that is not necessarily connected. This section aims to present the ideas used in the following section about  $k$ -connectivity. We use the following terminology: when a graph is disconnected, write  $G = \bigcup_{i=1}^m C_i$  as the unique decomposition of  $G$  into its connected components  $C_1, \dots, C_m$ , with  $C_i = (V_i, E_i)$ , and  $s_i := |V_i|$  for their sizes.

We make the following observation:

► **Observation 5.** *Let  $G = \bigcup_{i=1}^m C_i$  be a disconnected graph (i.e.,  $m \geq 2$ ), and let  $s = \frac{1}{m} \sum_{i \in [m]} s_i$ , then  $G$  is  $O(\frac{n}{s})$ -close to being connected in Hamming distance.*

Indeed, it holds that  $s = \frac{1}{m} \sum_{i \in [m]} s_i = n/m$ , which means that  $m = n/s$ . As a single edge can be used to connect two components, adding  $m - 1 = n/s - 1$  edges suffices to connect the graph.

The observation is also tight: there exist graphs that require exactly this number of additions. Joined with a Markovian argument, one can deduce that for any graph that is far from connectivity, there exists *many* small connected components. This is a key argument in the analysis of existing connectivity testers (using Hamming distance) [13].

The main part of this section deals with proving a statement of similar taste for stochastic distance. While the Hamming distance of a graph from being connected is dictated by the *average* size of a connected component, for stochastic distance this is dictated by the *minimum* size of a connected component. As a result, a graph that is far from being connected in stochastic distance is only guaranteed to have *one* small connected component. Formally, we prove the following lemma:

► **Lemma 6.** *Let  $G = \bigcup_{i=1}^m C_i$  be a disconnected graph (that is,  $m \geq 2$ ), with components of sizes  $s_i = |V_i|$ . Then  $G$  is  $O((n \log n)/s)$ -stochastically-close to being connected, where  $s = \min_{i \in [m]} \{s_i\}$ .*

**Proof.** Recall that when considering stochastic distance every non-edge is added with some probability  $p$ . Consider the set of bad events  $\{B_k\}_{k=1}^{\lfloor m/2 \rfloor}$ , where  $B_k$  is the event that there exists a set of exactly  $k$  connected components  $C_{i_1}, \dots, C_{i_k}$  such that none of the edges between  $\bigcup_{j=1}^k C_{i_j}$  and the rest of the graph are added. The important observation is that the graph stays disconnected if and only if one of these bad events occurs. We go on to bound the probability of each of these bad events.

Fix  $k$ . Our goal is to bound  $\Pr[B_k]$ . There are  $\binom{m}{k}$  ways to choose a subset of  $k$  components. Fix one such choice  $i_1, \dots, i_k$  and denote the set of vertices in these components by  $U = \bigcup_{j=1}^k V_{i_j}$ . As each component is of size at least  $s$ , we have  $|U| \geq ks$ , applying the same reasoning to the remaining graph, made of the rest of the components:  $|V \setminus U| \geq (m - k)s \geq ks$  nodes (the second inequality holds since  $k \leq m/2$ ). Thus, we have  $ks \leq |U| \leq n - ks$ , and consequently we get:

$$|U| \cdot |V \setminus U| = |U| \cdot (n - |U|) \geq ks(n - ks).$$

where the inequality is true since  $f(x) = x(n - x)$  is unimodal and symmetric on the interval  $[ks, n - ks]$ . The probability of  $U$  staying disconnected from  $V \setminus U$  is thus bounded by:

$$(1 - p)^{|U|(n - |U|)} \leq e^{-p|U|(n - |U|)} \leq e^{-pks(n - ks)}$$

And by a union bound over all choices of  $U$  with  $k$  connected components, we get:

$$\Pr[B_k] \leq \binom{m}{k} e^{-pks(n - ks)} \leq e^{-pks(n - ks) + k \log m} \leq e^{-pksn + p(ks)^2 + k \log n}$$

Thus, by taking  $p = 2(c+2) \log n / (sn)$ , the expression in the exponent is bounded by:

$$\begin{aligned} -\frac{2(c+2) \log n \cdot ksn}{sn} + \frac{2(c+2) \log n (ks)^2}{sn} + k \log n &= (2(c+2)(ks/n - 1) + 1)k \log n \\ &\leq -(c+1)k \log n \end{aligned}$$

where the inequality uses  $ks/n \leq (m/2)s/n \leq 1/2$ . This, in turn, bounds the probability of the bad event by:

$$\Pr[B_k] \leq e^{-(c+1)k \log n} \leq \left(\frac{1}{n}\right)^{-(c+1)k}$$

Using a union bound over all values of  $k$ , we get

$$\Pr\left[\bigvee_{k=1}^{\lfloor m/2 \rfloor} B_k\right] \leq \sum_{k=1}^{\lfloor m/2 \rfloor} n^{-(c+1)k} \leq \sum_{k=1}^{\infty} n^{-(c+1)k} \leq 2n^{-(c+1)} \leq n^{-c}$$

where the second to last inequality uses the sum of an infinite geometric series with common ratio  $n^{-(c+1)} \leq 1/2$ , and the last simply uses  $n \geq 2$ .

Finally, we get that  $G$  is connected w.h.p. This implies that  $G$  is  $t$ -stochastically-close to being connected, with  $t = O((n \log n)/s)$  (recall that  $|\bar{E}| = \Omega(n^2)$ ). ◀

### Tightness of Lemma 6

We focus on the smallest connected component,  $V_i$  of size  $s_i = s$ . There are at most  $s(n-s) \leq sn$  potential edges to connect  $V_i$  to the rest of the graph. If we take  $p' = c \log n / (4sn)$ , then the probability none of them is added satisfies:

$$(1 - p')^{s(n-s)} \geq (1 - p')^{sn} \geq e^{-2p'sn} = e^{-c \log n / 2} = n^{-c/2} > n^{-c},$$

where the second inequality uses  $1 - x \geq e^{-2x}$ , which holds for  $x \in [0, 1/2]$ .

Using the counter-positive of Lemma 6, a graph  $G$  that is  $O((n \log n)/s)$ -stochastically-far from being connected is guaranteed to have a connected component of size *at most*  $O(s)$ .

It is clear that a sequential tester is ill-suited to detect such small witnesses. Indeed, consider distinguishing the connected cycle over all  $n$  nodes, from a disconnected  $n$ -node graph consisting of an  $n - 1$  cycle and a single isolated node (chosen uniformly at random). On the one hand, all disconnected graphs are as stochastically far as a graph can be from connectivity (requiring roughly  $n \log n$  random edge additions). Still, a sequential tester would require  $\Omega(n)$  queries to an oracle in order to detect the isolated node.

In the CONGEST model, however, an efficient testing procedure exists.

► **Theorem 1.** *There exists a deterministic algorithm in the CONGEST model, that for a parameter  $s \in \mathbb{N}$  runs in  $O(s)$  rounds and distinguishes whether the graph  $G$  is connected, or is  $\Omega((n \log n)/s)$ -stochastically-far.*

**Proof.** Assume that the parameter  $s$  is known to all nodes in the network. Each node runs a distributed DFS algorithm. Every execution is associated with an ID, which is simply the ID of the root of the DFS tree. When multiple DFS executions visit the same node, all execution are terminated, except that with the maximum ID. When a DFS execution visits  $s$  nodes, it terminates and checks whether there is an outgoing edge from any visited node to any unvisited node. If there is, then it accepts (i.e., the graph is connected), otherwise it rejects (i.e., the graph is far from being connected). Correctness follows from Lemma 6. It is clear that there is no congestion and that the algorithm terminates in  $O(s)$  iterations. ◀

## 4 Stochastic Distance from $k$ -Connectivity

This section deals with  $k$ -connectivity, for any  $k \geq 1$ . We aim to characterize stochastic distance of a graph in terms of cuts, focusing on a specific parameter-of-interest denoted by  $s_k(G)$ : the smallest size of a vertex set that has a cut strictly smaller than  $k$ . In terms of this parameter, the following can be shown:

► **Theorem 7.** *Let  $G = (V, E)$  and  $s = s_k(G)$ , then  $G$  is  $O((k \cdot n \log n)/s)$ -stochastically-close to being  $k$ -connected.*

Similarly to Lemma 6, this theorem is tight, up to a factor of  $k$ . The rest of this section deals with proving the above theorem. First the parameter  $s_k(G)$  is formally defined and discussed. Later, we generalize Lemma 6 to bound the number of random edge additions required to increase the connectivity of a graph by one. In the last part we formally prove Theorem 7.

### 4.1 Properties of minimal cuts

For any vertex set,  $U \subseteq V$ , we write the cut size of  $U$  as  $c(U) := |E(U, V \setminus U)|$ . We use  $d(t) := t(n - t)$  for the *potential* amount of edges between any  $t$  vertices and the rest of the graph, and for a specific vertex set,  $U$ , we slightly abuse notation and write  $d(U) = d(|U|)$ .

For any parameter  $k \in \mathbb{N}$  and graph  $G = (V, E)$ , we define the collection of small cuts as the cuts that are strictly smaller than  $k$ :

$$\mathcal{S}_k(G) := \{U \subseteq V : c(U) < k \text{ and } U \neq \emptyset\}$$

A value of interest for us will be the size of the smallest set in such a collection. Formally we define:

$$s_k(G) := \min_{U \in \mathcal{S}_k(G)} |U|$$

When the connectivity parameter  $k$  and the graph  $G$  are clear from context, we omit either one or both (writing  $s_k, s(G)$  or simply  $s$  instead). If the collection is empty for some  $k$  and  $G$ , we define  $s_k(G) = n$ . Note that  $s_k(G) = n$  if and only if  $G$  is indeed  $k$ -connected.

We show that  $s_k(G)$  has certain monotonicity properties with respect to the parameters  $G$  and  $k$ . Indeed, by definition a larger value for  $k$  creates a larger collection of cuts, i.e.,  $\mathcal{S}_k(G) \subseteq \mathcal{S}_{k+1}(G)$ . On the other hand, adding edges to the graph can only increase the cut of any given vertex set,  $U$ . Thus, any  $U$  with a small cut after additions, also had a small cut before additions. Formally, if  $G \subseteq G'$  (i.e.,  $G = (V, E), G' = (V, E')$  and  $E \subseteq E'$ ), we have  $\mathcal{S}_k(G') \subseteq \mathcal{S}_k(G)$ . The minimum over elements in a collection can only decrease if we add elements to the collection, and hence we have:

► **Observation 8** (Monotonicity of  $s_k(G)$ ). *The parameter  $s_k(G)$  is monotone non-increasing in  $k$ , and monotone non-decreasing in  $G$ .*

Below, we will be interested in finding the smallest vertex set  $U$  in the collection  $\mathcal{S}_k(G)$ . This element determines the value  $s$ . The following proposition shows a property of such a set  $U$  that will be useful for the algorithm:

► **Proposition 9.** *Fix  $k \in \mathbb{N}$  and a graph  $G = (V, E)$ . For any subset  $U \subseteq V$  with a cut less than  $k$  ( $c(U) < k$ ) and of minimal size ( $|U| = s_k$ ) the induced subgraph  $G[U]$  is connected.*

**Proof.** Assume otherwise, then we can break  $G[U]$  into its connected components:  $U = \bigcup_i U_i$ . Each such component has strictly less nodes than  $U$ . Moreover, we have:

$$c(U_i) = E(U_i, V \setminus U_i) = E(U_i, V \setminus U) \leq E(U, V \setminus U) = c(U),$$

where the second equality holds since there are no edges between different components of  $U$ . We conclude that each  $U_i$  has a cut of size at most  $c(U) < k$ , but their size is strictly smaller than  $s$ , which leads to a contradiction. ◀

### 4.2 Increasing the connectivity by one

Using the notations of this section, the statement of Lemma 6 is that any graph that is “0-connected” (i.e., disconnected) is  $O(n \log(n)/s_1)$ -stochastically-close to being 1-connected. This is true since  $s_1$  is exactly the size of the smallest connected component in  $G$ .

We generalize this statement for  $k$ -connectivity:

► **Lemma 10.** *Any  $(k - 1)$ -connected graph  $G$  with  $n \geq 4k$  nodes is  $O(n \log(n)/s_k)$ -stochastically-close to being  $k$ -connected.*

**Proof.** For  $k = 1$ , the proof is complete due to Lemma 6. For  $k > 1$ , let  $G$  be a  $(k - 1)$ -connected graph. Thus, all minimum cuts have  $k - 1 \geq 1$  edges ( $G$  is connected). We estimate the number of random edges needed to make all sets in  $\mathcal{S}_k(G)$  have a cut of size at least  $k$ .

We identify minimum cut with a partition of  $V$  to  $U$  and  $V \setminus U$  (w.l.o.g,  $|U| \leq \lfloor n/2 \rfloor$ ). As in Lemma 6 assume that every non-edge is added with probability  $p$ . Consider the event  $B_U$  that  $U$  remains with cut of size  $k - 1$ . That is, not a single edge was added between  $U$  and  $V \setminus U$ . There are exactly  $d(U) - (k - 1)$  potential additions, and so:

$$\Pr[B_U] = (1 - p)^{d(U) - (k - 1)} = (1 - p)^{|U|(n - |U|) - (k - 1)} \leq (1 - p)^{s_k \cdot n/4} \leq e^{-s_k \cdot pn/4},$$

where the first inequality uses  $n - |U| \geq n/2$ ,  $|U| \geq s_k(G)$  and  $k \leq |U|n/4$  to lower bound the exponent.

By taking  $p = 4(c + 2) \log n / (s_k n)$ , this bound becomes

$$e^{-s_k \cdot pn/4} = e^{-(c+2) \log n} = n^{-(c+2)}$$

We finish the proof by using a union bound over all minimum cuts. There are at most  $\binom{n}{2} \leq n^2$  of them due to well known corollary of Karger’s Algorithm [15]. The probability that  $G$  is not  $k$ -connected after the edge additions is at most

$$\sum_{U \in \mathcal{S}_k(G)} \Pr[B_U] \leq n^2 \cdot n^{-(c+2)} = n^{-c}. \quad \blacktriangleleft$$

### 4.3 Putting it all together

We are now ready to prove Theorem 7. Our proof considers an alternative addition process which is easier to analyze. Intuitively, let  $p' \approx p/k$  and consider the following process. “Repeat  $k$  times: add each edge to the graph independently with probability  $p'$ ”. We formalize the above and bound the required value of  $p'$  for the alternative process, analyzing each of the  $k$  iterations separately with Lemma 10. We finish up by relating the original addition processes to the alternative one.

**Proof of Theorem 7.** Denote by  $r < k$  the connectivity of  $G$  (if  $G$  is disconnected, then  $r = 0$ ). We consider  $k - r$  (at most  $k$ ) iterations of additions, which we enumerate by  $r + 1, \dots, k$ . We further denote by  $G_i$  the graph after iteration  $i$  (and  $G_r = G$ ).

First we consider process (A), where at each iteration  $i \in \{r + 1, \dots, k\}$ , each edge is independently added with probability

$$p_i = 4(c + 3)n \log n / s_{i+1}(G_i).$$

Applying Lemma 10 for each iteration  $i$  we have the following: The probability that  $G_i$  is  $i$ -connected, *given that  $G_{i-1}$  is  $(i - 1)$ -connected* is at least  $1 - n^{-(c+1)}$ . Using a union bound over all  $k - r \leq n$  iterations, we have that with probability at least  $1 - n^{-c}$ , the final graph  $G_k$  is  $k$ -connected.

Next, consider an adjusted process (B) that also works in iterations, but uses a fixed value

$$p' = 4(c + 3)n \log n / s_k(G).$$

Using the monotonicity of  $s_k(G)$ , we have

$$s_k(G) = s_k(G_r) \leq s_{i+1}(G_r) \leq s_{i+1}(G_i),$$

and thus  $p_i \leq p'$  for all values of  $i$ .

Let us focus on a single non-edge of  $G$ , call it  $(u, v)$ , and follow it through the entire process. The probability  $(u, v)$  is added to  $G_k$  is higher in process (B) than it is in process (A), since  $p' \geq p_i$  for all  $i$ . On the other hand, this probability is at most  $p'/k$ , by a union bound over all iterations of process (B).

Lastly, consider process (C), a one-shot random addition, using

$$p = p'k = 4(c + 3)kn \log n / s_k(G).$$

The probability of every non-edge being added in process (C) is higher than it is in process (B) which is in turn higher than process (A). By monotonicity of  $k$ -connectivity (as a graph property), the probability that  $G_k$  is a  $k$ -connected graph is therefore also higher in process (C) than it is in process (A), and is therefore at least  $1 - n^{-c}$ . ◀

The counter-positive of Theorem 7 means that any graph  $G$  which is  $O((k \cdot n \log n)/s)$ -stochastically-far from being  $k$ -connected has a set  $W$  of at most  $s$  nodes with a cut smaller than  $k$ . We call such set  $W$  an  $(s, k)$ -witness, or simply a *witness* when  $k$  and  $s$  are clear from context.

## 5 Distributed algorithm for $k$ -connectivity

In this section, we provide a distributed algorithm that detects an  $(s, k)$ -witness within  $O(s^4 \log n)$  rounds in the CONGEST model w.h.p. We state with the following useful lemma<sup>4</sup>:

► **Lemma 11** (Lemma 3.16 in [13]). *Let  $W$  be an  $(s, k)$ -witness. Suppose that each edge in the graph is independently assigned a uniformly distributed cost in  $[0, 1]$ . Then, with probability at least  $\Theta(s^{-2(1-1/k)})$ ,  $W$  contains a spanning tree such that every edge in the tree has cost smaller than any edge in the cut  $E(W, V \setminus W)$ .*

<sup>4</sup> The original lemma in [13] uses the notion of a  $j$ -extreme node set which is equivalent to our notion of a  $(s, k)$ -witness.

## 57:10 Stochastic Distance in Property Testing

Specifically, if the tree guaranteed by the above lemma exists, the MST must also have the same guarantees. Furthermore, as all edge costs are unique w.h.p., the MST is unique w.h.p. When referring to the above lemma, it will be convenient to refer to a single tree, the MST induced by the cost function (i.e., when referring to the spanning tree guaranteed by Lemma 11, we always refer to an MST).

Given a starting vertex  $w$  and a size bound  $s$ , consider the following random process:

- Input: start vertex  $u \in V$ , size bound  $s \in \mathbb{N}$ .
- Assign uniformly random weights to all edges:  $w : E \rightarrow [0, 1]$ .
- Start with a singleton set  $W = \{u\}$ . As long as  $|W| < s$ , repeat the following:
  - Choose the smallest cut edge  $e = \operatorname{argmin}_{e \in E(W, V \setminus W)} w(e)$ .
  - Update  $W$  to include the new node of  $e$  in  $V \setminus W$ .
  - If  $c(W) < k$  then declare  $W$  as an  $(s, k)$ -witness.

Lemma 11 implies that repeating the above procedure  $\tilde{\Theta}(s^2)$  times detects a witness w.h.p.

In [13] a small amount of random nodes is sampled, and the above procedure is applied for each of them. This is possible since any graph that is far from  $k$ -connectivity in *Hamming* distance contains many witnesses. In our case, a graph that is *stochastically* far only guarantees a single witness, and therefore it is costly to detect the witness in the standard (query) model. We leverage the distributed nature of the system to apply the witness detection procedure to all nodes in parallel.

### Distributed implementation

The above algorithm admits a simple distributed implementation. First, we assign random weights in  $[0, 1]$  to all edges in the graph, this guarantees that with some small probability there exists a spanning tree within the witness component satisfying the guarantees of Lemma 11. Assume this tree exists and denote this tree by  $T$ . It will be clear from our algorithm that if this tree does not exist, the running time does not change however we may simply not detect the witness component if it exists.

Every node grows a cluster as follows. Every cluster can be implemented via a tree rooted at a leader node. All nodes in the cluster know for each neighbor whether it is in the cluster or not. To pick the next edge to be added to the cluster the edge weights are propagated along the tree towards the root, taking the minimum at every node. Finally, the root propagates the minimum value to all nodes in the cluster and the corresponding edge is added to the cluster. After each edge addition the cluster checks whether the current cut size is smaller than  $k$  and terminates if this is the case (a witness is found). For ease of analysis let us define an *iteration* as the step of adding a single edge (and vertex) to the cluster. When running this procedure from multiple nodes we can have every cluster wait for  $\Theta(i)$  rounds to complete the  $i$ -th iteration. This will guarantee when running this procedure from multiple nodes that the iterations are executed in lock-step. We execute this process for  $s$  iterations. This results in a running time of  $O(s^2)$  rounds.

In order to detect a witness component, we must execute the above algorithm to completion, starting from a node within the witness component. We do not know which nodes are within the witness component before executing the algorithm, and running the procedure to completion may cause congestion. To overcome this, we execute the procedure from all nodes simultaneously, but prioritize executions that overlap according to a priority condition.

The priority of the cluster at iteration  $i$  is the largest edge cost that was added to the cluster so far. Let us call this the *max-edge* value. Whenever multiple executions reach the same node, executions with higher max-edge values are terminated (ties are broken via

the cluster root IDs). As clusters add edges greedily according to edge weights, we know that only edges from  $T$  will be added to clusters whose execution starts from the witness component. That is, all edges in  $T$  will be added, at which point the small cut will be detected and all nodes in the cluster will reject.

As we terminate executions that visit the same node, we never experience congestion. It is sufficient to prove that at least one cluster execution that starts within the witness component survives. As all edges in the tree have weights smaller than the cut edges this means that the execution of clusters that start within the witness component is not affected by clusters that start from outside the component. This is because they always have a lower max-edge value due to guarantees on the weights of  $T$ . Furthermore, in every iteration at least one cluster in the witness component is not terminated. That is, the cluster with highest priority inside the witness component at iteration  $i$  must survive. We conclude that there exists a cluster construction that start within the component and terminates within  $O(s^2)$  rounds. To get the guarantee of Lemma 11 w.h.p., we must repeat the process  $\tilde{O}(s^2)$  times. Thus, the final running time is  $\tilde{O}(s^4)$ . We state the following theorem:

► **Theorem 2.** *There exists a randomized algorithm in the CONGEST model, that for a parameter  $s \in \mathbb{N}$  runs in  $\tilde{O}(s^4)$  rounds and distinguishes w.h.p whether the graph  $G$  is  $k$ -connected, or is  $\Omega((kn \log n)/s)$ -stochastically-far from being one.*

## A Robustness of Stochastic Closeness

The following claim is used to show robustness of stochastic closeness (Definition 4) with respect to the choice of the global constant  $c$ . Intuitively speaking, by repeating the random addition only a constant number of times, the probability of not attaining the property  $\mathcal{P}$  can be reduced to any small polynomial.

▷ **Claim 12.** Fix a monotone property  $\mathcal{P}$ , a graph  $G \notin \mathcal{P}$  over  $n$  vertices, and constant  $c > 1$ . If for some  $t \in [0, |\bar{E}|]$ , it holds that

$$\Pr[\text{Add}(G, t) \notin \mathcal{P}] \leq n^{-c},$$

then for any  $m \in \mathbb{N}$  such that  $mt \in [0, |\bar{E}|]$ , it holds that

$$\Pr[\text{Add}(G, mt) \notin \mathcal{P}] \leq n^{-mc}.$$

*Proof.* Recall that in the randomly augmented graph  $\text{Add}(G, t)$  each edge  $e \in \bar{E}$  is added independently with probability  $t/|\bar{E}|$ . Let  $G_1, \dots, G_m$  be  $m$  independent copies of  $\text{Add}(G, t)$ . By definition, we have

$$\Pr \left[ \bigwedge_{i=1}^m G_i \notin \mathcal{P} \right] = \prod_{i=1}^m \Pr[G_i \notin \mathcal{P}] \leq n^{-mc}.$$

Define  $G' = \bigcup_{i=1}^m G_i$ , the union of all  $m$  randomly augmented graphs.  $G'$  trivially contains all edges of  $G$ . On the one hand, the probability that each edge  $e \in \bar{E}$  appears in  $G'$  is at most  $(mt)/|\bar{E}|$ , by a union bound over the  $m$  attempts to add it. Since the property  $\mathcal{P}$  is monotone, we have

$$\Pr[\text{Add}(G, mt) \notin \mathcal{P}] \leq \Pr[G' \notin \mathcal{P}].$$

On the other hand,  $G'$  is a supergraph of  $G_i$  for all  $i \in [m]$ . Using again the monotonicity of  $\mathcal{P}$ , we can write

$$\Pr[G' \notin \mathcal{P}] = \Pr\left[\bigwedge_{i=1}^m G' \notin \mathcal{P}\right] \leq \Pr\left[\bigwedge_{i=1}^m G_i \notin \mathcal{P}\right] \leq n^{-mc},$$

which concludes the proof. ◁

# Expanderizing Higher Order Random Walks

## Abstract

We study a variant of the down-up (also known as the Glauber dynamics) and up-down walks over an  $n$ -partite simplicial complex, which we call *expanderized higher order random walks* – where the sequence of updated coordinates correspond to the sequence of vertices visited by a random walk over an auxiliary expander graph  $H$ . When  $H$  is the clique with self loops on  $[n]$ , this random walk reduces to the usual down-up walk and when  $H$  is the directed cycle on  $[n]$ , this random walk reduces to the well-known systematic scan Glauber dynamics. We show that whenever the usual higher order random walks satisfy a log-Sobolev inequality or a Poincaré inequality, the expanderized walks satisfy the same inequalities with a loss of quality related to the two-sided expansion of the auxiliary graph  $H$ . Our construction can be thought as a higher order random walk generalization of the derandomized squaring algorithm of Rozenman and Vadhan (RANDOM 2005).

We study the mixing times of our expanderized walks in two example cases: We show that when initiated with an expander graph our expanderized random walks have mixing time (i)  $O(n \log n)$  for sampling a uniformly random list colorings of a graph  $G$  of maximum degree  $\Delta = O(1)$  where each vertex has at least  $(11/6 - \varepsilon)\Delta$  and at most  $O(\Delta)$  colors, (ii)  $O_{\mathbf{h}}\left(\frac{n \log n}{(1 - \|\mathbf{J}\|_{\text{op}})^2}\right)$  for sampling the Ising model with a PSD interaction matrix  $\mathbf{J} \in \mathbb{R}^{n \times n}$  satisfying  $\|\mathbf{J}\|_{\text{op}} \leq 1$  and the external field  $\mathbf{h} \in \mathbb{R}^n$  – here the  $O(\bullet)$  notation hides a constant that depends linearly on the largest entry of  $\mathbf{h}$ . As expander graphs can be very sparse, this decreases the amount of randomness required to simulate the down-up walks by a logarithmic factor.

We also prove some simple results which enable us to argue about log-Sobolev constants of higher order random walks and provide a simple and self-contained analysis of local-to-global  $\Phi$ -entropy contraction in simplicial complexes – giving simpler proofs for many pre-existing results.

## 1 Introduction

Let  $U_1, \dots, U_n$  be a collection of finite sets. The *down-up walk*  $P^{\downarrow\uparrow}$  on  $\Omega \subset U_1 \times \dots \times U_n$  with respect to a given distribution  $\pi : \Omega \rightarrow \mathbb{R}_{\geq 0}$ , also known as the *Glauber dynamics* on  $\Omega$  according to  $\pi$ , is the following simple process: Starting from an arbitrary tuple  $\omega^{(0)}$ , we obtain the  $(t+1)$ -st tuple  $\omega^{(t+1)}$  visited by this random walk from the  $t$ -th tuple  $\omega^{(t)}$  as follows,

### Update Rule for the Down-Up Walk, $P^{\downarrow\uparrow}$

1. sample a uniformly random coordinate  $i \sim \text{uni}_{[n]}$ ,
2. sample a random tuple  $\omega^{(t+1)} \sim \pi$  conditional on  $\omega_j^{(t+1)} = \omega_j^{(t)}$  for all  $j \in [n] \setminus \{i\}$ .

The following variant of the down-up walk, called the *systematic scan*  $P_{\text{scan}}$  on  $\Omega$  according to  $\pi$ , is a variant of the down-up walk  $P^{\downarrow\uparrow}$  which uses less randomness and is easier to implement in practice: starting from an arbitrary tuple  $\omega^{(0)}$ , we obtain the  $(t+1)$ -st tuple  $\omega^{(t+1)}$  visited by this random walk from the  $t$ -th tuple  $\omega^{(t)}$  as follows,

### Update Rule for the Systematic Scan, $P_{\text{scan}}$

1. set  $i = t + 1 \pmod{n}$ ,
2. sample a random tuple  $\omega^{(t+1)} \sim \pi$  conditional on  $\omega_j^{(t+1)} = \omega_j^{(t)}$  for all  $j \in [n] \setminus \{i\}$ .

In both cases, the coordinate  $i$  that is sampled on the first step of the update can be thought as a vertex visited by the simple random walk on a graph. For the down-up walk, this is a random walk on the clique with self-loops, whereas for the systematic scan this is a (deterministic) walk on the directed cycle.

The main object of study in this paper will be the so-called *expanderized down-up walk*  $Q^{\downarrow\uparrow}$  on  $\Omega$  with respect to the distribution  $\pi : \Omega \rightarrow \mathbb{R}_{> 0}$  and the  $k$ -regular graph  $H = ([n], E)$  for some constant  $k$ . Starting this random-walk from an arbitrary coordinate  $i^{(0)} \in [n]$  and an arbitrary tuple  $\omega^{(0)}$ , we obtain the  $(t+1)$ -st coordinate  $i^{(t+1)}$  and tuple  $\omega^{(t+1)}$  according to the following update rule,

### Update Rule for the Expanderized Down-Up Walk $Q^{\downarrow\uparrow}$

1. sample a random neighbor  $s$  of  $i^{(t)}$  in  $H$ ,
2. sample a random tuple  $\omega^{(t+1)} \sim \pi$  conditional on  $\omega_j^{(t+1)} = \omega_j^{(t)}$  for all  $j \in [n] \setminus \{s\}$ ,
3. set  $i^{(t+1)}$  to be a random neighbor of  $s$  in  $H$ .

We notice that according to the above update rule when  $i^{(0)}$  is sampled uniformly at random and  $H$  equals the clique with self-loops on  $[n]$  the evolution of  $\omega^{(t)}$  is as dictated by the down-up walk  $P^{\downarrow\uparrow}$ . Similarly, when  $i^{(0)} = 1$  and  $H$  is the directed cycle,<sup>1</sup> the evolution of  $\omega^{(t)}$  is as dictated by the systematic scan  $P_{\text{scan}}$ .

<sup>1</sup> To be more precise,  $H$  needs to be a directed cycle of length  $2n$ , in which the vertices corresponding to the coordinates and *dummy* vertices are interleaved.

The main contribution of this paper is an analysis of the expanderized down-up walk assuming, (i) the graph  $H$  is a spectral expander<sup>2</sup> and (ii) the down-up walk  $P^{\downarrow\uparrow}$  satisfies some kind of isoperimetric inequality, e.g. a log-Sobolev inequality or a Poincaré inequality. Indeed our methods allow us to extend our results to all down-up and up-down walks.

**Motivation and Contributions.** The systematic scan  $P_{\text{scan}}$  is a random walk of great practical and theoretical interest. Yet, rapid mixing results for this walk are only known under restricted circumstances [18, 33, 23, 24, 51, 29] and it is very hard to directly relate the rapid mixing of  $P^{\downarrow\uparrow}$  to that of  $P_{\text{scan}}$ . A particularly useful framework for establishing rapid mixing for the down-up walk is the method of high-dimensional expansion, in particular the frameworks of spectral independence and entropic independence [2, 9, 16, 17, 14, 7, 6, 8] which led to many breakthrough results in the field of sampling algorithms.

In [3], an attempt was made to study the mixing of the systematic scan<sup>3</sup> using techniques of high-dimensional expansion – while their techniques allowed them to establish rapid mixing results for constant dimensional partite simplicial complexes, their result is too restrictive to take advantage of mixing results obtained through spectral independence or entropic independence. As a step towards directly being able to take advantage of the mixing results for  $P^{\downarrow\uparrow}$ , which could potentially be obtained through the high-dimensional expansion framework, we introduce our expanderized down-up walks  $Q^{\downarrow\uparrow}$ . As expander graphs have proven themselves very successful at approximating dense objects, we hope – and indeed also prove – that transferring mixing time bounds from the usual down-up walks to our expanderized walks to be an easier task than establishing mixing times for  $P_{\text{scan}}$ . As expander graphs can be very sparse, our expanderized walks can be thought as replacing the sparse object used in the definition of the systematic scan  $P_{\text{scan}}$ , i.e. the directed cycle, with another sparse yet highly connected object – an expander graph with constant degree.

In spirit, the expanderized walks can be thought as a higher order random walk analogue of the derandomized squaring algorithm introduced in [52]. This algorithm was introduced to simplify the seminal result of [49] concerning the existence of a logspace algorithm for deciding undirected connectivity. The derandomized squaring operation uses an auxiliary  $k$ -regular expander graph  $H$  on the vertex set  $[d]$  to approximate the square of a graph  $d$ -regular graph  $G$  on  $[n]$ . Whereas the actual square  $G^2$  is a  $d^2$ -regular graph, by picking  $k = O(1)$  one can ensure that the *derandomized square* is  $O(d)$ -regular, i.e. a much sparser object. This result rests on the observation that the actual square  $G^2$  is obtained from the graph  $G$  by attaching a clique to every vertex – replacing this clique with an expander graph suffices to ensure that the resulting *derandomized square* is closed to the actual square. Fortunately, the same intuition also leads to proofs showing that the expanderized walks approximate the standard walks well.

We show that we can use our expanderized walks to have more randomness efficient versions of several Markov chains of interest for sampling list colorings [10, 41] and for sampling from Ising Models [27, 7, 40], under assumptions ensuring bounded marginals. In these settings, our expanderized walks have the same asymptotic mixing time but use fewer random bits. To help us with our goals we also prove some simple estimates for the log-Sobolev constants of higher order random walks and provide a self-contained analysis of local-to-global  $\Phi$ -entropy contraction.

<sup>2</sup> i.e. all non-trivial eigenvalues of  $H$  are bounded away from 1

<sup>3</sup> More formally,  $n$  successive steps of the systematic scan, which the authors call the *sequential sweep*  $P_{\text{seq}}$ .

**Related Work.** High dimensional expansion has proven itself to be a very successful research program for establishing mixing times for down-up walks. For example [36, 21, 37, 20, 2] use spectral local-to-global arguments for establishing spectral gap bounds for these walks. In conjunction with the spectral independence framework, due to [9, 15, 30], these results paved the way for many new in the field of random sampling: rapid mixing of the down-up walk for the hardcore model in the uniqueness regime [9], rapid mixing of the down-up walk for sampling graph colorings in correlation decay regime [30, 15], optimal mixing for many Markov chains of interest [17, 10, 41]. For more information regarding spectral independence, we refer the reader to the excellent survey [54] and the dissertation [42]. In [6, 8, 17, 32] local-to-global strategies for establishing entropic contraction bounds was studied. In [14] a connection between these local-to-global methods and the stochastic localization framework of [25] was explored. We refer to the works [39, 26, 13, 38, 28, 27] and references therein for applications of the stochastic localization framework. Our inductive strategy for establishing  $\Phi$ -entropy contraction on simplicial complexes is heavily inspired by the presentation in [14]. In [40] mixing estimates about the walk  $P_{n \leftrightarrow n-1}^{\downarrow \uparrow}$  is used to obtain estimates for  $P_{n \leftrightarrow \ell}^{\downarrow \uparrow}$  for all  $\ell < n - 1$ . The key intuition behind this work is the observation that the down move of the down-up walk is (passively) utilizing an expander, the down-move of the down-up walk of the so-called *Bernoulli-Laplace model*, and that one can use the expansion of this walk to show that once  $\ell$  decreases the mixing times estimates get better and better. Morally, this is very similar to our idea of picking the replacement-indices for our expanderized walks via an expander walk as opposed to sampling them uniformly at random. For other classical techniques which can be used to bound mixing times of Markov chains, we refer the reader to the texts [1, 46, 55].

In contrast with down-up walks, results establishing rapid mixing for the random walk  $P_{\text{scan}}$  are fewer [18, 33, 23, 51] and mostly rely on estimates on the Dobrushin matrix [22]. [3] studied the mixing time of this random walk using techniques of high dimensional expansion, however their techniques fell short of establishing mixing time bounds under the assumption of spectral independence.

The work of [29] is also related to our work in spirit. In this work, the authors show that under suitable assumptions a wide array of random walks, including the single site systematic scan  $P_{\text{scan}}$  and the down-up walk  $P^{\downarrow \uparrow}$ , can be derandomized, i.e. they devise efficient deterministic counting algorithms on the basis of rapid mixing results for these chains. It is an interesting question whether one can carefully pick the expander graph  $H$ , to make this derandomization task more efficient.

As mentioned above our expanderized random walks are heavily inspired by the derandomized squaring algorithm of [52]. This algorithm was initially used to give an alternative and simpler proof of the seminal result of [49] concerning the derandomization of the complexity class  $\mathbf{SL}$  and establishing  $\mathbf{SL} = \mathbf{L}$ . Concretely, both [49] and the subsequent work of [52] show the existence of a deterministic logspace algorithm deciding undirected graph connectivity. Since then, the derandomized squaring algorithm has also found other uses in derandomization, e.g. [47, 48]. We conclude by noting that the initial algorithm of [49] was based on the zigzag product construction [50], which has also inspired research in the field of high dimensional expansion [35]. For more information on expander graphs, we refer the reader to the excellent survey [34].

## 2 Preliminaries

### 2.1 Linear Algebra

We will denote functions and vectors by bold faces, i.e.  $\mathbf{f} \in \mathbb{R}^V$ . The indicator function of  $i \in V$  will be denoted by  $\mathbf{1}_i$ , i.e.  $\mathbf{1}_i(j) = 0$  for all  $j \neq i$  and  $\mathbf{1}_i(i) = 1$ . For  $A \subseteq V$ , we will write  $\mathbf{1}_A = \sum_{a \in A} \mathbf{1}_a$ . We will adopt the convention of using  $\pi, \nu, \mu : V \rightarrow \mathbb{R}_{\geq 0}$  for various probability distributions over  $V$ .

Let  $\mathbf{f}, \mathbf{g} \in \mathbb{R}^V$  and a measure  $\pi : V \rightarrow \mathbb{R}_{>0}$  be given. We will use the notations  $\langle \mathbf{f}, \mathbf{g} \rangle_\pi$  and  $\|\mathbf{f}\|_\pi$  to denote the inner-product and the norm with respect to the distribution  $\pi$ , i.e.

$$\langle \mathbf{f}, \mathbf{g} \rangle_\pi = \mathbb{E}_{x \sim \pi} \mathbf{f}(x)\mathbf{g}(x) = \sum_{x \in V} \pi(x) \cdot \mathbf{f}(x)\mathbf{g}(x) \quad \text{and} \quad \|\mathbf{f}\|_\pi^2 = \langle \mathbf{f}, \mathbf{f} \rangle_\pi. \quad (1)$$

Given  $\mathbf{f}, \mathbf{g} \in \mathbb{R}^n$  we will write  $\langle \mathbf{f}, \mathbf{g} \rangle_{\ell_2}$  for the inner-product between  $\mathbf{f}$  and  $\mathbf{g}$  in the counting measure, i.e.  $\langle \mathbf{f}, \mathbf{g} \rangle_{\ell_2} = \sum_{i=1}^n \mathbf{f}(i)\mathbf{g}(i)$ . We will also write  $\|\mathbf{f}\|_{\ell_1}$ ,  $\|\mathbf{f}\|_{\ell_2}$ , and  $\|\mathbf{f}\|_{\ell_\infty}$  for the  $\ell_1$ ,  $\ell_2$ , and  $\ell_\infty$  norms of  $\mathbf{f}$  respectively. Formally,

$$\|\mathbf{f}\|_{\ell_2}^2 = \sum_{i=1}^n \mathbf{f}(i)^2 \quad ; \quad \|\mathbf{f}\|_{\ell_1} = \sum_{i=1}^n |\mathbf{f}(i)| \quad ; \quad \text{and} \quad ; \quad \|\mathbf{f}\|_{\ell_\infty} = \max_{i \in [n]} |\mathbf{f}(i)|.$$

### Matrices and Eigenvalues

In this section, we will recall some results concerning eigenvalues and eigenvectors of matrices.

Serif faces will be used to denote matrices, i.e.  $\mathbf{A}, \mathbf{B} \in \mathbb{R}^{U \times V}$ . We will call a matrix  $\mathbf{B} \in \mathbb{R}^{U \times V}$  row stochastic if rows of  $\mathbf{B}$  sum up to 1 and  $\mathbf{B}$  contains no negative entries. Formally,

$$\text{for all } u \in U, v \in V \quad \mathbf{B}(u, v) \geq 0 \quad \text{and} \quad \mathbf{B}\mathbf{1} = \mathbf{1}. \quad (\text{row stochastic})$$

Let  $\mathbf{B} \in \mathbb{R}^{U \times V}$  and distributions  $\pi_U : U \rightarrow \mathbb{R}_{>0}$  and  $\pi_V : V \rightarrow \mathbb{R}_{>0}$  be given. The adjoint  $\mathbf{B}^*$  of  $\mathbf{B}$  with respect to the measures  $\pi_U$  and  $\pi_V$  is the unique matrix which satisfies the following equation,

$$\langle \mathbf{f}, \mathbf{B}\mathbf{g} \rangle_{\pi_U} = \langle \mathbf{B}^*\mathbf{f}, \mathbf{g} \rangle_{\pi_V} \quad \text{for all } \mathbf{f} \in \mathbb{R}^U, \mathbf{g} \in \mathbb{R}^V. \quad (\text{adjoint})$$

If  $U = V$  and  $\pi_U = \pi_V$ , the operator  $\mathbf{B}$  is called self-adjoint when  $\mathbf{B}^* = \mathbf{B}$ . If  $\mathbf{B}$  is a row-stochastic matrix, we will call  $\mathbf{B}^*$  the time-reversal of  $\mathbf{B}$  with respect to  $\pi_U, \pi_V$  and say that  $\mathbf{B}$  is reversible if  $\mathbf{B} = \mathbf{B}^*$ . It is well known that the operator  $\mathbf{B}^* \in \mathbb{R}^{V \times U}$  is uniquely determined by the choice of  $\mathbf{B} \in \mathbb{R}^{U \times V}$  and the inner-products defined by  $\pi_U$  and  $\pi_V$  (see e.g. [53, p. 318]),

► **Proposition 1.** *Let  $\mathbf{B} \in \mathbb{R}^{U \times V}$  be arbitrary. We write  $\mathbf{B}^*$  for the adjoint operator to  $\mathbf{B}$  with respect to the inner-products defined by the distributions  $\pi_U$  and  $\pi_V$ . Then,*

$$\mathbf{B}^*(y, x) = \mathbf{B}(x, y) \cdot \frac{\pi_U(x)}{\pi_V(y)} \quad \text{for all } x \in U, y \in V.$$

We also recall the following standard fact which is an immediate consequence of Proposition 1,

► **Proposition 2.** *If  $\mathbf{B} \in \mathbb{R}^{U, V}$  is a row-stochastic matrix satisfying  $\pi_U \mathbf{B} = \pi_V$ , then the adjoint matrix  $\mathbf{B}^*$  with respect to  $\pi_U, \pi_V$  is also row-stochastic and satisfies  $\pi_V \mathbf{B}^* = \pi_U$ .*

## 58:6 Expanderizing Higher Order Random Walks

It is well known that a self-adjoint matrix  $A \in \mathbb{R}^{V \times V}$  has  $|V|$  real eigenvalues. We will write,  $\lambda_1(A) \geq \lambda_2(A) \geq \dots \geq \lambda_{|V|}(A) := \lambda_{\min}(A)$  for the sequence of eigenvalues of  $A$  sorted in decreasing order. We say that the matrix is positive semi-definite, henceforth PSD, if it is self-adjoint and satisfies  $\lambda_{\min}(A) \geq 0$ .

Given a matrix  $A \in \mathbb{R}^{V \times V}$  and a distribution  $\mu : V \rightarrow \mathbb{R}_{>0}$ , we will write  $\|A\|_{\text{op},\mu}$  for the operator norm of  $A$ , defined in the following manner

$$\|A\|_{\text{op},\mu} := \max \left\{ \frac{\|A\mathbf{f}\|_\mu}{\|\mathbf{f}\|_\mu} \mid \mathbf{f} \in \mathbb{R}^V \text{ and } \mathbf{f} \neq 0 \right\}. \quad (\text{operator norm})$$

If  $A$  is self-adjoint with respect to the measure  $\mu$ , we have  $\|A\|_{\text{op},\mu} = \max\{\lambda_1(A), |\lambda_{\min}(A)|\}$ .

Similarly when  $A \in \mathbb{R}^{V \times V}$  is a reversible row-stochastic matrix, with stationary measure  $\mu$ . We will write  $\lambda(A)$  for the two-sided expansion of  $A$ . Formally,

$$\lambda(A) = \max\{\lambda_2(A), |\lambda_{\min}(A)|\}. \quad (\text{two-sided expansion})$$

When  $A$  represents the simple random walk over an undirected graph  $H = (V, E)$ , i.e.

$$A(i, j) = \frac{\mathbf{1}[\{i, j\} \in E]}{\deg(i)} \quad \text{for all } i, j \in V,$$

we will simply write  $\lambda(H)$  instead of  $\lambda(A)$ . For convenience, we recall

► **Observation 3.** *Let  $H = (V, E)$  be a  $k$ -regular graph and suppose  $A$  represents the random walk over  $H$ . Then,  $\text{uni}_V A = \text{uni}_V$ , i.e. the uniform distribution on  $V$  is stationary for  $A$ .*

We note that there exist infinite families of graphs such that every graph  $H$  in the family has constant degree and  $\lambda(H)$  bounded above by a constant bounded above by 1 [43, 44]. In this paper, we will consider families that contain graphs on  $n$  vertices for *every* sufficiently large  $n$ . Such constructions were given in [5], and in particular were based on the infinite families from [43, 44]. We refer the reader to the excellent survey [34] for more information on expander graphs.

We will also make use of the following simple result,

► **Lemma 4.** *Let a matrix  $A \in \mathbb{R}^{U \times V}$  and measures  $\mu_U : U \rightarrow \mathbb{R}_{>0}$  and  $\mu_V : V \rightarrow \mathbb{R}_{>0}$  be given, such that  $\mu_U A = \mu_V$ . Assume without loss of generality that  $|U| \leq |V|$ , then  $\lambda_j(AA^*) = \lambda_j(A^*A)$  for all  $j = 1, \dots, |U|$ , where  $A^*$  is the adjoint of  $A$  with respect to the measures  $\mu_U$  and  $\mu_V$ .*

## 2.2 Probability Distributions

Throughout the paper, we will assume  $\Omega$  (or  $X^{(n)}$ ) to be a set of  $n$ -tuples for some  $n \geq 1$ . Given a set  $S \subset [n]$ , the projection of  $\Omega$  on  $S$  is denoted by  $\Omega[S]$ , i.e.

$$\Omega[S] = \{(\omega_s)_{s \in S} : (\omega_1, \dots, \omega_n) \in \Omega\}. \quad (\text{projection})$$

Let  $\mu : \Omega \rightarrow \mathbb{R}_{\geq 0}$  be a distribution. For  $\omega_S \in \Omega[S]$ , the notations  $\Omega_{\omega_S}$  and  $\mu^{(\omega_S)}$  will be used for the  $\omega_S$ -pinning of  $\Omega$  and  $\mu_S$  respectively, where

$$\Omega_{\omega_S} = \{\bar{\omega} \in \Omega[S^c] : \omega_S \oplus \bar{\omega} \in \Omega\} \quad \text{and} \quad \mu^{(\omega_S)}(\bar{\omega}) = \frac{\mu(\omega_S \oplus \bar{\omega})}{\sum_{\tilde{\omega} \in \Omega[S^c]} \mu(\omega_S \oplus \tilde{\omega})}, \quad (\omega_S\text{-pinning})$$

We recall that the total variation distance  $\|\mu - \nu\|_{\text{tv}}$  between two distributions  $\mu, \nu : \Omega \rightarrow \mathbb{R}_{\geq 0}$  is defined as follows,

$$\|\mu - \nu\|_{\text{tv}} = \frac{1}{2} \cdot \sum_{\omega \in \Omega} |\mu(\omega) - \nu(\omega)| \quad (\text{total variation distance})$$

Finally, we talk about some conventions that we will use throughout the paper: (i) We will be using the notation  $\text{uni}_A$  to denote the uniform distribution over various finite sets  $A$ . (ii) When we want to emphasize that the a distribution  $\mu : \Omega \rightarrow \mathbb{R}_{\geq 0}$  has full support, we will simply write  $\mu : \Omega \rightarrow \mathbb{R}_{> 0}$ .

Finally we recall that the product distribution  $\mu \otimes \nu \in \Delta_{\Omega \times \Omega'}$ , given  $\mu \in \Delta_{\Omega}$  and  $\nu \in \Delta_{\Omega'}$  is defined by:  $(\mu \otimes \nu)(\omega, \omega') = \mu(\omega) \cdot \nu(\omega')$  for all  $\omega \in \Omega, \omega' \in \Omega'$ .

### 2.3 Functional Inequalities, Isoperimetric Constants, and Mixing Times

Given a distribution  $\mu \in \Delta_{\Omega}$  and a convex function  $\Phi : \mathbb{R}_{\geq 0} \rightarrow \mathbb{R}_{\geq 0}$   $\Phi$ -entropy functional  $\text{Ent}_{\mu}^{\Phi}(\bullet)$  is defined by the equation,

$$\text{Ent}_{\mu}^{\Phi}(\mathbf{f}) = \mathbb{E}_{\omega \sim \mu} \Phi(\mathbf{f}(\omega)) - \Phi\left(\mathbb{E}_{\omega \sim \mu} \mathbf{f}(\omega)\right) \quad \text{for all } \mathbf{f} \in \mathbb{R}_{\geq 0}^{\Omega} \quad (\Phi\text{-entropy})$$

We also recall that for the special choices of  $\Phi(t) = t \log t$  and  $\Phi(t) = t^2$ , the  $\Phi$ -entropy equals the variance functional  $\text{Var}_{\mu}(\bullet)$  and entropy functional  $\text{Ent}_{\mu}(\bullet)$  respectively.

$$\text{Ent}_{\mu}(\mathbf{f}) = \mathbb{E}_{\omega \sim \mu} [\mathbf{f}(\omega) \log \mathbf{f}(\omega)] - \left(\mathbb{E}_{\omega \sim \mu} \mathbf{f}(\omega)\right) \log\left(\mathbb{E}_{\omega \sim \mu} \mathbf{f}(\omega)\right), \quad (\text{entropy})$$

$$\text{Var}_{\mu}(\mathbf{f}) = \mathbb{E}_{\omega \sim \mu} \mathbf{f}(\omega)^2 - \left(\mathbb{E}_{\omega \sim \mu} \mathbf{f}(\omega)\right)^2. \quad (\text{variance})$$

Let  $\mathbf{P} \in \mathbb{R}^{\Omega \times \Omega}$  be a reversible Markov chain, with stationary measure of  $\pi$ . A Poincaré inequality for  $\mathbf{P}$  is an inequality of the form,

$$C \cdot \text{Var}_{\pi}(\mathbf{f}) \leq \langle \mathbf{f}, (1 - \mathbf{P})\mathbf{f} \rangle_{\pi} \quad \text{for all } \mathbf{f} \in \mathbb{R}^{\Omega}. \quad (\text{Poincaré inequality})$$

The largest constant  $C > 0$  for which this inequality holds, is called the Poincaré constant or the spectral gap of  $\mathbf{P}$  and is denoted by  $\text{gap}(\mathbf{P})$ . This nomenclature is due to the following well-known consequence of the Courant-Fischer-Weyl Principle,

$$\text{gap}(\mathbf{P}) = \min \left\{ \frac{\langle \mathbf{f}, (1 - \mathbf{P})\mathbf{f} \rangle_{\pi}}{\text{Var}_{\pi}(\mathbf{f})} \mid \text{Var}_{\pi}(\mathbf{f}) \neq 0 \right\} = 1 - \lambda_2(\mathbf{P}). \quad (\text{spectral gap})$$

The log-Sobolev (LSI) inequality for a reversible random walk  $\mathbf{P} \in \mathbb{R}^{\Omega \times \Omega}$  with stationary measure  $\pi$  is defined to be,

$$C \cdot \text{Ent}_{\pi}(\mathbf{f}^2) \leq \langle \mathbf{f}, (1 - \mathbf{P})\mathbf{f} \rangle_{\pi} \quad \text{for all } \mathbf{f} \in \mathbb{R}_{\geq 0}^{\Omega}. \quad (\text{LSI})$$

The largest constants  $C \geq 0$  for which LSI holds is called the log-Sobolev constant of  $\mathbf{P}$  respectively and is denoted by  $\text{ls}(\mathbf{P})$ . Formally,

$$\text{ls}(\mathbf{P}) = \inf \left\{ \frac{\langle \mathbf{f}, (1 - \mathbf{P})\mathbf{f} \rangle_{\pi}}{\text{Ent}_{\pi}(\mathbf{f}^2)} \mid \text{Ent}_{\pi}(\mathbf{f}) \neq 0, \mathbf{f} \in \mathbb{R}_{\geq 0}^{\Omega} \right\}. \quad (2)$$

► **Lemma 5** ([19]). *Let  $\pi : \Omega \rightarrow \mathbb{R}_{>0}$  be a probability distribution and write  $J_\pi = \mathbf{1} \cdot \pi$ , i.e.  $J_\pi$  is the walk with stationary measure  $\pi$  which mixes in a single step.*

*Then,  $\mathbf{1s}(J_\pi) \geq \frac{1-2\pi_*}{\log(\pi_*^{-1}-1)}$  if  $|\text{supp}(\pi)| > 2$  else  $\mathbf{1s}(J_\pi) = 1$ . More generally for any reversible Markov chain  $M \in \mathbb{R}^{\Omega \times \Omega}$  and stationary distribution  $\pi$ , we have  $\mathbf{1s}(M) \geq \frac{1-2\pi_*}{\log(\pi_*^{-1}-1)} \cdot \text{gap}(M)$  if  $|\text{supp}(\pi)| > 2$  else  $\mathbf{1s}(J_\pi) = \text{gap}(M)$ .*

For a convex function  $\Phi : \mathbb{R}_{\geq 0} \rightarrow \mathbb{R}_{\geq 0}$ , we also define the  $\Phi$ -entropy contraction constant  $\text{cf}_\Phi(P)$  of a Markov chain  $P \in \mathbb{R}^{\Omega_1 \times \Omega_2}$  satisfying  $\pi_1 P = \pi_2$  for some choice of measures  $\pi_1 \in \Delta_{\Omega_1}, \pi_2 \in \Delta_{\Omega_2}$ , as the solution to the following variational problem,

$$\text{cf}_\Phi(P) = 1 - \sup \left\{ \frac{\text{Ent}_{\pi_1}^\Phi(P\mathbf{f})}{\text{Ent}_{\pi_2}^\Phi(\mathbf{f})} \mid \mathbf{f} \in \mathbb{R}_{\geq 0}^\Omega, \text{Ent}_{\pi_2}^\Phi(\mathbf{f}) \neq 0 \right\}. \quad (\Phi\text{-entropy contraction})$$

We note that  $\text{cf}_\Phi(P)$  crucially depends on the choice of distributions  $\pi_1, \pi_2$ . Since for our purposes the choice of measures  $\pi_1$  and  $\pi_2$  will always be clear, we will suppress this dependency.

It is equivalent to define  $\text{cf}_\Phi(P)$  as the largest constant  $C \in \mathbb{R}_{\geq 0}$  such that the inequality,

$$\text{Ent}_{\pi_1}^\Phi(P\mathbf{f}) \leq (1 - C) \cdot \text{Ent}_{\pi_2}^\Phi(\mathbf{f}),$$

is valid for each  $\mathbf{f} \in \mathbb{R}_{\geq 0}^{\Omega_2}$ . When  $\Phi(t) = t \log t$ , we will simply write  $\text{ec}(P)$  in place of  $\text{cf}_\Phi(P)$ . Similarly, for the choice of  $\Phi(t) = t^2$ , it is easy to observe that  $\text{cf}_\Phi(P) = \text{gap}(P^*P)$ .

We will also need the following consequence of Jensen's inequality.

► **Lemma 6** (Data Processing Inequality). *Let  $P \in \mathbb{R}^{\Omega_1 \times \Omega_2}$  be a row-stochastic matrix, satisfying  $\pi_1 P = \pi_2$  for probability distributions  $\pi_1 : \Omega_1 \rightarrow \mathbb{R}_{>0}$  and  $\pi_2 : \Omega_2 \rightarrow \mathbb{R}_{>0}$ . Then, for any convex function  $\Phi : \mathbb{R}_{\geq 0} \rightarrow \mathbb{R}_{\geq 0}$ , we have:  $\text{Ent}_{\pi_1}^\Phi(P\mathbf{f}) \leq \text{Ent}_{\pi_2}^\Phi(\mathbf{f})$  for all  $\mathbf{f} \in \mathbb{R}_{\geq 0}^{\Omega_2}$ .*

► **Lemma 7** (Proposition 6, [45]). *Let  $P \in \mathbb{R}^{\Omega_1 \times \Omega_2}$  satisfying  $\mu_1 P = \mu_2$ , for distributions  $\mu_1 : \Omega_1 \rightarrow \mathbb{R}_{>0}$  and  $\mu_2 : \Omega \rightarrow \mathbb{R}_{>0}$ . We have,  $\text{ec}(P) \geq \mathbf{1s}(P^*P)$ .*

The  $\varepsilon$ -mixing time  $\tau_{\text{mix}}(P, \varepsilon)$  of the random walk is the least time point  $t \in \mathbb{N}$ , such that the distribution  $\mu^{(t)} = \mu^{(0)} P^t$  of the random walk  $P$  is guaranteed to be  $\varepsilon$ -close to the stationary distribution  $\pi$  in the total variation distance regardless of the initial distribution  $\mu^{(0)}$ . In particular,

$$\tau_{\text{mix}}(P, \varepsilon) = \min \left\{ t \in \mathbb{N} \mid \left\| \mu^{(t)} - \pi \right\|_{\text{tv}} \leq \varepsilon \text{ for all } \mu^{(0)} \in \Delta_\Omega \right\} \quad (\varepsilon\text{-mixing time})$$

It is well known that the functional inequalities and the corresponding isoperimetric constants introduced previously can be used to bound mixing times. We recall in particular,

► **Theorem 8** ([11]). *There exists a universal constant  $C$  such that, for any reversible random walk  $P \in \mathbb{R}^{\Omega \times \Omega}$  with stationary distribution  $\pi : \Omega \rightarrow \mathbb{R}_{>0}$ , i.e.  $\pi P = \pi$ . We have*

$$\tau_{\text{mix}}(P, \varepsilon) \leq \frac{C}{\text{ec}(P)} \cdot \left( \log \log \frac{1}{\min_{\omega \in \Omega} \pi(\omega)} + \log \varepsilon^{-1} \right).$$

where the constant  $C$  does not depend on the pair  $(P, \pi)$ .

## 2.4 (Partite) Simplicial Complexes

A simplicial complex is a downward closed collection of subsets of a finite set  $U$ . Formally,  $X \subset 2^U$  and whenever  $\beta \in X$  for all  $\alpha \subset \beta$  we have  $\alpha \in X$ . The rank of a face  $\alpha$  is  $|\alpha|$ . Given some  $j$ , we will adopt the notation  $X^{(j)}$  to refer to the collection faces of  $X$  of rank  $j$

and the notation  $X^{(\leq j)}$  to refer to the collection of faces of  $X$  of rank at most  $j$ . We say  $X$  is a simplicial complex of rank  $n$  if the largest rank of any face  $\alpha \in X$  is  $n$ . We note that by definition  $X^{(0)} = \{\emptyset\}$ .

We say that a simplicial complex  $X$  of rank  $n$  is pure, if any face  $\alpha \in X^{(j)}$  for any  $j < n$  is contained in another face  $\beta \in X^{(n)}$ . Equivalently, in a pure simplicial complex the only inclusion maximal faces are those of maximal rank. In this article, we will only deal with pure simplicial complexes.

A rank- $n$  pure simplicial complex  $X$  is called  $n$ -partite if we can partition  $X^{(1)}$  into disjoint sets  $X[1], \dots, X[n]$  such that

$$\text{for all } \beta \in X^{(n)} \text{ and for all } i = 1, \dots, n \text{ we have } |\beta \cap X[i]| = 1. \quad (n\text{-partiteness})$$

We will call the sets  $X[1], \dots, X[n]$  the sides of the complex  $X$ . Equivalently, every element of a rank- $n$  face  $\beta \in X[n]$  comes from a distinct side  $X[i]$ . We observe that a bipartite graph is a 2-partite simplicial complex.

To keep our nomenclature simple, we will simply refer to a pure  $n$ -partite simplicial complex of rank  $n$  as an  $n$ -partite simplicial complex, i.e. we will not consider  $n$ -partite complexes which are not pure.

For a face  $\alpha \in X$  we introduce the notation,  $\text{type}(\alpha) = \{i \in [n] : \alpha \cap X[i] \neq \emptyset\}$  for the type of the face  $\alpha$ , i.e. the collection of sides of  $X$  that  $\alpha$  intersects.

For any  $i \in [n]$  and  $\beta \in X^{(n)}$  we will write  $\beta_i \in X^{(1)}$  for the unique element of  $\beta$  satisfying  $\{\beta_i\} = \beta \cap X[i]$ . We will refer to  $\beta_i$  as the  $i$ -th coordinate of  $\beta$ . We will also write  $\beta_T = \{\beta_t : t \in T\}$  for all  $T \subset [n]$ . We extend this notation to arbitrary faces  $\alpha \in X$  and  $T \subset \text{type}(\alpha)$ . In keeping with the view that a face  $\alpha \in X$  with  $\text{type}(\alpha) = \{t_1, \dots, t_k\}$  can be represented as a tuple  $(a_{t_1}, \dots, a_{t_k})$ , we will favour the notation  $\alpha \oplus \alpha'$  to denote the union of two faces  $\alpha, \alpha' \in X$  with  $\text{type}(\alpha) \cap \text{type}(\alpha') = \emptyset$  over the usual notation  $\alpha \cup \alpha'$ .

We observe that for facets  $\beta \in X^{(n)}$ , i.e. faces of maximal rank, we have  $\text{type}(\beta) = [n]$ . Given,  $\alpha \in X$  we recall that the link  $X_\alpha$  is defined as,  $X_\alpha = \{(\beta \setminus \alpha) \in X : \beta \in X, \beta \supset \alpha\}$ .

For  $T \subset [n]$ , we will also introduce the notation  $X[T]$  to refer to all faces of  $X$  of type  $T$ .

### Weighted Simplicial Complexes

A weighted simplicial complex  $(X, \pi)$  of rank  $n$  is a pure simplicial complex of rank  $n$  where  $\pi := \pi_n : X^{(n)} \rightarrow \mathbb{R}_{\geq 0}$  is a probability distribution with full support.

For  $j \in [0, n - 1]$ , we inductively define the probability distributions  $\pi_j : X^{(j)} \rightarrow \mathbb{R}$  as

$$\pi_j(\alpha) = \pi_j(\alpha) = \frac{1}{\binom{n}{j}} \sum_{\substack{\beta \supset \alpha \\ \beta \in X^{(n)}}} \pi_n(\beta). \quad (3)$$

Similarly, given a face  $\alpha \in X^{(j)}$ , we define the distribution  $\pi^{(\alpha)}$  on  $X_\alpha^{(n-j)}$  by conditioning  $\pi$  on the containment of  $\alpha$ . Of particular importance to us will be the link graph  $M_\alpha \in \mathbb{R}^{X_\alpha^{(1)} \times X_\alpha^{(1)}}$  given any  $\alpha \in X^{(\leq n-2)}$ . We recall that for all distinct pairs of vertices  $x, y \in X_\alpha^{(1)}$ , we have

$$M_\alpha(x, y) = \pi^{(\alpha \cup \{x\})}(y) = \frac{\Pr_{\omega \sim \pi_n}[\omega \supset \alpha \cup \{x, y\} \mid \omega \supset \alpha \cup \{x\}]}{n - |\alpha| - 1}, \quad (\text{link})$$

and  $M_\alpha(x, x) = 0$  for all  $x \in X_\alpha^{(1)}$ .

## 2.5 Higher Order Random Walks on Simplicial Complexes

Let  $(X, \pi)$  be a simplicial complex of rank  $n$ . The up-down walk  $P_{\ell \leftrightarrow n}^{\uparrow \downarrow} := \text{UpDown}_{\ell \leftrightarrow n}(X, \pi)$  between the  $\ell$ -th and  $n$ -th levels,  $X^{(\ell)}$  and  $X^{(n)}$  respectively, is defined as the following random walk on  $X^{(\ell)}$ : Starting from an arbitrary face  $\hat{\omega}^{(0)} \in X^{(\ell)}$  for all  $t \geq 1$  move from  $\hat{\omega}^{(t-1)}$  to  $\hat{\omega}^{(t)}$  according to the following simple rule,

**Update Rule For the Up-Down Walk,  $P_{\ell \leftrightarrow n}^{\uparrow \downarrow}$**

- sample  $\omega \sim \pi_n$ , conditional on  $\omega \supset \hat{\omega}^{(t-1)}$ ,
- draw a uniformly subset among all the subsets of  $\omega$  of size  $\ell$ , and output it as  $\hat{\omega}$ .

Similarly, the down-up walk  $P_{n \leftrightarrow \ell}^{\downarrow \uparrow}$  between the  $n$ -th and  $\ell$ -th levels,  $X^{(n)}$  and  $X^{(\ell)}$  respectively, as the following random walk  $X^{(n)}$ : Starting from an arbitrary  $\omega^{(0)} \in X^{(n)}$  and moves from  $\omega^{(t-1)}$  to  $\omega^{(t)}$  according to the following simple rule,

**Update Rule for the Down-Up Walk,  $P_{n \leftrightarrow \ell}^{\downarrow \uparrow}$**

- draw a subset  $\hat{\omega}$  of  $\omega$  of size  $\ell$ , uniformly at random,
- draw a subset  $\omega \sim \pi$  conditioned on containing  $\hat{\omega}$ , and output it as  $\omega^{(t)}$ .

It is well known, [2, 21, 20], that the random walks  $P_{n \leftrightarrow \ell}^{\downarrow \uparrow}$  and  $P_{\ell \leftrightarrow n}^{\uparrow \downarrow}$  can be decomposed as a product of random down- and up-movements on  $X$ . Formally, for  $0 \leq \ell \leq k \leq n$ , we define the up-walk  $P_{\ell \rightarrow k}^{\uparrow} := \text{Up}_{\ell \rightarrow k}(X, \pi)$  and the down-walk  $P_{k \rightarrow \ell}^{\downarrow} := \text{Down}_{k \rightarrow \ell}(X, \pi)$  as the following random walks,

$$P_{\ell \rightarrow k}^{\uparrow}(\hat{\omega}, \omega) = \pi_{k-\ell}^{(\hat{\omega})}(\omega) = \frac{\mathbf{1}[\omega \supset \hat{\omega}] \cdot \Pr_{\omega \sim \pi_n}[\tilde{\omega} \supset \omega \mid \tilde{\omega} \supset \hat{\omega}]}{\binom{n-\ell}{k-\ell}}, \quad (\text{up-walk})$$

$$P_{k \rightarrow \ell}^{\downarrow}(\omega, \hat{\omega}) = \frac{\mathbf{1}[\hat{\omega} \subset \omega]}{\binom{k}{\ell}}. \quad (\text{down-walk})$$

► **Proposition 9 (Folklore).** *Let  $(X, \pi)$  be a simplicial complex of rank  $n$ , then writing  $P_{n \leftrightarrow \ell}^{\downarrow \uparrow} := \text{DownUp}_{n \leftrightarrow \ell}(X, \pi)$ ,  $P_{\ell \leftrightarrow n}^{\uparrow \downarrow} := P_{\ell \leftrightarrow n}^{\uparrow \downarrow}(X, \pi)$ ,  $P_{\ell \rightarrow n}^{\uparrow} = \text{Up}_{\ell \rightarrow n}(X, \pi)$ , and  $P_{n \rightarrow \ell}^{\downarrow} = \text{Down}_{n \rightarrow \ell}(X, \pi)$  for the down-up, up-down, up- and down-walks between the  $n$ -th and  $\ell$ -th levels of  $X$  respectively, we have*

1.  $(P_{\ell \rightarrow n}^{\uparrow})^* = P_{n \rightarrow \ell}^{\downarrow}$ , i.e. the operators  $P_{\ell \rightarrow n}^{\uparrow}$  and  $P_{n \rightarrow \ell}^{\downarrow}$  are adjoint operators with respect to the measures  $\pi_n$  and  $\pi_\ell$ ,
2.  $P_{\ell \leftrightarrow n}^{\uparrow \downarrow} = P_{\ell \rightarrow n}^{\uparrow} P_{n \rightarrow \ell}^{\downarrow}$  - in particular the operator  $P_{\ell \leftrightarrow n}^{\uparrow \downarrow}$  is PSD,
3.  $P_{n \leftrightarrow \ell}^{\downarrow \uparrow} = P_{n \rightarrow \ell}^{\downarrow} P_{\ell \rightarrow n}^{\uparrow}$  - in particular the operator  $P_{n \leftrightarrow \ell}^{\downarrow \uparrow}$  is PSD.

For any  $\hat{\omega} \in X$  and any  $0 \leq \ell \leq n' = n - |\hat{\omega}|$ , we will write  $P_{\hat{\omega}, \ell \rightarrow n'}^{\uparrow}$ ,  $P_{\hat{\omega}, n' \rightarrow \ell}^{\downarrow}$ ,  $P_{\hat{\omega}, \ell \leftrightarrow n'}^{\uparrow \downarrow}$  and  $P_{\hat{\omega}, n' \leftrightarrow \ell}^{\downarrow \uparrow}$  for the corresponding up, down, up-down, and down-up walks in the complex  $(X_{\hat{\omega}}, \pi_{\hat{\omega}})$ .

## 2.6 Local to Global Analysis

Given a simplicial complex  $(X, \pi)$  of rank  $n$ , we define the local  $\Phi$ -entropy contraction factor  $\text{lc}_\Phi(\hat{\omega})$  for any  $\hat{\omega} \in X^{(\leq r-2)}$  as follows,

$$\text{lc}_\Phi(\hat{\omega}) := \sup \left\{ \frac{\text{Ent}_{\pi_1^{(\hat{\omega})}}^\Phi(P_{\hat{\omega}, 1 \rightarrow n'}^{\uparrow} \mathbf{g})}{\text{Ent}_{\pi_{n'}^{(\hat{\omega})}}^\Phi(\mathbf{g})} \mid \mathbf{g} \in \mathbb{R}^{X_{\hat{\omega}}^{(n')}} \text{ and } n' = n - |\hat{\omega}|. \right\} \quad (4)$$

Equivalently,  $\mathbf{1c}_\Phi(\hat{\omega}) \in \mathbb{R}_{>0}$  is the smallest constant satisfying the equality

$$\text{Ent}_{\pi_1}^\Phi(\mathbf{P}_{\hat{\omega},1 \rightarrow n'}^\uparrow \mathbf{g}) \leq \mathbf{1c}_\Phi(\hat{\omega}) \cdot \text{Ent}_{\pi_{n'}}^\Phi(\mathbf{g}) \quad \text{for all } \mathbf{g} \in \mathbb{R}^{X_{\hat{\omega}}^{(n')}} \quad \text{where } n' = n - |\hat{\omega}|.$$

When  $\Phi(t) = t \log t$ , we will simply write  $\mathbf{1ec}(\hat{\omega})$  in place of  $\mathbf{1c}_\Phi(\hat{\omega})$ . We also make the following observation for the special case  $\Phi(t) = t^2$ , i.e. when  $\text{Ent}_{\Phi}^\bullet(\bullet)$  equals the variance functional  $\text{Var}_\bullet(\bullet)$ . The following proposition is well understood,

► **Proposition 10.** <sup>4</sup> *Let  $(X, \pi)$  be a simplicial complex of rank  $n$ . Then, for the choice of  $\Phi(t) = t^2$ , for any  $\hat{\omega} \in X^{(\leq n-2)}$  we have*

$$\mathbf{1c}_\Phi(\hat{\omega}) = \frac{1}{n - |\hat{\omega}|} + \frac{n - |\hat{\omega}| - 1}{n - |\hat{\omega}|} \cdot \lambda_2(\mathbf{M}_{\hat{\omega}}),$$

where  $\mathbf{M}_{\hat{\omega}}$  is the link graph of  $\hat{\omega}$ .

A crucial tool we will be using in Section 4 is the so called Garland method, due to [31]. To this end, we define the localization  $\mathbf{f}|_{\hat{\omega}} \in \mathbb{R}^{X_{\hat{\omega}}^{(k-j)}}$  of a function  $\mathbf{f} \in \mathbb{R}^{X^{(k)}}$  on a link  $\hat{\omega} \in X^{(j)}$  for  $j \leq k$  as the following function,

$$\mathbf{f}|_{\hat{\omega}}(\alpha) = \mathbf{f}(\hat{\omega} \sqcup \alpha) \quad \text{for all } \alpha \in X_{\hat{\omega}}^{(k-j)}. \quad (\text{localization})$$

We first observe that by appealing to the chain rule for the  $\Phi$ -entropy, one can obtain a convenient expression for it in terms of localizations.

► **Lemma 11** (Chain Rule for  $\Phi$ -Entropy). <sup>5</sup> *Let  $(X, \pi)$  be a simplicial complex of rank  $n$ . For all  $0 \leq \ell \leq r \leq n$  and non-negative  $\mathbf{f} \in \mathbb{R}_{\geq 0}^{X^{(r)}}$ , we have*

$$\text{Ent}_{\pi_r}^\Phi(\mathbf{f}) = \mathbb{E}_{\hat{\omega} \sim \pi_\ell} \text{Ent}_{\pi_{r-\ell}}^\Phi(\mathbf{f}|_{\hat{\omega}}) + \text{Ent}_{\pi_\ell}(\mathbf{P}_{\ell \rightarrow r}^\uparrow \mathbf{f}),$$

where  $\mathbf{P}_{\ell \rightarrow r}^\uparrow := \text{Up}_{\ell \rightarrow r}(X, \pi)$  is the up-walk on  $X$

We also recall the following identities,

► **Lemma 12.** *Let  $(X, \pi)$  be a simplicial complex of rank  $n$ . Writing  $\mathbf{P}_{n \leftrightarrow r}^{\downarrow \uparrow} = \text{DownUp}_{n \leftrightarrow r}(X, \pi)$ ,  $\mathbf{P}_{n-1}^{\uparrow \downarrow} = \text{UpDown}_{n-1 \leftrightarrow n}(X, \pi)$ , and  $\mathbf{M}_{\hat{\omega}}$  for the link of the face  $\hat{\omega} \in X^{(\leq n-2)}$ , for all  $\mathbf{f} \in \mathbb{R}^{X^{(n)}}$  and  $\ell \leq r \leq n$ , we have*

1.  $\langle \mathbf{f}, \mathbf{f} \rangle_{\pi_n} = \mathbb{E}_{\hat{\omega} \sim \pi_\ell} \langle \mathbf{f}|_{\hat{\omega}}, \mathbf{f}|_{\hat{\omega}} \rangle_{\pi_{n-\ell}^{(\hat{\omega})}},$
2.  $\langle \mathbf{f}, \mathbf{P}_{n \leftrightarrow r}^{\downarrow \uparrow} \mathbf{f} \rangle_{\pi_n} = \mathbb{E}_{\hat{\omega} \sim \pi_\ell} \langle \mathbf{f}|_{\hat{\omega}}, \mathbf{P}_{\hat{\omega}, n-\ell \leftrightarrow r-\ell}^{\downarrow \uparrow} \mathbf{f}|_{\hat{\omega}} \rangle_{\pi_{n-\ell}^{(\hat{\omega})}},$
3.  $\langle \mathbf{f}, \mathbf{P}_{n-1}^{\uparrow \downarrow} \mathbf{f} \rangle_{\pi_n} = \mathbb{E}_{\hat{\omega} \sim \pi_{n-2}} \left( \langle \mathbf{f}|_{\hat{\omega}}, \left( \frac{1}{n} + \frac{n-1}{n} \cdot \mathbf{M}_{\hat{\omega}} \right) \mathbf{f}|_{\hat{\omega}} \rangle_{\pi_1^{(\hat{\omega})}} \right)$

We recall the following result due to [40],

► **Lemma 13** (Theorem 3.5, [40]). *Let  $(X, \pi)$  be an  $n$ -partite simplicial complex and let  $0 \leq k < n$ . If  $\mathbf{ec}(\mathbf{P}_{n-1 \rightarrow n}^\uparrow) \geq (Cn)^{-1}$  for some  $C \in \mathbb{R}_{>0}$ , then  $\mathbf{ec}(\mathbf{P}_{k \rightarrow k+1}^\uparrow) \geq \frac{1}{(k+1)(C+1)}$ .*

<sup>4</sup> We provide a proof for this statement in the full version of our paper, [4]

<sup>5</sup> A proof is supplied in the full version of our paper, [4]

### 3 Expanderized Random Walks

Let  $(X, \pi)$  be an  $n$ -partite simplicial complex. For any  $\ell \leq n$ , the up-down walk  $\mathbb{P}_{\ell \leftrightarrow n}^{\uparrow \downarrow} := \text{UpDown}_{\ell \leftrightarrow n}(X, \pi)$  on the  $\ell$ -th level  $X^{(\ell)}$  of  $X$  introduced in Section 2.5 admits the following alternative description: Starting from an arbitrary face  $\hat{\omega}^{(0)} \in X^{(\ell)}$  move from  $\hat{\omega}^{(t-1)}$  to  $\hat{\omega}^{(t)}$  according to the following simple rule,

**Update Rule for the Up-Down Walk,  $\mathbb{P}_{\ell \leftrightarrow n}^{\uparrow \downarrow}$**

- sample  $\omega \sim \pi$ , conditional on  $\omega \supset \hat{\omega}^{(t-1)}$ ,
- sample  $S \sim \text{uni}_{\binom{[n]}{\ell}}$ ,
- output  $\hat{\omega}^{(t)} = \omega_S$ .

We will expanderize the up-down walk  $\mathbb{P}_{\ell \leftrightarrow n}^{\uparrow \downarrow}$  in the following manner: Given a  $k$ -regular labelled graph  $H$  on the vertex set  $\binom{[n]}{\ell}$ , we will denote the  $a$ -th neighbor of vertex  $v$  by  $\text{Out}_H(v, a)$ . We define the expanderized up-down walk  $\mathbb{Q}_{\ell \leftrightarrow n}^{\uparrow \downarrow} = \text{UpDown}_{\ell \leftrightarrow n}(X, \pi, H)$  as the walk which starts from an arbitrary face  $\hat{\omega}^{(0)}$  and moves from  $\hat{\omega}^{(t-1)}$  to  $\hat{\omega}^{(t)}$  according to the following simple rule,

**Update Rule for the Expanderized Up-Down Walk,  $\mathbb{Q}_{\ell \leftrightarrow n}^{\uparrow \downarrow}$**

- sample  $\omega \sim \pi$ , conditional on  $\omega \supset \hat{\omega}^{(t-1)}$ ,
- sample  $a \sim \text{uni}_{[k]}$  and set  $S = \text{Out}_H(\text{type}(\hat{\omega}^{(t-1)}), a)$ ,<sup>a</sup>
- output  $\hat{\omega}^{(t)} = \omega_S$ .

<sup>a</sup> Where we recall that the type of  $\hat{\omega}$  is the sides of the simplicial complex that  $\hat{\omega}$  intersects

Similarly, the down-up walk  $\mathbb{P}_{n \leftrightarrow \ell}^{\downarrow \uparrow}$  between the  $n$ -th level  $X^{(n)}$  and the  $\ell$ -th level  $X^{(\ell)}$  of an  $n$ -partite simplicial complex  $(X, \pi)$  introduced in Section 2.5 admits the following alternative description: Start from  $\omega^{(0)} \in X^{(n)}$  and move from  $\omega^{(t-1)}$  to  $\omega^{(t)}$  according to the following simple rule,

**Update Rule for the Down-Up Walk,  $\mathbb{P}_{n \leftrightarrow \ell}^{\downarrow \uparrow}$**

- sample  $S \sim \text{uni}_{\binom{[n]}{\ell}}$  uniformly at random,
- set  $\hat{\omega} = \omega_S$ ,
- set  $\omega^{(t)}$  to be a random face drawn from  $\pi$ , conditional on containing  $\hat{\omega}$ .

Similarly, we define the expanderized down-up walk  $\mathbb{Q}_{n \leftrightarrow \ell}^{\downarrow \uparrow} = \text{DownUp}_{n \leftrightarrow \ell}(X, \pi, H)$  to be the random walk on  $X^{(n)} \times \binom{[n]}{\ell}$ , starting from an arbitrary face-subset pair  $(\omega^{(0)}, S^{(0)})$  and move from  $(\omega^{(t-1)}, S^{(t-1)})$  to  $(\omega^{(t)}, S^{(t)})$  according to the following simple rule,

**Update Rule for the Expanderized Down-Up Walk,  $\mathbb{Q}_{n \leftrightarrow \ell}^{\downarrow \uparrow}$**

- sample  $a \sim \text{uni}_{[k]}$  and set  $S' = \text{Out}_H(S^{(t-1)}, a)$ ,
- set  $\hat{\omega} = \omega_{S'}$ ,
- set  $\omega^{(t)} \sim \pi$  to be a random face conditional on containing  $\hat{\omega}$ ,
- sample  $b \sim \text{uni}_{[k]}$  and set  $S^{(t)} = \text{Out}_H(S^{(t-1)}, b)$ ,
- output  $(\omega^{(t)}, S^{(t)})$ .

For convenience we also define the expanderized down- and up-walks given a degree regular labelled graph  $H = (\binom{[n]}{\ell}, E)$

$$\mathbf{Q}_{n \rightarrow \ell}^\downarrow = \text{Down}_{n \rightarrow \ell}(X, \pi, H) \in \mathbb{R}^{(X^{(n)} \times \binom{[n]}{\ell}) \times X^{(\ell)}} \quad \text{and} \quad \mathbf{Q}_{\ell \rightarrow n}^\uparrow = \text{Up}_{\ell \rightarrow [n]}(X, \pi, H) \in \mathbb{R}^{X^{(\ell)} \times (X^{(n)} \times \binom{[n]}{\ell})},$$

as follows,

$$\mathbf{Q}_{n \rightarrow \ell}^\downarrow((\omega, S), \hat{\omega}) = \frac{\mathbf{1}[S \sim_H \text{type}(\hat{\omega})]}{k} \cdot \mathbf{1}[\omega \supset \hat{\omega}] \quad \text{for all } \omega \in X^{(n)}, \hat{\omega} \in X^{(\ell)}, S \in \binom{[n]}{\ell},$$

and  $\mathbf{Q}_{\ell \rightarrow n}^\uparrow = (\mathbf{Q}_{n \rightarrow \ell}^\downarrow)^*$  where the adjoint is taken with respect to the distributions  $\pi_n \otimes \text{uni}_{\binom{[n]}{\ell}}$  and  $\pi_\ell$ , i.e.

$$\mathbf{Q}_{\ell \rightarrow n}^\uparrow(\hat{\omega}, (\omega, S)) = \frac{\mathbf{1}[S \sim_H \text{type}(\hat{\omega})]}{k} \cdot \Pr_{\tilde{\omega} \sim \pi_n} [\tilde{\omega} = \omega \mid \omega \supset \hat{\omega}] \quad \text{for all } \omega \in X^{(n)}, \hat{\omega} \in X^{(\ell)}, S \in \binom{[n]}{\ell},$$

and the notation  $T \sim_H S$  is used to denote the adjacency relation in the graph  $H$ , i.e.  $\{S, T\} \in E(H)$ .

We summarize the random movements described by the expanderized up- and down-walks in words as follows: The expanderized down-walk  $\mathbf{Q}_{n \rightarrow \ell}^\downarrow$  first samples a random neighbor of  $T$  of  $S$  in  $\binom{[n]}{\ell}$ , and then restricts the coordinates of  $\omega$  to  $T$ , i.e. moves to  $\omega_T$ . The expanderized up-walk  $\mathbf{Q}_{\ell \rightarrow n}^\uparrow$  on the other hand first samples a facet  $\omega \in X^{(n)}$  from  $\pi$  conditional on containing  $\hat{\omega}$  and after picking a random neighbor  $S$  of  $\text{type}(\hat{\omega})$  in  $H$  moves to  $(\omega, S)$ .

► **Proposition 14.** *For any  $n$ -partite pure simplicial complex  $(X, \pi)$  and a  $k$ -regular labelled graph  $H = (\binom{[n]}{\ell}, E)$ , writing  $\mathbf{Q}_{n \rightarrow \ell}^\downarrow = \text{Down}_{n \rightarrow \ell}(X, \pi, H)$  and  $\mathbf{Q}_{\ell \rightarrow n}^\uparrow = \text{Up}_{\ell \rightarrow n}(X, \pi, H)$  we have,*

$$\left(\pi_n \otimes \text{uni}_{\binom{[n]}{\ell}}\right) \mathbf{Q}_{n \rightarrow \ell}^\downarrow = \pi_\ell \quad \text{and} \quad \pi_\ell \mathbf{Q}_{\ell \rightarrow n}^\uparrow = \pi_n \otimes \text{uni}_{\binom{[n]}{\ell}}.$$

**Proof.** Let  $(\omega, S) \sim \pi_n \otimes \text{uni}_{\binom{[n]}{\ell}}$  be a random sample. Notice that a random neighbor of  $S$  in  $H$  is still distributed uniformly at random as the uniform distribution stationary for the random walk over a  $k$ -regular graph, q.v. Observation 3. Thus, conditional on  $\omega$ , a single step of  $\mathbf{Q}_n^\downarrow$  ends up restricting  $\omega$  to a random set of coordinates  $S$  – this precisely yields the distribution  $\pi_\ell$ , q.v. Equation (3).

The second statement follows since  $\mathbf{Q}_{\ell \rightarrow n}^\uparrow$  is the adjoint operator, q.v. Proposition 1. ◀

The following is easy to verify,

► **Corollary 15.** *For any  $n$ -partite simplicial complex  $(X, \pi)$  and  $k$ -regular labelled graph  $H = (\binom{[n]}{\ell}, E)$ ,*

- $\text{UpDown}_{\ell \leftrightarrow n}(X, \pi, H^2) = \text{Up}_{\ell \rightarrow n}(X, \pi, H) \cdot \text{Down}_{n \rightarrow \ell}(X, \pi, H),$
- $\text{DownUp}_{n \leftrightarrow \ell}(X, \pi, H) = \text{Down}_{n \rightarrow \ell}(X, \pi, H) \cdot \text{Up}_{\ell \rightarrow n}(X, \pi, H).$

We now summarize several useful properties of the expanderized up- and down-walks,

► **Corollary 16.** *Let  $(X, \pi)$  be an  $n$ -partite complex and  $H = (\binom{[n]}{\ell}, E)$  a  $k$ -regular graph. For any  $\ell \leq n$ , writing  $\mathbf{Q}_{\ell \leftrightarrow n}^{\uparrow \downarrow} = \text{UpDown}_{\ell \leftrightarrow n}(X, \pi, H^2)$ ,  $\mathbf{Q}_{n \leftrightarrow \ell}^{\downarrow \uparrow} = \text{DownUp}_{n \leftrightarrow \ell}(X, \pi, H)$   $\mathbf{Q}_{n \rightarrow \ell}^\downarrow = \text{Down}_{n \rightarrow \ell}(X, \pi, H)$  and  $\mathbf{Q}_{\ell \rightarrow n}^\uparrow = \text{Up}_{\ell \rightarrow n}(X, \pi, H)$  we have,*

1.  $(\pi_n \otimes \text{uni}_{\binom{[n]}{\ell}}) \mathbf{Q}_{n \leftrightarrow \ell}^{\downarrow \uparrow} = \pi_n \otimes \text{uni}_{\binom{[n]}{\ell}}$ , i.e.  $\pi_n \otimes \text{uni}_{\binom{[n]}{\ell}}$  is the stationary distribution of  $\mathbf{Q}_{n \leftrightarrow \ell}^{\downarrow \uparrow}$ ,
2.  $\pi_\ell \mathbf{Q}_{\ell \leftrightarrow n}^{\uparrow \downarrow} = \pi_\ell$ , i.e.  $\pi_\ell$  is the stationary distribution of  $\mathbf{Q}_{\ell \leftrightarrow n}^{\uparrow \downarrow}$ .

3.  $Q_{n \leftrightarrow \ell}^{\downarrow \uparrow}$  and  $Q_{\ell \leftrightarrow n}^{\uparrow \downarrow}$  are PSD operators.
4.  $Q_{\ell \leftrightarrow n}^{\uparrow \downarrow}$  and  $Q_{n \leftrightarrow \ell}^{\downarrow \uparrow}$  are self-adjoint operators.

Since in our proofs it will be more convenient to use  $Q_{\ell \leftrightarrow n}^{\uparrow \downarrow} := \text{UpDown}_{\ell \leftrightarrow n}(X, \pi, H)$  directly, initialized with  $H$  and not  $H^2$ , we also note the following.

► **Proposition 17.** <sup>6</sup> Let  $(X, \pi)$  be an  $n$ -partite complex and  $H = (\binom{[n]}{\ell}, E)$  a  $k$ -regular graph. Then, the expanderized up-down walk  $Q_{\ell \leftrightarrow n}^{\uparrow \downarrow} := \text{UpDown}_{\ell \leftrightarrow n}(X, \pi, H)$  has the stationary distribution  $\pi_\ell$  and is reversible.

Now, we present the results we prove for expanderized random walks. Our first result shows that the expanderized up-down walk approximates the usual up-down walk in the operator norm,

► **Theorem 18.** Let  $(X, \pi)$  be an  $n$ -partite simplicial complex and let  $H$  be a  $k$ -regular labelled graph on the vertex set  $\binom{[n]}{\ell}$ . Writing  $Q_{\ell \leftrightarrow n}^{\uparrow \downarrow} := \text{UpDown}(X, \pi, H)$  and  $P_{\ell \leftrightarrow n}^{\uparrow \downarrow} := \text{UpDown}(X, \pi)$  for the expanderized- and the regular up-down walks on  $X^{(\ell)}$ , we have

$$\left\| Q_{\ell \leftrightarrow n}^{\uparrow \downarrow} - (1 - \lambda(H)) \cdot P_{\ell \leftrightarrow n}^{\uparrow \downarrow} \right\|_{\text{op}, \pi_\ell} \leq \lambda(H).$$

We present the proof of Theorem 18 in Section 3.1. Theorem 18 immediately implies the following bounds for the spectral gap of expanderized walks,

► **Corollary 19.** <sup>7</sup> Let  $(X, \pi)$  be an  $n$ -partite simplicial complex and let  $H$  be a  $k$ -regular labelled graph on the vertex set  $\binom{[n]}{\ell}$ . Writing  $Q_{\ell \leftrightarrow n}^{\uparrow \downarrow} := \text{UpDown}(X, \pi, H)$ ,  $P_{\ell \leftrightarrow n}^{\uparrow \downarrow} = \text{UpDown}_{\ell \leftrightarrow n}(X, \pi)$ ,  $Q_{n \leftrightarrow \ell}^{\downarrow \uparrow} = \text{DownUp}(X, \pi, H)$ , and  $P_{n \leftrightarrow \ell}^{\downarrow \uparrow} = \text{DownUp}_{n \leftrightarrow \ell}(X, \pi)$ , we have

$$\begin{aligned} \text{gap}\left(Q_{\ell \leftrightarrow n}^{\uparrow \downarrow}\right) &\geq \text{gap}\left(P_{\ell \leftrightarrow n}^{\uparrow \downarrow}\right) \cdot \text{gap}^*(H), \\ \text{gap}\left(Q_{n \leftrightarrow \ell}^{\downarrow \uparrow}\right) &\geq \text{gap}\left(P_{n \leftrightarrow \ell}^{\downarrow \uparrow}\right) \cdot \text{gap}^*(H^2), \end{aligned}$$

where  $\text{gap}^*(G) = 1 - \lambda(G)$  and  $\lambda(G)$  denotes the two-sided expansion of the graph  $G$ .

Unfortunately, a bound on the spectral gap is in many settings not enough to obtain optimal mixing time bounds. We show however, that Theorem 18 allows us to transfer log-Sobolev inequalities (LSI) for the usual up-down walks to the expanderized up-down walks,

► **Corollary 20.** Let  $(X, \pi)$  be an  $n$ -partite simplicial complex and let  $H$  be a  $k$ -regular labelled graph on the vertex set  $\binom{[n]}{\ell}$ . Writing  $Q_{\ell \leftrightarrow n}^{\uparrow \downarrow} := \text{UpDown}_{\ell \leftrightarrow n}(X, \pi, H)$  and  $P_{\ell \leftrightarrow n}^{\uparrow \downarrow} := \text{UpDown}_{\ell \leftrightarrow n}(X, \pi)$  for the up-down walk on  $X^{(\ell)}$ , we have

$$\text{ls}\left(Q_{\ell \leftrightarrow n}^{\uparrow \downarrow}\right) \geq \text{ls}\left(P_{\ell \leftrightarrow n}^{\uparrow \downarrow}\right) \cdot \text{gap}^*(H),$$

where  $\text{gap}^*(H) = 1 - \lambda(H)$  and  $\lambda(H)$  denotes the two-sided expansion of the graph  $H$ .

We will prove Corollary 20 in Section 3.2. We state a convenient corollary of Corollary 20 which immediately follows from Lemma 7, Corollary 16, and the data processing inequality Lemma 6,

<sup>6</sup> As Corollary 16 reaches the same end by replacing  $H$  with  $H^2$  we will omit this proof and refer the reader to the full version of our paper [4]

<sup>7</sup> Since this result does not get used in our applications, we refer the reader to the full-version of our paper [4] for a proof.

► **Corollary 21.** *Let  $(X, \pi)$  be an  $n$ -partite simplicial complex and let  $H$  be a  $k$ -regular labelled graph on the vertex set  $\binom{[n]}{\ell}$ . Then, writing  $\mathbf{Q}_{n \leftrightarrow \ell}^\downarrow = \text{Down}_{n \rightarrow \ell}(X, \pi, H)$  and  $\mathbf{P}_{\ell \leftrightarrow n}^{\uparrow \downarrow} = \text{UpDown}_{\ell \leftrightarrow n}(X, \pi)$  we have,*

$$\text{ec}(\mathbf{Q}_{n \leftrightarrow \ell}^\downarrow) \geq \text{ls}(\mathbf{P}_{\ell \leftrightarrow n}^{\uparrow \downarrow}) \cdot \text{gap}^*(H^2).$$

*In particular, we have for  $\mathbf{Q}_{\ell \leftrightarrow n}^{\uparrow \downarrow} := \text{UpDown}_{\ell \leftrightarrow n}(X, \pi, H^2)$  and  $\mathbf{Q}_{n \leftrightarrow \ell}^{\downarrow \uparrow} = \text{DownUp}_{n \leftrightarrow \ell}(X, \pi, H)$ ,*

$$\text{ec}(\mathbf{Q}_{\ell \leftrightarrow n}^{\uparrow \downarrow}) \geq \text{ls}(\mathbf{P}_{\ell \leftrightarrow n}^{\uparrow \downarrow}) \cdot \text{gap}^*(H^2) \quad \text{and} \quad \text{ec}(\mathbf{Q}_{n \leftrightarrow \ell}^{\downarrow \uparrow}) \geq \text{ls}(\mathbf{P}_{\ell \leftrightarrow n}^{\uparrow \downarrow}) \cdot \text{gap}^*(H^2),$$

*where  $\text{gap}^*(H^2) = 1 - \lambda(H^2)$  and  $\lambda(H^2)$  denotes the two-sided expansion of the graph  $H^2$ .*

As we will see in Section 5, Corollary 21 will indeed allow us to prove optimal mixing time bounds for the expanderized walks in many cases of interest.

### 3.1 Closeness in Operator Norm: Proof of Theorem 18

**Proof of Theorem 18 .** For convenience, we will write  $\mathbf{Q}^{\uparrow \downarrow} := \mathbf{Q}_{\ell \leftrightarrow n}^{\uparrow \downarrow}$  and  $\mathbf{P}^{\uparrow \downarrow} := \mathbf{P}_{\ell \leftrightarrow n}^{\uparrow \downarrow}$ . Let  $\mathbf{M}$  denote the random-walk matrix of the graph  $H$  where each transition occurs with the probability  $1/k$  and  $\mathbf{J}$  the random-walk matrix of the clique over  $\binom{[n]}{\ell}$  with self-loops, i.e.  $\mathbf{J} = \mathbf{1}\mathbf{1}^\top / \binom{[n]}{\ell}$ . We will write,  $\lambda := \lambda(\mathbf{M})$ .

Let  $S \in \binom{[n]}{\ell}$  be arbitrary and suppose some  $\bar{\omega} \in X^{(\ell)}$  is given such that  $\text{type}(\bar{\omega}) = S$ .

For all  $\mathbf{f} \in \mathbb{R}^{X^{(\ell)}}$ , we have

$$[\mathbf{Q}^{\uparrow \downarrow} \mathbf{f}](\bar{\omega}) = \sum_{\hat{\omega} \in X[S^c]} \Pr_{\omega \sim \pi}[\omega_{S^c} = \hat{\omega} \mid \omega_S = \bar{\omega}] \cdot \sum_{a \in [k]} \frac{\mathbf{f}((\bar{\omega} \oplus \hat{\omega})_{\text{out}_H(S,a)})}{k}.$$

Similarly, we have

$$[\mathbf{P}^{\uparrow \downarrow} \mathbf{f}](\bar{\omega}) = \sum_{\hat{\omega} \in X[S^c]} \Pr_{\omega \sim \pi}[\omega_{S^c} = \hat{\omega} \mid \omega_S = \bar{\omega}] \sum_{T \in \binom{[n]}{\ell}} \frac{\mathbf{f}((\bar{\omega} \oplus \hat{\omega})_T)}{\binom{[n]}{\ell}}.$$

For any given facet  $\omega \in X^{(n)}$  we define the function  $\mathbf{g}_\omega \in \mathbb{R}^{\binom{[n]}{\ell}}$  as,  $\mathbf{g}_\omega(T) = \mathbf{f}(\omega_T)$ .

We have,

$$[\mathbf{M}\mathbf{g}_\omega](T) = \sum_{a \in [k]} \frac{\mathbf{f}(\omega_{\text{out}_H(T,a)})}{k} \quad \text{and} \quad [\mathbf{J}\mathbf{g}_\omega](i) = \sum_{T \in \binom{[n]}{\ell}} \frac{\mathbf{f}(\omega_T)}{\binom{[n]}{\ell}}.$$

Thus, we have

$$[\mathbf{Q}^{\uparrow \downarrow} \mathbf{f}](\bar{\omega}) = \sum_{\hat{\omega} \in X[S^c]} \Pr_{\omega \sim \pi}[\omega_{S^c} = \hat{\omega} \mid \omega_S = \bar{\omega}] \cdot [\mathbf{M}\mathbf{g}_{\bar{\omega} \oplus \hat{\omega}}](S), \quad (5)$$

$$[\mathbf{P}^{\uparrow \downarrow} \mathbf{f}](\bar{\omega}) = \sum_{\hat{\omega} \in X[S^c]} \Pr_{\omega \sim \pi}[\omega_{S^c} = \hat{\omega} \mid \omega_S = \bar{\omega}] \cdot [\mathbf{J}\mathbf{g}_{\bar{\omega} \oplus \hat{\omega}}](S). \quad (6)$$

In particular combining Equation (5) and Equation (6) and noticing that for  $\omega \sim \pi$  the law of  $\omega_{S^c}$  conditional on  $\omega_S = \bar{\omega}$  is given by  $\pi_{n-\ell}^{(\bar{\omega})}$ ,

$$\begin{aligned} \|(Q^{\uparrow\downarrow} - (1-\lambda)P^{\uparrow\downarrow})\mathbf{f}\|_{\pi_\ell}^2 &= \mathbb{E}_{\bar{\omega} \sim \pi_\ell} \left( \mathbb{E}_{\hat{\omega} \sim \pi_{n-\ell}^{(\bar{\omega})}} [ [M\mathbf{g}_{\bar{\omega} \oplus \hat{\omega}}](\text{type}(\bar{\omega})) - (1-\lambda)[J\mathbf{g}_{\bar{\omega} \oplus \hat{\omega}}](\text{type}(\bar{\omega})) ] \right)^2, \\ &\leq \mathbb{E}_{\bar{\omega} \sim \pi_\ell} \mathbb{E}_{\hat{\omega} \sim \pi_{n-\ell}^{(\bar{\omega})}} \left[ \left( [M\mathbf{g}_{\bar{\omega} \oplus \hat{\omega}}](\text{type}(\bar{\omega})) - (1-\lambda)[J\mathbf{g}_{\bar{\omega} \oplus \hat{\omega}}](\text{type}(\bar{\omega})) \right)^2 \right]. \end{aligned}$$

where the last inequality is obtained by appealing to Jensen's inequality and the convexity of  $t \rightarrow t^2$ .

Now, we observe the law of  $\bar{\omega} \oplus \hat{\omega}$  obtained by first sampling  $\bar{\omega} \sim \pi_\ell$  and then  $\hat{\omega} \sim \pi_{n-\ell}^{(\bar{\omega})}$  is given by  $\pi$ . Furthermore, any  $\omega \in X^{(n)}$  occurs exactly  $\binom{[n]}{\ell}$  times in the expectation above – once for each  $S \in \binom{[n]}{\ell}$  acting as  $\text{type}(\bar{\omega})$ , which happens with probability  $\binom{[n]}{\ell}^{-1}$ . Thus,

$$\begin{aligned} \|(Q^{\uparrow\downarrow} - (1-\lambda)P^{\uparrow\downarrow})\mathbf{f}\|_{\pi_\ell}^2 &\leq \mathbb{E}_{\omega \sim \pi_n} \left[ \mathbb{E}_{S \sim \text{uni}^{(\binom{[n]}{\ell})}} \left( [(M - (1-\lambda)J)\mathbf{g}_\omega](S) \right)^2 \right], \\ &\leq \mathbb{E}_{\omega \sim \pi_n} \left[ \lambda^2 \cdot \|\mathbf{g}_\omega\|_{\text{uni}^{(\binom{[n]}{\ell})}}^2 \right] \end{aligned}$$

where the last inequality is due to  $\|M - (1-\lambda)J\|_{\text{op,uni}^{(\binom{[n]}{\ell})}} \leq \lambda$  as  $\lambda(M) \leq \lambda$ !

Now, we finally note

$$\mathbb{E}_{\omega \sim \pi} \left[ \|\mathbf{g}_\omega\|_{\text{uni}^{(\binom{[n]}{\ell})}}^2 \right] = \mathbb{E}_{\omega \sim \pi} \left[ \frac{1}{\binom{[n]}{\ell}} \sum_{S \in \binom{[n]}{\ell}} \mathbf{f}(\omega_S)^2 \right] = \mathbb{E}_{\bar{\omega} \sim \pi_\ell} \mathbf{f}(\bar{\omega})^2 = \|\mathbf{f}\|_{\pi_\ell}^2,$$

The last equality is due to the observation that first sampling  $\omega \sim \pi$  and then outputting  $\omega_S$  for  $S \sim \text{uni}^{(\binom{[n]}{\ell})}$  picked uniformly at random amounts to simply sampling  $\bar{\omega} \sim \pi_\ell$ , q.v. Equation (3).

In particular,

$$\|(Q^{\uparrow\downarrow} - (1-\lambda)P^{\uparrow\downarrow})\mathbf{f}\|_{\pi_\ell} \leq \lambda \cdot \|\mathbf{f}\|_{\pi_\ell}.$$

As  $\mathbf{f}$  was picked arbitrarily, this allows us to conclude the proof of our theorem by appealing to the definition of the operator norm.  $\blacktriangleleft$

### 3.2 Log-Sobolev Bound: Proof of Corollary 20

**Proof of Corollary 20.** Let  $\mathbf{f} \in \mathbb{R}_{\geq 0}^{X^{(\ell)}}$  be an arbitrary function satisfying  $\text{Ent}_{\pi_\ell}(\mathbf{f}^2) \neq 0$ . We have,

$$\frac{\langle \mathbf{f}, (I - Q_{\ell \leftrightarrow n}^{\uparrow\downarrow})\mathbf{f} \rangle_{\pi_\ell}}{\text{Ent}_{\pi_\ell}(\mathbf{f})^2} = \frac{\langle \mathbf{f}, (I - (1-\lambda(H)) \cdot P_{\ell \leftrightarrow n}^{\uparrow\downarrow})\mathbf{f} \rangle_{\pi_\ell}}{\text{Ent}_{\pi_\ell}(\mathbf{f}^2)} + \frac{\langle \mathbf{f}, ((1-\lambda(H))P_{\ell \leftrightarrow n}^{\uparrow\downarrow} - Q_{\ell \leftrightarrow n}^{\uparrow\downarrow})\mathbf{f} \rangle_{\pi_\ell}}{\text{Ent}_{\pi_\ell}(\mathbf{f}^2)}.$$

Notice that by Theorem 18, we should have

$$\langle \mathbf{f}, \left( (1-\lambda(H))P_{\ell \leftrightarrow n}^{\uparrow\downarrow} - Q_{\ell \leftrightarrow n}^{\uparrow\downarrow} \right) \mathbf{f} \rangle_{\pi_\ell} \geq -\lambda(H) \cdot \langle \mathbf{f}, \mathbf{f} \rangle_{\pi_\ell}.$$

Thus,

$$\begin{aligned} \frac{\langle \mathbf{f}, (I - Q_{\ell \leftrightarrow n}^{\uparrow\downarrow})\mathbf{f} \rangle_{\pi_\ell}}{\text{Ent}_{\pi_\ell}(\mathbf{f})^2} &\geq \frac{\langle \mathbf{f}, \left( I - \left( (1-\lambda(H)) \cdot P_{\ell \leftrightarrow n}^{\uparrow\downarrow} + \lambda(H) \cdot I \right) \right) \mathbf{f} \rangle_{\pi_\ell}}{\text{Ent}_{\pi_\ell}(\mathbf{f}^2)}, \\ &\geq \mathbf{1s} \left( (1-\lambda(H)) \cdot P_{\ell \leftrightarrow n}^{\uparrow\downarrow} + \lambda(H) \cdot I \right), \\ &= \mathbf{1s}(P_{\ell \leftrightarrow n}^{\uparrow\downarrow}) \cdot \text{gap}^*(H), \end{aligned}$$

where the last inequality is obtained by noticing:

$$\langle \mathbf{f}, (I - (a \cdot I + (1 - a)P))\mathbf{f} \rangle_\mu = (1 - a) \cdot \langle \mathbf{f}, (I - P)\mathbf{f} \rangle_\mu,$$

and the variational formula for the log-Sobolev constant (Equation (2)) . Appealing to the definition of the log-Sobolev inequality (LSI) once again yields the result. ◀

#### 4 Functional Inequalities on Simplicial Complexes

In this section, we will prove several functional inequalities involving the down-up walk  $P_{n \leftrightarrow \ell}^{\downarrow \uparrow}$ . For convenience we define the set  $\mathcal{C}_\ell(X)$  as the set of  $\ell$ -chains in  $X$ , i.e. the collection of sequences

$$\emptyset := \omega^{(0)} \subsetneq \omega^{(1)} \subsetneq \dots \subsetneq \omega^{(\ell)} \in X^{(\ell)},$$

such that  $\omega^{(i)} \in X^{(i)}$  for all  $i = 0, \dots, \ell$ . Similarly, for  $x \in X^{(1)}$  we define  $\mathcal{C}_\ell(x)$  as the set of  $\ell$ -chains in  $X$  starting from  $x \in X^{(1)}$ , i.e. the collection of sequences

$$x =: \omega^{(1)} \subsetneq \omega^{(2)} \subsetneq \dots \subsetneq \dots \subsetneq \omega^{(\ell)},$$

such that  $\omega^{(i)} \in X^{(i)}$  for all  $i = 0, \dots, \ell$ .

► **Theorem 22.** *For all  $n$ -partite simplicial complexes  $(X, \pi)$  and convex  $\Phi : \mathbb{R}_{\geq 0} \rightarrow \mathbb{R}_{\geq 0}$ , we have:*

$$\mathbf{cf}_\Phi(P_{\ell \rightarrow n}^\uparrow) \geq \min \left\{ \prod_{j=0}^{\ell-1} (1 - \mathbf{1c}_\Phi(\omega^{(j)})) \mid \emptyset =: \omega^{(0)} \subsetneq \omega^{(1)} \subsetneq \dots \subsetneq \omega^{(\ell)} \in \mathcal{C}_\ell(X) \right\}. \quad (7)$$

In particular, writing  $\mathbf{1c}_\Phi^{(i)}(X, \pi) = \max_{\hat{\omega} \in X^{(i)}} \mathbf{1c}_\Phi(\hat{\omega})$ , we have

$$\mathbf{cf}_\Phi(P_{\ell \rightarrow n}^\uparrow) \geq \prod_{j=0}^{\ell-1} (1 - \mathbf{1c}_\Phi^{(j)}(X, \pi)).$$

As mentioned before our proof is inspired by the exposition in [14] and follows the Garland method, [31]. After submitting our results to arxiv, it came to our attention that the same proof technique for proving a weaker version of Theorem 22 already appeared in [42] in the context of variance contraction. We will list a few immediate consequences of Theorem 22. The following bound is immediate given Proposition 10 and Theorem 22,

► **Corollary 23 (Spectral Gap Bound).** *Let  $(X, \pi)$  be a simplicial complex of rank  $n$ . We have,*

$$\mathbf{gap}(P_{n \leftrightarrow \ell}^{\downarrow \uparrow}) \geq \frac{n - \ell}{n} \cdot \min \left\{ \prod_{i=0}^{\ell-1} \mathbf{gap}(M_{z_i}) \mid \emptyset =: \omega^{(0)} \subsetneq \omega^{(1)} \subsetneq \dots \subsetneq \omega^{(\ell)} \in \mathcal{C}_{\ell-1}(X) \right\}. \quad (8)$$

In particular, writing  $\mathbf{gap}_k(X, \pi) := \min_{x \in X^{(k)}} \mathbf{gap}(M_x)$  we have

$$\mathbf{gap}(P_{n \leftrightarrow \ell}^{\downarrow \uparrow}) \geq \frac{n - \ell}{n} \cdot \prod_{i=0}^{\ell-1} \mathbf{gap}_i(X, \pi).$$

We also prove a useful lemma that shows we can directly relate the entropy contraction constant to the log-Sobolev constant of the down-up walk,

► **Lemma 24.** *Let  $(X, \pi)$  be a simplicial complex of rank  $n$ . For any  $\hat{\omega} \in X$ , we set*

$$\pi_{\hat{\omega}, k}^* = \min_{\tilde{\omega} \in X_{\hat{\omega}}^{(k)}} \pi_k^*(\tilde{\omega}), \quad \text{gap}_{n-2}(X, \pi) = \min_{\hat{\omega} \in X^{(n-2)}} \text{gap}(\mathbf{M}_{\hat{\omega}}), \quad \text{and}$$

$$C_{\hat{\omega}, k} = \begin{cases} 1 & \pi_{\hat{\omega}, k}^* > 1/2, \\ \frac{1-2\pi_{\hat{\omega}, k}^*}{\log\left(\left(\pi_{\hat{\omega}, k}^*\right)^{-1}-1\right)} & \text{otherwise.} \end{cases}$$

where  $\mathbf{M}_{\hat{\omega}}$  is the link of  $\hat{\omega}$  and  $\text{gap}(\bullet)$  denotes the spectral gap. We have,

$$\mathbf{1s}(\mathbf{P}_{n \leftrightarrow \ell}^{\downarrow \uparrow}) \geq \min\{C_{\omega^{(\ell)}, n-\ell} \mid \omega^{(\ell)} \in X^{(\ell)}\} \cdot \text{ec}(\mathbf{P}_{\ell \rightarrow n}^{\uparrow}),$$

$$\mathbf{1s}(\mathbf{P}_{n-1}^{\downarrow \uparrow}) \geq \frac{n-1}{n} \cdot \min\{C_{\omega^{(n-2)}, 1} \mid \omega^{(n-2)} \in X^{(n-2)}\} \cdot \text{gap}_{n-2}(X, \pi) \cdot \text{ec}(\mathbf{P}_{n-2 \rightarrow n-1}^{\uparrow}).$$

In particular, writing  $\mathbf{1ec}_i(X, \pi) := \min_{\hat{\omega} \in X^{(i)}} \mathbf{1ec}(\hat{\omega})$  and  $C_{\ell, k} = \min_{\hat{\omega} \in X^{(\ell)}} C_{\hat{\omega}, k}$ ,

$$\mathbf{1s}(\mathbf{P}_{n \leftrightarrow \ell}^{\downarrow \uparrow}) \geq C_{\ell, n-\ell} \cdot \prod_{i=0}^{\ell-1} (1 - \mathbf{1ec}_i(X, \pi))$$

We will prove this result in Section 4.2.

#### 4.1 Proof of $\Phi$ -Entropy Contraction Bounds, Theorem 22

**Proof of Theorem 22.** For  $\ell = 0$ , the LHS is equal to 0, thus we see the product in Equation (7) is taken over an empty set and equals 1. Thus, equality holds in this case with  $\text{cf}_{\Phi}(\mathbf{P}_{0 \rightarrow n}^{\uparrow}) = 1$ . We proceed by induction on the rank of the simplicial complex. We have by the chain rule for  $\Phi$ -entropy (Lemma 11),

$$\text{Ent}_{\pi_{\ell}}^{\Phi}(\mathbf{P}_{\ell \rightarrow n}^{\uparrow} \mathbf{f}) = \mathbb{E}_{x \sim \pi_1} \text{Ent}_{\pi_{\ell-1}^{(x)}}^{\Phi}(\mathbf{P}_{x, \ell-1 \rightarrow n-1}^{\uparrow} \mathbf{f}|x) + \text{Ent}_{\pi_1}^{\Phi}(\mathbf{P}_{1 \rightarrow n}^{\uparrow} \mathbf{f}),$$

where we have used (i)  $(\mathbf{P}_{\ell \rightarrow n}^{\uparrow} \mathbf{f})_x(\omega) = [\mathbf{P}_{x, \ell-1 \rightarrow n-1}^{\uparrow} \mathbf{f}|x](\omega \setminus x)$  and (ii) that  $\mathbf{P}_{\ell \rightarrow n}^{\uparrow}$  is row-stochastic, i.e.  $\mathbb{E}(\mathbf{P}_{\ell \rightarrow n}^{\uparrow} \mathbf{f}) = \mathbb{E} \mathbf{f}$ . Let  $c := \min_{x \sim X^{(1)}} \text{cf}_{\Phi}(\mathbf{P}_{x, \ell-1 \rightarrow n-1}^{\uparrow})$ . By the induction hypothesis,

$$c \geq \min \left\{ \prod_{j=1}^{\ell-1} (1 - \mathbf{1c}_{\Phi}(\omega^{(j)})) \mid x \in X^{(1)}, x =: \omega^{(1)} \subsetneq \omega^{(2)} \subsetneq \dots \subsetneq \omega^{(\ell-1)} \in \mathcal{C}_{\ell-1}(x) \right\}. \quad (9)$$

Hence, we obtain,

$$\text{Ent}_{\pi_{\ell}}^{\Phi}(\mathbf{P}_{\ell \rightarrow n}^{\uparrow} \mathbf{f}) \leq (1-c) \mathbb{E}_{x \sim \pi_1} \text{Ent}_{\pi_{n-1}^{(x)}}^{\Phi}(\mathbf{f}|x) + \text{Ent}_{\pi_1}^{\Phi}(\mathbf{P}_{1 \rightarrow n}^{\uparrow} \mathbf{f}).$$

Now, using the chain-rule (Lemma 11) for  $\Phi$ -entropy once more, we have  $\mathbb{E}_{x \sim \pi_1} \text{Ent}_{\pi_{n-1}^{(x)}}^{\Phi}(\mathbf{f}|x) = \text{Ent}_{\pi_n}^{\Phi}(\mathbf{f}) - \text{Ent}_{\pi_1}^{\Phi}(\mathbf{P}_{1 \rightarrow n}^{\uparrow} \mathbf{f})$ . Substituting this in the inequality above, we obtain:

$$\begin{aligned} \text{Ent}_{\pi_{\ell}}^{\Phi}(\mathbf{P}_{\ell \rightarrow n}^{\uparrow} \mathbf{f}) &\leq (1-c) \cdot \left( \text{Ent}_{\pi_n}^{\Phi}(\mathbf{f}) - \text{Ent}_{\pi_1}^{\Phi}(\mathbf{P}_{1 \rightarrow n}^{\uparrow} \mathbf{f}) \right) + \text{Ent}_{\pi_1}^{\Phi}(\mathbf{P}_{1 \rightarrow n}^{\uparrow} \mathbf{f}), \\ &= (1-c) \cdot \text{Ent}_{\pi_n}^{\Phi}(\mathbf{f}) + c \cdot \text{Ent}_{\pi_1}^{\Phi}(\mathbf{P}_{1 \rightarrow n}^{\uparrow} \mathbf{f}). \end{aligned}$$

Now, using  $\text{Ent}_{\pi_1}^{\Phi}(\mathbf{P}_{1 \rightarrow n}^{\uparrow} \mathbf{f}) \leq \mathbf{1c}_{\Phi}(\emptyset) \cdot \text{Ent}_{\pi_n}^{\Phi}(\mathbf{f})$  we obtain

$$\text{Ent}_{\pi_{\ell}}^{\Phi}(\mathbf{P}_{\ell \rightarrow n}^{\uparrow} \mathbf{f}) \leq (1-c \cdot (1 - \mathbf{1c}_{\Phi}(\emptyset))) \cdot \text{Ent}_{\pi_n}^{\Phi}(\mathbf{f}).$$

The statement now follows from Equation (9) and the definition of the  $\Phi$ -entropy contraction factor. ◀

## 4.2 Proof of the log-Sobolev Inequality, Lemma 24

**Proof of Lemma 24.** We follow a similar strategy to what we have followed to establish Theorem 22. We have,

$$\begin{aligned}
\langle \mathbf{f}, (1 - \mathbf{P}_{n \leftrightarrow \ell}^{\downarrow \uparrow}) \mathbf{f} \rangle_{\pi_n} &= \langle \mathbf{f}, \mathbf{f} \rangle_{\pi_n} - \langle \mathbf{P}_{\ell \rightarrow n}^{\uparrow} \mathbf{f}, \mathbf{P}_{\ell \rightarrow n}^{\uparrow} \mathbf{f} \rangle_{\pi_\ell}, \\
&= \mathbb{E}_{\hat{\omega} \sim \pi_\ell} \left[ \langle \mathbf{f} | \hat{\omega}, \mathbf{f} | \hat{\omega} \rangle_{\pi_{n-\ell}^{(\hat{\omega})}} - \mathbb{E}_{\hat{\omega} \sim \pi_\ell} \left[ \langle \mathbf{P}_{\hat{\omega}, 0 \rightarrow n-\ell}^{\uparrow} \mathbf{f} | \hat{\omega}, \mathbf{P}_{\hat{\omega}, 0 \rightarrow n-\ell}^{\uparrow} \mathbf{f} | \hat{\omega} \rangle_{\pi_{n-\ell}^{(\hat{\omega})}} \right] \right], \\
&= \mathbb{E}_{\hat{\omega} \sim \pi_\ell} \left[ \langle \mathbf{f} | \hat{\omega}, (1 - \mathbf{P}_{\hat{\omega}, n-\ell \leftrightarrow 0}^{\downarrow \uparrow}) \mathbf{f} | \hat{\omega} \rangle_{\pi_{n-\ell}^{(\hat{\omega})}} \right], \\
&= \mathbb{E}_{\hat{\omega} \sim \pi_\ell} \left[ \left\langle \mathbf{f} | \hat{\omega}, \left( 1 - \mathbf{J}_{\pi_{n-\ell}^{(\hat{\omega})}} \right) \mathbf{f} | \hat{\omega} \right\rangle_{\pi_{n-\ell}^{(\hat{\omega})}} \right],
\end{aligned}$$

where we have used Items (1) and (2) of Lemma 12 to obtain the second equality and have written  $\mathbf{J}_\mu = \mathbf{1}\mu$  for the clique with respect to  $\mu$ .

Now, by Lemma 5, we have  $\mathbf{1s}\left(\mathbf{J}_{\pi_{n-\ell}^{(\hat{\omega})}}\right) \geq C_{\hat{\omega}, n-\ell}$  – where  $C_{\hat{\omega}, n-\ell}$  is defined as in the statement of Lemma 24. Thus, writing  $C_{\ell, n-\ell} := \min_{\hat{\omega} \in X^{(\ell)}} C_{\hat{\omega}, n-\ell}$ , we have

$$\langle \mathbf{f}, (1 - \mathbf{P}_{n \leftrightarrow \ell}^{\downarrow \uparrow}) \mathbf{f} \rangle_{\pi_n} \geq C_{\ell, n-\ell} \cdot \mathbb{E}_{\hat{\omega} \sim \pi_\ell} \text{Ent}_{\pi_{n-\ell}^{(\hat{\omega})}}(\mathbf{f}^2 | \hat{\omega}), \geq C_{\ell, n-\ell} \cdot (\text{Ent}_{\pi_n}(\mathbf{f}^2) - \text{Ent}_{\pi_\ell}(\mathbf{P}_{\ell \rightarrow n}^{\uparrow} \mathbf{f}^2))$$

where we have used the chain rule for entropy, Lemma 11, to obtain the last statement.

Now, using the definition of  $\Phi$ -entropy contraction, i.e. writing for  $\Phi(t) = t \cdot \log t$ ,

$$\text{Ent}_{\pi_\ell}(\mathbf{P}_{\ell \rightarrow n}^{\uparrow} \mathbf{f}^2) \leq \left( 1 - \text{ec}\left(\mathbf{P}_{\ell \rightarrow n}^{\uparrow}\right) \right) \cdot \text{Ent}_{\pi_n}(\mathbf{f}^2).$$

Thus,

$$\langle \mathbf{f}, (1 - \mathbf{P}_{n \leftrightarrow \ell}^{\downarrow \uparrow}) \mathbf{f} \rangle_{\pi_n} \geq C_{\ell, n-\ell} \cdot \text{ec}\left(\mathbf{P}_{\ell \rightarrow n}^{\uparrow}\right) \cdot \text{Ent}_{\pi_n}(\mathbf{f}^2).$$

Now, the first statement follows by appealing to the definition of the log-Sobolev inequality (LSI) and the log-Sobolev constant (Equation (2)). The second statement concerning  $\mathbf{P}_{n \leftrightarrow \ell}^{\downarrow \uparrow}$  now immediately follows from Theorem 22.

To obtain the log-Sobolev inequality for  $\mathbf{P}_{n-1}^{\uparrow \downarrow}$ , we make use of Items (1) and (3) in Lemma 12 and proceed as above. We have,

$$\langle \mathbf{f}, (1 - \mathbf{P}_{n-1}^{\uparrow \downarrow}) \mathbf{f} \rangle_{\pi_{n-1}} = \frac{n-1}{n} \cdot \mathbb{E}_{\hat{\omega} \sim \pi_{n-2}} \left[ \langle \mathbf{f} | \hat{\omega}, (1 - \mathbf{M}_{\hat{\omega}}) \mathbf{f} | \hat{\omega} \rangle_{\pi_1^{(\hat{\omega})}} \right]$$

Now, appealing to Lemma 5, we obtain  $\mathbf{1s}(\mathbf{M}_{\hat{\omega}}) \geq \text{gap}(\mathbf{M}_{\hat{\omega}}) \cdot C_{\hat{\omega}, 1}$  for all  $\hat{\omega} \in X^{(n-2)}$ . Thus,

$$\begin{aligned}
\langle \mathbf{f}, (1 - \mathbf{P}_{n-1}^{\uparrow \downarrow}) \mathbf{f} \rangle_{\pi_{n-1}} &\geq \frac{n-1}{n} \cdot C_{n-2, 1} \cdot \text{gap}_{n-2}(X, \pi) \cdot \mathbb{E}_{\hat{\omega} \sim \pi_{n-2}} \text{Ent}_{\pi_1^{(\hat{\omega})}}(\mathbf{f}^2 | \hat{\omega}), \\
&= \frac{n-1}{n} \cdot C_{n-2, 1} \cdot \text{gap}_{n-2}(X, \pi) \cdot (\text{Ent}_{\pi_{n-1}}(\mathbf{f}^2) - \text{Ent}_{\pi_\ell}(\mathbf{P}_{n-2 \rightarrow n-1}^{\uparrow} \mathbf{f}^2)), \\
&= \frac{n-1}{n} \cdot C_{n-2, 1} \cdot \text{gap}_{n-2}(X, \pi) \cdot \text{ec}\left(\mathbf{P}_{n-2 \rightarrow n-1}^{\uparrow}\right) \cdot \text{Ent}_{\pi_{n-1}}(\mathbf{f}^2), \tag{10}
\end{aligned}$$

where we have appealed to the chain rule for entropy, Lemma 11, to obtain the first equality.  $\blacktriangleleft$

## 5 Application: Sampling Using the Expanderized Walks

In the present section, present our results concerning the rapid mixing of the expanderized walks for sampling (i) list-colorings and (ii) Ising models with bounded interaction matrix. First, we describe the random sampling problems we are interested in mention the state of

the art sampling results we are interested in expanderizing, and state our results and present a proof of the list coloring chain. Due to space considerations, we only present the proof of our list-coloring result here in Section 5.1 and refer the reader to the full version of our paper in [4] for the proof of our mixing time estimate for the Ising Model.

A list coloring instance  $(G, \mathcal{L})$  consists of a graph  $G = (V, E)$  and a collection of colours  $\mathcal{L} = (L(v))_v$  for every vertex. A valid list coloring of  $(G, \mathcal{L})$  is then a set of pairs  $\{(v, c(v))\}_{v \in V}$  satisfying the following two conditions,

1.  $c(v) \in L(v)$  for all vertices  $v \in V$ ,
2.  $c(u) \neq c(v)$  for all edges  $\{u, v\} \in E$ .

We will write  $(X^{(G, \mathcal{L})}, \text{uni}^{(G, \mathcal{L})})$  for the simplicial complex of proper list coloring of  $(G, \mathcal{L})$  weighted by the uniform distribution  $(G, \mathcal{L})$  on all list colorings, i.e.

$$X^{(G, \mathcal{L})} = \left\{ \alpha \subset \prod_{v \in V} \{v\} \times L(v) \mid \text{there is a proper list coloring } \chi \text{ of } (G, \mathcal{L}) \text{ such that } \alpha \subset \chi \right\}.$$

We will show that the expanderized walks rapidly mix when sampling list colorings of bounded degree graphs. Further, the lower bound in the number of colors matches with the state of the art – see [12, 41, 10].

► **Theorem 25.** *Let  $(G, \mathcal{L})$  be a list-coloring instance where  $G = (V, E)$  is a graph on  $n$  vertices of maximum degree  $\Delta \leq O(1)$  and  $H_n$  be a labelled graph on  $[n]$  of constant two-sided expansion  $\lambda(H_n)$  bounded away from 1. Then, for some absolute constant  $\varepsilon \approx 10^{-5,8}$  and any  $K = O(1)$ , if  $(11/6 + K)\Delta \geq |L(v)| \geq (11/6 - \varepsilon) \cdot \Delta$  for all vertices  $v \in V$ , the mixing time of the expanderized walks  $\mathcal{Q}_{n-1}^{\downarrow \uparrow} = \text{UpDown}_{\ell \leftrightarrow n}(X^{(G, \mathcal{L})}, \text{uni}^{(G, \mathcal{L})}, H^2)$  and  $\mathcal{Q}_n^{\downarrow \uparrow} = \text{DownUp}_{n \leftrightarrow \ell}(X^{(G, \mathcal{L})}, \text{uni}^{(G, \mathcal{L})}, H)$  satisfies,*

$$\tau_{\text{mix}}(\mathcal{Q}_{n-1}^{\downarrow \uparrow}, \varepsilon) \leq C_1 \cdot n(\log n + \log \varepsilon^{-1}) \quad \text{and} \quad \tau_{\text{mix}}(\mathcal{Q}_n^{\downarrow \uparrow}, \varepsilon) \leq C_2 \cdot n(\log n + \log \log \varepsilon^{-1}),$$

where  $C_1$  and  $C_2$  are universal constants not depending on  $n$  but on  $\Delta$ .

► **Remark 26.** By [5], we can pick a constant degree graph as the graph  $H_n$  in the statement of Theorem 25. Thus, a single step of the random walk can be implemented using  $O(1)$ -random bits – making the total number of random bits used in the random walk  $O(n \log n)$ . In contrast, the standard down-up walk or the up-down walk requires  $O(\log n)$  random bits to perform a single step, and  $O(n \log^2 n)$  random bits in total.

We recall that the Ising model  $\mu_{\mathbf{J}, \mathbf{h}} : \{+1, -1\}^n \rightarrow \mathbb{R}_{\geq 0}$  with interaction matrix  $\mathbf{J} \in \mathbb{R}^{n \times n}$  and external field  $\mathbf{h} \in \mathbb{R}^n$  from statistical physics is a probability distribution on the hypercube satisfying,

$$\mu_{\mathbf{J}, \mathbf{h}}(\mathbf{x}) = \frac{\exp\left(\frac{1}{2}\langle \mathbf{x}, \mathbf{J}\mathbf{x} \rangle_{\ell_2} + \langle \mathbf{h}, \mathbf{x} \rangle_{\ell_2}\right)}{Z(\mathbf{J}, \mathbf{h})} \quad \text{where} \quad Z(\mathbf{J}, \mathbf{h}) = \sum_{\mathbf{x} \in \{+1, -1\}^n} \exp\left(\frac{1}{2}\langle \mathbf{x}, \mathbf{J}\mathbf{x} \rangle_{\ell_2} + \langle \mathbf{h}, \mathbf{x} \rangle_{\ell_2}\right) \quad (11)$$

We notice that we can identify any  $\mathbf{x} \in \{+1, -1\}^n$  with a value by using the encoding,

$$\mathbf{x}^{\pm} = \{(i, \mathbf{x}(i)) \mid i \in [n]\}.$$

Thus, we define the simplicial complex  $(X^{(\mathbf{J}, \mathbf{h})}, \mu_{\mathbf{J}, \mathbf{h}})$ , where

$$X^{(\mathbf{J}, \mathbf{h})} = \{\alpha \subset [n] \times \{\pm 1\} \mid \text{for each } i \in [n], \alpha \text{ contains at most one element } (i, x)\}.$$

We show that our expanderize walks mix rapidly assuming that the external field  $\mathbf{h} \in \mathbb{R}^n$  is well-behaved, i.e.  $\|\mathbf{h}\|_{\ell_\infty}$  does not grow with  $n$ ,

<sup>8</sup> See [12].

► **Theorem 27.** Let  $(X^{(\mathbf{J}, \mathbf{h})}, \mu_{\mathbf{J}, \mathbf{h}})$  be the simplicial complex defined above corresponding to the Ising model defined by the interaction matrix  $\mathbf{J} \in \mathbb{R}^{n \times n}$  and external field  $\mathbf{h} \in \mathbb{R}^n$  and  $H_n$  a constant degree graph whose two-sided expansion is a constant bounded away from 1. Under the assumption that  $\mathbf{J}$  is PSD and satisfies  $\|\mathbf{J}\|_{\text{op}} \leq 1$ , the following hold,

$$\begin{aligned} \tau_{\text{mix}}(\mathbb{Q}_{n-1}^{\uparrow\downarrow}, \varepsilon) &\leq \frac{O(\|\mathbf{h}\|_{\ell_\infty}) \cdot n}{(1 - \|\mathbf{J}\|_{\text{op}})^2} (\log(n + \|\mathbf{h}\|_{\ell_1}) + \log \varepsilon^{-1}) \quad \text{and} \\ \tau_{\text{mix}}(\mathbb{Q}_n^{\downarrow\uparrow}, \varepsilon) &\leq \frac{O(\|\mathbf{h}\|_{\ell_\infty}) \cdot n}{(1 - \|\mathbf{J}\|_{\text{op}})^2} (\log(n + \|\mathbf{h}\|_{\ell_1}) + \log \varepsilon^{-1}), \end{aligned}$$

where the  $O(\bullet)$  notation hides a universal constant not depending on  $n, \mathbf{J}$ , or  $\mathbf{h}$ . Furthermore, the term  $(1 - \|\mathbf{J}\|_{\text{op}})^2$  in the denominator can be replaced with  $(1 - \|\mathbf{J}\|_{\text{op}})(1 - \theta)$  if the maximum operator norm of any two-by-two principal submatrix of  $\mathbf{J}$  is  $\theta$ .

► **Remark 28.** By [5], we can pick a constant degree graph as the graph  $H_n$  in the statement of Theorem 27. Thus, ignoring numerical difficulties in simulating biased coins, a single step of the random walk can be implemented using  $O(1)$ -random bits – making the total number of random bits used in the random walk  $O(n \log n)$  when  $\|\mathbf{h}\|_{\ell_\infty} = O(1)$ . In contrast, the standard down-up walk or the up-down walk requires  $O(\log n)$  random bits to perform a single step and  $O(n \log^2 n)$  random bits in total.

### 5.1 List Coloring of Bounded Degree Graphs

We make the following observations about the complex associated to proper list colorings,

► **Proposition 29** (Folklore).<sup>9</sup> Let  $(G = (V, E), \mathcal{L})$  be a list-coloring instance. Let  $K_+, K_- \in \mathbb{N}$  be parameters satisfying  $\deg(v) + K_+ \geq |L(v)| \geq \deg(v) + K_-$  for all  $v \in V$ . Then, writing  $(Y, \pi) := (X^{(G, \mathcal{L})}, \text{uni}^{(G, \mathcal{L})})$  we have,

$$\lambda_2(M_{\hat{\chi}}) \leq \frac{1}{K_-} \quad \text{for all } \hat{\chi} \in Y^{(n-2)},$$

where  $M_{\hat{\chi}}$  is the link of the face  $\hat{\chi}$ .

Similarly, for any  $\hat{\chi} \in Y^{(n-2)}$ , we have  $\min_{(u, c) \in Y_{\hat{\chi}}^{(1)}} \pi_1^{(\hat{\chi})}(u, c) \geq \frac{K_-}{(\Delta + K_+)^2}$  where  $\Delta = \max_{v \in V} \deg(v)$ .

We recall the following result of [41, 10],

► **Theorem 30** (Theorem 1.2, [41]). Let  $(G, \mathcal{L})$  be a list-coloring instance where  $G = (V, E)$  is a graph on  $n$  vertices of maximum degree  $\Delta \leq O(1)$ . Then, for some absolute constant  $\varepsilon \approx 10^{-5}$ ,<sup>10</sup> if  $|L(v)| \geq (11/6 - \varepsilon) \cdot \Delta$  for all vertices  $v \in V$ , then the spectral gap and the log-Sobolev constants (Equation (2)) of the down-up walk  $\mathbb{P}_n^{\downarrow\uparrow} = \text{DownUp}_{n \leftrightarrow n-1}(X^{(G, \mathcal{L})}, \text{uni}^{(G, \mathcal{L})})$  on the collection of proper list colorings is  $\Omega(n^{-1})$ .

Then, the following corollary immediately follows by Lemma 7 and Proposition 9,

► **Corollary 31.** Let  $(G, \mathcal{L})$  be a list-coloring instance where  $G = (V, E)$  is a graph on  $n$  vertices of maximum degree  $\Delta \leq O(1)$ . Then, for some absolute constant  $\varepsilon \approx 10^{-5}$ , if  $|L(v)| \geq (11/6 - \varepsilon) \cdot \Delta$  for all vertices  $v \in V$ , then the up-operator  $\mathbb{P}_{n-1 \rightarrow n}^{\uparrow} = \text{Up}_{n-1 \rightarrow n}(X^{(G, \mathcal{L})}, \text{uni}^{(G, \mathcal{L})})$  on the collection of proper list colorings of  $(G, \mathcal{L})$  satisfies  $\text{ec}(\mathbb{P}_{n-1 \rightarrow n}^{\uparrow}) \geq \Omega(n^{-1})$ .

<sup>9</sup> See the full version of this paper [4] for a proof.

<sup>10</sup> See [12]

**Proof of Theorem 25.** Notice that by Lemma 13, Corollary 31 implies that  $\text{ec}(P_{n-2 \rightarrow n-1}^\uparrow) \geq \Omega(n^{-1})$  since by Proposition 29 when  $\Delta = O(1)$ ,  $C_{n-2} = \Omega(1)$ , we have  $\text{gap}_{n-2}(X^{(G,\mathcal{L})}, \text{uni}^{(G,\mathcal{L})}) = \Omega(1)$ , by invoking Lemma 24 we obtain that the up-down walk  $P_{n-1}^{\uparrow\downarrow} = \text{UpDown}_{n-1 \leftrightarrow n}(X^{(G,\mathcal{L})}, \text{uni}^{(G,\mathcal{L})})$  satisfies,  $\text{ls}(P_{n-1}^{\uparrow\downarrow}) \geq \Omega(n^{-1})$ . Then, by Corollary 21 and the assumption that the two-sided expansion  $\lambda(H_n)$  is a constant bounded away from 1, we obtain  $\text{ec}(Q_n^{\uparrow\downarrow}), \text{ec}(Q_{n-1}^{\downarrow\uparrow}) \geq \Omega(n^{-1})$ . The result, concerning mixing times follows using Theorem 8 and the observation that the state space for both walks is of size at most  $n \cdot ((K + 11/6) \cdot \Delta)^n$ . ◀

## Abstract

We study Ramsey properties of randomly perturbed 3-uniform hypergraphs. For  $t \geq 2$ , write  $\tilde{K}_t^{(3)}$  to denote the 3-uniform *expanded* clique hypergraph obtained from the complete graph  $K_t$  by expanding each of the edges of the latter with a new additional vertex. For an even integer  $t \geq 4$ , let  $M$  denote the asymmetric maximal density of the pair  $(\tilde{K}_t^{(3)}, \tilde{K}_{t/2}^{(3)})$ . We prove that adding a set  $F$  of random hyperedges satisfying  $|F| \gg n^{3-1/M}$  to a given  $n$ -vertex 3-uniform hypergraph  $H$  with non-vanishing edge density asymptotically almost surely results in a perturbed hypergraph enjoying the Ramsey property for  $\tilde{K}_t^{(3)}$  and two colours. We conjecture that this result is asymptotically best possible with respect to the size of  $F$  whenever  $t \geq 6$  is even. The key tools of our proof are a new variant of the hypergraph regularity lemma accompanied with a *tuple lemma* providing appropriate control over joint link graphs. Our variant combines the so called strong and the weak hypergraph regularity lemmata.

## 1 Introduction

### 1.1 Ramsey properties of random hypergraphs

Given a distribution  $\mathcal{R}$  over  $n$ -vertex hypergraphs, as well as an  $n$ -vertex hypergraph  $H$ , referred to as the *seed* hypergraph, unions of the form  $H \cup R$  with  $R \sim \mathcal{R}$  define a distribution over the super-hypergraphs of  $H$ , denoted by  $H \cup \mathcal{R}$ . The hypergraphs  $H \cup \mathcal{R}$  are referred to as *random perturbations* of  $H$ . The study of the properties of such hypergraph distributions has its origins in the seminal work of Spielman and Teng [52, 53] who coined the term *Smoothed Analysis* whilst investigating the performance of algorithms on randomly perturbed inputs.

Recently, the paradigm of Smoothed Analysis, originating from Theoretical Computer Science, has captured the attention of numerous researchers in Combinatorics. In the latter avenue, two dominant strands of results have emerged. One strand pertains to the study of the thresholds for the emergence of various spanning and nearly-spanning configurations within such structures (see, e.g., [3, 4, 5, 6, 10, 11, 12, 13, 21, 28, 34, 35, 41]). The second strand pertains to the extremal and Ramsey-type properties (see, e.g., [1, 2, 6, 8, 18, 19, 20, 36, 46]) of such hypergraphs. Our result lies in the latter vein. We recall the arrow notation

$G \rightarrow (H_1, H_2)$ , signifying the validity of the asymmetric Ramsey statement that every 2-colouring of the edges of  $G$  yields a monochromatic copy of  $H_1$  in the first colour or a monochromatic copy of  $H_2$  in the second colour. Moreover, in the symmetric case when  $H_1 = H_2 = H$  we simply write  $G \rightarrow (H)$ .

Ramsey properties of randomly perturbed graphs were first investigated by Krivelevich, Sudakov, and Tetali [36]. In that work it was shown that  $n^{-2/(t-1)}$  is the threshold for the asymmetric Ramsey property  $G \cup \mathbb{G}(n, p) \rightarrow (K_3, K_t)$ , whenever  $G$  is an  $n$ -vertex graph of edge density  $d \in (0, 1/2)$  independent of  $n$ . The general problem, put forth by Krivelevich et al., of determining the threshold for the property  $G \cup \mathbb{G}(n, p) \rightarrow (K_s, K_t)$ , whenever  $G$  is dense and  $s, t \geq 4$ , was recently (essentially) resolved by Das and Treglown [20]. Those authors showed that  $n^{-1/m_2(K_t, K_{\lceil s/2 \rceil})}$  is the threshold for the property  $G \cup \mathbb{G}(n, p) \rightarrow (K_s, K_t)$ , when  $G$  is a dense  $n$ -vertex graph and  $t \geq s \geq 5$ , where  $m_2(H_1, H_2)$  denotes the asymmetric maximal 2-density of two graphs  $H_1$  and  $H_2$  (see equation (2) for the definition). For other values of  $t$  and  $s$  we also refer to the work of Das and Treglown [20, Theorem 1.7 and Theorem 5(ii)] and for the special case  $s = t = 4$  in addition to the work of Powierski [46, Theorem 1.8].

The aforementioned Ramsey-type results for randomly perturbed dense graphs are formulated for 2-colourings only. This restriction is well-justified. Indeed, suppose that more than two colours are available. The colouring in which the seed is coloured using one colour and the random perturbation is coloured using all the remaining colours, reduces the problem to that of studying the Ramsey property at hand for truly random hypergraphs.

The earlier results [20, 36, 46], as well as our result, stated in Theorem 1 below, are affected by and closely related to research on Ramsey properties in random graphs and hypergraphs (see, e.g., [17, 26, 27, 29, 30, 31, 38, 39, 40, 42, 44, 45, 47, 48, 49, 50]). For random graphs, the thresholds for *symmetric* Ramsey properties are well-understood due to work of Rödl and Ruciński [47, 49]. Minor exceptions for  $F$  being a star forest aside, this work asserts that  $n^{-1/m_2(F)}$  is the threshold for the property  $\mathbb{G}(n, p) \rightarrow (F)$ , where  $m_2(F)$  denotes the maximal 2-density of the given graph  $F$  (see equation (1) below). The 1-statement of the threshold was extended to random  $k$ -uniform hypergraphs by Conlon and Gowers [17] and by Friedgut, Rödl, and Schacht [26]. However, a complete characterisation of the exceptional cases is not yet available and for the progress towards the 0-statement we refer to the work of Nenadov et al. [44] and Gugelmann et al. [27].

The thresholds of asymmetric Ramsey properties in random graphs are the subject of the *Kohayakawa–Kreuter conjecture* [30]. The 1-statement stipulated by this conjecture has been fairly recently verified by Mousset, Nenadov, and Samotij [42] and progress has been made with respect to the corresponding 0-statement by several researchers [27, 29, 38, 40]. Following some progress [14, 37, 42], the conjecture was finally fully resolved by Christoph, Martinsson, Steiner, and Wigderson [15].

## 1.2 Main result

We study Ramsey properties of randomly perturbed hypergraphs; stating our results requires preparation. A hypergraph  $H$  is said to be *linear* if  $|e \cap f| \leq 1$  holds whenever  $e, f \in E(H)$  are distinct. Amongst the linear hypergraphs, *expanded cliques* are of special interest. Given  $t \geq 2$  and  $k \geq 2$ , the  *$k$ -uniformly expanded clique of order  $t$* , denoted by  $\tilde{K}_t^{(k)}$ , is the  $k$ -uniform hypergraph with vertex set of size  $t + \binom{t}{2}(k-2)$  obtained from the complete graph  $K_t$  by expanding every edge of  $K_t$  by  $k-2$  new vertices; in particular,  $\tilde{K}_t^{(2)} = K_t$  holds. Expanded cliques have attracted some attention in the literature and related extremal and Ramsey-type questions were addressed by Mubayi [43] and by Conlon, Fox, and Rödl [16].

Two natural measures of density, arising in the context of random hypergraphs, are the *maximum density* of a  $k$ -uniform  $H = (V, E)$ , denoted  $m(H)$ , and its *maximum  $k$ -density*, denoted  $m_k(H)$ . The former is given by

$$m(H) = \max \left\{ \frac{e(F)}{v(F)} : F \subseteq H \text{ and } v(F) \geq 1 \right\}$$

and the latter is defined by

$$m_k(H) = \max \{d_k(F) : F \subseteq H\}, \text{ where } d_k(F) = \begin{cases} 0, & \text{if } e(F) = 0, \\ \frac{1}{k}, & \text{if } e(F) = 1, v(F) = k, \\ \frac{e(H)-1}{v(H)-k}, & \text{otherwise.} \end{cases} \quad (1)$$

It is well known that  $n^{-1/m(H)}$  is the threshold for the appearance of  $H$  as a subhypergraph in the binomial random  $k$ -uniform hypergraph  $\mathbb{H}^{(k)}(n, p)$ . For  $\mathbb{H}^{(k)}(n, p)$  to satisfy the Ramsey property for  $H$  a.a.s. it is reasonable to expect that many intermingled copies of  $H$  are required; this as to create colour restrictions forcing the Ramsey property for  $H$ . Indeed, for (hypergraph) cliques it is necessary that many cliques sharing a single hyperedge would appear a.a.s. in  $\mathbb{H}^{(k)}(n, p)$ . This results in the higher threshold  $n^{-1/m_k(H)}$  being encountered for Ramsey properties.

For asymmetric Ramsey properties, another notion of hypergraph density arises. This notion traces back to the work of Kohayakawa and Kreuter [30]. Given two  $k$ -uniform hypergraphs  $H_1$  and  $H_2$ , each with at least one edge and satisfying  $m_k(H_1) \geq m_k(H_2)$ , the *asymmetric maximal  $k$ -density* of  $H_1$  and  $H_2$  is given by

$$m_k(H_1, H_2) = m_k(H_2, H_1) = \max \left\{ \frac{e(F)}{v(F) - k + 1/m_k(H_2)} : F \subseteq H_1 \text{ and } e(F) \geq 1 \right\}, \quad (2)$$

where here we do not mean that  $m_k(\cdot, \cdot)$  is symmetric only that in our notation we do not keep track over the location in which  $H_1$ , the hypergraph with the potentially higher  $m_k(\cdot)$ -density is higher, is placed. The equality  $m_k(H, H) = m_k(H)$  is easy to verify.

With the above notation in place, our main contribution can be stated; this can be viewed as a hypergraph extension of the aforementioned results of Das and Treglown [20]. Below we always tacitly assume that  $H_n$  and  $\mathbb{H}^{(3)}(n, p)$  share the same vertex set.

► **Theorem 1 (Main result).** *For every  $d > 0$  and every even integer  $t \geq 4$ , there exists a constant  $C > 0$  such that for every sequence of 3-uniform  $n$ -vertex hypergraphs  $(H_n)_{n \in \mathbb{N}}$  with  $e(H_n) \geq dn^3$  for every  $n \in \mathbb{N}$  we have*

$$\lim_{n \rightarrow \infty} \mathbb{P}(H_n \cup \mathbb{H}^{(3)}(n, p) \rightarrow (\tilde{K}_t^{(3)})) = 1,$$

whenever  $p = p(n) \geq Cn^{-\frac{1}{M}}$  for  $M = m_3(\tilde{K}_t^{(3)}, \tilde{K}_{t/2}^{(3)})$ .

Our proof of Theorem 1 relies on two main technical results, which are related to the regularity method for hypergraphs. We present these results in Section 1.3-1.4 below.

The proof of Theorem 1 presented here can be adapted for  $k$ -uniform hypergraphs and the asymmetric Ramsey properties  $H_n \cup \mathbb{H}^{(k)}(n, p) \rightarrow (\tilde{K}_s^{(k)}, \tilde{K}_t^{(k)})$  with  $t \geq s$ . For the sake of brevity, we restrict ourselves to 3-uniform hypergraphs and the symmetric case for even  $t$ . In particular, from here on, unless stated otherwise, we use the term hypergraph to mean a 3-uniform hypergraph. We conjecture that Theorem 1 uncovers the threshold for the Ramsey property in question.

► **Conjecture 2.** *For every even integer  $t \geq 6$  there exist constants  $d, c > 0$ , and there exists a sequence of 3-uniform  $n$ -vertex hypergraphs  $(H_n)_{n \in \mathbb{N}}$  with  $e(H_n) \geq dn^3$  for every  $n \in \mathbb{N}$  such that*

$$\lim_{n \rightarrow \infty} \mathbb{P}(H_n \cup \mathbb{H}^{(3)}(n, p) \longrightarrow (\tilde{K}_t^{(3)})) = 0,$$

whenever  $p \leq cn^{-1/M}$  for  $M = m_3(\tilde{K}_t^{(3)}, \tilde{K}_{t/2}^{(3)})$ .

Conjecture 2 may hold for  $t = 4$  as well. However, this value is excluded due to the distinct behaviour seen in the graph case [20, 46]. The proof of Theorem 1 presented here extends for the asymmetric Ramsey property  $H \longrightarrow (\tilde{K}_t^{(3)}, \tilde{K}_s^{(3)})$  for sufficiently large integers  $t \geq s$  and  $M$  replaced by  $m_3(\tilde{K}_t^{(3)}, \tilde{K}_{\lceil s/2 \rceil}^{(3)})$ . It seems plausible that the corresponding generalisation of Conjecture 2 may also hold.

### 1.3 A tuple lemma for link graphs

A key feature of the regularity method of graphs is the control over joint neighbourhoods in the regular environment provided by Szemerédi’s regularity lemma (see, e.g., Lemma 8 below). For the proof of Theorem 1, we establish a similar lemma in the context of the regularity method for hypergraphs.

For a vertex  $v$  in a hypergraph  $H = (V, E)$ , define the *link graph*  $L_H(v)$  of  $v$  to have vertex set  $V \setminus \{v\}$  and edge set comprised of those pairs of vertices which together with  $v$  form a hyperedge in  $H$ , i.e.,  $E(L_H(v)) = \{uv : uvw \in E\}$ . In particular,  $e(L_H(v))$  is the vertex degree of  $v$  in  $H$  and is also denoted by  $\deg_H(v)$ . Given a graph  $G$  with vertex set  $V(G) = V$  we define the *link graph of  $v$  supported on  $G$*  by

$$L_H(v, G) = E(L_H(v)) \cap E(G).$$

Link graphs are a natural hypergraph extension of vertex neighbourhoods in the context of graphs. A tuple lemma for hypergraphs would have to control the sizes of the intersections of link graphs. In that, given a set of vertices  $U \subseteq V$ , we seek to control the sizes of the *joint link graph* and the *joint link graph supported by  $G$*  given by

$$L_H(U) = \bigcap_{u \in U} L_H(u) \quad \text{and} \quad L_H(U, G) = \bigcap_{u \in U} L_H(u, G),$$

respectively. For a random hypergraph  $H = (V, E)$  with edge density  $d$ , one would expect  $|L_H(U)| \sim d^{|U|} \binom{|V|}{2}$  to hold with high probability. Our tuple lemma asserts that in the regular environment for hypergraphs this random intuition can be transferred to the deterministic situation. (We defer the definitions concerning regular hypergraphs to Section 2.)

► **Proposition 3 (Tuple lemma for joint links).** *For every  $t \geq 2$  and  $\varepsilon, d_3 > 0$ , there exists a  $\delta_3 > 0$  such that for every  $d_2 > 0$  there exist  $\delta_2 > 0$  and  $r \geq 1$  such that the following holds.*

*Let  $H = (X \cup Y \cup Z, E_H)$  be a tripartite hypergraph which is  $(\delta_3, d_3, r)$ -regular with respect to a  $(\delta_2, d_2)$ -triad  $P = (X \cup Y \cup Z, E_P)$ . Then, all but at most  $2\varepsilon|X|^t$  of the  $t$ -tuples of vertices  $X' = \{x_1, \dots, x_t\} \subseteq X$  satisfy*

$$|L_H(X', P) - d_3^t d_2^{2t+1} |Y||Z|| \leq \varepsilon d_2^{2t+1} |Y||Z|. \tag{3}$$

Due to space limitations, our proof of Proposition 3 is omitted and can be found in [7] - the full version of this extended abstract - the former extends to all hypergraph uniformities. Alternatives to Proposition 3 exerting some control over the sizes of joint link graphs of vertex tuples whilst relying on weaker versions of the hypergraph regularity do exist. Such alternatives are established in the extended account [7].

## 1.4 A variant of the hypergraph regularity lemma

The second main technical lemma is a new variant of the hypergraph regularity lemma established in [51]. The necessary definitions are deferred to Section 2.

► **Proposition 4** (Variant of the regularity lemma for hypergraphs). *For every  $\delta_3 > 0$  and functions  $\delta_2: \mathbb{N} \rightarrow (0, 1]$ ,  $r: \mathbb{N}^2 \rightarrow \mathbb{N}$ , and constants  $\ell_0$ ,  $t_0$ , and  $s \in \mathbb{N}$ , there exist  $n_0$  and  $T \in \mathbb{N}$  such that for every  $n \geq n_0$  and every family  $(H_1, \dots, H_s)$  of  $n$ -vertex hypergraphs satisfying  $V = V(H_1) = \dots = V(H_s)$ , there are integers  $t$  and  $\ell$  satisfying  $t \geq t_0$  and  $\ell \geq \ell_0$ , a vertex partition  $\mathcal{V}$  with  $V_1 \cup \dots \cup V_t = V$  and an  $\ell$ -equitable partition  $\mathcal{B}$  with respect to  $\mathcal{V}$  such that the following properties hold.*

(R.1)  $|V_1| \leq |V_2| \leq \dots \leq |V_t| \leq |V_1| + 1$ ,

(R.2) for all  $1 \leq i < j \leq t$  and  $\alpha \in [\ell]$ , the bipartite 2-graph  $B_\alpha^{ij}$  is  $(\delta_2(\ell), 1/\ell)$ -regular,

(R.3)  $H_i$  is  $\delta_2(\ell)$ -weakly regular with respect to  $\mathcal{V}$  for every  $i \in [s]$ , and

(R.4)  $H_i$  is  $(\delta_3, r(t, \ell))$ -regular with respect to  $\mathcal{B}$  for every  $i \in [s]$ .

Due to space limitations, our proof of Proposition 4 is omitted and can be found in [7] - the full version of this extended abstract. In Proposition 4 there is a combination of the environment of the hypergraph regularity lemma [51] (see Lemma 10) and the so-called weak hypergraph regularity lemma (see Lemma 9 below), which is the straightforward extension of Szemerédi's regularity for graphs. A lemma of similar spirit can be found in the work of Allen, Parczyk, and Pfenninger [9].

In the sequel, these hypergraph regularity lemmata are distinguished by referring to these as the *Strong Lemma* and *Weak Lemma*, respectively. The difference between the Strong Lemma and Proposition 4 is Property (R.3). The former, when applied to dense hypergraphs, provides access to triads  $P$  set over a vertex set, say,  $X \cup Y \cup Z$  with respect to which the regularised hypergraphs is  $(\delta_3, d, r)$ -regular. This, in turn, provides  $\zeta$ -weak regularity control for  $\zeta = \delta_3^{1/3}$ , by which we mean the ability to control the hyperedge distribution of the hypergraphs along sets  $X' \subseteq X$ ,  $Y' \subseteq Y$ , and  $Z' \subseteq Z$  satisfying  $|X'| \geq \zeta|X|$ ,  $|Y'| \geq \zeta|Y|$ , and  $|Z'| \geq \zeta|Z|$ .

The added Property (R.3), however, provides weak regularity control over vertex sets with much smaller density. In fact, there the control  $\delta_2$  is allowed to be a function of  $\ell$  and the quantification of the Strong Lemma leads to  $\delta_3 \gg \ell^{-1}$ .

## Organisation

Theorem 1 is proved in Section 3. Various required preliminaries are collected in Section 2. As mentioned above, the proofs of Propositions 3 and 4 are omitted from this account due to space limitations and can be seen in [7] - the full version of this account.

## Notational remark

Throughout, we often write the enumeration of a result in the subscripts of the constants that it presides over. For instance, the constant  $t_0$  in Proposition 4 becomes  $t_4$  and the constant  $\delta_3$  in the same lemma is written  $\delta_4^{(3)}$  and so on. This aids in keeping track of the various constants encountered throughout the proofs.

## 2 Preliminaries

Let  $V$  be a finite set. A partition  $\mathcal{U}$  of  $V$  given by  $V = U_1 \cup \dots \cup U_r$  is said to be *equitable* if  $|U_1| \leq |U_2| \leq \dots \leq |U_r| \leq |U_1| + 1$ . Given an additional partition of  $V$ , namely  $\mathcal{V}$ , of the form  $V = V_1 \cup \dots \cup V_\ell$ , we say that  $\mathcal{V}$  *refines*  $\mathcal{U}$ , and write  $\mathcal{V} \prec \mathcal{U}$ , if for every  $i \in [\ell]$  there

exists some  $j \in [r]$  such that  $V_i \subseteq U_j$  holds. For  $k \geq 2$ , write  $K^{(k)}(\mathcal{U})$  to denote the complete  $|\mathcal{U}|$ -partite  $k$ -uniform hypergraph whose vertex set is  $V$  and whose edge set is given by all sets of  $V^{(k)} = \{K \subseteq V: |K| = k\}$  meeting every member of  $\mathcal{U}$  (termed *cluster* hereafter) in at most one vertex. If  $\mathcal{U} = \{U, U'\}$  consists of only two clusters, then we abbreviate  $K^{(2)}(\mathcal{U})$  to  $K^{(2)}(U, U')$ . We write  $K^{(2)}(V)$  to denote the complete graph whose vertex set is  $V$ .

## 2.1 Graph regularity

Let  $d, \delta > 0$  be given. A bipartite 2-graph  $G = (X \cup Y, E)$  is said to be  $(\delta, d)$ -regular if

$$e_G(X', Y') = d|X'||Y'| \pm \delta|X||Y|$$

holds<sup>1</sup> for every  $X' \subseteq X$  and  $Y' \subseteq Y$ . If  $d$  coincides with the edge density of  $G$ , i.e.  $d = \frac{e(G)}{|X||Y|}$ , then we abbreviate  $(\delta, d)$ -regular to  $\delta$ -regular. It follows directly from the definition that  $G$  is a  $(\delta, d)$ -regular bipartite graph if, and only if, its (bipartite) complement is  $(\delta, 1 - d)$ -regular.

A tripartite 2-graph  $P$  with vertex set  $V(P) = X \cup Y \cup Z$  is said to be a  $(\delta, d)$ -*triad*, if  $P[X, Y]$ ,  $P[Y, Z]$ , and  $P[X, Z]$  are all  $(\delta, d)$ -regular. For a 2-graph  $G$ , let  $\mathcal{K}_3(G)$  denote the family of members of  $V(G)^{(3)}$  spanning a triangle in  $G$ . We shall employ the well known triangle counting lemma (see, e.g., [25, Fact A]).

► **Lemma 5** (Triangle counting lemma). *Let  $d > 0$ , let  $0 < \delta < d/2$ , and let  $P$  be a  $(\delta, d)$ -triad with vertex set  $V(P) = X \cup Y \cup Z$ . Then,*

$$(1 - 2\delta)(d - \delta)^3|X||Y||Z| \leq |\mathcal{K}_3(P)| \leq ((d + \delta)^3 + 2\delta)|X||Y||Z|.$$

In particular, if  $d \leq 1/2$ , then

$$|\mathcal{K}_3(P)| = (d^3 \pm 4\delta)|X||Y||Z| \tag{4}$$

holds. ┘

We shall also use the variant of the triangle counting lemma with only two of the bipartite graphs being regular and its proof is included for completeness.

► **Lemma 6.** *Let  $P = (X \cup Y \cup Z, E_P)$  be a tripartite 2-graph such that  $P[X, Y]$  and  $P[X, Z]$  are both  $(\delta, d)$ -regular. In addition, let  $X' \subseteq X$  be a set of size  $|X'| \geq \delta|X|$ . Then,*

$$(d - \delta)d|X'|e(P[Y, Z]) - 2\delta|X||Y||Z| \leq |\mathcal{K}_3(P, X')| \leq (d + \delta)d|X'|e(P[Y, Z]) + 2\delta|X||Y||Z|$$

holds, where  $\mathcal{K}_3(P, X')$  denotes the set of triangles of  $P$  meeting  $X'$ .

**Proof.** Let  $Y' \subseteq Y$  consist of all vertices  $y \in Y$  satisfying  $\deg_P(y, X') \geq (d - \delta)|X'|$ ; note that  $|Y'| \geq (1 - \delta)|Y|$  holds by Lemma 8. We may then write

$$\begin{aligned} |\mathcal{K}_3(P, X')| &\geq \sum_{y \in Y'} \left( d(d - \delta)|X'| \deg_P(y, Z) - \delta|X||Z| \right) \\ &= d(d - \delta)|X'| \left( \sum_{y \in Y} \deg_P(y, Z) - \sum_{y \in Y \setminus Y'} \deg_P(y, Z) \right) - \sum_{y \in Y'} \delta|X||Z| \\ &\geq d(d - \delta)|X'|e(P[Y, Z]) - d(d - \delta)\delta|X||Y||Z| - \delta|X||Y||Z| \\ &\geq d(d - \delta)|X'|e(P[Y, Z]) - 2\delta|X||Y||Z|. \end{aligned}$$

<sup>1</sup> Given  $x, y, z \in \mathbb{R}$ , we write  $x = y \pm z$  if  $y - z \leq x \leq y + z$ .

Next, we prove the upper bound. Let  $Y'' \subseteq Y$  consist of all vertices  $y \in Y$  satisfying  $\deg_P(y, X') \leq (d + \delta)|X'|$ ; note that  $|Y''| \geq (1 - \delta)|Y|$  holds by Lemma 8. We may then write

$$\begin{aligned} |\mathcal{K}_3(P, X')| &\leq \sum_{y \in Y''} \left( d(d + \delta)|X'| \deg_P(y, Z) + \delta|X||Z| \right) + \sum_{y \in Y \setminus Y''} |X'||Z| \\ &\leq d(d + \delta)|X'| \left( \sum_{y \in Y} \deg_P(y, Z) - \sum_{y \in Y \setminus Y''} \deg_P(y, Z) \right) \\ &\quad + \sum_{y \in Y''} \delta|X||Z| + \sum_{y \in Y \setminus Y''} |X||Z| \\ &\leq d(d + \delta)|X'|e(P[Y, Z]) + 2\delta|X||Y||Z|. \end{aligned} \quad \blacktriangleleft$$

The next lemma is commonly referred to as the *Slicing Lemma* (see, e.g., [33, Fact 1.5]).

► **Lemma 7** (Slicing lemma). *Let  $d = d_7$ , let  $\delta = \delta_7 > 0$ , and let  $G = (A \cup B, E)$  be a  $(\delta, d)$ -regular bipartite graph. Let  $\delta \leq \alpha = \alpha_7 \leq 1$ , and let  $A' \subseteq A$  and  $B' \subseteq B$  be sets of sizes  $|A'| \geq \alpha|A|$  and  $|B'| \geq \alpha|B|$ . Then,  $G[A', B']$  is  $(\delta', d')$ -regular where  $\delta' = \max\{\delta/\alpha, 2\delta\}$  and  $d' = d \pm \delta$ .  $\blacktriangleright$*

The *tuple property* of dense regular bipartite graphs, also referred to as the *intersection property*, reads as follows (see [33, Fact 1.4]).

► **Lemma 8** (Tuple lemma for graphs). *Let  $G = (X \cup Y, E)$  be a  $\delta$ -regular bipartite graph of edge density  $d > 0$ . Then, all but at most  $2\delta\ell|X|^\ell$  of the tuples  $\{x_1, \dots, x_\ell\} \subseteq X$  satisfy*

$$|N_G(x_1, \dots, x_\ell, Y')| = |\{y \in Y' : x_i y \in E(G) \text{ for all } i \in [\ell]\}| = (d \pm \delta)^\ell |Y'|, \quad (5)$$

whenever  $Y' \subseteq Y$  satisfies  $(d - \delta)^{\ell-1}|Y'| \geq \delta|Y|$ .  $\blacktriangleright$

## 2.2 Hypergraph regularity

A direct generalisation of the notion of  $\delta$ -regularity, defined in the previous section for 2-graphs, reads as follows. Let  $d, \delta > 0$ . A tripartite hypergraph  $H = (X \cup Y \cup Z, E)$  is said to be  $(\delta, d)$ -weakly regular if

$$e_H(X', Y', Z') = d|X'||Y'||Z'| \pm \delta|X||Y||Z|$$

holds whenever  $X' \subseteq X$ ,  $Y' \subseteq Y$ , and  $Z' \subseteq Z$ . If  $d = \frac{e(H)}{|X||Y||Z|}$ , then we abbreviate  $(\delta, d)$ -weakly regular to  $\delta$ -weakly regular.

Given a partition  $\mathcal{V}$  of a finite set  $V$  defined by  $V = V_1 \cup \dots \cup V_t$ , a hypergraph  $H$  with  $V(H) = V$  is said to be  $\delta$ -weakly regular with respect to  $\mathcal{V}$  if  $H[X, Y, Z]^2$  is  $\delta$ -weakly regular with respect to all but at most  $\delta \binom{t}{3}$  triples  $\{X, Y, Z\} \in \mathcal{V}^{(3)}$ . We state the straightforward adaptation of Szemerédi's graph regularity lemma [32, 33, 54].

► **Lemma 9** (Weak hypergraph regularity lemma). *For every  $\delta = \delta_9 > 0$  and positive integers  $s = s_9$ ,  $t = t_9$ , and  $h = h_9$  satisfying  $t \geq h$ , there exist positive integers  $n_0$  and  $T = T_9$  such that the following holds whenever  $n \geq n_0$ . Let  $(H_1, \dots, H_s)$  be a sequence of  $n$ -vertex hypergraphs, all on the same vertex set, namely  $V$ , and let  $\mathcal{U} = \mathcal{U}_9$  be a vertex partition of*

<sup>2</sup>  $H[X, Y, Z]$  is the subgraph of  $H$  over  $X \cup Y \cup Z$  whose edge set is  $\{\{x, y, z\} \in E(H) : x \in X, y \in Y, z \in Z\}$ .

$V$  given by  $V = U_1 \cup \dots \cup U_h$ . Then, there exists an equitable vertex partition  $\mathcal{V}$ , given by  $V = V_1 \cup V_2 \cup \dots \cup V_{t'}$ , where  $t \leq t' \leq T$ , such that  $\mathcal{V} \prec \mathcal{U}$  and, moreover,  $H_i$  is  $\delta$ -weakly regular with respect to  $\mathcal{V}$  for every  $i \in [s]$ .  $\lrcorner$

We proceed to the statement of the Strong hypergraph Regularity Lemma for hypergraphs following the formulation seen in [51]. Given a 2-graph  $G$ , the *relative density* of a hypergraph  $H$  with vertex set  $V(H) = V(G)$ , with respect to  $G$  is given by

$$d(H|G) = \frac{|E(H) \cap \mathcal{K}_3(G)|}{|\mathcal{K}_3(G)|}. \quad (6)$$

For  $\delta, d > 0$  and a positive integer  $r$ , a tripartite hypergraph  $H = (X \cup Y \cup Z, E_H)$  is said to be  $(\delta, d, r)$ -regular with respect to a tripartite 2-graph  $P = (X \cup Y \cup Z, E_P)$  if

$$\left| \left| \bigcup_{i=1}^r (E_H \cap \mathcal{K}_3(Q_i)) \right| - d \left| \bigcup_{i=1}^r \mathcal{K}_3(Q_i) \right| \right| \leq \delta |\mathcal{K}_3(P)| \quad (7)$$

holds for every family of, not necessarily disjoint, subgraphs  $Q_1, \dots, Q_r \subseteq P$  satisfying

$$\left| \bigcup_{i=1}^r \mathcal{K}_3(Q_i) \right| \geq \delta |\mathcal{K}_3(P)| > 0.$$

Let  $V$  be a finite set and let  $\mathcal{V}$  be a partition  $V_1 \cup \dots \cup V_h$  of  $V$ , where  $h$  is some positive integer. Given an integer  $\ell \geq 1$ , a partition  $\mathcal{B}$  of  $K^{(2)}(\mathcal{V})$  is said to be  $\ell$ -equitable with respect to  $\mathcal{V}$  if it satisfies the following conditions:

**(B.1)** every  $B \in \mathcal{B}$  satisfies  $B \subseteq K^{(2)}(V_i, V_j)$  for some distinct  $i, j \in [h]$ ; and

**(B.2)** for any distinct  $i, j \in [h]$ , precisely  $\ell$  members of  $\mathcal{B}$  partition  $K^{(2)}(V_i, V_j)$ .

We view partitions of  $K^{(2)}(\mathcal{V})$  as partitions of  $V^{(2)}$  under the *agreement*<sup>3</sup> that the set  $\{K^{(2)}(V_i) : i \in [h]\}$  of complete graphs is added to the former; such an addition of cliques does not hinder the equitability notion defined in (B.2); it does violate (B.1), but this will not harm our arguments. Moreover, it is under this agreement that we say that a partition of  $V^{(2)}$  refines a partition of  $K^{(2)}(\mathcal{V})$ .

For distinct indices  $i, j \in [h]$ , the partition of  $K^{(2)}(V_i, V_j)$  induced by  $\mathcal{B}$  is denoted by

$$\mathcal{B}^{ij} = \{B_\alpha^{ij} = (V_i \cup V_j, E_\alpha^{ij}) : \alpha \in [\ell]\}.$$

The *triads* of  $\mathcal{B}$  are the tripartite 2-graphs having the form

$$B_{\alpha\beta\gamma}^{ijk} = (V_i \cup V_j \cup V_k, E_\alpha^{ij} \cup E_\beta^{ik} \cup E_\gamma^{jk}),$$

where  $i, j, k \in [h]$  are distinct and  $\alpha, \beta, \gamma \in [\ell]$ . Recall that a triad is called a  $(\delta, d)$ -triad if each of the three bipartite graphs comprising it is  $(\delta, d)$ -regular. A hypergraph  $H$  with vertex set  $V(H) = V$  is said to be  $(\delta, r)$ -regular with respect to  $\mathcal{B}$  if

$$\left\{ \bigcup_{\substack{1 \leq i < j < k \leq h \\ \alpha, \beta, \gamma \in [\ell]}} \mathcal{K}_3(B_{\alpha\beta\gamma}^{ijk}) : H_{ijk} \text{ is not } (\delta, d(H|B_{\alpha\beta\gamma}^{ijk}), r)\text{-regular w.r.t. } B_{\alpha\beta\gamma}^{ijk} \right\} \leq \delta |V|^3,$$

where  $H_{ijk} = H[V_i \cup V_j \cup V_k]$ . A formulation of the Strong Lemma [51, Theorem 17] for hypergraphs, reads as follows.

<sup>3</sup> We appeal to this agreement in our proof of Proposition 4 omitted from this account and which can be found in [7].

► **Lemma 10** (Strong hypergraph regularity lemma). *For all  $0 < \delta_3 \in \mathbb{R}$ ,  $\delta_2: \mathbb{N} \rightarrow (0, 1]$ ,  $r: \mathbb{N}^2 \rightarrow \mathbb{N}$ , and  $s, t, \ell \in \mathbb{N}$ , there exist  $n_0, T \in \mathbb{N}$  such that for every  $n \geq n_0$  and every sequence of  $n$ -vertex hypergraphs  $(H_1, \dots, H_s)$ , satisfying  $V = V(H_1) = \dots = V(H_s)$ , there are  $t', \ell' \in \mathbb{N}$  satisfying  $t \leq t' \leq T$  and  $\ell \leq \ell' \leq T$ , a vertex partition  $V = V_1 \cup \dots \cup V_{t'}$ , namely  $\mathcal{V}$ , and an  $\ell'$ -equitable partition  $\mathcal{B}$  with respect to  $\mathcal{V}$  such that the following properties hold.*

- (S.1)  $|V_1| \leq |V_2| \leq \dots \leq |V_{t'}| \leq |V_1| + 1$ ;
- (S.2) for all  $1 \leq i < j \leq t'$  and  $\alpha \in [\ell']$ , the bipartite 2-graph  $B_\alpha^{ij}$  is  $(\delta_2(\ell'), 1/\ell')$ -regular; and
- (S.3)  $H_i$  is  $(\delta_3, r(t', \ell'))$ -regular with respect to  $\mathcal{B}$  for every  $i \in [s]$ . ◻

### 3 Monochromatic expanded cliques

In this section, we prove Theorem 1. The required Ramsey properties of  $\mathbb{H}^{(3)}(n, p)$  are collected in Section 3.1; a proof of Theorem 1 can be found in Section 3.2. For an integer  $t \geq 3$ , the  $t$  vertices of  $\tilde{K}_t^{(k)}$  having their 1-degree strictly larger than one are called the *branch-vertices* of  $\tilde{K}_t^{(k)}$ . Set

$$v(t) = v(\tilde{K}_t^{(3)}) \quad \text{and} \quad e(t) = e(\tilde{K}_t^{(3)}).$$

#### 3.1 Properties of random hypergraphs

The main goal of this section is to state Proposition 11 which is an adaptation of [20, Theorem 2.10]. This proposition collects the Ramsey properties of  $\mathbb{H}^{(3)}(n, p)$  that will be utilised throughout our proof of Theorem 1.

A  $k$ -graph  $H$  is said to be *balanced* if  $m_k(H) = d_k(H)$  holds; if all proper subgraphs  $F$  of  $H$  satisfy  $m_k(F) < m_k(H)$ , then  $H$  is said to be *strictly balanced*. It is not hard to verify that expanded cliques are strictly balanced. In particular,

$$m_k(\tilde{K}_t^{(k)}) = \frac{\binom{t}{2} - 1}{t + (k-2)\binom{t}{2} - k}$$

holds for any  $k \geq 2$  and  $t \geq 3$ . In the special case  $k = 3$  we obtain

$$m_3(\tilde{K}_t^{(3)}) = \frac{t^2 - t - 2}{t^2 + t - 6} = 1 - \frac{2t - 4}{t^2 + t - 6} < 1, \tag{8}$$

that is, 3-uniformly expanded cliques are *sparse*. Note that this is in contrast to graph cliques (on at least 3 vertices) whose 2-density is larger than one. For a simpler notation we set an integer  $t \geq 2$

$$m(t) = m(\tilde{K}_t^{(3)}) \quad \text{and} \quad M_t = m_3(\tilde{K}_t^{(3)}).$$

Similarly for integers  $t_1, t_2 \geq 2$  we set

$$M_{t_1, t_2} = M_{t_2, t_1} = m_3(\tilde{K}_{t_1}^{(3)}, \tilde{K}_{t_2}^{(3)}).$$

Let  $H_1$  and  $H_2$  be two  $k$ -graphs, each with at least one edge and such that  $m_k(H_1) \geq m_k(H_2)$ . If  $m_k(H_1) = m_k(H_2)$ , then  $m_k(H_1, H_2) = m_k(H_1)$ ; otherwise  $m_k(H_2) < m_k(H_1, H_2) < m_k(H_1)$  holds. The  $k$ -graph  $H_1$  is said to be *strictly balanced with respect to  $m_k(\cdot, H_2)$*  if no proper subgraph  $F \subsetneq H_1$  maximises  $\binom{2}{2}$ . For instance, it is not hard to verify that  $\tilde{K}_t^{(3)}$  is strictly balanced with respect to  $m_3(\cdot, \tilde{K}_{t/2}^{(3)})$ , assuming  $t \geq 4$  is even.

Let  $F$  and  $F'$  be  $k$ -graphs and let  $\mu = \mu(n)$  be given. An  $n$ -vertex  $k$ -graph  $H$  is said to be  $(F, \mu)$ -Ramsey if  $H[U] \rightarrow (F)_2$  holds for every  $U \subseteq V(H)$  of size  $|U| \geq \mu n$ . Similarly,  $H$  is said to be  $(F, F', \mu)$ -Ramsey if  $H[U] \rightarrow (F, F')$  holds for every  $U \subseteq V(H)$  of size  $|U| \geq \mu n$ . Given  $\mathcal{F} \subseteq \binom{[n]}{v(F)}$  and  $\mathcal{F}' \subseteq \binom{[n]}{v(F')}$ , we say that  $H$  is  $(F, F')$ -Ramsey with respect to  $(\mathcal{F}, \mathcal{F}')$  if any 2-colouring of  $E(H)$  yields a monochromatic copy  $K$  of  $F$  (in the first colour) with  $V(K) \notin \mathcal{F}$  or a monochromatic copy  $K'$  of  $F'$  (in the second colour) with  $V(K') \notin \mathcal{F}'$ .

► **Proposition 11.** *Let  $t \geq 4$  be an even integer. The binomial random hypergraph  $H \sim \mathbb{H}^{(3)}(n, p)$  a.a.s. satisfies the following properties.*

- (P.1) *There are constants  $\gamma_{11} = \gamma_{11}(t)$  and  $C_{11}^{(1)} = C_{11}^{(1)}(t)$  such that if  $\mathcal{F}_1 \subseteq \binom{[n]}{v(t)}$  and  $\mathcal{F}_2 \subseteq \binom{[n]}{v(t/2)}$  satisfy  $|\mathcal{F}_1| \leq \gamma_{11}n^{v(t)}$  and  $|\mathcal{F}_2| \leq \gamma_{11}n^{v(t/2)}$ , then  $H$  is  $(\tilde{K}_t^{(3)}, \tilde{K}_{t/2}^{(3)})$ -Ramsey with respect to  $(\mathcal{F}_1, \mathcal{F}_2)$ , whenever  $p = p(n) \geq C_{11}^{(1)}n^{-1/M_{t,t/2}}$ .*
- (P.2) *For every fixed  $\mu > 0$ , there exists a constant  $C_{11}^{(2)} = C_{11}^{(2)}(\mu, t)$  such that  $H$  is  $(\tilde{K}_{t-1}^{(3)}, \mu)$ -Ramsey, whenever  $p = p(n) \geq C_{11}^{(2)}n^{-1/M_{t-1}}$ .*
- (P.3) *For every fixed  $\mu > 0$ , there exists a constant  $C_{11}^{(3)} = C_{11}^{(3)}(\mu, t)$  such that  $H$  is  $(\tilde{K}_t^{(3)}, \tilde{K}_{t/2}^{(3)}, \mu)$ -Ramsey, whenever  $p = p(n) \geq C_{11}^{(3)}n^{-1/M_{t,t/2}}$ .*

► **Remark 12.** *A straightforward albeit somewhat tedious calculation shows that  $M_{t,t/2} \geq M_{t-1}$  holds for every even integer  $t \geq 4$ . It thus follows that Properties (P.1) and (P.3) are the most stringent in terms of the bound these impose on  $p$ . Hence, if  $p = p(n) \geq \max\{C_{11}^{(1)}, C_{11}^{(3)}\} \cdot n^{-1/M_{t,t/2}}$ , then a.a.s.  $H$  satisfies Properties (P.1), (P.2), and (P.3) simultaneously.*

Property (P.1) is modelled after [20, Theorem 2.10(i)]; Properties (P.2) and (P.3) are both specific instantiations of [20, Theorem 2.10(ii)]. The aforementioned results of [20] handle 2-graphs only. Nevertheless, proofs of Properties (P.1-3) can be attained by straightforwardly adjusting the proofs of their aforementioned counterparts in [20, Theorem 2.10] so as to accommodate the transition from 2-graphs to hypergraphs. Theorem 2.10 in [20] requires that the maximal 2-densities of the two (fixed) configurations would both be at least one; this can be omitted in our setting. Indeed, this condition is imposed in [20, Theorem 2.10] in order to handle setting (a) in that theorem where the maximal 2-densities of the two configurations coincide; by (8), this is not an issue in our case. The fact that  $\tilde{K}_t^{(3)}$  is strictly balanced with respect to  $m_3(\cdot, \tilde{K}_{t/2}^{(3)})$  is required by setting (b) appearing in [20, Theorem 2.10].

### 3.2 Proof of Theorem 1

We commence our proof of Theorem 1 with a few observations facilitating our arguments; proofs of these observations are included for completeness.

► **Observation 13.** *Let  $d \in (0, 1]$ , let  $G = (A \cup B, E)$  be a bipartite graph satisfying  $e(G) \geq d|A||B|$ , and let  $k \leq d|B|/2$  be a positive integer. Then,  $|\{v \in A : \deg_G(v) \geq k\}| \geq d|A|/2$ .*

**Proof.** Let  $A_k = \{v \in A : \deg_G(v) \geq k\}$  and suppose for a contradiction that  $|A_k| < d|A|/2$ . Then,

$$e(G) < k|A| + |A_k||B| < d|A||B|/2 + d|A||B|/2 \leq e(G)$$

which is clearly a contradiction. ◀

The next lemma captures the phenomenon of *supersaturation* (first <sup>4</sup> recorded in [22, 23, 24]) for bipartite graphs; to facilitate future references, we phrase this lemma with the host graph being bipartite as well.

► **Lemma 14.** *For every bipartite graph  $K$  and every  $d \in (0, 1)$ , there exists a constant  $\zeta = \zeta_{14} > 0$  and a positive integer  $n_0$  such that every  $n$ -vertex bipartite graph  $G = (A \cup B, E)$  satisfying  $n \geq n_0$ ,  $|A| \leq |B| \leq |A| + 1$ , and  $e(G) \geq d|A||B|$  contains at least  $\zeta n^{v(K)}$  distinct copies of  $K$ .*

► **Observation 15.** *For every graph  $K$  and every  $d \in (0, 1)$ , there exists a constant  $\xi = \xi_{15} > 0$  and an integer  $n_0$  such that the following holds whenever  $n \geq n_0$ . If an  $n$ -vertex graph  $G$  contains  $dn^{v(K)}$  distinct copies of  $K$ , then it contains at least  $\xi n$  pairwise vertex-disjoint copies of  $K$ .*

**Proof.** Any given copy of  $K$  meets  $O(n^{v(K)-1})$  copies of  $K$ . ◀

**Proof of Theorem 1.** Given  $d, t$ , and  $H$  as in the premise of Theorem 1, set

$$0 < d_3 \ll d \text{ and } 0 < \varepsilon \ll \min \left\{ d_3^{v(t/2)}, \gamma_{11}(t) \right\}. \quad (9)$$

The Tuple Property (Theorem 3) applied with  $t_3 = v(t/2)$ ,  $\varepsilon_3 = \varepsilon$ , and  $d_3^{(3)} = d_3$ , yields the existence of a constant

$$0 < \delta_3 = \delta_3^{(3)}(v(t/2), \varepsilon, d_3) \ll d_3 \quad (10)$$

as well as the functions

$$\tilde{\delta}_2(x) = \delta_3^{(2)}(x, t_3, \varepsilon, d_3, \delta_3) \text{ and } r(x) = r_3(x, t_3, \varepsilon, d_3, \delta_3),$$

where  $\tilde{\delta}_2 : \mathbb{R} \rightarrow (0, 1]$  and  $r : \mathbb{N} \rightarrow \mathbb{N}$ . Define  $\delta_2 : \mathbb{N} \rightarrow (0, 1]$  such that

$$0 < \delta_2(x) \ll \min \left\{ \tilde{\delta}_2(x), \frac{d_3^{2v(t/2)}}{v(t/2) \cdot x^{6 \cdot (2v(t/2)+1)}} \right\} \quad (11)$$

holds for every  $x \in \mathbb{N}$ . Lemma 4, applied with

$$H_1 = \dots = H_s = H, \delta_4^{(3)} = \delta_3, \delta_4^{(2)} = \delta_2, r_4 = r^5, \ell_4 \gg d_3^{-1}, \text{ and } t_4 \gg d^{-1}, \quad (12)$$

yields the existence of constants  $T_4, \tilde{t}, \ell \in \mathbb{N}$  satisfying  $t_4 \leq \tilde{t} \leq T_4$  and  $\ell_4 \leq \ell \leq T_4$ , along with partitions  $\mathcal{V} = V_1 \cup \dots \cup V_{\tilde{t}} = V(H)$  and  $(\mathcal{P}^{ij})_{1 \leq i < j \leq \tilde{t}}$  satisfying Properties (R.1-4). Set auxiliary constants

$$d_2 = 1/\ell \quad \text{and} \quad \eta = \frac{d_3^{v(t/2)} d_2^{2v(t/2)+1}}{2} \quad (13)$$

and fix

$$0 < \mu \ll \frac{\xi_{15}(\zeta_{14}(\eta/2)) \cdot d_3^{3+2v(t/2)} \cdot d_2^{10+4v(t/2)}}{v(t/2)^2 \cdot T_4}. \quad (14)$$

<sup>4</sup> Rademacher (1941, unpublished) was first to prove that every  $n$ -vertex graph with  $\lfloor n^2/4 \rfloor + 1$  edges contains at least  $\lfloor n/2 \rfloor$  triangles

## 59:12 Ramsey Properties of Randomly Perturbed Hypergraphs

We claim that there exist three distinct clusters  $X, Y, Z \in \mathcal{V}$  along with a  $(\delta_2(\ell), d_2)$ -triad  $P = P_{\alpha\beta\gamma}^{ijk}$ , with  $i, j, k, \alpha, \beta, \gamma$  appropriately defined, satisfying  $V(P) = X \cup Y \cup Z$  such that  $H[X \cup Y \cup Z]$  is  $\delta_2(\ell)$ -weakly-regular and, moreover,  $H[X \cup Y \cup Z]$  is  $(\delta_3, d_3, r)$ -regular with respect to  $P$ . To see this, note first that at most  $\tilde{t}^{\binom{n/\tilde{t}}{3}} \leq \frac{n^3}{\tilde{t}^2} \ll dn^3$  edges of  $H$  reside within the members of  $\mathcal{V}$ , where the last inequality relies on  $\tilde{t} \geq t_4 \gg d^{-1}$ , supported by (12). Second, by Property (R.3), the number of edges of  $H$  captured within  $\delta_2(\ell)$ -weakly-irregular triples  $(V_i, V_j, V_k)$ , where  $i, j, k \in [\tilde{t}]$ , is at most  $\delta_2(\ell) \cdot \tilde{t}^3 \cdot \left(\frac{n}{\tilde{t}} + 1\right)^3 \leq 2\delta_2(\ell)n^3 \ll dn^3$ , where the last inequality holds by (9) and (11). Third, by Property (R.4), the number of edges of  $H$  residing<sup>6</sup> in  $(\delta_3, d(H|P_{\alpha\beta\gamma}^{ijk}), r)$ -irregular triads  $P_{\alpha\beta\gamma}^{ijk}$  is at most  $\delta_3 n^3 \ll dn^3$ , where the last inequality holds by (9) and (10). Fourth and lastly, it follows by the Triangle Counting Lemma (Lemma 5) and by (6), that the number of edges of  $H$  found in  $(\delta_2(\ell), d_2)$ -triads  $P_{\alpha\beta\gamma}^{ijk}$ , where  $i, j, k \in [\tilde{t}]$  and  $\alpha, \beta, \gamma \in [\ell]$ , satisfying  $d(H|P_{\alpha\beta\gamma}^{ijk}) < d_3$  is at most

$$\tilde{t}^3 \ell^3 d_3 (d_2^3 + 4\delta_2(\ell)) \left(\frac{n}{\tilde{t}} + 1\right)^3 \leq 2d_3 (\ell^3 d_2^3 + 4\ell^3 \delta_2(\ell)) n^3 \stackrel{(13)}{=} (2 + 8\ell^3 \delta_2(\ell)) d_3 n^3 \ll dn^3,$$

where the last inequality holds by (9) and (11).

It follows that at least  $dn^3/2$  edges of  $H$  are captured in  $(\delta_2(\ell), d_2)$ -triads with respect to which  $H$  is  $(\delta_3, d_3, r)$ -regular and such that  $H$  is  $\delta_2(\ell)$ -weakly-regular with respect to the three members of  $\mathcal{V}$  defining the vertex-sets of these triads. The existence of  $X, Y, Z \in \mathcal{V}$  and  $P$  as defined above is then established. Throughout the remainder of the proof, we **identify**  $H$  with  $H[X \cup Y \cup Z]$ .

Let  $\mathcal{F} \subseteq \binom{X}{v(t/2)}$  be the family of all sets  $\{x_1, \dots, x_{v(t/2)}\} \subseteq X$  satisfying

$$\left| \bigcap_{j \in [v(t/2)]} L_H(x_j, P) \right| < \left( d_3^{v(t/2)} - \varepsilon \right) d_2^{2v(t/2)+1} |Y||Z|. \quad (15)$$

Then,

$$|\mathcal{F}| \leq \varepsilon |X|^{v(t/2)} \stackrel{(9)}{\ll} \gamma_{11}(t) |X|^{v(t/2)}$$

holds by (3). This application of the Tuple Lemma is supported by our choice  $\ell_4 \gg d_3^{-1}$ , seen in (12), ensuring that  $d_2 \ll d_3$  holds and thus fitting the quantification of the Tuple Lemma. With foresight (see (C.1) and (C.2) below), let

$$C = \max \left\{ C_{11}^{(1)}(t), C_{11}^{(2)}(\mu, t), C_{11}^{(3)}(\mu, t) \right\} \cdot \tilde{t}^{-1/M_{t,t/2}}$$

and put

$$p = p(n) = C \max \left\{ n^{-1/M_{t,t/2}}, n^{-1/M_{t-1}} \right\} = C n^{-1/M_{t,t/2}};$$

for the last equality consult Remark 12. Proposition 11 then asserts that the following properties are all satisfied simultaneously a.a.s. whenever  $R \sim \mathbb{H}^{(3)}(n, p)$ ; in the following list of properties, whenever an asymmetric Ramsey property is stated, the first colour is assumed to be red and the second colour is assumed to be blue.

<sup>6</sup> Supported by triangles of such triads.

- (C.1)  $R[X]$  is  $(\tilde{K}_t^{(3)}, \tilde{K}_{t/2}^{(3)})$ -Ramsey with respect to  $(\emptyset, \mathcal{F})$ ;  
(C.2)  $R[X]$  is  $(\tilde{K}_{t/2}^{(3)}, \tilde{K}_t^{(3)})$ -Ramsey with respect to  $(\mathcal{F}, \emptyset)$ ;  
(C.3)  $R$  is  $(\tilde{K}_{t-1}^{(3)}, \mu)$ -Ramsey;  
(C.4)  $R$  is  $(\tilde{K}_t^{(3)}, \tilde{K}_{t/2}^{(3)}, \mu)$ -Ramsey;  
(C.5)  $R$  is  $(\tilde{K}_{t/2}^{(3)}, \tilde{K}_t^{(3)}, \mu)$ -Ramsey.

Fix  $R \sim \mathbb{H}^{(3)}(n, p)$  satisfying Properties (C.1-5) and set  $\Gamma = H \cup R$ .

Let  $\psi$  be a red/blue colouring of  $E(\Gamma)$  and suppose for a contradiction that  $\psi$  does not yield any monochromatic copy of  $\tilde{K}_t^{(3)}$ . For every  $v \in V(H)$ , let  $L_H^{(r)}(v)$  denote the *red link graph of  $v$  in  $H$  under  $\psi$* , that is,  $L_H^{(r)}(v)$  is a spanning subgraph of  $L_H(v)$  consisting of the edges of  $L_H(v)$  that together with  $v$  yield a red edge of  $H$  under  $\psi$ . Similarly, let  $L_H^{(b)}(v)$  denote the *blue link graph of  $v$  in  $H$  under  $\psi$* . Note that, for any fixed vertex  $v$ , these two link subgraphs are edge-disjoint.

We say that blue (respectively, red) is a *majority colour* of  $\psi$  in  $H$  if  $|\{e \in E(H) : \psi(e) \text{ is blue}\}| \geq |\{e \in E(H) : \psi(e) \text{ is red}\}|$  (respectively,  $|\{e \in E(H) : \psi(e) \text{ is red}\}| \geq |\{e \in E(H) : \psi(e) \text{ is blue}\}|$ ).

▷ **Claim 16.** If blue is a majority colour of  $\psi$  in  $H$ , then  $e\left(L_H^{(r)}(v)\right) \leq \frac{\eta}{2v(t/2)} \cdot |Y||Z|$  holds for every  $v \in X$ .

*Proof.* Suppose for a contradiction that there exists a vertex  $v \in X$  which violates the assertion of the claim. The Triangle Counting Lemma (Lemma 5) coupled with the assumption of  $H$  being  $(\delta_3, d_3, r)$ -regular with respect to the  $(\delta_2(\ell), d_2)$ -triad  $P$  (take  $Q_1 = \dots = Q_r = P$  in (7)) collectively yield

$$\begin{aligned}
e(H) &\geq (d_3 - \delta_3)|\mathcal{K}_3(P)| \\
&\stackrel{(4)}{\geq} (d_3 - \delta_3)(d_2^3 - 4\delta_2(\ell))|X||Y||Z| \\
&\geq (d_3d_2^3 - \delta_3d_2^3 - 4d_3\delta_2(\ell))|X||Y||Z| \\
&\geq \frac{d_3d_2^3}{2}|X||Y||Z|,
\end{aligned} \tag{16}$$

where the last inequality is owing to  $\delta_3 \ll d_3$  and  $\delta_2(\ell) \ll d_2^3$  supported by (10) and (11), respectively. Blue being the majority colour implies that at least  $\frac{d_3d_2^3}{4}|X||Y||Z|$  of the edges of  $H$  are blue and thus there exists a vertex  $u \in Z$  satisfying  $e\left(L_H^{(b)}(u)\right) \geq \frac{d_3d_2^3}{4}|X||Y|$ ; note that  $L_H^{(b)}(u) \subseteq X \times Y$ . Set

$$A_v = \left\{z \in Z : \deg_{L_H^{(r)}(v)}(z) \geq t\right\} \subseteq Z \quad \text{and} \quad A_u = \left\{x \in X : \deg_{L_H^{(b)}(u)}(x) \geq t\right\} \subseteq X.$$

Then,

$$|A_v| \geq \frac{\eta}{4v(t/2)}|Z| \stackrel{(11)}{\geq} \delta_2(\ell)|Z| \quad \text{and} \quad |A_u| \geq \frac{d_3d_2^3}{8}|X| \stackrel{(11)}{\geq} \delta_2(\ell)|X| \tag{17}$$

both hold by Observation 13. Since  $H$  is  $\delta_2(\ell)$ -weakly-regular, it follows that

$$\begin{aligned}
e_H(A_u, Y, A_v) &\stackrel{(16)}{\geq} \left(\frac{d_3d_2^3}{2}\right) \cdot |A_u||Y||A_v| - \delta_2(\ell)|X||Y||Z| \\
&\stackrel{(17)}{\geq} \left(\frac{d_3d_2^3}{2}\right) \cdot \left(\frac{\eta}{4v(t/2)}\right) \cdot \left(\frac{d_3d_2^3}{8}\right) |X||Y||Z| - \delta_2(\ell)|X||Y||Z|
\end{aligned}$$

59:14 Ramsey Properties of Randomly Perturbed Hypergraphs

$$\begin{aligned}
 &= \left( \frac{d_3^2 d_2^6 \eta}{64v(t/2)} - \delta_2(\ell) \right) \cdot |X||Y||Z| \\
 &\stackrel{(11)}{\geq} \left( \frac{d_3^2 d_2^6 \eta}{65v(t/2)} \right) \cdot |X||Y||Z|. \tag{18}
 \end{aligned}$$

If red is a majority colour seen along  $E_H(A_u, Y, A_v)$ , then there exists a vertex  $v' \in A_v \subseteq Z$  satisfying

$$\left| E \left( L_H^{(r)}(v') \right) \cap (A_u \times Y) \right| \stackrel{(18)}{\geq} \left( \frac{d_3^2 d_2^6 \eta}{130v(t/2)} \right) |X||Y| \geq \left( \frac{d_3^2 d_2^6 \eta}{130v(t/2)} \right) |A_u||Y|.$$

Consequently, the set

$$A_{u,v'} = \left\{ x \in A_u : \deg_{L_H^{(r)}(v')}(x) \geq t \right\} \subseteq A_u \subseteq X$$

satisfies

$$\begin{aligned}
 |A_{u,v'}| &\geq \left( \frac{d_3^2 d_2^6 \eta}{260v(t/2)} \right) |A_u| \\
 &\stackrel{(17)}{\geq} \left( \frac{d_3^2 d_2^6 \eta}{260v(t/2)} \right) \cdot \left( \frac{d_3 d_2^3}{8} \right) |X| \\
 &\geq \left( \frac{d_3^3 d_2^9 \eta}{2100v(t/2)} \right) \cdot \left\lfloor \frac{n}{t} \right\rfloor \\
 &\stackrel{(14)}{\geq} \mu n,
 \end{aligned}$$

where the first inequality holds by Observation 13. We may then write that  $\Gamma[A_{u,v'}] \longrightarrow (\tilde{K}_{t-1}^{(3)})_2$  owing to  $R$  being  $(\tilde{K}_{t-1}^{(3)}, \mu)$ -Ramsey, by Property (C.3). Let  $K$  be a copy of  $\tilde{K}_{t-1}^{(3)}$  appearing monochromatically under  $\psi$  within  $\Gamma[A_{u,v'}]$ . Let  $x_1, \dots, x_{t-1}$  denote the branch vertices of  $K$ . It follows by the definition of  $A_{u,v'}$  that there are distinct vertices  $y_1, \dots, y_{t-1} \in Y$  such that  $\{x_i, y_i, v'\}$  is a red edge of  $H$  for every  $i \in [t-1]$ . Similarly, since  $A_{u,v'} \subseteq A_u$ , there are distinct vertices  $y'_1, \dots, y'_{t-1} \in Y$  such that  $\{x_i, y'_i, u\}$  is a blue edge of  $H$  for every  $i \in [t-1]$ . Therefore, if  $K$  is red, then it can be extended into a red copy of  $\tilde{K}_t^{(3)}$  including  $v'$ ; if, on the other hand,  $K$  is blue, then it can be extended into a blue copy of  $\tilde{K}_t^{(3)}$  including  $u$ . In either case, a contradiction to the assumption that  $\psi$  admits no monochromatic copies of  $\tilde{K}_t^{(3)}$  is reached.

It remains to consider the complementary case where blue is a majority colour in  $E_H(A_u, Y, A_v)$ . The argument in this case parallels that seen in the previous one with the sole cardinal difference being that instead of finding a monochromatic copy of  $\tilde{K}_{t-1}^{(3)}$  in a subset of  $A_u \subseteq X$ , such a copy is found in a subset of  $A_v \subseteq Z$ . An argument for this case is provided for completeness. If blue is a majority colour seen along  $E_H(A_u, Y, A_v)$ , then there exists a vertex  $u' \in A_u \subseteq X$  satisfying

$$\left| E \left( L_H^{(b)}(u') \right) \cap (Y \times A_v) \right| \stackrel{(18)}{\geq} \left( \frac{d_3^2 d_2^6 \eta}{130v(t/2)} \right) |Y||Z| \geq \left( \frac{d_3^2 d_2^6 \eta}{130v(t/2)} \right) |Y||A_v|.$$

Consequently, the set

$$A_{v,u'} = \left\{ z \in A_v : \deg_{L_H^{(b)}(u')}(z) \geq t \right\} \subseteq A_v \subseteq Z$$

satisfies

$$|A_{v,u'}| \geq \left( \frac{d_3^2 d_2^6 \eta}{260v(t/2)} \right) |A_v|$$

$$\begin{aligned}
&\stackrel{(17)}{\geq} \left( \frac{d_3^2 d_2^6 \eta}{260v(t/2)} \right) \cdot \left( \frac{\eta}{4v(t/2)} \right) |Z| \\
&\geq \left( \frac{d_3^2 d_2^6 \eta^2}{1100v(t/2)^2} \right) \cdot \left\lfloor \frac{n}{t} \right\rfloor \\
&\stackrel{(14)}{\geq} \mu n,
\end{aligned}$$

where the first inequality holds by Observation 13. Then,  $\Gamma[A_{v,u'}] \rightarrow (\tilde{K}_{t-1}^{(3)})_2$  owing to  $R$  being  $(\tilde{K}_{t-1}^{(3)}, \mu)$ -Ramsey, by Property (C.3). A monochromatic copy of  $\tilde{K}_{t-1}^{(3)}$  appearing in  $\Gamma[A_{v,u'}]$  can be either extended into a red copy of  $\tilde{K}_t^{(3)}$  including the vertex  $v$  or into a blue such copy including  $u'$ . In either case, a contradiction to the assumption that  $\psi$  admits no monochromatic copy of  $\tilde{K}_t^{(3)}$  is reached.  $\triangleleft$

The following counterpart of Claim 16 holds as well.

$\triangleright$  **Claim 17.** If red is a majority colour of  $\psi$  in  $H$ , then  $e(L_H^{(b)}(v)) \leq \frac{\eta}{2v(t/2)} \cdot |Y||Z|$  holds for every  $v \in X$ .

Proceeding with the proof of Theorem 1, assume first that blue is a majority colour of  $\psi$  in  $H$ . By Property (C.1), either there is a red copy of  $\tilde{K}_t^{(3)}$  (within  $X$ ) or there is a blue copy of  $\tilde{K}_{t/2}^{(3)}$  within  $X$  not supported on  $\mathcal{F}$ . If the former occurs, then the proof concludes. Assume then that  $K \subseteq \Gamma[X]$  is a blue copy of  $\tilde{K}_{t/2}^{(3)}$  such that  $V(K) \notin \mathcal{F}$ , and write  $L_H(K, P) = \bigcap_{x \in V(K)} L_H(x, P)$  to denote the joint link graph of the members of  $V(K)$  supported on  $P$ . Then,

$$e(L_H(K, P)) \geq \left( d_3^{v(t/2)} - \varepsilon \right) d_2^{2v(t/2)+1} |Y||Z|,$$

holds by (15). Remove  $E(L_H^{(r)}(x))$  from  $E(L_H(K, P))$  for every  $x \in V(K)$ ; that is, remove any edge in  $L_H(K, P)$  that together with a vertex of  $K$  gives rise to a red edge of  $H$  with respect to  $\psi$ . By Claim 16, at most

$$\sum_{x \in V(K)} e(L_H^{(r)}(x)) \leq v(t/2) \cdot \frac{\eta}{2v(t/2)} |Y||Z| = \frac{\eta}{2} |Y||Z|$$

edges are thus discarded from  $L_H(K, P)$ , leaving at least

$$\begin{aligned}
\left[ \left( d_3^{v(t/2)} - \varepsilon \right) d_2^{2v(t/2)+1} - \frac{\eta}{2} \right] |Y||Z| &\stackrel{(9)}{\geq} \left( \frac{d_3^{v(t/2)} d_2^{2v(t/2)+1}}{2} - \frac{\eta}{2} \right) |Y||Z| \\
&\stackrel{(13)}{=} \left( \eta - \frac{\eta}{2} \right) |Y||Z| \\
&= \frac{\eta}{2} |Y||Z|
\end{aligned}$$

edges in the *residual* joint link graph of  $K$ , denoted  $L'_H(K, P)$ . It follows by Lemma 14 and Observation 15 that  $L'_H(K, P)$  contains at least

$$\xi_{15}(\zeta_{14}(\eta/2)) \frac{2n}{T_4} \stackrel{(14)}{\geq} \mu n$$

vertex-disjoint copies of the bipartite graph  $K_{1,t/2}$ . Let  $S \subseteq V(L'_H(K, P))$  consist of the centre-vertices of all said copies of  $K_{1,t/2}$ . Property (C.4) coupled with  $|S| \geq \mu n$  collectively assert that  $\Gamma[S] \rightarrow (\tilde{K}_t^{(3)}, \tilde{K}_{t/2}^{(3)})$ . If the first alternative occurs, then there is a red copy

of  $\tilde{K}_t^{(3)}$  and thus the proof concludes. Suppose then that the second alternative takes place so that a blue copy  $K'$  of  $\tilde{K}_{t/2}^{(3)}$  arises in  $\Gamma[S]$ . Let  $u_1, \dots, u_{t/2}$  denote the branch-vertices of  $K'$  and let  $x_1, \dots, x_{t/2}$  denote the branch-vertices of  $K$ . It follows by the definitions of  $L'_H(K, P)$  and  $S$  that there are  $t^2/4$  distinct vertices  $\{w_{ij} : i, j \in [t/2]\} \subseteq V(L'_H(K, P)) \setminus \{u_1, \dots, u_{t/2}, x_1, \dots, x_{t/2}\}$  such that  $\{u_i, x_j, w_{ij}\}$  forms a blue edge of  $H$  for every  $i, j \in [t/2]$ . We conclude that  $\Gamma$  admits a copy of  $\tilde{K}_t^{(3)}$  which is blue under  $\psi$ .

Next, assume that red is a majority colour seen for  $\psi$  in  $H$ . Replacing the appeals to Claim 16, Properties (C.1) and (C.4) in the argument above with appeals to Claim 17 and Properties (C.2), and (C.5), respectively, leads to the rise of a monochromatic copy of  $\tilde{K}_t^{(3)}$  in  $\Gamma$  under  $\psi$  in this case as well.  $\blacktriangleleft$

## Abstract

In this paper, we study the problem of locally constructing a sparse spanning subgraph (LSSG), introduced by Levi, Ron, and Rubinfeld (ALGO'20). In this problem, the goal is to locally decide for each  $e \in E$  if it is in  $G'$  where  $G'$  is a connected subgraph of  $G$  (determined only by  $G$  and the randomness of the algorithm). We provide an LSSG that receives as a parameter a lower bound,  $\phi$ , on the conductance of  $G$  whose query complexity is  $\tilde{O}(\sqrt{n}/\phi^2)$ . This is almost optimal when  $\phi$  is a constant since  $\Omega(\sqrt{n})$  queries are necessary even when  $G$  is an expander. Furthermore, this improves the state of the art of  $\tilde{O}(n^{2/3})$  queries for  $\phi = \Omega(1/n^{1/12})$ .

We then extend our result for  $(k, \phi_{\text{in}}, \phi_{\text{out}})$ -clusterable graphs and provide an algorithm whose query complexity is  $\tilde{O}(\sqrt{n} + \phi_{\text{out}}n)$  for constant  $k$  and  $\phi_{\text{in}}$ . This bound is almost optimal when  $\phi_{\text{out}} = O(1/\sqrt{n})$ .

## 1 Introduction

When dealing with huge graphs, several practical constraints arise: (i) **Memory Limitations**: It is often impractical or infeasible to store the entire graph in the local memory of a processing unit. (ii) **Algorithmic Efficiency**: Due to the graph's size, running linear-time (or even slower) algorithms becomes challenging. (iii) **Parallel Computation**: Relying on a single processing unit for computations can be inefficient. The Centralized Local model, also called Locally Computable Algorithms (LCA), was introduced by Rubinfeld et al. [27] to address these challenges. This model treats the input graph as if it is stored in a (likely distributed) database. External processing units can query this database to perform computations efficiently. The system prohibits shared memory or communication between

querying processes to reduce coordination overhead. Instead, shared randomness accompanies input access. The approach involves running sublinear-time algorithms to extract global graph properties or locally examining the input graph as needed by applications.

One of the problems studied in this model is locally constructing a sparse spanning subgraph of a connected input graph. It was introduced and formalized by Levi, Ron, and Rubinfeld [17] as follows.

► **Definition 1** ([17]). *An algorithm  $\mathcal{A}$  is a Local Sparse Spanning Graph (LSSG) algorithm if, given  $n \geq 1$ ,  $\varepsilon > 0$ , a sequence of random bits  $r \in \{0, 1\}^*$  and query access to the incidence-lists representation of a connected graph  $G = (V, E)$  over  $n$  vertices,<sup>1</sup> it provides oracle access to a subgraph  $G' = (V, E')$  of  $G$  such that:*

- (1)  $G'$  is connected, and
- (2)  $|E'| \leq (1 + \varepsilon) \cdot n$  with probability at least  $1 - 1/\Omega(n)$ , where  $E'$  is determined by  $G$  and  $r$ .<sup>2 3</sup>

As observed in [17], if we insist that  $G'$  should have the minimum number of edges sufficient to span  $G$ , namely, that  $G'$  be a spanning tree, then the task cannot be performed by an LCA in general without inspecting almost all of  $G$ . On the other hand, even under the above relaxation, [17] showed that this task requires  $\Omega(\sqrt{n})$  queries.<sup>4</sup> They complimented this negative result with an almost tight upper bound that works under the promise that the input graph expands extremely fast. In particular, their algorithm is tight when the growth rate of their graph is  $\Omega(d)$  for small sets (of size roughly  $\sqrt{n}$ ), where  $d$  is the maximum vertex degree. In fact, their result achieves a sublinear query complexity only when the growth rate (on small sets) is at least  $d^{1/2+1/\log n}$ .<sup>5</sup> This raises the question *whether it is possible to obtain a similar result also for graphs whose growth rate is just a small constant?* (which, in particular, may not depend on  $d$ ). Namely, for graphs, which are just good expanders. We answer this question affirmatively by showing almost tight results for expanders. Moreover, our upper bound works for general graphs and receives as a parameter a lower bound on the conductance of the graph, defined as follows.

► **Definition 2** (Graph Conductance). *Let  $G = (V, E)$  be an undirected graph with maximum vertex degree  $d$ . Let  $S \subseteq V$  denote a nonempty subset of  $V$ , then the conductance of  $S$  w.r.t.  $G$  is  $\phi_G(S) \stackrel{\text{def}}{=} \frac{e(S, V \setminus S)}{d|S|}$ , where  $e(A, B) \stackrel{\text{def}}{=} |\{\{a, b\} \in E \mid a \in A, b \in B\}|$ , for  $A, B \subseteq V$ . The conductance of  $G$ ,  $\phi(G)$  is then defined as*

$$\phi(G) \stackrel{\text{def}}{=} \min_{\substack{S \subseteq V \\ |S| \leq |V|/2}} \phi_G(S). \quad (1)$$

To explain why conductance comes into play in our algorithm, we first describe a common paradigm for constructing sparse spanning subgraphs and spanners. In many cases, the paradigm is to select a random set of vertices, also referred to as *centers*, and to partition the vertices of the graphs into Voronoi cells according to this selection of centers. Usually, it is easy to span the Voronoi cells (assuming the centers are selected u.a.r.), and the challenging

<sup>1</sup> Namely, the algorithm can query each vertex  $v \in V$  and an index  $i$ , who is the  $i$ th neighbor of  $v$  (where if  $v$  has less than  $i$  neighbors, then a special symbol is returned, e.g., “no neighbor”).

<sup>2</sup>  $E'$  is determined only by  $G$  and  $r$  and not from, e.g., the queries made to the oracle or their order.

<sup>3</sup> We say that an event occurs *with high probability* (w.h.p) if it occurs with probability at least  $1 - 1/\Omega(n)$ .

<sup>4</sup> One way to show this is by reducing the problem of testing cycle-freeness to the LSSG problem.

<sup>5</sup> To illustrate this drawback, note that even for  $d = 5$  and growth rate = 2 their algorithm is not guaranteed to be sublinear.

part is to preserve the connectivity between Voronoi cells. This is also the approach taken by [17] (and generalized in [12, 23, 2]). To bypass the challenging part of connecting the Voronoi cells, we aim to choose centers that are initially connected and distributed nearly uniformly. To this end, we select the centers by performing random walks from a single vertex and taking the endpoints of these walks to be the set of centers. We set the length of the random walks to be at least the mixing time of the graph, which, in turn, depends on the conductance of the graph, so the selected centers are distributed almost uniformly. We then add the edges traversed by the random walks to our constructed subgraph, so it only remains to span the Voronoi cells (which can be done efficiently, assuming the centers are distributed almost uniformly).

Since every graph can be partitioned into expanders (see, e.g., [22]), one may wonder if this approach can be extended to work in general graphs. To make this question concrete, consider an input graph composed of two expanders (of equal size) connected with a single edge between them. While the *inner conductance* of each expander is high, the overall conductance of the graph is  $O(1/n)$ , and consequently, the mixing time of the graph is high. So, the question that might come to mind is whether it is possible to extend the approach mentioned above so the length of the random walks will depend on the inner-conductance of the expanders (which is a constant) and not on the conductance of the entire graph. This question becomes more interesting as the connectivity between the expanders, which is referred to as the *outer-conductance* of the expanders, grows but not to the extent in which the overall conductance is high. We show that our approach can be extended to support a wide range of inner-conductance and outer-conductance. More specifically, we extend our result to clusterable graphs as defined in the work of Gharan and Trevisan [9] and Czumaj, Peng, and Sohler [6].

► **Definition 3** (Graph Clusterability. Based by [6]). *Let  $G = (V, E)$  be an undirected graph with maximum degree  $d$ . Let  $n \stackrel{\text{def}}{=} |V|$ . For any  $S \subseteq V$ , let  $G[S]$  be the induced subgraph of  $G$  on the vertex set  $S$ . We say that a graph  $G$  is  $(k, \phi)$ -clusterable, where  $k \in \{1, \dots, n\}$ ,  $\phi \in [0, 1]$ , if there exists a partition of  $V$  into  $h$  sets  $C_1, \dots, C_h$  s.t.  $1 \leq h \leq k$ , and that for each  $i \in \{1, \dots, h\}$  it holds that  $\phi(G[C_i]) \geq \phi$ . We refer to each  $C_i$  as a  $\phi$ -cluster and the corresponding partition to  $h$  clusters as an  $(h, \phi)$ -clustering. Similarly, We say that a graph  $G$  is  $(k, \phi_{\text{in}}, \phi_{\text{out}})$ -clusterable, if for each  $i \in \{1, \dots, h\}$  it holds that  $\phi(G[C_i]) \geq \phi_{\text{in}}$  and  $\phi_G(C_i) \leq \phi_{\text{out}}$ . We refer to each  $C_i$  as a  $(\phi_{\text{in}}, \phi_{\text{out}})$ -cluster.*<sup>6</sup>

Aside from connectivity, another desirable property of  $G'$  is that it will preserve the pairwise distances between vertices. In particular, we say that the subgraph  $G'$  is an  $\alpha$ -spanner of  $G$  if for every  $u, v \in V$ ,  $\text{dist}_{G'}(u, v) \leq \alpha \cdot \text{dist}_G(u, v)$  where  $\text{dist}_{G'}(u, v)$  and  $\text{dist}_G(u, v)$  denote the length of the shortest path from  $u$  to  $v$  in  $G'$  and  $G$ , respectively. We refer to  $\alpha$  as the *stretch factor* of the spanner  $G'$ .

In the next section, we state the performances of our upper bounds in terms of their query complexity, the number of random bits they use, and the stretch factor of the obtained spanning subgraph,  $G'$ .

## 1.1 Our Results

Our first result is an LSSG that receives as a parameter a lower bound,  $\phi$ , on the conductance of the graph, whose query complexity is  $\tilde{O}(\sqrt{n}/\phi^2)$  for constant  $d$ , as stated next.

<sup>6</sup> Note that requiring  $\phi > 0$  implies that each induced cluster of  $G$  is also connected.

► **Theorem 4.** *There is an LSSG algorithm that given query access to a connected graph  $G = (V, E)$  and a lower bound  $\phi$  on  $\phi(G)$ , provides access to  $G' = (V, E')$  such that the following holds. (1) The graph  $G'$  is a connected subgraph of  $G$  and with high probability  $|E'| = n + O\left(\frac{\sqrt{n}\log^2 n}{\phi^2}\right)$ . Moreover, the stretch factor of  $G'$  is  $O\left(\frac{\log n}{\phi^2}\right)$ . (2) The query complexity of the algorithm is  $O\left(\sqrt{n} \cdot \left(\frac{\log^2 n}{\phi^2} + d^2\right)\right)$ , and (3) the number of random bits it uses is  $O\left(\frac{\log d \cdot \log^2 n}{\phi^2}\right)$ , where  $d$  is a bound on the maximum degree of  $G$ .*

Therefore, for constant  $\phi$  and constant  $d$  this upper bound is tight, up to polylogarithmic factors in  $n$ . Moreover, it improves the state-of-the-art upper bound for general bounded-degree graph of  $\tilde{O}(n^{2/3})$  queries by Lenzen and Levi [12] if and only if  $\phi > n^{-1/12}$ . Consequently, we may assume that  $\phi > n^{-1/12}$  throughout this paper. As a result, we obtain that  $|E'| = n + o(n)$ , which makes  $G'$  an ultra-sparse spanner of stretch  $O(\log n/\phi^2)$ .

Our next main result is stated in the next theorem.

► **Theorem 5.** *There is an LSSG algorithm that given query access to a connected  $(k, \phi_{\text{in}}, \phi_{\text{out}})$ -clusterable graph  $G = (V, E)$ , where each cluster is of size at least  $\beta \cdot n$ , provides access to  $G' = (V, E')$  such that the following holds. (1) The graph  $G'$  is a connected subgraph of  $G$  and with high probability  $|E'| \leq n(1 + \varepsilon)$ . Moreover, the stretch factor of  $G'$  is  $\Theta\left(\frac{\log n}{\phi_{\text{in}}^2}\right)$ . (2) The query complexity of the algorithm is  $O\left(\log^2 n \cdot (\beta\phi_{\text{out}})^{-1} + n \log^2 n \cdot k^3 d^3 \phi_{\text{out}} (\varepsilon\phi_{\text{in}})^{-1}\right)$ , and (3) the number of random bits it uses is  $O\left(\frac{\log d \cdot \log^2 n}{\phi_{\text{in}}^2}\right)$ , where  $d$  is a bound on the maximum degree of  $G$ .*

For instances where  $\phi_{\text{in}}, k, \beta, \varepsilon$ , and  $d$  are constants, we obtain the following corollary.

► **Corollary 6.** *There is an LSSG algorithm that given query access to a connected  $(\Theta(1), \Theta(1), \phi_{\text{out}})$ -clusterable graph  $G = (V, E)$ , where each cluster is of size at least  $\beta \cdot n$ , provides access to  $G' = (V, E')$  such that the following holds. (1) The graph  $G'$  is a connected subgraph of  $G$  and with high probability  $|E'| \leq n(1 + \varepsilon)$ . Moreover, the stretch factor of  $G'$  is  $\Theta(\log n)$ . (2) The query and time complexity of the algorithm is  $\tilde{O}(\sqrt{n} + \phi_{\text{out}} n)$ , and (3) the number of random bits it uses is  $O(\log^2 n)$ .*

Namely, our algorithm is nearly tight in this case as long as  $\phi_{\text{out}} = O(1/\sqrt{n})$  and improves over the state-of-the-art for  $\phi_{\text{out}} = O(1/n^{1/3})$ .

## 1.2 Overview of Our Algorithms

### 1.2.1 The case of a single cluster

We begin by describing our algorithm for  $k = 1$  for the case where the graph is rapidly mixing, namely, that its mixing time,  $\tau$ , is  $O(\log n)$ . We first describe the algorithm from a global point of view. The algorithm picks an arbitrary vertex as a *primary-center*. It then performs  $\tilde{\Theta}(\sqrt{n})$  lazy random walks of length  $\tau$  from that center, where  $\tau$  denotes the mixing time of the graph. The end-vertex of each one of these walks is added to the set of *secondary centers*. The edges traversed by these random walks are added to  $E'$ . Consequently, there is a path of length at most  $2\tau$  between every pair of secondary centers. In the second step, the graph's vertex set is partitioned into Voronoi-cells with respect to the selected secondary centers. Namely, each vertex joins the cell of its closest secondary center (breaking ties by ids). A spanning tree of each Voronoi-cell is then added to the spanner. The specific spanning tree added is rooted at the secondary center, where the path from each vertex to the root has the

least lexicographical order. As shown by [17], it is possible to reconstruct the edges incident to a vertex  $v$  in this tree at the same cost as performing the BFS exploration to find the secondary center of  $v$ . The resulting subgraph clearly spans the graph: for a pair of vertices  $u$  and  $v$  in the same Voronoi cell, there is a path between  $u$  and the respective secondary center of the cell and likewise for  $v$ ; If  $u$  and  $v$  are not in the same Voronoi cell, then their secondary centers are connected to the primary-center by paths of length at most  $\tau$ . Thus the stretch-factor of the spanner is  $O(\tau + \ell)$  where  $\ell$  is an upper bound on the diameter of the Voronoi-cells, which is bounded by  $O(\log n/\phi^2)$ .

The local implementation proceeds as follows. On query  $\{u, v\}$ , the local algorithm simulates the first step of the global algorithm and returns YES if  $\{u, v\}$  is an edge traversed by one of the random walks performed by the algorithm. Otherwise, it performs a BFS, layer by layer (that is, it reveals an entire layer in each step) from  $u$  until it finds the secondary center of  $u$ , likewise for  $v$ . If the centers of  $u$  and  $v$  are different, then the algorithm returns NO. Otherwise, it returns YES iff  $\{u, v\}$  is an edge of the tree selected to span the Voronoi-cell of  $u$  and  $v$  (as described above).

The query and time complexity of performing the first step of the local algorithm is clearly  $\tilde{O}(\sqrt{n} \cdot \tau)$ . For the second step, since the length of the random walks performed in the first step is  $\tau$ , the  $\Theta(\sqrt{n})$  secondary centers are distributed almost uniformly in the graph. Therefore, with high probability, each vertex in the graph sees a secondary center after exploring  $\tilde{O}(\sqrt{n})$  vertices. If this is not the case, we can afford to add all the edges incident to  $v$  to  $E'$  without harming the sparsity of  $G'$  while preserving the connectivity of  $G'$ .

### 1.3 The case of $k$ -clusterable graphs

We next describe our algorithm for  $k$ -clusterable graphs for the case that the mixing time of each cluster is  $O(\log n)$ , namely, that  $\phi_{\text{in}}$  is a constant, and  $\phi_{\text{out}}$  is  $O(1/\sqrt{n})$ . The first phase of the algorithm is similar to the algorithm for a single cluster. The only difference is that we start with  $\Theta(\log n)$  primary-centers (chosen uniformly at random) rather than a single one. Thus, with high probability we hit every cluster with at least one primary-center. Therefore, after the first phase, our spanner consists of edges of  $\tilde{\Theta}(\sqrt{n})$  random walks, traversed from each one of the primary centers, and the edges of the spanning trees of the Voronoi-cells which are constructed with respect to the set of secondary centers (which are now originated from several primary centers). Let us call the set of secondary centers originating from the same primary-center and their respective Voronoi-cells an *artificial-cluster*. Clearly, after the first step of the algorithm, the spanner spans each of the artificial clusters (from the same reasoning as above). Our goal is to ensure that every pair of artificial-clusters with an edge in their cut in the original graph will have an edge in their cut in the spanner. To this end, we sample u.a.r. a set of  $\Theta(\log n/\epsilon)$  edges and add these edges to the spanner. Let us denote this set of edges by  $\mathcal{T}$ . For every pair of artificial-clusters whose cut does not intersect the set  $\mathcal{T}$ , we add all the edges in their cut to the spanner. The rationale is that if the respective cut is large, it will intersect  $\mathcal{T}$ ; otherwise, we can afford to add its edges to the spanner.

**The analysis.** The challenging part in analyzing this algorithm is to show that the secondary centers are distributed (almost) uniformly in each one of the clusters. This is crucial for proving that the query complexity remains  $\tilde{O}(\sqrt{n})$ . More specifically, this is crucial for claiming that with high probability, each vertex sees a secondary center after exploring  $\tilde{O}(\sqrt{n})$  vertices. This is where the requirement on the outer-conductance of each cluster comes into play. We show that if the outer-conductance is  $O(1/\sqrt{n})$  then for a constant

fraction of the vertices in the cluster,  $v$ , the end-vertex of a random walk from  $v$  of length  $O(\log n)$  is likely to be any vertex in the cluster w.p. at least  $\Omega(1/n)$  except for a small set of vertices of size  $O(\sqrt{n})$ . This is sufficient to upper bound the query complexity of the BFS exploration to find the center.

## 1.4 Related Work

### 1.4.1 LSSG Algorithms

The problem of finding a sparse spanning subgraph in the Centralized Local model was first studied in [16, 17], where the authors show a lower bound of  $\Omega(\sqrt{n})$  queries for constant  $\varepsilon$  and  $\Delta$  (see also survey by Rubinfeld [26]). They also present an upper bound with nearly tight query complexity for graphs with very good expansion properties.

In [17], the authors also provide an efficient algorithm for minor-free graphs that was later improved in [19]. The algorithm presented in [19] achieves a polynomial query complexity in  $\Delta$  and  $1/\varepsilon$  and is independent of  $n$ . The stretch factor of this algorithm is also independent of  $n$  and depends only on  $\Delta$ ,  $1/\varepsilon$ , and the size of the excluded minor  $h$ . A more general family of graphs, hyperfinite graphs, is studied in [14]. They show an upper bound (which builds on an algorithm in [17]) that has a query complexity that is independent of  $n$  (however, super-exponential in  $1/\varepsilon$ ). Informally, both minor-free graphs and hyperfinite graphs are families of graphs that are, roughly speaking, sufficiently non-expanding everywhere. On the other hand, they show that, for a family of graphs with expansion properties that are slightly better, any local algorithm must have a query complexity that depends on  $n$ .

The first LSSG algorithm for general (bounded degree) graphs was introduced in [12], presenting a query complexity of  $\tilde{O}(n^{2/3} \cdot \text{poly}(1/\varepsilon, d))$  and a stretch factor of  $O(\log^2 n \cdot \text{poly}(d/\varepsilon))$ . Recently, Bodwin and Fleischmann [4] introduced an Adjacency Oracle for a Spanning Subgraph of  $(1 + \varepsilon)n$  edges for general (non-bounded degree) graphs that works in  $\tilde{O}(n/\varepsilon)$  time, hence sublinear in the number of edges on a dense graph. Adjacency Oracles are closely related to LCA, except that Adjacency Oracles are allowed to perform a centralized pre-processing but demand a query time of  $\tilde{O}(1)$ . Their Adjacency Oracle implies an LSSG algorithm for general (non-bounded degree) graphs in  $\tilde{O}(n)$  time, which works by constructing an Adjacency Oracle and uses it once for each query.

For more related work on LCAs for spanners, graph clustering, and LCAs for other graph problems, see Appendix A.

## 2 Preliminaries

In this section, we describe our main technical tools. Omitted proofs appear in Appendix B.

**Notation.** Throughout this paper, we consider a bounded degree (undirected) simple graph  $G = (V, E)$ , where  $V = [n]$  and its maximum degree is  $d = \max_{v \in V} d_G(v)$ , where  $d_G(v)$  denotes the degree of  $v$  w.r.t. the graph  $G$ . The identifier (ID in short) of a vertex  $v \in V$  is simply  $v$ . For each  $A \subseteq V$ , we define  $N_G(A)$  to be the number of neighbors of  $A$  *outside* of  $A$  in  $G$ , i.e.,  $N_G(A) \stackrel{\text{def}}{=} |\{v \in V \setminus A \mid \{u, v\} \in E, u \in A\}|$ . When the graph  $G$  is clear from the context, we omit the subscript  $G$ . For a vertex  $v$ , we call the set of vertices of distance at most  $\ell$  from  $v$  the  $\ell$ -ball around  $v$ . Let  $\Gamma_h(v)$  denote the minimum size ball around  $v$  that contains at least  $h$  vertices. Since the maximum degree of the graph is bounded by  $d$ , it holds that  $h \leq |\Gamma_h(v)| \leq (h - 1)d$ .

The total order over the vertices induces a total order (ranking)  $\rho$  over the edges of the graph in the following straightforward manner: for any  $\{u, v\}, \{u', v'\} \in E$ ,  $\rho(\{u, v\}) < \rho(\{u', v'\})$  if and only if  $\min\{u, v\} < \min\{u', v'\}$  or  $\min\{u, v\} = \min\{u', v'\}$  and  $\max\{u, v\} < \max\{u', v'\}$ . The total order over the vertices also induces an order over those vertices visited by a Breadth First Search (BFS) starting from any given vertex  $v$ , and whenever we refer to a BFS, we mean that it is performed according to this order. Instead of writing  $\log_2(\cdot)$ , we use  $\log(\cdot)$ . We use  $\tilde{O}$  for  $\tilde{O}(x) = O(x) \cdot \text{poly}(\log x)$ .

## 2.1 Mixing-Time of Regular Graphs

Let  $G = (V, E)$  be an undirected and  $d$ -regular graph (where self-loops and multiple edges are allowed). The *Adjacency Matrix of  $G$* , denoted by  $A(G)$  is real and symmetric and so it has  $n$  real eigenvalues  $\lambda_1 \geq \lambda_2 \dots \geq \lambda_n$  where  $\lambda_1 = d$  and  $\lambda_1 > \lambda_2$  iff  $G$  is connected. A  $d$ -regular graph on  $n$  vertices is called an  $(n, d, \alpha)$ -graph if  $|\lambda_2|, |\lambda_n| \leq \alpha d$ . Define  $\lambda(G) = \max(|\lambda_2|, |\lambda_n|)$  and  $\alpha(G) = \lambda(G)/d$ . Thus, every  $d$ -regular graph on  $n$  vertices is an  $(n, d, \alpha(G))$ -graph. Let  $\hat{A}(G) = \frac{1}{d}A(G)$  denote the *normalized adjacency matrix of  $G$* . Note that  $\hat{A}^t \vec{p}$  is the distribution on the vertices resulting from random walks of length  $t$  w.r.t. the initial vertex distribution  $\vec{p}$ . We shall use the following (folklore; see, e.g., [11, 10]) theorem and lemmas.

► **Theorem 7.** *Let  $G$  be an  $(n, d, \alpha)$ -graph with the normalized adjacency matrix  $\hat{A}$ . Then for any distribution vector  $\vec{p}$  and any positive integer  $t$ :  $\|\hat{A}^t \vec{p} - \vec{u}\|_1 \leq \sqrt{n} \cdot \alpha^t$ , where  $\vec{u}$  denotes the uniform distribution vector, i.e.,  $\vec{u} \stackrel{\text{def}}{=} \frac{1}{n} \cdot \vec{1}$ .*

One can obtain from Theorem 7 an upper bound,  $t$ , such that random walks of length at least  $t$  (independent of the initial vertex distribution) yield a distribution on the vertices that is almost uniform. We denote this upper bound by  $\tau(G)$  and refer to it as the *mixing time of  $G$* . When the graph  $G$  is evident from the context, we denote the mixing time by  $\tau$ .

► **Corollary 8.** *Let  $G$  be an  $(n, d, \alpha)$ -graph with the normalized adjacency matrix  $\hat{A}$ . For any  $\tau \geq \frac{\log(2n^{3/2})}{\log(1/\alpha)}$  and for any distribution vector  $\vec{p}$  it holds that  $(\hat{A}^\tau \vec{p})_i \in [\frac{1}{2n}, \frac{3}{2n}]$ , for every  $i \in [n]$ .*

## 2.2 Mixing-Time of General Bounded Degree Graphs

Given a  $d$ -bounded degree graph  $G = (V, E)$ , we would like to relate its mixing time to  $\phi(G)$ . For this purpose, we define  $(G)_{\text{reg}}^{2d} = (V, R)$  where  $R$  contains all the edges in  $E$  and self-loops. In particular we add  $2d - d_G(v)$  self-loops to each vertex  $v \in V$ . Thus,  $(G)_{\text{reg}}^{2d}$  is a  $2d$ -regular graph. When  $d$  is clear from the context, we use  $(G)_{\text{reg}}$  to denote  $(G)_{\text{reg}}^{2d}$ .

We shall use the following classical results to relate  $\phi(G)$  and the mixing-time of  $(G)_{\text{reg}}$ .

► **Theorem 9** (Perron-Frobenius, Symmetric Case (see e.g., [30])). *Let  $G$  be a connected (weighted) graph. Let  $A(G)$  be its adjacency matrix, and let  $\lambda_1 \geq \lambda_2 \geq \dots \geq \lambda_n$  be its eigenvalues. Then,*

- (1)  $\lambda_1$  has a strictly positive eigenvector,
- (2)  $\lambda_1 \geq -\lambda_n$ , and
- (3)  $\lambda_1 > \lambda_2$ .

► **Lemma 10** (Cheeger's Inequality [5]). *Let  $G$  be a  $d$ -regular graph with eigenvalues  $\lambda_1 \geq \lambda_2 \dots \geq \lambda_n$ . Then,  $\frac{d-\lambda_2}{2d} \leq \phi(G) \leq \frac{\sqrt{2d(d-\lambda_2)}}{d}$ .*

We first prove (following [29, P. 106]) that the maximum eigenvalue in absolute value of  $A((G)_{\text{reg}})$  is  $\lambda_2$ .

▷ Claim 11. Let  $G$  be a connected,  $d$ -bounded degree graph. Let  $\{\lambda_i\}_i$  denote the eigenvalues of  $A((G)_{\text{reg}})$ , then  $\max(|\lambda_2|, |\lambda_n|) = \lambda_2$ .

The following claim, combined with Corollary 8 provides an upper bound on the mixing-time of  $(G)_{\text{reg}}$ .

▷ Claim 12. Let  $G = (V, E)$  be a connected  $d$ -bounded degree graph on  $n$  vertices, then  $(G)_{\text{reg}}$  is an  $\left(n, 2d, \left(1 - \frac{\phi^2(G)}{2}\right)\right)$ -graph.

The next Corollary follows from Corollary 8 and Claim 12.

► **Corollary 13.** *Let  $G = (V, E)$  be a connected  $d$ -bounded degree graph on  $n$  vertices and let  $v \in V$ . If we perform a random-walk in  $(G)_{\text{reg}}$ , starting from  $v$ , of length at least  $\tau(G) \stackrel{\text{def}}{=} \frac{\log(2n^{3/2})}{\log\left(\left(1 - \frac{\phi^2(G)}{2}\right)^{-1}\right)}$ , then the probability this walk ends in  $u$  is at least  $1/(2n)$  for every  $u \in V$ .*

### 3 LSSG for a Single Cluster

In this section, we prove Theorem 4, in particular, we present and prove correct our LSSG algorithm for the case where the input graph is a single cluster, i.e., a  $(1, \phi)$ -clusterable graph. As such, our algorithm receives  $\phi$  as a parameter where  $\phi$  is a lower bound on the conductance of the input graph. We first describe our algorithm from a global point of view (Subsection 3.1) and then explain how this global algorithm can be implemented locally (Subsection 3.3).

#### 3.1 The Global Algorithm for a Single Cluster

The algorithm has two stages. In the first stage, it picks an arbitrary vertex,  $\mathcal{P}$ , as the *primary-center*. It then performs  $r \stackrel{\text{def}}{=} \tilde{\Theta}(\sqrt{n})$   $s$ -wise independent lazy random walks from  $\mathcal{P}$  and takes the end-vertices of these walks to be the set of *secondary centers* (Steps 4-5). As defined in Section 2, when performing a lazy random walk, in each step, an edge is selected uniformly and independently with probability  $1/2d$  (recall that we add  $2d - d_G(v)$  self-loops to each vertex  $v$  to obtain a  $2d$ -regular graph). The edges traversed by the random walks (which are not self-loops) are added to the spanner (Step 6). This guarantees that all the secondary centers are connected in the spanner. The length of the random walks  $\tau$  is determined by Corollary 8 to ensure that the secondary centers are distributed almost uniformly in  $V$ .

In the second stage, the algorithm constructs spanning trees of the Voronoi cells, which are defined w.r.t. the secondary centers (Steps 7-8). Since the secondary centers are distributed almost uniformly in  $V$ , with high-probability, all vertices  $v \in V$  will have a secondary center in  $\Gamma_h(v)$  where  $h \stackrel{\text{def}}{=} \sqrt{n}$ . If this is not the case (i.e., no secondary center is found in  $\Gamma_h(v)$ ), then all the edges incident to  $v$  are added to the spanner (Step 9). Note that removing Step 9 yields an LSSG algorithm that spans  $G$  w.h.p., while including it yields an algorithm that outputs a spanning subgraph with probability 1.

■ **Algorithm 1** Globally Computing a Sparse Spanning Subgraph.

---

**Input:** A graph  $G = (V, E)$  with conductance at least  $\phi$  and maximum degree bounded by  $d$ .

**Output:**  $G' = (V, E')$  is a sparse spanning subgraph of  $G$  w.h.p.

- 1  $E' \leftarrow \emptyset$ .
- 2 Select a *primary-center*  $\mathcal{P} \in V$  arbitrarily.
- 3 Let  $r \stackrel{\text{def}}{=} \Theta(\sqrt{n} \cdot \log n)$ ,  $h \stackrel{\text{def}}{=} \sqrt{n}$ ,  $s \stackrel{\text{def}}{=} \Theta(\log n)$ ,  $\tau \stackrel{\text{def}}{=} \Theta\left(\frac{\log n}{\phi^2}\right)$ .
- 4 Perform  $r$   $s$ -wise independent lazy random walks  $\mathcal{R} \stackrel{\text{def}}{=} \{\rho_1, \dots, \rho_r\}$  where  $\rho_i = (v_1^{(i)} = \mathcal{P}, \dots, v_\tau^{(i)})$ .
- 5 Let  $\mathcal{S}$  denote the set of *secondary centers* defined as follows  $\mathcal{S} \stackrel{\text{def}}{=} \bigcup_{i \in [r]} \{v_\tau^{(i)}\}$ . // The end-vertices of the random-walks are selected to be the set of secondary centers.
- 6  $E' \leftarrow E(\mathcal{R}) \cap E$ . // where  $E(\mathcal{R})$  denotes the edge set of the random walks in  $\mathcal{R}$ . Add all the edges traversed by the random walks (that are not self-loops) in  $\mathcal{R}$  to the set  $E'$ .
- 7 Every vertex  $v \in V$  assigns itself to the closest secondary center in  $\Gamma_h(v)$  denoted by  $\sigma(v)$  (break ties by choosing the one with the smallest ID). If  $\Gamma_h(v) \cap \mathcal{S} = \emptyset$  then set  $\sigma(v) = \perp$ .
- 8 For each  $s \in \mathcal{S}$ , let  $\text{Vor}(s) \stackrel{\text{def}}{=} \{v \in V \mid \sigma(v) = s\}$ . Let  $\text{STree}(s)$  denote the BFS tree that spans  $\text{Vor}(s)$ .  $E' \leftarrow E' \cup \text{STree}(s)$ .
- 9 Add to  $E'$  all the edges incident to vertices,  $v$ , such that  $\sigma(v) = \perp$ .
- 10 **return**  $G' = (V, E')$ .

---

### 3.2 Correctness of the Global Algorithm for a Single Cluster

To prove the correctness of the global algorithm, we claim that w.h.p. when the algorithm stops, there is a path in  $G'$  from each vertex to a secondary center and that this path is short; We begin by proving that w.h.p., every vertex  $v \in V$  has a secondary center in  $\Gamma_h(v)$ . We shall use the following concentration bound, which applies for  $s$ -wise independent random variables defined as follows.<sup>7</sup>

► **Definition 14** ( $s$ -wise independence). *A set of discrete random variables  $X_1, \dots, X_n$  are called  $s$ -wise independent if for any set  $I \subseteq \{1, \dots, n\}$  with  $|I| \leq s$  and any values  $x_i$  we have  $\Pr[\bigwedge_{i \in I} (X_i = x_i)] = \prod_{i \in I} \Pr[X_i = x_i]$ .*

Note that the random walks that the algorithm performs are also random variables. In particular, this is a set of  $s$ -wise independent random walks, i.e., any subset of size at most  $s$  of walks (out of the  $r$  walks that the algorithm performs) are mutually independent.

► **Theorem 15** (Theorem 5(III) in [28]). *If  $X$  is a sum of  $s$ -wise independent random variables, each of which is in the interval  $[0, 1]$  with  $\mu = \mathbb{E}(X)$ , then For  $\delta \leq 1$  and  $s \leq \lfloor \delta^2 \mu e^{-1/3} \rfloor$ , it holds that  $\Pr[|X - \mu| \geq \delta \mu] \leq e^{-\lfloor s/2 \rfloor}$ .*

▷ **Claim 16.** With high probability, for every  $u \in V$ ,  $\Gamma_h(u) \cap \mathcal{S} \neq \emptyset$ .

*Proof.* Fix  $\mathcal{P}$  and let  $v$  be a vertex in  $V$ . Consider a random walk on  $(G)_{\text{reg}}$  (or alternatively, a lazy random-walk on  $G$ ) that starts at  $\mathcal{P}$ . By Corollary 13, when performing a random-walk from  $\mathcal{P}$  of length  $\tau$  in  $(G)_{\text{reg}}$ , the probability that  $v$  is the end-vertex of the random walk is at

---

<sup>7</sup> Having bounded independence reduces the number of random bits used by the local implementation of this algorithm, as shown in the next section.

least  $\frac{1}{2n}$ . Let  $\mathcal{E}_i^v$  denote the event that the  $i$ -th random walk ended at  $v$ , namely the event that  $v_r^{(i)} = v$ , and let  $X_i^v$  denote the indicator variable for this event. Thus,  $\Pr[\mathcal{E}_i^v] = \mathbb{E}[X_i^v] \geq \frac{1}{2n}$ . Let  $H \subseteq V$  be a set of cardinality  $h$  and let  $\mathcal{E}_i^H$  denote the event that the  $i$ -th random walk ended at  $H$ . Let  $X_i^H$  denote the indicator variable for this event. Since the events  $\{\mathcal{E}_i^v\}_{v \in V}$  are disjoint (i.e. mutually exclusive) we obtain that  $\mathbb{E}[X_i^H] = \Pr[\mathcal{E}_i^H] = \sum_{v \in H} \Pr[\mathcal{E}_i^v] \geq \frac{h}{2n}$ . By linearity of expectation,  $\mathbb{E}\left[\sum_{i \in [r]} X_i^H\right] \geq \frac{hr}{2n} = \Theta(\log n)$ , where the last equality follows since  $h = \sqrt{n}$ . Since we perform  $r$   $s$ -wise independent random walks from  $\mathcal{P}$ , the random variables  $\{X_i^H\}_{i \in [r]}$  are also  $s$ -wise independent. Set  $Y \stackrel{\text{def}}{=} \sum_{i \in [r]} X_i^H$  and  $\mu \stackrel{\text{def}}{=} \mathbb{E}[Y] = \Theta(\log n)$ . By Theorem 15,  $\Pr[|Y - \mu| \geq \mu/2] \leq e^{-\lfloor s/2 \rfloor}$  where  $s \stackrel{\text{def}}{=} \lfloor \frac{1}{4} \left(\frac{hr}{2n}\right) e^{-1/3} \rfloor \leq \lfloor \frac{1}{4} \mu e^{-1/3} \rfloor$ . If  $|Y - \mu| < \mu/2$ , then  $Y > \mu/2 \geq 1$ . Thus, the probability that none of the  $r$  random-walks ends in  $H$  is at most  $e^{-\lfloor s/2 \rfloor} = 1/n^c$ , where  $c$  is determined by the exact setting of  $r$ . Hence, by the union bound over all vertices, we obtain that with high probability  $\Gamma_h(v) \cap \mathcal{S} \neq \emptyset$  for every  $v \in V$ .  $\triangleleft$

The following claim (the proof of which appears in Appendix C) argues that BFS trees are of height logarithmic in the number of their vertices.

$\triangleright$  **Claim 17.** Let  $G = (V, E)$  be a  $d$ -bounded degree graph and let  $\phi$  be a lower bound on  $\phi(G)$ . For any  $v \in V$  and  $x \leq |V|/2$ , the  $\ell$ -ball centered at  $v$  contains at least  $x$  vertices provided that  $\ell \geq \frac{\log x}{\log(1+\phi)}$ .

Claim 17 implies that the paths' length from every vertex to its secondary center is logarithmic in  $n$ , formalized as follows.

$\blacktriangleright$  **Corollary 18.** Let  $s \in \mathcal{S}$ . Then the depth of  $\text{STree}(s)$  is at most  $\frac{\log h}{\log(1+\phi)}$ .

We now prove the main theorem of this section, which bounds the stretch factor and size of the graph,  $G' = (V, E')$  obtained by Algorithm 1. In particular, for constant  $\phi$  it follows that  $|E'| = n + o(n)$ , and the stretch is  $\Theta(\log n)$ .

$\blacktriangleright$  **Theorem 19.** Algorithm 1 computes a Sparse Spanning Graph of  $G$ ,  $G' = (V, E')$ , such that:

- (1) The attained stretch is  $\Theta\left(\frac{\log n}{\phi^2}\right)$ , and
- (2)  $|E'| = n + O\left(\frac{\sqrt{n} \log^2 n}{\phi^2}\right)$  with high probability.

**Proof.** We first prove Item 1 of the claim. Consider an edge  $\{u, v\}$  which belongs to  $E$  but not to  $E'$ . We first note that it follows that both  $\sigma(u) \neq \perp$  and  $\sigma(v) \neq \perp$  because otherwise  $\{u, v\}$  is added to  $E'$  in Step 9. If  $u$  and  $v$  belong to the same Voronoi cell then the distance between them in  $G'$  is at most  $2 \frac{\log \sqrt{n}}{\log(1+\phi)}$  (since, by Corollary 18, the distance from every vertex to its secondary center is at most  $\frac{\log \sqrt{n}}{\log(1+\phi)}$ ). If  $u$  and  $v$  do not belong to the same Voronoi cell, then the distance in  $G'$  between their respective centers,  $\sigma(u)$  and  $\sigma(v)$  is at most  $2\tau$  (because the distance in  $G'$  between every secondary center to  $\mathcal{P}$  is at most  $\tau$ ), where  $\tau \stackrel{\text{def}}{=} \frac{\log(2n^{3/2})}{\log\left(\left(1 - \frac{\phi^2}{2}\right)^{-1}\right)}$ . Thus, in this case the distance in  $G'$  between  $u$  and  $v$  is at most  $2 \cdot \left(\tau + \frac{\log \sqrt{n}}{\log(1+\phi)}\right)$ . Since for all  $x \geq 0$  it holds that  $x - x^2/2 \leq \ln(1+x)$ , it follows that the attained stretch is  $\Theta\left(\frac{\log n}{\phi^2}\right)$ , as claimed.

Item 2 of the claim follows from the construction. More specifically, at Step 6, we add at most  $r \cdot \tau$  edges to  $E'$ . In Step 8, we add at most  $n - 1$  edges since the Voronoi cells are vertex-disjoint. Finally, by Claim 16, with high probability, in Step 9, we do not add any edges to  $E'$ .  $\blacktriangleleft$

### 3.3 Details of the Implementation of the Local Algorithm for a Single Cluster

In this section, we describe how to implement Algorithm 1 locally. We also bound the query and time complexity of the local algorithm as well as the total number of bits it uses. We conclude this section with the proof of Theorem 4.

**Performing lazy random-walks in  $G$ .** Performing a lazy-random walk of length  $\ell$  in  $G$  requires at most  $\ell$  probes to  $G$ . In each step, we select an index uniformly at random from  $i \in [2d]$  and perform a neighbor-query  $(v, i)$  to reveal the  $i$ th neighbor of  $v$ , where  $v$  denotes the ID of the current vertex.<sup>8</sup> If the probe returns a vertex ID, then we move to that neighbor; otherwise, the walk stays at  $v$ . We note that performing a lazy-random walk in  $G$  is equivalent to performing a random walk in  $(G)_{\text{reg}}$ .

**Bounding the Number of Random Bits.** Following [23], we shall use the classical result from [31] for obtaining random bits with bounded independence in a local manner.

► **Definition 20.** For  $N, M, s \in \mathbb{N}$  such that  $s \leq N$ , a family of functions  $\mathcal{H} = \{h : [N] \rightarrow [M]\}$  is  $s$ -wise independent if for all distinct  $x_1, \dots, x_s \in [N]$ , the random variables  $h(x_1), \dots, h(x_s)$  are independent and uniformly distributed in  $[M]$  when  $h$  is chosen randomly from  $\mathcal{H}$ .

► **Lemma 21** (Corollary 3.34 in [31]). For every  $\gamma, \beta, s \in \mathbb{N}$ , there is a family of  $s$ -wise independent functions  $\mathcal{H}_{\gamma, \delta} = \{h : \{0, 1\}^\gamma \rightarrow \{0, 1\}^\delta\}$  such that choosing a random function from  $\mathcal{H}_{\gamma, \delta}$  takes  $s \cdot \max\{\gamma, \delta\}$  random bits, and evaluating a function from  $\mathcal{H}_{\gamma, \delta}$  takes time  $\text{poly}(\gamma, \delta, s)$ .

▷ **Claim 22.** Performing  $r$   $s$ -wise independent random walks from  $\mathcal{P}$  in  $(G)_{\text{reg}}$  can be implemented by using  $O(\log n(\log n + \tau \log d))$  random bits and time-complexity  $r \cdot \text{poly}(\tau, \log n)$ .

Proof. Performing a single random-walk in  $(G)_{\text{reg}}$  of length  $\tau$  from  $\mathcal{P}$  requires  $O(\tau \log d)$  random bits (since we are performing  $\tau$  steps and in each step, we are selecting an edge u.a.r. out of  $2d$  edges). Let  $\gamma \stackrel{\text{def}}{=} \Theta(\log r)$  denote the number of bits that are required to indicate the index of the random walk in  $[r]$  and let  $\delta \stackrel{\text{def}}{=} \Theta(\tau \log d)$  denote the number of random bits that are required for performing a single walk. To perform  $r$   $s$ -wise independent random walks, it suffices to choose a random function from a family of  $s$ -wise independent functions,  $\mathcal{H}_{\gamma, \delta}$  which takes as parameter the index of the random walk and returns  $\delta$  bits. By Lemma 21 this can be done by using  $s \cdot \max\{\gamma, \delta\} = O(\log n(\log n + \tau \log d))$  random bits. Furthermore, the time complexity of retrieving the bits for performing a single random walk is  $\text{poly}(\gamma, \delta, s) = \text{poly}(\tau, \log n)$ . The claim follows. ◁

**Locally Computing a Sparse Spanning Subgraph.** On query  $\{u, v\}$ , the local algorithm first performs the random walks as listed in Algorithm 1, Step 4. If  $\{u, v\} \in E(\mathcal{R})$ , then the algorithm returns YES. Otherwise, it finds  $\sigma(u)$  and  $\sigma(v)$ . If either  $\sigma(u) = \perp$  or  $\sigma(v) = \perp$  then it returns YES. Otherwise, if  $\sigma(u) = \sigma(v)$ , then the algorithm returns YES iff  $\{u, v\} \in \text{STree}(\sigma(v))$ . Otherwise, if  $\sigma(u) \neq \sigma(v)$ , the algorithm returns NO. Finding  $\sigma(v)$

<sup>8</sup> A common assumption in LCA in general and hence also in LSSG's is that the algorithm knows  $n$ . Similarly, as in [17], for bounded-degree graphs, the bound on the maximum vertex degree  $d$  of the graph instance at hand is also known to the LSSG algorithm.

can be done by making  $O(hd^2)$  queries. To see this, observe that the number of vertices we explore by performing a BFS, layer by layer, until we first see at least  $h$  vertices is at most  $(h-1)d$ . The subgraph induced on these vertices contains at most  $hd^2$  edges, thus the query and time complexity of this step is indeed  $O(hd^2)$ <sup>9</sup>. Checking if  $\{u, v\} \in \text{STree}(\sigma(v))$  can be implemented at the same cost. To see this, observe that when we find  $\sigma(v)$  as described above, then we also reveal all the shortest paths between  $v$  and  $\sigma(v)$  in  $G$ . Since we can decide which one of these paths is the path between  $v$  and  $\sigma(v)$  in  $\text{STree}(\sigma(v))$ , we can decide if  $\{u, v\}$  belongs to this path at the same cost of finding  $\sigma(v)$  and  $\sigma(u)$ <sup>10</sup>. This concludes the description of the local implementation of Algorithm 1. We are now ready to prove Theorem 4.

**Proof of Theorem 4.** The correctness of the algorithm, that is, Item (1), follows from Theorem 19. As described above (in the analysis of the local implementation), the algorithm makes  $r \cdot \tau + hd^2 = O\left(\sqrt{n} \cdot \left(\frac{\log^2 n}{\phi^2} + d^2\right)\right)$  graph queries. By Claim 22 the local implementation of Algorithm 1 uses  $O(\log n(\log n + \tau \log d)) = O\left(\frac{\log d \cdot \log^2 n}{\phi^2}\right)$  random bits, which concludes the proof of the theorem. ◀

## 4 LSSG for Clusterable Graphs

In this section, we prove Theorem 5. First, we describe our LSSG algorithm that works under the promise that the input graph is a connected  $(k, \phi_{\text{in}}, \phi_{\text{out}})$ -clusterable graph where each cluster is of size at least  $\beta n$ .

### 4.1 The Global Algorithm for Clusterable graphs

The listing of our global algorithm appears as Algorithm 2. We next describe how it proceeds, step by step. All the parameters we will mention are defined in Step 2 of the algorithm. Initially, the set of edges of the spanner,  $E'$ , is empty (Step 1). The algorithm begins with selecting  $p$  primary-centers uniformly at random from  $V$  (Step 3). It then performs  $r$   $s$ -wise independent lazy-random walks from each primary center (Step 4). It picks the endpoints of these random-walks to be the set of *secondary-centers* (Step 5). Additionally, all the edges traversed by these random walks are added to  $E'$  (Step 4). After that, the vertices of the graph are partitioned as follows. Each one of the vertices,  $v$ , joins the cell of the secondary center, which is closest to  $v$  in  $\Gamma_h(v)$ , breaking ties by ID (Step 6). If  $\Gamma_h(v)$  does not include a secondary center, then all the edges that are incident to  $v$  are added to  $E'$  (Step 9). In Step 10 the algorithm picks  $t$  random pairs from  $V \times [d]$ . For each such pair,  $(v, i)$ , such that  $v$  has an  $i$ -th neighbor, the edge  $\{u, v\}$  is added to  $E'$  where  $u$  is the  $i$ -th neighbor of  $v$  (Step 10). We define an artificial-cluster to be a maximal set of vertices that agree on their primary-center (see formal definition in Step 7). For every pair of artificial-clusters such that  $E'$  does not include an edge from their cut, all the edges in the corresponding cut are added to  $E'$  (Step 11). This concludes the description of the algorithm.

### 4.2 Correctness of the Global Algorithm for Clusterable Graphs

To prove the correctness of the algorithm, we need to show that the obtained subgraph spans the graph with a logarithmic stretch and that it is sparse. Proving that the obtained subgraph spans the graph is relatively straightforward and follows by the design of the

<sup>9</sup> This procedure appears in [17] as Algorithm **Find-Center**.

<sup>10</sup> See more details in algorithm **Get BFS outgoing-edges endpoints** in [17].

■ **Algorithm 2** Globally Computing a Sparse Spanning Subgraph of a Clusterable Graph.

- 
- Input:** A connected  $(k, \phi_{\text{in}}, \phi_{\text{out}})$ -clusterable graph  $G = (V, E)$  where each cluster is of size at least  $\beta|V|$ .
- Output:**  $G' = (V, E')$  is a sparse spanning subgraph of  $G$  w.h.p.
- 1  $E' \leftarrow \emptyset$ .
  - 2 Let  $p \stackrel{\text{def}}{=} \Theta(\beta^{-1} \log n)$ ,  $r \stackrel{\text{def}}{=} \Theta(\frac{\log n}{\tau \phi_{\text{out}}})$ ,  $s \stackrel{\text{def}}{=} \Theta(\log n)$ ,  $\tau \stackrel{\text{def}}{=} \Theta(\frac{\log n}{\phi_{\text{in}}^2})$ , and  $h \stackrel{\text{def}}{=} \Theta(k\tau\phi_{\text{out}}n)$ .
  - 3 Select  $p$  primary-centers  $\mathcal{P} \stackrel{\text{def}}{=} \{\psi_1, \dots, \psi_p\}$  u.a.r. in  $V$ .
  - 4 From each primary-center,  $\psi \in \mathcal{P}$ , perform  $r$   $s$ -wise independent lazy random-walks. Add all the edges in  $E$  traversed by these random walks to  $E'$ .
  - 5 Let  $\mathcal{S}$  denote the set of endpoints of these random-walks. We refer to  $\mathcal{S}$  as the set of secondary centers. We say that the primary-center of  $v \in \mathcal{S}$  is  $\psi$  if the random-walk that ended in  $v$  started at  $\psi$  (break ties by choosing the one with the smallest ID).
  - 6 Every vertex  $v \in V$  assigns itself to the closest secondary center in  $\Gamma_h(v)$  denoted by  $\sigma(v)$  (break ties by choosing the one with the smallest ID). If  $\Gamma_h(v) \cap \mathcal{S} = \emptyset$  then set  $\sigma(v) = \perp$ .
  - 7 The primary-center of  $v$  is set to be the primary-center of  $\sigma(v)$ . The *artificial-cluster* of  $v$  is defined to be the set of all vertices whose primary-center equals the primary-center of  $v$ .
  - 8 For each  $s \in \mathcal{S}$ , let  $\text{Vor}(s) \stackrel{\text{def}}{=} \{v \in V \mid \sigma(v) = s\}$ . Let  $\text{STree}(s)$  be a spanning tree of  $\text{Vor}(s)$ .  $E' \leftarrow E' \cup \text{STree}(s)$ .
  - 9 Add to  $E'$  all the edges that are incident to vertices,  $v$ , such that  $\sigma(v) = \perp$ .
  - 10 Select  $t \stackrel{\text{def}}{=} \Theta(\varepsilon^{-1}k^2d \log n)$  pairs u.a.r. from  $V \times [d]$ . Let  $\mathcal{T}$  denote the set of edges that correspond to these pairs (an edge  $\{u, v\}$  corresponds to the pair  $(v, i)$  if  $u$  is the  $i$ -th neighbor of  $v$ ).  $E' \leftarrow E' \cup \mathcal{T}$ .
  - 11 Add to  $E'$  all the edges between artificial-clusters not connected by an edge in  $\mathcal{T}$ .
  - 12 **return**  $G' = (V, E')$ .
- 

algorithm. Both the proof of the low stretch and sparsity of the obtained spanner appears in Theorem 28, where for the sparsity proof, we need to show that the number of edges that we add in Steps 4, and 8-11 is not too much. The proof that the obtained spanner is of a low stretch is the main technical challenge of this section. To this end, it is sufficient to show that w.h.p. for every  $v \in V$ ,  $\Gamma_h(v)$  includes a secondary-center (see Claim 26). To this end, we next analyze the distribution of the endpoints of the lazy-random walks that the algorithm performs.

For any subset  $C \subseteq V$ , we slightly abuse notation and denote by  $(C)_{\text{reg}}$  the  $2d$ -regular graph  $(G[C])_{\text{reg}}$ , where  $G[C]$  is the subgraph induced on  $C$  in  $G$ .

Throughout this section,  $G = (V, E)$  is a  $(k, \phi_{\text{in}}, \phi_{\text{out}})$ -clusterable graph,  $C \subseteq V$  is a  $(\phi_{\text{in}}, \phi_{\text{out}})$ -cluster of  $G$  and  $S$  is the set of self-loops that are added to  $(C)_{\text{reg}}$  due to the edges in the cut between  $C$  and  $V \setminus C$ . Namely, for each  $v \in C$ ,  $S$  contains  $e(\{v\}, V \setminus C)$  self-loops of  $v$ .

For every  $u, v \in C$ , let  $p^{\ell, v}(u)$  denote the probability that an  $\ell$ -length random-walk that starts at  $v$  in  $(C)_{\text{reg}}$  ends at  $u$ . Thus  $\sum_{u \in C} p^{\ell, v}(u) = 1$ . We let  $p_{\text{bad}}^{\ell, v}(u)$  denote the probability that an  $\ell$ -length random-walk in  $(C)_{\text{reg}}$  that starts at  $v$  ends in  $u$  and traverses an edge of  $S$ . Let  $p_{\text{good}}^{\ell, v}(u) \stackrel{\text{def}}{=} p^{\ell, v}(u) - p_{\text{bad}}^{\ell, v}(u)$ .

▷ **Claim 23.** For at least half of the vertices  $v \in C$ , it holds that  $\sum_{u \in C} p_{\text{bad}}^{\ell, v}(u) \leq \ell\phi_{\text{out}}$ . We call such a vertex,  $v$ , useful.

*Proof.* We prove that if we perform an  $\ell$ -length random-walk,  $\rho$ , in  $(C)_{\text{reg}}$  from a vertex  $v$  selected u.a.r. from  $C$ , then the probability that  $\rho$  traverses an edge from  $S$  is at most  $\ell\phi_{\text{out}}/2$ . In other words, we will show that  $\mathbb{E}[\sum_{u \in C} p_{\text{bad}}^{\ell, v}(u)] \leq \ell\phi_{\text{out}}/2$ , where the expectation is taken over  $v$  which is selected u.a.r. from  $C$ . The claim will then follow by Markov's inequality.

Since  $(C)_{\text{reg}}$  is  $2d$ -regular and  $v$  is selected u.a.r. from  $C$ , all the vertices in  $\rho$  are distributed uniformly at random from  $C$  as well (since  $P\vec{u} = \vec{u}$  for every doubly-stochastic matrix  $P$ ). The probability of traversing an edge from  $S$  when we select a vertex u.a.r. from  $C$  and then take a single step from this vertex is  $\frac{|S|}{2d|C|}$ . This is simply because each one of the edges in  $S$  is traversed with probability  $\frac{1}{|C|} \cdot \frac{1}{2d}$  (recall that the edges in  $S$  correspond to self-loops). Thus, by union bound, the probability of traversing an edge from  $S$  in one of the  $\ell$  steps of the random walk is at most  $\frac{\ell|S|}{2d|C|}$ . Since  $\frac{|S|}{d|C|} \leq \phi_{\text{out}}$  we obtain that this probability is at most  $\ell\phi_{\text{out}}/2$ , as desired.  $\triangleleft$

The following claim relates random-walks in  $(G)_{\text{reg}}$  to random-walks in  $(C)_{\text{reg}}$ .

$\triangleright$  **Claim 24.** If we perform an  $\ell$ -length random-walk in  $(G)_{\text{reg}}$  from  $v \in C$  then the probability that this random walk ends at  $u \in C$  is at least  $p_{\text{good}}^{\ell,v}(u)$ .

*Proof.* Recall that  $p_{\text{good}}^{\ell,v}(u)$  is the probability that an  $\ell$ -length random-walk in  $(C)_{\text{reg}}$  that starts at  $v$  ends in  $u$  and does not traverse an edge of  $S$ . The edge set of  $(C)_{\text{reg}}$  includes parallel self-loops. If we identify each edge by its endpoints and the labels of its ports, then we get that from each vertex  $v \in C$ , there are exactly  $(2d)^\ell$  distinct paths of length  $\ell$  in  $(C)_{\text{reg}}$ . Let  $P^v$  denote the set of these paths. When we perform a random walk in  $(C)_{\text{reg}}$  from  $v$ , each path in  $P^v$  occurs with probability  $1/(2d)^\ell$ . Moreover, for every  $u \in C$ , let  $P_u^v$  denote the set of paths in  $P^v$  that end at  $u$  and do not traverse an edge from  $S$ . Each path in  $P_u^v$  contributes  $1/(2d)^\ell$  to  $p_{\text{good}}^{\ell,v}(u)$  and each path in  $P^v \setminus P_u^v$  contributes 0. Assume, w.l.o.g., that  $(C)_{\text{reg}}$  is obtained from  $G$  by first converting  $G$  to  $(G)_{\text{reg}}$  and then replacing the edges in the cut  $E(C, V \setminus C)$  with self-loops. This way, every self-loop in  $(C)_{\text{reg}}$  which does not belong to  $S$  also appears in  $(G)_{\text{reg}}$  (when taking into account the port numbers). Thus, if we perform a random-walk in  $(G)_{\text{reg}}$  from  $v$ , each path from  $P_u^v$  occurs with probability  $1/(2d)^\ell$  as well. The claim follows.  $\triangleleft$

$\triangleright$  **Claim 25.** Let  $v$  be a vertex which is useful w.r.t.  $C$ . For all  $u \in C$ , except for at most  $4\tau\phi_{\text{out}}|C|$  vertices, it holds that a  $\tau$ -length random-walk in  $(G)_{\text{reg}}$  from  $v$  ends at  $u$  with probability at least  $(4n)^{-1}$ .

*Proof.* Let  $v$  be a vertex, which is useful w.r.t.  $C$ , and let  $\ell \in \mathbb{N}$ . By Claim 23,  $\sum_{u \in C} p_{\text{bad}}^{\ell,v}(u) \leq \ell\phi_{\text{out}}$ . Therefore  $\mathbb{E}[p_{\text{bad}}^{\ell,v}(u)] \leq \frac{\ell\phi_{\text{out}}}{|C|}$ , where the expectation is taken over  $u$  selected u.a.r. from  $C$ . Thus, by Markov's inequality for at most  $\gamma$ -fraction of the vertices  $u \in C$  it holds that  $p_{\text{bad}}^{\ell,v}(u) > \frac{\ell\phi_{\text{out}}}{\gamma|C|}$ .

By replacing  $\ell$  with  $\tau$  and  $\gamma$  with  $4\tau\phi_{\text{out}}$  we obtain that for at least  $(1 - 4\tau\phi_{\text{out}})$ -fraction of the vertices  $u \in C$  it holds that  $p_{\text{good}}^{\tau,v}(u) \geq p^{\tau,v}(u) - \frac{1}{4|C|}$ . Since  $C$  is a  $(\phi_{\text{in}}, \phi_{\text{out}})$ -cluster in  $G$  it follows from Corollary 13 that  $p^{\tau,v}(u) \geq 1/(2|C|)$  for every  $u$ . Thus it holds that  $p_{\text{good}}^{\tau,v}(u) \geq 1/(4|C|) \geq 1/(4n)$ . Hence, the claim follows from Claim 24.  $\triangleleft$

$\triangleright$  **Claim 26.** Let  $G = (V, E)$  be a connected  $(k, \phi_{\text{in}}, \phi_{\text{out}})$ -clusterable graph and let  $C_1, \dots, C_f$  be a partition of  $G$  into  $f \leq k$   $(\phi_{\text{in}}, \phi_{\text{out}})$ -clusters. If for every  $i \in [f]$ ,  $C_i \cap \mathcal{P}$  contains a useful vertex w.r.t.  $C_i$ , then w.h.p. for every  $v \in V$ ,  $\Gamma_h(v) \cap \mathcal{S} \neq \emptyset$ .

*Proof.* Let  $G = (V, E)$  be a connected  $(k, \phi_{\text{in}}, \phi_{\text{out}})$ -clusterable graph and let  $C_1, \dots, C_f$  be a partition of  $G$  into  $f \leq k$   $(\phi_{\text{in}}, \phi_{\text{out}})$ -clusters. Assume for every  $i \in [f]$ ,  $C_i \cap \mathcal{P}$  contains a useful vertex,  $u_i$ , w.r.t.  $C_i$ . Let  $H$  be a set of vertices of cardinality at least  $h$  and let  $\gamma = 4\tau\phi_{\text{out}}$  where  $h$  and  $\tau$  are as defined in Step 2 of Algorithm 2. By Claim 25, for every  $i \in [f]$  and for all vertices  $u \in C_i$  except for at most  $\gamma|C_i|$  it holds that an  $\tau$ -length random-walk in  $(G)_{\text{reg}}$  from  $u_i$  ends at  $u$  with probability at least  $(4n)^{-1}$ . Let us call these vertices *good* w.r.t.  $C_i$ .

Let  $C_j$  be the dominant cluster in  $H$ . Namely, the cluster which maximizes the intersection with  $H$ . By an averaging argument  $C_j \cap H \geq h/k \geq 5\tau\phi_{\text{out}}n$ , where the last inequality holds for an appropriate setting of  $h$ . Since the number of vertices in  $C_j$  which are not good (w.r.t.  $C_j$ ) is at most  $\gamma|C_j| \leq 4\tau\phi_{\text{out}}n$ , we obtain that the number of good vertices in  $C_j$  is at least  $\tau\phi_{\text{out}}n$ . From this point, the rest of the proof is similar to the proof of Claim 16. For  $v \in V$ , let  $\mathcal{E}_i^v$  denote the event that the  $i$ -th random walk from  $u_j$  ended at  $v$  and let  $X_i^v$  denote the indicator variable for this event. Thus, for every good vertex,  $v$ , w.r.t.  $C_j$  holds that  $\Pr[\mathcal{E}_i^v] = \mathbb{E}[X_i^v] \geq \frac{1}{4n}$ . Let  $\mathcal{E}_i^H$  denote the event that the  $i$ -th random walk from  $u_j$  ended at  $H$ . Let  $X_i^H$  denote the indicator variable for this event. Since the events  $\{\mathcal{E}_i^v\}_{v \in V}$  are disjoint (i.e. mutually exclusive) we obtain that  $\mathbb{E}[X_i^H] = \Pr[\mathcal{E}_i^H] = \sum_{v \in H} \Pr[\mathcal{E}_i^v] \geq \frac{\tau\phi_{\text{out}}n}{4n} = \frac{\tau\phi_{\text{out}}}{4}$ . By linearity of expectation,  $\mathbb{E}\left[\sum_{i \in [r]} X_i^H\right] \geq r \cdot \frac{\tau\phi_{\text{out}}}{4} = \Theta(\log n)$ . Since we perform  $r$   $s$ -wise independent random walks from  $u_j$ , the random variables  $\{X_i^H\}_{i \in [r]}$  are also  $s$ -wise independent. Set  $Y \stackrel{\text{def}}{=} \sum_{i \in [r]} X_i^H$  and  $\mu \stackrel{\text{def}}{=} \mathbb{E}[Y] = \Theta(\log n)$ . By Theorem 15,  $\Pr[|Y - \mu| \geq \mu/2] \leq e^{-\lfloor s/2 \rfloor}$  where  $s \stackrel{\text{def}}{=} \lfloor \frac{1}{4} \left( \frac{r\tau\phi_{\text{out}}}{4} \right) e^{-1/3} \rfloor \leq \lfloor \frac{1}{4} \mu e^{-1/3} \rfloor$ . If  $|Y - \mu| < \mu/2$ , then  $Y > \mu/2 \geq 1$ . Thus, the probability that none of the  $r$  random-walks ends in  $H$  is at most  $e^{-\lfloor s/2 \rfloor} = 1/n^c$ , where  $c$  is determined by the exact setting of  $r$ . Thus, by union bound over all vertices, we obtain that with high probability  $\Gamma_h(v) \cap \mathcal{S} \neq \emptyset$  for every  $v \in V$ .  $\triangleleft$

We say that a pair of artificial-clusters are *heavy* if the number of edges in their edge-cut is at least  $\varepsilon n/(2k^2)$ .

$\triangleright$  **Claim 27.** With high probability,  $\mathcal{T}$  contains an edge from the cut of every pair of heavy artificial-clusters.

*Proof.* Let  $C_1$  and  $C_2$  be a heavy pair of artificial-clusters. By definition, the number of edges in their cut is at least  $\varepsilon n/(2k^2)$ . Thus the probability that a pair chosen u.a.r. from  $V \times [d]$  hits this cut is at least  $\frac{\varepsilon n}{2k^2} \cdot \frac{1}{dn} = \frac{\varepsilon}{2k^2d}$ . Thus, the claim follows by union bound over all pairs of artificial-clusters and the setting of  $t$ .  $\triangleleft$

We are now ready to prove the correctness of the global algorithm, as stated in the next theorem.

$\blacktriangleright$  **Theorem 28.** *Under the promise that the input graph,  $G = (V, E)$ , is a connected  $(k, \phi_{\text{in}}, \phi_{\text{out}})$ -clusterable graph, with clusters of size at least  $\beta n$ , Algorithm 2 computes a sparse spanning subgraph of  $G$ ,  $G' = (V, E')$ , such that:*

1. *The attained stretch is  $\Theta\left(\frac{\log n}{\phi_{\text{in}}^2}\right)$ , and*
2.  *$|E'| \leq n(1 + \varepsilon)$  with high probability.*

**Proof.** Let  $G = (V, E)$  be a connected  $(k, \phi_{\text{in}}, \phi_{\text{out}})$ -clusterable graph and let  $C_1, \dots, C_f$  be a partition of  $G$  into  $f \leq k$   $(\phi_{\text{in}}, \phi_{\text{out}})$ -clusters of size at least  $\beta n$ . We begin by proving Item 1 of the claim. Let  $\mathcal{E}_1$  denote the event that for every  $i \in [f]$ ,  $C_i \cap \mathcal{S}$  contains a useful vertex w.r.t.  $C_i$ . Fix  $i \in [f]$ . By definition (see Claim 23), at least half of the vertices in  $C_i$  are useful. Since  $|C_i| \geq \beta n$ , the probability that  $v$  which selected u.a.r. from  $V$  is a useful vertex of  $C_i$  is at least  $\beta/2$ . Therefore w.p. at least  $1 - 1/n^c$ ,  $\mathcal{P}$  contains a useful vertex w.r.t.  $C_i$  where  $c$  is determined by the exact setting of  $p$ . Thus, by union bound over all  $i \in [f]$ , w.h.p.  $\mathcal{E}_1$  occurs.

Let  $\mathcal{E}_2$  denote the event that for every  $v \in V$ ,  $\Gamma_h(v) \cap \mathcal{S} \neq \emptyset$ . Conditioned on  $\mathcal{E}_1$ , by Claim 26 w.h.p.  $\mathcal{E}_2$  occurs.

Consider an edge  $\{u, v\}$  which belongs to  $E$  but not to  $E'$ . We first note that it follows that both  $\sigma(u) \neq \perp$  and  $\sigma(v) \neq \perp$  because otherwise  $\{u, v\}$  is added to  $E'$  in Step 9. From Claim 17 it follows that for every  $v \in V$  such that  $\sigma(v) \neq \perp$  the distance from  $v$  to  $\sigma(v)$  is at

most  $\frac{\log h}{\log(1+\phi_{\text{in}})}$ . To see this, observe that the  $\ell$ -ball centered at  $v$  in  $G[C]$  is contained  $\ell$ -ball centered at  $v$  in  $G$  where  $C$  denotes the cluster of  $v$  according to the partition mentioned above (in other words the neighborhood of  $v$  expands in  $G$  at least as fast as it does in  $G[C]$ ). Thus, if  $u$  and  $v$  belong to the same Voronoi cell, then the distance between them in  $G'$  is at most  $2\frac{\log h}{\log(1+\phi_{\text{in}})}$ . If  $u$  and  $v$  belong to the same artificial-cluster then the distance in  $G'$  between their respective centers,  $\sigma(u)$  and  $\sigma(v)$  is at most  $2\tau$  (because the distance in  $G'$  between a secondary center to its primary center is at most  $\tau$ ). Thus, in this case the distance in  $G'$  between  $u$  and  $v$  is at most  $2 \cdot \left(\tau + \frac{\log h}{\log(1+\phi_{\text{in}})}\right)$ . Finally, if  $u$  and  $v$  belong to different artificial-clusters then by Steps 10 and 11 there exists  $\{u', v'\} \in E'$  such that  $u'$  and  $u$  are in the same artificial-cluster and likewise for  $v$  and  $v'$ . Thus, by the above the distance in  $G'$  between  $u$  and  $v$  is at most  $2 \cdot \left(2 \cdot \left(\tau + \frac{\log h}{\log(1+\phi_{\text{in}})}\right)\right) + 1$ , where  $\tau \stackrel{\text{def}}{=} \frac{\log(2n^{3/2})}{\log\left(\left(1 - \frac{\phi_{\text{in}}^2}{2}\right)^{-1}\right)}$ .

Since for all  $x \geq 0$  it holds that  $x - x^2/2 \leq \ln(1+x)$  and since w.l.o.g.  $h \leq n$ , it follows that the attained stretch is  $\Theta\left(\frac{\log n}{\phi_{\text{in}}^2}\right)$ , as claimed.

Item 2 of the claim follows from the construction. More specifically, at Step 4 we add at most  $p \cdot r \cdot \tau = \Theta(\phi_{\text{out}}^{-1} \beta^{-1} \log^2 n)$  edges to  $E'$ . This is  $o(n)$  since we may assume that our query complexity is  $\tilde{O}(n^{2/3}) = o(n)$  (otherwise we may run the algorithm by Lenzen and Levi [12]). In Step 8, we add at most  $n - 1$  edges due to the fact that the Voronoi cells are vertex-disjoint. Conditioned on  $\mathcal{E}_2$ , which occurs w.h.p., in Step 9 we do not add any edges to  $E'$ . In Step 10 we add at most  $t$  edges to  $E'$ . Let  $\mathcal{E}_3$  denote the event that  $\mathcal{T}$  contains an edge from the edge-cut of every pair of artificial-clusters. By Claim 27 w.h.p.  $\mathcal{E}_3$  occurs. Finally, Conditioned on  $\mathcal{E}_3$ , in Step 11 we add at most  $k^2 \cdot \varepsilon \cdot n / (2k^2) = \varepsilon n / 2$  edges to  $E'$ . The claim follows.  $\blacktriangleleft$

### 4.3 Details of the Local Algorithm

In this section, we describe how to implement Algorithm 2 locally. The local implementation of all the steps of the algorithm is similar to the local implementation of the analogous steps of Algorithm 1 (with different parameters). The only new ingredient in the local implementation is the implementation of Step 11. Next, we describe how this step can be implemented locally. On query  $\{u, v\}$ , if  $u$  and  $v$  belong to the same artificial-cluster, then we proceed as before. Namely, we return YES if and only if  $u$  and  $v$  belong to the same Voronoi cell and  $\{u, v\}$  belongs to the tree that spans the cell. If  $u$  and  $v$  belong to different artificial-clusters then we consider three cases. The first case we consider is when  $\{u, v\} \in \mathcal{T}$ , the sample of edges selected in Step 10. In this case, we would like to return YES on the query  $\{u, v\}$ . The second case is when  $\{u, v\} \notin \mathcal{T}$  but there exists  $\{u', v'\} \in \mathcal{T}$  such that  $u$  and  $u'$  are in the same artificial-cluster and likewise for  $v$  and  $v'$ . In this case, we would like to return NO. Otherwise, we would like to return YES. Therefore, we can decide if to return YES or NO if we find for each edge in  $\mathcal{T}$  the identities of the artificial-clusters (i.e., the IDs of the primary centers of the corresponding artificial-clusters) of its endpoints. This is accomplished as follows. For each one of the pairs,  $(v, i)$ , selected in Step 10, we perform a neighbor query to obtain the  $i$ -th neighbor of  $v$ . If such a neighbor exists then let us denote it by  $u$ . We then find  $\sigma(v)$  and  $\sigma(u)$  by making  $O(hd^2)$  queries. This also reveals to which artificial-cluster  $v$  belongs and likewise for  $u$ . This allows us to obtain the list of pairs of artificial-clusters that already have an edge from their cut in  $\mathcal{T}$ . Thus, on query  $\{u, v\}$  where  $u$  and  $v$  belong to different artificial-clusters which are not on that list, the algorithm will return YES. Overall, implementing this check requires  $O(thd^2)$  queries and  $\tilde{O}(thd^2)$  time. We conclude that the query complexity of the algorithm is dominated by the implementation of Step 4 which requires  $O(pr\tau) = O(\log^2 n / (\beta\phi_{\text{out}}))$  queries and Step 11 which requires  $O(thd^2) = O(\phi_{\text{in}}^{-1} \varepsilon^{-1} k^3 d^3 \phi_{\text{out}} \cdot n \log^2 n)$  queries.

In this next claim, we bound the number of random bits that our algorithm uses.

▷ **Claim 29.** Performing  $r$   $s$ -wise independent random walks from each  $\psi \in \mathcal{P}$  in  $(G)_{\text{reg}}$  can be implemented by using  $O(\log n(\log n + \tau \log d))$  random bits and time-complexity  $r \cdot \text{poly}(\tau, \log n)$ .

*Proof.* As claimed in the proof of Claim 22, performing a single random-walk in  $(G)_{\text{reg}}$  of length  $\tau$  from any vertex requires  $\tau \log(2d)$  random bits. If we choose a random function from a family of  $s$ -wise independent functions,  $\mathcal{H}_{\gamma, \beta} = \{h : \{0, 1\}^\gamma \rightarrow \{0, 1\}^\beta\}$ , where  $\gamma = \log(p \cdot r)$  is the number of bits that are required to indicate the index of the vertex in  $\mathcal{P}$  and the index of the walk in  $[r]$  and  $\beta = \tau \log(2d)$  is the number of bits that are required for performing the walk then we obtain that the total number of random bits that the algorithm uses for performing the walks is  $s \cdot \max\{\gamma, \beta\} = O(\log n(\log n + \tau \log d))$ . We obtain the desired result since performing a single random walk requires  $\text{poly}(\gamma, \beta, s) = \text{poly}(\tau, \log n)$  time. ◀

We are now ready to prove Theorem 5.

▶ **Theorem 5.** *There is an LSSG algorithm that given query access to a connected  $(k, \phi_{\text{in}}, \phi_{\text{out}})$ -clusterable graph  $G = (V, E)$ , where each cluster is of size at least  $\beta \cdot n$ , provides access to  $G' = (V, E')$  such that the following holds. (1) The graph  $G'$  is a connected subgraph of  $G$  and with high probability  $|E'| \leq n(1 + \varepsilon)$ . Moreover, the stretch factor of  $G'$  is  $\Theta\left(\frac{\log n}{\phi_{\text{in}}^2}\right)$ . (2) The query complexity of the algorithm is  $O(\log^2 n \cdot (\beta \phi_{\text{out}})^{-1} + n \log^2 n \cdot k^3 d^3 \phi_{\text{out}} (\varepsilon \phi_{\text{in}})^{-1})$ , and (3) the number of random bits it uses is  $O\left(\frac{\log d \cdot \log^2 n}{\phi_{\text{in}}^2}\right)$ , where  $d$  is a bound on the maximum degree of  $G$ .*

**Proof of Theorem 5.** The correctness of the algorithm, i.e., Item (1), follows from Theorem 19. The query complexity of the algorithm is analyzed in the description of the local implementation that appears above. Finally, by Claim 22 the local implementation of Algorithm 1 uses  $O(\log n(\log n + \tau \log d)) = O\left(\frac{\log d \cdot \log^2 n}{\phi_{\text{in}}^2}\right)$  random bits, as claimed. This concludes the proof of the theorem. ◀

To obtain Corollary 6 from Theorem 5, we observe that we can take the upper bound on  $\phi_{\text{out}}$  to be the maximum between  $\phi_{\text{out}}$  and  $1/\sqrt{n}$ . More specifically, if we consider  $k, d, \phi_{\text{in}}, \varepsilon$  and  $\beta$  to be constants then the query complexity is  $\tilde{O}(1/\phi_{\text{out}} + n\phi_{\text{out}})$ . Since  $1/\phi_{\text{out}} > n\phi_{\text{out}}$  only when  $\phi_{\text{out}} < 1/\sqrt{n}$  we only need to show that the query complexity in this case is  $\tilde{O}(\sqrt{n})$ . Indeed, since  $\phi_{\text{out}}$  is only an upper bound on the outer-conductance, we may take  $\phi_{\text{out}} = 1/\sqrt{n}$  in this case and obtain the desired complexity.

▶ **Corollary 6.** *There is an LSSG algorithm that given query access to a connected  $(\Theta(1), \Theta(1), \phi_{\text{out}})$ -clusterable graph  $G = (V, E)$ , where each cluster is of size at least  $\beta \cdot n$ , provides access to  $G' = (V, E')$  such that the following holds. (1) The graph  $G'$  is a connected subgraph of  $G$  and with high probability  $|E'| \leq n(1 + \varepsilon)$ . Moreover, the stretch factor of  $G'$  is  $\Theta(\log n)$ . (2) The query and time complexity of the algorithm is  $\tilde{O}(\sqrt{n} + \phi_{\text{out}} n)$ , and (3) the number of random bits it uses is  $O(\log^2 n)$ .*

## **A** Other Related Work

### **A.1** LCAs for Spanners

A desirable property for a spanning subgraph is that it also preserves, up to a predetermined multiplicative factor  $\alpha \geq 1$  (a.k.a the stretch factor), the pairwise distances of the vertices in the original graph. Such a spanning subgraph is called an  $\alpha$ -spanner. In [15, 25]  $\text{poly}(h \log(d)/\varepsilon)$ -spanners for minor-free graphs are presented. For general (bounded degree) graphs, the algorithm of [12] outputs an  $O(\log^2 n \cdot \text{poly}(d/\varepsilon))$ -spanner. Their result is later extended by Parter et al. [23], who presented an algorithm that constructs an  $O(k^2)$ -spanner, independent of both  $n$  and  $d$ , but has  $O(n^{1+1/k})$  edges. The query complexity of [23] is  $O(n^{2/3}d^4)$ , and is later improved by Arviv et al. [2] to  $O(n^{2/3}d^2)$ . A recent work by Biswas, Cao, Pyne, and Rubinfeld [3] presents several LCAs that receive random graphs (i.e., Erdős-Rényi or Preferential Attachment graph) as an input and gives access to a sparse spanner of that graph.

## A.2 Graph Clustering

In the Property Testing model, Czumaj et al. [6] introduce an algorithm for testing the clusterability of a graph. In the Property Testing model, an algorithm accepts (with constant probability) any graph that is  $(k, \phi)$ -clusterable and rejects graphs that are  $\varepsilon$  far from being  $(k, \phi^*)$ -clusterable, i.e.,  $\varepsilon dn$  edges are required to be either added or removed from the input graph so that it becomes  $(k, \phi^*)$ -clusterable, where  $\phi^* = O(\frac{\phi^2 \varepsilon^2}{\log n})$ . The query complexity of their algorithm is  $\tilde{O}(\sqrt{n} \cdot \text{poly}(\phi, k, 1/\varepsilon))$  and with a success probability of at least  $2/3$ . Peng [24] uses similar ideas as [6] to construct a clustering oracle that given an input graph that is  $\varepsilon$ -close from being  $(k, \phi, O(\frac{\varepsilon \phi}{k^3 \log n}))$ -clusterable gives w.h.p. query access to the adjacency list of a  $(k, \frac{\phi}{2}, O(\frac{\sqrt{\varepsilon} \phi^{1.5}}{k^3 \log n}))$ -clusterable graph with preprocessing and query complexity of  $O(\sqrt{n} \cdot \text{poly}(\frac{k \log n}{\phi \varepsilon}))$ , and with at most  $O(k \sqrt{\frac{\varepsilon}{\phi}} \cdot n)$  outliers (vertices that are not associated with any cluster).

## A.3 LCAs for Other Graph Problems

The model of *local computation algorithms* (LCA) (sometimes also referred to as The Centralized-Local model (CentLocal)) as used in this work, was defined by Rubinfeld et al. [27] (see also [1] and survey in [13]). Such algorithms for maximal independent set, hypergraph coloring,  $k$ -CNF, approximated maximum matching and approximated minimum vertex cover for bipartite graphs are given in [27, 1, 20, 21, 7, 18, 8].

## B Omitted Proofs of Section 2

**Proof of Coro. 8.** By Theorem 7, for any distribution vector  $\vec{p}$  it holds that  $\|\hat{A}^\tau \vec{p} - \vec{u}\|_1 \leq \sqrt{n} \cdot \alpha^{\frac{\log(2n^{3/2})}{\log(1/\alpha)}} = \frac{1}{2n}$ . If there exists an index  $i$  such that either  $(\hat{A}^\tau \vec{p})_i < \frac{1}{2n}$  or  $(\hat{A}^\tau \vec{p})_i > \frac{3}{2n}$  then  $|\left(\hat{A}^\tau \vec{p}\right)_i - \frac{1}{n}| > \frac{1}{2n}$ , which implies that  $\|\hat{A}^\tau \vec{p} - \vec{u}\|_1 > \frac{1}{2n}$ , in contradiction to the above Equation. ◀

Proof of Claim 11. Since  $(G)_{\text{reg}}$  is  $2d$ -regular it holds that  $\lambda_1 = 2d$ . Let  $\{\hat{\lambda}_i\}_i$  denote the eigenvalues of  $\hat{A}$  where  $\hat{A} = \frac{1}{2d} A((G)_{\text{reg}})$ . By Theorem 9, it follows that  $\hat{\lambda}_1 = 1 > \hat{\lambda}_2, \dots, \geq \hat{\lambda}_n \geq -1$ . Since  $\hat{A}_{i,j} \geq 0$  and  $\hat{A}_{j,j} \geq \frac{1}{2}$  it holds that the matrix  $M \stackrel{\text{def}}{=} 2\hat{A} - I$ , where  $I$  is the identity matrix, is non-negative. Hence,  $M$  corresponds to a weighted connected graph. Moreover, the eigenvalues of  $M$ ,  $\{\mu_i\}_i$  satisfy  $\mu_i = 2\hat{\lambda}_i - 1$ .<sup>11</sup> In particular,  $\mu_1 = 1$ . Thus, Theorem 9 applied on  $M$  implies that  $\mu_i \geq \mu_n \geq -1$  for all  $1 \leq i \leq n$ . Thus,  $2\hat{\lambda}_i - 1 \geq -1$  and hence  $\hat{\lambda}_i \geq 0$  for all  $1 \leq i \leq n$ . Since  $\lambda_i = 2d\hat{\lambda}_i$ , it follows that  $|\lambda_2| > |\lambda_n|$ . The claim follows. ◀

Proof of Claim 12. We first observe that  $\phi(G) = \phi((G)_{\text{reg}})$ . Since  $(G)_{\text{reg}}$  is  $2d$ -regular, by Cheeger's Inequality it holds that  $\lambda_2 \leq 2d \cdot \left(1 - \frac{\phi^2(G)}{2}\right)$ . Thus the claim follows from Claim 11. ◀

<sup>11</sup>To see why  $\mu_i = 2\hat{\lambda}_i - 1$ , multiply the eigenvector that corresponds to  $\hat{\lambda}_i$ ,  $\nu_i$ , by  $M$  which gives  $2\hat{\lambda}_i \nu_i - \nu_i$ .

**C** Omitted Proofs of Section 3

Proof of Claim 17. Let  $v$  be a vertex in  $G$ . By Equation (1), for any subset  $S \subseteq V$  of size at most  $|V|/2$  it holds that  $e(S, V \setminus S) \geq \phi \cdot d \cdot |S|$ . In particular, if  $S$  is the set of vertices of the  $j$ -ball centered at some vertex  $v$  then the  $j + 1$ -ball centered at  $v$  contains at least  $|S| + \phi|S| = (1 + \phi)|S|$  vertices. Thus, after exploring  $\ell$  layers of the BFS rooted at  $v$  at least one of the following holds: either we explored more than  $|V|/2$  vertices, or we explored at least  $(1 + \phi)^\ell$  vertices. Thus we explore at least  $x$  vertices for any  $\ell$  such that  $(1 + \phi)^\ell \geq x$ . The claim follows.  $\triangleleft$

# When Can an Expander Code Correct $\Omega(n)$ Errors in $O(n)$ Time?

## Abstract

---

Tanner codes are graph-based linear codes whose parity-check matrices can be characterized by a bipartite graph  $G$  together with a linear inner code  $C_0$ . Expander codes are Tanner codes whose defining bipartite graph  $G$  has good expansion property. This paper is motivated by the following natural and fundamental problem in decoding expander codes:

What are the sufficient and necessary conditions that  $\delta$  and  $d_0$  must satisfy, so that *every* bipartite expander  $G$  with vertex expansion ratio  $\delta$  and *every* linear inner code  $C_0$  with minimum distance  $d_0$  together define an expander code that corrects  $\Omega(n)$  errors in  $O(n)$  time?

For  $C_0$  being the parity-check code, the landmark work of Sipser and Spielman (IEEE-TIT'96) showed that  $\delta > 3/4$  is sufficient; later Viderman (ACM-TOCT'13) improved this to  $\delta > 2/3 - \Omega(1)$  and he also showed that  $\delta > 1/2$  is necessary. For general linear code  $C_0$ , the previously best-known result of Dowling and Gao (IEEE-TIT'18) showed that  $d_0 = \Omega(c\delta^{-2})$  is sufficient, where  $c$  is the left-degree of  $G$ .

In this paper, we give a near-optimal solution to the above question for general  $C_0$  by showing that  $\delta d_0 > 3$  is sufficient and  $\delta d_0 > 1$  is necessary, thereby also significantly improving Dowling-Gao's result. We present two novel algorithms for decoding expander codes, where the first algorithm is deterministic, and the second one is randomized and has a larger decoding radius.

## 1 Introduction

Graph-based codes are an important class of error-correcting codes that have received significant attention from both academia and industry. They have a long history in coding theory, dating back to Gallager's [19] celebrated *low-density parity-check codes* (LDPC codes for short). LDPC codes are a class of linear codes whose parity-check matrices can be characterized by low-degree (sparse) bipartite graphs, called *factor graphs*. Gallager analyzed the rate and distance of LDPC codes, showing that with high probability, randomly chosen factor graphs give rise to error-correcting codes attaining the Gilbert-Varshamov bound. He also presented an iterative algorithm to decode these codes from errors caused by a binary symmetric channel. Since the 1990s, LDPC codes have received increased attention due to their practical and theoretical performance (see [12, 14, 22, 35, 38, 42, 43]).

As a generalization of the LDPC codes, Tanner [49] introduced the so-called *Tanner codes*, as formally defined below. Let  $c, d, n$  be positive integers and  $L := [n]$ , where  $[n] = \{1, \dots, n\}$ . Given a  $(c, d)$ -regular bipartite graph  $G$  with bipartition  $V(G) = L \cup R$  and a  $[d, k_0, d_0]$ -linear code  $C_0$ <sup>1</sup>, the *Tanner code*  $T(G, C_0) \subseteq \mathbb{F}_2^n$  is the collection of all binary vectors  $x \in \mathbb{F}_2^n$  with the following property: for every vertex  $u \in R$ ,  $x_{N(u)}$  is a codeword of the inner code  $C_0$ , where  $N(u) \subseteq L$  is the set of neighbors of  $u$  and  $x_{N(u)} = (x_v : v \in N(u)) \in \mathbb{F}_2^d$  denotes the length- $d$  subvector of  $x$  with coordinates restricted to  $N(u)$ ; in other words,  $T(G, C_0) := \{x \in \mathbb{F}_2^n : x_{N(u)} \in C_0 \text{ for every } u \in R\}$ .

*Expander codes* are Tanner codes whose defining bipartite graphs have good expansion properties, namely, they are *bipartite expanders*. To be precise, for real numbers  $\alpha, \delta \in (0, 1]$ , a  $(c, d)$ -regular bipartite graph  $G$  with bipartition  $V(G) = L \cup R$  with  $L = [n]$  is called a  $(c, d, \alpha, \delta)$ -*bipartite expander* if for each subset  $S \subseteq L$  with  $|S| \leq \alpha n$ ,  $S$  has at least  $\delta c|S|$  neighbors in  $R$ , i.e.,  $|N(S)| := |\cup_{v \in S} N(v)| \geq \delta c|S|$ . As each  $S \subseteq L$  can have at most  $c|S|$  neighbors in  $R$ , being a  $(c, d, \alpha, \delta)$ -bipartite expander means that every bounded size subset in  $L$  has as many neighbors in  $R$  as possible, up to a constant factor.

Sipser and Spielman [46] studied the Tanner code  $T(G, C_0)$  with  $G$  being a bipartite expander and  $C_0$  being a parity-check code. For simplicity, let  $Par = \{(x_1, \dots, x_d) : \sum_{i=1}^d x_i = 0\}$  denote the parity-check code in  $\mathbb{F}_2^d$ . They remarkably showed that the expansion property of  $G$  can be used to analyze the minimum distance and the decoding complexity of  $T(G, Par)$ . Roughly speaking, they showed that for every bipartite expander  $G$  with sufficiently large *expansion ratio*  $\delta > 1/2$ ,  $T(G, Par)$  has minimum distance at least  $\alpha n$ , which further implies that  $T(G, Par)$  defines a class of *asymptotically good* codes. More surprisingly, they showed that if the expansion ratio is even larger, say  $\delta > 3/4$ , then for every such  $G$ ,  $T(G, Par)$  admits a linear-time decoding algorithm that corrects a linear number of errors in the adversarial noise model. Spielman [48] showed that expander codes can be used to construct asymptotically good codes that can be encoded and decoded both in linear time.

Besides the construction based on vertex expansion, [48] also provides a construction based on spectral expansion. This construction again inherits the general structure of Tanner code, i.e., it combines of an underlying bipartite graph and an inner code. The main difference is that the underlying graph is an edge-vertex incidence graph of a (non-bipartite) spectral expander. Spectral expander codes also have linear time encoding and decoding, and their (rate & distance) parameters are different from those of vertex expander codes. In this paper, we mainly focus on vertex expander codes. The reader is referred to references [5, 26, 34, 36, 37, 41, 47, 52, 53] for more details on spectral expanders.

<sup>1</sup> The reader is referred to Section 1.2 for basic definitions on graphs and codes.

Given the strong performance of expander codes, they have been of particular interest in both coding theory and theoretical computer science, and have been studied extensively throughout the years. For example, [23, 45] utilized expander codes to obtain near MDS codes with linear-time decoding. A line of research [2, 9, 16, 18, 44, 50, 51, 52] improved the distance analysis and decoding algorithm for expander codes in various settings. Very recently, a sequence of works applied expander codes on quantum LDPC and quantum Tanner code construction, finally achieving asymptotically good constructions and linear-time decoding [6, 7, 15, 17, 21, 24, 27, 29, 30, 31, 32, 33, 39, 40].

Given the discussion above, it is natural to suspect that the expansion ratio  $\delta$  plays a prominent role in analyzing the properties of  $T(G, Par)$ . More precisely, one can formalize the following question. We always assume  $c, d, \alpha, \delta$  are constants while  $n$  tends to infinity.

► **Question 1.** *What is the minimum  $\delta > 0$  such that every  $(c, d, \alpha, \delta)$ -bipartite expander  $G$  with  $V(G) = L \cup R$  and  $|L| = n$  defines an expander code  $T(G, Par) \subseteq \mathbb{F}_2^n$  that corrects  $\Omega_{c,d,\alpha,\delta}(n)$  errors in  $O_{c,d,\alpha,\delta}(n)$  time?*

This question has already attracted considerable attention. Sipser and Spielman [46] used the bit-flipping algorithm (developed on the original algorithm of Gallager [19]) to show that  $\delta > 3/4$  is sufficient to correct  $(2\delta - 1)\alpha n$  errors in  $O(n)$  time. Using linear programming decoding, Feldman, Malkin, Servedio, Stein and Wainwright [18] showed that  $\delta > \frac{2}{3} + \frac{1}{3c}$  sufficient to correct  $\frac{3\delta-2}{2\delta-1}\alpha \cdot n$  errors, while at the cost of a poly( $n$ ) decoding time. Viderman [50] introduced the “Find Erasures and Decode” algorithm to show that  $\delta > \frac{2}{3} - \frac{1}{6c}$  is sufficient to correct  $\Omega(n)$  errors in  $O(n)$  time. Moreover, he also shows that there exists a  $(c, d, \alpha, 1/2)$ -bipartite expander  $G$  such that  $T(G, Par)$  only has minimum distance two, and therefore cannot correct even one error. Viderman’s impossibility result implies that  $\delta > 1/2$  is necessary for the assertion of Question 1 holding for *every*  $(c, d, \alpha, \delta)$ -bipartite expander.

The above results only consider the case where the inner code  $C_0$  is a parity-check code. Therefore, it is tempting to think about whether one can benefit from a stronger inner code  $C_0$ . Let us call a code *good* if it can correct  $\Omega(n)$  errors in  $O(n)$  time. Chilappagari, Nguyen, Vasic and Marcellin [11] showed that if  $G$  has expansion ratio  $\delta > 1/2$  and  $C_0$  has minimum distance  $d(C_0) \geq \max\{\frac{2}{2\delta-1} - 3, 2\}$ , then every such Tanner code  $T(G, C_0)$  is good. The above result implies that for  $\epsilon \rightarrow 0$  and  $\delta = 1/2 + \epsilon$ ,  $d(C_0) = \Omega(\epsilon^{-1})$  is sufficient to make every Tanner code  $T(G, C_0)$  good. Very recently, Dowling and Gao [16] significantly relaxed the requirement on  $\delta$  by showing that for every  $\delta > 0$ ,

$$d(C_0) \geq \Omega(c\delta^{-2}) \tag{1}$$

is sufficient<sup>2</sup> to make every Tanner code  $T(G, C_0)$  good, and be able to correct  $\alpha n$  errors. In particular, their result implies that, as long as the minimum distance of  $C_0$  is large enough, any tiny positive expansion ratio is sufficient to construct a good Tanner code.

Putting everything together, it is interesting to understand how the expansion ratio  $\delta$  of  $G$  and the minimum distance  $d_0$  of  $C_0$  affect the goodness of the Tanner code. We have the following generalized version of Question 1.

► **Question 2.** *What are the sufficient and necessary conditions that  $\delta$  and  $d_0$  must satisfy, so that every  $(c, d, \alpha, \delta)$ -bipartite expander  $G$  with  $V(G) = L \cup R$ ,  $|L| = n$ , and every inner linear code  $C_0 \subseteq \mathbb{F}_2^d$  with  $d(C_0) \geq d_0$ , together define an expander code  $T(G, C_0) \subseteq \mathbb{F}_2^n$  that corrects  $\Omega_{c,d,\alpha,\delta}(n)$  errors in  $O_{c,d,\alpha,\delta}(n)$  time?*

<sup>2</sup> More precisely,  $d(C_0) \geq 2t + c(t-1)^2 - 1$  with  $t > \frac{1}{\delta}$ .

The main purpose of this paper is to provide a near-optimal solution to the above question, as presented in the next subsection. On the negative side, we show that when  $d_0\delta \leq 1$ , there exists an extension of Videman's construction, yielding expander codes of constant distance (see Proposition 4 below). Therefore,  $d_0\delta > 1$  is a necessary condition for a general expander code  $T(G, C_0)$  to be considered good (compared to the  $\delta > \frac{1}{2}$  condition in the case of  $T(G, Par)$ ). On the positive side, we show that  $d_0\delta > 3$  is sufficient to make every expander code good (see Theorem 3 below for details). Our result only loses a multiplicity by three compared to the above necessary result.

## 1.1 Main results

### Deterministic decoding of expander codes

Our main result, which significantly improves on (1), is presented as follows.

► **Theorem 3.** *Let  $G$  be a  $(c, d, \alpha, \delta)$ -bipartite expander and  $C_0$  be a  $[d, k_0, d_0]$ -linear code, where  $c, d, \alpha, \delta, d_0, k_0$  are positive constants. If  $\delta d_0 > 3$ , then there exists a linear-time decoding algorithm for the Tanner code  $T(G, C_0)$  that can correct  $\gamma n$  errors, where  $\gamma = \frac{2\alpha}{d_0(1+0.5c\delta)}$ .*

Theorem 3 shows that  $\delta d_0 > 3$  is sufficient to make every Tanner code  $T(G, C_0)$  good. On the other hand, the next proposition shows that for every  $d_0 \geq 2$ ,  $\delta d_0 > 1$  is necessary.

► **Proposition 4.** *For every  $d, d_0 \geq 2$  and  $n \geq 10d_0$ , there exist constants  $0 < \alpha < 1, c \geq 3$  and a  $(c, d, 0.9\alpha, \frac{1}{d_0})$ -bipartite expander  $G$  with  $V(G) = L \cup R$  and  $|L| = n$  such that for every  $[d, k_0, d_0]$ -linear code  $C_0$ ,  $T(G, C_0)$  has minimum Hamming distance at most  $d_0$ .*

Theorem 3 and Proposition 4 together show that our requirement  $\delta d_0 = \Omega(1)$  is in fact almost optimal for Question 2. Moreover, we have the following conjecture on the fundamental trade-off between  $\delta$  and  $d_0$ .

► **Conjecture 5.** *If  $\delta d_0 > 1$ , then for every  $(c, d, \alpha, \delta)$ -bipartite expander  $G$  and every inner code  $C_0 \subseteq \mathbb{F}_2^d$  with  $d(C_0) \geq d_0$ , the expander code  $T(G, C_0) \subseteq \mathbb{F}_2^n$  can correct  $\Omega_{c,d,\alpha,\delta}(n)$  errors in  $O_{c,d,\alpha,\delta}(n)$  time.*

Due to space limit, we will omit the proof of the linear-running time of our algorithm, as well as the proof of Proposition 4. They can be found in the full version of this paper [10].

### Randomized decoding of expander codes

Another important direction in the study of expander codes is to understand the maximum number of errors that can be corrected in a linear-time decoding algorithm. Chen, Cheng, Li, and Ouyang [9] obtained a quite satisfactory answer to this problem for  $T(G, Par)$ . They showed that for every  $\delta > 1/2$  and  $(c, d, \alpha, \delta)$ -bipartite expander  $G$ ,  $T(G, Par)$  has minimum distance at least  $\frac{\alpha}{2(1-\delta)} \cdot n - O(1)$ , and this is tight up to a  $1 - o(1)$  factor. Moreover, for  $\delta > \frac{3}{4}$ , they also gave a linear-time decoding algorithm which corrects  $\frac{3\alpha}{16(1-\delta)} \cdot n$  errors. A similar problem for general expander codes  $T(G, C_0)$  was studied by [16].

Our decoding algorithm for Theorem 3 is deterministic and corrects  $\gamma n$  errors in linear time. Theorem 6 shows that one can correct more errors by using a randomized algorithm.

► **Theorem 6.** *Let  $G$  be a  $(c, d, \alpha, \delta)$ -bipartite expander and  $C_0$  be a  $[d, k_0, d_0]$ -linear code, where  $c, d, \alpha, \delta, d_0, k_0$  are positive constants. If  $\delta d_0 > 3$ , then there exists a linear-time randomized decoding algorithm for Tanner code  $T(G, C_0)$  such that if the input has at most  $\alpha n$  errors from a codeword, then with probability  $1 - \exp\{-\Theta_{c,\delta,d_0}(n)\}$ , the decoding algorithm can output the correct codeword.*

## 1.2 Notations and definitions

A graph is a pair  $G = (V, E)$ , where  $V$  is a set whose elements are called vertices and  $E$  is a set of 2-subsets of  $V$ , whose elements are called edges. For a vertex  $u \in V$ , the set of *neighbors* of  $u$  in  $G$  is denoted by  $N(u) := \{v \in V : \{u, v\} \in E\}$ . For a subset  $S \subseteq V(G)$ , let  $N(S) = \cup_{u \in S} N(u)$  be the set of all the neighbors of the vertices in  $S$ . A graph  $G$  is *bipartite* if  $V(G)$  admits a bipartition  $V(G) = L \cup R$  such that both  $L$  and  $R$  contain no edge. Furthermore,  $G$  is  $(c, d)$ -regular if every vertex  $v \in L$  has exactly  $c$  neighbors in  $R$  and every vertex  $u \in R$  has exactly  $d$  neighbors in  $L$ .

Let  $\mathbb{F}_2 = \{0, 1\}$  denote the finite field of size 2. A code  $C$  is simply a subset of  $\mathbb{F}_2^n$ . For two vectors  $x = (x_1, \dots, x_n)$ ,  $y = (y_1, \dots, y_n) \in \mathbb{F}_2^n$ , the *Hamming distance* between  $x$  and  $y$ , denoted by  $d_H(x, y)$ , is the number of coordinates where  $x$  and  $y$  differ, that is,  $d_H(x, y) = |\{i \in [n] : x_i \neq y_i\}|$ . The *minimum distance* of a code  $C \subseteq \mathbb{F}_2^n$ , denoted by  $d(C)$ , is the minimum of  $d_H(x, y)$  among all distinct  $x, y \in C$ . Let  $\text{wt}(x)$  denote the number of nonzero coordinates of  $x$ . A code  $C \subseteq \mathbb{F}_2^n$  is said to be an  $[n, k, d(C)]$ -linear code if it is a linear subspace in  $\mathbb{F}_2^n$  with dimension  $k$  and minimum distance  $d(C)$ . It is well-known that for every linear code  $C$ ,  $d(C) = \min\{\text{wt}(x) : x \in C \setminus \{0\}\}$ .

Throughout, let  $G$  be a  $(c, d, \alpha, \delta)$ -bipartite expander, and  $C_0$  be a  $[d, k_0, d_0]$  linear code. Let  $T(G, C_0)$  be the Tanner code defined by  $G$  and  $C_0$ . Let *Check* be the error-detection algorithm of  $C_0$ , which checks whether a vector in  $\mathbb{F}_2^d$  is a codeword of  $C_0$ . Assume that *Check* takes  $h_0$  time. Similarly, let *Decode* be the correct-correction algorithm for  $C_0$ , which corrects up to  $\lfloor \frac{d_0-1}{2} \rfloor$  errors. Assume that *Decode* takes  $t_0$  time. Note that  $h_0, t_0$  are constants depending only on  $C_0$  but not on  $n$ .

Conventionally speaking, let us call the vertices in  $L$  *variables* and the vertices in  $R$  *constraints*. Given a vector  $x \in \mathbb{F}_2^n$ , which is corrupted from some codeword  $y \in T(G, C_0)$ , let us call a constraint  $u \in R$  *satisfied* if  $x_{N(u)} \in C_0$ , otherwise call it *unsatisfied*.

## 1.3 Some related works

Below, we briefly review two previous works [16, 46] that are closely related to our decoding algorithms for Theorems 3 and 6. Let us start from the decoding algorithm of Sipser and Spielman [46]. We summarize as follows the so-called iterated decoding or message-passing algorithm of [46] that decodes  $T(G, Par)$ .

- Let  $y \in T(G, Par)$  be the correct codeword that we want to decode from the received vector  $x$ . In the first round, the algorithm runs  $\text{Check}(x_{N(u)})$  for every  $u \in R$ . If a constraint  $u$  is unsatisfied, then it sends a “flip” message to every variable in  $N(u) \subseteq L$ . Sipser and Spielman showed that as long as the expansion ratio of  $G$  is sufficiently large ( $\delta > 3/4$ ) and the number of corruptions in  $x$  is sufficiently small but not identically zero (that is,  $1 \leq d_H(x, y) \leq (2\delta - 1)\alpha \cdot n$ ), then there must exist a variable  $v \in L$  that receives  $> c/2$  flip messages, which implies that more than half constraints in  $N(v)$  are unsatisfied. The algorithm then flips  $x_v$  and updates  $x$  and the status of the constraints in  $N(v)$ . Note that since  $Par$  is the parity-check code, flipping  $x_v$  makes all satisfied constraints in  $N(v)$  unsatisfied and all unsatisfied constraints in  $N(v)$  satisfied. Therefore, by flipping  $x_v$  one can strictly reduce the number of unsatisfied constraints.
- The algorithm then runs the above process repeatedly. As long as there are still unsatisfied constraints, it finds the desired  $v \in L$  so that flipping  $x_v$  strictly reduces the number of unsatisfied constraints. As there are at most  $|R| = cn/d$  unsatisfied constraints, the above process must stop in  $O(n)$  rounds and therefore yields an  $O(n)$  time decoding algorithm.

Dowling and Gao [16] extend Sipser and Spielman’s algorithm from  $T(G, Par)$  to the more general setting  $T(G, C_0)$  by making use of the minimum distance of  $C_0$ . Their algorithm works for linear codes defined on any finite field, but we will describe it only for  $\mathbb{F}_2$ .

- The algorithm begins by setting a threshold  $t \leq \lfloor \frac{d_0-1}{2} \rfloor$  and then runs  $\text{Decode}(x_{N(u)})$  for every  $u \in R$ . If a constraint  $u \in R$  satisfies  $1 \leq d_H(\text{Decode}(x_{N(u)}), x_{N(u)}) \leq t-1$ , then it sends a “flip” message to every variable  $v \in N(u)$  with  $\text{Decode}(x_{N(u)})_v \neq x_v$ . Note that  $\text{Decode}(x_{N(u)}) \in \mathbb{F}_2^d$  is a codeword in  $C_0$ . The algorithm then flips all  $x_v$  for those  $v$  receiving at least one flip, and then updates  $x$ . [16] showed that as long as the minimum distance  $d_0$  of  $C_0$  is sufficiently large (see (1)), then flipping all variables that receive at least one flip can reduce the number of corrupted variables in  $x$  by some positive fraction.
- In the next steps, the algorithm runs the above process repeatedly. As the number of corrupted variables is at most  $O(n)$ , the algorithm will stop in  $O(\log n)$  rounds. Crucially, in order to show that the running time of the algorithm is still linear-order but not of order  $n \log n$ , the authors proved that the running time of every single round is within a constant factor of the number of corrupted variables at the beginning of this round. As the numbers of corrupted variables form a decreasing geometric sequence with the leading term at most  $n$ , the total running time, which is within a constant factor of the sum of this geometric sequence, is also  $O(n)$ .

Lastly, it is worth mentioning that there are several very recent works on the explicit constructions of bipartite graphs with good vertex expansion properties, including the lossless expanders [8, 13, 20] and the unique-neighbor expanders [1, 3, 4, 25, 28].

#### 1.4 Key new ideas in our work

In this subsection, we briefly introduce the key new ideas in our work. Let us focus on the deterministic decoding algorithm that proves Theorem 3. Let us begin by analyzing the following two possible places where the previous algorithm in [16] could be improved.

In every decoding round of the above algorithm, the constraints in  $R$  which satisfy  $1 \leq d_H(\text{Decode}(x_{N(u)}), x_{N(u)}) \leq t-1$  (and hence send at least one and at most  $t-1$  flips to  $L$ ) in fact have two statuses, as detailed below. Let  $A$  be the set of constraints  $u \in R$  that sends at least one flip and  $\text{Decode}(x_{N(u)})$  computes the correct codeword in  $C_0$  (i.e.,  $\text{Decode}(x_{N(u)}) = y_{N(u)}$ ); let  $B$  be the set of constraints  $u \in R$  that sends at least one flip and  $\text{Decode}(x_{N(u)})$  computes an incorrect codeword in  $C_0$  (i.e.,  $\text{Decode}(x_{N(u)}) \neq y_{N(u)}$ ).

##### Two possible places where the previous algorithm could be improved

- (i) It could be the case that every constraint  $u \in A$  satisfies  $d_H(\text{Decode}(x_{N(u)}), x_{N(u)}) = 1$  and hence sends only one correct flip to  $L$ ; in the meanwhile, every constraint  $u \in B$  may satisfy  $d_H(\text{Decode}(x_{N(u)}), x_{N(u)}) = t-1$  and sends as many as  $t-1$  flips to  $L$ , which could be all wrong. In this case, the constraints in  $R$  altogether send  $|A|$  correct flips and  $(t-1)|B|$  wrong flips to the variables in  $L$ .
- (ii) Unfortunately, the situation could be worse. Since our bipartite graph  $G$  is  $(c, d)$ -regular, it could be the case that the neighbors of the constraints in  $A$  are highly concentrated (e.g., all  $|A|$  correct flips are received by as few as  $|A|/c$  variables in  $L$ ), and the neighbors of the constraints in  $B$  are highly dispersed (e.g., all  $(t-1)|B|$  possibly wrong flips are received by as many as  $(t-1)|B|$  variables in  $L$ ). Consequently, a small number of corrupted variables but a large number of correct variables in  $L$  receive flip messages.

Given the two issues above, if we flip all variables that receive at least one flip, then in the worst case, we could correct  $|A|/c$  old corrupt variables but produce  $(t-1)|B|$  new corrupt variables. Recall that to make the algorithm in [16] work, in each round, we need

to reduce the number of corrupted variables by at least a positive fraction, which implies that in the worst case it is necessary to have  $|A|/c \geq (t-1)|B|$ . Together with some lower bound on  $|A|$  and upper bound on  $|B|$  (see [16] for details), one can prove that in such worst scenario (1) is necessary for Dowling and Gao's algorithm to work.

Our new algorithm begins by noting that we could indeed fix the two problems mentioned above. To do so, we introduce several new ideas as briefly presented below.

### Key new ideas in our work

Let  $F := \{i \in [n] : x_i \neq y_i\}$  be the set of corrupt variables in  $x$ . Similarly to [16], our new algorithm begins by setting a threshold  $t = \lfloor \frac{1}{\delta} \rfloor$  and then runs  $\text{Decode}(x_{N(u)})$  for every  $u \in R$ .

- (a) To fix the first problem, if a constraint  $u \in R$  satisfies  $1 \leq d_H(\text{Decode}(x_{N(u)}), x_{N(u)}) \leq t-1$ , then instead of sending a flip message to every  $v \in N(u)$  with  $\text{Decode}(x_{N(u)})_v \neq x_v$ , the new algorithm just arbitrarily picks *exactly one* such variable  $v$ , and sends a flip message to *only* this specific  $v$ . So, every constraint in  $A \cup B$  sends exactly one flip to  $L$ .
- (b) To fix the second problem, we associate each  $v \in L$  with a counter  $\tau_v \in \{0, 1, \dots, c\}$  that counts the number of flips received by  $v$ . For each  $m \in [c]$ , let  $S_m$  denote the set of variables that receive exactly  $m$  flips. Then, instead of flipping every variable that receives at least one flip, i.e., instead of flipping  $\cup_{m=1}^c S_m$ , we only flip  $S_m$  for some  $m \in [c]$ . Crucially, we show that if the number  $|F|$  of corrupt variables is not too large, then there must *exist* some  $m \in [c]$  such that  $|S_m|$  has the same order as  $|F|$ , and more importantly, a  $(1/2 + \kappa)$ -fraction of variables in  $|S_m|$  are corrupted (and therefore can be corrected by the flipping operation), where  $\kappa$  is an absolute positive constant. Therefore, it follows that by flipping all variables in  $S_m$ , one can reduce  $|F|$  by some positive fraction.

Note that the details of (a) and (b) can be found in Section 3.2, where we call the algorithm corresponding to (a) and (b) “EasyFlip” and write  $\text{EasyFlip}(x, m)$  as the output of the EasyFlip if  $x$  is the input vector and  $S_m$  is flipped (see Algorithm 2).

However, there is still a gap that needs to be fixed, that is, how to find the required  $S_m$ ? A plausible solution is to run  $\text{EasyFlip}(x, m)$  for every  $m \in [c]$ . This would roughly increase the total running time by a  $c$  factor, which will still be  $O(n)$ , provided that the original running time is  $O(n)$ . Unfortunately, by doing so we still cannot *precisely* identify the required  $S_m$ , as in general we do not know how to count the number of corrupted variables in some corrupted vector. We will fix this issue by introducing our third key new idea:

- (c) Note that what we can explicitly count in each round of the algorithm is the number of unsatisfied constraints. Roughly speaking, our strategy is to run EasyFlip iteratively for a large but still constant number of times and then pick the final output that significantly reduces the number of unsatisfied constraints.

More precisely, assume that we will run EasyFlip iteratively for  $s$  rounds. Let  $x^0 := x$  and write  $x^1 := \text{EasyFlip}(x^0, m_1)$  as the output of the 1st EasyFlip invocation where the variables in  $S_{m_1}$  are flipped for some  $m_1 \in [c]$ ; more generally, for  $k \in [s]$ , write  $x^k := \text{EasyFlip}(x^{k-1}, m_k)$  as the output of the  $k$ th EasyFlip invocation where the variables in  $S_{m_k}$  is flipped for some  $m_k \in [c]$ . Note that in Algorithm 3 we call the above iterated invocations of EasyFlip as “DeepFlip”, and write  $x^k := \text{DeepFlip}(x, (m_1, \dots, m_k))$  as the output of the  $k$ th EasyFlip invocation. For  $0 \leq k \leq s$ , let  $F^k \subseteq L$  and  $U^k \subseteq R$  denote the sets of corrupted variables and unsatisfied constraints caused by  $x^k$ , respectively. We prove that there are constants  $0 < \epsilon \ll \epsilon' \ll \epsilon'' < 1$  such that the following two wordy but useful observations hold:

- (c1) If the number of corrupted variables is reduced *dramatically* then the number of unsatisfied constraints is reduced *significantly*, i.e., if for some  $k \in [s]$ ,  $|F^k| \leq \epsilon|F^0|$ , then  $|U^k| \leq \epsilon'|U|$ ;
- (c2) If the number of unsatisfied constraints is reduced *significantly*, then the number of corrupted variables must be reduced by a least a constant fraction i.e., if for some  $k \in [s]$ ,  $|U^k| \leq \epsilon'|U^0|$ , then  $|F^k| \leq \epsilon''|F|$ .

In the following, we will briefly argue how we will make use of the two observations (c1) and (c2). Recall that in (b) we have essentially guaranteed that for every  $k \in [s]$ , there exists some  $m_k^* \in [c]$  such that by flipping  $S_{m_k^*}$  in EasyFlip, one could reduce the number of corrupted variables by an  $\eta$ -fraction for some  $\eta \in (0, 1)$ . It follows that if we run DeepFlip iteratively for  $(m_1, \dots, m_s) = (m_1^*, \dots, m_s^*)$ , then we have  $|F^s| \leq (1 - \eta)^s |F| < \epsilon|F|$ , provided that  $s > \log_{(1-\eta)^{-1}} \epsilon^{-1}$  is sufficiently large (but still a constant independent of  $n$ ). Therefore, if we run DeepFlip thoroughly for all  $(m_1, \dots, m_s) \in [c]^s$ , then by (c1) there must exist at least one<sup>3</sup>  $x^k := \text{DeepFlip}(x, (m_1, \dots, m_k))$  with  $k \leq s$  such that  $|U^k| \leq \epsilon'|U|$ . Moreover, using the last inequality, such  $x^k$  and  $(m_1, \dots, m_k)$  can be explicitly identified. Now, by (c2) we can conclude that the number of corrupted variables is indeed reduced by at least a constant fraction.

Note that the above brute-force search only increases the total running time by at most a  $c^s$  factor. The details of (c) and the analysis of DeepFlip can be found in Section 3.3 and Algorithm 3. Moreover, we call the algorithm that runs  $\text{DeepFlip}(x, (m_1, \dots, m_s))$  thoroughly for all  $(m_1, \dots, m_s) \in [c]^s$  as “HardSearch”, and is discussed in Section 3.4 and Algorithm 4. The discussion above basically shows that every HardSearch invocation could reduce the number of corrupted variables by a constant fraction.

Running HardSearch iteratively for  $O(\log n)$  rounds, the total number of corrupted variables will be smaller than  $\lfloor \frac{d_0-1}{2} \rfloor$ , which can be easily corrected by running Decode for every  $u \in R$ . The main algorithm that puts everything together is called “MainDecode”, and is presented in Section 3.1 and Algorithm 1.

To show that the total running time is still linear in  $n$ , we adopt an argument similar to that in the previous works (e.g., [16]). We show that the running time of every HardSearch invocation is within a constant factor of the number of corrupted variables at the beginning of this invocation.

Lastly, we would like to mention that our randomized decoding algorithm (see Algorithm 5), which proves Theorem 6 and has a larger decoding radius than the deterministic algorithm, basically follows from the same framework mentioned above. Loosely speaking, the high-level idea of the randomized algorithm is to reduce the number of corruptions to a moderate size that can be handled by the deterministic algorithm. For that purpose, we design a random flip strategy which can be summarized as follows.

Recall that for every  $m \in [c]$ ,  $S_m$  denotes the set of all variables that receive exactly  $m$  flips. First, for every constraint  $u \in R$  satisfying  $1 \leq d_H(\text{Decode}(x_{N(u)}), x_{N(u)}) \leq t$ , we arbitrarily pick exactly one variable  $v \in N(u)$  with  $\text{Decode}(x_{N(u)})_v \neq x_v$  and send a flip message to this specific  $v$ . Then, we collect all suspect variables that receive at least one flip. Subsequently, we design a random sampling procedure to select a subset of  $\cup_{m \in [c]} S_m$  to flip. We show that this procedure can ensure, with high probability, that this subset has more corrupted variables than correct variables, as long as the total number of corruptions is at most  $\alpha n$ . By applying this strategy iteratively, we can show that in each iteration, the number of corruptions will be reduced by a positive fraction. Then, after running a

<sup>3</sup> Clearly,  $\text{DeepFlip}(x, (m_1^*, \dots, m_s^*))$  gives a candidate for such  $x^k$ .

constant number of iterations, the number of corrupted bits can be reduced to a range that the deterministic algorithm can handle. At this point, the deterministic algorithm is invoked to correct all remaining corrupted variables. Moreover, as  $n$  increases, the fail probability of each iteration tends to 0. So the overall random algorithm will succeed with high probability.

## 2 An auxiliary lemma

Given two subsets  $S, T \subseteq V(G)$ , let  $E(S, T)$  denote the set of edges with one endpoint in  $S$  and another endpoint in  $T$ . For every positive integer  $t$ , let

- $N_{\leq t}(S) = \{u \in V(G) : 1 \leq |N(u) \cap S| \leq t\}$ ,
- $N_t(S) = \{u \in V(G) : |N(u) \cap S| = t\}$ ,
- and  $N_{\geq t}(S) = \{u \in V(G) : |N(u) \cap S| \geq t\}$ .

We will make use of the following crucial property of bipartite expander graphs.

► **Proposition 7 (Folklore).** *Let  $G$  be a  $(c, d, \alpha, \delta)$ -bipartite expander. Then, for every set  $S \subseteq L$  with  $|S| \leq \alpha n$  and every integer  $t \in [d]$ , we have that  $|N_{\leq t}(S)| \geq \frac{\delta(t+1)-1}{t} \cdot c|S|$ .*

## 3 Deterministic decoding: Decoding $\Omega(n)$ corruptions in $O(n)$ time

We need to set some parameters. Suppose that  $d_0 > \frac{3}{\delta} - 1$ . Let  $t = \lfloor \frac{1}{\delta} \rfloor$ . Take  $\epsilon_0 > 0$  such that  $d_0 > \frac{3}{\delta} - 1 + 2\epsilon_0$  and  $\lfloor \frac{1}{\delta} + \epsilon_0 \rfloor = \lfloor \frac{1}{\delta} \rfloor$ . For every  $0 < \epsilon_1 < \frac{\epsilon_0 \delta^2}{100}$ , let  $\epsilon_2 = \frac{\epsilon_1}{c+1} \cdot \frac{\delta(t+1)-1}{t} > 0$  and  $\epsilon_3 = \epsilon_2 \left( 2(1 - \epsilon_1) \left( \frac{1}{2} + \frac{\epsilon_0 \delta^2}{2} \right) - 1 \right) > 0$ . It is not hard to check that  $\epsilon_1, \epsilon_2$  and  $\epsilon_3$  are all well-defined. Lastly, let  $\epsilon_4 = \frac{\delta d_0 - 1}{d_0 - 1} \cdot (1 - \epsilon_3)$ ,  $\ell = \left\lceil \log_{1-\epsilon_3} \left( \lfloor \frac{d_0-1}{2} \rfloor \frac{1}{\gamma n} \right) \right\rceil$  and  $s_0 = \left\lceil \log_{1-\epsilon_3} \left( \epsilon_4 \frac{\delta d_0 - 1}{d_0 - 1} \right) \right\rceil$ .

### 3.1 The main decoding algorithm – MainDecode

Given a corrupt vector  $x \in \mathbb{F}_2^n$  with at most  $\gamma n$  corruptions, our main decoding algorithm (see Algorithm 1 below) works as follows. The algorithm is divided into two parts. In the first part (see steps 2-10 below), it invokes `HardSearch` (see Algorithm 4 below) recursively for  $\ell$  rounds, where in every round the number of corrupt variables is reduced by a  $(1 - \epsilon_3)$ -fraction. After  $\ell$  executions of `HardSearch`, the number of corrupt variables is reduced to at most  $\lfloor \frac{d_0-1}{2} \rfloor$ . Then, in the second part of the algorithm (see steps 11-13 below), the decoder of the inner code  $C_0$  is applied to finish decoding.

The next two lemmas justify the correctness and the linear running time of `MainDecode`.

► **Lemma 8.**

- (i) *Let  $x$  be the input vector of `HardSearch` and let  $F$  be the set of corrupt variables of  $x$ . Let  $x' := \text{HardSearch}(x)$  and  $F'$  be the set of corrupt variables of  $x'$ . If  $|F| \leq \gamma n$ , then  $|F'| \leq (1 - \epsilon_3) \cdot |F|$ .*
- (ii) *In step 11 of `MainDecode`, the number of corrupt variables in  $x^\ell$  is at most  $\lfloor \frac{d_0-1}{2} \rfloor$ .*

► **Lemma 9.**

- (i) *Let  $x$  be the input vector of `HardSearch` and let  $F$  be the set of corrupt variables of  $x$ . If  $|F| \leq \gamma n$ , then the running time of `HardSearch` is at most  $O(n + |F|)$ .*
- (ii) *Furthermore, if the number of corrupt variables in the input vector of `MainDecode` is at most  $\gamma n$ , then the running time of `MainDecode` is  $O(n)$ .*

## 61:10 When Can an Expander Code Correct $\Omega(n)$ Errors in $O(n)$ Time?

■ **Algorithm 1** Main decoding algorithm for expander codes – MainDecode.

---

**Input:**  $G, C_0, x \in \mathbb{F}_2^n$   
**Output:**  $x' \in \mathbb{F}_2^n$

- 1 Set  $i = 1$  and  $x^0 = x$ ;
- 2 **for**  $1 \leq i \leq \ell$  **do**
- 3      $U^{i-1} \leftarrow \{u \in R : x_{N(u)}^{i-1} \notin C_0\}$ ;
- 4     **if**  $|U^{i-1}| = 0$  **then**
- 5         return  $x' \leftarrow x^{i-1}$ ;
- 6     **else**
- 7          $x^i \leftarrow \text{HardSearch}(x^{i-1})$ ;
- 8          $i \leftarrow i + 1$  ;
- 9     **end**
- 10 **end**
- 11 **for every**  $u \in R$  **such that**  $x_{N(u)}^\ell \notin C_0$  **do**

- 13 **end**
- 14 return  $x' \leftarrow x^\ell$ ;

---

**Proof of Theorem 3.** Let  $y \in T(G, C_0)$  be a codeword and  $x \in \mathbb{F}_2^n$  be a corrupted vector. Let  $F = \{i \in [n] : x_i \neq y_i\}$  be the set of corrupt variables of  $x$  with respect to  $y$ . To prove the theorem, it suffices to show that as long as  $|F| \leq \gamma n$ , MainDecode finds  $y$  correctly in linear time. We will analyze the following two cases:

- If the algorithm returns  $x^i$  for some  $0 \leq i \leq \ell - 1$ , then as  $|U^i| = 0$ , we must have  $x^i \in T(G, C_0)$ . Let  $F^i$  be the set of the corrupt variables of  $x^i$ . Then it follows by Lemma 8 (i) that  $d(x^i, y) = |F^i| \leq (1 - \epsilon_3)^i |F| \leq (1 - \epsilon_3)^i \gamma n < d(T(G, C_0))$ , which implies that  $x^i = y$ .
- If the algorithm does not return  $x^i$  for any  $0 \leq i \leq \ell - 1$ , then it follows by Lemma 8 (ii) that  $d(x^\ell, y) \leq \lfloor \frac{d_0 - 1}{2} \rfloor$ . Therefore, one can find  $y$  by running Decode for every  $u \in R$ .

Moreover, by Lemma 9 the running time of MainDecode is  $O(n)$ . ◀

The remaining part of this section is organized as follows. In Section 3.2 below, we will introduce the basic building block of deterministic decoding – EasyFlip, which also corresponds to items (a) and (b) in Section 1.4. In Section 3.3 we will introduce the algorithm DeepFlip, which runs EasyFlip iteratively for a constant number of times. DeepFlip corresponds to item (c) in Section 1.4. In Section 3.4 we will introduce HardSearch, which is designed by running DeepFlip thoroughly for all choices of  $(m_1, \dots, m_s)$  until the number of unsatisfied constraints is significantly reduced. The proof of Lemma 8 is also presented in Section 3.4.

### 3.2 The basic building block of deterministic decoding – EasyFlip

In this subsection, we will present the algorithm EasyFlip (see Algorithm 2 below), which is the basic building block of our deterministic decoding. It contains the following two parts:

- EasyFlip (i): in the first part (see steps 1-6 below), it invokes Decode for each constraint  $u \in R$  and sends flips to some variables  $v \in L$ ;
- EasyFlip (ii): in the second part (see steps 7-11 below), it counts the number of flips received by each variable in  $L$  and flips all variables that receive exactly  $m$  flips.

■ **Algorithm 2** Flip all variables receiving exactly  $m$  flips – EasyFlip.

---

**Input:**  $G, C_0, x \in \mathbb{F}_2^n$ , and  $m \in [c]$   
**Output:**  $x' \in \mathbb{F}_2^n$

```

1 for every  $u \in R$  do
2    $\omega \leftarrow \text{Decode}(x_{N(u)});$ 
3   if  $1 \leq d_H(\omega, x_{N(u)}) \leq t$  then
4     send a “flip” to an arbitrary vertex  $v \in N(u)$  with  $\omega_v \neq x_v$ 
5   end
6 end
7 for every  $v \in L$  do
8   if  $v$  receives exactly  $m$  flips then
9     flip  $x_v$ 
10  end
11 end
12 return  $x' \leftarrow x$ 

```

---

Our goal is to show that there must exist an integer  $m \in [c]$  such that by flipping all variables  $v \in L$  that receive exactly  $m$  flips, one can reduce the number of corrupt variables in  $x'$  by a  $(1 - \epsilon_3)$ -fraction, as compared with  $x$ . Note that for this moment, it suffices to prove the existence of such an  $m$  and we do not need to find it explicitly. In fact, later we will find the required  $m$  by exhaustive search.

We make the discussion above precise by the following lemma.

► **Lemma 10.** *Let  $x$  be the input vector of EasyFlip and let  $F$  be the set of corrupt variables of  $x$ . If  $|F| \leq \alpha n$ , then there exists an integer  $m \in [c]$  such that the following holds. Let  $x' = \text{EasyFlip}(x, m)$  be the output vector of EasyFlip and  $F'$  be the set of corrupt variables of  $x'$ . Then  $|F'| \leq (1 - \epsilon_3)|F|$ .*

### 3.2.1 Proof of Lemma 10

Let us first introduce some notation and easy inequalities. Let  $y \in T(G, C_0)$  be the correct codeword that we want to decode from  $x$ . Let  $A$  be the set of constraints  $u \in R$  that sends a flip and  $\text{Decode}(x_{N(u)})$  computes the correct codeword in  $C_0$  (that is,  $\text{Decode}(x_{N(u)}) = y_{N(u)}$ ). Similarly, let  $B$  be the set of constraints  $u \in R$  that sends a flip and  $\text{Decode}(x_{N(u)})$  computes an incorrect codeword in  $C_0$  (i.e.,  $\text{Decode}(x_{N(u)}) \neq y_{N(u)}$ ).

By the definitions of  $A$  and  $N_{\leq t}(F)$ , it is easy to see that

$$A = \{u \in R : 1 \leq |N(u) \cap F| \leq t\} = N_{\leq t}(F). \quad (2)$$

Therefore, it follows by (2) and Proposition 7 that

$$|A| \geq \frac{\delta(t+1) - 1}{t} \cdot c|F|. \quad (3)$$

Moreover, since a constraint  $u \in R$  computes an incorrect codeword in  $C_0$  only if it sees at least  $d_0 - t$  corrupt variables in its neighbors (recall that  $d(C_0) \geq d_0$ ), we have that

$$B = \{u \in R : |N(u) \cap F| \geq d_0 - t \text{ and } \exists \omega \in C_0 \text{ s.t. } 1 \leq d_H(\omega, x_{N(u)}) \leq t\} \subseteq N_{\geq d_0-t}(F). \quad (4)$$

By counting the number of edges between  $F$  and  $N(F)$ , we see that

$$(d_0 - t)|B| \leq |E(F, B)| \leq |E(F, N(F))| = c|F|,$$

## 61:12 When Can an Expander Code Correct $\Omega(n)$ Errors in $O(n)$ Time?

which implies that

$$|B| \leq \frac{c|F|}{d_0 - t}. \quad (5)$$

Consider the following two equalities,

$$\sum_{k=1}^d k \cdot |N_k(F)| = c|F| \quad \text{and} \quad \sum_{k=1}^d |N_k(F)| = |N(F)| \geq \delta c|F|.$$

By multiplying the second by  $\frac{1}{\delta} + \epsilon_0$  and subtracting the first one, we have

$$\sum_{k=1}^t \left(\frac{1}{\delta} + \epsilon_0 - k\right) |N_k(F)| - \sum_{k=t+1}^d \left(k - \frac{1}{\delta} - \epsilon_0\right) |N_k(F)| \geq \left(\left(\frac{1}{\delta} + \epsilon_0\right) \delta - 1\right) c|F| \geq \epsilon_0 \delta c|F|,$$

Moreover, it follows by (2) and (4) that

$$\begin{aligned} & \sum_{k=1}^t \left(\frac{1}{\delta} + \epsilon_0 - k\right) |N_k(F)| - \sum_{k=t+1}^d \left(k - \frac{1}{\delta} - \epsilon_0\right) |N_k(F)| \\ & \leq \sum_{k=1}^t \left(\frac{1}{\delta} + \epsilon_0 - k\right) |N_k(F)| - \sum_{k=d_0-t}^d \left(k - \frac{1}{\delta} - \epsilon_0\right) |N_k(F)| \\ & \leq \left(\frac{1}{\delta} + \epsilon_0 - 1\right) |N_{\leq t}(F)| - \left(d_0 - t - \frac{1}{\delta} - \epsilon_0\right) |N_{\geq d_0-t}(F)| \\ & \leq \left(\frac{1}{\delta} + \epsilon_0 - 1\right) |A| - \left(d_0 - t - \frac{1}{\delta} - \epsilon_0\right) |B|. \end{aligned}$$

As  $d_0 > \frac{3}{\delta} - 1 + 2\epsilon_0$  and  $t = \lfloor \frac{1}{\delta} \rfloor$ , we have  $d_0 - t - \frac{1}{\delta} - \epsilon_0 > \frac{1}{\delta} + \epsilon_0 - 1$ . Combining the above two inequalities, one can infer that

$$\epsilon_0 \delta c|F| \leq \left(\frac{1}{\delta} + \epsilon_0 - 1\right) |A| - \left(d_0 - t - \frac{1}{\delta} - \epsilon_0\right) |B| \leq \left(\frac{1}{\delta} + \epsilon_0 - 1\right) (|A| - |B|) \leq \frac{1}{\delta} (|A| - |B|),$$

which implies that

$$|A| - |B| \geq \epsilon_0 \delta^2 c|F|. \quad (6)$$

On the other hand, since  $A$  and  $B$  are disjoint subsets of  $N(F)$ , we have that

$$|A| + |B| \leq |N(F)| \leq c|F|. \quad (7)$$

For every integer  $m \in [c]$ , let  $S_m$  be the set of variables in  $L$  that receive exactly  $m$  flips. Then the variables in  $S_m$  receive a total number of  $m|S_m|$  flips. In EasyFlip, every constraint in  $A \cup B$  sends exactly one flip to  $L$ . The total number of flips sent by constraints in  $R$  and received by variables in  $L$  is exactly

$$|A| + |B| = \sum_{m=1}^c m|S_m|. \quad (8)$$

Let  $Z$  be the set of correct variables that receive at least one flip, i.e.,  $Z = (\cup_{m=1}^c S_m) \setminus F$ . Observe that the set  $F'$  of corrupt variables in the output vector  $x'$  consists of corrupt variables not flipped by EasyFlip, which is  $F \setminus S_m$ , and correct variables that are erroneously flipped by EasyFlip, which is  $S_m \cap Z$ . Therefore,

$$F' = (F \setminus S_m) \cup (S_m \cap Z). \quad (9)$$

Let  $\alpha_m$  be the fraction of corrupt variables in  $S_m$ . Then we have that

$$\alpha_m = \frac{|S_m \cap F|}{|S_m|} \quad \text{and} \quad 1 - \alpha_m = \frac{|S_m \cap Z|}{|S_m|}. \quad (10)$$

Let  $\beta_m$  denote the fraction of flips sent from  $A$  to  $S_m$  among all flips received by  $S_m$ , i.e.,

$$\beta_m = \frac{\text{the number of flips sent from } A \text{ to } S_m}{m|S_m|}. \quad (11)$$

The following inequality is crucial in the analysis of EasyFlip.

▷ **Claim 11.** For every  $m \in [c]$ ,  $\alpha_m \geq \beta_m$ .

*Proof.* As every variable in  $S_m$  receives the same number of  $m$  flips, by (10) the number of flips received by  $S_m \setminus F$  is  $(1 - \alpha_m)m|S_m|$ . Moreover, by (11) the number of flips sent from  $B$  to  $S_m$  is  $(1 - \beta_m)m|S_m|$ . Since the constraints in  $A$  always compute the correct codewords in  $C_0$ , they always send correct flips to their neighbors in  $L$ . Therefore, the flips received by  $S_m \setminus F$  (which are the wrong flips) must be sent by  $B$ , which implies that  $(1 - \alpha_m)m|S_m| \leq (1 - \beta_m)m|S_m|$ , where the inequality follows from the fact that  $B$  could also send flips to  $S_m \cap F$  (which are the correct flips). Thus,  $\alpha_m \geq \beta_m$ , as needed. ◁

The following result shows that there exists an integer  $m \in [c]$  such that there exists a large set  $S_m$  that contains many corrupt variables.

▷ **Claim 12.** If  $|F| \leq \alpha n$ , then there exists an integer  $m \in [c]$  such that  $\alpha_m \geq (1 - \epsilon_1) \frac{|A|}{|A| + |B|}$  and  $|S_m| \geq \epsilon_2 |F|$ .

*Proof.* Suppose for the sake of contradiction that for every  $m \in [c]$ , we have either  $\alpha_m < (1 - \epsilon_1) \frac{|A|}{|A| + |B|}$  or  $|S_m| < \epsilon_2 |F|$ . Then, by counting the number of flips sent from  $A$  to  $L$  (which is exactly  $|A|$ ), we have that

$$\begin{aligned} |A| &= \sum_{m=1}^c \beta_m m |S_m| \leq \sum_{m=1}^c \alpha_m m |S_m| < (1 - \epsilon_1) \frac{|A|}{|A| + |B|} \sum_{m=1}^c m |S_m| + \sum_{m=1}^c m \epsilon_2 |F| \\ &= (1 - \epsilon_1) |A| + \frac{c(c+1)}{2} \cdot \epsilon_2 |F|, \end{aligned}$$

where the first inequality follows from Claim 11, the second inequality follows from our assumption on  $\alpha_m$  and  $|S_m|$ , and the last equality follows from (8).

Rearranging gives that  $|A| < \frac{\epsilon_2(c+1)}{2\epsilon_1} \cdot c|F| = \frac{\delta(t+1)-1}{2t} \cdot c|F|$ , contradicting (3). ◁

Next, we will show that by flipping all the variables in  $S_m$ , where  $m$  satisfies the conclusion of Claim 12, one can reduce the size of the set of corrupt variables by a  $(1 - \epsilon_3)$ -fraction, thereby proving Lemma 10.

**Proof of Lemma 10.** Let  $m \in [c]$  satisfy the conclusion of Claim 12. Combining the two inequalities (6) and (7), one can infer that

$$\frac{|A|}{|A| + |B|} = \frac{1}{2} + \frac{|A| - |B|}{2(|A| + |B|)} \geq \frac{1}{2} + \frac{\epsilon_0 \delta^2 c |F|}{2c|F|} = \frac{1}{2} + \frac{\epsilon_0 \delta^2}{2}. \quad (12)$$

Therefore, it follows by (12) that

$$\alpha_m \geq (1 - \epsilon_1) \frac{|A|}{|A| + |B|} \geq (1 - \epsilon_1) \left( \frac{1}{2} + \frac{\epsilon_0 \delta^2}{2} \right). \quad (13)$$

## 61:14 When Can an Expander Code Correct $\Omega(n)$ Errors in $O(n)$ Time?

It follows by (9) that

$$\begin{aligned} |F'| &= (|F| - |S_m \cap F|) + |S_m \cap Z| = |F| - (2\alpha_m - 1)|S_m| \\ &\leq |F| - \left(2(1 - \epsilon_1) \left(\frac{1}{2} + \frac{\epsilon_0 \delta^2}{2}\right) - 1\right) |S_m| = |F| - (\epsilon_3/\epsilon_2)|S_m| \leq |F| - \epsilon_3|F|, \end{aligned}$$

as needed, where the second equality follows by (10), the first inequality follows by (13), the last equality follows by the definition of  $\epsilon_3$  and the last inequality follows by Claim 12. ◀

We will conclude by the following inequality, which shows that for an arbitrary  $m \in [c]$ , flipping  $S_m$  would not significantly increase the number of corrupt variables.

▷ **Claim 13.** For arbitrary  $x \in \mathbb{F}_2^n$  and  $m \in [c]$ , let  $x' := \text{EasyFlip}(x, m)$ . Let  $F$  and  $F'$  be the sets of corrupt variables of  $x$  and  $x'$ , respectively. Then  $|F'| \leq (1 + \frac{c}{d_0 - t})|F|$ .

*Proof.* Since the constraints in  $A$  always compute the correct codewords in  $C_0$ , they always send correct flips to their neighbors in  $L$ . Therefore, the wrong flips must be sent by  $B$ . Therefore, in the worst case (i.e., assuming that  $A = \emptyset$ ), we have that

$$|F'| \leq |F| + |B| \leq \left(1 + \frac{c}{d_0 - t}\right) |F|,$$

where the second inequality follows from (5). ◀

### 3.3 Running EasyFlip iteratively for a constant number of times – DeepFlip

In this subsection, we will present and analyze DeepFlip (see Algorithm 3 below), which is designed by running EasyFlip iteratively for  $s$  times for a particular choice of  $(m_1, \dots, m_s) \in [c]^s$ . By iteratively we mean a sequence of operations  $x^0 := x, x^1 := \text{EasyFlip}(x^0, m_1), \dots, x^s = \text{EasyFlip}(x^{s-1}, m_s)$ .

■ **Algorithm 3** Running EasyFlip iteratively for a particular choice  $(m_1, \dots, m_s) \in [c]^s$  – DeepFlip.

---

**Input:**  $G, C_0, x \in \mathbb{F}_2^n$ , and  $(m_1, \dots, m_s) \in [c]^s$   
**Output:**  $x^s \in \mathbb{F}_2^n$  or  $\perp$

- 1 Set  $k = 1$  and  $x^0 = x$ ;
- 2 **for**  $1 \leq k \leq s$  **do**
- 3      $x^k \leftarrow \text{EasyFlip}(x^{k-1}, m_k)$ ;
- 4      $U^k \leftarrow \{u \in R : x_{N(u)}^k \notin C_0\}$ ;
- 5     **if**  $|U^k| > (1 - \epsilon_3)^k \cdot c\gamma n$  **then**
- 6         **return**  $\perp$
- 7     **else**
- 8          $k \leftarrow k + 1$
- 9     **end**
- 10 **end**
- 11 **return**  $x^s$

---

Our goal is to show that as long as the number of corrupt variables in  $x$  is not too large, by running EasyFlip iteratively for a large enough (but still constant) number of times, there exists a vector  $(m_1, \dots, m_s) \in [c]^s$  such that the number of corrupt variables in the final

output  $x^s$  is at most a  $(1 - \epsilon_3)$ -fraction of the number of corrupt variables in the initial input  $x$ . Most importantly, later we will show that such a vector  $(m_1, \dots, m_s)$  can be found *explicitly* and *efficiently*.

The above assertion will be made precise by the following lemma.

► **Lemma 14.** *Let  $x$  be the input vector of DeepFlip and let  $F$  be the set of corrupt variables of  $x$ . If  $|F| \leq \gamma n$ , then for every  $s \geq s_0$  there exists a nonempty subset  $M \subseteq [c]^s$  such that the following holds for every  $(m_1, \dots, m_s) \in M$ . Let  $x^s := \text{DeepFlip}(x, (m_1, \dots, m_s))$  be the output vector of DeepFlip and  $F^s$  be the set of corrupt variables of  $x^s$ . Then  $|F^s| \leq (1 - \epsilon_3)|F|$ .*

### 3.3.1 Proof of Lemma 14

Given  $(m_1, \dots, m_s) \in [c]^s$  and  $x^0 := x$ , for each  $k \in [s]$ , let  $x^k := \text{EasyFlip}(x^{k-1}, m_k)$ . With this notation,  $x^s = \text{EasyFlip}(x^{s-1}, m_s) = \text{DeepFlip}(x, (m_1, \dots, m_s))$ , is exactly the output vector of DeepFlip. Let  $F$  be the set of corrupt variables in  $x$  and  $U$  be the set of unsatisfied constraints with respect to  $x$ . Sometimes, we will also use  $F^0 := F$  and  $U^0 := U$ . For  $k \in [s]$ , define  $F^k$  and  $U^k$  similarly with  $x$  replaced by  $x^k$ . Then

$$N_{\leq d_0-1}(F) \subseteq U \subseteq N(F), \quad (14)$$

where the first inclusion holds since  $d(C_0) = d_0$ .

The following lemma can be viewed as an “idealized” version of Lemma 14.

► **Lemma 15.** *With the above notation, the following holds. If  $|F| \leq \alpha n$ , then there exists a vector  $(m_1, \dots, m_s) \in [c]^s$  such that*

- (i)  $|F^s| \leq (1 - \epsilon_3)^s |F|$ ;
- (ii) for each  $k \in [s]$ ,  $|U^k| \leq (1 - \epsilon_3)^k \cdot c|F|$ ;
- (iii)  $|U^s| \leq (1 - \epsilon_3)^s \cdot \frac{d_0-1}{\delta d_0-1} \cdot |U|$ .

**Proof.** As  $|F| \leq \alpha n$ , by Lemma 10, there exists  $m_1 \in [c]$  such that  $x^1 = \text{EasyFlip}(x, m_1)$  satisfies  $|F^1| \leq (1 - \epsilon_3)|F| \leq \alpha n$ . Continuing this process, it follows by Lemma 10 that for each  $k \in [s]$ , there exists  $m_k \in [c]$  such that  $x^k = \text{EasyFlip}(x^{k-1}, m_k)$  satisfies

$$|F^k| \leq (1 - \epsilon_3)|F^{k-1}| \leq (1 - \epsilon_3)^k |F| \leq \alpha n. \quad (15)$$

Such a vector  $(m_1, \dots, m_s) \in [c]^s$  clearly satisfies property (i).

To prove (ii), note that it follows by (14) and (15) that for each  $k \in [s]$ ,

$$|U^k| \leq |N(F^k)| \leq c|F^k| \leq (1 - \epsilon_3)^k \cdot c|F|.$$

To prove (iii), as  $|F| \leq \alpha n$ , applying Proposition 7 in concert with (14) gives that  $\frac{\delta d_0-1}{d_0-1} \cdot c|F| \leq |N_{\leq d_0-1}(F)| \leq |U|$ . Combining the equation above and (i) gives that  $|U^s| \leq c|F^s| \leq (1 - \epsilon_3)^s \cdot c|F| \leq (1 - \epsilon_3)^s \cdot \frac{d_0-1}{\delta d_0-1} \cdot |U|$ , completing the proof of (iii). ◀

Lemma 15 (i) indicates that there exists an “ideal” choice, say  $(m_1^*, \dots, m_s^*) \in [c]^s$ , such that if  $|F| \leq \alpha n$ , then after the execution of EasyFlip iteratively for  $s$  times (directed by  $(m_1^*, \dots, m_s^*)$ ), the number of corrupt variables in the final output  $x^s$  is at most a  $(1 - \epsilon_3)^s$ -fraction of the number of corrupt variables in the initial input  $x^0 = x$ .

Unfortunately, in general, there is no way to compute the number of corrupt variables in the input and output of each execution of EasyFlip. From this perspective, there is no easy way to *explicitly* find the ideal  $(m_1^*, \dots, m_s^*) \in [c]^s$ . However, Lemma 15 (iii), which is a consequence of Lemma 15 (i), essentially shows that if the number of corrupt variables

## 61:16 When Can an Expander Code Correct $\Omega(n)$ Errors in $O(n)$ Time?

reduces *dramatically*, then the number of unsatisfied constraints also reduces *significantly* - fortunately, it is clear that this quantity can be computed in linear time! The analysis of our deterministic decoding algorithm relies heavily on this observation.

The above discussion motivates the following definition.

► **Definition 16.** *Given the input vector  $x$  of DeepFlip, let  $M$  be the set consisting of all vectors  $(m_1, \dots, m_s) \in [c]^s$  which satisfy the following two properties:*

- (a) *for each  $k \in [s]$ ,  $|U^k| \leq (1 - \epsilon_3)^k \cdot c\gamma n$ ;*
- (b)  *$|U^s| \leq \epsilon_4 |U|$ , where  $\epsilon_4 = \frac{\delta d_0 - 1}{d_0 - 1} \cdot (1 - \epsilon_3)$ .*

The following result is an easy consequence of Lemma 15.

▷ **Claim 17.** *If  $|F| \leq \gamma n$  and  $s \geq s_0$ , then  $M \neq \emptyset$ .*

*Proof.* Since  $|F| \leq \gamma n < \alpha n$ , there exists a vector  $(m_1, \dots, m_s) \in [c]^s$  that satisfies Lemma 15. By substituting  $|F| \leq \gamma n$  into Lemma 15 (ii), it is easy to see that such a vector also satisfies Definition 16 (a). Moreover, by substituting  $s \geq s_0 = \left\lceil \log_{1-\epsilon_3} \left( \epsilon_4 \frac{\delta d_0 - 1}{d_0 - 1} \right) \right\rceil$  into Lemma 15 (iii), it is not hard to see that Definition 16 (b) also holds. Therefore,  $M \neq \emptyset$ , as needed. ◁

As briefly mentioned above, in general one cannot explicitly find the ideal  $(m_1^*, \dots, m_s^*) \in [c]^s$  which dramatically reduces the number of corruptions. Instead, under a stronger condition  $|F| \leq \gamma n$  (recall that Lemma 15 assumes  $|F| \leq \alpha n$ ), Lemma 14 shows that for every  $(m_1, \dots, m_s) \in M$ ,  $x^s = \text{DeepFlip}(x, (m_1, \dots, m_s))$  reduces the number of corrupt variables of  $x$  by a  $(1 - \epsilon_3)$ -fraction, which makes every member of  $M$  an *acceptable* (which may be not ideal) choice for DeepFlip.

Now we are ready to present the proof of Lemma 14.

**Proof of Lemma 14.** First of all, we would like to show that Lemma 14 is well defined, namely, for every  $|F| \leq \gamma n$  and  $(m_1, \dots, m_s) \in M$ ,  $\text{DeepFlip}(x, (m_1, \dots, m_s))$  does not return  $\perp$ . Indeed, as  $(m_1, \dots, m_s) \in M$ , by Definition 16 (a) we have that for every  $1 \leq k \leq s$ ,  $|U^k| \leq (1 - \epsilon_3)^k \cdot c\gamma n$ , which implies that  $U^k$  always passes the test in step 5 of Algorithm 3. Therefore, under the assumption of Lemma 14, the output of DeepFlip is a vector  $x^s \in \mathbb{F}_2^n$ .

To prove the lemma, assume for the moment that  $|F^s| \leq \alpha n$ . Given the correctness of this assertion, applying Proposition 7 in concert with (14) gives that

$$\frac{\delta d_0 - 1}{d_0 - 1} \cdot c|F^s| \leq |N_{\leq d_0 - 1}(F^s)| \leq |U^s|.$$

Moreover, by combining the above equation and Definition 16 (b), we have

$$\frac{\delta d_0 - 1}{d_0 - 1} \cdot c|F^s| \leq |U^s| \leq \epsilon_4 |U| \leq \frac{\delta d_0 - 1}{d_0 - 1} \cdot (1 - \epsilon_3) \cdot c|F|,$$

which implies that  $|F^s| \leq (1 - \epsilon_3)|F|$ , as needed.

Therefore, it remains to show that  $|F^s| \leq \alpha n$ . We will prove by induction that for each  $0 \leq k \leq s$ ,  $|F^k| \leq \frac{\alpha n}{1 + c/(d_0 - t)} \leq \alpha n$ . For the base case  $k = 0$ , it follows by assumption that  $|F^0| \leq \gamma n < \frac{\alpha n}{1 + c/(d_0 - t)}$  as  $d_0 \geq 3$ ,  $\delta d_0 > 3$  and  $t = \lfloor \frac{1}{\delta} \rfloor$ . Suppose that for some  $k \in [s]$  we have  $|F^{k-1}| \leq \frac{\alpha n}{1 + c/(d_0 - t)}$ . Since  $x^k = \text{EasyFlip}(x^{k-1}, m_k)$ , it follows by Claim 13 that  $|F^k| \leq (1 + \frac{c}{d_0 - t})|F^{k-1}| \leq \alpha n$ . Therefore, we have

$$\frac{\delta d_0 - 1}{d_0 - 1} \cdot c|F^k| \leq |N_{\leq d_0 - 1}(F^k)| \leq |U^k| \leq (1 - \epsilon_3)^k \cdot c\gamma n \leq c\gamma n,$$

where the first inequality follows from Proposition 7, the second inequality follows from (14), and the third inequality follows from Definition 16 (a). The last equation implies that  $|F^k| \leq \frac{d_0-1}{\delta d_0-1} \gamma n < \frac{d_0}{2} \gamma n \leq \frac{\alpha n}{1+c/(d_0-t)}$ , as needed, where the second inequality follows from the assumption  $\delta d_0 > 3$  and the last inequality follows from the definition of  $\gamma$  in Theorem 3,  $\delta d_0 > 3$  and  $t = \lfloor \frac{1}{\delta} \rfloor$ . The proof of the lemma is thus completed.  $\blacktriangleleft$

### 3.4 Running DeepFlip thoroughly until significantly reducing the number of unsatisfied constraints – HardSearch

In this subsection, we describe and analyze HardSearch (see Algorithm 4 below). Given an input vector  $x \in \mathbb{F}_2^n$  with at most  $\gamma n$  corruptions, HardSearch runs DeepFlip( $x, (m_1, \dots, m_s)$ ) over all choices of  $(m_1, \dots, m_s) \in [c]^s$  until it finds one, say  $(m'_1, \dots, m'_s)$ , such that the number of unsatisfied constraints with respect to DeepFlip( $x, (m'_1, \dots, m'_s)$ ) is at most an  $\epsilon_4$ -fraction of the number of unsatisfied constraints with respect to  $x$ . Then Lemma 8 shows that the number of corruptions in  $x'$  is at most a  $(1 - \epsilon_3)$ -fraction of the number of corruptions in  $x$ . Therefore, running HardSearch iteratively for  $\ell$  rounds gives us a  $(1 - \epsilon_3)^\ell$ -reduction on the number of corruptions.

■ **Algorithm 4** Running DeepFlip over all  $(m_1, \dots, m_s) \in [c]^s$  until finding an “acceptable” one – HardSearch.

---

**Input:**  $G, C_0, x \in \mathbb{F}_2^n$ , and  $s = s_0$   
**Output:**  $x' \in \mathbb{F}_2^n$

- 1  $U \leftarrow \{u \in R : x_{N(u)} \notin C_0\};$
- 2 **for** every  $(m_1, \dots, m_s) \in [c]^s$  **do**
- 3      $x' \leftarrow \text{DeepFlip}(x, (m_1, \dots, m_s));$
- 4     **if**  $x' \neq \perp$  **then**
- 5          $U' \leftarrow \{u \in R : x'_{N(u)} \notin C_0\};$
- 6         **if**  $|U'| \leq \epsilon_4 |U|$  **then**
- 7             return  $x'$
- 8         **end**
- 9     **end**
- 10 **end**

---

#### 3.4.1 Proof of Lemma 8

To prove (i), let  $M$  be the set of vectors in  $[c]^s$  which satisfy the two conditions in Definition 16 with respect to  $F$  and  $s$ , where  $|F| \leq \gamma n$  and  $s = s_0$ . By our choices of  $F$  and  $s$ , it follows by Claim 17 that  $M \neq \emptyset$ . By Lemma 14, as long as HardSearch finds a vector  $(m_1, \dots, m_s) \in M$ , it would output a vector  $x' = \text{DeepFlip}(x, (m_1, \dots, m_s))$  such that  $|U'| \leq \epsilon_4 |U|^4$  and  $|F'| \leq (1 - \epsilon_3) |F|$ , as needed.

It remains to prove (ii), which is an easy consequence of (i). Let  $F^i$  be the set of corruptions in  $x^i$  for all  $0 \leq i \leq \ell$ . Then by (i) for every  $0 \leq i \leq \ell - 1$ , we have either  $x^i \in T(G, C_0)$  (if  $|U^i| = 0$ ) or  $|F^{i+1}| \leq (1 - \epsilon_3) |F^i|$  (if  $|U^i| \neq 0$ ). Therefore, after at most  $\ell = \left\lceil \log_{1-\epsilon_3} \left( \left\lfloor \frac{d_0-1}{2} \right\rfloor \frac{1}{\gamma n} \right) \right\rceil$  iterative executions of HardSearch, the number of corrupt variables is at most  $(1 - \epsilon_3)^\ell \gamma n \leq \left\lfloor \frac{d_0-1}{2} \right\rfloor \frac{1}{\gamma n} \cdot \gamma n = \left\lfloor \frac{d_0-1}{2} \right\rfloor$ , as needed.

<sup>4</sup> This holds since  $(m_1, \dots, m_s) \in M$  satisfies Definition 16 (b).

#### 4 Randomized decoding: Reduce large corruptions to a moderate size

In this section, we present our randomized decoding for Tanner codes which can correct more errors. The general strategy is as follows. First, we use a voting process to derive a set  $S := \cup_{m \in [c]} S_m$  of candidate variables to flip. More precisely, each constraint  $u \in R$  that satisfies  $1 \leq d_H(\text{Decode}(x_{N(u)}), x_{N(u)}) \leq t$  sends exactly one flip to an arbitrary variable  $v \in N(u)$  with  $\text{Decode}(x_{N(u)})_v \neq x_v$ . We then design a special sampling process to pick a large fraction of variables from  $S$  and flip them. This process can, with high probability, reduce the number of corrupted variables by a positive fraction. We repeat the above random process until the number of corrupted variables drops below  $\gamma n$ , in which case our deterministic decoding MainDecode in Algorithm 1 can work correctly, or we run out of time and stop. Finally, we use MainDecode to get the codeword.

Let  $\gamma$  be the relative decoding radius of Theorem Theorem 3. The exact randomized decoding is given as Algorithm 5, which yields the following result.

##### Algorithm 5 Randomized Decoding.

---

**Input:**  $x \in \mathbb{F}_2^n$  with at most  $\alpha$  fraction errors  
**Output:** a codeword in  $T(G, C_0)$  or  $\perp$

- 1 Set  $t = \lfloor \frac{1}{\delta} \rfloor$ ;
- 2 **for**  $\ell = 1, \dots, \left\lceil \frac{\log \frac{\gamma}{\alpha}}{\log \left(1 - \frac{3\epsilon(\delta(t+1)-1)}{4t}\right)} \right\rceil$  **do**
- 3     **for every**  $u \in R$  **do**
- 4          $\omega \leftarrow \text{Decode}(x_{N(u)})$ ;
- 5         **if**  $1 \leq d_H(\omega, x_{N(u)}) \leq t$  **then**
- 6             send a “flip” message to the vertex  $v \in N(u)$  with the smallest index such  
            that  $\omega_v \neq x_v$
- 7         **end**
- 8     **end**
- 9      $\forall m \in [c], S_m \leftarrow \{v \in L : v \text{ receives } m \text{ “flip” messages}\}$ ;
- 10      $S \leftarrow \bigcup_m S_m$ ;
- 11     Randomly pick  $P \subseteq S$ : for every  $m \in [c]$ , for each variable in  $S_m$ , pick it with  
        probability  $\frac{m}{2c}$ , using independent randomness;
- 12     Flip all bits in  $P$ ;
- 13      $U \leftarrow \{u \in R : x_{N(u)} \notin C_0\}$ ;
- 14     **if**  $|U| \leq \left(\delta - \frac{1}{d_0}\right) c\gamma n$  **then**
- 15         return MainDecode( $x$ )
- 16     **end**
- 17 **end**
- 18 return  $\perp$

---

The following two lemmas demonstrate the correctness and linear running time of Algorithm 5, respectively<sup>5</sup>.

► **Lemma 18.** *If the input has distance at most  $\alpha n$  from a codeword, then with probability  $1 - \exp\{-\Theta_{c,\delta,d_0}(n)\}$ , Algorithm 5 outputs the correct codeword.*

<sup>5</sup> We only prove Lemma 18. The proof of Lemma 19 can be found in the full version of this paper [10]

► **Lemma 19.** *If the input has distance at most  $\alpha n$  from a codeword, then Algorithm 5 runs in linear time.*

Assuming the correctness of the above lemmas, we can prove Theorem 6 as follows.

**Proof of Theorem 6.** If the input word has at most  $\alpha n$  errors, then by Lemma 18, with probability  $1 - \exp\{-\Theta_{c,\delta,d_0}(n)\}$ , the decoding outputs the correct codeword. Furthermore, the running time is linear by Lemma 19. ◀

## 4.1 Proof of Lemma 18

Recall that we defined  $A$  as the set of constraints  $u \in R$  that sends a flip and  $\text{Decode}(x_{N(u)})$  computes the correct codeword in  $C_0$  (see (2)), and  $B$  to be the set of constraints  $u \in R$  that sends a flip and  $\text{Decode}(x_{N(u)})$  computes an incorrect codeword in  $C_0$  (see (4)). Also, recall we let  $\alpha_m$  denote the fraction of corrupt variables in  $S_m$  (see (10)) and we let  $\beta_m$  denote the fraction of flips sent from  $A$  to  $S_m$  among all flips received by  $S_m$  (see (11)). Now we let  $M := A \cup B$ .

First, we bound the size of  $P$  in an arbitrary iteration.

▷ **Claim 20.** For every constant  $\epsilon > 0$ , with probability  $\geq 1 - \exp\{-\Theta_{c,\epsilon}(|M|)\}$ , the size of  $P$  is in  $\left[(1 - \epsilon)\frac{|M|}{2c}, (1 + \epsilon)\frac{|M|}{2c}\right]$ .

*Proof.* In Algorithm 5, for every  $m \in [c]$ , each variable in  $S_i$  is picked independently with probability  $\frac{m}{2c}$ . For each  $v \in S$ , let  $X_v$  be the indicator random variable of the event that the variable  $v$  is picked. So for every  $v \in S_m$ ,  $\Pr[X_v = 1] = \frac{m}{2c}$ . Let  $X = \sum_{v \in S} X_v$ . It is easy to see that  $X = |P|$ . By the linearity of expectation, we have that

$$\mathbb{E}X = \sum_{v \in S} \mathbb{E}X_v = \sum_{m \in [c]} \frac{m}{2c} |S_m| = \frac{|M|}{2c}.$$

By Hoeffding's inequality,

$$\Pr \left[ X \in \left[ (1 - \epsilon)\frac{|M|}{2c}, (1 + \epsilon)\frac{|M|}{2c} \right] \right] \geq 1 - 2 \exp \left\{ -\frac{2 \left( \epsilon \frac{|M|}{2c} \right)^2}{|S|} \right\} \geq 1 - 2 \exp \left\{ -\frac{\epsilon^2 |M|}{2c^2} \right\},$$

where the second inequality follows from the fact that  $|S| \leq |M|$ . ◀

Next, we show that  $P$  contains significantly more corrupted variables than correct variables.

▷ **Claim 21.** There exists a constant  $\epsilon$  such that with probability  $\geq 1 - \exp\{-\Theta_{c,\epsilon}(|M|)\}$ , the number of corrupted variables in  $P$  is at least  $(1/2 + \epsilon)\frac{|M|}{2c}$ .

*Proof of Claim 21.* For every  $v \in S$ , let  $Y_v$  be the indicator random variable of the event that  $X_v = 1$  and  $v \in F$ . Let  $Y = \sum_{v \in S} Y_v$ . By definition,  $Y = P \cap F$ . Note that for every  $v \notin S \cap F$ ,  $\Pr[Y_v = 1] = 0$ . By the linearity of expectation, we have that

$$\mathbb{E}Y = \sum_{v \in S} \mathbb{E}Y_v = \sum_{m \in [c]} \sum_{v \in S_m} \mathbb{E}Y_v = \sum_{m \in [c]} \sum_{v \in S_m \cap F} \frac{m}{2c} = \sum_{m \in [c]} \frac{m}{2c} \alpha_m |S_m| \geq \sum_{m \in [c]} \frac{m}{2c} \beta_m |S_m|, \quad (16)$$

where the inequality follows from Claim 11.

## 61:20 When Can an Expander Code Correct $\Omega(n)$ Errors in $O(n)$ Time?

By the definition of  $\beta_m$ ,  $m\beta_m|S_m| = |\{\text{The number of "flips" sent from } A \text{ to } S_m\}|$ . Hence, one can infer that

$$\begin{aligned} \text{E}Y &\geq \sum_{m \in [c]} \frac{|\{\text{The number of "flips" sent from } A \text{ to } S_m\}|}{2c} \\ &= \frac{|\{\text{The number of "flips" sent from } A \text{ to } S\}|}{2c} = \frac{|A|}{2c}, \end{aligned}$$

where the last equality is due to that each constraint in  $R$  can only send at most 1 message.

Set  $\epsilon = \frac{\epsilon_0 \delta^2}{4} > 0$ . It follows by (12) that  $|A| \geq \left(\frac{1}{2} + \frac{\epsilon_0 \delta^2}{2}\right) |M| = \left(\frac{1}{2} + 2\epsilon\right) |M|$ . Thus, we can infer that  $\text{E}Y \geq \frac{|A|}{2c} \geq \left(\frac{1}{2} + 2\epsilon\right) \frac{|M|}{2c}$ .

By Hoeffding's inequality,

$$\Pr \left[ Y \leq \left(\frac{1}{2} + \epsilon\right) \frac{|M|}{2c} \right] \geq 1 - \exp \left\{ -\frac{2 \left(\epsilon \frac{|M|}{2c}\right)^2}{|S|} \right\} \geq 1 - \exp \left\{ -\frac{\epsilon^2 |M|}{2c^2} \right\},$$

where the second inequality follows from that  $|S| \leq |M|$ .  $\triangleleft$

The following claim shows that as long as the number of unsatisfied constraints is small enough, we can ensure that the number of corrupt variables is at most  $\gamma n$ . Hence, we can handle the matter with Algorithm 1.

$\triangleright$  **Claim 22.** If  $|U| \leq \left(\delta - \frac{1}{d_0}\right) c\gamma n$  and  $|F| \leq \alpha n$ , then  $|F| \leq \gamma n$ .

*Proof.* Suppose that  $\gamma n < |F| \leq \alpha n$ . By Proposition 7, we have that

$$|U| \geq \frac{\delta d_0 - 1}{d_0 - 1} c|F| > \left(\delta - \frac{1}{d_0}\right) c\gamma n,$$

which is a contradiction.  $\triangleleft$

Now, we can give the proofs of Lemma 18 and Lemma 19, respectively, as follows.

**Proof of Lemma 18.** In each iteration, consider the case that the number of errors  $|F|$  is at most  $\alpha n$ . If  $|U| \leq \left(\delta - \frac{1}{d_0}\right) c\gamma n$ , then by Claim 22,  $|F| \leq \gamma n$ . Therefore, it follows by Theorem 3 that when  $\delta d_0 > 3$ , all errors can be corrected. Otherwise, we claim that the number of corrupt variables can be decreased by a constant fraction in this iteration.

Recall that  $M = A \cup B \subseteq U$ . It follows by (3) that

$$|M| = |A| + |B| \geq \frac{\delta(t+1) - 1}{t} c|F|. \quad (17)$$

Note that by Claim 21, with probability  $1 - \exp\{-\Theta_{c,\delta,d_0}(n)\}$ , the number of corruptions in  $P$  is at least  $(1/2 + \epsilon) \frac{|M|}{2c}$  where  $\epsilon > 0$  is a constant. Also note that by Claim 20, with probability  $1 - \exp\{-\Theta_{c,\delta,d_0}(n)\}$ , the size of  $P$  is in  $\left[(1 - \epsilon/2) \frac{|M|}{2c}, (1 + \epsilon/2) \frac{|M|}{2c}\right]$ . When both of these events occur, by flipping all variables in  $\hat{P}$ , the number of corruptions is reduced by at least  $\frac{3\epsilon|M|}{4c}$ . It follows by (17) that  $\frac{3\epsilon|M|}{4c} \geq \frac{3\epsilon(\delta(t+1)-1)}{4t} |F|$ . This shows the number of corrupt variables indeed is decreased by a constant fraction in this iteration.

As a result, after at most  $\frac{\log \frac{\gamma}{\alpha}}{\log\left(1 - \frac{3\epsilon(\delta(t+1)-1)}{4t}\right)}$  iterations, the number of corruptions is at most  $\gamma n$ . Then the decoding can call Algorithm 1 to correct all errors.  $\blacktriangleleft$

## Abstract

We give new bounds on the cosystolic expansion constants of several families of high dimensional expanders, and the known coboundary expansion constants of order complexes of homogeneous geometric lattices, including the spherical building of  $SL_n(\mathbb{F}_q)$ . The improvement applies to the high dimensional expanders constructed by Lubotzky, Samuels and Vishne, and by Kaufman and Oppenheim.

Our new expansion constants do not depend on the degree of the complex nor on its dimension, nor on the group of coefficients. This implies improved bounds on Gromov’s topological overlap constant, and on Dinur and Meshulam’s cover stability, which may have applications for agreement testing.

In comparison, existing bounds decay exponentially with the ambient dimension (for spherical buildings) and in addition decay linearly with the degree (for all known bounded-degree high dimensional expanders). Our results are based on several new techniques:

- We develop a new “color-restriction” technique which enables proving dimension-free expansion by restricting a multi-partite complex to small random subsets of its color classes.
- We give a new “spectral” proof for Evra and Kaufman’s local-to-global theorem, deriving better bounds and getting rid of the dependence on the degree. This theorem bounds the cosystolic expansion of a complex using coboundary expansion and spectral expansion of the links.
- We derive absolute bounds on the coboundary expansion of the spherical building (and any order complex of a homogeneous geometric lattice) by constructing a novel family of very short cones.

## 1 Introduction

High dimensional expansion, which is a generalization of graph expansion to higher dimensional objects, is an active topic in recent years. The importance of graph expansion across many areas of computer science and mathematics, suggests that high dimensional expansion

may also come to have significant impact. So far we have seen several exciting applications including analysis of convergence of Markov chains [1], and constructions of locally testable codes and quantum LDPC codes [16, 55].

Several notions of expansion that are equivalent in graphs, such as convergence of random walks, spectral expansion, and combinatorial expansion, turn out to diverge into two main notions in higher dimensions.

The first is the notion of local link expansion which has to do with the expansion of the graph underlying each of the links of the complex; where a link is a sub-complex obtained by taking all faces that contain a fixed lower-dimensional face. This notion is qualitatively equivalent to convergence of random walks, it implies agreement testing, and it captures a spectral similarity between a (possibly sparse) high dimensional expander and the dense complete complex. It allows a spectral decomposition of functions on the faces of the complex in the style of Fourier analysis on the Boolean hypercube, see [13, 41, 31, 3, 25].

The second notion is coboundary and cosystolic expansion. Here we look at the complex not only as a combinatorial object but also as a sequence of linear maps, called coboundary maps, defined by the incidence relations of the complex. The  $i$ -th coboundary map  $\delta_i$  maps a function on the  $i$ -faces to a function on the  $i + 1$ -faces,  $C^0 \xrightarrow{\delta_0} C^1 \xrightarrow{\delta_1} \dots \xrightarrow{\delta_{d-1}} C^d$  where  $C^i = C^i(X, \mathbb{F}_2) = \{f : X(i) \rightarrow \mathbb{F}_2\}$  is the space of functions on  $i$  faces with coefficients in  $\mathbb{F}_2$  (we will consider general groups of coefficients, beyond  $\mathbb{F}_2$ ). These functions are called  $i$ -chains. The coboundary map  $\delta_i$  is defined in a very natural way: the value of  $\delta f(s)$  for any  $s \in X(i + 1)$  is the sum of  $f(t)$  for all  $s \supset t \in X(i)$  (the precise definition is in Section 2).

Coboundary (or cosystolic<sup>1</sup>) expansion captures how well the coboundary map tests its own kernel, in the sense of property testing. Given  $f \in C^i$  such that  $\delta f \approx 0$ , coboundary expansion guarantees existence of some  $g \in \ker \delta_i$  such that  $f \approx g$ . More precisely, a complex is a  $\beta$  coboundary (or cosystolic) expander if

$$wt(\delta f) \geq \beta \cdot \min_{g \in \ker \delta} \text{dist}(f, g)$$

where  $wt(\delta f)$  is the hamming weight of  $\delta f$ . We denote by  $h^i(X)$  the largest value of  $\beta$  that satisfies the above inequality for all  $f$ .

Whereas for  $i = 0$  coboundary expansion coincides with the combinatorial definition of edge expansion, for larger  $i$ , it may appear at first glance to be quite mysterious. However, this definition is far from being a merely syntactical generalization of the  $i = 0$  case and turns out to provide a rich connection between topological and cohomological concepts and between several important concepts in TCS, which we describe briefly below.

The study of coboundary and cosystolic expansion was initiated independently by Linial, Meshulam and Wallach [45], [51] in their study of connectivity of random complexes, and by Gromov [29] in his work on the topological overlapping property. Kaufman and Lubotzky [36] were the first to realize the connection between this definition and property testing. This point of view is important in the recent breakthroughs constructing locally testable codes and quantum LDPC codes [16, 55] (see also earlier works [23]).

Moreover, the coboundary maps come from a natural way to associate a (simplicial) complex to a constraint satisfaction problem. Attach a Boolean variable to each  $i$ -face, and view the  $(i + 1)$ -faces as parity constraints. The value that an assignment  $f : X(i) \rightarrow \mathbb{F}_2$

<sup>1</sup> The difference between coboundary and cosystolic expansion is just whether the cohomology is 0 or not (i.e. whether  $\ker \delta_{i+1} = \text{Im} \delta_i$ ). This distinction is not important for this exposition and the expansion inequality is the same in both cases.

gives on  $s \in X(i + 1)$  is  $\delta f(s)$ . This connection to CSPs has been harnessed towards showing that the CSPs derived from certain cosystolic expanders are hard to refute for resolution and for the sum of squares hierarchy, [17, 33].

In addition, cosystolic expansion of 1-chains (with non-abelian coefficients) of a complex has been connected to the stability of its topological covers [20]. Informally, a complex is cover-stable if slightly faulty simplicial covers are always “fixable” to valid simplicial covers. Perhaps surprisingly, this is related to agreement testing questions, particularly in the small 1% regime, which is a basic PCP primitive and part of the initial motivation for this work. We discuss agreement testing and its relation to coboundary expansion in more detail further below in this introduction.

In light of all of the above, we believe that cosystolic expansion is a fundamental notion that merits a deeper systematic study. Along with the aim of exploring its various implications, a more concrete research goal would be to give strong bounds, and ultimately nail down exactly, the correct expansion values for the most important and well-studied high dimensional expanders. We mention that to the best of our knowledge even for the simplest cases, such as expansion of  $k$ -chains in the  $n$ -simplex, exact expansion values are not yet completely determined.

In this work we provide new bounds for the coboundary expansion of the spherical building, and the cosystolic expansion of known bounded-degree high dimensional expanders including the complexes of [49, 48, 42].

Two of the most celebrated results in this area are the works of [35] and [22] showing that the bounded-degree families of Ramanujan complexes of [48] are cosystolic expanders. These works introduce an elegant local-to-global criterion, showing that if the links are coboundary expanders, and further assuming spectral expansion, then the entire complex is a cosystolic expander.

The estimates proven by [35, 22] for the coboundary expansion parameters are roughly  $h^k(X) \geq \min\left(\frac{1}{Q}, (d!)^{-O(2^k)}\right)$ . Here  $X$  is a  $d$  dimensional LSV complex and  $Q$  is the maximal degree of a vertex which is roughly equal to  $1/\lambda^{O(d^2)}$  in these complexes, where  $\lambda$  is the spectral bound on the expansion of the links. Subsequent works by Kaufman and Mass [37, 38, 39], improved this bound to

$$h^k(X) \geq \min\left(\frac{1}{Q}, (d!)^{-O(k)}\right). \tag{1}$$

We completely get rid of the dependence on the ambient dimension  $d$  and on the maximal degree  $Q$ , and prove

► **Theorem 1.** *For every integer  $d > 1$  and every small enough  $\lambda > 0$  let  $X$  be a  $d$ -dimensional LSV complex whose links are  $\lambda$ -one-sided expanders. For every group <sup>2</sup>  $\Gamma$ , every small enough  $\lambda > 0$  and every integer  $k < d - 1$ ,  $h^k(X, \Gamma) \geq \exp(-O(k^6 \log k))$ .*

Our bounds for  $h^k$  only depend on the dimension  $k$  of the chains, so for  $k = 1$  they are absolute constants. For larger  $k$  we still suffer an exponential decay. We do not know what the correct bound should be and whether dependence on  $k$  is at all necessary.

The case of  $k = 1$  is interesting even in complexes whose dimension is  $d \gg 1$ , because  $h^1$  controls the cover stability of the complex, as shown in [20]. Our bounds also immediately give an improvement for the topological overlap constants, when plugged into the Gromov machinery [30, 21, 22]. We elaborate on both of these applications later below.

---

<sup>2</sup> The theorem holds for every group  $\Gamma$  for which cohomology is defined, namely, abelian groups for  $k > 1$  and any group for  $k = 1$ .

The result is proven by enhancing the local-to-global criterion of [22], and introducing a variant of the local correction algorithm that makes local fixes only if they are sufficiently cost-effective. This is inspired by and resembles the algorithms in [22, 16, 55].

Our analysis is novel and departs from previous proofs: instead of relying on the so-called “fat machinery” of [22] (and its adaptations [37, 38]), our proof is 100% fat free and relies on the up/down averaging operators on *real-valued functions*. Our main argument is to show that, for a function  $h$  that is the indicator of the support of a (locally minimal)  $k$ -chain,

$$\|D \cdots Dh\|^2 \gtrsim \cdots \gtrsim \|DDh\|^2 \gtrsim \|Dh\|^2 \gtrsim \|h\|^2,$$

where  $D$  is the down averaging operator, and we write  $a \gtrsim b$  whenever  $a \geq \Omega(b)$ . From here we easily derive a lower bound on  $\|h\|^2$  showing that either the correction algorithm has found a nearby cocycle, or else the coboundary of our function was initially very large to begin with.

This method gives universal bounds on the cosystolic expansion of any complex whose links have both sufficient coboundary-expansion and sufficient local spectral expansion,

► **Theorem 2.** *Let  $\beta, \lambda > 0$  and let  $k > 0$  be an integer. Let  $X$  be a  $d$ -dimensional simplicial complex for  $d \geq k + 2$  and assume that  $X$  is a  $\lambda$ -one-sided local spectral expander. Let  $\Gamma$  be any group. Assume that for every non-empty  $r \in X$ ,  $X_r$  is a coboundary expander and that  $h^{k+1-|r|}(X_r, \Gamma) \geq \beta$ . Then*

$$h^k(X, \Gamma) \geq \frac{\beta^{k+1}}{(k+2)! \cdot 4} - e\lambda.$$

Here  $e \approx 2.71$  is Euler’s number.

Armed with an improved local-to-global connection, we derive Theorem 1 from Theorem 2 by further strengthening the coboundary expansion of the links of the LSV complexes, namely spherical buildings. The best previously known bound on coboundary expansion of  $k$ -cochains in spherical buildings is due to [30] and [47]. They proved a lower bound of  $\left(\binom{d+1}{k+1}(d+2)!\right)^{-1}$ . This decays exponentially with the ambient dimension  $d$ , and with the cochain level  $k$ . We remove the dependence on  $d$  by developing a new technique which we call “color-restriction”. The  $d$ -dimensional spherical buildings are colored, namely, they are  $d+1$ -partite. For a set of  $\ell$  colors  $F \subset [d+1]$ , the color restriction  $X^F$  is the complex induced on vertices whose color is contained in  $F$ . The restriction to the colors of  $F$  reduces the dimension of  $X$  from  $d$  to  $\ell - 1$ . We say that a color restriction  $X^F$  is a  $\beta$ -local coboundary expander, if  $X^F$  is a  $\beta$ -coboundary expander, and the same holds for the intersection of  $X^F$  with links (neighbourhoods) of faces whose color is disjoint from  $F$ . We show that if a typical color-restriction is a local coboundary expander, then the entire complex is a coboundary expander, and the expansion is independent of the dimension. Namely,

► **Theorem 3.** *Let  $k, \ell, d$  be integers so that  $k + 2 \leq \ell \leq d$  and let  $\beta, p \in (0, 1]$ . Let  $X$  be a  $(d + 1)$ -partite  $d$ -dimensional simplicial complex so that*

$$\mathbb{P}_{F \in \binom{[d+1]}{\ell}} [X^F \text{ is a } \beta\text{-locally coboundary expander}] \geq p.$$

Then  $h^k(X) \geq \frac{p\beta^{k+1}}{e(k+2)!}$ .

Finally, to prove that the spherical building satisfies the conditions of this theorem, we need to show that a typical random color-restriction is a good coboundary expander. For this we rely on the “cone machinery” developed by Gromov [30], Kozlov and Meshulam [44], and Kaufman and Oppenheim [42]. We construct in the full version of this paper [10], a novel family of short cones, thus proving the following.

► **Theorem 4.** *Let  $k \geq 0$ . There is an absolute constant  $\beta_k = \exp(-O(k^5 \log k)) \geq 0$  so that the following holds. Let  $X$  be the  $SL_n(\mathbb{F}_q)$ -spherical building for any integer  $n \geq k + 1$  and prime power  $q$ . Let  $\Gamma$  be any group. Then  $X$  is a coboundary expander with constant  $h^k(X, \Gamma) \geq \beta_k$ .*

In fact, we prove a more general version of this theorem, that holds for the order complex of any homogeneous geometric lattice, see the full version of this paper [10].

Most earlier works on cosystolic expansion focus on  $\mathbb{F}_2$  coefficients (see [37] and [20] for two exceptions). This is an important case especially in light of Gromov’s result connecting  $\mathbb{F}_2$ -expansion and topological overlap. However, expansion (of 1-chains) with respect to more general coefficients is necessary for results on topological covers and in turn for agreement testing. The theorems stated above show expansion of  $k$ -chains with respect to coefficients not only in  $\mathbb{F}_2$  but in general abelian groups  $\Gamma$ , and when  $k = 1$  also for non abelian groups  $\Gamma$ . In other words, the theorems hold for all groups of coefficients where the cohomology is defined.

Finally, we end with an upper bound. While most of our work is focused on lower bounds for coboundary and cosystolic expansion, we show in the full version of this paper [10] that families of dense simplicial complexes cannot have cosystolic expansion greater than  $1 + o(1)$ . This implies that high degree, in some weak sense, limits cosystolic expansion. It is interesting to compare this to a result of Kozlov and Meshulam that shows upper bounds on coboundary expansion of complexes with bounded degree [44].

### 1.1 Applications of cosystolic expansion

We describe two applications of cosystolic expansion for deriving topological properties of simplicial complexes.

#### Topological overlap

Cosystolic expansion was studied by [30] to give a combinatorial criterion for the topological overlapping property. Let  $f : X \rightarrow \mathbb{R}^k$  be continuous mapping (with respect to the natural topology on  $X$ ), i.e.  $f$  realizes  $X$  in  $\mathbb{R}^k$ . A point  $p \in \mathbb{R}^k$  is called  $c$ -heavily covered if

$$\mathbb{P}_{s \in X^{(k)}} [p \in f(s)] \geq c.$$

A well known result by [24] showed that for every affine map from the complete 2-dimensional complex to the plane, there exists a  $\frac{1}{27}$ -heavily covered point. Gromov’s greatly generalized this theorem to all *continuous* functions (instead of only affine functions), all dimensions  $k$  (instead of  $k = 2$ ) and complexes that are cosystolic expanders (instead of the complete complex), with  $c$  that depends on the dimension of the map  $k$ , as well as the cosystolic expansion constant. For a precise statement, see the full version of this paper [10].

The motivation for [22] was to show that there exists families of bounded degree simplicial complexes which have this property. They use [48] complexes and achieve a lower bound of  $c \geq \min(\frac{1}{Q}, (d!)^{-O(2^k)})$ , which comes from their bound on cosystolic expansion. This bound has been improved as a corollary of [39] to  $\min(\frac{1}{Q}, (d!)^{-O(k)})$ . Here again,  $d$  is the dimension of  $X$ , which may be much larger than  $k$ , and  $Q$  is the maximal degree of a vertex in  $X$ .

Plugging in our bounds into Gromov’s theorem gives the bound  $c \geq \exp(-O(k^7 \log k))$  for the topological overlapping property. This bound is free of the ambient dimension and of the degree.

### Cover stability

The second author and Meshulam studied a topological locally testable property called *cover stability* [20]. This property is equivalent to cosystolic expansion of 1-chains. A covering map between two simplicial complexes  $X, Y$  is a surjective  $t$ -to-1 simplicial map<sup>3</sup>  $\rho : Y(0) \rightarrow X(0)$  such that for every  $\tilde{u} \in Y(0)$  and  $\rho(\tilde{u}) = u \in X(0)$ , it holds that the links of  $\tilde{u}, u$  are isomorphic  $Y_{\tilde{u}} \cong X_u$ .

Graph covers (also known as lifts) have been quite useful in construction of expander graphs. Bilu and Linial showed that random covers of Ramanujan graphs are almost Ramanujan [6]. A celebrated result by [50] used these techniques to construct bipartite Ramanujan graphs of every degree. Recently, [9] showed that random covers could also be applied for constructing new simplicial complexes that are local spectral expanders.

Dinur and Meshulam [20] show that there exists a test that for any simplicial complex  $X$  and an alleged cover given by a simplicial map  $\rho : Y \rightarrow X$  samples  $q$  points  $(u_i, \rho(u_i))$  and measures how close  $\rho$  is to an actual covering map. The query complexity of the test is  $q = 3t$  points. Its soundness is affected by the cosystolic expansion of 1-chains. Using our new bounds on cosystolic expansion, we show that the complexes constructed in [48] or in [42] are cover-stable, i.e. that there exists some universal constant  $c > 0$ , such that for every  $\rho : Y(0) \rightarrow X(0)$

$$\mathbb{P}_{(u_i, \rho(u_i))_{i=1}^q} [\text{test fails}] \geq c \cdot \min \{ \text{dist}(\rho, \psi) \mid \psi : Y(0) \rightarrow X(0) \text{ is a cover} \},$$

where the distance is Hamming distance.

### Agreement testing

Coboundary expansion found an exciting new application in agreement testing [28, 11, 5]. An agreement test is a consistency test that originated as a component in low degree testing [58, 2, 56], but has been extensively studied ever since (see e.g. [26, 34, 18]). This test is a crucial component in many PCP constructions [57, 26, 15, 34, 19]. Given a set of partial functions on a set, an agreement test is a way to test whether these functions are correlated with some function that defined on the whole vertex set. The works [28, 11, 5] mentioned above use coboundary expansion to characterize when an agreement test is sound. Via this characterization they analyze agreement tests on high dimensional expanders. Continuing this line of works, [12, 14, 4] use theorems and tools developed in a preliminary version of this paper, to lower bound coboundary expansion of new high dimensional expanders, and with these lower bounds they obtain new agreement tests. These include the first agreement tests where the underlying complex family is bounded degree in the so called “list decoding regime” (the regime that is relevant to high-soundness PCPs such as the parallel repetition PCP [57, 34]).

---

<sup>3</sup> simplicial means that every  $i$ -face in  $Y$  is sent to an  $i$ -face in  $X$ .

## 1.2 Related work

Coboundary and Cosystolic expansion was defined by Linial, Meshulam and Wallach [45], [51], and independently by Gromov [30]. Gromov studied cosystolic expansion as a proxy for showing the topological overlapping property. Linial, Meshulam and Wallach were interested in analyzing high dimensional connectivity of random complexes.

Kaufman, Kazhdan and Lubotzky [35] introduced an elegant local to global argument for proving cosystolic expansion of 1-chains in the *bounded-degree* Ramanujan complexes of [49, 48]. This was significantly extended by Evra and Kaufman [22] to cosystolic expansion in all dimensions, thereby resolving Gromov’s conjecture about existence of bounded degree simplicial complexes with the topological overlapping property in all dimensions. Kaufman and Mass [37, 38] generalized the work of Evra and Kaufman from  $\mathbb{F}_2$  to all other groups as well, and used this to construct lattices with good distance. The best previously known bound for LSV complexes (1) was shown by Kaufman and Mass in [39].

Following ideas that appeared implicitly in Gromov’s work, Lubotzky Mozes and Meshulam analyzed the expansion of many “building like” complexes [47]. Kozlov and Meshulam [44] abstracted the main lower bound in [47] to the definition of cones (which they call chain homotopies), in order to analyze the coboundary expansion of geometric lattices and other complexes. Their work also connects coboundary expansion to other homological notions, and gives an upper bound to the coboundary expansion of bounded degree simplicial complexes. In [42], Kaufman and Oppenheim defined the notion of cones in order to analyze the cosystolic expansion of their high dimensional expanders (see [40]). In addition, they also come up with a criterion for showing that complexes admit short cones. They prove lower bounds on the cosystolic expansion of their complexes for 0- and 1-chains. The case of  $k$ -chains with  $k \geq 2$  is still open.

Several works tried to define quantum LDPC codes as cohomologies of simplicial complexes. Cosystolic expansion is used for analyzing the distance of the quantum code. Works by Evra, Kaufman and Zémor [23] and by Kaufman and Tessler [43] used cosystolic expansion in Ramanujan complexes to construct quantum codes that beat the  $\sqrt{n}$ -distance barrier. This continued in a sequence of works [54, 32, 7] which culminated in the breakthrough work of [55] that construct quantum LDPC codes with constant rate and distance. This later code is a cohomology of a certain chain complex, albeit not a simplicial complex; and it is analyzed essentially through the cosystolic expansion. Developing new techniques for cosystolic expansion can be potentially useful in this domain as well.

## 1.3 Open questions

The works by [47], [44] and [42] analyze a variety of symmetric complexes (that support a transitive group action). Could one combine our “color restriction” technique with the cone machinery to get lower bounds independent of degree and dimension on these complexes as well? There are a number of concrete constructions of local spectral high dimensional expanders that have excellent local spectral properties [8, 46, 27, 52, 9]. Are any of them cosystolic expanders?

Another intriguing direction of research is to develop additional techniques for analyzing coboundary or cosystolic expansion. The current techniques are limited to complexes that either have a lot of symmetry, or have excellent local expansion properties. Are there other complexes with these properties?

Our expansion bounds still have a dependence on the level ( $k$ ) of the chains. In the complete complex, for instance, this is not necessary. The complete complex is a  $\beta = 1 + o(1)$  coboundary expander for all  $k$ -chains [47]. It is not clear whether a dependence on  $k$  is necessary even in the spherical building. Which complexes have coboundary expansion that does not decay with the size of the chains?

Finally, the notion of coboundary and cosystolic expansion is closely related to locally testable codes and quantum LDPC codes. They also have connections to agreement expanders. It is interesting to find additional applications for these expanders.

## 1.4 Overview of the proof of Theorem 1

We start with a complex  $X$  that is a finite quotient of the affine building, as constructed by [48]. Our goal is to lower bound the cosystolic expansion of  $X$ . The proof has three components:

- (Theorem 2) A new local-to-global argument that derives cosystolic expansion of the complex from coboundary and spectral expansion of its links.
- (Theorem 3) A general color restriction technique that reduces the task of analyzing the coboundary expansion of a partite complex, to that of analyzing the local coboundary expansion of random color restrictions of it.
- (Theorem 4) Bounds on random color restrictions of (links of) the spherical building. Towards this end we construct a novel family of short cones for the spherical building (not based on apartments as in previous works [47]).

Below we give a short overview of each of these steps. For simplicity we assume in this subsection that  $\Gamma = \mathbb{F}_2$ , which captures the main ideas.

### The local to global argument, Theorem 2

Let  $X$  be our simplicial complex. We describe a correction algorithm, that takes as input a  $k$ -chain  $f : X(k) \rightarrow \mathbb{F}_2$ , with small coboundary  $\mathbb{P}[\delta f \neq 0] = \varepsilon$  and outputs a  $k$ -chain  $\tilde{f} : X(k) \rightarrow \mathbb{F}_2$  close to  $f$  that has no coboundary, i.e.  $\delta \tilde{f} = 0$ . For this overview, we focus on  $k = 1$ , i.e.  $f$  is a function on edges, which already exhibits the main ideas.

Let  $\eta > 0$  be some predetermined parameter. Our algorithm locally fixes “stars” of lower dimensional faces, that is, sets  $Star_k(r) = \{s \in X(k) \mid s \supseteq r\}$  for  $r \in X(j)$  (when  $j \leq k$ ). The fix takes place only if it is sufficiently useful: whenever it decreases the weight of  $\delta f$  by at least  $\eta \mathbb{P}[Star_k(r)]$ . In the case at hand,  $k = 1$ , so  $r$  is either a vertex or an edge, so

1. If  $r \in X(1)$ ,  $Star_1(r) = \{r\}$  and a fix just means changing the value of  $f(r)$ .
2. If  $r \in X(0)$ ,  $Star_1(r) = \{ru\}_{u \sim r}$  are all edges adjacent to  $r$ . Here a fix means changing the values of all  $\{f(ru) \mid u \sim r\}$  simultaneously.

#### ► Algorithm 5.

1. Set  $f_0 := f$ . Set  $i = 0$ .
2. While there exists a vertex or edge  $r \in X(0) \cup X(1)$  so that  $Star_k(r)$  has an assignment that satisfies a  $\eta \mathbb{P}[Star_k(r)]$ -fraction of faces more than the current assignment.
  - Let  $fix_r : Star_k(r) \rightarrow \Gamma$  be an optimal assignment to  $Star_k(r)$ .
  - Set  $f_{i+1}(s) = \begin{cases} f_i(t) & r \not\subseteq s \\ fix_r(s) & r \subseteq s \end{cases}$ .
  - Set  $i := i + 1$ .
3. Output the final function  $\tilde{f} := f_i$ .

The fact that we correct  $f$  locally only if the fix satisfies  $\eta$  fraction more triangles will promise that  $\text{dist}(f, \tilde{f}) \leq \frac{1}{\eta} \text{wt}(\delta f)$ . The output of the algorithm,  $\tilde{f}$ , is *not* necessarily locally minimal in the sense of [35, 22], but it is “ $\eta$ -locally-minimal”.

Notation: For functions  $g, h : X(\ell) \rightarrow \mathbb{R}$  we denote by  $\langle g, h \rangle = \mathbb{E}_{r \in X(\ell)} [g(r)h(r)]$  the usual inner product. For  $\ell = 1, 2$ , denote by  $D^\ell$  the *down operator* that takes  $h : X(2) \rightarrow \mathbb{R}$  and outputs  $D^\ell h : X(2 - \ell) \rightarrow \mathbb{R}$  via averaging. Namely  $D^\ell h(r)$  is the average of  $h(s)$  over  $s \supseteq r$ ,  $\mathbb{E}_{s \supseteq r} [h(s)]$ .

Let  $h : X(2) \rightarrow \mathbb{R}$  indicate the support of a  $\delta \tilde{f}$ , so  $h(t) = 1$  iff  $\delta \tilde{f} \neq 0$ . Our main argument is to show

$$\|D^3 h\|^2 \gtrsim \|D^2 h\|^2 \gtrsim \|Dh\|^2 \gtrsim \|h\|^2.$$

Eventually  $D^3 h = \mathbb{E}[h]^2$  is just a constant function. This shows that  $(\mathbb{E}[h])^2 = \text{const} \cdot \mathbb{E}[h]$  which implies that either the algorithm corrected  $f$  to a cosystol, i.e.  $h = 0$ , or that  $h$  has large weight, which implies that  $\delta f$  had large weight to begin with.

Let us show for example that  $\|D^3 h\|^2 \gtrsim \|D^2 h\|^2$  given that  $\|D^2 h\|^2 \gtrsim \|Dh\|^2 \gtrsim \|h\|^2$ . To do so, we define an auxiliary averaging operator  $N$  based on a random walk from vertices to triangles, and use the fact that in local spectral expanders,

$$\|D^3 h\|^2 \approx \langle Nh, D^2 h \rangle. \tag{2}$$

The operator  $N : \ell_2(X(2)) \rightarrow \ell_2(X(0))$  is defined by  $Nh(v) = \mathbb{E}_s [h(s)]$ , where  $s$  is sampled according to the following walk: Given  $v \in X(0)$ , sample some  $t \in X(3)$  such that  $v \in t$ , and then go to the triangle  $s = t \setminus \{v\}$ . We mention that the concept of localizing over such a distribution has appeared in [39]. The proof of (2) follows by localizing the expectation to the links and relying on the link expansion as in [53], [13, Claim 8.8] and in [41].

The key lemma in the proof shows that if there are many faces  $s' \supseteq v_0$  such that  $h(s') = 1$ , then there are many  $s$  such that  $v \notin s, \{v\} \cup s = t \in X(3)$ , where  $h(s) = 1$ . More precisely, we will show that for every  $v \in X(0)$  it holds that

$$Nh(v) \gtrsim \beta(D^2 h(v) - \eta)^4. \tag{3}$$

This immediately implies that

$$\begin{aligned} \langle Nh, D^2 h \rangle &= \mathbb{E}_v [D^2 h(v)Nh(v)] \\ &\stackrel{(3)}{\gtrsim} \beta(\mathbb{E}_v [(D^2 h(v))^2] - \eta \mathbb{E}_v [D^2 h(v)]) \\ &\gtrsim \beta\|D^2 h\|^2 - \beta\eta\|h\|^2 \\ &\gtrsim \beta\|D^2 h\|^2. \end{aligned}$$

The second inequality follows from  $\mathbb{E}_v [D^2 h(v)] = \mathbb{E}_s [h(s)] = \|h\|^2$ . The last inequality follows from the assumption that  $\|h\|^2 = O(\|D^2 h\|^2)$ . Combining this with (2) gives us the desired inequality.

Let us understand what is written in (3). On the right-hand side,  $D^2 h(v) = \mathbb{P}_{xy \in X_v(1)} [h(vxy) = 1]$  is the fraction of triangles  $vxy$  containing  $v$ , such that  $\delta \tilde{f}(vxy) \neq 0$ . On the left-hand side,  $Nh(v)$  is the fraction of  $s$  that complete  $v$  to some  $t = v \cup s \in X(3)$ , so that  $\delta \tilde{f}(s) \neq 0$ . For such an  $s = uxy$ ,

$$0 = \delta \delta \tilde{f}(vuxy) = \delta \tilde{f}(uxy) + (\delta \tilde{f}(vux) + \delta \tilde{f}(vuy) + \delta \tilde{f}(vxy)). \tag{4}$$

Set  $g : X_v(1) \rightarrow \mathbb{F}_2$  to be  $g(xy) = \delta \tilde{f}(vxy)$ , and note that  $g$  has the following properties:

1. By (4),  $\delta\tilde{f}(uxy) = 1 \iff \delta g(uxy) = 1$ .
2.  $\mathbb{P}[g \neq 0] = \mathbb{P}_{s \ni v}[\delta\tilde{f}(s) \neq 0] = D^2h(v)$ .
3.  $\eta$ -local-minimality: which is  $\text{dist}(g, B^1(X_v)) \geq \mathbb{P}[g \neq 0] - \eta$ , where  $B^1(X_v) = \{\delta\psi \mid \psi : X_v(0) \rightarrow \mathbb{F}_2\}$  is the set of coboundaries.

We explain the third item. Assume towards contradiction that  $\text{dist}(g, B^1(X_v)) < \mathbb{P}[g \neq 0] - \eta$  and let  $\delta\psi$  be a coboundary closest to  $g$ . Then by changing the values of  $\tilde{f}$  on  $\text{Star}(v)$  to be  $\tilde{f}'(vu) := \tilde{f}(vu) + \psi(u)$ , we have that whenever  $g(xy) = \delta\psi(xy)$ , then the fixed function satisfies  $\delta\tilde{f}'(vxy) = 0$ . I.e.

$$\text{dist}(g, \delta\psi) = \mathbb{P}_{vxy}[\delta\tilde{f}'(vxy) = 0] < \mathbb{P}_{vxy}[\delta\tilde{f}(vxy) = 0] - \eta.$$

This is a contradiction to the  $\eta$ -local minimality of  $\tilde{f}$  which is guaranteed by the algorithm.

Here is where the coboundary expansion of  $X_v$  comes into play. By coboundary expansion, we have that  $\mathbb{P}[\delta g(uxy) = 1] \geq \beta \text{dist}(g, B^1(X_v))$ . By combining the above we will get that

$$Nh(v) = \mathbb{P}_{uxy \in X_v(2)}[\delta\tilde{f}(uxy) \neq 0] \geq \beta \left( \mathbb{P}_{xy \in X_v(1)}[g(xy) \neq 0] - \eta \right) = \beta(D^2h(v) - \eta).$$

### The “color restriction” technique, Theorem 3

For this overview, assume that  $k = 2$ . The full details are in the full version of this paper [10]. Let  $Y$  be a  $d$ -dimensional  $(d+1)$ -partite complex so that a  $p$ -fraction of its color restrictions  $Y^F$  are  $\beta$ -local-coboundary expanders. We begin with a 2-chain  $f : Y(2) \rightarrow \mathbb{F}_2$  with small coboundary, namely  $\mathbb{P}_{s \in Y(3)}[\delta f(s) \neq 0] = \varepsilon$ . We need to find a 1-chain  $g : Y(1) \rightarrow \mathbb{F}_2$  so that  $\text{dist}(f, \delta g) \leq O(\frac{\varepsilon}{\beta^3 p})$ .

We first select a random color restriction, i.e. a set of colors so that  $Y^F$  is a local coboundary expander, that the weight of  $\delta f$  when restricted to triangles whose colors are in  $F$  is close to weight of  $\delta f$  on all  $Y$ . Averaging arguments guarantee that such  $F$  exists. Using this  $F$ , we construct  $g$  in three steps. In the first step we define  $g$  on edges with both endpoints colored in  $F$ ,  $uv \in Y^F$ . In the second step we define  $g$  on edges with one endpoint colored in  $F$ , i.e.  $uv \in Y(1)$  where  $u \in Y^F$  and  $v \notin Y^F$ . In the third step we define  $g$  on edges  $uv \in X(1)$  with neither endpoints colored in  $F$ , i.e. where  $u, v \notin Y^F$ . Every step uses the values of  $g$  that were constructed in the step before. For  $k > 2$  the  $(k-1)$ -chain is constructed following a similar sequence of  $k+1$  steps.

1. We start with the values of  $g$  on edges  $vu \in Y^F(1)$ . By the choice of  $F$ , the weight of  $\delta f$  inside  $Y^F$  is roughly  $\varepsilon$ . Local coboundary expansion implies that there exists a 1-chain  $g_0$  whose coboundary is close to  $f$  on  $Y^F$ . We set  $g(uv) = g_0(uv)$  for all  $uv \in Y^F(1)$ .
2. Next we define  $g$  on edges  $vu$  so that  $v \notin Y^F$  and  $u \in Y^F$ . Fix some  $v \notin Y^F$ . Let  $Y_v^F = \{s \in Y^F \mid s \cup v \in Y\}$ . This is the color restriction of the link of  $v$ . We wish to set values for  $g(vu)$  for all edges  $vu$  such that  $u \in Y_v^F(0)$ . We describe a system of equations that we use to set the values of  $g$  on the edges  $vu$  so as to satisfy a maximal number of equations. For every  $u_1u_2 \in Y_v^F(1)$ , the triangle  $vu_1u_2$  defines an equation:

$$f(vu_1u_2) + g(u_1u_2) = g(u_1v) + g(u_2v). \quad (5)$$

Note that the left-hand side of the equation is known since we have the values of  $f$  on all triangles, and we already constructed  $g$  for edges  $u_1u_2 \in Y^F(1)$ . So the above is an equation with two unknowns. We set  $g(vu)$  simultaneously for all  $u \in Y_v^F(1)$  to be an assignment that satisfies the largest fraction of equations (ties broken arbitrarily).

The idea behind this step is the following. Obviously, we'd like that  $f(vu_1u_2) = g(u_1u_2) + g(u_1v) + g(u_2v)$  for as many triangles as possible, so it makes sense to define  $g$  to satisfy

■ **Figure 1** Tiling a cycle.

the largest amount of equations (5). Let  $h_v : Y_v^F(1) \rightarrow \mathbb{F}_2$  be the left-hand side of (5), i.e.  $h_v(u_1u_2) = f(vu_1u_2) + g(u_1u_2)$ . We want to find an assignment  $g_v : Y_v^F(0) \rightarrow \mathbb{F}_2$  so that  $h_v(u_1u_2) = g_v(u_1) + g_v(u_2)$  for as many equations (5) as possible (and set  $g(vu) = g_v(u)$ ). Finding a solution  $g_v : Y_v^F(0) \rightarrow \mathbb{F}_2$  that satisfies (5) is equivalent finding  $g_v$  so that  $h_v(u_1u_2) = \delta g_v(u_1u_2)$ . Hence, to find an assignment that satisfies most of the equations is the same showing that  $h_v$  is close to a coboundary. In the analysis we show that  $\delta h_v \approx 0$ . This together with the local coboundary expansion of  $Y^F$  (which says that  $h^1(Y_v^F, \mathbb{F}_2) \geq \beta$ ) will show that indeed we can find satisfying  $\{g_v\}_{v \notin Y^F}$  so that  $f \approx \delta g$  where the distance is over edges  $uv$  where  $v \notin Y^F, u \in Y^F$ .

3. Finally we need to define the values of  $g$  on edges  $vu$  so that  $v, u \notin Y^F$ . Let  $vu$  be such an edge. Every triangle  $uvw$  where  $w \in Y_{vu}^F(0)$  defines a constraint on  $g(vu)$ :

$$f(uvw) + g(uw) + g(vw) = g(vu). \tag{6}$$

As in the previous case,  $f(uvw)$  is known, and  $g(uw), g(vw)$  were determined in step 2. We set  $g(vu) = \text{maj} \{f(uvw) + g(uw) + g(vw) \mid w \in Y_{vu}^F(0)\}$ . Ties are broken arbitrarily. Here we use the local coboundary expansion of  $Y^F$  in a way similar to the previous step, to show that indeed  $f \approx \delta g$ .

### New bounds on color-restrictions of the spherical building via cones, Theorem 4

In order to apply the color restriction technique we need to show that for a  $d$ -dimensional spherical building, many color restrictions are coboundary expanders<sup>5</sup>. For this overview we assume that  $k = 1$  and  $|F| = 5$ . Let us see how to bound coboundary expansion by constructing short cones.

It turns out easier to do so when the set of colors is a set of colors that are geometrically increasing (e.g. for  $k = 1$  we need colors  $F = \{i_1, i_2, \dots, i_5\}$  so that  $i_j \geq 10i_{j-1}$ ). The fraction of such sets of colors  $F$  is a constant that doesn't depend on  $d$  (it may depend on  $k$ ). For example, there is a constant probability that we select colors  $F$  so that for  $j = 1, 2, \dots, 5$ ,  $\frac{d}{10^{16-3j}} \leq i_j < \frac{2d}{10^{16-3j}}$ , since each of these intervals are a constant fraction of the interval  $[1, 2, \dots, d]$ . When these inequalities hold then  $i_j \geq 10i_{j-1}$ .

Denote by  $Y$  the  $SL_d(\mathbb{F}_q)$ -spherical building. Let  $Y^F$  be a complex induced by the subspaces of dimensions (i.e., colors)  $F = \{i_1, i_2, \dots, i_5\}$  so that  $i_j \geq 10i_{j-1}$ . Using the cone technology described in the full version of this paper [10], showing the  $Y^F$  is a coboundary expander reduces to showing that there is a short 1-cone on  $Y^F$ . A 1-cone consists of three things:

<sup>5</sup> In fact, we need to show that the links of the color restrictions are also coboundary expanders, but we ignore this point in the overview for brevity.

1. A vertex  $v \in X(0)$  (sometimes called the apex).
  2. For every  $u$ , a path  $p_u$  from the apex  $v$  to  $u$  in  $Y^F(1)$ .
  3. For every edge  $uw \in$ , a tiling by triangles  $t_{uw} \subset Y^F(2)$  of the cycle that consists of the path  $p_u$  from  $v$  to  $u$ , the edge  $uw$  and the path  $p_w$  from  $w$  back to  $v$ . Denote this cycle by  $p_u \circ uw \circ p_w$ . Here a tiling is a set of triangles whose boundary is the edges of the cycle.
- We give a formal and general definition of cones in the full version of this paper [10]. The radius of a cone is  $\text{rad}((v, \{p_u\}_{u \in Y^F(0)}, \{t_{uw}\}_{uw \in Y^F(1)})) = \max_{uw \in X(1)} |t_{uw}|$ .

We start by choosing an apex  $v = v_0$  of dimension  $i_1$  arbitrarily. Next we choose our paths to be as short as possible, and to consist of subspaces of dimension as low as possible. Explicitly we do the following.

1. For  $u$  adjacent to  $v_0$ , set  $p_u = (v_0, u)$ .
2. For  $u$  of the same dimension as  $v_0$  we find some  $w$  of dimension  $i_2$  so that  $w$  is a neighbour of  $v_0$  and  $u$ , and set  $p_u = (v_0, w, u)$ . This is always possible since the dimension of  $u + v_0$  is at most  $2i_1$ , so we can take any  $w$  of dimension  $i_2 \geq 2i_1$  that contains the sum of spaces. (Notice how the fact that dimensions are geometrically increasing is important here).
3. For other  $u \in Y^F(0)$ , we first take some  $w_2 \subseteq u$  of dimension  $i_1$ . Then we find some  $w_1$  who is a neighbour of  $v_0$  and of  $w_2$  and we set  $p_u = (v_0, w_1, w_2, u)$ .

Constructing  $t_{w_1 w_2}$  requires more care. Let us first consider the easier case. If  $\dim(w_1), \dim(w_2) \leq i_4$  then the cycle  $p_{w_1} \circ w_1 w_2 \circ p_{w_2}$  contains at most 7 vertices, all of dimension  $\leq i_4$ . In particular, the sum of all the vertices/subspaces is of dimension at most  $7i_4 \leq i_5$ , so there is a vertex  $u^*$  of dimension  $i_5$  that contains all the vertices in the cycle. The set of triangles  $u^*xy$  for all edges  $xy$  in the cycle is indeed a tiling of the cycle.

In the general case, it could be that the dimension of (say)  $w_1$  is  $i_5$ . For example, assume that  $\dim(w_1) = i_5, \dim(w_2) = i_4$  (in particular  $w_2 \subseteq w_1$ ). It is useful to read this description while looking at Figure 1. In this case, we first find a tiling that “shifts” the cycle to a cycle of low dimension vertices. More explicitly, we find some  $w'_2 \subseteq w_2$  of dimension  $i_3$ , that is also connected to  $w$ ’s neighbours in the cycle. These neighbours are  $w_1$  (and any subspace of  $w_2$  is connected to it), and some  $u'_2$  of dimension  $\leq i_2$ , so we can indeed find some  $w'_2$  that is connected to  $u$  and  $u'_2$  of dimension  $i_3$ . We tile the cycle with  $w_2 w'_2 u'_2, w_2 w'_2 w_1$ . This exchanges  $w_2$  with  $w'_2$  in the untiled cycle. We perform a similar vertex-switch, for  $w_1$  as well, finding some  $w'_1$  of dimension  $i_4$  that is connected to  $w_1$  neighbours in the untiled cycle. After these two steps, we can find a  $u^*$  that is connected to all the (now low-dimensional) cycle as in the previous case.

## 1.5 Organization of this paper and the full version

Section 2 contains preliminaries. We prove Theorem 2 that connects coboundary expansion in links to cosystolic expansion in Section 3 via the local correction algorithm. We develop the “color restriction” technique and prove Theorem 3 in the full version of this paper [10]. We analyze the expansion of the spherical building and other homogeneous geometric lattices in the full version of this paper [10]. In the full version [10], we also tie everything up and prove Theorem 1, as well as present the aforementioned applications of this bound. We also give there an upper bound on the cosystolic expansion of dense complexes.

## 2 Preliminaries and notation

For a more thorough preliminary section, see the full version of the paper [10].

### Simplicial complexes

A pure  $d$ -dimensional simplicial complex  $X$  is a set system (or hypergraph) consisting of an arbitrary collection of sets of size  $d + 1$  together with all their subsets. The sets of size  $i + 1$  in  $X$  are denoted by  $X(i)$ , and in particular, the vertices of  $X$  are denoted by  $X(0)$ . We will sometimes omit set brackets and write for example  $uvw \in X(2)$  instead of  $\{u, v, w\} \in X(2)$ . As convention  $X(-1) = \{\emptyset\}$ . Unless it is otherwise stated, we always assume that  $X$  is finite. Let  $X$  be a  $d$ -dimensional simplicial complex. Let  $k \leq d$ . We denote the set of oriented  $k$ -faces in  $X$  by  $\vec{X}(k) = \{(v_0, v_1, \dots, v_k) \mid \{v_0, v_1, \dots, v_k\} \in X(k)\}$ . For  $s = (v_0, v_1, \dots, v_k) \in \vec{X}(k)$  we denote  $set(s) = \{v_i\}_{i=0}^k$ , but when its clear from context we abuse notation and write  $s$  for its underlying set instead of  $set(s)$ . For an oriented face  $s \in \vec{X}(k)$  and an index  $i \in \{0, 1, \dots, k\}$ , we denote by  $s_i$  the face obtained by removing the  $i$ -th vertex of  $s$ .

Finally, Let  $s = (v_0, \dots, v_i)$ , and  $t = (u_0, \dots, u_j)$ . We denote by the concatenation  $s \circ t = (v_0, v_1, \dots, v_i, u_0, u_1, \dots, u_j)$ .

### Probability over simplicial complexes

Let  $X$  be a simplicial complex and let  $\mathbb{P}_d : X(d) \rightarrow (0, 1]$  be a density function on  $X(d)$  (i.e.  $\sum_{s \in X(d)} \mathbb{P}_d(s) = 1$ ). This density function induces densities on lower level faces  $\mathbb{P}_k : X(k) \rightarrow (0, 1]$  by  $\mathbb{P}_k(t) = \frac{1}{\binom{d+1}{k+1}} \sum_{s \in X(d), s \supset t} \mathbb{P}_d(s)$ . We can also define a probability over directed faces, where we choose an ordering uniformly at random. Namely, for  $s \in \vec{X}(k)$ ,  $\mathbb{P}_k(s) = \frac{1}{(k+1)!} \mathbb{P}_k(set(s))$ . When it's clear from the context, we omit the level of the faces, and just write  $\mathbb{P}[T]$  or  $\mathbb{P}_{t \in X(k)}[T]$  for a set  $T \subseteq X(k)$ .

## 2.1 Coboundary and cosystolic expansion

### Asymmetric functions

Let  $X$  be a  $d$ -dimensional simplicial complex. Let  $-1 \leq k \leq d$  be an integer. Let  $\Gamma$  be a group. A function  $f : \vec{X}(k) \rightarrow \Gamma$  is *asymmetric* if for every  $(v_0, v_1, \dots, v_k) \in \vec{X}(k)$ , and every permutation  $\pi : [k] \rightarrow [k]$  it holds that

$$f(v_0, v_1, \dots, v_k) = f(v_{\pi(0)}, v_{\pi(1)}, \dots, v_{\pi(k)})^{sign(\pi)}.$$

We denote the set of these functions by  $C^k(X, \Gamma)$ . We note that by fixing some order to the vertices  $X(0) = \{v_0, v_1, \dots, v_n\}$ , there is a bijection between functions  $f : X(k) \rightarrow \Gamma$  and asymmetric functions  $\vec{f} : \vec{X}(k) \rightarrow \Gamma$ . Given  $f : X(k) \rightarrow \Gamma$  and a set  $s = \{v_{i_0}, v_{i_1}, \dots, v_{i_k}\}$  so that  $i_0 < i_1 < \dots < i_k$ , we set  $\vec{f}(v_{\pi(i_0)}, v_{\pi(i_1)}, \dots, v_{\pi(i_k)}) = f(s)^{sign(\pi)}$ .

Let  $f : \vec{X}(k) \rightarrow \Gamma$ . The weight of  $f$  is  $wt(f) = \mathbb{P}_{t \in X(k)}[f(t) \neq 0]$ . For two functions  $f, g : \vec{X}(k) \rightarrow \Gamma$  the distance between  $f$  and  $g$  is  $dist(f, g) = wt(f - g) = \mathbb{P}_{t \in X(k)}[f(t) \neq g(t)]$ .

### Cohomology

Let  $\Gamma$  be an abelian group. The coboundary operator  $\delta_k : C^k(X, \Gamma) \rightarrow C^{k+1}(X, \Gamma)$  is defined by  $\delta_k f(s) = \sum_{i=0}^k (-1)^i f(s_i)$ . It is a direct calculation to verify that for any asymmetric function  $f \in C^k$  the function  $\delta_k f$  is indeed an asymmetric function, and that  $\delta_{k+1} \circ \delta_k = 0$ .

## 62:14 Coboundary and Cosystolic Expansion Without Dependence on Dimension or Degree

Let  $B^k(X, \Gamma) = \text{Im}(\delta_{k-1})$  be the space of coboundaries. Let  $Z^k(X, \Gamma) = \text{Ker}(\delta_k)$  be the space of cosystols. As  $\delta_{k+1} \circ \delta_k = 0$ , it holds that  $B^k(X, \Gamma) \subseteq Z^k(X, \Gamma)$ . The  $k$ -cohomology is  $H^k(X, \Gamma) = Z^k(X, \Gamma)/B^k(X, \Gamma)$ .

### Coboundary expansion

For a function  $f : \vec{X}(k) \rightarrow \Gamma$  let  $\text{dist}(f, B^k) = \min_{g \in C^{k-1}} \text{dist}(f, \delta g)$ , be the minimal distance between  $f$  and a coboundary. The  $k$ -th coboundary constant of a complex  $X$  (with respect to an abelian group  $\Gamma$ ) is  $h^k(X, \Gamma) = \min_{f \in C^k \setminus B^k} \frac{wt(\delta f)}{\text{dist}(f, B^k)}$  where  $B^k = B^k(X, \Gamma)$ . Note that  $h^k(X, \Gamma) > 0$  if and only if  $H^k = 0$ .

### Cosystolic expansion

A very related high dimensional notion of expansion is cosystolic expansion. The  $k$ -th cosystolic expansion constant of  $X$  (with respect to an abelian group  $\Gamma$ ) is

$$h^k(X, \Gamma) = \min_{f \in C^k \setminus Z^k} \frac{wt(\delta f)}{\text{dist}(f, Z^k)},$$

where  $Z^k = Z^k(X, \Gamma)$ . Notice that when  $B^k(X, \Gamma) = Z^k(X, \Gamma)$ , namely, when  $H^k = 0$ , this coincides with the definition of coboundary expansion, and this justifies using the same notation  $h^k$ , where the term coboundary expansion (as opposed to cosystolic expansion) is taken to indicate  $H^k = 0$ .

Another useful way to understand the constant is the following.  $h^k(X, \Gamma) \geq \beta$  if and only if for every  $f : \vec{X}(k) \rightarrow \Gamma$  there is some  $h \in Z^k(X, \Gamma)$  so that  $\beta \text{dist}(f, h) \leq wt(\delta f)$ . We note that in the work of [22] cosystolic expanders were also required to have no small weight  $f \in Z^k(X, \Gamma) \setminus B^k(X, \Gamma)$ . We don't focus on this notion in our work.

### Non abelian coboundary and cosystolic expansion

For  $k = 0, 1$  we can define the cohomology with respect to non abelian groups as well. Let  $\Gamma$  be a non abelian group. As before, for every  $k$  we can define  $C^k(X, \Gamma)$ . We define the coboundary operators as follows:

1.  $\delta_{-1} : C^{-1}(X, \Gamma) \rightarrow C^0(X, \Gamma)$  is  $\delta_{-1}h(v) = h(\emptyset)$ .
2.  $\delta_0 : C^0(X, \Gamma) \rightarrow C^1(X, \Gamma)$  is  $\delta_0h(vu) = h(v)h(u)^{-1}$ .
3.  $\delta_1 : C^1(X, \Gamma) \rightarrow C^2(X, \Gamma)$  is  $\delta_1h(vuw) = h(vu)h(uw)h(wv)$ .

It is easy to check that  $\delta_{k+1} \circ \delta_k f = e$  where  $e \in \Gamma$  is the unit. The definitions for  $h^k(X, \Gamma)$  and coboundary expansion are the same as in the abelian case for  $k = 0, 1$ .

## 2.2 Local properties of simplicial complexes

### Links of faces

Let  $X$  be a  $d$ -dimensional simplicial complex. Let  $k < d$  and  $s \in X(k)$ . The link of  $s$  is a  $d - k - 1$ -dimensional simplicial complex defined by  $X_s = \{t \setminus s \mid t \in X, t \supseteq s\}$ . We point out that the link of the empty set is  $X_\emptyset = X$ . Let  $s \in X(k)$  for some  $k \leq d$ . The density function  $\mathbb{P}_d$  on  $X$  induces on the link is  $\mathbb{P}_{d-k-1}^s : X(d - k - 1) \rightarrow (0, 1]$  where  $\mathbb{P}_{d-k-1}^s[t] = \frac{\mathbb{P}[t \cup s]}{\mathbb{P}[s] \binom{d+1}{k+1}}$ . We usually omit  $s$  in the probability, and for  $T \subseteq X_s(k)$  we write  $\mathbb{P}_{t \in X_s(k)}[T]$  instead.

### High dimensional local spectral expanders

Let  $X$  be a  $d$ -dimensional simplicial complex. Let  $k \leq d$ . The  $k$ -skeleton of  $X$  is  $X^{\leq k} = \bigcup_{j=-1}^k X(j)$ . In particular, the 1-skeleton of  $X$  is a graph.

► **Definition 6** (Spectral expander). Let  $G = (V, E)$  be a graph (that is, a 1-dimensional simplicial complex). Let  $A$  be its normalized adjacency operator, i.e. for every  $f : V \rightarrow \mathbb{R}$ ,  $Af : V \rightarrow \mathbb{R}$  is the function  $Af(v) = \mathbb{E}_{uv \in E} [f(u)]$ . Let  $1 = \lambda_1 \geq \lambda_2 \geq \dots \geq \lambda_{|V|} \geq -1$  be the eigenvalues of  $A$ .

Let  $\lambda \geq 0$ . We say that  $G$  is a  $\lambda$ -one sided spectral expander if  $\lambda_2 \leq \lambda$ . We say that  $G$  is a  $\lambda$ -two sided spectral expander if  $\lambda_2 \leq \lambda$  and  $\lambda_{|V|} \geq -\lambda$ .

► **Definition 7** (high dimensional local spectral expander). Let  $X$  be a  $d$ -dimensional simplicial complex. Let  $\lambda \geq 0$ . We say that  $X$  is a  $\lambda$ -one sided (two sided) local spectral expander if for every  $s \in X^{\leq d-2}$ , the 1-skeleton of  $X_s$  is a  $\lambda$ -one sided (two sided) spectral expander.

### 3 Cosystolic expansion

In this section we prove that local spectral expanders whose links are coboundary expanders are cosystolic expanders, that is, Theorem 2.

In fact, we prove a slightly more general statement, allowing for different coboundary expansion in every level.

► **Theorem 8.** Let  $k > 0$  be an integer and let  $\beta_0, \beta_1, \beta_2, \dots, \beta_k \in (0, 1]$  and  $\lambda > 0$ . Let  $X$  be a  $d$ -dimensional simplicial complex for  $d \geq k + 2$  and assume that  $X$  is a  $\lambda$ -one-sided local spectral expander. Let  $\Gamma$  be any group. Assume that for every  $0 \leq \ell \leq k$  and  $r \in X(\ell)$ ,  $X_r$  is a coboundary expander and that  $h^{k-\ell}(X_r, \Gamma) \geq \beta_{k-\ell}$ . Then  $h^k(X, \Gamma) \geq \frac{\prod_{\ell=0}^k \beta_\ell}{(k+2)! \cdot 4} - e\lambda$ .

Here  $e \approx 2.71$  is Euler's number. Obviously, Theorem 2 follows from Theorem 8 by setting  $\beta_\ell = \beta$  for every  $\ell = 0, 1, 2, \dots, k$ . The following proposition, that is important for the topological overlapping property will also be proven via similar arguments.

► **Proposition 9.** Let  $k > 0$  be an integer and let  $\beta_0, \beta_1, \beta_2, \dots, \beta_{k-1} \in (0, 1]$  and  $\lambda > 0$ . Let  $X$  be a  $d$ -dimensional simplicial complex for  $d \geq k + 1$  and assume that  $X$  is a  $\lambda$ -one-sided local spectral expander. Let  $\Gamma$  be any group. Assume that for every  $0 \leq \ell \leq k - 1$  and  $r \in X(\ell)$ ,  $X_r$  is a coboundary expander and that  $h^{k-\ell}(X_r, \Gamma) \geq \beta_{k-\ell-1}$ . Then every  $g \in Z^k(X, \Gamma) \setminus B^k(X, \Gamma)$ , has  $wt(g) \geq \frac{\prod_{\ell=0}^{k-1} \beta_\ell}{(k+1)!} - e\lambda$ .

We remark that the when  $\Gamma$  is non abelian, these statements make sense only when  $k = 1$ . Turning back to Theorem 8, we present a correction algorithm. We will show that when  $f \in C^k(X, \Gamma)$  has a small coboundary, then the algorithm below returns some  $\tilde{f} \in Z^k(X, \Gamma)$  that is close to  $f$ .

► **Algorithm 10.** Input: A function  $f : \vec{X}(k) \rightarrow \Gamma$ , a parameter  $\eta \leq 1$ . Output: A function  $\tilde{f} : \vec{X}(k) \rightarrow \Gamma$ .

1. Set  $f_0 := f$ . Set  $i = 0$ .
2. While there exists  $\ell \leq k$ , and a face  $r \in \vec{X}(\ell)$  so that  $Star_k(r) = \{s \in X(k) \mid r \subseteq s\}$  has an assignment that satisfies a  $\eta \mathbb{P}[Star_k(r)]$ -fraction of faces more than the current assignment, do:
  - Let  $fix_r : Star_k(r) \rightarrow \Gamma$  be an optimal assignment to  $Star_k(r)$ , satisfying the maximal number of  $k + 1$ -faces containing  $r$ .
  - Set  $f_{i+1}(s) = \begin{cases} f_i(s) & r \not\subseteq s \\ fix_r(s) & r \subseteq s \end{cases}$ .
  - Set  $i := i + 1$ .
3. Output  $\tilde{f} := f_i$ .

### 3.1 Properties of Algorithm 10

Before proving Theorem 8 we record some properties of Algorithm 10.

▷ Claim 11. Algorithm 10 halts on every input.

▷ Claim 12. Let  $f : \vec{X}(k) \rightarrow \Gamma$  and let  $\eta \leq 1$ . Let  $\tilde{f} : \vec{X}(k) \rightarrow \Gamma$  be the output of Algorithm 10 on  $(f, \eta)$ . Then  $\eta \text{dist}(f, \tilde{f}) \leq \text{wt}(\delta f)$ .

These claims are elementary, they proven in full in the full version of this paper [10].

### 3.2 Local minimality

► **Definition 13** (Restriction). Let  $g \in C^k(X, \Gamma)$  and let  $r \in X(\ell)$  for some  $0 \leq \ell \leq k - 1$ . The restriction of  $g$  to  $r$  is the function  $g_r \in C^{k-\ell-1}(X_r, \Gamma)$  is defined by  $g_r(p) = g(r \circ p)$ .

► **Definition 14** (Local minimality). Let  $\eta \geq 0$  and let  $g \in C^k(X, \Gamma)$ . We say that  $g$  is  $\eta$ -locally minimal, if for every  $0 \leq \ell \leq k - 1$ , every  $r \in X(\ell)$ , and every  $h \in C^{k-\ell-2}(X_r, \Gamma)$  it holds that  $\text{wt}(g_r) \leq \text{wt}(g_r + \delta h) + \eta$ .

► **Definition 15** (Non abelian local minimality). If  $\Gamma$  is non-abelian we need the correct analogy to adding coboundaries. The definition of  $\eta$ -minimality is as follows. If  $k = 1$ , we say that  $g$  is  $\eta$ -locally minimal if for every  $v \in X(0)$ , and every  $\gamma \in \Gamma$ , it holds that  $\text{wt}(g_v) \leq \text{wt}(\gamma \cdot g_v) + \eta$ . If  $k = 2$ , we say that  $g$  is  $\eta$ -locally minimal if:

1. For every edge  $uv$  and every  $\gamma \in \Gamma$ , it holds that  $\text{wt}(g_{uv}) \leq \text{wt}(\gamma \cdot g_{uv}) + \eta$ .
2. For every vertex  $v$  and every function  $h : X_v(0) \rightarrow \Gamma$ , it holds that  $\text{wt}(g_v) \leq \text{wt}(g_v^h) + \eta$ , where  $g_v^h(uw) = h^{-1}(u)g_v(uw)h(w)$ .

The following claim is standard and is proven in the full version of this paper [10]

▷ Claim 16. Let  $f : \vec{X}(k) \rightarrow \Gamma$  and let  $\eta \leq 1$ . Let  $\tilde{f} : \vec{X}(k) \rightarrow \Gamma$  be the output of Algorithm 10 on  $(f, \eta)$ . Then  $\delta \tilde{f}$  is  $\eta$ -locally minimal.

### 3.3 Locally minimal cosystols are heavy

The following lemma states that non-zero functions that are locally minimal must have large weight.

► **Lemma 17.** Let  $\beta_0, \dots, \beta_{k-1}$  and  $\lambda$  be as in Theorem 8. Let  $X$  be such that for every  $0 \leq \ell \leq k - 1$  and every  $s \in X(\ell)$  it holds that  $X_s$  is a coboundary expander and  $h^{k-\ell-1}(X_s, \Gamma) \geq \beta_{k-\ell-1}$ . Assume further that  $X$  is a  $\lambda$ -local spectral expander. Let  $g \in Z^k(X, \Gamma)$  be non-zero and  $\eta$ -locally minimal. Then

$$\text{wt}(g) \geq \frac{\prod_{\ell=0}^{k-1} \beta_\ell}{(k+1)!} - e(\eta + \lambda). \quad (7)$$

Additionally, for the case of non-abelian  $\Gamma$ , when  $k = 2$ , (7) holds for  $\eta$ -locally minimal and non-zero  $g = \delta f$ , for any  $f \in C^1(X, \Gamma)$ .

The last remark regarding  $k = 2$  is needed since  $Z^2(X, \Gamma)$  is not defined for non-abelian groups  $\Gamma$ . This lemma implies Theorem 2 and Proposition 9 directly.

**Proof of Theorem 8, given Lemma 17.** Fix  $\eta = \frac{\prod_{\ell=0}^k \beta_\ell}{4((k+2)!)}.$  Let  $\tilde{f}$  be the output of Algorithm 10 for some function  $f$  and  $\eta$ . If  $wt(\delta f) \geq \frac{\prod_{\ell=0}^k \beta_\ell}{4((k+2)!)} - e\lambda$  there is nothing to prove, so we assume that  $wt(\delta f) < \frac{\prod_{\ell=0}^k \beta_\ell}{4((k+2)!)} - e\lambda$ . Then  $\delta \tilde{f} \in Z^{k+1}(X, \Gamma)$  is an  $\eta$ -locally minimal function so that  $wt(\delta \tilde{f}) \leq wt(\delta f)$ . Hence by Lemma 17 (applied with  $k + 1$  instead of  $k$ ),  $\delta \tilde{f} = 0$  and  $\tilde{f}$  is a cosystol. By Claim 12,  $\eta \text{dist}(f, \tilde{f}) \leq wt(\delta f)$ , and we are done. ◀

**Proof of Proposition 9, given Lemma 17.** For every  $r \in X(j)$  and  $h \in C^{k-j-1}(X_r, \Gamma)$ , we define  $h^\uparrow : X(k) \rightarrow \Gamma$  by

$$h^\uparrow(s) = \begin{cases} h(p) & s = r \circ p \\ 0 & r \not\subseteq s. \end{cases}$$

It is easy to see that  $g_r + \delta h = (g + \delta h^\uparrow)_r$ .

Now let  $0 \neq g \in Z^k(X, \Gamma) \setminus B^k(X, \Gamma)$  be minimal among all  $Z^k(X, \Gamma) \setminus B^k(X, \Gamma)$ . By the above,  $g$  is also 0-locally minimal (since otherwise we could have found some non-zero coboundary  $\delta h^\uparrow$  to add to  $g$  and decrease its weight). Thus  $wt(g) \geq \frac{\prod_{\ell=0}^{k-1} \beta_\ell}{(k+1)!} - e\lambda$  as required.

We remark that the case where  $\Gamma$  is non-abelian and  $k = 1$  is similar. Given  $g \in Z^1(X, \Gamma) \setminus B^1(X, \Gamma)$  that is non-zero and has minimal weight over all such functions. First we establish that it is locally minimal. Indeed, assume towards contradiction that there is some vertex  $v \in X(0)$  and  $\gamma \in \Gamma$  so that  $wt(g_v) < wt(\gamma g_v)$ . Then the function

$$g'(xy) = \begin{cases} \gamma g(xy) & x = v \\ g(xy)\gamma^{-1} & y = v \\ g(xy) & \text{otherwise} \end{cases}$$

is also a cosystol. Taking some triangle  $vuw \in X(2)$  that contains  $v$ , the value of

$$\delta g'(vuw) = \gamma \delta g(vuw) \gamma^{-1} = e$$

(the identity in  $\Gamma$ ). For any triangle  $uwx$  that doesn't contain  $v$  we have that  $\delta g'(uwx) = \delta g(uwx) = e$ . On the other hand,  $wt(g') < wt(g)$  so  $g'$  is trivial, which implies that  $g = \delta h$  where  $h(v) = \gamma$  and  $h(u) = e$ . A contradiction to the fact that  $g \notin B^1(X, \Gamma)$ . ◀

The remainder of this section is devoted to proving Lemma 17. For this we need to define averaging operators that play a crucial role in the theory behind local-spectral expanders. We will only define what we need so for a more thorough exposition see e.g. [13]. Let  $\ell_2(X(j))$  be the Hilbert space of all functions  $f : X(j) \rightarrow \mathbb{R}$  where the inner product is  $\langle f, g \rangle = \mathbb{E}_{r \in X(j)} [f(r)g(r)]$ . Let  $D_k : \ell_2(X(k)) \rightarrow \ell_2(X(k-1))$  be the following operator

$$D_k f(s) = \mathbb{E}_{t \supseteq s} [f(t)].$$

This operator's adjoint is  $U_{k-1} : \ell_2(X(k-1)) \rightarrow \ell_2(X(k))$  that is defined by

$$U_{k-1} f(t) = \mathbb{E}_{s \subseteq t} [f(s)].$$

As a shorthand we write  $D_k^\ell = D_{k-\ell+1} D_{k-\ell+2} \dots D_k$  for  $\ell \geq 1$  (and the same for  $U$ ). For  $\ell = 0$   $D_k^0 = U_k^0 = Id$ . We record that  $D_k^\ell f$  is a function whose domain is  $X(k-\ell)$ , and that  $U_k^\ell f$  is a function whose domain is  $X(k+\ell)$ .

Let  $j \leq k < d$ . The operator  $N_{k \rightarrow j} : \ell_2(X(k)) \rightarrow \ell_2(X(j))$  is defined by

$$N_{k \rightarrow j} f(r) = \mathbb{E}_{t \in X(k+1), t \supseteq r} \left[ \mathbb{E}_{s \subseteq t, r \not\subseteq s} [f(s)] \right].$$

Let us spell out this expression. We average over  $f(s)$  where  $s$  is chosen according to the following rule. We first sample some  $t \supseteq r$  in  $X(k+1)$ , and then we sample  $s \subseteq t$  given that it does not contain  $r$ .

When  $j, k$  is clear from the context we simply write  $D, U, N$ .

The following is an operator norm inequality that is similar to [13], but for the one-sided case. We prove it in the full version of this paper [10].

▷ **Claim 18.** Let  $X$  be a  $\lambda$ -one-sided local spectral expander. Then  $U_j^{k-j} N_{k \rightarrow j} \preceq U_{j-1}^{k-j+1} D_k^{k-j+1} + \lambda Id$  for every  $j \leq k$ .

Here  $A \preceq B$  for self adjoint operators  $A, B$  means that  $B - A$  is positive semi-definite, that is,  $\langle (B - A)h, h \rangle \geq 0$  for every function  $h$  in the domain of  $A, B$ .

**Proof of Lemma 17.** Let  $h = \mathbf{1}_{g \neq 0}$ . We will prove that  $wt(g) = \mathbb{E}[h] \geq \frac{\prod_{\ell=0}^{k-1} \beta_\ell}{(k+1)!} - e(\eta + \lambda)$ . We do this by showing that

1.  $\|D_k h\|^2 \geq \frac{1}{k+1} \|h\|^2 - \lambda \|h\|^2$ .
2. For  $0 \leq j < k$ ,  $\|D_k^{k-j+1} h\|^2 \geq \frac{\beta_{k-j-1}}{j+1} \cdot \|D_k^{k-j} h\|^2 - \left( \frac{\beta_{k-j-1}\eta}{j+1} + \lambda \right) \|h\|^2$ .

We note that  $D^{k+1}h$  is a constant (as  $\lambda$ -local spectral expansion says in particular that the complex is connected) - the average of  $h$  on all faces. Hence  $\|D^{k+1}h\|^2 = \mathbb{E}[h]^2$ . By iteratively applying these inequalities we get that

$$\begin{aligned} \mathbb{E}[h]^2 &= \|D^{k+1}h\|^2 \\ &\geq \beta_{k-1} \|D^k h\|^2 - (\beta_{k-1}\eta + \lambda) \|h\|^2 \\ &\geq \frac{\beta_{k-1}\beta_{k-2}}{2} \|D^{k-1}h\|^2 - \beta_{k-1} \left( \frac{\beta_{k-2}\eta}{2} + \lambda \right) \|h\|^2 - (\beta_{k-1}\eta + \lambda) \|h\|^2 \\ &\dots \\ &\geq \|h\|^2 \cdot \left( \frac{\prod_{\ell=0}^{k-1} \beta_\ell}{(k+1)!} - \eta \sum_{j=0}^{k-1} \frac{\beta_j}{(k-j+1)!} - \lambda \left( 1 + \sum_{j=0}^{k-1} \frac{\beta_j}{(k-j+1)!} \right) \right). \end{aligned}$$

By assuming  $\beta_j \leq 1$ , we upper bound  $\sum_{j=0}^{k-1} \frac{\beta_j}{(k-j+1)!} \leq \sum_{j=0}^{\infty} \frac{1}{j!} = e$ , and get  $\mathbb{E}[h]^2 \geq \|h\|^2 \cdot \frac{\prod_{\ell=0}^{k-1} \beta_\ell}{(k+1)!} - e(\eta + \lambda)$ . As  $\|h\|^2 = \mathbb{E}[h]$  the lemma follows.

Let us begin with the first item. we call  $s \in X(k)$  *active* if  $h(s) = 1$ . By assumption,  $g \in Z^k(X, \Gamma)$ , i.e.

$$\delta g(t) = \sum_{i=0}^{k+1} (-1)^i g(t_i) = 0.$$

Thus if  $t \in X(k+1)$  contains an active  $s = t_{i_1}$ , then it must also contain a second active

$s' = t_{i_2}$ <sup>6</sup>. This implies that  $N_{k \rightarrow k} h(s) \geq \frac{1}{k+1} h(s)$ , and so

$$\langle h, N_{k \rightarrow k} h \rangle = \mathbb{E}_t [h(t) N_{k \rightarrow k} h(t)] \geq \frac{1}{k+1} \|h\|^2.$$

By Claim 18  $N^{k \rightarrow k} \preceq UD + \lambda Id$ , so

$$\frac{1}{k+1} \|h\|^2 \leq \langle N_{k \rightarrow k} h, h \rangle \leq \langle UDh, h \rangle + \lambda \|h\|^2 = \|Dh\|^2 + \lambda \|h\|^2$$

so the first item is proven.

Next, we will prove the second item. As before, we will show that

$$\langle U^{k-j} N_{k \rightarrow j} h, h \rangle \geq \frac{\beta_{k-j-1}}{j+1} \cdot (\|D^{k-j} h\|^2 - \eta \|h\|^2). \quad (8)$$

Then we rely on Claim 18

$$\|D^{k-j+1} h\|^2 \geq \langle U^{k-j} N_{k \rightarrow j} h, h \rangle - \lambda \|h\|^2. \quad (9)$$

Combining these inequalities completes the proof.

We now state the following claim, which is proven using the coboundary expansion of  $X_r$  where  $r$  is a  $j$ -face.

► **Lemma 19** (Key lemma). *Let  $r \in X(j)$ . Then*

$$N_{k \rightarrow j} h(r) \geq \frac{\beta_{k-j-1}}{j+1} (D^{k-j} h(r) - \eta).$$

From this pointwise inequality, (8) follows easily:

$$\begin{aligned} \langle U^{k-j} N_{k \rightarrow j} h, h \rangle &= \langle N_{k \rightarrow j} h, D^{k-j} h \rangle \geq \mathbb{E}_r \left[ D^{k-j} h(r) \cdot \frac{\beta_{k-j-1}}{j+1} \cdot (D^{k-j} h(r) - \eta) \right] \\ &= \frac{\beta_{k-j-1}}{j+1} \cdot (\|D^{k-j} h\|^2 - \eta \|h\|^2) \end{aligned} \quad (10)$$

◀

We will prove Lemma 19 under the assumption that  $\Gamma$  is abelian since additive notation is more convenient. For non-abelian groups, see Remark 20.

**Proof of Lemma 19.** First, let us understand the meaning of the inequality in Lemma 19. Recall that  $N_{k \rightarrow j} h(r)$  is an average of  $h(s)$  over faces  $s \in X(k)$  so that  $r, s \subseteq t$  for some  $t \in X(k+1)$  and  $r \not\subseteq s$ . As  $h$  is an indicator function this is the same as writing

$$N_{k \rightarrow j} h(r) = \mathbb{P}_{t,s} [h(s) = 1],$$

where  $t, s$  are as above. On the other side of the inequality there is  $D^{k-j} h(r) = \mathbb{P}_{s \supseteq r} [h(s) = 1]$ . Hence, we need to show that if there are many active faces that contain  $r$ , there must also be many active faces that “complete”  $r$  to a  $(k+1)$ -face.

We first note that

$$N_{k \rightarrow j} h(r) = \mathbb{P}_{t,s} [h(s) = 1] \geq \frac{1}{j+1} \mathbb{P}_t [\exists s \subseteq t \ h(s) = 1 \text{ and } r \not\subseteq s], \quad (11)$$

so we shall actually lower bound  $\mathbb{P}_t [\exists s \subseteq t \ h(s) = 1 \text{ and } r \not\subseteq s]$ .

<sup>6</sup> in the case where  $\Gamma$  is non-abelian and  $g = \delta f \in C^2(X, \Gamma)$ , even though  $\delta g(abcd)$  is not defined, one still observes that  $\delta f(abc) = \delta f(acd) = \delta f(abd) = e$  implies that  $\delta f(bcd) = 0$  so the same conclusion holds.

As  $g \in Z^k(X, \Gamma)$ , for every  $t = r \circ p \in X(k+1)$

$$0 = \delta g(r \circ p) = \sum_{i=0}^j (-1)^i g(r_i \circ p) + (-1)^j \sum_{i=0}^{k-j} (-1)^i g(r \circ p_i). \quad (12)$$

And in particular

$$\sum_{i=0}^{k-j} (-1)^i g(r \circ p_i) \neq 0 \iff \sum_{i=0}^j (-1)^i g(r_i \circ p) \neq 0. \quad (13)$$

Recall that the restriction of  $g$  is  $g_r : X_r(k-j-1) \rightarrow \Gamma$ , defined by  $g_r(p) = g(r \circ p)$ . As we can see,  $\delta g_r(p)$  is the left-hand side of (13). Thus

$$\mathbb{P}_t [\exists s \subseteq t \ h(s) = 1 \text{ and } r \not\subseteq s] \geq \mathbb{P}_{t=r \circ p} \left[ \sum_{i=0}^{k-j} (-1)^i g(r \circ p_i) \neq 0 \right] \quad (14)$$

$$= \mathbb{P}_{p \in X_r(k-j)} [\delta g_r(p) \neq 0]. \quad (15)$$

By assumption  $X_r$  is a  $\beta_{k-j-1}$ -coboundary expander, this is at least  $\beta_{k-j-1} \cdot \text{dist}(g_r, B^{k-j-1}(X_r, \Gamma))$ .

To conclude we need to show that

$$\text{dist}(g_r, B^{k-j-1}(X_r, \Gamma)) \geq \mathbb{P}_{s \supseteq r} [g(s) \neq 0] - \eta. \quad (16)$$

But

$$\text{dist}(g_r, B^{k-j-1}(X_r, \Gamma)) = \min_{f \in C^{k-j-2}(X_r, \Gamma)} \{wt(g_r + \delta f)\} \geq wt(g_r) - \eta. \quad (17)$$

where the inequality follows from  $\eta$ -minimality of  $g$ . As  $wt(g_r) = \mathbb{P}_{s \supseteq r} [h(s) = 1]$  we have proven

$$N_{k \rightarrow j} h(r) \geq \frac{\beta_{k-j-1}}{j+1} \text{dist}(g_r, B^{k-j-1}(X_r, \Gamma)) \geq \frac{\beta_{k-j-1}}{j+1} \left( \mathbb{P}_{s \supseteq r} [h(s) = 1] - \eta \right). \quad \blacktriangleleft$$

► **Remark 20 (The non-abelian case).** The first place where we need to accommodate for the non-commutativity is in the derivation of (14). Let us understand how to substitute (12) which implies (13), for non-abelian groups.

If for example, if  $r \in X(0)$  and  $g \in Z^1(X, \Gamma)$ , and  $ruw \in X(2)$  we can write

$$e = \delta g(ruw) = g(ru)g(uw)g(wr)$$

instead of (12). This implies that

$$g(uw) = g(ur)g(rw) \quad (18)$$

or

$$g(rw)g(uw)g(wr) = g(rw) \cdot (g(ur)g(rw)) \cdot g(wr) = g(rw)g(ru)^{-1} = g_r(w)g_r(u)^{-1} = \delta g_r(wu)$$

where in the first equality we plugged in the first part of (18) and in the second to last equality we plugged in the second part of (18). Since the left hand side is a conjugation of  $g(uw)$ , we deduce that  $g(uw) \neq e \iff \delta g_r(wu) \neq e$ . This is the same conclusion as we get in (12). The case where  $r \in X(1)$  is similar.

If  $k = 2$  we cannot even define (12) since the coboundary map is not defined. Still, let us see that a similar conclusion to (13) holds. Let  $g = \delta f \in C^2(X, \Gamma)$ . Let  $r = ab \in X(1)$  and  $t = abcd \in X(3)$ . Denote by  $\gamma = f(ab)f(bc)f(cd)$ . Then

$$\begin{aligned} \gamma^{-1} \delta g_r(cd) \gamma &= \gamma^{-1} g(rc) g(rd)^{-1} \gamma \\ &= \gamma^{-1} g(abc) g(adb) \gamma \\ &= f(dc) \cdot \overline{(f(cb)f(ba)f(ab)f(bc))} \cdot f(ca) f(ad) f(db) \cdot \overline{(f(ba)f(ab))} \cdot f(bc) f(cd) \\ &= (f(dc) \overline{f(ca) f(ad)}) (f(db) f(bc) f(cd)) \\ &= \delta f(dca) \delta f(dbc) \\ &= g(dca) g(dcb)^{-1}. \end{aligned}$$

In particular, we deduce that  $g(dca)g(dcb)^{-1} \neq e \iff \delta g_r(cd) \neq e$ , and (14) now becomes

$$\mathbb{P}_t [\exists s \subseteq t \ h(s) = 1 \text{ and } r \not\subseteq s] \geq \mathbb{P}_{t=r \circ cd} [g(dca)g(dcb)^{-1} \neq 0] = \mathbb{P}_{cd \in X_r(1)} [\delta g_r(cd) \neq 0]. \quad (19)$$

Similarly, when  $r = a \in X(0)$  and  $t = abcd$  we observe similarly that

$$\begin{aligned} f(ab)g(bcd)f(ba) &= f(ab)(f(bc)f(cd)f(db))f(ba) \\ &= f(ab)f(bc) \cdot (f(ca)f(ac)) \cdot f(cd) \cdot (f(da)f(ad)) \cdot f(db)f(ba) \\ &= \delta f(abc) \delta f(acd) \delta f(adb) \\ &= g_a(bc) g_a(cd) g_a(db) \\ &= \delta g_a(bcd), \end{aligned}$$

and in particular

$$\mathbb{P}_t [\exists s \subseteq t \ h(s) = 1 \text{ and } r \not\subseteq s] \geq \mathbb{P}_{t=a \circ bcd} [g(bcd) \neq e] = \mathbb{P}_{bcd \in X_a(2)} [\delta g_a(bcd) \neq e]. \quad (20)$$

The second equality we need to modify is (17). For example, take an  $\eta$ -locally minimal  $g \in C^2(X, \Gamma)$ , a vertex  $r \in X(0)$ , and  $\delta h \in B^1(X_r, \Gamma)$  that is a closest coboundary to  $g_r \in C^1(X_r, \Gamma)$ . Then

$$\text{dist}(g_r, \delta h) = \mathbb{P} [g_r(vu) \neq h(v)h(u)^{-1}] = wt(g_r^h) \geq wt(g_r) - \eta.$$

The case where  $r \in X(1)$  is similar.

## Abstract

Let  $G = (V, E)$  be a graph on  $n$  vertices and let  $m^*(G)$  denote the size of a maximum matching in  $G$ . We show that for any  $\delta > 0$  and for any  $1 \leq k \leq (1 - \delta)m^*(G)$ , the down-up walk on matchings of size  $k$  in  $G$  mixes in time polynomial in  $n$ . Previously, polynomial mixing was not known even for graphs with maximum degree  $\Delta$ , and our result makes progress on a conjecture of Jain, Perkins, Sah, and Sawhney [STOC, 2022] that the down-up walk mixes in optimal time  $O_{\Delta, \delta}(n \log n)$ .

In contrast with recent works analyzing mixing of down-up walks in various settings using the spectral independence framework, we bound the spectral gap by constructing and analyzing a suitable multi-commodity flow. In fact, we present constructions demonstrating the limitations of the spectral independence approach in our setting.

## 1 Introduction

Sampling and counting matchings in graphs is a central and well-studied problem. An early success in this direction is the classical algorithm of Kasteleyn for counting the number of perfect matchings in a planar graph [18]. Starting with the foundational work of Valiant [23], it was established that Kasteleyn’s algorithm is exceptional in the sense that it is #P-hard to (exactly) count the number of perfect matchings, even for restricted classes of input graphs such as bipartite graphs and graphs of bounded degree. In fact, perhaps quite surprisingly, the more general problem of counting matchings of a given size is #P-hard, even restricted to the class of planar graphs [15].

Given the above hardness results, the best one can hope for is fully polynomial-time (possibly randomized) approximation schemes. In particular, in connection with fully polynomial-time randomized approximation schemes (FPRAS) for the number of matchings (possibly of a given size), as well as being an important problem in its own right, much work has been devoted to the problem of approximately sampling from various distributions on matchings of a graph. The celebrated work of Jerrum and Sinclair [16] showed that for the monomer-dimer model at activity  $\lambda$  (i.e. the distribution on matchings where the probability

of a matching  $M$  is proportional to  $\lambda^{|M|}$ ;  $\lambda$  is known as the activity), the Glauber dynamics mixes in time polynomial in  $n$  and  $\lambda$ . For graphs  $G = (V, E)$  of bounded degree and  $\lambda = O(1)$ , the optimal mixing time  $O(|E| \log n)$  was obtained by Chen, Liu, and Vigoda [6].

By combining with a rejection sampling procedure, both of these works give polynomial time algorithms to approximately sample from the uniform distribution on matchings of size  $k \leq (1 - \delta)m^*(G)$  for any fixed  $\delta > 0$ , where  $m^*(G)$  denotes the matching number of  $G$  i.e. the size of a largest matching in  $G$ ; approximately sampling from the uniform distribution on perfect matchings of a graph remains a major open problem, although in the bipartite case, this was famously resolved by Jerrum, Sinclair, and Vigoda [17]. For the class of bounded degree graphs, an algorithm with near-optimal run time was provided by a recent work of Jain, Perkins, Sah, and Sawhney [14]; they gave an algorithm which, given a graph  $G$  of maximum degree  $\Delta$ , an integer  $1 \leq k \leq (1 - \delta)m^*(G)$ , and a parameter  $\varepsilon > 0$ , outputs a random matching  $M$  of size  $k$  in time  $\tilde{O}_{\Delta, \delta}(n)$ <sup>1</sup> such that the total variation distance is less than  $\varepsilon$  between the distribution on  $M$  and the uniform distribution on  $\mathcal{M}_k(G)$ : the matchings in  $G$  of size  $k$ .

Despite this progress, the mixing time of perhaps the simplest random walk on  $\mathcal{M}_k(G)$  – the so-called down-up walk – is not understood. By the down-up walk for matchings of size  $k$ , we refer to the following chain:

1. Denote the state at time  $t$  by  $M_t \in \mathcal{M}_k$ .
2. Choose  $e \in M_t$  and  $e' \in E$  uniformly at random.<sup>2</sup>
3. Let  $M' := M_t \cup \{e'\} \setminus \{e\}$ . If  $M' \in \mathcal{M}_k$ , then  $M_{t+1} = M'$ . Else,  $M_{t+1} = M_t$ .

It is clear that the down-up walk is reversible with respect to the uniform distribution on  $\mathcal{M}_k$  so that whenever it is ergodic (this need not be the case; for instance, consider the uniform distribution on perfect matchings of an even cycle), it converges to the uniform distribution on  $\mathcal{M}_k$ . It is believed that for any fixed  $\delta > 0$  the down-up walk on  $\mathcal{M}_k$  mixes in polynomial time for all  $1 \leq k \leq (1 - \delta)m^*(G)$ .<sup>3</sup> In fact, it was conjectured by Jain, Perkins, Sah, and Sawhney [14, Conjecture 1.4] that for graphs  $G$  of maximum degree  $\Delta$  and  $1 \leq k \leq (1 - \delta)m^*(G)$ , the  $\varepsilon$ -total-variation mixing time of the down-up walk on  $\mathcal{M}_k(G)$  is  $O_{\Delta, \delta}(n \log(n/\varepsilon))$ , which would be optimal up to the implicit constants.

The main result of this note establishes that the down-up walk on  $\mathcal{M}_k(G)$  mixes in polynomial time for all  $1 \leq k \leq (1 - \delta)m^*(G)$ . While our mixing time is unfortunately not sharp enough to resolve the aforementioned conjecture from [14], our result has the benefit of being applicable to arbitrary graphs (as opposed to graphs of bounded degree).

► **Theorem 1.** *Let  $\delta \in (0, 1)$ . For a graph  $G = (V, E)$  on  $n$  vertices and  $m$  edges, and an integer  $1 \leq k \leq (1 - \delta)m^*(G)$ , the down-up walk on matchings of size  $k$  has  $\varepsilon$ -mixing time  $O(n^{4/\delta} m^4 k \log(1/\varepsilon))$ .*

► **Remark 2.** Restricted to the class of graphs of maximum degree  $\Delta$ , our proof gives the improved  $\varepsilon$ -mixing time bound of  $O_{\Delta, \delta}(n^\delta k \log(1/\varepsilon))$  by Equation (7) and Equation (1). We leave it as a very interesting open problem whether the mixing time can be improved to  $\tilde{O}_{\Delta, \delta}(n)$  in this case (as was conjectured in [14]).

<sup>1</sup>  $\tilde{O}$  hides polylogarithmic factors in  $n$  and  $1/\varepsilon$ .

<sup>2</sup> Another convention is to choose  $e'$  uniformly at random among those edges for which  $M_t \cup \{e'\} \setminus \{e\} \in \mathcal{M}_k$ ; in our setting, this would only have the effect of leading to a constant factor speed-up in the mixing time.

<sup>3</sup> Some restriction on the range of  $k$  is needed since, as just mentioned, the down-up walk is not even ergodic in general.

Our proof is based on bounding the spectral gap using a carefully constructed flow. It is natural to ask whether the powerful spectral independence framework (developed in [3]) can be used to derive a similar result; in Section 3, we present examples showing that there are serious barriers to this, even for the class of bounded degree graphs. Roughly, the main point is that the condition  $k \leq (1 - \delta)m^*(G)$  is not closed under pinnings (even if we take pinnings at random); this is not the case for the parameter range of independent sets considered in [13] and is key to making the spectral independence approach amenable in their setting.

## 1.1 Related work

For the down-up walk, notice that even the case when  $G$  is itself a matching is already interesting; in this case, the down-up walk coincides with the classical and well-studied Bernoulli-Laplace chain to sample from the uniform distribution on  $\binom{[n]}{k}$  (e.g. [10, 19]). As discussed earlier, there are polynomial time algorithms, based on the rapid mixing of Glauber dynamics for the monomer-dimer model, to approximately sample from the uniform distribution on  $\mathcal{M}_k(G)$ ,  $1 \leq k \leq (1 - \delta)m_k^*(G)$ ; instead of combining rejection sampling with the Glauber dynamics, one may also combine rejection sampling with a local random walk to sample from the uniform distribution on the union of matchings of size  $k$  and  $k - 1$  (the rapid mixing of this walk is shown in [8]). For bipartite graphs [17] and planar graphs [1], there are polynomial time algorithms to approximately sample from the uniform distribution on  $\mathcal{M}_k(G)$  for all  $1 \leq k \leq m^*(G)$ .

Perhaps most relevant to this note is recent work of Jain, Michelen, Pham, and Vuong [13] which established optimal mixing of the down-up walk on *independent sets* of a given size  $1 \leq k \leq (1 - \delta)\alpha_c(\Delta)n$ , for the class of  $n$  vertex graphs  $G$  with maximum degree  $\Delta$  (using the spectral independence framework). Here,  $\alpha_c(\Delta)$  is a function such that the problem of (approximately) sampling independent sets of size  $k > \alpha_c(\Delta)n$  on  $n$  vertex graphs with maximum degree  $\Delta$  is computationally intractable, unless  $\text{NP} = \text{RP}$ ; this was shown by Davies and Perkins [9]. In the same paper, Davies and Perkins showed that by combining the rapid mixing of the Glauber dynamics for the hard-core model in the tree uniqueness regime ([3, 6]) with a rejection sampling step, one can obtain a polynomial time algorithm to approximately sample from the uniform distribution on independent sets of size  $k$  provided that  $1 \leq k \leq (1 - \delta)\alpha_c(\Delta)n$ ; this is entirely analogous to how [16, 6] imply polynomial time approximate samplers for the uniform distribution on  $\mathcal{M}_k(G)$  for  $1 \leq k \leq (1 - \delta)m^*(G)$ . Davies and Perkins conjectured [9, Conjecture 5] that the down-up walk for independent sets mixes in polynomial time provided that  $1 \leq k \leq (1 - \delta)\alpha_c(\Delta)n$  and this was resolved (in a stronger form) by [13]; our work may be viewed as resolving the analog of the conjecture of Davies and Perkins for matchings.

Finally, we remark that there is a large body of literature in probability concerned with the mixing of analogous walks for product(-like) domains with conservation laws (in our setting, the size of the matching is a conserved quantity); see, e.g., [5, 12] and the references therein. In our setting, the base measure (the natural choice is the monomer-dimer model at a suitable activity) is significantly more complicated and very far from being a product distribution, although we remark works are often able to exploit product structure and other symmetries to obtain rather precise results.

## 1.2 Organization

In Section 2, we present the proof of Theorem 1. In Section 3, we discuss barriers to a potential spectral independence approach for proving Theorem 1. In each (sub)section, we begin with an overview of the proof and some motivation.

## 2 Proof of Theorem 1

### 2.1 Preliminaries

Let  $P$  denote the transition matrix of an ergodic Markov chain on the finite state space  $\Omega$ , which is reversible with respect to the (unique) stationary distribution  $\pi$ . Let  $E(P) = \{(x, y) \in \Omega \times \Omega : P(x, y) > 0\}$  denote the “edges” of the transition matrix. Recall that the *Dirichlet form* is defined for  $f, g : \Omega \rightarrow \mathbb{R}$  by

$$\mathcal{E}_P(f, g) := \frac{1}{2} \sum_{x, y \in \Omega} \pi(x) P(x, y) (f(x) - f(y))(g(x) - g(y)).$$

The *spectral gap*  $\alpha$  is defined to be the largest value such that for all  $\varphi : \Omega \rightarrow \mathbb{R}$ ,

$$\alpha \operatorname{Var}_\pi[\varphi] \leq \mathcal{E}_P(\varphi, \varphi).$$

The (total-variation) *mixing time* is defined by

$$\tau_{\text{mix}} = \max_{x \in \Omega} \min\{t : d(P^t x, \pi)_{\text{TV}} < 1/4\},$$

where  $d(\cdot, \cdot)_{\text{TV}}$  denotes the total variation distance between probability distributions.<sup>4</sup> The following relationship between the spectral gap and the mixing time is standard (see, e.g. [20]):

$$\tau_{\text{mix}} \leq \alpha^{-1} \log\left(\frac{1}{\min_{x \in \Omega} \pi(x)}\right). \quad (1)$$

In order to bound the spectral gap of the down-up walk, we will use the technology of multicommodity flows ([22, 11]).

► **Definition 3.** Consider the undirected graph  $H = (\Omega, E(P))$ . For  $x, y \in \Omega$ , let  $\mathcal{Q}_{xy}$  denote the set of all simple paths from  $x$  to  $y$  in  $H$ . Let  $\mathcal{Q} = \bigcup_{x, y} \mathcal{Q}_{xy}$ . A *flow* is a function  $f : \mathcal{Q} \rightarrow \mathbb{R}_{\geq 0}$  such that  $\sum_{q \in \mathcal{Q}_{xy}} f(q) = \pi(x)\pi(y)$ . Given a flow  $f$ , we define its cost by

$$\rho(f) = \max_{(x, y) \in E(P)} \frac{1}{\pi(x)P(x, y)} \sum_{q \ni (x, y)} f(q),$$

and its length by

$$\ell(f) = \max_{q: f(q) > 0} |q|,$$

where  $|q|$  denotes the number of edges in the path  $q$ .

It was shown in [22, 11] that any flow gives a lower bound on the spectral gap.

► **Theorem 4.** Let  $P$  be a reversible ergodic Markov chain and  $f$  be a flow. Then the spectral gap  $\alpha$  satisfies

$$\alpha \geq 1/(\rho(f)\ell(f)).$$

For each  $t \in E(P)$ , let  $\text{paths}(t) = \{q \ni t : f(q) > 0\}$ . A common tool (see, e.g., [22]) for bounding  $\rho(f)$  is a *flow encoding*, which is a collection of maps  $\eta_t : \text{paths}(t) \rightarrow \Omega$  for all  $t \in E(P)$ . If all the maps are poly( $n$ )-to-one and the measure  $\pi$  is “fairly tame” (the uniform measure on  $\Omega$  automatically satisfies this condition), then this gives an inverse polynomial bound on the spectral gap.

<sup>4</sup> Note that the quantity  $1/4$  is fairly arbitrary here. Replacing  $1/4$  with  $\varepsilon$  increases the mixing time by at most a factor of  $\log_2(\varepsilon^{-1})$ .

## 2.2 Constructing a flow

Recall that  $1 \leq k \leq (1 - \delta)m^*(G)$  and  $\Omega$  denotes the set of matchings in  $G$  of size exactly  $k$ . Given two matchings  $x, y \in \Omega$ , our flow will be constructed by uniformly distributing the demand  $\pi(x)\pi(y)$  over a collection of carefully constructed paths. Compared to the construction of a flow in [16], we face two challenges:

- First, since we are not working with perfect matchings (or matchings which are a constant additive size away from being perfect), using just one path to route all the flow for each pair of matchings in the natural fashion results in a flow with exponentially high cost. To get around this issue, we use the (standard) idea of distributing the flow uniformly among essentially all possible paths, as is done for the Bernoulli-Laplace model (see [22]) and also for a random walk on the union of matchings of size  $k$  and  $k - 1$  [8].
- Second – and this is the main new ingredient in our construction – our state space consists of matchings of a fixed size, whereas all previous walks and flow constructions (e.g. [16, 8]) required working with matchings of at least two adjacent sizes. In order to route flow along such paths while still incurring only polynomial cost, we divide pairs of matchings into a “good” set and a “bad” set depending on the combinatorial structure of the symmetric difference. For the good set, it is fairly simple to construct a flow, incorporating the above idea of distributing the flow uniformly among all possible paths. For a pair in the bad set  $(x, y)$ , we show that there is a nearby good pair  $(\tilde{x}, y)$ , in the sense that  $x$  can be transformed into  $\tilde{x}$  using a short path. The fact that we can transform  $x$  to a suitable  $\tilde{x}$  with a short path is key to bounding the cost of the flow, and this is where we use that  $k \leq (1 - \delta)m^*(G)$ .

Let  $x \oplus y$  denote the symmetric difference  $(x \setminus y) \cup (y \setminus x)$ . Since  $x$  and  $y$  are each matchings and so have maximum degree 1,  $x \oplus y$  is a disjoint union of paths and even-length cycles. For the sake of analysis, place arbitrary total orders on the set of even length paths in  $G$  and the set of even length cycles in  $G$ . Associate to each cycle one arbitrary distinguished vertex and to each odd-length path one arbitrary distinguished endpoint. These will all remain fixed for the remainder of the paper.

We partition  $\Omega^2 := \Omega \times \Omega$  into  $(\Omega^2)_g \cup (\Omega^2)_b$  where

$$(\Omega^2)_b = \{(x, y) : x \oplus y \text{ contains a cycle and no odd-length paths}\},$$

$$(\Omega^2)_g = \Omega^2 \setminus (\Omega^2)_b.$$

We will first describe the collection of paths between the “good pairs”  $(\Omega^2)_g$ . Later, we will leverage this collection on paths along with an additional idea to obtain a suitable collection of paths between the “bad pairs”  $(\Omega^2)_b$ .

### Good pairs

Let  $(x, y) \in (\Omega^2)_g$ . The symmetric difference  $x \oplus y$  consists of even length paths, even length cycles, odd length paths with more edges in  $y$  (which are necessarily  $x$ -augmenting paths), and odd length paths with more edges in  $x$  (which are necessarily  $y$ -augmenting paths). We have an induced ordering on the even paths and the cycles from our total order. Since  $|x| = |y|$ ,  $x \oplus y$  contains the same number of  $x$ -augmenting and  $y$ -augmenting paths; suppose there are  $2j$  total odd-length paths. Let  $\sigma_x, \sigma_y$  be permutations of the sets of  $x$ -augmenting,  $y$ -augmenting paths respectively. For each such choice of  $(\sigma_x, \sigma_y)$ , we construct a path as follows from  $x$  to  $y$  in  $\Omega$ . Before proceeding to the formal details, let us briefly describe the procedure: we first change  $x$  to  $y$  along all even paths. We then change  $x$  to  $y$  along the

first  $x$ -augmenting path  $\sigma_x(1)$ ; at the end of such a path, there is an additional  $y$ -edge to be added, which gives us the necessary room to switch from  $x$  to  $y$  along all cycles, while still remaining in  $\Omega$ . At the end of the cycle processing stage, there is an additional  $y$ -edge to be added; we pair this up with switching  $x$  to  $y$  along the first  $y$ -augmenting path  $\sigma_y(1)$ . Finally, we switch  $x$  to  $y$  along pairs of  $x$ -augmenting and  $y$ -augmenting paths  $\sigma_x(i), \sigma_y(i)$  in the natural fashion.

Formally, set  $M_0 = x$  and proceed as follows:

1. Process all even length paths in order. To process an even path, enumerate the edges  $e_1, e_2, \dots, e_{2\ell}$  such that  $e_i \cap e_{i+1} \neq \emptyset$  and  $e_1 \in y$ . This places all odd edges in  $y$  and the evens in  $x$ . Suppose  $t$  steps have been taken. First make the transition  $M_{t+1} = M_t \cup e_1 \setminus e_2$ ,<sup>5</sup> then  $M_{t+2} = M_{t+1} \cup e_3 \setminus e_4$ , and continue until  $M_{t+\ell} = M_{t+\ell-1} \cup e_{2\ell-1} \setminus e_{2\ell}$ . After processing all even paths, if we have reached  $y$ , terminate.
2. Process the first  $x$ -augmenting path  $p = \sigma_x(1)$ . Let  $e^* \in p$  be the edge incident to the distinguished endpoint. Process  $p \setminus e^*$  as an even path as in step (1), leaving only  $e^*$  to be added.
3. Process all cycles in order. For a cycle  $c$ , let  $e$  (respectively  $e'$ ) be the edge in  $c \cap x$  (respectively  $c \cap y$ ) incident to the distinguished vertex of  $c$ . First, let  $M_{t+1} = M_t \cup e^* \setminus e$  to complete the previous path and puncture the cycle. Now, process  $c \setminus \{e, e'\}$  as an even path as in step (1). Label  $e^* := e'$  and process the next cycle in the same way. At the end of this step, some  $e^*$  will remain.
4. Process the first  $y$ -augmenting path  $p = \sigma_y(1)$ . Let  $e \in p$  be the edge incident to the distinguished endpoint. Begin with  $M_{t+1} = M_t \cup e^* \setminus e$ , then process  $p \setminus e$  as an even path as in step (1).
5. Process any remaining  $x$ -augmenting and  $y$ -augmenting paths in pairs  $p = \sigma_x(i), p' = \sigma_y(i)$ . Let  $e$  (respectively  $e'$ ) denote the edges incident to the distinguished endpoints of  $p$  (respectively  $p'$ ). First process  $p \setminus e$  as an even path, then exchange  $M_{t+1} = M_t \cup e \setminus e'$ , then process  $p' \setminus e'$  as an even path.

This defines a unique path from  $x$  to  $y$  for any two permutations  $\sigma_x, \sigma_y$ , and so gives  $(j!)^2$  total paths  $x \rightarrow y$ . We uniformly distribute the demand  $\pi(x)\pi(y) = 1/|\Omega^2|$  by setting  $f(q) = 1/(|\Omega|^2(j!)^2)$  for each path  $q$  thus defined.

### Bad pairs

Given  $(x, y) \in (\Omega^2)_b$ , we will route the flow through  $(\Omega^2)_g$  by choosing some suitable  $(\tilde{x}, y) \in (\Omega^2)_g$  and adding a suitable prefix to all paths (as above) from  $\tilde{x}$  to  $y$ . Since  $|x| \leq (1 - \delta)m^*(G)$ ,  $x$  has some augmenting path  $p$  of length at most  $2\delta^{-1}$ . This follows from the pigeonhole principle: for  $M^*$  a maximum matching in  $G$ ,  $x \oplus M^*$  is a graph with at most  $2m^*(G)$  non-isolated vertices and at least  $\delta m^*(G)$  disjoint  $x$ -augmenting paths, so that there must be an  $x$ -augmenting path of length at most  $2\delta^{-1}$ . Consider now  $x^+ := x \oplus p$ ; this is a matching of size  $k + 1$ . We claim that there exists some  $e \in x^+$  such that for  $\tilde{x} := x^+ \setminus e$  satisfies  $(\tilde{x}, y) \in (\Omega^2)_g$ . To see this, note that since  $|x^+| > |y|$ ,  $x^+ \oplus y$  contains a  $y$ -augmenting path  $p'$ . If  $x^+ \subset p'$ , then  $x^+ \oplus y$  cannot contain a cycle, as  $p'$  is an alternating path between edges in  $x^+$  and in  $y$ , and  $|x^+| = |y| + 1$ , and so  $y \subset p'$  as well. Thus  $x^+ \oplus y = p'$  is a single path and contains no cycles, so we may choose any  $e \in x^+$  and  $(\tilde{x}, y) \in (\Omega^2)_g$ . Otherwise, by choosing any edge  $e \in x^+ \setminus p'$ , we guarantee  $\tilde{x} \oplus y$  has odd-length paths (in particular,  $p'$ ) and so  $(\tilde{x}, y) \in (\Omega^2)_g$ .

<sup>5</sup> As a slight abuse of notation, when  $m$  is a matching, we will write  $m \cup e$  to mean  $m \cup \{e\}$  and similarly  $m \setminus e$  instead of  $m \setminus \{e\}$ .

For every pair  $(x, y) \in (\Omega^2)_b$ , we make a fixed (but otherwise arbitrary) choice of  $p$  (an  $x$ -augmenting path of length at most  $2\delta^{-1}$ ) and  $e$  as above. For a path  $\tilde{q} \in \mathcal{Q}_{\tilde{x}y}$ , we define  $q \in \mathcal{Q}_{xy}$  as follows.

1. Process  $p$  as an  $x$ -augmenting path (see previous step 2), leaving some  $e^*$  to be added.
2. Make the exchange  $M_{t+1} = M_t \cup e^* \setminus e$ , arriving at  $\tilde{x}$ .
3. Follow the path  $\tilde{q}$ .

We assign  $f(q) = f(\tilde{q})$  so that the same amount of flow is routed from  $x$  to  $y$  as from  $\tilde{x}$  to  $y$ . We remark that choosing an augmenting path of length  $O_\delta(1)$  is crucial for bounding the cost of the flow below.

### 2.3 Flow encoding

For  $t \in E(P)$ , we now bound  $f(t) := \sum_{q \ni t} f(q)$  using the method of flow encodings. Recall that  $\text{paths}(t) = \{q \ni t : f(q) > 0\}$ . Fix some transition  $t = (z, z') \in E(P)$ . We will partition  $\text{paths}(t)$  into three sets and bound the contribution to  $f(t)$  from each of the three using a ‘‘partial flow encoding’’. We have the ‘‘good’’ paths  $\text{paths}_g(t)$  consisting of paths  $q \in \text{paths}(t)$  whose endpoints are in  $(\Omega^2)_g$ . Recall that the paths in  $(\Omega^2)_b$  consist of two phases: the prefix from  $x \rightarrow \tilde{x}$ , and then a good path from  $\tilde{x} \rightarrow y$ . Denote by  $\text{paths}_a(t)$  those paths which use the transition  $t$  in the prefix  $x \rightarrow \tilde{x}$ , and by  $\text{paths}_b(t)$  those paths which use the transition  $t$  in the path from  $\tilde{x} \rightarrow y$ . We will frequently need the set of short paths in  $G$

$$\mathcal{P}_\delta := \left\{ (v_1 v_2 \cdots v_\ell) : \{v_i, v_{i+1}\} \in E(G), \ell \leq 2/\delta \right\}.$$

We will construct  $\Omega \times \mathcal{P}_\delta$ -valued functions  $\eta_g, \eta_b, \eta_a$  on these subsets of  $\text{paths}(t)$ .

#### Construction of $\eta_g$

We first construct  $\eta_g : \text{paths}_g(t) \rightarrow \Omega \times \mathcal{P}_\delta$ . Let  $t = (z, z') \in E(P)$ . For a path  $q$ , let  $q^-, q^+$  be the endpoints. Let  $m = q^- \oplus q^+ \oplus (z \cup z')$ . It is easily checked that  $m$  is a matching of size  $k - 1$  and that  $m' \oplus (z \cup z') = q^- \oplus q^+$  (the same construction is used in [16]). For consistency, we further map  $m$  into an element of  $\Omega \times \mathcal{P}_\delta$  using a fixed (but otherwise arbitrary)  $m'$ -augmenting path  $p \in \mathcal{P}_\delta$ . The existence of a short  $m$ -augmenting path is guaranteed by the fact that  $|m| < (1 - \delta)m^*(G)$ . Formally, we have

$$\begin{aligned} \eta_g : \text{paths}_g(t) &\rightarrow \Omega \times \mathcal{P}_\delta \\ q &\mapsto (q^- \oplus q^+ \oplus (z \cup z') \oplus p, p). \end{aligned}$$

Note that given the image  $(m \oplus p, p)$ , we take  $(m' \oplus p) \oplus p$  to recover  $m$ , which then recovers  $q^- \oplus q^+$  as before. We can now reindex the sum

$$\sum_{q \in \text{paths}_g(t)} f(q) = \sum_{(m,p) \in \Omega \times \mathcal{P}_\delta} \sum_{q \in \eta_g^{-1}(m,p)} f(q).$$

The endpoints of every  $q \in \eta_g^{-1}(m, p)$  have the same symmetric difference as noted above. Let this symmetric difference have  $2j$  odd-length paths. By our construction of the flow,  $f(q) = |\Omega|^{-2} (j!)^{-2}$  for all  $q \in \eta_g^{-1}(m, p)$ . We now count how many paths use the transition  $(z, z')$  based on which  $G$ -paths it is processing. This requires some case analysis, but ultimately, is based on blending the analysis of the flow encoding for the Glauber dynamics for the monomer-dimer model in [16] with the flow encoding for the Bernoulli-Laplace model [22].

- Case I:** If  $(z, z')$  is processing even length paths, then we can use our total order on even length paths to identify which parts of each cycle belong to  $q^-$  and to  $q^+$ . We know that we have not yet begun processing odd paths or cycles, so the parts in  $z$  belong to  $q^-$  and those outside  $z$  belong to  $q^+$ . We thus know  $q^-$  and  $q^+$  and so there are exactly  $(j!)^2$  paths using  $(z, z')$ .
- Case II:** If  $(z, z')$  finishes processing an odd-length  $G$ -path and begins processing a cycle, then we know the odd  $G$ -path is the first such processed, and by the same reasoning as before, we can deduce the endpoints  $q^-$  and  $q^+$ . We also know  $\sigma_x(1)$  is the path intersecting  $z \oplus z'$ . The remainder of  $\sigma_x$  and the entirety of  $\sigma_y$  is free, so there are  $(j!)^2/j$  paths using  $(z, z')$ .
- Case III:** If  $(z, z')$  is processing entirely cycles, then  $z$  has a perfect matching on  $j + 1$  of the odd-length paths and the interior edges on  $j - 1$  of the odd-length paths. One of these  $G$ -paths has already been augmented, and then there will be a path for every ordering of the remaining  $G$ -paths. Thus there are  $(j + 1)j!(j - 1)! = (1 + 1/j)(j!)^2$  paths.
- Case IV:** If  $(z, z')$  finishes a cycle and begins an odd-length path, then  $z$  has a perfect matching on  $j + 1$  odd paths (one of which is being de-augmented in  $(z, z')$ ) and the interior edges on  $j - 1$  odd paths. The path touched by  $z \oplus z'$  is  $\sigma_y(1)$ . We must choose one of the remaining  $j$  perfectly matched paths to be  $\sigma_x(1)$ , and then the remainder of  $\sigma_x, \sigma_y$  are free on the sets of  $j - 1$  interior, perfect paths respectively. There are thus  $j((j - 1)!)^2 = (j!)^2/j$  paths using  $(z, z')$ .
- Case V:** If  $(z, z')$  is augmenting an odd-length path, then of the other  $2j - 1$  paths,  $z$  is perfect on  $j$  and interior on  $j - 1$ . Suppose  $2r$  paths have already been processed. Then we may choose the already-augmented paths ( $\binom{j}{r}$  choices), the already-de-augmented paths ( $\binom{j-1}{r}$  choices), the order for each ( $(r!)^2$  choices), and the order for the remaining augmentations and de-augmentations ( $(j - r)!(j - 1 - r)!$  choices). This gives  $j!(j - 1)!$  paths through  $(z, z')$  that have already processed  $r$  pairs of  $G$ -paths. We now sum over  $0 \leq r \leq j - 1$  to get  $j(j!)(j - 1)! = (j!)^2$  total paths through  $(z, z')$ .
- Case VI:** If  $(z, z')$  is de-augmenting an odd-length path, then by the same logic but with  $j - 1$  perfect paths and  $j$  interior paths, we again have  $(j!)^2$  total paths.
- Case VII:** If  $(z, z')$  finishes augmenting one odd path and begins de-augmenting the next, then we know these  $G$ -paths occur adjacently in the path  $q$ . Then by the same reasoning as Case V but with  $j - 1$  perfect paths and  $j - 1$  interior paths, we will get  $(j!)^2/j$  total paths through  $(z, z')$ .

In all cases, we have at most  $(1 + 1/j)(j!)^2 \leq 2(j!)^2$  paths in  $\eta_g^{-1}(m, p)$  that use the transition  $(z, z')$ . As each has weight  $f(q) = |\Omega|^{-2}(j!)^{-2}$ , this means the inner sum is at most  $2/|\Omega|^2$  and so we can bound

$$\sum_{q \in \text{paths}_g(t)} f(q) = \sum_{(m,p) \in \Omega \times \mathcal{P}_\delta} \sum_{q \in \eta_g^{-1}(m,p)} f(q) \leq \sum_{(m,p) \in \Omega \times \mathcal{P}_\delta} \frac{2}{|\Omega|^2} = \frac{2|\mathcal{P}_\delta|}{|\Omega|}. \quad (2)$$

### Construction of $\eta_b$

Recall that  $\text{paths}_b(t)$  are those paths that use the transition  $t$  as part of following a “good” path from  $\tilde{x}$  to  $y$ . Thus we may instead choose the good path  $q$  that is routed through  $t$ , and then count how many starting points  $x$  could route through  $q^-$  (the starting point of  $q$ ) to get to  $q^+$  (the ending point of  $q$ ). By the construction of our paths, this requires  $x \oplus q^-$  to be a single short augmenting  $G$ -path in  $\mathcal{P}_\delta$  together with a single edge in  $E(G)$ . These

together will uniquely determine the total path  $x \rightarrow q^+$ . Thus each good path through  $t$  is used in at most  $|\mathcal{P}_\delta| |E(G)|$  bad paths, and the value of  $f$  is unchanged by the prefix, so we may bound using Equation (2)

$$\sum_{q \in \text{paths}_b(t)} f(q) \leq \sum_{\tilde{q} \in \text{paths}_g(t)} |\mathcal{P}_\delta| |E(G)| f(\tilde{q}) \leq \frac{2|\mathcal{P}_\delta|^2 |E(G)|}{|\Omega|}. \quad (3)$$

### Construction of $\eta_a$

Finally, for  $t = (z, z^-)$  and  $q \in \text{paths}_a(t)$ , let  $p$  be the  $G$ -path that is augmented during the prefix. Then, define the function

$$\begin{aligned} \eta_a : \text{paths}_a(t) &\rightarrow \Omega \times \mathcal{P}_\delta \\ q &\mapsto (q^+, p). \end{aligned}$$

Suppose  $q \in \eta_a^{-1}(m, p)$  for some matching  $m \in \Omega$  and  $G$ -path  $p \in \mathcal{P}_\delta$  and let  $t = (z, z^-)$ . Then we know that  $q^+ = m$ , and we know that  $q^-$  consists of  $z \setminus p$  and the interior alternating edges of  $p$ . Thus all paths in  $\eta_a^{-1}(m, p)$  have the same endpoints, and so their total flow is at most the net flow between those two points, which is  $|\Omega|^{-2}$ . We can then calculate

$$\sum_{q \in \text{paths}_a(t)} f(q) = \sum_{(m,p) \in \Omega \times \mathcal{P}_\delta} \sum_{q \in \eta_a^{-1}(m,p)} f(q) \leq \sum_{(m,p) \in \Omega \times \mathcal{P}_\delta} \frac{1}{|\Omega|^2} = \frac{|\mathcal{P}_\delta|}{|\Omega|}. \quad (4)$$

### Bounding the cost of the flow

Using Equation (2), Equation (3), and Equation (4), for any transition  $t \in E(P)$ ,

$$\sum_{q \in \text{paths}(t)} f(q) = \sum_{q \in \text{paths}_g(t)} f(q) + \sum_{q \in \text{paths}_b(t)} f(q) + \sum_{q \in \text{paths}_a(t)} f(q) \leq \frac{3|\mathcal{P}_\delta| + 2|\mathcal{P}_\delta|^2 |E(G)|}{|\Omega|}. \quad (5)$$

Since  $\pi(z) = 1/|\Omega|$  for all  $z \in \Omega$  and  $P(z, z') \geq 1/(k|E(G)|)$  (since the possible transitions from  $z$  consist of removing one of  $k$  edges and adding one of  $|E(G)|$  edges), we get that

$$\rho(f) \leq |\Omega| \cdot k|E(G)| \cdot \frac{3|\mathcal{P}_\delta| + 2|\mathcal{P}_\delta|^2 |E(G)|}{|\Omega|} \leq 3k|E(G)|^2 |\mathcal{P}_\delta|^2.$$

Finally, let  $\Delta$  denote the maximum degree of  $G$  and note that  $|\mathcal{P}_\delta| \leq 2n\Delta^{2/\delta-1}$  to get that

$$\rho(f) \leq 12k|E(G)|^2 \cdot n^2 \Delta^{4/\delta-2}. \quad (6)$$

## 2.4 Rapid mixing

We will use Theorem 4 to bound the spectral gap via the flow  $f$  defined in Section 2.2. Note that the down-up walk is reversible with respect to the uniform distribution, aperiodic since  $P(x, x) > 0$ , and irreducible (for instance, by using the paths used in our flow  $f$ ). Therefore, the assumptions of Theorem 4 are satisfied. To bound the maximum length  $\ell(f)$  of any path used in our flow, note that by construction, any edge in  $G$  is included in at most three exchanges. Hence,  $\ell(f) \leq 3|E(G)|$ . Combining this with Equation (6), we see that the spectral gap  $\alpha$  of the down-up walk satisfies

$$\alpha^{-1} \leq 36k|E(G)|^3 \cdot n^2 \Delta^{4/\delta-2}. \quad (7)$$

Finally, the mixing time bound in Theorem 1 follows from Equation (1) by noting that  $\log |\Omega| \leq \log 2^{|E(G)|} \leq |E(G)|$ .

### 3 Barriers to the spectral independence approach

For a distribution  $\pi$  on  $\binom{[n]}{k}$ , we define the (signed) pairwise influence matrix  $M_\pi \in \mathbb{R}^{n \times n}$  by

$$M_\pi(i, j) = \begin{cases} 0 & \text{if } j = i, \\ \mathbb{P}_\pi[j | i] - \mathbb{P}_\pi[j | \bar{i}] & \text{otherwise.} \end{cases}$$

where  $\mathbb{P}_\pi[i] = \mathbb{P}_{S \sim \pi}[i \in S]$  and  $\mathbb{P}_\pi[\bar{i}] = \mathbb{P}_{S \sim \pi}[i \notin S]$ . We say that  $\pi$  is  $\eta$ -spectrally independent (at link  $\emptyset$ ) if  $\lambda_{\max}(M_\pi) \leq \eta$  and that  $\pi$  is  $\eta$ - $\ell_\infty$ -independent (at link  $\emptyset$ ) if  $\max_{i \in [n]} \sum_{j=1}^n |M_\pi(i, j)| \leq \eta$ . Note that the latter condition implies the former.

We begin by noting that for the class of bounded degree graphs, for  $k$  bounded away from the matching number, the uniform distribution on matchings of size  $k$  is  $O(1)$ - $\ell_\infty$ -independent.

► **Proposition 5.** *Let  $G = (V, E)$  be a graph on  $n$  vertices with maximum degree  $\Delta$ . Let  $\delta > 0$  and for  $1 \leq k \leq (1 - \delta)m^*(G)$ , let  $\pi$  be the uniform distribution on matchings of  $G$  of size  $k$ . Then  $\pi$  is  $O_{\delta, \Delta}(1)$ - $\ell_\infty$ -independent (at link  $\emptyset$ ).*

**Proof.** For  $k = o(n)$ , this is implied by a coupling argument (e.g. [21]). For  $k = \Omega(n)$ , the proof follows from the same argument as in the proof of [13, Theorem 8]: the differences are that we compare to the monomer-dimer model at activity  $\lambda = O_{\delta, \Delta}(1)$  using [14, Lemma 4.1], replace [13, Theorem 9] by [6, Theorem 2.10], and replace [13, Theorem 15] by a suitable multivariate zero-free region for the matching polynomial (e.g. [7]). We omit further details. ◀

Given Proposition 5, one might hope to obtain an inverse polynomial bound on the spectral gap of the down-up walk (at least for the class of bounded degree graphs) using the powerful spectral independence framework as is done, for instance, in the case of the down-up walk on independent sets of a fixed size in [13]; we refer the reader to [3] for an introduction to this framework. In order to do this, we need to show that the distribution remains  $O_{\delta, \Delta}(1)$ -spectrally independent under any pinning. In our situation, a pinning  $\tau$  is a matching of size  $\ell < k$ . We would then consider  $\Omega_\tau = \{m \in \Omega : \tau \subset m\}$  under the distribution induced by  $\pi$  (uniform, in our case), and show  $O_{\delta, \Delta}(1)$ -spectral independence of this space. We note that there is a more powerful “average-case” version of this argument, which (roughly) allows us to consider typical pinning obtained by starting from some fixed matching of size  $k$  and pinning a random subset of  $k - \ell$  edges to be included (see [4, 2]). We present barriers to this approach.

- We observe that such an approach cannot work for the down-up walk. Indeed, if it were to work, then one would also be able to show that the down-up walk has inverse polynomial spectral gap for the induced uniform distribution on size  $\ell$  matchings obtained by starting with an arbitrary matching of size  $k$  and pinning a uniform subset of  $k - \ell$  edges to belong to the matching. However, as we discuss below, it is easy to construct an example where even for polynomially large  $\ell$ , with high probability, the down-up walk is not even ergodic (Claim 7).
- In the above example, the failure of ergodicity may be circumvented by using an  $O(1)$ -step down-up walk. However, it is still the case that proving mixing of the  $O(1)$ -step down-up walk using the (average) spectral independence framework necessitates proving mixing for the  $O(1)$ -step down-up walk for the aforementioned induced distributions on matchings of size  $\ell$ . We present a construction (Claim 6) showing that these induced distributions can correspond to the uniform distribution on size  $\ell$  matchings in pretty arbitrary graphs

with matching number  $\ell(1 + o(1))$ ; hence, there does not seem to be a way to use this machinery without basically showing that  $O(1)$ -step down-up walks mix rapidly for (almost) maximum matchings in arbitrary bounded-degree graphs, which is a major open problem.

Our examples will follow the same general template. To set up some notation, given a graph  $G = (V, E)$  and a pinning  $\tau$  (a matching  $\tau$  in  $G$ ), define the *residual graph*  $G_\tau$  to be the induced subgraph

$$G_\tau = G[V(G_\tau)],$$

where

$$V(G_\tau) = V(G) \setminus \bigcup_{e \in \tau} e.$$

Sampling from the uniform distribution on matchings in  $G$  of size  $k$ , conditioned on pinning  $\tau$  to be in the matching, is equivalent to finding a matching of size  $k - |\tau|$  in  $G_\tau$ .

We are now ready to construct our examples. Fix some  $0 < \delta < 1/5$  the desired gap from maximality, as in the statement of Theorem 1. We define a graph  $G = (V, E)$  where  $|V| = n$  as follows:  $G$  consists of  $\delta n/2$  disjoint copies of  $P_9$  (the path with 10 vertices and 9 edges) and an arbitrary graph  $G'$  on the remaining  $(1 - 5\delta)n$  vertices such that  $G'$  has a perfect matching. Let  $M$  be the matching given by taking the union of a perfect matching  $M'$  in  $G'$  with the interior alternating edges on each  $P_9$ ; note that  $|M| = n/2 - \delta n/2 = (1 - \delta)m^*(G)$ . We will be considering pinning a uniform random subset of  $M$  of a fixed size.

▷ **Claim 6.** For a random pinning  $\tau$  of size  $(1 - \lambda)|M|$ , the ratio

$$\mathbb{E} \left[ 1 - \frac{|M| - |\tau|}{m^*(G_\tau)} \right] = O(\delta\lambda^4).$$

The implication of this claim is that, while we started with the uniform distribution on matchings of size at most  $(1 - \delta)$  of the maximum matching in  $G$ , we now need to deal with the uniform distribution on matchings of size at least  $(1 - \delta\lambda^4)$  times the maximum matching in  $G_\tau$ .

*Proof.* Let  $\tau$  be a random pinning of size  $(1 - \lambda)|M|$ . Let  $X_\tau$  be the number of  $P_9$ s that  $\tau$  does not intersect. Then by linearity of expectation,

$$\mathbb{E}[X_\tau] = \frac{\delta n}{2} \Pr[\tau \text{ avoids a fixed } P_9] = O(\delta n \lambda^5). \tag{8}$$

The key observation here is that once we have pinned any edge in  $M \cap P_9$  for some copy of  $P_9$ , we have split  $P_9$  into two even paths and are demanding a maximum matching on each of those. Hence, by construction, we see that  $m^*(G_\tau) = |M| - |\tau| + X_\tau$ . We now compute

$$\begin{aligned} \mathbb{E} \left[ 1 - \frac{|M| - |\tau|}{m^*(G_\tau)} \right] &= 1 - \mathbb{E} \left[ \frac{|M| - |\tau|}{|M| - |\tau| + X_\tau} \right] \leq 1 - \frac{|M| - |\tau|}{|M| - |\tau| + \mathbb{E}[X_\tau]} \\ &\leq \frac{\mathbb{E}[X_\tau]}{\lambda|M|} = O(\delta\lambda^4), \end{aligned}$$

where the first line uses Jensen's inequality and the second line uses Equation (8). ◀

In the above construction, take  $G'$  to be a disjoint union of  $(1 - 5\delta)n/4$  copies of  $C_4$  (the 4-cycle) and accordingly, take  $M'$  to be a union of perfect matchings on each  $C_4$ .

## 63:12 Rapid Mixing of the Down-Up Walk on Matchings of a Fixed Size

▷ Claim 7. For a random pinning  $\tau$  of size  $n/2 - n^{2/3}$ , with high-probability, the down-up walk on matchings of size  $|M| - \tau$  on the induced graph  $G_\tau$  is not ergodic.

Proof. It suffices to show that for a random pinning  $\tau$  of size  $n/2 - n^{2/3}$ , with high probability, (i)  $\tau$  intersects every  $P_9$ , (ii)  $\tau$  fails to intersect some  $C_4$ .

For (i), by a union bound and direct computation, we get that

$$\mathbb{P}[\tau \text{ avoids some } P_9 \cap M] \leq \frac{\delta n}{2} \mathbb{P}[\tau \text{ avoids a fixed } P_9 \cap M] = O(\delta n^{-1/3}).$$

For (ii), we get that

$$\begin{aligned} \mathbb{P}[\tau \text{ intersects all } C_4] &= \mathbb{P}[\tau^c \text{ contains no } C_4 \cap M] \\ &\leq n^{O(1)} \mathbb{P}[\tau^c \text{ does not contain a fixed } C_4 \cap M]^{(1-5\delta)n/4} \\ &\leq \exp(-\Theta(n^{1/3})), \end{aligned}$$

where the second follows by comparing probabilities between the independent model of density  $\Theta(n^{-1/3})$  and the slice model and the last line follows by direct computation. The union bound now shows that with high probability, (i) and (ii) simultaneously hold. ◁

## Abstract

A tournament is a complete directed graph. A source in a tournament is a vertex that has no in-neighbours (every other vertex is reachable from it via a path of length 1), and a king in a tournament is a vertex  $v$  such that every other vertex is reachable from  $v$  via a path of length at most 2. It is well known that every tournament has at least one king. In particular, a maximum out-degree vertex is a king. The tasks of finding a king and a maximum out-degree vertex in a tournament has been relatively well studied in the context of query complexity. We study the *communication complexity* of finding a king, of finding a maximum out-degree vertex, and of finding a source (if it exists) in a tournament, where the edges are partitioned between two players. The following are our main results for  $n$ -vertex tournaments:

- We show that the communication task of finding a source in a tournament is *equivalent* to the well-studied Clique vs. Independent Set (CIS) problem on undirected graphs. As a result, known bounds on the communication complexity of CIS [Yannakakis, JCSS'91, Göös, Pitassi, Watson, SICOMP'18] imply a bound of  $\tilde{\Theta}(\log^2 n)$  for finding a source (if it exists, or outputting that there is no source) in a tournament.
- The deterministic and randomized communication complexities of finding a king are  $\Theta(n)$ . The quantum communication complexity of finding a king is  $\tilde{\Theta}(\sqrt{n})$ .
- The deterministic, randomized, and quantum communication complexities of finding a maximum out-degree vertex are  $\Theta(n \log n)$ ,  $\tilde{\Theta}(n)$  and  $\tilde{\Theta}(\sqrt{n})$ , respectively.

Our upper bounds above hold for all partitions of edges, and the lower bounds for a specific partition of the edges.

One of our lower bounds uses a fooling-set based argument, and all our other lower bounds follow from carefully-constructed reductions from Set-Disjointness. An interesting point to note here is that while the deterministic query complexity of finding a king has been open for over two decades [Shen, Sheng, Wu, SICOMP'03], we are able to essentially resolve the complexity of this problem in a model (communication complexity) that is usually harder to analyze than query complexity.

## 1 Introduction

Graph problems have been very widely studied through the lens of query and communication complexity. In the most natural query setting, an algorithm has query access to an oracle that on being input a pair of vertices, outputs whether or not an edge exists between those vertices. In the basic communication complexity setup for graph problems, two parties, say Alice and Bob, are given the information about the edges in  $E_1$  and  $E_2$ , respectively, where  $E_1$  and  $E_2$  are disjoint subsets of all possible edges in the underlying graph. Their task, just as in the query model, is to jointly solve a known graph problem on the graph formed by the edges in  $E_1 \cup E_2$ . Several interesting results are known in these basic query and communication settings in the deterministic, randomized, and quantum models, see, for example, [5, 27, 19, 29, 40, 9, 11] and the references therein.

A prime example of a graph problem whose query complexity and communication complexities have been widely studied is *Graph Connectivity*. The randomized and quantum communication complexities of this problem are known to be  $O(n \log n)$  and  $\Omega(n)$ . This gap has been open for a long time, and the question of closing it has been explicitly asked [29, 27]. On the other hand, its deterministic communication complexity is known to be  $\Theta(n \log n)$  [27].

A graph problem that has been extensively studied in the context of communication complexity is the Clique vs. Independent Set (CIS) problem [47, 25, 26, 8]. The CIS problem is so fundamental that it makes an appearance in the first chapter of standard textbooks on communication complexity [32, 41] (in fact, it is defined on the first page of the latter textbook). The CIS problem is parametrized by a graph  $G = ([n], E)$ , known to both Alice and Bob. Alice is given  $C \subseteq [n]$  that forms a clique in  $G$ , Bob is given  $I \subseteq [n]$  that forms an independent set in  $G$ , and their task is to determine whether or not  $C \cap I = \emptyset$ . Note that if  $C \cap I \neq \emptyset$ , then it must be the case that  $|C \cap I| = 1$ . It was long known that the communication complexity of CIS is  $O(\log^2 n)$  for all graphs  $G$ . More than two decades after this upper bound was discovered, a near-matching lower bound of  $\tilde{\Omega}(\log^2 n)$  was shown to hold for a particular  $G$ , in a culmination of a long line of ground-breaking work [31, 28, 3, 45, 25, 26].

► **Theorem 1** ([47], [26, Theorem 1.2]). *Let  $G$  be an  $n$ -vertex graph. Then,  $D^{\text{cc}}(\text{CIS}_G) = O(\log^2 n)$ . Furthermore, there exists an  $n$ -vertex graph  $G$  such that  $D^{\text{cc}}(\text{CIS}_G) = \tilde{\Omega}(\log^2 n)$ .*

This lower bound on the communication complexity of CIS also gives the currently-best-known lower bound for the exponent in the famous log-rank conjecture [35]. We remark that the upper bound above also holds if the task is to output the label of the unique intersection of  $C$  and  $I$  if  $C \cap I \neq \emptyset$ .

While not as well-studied as the undirected case, communication complexity of directed graph problems has also received some attention in the past (see, for example, [29, 6, 13]). In this work, we consider *tournaments*, which are directed graphs with exactly one directed edge between each pair of vertices (i.e. the underlying undirected graph is complete). We adopt the natural communication complexity setting where Alice knows the orientation of a subset  $E$  of the edges, Bob knows the orientation of the remaining edges, and their goal is to jointly solve a known task on the tournament.

A source of a tournament is a vertex with no in-neighbour. The first problem that we study is source-finding: finding the source of a tournament (if it exists, and reporting that no source exists otherwise). The source-finding problem has recently played a central role in the recent breakthrough by Chattopadhyay, Mande and Sherif that refuted the log approximate-rank conjecture [15] which is the randomized analog of the famous log-rank conjecture [35] of communication complexity. It was also used in the follow-up results [4, 46] that refuted the quantum version of this conjecture. Source-finding has been studied in the context of query complexity and voting theory (see [18] and the references therein). In fact, the problem of finding a source in a tournament (in the bounded-round communication complexity setting) has been studied by Chakrabarti et al. [13, Sections 3, 4] with applications to streaming lower bounds. In a recent preprint, Ghosh and Kuchlous [24] studied the communication complexity of source-finding in general graphs. Interestingly, they showed that source-finding in general directed graphs can be exponentially harder than source-finding in tournaments as demonstrated by our results (Corollary 3).

We denote the source-finding problem in the specific communication setting discussed above by  $\text{SRC}_E$  (recall that  $E$  is the set of edges whose orientation is known to Alice). Perhaps surprisingly, we show that this task is *equivalent* to the CIS problem on undirected graphs.

► **Theorem 2.**

- For all  $n$ -vertex graphs  $G = ([n], E)$ ,  $D^{\text{cc}}(\text{CIS}_G) \leq D^{\text{cc}}(\text{SRC}_E) + O(\log n)$ .
- For all subsets of edges  $E$  of the complete  $n$ -vertex graph, there exists an  $n$ -vertex graph  $G$  such that  $D^{\text{cc}}(\text{SRC}_E) \leq D^{\text{cc}}(\text{CIS}_G)$ .

Using known near-tight bounds on the communication complexity of CIS (Theorem 1), Theorem 2 immediately yields the following corollary which gives near-tight bounds on the communication complexity of finding a source in a tournament.

► **Corollary 3.** For all subsets  $E$  of the edges of the complete  $n$ -vertex graph, the deterministic communication complexity of finding a source of a tournament if it exists, or outputting that there is no source is

$$D^{\text{cc}}(\text{SRC}_E) = O(\log^2 n).$$

Furthermore, there exists a subset  $E$  of edges of the complete  $n$ -vertex graph such that the deterministic communication complexity of finding a source is

$$D^{\text{cc}}(\text{SRC}_E) = \tilde{\Omega}(\log^2 n).$$

We believe that this equivalence between SRC and CIS will generate further insights into relationships among complexity measures in query and communication settings that are yet to be resolved. Recall that the source-finding function was also recently used to refute the randomized and quantum versions of the log-rank conjecture [15, 4, 46]. In particular, these works showed that the randomized and quantum communication complexities of finding a source in a tournament is polynomially large in the input size. However, in their settings, Alice and Bob each know a bit per edge, and that edge’s direction is determined by the bitwise XOR of Alice and Bob’s bits for that edge. In view of this, Corollary 3 demonstrates a fundamental difference between the communication complexities of the source-finding problem when the edge directions are partitioned between Alice and Bob, and when Alice and Bob jointly have partial information about each edge.

Motivated to find a “most-dominant vertex” in a tournament, Landau defined the notion of a *king* in a tournament [34]. A king in a tournament is a vertex  $v$  such that every other vertex  $w$  is either reachable via a path of length 1 or length 2 from  $v$ . While it is easy

to see that there are tournaments that do not have a source, it is also easy to show that every tournament has a king [34, 38]. If a tournament has a source, then it is a unique king in the tournament. In view of this, a natural variant of  $\text{SRC}_E$  (and hence CIS, in view of Theorem 2) is the communication task of finding a king in a tournament.

We remark here that the deterministic query complexity of finding a king in an  $n$ -vertex tournament is still unknown, and the state-of-the-art bounds are  $\Omega(n^{4/3})$  and  $O(n^{3/2})$ , and are from over 2 decades ago [44]. Recently, [37] essentially resolved the randomized and quantum query complexities of this problem: they showed that the randomized query complexity of finding a king in an  $n$ -vertex tournament is  $\tilde{\Theta}(n)$ , and the quantum query complexity is  $\Theta(\sqrt{n})$ . The complexity of finding a king and natural variants of it have also been fairly well-studied in different contexts [44, 2, 10, 33].

We consider the communication complexity of finding a king in an  $n$ -vertex tournament, denoting this task by  $\text{KING}_n$ . Perhaps surprisingly, while resolving the query complexity of finding a king in a tournament seems hard, we are able to essentially resolve its asymptotic deterministic, randomized, and quantum communication complexities.

► **Theorem 4.** *For all disjoint partitions  $E_1, E_2$  of the edges of a tournament, the deterministic, randomized, and quantum communication complexities of finding a king (where Alice knows the edge directions of edges in  $E_1$  and Bob knows the edge directions of edges in  $E_2$ ) are as follows:*

$$\text{D}^{\text{cc}}(\text{KING}_n) = O(n), \quad \text{R}^{\text{cc}}(\text{KING}_n) = O(n), \quad \text{Q}^{\text{cc}}(\text{KING}_n) = O(\sqrt{n} \log n).$$

Furthermore, there exists a disjoint partition  $E_1, E_2$  such that the deterministic, randomized, and quantum communication complexities of finding a king are as follows:

$$\text{D}^{\text{cc}}(\text{KING}_n) = \Omega(n), \quad \text{R}^{\text{cc}}(\text{KING}_n) = \Omega(n), \quad \text{Q}^{\text{cc}}(\text{KING}_n) = \Omega(\sqrt{n}).$$

In order to show our deterministic and randomized upper bounds, we give a  $O(n)$  cost deterministic protocol. Our quantum upper bound follows from the upper bound in Theorem 5 (the upper bound in Theorem 5 is for the problem of finding a vertex of maximum out degree in the same setting, which is always a king [34]). Our lower bounds follow from a carefully constructed reduction from Set-Disjointness. We sketch our proofs in Section 1.1.

Interestingly, our lower bounds actually hold for tournaments that are promised to have exactly 3 kings. It is well known that a tournament cannot have exactly 2 kings [38]. Thus, the only “easier” case than this promised one is that where the input tournament is promised to have exactly one king. This case is handled in Corollary 3 (it is easy to see that a tournament has a unique king iff the unique king is a source in the tournament).

It is folklore [34] that a vertex with maximum out-degree in a tournament is also a king in the tournament. Thus, another natural question that arises is: what is the complexity of finding a maximum out-degree vertex? The deterministic and randomized query complexity of this task is known to be  $\Theta(n^2)$ , and its quantum query complexity is between  $\Omega(n)$  and  $O(n^{3/2})$  [7, 37]. Let  $\text{MOD}_n$  denote the search problem of finding a maximum out-degree vertex in an  $n$ -vertex tournament. We study the communication complexity of  $\text{MOD}_n$ , again in the natural setting where the edges of the tournament are partitioned between Alice and Bob. We show the following:

► **Theorem 5.** *For all disjoint partitions  $E_1, E_2$  of the edges of a tournament, the deterministic, randomized, and quantum communication complexities of finding a maximum out-degree vertex (where Alice knows the edge directions of edges in  $E_1$  and Bob knows the edge directions of edges in  $E_2$ ) are as follows:*

$$\text{D}^{\text{cc}}(\text{MOD}_n) = O(n \log n), \quad \text{R}^{\text{cc}}(\text{MOD}_n) = O(n \log \log n), \quad \text{Q}^{\text{cc}}(\text{MOD}_n) = O(\sqrt{n} \log n).$$

Furthermore, there exist disjoint partitions such that the deterministic, randomized, and quantum communication complexities of finding a maximum out-degree vertex are as follows:<sup>1</sup>

$$D^{\text{cc}}(\text{MOD}_n) = \Omega(n \log n), \quad R^{\text{cc}}(\text{MOD}_n) = \Omega(n), \quad Q^{\text{cc}}(\text{MOD}_n) = \Omega(\sqrt{n}).$$

We direct the reader's attention to the similarity between our communication complexity bounds for  $\text{MOD}_n$  and known bounds for the communication complexity of Graph Connectivity mentioned earlier in this section: just like in that case we are able to give tight bounds on the deterministic communication complexity, but our bounds are loose by logarithmic factors in the randomized and quantum settings.<sup>2</sup> Our randomized and quantum lower bounds follow using exactly the same reduction from Set-Disjointness as in Theorem 4. Our deterministic lower bound follows by a carefully constructed *fooling set* lower bound. We give a sketch of our proofs in Section 1.1.

While most of the relevant literature of finding kings in tournaments deals with minimizing the number of queries to find a king (which is equivalent to minimizing the depth of a decision tree that solves KING), none deal with minimizing the *size complexity* of a decision tree that solves KING. Logarithm of decision tree size complexity is characterized, upto a log factor in the input size, by the *rank* of the underlying relation (see [36] for definition of size), and these are measures that have gained a significant interest in the past few years in various contexts (see, for instance, [14, 17, 16] and the references therein). While the decision tree depth complexity of  $\text{KING}_n$  lies between  $\Omega(n^{4/3})$  and  $O(n^{3/2})$ , we show a tight bound of  $n - 1$  on  $\text{rank}(\text{KING}_n)$ , which implies an  $\Omega(n)$  lower bound and an  $O(n \log n)$  upper bound on the logarithm of decision tree size for  $\text{KING}_n$ . We omit the statement of this result and its proof due to lack of space, and refer the reader to the full version of the paper [36].

## 1.1 Sketch of proofs of main results

### 1.1.1 Equivalence of source-finding and CIS

We first sketch the proof of Theorem 2, which is the equivalence of finding a source in a tournament and the Clique vs. Independent Set problem. Below is a sketch of the proof of the first part of this theorem. Consider a graph  $G = ([n], E)$ , and an input  $C, I$  to the Clique vs. Independent Set problem. Here Bob is given  $C \subseteq [n]$  which is a clique in  $G$ , and Alice is given  $I \subseteq [n]$  which is an independent set in  $G$  (we switch the order of inputs for convenience). Alice and Bob construct the following instance to the source-finding problem:

- Alice has the edge directions of all edges in  $E$ , and Bob has the remaining edge directions in  $\bar{E}$ .
- Alice constructs her edge directions such that all vertices in  $I$  have in-degree 0 with respect to her edge directions in  $E$ . This is easy to do since there are no edges between any pair of vertices in  $I$ . She also ensures that all vertices in  $[n] \setminus I$  have in-degree at least 1, with respect to her edge directions in  $E$ . She can ensure this if  $G$  is a connected graph. (see Section 3.)
- Just as the above, Bob ensures that all vertices in  $C$  have in-degree 0 w.r.t.  $\bar{E}$ , and all vertices in  $[n] \setminus C$  have in-degree at least 1 w.r.t.  $\bar{E}$ .

<sup>1</sup> The edge partition we use to prove our deterministic lower bound is different from the partition we use to prove our randomized and quantum lower bounds.

<sup>2</sup> After a full version of our work appeared in the public domain [36], Ghosh [23] communicated to us a proof of a matching randomized  $\Omega(n \log \log n)$  lower bound in Theorem 5, showing that our randomized upper bound is tight.

Using the properties above, it is not hard to show that  $s = C \cap I$  iff  $s$  is a source in the tournament jointly constructed by Alice and Bob above. This concludes the reduction from CIS to source-finding.

In the other direction, if Alice is given edge directions for the subset  $E$  of edges of the complete  $n$ -vertex graph, then the underlying graph  $G$  that Alice and Bob construct for the CIS problem is  $G = ([n], E)$ . For the purpose of this reduction, we assume that Alice has an independent set as input to CIS, and Bob has a clique. Alice considers her input, an independent set,  $I$  to the CIS problem to be the set of all vertices with in-degree 0 w.r.t.  $E$  (note that these vertices must form an independent set in  $G$ ), and Bob constructs his input clique  $C$  to be all vertices with in-degree 0 w.r.t. his edges (these form a clique w.r.t.  $E$ , and hence in  $G$ ). Note that a source in the initial tournament, if it exists, must be a vertex in  $I \cap C$  since it must have in-degree 0 both w.r.t. Alice's and w.r.t. Bob's edges. Moreover this is the only way in which  $I$  intersection  $C$  is non-empty. In other words,  $I \cap C \neq \emptyset$  iff there is a source in the initial tournament. This concludes the reduction from source-finding to CIS, and hence Theorem 2. Known upper bounds and lower bounds on the communication complexity of the Clique vs. Independent Set problem (Theorem 1) then yield Corollary 3.

Some of our proofs of the lower bounds in Theorems 4 and 5 follow the same outline. In the next section, we sketch our upper bounds, and we sketch our lower bounds in the following section.

### 1.1.2 Upper bounds

We start with ideas behind the upper bounds in Theorem 4. Throughout this paper, we will view a  $n$ -vertex tournament as a string  $G \in \{0, 1\}^{\binom{n}{2}}$ , where the indices are labeled by pairs  $\{i < j \in [n]\}$  and  $G_{i,j} = 1$  means the edge between vertices  $i$  and  $j$  is directed from  $i$  to  $j$ . Recall that the goal is to construct a communication protocol for finding a king in a tournament  $G \in \{0, 1\}^{\binom{n}{2}}$  whose edges are partitioned into  $E_1$  (with Alice) and  $E_2$  (with Bob).

Consider the deterministic communication model. At a high level, our protocol proceeds in rounds, and in each round Alice and Bob reduce the problem to king-finding in a smaller subtournament. In the beginning of each round assume without loss of generality that Alice has a larger number of edges. Alice sends Bob the label of a vertex  $v$  with maximum number of out-neighbours in  $E_1$  along with the in-neighbourhood of  $v$  in  $E_1$  as a bit-string (one bit for every other vertex  $u$  in the current subtournament for which Alice knows the direction of the edge between  $u$  and  $v$ ). Upon receiving  $v$ , Bob also sends the in-neighbourhood of  $v$  in  $E_2$  as a bit-string. Thus both players know the entire in-neighbourhood of  $v$  in the entire tournament by the end of the round. The communication cost so far is at most  $2n + \log n = O(n)$ , where  $n$  is the number of vertices in the current tournament. The players now reduce to finding a king in the in-neighbourhood of  $v$ , since by [38] (also see Lemma 11), this would give a king in the tournament  $G$ . Since  $|E_1| \geq |E_2|$ , the number of out-neighbours of  $v$  is at least  $(n-1)/4$ . This yields a communication protocol of cost  $T(n)$  that is described by a recurrence of the form  $T(n) \leq T(3n/4) + O(n)$ , which is easily seen to give a solution of  $T(n) = O(n)$ . For the quantum upper bound, we note that a maximum out-degree vertex is always a king [34]. Our  $O(\sqrt{n} \log n)$  quantum upper bound for finding a king then immediately follows from Theorem 5, which we describe shortly.

We now sketch proofs of the upper bounds in Theorem 5. Our upper bounds follow from communication protocols for the following problem: Alice and Bob are given  $A \in [n]^n$  and  $B \in [n]^n$ , respectively. Their goal is to output an index  $i \in [n]$  that maximizes  $a_i + b_i$ . We call

this communication problem  $\text{MAXSUM}_{n,n}$ . The reduction from  $\text{MOD}_n$  to  $\text{MAXSUM}_{n,n}$  is easy to see: Alice and Bob construct  $A, B$  to be the vector of out-degrees of all vertices w.r.t. their edges. Thus a deterministic communication protocol of cost  $O(n \log n)$  immediately follows for  $\text{MOD}_n$ : Alice sends  $A$  to Bob, who then computes an answer. We now sketch the randomized upper bound. Let  $S = (s_1, \dots, s_n)$  where  $s_i = a_i + b_i$ . The first observation is that deciding  $s_i \geq s_j$  is equivalent to deciding  $a_i - a_j \geq b_j - b_i$ . The latter can be done with cost  $O(\log \log n)$  and error at most  $1/3$  by using the communication protocol of Greater-Than due to [39, Theorem 1] (see Theorem 21). Thus Alice and Bob have access to a “noisy” oracle that decides whether  $s_i \geq s_j$ , for all  $i, j \in [n]$ , independently with probability at least  $2/3$ . Finding  $\arg \max_{i \in [n]} s_i$  with error probability  $1/3$  can be done by making  $O(n)$  such queries (due to [21], see Theorem 20). This gives a protocol with an overall communication cost of  $O(n \log \log n)$ . The quantum communication protocol is an application of a result of [12], along with a quantum query upper bound for computing  $\arg \max$  (see Theorem 15), see Section 5 for details.

### 1.1.3 Lower bounds

Our intuition for the lower bounds is that a “hard” partition of edges between Alice and Bob should be such that every vertex has an equal number of incident edges with Alice and with Bob. One such natural partition of the edges is as follows: Alice receives the complete tournament restricted to the first  $n/2$  vertices and the complete tournament restricted to the last  $n/2$  vertices, and Bob receives all of the edges between these vertices. While we are unable to use this partition of edges to prove a lower bound for  $\text{KING}_n$ , we do use it to show a deterministic lower bound for  $\text{MOD}_n$ . Our approach to showing a deterministic communication lower bound for  $\text{MOD}_n$  is to construct a large *fooling set* (see Lemma 19). More precisely, for a permutation  $\sigma \in S$ , where  $S$  is a suitably chosen large (size  $2^{\Omega(n \log n)}$ ) subset of  $\mathcal{S}_n$ , we construct inputs  $A_\sigma, B_\sigma$  to Alice and Bob such that vertex 1 is a unique maximum out-degree vertex for all  $\sigma \in S$ . We also ensure that “cross-inputs”  $(A_\sigma, B_{\sigma'})$  with  $\sigma \neq \sigma'$  lead to vertex 1 not being a maximum out-degree vertex as long as  $\sigma$  and  $\sigma'$  are far away in the  $\ell_\infty$  norm, which we force to be true for all permutations in  $S$  by our construction. We refer the reader to Section 5 for technical details.

While we are unable to make the same reduction work to show the communication lower bounds for  $\text{KING}_n$  (and for good reason, since this argument gives an  $\Omega(n \log n)$  lower bound, and there is an  $O(n)$  upper bound for the communication complexity of  $\text{KING}_n$ ) and randomized and quantum communication lower bounds for  $\text{MOD}_n$ , our partition constructed there has a similar flavor to that above. A key intermediate function that we consider for showing our remaining lower bounds is a variant of  $\text{KING}$  inspired by the well-studied Indexing function. Aptly, we name our variant  $\text{IndexKING}$ , defined below. For a tournament  $G \in \{0, 1\}^{\binom{n}{2}}$  with vertex set  $[n]$ , and a set  $S \subseteq [n]$ , we use the notation  $G|_S$  to denote the subtournament of  $G$  induced on the vertices in  $S$ .

► **Definition 6.** Let  $n > 0$  be a positive integer. Define the  $\text{IndexKING}_n$  communication problem as follows: Alice is given a set  $S \subseteq [n]$  and Bob is given a tournament  $G \in \{0, 1\}^{\binom{n}{2}}$  on  $n$  vertices. Their goal is to output a king in  $G|_S$ .

We consider the restriction of  $\text{IndexKING}$  to those inputs where Bob’s tournament is a transitive tournament (see Definition 12). We denote this variant by  $\text{t-IndexKING}$ . A moment’s observation (see Observation 8) reveals that this problem is equivalently formulated as follows. We name this version the *Permutation Maximum Finding* problem, defined below, and we believe that this problem is of independent interest.

► **Definition 7** (Permutation Maximum Finding). *Let  $n > 0$  be a positive integer. In the Permutation Maximum Finding problem,  $\text{PMF}_n$ , Alice is given as input a subset  $S$  of  $[n]$ , Bob is given a permutation  $\sigma \in \mathcal{S}_n$ , and their goal is to output*

$$\text{PMF}_n(S, \sigma) = \begin{cases} \perp & S = \emptyset \\ \arg \max_{j \in S} \sigma(j) & S \neq \emptyset. \end{cases}$$

Unless explicitly mentioned otherwise, we assume that Alice’s input  $S$  to  $\text{PMF}_n$  is always a non-empty set. In other words, in the PMF problem, Alice is given a subset of  $[n]$ , Bob is given a ranking of all elements in  $[n]$  (here,  $\sigma(i)$  denotes the rank of  $i$ ), and their goal is to find the element in Alice’s set that has the largest rank.

► **Observation 8.** *Let  $n > 0$  be a positive integer. Then,  $\text{cost}(\text{PMF}_n) = \text{cost}(\text{t-IndexKING}_n)$ , where  $\text{cost} \in \{\text{D}^{\text{cc}}, \text{R}^{\text{cc}}, \text{Q}^{\text{cc}}\}$ .<sup>3</sup>*

We refer the reader to the full version [36] for a proof.

We show that Set-Disjointness reduces to PMF (see Lemma 28 and its proof). The lower bound results for PMF follow from known results for communication complexity of Set-Disjointness (see Theorem 17).

Next we reduce from  $\text{PMF}_n$  to KING. Our reduction ensures that an instance  $(S, \sigma)$  to  $\text{PMF}_n$  gives us a tournament  $G_{S, \sigma}$  with the following properties:

- The tournament has  $3n$  vertices, partitioned into  $V_1, V_2, V_3$ , of  $n$  vertices each, each labeled by elements of  $[n]$ . The internal edges (edges in  $\binom{V_1}{2}, \binom{V_2}{2}$  and  $\binom{V_3}{2}$ ) in each of the partitions are with Bob, and these correspond to transitive tournaments defined by  $\sigma$ .
- The remaining “cross” edges are all with Alice, and the directions of these are determined by  $S$  (see Figure 1 for details).
- The tournament  $G_{S, \sigma}$  has exactly three kings (which are also the three unique maximum out-degree vertices), one in each  $V_i$ , and each of these is labeled by  $\text{PMF}_n(S, \sigma)$ .

Thus finding a king or a maximum out-degree vertex in  $G_{S, \sigma}$  amounts to Alice and Bob solving  $\text{PMF}_n$ , which we’ve already sketched to be hard via a reduction from Set-Disjointness. An interesting point to note is that this actually shows a lower bound on the communication complexity of finding a king, even when the input tournament is promised to have exactly three kings. Recall that we showed that finding a king can be done with  $O(\log^2 n)$  deterministic communication when an input is promised to have exactly one king (Corollary 3). Also it is easy to show using Lemma 11 that there are no tournaments with exactly two kings. Thus, the “easiest” non-trivial case of a promised tournament with exactly three kings is already hard for communication.

## 2 Preliminaries

Let  $[n] = \{1, \dots, n\}$ . We use the notation  $\text{polylog}(n)$  to denote  $O(\log(n)^c)$  for some fixed constant  $c$ . For  $f : \mathbb{N} \rightarrow \mathbb{N}$ , we use the notation  $\tilde{O}(f)$  to denote  $O(f \log^{c_1} f)$  and  $\tilde{\Omega}(f)$  to denote  $\Omega(f / (\log^{c_2} f))$ , for some constants  $c_1, c_2$ .

A tournament  $G \in \{0, 1\}^{\binom{[n]}{2}}$  is a complete directed graph on  $n$ -vertices. For  $v, w \in [n]$  such that  $v < w$ , if  $G_{v, w} = 1$  then there is an out-edge from  $v$  to  $w$ , i.e.  $v \rightarrow w$  (otherwise there is an out-edge from  $w$  to  $v$ ). In this case we say that  $v$  1-step dominates  $w$ . Similarly, for  $u, w \in [n]$ , if there exists a  $v \in [n]$  such that  $u \rightarrow v$  and  $v \rightarrow w$  then we say that  $u$  2-step

<sup>3</sup> We actually prove the stronger statement that the problems  $\text{PMF}_n$  and  $\text{t-IndexKING}_n$  are equivalent, in the sense that Alice and Bob need not communicate to go one from one problem to another.

dominates  $w$ . Let  $S \subseteq [n]$  be such that  $v$  2-step (1-step) dominates  $w$  for all  $w \in S$ . We then say that  $v$  2-step (1-step) dominates  $S$ . It is easy to see that there are tournaments where no vertex 1-step dominates all other vertices (such a vertex is called the *source* of  $G$ ). However, it is now folklore that every tournament has a vertex  $v$  such that every vertex  $w \neq v$  is either 1-step or 2-step dominated by  $v$ . Such a vertex is called a *king* of the tournament (see [34]).

► **Lemma 9** (Folklore). *Let  $G \in \{0, 1\}^{\binom{n}{2}}$  be a tournament. Then there exists a vertex  $v \in [n]$  such that  $v$  is a king of  $G$ .*

For a vertex  $v \in [n]$ , let  $N^-(v) = \{w \in [n] : w \rightarrow v\}$  and  $N^+(v) = \{w \in [n] : v \rightarrow w\}$ . Thus  $N^-(v)$  and  $N^+(v)$  denote the in-neighbourhood and out-neighbourhood of  $v$  in  $G$ , respectively. The in-degree of  $v$ , denoted by  $d^-(v)$  is defined as  $|N^-(v)|$ , and similarly the out-degree of  $v$  is denoted by  $d^+(v)$  and is defined as  $|N^+(v)|$ . If a vertex has maximum out-degree in the tournament, then that vertex is a king of the tournament (a proof can be found in [38]).

► **Lemma 10** ([34]). *Let  $G \in \{0, 1\}^{\binom{n}{2}}$  be a tournament and  $v \in [n]$  be a vertex of maximum out-degree in  $G$ . Then  $v$  is a king in  $G$ .*

For  $S \subseteq [n]$  let  $G|_S$  be the tournament induced on  $S$  by  $G$ , i.e.  $G|_S$  is a tournament with vertex set as  $S$  and direction of edges in  $S$  are same as that in  $G$ .

The following is an important lemma that we use often.

► **Lemma 11** ([38]). *Let  $G \in \{0, 1\}^{\binom{n}{2}}$  be a tournament and  $v \in [n]$ . If a vertex  $u$  is a king in  $G|_{N^-(v)}$ , then  $u$  is a king in  $G$ .*

A special class of tournaments is the class of transitive tournaments, which we define next.

► **Definition 12** (Transitive Tournament). *A tournament  $G \in \{0, 1\}^{\binom{n}{2}}$  is transitive if it satisfies the following property: for all  $u, v, w \in [n]$ ,  $u \rightarrow v$  and  $v \rightarrow w$  implies  $u \rightarrow w$ .*

In other words, a transitive tournament is a tournament which is a directed acyclic graph.

► **Lemma 13** (Properties of Transitive Tournaments). *Let  $G \in \{0, 1\}^{\binom{n}{2}}$  be a transitive tournament. There is an ordering  $v_1, \dots, v_n$  of  $[n]$  such that*

- $v_1$  is a source vertex and hence a unique king in  $G$ , and
- for all  $i \in \{2, \dots, n\}$ ,  $v_i$  is source vertex in  $G|_{[n] \setminus \bigcup_{j=1}^{i-1} \{v_j\}}$ .

**Proof.** Since  $G$  is a directed acyclic graph, a topological sort on the vertices gives a source of the graph. Let this vertex be  $v_1$ . The vertex  $v_i$  is obtained by applying the same argument over the transitive tournament  $G|_{[n] \setminus \bigcup_{j=1}^{i-1} \{v_j\}}$ . ◀

## 2.1 Query and Communication Complexity

We refer the reader to the full version [36] of our paper for the formal setup of deterministic, randomized, and quantum query complexity.

► **Definition 14** ( $\text{ARGMAX}_{k,n}$ ). *Let  $k$  be a positive integer and let  $a \in ([k])^n$ . Given query access to  $a$ , find  $i \in [n]$  such that  $a_i \geq a_j$  for all  $j \neq i \in [n]$ .*

► **Theorem 15** ([20]). *There exists a quantum query algorithm for  $\text{ARGMAX}_{k,n}$  with query cost  $O(\sqrt{n})$ .*

## 64:10 On the Communication Complexity of Finding a King in a Tournament

We refer the reader to the full version [36] of our paper for the formal setup of deterministic, randomized, and quantum communication complexity.

► **Definition 16** (Set-Disjointness). *Let  $n > 0$  be a positive integer. The Set-Disjointness problem is denoted by  $\text{DISJ}_n : \{0, 1\}^n \times \{0, 1\}^n \rightarrow \{0, 1\}$  and is defined by*

$$\text{DISJ}_n(A, B) = 1 \iff A \cap B = \emptyset,$$

where  $A, B \subseteq [n]$  are the characteristic sets of Alice and Bob's inputs, respectively.

The communication complexity of  $\text{DISJ}_n$  is extensively studied. We require the following known bounds on its communication complexity [5, 30, 43, 42, 1].

► **Theorem 17** (Communication complexity of Set-Disjointness). *The deterministic, randomized, and quantum communication complexity of  $\text{DISJ}_n$  is as follows:*

$$D^{\text{cc}}(\text{DISJ}_n) = n, \quad R^{\text{cc}}(\text{DISJ}_n) = \Theta(n), \quad Q^{\text{cc}}(\text{DISJ}_n) = \Theta(\sqrt{n}).$$

It is a folklore result that, classically, query algorithms for functions give communication protocols for these functions composed with small gadgets with very little blowup in the complexity. In the quantum setup we have the following theorem, that essentially follows from [12].

► **Theorem 18** ([12]). *Let  $f \subseteq \mathcal{D}_f^n \times \mathcal{R}$  be a relation where  $\mathcal{D}_f = [k]$  for some finite  $k$ , and let  $g : \mathcal{D}_g \times \mathcal{D}_g \rightarrow \mathcal{D}_f$  be a function. For all  $\varepsilon > 0$ , if  $Q_\varepsilon(f) \leq T$  then  $Q_\varepsilon^{\text{cc}}(f \circ g) \leq 2T(\lceil \log n \rceil + \lceil \log k \rceil + \lceil \log |\mathcal{D}_g| \rceil)$ .*

We refer the reader to the full version [36] of our paper for a proof.

A *fooling set* for a communication problem  $f \subseteq (\mathcal{X} \times \mathcal{Y}) \times \mathcal{R}$  is a set  $S \subseteq \mathcal{X} \times \mathcal{Y}$  such that for all pairs  $s_1 = (x_1, y_1)$  and  $s_2 = (x_2, y_2)$  in  $S$ , we have

$$\{r \in \mathcal{R} \mid (x_1, y_1, r) \in f \wedge (x_1, y_2, r) \in f \wedge (x_2, y_1, r) \in f \wedge (x_2, y_2, r) \in f\} = \emptyset.$$

► **Lemma 19.** *Let  $f \subseteq (\mathcal{X} \times \mathcal{Y}) \times \mathcal{R}$  be a communication problem, and let  $S \subseteq \mathcal{X} \times \mathcal{Y}$  be a fooling set for  $f$ . Then,  $D^{\text{cc}}(f) \geq \log |S|$ .*

We refer the reader to standard texts for a formal proof [32, Lemma 1.20]. We remark that standard texts usually frame the fooling set lower bound as a lower bound technique for communication complexity of functions rather than relations, but the same proof technique is easily seen to show the statement above as well. A sketch of the proof is as follows: The leaves of a protocol tree of depth  $c$  yields a partition of the space  $\mathcal{X} \times \mathcal{Y}$  into  $2^c$  rectangles, each of which has at least one  $r \in \mathcal{R}$  that is a valid output for all pairs of inputs in the rectangle. By the property of a fooling set, each element of it must belong to a different leaf. This implies the number of leaves in any protocol for  $f$  must be at least  $|S|$ , implying that the depth of any protocol must be at least  $\log |S|$ .

We require the following theorem that gives an algorithm to find the maximum in a list given noisy comparison oracle access. The formulation we use below follows easily from [21, Theorem 15].

► **Theorem 20** ([21, Theorem 15]). *Let  $S = (s_1, \dots, s_n)$  be a list of  $n$  numbers. Suppose we have access to a “noisy” oracle, that takes as input a pair of indices  $i \neq j \in [n]$ , and outputs a bit that equals  $\mathbb{I}[s_i \geq s_j]$  with probability at least  $2/3$ , independent of the outputs to the other queries. Then there is an algorithm that makes  $O(n)$  queries to the noisy oracle and outputs  $\arg \max_{i \in [n]} s_i$  with probability at least  $2/3$ .*

► **Theorem 21** ([39, Theorem 1]). *Let  $n > 0$  be a positive integer. The  $\text{GT} : [n] \times [n] \rightarrow \{0, 1\}$ , where Alice is given  $x \in [n]$  and Bob is given  $y \in [n]$  is defined as  $\text{GT}(x, y) = 1$  if and only if  $x \geq y$ . The randomized communication complexity of  $\text{GT}$  is  $O(\log \log n)$ .*

## 2.2 Formal definitions of graph problems of interest

For clarity and completeness, we include formal definitions of the tasks of finding a king and finding a maximum out-degree vertex in this section.

► **Definition 22.** *Let  $n > 0$  be a positive integer. Define  $\text{KING}_n \subseteq \{0, 1\}^{\binom{n}{2}} \times [n]$  to be*

$$(G, v) \in \text{KING}_n \iff v \text{ is a king in the tournament } G.$$

► **Definition 23.** *Let  $n > 0$  be a positive integer. Define  $\text{MOD}_n \subseteq \{0, 1\}^{\binom{n}{2}} \times [n]$  to be*

$$(G, v) \in \text{MOD}_n \iff v \text{ is a maximum out-degree vertex in the tournament } G.$$

When we give communication upper bounds for these problems, our upper bounds hold for all partitions of the input variables  $\binom{n}{2}$  between Alice and Bob. When we give lower bounds, we exhibit specific partitions for which our lower bounds hold.

## 3 Communication complexity of finding a source

We consider the communication complexity of finding a source in a tournament if it exists. Alice knows the edge directions of a subset  $E_A$  of the edges of a tournament  $T \in \{0, 1\}^{\binom{n}{2}}$ , Bob knows the directions of the remaining edges  $E_B$ , and their goal is to output the label of a source in the whole tournament if it exists, or output that the tournament has no source. Formally, for a partition of edges  $E_A, E_B$  of the complete  $n$ -vertex graph, define

$$\text{SRC}_{E_A} : \{0, 1\}^{E_A} \times \{0, 1\}^{E_B} \rightarrow \{0, 1, \dots, n\} \quad (1)$$

to be  $\text{SRC}_{E_A}(a, b) = 0$  if there is no source in the tournament defined by edge directions  $a, b$ , and  $\text{SRC}_{E_A}(a, b) = i$  if vertex  $i$  is the (unique) source in the same tournament. We define the decision version of this problem to be  $\text{SRC}_{E_A}^{\text{dec}} : \{0, 1\}^{E_A} \times \{0, 1\}^{E_B} \rightarrow \{0, 1\}$ . That is,  $\text{SRC}_{E_A}^{\text{dec}}$  outputs 0 if there is no source in the tournament, and outputs 1 if there is a source.

Below, we define the celebrated Clique vs. Independent Set problem on an  $n$ -vertex graph  $G$  [47], which we henceforth abbreviate as  $\text{CIS}_G$ . The  $\text{CIS}_G$  problem is associated with an  $n$ -vertex undirected graph  $G = (V, E)$ . In this problem, Alice and Bob both know  $G$ . Alice is given as input a clique  $x \subseteq [n]$  in  $G$ , Bob is given as input an independent set  $y \subseteq [n]$ , and their goal is to either output that  $x \cap y = \emptyset$ , or output the label of the (unique) vertex  $v$  with  $\{v\} = x \cap y$ .<sup>4</sup>

There has been a plethora of work on the Clique vs. Independent set problem, see for example, [47, 25, 26, 8]. Of relevance to us is Theorem 1, which gives near-tight bounds on the deterministic communication complexity of this problem.

Perhaps surprisingly, we show that the communication problem of finding a source in a tournament is *equivalent* to the Clique vs. Independent Set problem. Corollary 3 would then immediately follow. We now prove Theorem 2.

<sup>4</sup> Conventionally, the Clique vs. Independent Set problem is phrased as a decision problem, where the task is to determine if  $x \cap y$  is empty or non-empty. The known bounds we state here are easily seen to hold for the “search version” that we consider as well.

## 64:12 On the Communication Complexity of Finding a King in a Tournament

**Proof of Theorem 2.** In this proof, we assume for convenience that in the Clique vs. Independent Set Problem, Alice is given an independent set and Bob is given a clique.

- Let  $G = (V, E)$  be an  $n$ -vertex graph. Let  $I, C \subseteq [n]$  be Alice and Bob's input to  $\text{CIS}_G$ , respectively. Recall that the vertices in  $I$  form an independent set in  $G$  and the vertices in  $C$  form a clique in  $G$ . We now describe the reduction from  $\text{CIS}_G$  to  $\text{SRC}_E$ . Before delving into the main reduction, we do a preprocessing of small communication cost to make sure that  $G$  is connected and the size of the independent set  $I$  is at least 3.

Preprocessing: Bob sends the label of the connected component in  $G$  that his clique  $C$  is part of. Alice removes from her independent set  $I$ , all vertices that aren't part of this connected component. She now sends a bit to Bob to indicate whether  $|I| \geq 3$ . If not, she further sends labels of the two vertices in  $I$  to Bob who then responds with an answer. This requires a total of  $O(\log n)$  communication cost. We can therefore assume that the graph  $G$  is connected and  $|I| \geq 3$  for the rest of the reduction. Alice and Bob locally construct the following inputs to  $\text{SRC}_E$  (recall that Alice must construct edge directions in  $E$ , and Bob must construct the remaining edge directions).

- Alice orients the edges in  $E$ , using Claim 24 and the fact that  $G$  is a connected graph, such that only the vertices in  $I$  have in-degree 0.
- Bob orients the edges in  $\bar{E}$  as follows. For vertices in  $C$ , he orients the edges in their connected components in  $\bar{G}$ , using Claim 24, such that only the vertices in  $C$  have in-degree 0. Next he orients the edges of connected components that don't contain vertices of  $C$ . If this connected component is not a tree, he uses Claim 25 to orient the edges such that no vertex has in-degree 0. If the connected component is a tree, he orients the edges in an arbitrary way.

Let  $T$  denote the tournament constructed above. We next show that  $(I, C)$  is a 1-input to  $\text{CIS}_G$  iff there exists a source in  $T$ . This would prove the first part of the theorem. Moreover, we show that when there is a source in the constructed tournament, the source vertex is the same as the unique vertex in  $I \cap C$ .

Let  $(I, C)$  be a 1-input to  $\text{CIS}_G$  and  $s$  be the unique vertex in  $I \cap C$ . We show that  $s$  is the source in the tournament  $T$ . By construction, the neighbours of  $s$  in  $E$  are the outneighbours of  $s$  in Alice's input, and the neighbours of  $s$  in  $\bar{E}$  are the outneighbours of  $s$  in Bob's input.

We prove the contrapositive for the other direction. Let  $(I, C)$  be a 0-input to  $\text{CIS}_G$ , i.e.,  $I \cap C = \emptyset$ . We show that there is no source in  $T$ . Vertices in  $\bar{I}$  are ruled out from being a source by the orientation of Alice's edges. Now the vertices of  $I$  form a clique in Bob's input, thus they form a connected component that is not a tree (since  $|I| \geq 3$ ). Since this connected component does not contain a single vertex from  $C$  (since we assumed  $I \cap C = \emptyset$ ), the construction above (using Claim 25) implies that all vertices in  $I$  have in-degree at least 1 w.r.t. Bob's edge directions. Thus, there is no source in the entire tournament.

- In the other direction, let  $\{0, 1\}^{E_A}$  and  $\{0, 1\}^{E_B}$  be Alice and Bob's input to  $\text{SRC}_{E_A}$ , where  $E_A, E_B$  form a partition of the edges of the  $n$ -vertex complete graph. Say that the tournament formed by these inputs is  $T$ . Alice and Bob construct the following instance to the Clique vs. Independent Set problem.
  - The graph is  $G = (V, E)$  with  $V = [n]$  and  $E = E_A$ .
  - Alice constructs  $I \subseteq [n]$  to be all of the vertices with in-degree 0 w.r.t.  $E_A$ . It is easy to see that  $I$  forms an independent set in  $G$  since any edge between vertices in  $I$  causes one of the vertices in  $I$  to have in-degree at least 1.
  - Bob constructs  $C \subseteq [n]$  to be all of the vertices with in-degree 0 w.r.t.  $E_B$ . As in the previous bullet, it is easy to see that  $C$  forms an independent set in  $\bar{G}$ , and hence a clique in  $G$ .

Consider the input  $(I, C)$  to  $\text{CIS}_G$  as constructed above. We show now that  $I \cap C \neq \emptyset$  iff there is a source in  $T$ , which would prove the second part of the theorem since  $(I, C)$  and  $G$  were constructed using no communication.

Suppose  $s$  is a source in  $T$ . Since  $s$  has in-degree 0 w.r.t. both  $E_A$  and  $E_B$ , we must have  $s \in I \cap C$ . Moreover, since every other vertex must have in-degree at least 1, such a vertex is either not in  $I$  or not in  $C$ . Thus,  $s = I \cap C$ . In the other direction, suppose  $s = I \cap C$ . By the construction above,  $s$  must have in-degree 0 w.r.t. both  $E_A$  and  $E_B$ , and hence is a source in  $T$ . ◀

▷ **Claim 24.** Let  $T$  be a tree,  $V$  be its vertex set and  $I$  be an independent set in  $T$ . Then there exists an orientation of the edges of  $T$  such that exactly the vertices in  $V \setminus I$  have in-degree at least 1.

*Proof of Claim 24.* We now show a procedure to orient the edges such that the set of vertices with in-degree 0 equals the set  $I$ . Consider a (left-to-right) listing of subsets of vertices based on their distances from the set  $I$ . So if the listing looks like  $V_0, V_1, \dots, V_j, \dots$ , then  $V_0 = I$ , and  $V_j \subseteq V \setminus I$  is the set of vertices such that the length of a shortest path to reach a vertex in  $I$  equals  $j$ . We orient the edges from  $V_i \rightarrow V_{i+1}$  for  $i \geq 0$ . The edges within a partition, say  $V_i$ , are oriented arbitrarily. Now using the fact that tree is a connected graph, it is easily seen that every vertex in  $V \setminus I$  has in-degree at least 1. Moreover, by our construction, all vertices in  $V_0 = I$  has in-degree 0. ◀

▷ **Claim 25.** Let  $G$  be a connected graph that is not a tree. Then, there exists an orientation of the edges of  $G$  such that every vertex of  $G$  has in-degree at least 1.

*Proof of Claim 25.* Since  $G$  is connected but not a tree, it contains a cycle, say  $C$ . Orient the edges of  $C$  in a cyclic way to give in-degree 1 to every vertex in  $C$ , and then orient the edges “away” from the cycle  $C$  (in a manner similar to the proof in Claim 24 where  $V_0 = C$  here) to add 1 to in-degrees of vertices in  $V \setminus C$ . Thus the directed graph so constructed has no vertex with in-degree 0. ◀

## 4 Communication complexity of KING

The proof of Theorem 4 is divided into two parts. We show the upper bounds in Section 4.1 and the lower bounds in Section 4.2.

### 4.1 Upper bounds on communication complexity of $\text{KING}_n$

We start by proving an  $O(n)$  upper bound on the deterministic communication complexity which also implies an  $O(n)$  upper bound on the randomized communication complexity.

► **Lemma 26.** *Let  $G \in \{0, 1\}^{\binom{n}{2}}$  be a tournament and let  $E_1, E_2$  be a partition of the edges of  $G$ . The deterministic and randomized communication complexity of finding a king of  $G$ , where Alice is given  $E_1$  and Bob is given  $E_2$ , is upper bounded as follows*

$$D^{\text{cc}}(\text{KING}_n) = O(n), \quad R^{\text{cc}}(\text{KING}_n) = O(n).$$

## 64:14 On the Communication Complexity of Finding a King in a Tournament

**Proof.** The proof follows via the Protocol in Algorithm 1.

■ **Algorithm 1** Deterministic Communication Protocol for  $\text{KING}_n$ .

---

```

1: Input: Let  $G \in \{0,1\}^{\binom{n}{2}}$  be a tournament and  $E_1, E_2 \subseteq \{(i,j) : i < j \in [n]\}$  be a
   partition of the edges of  $G$ . Alice (Player 1) is given  $\{0,1\}^{E_1}$  and Bob (Player 2) is given
    $\{0,1\}^{E_2}$ .
2:  $S = [n]$ 
3: while  $|E_1| > n$  and  $|E_2| > n$  do
4:    $b \leftarrow \arg \max_{i \in \{0,1\}} |E_i|$  ▷ Ties broken arbitrarily
5:    $v \leftarrow \arg \max_{w \in [n]} \{\text{out-degree}(w) \text{ in } E_b\}$  ▷ Ties broken arbitrarily
6:   Player  $b$  sends to Player  $1 - b$  the label of  $v$  along with a  $|S|$ -bit indicator vector of
   the in-neighbourhood of  $v$  in  $E_b$ 
7:   Player  $1 - b$  sends an  $|S|$ -bit indicator vector of the in-neighbourhood of  $v$  in  $E_{1-b}$ 
8:    $S \leftarrow S \cap N^-(v)$ 
9:    $E_1 \leftarrow$  the edges of  $E_1$  that are present in  $G|_S$ 
10:   $E_2 \leftarrow$  the edges of  $E_2$  that are present in  $G|_S$ 
11: end while
12: if  $|E_1| \leq n$  then
13:   Alice sends  $E_1$  to Bob
14:   Bob outputs a king of the tournament.
15: else if  $|E_2| \leq n$  then
16:   Bob sends  $E_1$  to Alice
17:   Alice outputs a king of the tournament.
18: end if

```

---

**Correctness.** It is easy to see that in every iteration of the **while** loop, the size of either  $E_1$  or  $E_2$  decreases by at least 1. This shows that our algorithm always terminates.

Let  $S^{(i)}$  denote the set  $S$  in  $i$ 'th iteration of the **while** loop, where  $S^{(1)} = [n]$ . We maintain the invariant that in every iteration of the **while** loop, a king in  $G|_{S^{(i+1)}}$  is also a king in  $G|_{S^{(i)}}$ . This follows easily from Lemma 11 since  $S^{(i+1)}$  is obtained from  $S^{(i)}$  by restricting to vertices in the in-neighbourhood of some vertex  $v$  in Line 8. Assume without loss of generality that the **while** loop terminates with  $|E_1| \leq n$ . In this case, in Line 13, Alice sends her edges to Bob who outputs a king of  $G$ .

**Cost.** We show that the cost of Protocol 1 is upper bounded by  $O(n)$  for all tournaments  $G \in \{0,1\}^{\binom{n}{2}}$ . Suppose we enter the **while** loop with  $|S| = k$ . Let  $c(k)$  be the number of bits communicated during the execution of the **while** loop. Consider Line 6, and assume without loss of generality that  $|E_1| \geq |E_2|$ , thus  $|E_1| \geq (1/2 \cdot \binom{k}{2})$ . Since every edge in  $E_1$  is an out-edge for some vertex (note that  $E_1$  and  $E_2$  are subsets of edges of  $G|_S$  due to Line 9 and Line 10) we have  $\sum_{u \in S} d^+(u) \geq (1/2 \cdot \binom{k}{2})$  (where the out-degrees are only computed in  $E_1$ ) and hence by an averaging argument there exists  $v \in S$  such that the out-degree of  $v$  when restricted to  $E_1$  (and therefore  $S$ ) is at least  $(k-1)/4$ . Thus the in-degree of  $v$  in  $S$  is at most  $(3/4 \cdot (k-1))$ . Furthermore, in each iteration of the **while** loop,  $\lceil \log k \rceil + k$  bits are communicated in Line 6 and  $k$  bits are communicated in Line 7. We have the following upper bound on  $c(k)$ :  $c(k) \leq c(3k/4) + \lceil \log k \rceil + 2k$ , and thus  $c(n) = O(n)$ . Also observe that either Line 13 or Line 16 is executed and in each case at most  $n$  bits are communicated. Thus the overall number of bits communicated is  $O(n)$ . ◀

Next, we give an  $O(\sqrt{n} \log n)$  cost quantum communication protocol for  $\text{KING}_n$ . Our quantum communication upper bound is a corollary of Theorem 5 which gives a quantum communication protocol for finding a maximum out-degree vertex in a tournament (such a vertex is also a king, see Lemma 10).

► **Lemma 27.** *Let  $G \in \{0, 1\}^{\binom{n}{2}}$  be a tournament and let  $E_1, E_2$  be a partition of  $E$ . The quantum communication complexity, where Alice is given  $E_1$  and Bob is given  $E_2$ . Then*

$$Q^{\text{cc}}(\text{KING}_n) = O(\sqrt{n} \log n).$$

## 4.2 Lower bounds on communication complexity of $\text{KING}_n$

Next, we prove the lower bound. In order to do this, we first give a lower bound on the communication complexity of  $\text{PMF}_n$ . Recall that, in this problem, Alice is given as input a subset  $S$  of  $[n]$ , Bob is given a ranking of elements of  $[n]$  defined by  $\sigma$ , and their goal is to output the element in  $S$  that has the largest rank according to  $\sigma$ .

► **Lemma 28.** *The deterministic, randomized, and quantum communication complexity of  $\text{PMF}_n$  is as follows:*

$$D^{\text{cc}}(\text{PMF}_n) = \Omega(n), \quad R^{\text{cc}}(\text{PMF}_n) = \Omega(n), \quad Q^{\text{cc}}(\text{PMF}_n) = \Omega(\sqrt{n}).$$

**Proof.** We show that Set-Disjointness reduces to  $\text{PMF}_n$  and the lemma follows from Theorem 17. We describe the reduction next.

Consider an input to Set-Disjointness,  $S, T \subseteq [n]$  where  $S$  is with Alice and  $T$  is with Bob. Alice and Bob locally construct the following instance of  $\text{PMF}_n$ : Alice retains her set  $S$ , and Bob creates an arbitrary  $\sigma$  such that the following holds:

$$\forall i \neq j \in [n], \quad (T_i = 0) \wedge (T_j = 1) \implies \sigma(i) < \sigma(j).$$

In other words, Bob creates a permutation  $\sigma$  of  $[n]$  that ranks all of the indices in  $T$  higher than all of the indices outside  $T$ . They then run a protocol for  $\text{PMF}_n$  with inputs  $S, \sigma$ , let  $k$  be the output of this protocol. If  $k \in T$  then they return  $S \cap T \neq \emptyset$  else they return  $S \cap T = \emptyset$ .

**Correctness.** If  $\text{PMF}_n(S, \sigma) = \perp$ , then the players know (without any additional communication) that  $S = \emptyset$  and hence  $\text{DISJ}_n(S, T) = 1$ . Thus, we may assume  $S \neq \emptyset$ . Since any protocol for  $\text{PMF}_n$  must output an index  $k \in S$ . By Bob's construction of  $\sigma$ , the elements of  $T$  are ranked higher than elements that are not in  $T$ . Since  $k$  is the output of a protocol for  $\text{PMF}_n$ ,  $k$  is the highest ranked element in  $S$  by  $\sigma$ . Thus if  $k$  is not among the top  $|T|$  ranked elements, then all elements of  $S$  are ranked lower than all elements of  $T$  (by Bob's construction of  $\sigma$ ) and  $S \cap T = \emptyset$ . On the other hand if  $k$  is among the top  $|T|$  ranked elements then  $k \in T \cap S$ . These conditions can be checked by Bob who has  $\sigma$  and  $k$ . ◀

By the equivalence of  $\text{PMF}$  and the transitive variant of  $\text{IndexKING}$  (Observation 8), Lemma 28 implies the same lower bounds on  $\text{t-IndexKING}_n$ .

We thus immediately conclude the same lower bounds on the general  $\text{IndexKING}$  problem (where Bob's tournament is arbitrary, and need not be transitive).

► **Corollary 29.** *The deterministic, randomized, and quantum communication complexity of  $\text{IndexKING}_n$  is as follows:*

$$D^{\text{cc}}(\text{IndexKING}_n) = \Omega(n), \quad R^{\text{cc}}(\text{IndexKING}_n) = \Omega(n), \quad Q^{\text{cc}}(\text{IndexKING}_n) = \Omega(\sqrt{n}).$$

- **Figure 1** Visual depiction of  $G_{S, \sigma}$ . For each  $b \in \{0, 1, 2\}$ ,  $S_b$  contains the vertices  $\{i_b : i \in S\}$  and  $T_b$  contains the vertices  $\{i_b : i \notin S\}$ . There are four types of edges (also see Definition 30):
- Edges of **Type 1** are those within each  $T_b \cup S_b$ , here  $i_b \rightarrow j_b$  iff  $\sigma(i) > \sigma(j)$ .
  - Edges of **Type 2** are those between  $S_b$  and  $T_{b'}$  for  $b \neq b'$ , here  $i_b \rightarrow j_{b'}$ .
  - Edges of **Type 3** are those between  $S_b$  and  $S_{b'}$  for  $b \neq b'$ , here  $i_b \rightarrow j_{b'}$  iff  $b' = b + 1 \pmod{3}$ .
  - Edges of **Type 4** are those between  $T_b$  and  $T_{b'}$  for  $b \neq b'$ , here  $i_b \rightarrow j_{b'}$  iff  $b' = b + 1 \pmod{3}$ .

We now give a lower bound on the communication complexity of  $\text{KING}_n$ . For this we first define a class of tournaments that we use in our proof.

### 4.3 A class of tournaments

In this section, we define a special class of tournaments on  $3n$  vertices, that are parametrized by a subset  $S \subseteq [n]$  and an ordering  $\sigma$  of  $[n]$ .

► **Definition 30.** Given a set  $S \subseteq [n]$  and  $\sigma \in \mathcal{S}_n$ , define the tournament  $G_{S, \sigma}$  on  $3n$  vertices as follows:

- The vertex set is  $V = \{i_b : i \in [n], b \in \{0, 1, 2\}\}$ .
- For each  $b \in \{0, 1, 2\}$  and all  $i \neq j \in [n]$ , the direction of the edge between  $i_b$  and  $j_b$  is  $i_b \rightarrow j_b$  iff  $\sigma(i) > \sigma(j)$ . We refer to these as **Type 1** edges.
- For all  $b \neq b' \in \{0, 1, 2\}$ , all  $i \in S$  and all  $j \notin S$ ,  $i_b \rightarrow j_{b'}$  is an edge. We refer to these as **Type 2** edges.
- For all  $b \neq b' \in \{0, 1, 2\}$  and all  $i \neq j \in S$ , the direction between the edge  $i_b$  and  $j_{b'}$  is  $i_b \rightarrow j_{b'}$  iff  $b' = b + 1 \pmod{3}$ . We refer to these as **Type 3** edges.
- For all  $b \neq b' \in \{0, 1, 2\}$  and all  $i \neq j \notin S$ , the direction between the edge  $i_b$  and  $j_{b'}$  is  $i_b \rightarrow j_{b'}$  iff  $b' = b + 1 \pmod{3}$ . We refer to these as **Type 4** edges.

We refer the reader to Figure 1 for a pictorial representation and some additional notation.

► **Lemma 31.** Let  $n > 0$  be a positive integer,  $S \subseteq [n]$  and  $\sigma \in \mathcal{S}_n$ . Then, the tournament  $G_{S, \sigma}$  has exactly three kings, namely  $k_0, k_1, k_2$ , where  $k = \arg \max_{j \in S} \sigma(j)$ . Moreover,  $k_0, k_1, k_2$  are the only vertices with maximum out-degree in  $G_{S, \sigma}$ .

**Proof.** We first show that  $k_0$  is a king. The argument for  $k_1, k_2$  being kings follows similarly. To show that  $k_0$  is a king, we exhibit paths of length one or two from  $k_0$  to all other vertices in the tournament.

- First note that for any element  $j \in S$ , there is an edge from  $k_0$  to  $j_0$  since  $k = \arg \max_{j \in S} \sigma(j)$  (this is an edge of Type 1). Thus,  $k_0$  1-step dominates  $S_0$ .
- For all  $j \notin S$  and  $b \in \{1, 2\}$ , there is an edge (of Type 2) from  $k_0$  to  $j_b$ . Thus,  $k_0$  1-step dominates  $T_1$  and  $T_2$ .
- For  $j, j' \in S$ , there is an edge (of Type 3) from  $k_0$  to  $j_1$ . Thus  $k_0$  1-step dominates  $S_1$ . There is also an edge (also of Type 3) from  $j_1$  to  $j'_2$ . Thus,  $k_0$  2-step dominates  $S_2$ .
- For an arbitrary  $j \in S$ , as noted above, there is an edge from  $k_0$  to  $j_1$ . For  $j' \notin S$ , there is an edge (of Type 2) from  $j_1$  to  $j'_0$ . Thus,  $k_0$  2-step dominates  $T_0$ .

This shows that  $k_0$  (and similarly  $k_1$  and  $k_2$ ) is a king in  $G_{S,\sigma}$ .<sup>5</sup> We next show that no other vertex is a king. We do this by showing for every other vertex  $k'_b$ , a vertex that is not 1-step or 2-step dominated by  $k'_b$ .

- Consider  $k' \neq k \in S$  and  $b \in \{0, 1, 2\}$ . We now show that  $k'_b$  does not 1-step or 2-step dominate  $k_b$ .
  - Since  $k_b$  is the unique king in the transitive tournament  $(G_{S,\sigma})|_{S_b}$  (see Lemma 13),  $k'_b$  does not 1-step dominate  $k_b$  via Type 1 edges. Moreover, the only vertices that are 1-step dominated by  $k'_b$  via Type 1 edges are a subset of vertices in  $S_b \cup T_b$ . None of these vertices can 1-step dominate  $k_b$  since  $(G_{S,\sigma})|_{S_b \cup T_b}$  is a transitive tournament. This shows that  $k'_b$  cannot 1-step dominate or 2-step dominate  $k_b$  by first using an edge of Type 1.
  - The only other out-going edges from  $k'_b$  are either of Type 2 or Type 3.
  - Consider a Type 2 edge which goes from  $k'_b$  to  $T_{b+1 \pmod 3}$  ( $T_{b+2 \pmod 3}$  follows similarly). By construction, there is no edge from any vertex in  $T_{b+1 \pmod 3}$  to  $k_b$  (see Figure 1).
  - Now consider a Type 3 edge which goes from  $k'_b$  to  $S_{b+1 \pmod 3}$ . By construction, there is no edge from any vertex in  $S_{b+1 \pmod 3}$  to  $k_b$  (see Figure 1).
- Consider  $k' \notin S$  and  $b \in \{0, 1, 2\}$ . We now show that  $k'_b$  does not 1-step or 2-step dominate  $k_{b+2 \pmod 3}$ .
  - The only out-going edges from  $k'_b$  are either of Type 1 or Type 4. On taking a Type 1 edge,  $k'_b$  can only 1-step dominate a subset of vertices of  $S_b \cup T_b$ . None of these vertices have an edge to  $k_{b+2 \pmod 3}$  (see Figure 1). Thus,  $k'_b$  cannot 2-step dominate  $k_{b+2 \pmod 3}$  by first taking a Type 1 edge.
  - A Type 4 edge goes from  $k'_b$  to a vertex in  $T_{b+1 \pmod 3}$ . By construction, no vertex in  $T_{b+1 \pmod 3}$  has an edge to  $k_{b+2 \pmod 3}$  (see Figure 1).

Finally, we observe that  $k_0, k_1, k_2$  are the only three vertices with maximum out-degree in  $G_{S,\sigma}$ . Observe that the out-degrees of  $k_0, k_1, k_2$  are all equal by symmetry. By Lemma 10, a vertex with maximum out-degree in  $G_{S,\sigma}$  is a king in  $G_{S,\sigma}$ . This, along with the proof above that shows that  $k_0, k_1, k_2$  are the only kings in  $G_{S,\sigma}$ , immediately implies that  $k_0, k_1, k_2$  are the only three vertices with maximum out-degree in  $G_{S,\sigma}$ . ◀

#### 4.4 Proof of Theorem 4

We now prove Theorem 4. The upper bounds follow from the arguments in Section 4.1. For the lower bounds, we do a reduction from PMF. The class of tournaments constructed in Section 4.3, and its properties, play a crucial role in the reduction.

---

<sup>5</sup> We remark here that there is an alternative proof that shows  $k_0$  to be a king: consider an arbitrary  $j_1$  for an arbitrary  $j \in S$ . The in-neighborhood of  $j_1$  contains  $S_0$  and a subset of  $S_1 \cup T_1$ . It can be verified that  $k_0$  is a source (and hence a king) in the tournament restricted to the in-neighbourhood of  $j_1$ . Lemma 11 then implies that  $k_0$  is a king. We choose to keep the current proof for clarity.

**Proof of Theorem 4.** The upper bounds follow from Lemma 26 and Lemma 27.

For the lower bounds, consider an input  $S \subseteq [n]$  to Alice and  $\sigma \in \mathcal{S}_n$  to Bob for  $\text{PMF}_n$ . Alice and Bob jointly construct the tournament  $G_{S,\sigma}$ . Note that this construction is completely local and involves no communication; Alice can construct all edges of Types 2, 3 and 4, and Bob can construct all edges of Type 1 (see Figure 1). By Lemma 31, there are exactly 3 kings in  $G_{S,\sigma}$  and these are  $\{i_b : b \in \{0, 1, 2\}, i = \arg \max_{j \in S} \sigma(j) = \text{PMF}_n(S, \sigma)\}$  (recall Definition 7). Thus, running a protocol for  $\text{KING}_{3n}$  on input  $G_{S,\sigma}$  (where Alice has edges of Types 2, 3 and 4, and Bob has edges of Type 1) gives the solution to  $\text{PMF}_n(S, \sigma)$  at no additional cost. Lemma 28 implies the required lower bounds. ◀

## 5 Communication complexity of MOD

Recall that in the  $\text{MOD}_n$  communication problem, Alice and Bob are given inputs in  $\{0, 1\}^{E_1}$  and  $\{0, 1\}^{E_2}$ , respectively, where  $E_1$  and  $E_2$  form a partition of the edge set  $\binom{[n]}{2}$ . Their goal is to output a vertex  $v$  that has maximum out-degree in the tournament formed by the union of their edges. We next prove Theorem 5. In this theorem we settle the communication complexity of finding a maximum out-degree vertex in a tournament in the deterministic, randomized, and quantum models, up to logarithmic factors in the input size. In the deterministic model we are able to show a tight  $\Theta(n \log n)$  bound.

We first define an intermediate communication problem,  $\text{MAXSUM}_{n,k}$ , which seems independently interesting to study from the perspective of communication complexity.

► **Definition 32.** Let  $n, k > 0$  be positive integers. In the  $\text{MAXSUM}_{n,k}$  problem, Alice is given  $A = (a_1, \dots, a_n) \in [k]^n$ , Bob is given  $B = (b_1, \dots, b_n) \in [k]^n$ , and their goal is to output  $\arg \max_{j \in [n]} (a_j + b_j)$  (if there is a tie, they can output any of the tied indices).

$\text{MAXSUM}_{n,k}$  is easily seen to be the composition of two problems: the outer problem is  $\text{ARGMAX}_{2k,n}$  (see Definition 14) and the inner function is  $\text{SUM}_k$  (which adds two integers in  $[k]$ , one with Alice and the other with Bob). It is also easy to see that  $\text{MOD}_n$  reduces to  $\text{MAXSUM}_{n,2n}$ : Alice and Bob can locally construct  $(a_1, \dots, a_n)$  and  $(b_1, \dots, b_n)$  to be the out-degree vectors of all the vertices restricted to edges in their inputs. Thus, a cost- $c$  protocol for  $\text{MAXSUM}_{n,2n}$  also gives a protocol for  $\text{MOD}_n$ .

We note here that our upper bounds (Theorem 5) actually give upper bounds for the more general  $\text{MAXSUM}_{n,k}$  problem; the deterministic, randomized, and quantum communication upper bounds here are  $O(n \log k)$ ,  $O(n \log \log k)$  and  $O(\sqrt{n} \log k \log n)$ , respectively. Next, we proceed to give a proof of Theorem 5.

**Proof of Theorem 5.** For the upper bounds, we exhibit protocols of the required cost for  $\text{MAXSUM}_{n,n}$ , which is only a (potentially) harder problem.

- For the deterministic upper bound, note that Alice can just send her input to Bob with cost  $n \log n$ , and Bob can output the answer.
- The randomized upper bound follows by using Theorem 20 with the list  $s = (a_1 + b_1, \dots, a_n + b_n)$ , and observing that testing whether  $a_i + b_i \geq a_j + b_j$  can be done with communication  $O(\log \log n)$  and success probability at least  $2/3$  (Theorem 21).
- For the quantum upper bound, recall that  $\text{MAXSUM}_{n,n}$  is the composition of  $\text{ARGMAX}_{2n,n}$  (with an input list in  $[2n]^n$ ) and  $\text{SUM}$  (sum of 2 integers in  $[n]$ , one with Alice and the other with Bob). Here,  $\text{ARGMAX}_{2n,n}$  has query complexity  $O(\sqrt{n})$ , where query access is to the values of the elements of the list (see Theorem 15) and  $\text{SUM} : [n] \times [n] \rightarrow [2n]$ . Setting  $\mathcal{D}_g = [n]$ ,  $\mathcal{D}_f = [2n]$ ,  $g = \text{SUM}_n : \mathcal{D}_g \times \mathcal{D}_g \rightarrow \mathcal{D}_f$ ,  $f = \text{ARGMAX}_{2n,n} \subseteq \mathcal{D}_f^n \times [n]$  in Theorem 18, this gives a quantum communication upper bound of  $O(\sqrt{n} \log n)$ .

**Randomized and quantum lower bounds.** The randomized and quantum lower bounds follow the same proof as that of Theorem 4 (see Section 4.4) because the three kings in  $G_{S,\sigma}$  are precisely the maximum out-degree vertices there as well (see Lemma 31). This argument also shows a deterministic lower bound of  $\Omega(n)$ .

**Deterministic lower bound.** We now turn our attention to the deterministic lower bound of  $\Omega(n \log n)$ , which does not use the same reduction as in the proof of Theorem 4. We show this via a fooling set argument (Lemma 19). Below, we assume that the first half of Alice’s input corresponds to the out-degree sequence of a tournament on vertex set  $L = \{1, 2, \dots, n/2\}$ , the second half of her input corresponds to the out-degree sequence of a tournament on vertex set  $R = \{1', 2', \dots, (n/2)'\}$ , and Bob’s input is the out-degree sequence of the complete bipartite tournament between  $L$  and  $R$ . We focus on inputs that are induced by tournaments of the following form, that are defined for a permutation  $\sigma \in \mathcal{S}_{n/2-1}$  that acts in an identical fashion on  $\{2, 3, \dots, n/2\}$  and  $\{2', 3', \dots, (n/2)'\}$ . We call Alice and Bob’s input constructed below  $A_\sigma$  and  $B_\sigma$ , respectively.

1. Vertex 1 is the source in  $L$ , and vertex  $1'$  is the source in  $R$ . These edges are with Alice.<sup>6</sup>
2. Vertex 1 has edges towards  $1'$  and  $\sigma^{-1}(2')$ . All other vertices in  $\{3', 4', \dots, (n/2)'\}$  have edges pointing towards vertex 1. These edges are with Bob.
3. For all  $i, j \in \{2, 3, \dots, n/2\}$ , there is an edge from  $i$  to  $j$  iff  $\sigma(i) < \sigma(j)$ . Similarly there is an edge from  $i'$  to  $j'$  iff  $\sigma(i') < \sigma(j')$ . These edges are with Alice.
4. For  $i \in \{2, 3, \dots, n/2\}$ , there is an edge from  $i$  to  $1'$ . These edges are with Bob.
5. For  $i, j \in \{2, 3, \dots, n/2\}$ , there is an edge from  $i$  to  $j'$  iff  $\sigma(i) \leq \sigma(j)$ . These edges are with Bob.

We now verify that vertex 1 is the unique vertex with maximum out-degree in the whole tournament (and hence the first coordinate must be output in the corresponding inputs to Alice and Bob for  $\text{MOD}_n$ ).

- Items 1 and 2 above ensure that vertex 1 has out-degree  $n/2 - 1 + 2 = n/2 + 1$ .
- Item 1 and Item 4 ensure that the out-degree of vertex  $1'$  is  $n/2 - 1$ .
- Item 1 and Item 5 ensure that vertex  $\sigma^{-1}(2')$  has out-degree  $n/2 - 2$ .
- For  $i \in \{2, 3, \dots, n/2\}$ , the out-degree of vertex  $\sigma^{-1}(i)$  is  $n/2 - i$  from Alice’s input (Item 3) plus  $i$  from Bob’s input (Item 5), which gives a total of  $n/2$ .
- For  $i \in \{3, 4, \dots, n/2\}$ , the out-degree of vertex  $\sigma^{-1}(i')$  is  $n/2 - i$  from Alice’s input (Item 3) plus  $i - 1$  from Bob’s input (Item 5), which gives a total of  $n/2 - 1$ .

These bullets verify that for input  $(A_\sigma, B_\sigma)$ , vertex 1 is the unique maximum out-degree vertex. Our fooling set will be of the form  $F = \{(A_\sigma, B_\sigma) : \sigma \in S\}$ , where  $S \subseteq \mathcal{S}_{n/2-1}$  is chosen appropriately. The property that  $S$  will satisfy is that for all  $\sigma \neq \sigma' \in S$ , at least one of the inputs  $(A_\sigma, B_{\sigma'})$  or  $(A_{\sigma'}, B_\sigma)$  will *not* have vertex 1 as a maximum out-degree vertex. We will also construct  $S$  such that  $|S| = 2^{\Omega(n \log n)}$ . Lemma 19 will then imply the required deterministic communication lower bound of  $\Omega(n \log n)$ .

It remains to construct  $S \subseteq \mathcal{S}_{n/2-1}$ , which we do in the remaining part of this proof. We construct  $S$  such that it satisfies the following property.

$$\forall \sigma \neq \sigma' \in S, \quad \exists i \in \{2, 3, \dots, n/2\} : |\sigma(i) - \sigma'(i)| \geq 2.$$

<sup>6</sup> When we say “edges are with Alice/Bob”, we actually mean Alice/Bob’s out-degree of vertices is determined by the directions of the underlying edges. In this case we mean Alice’s first coordinate is  $n/2 + 1$  because vertex 1 is a source in  $L$ .

In the two bullets below, we first show why such an  $S$  satisfies the required fooling set property, and then show a construction of  $S$  of size  $2^{\Omega(n \log n)}$ .

- Let  $\sigma \neq \sigma'$  be an arbitrary pair of elements of  $S$ . Without loss of generality, assume that  $i \in \{2, 3, \dots, n/2\}$  is such that  $\sigma'(i) - \sigma(i) \geq 2$  (otherwise switch the roles of  $\sigma$  and  $\sigma'$  and run the same argument). Consider the input  $(A_\sigma, B_{\sigma'})$ . Note that the out-degree of vertex 1 remains  $n/2 + 1$  because all edges incident on it are fixed for all inputs in our fooling set. Alice's contribution to the out-degree of vertex  $i$  is  $n/2 - \sigma(i)$ , and Bob's contribution is  $\sigma'(i)$ , which gives a total of  $n/2 + \sigma'(i) - \sigma(i) \geq n/2 + 2$ . Thus vertex 1 cannot be a maximum out-degree vertex in the input  $(A_\sigma, B_{\sigma'})$ .
- We construct such an  $S$  greedily one element at a time. At any step in the construction we maintain the invariant that the current set  $T$  satisfies

$$\forall \sigma \neq \sigma' \in T, \quad \exists i \in \{2, 3, \dots, n/2\} : |\sigma(i) - \sigma'(i)| \geq 2.$$

Additionally we maintain a “candidate” set of permutations in  $\mathcal{S}_{n/2-1}$  that are not in  $T$ , and have the property that adding any of them to  $T$  will satisfy  $T$ 's invariant. Initially we start with  $T = \emptyset$  and the candidate set as  $\mathcal{S}_{n/2-1}$ , which clearly satisfies the required invariant. At any stage, after adding  $\sigma$  to  $T$ , we remove the set  $S_\sigma$  from the candidate set, where  $S_\sigma$  is defined as

$$S_\sigma := \{\tau \in \mathcal{S}_{n/2-1} : |\tau(i) - \sigma(i)| < 2 \ \forall i \in \{2, 3, \dots, n/2\}\}.$$

It is easy to verify by induction that  $T$  and the candidate set thus constructed always satisfy the required invariant. The initial size of the candidate set is  $(n/2-1)! = 2^{\Omega(n \log n)}$ , and at each step we are removing at most  $3^n$  elements from the candidate set. This means that the number of iterations of this construction is at least  $2^{\Omega(n \log n - n)} = 2^{\Omega(n \log n)}$ , which is what we needed. ◀

We remark that while it may seem like the argument used in the previous proof may be adaptable to prove a deterministic communication lower bound of  $\Omega(n \log n)$  for  $\text{KING}_n$ , this is not possible in view of our  $O(n)$  deterministic communication upper bound for  $\text{KING}_n$  from Theorem 4. This shows an inherent difference between  $\text{MOD}_n$  and  $\text{KING}_n$  in the setting of deterministic communication complexity.

► **Remark 33.** We note that our  $\Omega(n \log n)$  lower bound for  $\text{MOD}_n$  also solves Problem 2 in [22].

## Abstract

To ensure differential privacy, one can reveal an integer fuzzily in two ways: (a) add some Laplace noise to the integer, or (b) encode the integer as a binary string and add iid BSC noise. The former is simple and natural while the latter is flexible and affordable, especially when one wants to reveal a sparse vector of integers. In this paper, we propose an implementation of (b) that achieves the capacity of the BSC with positive error exponents. Our implementation adds error-correcting functionality to Gray codes by mimicking how software updates back up the files that are getting updated (“coded Gray code”). In contrast, the old implementation of (b) interpolates between codewords of a black-box error-correcting code (“Grayed code”).

## 1 Introduction

Differential privacy is the art of publishing collective facts without leaking any detail of any user. A mathematically rigorous way to do so is adding noise to an aggregation function that is Lipschitz continuous (sometimes of bounded variation) in every argument. More concretely, suppose that we are interested in a feature  $\varphi: \{0, 1\}^n \rightarrow [m]$  that satisfies

$$|\varphi(u) - \varphi(u')| \leq 1, \text{ for } u := (u_1, \dots, u_i, \dots, u_n) \text{ and } u' := (u_1, \dots, 1 - u_i, \dots, u_n),$$

i.e., changing the data of the  $i$ th user does not change the feature too much. Then publishing  $\varphi(u) + L$ , where  $L$  follows the Laplace distribution with decay rate  $\varepsilon$ , is  $\varepsilon$ -differentially private [3]. That is,

$$\text{Prob}\{\varphi(u) + L < t\} \leq \exp(\varepsilon) \text{Prob}\{\varphi(u') + L < t\} \quad (1)$$

for any number  $t \in \mathbb{R}$ , meaning that a data broker will have a hard time telling if  $u_i$  is 0 or 1.

Publishing  $\varphi(u) + L$  is called the *Laplace mechanism* [3]. It is optimal<sup>1</sup> privacy-wise as (1) assumes equality half of the time. But it turns out to be randomness-costly and space-inefficient when we have many features  $\varphi_1, \dots, \varphi_\ell$  to publish, wherein only  $k \ll \ell$  of them are non-zero<sup>2</sup> for a given  $x$ . In this case, the Laplace mechanism will add noise to

---

<sup>1</sup> Note that we can always choose to publish  $\varphi(u) + 100L$ , which is more private than  $\varphi(u) + L$  by being less informative and less useful. We say that  $\varphi(u) + L$  is optimal because it strikes a balance between (1) and utility.

<sup>2</sup> For example,  $\varphi_i(u)$  could be the number of times the  $i$ th English word was mentioned in a forum archive  $u$ . Most word counts are going to be zero.

are the first nine strings. (Digits that are flipped are highlighted.)

A *robust Gray code* [1, 6] encodes integers as binary strings such that they can be fuzzily recovered even if some bits are erased or corrupted. Given the motivational Figure 1, let us use the binary symmetric channels (BSC) with crossover probability  $p \in (0, 1/2)$  to model the errors. Then a robust Gray code is a pair of encoder

$$\mathcal{E}: [m] \rightarrow \{0, 1\}^{1 \times n}$$

and decoder

$$\mathcal{D}: \{0, 1\}^{1 \times n} \rightarrow [m]$$

such that (a)  $\mathcal{E}(x)$  and  $\mathcal{E}(x+1)$  differ by one bit and (b)

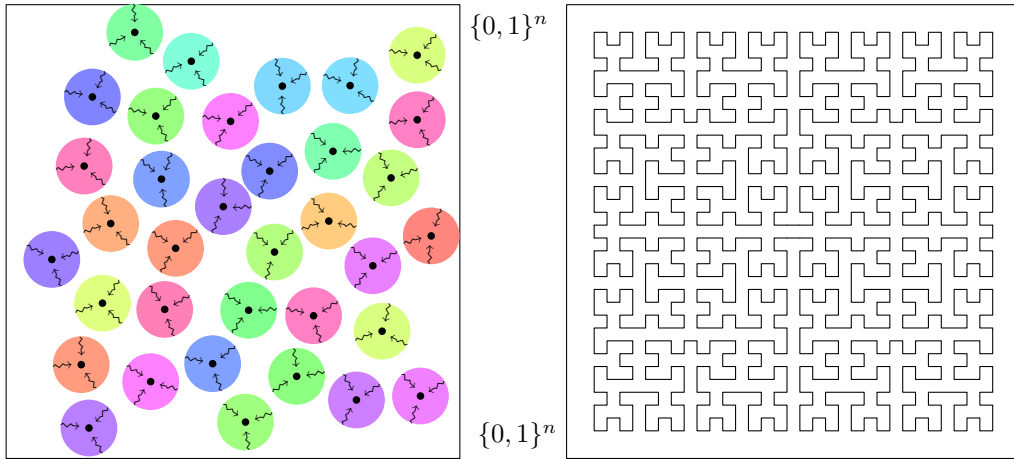

$$\text{Prob}\left\{\left|\mathcal{D}(\text{BSC}_p^n(\mathcal{E}(x))) - x\right| > t\right\} < 2^{-\Omega(n)} + 2^{-\Omega(t)} \quad (3)$$

for all  $x \in [m-1]$  and all  $t > 1$ . Here,  $\text{BSC}_p^n$  flips each of the  $n$  bits with probability  $p$ . Note that (3) is almost as good as the Laplace mechanism in that  $2^{-\Omega(t)}$  decays exponentially in  $t$ . The only catch is that when  $t \gg n$ , the other error term  $2^{-\Omega(n)}$  dominates  $2^{-\Omega(t)}$ . This  $2^{-\Omega(n)}$  is unavoidable because there is always<sup>3</sup> a  $2^{-\mathcal{O}(n)}$  chance that BSC will flip all ones to zero.

Apart from robustness, we also care about space efficiency. We know that, by Shannon's theory, the code rate  $\log_2(m)/n$  cannot exceed the capacity of  $\text{BSC}_p$ , which is  $1 + p \log_2(p) - (1-p) \log_2(1-p)$ . But how close can they be? Before our work, Lolck and Pagh's construction [6] achieves 1/4 of the capacity (1/3 in [6, Appendix A]) and Fathollahi and Wootters's construction [4] achieves 1/2 of the capacity. This means that the latter uses half of the space to achieve the same privacy level.

In this work, and in a concurrent work by Con, Fathollahi, Gabrys, and Yaakobi [2], we will show that the capacity can be achieved. This means that, subject to the framework of Figure 1, the tradeoff between privacy and space is now asymptotically tight. We also show that our code has linear encoding and decoding complexity, meaning that even the speed cannot be significantly improved.

<sup>3</sup> Note that we implicitly assume that  $p$  is bounded away from zero. This is a common practice in coding theory where channel parameters,  $p$  in this case, are fixed while the other parameters vary. Also note that  $\text{BSC}_p$  here plays the role of the Laplace noise, so it would make less sense to have  $p$  too close to zero unless, of course, one is aiming for some special privacy regime.

(a) An error-correcting code is some points that can be decoded up to some radius.

(b) A gray code is a Hamiltonian cycle that only goes in the cardinal directions.

■ **Figure 2** Figurative illustrations of error-correcting codes and Gray codes.

## 1.2 Previous approaches

Earlier works [6, 4] baked robust Gray codes with the following recipe.

- Take a good  $[n, k]$ -error correcting code  $\mathcal{C} = \{c^1, c^2, \dots, c^{2^k}\} \subset \{0, 1\}^{1 \times n}$ .
- Let  $\mathcal{E}$  map “milestone” integers  $1 =: \mu_1 < \mu_2 < \dots < \mu_{2^k} := m$  to the codewords of  $\mathcal{C}$ , i.e.,  $\mathcal{E}(\mu_j) := c^j$ .
- “Interpolate” between the milestones. That is, if  $x \in [\mu_j, \mu_{j+1}]$ , then the prefix of  $\mathcal{E}(x)$  will come from  $\mathcal{E}(\mu_j)$  and the suffix from  $\mathcal{E}(\mu_{j+1})$ .

The technicality is with the third bullet point. A decoder of  $\mathcal{C}$  can translate  $\mathcal{E}(x)$  back to  $\mu_j$  if  $x$  is close enough to  $\mu_j$ . But there is going to be a middle ground between  $\mu_j$  and  $\mu_{j+1}$  such that the decoder will be confused.

To eliminate the confusion, Lolck and Pagh [6] proposed the following data structure

$$\mathcal{E}(\mu_j) := c^j \| c^j \| c^j \| c^j \in \{0, 1\}^{1 \times 4n},$$

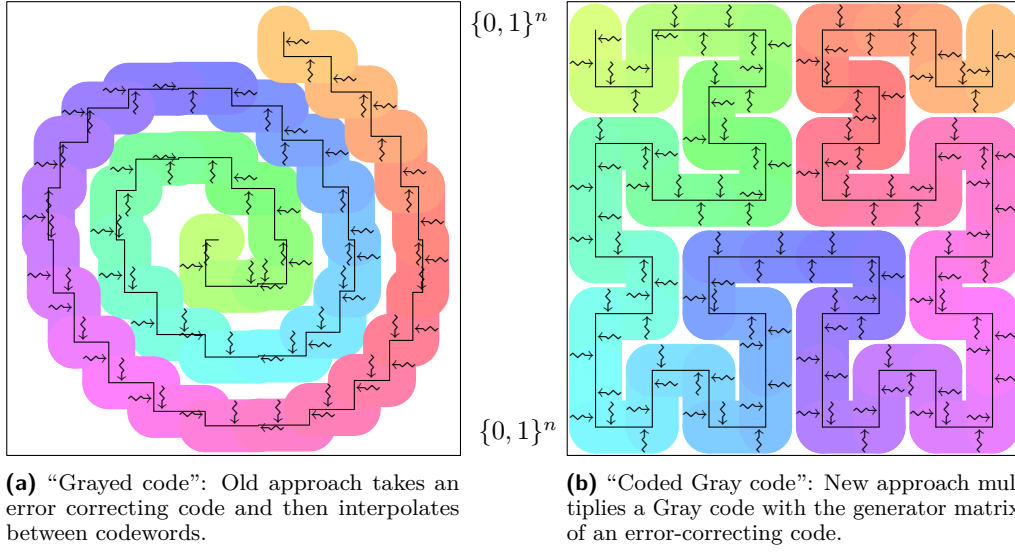

where  $\|$  is the string concatenation operator. They then interpolate between consecutive milestones  $\mu_j$  and  $\mu_{j+1}$  as

$$\begin{aligned} \mathcal{E}(\mu_{j.1}) &:= c^j \| c^j \| c^j \| c^j, \\ \mathcal{E}(\mu_{j.2}) &:= c^{j+1} \| c^j \| c^j \| c^j, \\ \mathcal{E}(\mu_{j.3}) &:= c^{j+1} \| c^{j+1} \| c^j \| c^j, \\ \mathcal{E}(\mu_{j.4}) &:= c^{j+1} \| c^{j+1} \| c^{j+1} \| c^j, \\ \mathcal{E}(\mu_{j.5}) &:= c^{j+1} \| c^{j+1} \| c^{j+1} \| c^{j+1} \end{aligned}$$

for some minor milestones  $\mu_j =: \mu_{j.1} < \mu_{j.2} < \mu_{j.3} < \mu_{j.4} < \mu_{j.5} := \mu_{j+1}$ . Note that only one copy is undergoing interpolation at any given time (which is highlighted). So the advantage of repeating  $c^j$  four times is that there are always two other copies that will decode to the same codeword. To elaborate, between  $\mu_{j.1}$  and  $\mu_{j.3}$ , the two  $c^j$  to the right will decode correctly; between  $\mu_{j.3}$  and  $\mu_{j.5}$ , the two  $c^{j+1}$  to the left will decode correctly.

Later, Fathollahi and Wootters [4] streamlined the data structure from  $4n$  bits to  $(2+3\epsilon)n$  bits by using *buffers* – consecutive zeros and ones. They map milestones to

$$\mathcal{E}(\mu_j) := 0^{\epsilon n} \| c^j \| 0^{\epsilon n} \| c^j \| 0^{\epsilon n} \in \{0, 1\}^{1 \times (2+3\epsilon)n}$$

■ **Figure 3** Old approach (not capacity-achieving) versus new approach (capacity-achieving).

if  $j$  is even, and to

$$\mathcal{E}(\mu_j) := 1^{\varepsilon n} \|c^j\| 1^{\varepsilon n} \|c^j\| 1^{\varepsilon n} \in \{0, 1\}^{1 \times (2+3\varepsilon)n}$$

if  $j$  is odd. They then interpolate between the milestones as

$$\begin{aligned} \mathcal{E}(\mu_{j.1}) &:= 0^{\varepsilon n} \|c^j\| 0^{\varepsilon n} \|c^j\| 0^{\varepsilon n}, \\ \mathcal{E}(\mu_{j.2}) &:= 1^{\varepsilon n} \|c^j\| 0^{\varepsilon n} \|c^j\| 0^{\varepsilon n}, \\ \mathcal{E}(\mu_{j.3}) &:= 1^{\varepsilon n} \|c^{j+1}\| 0^{\varepsilon n} \|c^j\| 0^{\varepsilon n}, \\ \mathcal{E}(\mu_{j.4}) &:= 1^{\varepsilon n} \|c^{j+1}\| 1^{\varepsilon n} \|c^j\| 0^{\varepsilon n}, \\ \mathcal{E}(\mu_{j.5}) &:= 1^{\varepsilon n} \|c^{j+1}\| 1^{\varepsilon n} \|c^{j+1}\| 0^{\varepsilon n}, \\ \mathcal{E}(\mu_{j.6}) &:= 1^{\varepsilon n} \|c^{j+1}\| 1^{\varepsilon n} \|c^{j+1}\| 1^{\varepsilon n} \end{aligned}$$

for some minor milestones  $\mu_j =: \mu_{j.1} < \mu_{j.2} < \mu_{j.3} < \mu_{j.4} < \mu_{j.5} < \mu_{j.6} =: \mu_{j+1}$ . In this construction, the decoder is left with two, not four, copies of  $c^j$ . It knows that the one sandwiched between  $0^{\varepsilon n}$  and  $1^{\varepsilon n}$  is the one undergoing interpolation, and hence the other one will decode correctly. To be more precise, between  $\mu_{j.1}$  and  $\mu_{j.4}$ , the left one is undergoing interpolation and the right  $c^j$  is trustworthy; between  $\mu_{j.3}$  and  $\mu_{j.6}$ , the right one is undergoing interpolation and the left  $c^{j+1}$  is trustworthy.

### 1.3 New approach

While this paper was in preparation, it came to our attention that Con, Fathollahi, Gabrys, Wootters, and Yaakobi have achieved similar results, but with different techniques [2]. In particular, their approach uses code concatenation.

In this and the concurrent work by Con, Fathollahi, Gabrys, Wootters, and Yaakobi, we aim to rightsize the length to  $n + \Theta(\varepsilon n)$  bits. While their work uses code concatenation, we begin with a generator matrix  $A \in \{0, 1\}^{k \times n}$  of some error-correcting code. We then reorder the codewords  $c^1, \dots, c^{2^k}$  using Gray code:

$$c^{j+1} = g^{j+1}A = (g^j + e^{\rho_j})A = c^j + A^{\rho_j} \in \{0, 1\}^{1 \times n}.$$

## 65:6 Capacity-Achieving Gray Codes

Here,  $g^j$  is the  $j$ th string of the Gray code,  $e^{\rho_j}$  is the  $\rho_j$ th cardinal vector, and  $A^{\rho_j}$  is the  $\rho_j$ th row of  $A$ , all as row vectors. Our data structure will look like

$$c^j \| 0^{\varepsilon n} \| \rho_j \| \beta^j \| 0^{\varepsilon n} \| \rho_j \| \beta^j \| 0^{\varepsilon n}$$

or

$$c^j \| 1^{\varepsilon n} \| \rho_j \| \beta^j \| 1^{\varepsilon n} \| \rho_j \| \beta^j \| 1^{\varepsilon n}$$

depending on the parity of  $j$ . Here,  $\beta^j$  is a subvector of  $c^j$  obtained by collecting bits where  $A^{\rho_j}$  has 1. More precisely, if  $A^{\rho_j}$  has 1 at indices  $i_1, i_2, \dots, i_w$ , then  $\beta^j := c_{i_1}^j c_{i_2}^j \dots c_{i_w}^j \in \{0, 1\}^{1 \times w}$ , where  $w$  is the Hamming weight of  $A^{\rho_j}$ .

The purpose of keeping  $\rho_j$  in  $\mathcal{E}$  is to take note of which row of  $A$  we are going to add to  $c^j$  to obtain  $c^{j+1}$ . The purpose of keeping  $\beta^j$  in  $\mathcal{E}$  is to back up the bits of  $c^j$  that are going to be modified. We then interpolate between minor milestones

$$\begin{array}{l} c^j \| 0^{\varepsilon n} \| \rho_j \| \beta^j \| 0^{\varepsilon n} \| \rho_j \| \beta^j \| 0^{\varepsilon n}, \\ c^{j+1} \| 0^{\varepsilon n} \| \rho_j \| \beta^j \| 0^{\varepsilon n} \| \rho_j \| \beta^j \| 0^{\varepsilon n}, \\ c^{j+1} \| 1^{\varepsilon n} \| \rho_j \| \beta^j \| 0^{\varepsilon n} \| \rho_j \| \beta^j \| 0^{\varepsilon n}, \\ c^{j+1} \| 1^{\varepsilon n} \| \rho_{j+1} \| \beta^j \| 0^{\varepsilon n} \| \rho_j \| \beta^j \| 0^{\varepsilon n}, \\ c^{j+1} \| 1^{\varepsilon n} \| \rho_{j+1} \| \beta^{j+1} \| 0^{\varepsilon n} \| \rho_j \| \beta^j \| 0^{\varepsilon n}, \\ c^{j+1} \| 1^{\varepsilon n} \| \rho_{j+1} \| \beta^{j+1} \| 1^{\varepsilon n} \| \rho_j \| \beta^j \| 0^{\varepsilon n}, \\ c^{j+1} \| 1^{\varepsilon n} \| \rho_{j+1} \| \beta^{j+1} \| 1^{\varepsilon n} \| \rho_{j+1} \| \beta^j \| 0^{\varepsilon n}, \\ c^{j+1} \| 1^{\varepsilon n} \| \rho_{j+1} \| \beta^{j+1} \| 1^{\varepsilon n} \| \rho_{j+1} \| \beta^{j+1} \| 0^{\varepsilon n}, \\ c^{j+1} \| 1^{\varepsilon n} \| \rho_{j+1} \| \beta^{j+1} \| 1^{\varepsilon n} \| \rho_{j+1} \| \beta^{j+1} \| 1^{\varepsilon n}, \end{array}$$

Note that we use Fathollahi and Wootters's data structure to protect  $\rho_j$  and  $\beta^j$ , and so the backup data is almost always available.<sup>4</sup>

An analogy of this construction is to think of  $c_j$  as the state of our computer at version  $j$ . Now a software update comes in and attempts to add  $A^{\rho_j}$  to  $c_j$ . To avoid messing things up, the updater backs up the files that are going to be updated, which are at  $i_1, \dots, i_w$ ; and  $\beta^j$  is the backup data.

Our construction, at any code rate below capacity, achieves positive error exponents and linear encoding and decoding complexity.

► **Theorem 1 (Main theorem).** *Fix a BSC with  $p \in (0, 1/2)$  and a gap to capacity  $\varepsilon > 0$ . For sufficiently large  $n$ , there exists a pair of encoder  $\mathcal{E}: [m] \rightarrow \{0, 1\}^{1 \times n}$  and decoder  $\mathcal{D}: \{0, 1\}^{1 \times n} \rightarrow [m]$  with code size  $m > 2^{(\text{Capacity}(\text{BSC}_p) - \varepsilon)n}$  such that (a)  $\mathcal{E}(x)$  and  $\mathcal{E}(x + 1)$  differ by one bit and (b)*

$$\text{Prob} \left\{ \left| \mathcal{D}(\text{BSC}_p^n(\mathcal{E}(x))) - x \right| > t \right\} < 2^{-\Omega(n)} + 2^{-\Omega(t)}$$

for all  $x \in [m - 1]$  and all  $t > 1$ . Moreover, the time complexity of  $\mathcal{E}$  and  $\mathcal{D}$  scales<sup>5</sup> linearly in  $n$ .

### Organization

The rest of the paper is dedicated to proving Theorem 1.

<sup>4</sup> There is no reason not to protect  $\rho_j$  and  $\beta^j$  using error-correcting codes. We omit that here but will discuss in the formal proof.

<sup>5</sup> exponentially in  $1/\text{poly}(\varepsilon)$

## 2 Proof of Theorem 1

Fix a crossover probability  $p$  and a gap to capacity  $\varepsilon > 0$ . Let  $n$  and  $k$  be very large.

### 2.1 The building blocks $\mathcal{B}$ and $\mathcal{C}$

We begin with a linear code  $\mathcal{B}$  with block length  $\varepsilon n$  and dimension  $\varepsilon k$ . Using well-known constructions [5, Theorem 8], we can make the code rate  $k/n$   $\varepsilon$ -close to the capacity if  $n$  is large enough. Moreover, the encoding and decoding complexity can be made linear in  $n$ . Let  $B$  be the generator matrix of  $\mathcal{B}$ .

We stack  $B$  to construct a larger generator matrix

$$A := \begin{bmatrix} B & \bar{B} & & & & \\ & B & \bar{B} & & & \\ & & B & \bar{B} & & \\ & & & \ddots & \ddots & \\ & & & & B & \bar{B} \end{bmatrix} \in \{0, 1\}^{k \times (1+\varepsilon)n} \quad (4)$$

and denote the corresponding code by  $\mathcal{C} \subset \{0, 1\}^{1 \times (1+\varepsilon)n}$ . Here,  $\bar{B}$  is the bitwise complement of  $B$ . We put  $\bar{B}$  next to  $B$  so that all rows of  $[B \ \bar{B}]$  has the same Hamming weight,  $\varepsilon n$ . This means that the backup data  $\beta^j$  will be exactly  $\varepsilon n$  bits long. We repeat  $B$  and  $\bar{B}$   $1/\varepsilon$  times so that  $A$  has block length  $(1 + \varepsilon)n$  and dimension  $k$ . This makes the code rate of  $\mathcal{C}$   $2\varepsilon$ -close to the capacity.

Decoding  $\mathcal{C}$  is straightforward. Given a received word  $y \in \{0, 1\}^{1 \times (1+\varepsilon)n}$ , apply  $\mathcal{B}$ 's decoder to  $y_1, \dots, y_{\varepsilon n}$  to obtain  $x_1, \dots, x_{\varepsilon n}$ . Subtract the influence of  $x_1, \dots, x_{\varepsilon n}$  from  $y_{\varepsilon n+1}, \dots, y_{2\varepsilon n}$  and apply  $\mathcal{B}$ 's decoder to obtain  $x_{\varepsilon n+1}, \dots, x_{2\varepsilon n}$ . Repeat this process until we obtain  $x_n$ .

We also use  $\mathcal{B}$  to protect the row index  $\rho_j \in [k]$  and the backup data  $\beta^j \in \{0, 1\}^{\varepsilon n}$ . Denote by  $\mathcal{B}(\rho_j, \beta^j)$  the result of encoding these  $\log_2(k) + \varepsilon n$  bits of information using

$$\frac{2n}{k} \geq \left\lceil \frac{\log_2(k) + \varepsilon n}{\varepsilon k} \right\rceil$$

blocks of  $\mathcal{B}$ . This means that  $\mathcal{B}(\rho_j, \beta^j)$  has length  $2\varepsilon n^2/k$ .

### 2.2 Encoding $\mathcal{E}$

Recall that  $\rho_j$  is the ruler sequence defined in (2) capped at  $k$ . Recall that  $g^j$  is the  $j$ th string of the Gray code and is obtained by flipping the  $\min(\rho_{j-1}, k)$ th bit of  $g^{j-1}$ . We assume an ordering on the codewords  $\mathcal{C} = \{c^1, \dots, c^{2^k}\}$  by Gray code, i.e.,  $c^j := g^j A$ . Let  $\beta^j$  be the subvector of  $c^j$  obtained by deleting the bits where  $A^{\rho_j}$  has 0.

We now place the milestones at

$$\mu_j := j\varepsilon n(4 + 2n/k)$$

for  $j \in [2^k]$ . Consequently,  $\mathcal{E}$  will encode integers up to  $m := (2^k - 1)\varepsilon n(4 + 2n/k) + 1 = (1 + o(1))2^k$ . We then define data structure:

$$\mathcal{E}(\mu_j) := c^j \|0^{\varepsilon n} \| \mathcal{B}(\rho_j, \beta^j) \| 0^{\varepsilon n} \| \mathcal{B}(\rho_j, \beta^j) \| 0^{\varepsilon n}$$

and

$$\mathcal{E}(\mu_j) := c^j \|1^{\varepsilon n} \| \mathcal{B}(\rho_j, \beta^j) \| 1^{\varepsilon n} \| \overline{\mathcal{B}(\rho_j, \beta^j)} \| 1^{\varepsilon n}$$

depending on the parity of  $j$ . Here,  $\overline{\mathcal{B}(\rho_j, \beta^j)}$  is the bitwise complement of  $\mathcal{B}(\rho_j, \beta^j)$ . Note that each  $\mathcal{E}(\mu_j)$  is  $(1 + 4\varepsilon + 4\varepsilon n/k)n$  bits long. We infer that the code rate of  $\mathcal{E}$  is  $\mathcal{O}(\varepsilon)$ -close to the capacity.

Next, we show that the Hamming distance between  $\mathcal{E}(\mu_j)$  and  $\mathcal{E}(\mu_{j+1})$  is  $\varepsilon n(4 + 2n/k)$ . Trivially, the consecutive zeros and ones contributes  $3\varepsilon n$  bits of Hamming distance. Next, note that

$$c^{j+1} - c^j = g^{j+1}A - g^jA = (g^{j+1} - g^j)A = e^{\rho_j}A = A^{\rho_j}.$$

This is the  $\rho_j$ th row of  $A$ . By the construction (4), any row of  $A$  contributes exactly  $\varepsilon n$  bits of Hamming distance. Next,  $\mathcal{B}(\rho_j, \beta^j)$  and  $\mathcal{B}(\rho_{j+1}, \beta^{j+1})$  contributes an unknown amount of distance. But it is complement to the distance between  $\mathcal{B}(\rho_j, \beta^j)$  and  $\overline{\mathcal{B}(\rho_{j+1}, \beta^{j+1})}$ . Therefore, the  $\mathcal{B}$  part contributes exactly  $2\varepsilon n^2/k$ . In total, the Hamming distance is exactly  $\varepsilon n(4 + 2n/k)$ .

Now that the distance between consecutive milestones matches the Hamming distance, we can interpolate between them. In particular, for even  $j$ ,

$$\begin{aligned} \mathcal{E}(\mu_j) &:= c^j \|0^{\varepsilon n}\| \mathcal{B}(\rho_j, \beta^j) \|0^{\varepsilon n}\| \mathcal{B}(\rho_j, \beta^j) \|0^{\varepsilon n}\|, \\ \mathcal{E}(\mu_j + \varepsilon n) &:= c^{j+1} \|0^{\varepsilon n}\| \mathcal{B}(\rho_j, \beta^j) \|0^{\varepsilon n}\| \mathcal{B}(\rho_j, \beta^j) \|0^{\varepsilon n}\|, \\ \mathcal{E}(\mu_j + 2\varepsilon n) &:= c^{j+1} \|1^{\varepsilon n}\| \mathcal{B}(\rho_j, \beta^j) \|0^{\varepsilon n}\| \mathcal{B}(\rho_j, \beta^j) \|0^{\varepsilon n}\|, \\ \mathcal{E}(\mu_j + 2\varepsilon n + d) &:= c^{j+1} \|1^{\varepsilon n}\| \mathcal{B}(\rho_{j+1}, \beta^{j+1}) \|0^{\varepsilon n}\| \mathcal{B}(\rho_j, \beta^j) \|0^{\varepsilon n}\|, \\ \mathcal{E}(\mu_j + 3\varepsilon n + d) &:= c^{j+1} \|1^{\varepsilon n}\| \mathcal{B}(\rho_{j+1}, \beta^{j+1}) \|1^{\varepsilon n}\| \mathcal{B}(\rho_j, \beta^j) \|0^{\varepsilon n}\|, \\ \mathcal{E}(\mu_j + 3\varepsilon n + 2\varepsilon n^2/k) &:= c^{j+1} \|1^{\varepsilon n}\| \mathcal{B}(\rho_{j+1}, \beta^{j+1}) \|1^{\varepsilon n}\| \overline{\mathcal{B}(\rho_{j+1}, \beta^{j+1})} \|0^{\varepsilon n}\|, \\ \mathcal{E}(\mu_j + 4\varepsilon n + 2\varepsilon n^2/k) &:= c^{j+1} \|1^{\varepsilon n}\| \mathcal{B}(\rho_{j+1}, \beta^{j+1}) \|1^{\varepsilon n}\| \overline{\mathcal{B}(\rho_{j+1}, \beta^{j+1})} \|1^{\varepsilon n}\|, \end{aligned}$$

where  $d$  is the Hamming distance between  $\mathcal{B}(\rho_j, \beta^j)$  and  $\mathcal{B}(\rho_{j+1}, \beta^{j+1})$ .

## 2.3 Decoding $\mathcal{D}$

Suppose that we are given

$$c \| \phi \| B' \| \phi' \| B'' \| \phi''' \tag{5}$$

as the noisy version of  $\mathcal{E}(x)$  for some  $x \in [m]$ , where

- $c \in \{0, 1\}^{1 \times (1+\varepsilon)n}$  is the noisy version of  $c^j$ ,  $c^{j+1}$ , or anything in between,
- $\phi, \phi', \phi'' \in \{0, 1\}^{1 \times \varepsilon n}$  are the noisy version of the buffers, and
- $B', B'' \in \{0, 1\}^{1 \times 2\varepsilon n^2/k}$  are the noisy version of the  $\mathcal{B}$  part.

We first apply Fathollahi and Wootters's decoder [4] to the second half of (5)

$$\phi \| B' \| \phi' \| B'' \| \phi'''.$$

Their decoder counts how many ones and zeros are in  $\phi$ ,  $\phi'$ , and  $\phi''$ . This tells us which minor milestone we are at. We use this information to determine which of  $B'$  or  $B''$  is undergoing interpolation, and which is trustworthy. And then, we use the trustworthy one to recover the row index  $\rho_j$  and the backup data  $\beta^j$  (or  $\rho_{j+1}$  and  $\beta^{j+1}$  depending on if  $x$  is past  $\mu_j + 2.5\varepsilon n + d$  or not). From now on, we just call them  $\rho$  and  $\beta$ .

We define the rollback function  $\text{Roll}: \{0, 1\}^{(1+\varepsilon)n} \times [k] \times \{0, 1\}^{\varepsilon n} \rightarrow \{0, 1\}^{(1+\varepsilon)n}$  that overwrites messed-up bits using backup data. More precisely,  $\text{Roll}(c, \rho, \beta)$  will be the vector  $c$  after replacing  $c_{i_1}$  with  $\beta_1$ ,  $c_{i_2}$  with  $\beta_2$ , and so on, where  $i_1, i_2, \dots$  are the indices where  $A^\rho$  has 1. Our claim is that, it does not matter if it is  $c^j$ ,  $0^{\varepsilon n}$ , or  $\mathcal{B}$  that is undergoing interpolation,  $\text{Roll}(c, \rho, \beta)$  will just look like the noisy version of  $c^j$  or  $c^{j+1}$ , which can be decoded by the decoder of  $\mathcal{C}$ . This can be seen more clearly by considering three cases.

Case 1:  $x$  is between  $\mu_j$  and  $\mu_j + \varepsilon n$ . This is the stage where we are adding  $A^p$  to  $c^j$ . In this case, the  $\mathcal{B}$  part backs up the subvector of  $c^j$  that is undergoing interpolation;  $\text{Roll}(c, \rho, \beta)$  would just be a noisy version of  $c^j$  that can be decoded by  $\mathcal{C}$ .

Case 2:  $x$  is between  $\mu_j + \varepsilon n$  and  $\mu_j + 2.5\varepsilon n + d$ . This is the case where  $B'$  is not trustworthy and so Fathollahi and Wootters's decoder will decode  $B''$  to  $(\rho_j, \beta^j)$ . In this case,  $\text{Roll}(c, \rho_j, \beta^j)$  will be a noisy version of  $c^j$  that can be decoded by  $\mathcal{C}$ .

Case 3:  $x$  is between  $\mu_j + 2.5\varepsilon n + d$  and  $\mu_j + 4\varepsilon n + 2\varepsilon n^2/k$ . This is the case where  $B''$  is not trustworthy and so Fathollahi and Wootters's decoder will decode  $B'$  to  $\rho_{j+1}, \beta^{j+1}$ . In this case,  $\text{Roll}(c, \rho_{j+1}, \beta^{j+1})$  will be a noisy version of  $c^{j+1}$  that can be decoded by  $\mathcal{C}$ .

Examining these three cases, we can see that  $\text{Roll}(c, \rho, \beta)$  will always yield  $c^j$  or  $c^{j+1}$ . With that, we can compute  $g^j$  and  $j$ . Now that we know  $x \in [\mu_j, \mu_{j+1}]$ , it suffices to compare (5) with  $\mathcal{E}(\mu_j), \dots, \mathcal{E}(\mu_{j+1})$  and see which one minimizes the Hamming distance. The minimizer will be our best bet of  $x$ .

## 2.4 Complexity and tail estimation

The complexity of  $\mathcal{E}$  and  $\mathcal{D}$  is linear in  $n$ . This is because Gray's encoding, Gray's decoding,  $\mathcal{B}$ 's encoding,  $\mathcal{B}$ 's decoding, determining whether  $\phi, \phi'$ , and  $\phi''$  are zeros or ones, determining whether  $B'$  or  $B''$  is trustworthy, and Roll are all linear in  $n$ .

The tail estimation (3) boils down to the following components.

- With probability  $2^{-\Omega(n)}$ , we obtain the wrong  $j$ , i.e.,  $x \notin [\mu_j, \mu_{j+1}]$ .
- The guesswork of  $x$  conditioned on correct  $j$  has tail probability  $2^{-\Omega(t)}$ .

The first bullet point is a consequence of the error probability of  $\mathcal{B}$  being  $2^{-\Omega(\varepsilon n)}$ , which is  $2^{-\Omega(n)}$  as we fixed  $\varepsilon$ . The second bullet point relies on what minimizes the Hamming distance between (5) and  $\mathcal{E}(\mu_j), \dots, \mathcal{E}(\mu_{j+1})$ . Such analysis has been done before [6, Lemma 3.7] [4, Lemma 13], and we do not repeat it here. This finishes the proof.

## Abstract

---

The relationships between various meta-complexity problems are not well understood in the *worst-case regime*, including whether the search version is harder than the decision version, whether the hardness scales with the “threshold”, and how the hardness of different meta-complexity problems relate to one another, and to the task of function inversion.

In this work, we present resolutions to some of these questions with respect to the *black-box* analog of these problems. In more detail, let  $\text{MK}_M^t P[s]$  denote the language consisting of strings  $x$  with  $K_M^t(x) < s(|x|)$ , where  $K_M^t(x)$  denotes the  $t$ -bounded Kolmogorov complexity of  $x$  with  $M$  as the underlying (Universal) Turing machine, and let  $\text{search-MK}_M^t P[s]$  denote the search version of the same problem.

We show that if for *every* Universal Turing machine  $U$  there exists a  $2^{\alpha n} \text{poly}(n)$ -size  $U$ -oracle aided circuit deciding  $\text{MK}_U^t P[n - O(1)]$ , then for every function  $s$ , and every *not necessarily universal* Turing machine  $M$ , there exists a  $2^{\alpha s(n)} \text{poly}(n)$ -size  $M$ -oracle aided circuit solving  $\text{search-MK}_M^t P[s(n)]$ ; this in turn yields circuits of roughly the same size for both the Minimum Circuit Size Problem (MCSP), and the function inversion problem, as they can be thought of as instantiating  $\text{MK}_M^t P$  with particular choices of (a non-universal) TMs  $M$  (the circuit emulator for the case of MCSP, and the function evaluation in the case of function inversion).

As a corollary of independent interest, we get that the complexity of black-box function inversion is (roughly) the same as the complexity of black-box deciding  $\text{MK}_U^t P[n - O(1)]$  for any universal TM  $U$ ; that is, also in the worst-case regime, black-box function inversion is “equivalent” to black-box deciding  $\text{MK}_U^t P$ .

## 1 Introduction

We consider the worst-case complexity of solving standard meta-complexity Programs, notably the the *Time-Bounded Kolmogorov Complexity Problem* [10, 19, 1, 9, 5, 18] – computing the length, denoted  $K_U^t(x)$  of the shortest program (evaluated on some particular Universal

Turing machine (TM)  $U$  that generates a given string  $x$ , within time  $t(|x|)$ , where  $t$  is a polynomial, and the (b) the *Minimum Circuit Size problem* (MCSP) [8, 20] – finding the smallest Boolean circuit that computes a given function  $x$ . For both of these problem one may also consider *thresholds* versions,  $\text{MK}_{\cup}^t\text{P}[s]$  and  $\text{MCSP}[s]$ , where  $\text{MK}_{\cup}^t\text{P}[s]$  (resp.  $\text{MCSP}[s]$ ) is the languages of strings  $x$  s.t.  $K_{\cup}^t(x)$  (resp. the circuit size of  $x$ ) is less than  $s(|x|)$ , as well as *search* versions  $\text{search-MK}_{\cup}^t\text{P}[s]$ , where the goal is not only to compute/decide the complexity of a string  $x$  but also to *find* a short description that witnesses this complexity.

The relationship between these various meta-complexity problems are not well understood. In particular:

1. **Decision-to-Search:** Solving the search version trivially yields a solver for the decisional (or computational) version with roughly the same complexity. Does the converse hold: Does a  $T(n)$ -size circuit for solving the decision version imply a, roughly,  $T(n)$ -size circuit solving the search version?
2. **Hardness Scaling to the Threshold:** Intuitively, the threshold version of the problem, for small thresholds  $s(n) \ll n$  ought to be easier than the threshold  $n$  version (or computational) version since there exist trivial  $2^{s(n)}\text{poly}(n)$  time algorithms for the threshold version (simply doing brute force search). Does this hold more generally: Does a  $T(n)$ -size circuit solving  $\text{MK}_{\cup}^t\text{P}[n - O(1)]$  imply a roughly  $T(s(n))$ -size circuit for solving  $\text{MK}_{\cup}^t\text{P}[s(n)]$ ?
3. **The “Model of Computation” and the Relationship to Function Inversion:** Other meta-complexity problems, such as the MCSP problem, can be stated as an  $\text{MK}_M^t\text{P}$  problem with respect to a particular *non-universal* underlying TM  $M$  (performing circuit emulation). Additionally, a solver for the search- $\text{MK}_M^t\text{P}$  problem with respect to *any* (non-universal) TM  $M$  is also equivalent to a solver for the function inversion problem (i.e., the problem of inverting any function on every input). Does a  $T(n)$ -size solver for  $\text{MK}_{\cup}^t\text{P}[s(n)]$  with respect to any underlying Universal TM  $U$ , imply one (of size roughly  $T(n)$ ) that also works with respect non-universal TMs (and thus also for MCSP and function inversion)?

In the *average-case regime*, positive answers to these questions – when restricting to efficient underlying (Universal) TMs – were provided in respectively [11] (for question 1), [12] (for question 2) and [11, 17] (for question 3), but they remain wide open in the worst-case regime. This is the focus of the current paper, but rather than restricting to efficient underlying TMs, we will consider *arbitrary* TMs (with potentially a large description or running time).

In particular, very recently non-trivial circuits for the various different meta-complexity problems were given. In [14], the current authors show that for any efficient Universal TM  $U$ , there exists a circuit of size  $2^{4n/5}\text{poly}(n, t(n))$  that solves the search version of the  $K_{\cup}^t$  (and thus also search- $\text{MK}_{\cup}^t\text{P}$ ). A different, independent, paper by Hirahara, Ilango and Williams [6] focuses on the threshold version of the above meta-complexity problems and presents circuits of size respectively  $2^{(4/5)s(n)} \cdot \text{poly}(n, t(n))$  and  $2^{(4/5+o(1)) \cdot s(n) \log s(n)}$  for them. In both cases, the core of the technical work consist of providing a circuit implementation of the function inversion algorithm from Fiat and Naor [3], and next applying this function inversion algorithm to the one-way function construction of [11] (or variants thereof, notably the variant of [17] to deal with the MCSP problem) based on the hardness of meta-complexity problems – an approach first envisioned by Ren and Santhanam [17].<sup>1</sup> As such, the worst-case

<sup>1</sup> [17] noted that the function inversion algorithm of [3] could be applied to the one-way function construction of [11] to get a non-trivial non-uniform RAM program that solves the  $\text{MK}^t\text{P}$  problem, but left open whether a circuit implementation can be given.

complexity bounds obtained are roughly the same for (a) the search and the decisional version (as the function inverter also directly solves the search problem in [11]), (b) they naturally scale with the threshold  $s$  of  $\text{MK}^t\text{P}[s]$  (based on an extension of the function inversion attack of Fiat-Naor done in [6]), and (c) are the roughly the same for  $\text{MK}^t\text{P}$ ,  $\text{MCSP}$  and function inversion (since the one-way function constructions in [11, 17] are length preserving). These works thus indicate that perhaps the same phenomena that are known in the average-case setting may also hold in the worst-case setting.

In this paper, we demonstrate that this is not a coincidence. Indeed, we provide a positive answer to all the above questions also in the worst-case regime, when restricting attention to *black-box* solvers and thus all the above result follow from simply obtaining a circuit for black-box solving the decisional  $\text{MK}^t\text{P}$  problem.

### Black-box Solvers

As noted in [14], their algorithm for  $K_{\cup}^t$  works for any Universal TM  $U$  (as long as the algorithm gets oracle access to  $U$ ): for *any* (not necessarily efficient) Universal TM  $U$ , there exists a  $U$ -oracle aided circuit of size  $2^{4n/5}\text{poly}(n, t(n))$  that solves the search version of the  $K_{\cup}^t$ . Following [14], we say that  $\text{MK}^t\text{P}[s]$  (resp search-  $\text{MK}^t\text{P}[s]$ ) *admits a  $T(n)$ -size black-box solver* if for every universal TM  $U$ , there exists a  $T(n)$  size  $U$ -oracle aided circuit for solving  $\text{MK}_{\cup}^t\text{P}[s]$  (resp search-  $\text{MK}_{\cup}^t\text{P}[s]$ ). We additionally say that these problems admit a  $T(n)$ -size *generalized black-box solver* if the same holds not only with respect to any *universal* TM  $U$  but also for *non-universal* TMs  $M$  (satisfying the minimal condition that the emulation by  $M$  has a unique output:  $M(\Pi, 1^{t_1}) = M(\Pi, 1^{t_2})$  if either of those provide some output). Considering generalized black-box solvers is what will allow us to answer question 3 above, but actually, also from a technical point of view, will also be instrumental also to deal with question 1.

[14] proved a lower bound of  $2^{n/2-o(n)}$  on the size of black-box  $K^t$  solvers.

## 1.1 Our Results

Our main result shows that the existence of a  $2^{\alpha n+o(n)}$ -size black-box solver for  $\text{MK}^t\text{P}[n - O(1)]$  implies the existence of a  $2^{\alpha s(n)+o(n)}$ -size *generalized* black-box solver for search-  $\text{MK}^t\text{P}[s]$ , thus providing a positive answer to all the above questions with respect to black-box solvers.

► **Theorem 1.** *Assume the existence of a  $2^{\alpha n} \cdot \text{poly}(n)$ -size black-box solver for  $\text{MK}^t\text{P}[n - 4]$  for  $t(n) = n$ . Then there exists a  $2^{\alpha s(n)} \cdot \text{poly}(n)$ -size generalized black-box solver for search-  $\text{MK}^t\text{P}[s]$  for every function  $t'(\cdot)$  and every function  $s(n) \leq 2n - \lceil \log n \rceil$ .*

We highlight that generalized black-box solvers can solve  $\text{MCSP}$  (since, as implicitly observed in [6] following [17, 4]), the  $\text{MCSP}$  problem can be stated as an  $\text{MK}_{\mathcal{M}}^t\text{P}$  problem with respect to a particular *non-universal* underlying TM  $M$  (performing circuit emulation) – see Lemma 19 in the Appendix). As a direct corollary of Theorem 1 and Lemma 19, we thus get:<sup>2</sup>

► **Corollary 2.** *Let  $p \in \text{poly}$  and  $\alpha > 0$ , and assume that for  $t(n) = n$  there exists a black-box  $\text{MK}^t\text{P}[n - 4]$  solver of size  $2^{\alpha n} \cdot p(n)$ . Then for every  $s(n) \leq 1.9n/\log n$ , search-  $\text{MCSP}[s]$  can be solved with a circuit family of size  $2^{(\alpha+o(1)) \cdot s(n) \cdot \log(s(n)+\log n)} \cdot \text{poly}(n)$ .*

<sup>2</sup> When  $s(n) \geq 1.1 \cdot n/\log n$  then  $\text{MCSP}[s]$  is the trivial language consisting of all strings due to the result of [13], so the corollary below actually works for all  $s$ .

Additionally, we observe that generalized black-box solvers for search- $\text{MK}^{\text{tP}}[n]$  can easily be seen to be equivalent to function inversion circuits (for all functions  $f$ ) of roughly the same size – see Lemmas 16 and 17 in the Appendix. As a corollary of Theorem 1, we thus get that – in the black-box regime – solving the function inversion problem is not only sufficient (as shown in [14, 6] for solving  $\text{MK}^{\text{tP}}[n - O(1)]$ ) but also *necessary*. This matches the converse direction of the *average-case* characterization of one-way functions through the hardness of  $\text{MK}^{\text{tP}}$  from [11], and yields a characterization of the *black-box* worst-case hardness of  $\text{MK}^{\text{tP}}$  through the black-box worst-case hardness of one-way functions. In particular, black-box solving just  $\text{MK}^{\text{tP}}[n - O(1)]$  is no easier than (black-box) function inversion.

► **Theorem 3.** *There exists a black-box  $\text{MK}^{\text{tP}}[n - O(1)]$  solver of size  $2^{\alpha n} \cdot \text{poly}(n)$  for every polynomial  $t$  if and only if every function  $f$  can be inverted by an  $f$ -oracle aided circuit of size  $2^{\alpha n} \cdot \text{poly}(n)$ .*

As a consequence of Theorem 3, and Impagliazzo’s lower bound on the circuit size of black-box one-way function inversion [7]<sup>3</sup>, we directly get a lower bound on the complexity of black-box  $\text{MK}^{\text{tP}}$  solvers; such a lower bound was previously proved directly for the  $\text{MK}^{\text{tP}}$  problem in [14] but it required a significantly more complicated proof and employing heavier machinery.

► **Corollary 4.** *There is no black-box  $\text{MK}^{\text{tP}}[n - 4]$  solver of size  $2^{n/2 - o(n)}$ .*

## 1.2 Proof Outline

Theorem 1 is proved in two steps. The first step is formally stated in Corollary 13 and the second in Corollary 15.

### Step 1: From Black-box to Generalized Black-Box for Small Thresholds

We first show that any black-box solver for  $\text{MK}^{\text{tP}}[n - 4]$  of size  $T(n)$  implies a generalized black box  $\text{MK}^{\text{tP}}[s(n)]$  solver of size  $T(s(n) + O(1))\text{poly}(n, t(n))$ .<sup>4</sup> The proof follows standard techniques from the literature on hardness magnification (i.e., hashing down the statement  $x$  using a pairwise independent hash function  $h$  to roughly the threshold size, and then applying the solver of a related language on the smaller instance  $h(x)$  and thereby improving the running time) [16, 2, 15]. The key difference with our approach is that by leveraging the black-box property of the algorithm, we can use an algorithm for the *same* problem, but parameterized by a different universal TM  $M_h$ , as opposed to a general **NP** problem as in those earlier works – that is, we get “self hardness magnification” [12]). (We highlight that [6] also rely on a similar hashing technique to *directly* present an attack on the threshold version of  $\text{MK}^{\text{tP}}$  but do so in a slightly different context: in particular, they use hashing to develop a function inversion algorithm whose circuit complexity only depends on the input size of the function and not the output size, and next function inversion with an input size that depends on the threshold to solve  $\text{MK}^{\text{tP}}[s]$ . Nevertheless, our usage of this approach is inspired by theirs.) Additionally, and perhaps more surprisingly, we show that this technique allows us to solve the orthogonal problem of dealing with *non-universal* Turing machines (so that we can get a generalized black-box solver): in essence, the idea is to define a universal

<sup>3</sup> Impagliazzo shows that for every large enough  $n \in \mathbb{N}$ , there exists a permutation  $\sigma: \{0, 1\}^n \rightarrow \{0, 1\}^n$  such that every  $\sigma$ -oracle aided circuit  $C$  of size at most  $2^{n/2 - 2 \log^2 n}$  fails to invert  $f$ . See also [21].

<sup>4</sup> This reduction also works for the search version of these problems.

TM  $M_h$  that has two tracks: if the first bit of the input “program”  $\Pi$  is 0, it simply runs some Universal TM  $U(\Pi_{>1})$  on the rest of the input  $\Pi_{>1}$ , and if it is 1, then it outputs  $h(M(\Pi_{>1}))$  where  $M$  is the non-universal TM that we want a  $\text{MK}_M^t\text{P}[s]$  solver for. The key point is that due to pairwise independence property of the hash function,  $h(x)$  is uniform (for a random choice of  $h$ ) and thus with high probability  $h(x)$  has essentially maximal  $K_U^t$  complexity, and thus the existence of the first “track” does not disrupt the hardness magnification reduction.

## Step 2: From Decision to Search

Our next result shows how any generalized  $\text{MK}^t\text{P}[s]$  solver of size  $2^{\alpha s(n)}$  can be used to solve also the *search version* of the problem with roughly the same running time. In particular, to solve search- $\text{MK}_M^t\text{P}[s]$ , we will rely on a circuit deciding  $\text{MK}_{M_n}^t\text{P}[s + \lceil \log n \rceil]$  where  $M_n$  is defined as a TM that given a program  $\Pi = (i, \Pi')$  where  $i$  is defined as the first  $\lceil \log n \rceil$  bits of  $\Pi$ , checks if  $\Pi'$  generates an output  $x$  of exactly  $n$  bits, and if so outputs  $x$  concatenated with the first  $i$  bits of  $\Pi'$ . The key point is that for every  $n$ -bit length string  $x$ ,  $K_{M_n}^t(x) = K_M^t(x) + \lceil \log n \rceil$  (obtained by letting  $i = 0$ ). Furthermore, this Kolmogorov complexity can be maintained if we concatenate the prefix of any minimum length program  $\Pi'$  that generates  $x$ , so the bits of any such minimum length program can be iteratively recovered given an oracle computing  $K_{M_n}^t$ . The same argument also works if we only have access to a decision oracle for the threshold  $s + \lceil \log n \rceil$ , but then we only recover a program of length at most  $s$ .

## 2 Preliminaries

### 2.1 Notations

All logarithms are taken in base 2. We use calligraphic letters to denote sets and distributions, uppercase for random variables, and lowercase for values and functions. Let  $\text{poly}$  stand for the set of all polynomials. Given a vector  $v \in \Sigma^n$ , let  $v_i$  denote its  $i^{\text{th}}$  entry, let  $v_{<i} = (v_1, \dots, v_{i-1})$  and  $v_{\leq i} = (v_1, \dots, v_i)$ . Similarly, for a set  $\mathcal{I} \subseteq [n]$ , let  $v_{\mathcal{I}}$  be the ordered sequence  $(v_i)_{i \in \mathcal{I}}$ . For a function  $f: \mathcal{D} \rightarrow \mathcal{R}$ , and a set  $\mathcal{S} \subseteq \mathcal{D}$ , we let  $f(\mathcal{S}) = \{f(x) : x \in \mathcal{S}\}$ .

### 2.2 Distributions and Random Variables

When unambiguous, we will naturally view a random variable as its marginal distribution. The support of a finite distribution  $\mathcal{P}$  is defined by  $\text{Supp}(\mathcal{P}) := \{x : \Pr_{\mathcal{P}}[x] > 0\}$ . For a (discrete) distribution  $\mathcal{P}$ , let  $x \leftarrow \mathcal{P}$  denote that  $x$  was sampled according to  $\mathcal{P}$ . Similarly, for a set  $\mathcal{S}$ , let  $x \leftarrow \mathcal{S}$  denote that  $x$  is drawn uniformly from  $\mathcal{S}$ .

### 2.3 Kolmogorov Complexity

Roughly speaking, the *t-time-bounded Kolmogorov complexity*,  $K^t(x)$ , of a string  $x \in \{0, 1\}^*$  is the length of the shortest program  $\Pi = (M, y)$  such that, when simulated by an universal Turing machine,  $\Pi$  outputs  $x$  in  $t(|x|)$  steps. Here, a program  $\Pi$  is simply a pair of a Turing Machine  $M$  and an input  $y$ , where the output of  $P$  is defined as the output of  $M(y)$ . When there is no running time bound (i.e., the program can run in an arbitrary number of steps), we obtain the notion of Kolmogorov complexity.

In the following, let  $U(\Pi, 1^t)$  denote the output of  $\Pi$  when emulated on  $U$  for  $t$  steps. We now define the notion of Kolmogorov complexity with respect to the universal TM  $U$ .

## 66:6 On Black-Box Meta Complexity and Function Inversion

► **Definition 5.** Let  $t$  be a polynomial. For all  $x \in \{0, 1\}^*$ , define

$$K_{\mathcal{U}}^t(x) = \min_{\Pi \in \{0, 1\}^*} \{|\Pi| : \mathcal{U}(\Pi, 1^{t(|x|)}) = x\}$$

where  $|\Pi|$  is referred to as the description length of  $\Pi$ .

It is well known that for every  $x$ ,  $K^t(x) \leq |x| + c$ , for some constant  $c$  depending only on the choice of the universal TM  $\mathcal{U}$ .

► **Fact 6.** For every universal TM  $\mathcal{U}$ , there exists a constant  $c$  such that for every  $x \in \{0, 1\}^*$ , and for every  $t$  such that  $t(n) > 0$ ,  $K_{\mathcal{U}}^t(x) \leq |x| + c$ .

We will use the following bound on the Kolmogorov complexity of strings sampled from the uniform distribution.

► **Lemma 7.** For any universal TM  $\mathcal{U}$  and every  $n \in \mathbb{N}$ , it holds that

$$\Pr_{x \leftarrow \{0, 1\}^n} [K_{\mathcal{U}}^t(x) \geq n - i] \geq 1 - 2^{-i}.$$

### 3 Definitions

Given some efficient threshold function  $s$ , let  $\text{MK}_{\mathcal{M}}^t\text{P}[s]$  denote the set of strings  $x$  s.t.  $K_{\mathcal{M}}^t(x) \leq s(|x|)$  (where we let  $K_{\mathcal{M}}^t(x) = \infty$  if there is no  $\Pi$  such that  $M(\Pi, 1^t) = x$ ). Let search- $\text{MK}_{\mathcal{M}}^t\text{P}[s]$  denote the search problem in which given a string  $x$  with  $K_{\mathcal{M}}^t(x) \leq s(|x|)$ , the output is a program  $\Pi$  of length at most  $s(|x|)$  with  $M(\Pi, 1^{t(n)}) = x$ .

We start with the definition of a black-box emulator and a black-box universal TM.

► **Definition 8** (Black-box emulator/Black-box Universal TM). A function  $M : \{0, 1\}^* \times 1^* \rightarrow \{0, 1\}^* \cup \{\perp\}$ , is a black-box TM emulator if  $M$  has “unique outputs”: For any  $\Pi \in \{0, 1\}^*$ ,  $t_1, t_2 \in \mathbb{N}$ ,  $t_1 \leq t_2$ , if  $M(\Pi, 1^{t_1}) \neq \perp$ ,  $M(\Pi, 1^{t_2}) = M(\Pi, 1^{t_1})$ . A black-box TM emulator  $\mathcal{U}$  is a black-box universal Turing machine (black-box UTM) if there exists a universal Turing machine  $\mathcal{U}_0$  such that for any  $(\Pi, 1^t)$ , if  $\Pi$  is a valid description of a Turing machine (w.r.t  $\mathcal{U}_0$ ), then  $\mathcal{U}(\Pi, 1^t) = \mathcal{U}_0(\Pi, 1^t)$ .

We next define black-box solvers for  $\text{MK}_{\mathcal{M}}^t\text{P}[s]$ . For a TM  $M$ , a function  $t : \mathbb{N} \rightarrow \mathbb{N}$ , and a number  $n \in \mathbb{N}$ , we let  $f_n^{M,t} : \{0, 1\}^{\leq 2n} \rightarrow \{0, 1\}^*$  be the function defined by  $f_n^{M,t}(\Pi) = M(\Pi, 1^{t(n)})$  for any  $\Pi \in \{0, 1\}^{\leq 2n}$ .

► **Definition 9** (Black-box  $\text{MK}^t\text{P}$ -solver). For functions  $t, s, T : \mathbb{N} \rightarrow \mathbb{N}$ , we say that  $\text{MK}^t\text{P}[s]$  admits a black-box  $\text{MK}^t\text{P}[s]$ -solver of size  $T(n)$  if for every black-box universal TM  $\mathcal{U}$ , there exists a circuit family  $\mathcal{C} = \{C_n\}_{n \in \mathbb{N}}$  of size at most  $T(n)$ , such that for every  $n \in \mathbb{N}$ ,  $C_n$  is a  $f_n^{\mathcal{U},t}$ -oracle aided circuit that decides  $\text{MK}_{\mathcal{U}}^t\text{P}[s]$  on inputs of length  $n$ .

► **Remark 10** (Black-Box vs. Fully Black-Box solvers). In [14] there are two definitions for  $K^t$  solvers: fully black-box and (plain) black-box. The (plain) black-box is defined as in the definition above, while for fully black-box the circuit family  $\mathcal{C}$  can be used to compute the  $K_{\mathcal{U}}^t$  complexity with respect to any universal TM  $\mathcal{U}$ .

The construction of  $K^t$  solver given in [14] is not fully black-box. Indeed, the circuit family in [14] construct is dependent in the universal TM with respect to we defined  $K^t$ . Moreover, proving lower bounds for (plain) black-box solvers is stronger.

We define generalized black-box solver in exactly the same way except that we quantify over all black-box TM emulators (as opposed to just universal ones).

► **Definition 11** (Generalized black-box MK<sup>t</sup>P-solver). *For functions  $t, s, T: \mathbb{N} \rightarrow \mathbb{N}$ , we say that  $\text{MK}^t\text{P}[s]$  admits a generalized black-box MK<sup>t</sup>P[s]-solver of size  $T(n)$  if the following holds for every black-box TM  $M$ , there exists a circuit family  $\mathcal{C} = \{C_n\}_{n \in \mathbb{N}}$  of size at most  $T(n)$ , such that for every  $n \in \mathbb{N}$ ,  $C_n$  is a  $f_n^{M,t}$ -oracle aided circuit that decides  $\text{MK}_M^t\text{P}[s]$  on inputs of length  $n$ .*

We similarly define black-box solvers and generalized black box solvers for search-MK<sup>t</sup>P.

## 4 Generalized Solvers Scaling with the Threshold

We show how to turn a black-box solver into a *generalized* black-box solver where the circuit size *scales with the threshold*. As mentioned before, proof follows standard techniques from the literature on hardness magnification (i.e., hashing down the statement to roughly the threshold size, and then applying the solver on the smaller instance and thereby improving the running time) [16, 2, 15].

► **Theorem 12.** *There exists  $q \in \text{poly}$  such that the following holds. Let  $T: \mathbb{N} \rightarrow \mathbb{N}$  be a function, and assume that for  $t(n) = n$  there exists a black-box  $\text{MK}^t\text{P}[n - 4]$  solver of size  $T(n)$ . Then, there exists a generalized black-box  $\text{MK}^t\text{P}[s]$  solver of size  $T(s(n) + 5) \cdot q(n)$  for every function  $s(\cdot)$  with  $s(n) \leq 2n$  and for every function  $t'(\cdot)$ .<sup>5</sup>*

**Proof of Theorem 12.** Fix an efficient universal TM  $U$ , and let  $p \in \text{poly}$  be such that  $p(n, t)$  bounds the size of a circuit implementing  $U(\Pi, 1^t)$  for inputs  $(\Pi, 1^t)$  with  $|\Pi| = n$ . Let  $M$ ,  $s(n)$ , and  $t'(n)$  be the TM, time function and threshold for which we want to solve  $\text{MK}_M^t\text{P}[s]$ . Let  $t(n) = n$ . For every  $n \in \mathbb{N}$ , let  $\mathcal{H}_n = \left\{ h: \{0, 1\}^n \rightarrow \{0, 1\}^{s(n)+5} \right\}$  be a pairwise independent hash family, such that there exists  $m \in \text{poly}$  for which  $m(n + s(n))$  bounds the circuit size evaluating  $h$  for every  $h \in \mathcal{H}_n$ . Fix  $n \in \mathbb{N}$ . We start by showing a distribution over circuits that solves  $\text{MK}_M^t\text{P}[s]$  with good probability.

For every  $h \in \mathcal{H}_n$ , we define  $U_h$  to be the following black-box universal TM:

$$U_h(\Pi, 1^t) = \begin{cases} U(\Pi_{>1}, 1^t) & \text{if } \Pi_1 = 0 \\ h(M(\Pi_{>1}, 1^{t'(n)})) & \text{if } |\Pi| \leq 2n + 1, \Pi_1 = 1 \text{ and } \left| M(\Pi_{>1}, 1^{t'(n)}) \right| = n \\ \perp & \text{Otherwise} \end{cases}$$

By the assumption that there exists a black-box solver of size  $T(n)$  for every black-box universal TM, there exists a circuit of size  $C_h^s$  of size  $T(s(n) + 5)$  that solves  $\text{MK}_{U_h}^t\text{P}[n - 4]$  on input of length  $n' = s(n) + 5$ , and using oracle to the function  $f_n^h: \{0, 1\}^{\leq 2n'} \rightarrow \{0, 1\}^*$  defined by  $f_n^h(\Pi) = U_h(\Pi, 1^{t'(n')})$ .

Let  $C_h$  be the circuit that given input  $x \in \{0, 1\}^n$ , computes  $h(x)$  and outputs  $C_h^s(h(x))$ . We claim that for every  $x \in \{0, 1\}^n$ ,

1. if  $K_M^{t'}(x) \leq s(n)$ ,  $C_h(x)$  outputs Yes for every  $h$ , and,
2. if  $K_M^{t'}(x) > s(n)$ , it holds that for  $h \leftarrow \mathcal{H}_n$ ,  $C_h(x)$  outputs No with probability at least  $3/4$ .

<sup>5</sup> We remark that the theorem extends also to the search versions of the same problems with essentially identically the same proof. Since we later will show a generic decision-to-search reduction, we omit the details.

To see (1), consider any  $x \in \{0, 1\}^n$  s.t.  $K_M^{t'}(x) \leq s(n)$ . Then there exists a program  $\Pi$  of length at most  $s(n)$  such that  $M(\Pi, 1^{t(n)}) = x$ . Therefore  $U_h(1|\Pi, 1^{t(n)}) = h(M(\Pi, 1^{t(n)})) = h(x)$  and thus  $K_{U_h}^t(h(x)) \leq s(n) + 1 \leq n' - 4$ , so  $C_h(x)$  will always answer Yes.

For (2), consider any  $x \in \{0, 1\}^n$  s.t.  $K_M^{t'}(x) > s(n)$ . We claim that with probability at least  $3/4$  over the choice of a random  $h \leftarrow \mathcal{H}_n$ , it holds that  $K_{U_h}^t(h(x)) > n' - 4$ , which implies that  $C_h(x)$  outputs No. To see the above, assume that for some  $h$ ,  $K_{U_h}^t(h(x)) \leq n' - 4$ . Then there exists  $\Pi$  such that  $|\Pi| \leq n' - 4$ , and  $U_h(\Pi, 1^{t(n)}) = h(x)$ . By the definition of  $U_h$ , it either holds that  $\Pi_1 = 0$ , and then  $K_{U_h}^t(h(x)) \leq n' - 5$ , or  $\Pi_1 = 1$ , which means that  $h(x) = h(x')$  for some  $x'$  with  $K_M^{t'}(x') \leq n' - 5 = s(n)$ . In the following we show that the probability that one of the above happens is at most  $1/4$  (over a random choice of  $h \leftarrow \mathcal{H}_n$ ). Indeed, since  $\mathcal{H}_n$  is a pairwise independent family,  $h(x)$  uniformly distributed when  $h \leftarrow \mathcal{H}_n$ . Therefore,

$$\Pr_{h \leftarrow \mathcal{H}_n} [K_{U_h}^t(h(x)) \leq n' - 4] = \Pr_{y \leftarrow \{0,1\}^{n'}} [K_U^t(y) \leq n' - 4] \leq 2^{-3}.$$

Moreover, for every  $x' \neq x$ , it holds that  $\Pr_{h \leftarrow \mathcal{H}_n} [h(x) = h(x')] \leq 2^{-s(n)-5}$ . By a union bound over all  $x'$  with  $K_M^{t'}(x') \leq s(n)$ , we get that the probability of collision  $h(x) = h(x')$  with such  $x'$  is at most  $2^{-4}$ . Using the union bound again, it holds that with probability at least  $1 - 2^{-3} - 2^{-4} > 3/4$ , both  $K_{U_h}^t(h(x)) > n' - 4$  and there is no  $x' \neq x$  with  $K_M^{t'}(x') \leq s(n)$  such that  $h(x) = h(x')$ . In this case,  $K_{U_h}^t(h(x)) > n' - 4$ , and  $C_h(h(x))$  answers No.

The proof now follows by simple amplification: for  $h_1, \dots, h_n \in \mathcal{H}_n$ , let  $C_{h_1, \dots, h_n}$  be the circuit that computes  $C_{h_1}(x), \dots, C_{h_n}(x)$  and outputs No if one of the execution output No. It follows using a standard Union bound, that with positive probability over the random choice of  $h_1, \dots, h_n \leftarrow \mathcal{H}_n$ ,  $C_{h_1, \dots, h_n}$  outputs the right answer for all  $x \in \{0, 1\}^n$ ; thus, there exists a fixed choice of  $h_1, \dots, h_n$  that works for every input.

We finally bound the size of  $C_{h_1, \dots, h_n}$ . We start with bounding the size of a circuit with  $f_n^h$  oracle, for every  $h \in \{h_1, \dots, h_n\}$ . In this case,

$$\begin{aligned} |C_{h_1, \dots, h_n}| &\leq n \cdot m(n + s(n)) + n \cdot |C_h^s| + O(n) \\ &\leq n \cdot m(n + s(n)) + n \cdot T(s(n) + 5) + O(n). \end{aligned}$$

Next, observe that each  $f_n^h$  oracle can be implemented using a circuit of size  $m(n + s(n)) + p(2n', 2n')$  using oracle to the function  $f_n^{M, t'}: \{0, 1\}^{\leq 2n} \rightarrow \{0, 1\}^*$  defined by  $f_n^{M, t'}(\Pi) = M(\Pi, 1^{t(n)})$ . Thus, the size of a  $f_n^{M, t'}$ -oracle aided circuit computing  $C_{h_1, \dots, h_n}$  is at most  $T(s(n) + 5) \cdot q(n)$  for  $q(n) = (m(n + s(n)))^2 + p(2(s(n) + 5), 2(s(n) + 5))$ . ◀

By taking  $T(n) = 2^{\alpha \cdot n \cdot \text{poly}(n)}$ , we get the following corollary.

► **Corollary 13.** *Assume the existence of a  $2^{\alpha n} \cdot \text{poly}(n)$ -size black-box solver for  $\text{MK}^t\text{P}[n-4]$  for  $t(n) = n$ . Then there exists a generalized black box  $\text{MK}^t\text{P}[s]$  solver of size  $2^{\alpha \cdot s(n)} \cdot \text{poly}(n)$  for all functions  $t'(\cdot)$  and  $s = s(n)$  with  $s(n) \leq 2n$ .*

## 5 From Decision to Search

In this section we show that if there exists a non-trivial black box solver to  $\text{MK}^t\text{P}$ , then such a solver (with roughly the same efficiency) exists also for search- $\text{MK}^t\text{P}$ .

► **Theorem 14.** *There exists  $q \in \text{poly}$  such that the following holds. Let  $p: \mathbb{N} \rightarrow \mathbb{N}$  be a monotone function, and let  $T: \mathbb{N} \rightarrow \mathbb{N}$  and  $t: \mathbb{N} \rightarrow \mathbb{N}$  be functions. Assume that for every  $s: \mathbb{N} \rightarrow \mathbb{N}$  with  $s(n) \leq 2n$  there exists a generalized black-box  $\text{MK}^t\text{P}[s]$  solver of size  $T(s(n)) \cdot p(n)$ . Then, there exists a generalized black-box search- $\text{MK}^t\text{P}[s]$  solver of size  $T(s(n) + \lceil \log n \rceil) \cdot p(n + s(n)) \cdot q(n)$  for every  $s: \mathbb{N} \rightarrow \mathbb{N}$  such that  $s(n) \leq 2n - \lceil \log n \rceil$ .*

**Proof.** Let  $M$  be a black-box TM emulator, and for every  $n \in \mathbb{N}$ , let  $M_n$  be the following black-box TM emulator. Given  $\Pi$  and  $1^{t'}$ ,  $M_n$  interprets  $\Pi = i|\Pi'$ , where the first  $\lceil \log n \rceil$  bits of  $\Pi$  interpreted as an index  $i \in [n]$ , and the rest of the bits interpreted as a program  $\Pi'$ . Then,  $M_n$  acts as follows:

$$M_n(i, \Pi', 1^{t'}) = \begin{cases} M(\Pi', 1^{t(n)})|\Pi'_{\leq i} & \text{if } i \leq n, |\Pi'| \leq 2n \text{ and } |M(\Pi', 1^{t(n)})| = n \\ \perp & \text{Otherwise} \end{cases}$$

We observe that for every  $x$ , for every  $i \in [n]$ , and for every program  $\Pi'$  of length  $\ell \leq 2n$  such that  $M(\Pi', 1^t) = x$ , it holds that  $K_M^t(x) + \lceil \log n \rceil \leq K_{M_n}^t(x|\Pi'_{\leq i}) \leq \ell + \lceil \log n \rceil$ . In particular, assuming that  $K_M^t(x) \leq 2n$ , for the minimal-length program  $\Pi'$  such that  $M(\Pi', 1^t) = x$  it holds that  $K_{M_n}^t(x|\Pi'_{\leq i}) = K_M^t(x) + \lceil \log n \rceil$ . Moreover, for every  $z \in \{0, 1\}^*$  such that  $z$  is not a prefix of a program of length at most  $\ell$  that outputs  $x$ , it holds that  $K_{M_n}^t(x|z) > \ell + \lceil \log n \rceil$ . We can thus use an algorithm that decides  $\text{MK}_{M_n}^t \text{P}$  to find a program  $\Pi$  of length at most  $s$  such that  $M(\Pi, 1^t) = x$ . This can be done by the following process:

1. Check if  $K_{M_n}^t(x) \leq s(n) + \lceil \log n \rceil$ . If not output  $\perp$ .
2. Let  $z = \perp$ .
3. For every  $i \in [s(n)]$ :
  - a. Check if  $M(z, 1^t) = x$ . If it does, output  $z$ .
  - b. Check if  $K_{M_n}^t(x|z|0) \leq s(n) + \lceil \log n \rceil$ , let  $z = z|0$ . Otherwise let  $z = z|1$ .
4. Output  $z$ .

Since  $K_{M_n}^t(x|z|0) \leq s(n) + \lceil \log n \rceil$  if and only if  $z|0$  is a prefix of a program  $\Pi$  of length at most  $s$  such that  $M(\Pi, 1^t) = x$ , the above process always finds such a program. We left to show that the above process can be implemented using a circuit of size  $T(s(n) + \lceil \log n \rceil) \cdot p(n + s(n)) \cdot \text{poly}(n)$ .

Let  $s'$  be the function defined by  $s'(k) = 1$  for every  $k < n$ , and  $s'(k) = s(n) + \lceil \log n \rceil$  otherwise. Then if  $s(n) \leq 2n - \lceil \log n \rceil$ , it holds that  $s'(k) \leq 2k$ . By our assumption, for every  $n'$  there exists a  $f_{n'}^{M_n, t}$ -oracle aided circuit  $C_{n'}$  of size  $T(s'(n')) \cdot p(n')$  that decides  $\text{MK}_{M_n}^t \text{P}[s']$  on inputs of length  $n'$ . We observe that the above process can be implemented with one call to each of  $C_{n'}$ , for  $n' \in \{n, \dots, n + s(n)\}$ . Moreover, the  $f_{n'}^{M_n, t}$ -oracle can be implemented by a poly-size circuit using an  $f_n^{M, t}$ -oracle. Thus, the above process can be implemented using a circuit of size at most  $s(n) \cdot T(s(n) + \lceil \log n \rceil) \cdot p(n + s(n)) \cdot \text{poly}(n)$ , as required.  $\blacktriangleleft$

By taking  $T(s(n)) = 2^{\alpha \cdot s(n)}$ , we get the following corollary.

**► Corollary 15.** *Assume there exists a generalized black box  $\text{MK}^t \text{P}[s]$  solver of size  $2^{\alpha \cdot s(n)} \cdot \text{poly}(n)$  for all functions  $t(\cdot)$  and  $s = s(n)$  with  $s(n) \leq 2n$ . Then there exists a  $2^{\alpha \cdot s(n)} \cdot \text{poly}(n)$ -size generalized black-box solver for search- $\text{MK}^t \text{P}[s]$  for every function  $t'(\cdot)$  and every function  $s(n) \leq 2n - \lceil \log n \rceil$ .*

## **A** search- $MK^tP$ and Function Inversion

We observe that generalized black-box solvers for search- $MK^tP$  directly yield function inverters with roughly the same complexity, and vice versa.

► **Lemma 16.** *There exists  $p \in \text{poly}$  such that the following holds. Assume that for some  $t = t(n)$  there exists a generalized black-box search- $MK^tP[n]$  solver of size  $T = T(n)$ . Then for every function  $\pi : \{0, 1\}^n \rightarrow \{0, 1\}^n$  there exists a  $\pi$ -oracle aided circuit of size  $T(n) \cdot p(n)$  that inverts  $\pi$ .*

**Proof.** Let  $M$  be the black box TM that on input  $x \in \{0, 1\}^n$ ,  $1^t$  outputs  $y = \pi(x)$ . By assumption, there exists a  $f_n^{M,t}$ -oracle aided circuit of size at most  $T(n)$ , that given an input  $y \in \{0, 1\}^n$  finds an input  $x$  of length at most  $n$ , such that  $M(x, 1^{t(n)}) = y$ , if such exists. Since  $M(x, 1^{t(n)}) = \pi(x)$ , such an  $x$  is a pre-image of  $y$ . Moreover, by the definition of  $M$ , the  $f_n^{M,t}$ -oracle can be implemented efficiently using a  $\pi$ -oracle. ◀

The converse of Lemma 16 was implicitly proven in [14]; we repeat the proof for the convenience of the reader.

► **Lemma 17.** *There exists  $p \in \text{poly}$  such that the following holds. Assume that for every function  $\pi: \{0, 1\}^n \rightarrow \{0, 1\}^n$  there exists a  $\pi$ -oracle aided circuit of size  $T(n)$  that inverts  $\pi$  with probability 1 (for every  $y = \pi(x)$ ,  $f(C(y)) = y$ ). Then there exists a black-box  $\text{MK}^t\text{P}[s]$  solver of size  $T(n + \lceil \log n \rceil) \cdot p(n)$  for every  $t: \mathbb{N} \rightarrow \mathbb{N}$  and every  $s: \mathbb{N} \rightarrow \mathbb{N}$  with  $s(n) \leq n$ .*

**Proof.** Let  $U$  be a black-box universal TM. Let  $f'_n: \{0, 1\}^n \times [n] \rightarrow \{0, 1\}^n \times [n]$  be defined as

$$f'_n(\Pi, i) = \begin{cases} (U(\Pi_{\leq i}, 1^{t(n)}), i) & |U(\Pi_{\leq i}, 1^{t(n)})| = n \\ 0^n & \text{Otherwise} \end{cases}$$

Let  $n' = n + \lceil \log n \rceil$ . In the following, we assume that both the domain and the range of  $f'_n$  is  $\{0, 1\}^{n'}$ , by the use of appropriate encoding and padding. By assumption, there is a circuit family  $\widehat{C} = \{\widehat{C}_n\}_{n \in \mathbb{N}}$  with  $f'_n$  oracle, of size  $T(n')$  that inverts  $f'_n$  with probability 1.

Given a circuit  $\widehat{C}_n$  that inverts  $f'_n$ , we can construct a ( $f'_n$ -oracle aided) circuit  $C_n$  that computes the  $K_{\cup}^t$  complexity of any string  $x$  of length  $n$  with  $K_{\cup}^t(x) \leq n$ . This can be done by computing  $f'^{-1}_n(x, 1), \dots, f'^{-1}_n(x, n)$  and outputting Yes if there exists  $(\Pi, i)$  such that  $U(\Pi_{\leq i}, 1^{t(n)}) = x$  and  $i \leq s(n)$  (the  $t$ -bounded Kolmogorov complexity of the string  $0^n$  can be hardcoded in the circuit).

Observe that the size of  $C_n$  is  $n' \cdot |\widehat{C}_n| + \text{poly}(n)$ . Thus, there exists a circuit family of size  $n' \cdot T(n') + \text{poly}(n) = T(n') \cdot \text{poly}(n)$ , with  $f'_n$  oracle, that solves  $\text{MK}^t_{\cup}\text{P}[s]$ . Lastly, observe that  $f'_n$  can be efficiently computed from  $f_n^{U,t}$ , thus we can replace the  $f'_n$  oracle with a small circuit using an  $f_n^{U,t}$ -oracle, to get a circuit of size  $T(n + \lceil \log n \rceil)\text{poly}(n)$ . ◀

## B MCSP[s] as a special case of $\text{MK}^t_{\text{M}}\text{P}$

We note that any generalized black-box  $\text{MK}^t\text{P}[s]$  solver can be used to solve  $\text{MCSP}[s]$ . In fact, we observe that the  $\text{MCSP}[s]$  problem can be formulated as a  $\text{MK}^t_{\text{M}}\text{P}[s']$  instance for a particular choice of an (efficient but non-universal) TM  $M$ , and for a function  $s'(n) \approx s(n)$ .

Towards this, we will rely on the fact that circuits can be *succinctly* encoded as bit strings from which the circuit can be efficiently decoded. In particular, as observed in [17, 6], the encoding from [4] satisfies this requirement.

► **Lemma 18** (Implicit in [4], see also [17, 6]). *There exists an efficiently computable function  $\ell(s, k) \in (1 + o(1))(s \cdot \log(s + k))$  such that  $\ell$  is monotone in  $s$  and the following holds. There exists an efficient algorithm  $\text{Dec}$ , such that for every circuit  $C: \{0, 1\}^k \rightarrow \{0, 1\}$  of size  $s$ , there exists  $x \in \{0, 1\}^{\ell(s,k)}$  such that  $\text{Dec}(x)$  is a circuit of size  $s$  that computes the same function as  $C$ . Moreover, for every  $x$  such that  $\text{Dec}(x)$  outputs a circuit  $C: \{0, 1\}^k \rightarrow \{0, 1\}$  of size  $s$ , it holds that  $|x| = \ell(s, k)$ .<sup>6</sup>*

<sup>6</sup> Note that we here requires the length of an encoding of a circuit of size  $s$  to be *exactly*  $\ell(s, k)$  (in contrast to bounded by  $\ell(s, k)$ ). As far as we can tell, this property has not been previously stated but it can be assumed without loss of generality using padding, and by assuming that given an input  $x$ ,  $\text{Dec}$  only outputs a circuit  $C$  of size  $s$  if it holds that  $|x| = \ell(s, k)$ , or outputs  $\perp$  otherwise.

## 66:12 On Black-Box Meta Complexity and Function Inversion

We now observe that the MCSP is a special-case of the  $\text{MK}_M^t\text{P}$  problem for a specific choice of the TM  $M$ .

► **Lemma 19.** *There exists an efficient TM  $M$  such that the following holds for every  $s: \mathbb{N} \rightarrow \mathbb{N}$  and every  $t: \mathbb{N} \rightarrow \mathbb{N}$  with  $t(n) \geq n$ . Deciding  $\text{MCSP}[s]$  is equivalent to deciding  $\text{MK}_M^t\text{P}[s']$ , for  $s'(n) = \ell(s(n), \lfloor \log n \rfloor)$ .*

**Proof.** Let  $Dec$  be the function from Lemma 18, and let  $M$  be the TM that given an input  $x, 1^t$ , computes  $Dec(x)$  to get a circuit  $C: \{0, 1\}^k \rightarrow \{0, 1\}$ . If  $x$  is not valid encoding of a circuit, or  $2^k \neq |x|$ ,  $M$  outputs  $\perp$ . If  $t \leq 2^k$ ,  $M$  also outputs  $\perp$ . Otherwise,  $M$  outputs the truth table of  $C$ . Since  $\ell$  is monotone in  $s$ , there exists a program of length less than  $s'(n)$  if and only if there exists a circuit of size less than  $s(n)$  for  $x$ . ◀

# Explicit and Near-Optimal Construction of $t$ -Rankwise Independent Permutations

## Abstract

Letting  $t \leq n$ , a family of permutations of  $[n] = \{1, 2, \dots, n\}$  is called  $t$ -rankwise independent if for any  $t$  distinct entries in  $[n]$ , when a permutation  $\pi$  is sampled uniformly at random from the family, the order of the  $t$  entries in  $\pi$  is uniform among the  $t!$  possibilities.

Itoh et al. show a lower bound of  $(n/2)^{\lfloor \frac{t}{4} \rfloor}$  for the number of members in such a family, and provide a construction of a  $t$ -rankwise independent permutation family of size  $n^{O(t^2/\ln(t))}$ .

We provide an explicit, deterministic construction of a  $t$ -rankwise independent family of size  $n^{O(t)}$  for arbitrary parameters  $t \leq n$ . Our main ingredient is a way to make the elements of a  $t$ -independent family “more injective”, which might be of independent interest.

## 1 Introduction

An important topic in the area of pseudorandomness is the construction of random variables such that any  $t$  of them are independent (for some parameter  $t \in \mathbb{N}$ ), given a small source of purely random bits. A fundamental notion introduced by Wegman and Carter in 1979 [2] is that of a  $t$ -independent family<sup>1</sup>, defined as follows (see also [9, Definition 3.31]).

► **Definition 1** ( $t$ -independent family). *Let  $m, n, t$  be positive integers with  $t \leq m$ . A family  $\mathcal{H}$  of functions mapping  $[m] \rightarrow [n]$  is called  $t$ -independent if, when  $h \in \mathcal{H}$  is chosen uniformly at random, for any  $t$  distinct  $x_1, \dots, x_t \in [m]$  and  $t$  elements  $y_1, \dots, y_t \in [n]$ ,*

$$\mathbb{P}(h(x_i) = y_i \text{ for } i = 1, \dots, t) = \frac{1}{n^t},$$

*or equivalently, that the  $t$  random variables  $h(x_1), \dots, h(x_t)$  are independently and uniformly distributed in  $[n]$ .*

These  $t$ -independent families are well-studied, and have found various applications. One example is to derandomize a randomized algorithm that uses certain independent random variables, but one can relax the assumption of being *mutually* independent to any  $t$  of them being independent. Then often one can derandomize the algorithm by iterating over the elements of  $\mathcal{H}$  to find a function for which the algorithm succeeds. See [9, section 3.5] for such

---

<sup>1</sup> Throughout this paper, we use the term “family” to refer to a multiset, meaning that the members need not be distinct.

an application for the MaxCut problem. It is then desirable to have explicit constructions of such a family  $\mathcal{H}$  with small size. In fact, explicit constructions of such families of near-optimal size are known [4] for any parameters  $1 \leq t \leq m$  and any  $n$ .

One can also define analogous families when restricting to permutations of  $[n]$  instead of general functions. This natural restriction yields the notion of  $t$ -independent permutations.

► **Definition 2** ( *$t$ -independent permutation*). *A family  $\Pi$  is called  $t$ -independent if it contains permutations of  $[n]$  such that, for any  $t$  distinct  $x_1, \dots, x_t \in [n]$  and any  $t$  distinct elements  $y_1, \dots, y_t \in [n]$ ,*

$$\mathbb{P}(\pi(x_i) = y_i \text{ for } i = 1, \dots, t) = \prod_{i=0}^{t-1} \frac{1}{n-i}$$

when  $\pi \in \Pi$  is chosen uniformly at random.

Explicit construction of such families with a small size, namely such that  $|\Pi| \leq n^{O(t)}$ , remains an open problem. This bound is near-optimal, since there is an obvious lower bound of  $|\Pi| \geq \prod_{i=0}^{t-1} (n-i)$ , which follows from the definition.

In fact, there are few non-trivial constructions of such families for any  $t \geq 4$ . Perhaps the closest result in this direction is a probabilistic proof for the existence of small (i.e., with  $|\Pi| \leq n^{O(t)}$ )  $t$ -independent permutations for any  $1 \leq t \leq n$  due to Kuperberg, Lovett and Peled [7]. However, their proof does not seem to yield an efficient deterministic or randomized construction of the family, as it has a tiny success probability.

Many relaxed notions related to  $t$ -independence have been proposed for permutation families, including “ $t$ -restricted min-wise independent” [1] and “ $t$ -rankwise independent” families [5]. The latter is the focus of this paper.

► **Definition 3** ( *$t$ -rankwise independent permutation*). *A family  $\Pi$  of permutations over  $[n]$  is called  $t$ -rankwise independent if for any  $t$  distinct points  $x_1, \dots, x_t \in [n]$ ,*

$$\mathbb{P}(\pi(x_1) < \pi(x_2) < \dots < \pi(x_t)) = \frac{1}{t!}$$

when  $\pi \in \Pi$  is chosen uniformly at random.

Another interesting type of permutation families has recently been proposed in the cryptography community. This is the notion of a *perfect sequence covering array* (PSCA).

► **Definition 4** (Yuster [10]). *Let  $t \leq n$ . The family  $\Pi$  of permutations of  $[n]$  is called a PSCA( $n, t$ ) if there exists a fixed  $\lambda \in \mathbb{N}$  such that for any  $t$  distinct indices  $i_1, \dots, i_t \in [n]$ , there are exactly  $\lambda$  permutations  $\pi \in \Pi$  such that*

$$(i_1, i_2, \dots, i_t) \text{ is a subsequence of } (\pi(1), \pi(2), \dots, \pi(n)).$$

(The notation and wording have been adapted to match ours.)

Let  $g^*(n, t)$  denote the smallest size of a PSCA family  $\Pi$ . Naturally, researchers in this field are interested in the value of  $g^*(n, t)$ , and in the construction of families that asymptotically achieve this minimum size.

It was observed in [6] that  $t$ -rankwise independent families and PSCAs are isomorphic. Specifically,  $\Pi$  is a PSCA( $n, t$ ) family if and only if  $\Pi^{-1} = \{\pi^{-1} : \pi \in \Pi\}$  is a  $t$ -rankwise independent family of permutations over  $[n]$ . Consequently, our construction of  $t$ -rankwise independent permutations can immediately be translated into a construction of PSCAs. Henceforth we will only use the terminology of  $t$ -rankwise independent families, and will no longer refer to PSCAs.

Itoh et al. [5] show a lower bound of  $(n/2)^{\lfloor \frac{t}{4} \rfloor} \leq |\Pi|$  for the size of a  $t$ -rankwise independent family  $\Pi$ . They also construct a family  $\Pi$  with  $|\Pi| \leq n^{O(t^2/\ln(t))}$ , which does not asymptotically match the lower bound.

We present a deterministic algorithm for constructing a  $t$ -rankwise independent family  $\Pi$  of permutations over  $[n]$ , with  $|\Pi| \leq n^{O(t)}$ . This asymptotically matches the known lower bound. Formally, the following is our main result.

► **Theorem 5 (Main).** *There exists a constant  $C > 0$  such that the following is true. Let  $n, t$  be positive integers with  $t \leq n$ . Then there exists a  $t$ -rankwise independent family  $\Pi$  consisting of permutations of  $[n]$  such that  $|\Pi| \leq (Cn)^{35t}$ . Furthermore, the whole family can be constructed by a deterministic algorithm in  $n^{O(t)}$  time. (The implied constant in the  $O(\cdot)$  notation does not depend on either  $n$  or  $t$ ).*

Our construction starts in Section 2.2 with a  $t$ -independent family  $\mathcal{H}$ , based on Reed-Solomon codes. The next step, appearing in Section 2.3, modifies it to obtain another  $t$ -independent family  $\mathcal{G}$  whose members, roughly speaking, look “more injective”. This step is the main technical contribution of the paper, and might be of independent interest. (Note that, since  $\mathcal{G}$  is a  $t$ -independent family, not all the maps in  $\mathcal{G}$  can be injective). Finally, in Section 2.4, we use this  $t$ -independent family  $\mathcal{G}$  to construct permutations of  $[n]$ , yielding the  $t$ -rankwise independent family  $\Pi$ .

## 2 The construction

### 2.1 Overview

Our construction involves three steps, which build upon each other.

1. Construct  $\mathcal{H}$ , a  $t$ -independent family of  $[n] \rightarrow \mathbb{Z}_N$  maps, where  $N = \Theta(n^3)$ .
2. Construct  $\mathcal{G}$ , a  $t$ -independent family of  $[n] \rightarrow \mathbb{Z}_N$  maps, such that each map’s image has size at least  $n - 16t$ . Intuitively, this condition says that each map has very few collisions, or is almost injective. (Being injective is equivalent to the image having size exactly  $n$ ).
3. Construct  $\Pi$ , a  $t$ -rankwise independent family of permutations on  $[n]$ .

The most substantial of these steps is the construction of  $\mathcal{G}$ , whereas the construction of  $\mathcal{H}$  is the most trivial. We explain these steps in the following sections.

### 2.2 Construction of $\mathcal{H}$

The construction of  $\mathcal{H}$  is standard. The first step is to find a prime  $p$  in the interval  $[n^3, 2n^3]$ . This must exist, by Bertrand’s postulate, and can be found in  $\tilde{O}(n^3)$  time using exhaustive search and a deterministic primality test. We set  $N = p$ , and therefore

$$n^3 \leq N \leq 2n^3. \tag{1}$$

Let  $\mathcal{H}$  be the family of  $[n] \rightarrow \mathbb{F}_N$  maps defined by polynomials over  $\mathbb{F}_N$  of degree less than  $t$ , namely

$$\mathcal{H} = \left\{ \sum_{0 \leq i \leq t-1} a_i x^i : a_i \in \mathbb{F}_N \right\}.$$

This family is well-known to be  $t$ -independent; see, e.g., [3, Exercise 5.8]. Note that the size of the family is  $|\mathcal{H}| = p^t = N^t$ .

### 2.3 Construction of $\mathcal{G}$

The next step is to use the family  $\mathcal{H}$  to build a family  $\mathcal{G}$ . Each map in  $\mathcal{H}$  will yield exactly one map in  $\mathcal{G}$ . The family  $\mathcal{G}$  will retain  $\mathcal{H}$ 's property of being  $t$ -independent. In addition, we will be able to guarantee that every map in  $\mathcal{G}$  has image size at least  $n - 16t$ . Thus each map has few collisions (although this is an informal term that we have not yet defined).

The family  $\mathcal{G}$  has a simple form, and it is constructed by the pseudocode shown in Algorithm 1. This algorithm computes a single, specific map  $\alpha : [n] \rightarrow \mathbb{Z}_N$ , then it constructs

$$\mathcal{G} = \{ h + \alpha : h \in \mathcal{H} \}.$$

▷ **Claim 6.** For any map  $\alpha$ , the resulting family  $\mathcal{G}$  will be  $t$ -independent.

*Proof.* Suppose that  $h$  is chosen uniformly at random from  $\mathcal{H}$ . For any  $t$  distinct entries  $x_1, \dots, x_t \in [n]$ ,  $\{h(x_i)\}_{i \in [t]}$  are independent, and hence  $\{f_i(h(x_i))\}_{i \in [t]}$  are independent for any deterministic functions  $f_i$ . In particular, since  $\alpha$  is not random, letting  $f_i(z) = z + \alpha(x_i)$ , we have that  $\{h(x_i) + \alpha(x_i)\}_{i \in [t]}$  remain independent. Lastly, for any  $k \in [n]$ ,  $h(k) + \alpha(k)$  is uniformly distributed since  $h(k)$  is uniform in  $\mathbb{Z}_N$ , and  $\alpha$  is not random. Thus  $\{(h + \alpha)(x_i)\}_{i \in [t]}$  are independent and uniform in  $\mathbb{Z}_N$ , as desired. ◁

We will prove that there is a specific choice of  $\alpha$  such that every  $h \in \mathcal{H}$  satisfies

$$|(h + \alpha)([n])| = |\{ h(x) + \alpha(x) : x \in [n] \}| \geq n - 16t,$$

which is the desired property of the family  $\mathcal{G}$ . In fact, it is possible to show that a random choice of  $\alpha$  will satisfy this property with positive probability. However, this would not quite achieve the goals of this paper, since ultimately we want an explicit, deterministic construction of a  $t$ -rankwise independent family of permutations. Instead, we will obtain a deterministic construction by derandomizing the randomized construction of  $\alpha$ .

Algorithm 1 contains pseudocode for this procedure, which we now briefly explain. The algorithm computes the values  $\alpha(1), \alpha(2), \dots, \alpha(n)$  one-by-one, in that order. Thinking of  $h + \alpha$  as mapping the “balls”  $[n]$  to the “bins”  $\mathbb{Z}_N$ , then  $S_k^h$  is the set of bins that have already received balls (for this particular function  $h$ ). In order to be as injective as possible, we want to avoid a collision (for every  $h$ ) between the  $k^{\text{th}}$  ball and these bins – that is, we want  $(h + \alpha)(k) \notin S_k^h \forall h \in \mathcal{H}$ . To do so, the algorithm uses a potential function (shown in (2)) in which the variable  $x$  corresponds to the value that will be used for  $\alpha(k)$ . This function penalizes any value  $x$  which would cause any further collision among any function  $h \in \mathcal{H}$ . This potential function is essentially a pessimistic estimator, as explained in Section 2.3.1 below.

► **Lemma 7.** *Algorithm 1 returns a  $t$ -independent family  $\mathcal{G}$  satisfying the following.*

$$|g([n])| \geq n - 16t \quad \forall g \in \mathcal{G}$$

The subset of the codomain that experienced a “collision” is defined to be

$$\mathcal{Y} = \{ y \in \mathbb{Z}_N : |g^{-1}(y)| \geq 2 \},$$

and the subset of the domain involved in these collisions is defined to be

$$\mathcal{X} = \bigcup_{y \in \mathcal{Y}} g^{-1}(y) = g^{-1}(\mathcal{Y}).$$

► **Corollary 8.** *The family  $\mathcal{G}$  produced by Lemma 7 satisfies  $|\mathcal{X}| \leq 32t$ .*

■ **Algorithm 1** Main Algorithm.

---

A formal proof is in Appendix A, and here we present only a sketch.

**Proof (Sketch).** The size of  $\mathcal{X}$  is maximized by having exactly  $16t$  bins containing exactly 2 balls, and  $n - 32t$  bins containing exactly 1 ball. ◀

### 2.3.1 Proof of Lemma 7

For each function  $h \in \mathcal{H}$  and integer  $k \in [n]$ , there is a function  $\beta_k^h: \mathbb{Z}_N^k \rightarrow \{0, 1\}$  that is defined in Algorithm 1, and which we define equivalently here as

$$\beta_k^h(x_1, \dots, x_k) = \begin{cases} 1 & \text{if } \exists 1 \leq i \leq k-1 \text{ s.t. } h(k) + x_k = h(i) + x_i \pmod{N} \\ 0 & \text{otherwise.} \end{cases}$$

We will use the notation  $\beta_k^h(x_k)$  for  $\beta_k^h(x_1, \dots, x_k)$  when  $x_1, \dots, x_{k-1}$  are clear from context.

The scalar  $\lambda > 0$  is as defined as in Algorithm 1. Additionally, define the scalar  $c_\lambda > 0$  and the function  $\psi_k: \mathbb{Z}_N^k \rightarrow \mathbb{R}^+$  by

$$c_\lambda = \mathbb{E} \exp(\lambda Y) > 0$$

$$\psi_k(x_1, \dots, x_k) = \sum_{h \in \mathcal{H}} \exp\left(\lambda \sum_{i=1}^k \beta_i^h(x_1, \dots, x_i)\right) \cdot c_\lambda^{n-k}, \quad (3)$$

where  $Y$  is a random variable having the Bernoulli distribution with parameter  $n/N$ , which we write as  $\text{Bern}(n/N)$ . We will often write  $\psi_k(x_k)$  instead of  $\psi_k(x_1, \dots, x_k)$  for notational convenience.

Intuitively,  $\psi_k(x_1, \dots, x_k)$  is a pessimistic estimator of the expected number of functions  $h \in \mathcal{H}$  which would have  $|(h + \alpha)([n])| > n - 16t$  given that  $\alpha(i) = x_i \forall i \in [k]$ , and that the rest of the entries  $\alpha(k+1), \dots, \alpha(n)$  are chosen uniformly at random from  $\mathbb{Z}_N$ .

Let  $\alpha: [n] \rightarrow \mathbb{Z}_N$  be the mapping constructed by Algorithm 1.

▷ **Claim 9.**  $\psi_0 \geq \psi_1(\alpha(1)) \geq \psi_2(\alpha(2)) \geq \dots \geq \psi_n(\alpha(n))$ , where here we use the notation  $\psi_i(\alpha(i))$  to denote  $\psi_i(\alpha(1), \alpha(2), \dots, \alpha(i))$ .

▷ **Claim 10.**  $1 > \psi_0 = \exp(-16\lambda t) \cdot |\mathcal{H}| \cdot [\mathbb{E} \exp(\lambda Y)]^n$ .

Together, Claims 9 and 10 imply that

$$1 > \psi_n(\alpha(n)) = \sum_{h \in \mathcal{H}} \exp\left(\lambda \left(\sum_{i=1}^k \beta_i^h(\alpha(i))\right) - 16\lambda t\right).$$

Since all summands are non-negative, it follows that, for every  $h \in \mathcal{H}$ , we have

$$\exp\left(\lambda \left(\sum_{i=1}^k \beta_i^h(\alpha(i))\right) - 16\lambda t\right) < 1.$$

Observe that  $\sum_{i \leq k} \beta_i^h(\alpha(i)) = k - |S_k^h| \forall k, h$ . Taking the log and rearranging, we obtain that

$$n - |S_n^h| = \sum_{i=1}^n \beta_i^h(\alpha(i)) < 16t \quad \forall h \in \mathcal{H}.$$

Let  $g = h + \alpha$ . Since  $|g([n])| = |S_n^h|$ , we have  $|g([n])| > n - 16t$  for all  $h \in \mathcal{H}$ . This completes the proof of Lemma 7.

**Proof of Claim 9.** We will show that  $\psi_k(\alpha(k)) \leq \psi_k(\alpha(k-1)) \forall 1 \leq k \leq n$ . So let  $k \in [n]$  be arbitrary.

Our first observation is that, in the algorithm's iteration  $k$ , it chooses the value  $a = \alpha(k)$  to minimize  $\psi_k(\alpha(1), \dots, \alpha(k-1), a)$ . This holds because the functions

$$\sum_{h \in \mathcal{H}} \exp\left(\lambda \beta_k^h(x) + \lambda \sum_{i=1}^{k-1} \beta_i^h(\alpha(i))\right) \quad \text{and} \quad \psi_k(\alpha(1), \alpha(2), \dots, \alpha(k-1), x)$$

are positive multiples of each other.

Since  $\alpha(k)$  minimizes  $\psi_k$ , we clearly have

$$\psi_k(\alpha(1), \dots, \alpha(k)) \leq \mathbb{E}_{U \sim \text{Unif}(\mathbb{Z}_N)} \psi_k(\alpha(1), \dots, \alpha(k-1), U),$$

where  $\text{Unif}(S)$  denotes the uniform distribution on the set  $S$ . Hence in order to show that  $\psi_k(\alpha(k)) \leq \psi_{k-1}(\alpha(k-1))$ , it suffices to prove that

$$\mathbb{E}_{U \sim \text{Unif}(\mathbb{Z}_N)} \psi_k(\alpha(1), \dots, \alpha(k-1), U) \leq \psi_{k-1}(\alpha(k-1)). \quad (4)$$

Since  $\psi_k$  and  $\psi_{k-1}$  are both sums over  $h \in \mathcal{H}$ , it will suffice to prove this inequality for each summand. More specifically, we will ignore the  $e^{-16\lambda t}$  constant and define

$$\psi_k^h(x) = \exp\left(\lambda \sum_{i=1}^{k-1} \beta_i^h(\alpha(i)) + \lambda \beta_k^h(x)\right) \cdot c_\lambda^{n-k},$$

where, as above,  $c_\lambda = \mathbb{E} \exp(\lambda Y)$ , and  $Y$  is  $\text{Bern}(n/N)$ . Towards our inductive proof, we may rewrite this as

$$\psi_k^h(x) = \psi_{k-1}^h(\alpha(k-1)) \cdot \frac{1}{c} \cdot \exp(\lambda \beta_k^h(\alpha(1), \dots, \alpha(k-1), x)).$$

Plugging this into our goal (4), it suffices to prove that

$$\mathbb{E}_{U \sim \text{Unif}(\mathbb{Z}_N)} \psi_{k-1}^h(\alpha(k-1)) \cdot \frac{1}{c} \cdot \exp(\lambda \beta_k^h(\alpha(1), \dots, \alpha(k-1), U)) \leq \psi_{k-1}(\alpha(k-1)),$$

or equivalently (observing that  $\psi_{k-1}^h(\alpha(k-1)) > 0$ ),

$$\mathbb{E}_{U \sim \text{Unif}(\mathbb{Z}_N)} \exp(\lambda \beta_k^h(\alpha(1), \dots, \alpha(k-1), U)) \leq c_\lambda = \mathbb{E} \exp(\lambda Y). \quad (5)$$

Note that there are exactly  $|S_k^h|$  values of  $U$  that result in  $\beta_k^h(\alpha(1), \alpha(2), \dots, \alpha(k-1), U)$  taking the value 1, whereas the rest result in the value 0. Since  $U$  is uniformly distributed on  $\mathbb{Z}_N$  and  $|S_k^h| \leq n$  for all  $k \in [n]$ ,  $h \in \mathcal{H}$ , it follows that  $\beta_k^h(\alpha(1), \dots, \alpha(k-1), U)$  has a Bernoulli distribution  $\text{Bern}(p)$  where  $p \leq n/N$ . Since  $Y$  has the distribution  $\text{Bern}(n/N)$ , the desired inequality (5) follows.  $\triangleleft$

For the next proof, we will require the following statement of the Chernoff bound. A proof is given in Appendix A.

► **Theorem 11** (Poisson tail of Chernoff bound). *Let  $Y_1, \dots, Y_n$  be independent random variables supported on  $[0, 1]$ . Let  $\mu = \mathbb{E} \sum_{i=1}^n Y_i$ . Then, for any  $\delta \geq 1$ , if  $\lambda = \ln(1 + \delta)$  then*

$$\mathbb{P} \left( \sum_{i=1}^n Y_i \geq (1 + \delta)\mu \right) \leq \mathbb{E} \exp \left( \lambda \sum_{i=1}^n Y_i - \lambda(1 + \delta)\mu \right) \leq (1 + \delta)^{-(1+\delta)\mu/4}.$$

Proof of Claim 10. Let  $Y_1, \dots, Y_n$  be i.i.d.  $\text{Bern}(\frac{n}{N})$  random variables. We may rewrite the definition of  $\psi_0$  from (3) using these  $Y_i$  random variables as

$$\psi_0 = |\mathcal{H}| \cdot \mathbb{E} \exp \left( \lambda \sum_{i=1}^n Y_i - 16\lambda t \right).$$

To prove the claim, we must show that this is less than 1.

To do so, consider any fixed  $h \in \mathcal{H}$ . We will use the Chernoff bound as stated in Theorem 11, with  $1 + \delta = 16tN/n^2$ . (Note that  $\delta \geq 1$ , as required, since  $N \geq n^3$ .) The value of  $\lambda$  required by the theorem is  $\ln(1 + \delta) = \ln(16tN/n^2)$ , which matches the definition in Algorithm 1. Lastly, note that

$$\mu = \mathbb{E} \sum_{i=1}^n Y_i = n^2/N,$$

since each  $Y_i$  is  $\text{Bern}(n/N)$ . Thus  $\lambda(1 + \delta)\mu = 16\lambda t$ . Applying the theorem, we obtain

$$\mathbb{E} \exp \left( \lambda \sum_{k=1}^n Y_i - 16\lambda t \right) \leq (1 + \delta)^{-(1+\delta)\mu/4} = (16tN/n^2)^{-4t} < n^{-4t} \leq N^{-t},$$

since  $n^3 \leq N \leq 2n^3$  by (1), and also using  $n \geq 2$ . Thus, in conclusion

$$\psi_0 < |\mathcal{H}| \cdot N^{-t} = 1. \quad \triangleleft$$

---

**Algorithm 2** Construction of  $\Pi$  from  $\mathcal{G}$ .
 

---

**Input:**  $t$ -independent family  $\mathcal{G}$  of  $[n] \rightarrow \mathbb{Z}_N$  maps.

**Output:**  $t$ -rankwise independent family of permutations on  $[n]$ .

```

1: Let  $\Pi \leftarrow \emptyset$ 
2: Let  $\tau \leftarrow 32t$ 
3: for  $g \in \mathcal{G}$  do
4:   Let  $\Sigma = \{ (\sigma_1, \dots, \sigma_N) : \sigma_i \text{ is a permutation of } g^{-1}(i) \}$ 
5:   Let  $s \leftarrow \tau! / |\Sigma|$ 
6:   for  $(\sigma_1, \dots, \sigma_N) \in \Sigma$  do
7:     Let  $L \leftarrow []$  be an empty list
8:     for  $i = 1, \dots, N$  do
9:       Append to  $L$  the elements of  $g^{-1}(i)$  in the order given by  $\sigma_i$ 
10:    end for
11:    Add  $s$  copies of the permutation  $\pi : [n] \rightarrow [n]$ , where  $\pi(i) = L[i]$ , to the set  $\Pi$ 
12:  end for
13: end for
14: return  $\Pi$ 
    
```

---

## 2.4 Construction of $\Pi$

The last step is to use the family  $\mathcal{G}$  of maps to build the  $t$ -rankwise independent family  $\Pi$  of permutations on  $[n]$ . Pseudocode for this process is shown in Algorithm 2. Roughly speaking, the algorithm first sorts the elements of  $[n]$  according to the order induced by the functions in  $\mathcal{G}$  and then “breaks ties” using permutations in  $\Sigma$  (see line 4); also note that the number of new permutations will hence depend on  $|\Sigma|$  which is not necessarily fixed for all  $g \in \mathcal{G}$ . The algorithm finally inserts the new permutations in  $\Pi$ . Note that in the algorithm, we view integers  $i \in [N]$  as elements of  $\mathbb{Z}_N$  in the natural manner.

In order for line 11 to make sense, we must establish the following claim.

▷ **Claim 12.** The value  $s = \tau! / |\Sigma|$  is a positive integer.

*Proof.* As above, define

$$\begin{aligned} \mathcal{Y} &= \{ y \in \mathbb{Z}_N : |g^{-1}(y)| \geq 2 \} \\ \mathcal{X} &= \bigcup_{y \in \mathcal{Y}} g^{-1}(y) = g^{-1}(\mathcal{Y}). \end{aligned}$$

Informally,  $\mathcal{Y}$  is the set of bins containing multiple balls, and  $\mathcal{X}$  is the set of balls that are not alone in their bin. By Lemma 7, we know that  $|\mathcal{X}| \leq 32t = \tau$ .

Let  $S_K$  denote the symmetric group on the set  $K$ . Observe that  $\Sigma$  is simply the direct product  $\prod_{y \in \mathbb{Z}_N} S_{g^{-1}(y)}$ , which has an obvious isomorphism to  $\prod_{y \in \mathcal{Y}} S_{g^{-1}(y)}$ , since we can ignore  $y$  with  $|g^{-1}(y)| \in \{0, 1\}$ . In turn, this is isomorphic to a subgroup of  $S_{\mathcal{X}}$ . It follows that  $|\Sigma|$  divides  $|S_{\mathcal{X}}|$ , which divides  $\tau!$  since  $|\mathcal{X}| \leq \tau$ . ◁

▷ **Claim 13.** The family  $\Pi$  is  $t$ -rankwise independent.

*Proof.* We want to show

$$\mathbb{P}(\pi(x_1) < \dots < \pi(x_t)) = \frac{1}{t!} \tag{6}$$

for any  $t$  distinct indices  $x_1, \dots, x_t$ . For notational convenience, let us assume  $x_1 = 1, x_2 = 2, \dots, x_t = t$ . It can be seen that our proof does not use the indices  $x_1, \dots, x_t$ .

To generate  $\pi$ , we will first pick  $g \in \mathcal{G}$  uniformly at random, then pick  $(\sigma_1, \dots, \sigma_N) \in \Sigma$  uniformly at random. Since each  $g \in \mathcal{G}$  produces exactly  $\tau!$  elements in  $\Pi$ , this is equivalent to picking  $\pi$  uniformly. Note that, since  $\Sigma$  is a Cartesian product, the distribution on the  $\sigma_i$  is equivalent to picking  $\sigma_i \in S_{g^{-1}(i)}$  uniformly and independently at random.

For  $i \in [t]$  define

$$R_i = \text{rank of } \pi(i) \text{ among } \pi(1), \dots, \pi(t) = |\{j \in [t]: \pi(j) \leq \pi(i)\}|.$$

Let  $\bar{R} = (R_1, \dots, R_t)$ . Let us view  $\bar{R}$  as an element of the symmetric group  $S_t$  (with  $\bar{R}(i) = R_i$ ). In the remainder of the proof, we will establish that

$$\mathbb{P}(\bar{R} = r) = \mathbb{P}(\bar{R} = r\rho) \quad \forall r, \rho \in S_t. \tag{7}$$

Together with the fact that  $1 = \sum_{\rho \in S_t} \mathbb{P}(\bar{R} = r\rho)$ , we obtain  $\mathbb{P}(\bar{R} = r) = \frac{1}{t!} \forall r \in S_t$ . Thus, when  $r$  is the identity permutation, this establishes (6), for the case  $x_i = i \forall i \in [t]$ .

In order to prove (7), let us introduce some notation for convenience. Throughout the proof, let  $\bar{X}$  denote the random vector  $(X_1, X_2, \dots, X_t)$  where  $X_i = g(i)$ . Let  $\bar{i}$  denote the  $t$ -tuple  $\bar{i} = (i_1, \dots, i_t) \in \mathbb{Z}_N^t$ . Intuitively,  $X$  gives the random locations of the first  $t$  balls, and  $\bar{i}$  gives a specific list of locations that might be the outcome for those balls.

By the law of total probability

$$\mathbb{P}(\bar{R} = r) = \sum_{\bar{i} \in \mathbb{Z}_N^t} \mathbb{P}(\bar{R} = r \mid \bar{X} = \bar{i}) \cdot \mathbb{P}(\bar{X} = \bar{i}) \tag{8}$$

$$\mathbb{P}(\bar{R} = r\rho) = \sum_{\bar{i} \in \mathbb{Z}_N^t} \mathbb{P}(\bar{R} = r\rho \mid \bar{X} = \bar{i}) \cdot \mathbb{P}(\bar{X} = \bar{i}) \tag{9}$$

Since  $\rho$  is a permutation, one can write the second equation as

$$\mathbb{P}(\bar{R} = r\rho) = \sum_{\bar{i} \in \mathbb{Z}_N^t} \mathbb{P}(\bar{R} = r\rho \mid \bar{X} = \bar{i}\rho) \cdot \mathbb{P}(\bar{X} = \bar{i}\rho), \tag{10}$$

where, for a  $t$ -tuple  $v$  and permutation  $\rho \in S_t$ , the notation  $v\rho$  denotes the  $t$ -tuple whose coordinates are permuted according to  $\rho$ , i.e.,  $(v\rho)_i = v_{\rho(i)}$ .

Observe that by the  $t$ -independence of  $X_1, \dots, X_t$ , we have

$$\mathbb{P}(\bar{X} = \bar{i}) = \mathbb{P}(\bar{X} = \bar{i}\rho) = \frac{1}{N^t}.$$

Thus to show (8) equals (10), it suffices to show that

$$\mathbb{P}(\bar{R} = r \mid \bar{X} = \bar{i}) = \mathbb{P}(\bar{R} = r\rho \mid \bar{X} = \bar{i}\rho).$$

Call the permutation  $r \in S_t$  “feasible” w.r.t. the sequence  $i_1, \dots, i_t$  if for any  $p, q \in [t]$ , if  $i_p < i_q$  then  $r(p) < r(q)$ . In words, this means that the order of  $i_1, \dots, i_t$  is given by the permutation  $r$ . It is possible that several indices in  $[t]$  have the same value in the sequence  $i_1, \dots, i_t$ , in which case  $r$  is allowed to induce any ordering among them.

We observe that  $\mathbb{P}(\bar{R} = r \mid \bar{X} = \bar{i}) = 0 \iff r$  is not feasible w.r.t  $\bar{i}$ . We also note that  $r$  is feasible w.r.t  $\bar{i}$  iff  $r\rho$  is feasible w.r.t  $\bar{i}\rho$ , and hence

$$\mathbb{P}(\bar{R} = r \mid \bar{X} = \bar{i}) = 0 \iff \mathbb{P}(\bar{R} = r\rho \mid \bar{X} = \bar{i}\rho) = 0.$$

So it remains to check the equality of the conditional probabilities for a permutation  $r$  feasible to the  $t$ -tuple  $\bar{i}$ . In fact we can calculate the conditional probability explicitly.

## 67:10 Explicit and Near-Optimal Construction of $t$ -Rankwise Independent Permutations

Let  $S = \{i_1, \dots, i_t\}$  and for  $s \in \mathbb{Z}_N$ , let  $B_s = \{k \in [t] : i_k = s\} \subseteq g^{-1}(s)$  (observe that  $B_s = \emptyset \forall s \notin S$ ). If one views the indices  $[t]$  as balls being thrown into the bins  $\mathbb{Z}_N$ , then  $S$  would be the set of bins occupied by  $[t]$  and  $B_s$  represents balls among  $[t]$  falling into bin  $s$ . For  $s \in \mathbb{Z}_N$  define the event

$$E_s = \{ \forall i, j \in B_s, \sigma_s(i) < \sigma_s(j) \iff r(i) < r(j) \} = \{ \sigma_s \text{ permutes } B_s \text{ according to } r \}.$$

Note that the permutation  $\sigma_s$  is chosen uniformly at random from  $S_{g^{-1}(s)}$ , and hence there is  $\frac{1}{|B_s|!}$  probability that the rank induced over the indices appearing in  $B_s$  is the same rank as the one induced by  $r$ . That is,

$$\mathbb{P}(E_s \mid \bar{X} = \bar{i}) = \frac{1}{|B_s|!}.$$

Note that assuming  $r$  is feasible w.r.t  $\bar{i}$ , we have  $\bar{R} = r$  iff  $\bar{R}$  and  $r$  induce the same order over all the entries of  $B_s$  for all  $s \in S$ . That is,

$$\{\bar{R} = r\} = \bigcap_{s \in S} E_s$$

conditioned on  $\bar{X} = \bar{i}$ .

Note that the permutations  $\{\sigma_s : s \in S\}$  are chosen independently when conditioned on  $\bar{X} = \bar{i}$  so  $\{E_s\}_{s \in S}$  are independent and hence

$$\mathbb{P}(\bar{R} = r \mid \bar{X} = \bar{i}) = \mathbb{P}\left(\bigcap_s E_s \mid \bar{X} = \bar{i}\right) = \prod_{s \in S} \mathbb{P}(E_s \mid \bar{X} = \bar{i}) = \prod_{s \in S} \frac{1}{|B_s|!}.$$

Finally, we verify that the analogous computation for  $\mathbb{P}(\bar{R} = r \mid \bar{X} = \bar{i}\rho)$  yields the same result. Let  $S' = \{(\bar{i}\rho)_k : k \in [t]\}$ ; since  $\rho$  is a permutation, it follows that  $S' = S$ . Similarly letting  $B'_s = \{k \in [t] : (\bar{i}\rho)_k = s\}$ , this time we have

$$\mathbb{P}(\bar{R} = r \mid \bar{X} = \bar{i}\rho) = \prod_{s \in S' = S} \frac{1}{|B'_s|!}.$$

However it is clear that  $|B_s| = |B'_s| \forall s \in \mathbb{Z}_N$ , as  $B'_s = (\rho^{-1})(B_s)$  (since  $\rho^{-1}$  is a bijection between the two sets). Therefore

$$\prod_{s \in S'} \frac{1}{|B'_s|!} = \prod_{s \in S} \frac{1}{|B_s|!}$$

which we argued earlier is sufficient to prove (7). ◁

▷ **Claim 14.** There is a constant  $C > 0$  such that  $|\Pi| \leq (Cn)^{35t}$ .

*Proof.* It is clear that each map  $g \in \mathcal{G}$  contributes exactly  $|\Sigma| \cdot s = \tau!$  permutations to  $\Pi$ . Thus,

$$|\Pi| = \tau! \cdot |\mathcal{G}| \leq (32t)^{32t} \cdot |\mathcal{H}| \leq (32n)^{32t} \cdot N^t \leq (32n)^{32t} \cdot (2n^3)^t,$$

by (1). ◁

### 3 Conclusion and Future Work

Our algorithm for constructing  $\Pi$  runs in time  $n^{O(t)}$ , which is quite efficient size  $|\Pi| = n^{O(t)}$ . However, in applications often one is interested in sampling only a single permutation from  $\Pi$ . In this case, it may be unnecessary to construct the whole family. It is natural to ask if one can give a more explicit construction of  $t$ -rankwise independent families. That is, can a  $t$ -rankwise independent family  $\Pi$  of permutations of  $[n]$  be constructed such that

- $|\Pi| \leq n^{O(t)}$ , and
- sampling a single permutation from  $\Pi$  can be done in time  $O(n)$ ?

We also re-emphasize that the problem of explicitly constructing a  $t$ -independent permutation family  $\Pi$  over  $[n]$  with  $|\Pi| \leq n^{O(t)}$  remains open. Such a construction would strengthen the results of this paper, as it would be a  $t$ -rankwise independent permutation family as well.

### A Omitted proofs

**Proof of Corollary 8.** For notational convenience, let  $X_i = |g^{-1}(i)|$  for  $i \in [N]$ . Observe that  $n = \sum_{i \in [N]} X_i$  and  $|g([n])| = \sum_{i \in [N]} 1_{\{X_i \geq 1\}}$ . Then we may write

$$\begin{aligned} 2 \cdot (n - |g([n])|) &= 2 \sum_{i \in [N]} \underbrace{(X_i - 1_{\{X_i \geq 1\}})}_{=0 \text{ if } X_i \in \{0, 1\}} = \sum_{i \in [N]} \underbrace{1_{\{X_i \geq 2\}} \cdot 2(X_i - 1)}_{\geq 1_{\{X_i \geq 2\}} \cdot X_i} \\ &\geq \sum_{i \in [N]} 1_{\{X_i \geq 2\}} \cdot X_i = |\mathcal{X}|. \end{aligned}$$

Thus, by Lemma 7,  $|\mathcal{X}| \leq 2 \cdot (n - |g([n])|) \leq 2 \cdot (16t) = 32t$ . ◀

## 67:12 Explicit and Near-Optimal Construction of $t$ -Rankwise Independent Permutations

**Proof of Theorem 11.** Observe that

$$\mathbb{1}_{\{\sum_{i=1}^n Y_i \geq (1+\delta)\mu\}} \leq \exp\left(\lambda \sum_{i=1}^n Y_i - \lambda(1+\delta)\mu\right)$$

and hence taking expectations implies

$$\mathbb{E}\mathbb{1}_{\{\sum_{i=1}^n Y_i \geq (1+\delta)\mu\}} = \mathbb{P}\left(\sum_{i=1}^n Y_i \geq (1+\delta)\mu\right) \leq \mathbb{E}\exp\left(\lambda \sum_{i=1}^n Y_i - \lambda(1+\delta)\mu\right).$$

Next, as shown in [8, Theorem 4.1 and its proof], letting  $\lambda = \ln(1+\delta)$ , we have the inequality

$$\mathbb{E}\exp\left(\lambda \sum_{i=1}^n Y_i - \lambda(1+\delta)\mu\right) \leq \left(\frac{e^\delta}{(1+\delta)^{1+\delta}}\right)^\mu.$$

It remains to prove that

$$\left(\frac{e^\delta}{(1+\delta)^{1+\delta}}\right)^\mu \leq (1+\delta)^{-(1+\delta)\mu/4} \quad \forall \delta \geq 1.$$

As  $0 \leq \mu$ , it suffices to show

$$\frac{e^\delta}{(1+\delta)^{1+\delta}} \leq (1+\delta)^{-(1+\delta)/4} \quad \forall \delta \geq 1.$$

After taking logs and performing simple algebraic manipulations, we arrive at another equivalent inequality

$$\frac{4}{3} \leq \left(1 + \frac{1}{\delta}\right) \ln(1+\delta) \quad \forall \delta \geq 1.$$

For  $x \geq 0$ , let  $f(x) = \left(1 + \frac{1}{x}\right) \ln(1+x)$ . We note that

$$f'(x) = \frac{x - \ln(1+x)}{x^2} \geq 0 \quad \forall x > 0$$

since  $\ln(x+1) \leq x \quad \forall x > 0$ . Thus in particular  $f$  is non-decreasing over  $[1, \infty)$  and hence

$$\left(1 + \frac{1}{\delta}\right) \ln(1+\delta) = f(\delta) \geq f(1) = 2 \ln(2) > \frac{4}{3} \quad \forall \delta \geq 1$$

as desired. ◀

# Sparse High Dimensional Expanders via Local Lifts

## Abstract

---

High dimensional expanders (HDXs) are a hypergraph generalization of expander graphs. They are extensively studied in the math and TCS communities due to their many applications. Like expander graphs, HDXs are especially interesting for applications when they are bounded degree, namely, if the number of edges adjacent to every vertex is bounded. However, only a handful of constructions are known to have this property, all of which rely on algebraic techniques. In particular, no random or combinatorial construction of bounded degree high dimensional expanders is known. As a result, our understanding of these objects is limited.

The degree of an  $i$ -face in an HDX is the number of  $(i + 1)$ -faces that contain it. In this work we construct complexes whose higher dimensional faces have bounded degree. This is done by giving an elementary and deterministic algorithm that takes as input a regular  $k$ -dimensional HDX  $X$  and outputs another regular  $k$ -dimensional HDX  $\widehat{X}$  with twice as many vertices. While the degree of vertices in  $\widehat{X}$  grows, the degree of the  $(k - 1)$ -faces in  $\widehat{X}$  stays the same. As a result, we obtain a new “algebra-free” construction of HDXs whose  $(k - 1)$ -face degree is bounded.

Our construction algorithm is based on a simple and natural generalization of the expander graph construction by Bilu and Linial [12], which build expander graphs using lifts coming from edge signings. Our construction is based on *local lifts* of high dimensional expanders, where a local lift is a new complex whose top-level links are lifts of the links of the original complex. We demonstrate that a local lift of an HDX is also an HDX in many cases.

In addition, combining local lifts with existing bounded degree constructions creates new families of bounded degree HDXs with significantly different links than before. For every large enough  $D$ , we use this technique to construct families of bounded degree HDXs with links that have diameter  $\geq D$ .

## 1 Introduction

Expander graphs are graphs that are well connected. These objects are studied extensively in computer science and mathematics [40], and since their discovery they have found numerous applications in complexity [25, 62], coding theory [64, 66, 26], derandomization [40, 33] and more. Most of these applications rely on families of expander graphs that have a bounded degree. It is well known that random regular graphs are expanders, and many explicit bounded degree constructions are also in hand [55, 51, 63, 12, 54].

Recently, the study of *high dimensional expanders* (HDXs) emerged (see surveys [49, 37]). These are hypergraph analogues of expander graphs. While the full potential of high dimensional expanders is yet to be discovered, they are already important objects of study. High dimensional expanders, and especially bounded degree high dimensional expanders<sup>1</sup> have already yielded exciting applications in various areas such as locally testable codes [26, 61, 28], quantum complexity [7], sampling and Markov chains [27, 43], agreement testing [27, 24, 8], high dimensional geometry and topology [38, 30], pseudorandomness [19] and random (hyper)graph theory [46, 56].

The specific family of high dimensional expanders used in many of the aforementioned applications is tailor-made to satisfy other desired properties, in addition to high dimensional expansion. For example, the local neighborhoods in the high dimensional expanders used in [26, 61, 28] are tailored so that one can define a small locally testable code on them; the high dimensional expanders in [38, 24, 8] also have a vanishing 1-cohomology over certain group coefficients.

However, constructing bounded degree high dimensional expanders (for arbitrarily small spectral expansion of the links) is still a serious challenge. No random model for bounded degree high dimensional expanders is known, and all deterministic constructions known use non-trivial algebraic techniques. The fact that we have only a handful of bounded degree constructions to choose from, makes these objects difficult to understand and to work with. We believe that many further applications await us once we learn how to diversify these constructions, in the same way that many of the above-mentioned applications of expander graphs grew out of more varied expander constructions that were discovered.

Nowadays, all known constructions of HDXs rely on algebraic techniques, including quotients of the Bruhat Tits buildings [10, 16, 45, 52, 22, 24, 8] and coset complexes [42, 31, 59] (see also [39] for a more elementary analysis of some of these HDXs). There have been attempts at constructing bounded degree HDXs with combinatorial tools, but all these constructions fall short either in bounded degree [35, 47] or in their local spectral expansion [20, 21, 17, 48, 34].

In particular, it is an important open question whether an algorithm à la Zig-Zag product [63] exists for bounded degree high dimensional expanders. That is, an algorithm that given a bounded degree high dimensional expander as input, outputs another high dimensional expander with more vertices and the same bound on the degree and spectral expansion.

As an intermediate result, in this work we develop an algorithm that takes a high dimensional expander as input, and outputs another high dimensional expander with more vertices, the same bound on spectral expansion and the same bound on *the degree of high dimensional faces* (but not on the degree vertices). This algorithm is entirely combinatorial, relying only on the theory of graph covers initiated by [5, 12]. While families of complexes

---

<sup>1</sup> A family of HDXs is called *bounded degree* if there is some  $M > 0$  so that all vertices in every HDX in the family have degree at most  $M$ .

constructed via such an algorithm are not sufficient for applications that require the vertex degree to be bounded, we view this as a stepping stone towards an “algebra free” construction of bounded degree HDXs. One exception to this is the recent work by [3], which analyzes a variant of the well known Glauber dynamics (or up-down) random walk on HDXs. The walk that [3] analyzes has bounded degree if and only if the underlying HDX is  $(k - 1)$ -bounded degree.

## 1.1 Preliminaries on High Dimensional Expanders

To better understand our results, let us introduce some standard definitions and notation on simplicial complexes (see Section 2.3 for a more elaborated definitions). A simplicial complex is a hypergraph that is downwards closed to containment. A simplicial complex is  $k$ -dimensional if the largest hyperedge in the complex is of size  $(k + 1)$ . We denote by  $X(\ell)$  the sets (aka faces) of size  $\ell + 1$ . Let  $X$  be a  $k$ -dimensional simplicial complex.

The degree of a face  $\sigma \in X(\ell)$ , is  $d(\sigma) := |\{\tau \in X(\ell + 1) \mid \tau \supseteq \sigma\}|$ . A family of complexes  $\{X_i\}_{i=0}^\infty$  is  $\ell$ -bounded degree if there exists an  $M > 0$  that bounds the degrees of *all*  $\ell$ -faces across *all the complexes simultaneously*. That is, for every  $i$  and any  $\sigma \in X_i(\ell)$ ,  $d(\sigma) \leq M$ . We say that a family of complexes are bounded degree if they are 0-bounded degree. We say that a complex is  $(d_0, d_1, \dots, d_{k-1})$ -regular if for every  $\sigma \in X(\ell)$ ,  $d(\sigma) = d_\ell$ .

In this paper we are mainly interested in the local spectral expansion definition of high dimensional expanders (see [49] for a survey on other definitions). For this we need to define “links”, the generalization of vertex neighborhoods in graphs. For a face  $\sigma \in X$ , the link of  $\sigma$  is the simplicial complex  $X_\sigma = \{\tau \setminus \sigma \mid \sigma \subseteq \tau \in X\}$ . We will be interested in the graph structure underlying the complex and its links. The 1-skeleton of  $X$  is the graph whose vertices are  $X(0)$  and whose edges are  $X(1)$ .

► **Definition 1** (High dimensional expander). *For  $\lambda > 0$  we say that  $X$  is a  $\lambda$ -two sided (one sided) high dimensional expander if for every  $\ell \leq k - 2$  and  $\sigma \in X(\ell)$ , the 1-skeleton of  $X_\sigma$  is a  $\lambda$ -two sided (one sided) spectral expander.*

## 1.2 Our Results

Our results are based on the notion of a graph lifts. We say a graph  $\widehat{G} = (\widehat{V}, \widehat{E})$  is a lift of a graph  $G = (V, E)$  if there exists a graph homomorphism  $\phi : \widehat{V} \rightarrow V$  such that for every  $\hat{v} \in \widehat{V}$ , the mapping  $\phi$  is a bijection on the neighborhood of  $\hat{v}$ . Intuitively, a lift of a graph  $G$  is a large graph  $\widehat{G}$  that locally looks the same as  $G$ . Graph lifts are essential in many constructions of expander graphs [5, 12, 54], and our construction builds on the beautiful work of [12]. We elaborate more on this below.

Our main result is a construction algorithm that maintains both expansion and the degree of the  $(k - 1)$ -faces of a regular complex. This algorithm takes as input a  $(d_0, d_1, \dots, d_{k-1})$ -regular  $\lambda$ -high dimensional expander  $X$ , and outputs a  $(2d_0, 2d_1, \dots, 2d_{k-2}, d_{k-1})$ -regular  $\widehat{X}$  with twice as many vertices that is also a  $\lambda$ -HDX (even though the number of intermediate faces grows like  $|\widehat{X}(i)| = 2^i |X(i)|$  for  $i \leq k - 1$ ). This algorithm uses the notion of random lifts [12], and in particular, it requires no algebraic machinery for the construction nor the analysis. More formally, this is the theorem we prove.

► **Theorem 2** (See Theorem 28 for a more precise statement). *There exists a randomized algorithm  $\mathcal{A}$  that takes as input a  $k$ -dimensional complex  $X_0$  and an integer  $i \geq 1$ , runs in expected time  $\text{poly}((2^i |X_0(0)|)^k)$  at most, and outputs a  $k$ -dimensional complex  $X_i$  with  $2^i |X_0(0)|$  vertices. The algorithm has the following guarantees.*

1. If  $X_0$  is a  $(d_0, d_1, \dots, d_{k-1})$ -regular  $\lambda$ -two sided high dimensional expander, then  $X_i$  is a  $(2^i d_0, \dots, 2^i d_{k-2}, d_{k-1})$ -regular  $\lambda'$ -two sided high dimensional expander where  $\lambda' = O\left(\max\left\{\lambda\left(1 + \log \frac{1}{\lambda}\right), \sqrt{\frac{\log^3 d_{k-1}}{d_{k-1}}}\right\}\right)$ .
2. For every  $\hat{\sigma} \in X_i(k-2)$ , the link  $(X_i)_{\hat{\sigma}}$  is a lift of  $(X_{i-1})_{\sigma}$  for some  $\sigma \in X_{i-1}(k-2)$ . For every  $j \leq k-2$ ,  $|X_i(j)| = 2^{(j+1)i}|X_0(j)|$ .

There are various complexes in hand that one can use as the input to this algorithm. These include the complete complex, the complexes from [50], and even complexes from bounded degree families that are regular, such as those constructed by [31].

We give two proofs to Theorem 2, building on the techniques developed by [12] to analyze lifts in expander graphs, and extend them to high dimensional expanders.

While most of the work in [12] regards random lifts of graphs, they also show how to deterministically find expander graphs using lifts. Building on their method, we also give a deterministic algorithm for finding the complexes in Theorem 2, albeit under some more assumptions on the input  $X_0$ . This provides a *deterministic, polynomial time and elementary* construction of a family of  $(k-1)$ -bounded  $k$ -dimensional high dimensional expanders.

► **Theorem 3** (See Theorem 35). *There exists a deterministic algorithm  $\mathcal{B}$  that takes as input a  $k$ -dimensional complex  $X_0$  and an integer  $i \geq 1$ , runs in time  $\text{poly}((2^i |X_0(0)|)^k)$  at most, and outputs a  $k$ -dimensional complex  $X_i$  with  $2^i |X_0(0)|$  vertices. The algorithm has the following guarantees.*

1. If  $X_0$  is a  $(d_0, d_1, \dots, d_{k-1})$ -regular  $\lambda$ -two sided high dimensional expander, such that  $d_{k-1} > 2^{10k}$  and  $|X_0(k-2)| \leq (d_{k-2})^{10k}$ , then  $X_i$  is a  $(2^i d_0, \dots, 2^i d_{k-2}, d_{k-1})$ -regular  $\lambda'$ -two sided high dimensional expander where  $\lambda' = O\left(2^{5k} \max\left\{\lambda\left(1 + \log \frac{1}{\lambda}\right), \sqrt{\frac{\log^3 d_{k-1}}{d_{k-1}}}\right\}\right)$ .
2. For every  $\hat{\sigma} \in X_i(k-2)$ , the link  $(X_i)_{\hat{\sigma}}$  is a lift of  $(X_{i-1})_{\sigma}$  for some  $\sigma \in X_{i-1}(k-2)$ . For every  $j \leq k-2$ ,  $|X_i(j)| = 2^{(j+1)i}|X_0(j)|$ .

Not only is our construction deterministic, but it is also simple and versatile; one can apply it to various kinds of high dimensional expanders, and the family of HDXs obtained by doing so is changes according to the initiating HDX given at the beginning of the process.

### 1.3 Comparing to Random Constructions of HDXs

In the graph case the configuration model yields regular and bounded degree expanders. In contrast, there is no immediate generalization of this model to higher dimensions, that leads to bounded degree HDXs, even if one only wishes to bound the degrees of higher dimensional faces. If one settles for logarithmic degree, then one could use the [46] random model to construct random HDXs. The degree of the top-level faces of these complexes is  $O(\log n)$ , where  $n$  is the number of vertices, and the degree of the lower dimensional faces is polynomial in  $n$ . For 2-dimensional complexes, the random geometric model in [47] offers an improvement to the vertex degree that one gets from [46], but it is still polynomial.

It is tempting to try and adapt the [46] model for constructing  $(k-1)$ -bounded degree HDXs, but doing so in a straightforward manner falls short of achieving that. The work by [50] found an appropriate generalization of the random model that gives  $(k-1)$ -bounded degree HDXs, utilizing the breakthrough work of [44] on Steiner systems. In their model, one takes a complete  $(k-1)$ -skeleton and samples  $k$ -faces by sampling random Steiner systems on this complex.

Our construction sidesteps this difficulty by taking a different approach; it uses random *local lifts* of HDXs (presented in the following subsection) instead of trying to construct random ones from scratch. In this setting, the high dimensional case behaves more similar

to the 1-dimensional one - our work shows that random local lifts of HDXs are HDXs with high probability. Of course, this requires an appropriate modification of the lift notion to local lifts.

### 1.4 The Construction

We now dive into the heart of Theorem 2. Our construction builds upon the work of random lifts of graphs studied in [12]. Random lifts of expanders have been subject to extensive research (e.g., [6, 12, 2, 54, 14]). However, in this work, we do not try to lift the complex itself. Instead, we construct another complex where the  $(k - 2)$ -links are lifts of links in the original complex. We call such a complex a *local lift*.

Let us first explain the idea behind the work of [12]. Their work suggests a construction of bounded degree family of expander graphs  $\{G_i\}_{i=0}^\infty$ , where for every  $i$ ,  $G_{i+1}$  is a lift of  $G_i$ . The fact that the maximal degree of  $G_{i+1}$  is equal to the maximal degree of  $G_i$  promises that the sequence is bounded degree. Therefore, one only needs to worry about expansion.

The work [12] studies random lifts sampled using signings on the edges of a graph  $G = (V, E)$ , that is, functions  $f : E \rightarrow \{\pm 1\}$ . Given such a signing  $f$ , one can construct the following lift  $\widehat{G} = (\widehat{V}, \widehat{E})$  by setting  $\widehat{V} = V \times \{\pm 1\}$  and  $\{(v, i), (u, j)\} \in \widehat{E}$  if  $\{v, u\} \in E$  and  $i \cdot j = f(\{u, v\})$ .

The work of [12] analyzes when a lift  $\widehat{G}$  obtained by random signing  $f$  is an expander graph. They give a proof (based on the Lovász Local Lemma) that every expander  $G$  has such a “good” signing. They also provide a deterministic algorithm to construct such a lift using the conditional probabilities method [4]. Our construction generalizes this idea, only instead of lifts coming from edge signings, we define *local lifts* coming from *face*-signings.

Let  $X$  be a  $k$ -dimensional simplicial complex and let  $f : X(k) \rightarrow \{\pm 1\}$ . Define the  $k$ -dimensional complex  $\widehat{X}$  (where  $f$  is implicit in the notation) as a complex whose vertices are  $\widehat{X}(0) = X(0) \times \{\pm 1\}$ , and whose  $k$ -faces are

$$\widehat{X}(k) = \left\{ \left\{ v_0^{j_0}, v_1^{j_1}, \dots, v_k^{j_k} \right\} \mid \{v_0, v_1, \dots, v_k\} \in X(k) \text{ and } \prod_{i=0}^k j_i = f(\{v_0, v_1, \dots, v_k\}) \right\}.$$

For  $1 \leq \ell \leq k - 1$  the  $\ell$ -faces are independent of the second coordinate, that is,

$$\widehat{X}(\ell) = \left\{ \left\{ v_0^{j_0}, v_1^{j_1}, \dots, v_\ell^{j_\ell} \right\} \mid \{v_0, v_1, \dots, v_\ell\} \in X(\ell) \right\}.$$

Obviously, the underlying graph of  $\widehat{X}$  is *not* a lift of the underlying graph of  $X$ . Indeed, the degree of each vertex is doubled. However, for every  $\hat{\sigma} \in \widehat{X}(k - 2)$ , we show that  $\widehat{X}_{\hat{\sigma}}$  is isomorphic to a lift of  $X_\sigma$  (where  $\sigma = \{v \mid v^j \in \hat{\sigma}\}$ ).

Indeed, let us assume for simplicity that  $k = 2$ . Consider the link of a vertex  $v^j \in \widehat{X}(0)$  and define the function  $g : X_v(1) \rightarrow \{\pm 1\}$  by  $g(uw) = j \cdot f(uw)$ . We claim that  $\widehat{X}_{v^j}$  is the cover  $g$  induces on  $X_v$ . It is easy to see that its vertices are  $\widehat{X}_{v^j}(0) = X_v(0) \times \{\pm 1\}$ , since the vertices in  $\widehat{X}_{v^j}$  correspond to edges in  $\widehat{X}(1)$ . These are precisely all  $u^1, u^{-1}$  where  $u \in X_v(0)$ .

The edges are more delicate. Edges  $\{u^{j'}, w^{j''}\} \in \widehat{X}_{v^j}(1)$  correspond to triangles  $\{v^j, u^{j'}, w^{j''}\} \in \widehat{X}$ . Indeed, such a triangle is in  $\widehat{X}$  if and only if  $\{u, w\} \in X_v(1)$  and  $j \cdot j' \cdot j'' = f(\{v, u, w\})$ . The second condition occurs if and only if  $j \cdot j' \cdot j'' = g(uw)$ . Hence,  $\widehat{X}_{v^j}$  is the cover  $g$  induces on  $X_v$ .

As mentioned above, we give two proofs that signings  $f$  so that  $\widehat{X}$  is a high dimensional expander exist. The first proof is based on the Lovász Local Lemma and follows the argument in [12, Lemma 3.3], and generalizes it so that multiple links may be taken into account

simultaneously. The second proof is based on a different way to use the Lovász Local Lemma (together with other results from [12]) which we find simpler, to deduce high dimensional expansion. This proof, while more restrictive on the link sizes, can be combined with the algorithmic version of the Lovász Local Lemma [57], to prove Theorem 2. Afterwards, we show that if the links of the complex  $X$  are already dense, then the derandomization technique in [12] works for high dimensional expanders, and we can obtain a deterministic construction for  $(k - 1)$ -bounded  $k$ -dimensional high dimensional expanders, proving Theorem 3.

## 1.5 Understanding Vertex vs. Edge Degree in Bounded-Degree Constructions

We can use Theorem 2 to diversifying links in other existing bounded degree constructions, and thus gain more understanding on how possible high dimensional expanders may look like. For simplicity, let us stick to the 2-dimensional case, and consider the question *how small could  $d_1$  be given  $d_0$  in a  $(d_0, d_1)$ -regular high dimensional expander?*

Let us consider the behavior of  $d_0$  and  $d_1$  in the known bounded degree constructions [10, 16, 45, 52, 42, 31, 22, 24, 8]. In all the above,  $d_0$  grows to infinity as  $\lambda$  goes to 0, and  $d_1 = \text{poly}(d_0)^2$ . In other words, the links themselves are “locally” dense. A natural question to ask is whether the lower bound of  $d_1 \geq d_0^{\Omega(1)}$  is necessary for *bounded degree* constructions. In expander *graphs* it is well known that one can increase the size of the graph without increasing the bound on the degree, but this is not the behavior in the known bounded-degree HDX constructions.

We note that if one allows  $d_0$  to tend to infinity with  $n$ , rather than staying constant, then works such as [50] (and also infinite families of complexes constructed by iteratively applying Theorem 3) show that this is false. But this question is more interesting when its bounded degree.

Theorem 3 gives a negative answer to this question in the 2-dimensional case, by proving the following.

► **Theorem 4.** *For every  $\lambda > 0$  and any sufficiently large  $M > 0$ , there exists an infinite family of 2-dimensional  $\lambda$ -two sided high dimensional expanders that are  $(d_0, \exp(\text{poly}(\frac{1}{\lambda})))$ -regular, for  $M \leq d_0 \leq 2M$ .*

*In particular, for every large enough  $D > 0$ , there exists an infinite family of 2-dimensional  $\lambda$ -two sided HDXs such that the diameter in every link  $X_v$ , is at least  $D$ .*

We stress that  $d_1 = \exp(\text{poly}(\frac{1}{\lambda}))$  depends only on the spectral expansion and not on the number of vertices or  $d_0$ .

The proof of Theorem 4 appears in the full version of this paper [11].

## 1.6 Related Work

### Bounded degree HDX

As discussed above, all known constructions of bounded degree high dimensional expanders use algebraic techniques. The first bounded degree high dimensional expanders for arbitrarily small  $\lambda > 0$  was by [10]. This was followed by many other works that aimed to construct the high dimensional equivalent to Ramanujan graphs [16, 45, 53, 52]. All these constructions

---

<sup>2</sup> Technically most of the constructions above are not *regular*, only bounded degree, so  $d_0$  and  $d_1$  should be average values, but we ignore this point for the sake of presentation.

are quotients of  $\tilde{A}$ -type Bruhat Tits buildings. The work by [22] used this building together with complex lifts to construct other high dimensional expanders. Recently, high dimensional expanders that come from  $\tilde{C}$  Bruhat Tits buildings were also constructed and studied [18, 24, 8]. A second type of constructions come from coset complexes, first studied by [42]. More complexes of this type were constructed by [31, 59]. We mention that the work by [39] simplified the analysis of these coset complexes, and gave a description of the complexes in [42] in relatively elementary means (albeit still relying on algebraic methods).

Interestingly, [50] give a randomized construction of a  $(k - 1)$ -bounded degree family of  $\lambda$ -HDXs for arbitrarily small  $\lambda > 0$ . This construction is based on random Steiner systems and given in the breakthrough result of [44]. The underlying  $(k - 1)$ -skeletons of the complexes in that family are complete.

There are other bounded degree constructions [20, 21, 17, 48, 34]. These constructions have various mixing properties, but none of them are  $\lambda$ -HDXs for  $\lambda < \frac{1}{2}$  (where  $\lambda$  is normalized between 0 and 1). There are other constructions of  $\lambda$ -HDXs for  $\lambda < \frac{1}{2}$ , which are not bounded degree, but are still non-trivially sparse. These include [35] - based on Grassmann posets, and [47] - based on random geometric graphs of the sphere.

Finally, we comment that previous works also considered the possible degrees  $(d_0, d_1)$  possible in a high dimensional expanders. The work by [31] used irregular algebraic constructions of bounded degree  $\lambda$ -HDXs and “regularized” them, thus showing that there exists bounded degree HDXs that are regular for arbitrarily small  $\lambda$ . The work by [17] gives a lower bound on the expansion of the underlying graph of the complex in terms of  $(d_0, d_1)$ , but this lower bound does not rule out (or construct) such HDXs with  $d_1 \ll d_0$ .

## Graph and HDX lifts

The study of random graph lifting was initiated in [5]. Random lifts from signings of expanders were studied in [12] where it was proven that with high probability they are also expanders. This was extended to larger lifts as well [60, 1]. Friedman showed that random lifts of Ramanujan graphs are nearly Ramanujan [32] (see also [14]). In the seminal paper by [54], Ramanujan bipartite graphs were constructed by using graph lifts. One can also define lifts of simplicial complexes. Most known bounded degree high dimensional expanders are constructed using a dual notion of lifts - that is, taking quotients of an infinite object [10, 16, 45, 53, 52, 42], in a way such that the infinite object is a lift of the complex that is constructed. [22] studied taking random lifts of simplicial complexes as in [12], but the construction there needed the use of algebraic techniques as well.

## 1.7 Open Questions

### Combinatorial constructions

As we mention earlier, there is no construction of bounded degree high dimensional expanders that does not rely on non-trivial algebraic techniques. As an intermediate step towards such a construction, can one give a construction of  $k$ -dimensional simplicial complexes that are  $(k - 2)$ -bounded degree (or  $i$ -bounded degree for any  $i < k - 1$ )?

### Links with other properties

Fix a vertex set  $[n]$  and graphs  $\{G_i\}_{i=1}^n$  (one graph for every vertex  $i \in [n]$ ). It is interesting to understand whether there exists a graph whose vertex set is  $V = [n]$ , and such that the neighborhood of every vertex  $i \in V$  is (isomorphic to)  $G_i$ . The structure of such graphs is an

extensive topic of study, especially in the case where all  $G_i$ 's are equal (see, e.g., [15, 13, 58]). One of the major components in the works [26, 61] that constructed asymptotically good locally testable codes and quantum codes, is a construction of graphs that locally look like a neighborhood of a graph product, but globally have improved expansion properties.

In this work, we propose a technique that addresses a related problem. Given a graph  $G$  (which is the one skeleton of a regular 2-dimensional complex  $X$ ), we find a graph  $\widehat{G}$  where every neighborhood in  $\widehat{G}$  is a random (or deterministic) 2-lift of a corresponding neighborhood in  $G$ . Is there a technique that allows us to do so for *any* set of 2-lifts of the respective vertex neighborhoods?

### Other notions of expansion

In this paper we mainly deal with local spectral expansion, but other definitions of high dimensional expansion also exist. Most notable is the notion of coboundary expansion defined independently in [46] and [38]. This notion is important for many applications of high dimensional expanders such as code construction [26], topological expansion [38] and property testing [41, 36, 23, 9]. Does a local lift maintain coboundary expansion? If not, is it maintained in interesting special cases?

### Better local spectral expansion

Works following [12] such as [54, 14] improved the bounds on the spectrum of lifts of regular graphs. Can one construct local lifts of regular high dimensional expanders that are also *Ramanujan*?

## 1.7.1 Organization of This Paper

The necessary preliminaries are given in Section 2. We describe local lifts in Section 3 and describe some of their basic properties. In Section 4 we show existence of good local lifts by modifying a Lovász Local Lemma argument by [12]. In Section 5 we prove Theorem 2 using the algorithmic Lovász Local Lemma [57] and derive Theorem 4. In Section 6 we show that the method of derandomization in [12] could be generalized to our case as well and prove Theorem 3.

## 2 Preliminaries

Unless explicitly stated, all logarithms are with base 2. The  $\ln$  function is a logarithm with base  $e$ . We write  $A \sqcup B$  to denote a disjoint union of sets  $A, B$ . For  $n \geq 0$  we write  $[n] = \{0, 1, \dots, n\}$ . For a square matrix (or equivalently, a linear operator on a finite vector space), we write  $\|A\|$  to denote the operator norm.

### 2.1 Graphs

Let  $G = (V, E)$  be a graph. For  $u, v \in V$  we write  $\Gamma(v)$  for the set of  $v$ 's neighbors in  $G$  and  $u \sim v$  if  $u$  and  $v$  are neighbors. The *indicator vector* of a set  $S \subseteq V$ , denoted by  $\mathbf{1}_S$ , is  $\mathbf{1}_S : V \rightarrow \{0, 1\}$  with  $\mathbf{1}_S(v) = 1 \iff v \in S$ . For two sets  $S, T \subseteq V$  we write  $E_G(S, T)$  for the set of edges in  $G$  between  $S$  and  $T$ . The *graph induced by  $S$  and  $T$*  is  $G' = (S \cup T, E_G(S, T))$ . For a  $d$ -regular graph we denote  $\ell_2(V) = \{f : V \rightarrow \mathbb{R}\}$  endowed with the inner product  $\langle f, g \rangle = \sum_{v \in V} f(v)g(v)$ .

### 2.1.1 Expander Graphs

Expander graphs are graphs with good connectivity properties. There are many equivalent ways to define expanders [40]. In this manuscript we focus on *spectral expansion*.

Let  $G = (V, E)$  be a  $d$ -regular graph. The *random walk matrix* of  $G$  is a matrix  $A \in \mathbb{R}^{V \times V}$  defined by  $A(u, v) = \frac{1}{d}$  if  $u \in \Gamma(v)$  and otherwise 0. Equivalently, it corresponds to the random walk operator  $A : \ell_2(V) \rightarrow \ell_2(V)$  with  $Af(v) = \frac{1}{d} \sum_{u \in \Gamma(v)} f(u)$ . We abuse notation and use  $A$  for both the matrix and the random walk operator it represents. We sometimes denote this operator by  $A_G$  when  $G$  is unclear from the context.

The operator  $A$  is self adjoint with respect to the inner product. Therefore, it has an orthonormal basis of real-valued eigenvectors, where the eigenvalues are denoted by  $1 = \lambda_1 \geq \lambda_2 \geq \dots \geq \lambda_n$ . We elaborate and write  $\lambda_i(G)$  when the graph in question is unclear from the context. The *spectrum of  $G$*  is the spectrum of its random walk matrix and is denoted by  $\text{Spec}(G)$ .

► **Definition 5** (spectral expander). *For  $\lambda \in [0, 1]$  we say that  $G$  is  $\lambda$ -two sided (resp. one sided) spectral expander (or expander for short) if  $\lambda \geq \max\{\lambda_2, |\lambda_n|\}$  (resp.  $\lambda \geq \lambda_2$ ).*

### 2.1.2 Tensor Product

Let  $G, H$  be any graphs. The *tensor product* of  $G$  and  $H$ , denoted by  $G \otimes H$ , is the graph with vertices  $V(G) \times V(H)$ , and edges  $E(G \otimes H) = \{(a, b)(a', b') \mid \{a, a'\} \in E(G) \text{ and } \{b, b'\} \in E(H)\}$ . The following fact is well known.

► **Fact 6.** *Let  $G, H$  be graphs. If  $H, G$  are  $\lambda, \lambda'$ -two sided spectral expanders respectively, then  $G \otimes H$  is a  $\max\{\lambda, \lambda'\}$ -two sided spectral expander. Moreover, if  $H$  is a  $\lambda$ -two sided spectral expander and  $G$  is a  $\lambda'$ -one sided spectral expander, then  $G \otimes H$  is a  $\max\{\lambda, \lambda'\}$ -one sided spectral expander.*

## 2.2 Graph Lifts

Graph lifts are an important notion, studied first by [5, 6] (although the notion of lifts themselves is a classical notion in algebraic topology known for about a century).

► **Definition 7** (lift). *For finite, connected and simple graphs  $G$  and  $\widehat{G}$ , a lift (also known as a covering map)  $\phi : \widehat{G} \rightarrow G$  is a graph homomorphism with the property that for all  $\hat{v} \in V(\widehat{G})$ ,  $\phi$  maps the neighborhood of  $\hat{v}$  in  $\widehat{G}$  onto the neighborhood of  $\phi(\hat{v})$  in  $G$ . Finally, we say that  $\widehat{G}$  is an  $\ell$ -lift of  $G$  if there exists an  $\ell$ -to-1 covering map  $\phi : \widehat{G} \rightarrow G$ .*

One way to construct a 2-lift is to use a signing function on the edges as follows.

► **Definition 8** (Function induced lift). *Let  $G = (V, E)$  be a graph and let  $f : E \rightarrow \{\pm 1\}$  be a signing. The  $f$ -induced lift  $\widehat{G} = \widehat{G}^f$  is the graph whose vertices are  $\widehat{V} = V \times \{\pm 1\} = \{v^j \mid v \in V, j \in \{\pm 1\}\}$  and whose edges are  $\widehat{E} = \{\{v^j, u^i\} \mid \{v, u\} \in E, ij = f(\{u, v\})\}$ . The lift map is  $\phi(v^j) = v$ .*

It is elementary to prove this construction is indeed a lift, so we omit this proof. It is also easy to show that any 2-lift is an induced lift for some signing  $f : V(G) \rightarrow \{\pm 1\}$ . See [65] for a more general statement and proof.

In Section 3 we generalize the notion of graph lifts to *local lifts* of simplicial complexes.

### 2.2.1 Signing Functions and Lift Expansion

Fix a graph  $G$  and a signing  $f : E(G) \rightarrow \{\pm 1\}$ . In this subsection, we characterize the eigenvalues of an  $f$ -induced lift. For this, we need to define the  $f$ -signing of an adjacency operator. For a  $d$ -regular graph the  $f$ -signing of the adjacency operator is the matrix  $A^f(u, v) = f(u, v) \cdot A(u, v)$  for  $\{u, v\} \in E$  and  $A^f(u, v) = 0$  if  $\{u, v\} \notin E$ .

This signing matrix is closely related to the random walk operator of the lift. In particular, the following is by now classical.

► **Lemma 9.** *Let  $G$  be a  $d$ -regular graph and let  $\widehat{G}$  be an  $f$ -induced 2-lift. Then the eigenvalues of  $A_{\widehat{G}}$  are the union (with multiplicities) of the eigenvalues of  $A$  and those of  $A^f$ . In particular, if  $\|A^f\| \leq \lambda$  and  $G$  is a  $\lambda'$ -two sided (resp. one sided) spectral expander, then  $\widehat{G}$  is a  $\max\{\lambda, \lambda'\}$ -two sided (resp. one sided) spectral expander.*

Using this lemma, [12] gave a criterion for the expansion of the lift graph.

► **Lemma 10** ([12, Lemma 3.3]). *Let  $G, f$  and  $A^f$  be as above and assume that  $G$  is a  $\lambda$ -two sided (resp. one sided) spectral expander with no self loops. Assume that for any pair of disjoint  $S, T \subseteq V(G)$  it holds that  $|\langle \mathbf{1}_S, A^f \mathbf{1}_T \rangle| \leq \alpha \sqrt{|S||T|}$ , then  $\widehat{G}^f$  is a  $\lambda'$ -two sided (resp. one-sided) spectral expander where  $\lambda' = \max\{\lambda, O(\alpha(1 + \log \frac{1}{\alpha}))\}$ .*

We note that there is a nice formula for this inner product, which is  $\langle \mathbf{1}_S, A^f \mathbf{1}_T \rangle = \frac{1}{d} \sum_{(v,u):\{v,u\} \in E(G)} f(u, v) \mathbf{1}_S(v) \mathbf{1}_T(u)$ .

## 2.3 High Dimensional Expanders

► **Definition 11** (simplicial complex). *A  $k$ -dimensional simplicial complex is a finite hypergraph  $X$  that is downwards closed to containment. That is, if  $\tau \in X$  and  $\sigma \subseteq \tau$  then  $\sigma \in X$ .*

We write  $X = X(-1) \sqcup X(0) \sqcup X(1) \sqcup \dots \sqcup X(k)$ , where  $X(\ell) = \{\sigma \in X \mid |\sigma| = \ell + 1\}$  (here  $X(-1) = \{\emptyset\}$  is mainly a formality) and the maximal size of a set  $\sigma \in X$  is  $k + 1$ . We call elements  $\sigma \in X(\ell)$   $\ell$ -faces, and in this case we say that  $X$  is  $k$ -dimensional. In this paper we will always assume the simplicial complex in question is *pure*, that is, that every  $\sigma \in X(\ell)$  contained in some  $\tau \in X(k)$ . In addition, we assume it has no self-loops or multifaces. Namely, every vertex appears at most once in each face and any face appears at most once in  $X$ .

The degree of a face  $\sigma \in X(i)$  is  $d(\sigma) = |\{\tau \in X(i+1) \mid \tau \supseteq \sigma\}|$ . We say that a family of simplicial complexes  $\{X_i\}_{i=0}^\infty$  is  $j$ -bounded degree if there is an integer  $M > 0$  so that for all  $X_i$  and all  $\sigma \in X_i(j)$ ,  $d(\sigma) \leq M$ . If the family is 0-bounded degree, we sometimes just say bounded degree (without the zero).

► **Definition 12** (hyper-regularity). *Let  $d_0 \geq d_1 \geq \dots \geq d_{k-1}$  be positive integers. A  $k$ -dimensional simplicial complex  $X$  is  $(d_0, d_1, \dots, d_{k-1})$ -regular if for any  $i \in \{0, \dots, k-1\}$  and any  $i$ -face  $\sigma$ ,  $d(\sigma) = d_i$ .*

We say that  $X$  is regular if there exists such a tuple so that  $X$  is  $(d_0, d_1, \dots, d_{k-1})$ -regular. In this case we denote by  $d_i(X) = d_i$ .

The  $j$ -skeleton of a simplicial complex  $X$  is the simplicial complex obtained by taking all the  $i$ -faces of  $X$ , for all  $i \leq j$ . The 1-skeleton of a complex is also called an *underlying graph*.

A link is a generalization of a graph neighborhood.

► **Definition 13** (link). *For a  $k$ -dimensional simplicial complex  $X$  and a face  $\sigma \in X$ , the link of  $\sigma$  is the  $(k-1-|\sigma|)$ -dimensional simplicial complex  $X_\sigma = \{\tau \setminus \sigma \mid \tau \in X, \tau \supset \sigma\}$ .*

For  $\ell \leq k-2$  and  $\sigma \in X(\ell)$  we denote by  $A_\sigma$  the random walk operator of the 1-skeleton of  $X_\sigma$ . We often abuse of notation and for a face  $\sigma = \{v_0, \dots, v_\ell\} \in X(\ell)$  write  $\sigma = v_0 \dots v_\ell$ .

Natural analogues of expander graphs to higher dimensions are simplicial complexes where the neighborhoods of the faces are themselves expander graphs. See Section 1 for more context on this important definition.

► **Definition 14** ( $\lambda$ -high dimensional expander). *Let  $\lambda \in [0, 1]$ . A  $k$ -dimensional simplicial complex  $X$  is a  $\lambda$ -two sided (resp. one sided) high dimensional expander if for all  $i \leq k - 2$  and all  $\sigma \in X(i)$ , the 1-skeleton of  $X_\sigma$  is a  $\lambda$ -two sided (resp. one sided) spectral expander.*

## 2.4 The Lovász Local Lemma

The Lovász Local Lemma is a classical result in the probabilistic method.

► **Lemma 15** (Lovász Local Lemma [29]). *Let  $\mathfrak{B} = \{B_1, \dots, B_n\}$  be a finite set of events in some arbitrary probability space. The dependency graph of  $\mathfrak{B}$  is a digraph  $G_{\mathfrak{B}} = (\mathfrak{B}, E)$  so that any event  $B_i \in \mathfrak{B}$  is mutually independent of all the events  $\mathfrak{B} \setminus \Gamma(B_i)$ , where  $\Gamma(B_i)$  is the neighborhood of  $B_i$  in  $G_{\mathfrak{B}}$ .*

*If there exists a real function  $\rho : \mathfrak{B} \rightarrow [0, 1)$  so that*

$$\mathbb{P}[B_i] \leq \rho(B_i) \prod_{B_j \sim B_i} (1 - \rho(B_j)) \tag{2.1}$$

*for any  $B_i \in \mathfrak{B}$ , then with strictly positive probability, none of the events  $B_i$  occur.*

This lemma also has an algorithmic version, first given in the seminal work of [57]. We give below a slightly less general version than the one in [57].

► **Lemma 16** ([57]). *Let  $\Omega$  be a finite set and let  $\mathfrak{P} = (P_1, P_2, \dots, P_m)$  be a tuple of independent random variables supported on  $\Omega^m$ . Let  $\mathfrak{B} = \{B_1, B_2, \dots, B_n\}$  be a finite set of events in the sigma algebra of  $\mathfrak{P}$ . Let the dependency graph and the assignment  $\rho : \mathfrak{B} \rightarrow [0, 1)$  be as in Lemma 15. Then there exists a randomized algorithm that finds an assignment  $p \in \Omega^m$  such that  $p \notin \bigcup_{i=1}^n B_i$ . If one can verify whether  $B_i$  holds in time  $t$ , then the randomized algorithm runs in  $tn \sum_{i=1}^n \frac{\rho(B_i)}{1 - \rho(B_i)}$  expected time.*

The algorithm described in this lemma is simple. The algorithm starts with randomly sampling some  $p \in \Omega^m$ . While there exists some  $B_i$  such that  $p \in B_i$ , the algorithm takes an arbitrary such  $B_i$ , and resamples all the coordinates  $P_j$  that  $B_i$  depends upon. Of course, if the algorithm halts, then  $p \notin \bigcup_{i=1}^n B_i$ . The paper [57] shows that the expected number of times an event  $B_i$  is resampled is at most  $\frac{\rho(B_i)}{1 - \rho(B_i)}$  which explains the runtime of this algorithm.

## 3 Local lifts

This section presents our basic construction, the *local lift* of a complex. We will define this construction formally and describe some of its properties.

► **Construction 17** (Local Lift). *Let  $X$  be a  $k$ -dimensional simplicial complex and let  $f : X(k) \rightarrow \{\pm 1\}$ . The  $f$ -local lift of  $X$  denoted by  $\widehat{X} = \widehat{X}^f$ , is the following  $k$ -dimensional simplicial complex:*

- $\widehat{X}(0) = X(0) \times \{\pm 1\}$  and we denote the vertices by  $\widehat{X}(0) = \{v^j \mid v \in X(0), j \in \{\pm 1\}\}$ .
- For any  $1 \leq \ell \leq k - 1$ ,

$$\widehat{X}(\ell) = \left\{ \{v_0^{j_0}, v_1^{j_1}, \dots, v_\ell^{j_\ell}\} \mid \{v_0, v_1, \dots, v_\ell\} \in X(\ell), j_0, \dots, j_\ell \in \{\pm 1\} \right\}.$$

## 68:12 Sparse High Dimensional Expanders via Local Lifts

- Finally,  $\widehat{X}(k)$  is the set of all faces  $\sigma = \{v_0^{j_0}, v_1^{j_1}, \dots, v_k^{j_k}\}$  so that the face without the signs is  $\{v_0, v_1, \dots, v_k\} \in X(k)$ , and the product of the  $j_i$ 's are equal to  $f(\sigma)$ . Namely,

$$\widehat{X}(k) = \left\{ \left\{ v_0^{j_0}, v_1^{j_1}, \dots, v_k^{j_k} \right\} \mid \{v_0, v_1, \dots, v_k\} \in X(k), f(\{v_0, v_1, \dots, v_k\}) = \prod_{i=0}^k j_i \right\}.$$

One can already see that the  $(k-1)$ -skeleton of  $\widehat{X}$  doesn't depend on  $f$  and is just some inflation of the original complex. The dependence on  $f$  is only in the top-level faces. Thus, in particular,  $\widehat{X}$  is not a lift of (the underlying graph) of  $X$ , except when  $k=1$ . However, the links of  $(k-2)$ -faces in  $\widehat{X}$  are lifts of links in  $X$ , which is why we named this complex a local lift. We will see this in the next subsection.

### 3.1 Local Properties of Local Lifts

For the rest of this subsection, we fix  $X$  to be a  $k$ -dimensional pure simplicial complex,  $f : X(k) \rightarrow \{\pm 1\}$  to be a signing function, and  $\widehat{X}$  to be the  $f$ -local lift of  $X$ . We also need the following three pieces of notation:

- Let  $\pi : \widehat{X}(0) \rightarrow X(0)$  be the projection map  $\pi(v^j) = v$ , and we extend it to higher dimensional faces as well by  $\pi(\{v_0^{j_0}, v_1^{j_1}, \dots, v_i^{j_i}\}) = \{v_0, v_1, \dots, v_i\}$ .
- Let  $\text{sign} : \widehat{X} \rightarrow \{\pm 1\}$  be  $\text{sign}(\hat{\sigma}) \rightarrow \prod_{v^j \in \hat{\sigma}} j$ .
- For any  $\hat{\sigma} \in \widehat{X}(k-2)$  with  $\sigma = \pi(\hat{\sigma})$  we denote by  $f_\sigma : X_\sigma(1) \rightarrow \{\pm 1\}$  the function  $f_\sigma(e) = f(\sigma \sqcup e)$  and by  $f_{\hat{\sigma}} : X_{\hat{\sigma}}(1) \rightarrow \{\pm 1\}$  the function  $f_{\hat{\sigma}}(e) = \text{sign}(\hat{\sigma}) \cdot f_\sigma(e)$ .

The first observation is that the degrees of  $\widehat{X}$  are twice the degrees of  $X$ , except for  $d_{k-1}$ , which stays the same.

► **Observation 18.** *If  $X$  is  $(d_0, \dots, d_{k-1})$ -regular then  $\widehat{X}$  is  $(2d_0, 2d_1, \dots, 2d_{k-2}, d_{k-1})$ -regular.* ◄

It is a direct calculation, so we have omitted its proof. We just comment that the reason that  $d_{k-1}$  remains the same is that for every  $\hat{\sigma} \in \widehat{X}(k-1)$  and  $v \in X_{\pi(\hat{\sigma})}(0)$  there is exactly one  $j \in \{\pm 1\}$  such that  $\hat{\sigma} \cup \{v^j\} \in \widehat{X}(k)$ . Therefore,  $d_{k-1}(X) = |X_{\pi(\hat{\sigma})}(0)| = |\widehat{X}_{\hat{\sigma}}(0)| = d_{k-1}(\widehat{X})$ .

The next lemma gives a complete description of the links of  $\widehat{X}$ .

- **Lemma 19** (on the structure of the links). *Let  $\hat{\sigma} \in \widehat{X}$  and denote by  $\sigma = \pi(\hat{\sigma})$ .*
- If  $\dim(\hat{\sigma}) < k-2$ , then the 1-skeleton of  $\widehat{X}_{\hat{\sigma}}$  (the  $\hat{\sigma}$ -link of  $\widehat{X}$ ), is isomorphic to the 1-skeleton of  $X_\sigma$  tensored with the complete graph on two vertices with self loops<sup>3</sup>.*
  - If  $\dim(\hat{\sigma}) = k-2$ , then  $\widehat{X}_{\hat{\sigma}}$  is isomorphic to a lift of  $X_\sigma$  induced by  $f_{\hat{\sigma}}$ .*

**Proof.** The first item directly follows from the definition of a tensor product. For the second item, suppose  $\dim(\hat{\sigma}) = k-2$ . Both the vertices of  $\widehat{X}_{\hat{\sigma}}$  and of the  $f_{\hat{\sigma}}$ -induced lift of  $X_\sigma$  are  $X_\sigma(0) \times \{\pm 1\}$ . As for the edges,  $\{u^i, v^j\} \in \widehat{X}_{\hat{\sigma}}(1)$  if and only if  $\{u, v\} \in X_\sigma(1)$  and  $ij \cdot \text{sign}(\hat{\sigma}) = f(\sigma \sqcup \{u, v\})$  (or equivalently  $ij = f_{\hat{\sigma}}(\{u, v\})$ ). This is precisely the relation that defines edges in the  $f_{\hat{\sigma}}$ -induced lift of  $X_\sigma$ . ◄

<sup>3</sup> Note that this is also true for the link of  $\sigma = \emptyset$ , i.e.  $\widehat{X}$  itself.

The following corollary that bounds the spectrum of the links is direct.

► **Corollary 20.** *Let  $\hat{\sigma} \in \widehat{X}$  and denote  $\sigma = \pi(\hat{\sigma})$ .*

1. *If  $\dim(\hat{\sigma}) < k - 2$  then  $\lambda(\widehat{X}_{\hat{\sigma}}) = \lambda(X_{\sigma})$ .*
2. *If  $\dim(\hat{\sigma}) = k - 2$  then  $\text{Spec}(\widehat{X}_{\hat{\sigma}}) = \text{Spec}(A_{\sigma}) \cup \text{Spec}(A_{\sigma}^{f_{\hat{\sigma}}})$ , where  $A_{\sigma}$  is the normalized adjacency matrices of  $X_{\sigma}$  and  $A_{\sigma}^{f_{\hat{\sigma}}}$  is its signed normalized adjacency matrix with respect to  $f_{\hat{\sigma}}$ .*

**Proof.** The first item follows from the first item in Lemma 19 that shows the link of  $\widehat{X}_{\hat{\sigma}}$  is isomorphic to the link of  $X_{\sigma}$  tensored with a complete graph, and Fact 6 that bounds the expansion of such a graph. The second item follows from Lemma 9 and the fact that the link is the  $f_{\hat{\sigma}}$ -induced lift of  $X_{\sigma}$  as we saw in Lemma 19. ◀

## 4 Families of HDXs via Random Local Lifts

This section is dedicated to existential proofs of high dimensional expanders based on our local lifts from Construction 17. We start by stating the main theorem of this section which asserts that given an arbitrary HDX  $X$ , there exists a family of HDXs with parameters comparable to those of  $X$  so that any member of the family is a local lift of the former. Formally,

► **Theorem 21.** *Let  $X_0$  be a  $(d_0, d_1, \dots, d_{k-1})$ -regular  $\lambda$ -two sided (resp. one sided) HDX over  $n$  vertices, for  $\lambda \in [0, 1]$ . Then there exists a family of  $\max\left\{\lambda, O\left(\sqrt{\frac{k^2 \log^3 d_{k-1}}{d_{k-1}}}\right)\right\}$ -two sided (resp. one sided) high dimensional expanders  $\{X_i\}_{i=0}^{\infty}$  so that  $X_i$  is a  $(2^i d_0, \dots, 2^i d_{k-2}, d_{k-1})$ -regular complex over  $2^i n$  vertices and  $X_{i+1}$  is a local lift of  $X_i$ .*

The proof of Theorem 21 is based on proving the single-step version of it, given in Theorem 22, and applying it iteratively.

► **Theorem 22.** *Let  $\lambda \in [0, 1]$ . For any  $k$ -dimensional,  $(d_0, \dots, d_{k-1})$ -regular,  $\lambda$ -two sided (resp. one sided) high dimensional expander  $X$  over  $n$  vertices, there exists a signing  $f : X(k) \rightarrow \{\pm 1\}$  so that  $\widehat{X}$  is a  $\max\left\{\lambda, O\left(\sqrt{\frac{k^2 \log^3 d_{k-1}}{d_{k-1}}}\right)\right\}$ -two sided (resp. one sided) high dimensional expander with regularity  $(2d_0, \dots, 2d_{k-2}, d_{k-1})$  and  $2n$  vertices.*

We start by proving Theorem 21 given Theorem 22. The proof of Theorem 22 is more involved and is provided in the remainder of this section.

**Proof of Theorem 21 assuming Theorem 22.** Let  $X_0$  as specified in Theorem 21 and denote  $\lambda' := \max\left\{\lambda, O\left(\sqrt{\frac{k^2 \log^3 d_{k-1}}{d_{k-1}}}\right)\right\}$ . The proof is by induction on  $i$ . Clearly  $X_0$  holds the requirements.

For the induction step, let  $X_i$  be a  $(2^i d_0, \dots, 2^i d_{k-2}, d_{k-1})$ -regular  $\lambda'$ -two sided (resp. one sided) HDX with  $2^i n$  vertices received in the  $i$ -th step of the process. By Theorem 22, there exists a signing function  $f_i : X_i(k) \rightarrow \{\pm 1\}$  so that the  $f_i$ -local lift of  $X_i$  (denoted by  $\widehat{X}_i$ ) is a  $(2^{i+1} d_0, \dots, 2^{i+1} d_{k-2}, d_{k-1})$ -regular  $\lambda'$ -two sided (resp. one sided) HDX over  $2^{i+1} n$  vertices. Setting  $X_{i+1} := \widehat{X}_i$  concludes the proof. ◀

### 4.1 Proof Outline of Theorem 22

The proof of Theorem 22 is based on Lovász Local Lemma [29] and Lemma 10, and closely follows the lines of the existential proof in [12].

Recall that one approach for proving a given  $k$ -dimensional simplicial complex is  $\lambda$ -HDX, is considering all of its  $\ell$ -links for  $\ell \leq k-2$  and bound the spectrum of each of their 1-skeletons by  $\lambda$ . By Corollary 20, the only links one should be concerned with are those obtained by  $(k-2)$ -faces, as the links of all other faces inherit the expansion from the initial HDX. In addition, by the same corollary, it's enough to analyze the spectra of the signed random walk matrices of the  $(k-2)$ -links of  $X$ , with respect to the signing induced on them as defined in Lemma 19. Indeed, doing so is the most technical part of the proof and follows by the next lemma combined with Lemma 10:

► **Lemma 23.** *For any  $k$ -dimensional pure  $(d_0, \dots, d_{k-1})$ -regular simplicial complex  $X$  over  $n$  vertices, there exists a signing function  $f : X(k) \rightarrow \{\pm 1\}$  such that for any  $(k-2)$ -face  $\hat{\sigma} \in \widehat{X}$  and any disjoint subsets of vertices  $S, T \subseteq X_\sigma(0)$  for  $\sigma = \pi(\hat{\sigma})$ ,*

$$|\langle \mathbf{1}_S, A_\sigma^{f_{\hat{\sigma}}} \mathbf{1}_T \rangle| \leq 10 \sqrt{\frac{k^2 \log d_{k-1}}{d_{k-1}} |S||T|} \quad (4.1)$$

where  $f_{\hat{\sigma}}$  is the signing on  $X_\sigma$ 's edges induced by  $f$  as defined in Section 3.1.

By the  $(d_0, \dots, d_{k-1})$ -regularity of  $X$ ,  $X_\sigma$  is a  $d_{k-1}$ -regular graph over  $d_{k-2}$ -vertices. Furthermore, since any signing over the  $k$ -faces induces a signing function on the edges of any  $(k-2)$ -link, our goal is to find a single signing function  $f$  such that these lifts of all the links of the  $(k-2)$ -dimensional faces expand.

The proof of Lemma 23 is by the Lovász Local Lemma Lemma 15. We define the set of “bad” events  $\mathfrak{B} = \{B_\sigma^{S,T}\}$ . The event  $B_\sigma^{S,T}$  is that (4.1) doesn't hold for a fixed  $\sigma \in X(k-2)$  and fixed disjoint sets  $S, T \subseteq X_\sigma(0)$ . In [12], similar bad events were considered, but only the sets  $S, T$  needed to be specified. The main difference between our proof and theirs is that we need to take care of the dependencies between events corresponding to different  $(k-2)$ -faces  $\sigma, \sigma'$ .

To apply the lemma and deduce Lemma 23, one needs to understand and analyze the dependency relation of the events in  $\mathfrak{B}$ .

### On the dependency of bad events in $\mathfrak{B}$

Fix  $\hat{\sigma} \in \widehat{X}(k-2)$  and disjoint  $S, T \subseteq X_\sigma(0)$  for  $\sigma = \pi(\hat{\sigma})$ , and define  $F(\sigma, S, T) \subseteq X(k)$  to be the set of all  $k$ -faces of  $X$  so that  $\sigma \subseteq \tau$  and  $\tau \setminus \sigma$  is an edge in the graph induced by  $S \sqcup T$  on  $X_\sigma$ . Recall that  $\text{sign} : \widehat{X} \rightarrow \{\pm 1\}$  is defined by  $\text{sign}(\hat{\sigma}) = \prod_{v \in \hat{\sigma}} j$ , and note that

$$d_{k-1} \langle \mathbf{1}_S, A_\sigma^{f_{\hat{\sigma}}} \mathbf{1}_T \rangle = \sum_{\substack{uv \in X_\sigma(1) \\ \text{s.t. } u \in S, v \in T}} f_{\hat{\sigma}}(uv) = \text{sign}(\hat{\sigma}) \sum_{\substack{uv \in X_\sigma(1) \\ \text{s.t. } u \in S, v \in T}} f(\sigma \sqcup uv) = \text{sign}(\hat{\sigma}) \sum_{\tau \in F(\sigma, S, T)} f(\tau).$$

Since the signs  $f$  assigns to the  $k$ -faces are chosen independently, if the event  $B_\sigma^{S,T}$  is *not* mutually independent of a subset  $\mathfrak{A} \subseteq \mathfrak{B}$ , there must exist some event  $B_{\sigma'}^{S',T'} \in \mathfrak{A}$  for which  $F(\sigma, S, T) \cap F(\sigma', S', T')$  is not empty.

Towards using the Lovász Local Lemma, we need to bound the probability of the event  $B_\sigma^{S,T}$  as well as the number of neighbors it has in the dependency graph considered in the Local Lemma. The bound on the probability follows directly from the arguments in [12], but bounding the number of neighbors each event is more involved. In contrast to the expander graph case considered in [12] (where the “bad” events only depend on  $S$  and  $T$ ), in simplicial complexes events corresponding to different faces  $\sigma, \sigma'$  (and therefore to different links) can depend on one another as long as they have a common  $k$ -face in  $F(\sigma, S, T) \cap F(\sigma', S', T')$ .

A naive count of the number of such  $k$ -faces won't suffice, and would lead the bound in Equation (4.1) to scale with  $d_{k-2}$ . Therefore, we need to carefully characterize when exactly  $F(\sigma, S, T)$  and  $F(\sigma', S', T')$  intersect.

The first case where dependency can occur is when  $\sigma = \sigma'$ . In this case, we are in the same setting as in [12], which observed that there must be an edge in the subgraph induced by  $S \cup T$  as well as in the one induced by  $S' \cup T'$  for a dependency to happen.

In the second case, which is new to our proof,  $\sigma \neq \sigma'$  meaning that each of the events considers a different graph. In this case, we observe that this implies both that there is a  $k$ -face  $\tau$  containing both  $\sigma, \sigma'$  and that either there exist vertices  $v \in \sigma \cap (S' \sqcup T')$  and  $s \in S \sqcup T$  so that  $\tau \setminus \sigma' = \{v, s\}$ , or that  $\tau \setminus \sigma' \subseteq \sigma$ . As we show below, this characterization is useful to bound the number of possible events that are dependent on a certain  $B_\sigma^{S,T}$ . The following claim gives this characterization formally.

▷ **Claim 24.** Let an event  $B_\sigma^{S,T} \in \mathfrak{B}$  and some subset  $\mathfrak{A} \subseteq \mathfrak{B}$ . If

- for any  $B_{\sigma'}^{S',T'} \in \mathfrak{A}$  with  $\sigma = \sigma'$  there is no edge lying in both  $E_{X_\sigma}(S, T)$  and  $E_{X_{\sigma'}}(S', T')$ , and
  - for any  $B_{\sigma'}^{S',T'} \in \mathfrak{A}$  with  $\sigma \neq \sigma'$  there is no  $k$ -face  $\tau \in X$  containing both  $\sigma$  and  $\sigma'$ , so that  $\tau \setminus \sigma$  and  $\tau \setminus \sigma'$  are edges in  $E_{X_\sigma}(S, T)$  and  $E_{X_{\sigma'}}(S', T')$  respectively,
- then  $B_\sigma^{S,T}$  is mutually independent of  $\mathfrak{A}$ .

All left to conclude the proof of Lemma 23 is carefully counting the number of events that fulfill one of the claim conditions and provide a real function that bounds the probability of each event as in Equation (2.1). We leave the details for the formal proof, which is given in the next section.

## 4.2 Proving Lemma 23

This subsection is dedicated to the proof of Lemma 23 together with the subclaims it requires. We start by setting notations and highlighting features that will be needed for the proof.

### Notations

We say that sets  $S, T \subseteq X_\sigma(0)$  induce a *connected subgraph* if the subgraph obtained by projecting  $X_\sigma$  on  $S \cup T$  is connected. In addition, we write  $E_{X_\sigma}(S, T)$  to indicate the set of edges between  $S$  and  $T$  in  $X_\sigma$ . For  $\hat{\sigma} \in \widehat{X}(k-2)$ , we denote  $\sigma = \pi(\hat{\sigma})$ . When the face  $\hat{\sigma}$  being considered is clear from the context we abbreviate and write  $f$  for  $f_{\hat{\sigma}}$ .

In addition, we rely on the following observation:

► **Observation 25.** *If a signing  $f : X(k) \rightarrow \{\pm 1\}$  independently assigns a uniform sign to each  $k$ -face, then for any  $\hat{\sigma} \in \widehat{X}(k-2)$ ,  $f_{\hat{\sigma}}$  independently assigns a uniform sign to each edge in  $X_\sigma$ .*

**Proof.** Let  $\hat{\sigma} \in \widehat{X}(k-2)$  and let  $e \neq e' \in X_\sigma(1)$ . Then for any  $j, j' \in \{\pm 1\}$

$$\begin{aligned} \mathbb{P}[f_{\hat{\sigma}}(e) = j \wedge f_{\hat{\sigma}}(e') = j'] &= \mathbb{P}[\text{sign}(\hat{\sigma}) \cdot f(\sigma \sqcup e) = j \wedge \text{sign}(\hat{\sigma}) \cdot f(\sigma \sqcup e') = j'] \\ &= \mathbb{P}[\text{sign}(\hat{\sigma}) \cdot f(s \sqcup e) = j] \cdot \mathbb{P}[\text{sign}(\hat{\sigma}) \cdot f(\sigma \sqcup e') = j'] = \frac{1}{4}. \quad \blacktriangleleft \end{aligned}$$

In addition, as in [12], we can restrict the proof to consider only a pair of sets inducing connected subgraphs and deduce the result to any pair of sets. In addition, we can assume that  $d$  is as large as 996 as it is always the case that  $\langle \mathbf{1}_S, A_\sigma^f \mathbf{1}_T \rangle \leq \sqrt{|S||T|}$  and  $1 \leq 10\sqrt{\frac{k^2 \log d_{k-1}}{d_{k-1}}}$  for  $d_{k-1} \in [1, 996]$ .

We are now ready to prove Lemma 23.

**Proof of Lemma 23.** We set  $f$  to be a randomized signing of  $X(k)$  by setting a uniform and independent sign from  $\{\pm 1\}$  to any  $k$ -face. Fix some face  $\hat{\sigma} \in \widehat{X}(k-2)$  with  $\pi(\hat{\sigma}) = \sigma$ , and disjoint sets  $S, T \subseteq X_\sigma(0)$ . Denote the “bad” event in which the claim does not hold for our fixed face and sets by  $B_\sigma^{S,T}$ . That is,  $\mathbb{P}[B_\sigma^{S,T}] = \mathbb{P}\left[|\langle \mathbf{1}_S, A_\sigma^f \mathbf{1}_T \rangle| > 10\sqrt{\frac{k^2 \log d_{k-1}}{d_{k-1}} |S||T|}\right]$ .

Fix for a moment some edge  $uv \in X_\sigma(1)$ , and consider the  $(u, v)$ -th entry of  $A_\sigma^f$ . By Definition 8,  $A_\sigma^f(u, v) = \frac{1}{d_{k-1}} f_{\hat{\sigma}}(uv)$ , which, per Observation 25, distributed uniformly in  $\{\pm 1\}$  and is independent of all other edges signs. In addition, since

$$\langle \mathbf{1}_S, A_\sigma^f \mathbf{1}_T \rangle = \frac{1}{d_{k-1}} \sum_{uv \in E_{X_\sigma}(S, T)} f_{\hat{\sigma}}(uv),$$

$\langle \mathbf{1}_S, A_\sigma^f \mathbf{1}_T \rangle$  is a sum of independent uniform random variables over  $\{\pm 1\}$ , implying that

$$\mathbb{E}_f[\langle \mathbf{1}_S, A_\sigma^f \mathbf{1}_T \rangle] = \frac{1}{d_{k-1}} \sum_{uv \in E_{X_\sigma}(S, T)} \mathbb{E}_f[f_{\hat{\sigma}}(uv)] = 0.$$

Hence, by Hoeffding’s inequality,

$$\begin{aligned} \mathbb{P}[B_\sigma^{S,T}] &= \mathbb{P}\left[|\langle \mathbf{1}_S, A_\sigma^f \mathbf{1}_T \rangle| > 10\sqrt{\frac{k^2 \log d_{k-1}}{d_{k-1}} |S||T|}\right] \\ &\leq 2 \exp\left(-\frac{2 \cdot 100 \frac{k^2 \ln d_{k-1}}{d_{k-1}} |S||T|}{\sum_{uv \in E_{X_\sigma}(S, T)} \left(\frac{1}{d_{k-1}} - \left(-\frac{1}{d_{k-1}}\right)\right)^2}\right). \end{aligned} \quad (4.2)$$

Assuming w.l.o.g. that  $|S| \geq |T|$  we get

$$\begin{aligned} \frac{200 \frac{k^2 \ln d_{k-1}}{d_{k-1}} |S||T|}{\sum_{uv \in E_{X_\sigma}(S, T)} \left(\frac{1}{d_{k-1}} - \left(-\frac{1}{d_{k-1}}\right)\right)^2} &= \frac{200k^2 d_{k-1} (\ln d_{k-1}) |S||T|}{4|E_{X_\sigma}(S, T)|} \geq \frac{50k^2 d_{k-1} (\ln d_{k-1}) |S||T|}{d_{k-1} |T|} \\ &\geq 25k^2 \ln d_{k-1} |S \sqcup T|. \end{aligned}$$

Hence, denoting  $c = |S \sqcup T|$ ,

$$\text{Equation (4.2)} \leq 2 \exp(-25ck^2 \ln d_{k-1}) \leq d_{k-1}^{-10ck^2}. \quad (4.3)$$

We turn to analyze the dependency graph of the “bad” events:<sup>4</sup> Recall that  $\mathfrak{B}$  is the set of all events  $B_\sigma^{S,T}$  for  $\sigma \in X(k-2)$  and disjoint subsets  $S, T \subseteq X_\sigma(0)$ . Using the characterization of correlated events in  $\mathfrak{B}$  given in Claim 24, we get the following bound on the neighborhood size of the events in the dependency graph:

▷ **Claim 26.** Let  $B_\sigma^{S,T} \in \mathfrak{B}$  and denote  $c = |S \sqcup T|$ . Then  $B_\sigma^{S,T}$  has at most  $3k^2 cd^{c'-1}$  neighbors  $B_{\sigma'}^{S',T'}$  with  $|S' \sqcup T'| = c'$ .

Now, to apply Lovász Local Lemma, one needs to define a function  $\rho : \mathfrak{B} \rightarrow [0, 1)$  such that  $\mathbb{P}[B_\sigma^{S,T}] \leq \rho(B_\sigma^{S,T}) \prod_{B_{\sigma'}^{S',T'} \sim B_\sigma^{S,T}} \left(1 - \rho(B_{\sigma'}^{S',T'})\right)$ . Set  $\rho(B_\sigma^{S,T}) = d_{k-1}^{-3ck^2}$ . Indeed

<sup>4</sup> Recall that the dependency graph of a set of events  $\mathfrak{B}$  is a digraph with a vertex for each event  $B \in \mathfrak{B}$  and any event  $B$  is mutually independent of  $\mathfrak{B} \setminus \Gamma(B)$ .

$$\begin{aligned} \rho(B_\sigma^{S,T}) \prod_{B_\sigma^{S',T'} \in \sim B_\sigma^{S,T}} \left(1 - \rho(B_\sigma^{S',T'})\right) &= d_{k-1}^{-3ck^2} \prod_{B_\sigma^{S',T'} \sim B_\sigma^{S,T}} \left(1 - d_{k-1}^{-3|S' \cup T'|k^2}\right) \\ &= d_{k-1}^{-3ck^2} \prod_{c' \in [n]} \left(1 - d_{k-1}^{-3c'k^2}\right)^{2^{c'} 3ck^2 d_{k-1}^{c'-1}} \end{aligned} \quad (4.4)$$

$$\geq d_{k-1}^{-3ck^2} \exp\left(-6ck^2 \sum_{c' \in [n]} 2^{c'} d_{k-1}^{c'-1} d_{k-1}^{-3c'k^2}\right) \quad (4.5)$$

$$\begin{aligned} &\geq d_{k-1}^{-3ck^2} e^{-7ck^2} \\ &\geq d_{k-1}^{-10ck^2} \geq \mathbb{P}[B_\sigma^{S,T}] \end{aligned} \quad (4.6)$$

where Equation (4.4) is since for any  $U \subseteq X_\sigma(0)$  of cardinality  $c'$ , there are at most  $2^{c'}$  pairs of disjoint sets  $S', T'$  with  $S' \sqcup T' = U$ , Equation (4.5) is by  $e^{-x} \leq 1 - \frac{x}{2}$  for any  $x \in [0, 1.59]$  and Equation (4.6) is by taking  $d_{k-1} \geq 3$ . Together with Equation (4.3), this concludes the proof.  $\blacktriangleleft$

The formal proofs of Claim 24 and Claim 26, and the proof of Theorem 22 given Lemma 23 appear in the full version of this paper [11].

### 4.3 Concluding Theorem 22

**Proof of Theorem 22.** Let  $X$  be a  $(d_0, \dots, d_{k-1})$ -regular,  $\lambda(X)$ -two sided (resp. one sided) HDX over  $n$  vertices, fix  $f$  to be the signing provided by Lemma 23, and set  $\widehat{X}$  to be the  $f$ -local lift of  $X$ .

By Observation 18,  $\widehat{X}$  is a  $(2d_0, \dots, 2d_{k-2}, d_{k-1})$ -regular graph over  $2n$  vertices. We need to prove that for any  $\widehat{\sigma} \in \widehat{X}$  of dimension  $\leq k-2$ , the 1-skeleton of  $\widehat{X}_{\widehat{\sigma}}$  is a  $\max\left\{\lambda(X), O\left(\sqrt{\frac{k^2 \log^3 d_{k-1}}{d_{k-1}}}\right)\right\}$ -two sided (resp. one sided) expander.

By Corollary 20, the spectra of all links  $\widehat{X}_{\widehat{\sigma}}$  with  $\widehat{\sigma}$  of dimension  $< k-2$  are bounded by  $\lambda(X)$ . In addition, by Lemma 23, for any  $\widehat{\sigma} \in \widehat{X}(k-2)$  and any disjoint sets  $S, T \subseteq X_\sigma(0)$  for  $\sigma = \pi(\widehat{\sigma})$ , we have that  $|\langle \mathbf{1}_S, A_\sigma^f \mathbf{1}_T \rangle| \leq O\left(\sqrt{\frac{k^2 \log d_{k-1}}{d_{k-1}} |S||T|}\right)$  where  $A_\sigma^f$  is the  $f_\sigma$ -signed random walk matrix of  $X_\sigma$ . Together with Lemma 10 this implies

$$\begin{aligned} \lambda(X_\sigma) &= O\left(\sqrt{\frac{k^2 \log d_{k-1}}{d_{k-1}} \left(1 + \log\left(\sqrt{\frac{d_{k-1}}{k^2 \log d_{k-1}}}\right)\right)}\right) \\ &\leq O\left(\sqrt{\frac{k^2 \log d_{k-1}}{d_{k-1}}} \cdot \log \sqrt{d_{k-1}}\right) = O\left(\sqrt{\frac{k^2 \log^3 d_{k-1}}{d_{k-1}}}\right) \end{aligned}$$

hence, by Lemma 9,  $\lambda(X_\sigma) = \max\left\{\lambda(X), O\left(\sqrt{\frac{k^2 \log^3 d_{k-1}}{d_{k-1}}}\right)\right\}$  and by Corollary 20, this is also the case for  $\lambda(\widehat{X}_{\widehat{\sigma}})$ .  $\blacktriangleleft$

## 5 An Algorithmic Version of Theorem 21

In this subsection, we prove that there is a randomized algorithm that finds a family of local lifts as in Theorem 21 when  $X$  is a high dimensional expander under mild assumptions on the degree sequence which we encapsulate in the following definition.

► **Definition 27** (Nice complex). *Let  $X$  be a  $k$ -dimensional simplicial complex. We say that  $X$  is nice if  $X$  is regular, and*

$$d_{k-2}^{1-4 \log d_{k-1}} < \frac{2}{e(k+1)kd_{k-1} + 1}. \quad (5.1)$$

We prove the following.

► **Theorem 28.** *There exists a randomized algorithm  $\mathcal{A}$  that takes as input a  $k$ -dimensional complex  $X_0$  and an integer  $i \geq 1$ , runs in expected time  $\text{poly}((2^i |X_0(0)|)^k)$  at most, and outputs a  $k$ -dimensional complex  $X_i$  with  $2^i |X_0(0)|$  vertices. The algorithm has the following guarantee.*

*If  $X_0$  is a nice  $(d_0, \dots, d_{k-1})$ -regular  $\lambda$ -two sided high dimensional expander, then  $X_i$  is a  $(2^i d_0, \dots, 2^i d_{k-2}, d_{k-1})$ -regular  $\lambda'$ -two sided high dimensional expander where  $\lambda' = O\left(\max\left\{\lambda\left(1 + \log \frac{1}{\lambda}\right), \sqrt{\frac{\log^3 d_{k-1}}{d_{k-1}}}\right\}\right)^5$ .*

*Moreover, one can modify the algorithm so that it outputs a sequence  $X_1, X_2, \dots, X_i$  of complexes all satisfying the same guarantees (instead of just the last one), so that for every  $j = 0, 1, \dots, i-1$ ,  $X_{j+1}$  is a local lift of  $X_j$ .*

Loosely speaking, in order to prove Theorem 28, we need to prove that there is an algorithm  $\mathcal{A}$  that finds a single local lift for  $X$  in polynomial time (just as Theorem 21 was proved by the “one-step theorem” Theorem 22) with good enough spectral expansion. Then we just iteratively use  $\mathcal{A}$  on its own output, setting  $X_{j+1} = \mathcal{A}(X_j)$ , until reaching  $j = i-1$ . For this to work, we also need to address the issue that  $\lambda' \geq \lambda$  so naively the expansion deteriorates as we reiterate. We defer the proof of Theorem 28 for the full version of this paper [11].

► **Remark 29** (A non-uniform algorithm for any HDX). Theorem 28 requires that  $X_0$  be a nice complex, i.e. that (5.1) holds. However, in any family  $\{X_i\}_{i=0}^\infty$  where  $X_{i+1}$  is a local lift of  $X_i$ , the degree  $d_{k-2}(X_i)$  tends to infinity with  $i$  while the other side of both inequalities stays fixed. Thus, the inequalities will eventually hold for any family of consecutive local lifts. In fact, they should hold for any  $i \geq C \log(k + d_{k-1}(X_0))$  for some large enough constant  $C > 0$ . Thus we can modify the algorithm to work even if  $X_0$  is not nice (albeit with the spectral expansion bound guaranteed in Theorem 21, which is slightly worse than the expansion in Theorem 28). This is done by allowing the algorithm to do a brute-force search for the first few steps, to produce a nice  $X_i$ , and then continuing as the original algorithm does. The first few steps will eventually stop because Theorem 21 promises the existence of such an  $X_j$ . This process takes  $\text{poly}(|X_i|^k) + \exp(O(|X_0|^k))$  time.

Towards the proof of Theorem 28, we need the following definition and lemma from [12].

► **Definition 30.** *A graph  $G$  with adjacency operator  $A$  is said to be  $(\beta, t)$ -sparse if for every  $S, T \subseteq V(G)$  such that  $|S \cup T| \leq t$ ,  $\langle \mathbf{1}_S, A \mathbf{1}_T \rangle \leq \beta \sqrt{|S||T|}$ . For a  $k$ -dimensional hyper-regular complex  $X$ , we say that it is  $(\beta, t)$ -sparse if for every  $\sigma \in X(k-2)$ , the graph  $X_\sigma$  is  $(\beta, t)$ -sparse.*

► **Remark 31.** While the definition here regards any  $S, T$  with  $|S \cup T| \leq t$ , it is in fact equivalent to regarding only  $S, T$  with  $|S \cup T| \leq t$  such that the graph induced on  $S \cup T$  is connected. We also remark that if  $X$  is  $(\beta, t)$ -sparse then it is also  $(\beta', t)$ -sparse for any  $\beta' \geq \beta$ .

<sup>5</sup> We will not calculate the constants in the big  $O$  notation explicitly.

The reason we need this definition of sparseness is that in a random local lift, sparseness does not deteriorate with high probability. More formally, the following lemma was proven in [12].

► **Lemma 32** ([12, Lemma 3.4]). *Let  $G = (V, E)$  be a  $d$ -regular graph with  $n$  vertices that is  $(\beta, \log n)$ -sparse for  $\beta \geq 10\sqrt{\frac{\log d}{d}}$ . Then with probability  $\geq 1 - n^{-4 \log d}$  over  $f : E \rightarrow \{\pm 1\}$ :*

- For every  $S, T \subseteq V$ ,  $|\langle \mathbf{1}_S, A^f \mathbf{1}_T \rangle| \leq \beta \sqrt{|S||T|}$  and,
- $\widehat{G}^f$  is  $(\beta, \log n + 1)$ -sparse,

We comment that [12, Lemma 3.4] does not explicitly calculate the probability  $1 - n^{-4 \log d}$ ; rather, they only say the events happen with high probability. This is the probability that is implicit in their proof. They also prove this theorem for  $\beta = 10\sqrt{\frac{\log d}{d}}$  but the same proof extends to  $\beta \geq 10\sqrt{\frac{\log d}{d}}$  with no additional changes.

This next claim easily follows from the definition of expansion and says that a spectral expander is sparse.

▷ **Claim 33.** Let  $G$  be a  $d$ -regular  $\lambda$ -two sided spectral expander over  $n$  vertices such that  $\lambda > \frac{1}{\sqrt{d}}$  and  $d \geq 3$ . Then  $G$  is  $(2\lambda, \log n)$ -sparse.

Proof. Fix  $S, T$  such that with  $|S \cup T| \leq \log n$ . By the  $\lambda$ -expansion and the expander mixing lemma (see e.g. [40]),  $\langle \mathbf{1}_S, A \mathbf{1}_T \rangle \leq \frac{|S||T|}{n} + \lambda \sqrt{|S||T|}$ . We bound this term by  $(\lambda + \frac{\log n}{n}) \sqrt{|S||T|}$ . As  $\frac{\log n}{n} \leq \frac{1}{\sqrt{n}} \leq \frac{1}{\sqrt{d}} \leq \lambda$  the claim follows. ◁

We are ready to state our one-step theorem.

► **Theorem 34.** *There exists a randomized algorithm  $\mathcal{A}$  with the following guarantees. Let  $X$  be a  $k$ -dimensional  $\bar{d}$ -regular  $\lambda$ -two sided (resp. one sided) high dimensional expander over  $n$  vertices, where  $\bar{d} = (d_0, \dots, d_{k-1})$ . Let  $\beta \geq 10\sqrt{\frac{\log d_{k-1}}{d_{k-1}}}$  and denote by*

$\lambda' = \max \left\{ \lambda, O(\beta(1 + \log \frac{1}{\beta})) \right\}$ . *Assume that  $X$  is  $(\beta, \log d_{k-2})$ -sparse, and suppose that  $d_{k-2}$  and  $d_{k-1}$  satisfy  $d_{k-2} > d_{k-1}^2$  and (5.1). Then  $\mathcal{A}(X) = \widehat{X}$  is a local lift of  $X$  such that:*

1. *The complex  $\widehat{X}$  is a  $\lambda'$ -two sided (resp. one sided) high dimensional expander.*
2. *The complex  $\widehat{X}$  is  $(\beta, \log 2d_{k-2})$ -sparse.*

*Upon input  $X$  satisfying the above, the algorithm runs in time  $\text{poly}(|X(0)|^k)$ .*

**Proof of Theorem 34.** We intend to use Lemma 16. For this, we fix the following “bad” events  $\mathfrak{C} = \{C_\sigma \mid \sigma \in X(k-2)\}$  where  $C_\sigma \subseteq \{f : X(k) \rightarrow \{\pm 1\}\}$  is the event where :

1. Either  $\widehat{X}_\sigma^{\pm f_\sigma}$  is not a  $\lambda'$ -two sided spectral expander, or
2.  $\widehat{X}_\sigma^{\pm f_\sigma}$  is not  $(\beta, \log 2d_{k-2})$ -sparse.

By Lemma 32 (and Lemma 10 that relates the first item in Lemma 32 to spectral expansion),  $\mathbb{P}_f [C_\sigma] \leq 2d_{k-2}^{-4 \log d_{k-1}}$ . Moreover, because every link of a  $\hat{\sigma} \in \widehat{X}(k-2)$  is a lift of  $X_\sigma$  with respect to  $f_{\hat{\sigma}}$ , then if none of the events  $C_\sigma$  occur, then  $\widehat{X}$  satisfies both items in Theorem 34. We will use Lemma 16 to find such an assignment.

We now construct a dependency graph for  $\mathfrak{C}$ . Let  $\sigma \in X(k-2)$  and  $U \subseteq X(k-2)$ . The event  $C_\sigma$  only depends on  $f_\sigma$ , so it only depends on  $k$ -faces  $\tau \supseteq \sigma$ . Therefore, if  $C_\sigma$  and  $\{C_{\sigma'} \mid \sigma' \in U\}$  are not mutually independent, then in particular there is a  $k$ -face  $\tau \in X$  and  $\sigma' \in U$  such that  $\tau \supseteq \sigma, \sigma'$ . Hence, in our dependency graph we connect  $C_\sigma \sim C_{\sigma'}$  if there exists such a  $k$ -face containing both  $\sigma$  and  $\sigma'$ . Let us upper bound the neighborhood size of an event  $C_\sigma$ . The number of neighbors that  $C_\sigma$  has is upper bounded by the number of  $k$ -faces containing  $\sigma$  times  $\binom{k+1}{k-1}$  (the number of ways to choose  $\sigma' \subseteq \tau$ ). Therefore, the number of neighbors is bounded by

$$D := \binom{k+1}{k-1} \cdot |\{\tau \in X(k) \mid \tau \supseteq \sigma\}| = \binom{k+1}{k-1} |X_\sigma(1)| = \frac{(k+1)k}{4} d_{k-2} d_{k-1}.$$

By setting  $\rho : \mathfrak{C} \rightarrow [0, 1)$  to be the constant function  $\rho(C_\sigma) = \frac{1}{D+1}$  we have that  $\mathbb{P}[C_\sigma] \leq \rho(C_\sigma) \prod_{\sigma' \sim \sigma} (1 - \rho(C_{\sigma'}))$ , because  $\rho(C_\sigma) \prod_{\sigma' \sim \sigma} (1 - \rho(C_{\sigma'})) \geq \frac{1}{D+1} \left(1 - \frac{1}{D+1}\right)^D \geq \frac{1}{e(D+1)}$  and  $\mathbb{P}[C_\sigma] \leq 2d_{k-2}^{-4 \log d_{k-1}} \leq \frac{1}{e(D+1)}$  by (5.1).

Let us now verify that the algorithm in Lemma 16 runs in polynomial time. We note that there the number of events in  $\mathfrak{C}$  is  $\text{poly}(|X(0)|^k)$ , and checking whether  $C_\sigma$  occurs could be done in  $\text{poly}(|X(0)|)$ -time because it amounts to:

1. Find the spectrum of a signed adjacency operator of a  $d_{k-2}$ -sized graph.
  2. Going over all connected sets  $U \subseteq \widehat{X}_\sigma^{\pm f_\sigma}$  of size  $\leq \log 2d_{k-2}$  for every  $\sigma \in X(k-2)$ , finding  $S, T$  such that  $S \cup T = U$ , and counting the number of edges between  $S$  and  $T$  to check if the pair  $S, T$  violates sparseness. There is a  $\text{poly}(|X(0)|)$  such  $U, S, T$  at most.
- Therefore, the randomized algorithm in Lemma 16 will find a signing in  $\text{poly}(|X(0)|^k) \cdot \sum_{\sigma \in X(k-2)} \frac{1}{D} = \text{poly}(|X(0)|^k)$ -time.  $\blacktriangleleft$

## 6 Derandomizing the Construction

In this section we provide a deterministic construction of  $(k-1)$ -bounded families of high dimensional expanders, as referred to in Theorem 3. For the rest of this section, we denote  $\alpha_k(d) = 10\sqrt{\frac{k^2 \log d}{d}}$  (when  $k$  is clear from context, we will write  $\alpha(d)$ ).

We will prove the following theorem.

**► Theorem 35** (Restatement of Theorem 3). *There exists a deterministic algorithm  $\mathcal{B}$  that takes as input a  $k$ -dimensional complex  $X_0$  and an integer  $i \geq 1$ , runs in time  $\text{poly}((2^i |X_0(0)|)^k)$ , and outputs a  $k$ -dimensional complex  $X_i$  with  $2^i |X_0(0)|$  vertices. The algorithm has the following guarantee: If  $X_0$  is a  $(d_0, \dots, d_{k-1})$ -regular  $\lambda$ -two sided high dimensional expander, with  $\lambda > \alpha_k(d_{k-1})$ ,  $d_{k-1} > 2^{10k}$  and  $|X_0(k-2)| \leq d_{k-2}^{10k}$ , then  $X_i$  is a  $(2^i d_0, \dots, 2^i d_{k-2}, d_{k-1})$ -regular  $\lambda'$ -two sided high dimensional expander where  $\lambda' = O(2^{5k} \lambda (1 + \log \frac{1}{\lambda}))^6$ . In particular, for every  $n \in \mathbb{N}$ , choosing  $i = \log n$  yields a complex with at least  $n$ -vertices.*

This explicit construction generalizes the explicit construction for expanders given in [12], which is based on the conditional probabilities method [4, Chapter 16].

We first observe that under the assumption that the base complex is sparse (as in Definition 30) and that  $|X(k-2)|$  is not too large, then a random local lift of  $X$  is also sparse and is a high dimensional expander with high probability. Then, we explain how we can find such a lift deterministically by greedily selecting the values  $f(\tau)$  one  $k$ -face at a time.

**► Lemma 36.** *Let  $X$  be a  $k$ -dimensional,  $(d_0, \dots, d_{k-1})$ -regular and  $(\beta, \log d_{k-2})$ -sparse simplicial complex so that  $\beta \geq \alpha(d_{k-1})$  and  $|X(k-2)| \leq d_{k-2}^{\log d_{k-1}}$ .*

*Then, for  $f : X(k) \rightarrow \{\pm 1\}$  drawn uniformly at random, with probability at least  $1 - d_{k-2}^{-3 \log d_{k-1}}$ :*

1. *For every  $\sigma \in X(k-2)$  and every  $S, T \subseteq X_\sigma(0)$ :  $|\langle \mathbf{1}_S, A_\sigma^f \mathbf{1}_T \rangle| \leq \beta \sqrt{|S||T|}$ .*
2. *The local lift  $\widehat{X} = \widehat{X}^f$  is  $(\beta, \log d_{k-2} + 1)$ -sparse.*  $\blacktriangleright$

<sup>6</sup> We will not calculate the constants in the big  $O$  notation explicitly.

We comment that the condition  $|X(k-2)| \leq d_{k-2}^{\log d_{k-1}}$  may seem odd at first glance. However, similar to Remark 29, this is eventually satisfied by every sequence  $\{X_i\}_{i=0}^\infty$  where  $X_{i+1}$  is a local lift of  $X_i$ . Thus, we do not lose too much generality by assuming it.

The proof of Lemma 36 follows by applying Lemma 32 to every link and taking a union bound over the links. We omit the proof since it is a direct calculation.

The deterministic construction mentioned at the beginning of this section is composed of iterative applications of the local lift, where each application is according to the algorithm described in the following lemma.

► **Lemma 37.** *Let  $X$  be a  $k$ -dimensional  $(d_0, \dots, d_{k-1})$ -regular  $(\beta, \log d_{k-2})$ -sparse simplicial complex with  $d_{k-1} > 2^{10k}$ ,  $\beta \geq \alpha(d_{k-1})$  and such that  $|X(k-2)| \leq d_{k-2}^{10k}$ .*

*Then, there is a deterministic  $\text{poly}(|X(0)|^k)$  time algorithm for finding a function  $f : X(k) \rightarrow \{\pm 1\}$  such that:*

1. *For every  $\sigma \in X(k-2)$ ,  $\|A_\sigma^f\| = O\left(2^{5k}\beta\left(1 + \log \frac{1}{\beta}\right)\right)$ .*
2.  *$\widehat{X}^f$  is  $(\beta, \log d_{k-2} + 1)$ -sparse.*

The proof of Lemma 37 appears in the full version of this paper [11]. We give here a short discussion of the techniques used there. The proof uses the method of conditional probabilities. The main idea is that, given the conditions on the input complex, we can define random variables denoted  $Z^{(\sigma)}$ , which serve as “error” indicators, where these errors occur with very small probability. By defining another set of random variables  $Y^{(\sigma)}$  which correlate with the links’ expansions, and amplifying the impact of each error, we are able to choose  $f(\tau)$   $k$ -face by  $k$ -face, while tracking the expected value of the sum of those variables efficiently and making sure no error occurs. We are now ready to prove our main result in this section.

**Proof of Theorem 35.** Let  $\bar{d} = (d_0, d_1, \dots, d_{k-1} = d)$  and let  $X_0$  be a  $\bar{d}$ -regular  $\lambda$ -two sided high dimensional expander for  $\lambda > \alpha_k(d)$ , such that  $|X_0(k-2)| \leq d_{k-2}^{10k}$ . By Claim 33, it is also  $(2\lambda, \log d_{k-2})$ -sparse.

Denote by  $\mathcal{B}'$  the algorithm suggested by Lemma 37, and let  $X_1, X_2, \dots, X_i$  be such that  $X_j = \mathcal{B}'(X_{j-1})$  for  $j \in [i]$ . We set  $X_i$  to be  $\mathcal{B}'$ ’s output.

Let us show that,  $X_i$  meets the guarantees of Theorem 35. By Observation 18, for every  $j \in [i]$ ,  $X_j$  is  $(2^j d_0, 2^j d_1, \dots, 2^j d_{k-2}, d)$ -regular and  $|X_j(0)| = 2^j |X_0(0)|$ .

In addition, one can verify by a direct calculation that, for any  $j \in [i]$ ,  $|X_j(k-2)| = 2^{k-1} |X_{j-1}(k-2)|$ , so if  $|X_{j-1}(k-2)| \leq d_{k-2} (X_{j-1})^{10k}$  then  $|X_j(k-2)| = 2^{k-1} |X_{j-1}(k-2)| \leq d_{k-2} (X_{j-1})^{10k} \cdot 2^{k-1} \leq d_{k-2} (X_j)^{10k}$ . Thus, by induction and the fact that this inequality holds for  $X_0$ , this holds for every  $j$ .

Finally, by Lemma 37 one inductively obtains that for any  $j$ :

1.  $X_j$  is an  $O\left(2^{5k}\lambda\left(1 + \log \frac{1}{\lambda}\right)\right)$ -high dimensional expander.
2.  $X_j$  is  $(2\lambda, \log d_{k-2}(X_j))$ -sparse.
3.  $X_j$  computed in time  $\text{poly}(|X_{j-1}(0)|^k) = \text{poly}(2^{j-1}|X_0(0)|^k)$ .

as required. ◀

## Abstract

We study randomness extractors in  $AC^0$  and  $NC^1$ . For the  $AC^0$  setting, we give a logspace-uniform construction such that for every  $k \geq n/\text{poly log } n$ ,  $\varepsilon \geq 2^{-\text{poly log } n}$ , it can extract from an arbitrary  $(n, k)$  source, with a small constant fraction entropy loss, and the seed length is  $O(\log \frac{n}{\varepsilon})$ . The seed length and output length are optimal up to constant factors matching the parameters of the best polynomial time construction such as [13]. The range of  $k$  and  $\varepsilon$  almost meets the lower bound in [10] and [7]. We also generalize the main lower bound of [10] for extractors in  $AC^0$ , showing that when  $k < n/\text{poly log } n$ , even strong dispersers do not exist in non-uniform  $AC^0$ . For the  $NC^1$  setting, we also give a logspace-uniform extractor construction with seed length  $O(\log \frac{n}{\varepsilon})$  and a small constant fraction entropy loss in the output. It works for every  $k \geq O(\log^2 n)$ ,  $\varepsilon \geq 2^{-O(\sqrt{k})}$ .

Our main techniques include a new error reduction process and a new output stretch process, based on low-depth circuit implementations for mergers, condensers, and somewhere extractors.

## 1 Introduction

Randomness extractors are functions that can transform weak random sources into distributions close to uniform. A typical definition of weak random sources is by min-entropy. A random variable (weak source)  $X$  has min-entropy  $k$  if for every  $x$  in the support of  $X$ ,  $\log \frac{1}{\Pr[X=x]} \geq k$ . To extract from an arbitrary weak source of a certain min-entropy, Nisan and Zuckerman [23] introduced the definition of seeded extractor, where the extractor has a short uniform random seed as an extra input. Specifically, a function  $\text{EXT} : \{0, 1\}^n \times \{0, 1\}^d \rightarrow \{0, 1\}^m$  is defined to be a strong  $(k, \varepsilon)$ -extractor, if for every source  $X$  with min-entropy  $k$ ,

$$\|(U_d, \text{EXT}(X, U_d)) - U_{d+m}\| \leq \varepsilon,$$

where  $U_d$  and  $U_m$  are uniform distributions over  $\{0, 1\}^d$  and  $\{0, 1\}^m$  respectively, and  $\|\cdot\|$  is the statistical distance. The entropy loss of such a strong extractor is  $k - m$ . On the contrary, a weak  $(k, \varepsilon)$ -extractor has the same definition except we only require

$$\|\text{EXT}(X, U_d) - U_m\| \leq \varepsilon.$$

The entropy loss of such a weak extractor is  $k + d - m$ .

As a fundamental pseudorandom construction, extractors are closely related to other pseudorandom objects and also have various applications in computational complexity, combinatorics, algorithm design, information theory, and cryptography. See surveys [21, 29, 37, 30, 1, 38].

Optimizing extractor constructions aims to get, for every  $k$  and  $\varepsilon$ , an extractor with  $d$  as small as possible, and  $m$  as large as possible. An existential bound for strong extractors can be given by a probabilistic argument, which has  $d = \log(n - k) + 2\log(1/\varepsilon) + O(1)$ ,  $m = k - 2\log(1/\varepsilon) - O(1)$ . This is optimal up to some additive constants for  $k \leq n/2$ , due to the lower bound by [24]. After [23], a long line of work has been done to seek explicit extractors with parameters close to the existential bounds [40, 31, 11, 32, 41, 25, 21, 27, 36, 33, 26, 20, 13, 34, 9, 19]. Among them, [13] first achieves  $d = \log n + O(\log(k/\varepsilon))$  and an arbitrary constant factor entropy loss, and also achieves  $m = k - 2\log(1/\varepsilon) - O(1)$  with  $d = \log n + O(\log k \cdot \log(k/\varepsilon))$ . [34] and [19] can also achieve the same parameters by replacing the condenser in [13] with their condenser versions. On the other hand, [34] and [9] achieve subconstant entropy loss  $m = (1 - 1/\text{poly log } n)k$ ,  $d = O(\log n)$  when  $\varepsilon \geq 1/2^{\log^\beta n}$  for any constant  $\beta < 1$ .

In terms of computational complexity, an explicit construction is an algorithm that can compute the function in deterministic polynomial time on given parameters. A natural question is whether one can construct extractors in lower complexity classes, with matching parameters to the current best explicit ones. Some early work on extractors already pays attention to constructions in low-complexity models. For example, Zuckerman [41] showed that his construction is actually in  $NC$ . Also Bar-Yossef, Reingold, Shaltiel, and Vadhan [2] showed streaming constructions for several pseudorandom objects including extractors. Furthermore, extractors in low-complexity models have already been used in derandomization tasks for certain low-complexity classes, such as in [35, 8]. In this paper, we specifically focus on two low-complexity classes, i.e.  $AC^0$  and  $NC^1$ .  $AC^0$  is the class of all uniform circuit families of polynomial-size, constant depth, with NOT, AND, and OR gates, where AND and OR gates have unbounded fan-in.  $NC^1$  is the class of all uniform circuit families of polynomial-size,  $O(\log n)$  depth, with NOT, AND, and OR gates, where AND, OR gates have fan-in 2. Unless otherwise specified, our constructions are all logspace-uniform circuit families, i.e. there exists a logspace Turing machine that can output the description for each circuit in the family.

Viola [39] raised the question on extractor construction in  $AC^0$  and showed that for every constant  $D$ , there exists a polynomial  $p$  such that as long as  $k \leq n/p(\log n)$ , no extractor in  $AC^0$  with depth  $D$  extract even 1 bit with a constant error, no matter how long the seed is. Goldreich and Wigderson [10] extend the result for bit-fixing sources. This rules out the possibility for the case that  $k = n/\log^{\omega(1)} n$ . For the case  $k \geq n/\text{poly log } n$ , [10] gives a strong extractor in  $AC^0$  that has an output length linear to the seed length. Lately Cheng and Li [7] give a construction that significantly improves the parameters. For the case that  $\varepsilon = 1/\text{poly } n$ ,  $\delta = 1/\text{poly log } n$ , they achieve  $d = O(\log n)$ ,  $m = O(\delta n)$ . For the more general case that  $\varepsilon = 2^{-\text{poly log } n}$ ,  $\delta = 1/\text{poly log } n$ , they achieve  $d = O\left(\log n + \frac{\log(n/\varepsilon)\log(1/\varepsilon)}{\log n}\right)$ ,  $m = O(\delta n)$ . They also show that  $\varepsilon$  has to be at least  $2^{-\text{poly log } n}$  for  $AC^0$  extractors.

For extractors in  $NC^1$ , unlike the  $AC^0$  case, there are no known lower bounds for  $k$  or  $\varepsilon$ . Indeed the extractor based on universal hash functions [5], argued by the leftover hash lemma [16], can achieve an arbitrary  $\varepsilon$  and  $k$ . It can be realized in  $NC^1$  since there are simple linear function constructions for such hash functions. Trevisan's extractor [36], and its improved version [26] can also be realized in  $NC^1$ , since their main components, the average-case hard function based on local list-decodable codes can be computed in  $NC^1$ .

Extractors can also be derived from averaging samplers [41]. Healy [15] constructs a sampler in  $\text{NC}^1$ . However if one simply applies the transformation of [41] on it, then this can only give an extractor with a constant error. So it is still a question whether one can achieve extractors in  $\text{NC}^1$  with better parameters for arbitrary  $k$  and  $\varepsilon$ .

## 1.1 Our results

Our main positive result is an  $\text{AC}^0$  computable extractor with parameters optimal up to constant factors.

► **Theorem 1.** *For every constant  $a, c > 0, \gamma \in (0, 1)$ , every  $k \geq \frac{n}{\log^a(n)}, \varepsilon \geq 2^{-\log^c(n)}$ , there exists an explicit  $(k, \varepsilon)$ -strong extractor  $\text{EXT} : \{0, 1\}^n \times \{0, 1\}^d \rightarrow \{0, 1\}^m$  in  $\text{AC}^0$  with depth  $O((a + c + 1)^2)$ , such that  $d = O(\log \frac{n}{\varepsilon})$ , and  $m \geq (1 - \gamma)k$ .*

Notice that this is much better in seed length compared to the previous best  $\text{AC}^0$  constructions [7], which requires  $d = O\left(\left(\log n + \frac{\log(n/\varepsilon)\log(1/\varepsilon)}{\log n}\right) \log^a n\right)$  for such an output length. Also, notice that there are lower bounds for  $k$  and  $\varepsilon$  in the  $\text{AC}^0$  construction setting, i.e.  $k$  has to be at least  $n/\text{poly log } n$  by [10] and  $\varepsilon$  has to be  $2^{-\text{poly log } n}$  by [7]. Thus roughly in the plausible range for  $k$  and  $\varepsilon$ , we achieve parameters optimal up to constant factors.

Our method can also be used to give  $\text{NC}^1$  computable extractors.

► **Theorem 2.** *For every constant  $\gamma \in (0, 1)$  every  $k \geq \Omega(\log^2(n)), \varepsilon \geq 2^{-O(\sqrt{k})}$ , there exists a strong  $(k, \varepsilon)$  extractor  $\text{EXT} : \{0, 1\}^n \times \{0, 1\}^d \rightarrow \{0, 1\}^m$  computable in  $\text{NC}^1$ , with  $d = O(\log(n/\varepsilon))$ ,  $m = (1 - \gamma)k$ .*

To our knowledge, the previous best known  $\text{NC}^1$  construction is the improved Trevisan's extractor from [26], which has seed length  $O(\log^2 n \log \frac{1}{\varepsilon})$ , for all  $k, \varepsilon$ . Our parameters are optimal up to constant factors for ranges of  $k, \varepsilon$  as stated.

Our negative result generalizes the previous entropy parameter lower bound by [10] for strong extractors in  $\text{AC}^0$  to strong dispersers in  $\text{AC}^0$ .

► **Theorem 3.** *For every  $d, s > 0$ , every constant  $\delta \in (0, 1)$ , if  $C : \{0, 1\}^n \times \{0, 1\}^r \rightarrow \{0, 1\}$  is a  $(k, \frac{1}{2} - \delta)$ -disperser that can be computed by a non-uniform  $\text{AC}$  circuit of size  $s$  and depth  $d$ , then  $k \geq \Theta\left(\frac{\delta n}{\log^{d-1} s}\right)$ .*

## 1.2 Technique Overview

### 1.2.1 Extractor in $\text{AC}^0$

Our  $\text{AC}^0$  computable extractor is constructed by three main parts.

#### 1.2.1.1 Merger in $\text{AC}^0$

In this part, we show that any somewhere high-entropy source  $X$  can be merged to be a high-entropy source in  $\text{AC}^0$  under a restricted setting of parameters. The merger is a crucial building block in the construction of our extractor.

Recall that  $X = (X_1, \dots, X_\Lambda)$  is a simple somewhere  $(n, k)$  source if there exists  $i \in [\Lambda]$ ,  $X_i$  is a  $(n, k)$  source. We call each  $X_i$  a segment. A somewhere  $(n, k)$  source is a convex combination of simple somewhere  $(n, k)$  sources. A  $(k, k', \varepsilon)$  merger is a function  $\text{Merge} : \{0, 1\}^{n\Lambda} \times \{0, 1\}^d \rightarrow \{0, 1\}^m$ , such that for any input somewhere  $(n, k)$  source  $X$ ,  $\text{Merge}(X, U)$  has entropy  $k'$ . [9] gives a fairly good merger for somewhere uniform sources, which has  $m = n = k, k' = (1 - \delta)k, d = \frac{1}{\delta}(\log \frac{2\Lambda}{\varepsilon})$ . Our key observation is that if the

number of segments in the somewhere uniform source is  $\text{poly log } n$ ,  $\delta$  is a small constant, and error  $\varepsilon = 2^{-\text{poly log } n}$ , then this merger can be computed in  $AC^0$ . To see this, note that the computation of [9] is over a finite field  $F_q$ , where  $q = 2^d = 2^{\text{poly log } n}$  in this setting. The computation only involves three operations: (1) the summation of  $\text{poly log } n$  elements; (2) the powering  $y^i$  where  $y \in \mathbb{F}_q, i = \text{poly log } n$ ; (3) the product of a constant number of field elements. (1) is clearly in  $AC^0$  since it is actually the summation of  $\text{poly log } n$  bits, while (2) and (3) are shown to be in  $AC^0$  by [14]. Note that this can be straightforwardly generalized to a merger for somewhere high-entropy source by first applying an extractor to each segment and then merging them.

### 1.2.1.2 Error Reduction

In this part, we give a new error reduction that can be realized in a highly parallel way. The required seed length is optimal up to constant factors, significantly better than [7]. Our method takes the basic extractor from [7], applies error reduction and stretches the output length to  $\text{poly}(\log n)$  bits. The stretching is designed to satisfy the requirement in the next part.

Let  $X$  be an input  $(n, k)$ -source with  $k = n/\log^a n$  for some constant  $a$ . We start from an  $AC^0$  computable  $(k, \varepsilon_0)$  extractor  $\text{EXT}_0 : \{0, 1\}^n \times \{0, 1\}^{d_0} \rightarrow \{0, 1\}^{m_0}$  where  $\varepsilon_0 = 1/n$ ,  $d_0 = O(\log n)$ ,  $m_0 = O(k^2/n)$ , which is achieved in [7]. Then for every given constant  $c$ , the new error reduction can reduce the error to be as small as  $\varepsilon = 2^{-\log^c(n)}$ , with a seed length  $O(\log \frac{n}{\varepsilon})$ . We briefly describe the main steps of the procedure along with their arguments.

1. Apply  $\text{EXT}_0$  to  $X$  for  $t = \frac{\log(n/\varepsilon)}{\log n}$  times in parallel, using independent seeds, outputting  $Y_1, Y_2, \dots, Y_t$  respectively, each of length  $m_0$ .  
Notice that by the error reduction of [25], one can show that with probability at least  $1 - \varepsilon' \geq 1 - O(\varepsilon_0)^t$ , there exists  $i$  such that  $Y_i$  has min-entropy at least  $m_0 - O(\log t)$ , while the seed length used here is only  $td_0 = O(\log(n/\varepsilon))$ . Hence one can deduce that  $(Y_1, \dots, Y_t)$  is  $t\varepsilon'$  close to a somewhere  $(m_0, m_0 - O(\log t))$  source. We stress that this step is also the first step in the error reduction of [7]. But we differ from [7] after then.
2. For each  $i$ , cut  $Y_i$  into  $l = O(\log n)$  blocks such that their lengths form a geometric sequence. That is  $Y_i = (Y_{i,1}, Y_{i,2}, \dots, Y_{i,l})$ , where we let  $m_j = |Y_{i,j}| = m_0^{0.1} \cdot 3^j$ . Denote  $Y_{i,1\dots j}$  as the first  $j$  blocks of  $Y_i$ . Then for each  $j$ , let  $B_j = (Y_{1,1\dots j}, Y_{2,1\dots j}, \dots, Y_{t,1\dots j})$ , i.e. the  $i$ -th segment of  $B_j$  is the first  $j$  blocks from  $Y_i$ . Regard  $B_j$  as a somewhere high-entropy source and merge it by the merger from the previous part, attaining  $Z_j$ . Here we use the same seed for each  $j$ . Then we regard  $(Z_1, Z_2, \dots, Z_l)$  as a block source and extract in a standard way by using an extractor  $\text{EXT}_1$ . Here  $\text{EXT}_1$  is constructed by first sampling  $O(\log \frac{n}{\varepsilon})$  bits from the source and then applying universal hashing.  
Notice that since the high entropy segment of  $Y$  is a  $(m_0, m_0 - O(\log t))$  source, each  $B_j$  has to be a somewhere  $(M_j, M_j - O(\log t))$  source, where  $M_j = m_1 + m_2 + \dots + m_j$ . Also, as  $t = \text{poly log } n$ , the merger can be implemented in  $AC^0$ . As a result of merging,  $Z_j$  has a high constant entropy rate. Since  $m_j, j \in [l]$  forms a geometric sequence,  $Z_j$  is a constant times longer than  $Z_{j-1}$ . Thus  $(Z_1, Z_2, \dots, Z_l)$  is indeed very close to a block source that has a constant conditional entropy rate. The output length is  $\Omega(\log n \log \frac{n}{\varepsilon})$  since for each block we can sample  $O(\log \frac{n}{\varepsilon})$  bits and then apply an extractor from the left-over hash lemma. The seed length is  $O(\log \frac{n}{\varepsilon})$  since both the merger and the sample-then-extract have a seed length  $O(\log \frac{n}{\varepsilon})$ .
3. Assume the previous steps give an extractor  $\text{EXT}'$ . To increase the output length, we run the above steps again but instead use  $\text{EXT}'$  to replace  $\text{EXT}_1$  in the second step. This can increase the output length by a  $\Omega(\log n)$  factor. We do this for  $b$  times to finally get an extractor with output length  $\Omega(\log^b n \cdot \log \frac{n}{\varepsilon})$ , for a given arbitrary constant  $b$ .

Note that in this way the circuit depth has a factor  $b$  blow-up. The seed length also has a factor  $b$  blow-up. But as  $b$  is a constant, the construction is still in  $AC^0$  and the seed length is still  $O(\log \frac{n}{\varepsilon})$ .

### 1.2.1.3 Output Stretch

The last part is a new output stretch procedure for  $AC^0$  computable extractors. Compared to the one in [7], the new method attains an output length  $(1 - \gamma)k$  with a seed length  $O(\log \frac{n}{\varepsilon})$ .

Observe that if the input source already has a constant entropy rate, then this is an easy case. Because one can do sampling to get a two-block source with constant conditional entropy rates. Then one can use the extractor derived from the previous part to extract from the second source, attaining a  $\text{poly} \log \frac{n}{\varepsilon}$  length output, and then use it to extract the first block by applying the main extractor from [7]. However, the hard case is when the entropy rate is sub-constant i.e.  $k = \frac{n}{\log^a n}$ . The above simple strategy does not work since we don't know how to argue that the block attained from sampling can keep a constant fraction of all entropy while conditioned on this block, the source still keeps a fairly large conditional entropy. To resolve this issue, we follow a general strategy used in [9]. We describe the following 3 steps to reduce the hard case to the easy case.

1. Use Ta-shma's somewhere-block-source converter [33] to convert the original source into a somewhere-two-block-source.

Recall that Ta-shma's converter tries every position of the input source. For each position, the source is cut into two substrings. To avoid having too many segments in the resulting somewhere-two-block-source, one can pick a cutting position after, for example, every  $n / \log^{2a} n$  consecutive positions. In this way, the number of segments is  $\Lambda = \log^{2a} n$ . [33] shows that for at least one of the position choices, the cutting can give a two-block source where the first block has entropy  $\Omega(k)$ , and the second has conditional entropy  $\Omega(k)$ .

2. For each segment, apply our extractor in the error reduction part for the second block and then use the output as a seed to extract the first block by the extractor in [7].

As at least one segment of the somewhere source is indeed a two-block source, the extraction for the second block can provide an output of length  $\text{poly} \log \frac{n}{\varepsilon}$ . This is enough to extract a constant fraction of entropy i.e.  $\Omega(k)$  from the first block by [7]. Then what we get is very close to a somewhere uniform source.

3. Use the merger in  $AC^0$  from the previous part to get a source with a constant entropy rate and min-entropy  $\Omega(k)$ .

As we only have  $\text{poly} \log n$  segments,  $\varepsilon = 2^{-\text{poly} \log n}$ , and the entropy rate attained is a constant, it holds that the merger is in  $AC^0$ , with a seed length  $O(\log \frac{n}{\varepsilon})$ . Then after merging, the hard setting is reduced to the previously discussed easy setting, i.e. the constant entropy rate case.

### 1.2.2 Extractor in $NC^1$

Our construction for extractor in  $NC^1$  can be described by the following 3 steps.

1. First apply a condenser from [19]. Regard the output as  $(Y_1, Y_2)$  such that  $Y_1, Y_2$  have a equal length.

Compared to the condenser in [13], the condenser in [19] can only work for  $k \geq \Omega(\log^2(n)), \varepsilon \geq 2^{-O(\sqrt{k(n)})}$ . However, the advantage is that it is computable in  $NC^1$ . Recall that the [19]  $(k, k + d, \varepsilon)$  condenser can actually be viewed as  $\text{Cond} : \mathbb{F}_q^n \times \mathbb{F}_q \rightarrow \mathbb{F}_q^m$ . It views the input source as coefficients of a degree  $n - 1$  polynomial  $f(x) = \sum_{i=0}^{n-1} a_i x^i$

over field  $\mathbb{F}_q$ ,  $\log q = O(\log \frac{n}{\epsilon})$ . The seed is a random element of  $\mathbb{F}_q$ . The computation is actually  $\text{Cond}(f, u) = (u, f(u), f^{(1)}(u), \dots, f^{(m)}(u))$ . Where  $f^{(j)}(u) = \sum_{i=0}^d \frac{i!}{(i-j)!} a_i u^{i-j}$  is the  $j$ -th derivative of  $f$ . Notice that all these coefficients  $\frac{i!}{(i-j)!}$  can be precomputed and hardwired in the circuits. The polynomial evaluation consists of three operations: (1) the powering  $x^{i-j}$ , (2) the multiplication of two  $\mathbb{F}_q$  elements, and (3) the summation of a polynomial number of elements. The powering could be implemented with two steps: powering in  $\mathbb{N}$  and then divided by  $q$ , which is computable in  $NC^1$  by [4]. The multiplication and summation are both in  $NC^1$  by straightforward realizations. So after condensing, we get a source  $(Y_1, Y_2)$  with an entropy rate  $> 3/4$ . As  $Y_1$  and  $Y_2$  have an equal length, they form a two-block source with constant conditional entropy rates.

2. For  $Y_2$ , apply the extractor from our error reduction to get  $Z$  of length  $O(\log^2 n \log(n/\epsilon))$ . This step is basically the same as the  $AC^0$  case. We make sure the error reduction can also be done in  $NC^1$  under this parameter setting, and the seed length is still  $O(\log \frac{n}{\epsilon})$ .
3. Apply the improved Trevisan's extractor [26] to  $Y_1$  using  $Z$  as the seed.

Notice that this extracts  $O(k)$  bits with a desired error. It can be further stretched to  $(1 - \gamma)k$  by a standard parallel method. Also, notice that it is a folklore that Trevisan's extractor [36] and its improved version [26] can be realized in  $NC^1$ . So our whole construction is in  $NC^1$ . The required seed length for improved Trevisan's extractor is  $O(\log^2 n \log(n/\epsilon))$ , and the output from step 2 is enough to feed it. Hence the overall seed length is  $O(\log \frac{n}{\epsilon})$ .

### 1.2.3 A lower bound for $AC^0$ computable dispersers

Our lower bound follows from the improved switching lemma in [28]. Assume  $\text{Disp} : \{0, 1\}^n \times \{0, 1\}^r \rightarrow \{0, 1\}$  is a strong  $(k, \frac{1}{2} - \delta)$ -disperser computable in  $AC^0$  with depth  $d$  and size  $s$ . Notice that we only need to consider the 1 bit output setting. Consider that for a fixed seed  $y \in \{0, 1\}^r$ , we apply a random restriction on  $C_y := \text{Disp}(\cdot, y)$ . Let the random restriction be  $R_p$  over  $\{0, 1, *\}^n$  such that for every  $i \in [n]$ , independently we have  $\Pr[R_p(i) = *] = p, \Pr[R_p(i) = 0] = \Pr[R_p(i) = 1] = \frac{1-p}{2}$ . For a restriction  $\rho$  sampled from  $R_p$ , the function  $C_y|_\rho$  is defined to be a function such that if  $\rho_i$  is 1 or 0 then fix the  $i$ -th input to be  $\rho_i$ , otherwise leave it unfixed, and then apply  $C_y$  on this modified input. The switching lemma from [28] basically shows that  $\Pr_{\rho \sim R_p}[C_y|_\rho \text{ is not constant}] \leq \delta$ , if  $p = \frac{\delta}{\Theta((\log s)^{d-1})}$ . Also notice that when  $\delta$  is a constant, with probability at least  $1 - 2^{-O(pn)} > 1 - \delta$ , the number of stars in  $\rho$  is at least  $p/2$  fraction. By a union bound and an averaging argument, one can show that there exists a  $\rho$  which has at least  $pn/2$  stars such that for  $> 1 - 2\delta$  fraction of  $y$ ,  $C_y|_\rho$  is a constant. Notice that if we take this  $\rho$  for a uniform input source, then it becomes a bit-fixing source of entropy  $k \geq pn/2 = \Theta(\frac{\delta n}{(\log^{d-1} s)})$ . Also notice that for every  $y$  such that  $C_y|_\rho$  is not fixed,  $\text{Supp}(C_y|_\rho(X)) \leq 2$  as  $C_y$  only has 1 bit output. This implies that  $|\text{Supp}(U, \text{Disp}(X, U))|$  is less than  $2\delta 2^r \cdot 2 + (1 - 2\delta)2^r \leq (\frac{1}{2} + \delta)2^{r+1}$ , a contradiction to the disperser definition.

## 1.3 Paper Organization

In Section 2 we prepare some basic tools used in the rest of the paper. In Section 3 we show that merger can be implemented in  $AC^0$ . In Section 4 we give our new error reduction. In Section 5 we give our new output stretch and show our  $AC^0$  computable extractor finally. In Section 6 we show our  $NC^1$  computable extractor. In Section 7 we give our lower bound for dispersers in  $AC^0$ . In Section 8 we describe some open questions.

## 2 Preliminaries

We use the following results from previous works. First, we review the extractors in  $\text{AC}^0$  from [7]. They are actually logspace-uniform constructions, though [7] did not explicitly mention this. We briefly explain the reason after exhibiting their results.

► **Theorem 4** ([7]). *For every constant  $a, c \geq 1$ , every  $k = \delta n = \Theta(n/\log^a n)$  there exists an explicit  $(k, 1/n^c)$ -extractor  $\text{EXT} : \{0, 1\}^n \times \{0, 1\}^d \rightarrow \{0, 1\}^m$  computable in  $\text{AC}^0$  with depth  $O(a)$ , where  $d = O(\log n)$ ,  $m = k^{0.01}$ .*

► **Remark 5.** Theorem 4 uses several tools and all of them can be implemented by logspace-uniform  $\text{AC}^0$  circuits. Specifically they use hardness amplifications from [17] and [18] and the Nisan-Wigderson (NW) generator [22]. These tools only use 4 kinds of operations: 1) pairwise independent generator; 2) inner product in  $\mathbb{F}_2^{O(\log n)}$ ; 3) parity function on  $O(\log n)$  bits; 4) Construct a combinatorial design and run the NW generator. It is straightforward to see that Procedure 1), 2) and 3) are all logspace-uniform. Procedure 4) is also logspace-uniform by Lemma A.3 in [6].

For smaller errors, they have the following theorem.

► **Theorem 6** ([7] for small entropy). *For every constant  $\gamma \in (0, 1)$ ,  $a, c \geq 1$ ,  $k = \delta n = \Theta(n/\log^a n)$ ,  $\varepsilon = 2^{-\Theta(\log^c n)}$ , there exists an explicit  $(k, \varepsilon)$ -extractor  $\text{EXT} : \{0, 1\}^n \times \{0, 1\}^d \rightarrow \{0, 1\}^m$  in  $\text{AC}^0$  with depth  $O(a+c)$ , where  $d = O\left(\left(\log n + \frac{\log(n/\varepsilon)\log(1/\varepsilon)}{\log n}\right)/\delta\right)$ ,  $m \geq (1-\gamma)k$ .*

Also, recall the sample-then-extract technique in  $\text{AC}^0$ .

► **Theorem 7** ([7] Sample-then-extract). *For every constant  $\delta \in (0, 1]$ ,  $c \geq 1$  and every  $\varepsilon = 2^{-\log^c n}$ , there exists an explicit strong  $(\delta n, \varepsilon)$ -extractor  $\text{EXT} : \{0, 1\}^n \times \{0, 1\}^d \rightarrow \{0, 1\}^m$  in  $\text{AC}^0$  with depth  $O(c)$ , where  $d = O(\log(n/\varepsilon))$ ,  $m = \Theta(\log(n/\varepsilon))$ .*

► **Remark 8.** Theorem 7 has two main ingredients: 1) The  $\text{NC}^1$  sampler from [15]. 2) Transforming a circuit of input length  $l = \Theta(\log^c n)$ , depth  $O(\log l)$  and size  $\text{poly}(l)$  to a  $\text{AC}^0$  circuit, from [12] (See also Lemma 12). Both of them are indeed logspace-uniform.

Theorem 6 uses Theorem 4 together with an error reduction and output stretch procedure. Both the error reduction and output stretch only consist of some sample-then-extract techniques and some utilities of the transformation from [12]. Hence it is also logspace-uniform.

Leftover hash lemma is also needed in our construction.

► **Lemma 9** (Leftover Hash Lemma [16]). *Let  $X$  be an  $(n', k = \delta n')$ -source. For any  $\Delta > 0$ , let  $H$  be a universal family of hash functions mapping  $n'$  bits to  $m = k - 2\Delta$  bits. The distribution  $U \circ \text{EXT}(X, U)$  is at distance at most  $1/2^\Delta$  to uniform distribution where the function  $\text{EXT} : \{0, 1\}^{n'} \times \{0, 1\}^d \rightarrow \{0, 1\}^m$  chooses the  $U$ 'th hash function  $h_U$  in  $H$  and outputs  $h_U(X)$ .*

*For universal hash functions, we use the construction from Toeplitz matrices. For every  $u$ , the hash function  $h_A(x)$  equals to  $Ax$  where  $A$  is a Toeplitz matrix.*

Error reduction for extractors has been extensively studied in previous works. We recall the following key ingredient in the classic error-reducing technique [25].

► **Lemma 10** ( $G_x$  Property [25]). *Let  $\text{EXT} : \{0, 1\}^n \times \{0, 1\}^d \rightarrow \{0, 1\}^m$  be a  $(k, \varepsilon)$ -extractor with  $\varepsilon < 1/4$ . Let  $X$  be any  $(n, k+t)$ -source. For every  $x \in \{0, 1\}^n$ , there exists a set  $G_x$  such that the following holds.*

## 69:8 Randomness Extractors in $AC^0$ and $NC^1$ : Optimal up to Constant Factors

- For every  $x \in \{0, 1\}^n$ ,  $G_x \subset \{0, 1\}^d$  and  $|G_x|/2^d = 1 - 2\epsilon$ .
- If we draw a  $y$  from  $\text{EXT}(X, G_X)$  (draw an  $x$  from  $X$ , then draw  $g_x$  uniformly from the set  $G_x$ , take  $y = \text{EXT}(x, g_x)$ ), then with probability at least  $1 - 2^{-t}$  over this random drawing, the  $y$  we get can have the property that  $\Pr[\text{EXT}(X, G_X) = y] \leq 2^{-(m-1)}$ . Here  $\text{EXT}(X, G_X)$  is obtained by first sampling  $x$  according to  $X$ , then choosing  $r$  uniformly from  $G_x$ , and outputting  $\text{EXT}(x, r)$ .

We also need to use the following lemmas about low-depth circuits computing.

► **Lemma 11** (folklore, see also [7]). *Let  $a > 0$  be an absolute constant. Then  $\log^a(n)$ -bit parity can be computed by an  $AC^0$  circuit with  $O(a)$  depth and  $\text{poly}(n)$  size.*

► **Lemma 12** ([12]). *For every  $c \in \mathbb{N}$ , every integer  $l = \Theta(\log^c n)$ , if the function  $f_l : \{0, 1\}^l \rightarrow \{0, 1\}$  can be computed by circuits of depth  $O(\log l)$  and size  $\text{poly}(l)$ , then it can be computed by  $AC^0$  circuits of depth  $c + 1$ , size  $\text{poly}(n)$ .*

► **Remark 13.** The transformation from [12] mainly uses Barrington's Theorem [3] which provides a Dlogtime-uniform  $AC^0$  reduction from any  $NC^1$  circuit to a downward self-reducible  $NC^1$ -complete language. The self-reducible here is logspace-uniform  $NC^0$  reduction. Thus the  $NC^1$  complete language of input size  $l = \Theta(\log^c n)$  can be reduced to a language of input size  $O(\log n)$  and thus can be decided by logspace-uniform  $AC^0$  circuits.

Finally, we use some folklore facts about block sources. Proofs of them can be found in the full version.

► **Definition 14** (block source). *Let  $X = (X_1, \dots, X_l)$  such that each  $X_i$  is distributed on  $\{0, 1\}^{n_i}$ . We say  $X$  is a  $(n_1, k_1, n_2, k_2, \dots, n_l, k_l)$ -block source if for every  $i \in [l]$  and  $(x_1, \dots, x_{i-1}) \in \{0, 1\}^{n_1 + \dots + n_{i-1}}$ ,  $X_i|_{X_1=x_1, \dots, X_{i-1}=x_{i-1}}$  is a  $(n_i, k_i)$ -source.*

► **Lemma 15.** *Fix  $t \in \mathbb{N}$  and  $k, s, n, n_1, \dots, n_k \in \mathbb{N}$  such that  $n_1 + \dots + n_k = n$ . Let  $X = (X_1, \dots, X_l)$  be a  $(n, n - k)$ -source on  $\{0, 1\}^n$  such that  $X_i$  is distributed on  $\{0, 1\}^{n_i}$  for each  $i \in [t]$ . Then  $(X_1, \dots, X_l)$  is  $l \cdot 2^{-s}$ -close to a  $(n_1, n_1 - k, n_2, n_2 - k - s, \dots, n_l, n_l - k - s)$ -source.*

► **Lemma 16.** *Let  $X = (X_1, \dots, X_l)$  be a  $(n_1, k_1, n_2, k_2, \dots, n_l, k_l)$ -block source on  $\{0, 1\}^n$ . Suppose that  $\text{EXT}_i : \{0, 1\}^{n_i} \times \{0, 1\}^r \rightarrow \{0, 1\}^{m_i}$  is a strong  $(k_i, \epsilon)$ -extractor for each  $i \in [l]$ . Let  $Y$  be a uniformly random variable on  $\{0, 1\}^r$ . Take  $Z = (Z_1, \dots, Z_l)$  such that  $Z_i = \text{EXT}_i(X_i, Y)$ . Then  $(Y, Z)$  is  $l \cdot \epsilon$ -close to uniform.*

► **Definition 17** (strong two-block extractor). *We say a function  $\text{EXT} : \{0, 1\}^{n_1} \times \{0, 1\}^{n_2} \times \{0, 1\}^r \rightarrow \{0, 1\}^m$  is a strong  $(k_1, k_2, \epsilon)$ -two-block extractor, if for any  $(k_1, k_2)$ -block-source  $X = (X_1, X_2)$  and independent uniform random distribution  $U_r$  on  $\{0, 1\}^r$ , the joint distribution  $(U_r, \text{EXT}(X_1, X_2, U_r))$  is  $\epsilon$ -close to uniform distribution on  $\{0, 1\}^r \times \{0, 1\}^m$ .*

► **Lemma 18.** *Let  $\text{EXT}_1 : \{0, 1\}^{n_1} \times \{0, 1\}^{m_1} \rightarrow \{0, 1\}^{m_2}$  be a  $(k_1, \epsilon_1)$ -strong extractor, and  $\text{EXT}_2 : \{0, 1\}^{n_2} \times \{0, 1\}^r \rightarrow \{0, 1\}^{m_1}$  be a  $(k_2, \epsilon_2)$ -strong extractor. Then the construction*

$$\text{EXT}(X_1, X_2, U_r) = \text{EXT}_1(X_1, \text{EXT}_2(X_2, U_r)) \quad (1)$$

*is a strong  $(k_1, k_2, \epsilon_1 + \epsilon_2)$ -two-block extractor*

### 3 Merger in $AC^0$

In this section, we will examine the merger construction in [9] and show that the merger can indeed be implemented in  $AC^0$  for some specific setting of parameters.

We start by defining somewhere- $(n, k)$  sources.

► **Definition 19** (somewhere- $(n, k)$  source). *Let  $X = (X_1, \dots, X_\Lambda)$  such that each  $X_i$  is distributed on  $\{0, 1\}^n$ . We say  $X$  is a simple somewhere- $(n, k)$  source with  $\Lambda$  segments if there exists  $i \in [\Lambda]$  such that  $X_i$  is a  $(n, k)$ -source on  $\{0, 1\}^n$ . We say  $X$  is a somewhere-uniform source if  $X$  is a convex combination of simple somewhere- $(n, k)$  sources.*

*If  $n = k$  in the above definition, which means that  $X_i$  is uniform, we say  $X$  is a somewhere-uniform source.*

A merger is a function that takes a somewhere-uniform source and a uniform random seed as input and outputs a  $(m, k')$ -source. The remaining entropy  $k'$  is usually less than the original entropy  $k$ .

► **Definition 20** (merger and strong merger). *We say  $\text{Merge} : \{0, 1\}^{\Lambda \cdot n} \times \{0, 1\}^r \rightarrow \{0, 1\}^m$  is a  $(k, k', \varepsilon)$ -merger if for any somewhere- $(n, k)$  source  $X = (X_1, \dots, X_\Lambda)$ , the distribution  $\text{Merge}(X, U_r)$  is  $\varepsilon$ -close to a  $k'$ -source. Here  $U_r$  is a independent uniform random distribution on  $\{0, 1\}^r$*

*Furthermore, if  $(U_r, \text{Merge}(X, U_r))$  is  $\varepsilon$ -close to  $(U_r, W)$ , we say  $\text{Merge}$  is a strong  $(k, k', \varepsilon)$ -merger. Here  $W$  is a distribution such that for all  $a \in \{0, 1\}^r$ ,  $W|_{U_r=a}$  is a  $k'$ -source.*

We examine the merger introduced in [9], and find that the merger can be implemented in  $AC^0$  if the number of segments is not too large.

► **Theorem 21** (merger in [9]). *For any constant  $a, c > 0$ ,  $\delta \in (0, 1)$ , let  $\Lambda(n) \leq \log^a(n)$ ,  $\varepsilon(n) \geq 2^{-\log^c(n)}$ . Then there exists explicit  $(n, \delta n, \varepsilon(n))$ -mergers  $\text{Merge} : \{0, 1\}^{\Lambda(n) \cdot n} \times \{0, 1\}^{r(n)} \rightarrow \{0, 1\}^n$ . Here  $r(n) = O(\log(\frac{1}{\varepsilon}))$ .*

*Furthermore, the mergers can be implemented in  $AC^0$  with  $O(a + c + 1)$  depth and  $\text{poly}(n)$  size,*

The merger in [9] is defined as follows:

Define  $q = 2^s$  be a power of two which is decided later. Let  $\mathbb{F}_q$  be the finite field of order  $q$ . Let  $X = (X_1, \dots, X_\Lambda)$  be a somewhere-uniform-source with  $\Lambda$  segments. Regard each  $X_i$  as distributed on  $\mathbb{F}_q^K$  with  $K = \frac{n}{s}$ . Then

$$X_i = (X_{i,1}, \dots, X_{i,K}), \quad X_{i,j} \in \mathbb{F}_q. \quad (2)$$

Note that the uniform distribution on  $\mathbb{F}_q^K$  is equivalent to the uniform distribution on  $\{0, 1\}^n$ .

Take  $\gamma_1, \dots, \gamma_\Lambda$  be  $\Lambda$  unique points in  $\mathbb{F}_q$ . Let  $C_1, \dots, C_\Lambda$  be  $\Lambda$  unique polynomials in  $\mathbb{F}_q[x]$  of degree at most  $\Lambda - 1$ , such that  $C_i(\gamma_j) = 1$  if  $i = j$  and  $C_i(\gamma_j) = 0$  if  $i \neq j$ . Then the merger is defined as:

$$\text{Merge}(X, y) = \left( \sum_{i=1}^{\Lambda} C_i(y) X_{i,1}, \dots, \sum_{i=1}^{\Lambda} C_i(y) X_{i,K} \right), \quad (3)$$

where  $y \in \mathbb{F}_q$ .

## 69:10 Randomness Extractors in $AC^0$ and $NC^1$ : Optimal up to Constant Factors

► **Lemma 22** (merger in [9]). *For any constant  $\delta > 0$ , let  $q \geq (\frac{2\Lambda}{\varepsilon})^{1/\delta}$ . Then the function  $\text{Merge} : \mathbb{F}_q^{K \cdot \Lambda} \times \mathbb{F}_q \rightarrow \mathbb{F}_q^K$  is a  $(K \log q, k, \varepsilon)$ -merger, where  $k = (1 - \delta) \cdot K \cdot \log q$ .*

The condition  $q \geq (\frac{2\Lambda}{\varepsilon})^{1/\delta}$  is equivalent to  $r \geq \frac{1}{\delta} \log(\frac{2\Lambda}{\varepsilon})$ . When  $\Lambda = \log^a(n)$ ,  $\varepsilon = 2^{-\log^c(n)}$ , this requires  $r \geq \frac{2}{\delta} \log^c(n)$ . So we can pick  $r(n) = \min\{s \in \mathbb{N} \mid s \geq \frac{2}{\delta} \log^c(n), \exists d \in \mathbb{N}, s = 3 \cdot 2^d\}$ . As  $\delta$  is a constant,  $r(n) = O(\log^c(n)) = O(\log(\frac{1}{\varepsilon}))$ .

► **Lemma 23.** *For any constant  $a, c, \delta \in (0, 1)$ , let  $\Lambda(n) \leq \log^a n$ ,  $\varepsilon(n) \geq 2^{-\log^c(n)}$ . Define  $r(n) = \min\{s \in \mathbb{N} \mid s \geq \frac{2}{\delta} \log^c(n), \exists d \in \mathbb{N}, s = 3 \cdot 2^d\}$ ,  $q(n) = 2^{r(n)}$ ,  $K(n) = \frac{n}{r(n)}$ . Then the  $(n, \delta n, \varepsilon)$ -merger  $\text{Merge} : \{0, 1\}^{\Lambda(n) \cdot n} \times \{0, 1\}^{r(n)} \rightarrow \{0, 1\}^n$  can be implemented in uniform  $AC^0$  with  $O(a + c + 1)$  depth and  $\text{poly}(n)$  size.*

To prove the lemma, we can express the  $\Lambda$  polynomials  $C_1, \dots, C_\Lambda$  by their  $\Lambda^2$  coefficients. That is:

$$C_i(y) = \sum_{j=1}^{\Lambda} c_{i,j} y^{j-1}, \quad c_{i,j} \in \mathbb{F}_q, \quad i \in [\Lambda].$$

These coefficients are not necessarily computable in  $AC^0$ . Instead, they can be pre-determined and stored in the circuit. Note that  $\Lambda = \log^a(n)$  and  $r_2(n) = O(\log^c(n))$ . Therefore it requires  $O(\log^c(n))$  bits to store one coefficient, and  $O(\log^{2a+c}(n))$  bits to store all the coefficients.

Therefore, the  $AC^0$  circuit for the merger is only required to do three types of operations: powering, multiplication and summation. The parameters of these operations satisfies the following conditions:

1. The powering operation is to compute  $y^j$ , where  $j \leq \log^a(n)$ , and  $y \in \mathbb{F}_q$ . The order  $q = 2^s$  is a power of 2, and  $s = O(\log^c(n))$ .
2. The multiplication operation is to compute  $c_{i,j} y^{j-1} X_{i,k}$ , for each  $i \in [\Lambda], j \in [\Lambda], k \in [K]$ . All of the three multipliers are in  $\mathbb{F}_q$ .
3. The summation operation is to compute  $\sum_{i=1}^{\Lambda} \sum_{j=1}^{\Lambda} c_{i,j} y^{j-1} X_{i,k}$  for each  $k \in [K]$ . All the addends are in  $\mathbb{F}_q$ , and the total number of them is  $\log^{4a}(n)$ .

The following theorems in the work of Healy and Viola [14] show that the powering and multiplication are indeed in  $AC^0$ .

► **Lemma 24** ([14, Corollary 6(1)]). *Let  $a, c > 0$  be absolute constants. Let  $y \in \mathbb{F}_q$  where  $q = 2^s$  and  $s = 2 \cdot 3^d$  for some  $d \in \mathbb{N}$ . Suppose that  $j \leq \log^a(n)$  and  $s \leq \log^c(n)$ , then  $y^j$  can be computed by a logspace-uniform  $AC^0$  circuit with  $O(a + c)$  depth and  $\text{poly}(n)$  size.*

► **Lemma 25** ([14, Corollary 6(2)]). *Let  $a, c > 0$  be absolute constants. Let  $y_1, y_2 \in \mathbb{F}_q$  where  $q = 2^s$  and  $s = 2 \cdot 3^d$  for some  $d \in \mathbb{N}$ . Suppose that  $s \leq \log^c(n)$ , then  $y_1 \cdot y_2$  can be computed by a logspace-uniform  $AC^0$  circuit with  $O(c)$  depth and  $\text{poly}(n)$  size.*

The summation operation is also in  $AC^0$ , as the summation of elements in  $\mathbb{F}_q$  where  $q = 2^s$  is equivalent to bitwise parity of the binary representation of the elements if we implement  $\mathbb{F}_q$  by polynomial fields with coefficients in  $\mathbb{F}_2$ . When the number of addends is  $\text{poly} \log n$ , it is in  $AC^0$  by Lemma 11.

With these results, the merger can be implemented in  $AC^0$  with  $O(a + c)$  depth and  $\text{poly}(n)$  size.

**Proof of Lemma 23.** It is sufficient prove that each  $\sum_{i=1}^{\Lambda} \sum_{j=1}^{\Lambda} c_{i,j} y^{j-1} X_{i,k}$  can be computed in  $\text{AC}^0$  with  $O(a+c)$  depth and  $\text{poly}(n)$  size. The powering could be computed in  $O(a+c)$  depth and  $\text{poly}(n)$  size by Lemma 24. The multiplication could be computed in  $O(c)$  depth and  $\text{poly}(n)$  size by Lemma 25. The summation could be computed in  $O(a)$  depth and  $\text{poly}(n)$  size by Lemma 11.  $\blacktriangleleft$

Theorem 21 follows directly from Lemma 22 and Lemma 23.

**Proof of Theorem 21.** Take  $r(n) = \min\{s \in \mathbb{N} | s \geq \frac{2^{\log^c(n)}}{\delta}, \exists d \in \mathbb{N}, s = 3 \cdot 2^d\}$ ,  $q(n) = 2^{r(n)}$ ,  $K(n) = \frac{n}{r(n)}$  as discussed above. By Lemma 22, we know that the merger is a  $(n, k(n), \varepsilon(n))$ -merger, where  $k(n) = (1-\delta)n$ . By Lemma 23, we know that the merger can be implemented in  $\text{AC}^0$  with  $O(a+c)$  depth and  $\text{poly}(n)$  size.  $\blacktriangleleft$

As noted in [9], their merger for somewhere uniform sources can be extended to handle somewhere high entropy sources. Following their idea, we also prepare a merger for somewhere high entropy sources, and furthermore, it is computable by low-depth circuits.

► **Corollary 26.** *Let  $\delta \in (0, 1)$ ,  $\Lambda(n) \leq \text{poly}(n)$ ,  $\varepsilon(n) = 2^{-O(n)}$ ,  $\Delta(n) = O(\log(\frac{n}{\varepsilon}))$ . Then there exists a strong  $(n - \Delta(n), \delta m(n), \varepsilon(n))$ -merger  $\text{Merge} : \{0, 1\}^{\Lambda(n) \cdot n} \times \{0, 1\}^{r(n)} \rightarrow \{0, 1\}^{m(n)}$ . Here  $r(n) = O(\log(\frac{n}{\varepsilon}))$  and  $m(n) = \Omega(n)$ . The merger is computable in logspace-uniform  $\text{AC}^0[2]$ .*

*If  $\Lambda(n) \leq \log^a(n)$ ,  $\varepsilon(n) \geq 2^{-\log^c(n)}$  for constant  $a, c > 0$ , then the merger can be implemented in  $\text{AC}^0$  with  $O(a+c+1)$  depth and  $\text{poly}(n)$  size.*

## 4 Error Reduction

The main theorem of this section is the following:

► **Theorem 27.** *For any constant  $a, c > 0$ ,  $b \in \mathbb{N}^+$ , every  $k(n) \geq n/\log^a(n)$ ,  $\varepsilon(n) \geq 2^{-\log^c(n)}$ , there exists a strong  $(k(n), \varepsilon(n))$ -extractor  $\text{EXT} : \{0, 1\}^n \times \{0, 1\}^{r(n)} \rightarrow \{0, 1\}^{m(n)}$ , where  $r(n) = O(\log(\frac{n}{\varepsilon(n)}))$ ,  $m(n) = \Theta(\log^b(n) \cdot \log(\frac{n}{\varepsilon(n)}))$ .*

*Furthermore, the extractor can be implemented in  $\text{AC}^0$  with  $O(b(a+c+1))$  depth.*

We show this theorem by giving a new error reduction stated as the following. To describe it, We fix  $a > 0$  to be a constant and  $k(n) = \frac{n}{\log^a n}$ .

► **Lemma 28.** *For any  $\varepsilon_0 \in (0, 1)$  every constant  $c > 0$  and  $\varepsilon = 2^{-\log^c n}$ , suppose there exists a  $(k, \varepsilon_0)$ -extractor  $\text{EXT}_0 : \{0, 1\}^n \times \{0, 1\}^{d_0} \rightarrow \{0, 1\}^{m_0}$  with  $m_0 \geq k^{0.01}$  and a family of strong  $(n_1/100, \varepsilon)$ -extractors  $\text{EXT}_1 : \{0, 1\}^{n_1} \times \{0, 1\}^{d_1} \rightarrow \{0, 1\}^{m_1}$  for every  $n_1 \in [m_0^{0.1}, m_0]$ , Then for any  $\varepsilon = 2^{-\log^c n}$ , there exists a strong  $(k, \varepsilon)$ -extractor  $\text{EXT}' : \{0, 1\}^n \times \{0, 1\}^d \rightarrow \{0, 1\}^m$ , where  $d = O(d_1 + d_0 \cdot \frac{\log \varepsilon}{\log \varepsilon_0})$ ,  $m = \Theta(m_1 \cdot \log n)$ .*

*If  $\text{EXT}_0$  and  $\text{EXT}_1$  can be realized by depth  $h$  and  $g$  AC circuits respectively, then  $\text{EXT}'$  can be realized by a depth  $O(h+g+c+1)$  AC circuit.*

Now we describe the construction and analysis of Lemma 28.

### 4.1 Step 1: extracting in parallel

We apply  $\text{EXT}_0$  for  $t = \frac{\log(1/\varepsilon)}{\log(1/\varepsilon_0)}$  times in parallel, with independent seeds. Specifically, take  $U_{1,i}$  be independent uniform seeds in  $\{0, 1\}^{d_0}$  for every  $i \in [t]$ . Let  $Y = (Y_1, Y_2, \dots, Y_t)$ , where  $Y_i = \text{EXT}_0(X, U_{1,i})$ .

The step can be computed by depth  $h$  AC circuits because the extractor  $\text{EXT}_0$  has depth  $h$ , and the parallel extraction can be done without increasing the depth.

### Analysis

We now show that  $Y$  is close to a somewhere- $(m_0(n), m_0(n) - O(\log t))$ -source. The main idea is that by Lemma 10, we know that with high probability, at least one of the seeds  $U_i$  lands in  $G_x$ , which makes  $Y_i$  a good source with a high entropy rate. The following lemma states this formally:

► **Lemma 29.** *Let  $\text{EXT}_0 : \{0, 1\}^n \times \{0, 1\}^{d_0} \rightarrow \{0, 1\}^{m_0}$  be an  $(k, \varepsilon_0)$ -extractor and  $X$  be a  $(n, k + s)$ -source. Take independent seeds  $U_1, U_2, \dots, U_s \in \{0, 1\}^{d_0}$ . Let  $Y = (Y_1, Y_2, \dots, Y_t)$ , where  $Y_i = \text{EXT}_0(X, U_i)$ . Then  $Y$  is  $(2\varepsilon_0)^t + t \cdot 2^{-s}$ -close to a somewhere- $(m_0, m_0 - O(\log t))$ -source*

Take  $x$  from a fixed distribution  $X$  and fix extractor  $\text{EXT}$ . Let  $G_x$  be the set of good seeds from Lemma 10. We first denote event  $\text{BAD}_i = \{U_i \notin G_x\}$ . Note that these events are not necessarily independent. However, the probability that all of them happen is exponentially small, as the following claim shows.

▷ **Claim 30.**  $\Pr[\text{BAD}_1 \wedge \text{BAD}_2 \wedge \dots \wedge \text{BAD}_t] \leq (2\varepsilon_0)^t$ .

We define an indicator random variable  $I \in \{0, 1\}^{[t]}$  as follows:

$$\forall i \in [t], i \in I \iff U_i \in G_x. \quad (4)$$

With probability at least  $1 - (2\varepsilon_0)^t$ , The set  $I$  is not an empty set. Take  $Y_i = \text{EXT}(X, U_i)$ . By Lemma 10,  $Y_i|_{(\text{BAD}_i)^c} = Y_i|_{i \in I}$  is  $2^{-s}$ -close to a  $(m_0, m_0 - O(1))$  source.

We apply the technique from [20] to prove that  $(Y_1, Y_2, \dots, Y_t)$  is indeed close to a somewhere- $(m_0, m_0 - O(\log t))$ -source.

► **Lemma 31** ([20]). *Let  $Y = (Y_1, \dots, Y_t)$  be the random variable defined in Lemma 29. Let  $I$  be a random set subset of  $[t]$ . Assume  $I \neq \emptyset$ , and for every  $i \in [t]$ ,  $Y_i|_{i \in I}$  is  $\varepsilon$ -close to a  $(m, k)$ -source. Then  $Y$  is  $(t \cdot \varepsilon)$ -close to a somewhere- $(m, k - \log t)$  source.*

By Claim 30 and Lemma 31, we can prove Lemma 29:

**Proof of Lemma 29.** Take  $I$  as the random set indicator defined above. By Lemma 10,  $Y_i|_{(\text{BAD}_i)^c} = Y_i|_{i \in I}$  is  $2^{-s}$ -close to a  $(m_0, m_0 - O(1))$  source. By Claim 30, we know that with probability at least  $1 - (2\varepsilon_0)^t$ ,  $I$  is not an empty set. Conditioning on such events, Lemma 31 implies that  $Y|_{\{I \neq \emptyset\}}$  is  $t \cdot 2^{-s}$ -close to a somewhere- $(m_0, m_0 - O(\log t))$  source. The lemma follows. ◀

## 4.2 Step 2: divide and merge

Assume we have a somewhere- $(m_0, m_0 - O(\log t))$ -source. We divide each segment of the source into a sequence of blocks whose lengths form a geometric sequence. Specifically, take  $Y = (Y_1, Y_2, \dots, Y_t)$  to be a simple somewhere- $(m_0, m_0 - O(\log t))$ -source. We divide each  $Y_i$  into  $l + 1$  blocks of length  $m_1, m_2, \dots, m_{l+1}$  respectively, such that

$$Y_i = (Y_{i,1}, Y_{i,2}, \dots, Y_{i,l+1}) \text{ for every } i \in [t]. \quad (5)$$

The lengths satisfies

$$m_j = m_0^{0.1} \cdot 3^{j-1} \text{ for every } j \in [l]. \quad (6)$$

where  $l = \lceil \log_3 m_0^{0.9} \rceil$ . Denote  $Y_{i,1\dots j} = (Y_{i,1}, Y_{i,2}, \dots, Y_{i,j})$  for every  $i \in [t]$  and  $j \in [l]$ . Define  $B_j$  as:

$$B_j = (Y_{1,1\dots j}, Y_{2,1\dots j}, \dots, Y_{t,1\dots j}) \text{ for every } j \in [l]. \quad (7)$$

We denote  $M_j = m_1 + m_2 + \dots + m_j$  for every  $j \in [l]$ .

Let  $\text{Merge}_j : \{0, 1\}^{t \cdot M_j} \times \{0, 1\}^{d_2(n)} \rightarrow \{0, 1\}^{(1-\alpha)M_j}$  be a strong  $(M_j - \Delta, \frac{3}{4}(1-\alpha)M_j, \varepsilon(n)/l)$ -merger from Corollary 26 for every  $j \in [l]$ , where  $\alpha$  is a constant. The seed length of the merger is  $d_2(n) = O(\log(\frac{M_j}{\varepsilon(n)})) = O(\log(\frac{m(n)}{\varepsilon(n)}))$ . Let  $U_2$  be a uniform random variable on  $\{0, 1\}^{d_2(n)}$ . Define

$$Z_j = \text{Merge}_j(B_j, U_2) \text{ for every } j \in [l]. \quad (8)$$

The gap between source length and source entropy is  $\Delta = O(\log t) = O(\log \frac{1}{\varepsilon(n)})$ , which meets the requirement that  $\Delta = O(\log \frac{M_j}{\varepsilon(n)})$  in Corollary 26.

Next, we apply the strong extractor family  $\text{EXT}_1$  to extract from the block source. Let  $\text{EXT}_{1,j} : \{0, 1\}^{(1-\alpha)M_j} \times \{0, 1\}^{d_3(n)} \rightarrow \{0, 1\}^{m'(n)}$  be a strong  $((1-\alpha)M_j/100, \varepsilon(n)/l)$ -extractor for every  $j \in [l]$ . These  $\text{EXT}_{1,j}, j \in [l]$  with different input lengths, are all from the family  $\text{EXT}_1$ . Let  $U_3$  be a uniform random variable on  $\{0, 1\}^{d_3(n)}$ . Then

$$W_j = \text{EXT}_{1,j}(Z_j, U_3) \text{ for every } j \in [l]. \quad (9)$$

### Analysis

Now we give our analysis. Note that since  $Y$  is a simple somewhere high entropy source, by dividing it into blocks, each prefix  $B_j$  is a simple somewhere- $(M_j, M_j - O(\log t))$ -source. Through merging,  $Z_j$ 's are correlated high-entropy sources with different lengths. They are close to a block source.

► **Lemma 32.**  $Z_j$  is  $\varepsilon(n)/l$ -close to a  $((1-\alpha)M_j, \frac{3}{4}(1-\alpha)M_j)$ -source for every  $j \in [l]$ .

**Proof.** Let  $Y_i$  be a  $(m_0, m_0 - O(\log t))$ -source in  $Y$ . Then  $Y_{i,1\dots j}$  must have entropy at least  $m_j - O(\log t)$ . Therefore  $B_j$  is a somewhere- $(m_j, m_j - O(\log t))$ -source. By Corollary 26,  $Z_j$  is  $\varepsilon(n)/l$ -close to a  $((1-\alpha)M_j, \frac{3}{4}(1-\alpha)M_j)$ -source. The claim follows. ◀

Denote  $Z_0 = (U_1, U_2)$  as the seeds used in all previous steps to obtain  $Z_1, \dots, Z_j$ . We stress that the sequence  $Z_0, Z_1, \dots, Z_l$  is of exponentially increasing length and each contains  $|Z_j| - O(\log \frac{1}{\varepsilon(n)})$  bits of min-entropy. Therefore, even if all the randomness in  $(Z_0, \dots, Z_i)$  is contained in  $Z_{i+1}$ , there still must be  $\Omega(|Z_{i+1}|)$  bits of conditional min-entropy within  $Z_{i+1}$ . That makes the sequence a block source. We formalize the inspection into the following lemma.

► **Lemma 33.**  $(Z_0, Z_1, Z_2, \dots, Z_l)$  is  $2\varepsilon(n)$ -close to a block source  $(Z_0, Z'_1, Z'_2, \dots, Z'_l)$ . The conditional entropy of  $Z'_j$  is larger than  $(1-\alpha)M_j/100 = \Omega((1-\alpha)M_j)$  for each  $j \in [l]$

Then we can extract from the block-source  $(Z_0, Z_1, Z_2, \dots, Z_l)$  using standard methods, which gives  $(Z_0, U_3, W_1, W_2, \dots, W_l)$ :

► **Lemma 34.**  $(Z_0, U_3, W_1, W_2, \dots, W_l)$  is  $3\varepsilon(n)$ -close to  $(Z_0, U_3, V)$ , where  $V$  is a independent uniform distribution.

### 4.3 Wrap-up to prove Lemma 28 and Theorem 27

**Proof of Lemma 28.** Take  $X$  be the sources,  $U_1, U_2, U_3$  be the seeds. Let  $Y = (Y_1, Y_2, \dots, Y_t)$  such that  $Y_i = \text{EXT}_0(X, U_{1,i})$  for every  $i \in [t]$  as in the first step. By Lemma 29,  $Y$  is  $\varepsilon(n)$ -close to a somewhere- $(m(n), m(n) - O(\log t))$ -source. Let  $B_j$  be the source  $(Y_{1,1\dots j}, Y_{2,1\dots j}, \dots, Y_{t,1\dots j})$  for every  $j \in [l]$ . Then take  $Z_j = \text{Merge}_j(B_j, U_2)$  and  $W_j = \text{EXT}_{1,j}(Z_j, U_3)$  for every  $j \in [l]$  as in the second step. Here  $\text{EXT}_{1,j}$  is the strong extractor from family  $\text{EXT}_1$  with source length  $n_1 = m_j$ . By Lemma 34 and its remark,  $(U_1, U_2, U_3, W)$  is  $3\varepsilon(n)$ -close to uniform if  $Y$  is a somewhere- $(m(n), m(n) - O(\log t))$ -source. By the triangle inequality,  $W$  is  $4\varepsilon(n)$ -close to uniform.

Step 1 executes the extractor  $\text{EXT}_0$  in parallel, which costs depth  $h$ . Step 2 executes the merger  $\text{Merge}_j$  from Corollary 26 and the extractor  $\text{EXT}_{1,j}$ , for every  $j \in [l]$  in parallel. This takes depth  $O(c + g)$ . So the overall depth is as the lemma stated.

The seed length of the extractor is  $d(n) = |U_1| + |U_2| + |U_3|$ .  $U_1 = (U_{1,1}, U_{1,2}, \dots, U_{1,t})$  where  $|U_{1,i}| = d_0$  for every  $i \in [t]$  and  $t = \frac{\log \varepsilon(n)}{\log \varepsilon_0}$ .  $|U_2| = O(\log(\frac{n}{\varepsilon(n)}))$  and  $|U_3| = d_1$ . Therefore  $d = O(d_1 + d_0 \cdot \frac{\log \varepsilon}{\log \varepsilon_0})$ .

The output consists of  $\Theta(\log n)$  parts of length  $m_1$ . Therefore the output length is  $m = \Theta(m_1 \cdot \log n)$ .  $\blacktriangleleft$

We instantiate  $\text{EXT}_0$  as the extractor from Theorem 4 and  $\text{EXT}_1$  as the strong extractors from Theorem 7, which gives the following theorem:

► **Corollary 35.** *For any constant  $a, c > 0$ , every  $k(n) \geq n/\log^a(n)$ ,  $\varepsilon(n) \geq 2^{-\log^c(n)}$ , there exists a strong  $(k(n), \varepsilon(n))$ -extractor  $\text{EXT} : \{0, 1\}^n \times \{0, 1\}^{r(n)} \rightarrow \{0, 1\}^{m(n)}$ , where  $r(n) = O(\log(\frac{n}{\varepsilon(n)}))$ ,  $m(n) = \Theta(\log(n) \cdot \log(\frac{n}{\varepsilon(n)}))$ .*

*Furthermore, the extractor can be implemented in uniform  $\text{AC}^0$  with  $O(a + c + 1)$  depth.*

The only gap between Corollary 35 and Theorem 27 is that the output length of Corollary 35 is only  $\Theta(\log(n) \cdot \log(\frac{n}{\varepsilon}))$  instead of  $\Theta(\log^b(n) \cdot \log(\frac{n}{\varepsilon}))$ . We resolve the issue by repeatedly using Lemma 28, each time instantiating  $\text{EXT}_1$  in Lemma 28 as the strong extractor family provided by the immediate previous using of Lemma 28. After an iteration, the output length is multiplied by a  $\Theta(\log n)$  factor. Therefore we can achieve the parameter as in Theorem 27 after  $b$  iterations.

## 5 Output Stretch

In this section, we will use the framework introduced in [9], to further stretch the output length from  $O(\log^c(n))$  to a near-optimal  $O(k)$ . The main theorem of this section is the following:

► **Theorem 36.** *For any constant  $a, c > 0$  and  $\gamma \in (0, 1)$ , let  $k(n) \geq \frac{n}{\log^a(n)}$ ,  $\varepsilon(n) \geq 2^{-\log^c(n)}$ . Then there exists a  $(k(n), \varepsilon(n))$ -strong extractor  $\text{EXT} : \{0, 1\}^n \times \{0, 1\}^{r(n)} \rightarrow \{0, 1\}^{m(n)}$ , such that  $r(n) = O(\log(\frac{n}{\varepsilon}))$ , and  $m(n) \geq (1 - \gamma) \cdot k(n)$ .*

*Furthermore, the extractor can be implemented in  $\text{AC}^0$ , with  $O(a + c + 1)^2$  depth and  $\text{poly}(n)$  size.*

We use a four-step method to extract randomness.

## 5.1 Step 1: Converting to a somewhere-block-source

In this subsection, we will convert the original  $k$ -source into a somewhere-block-source. First, we define the concept:

► **Definition 37** (somewhere-block-source). *Let  $X = (X_1, \dots, X_\Lambda)$  be a random variable with  $\Lambda$  segments, each  $X_i$  distributed on  $\{0, 1\}^{n_1} \times \{0, 1\}^{n_2}$ . We say  $X$  is a simple  $(k_1, k_2)$ -somewhere-block-source if there exists  $i \in [\Lambda]$  such that  $X_i$  is a  $(k_1, k_2)$ -block-source. We say  $X$  is a  $(k_1, k_2)$ -somewhere-block-source if  $X$  is a convex combination of simple  $(k_1, k_2)$ -somewhere-block-sources.*

Ta-shma's somewhere-block-source converter [33] is a deterministic function that converts a  $k_1 + k_2 + s$ -source into a  $(k_1 - O(n/\Lambda), k_2)$ -somewhere-block-source, which has  $\Lambda$  segments.

Take  $X_1 \in \{0, 1\}^n$  as the original source, assume  $n$  is divisible by  $\Lambda$ , otherwise pad  $X_1$  with 0's. Regard  $X_1$  as a source with  $\Lambda$  parts, each of length  $n/\Lambda$ :

$$X_1 = (X_{1,1}, \dots, X_{1,\Lambda}) \in \left(\{0, 1\}^{n/\Lambda}\right)^\Lambda. \quad (10)$$

Now define the following separation of these parts into  $(Y_i, Z_i)$ :

$$Y_i = (X_{1,1}, \dots, X_{1,i}, 0^{(\Lambda-i) \cdot (n/\Lambda)}), \quad (11)$$

$$Z_i = (0^{i \cdot (n/\Lambda)}, X_{1,i+1}, \dots, X_{1,\Lambda}). \quad (12)$$

Then  $(Y_i, Z_i) \in \{0, 1\}^{2n}$ . The Ta-shma's somewhere-block-source converter is defined as the collection of all  $(Y_i, Z_i)$ , for  $i \in [\Lambda]$ :

$$B_{TS}^\Lambda(X_1) = \{(Y_i, Z_i) \in \{0, 1\}^{2n} \mid i \in [\Lambda]\}. \quad (13)$$

► **Theorem 38** ([33]). *Let  $\Lambda$  be an integer and  $\Lambda$  divides  $n$ . Let  $B_{TS}^\Lambda$  be the Ta-shma's somewhere-block-source converter defined above. Fix  $k, k_1, k_2, s \in \mathbb{N}$  such that  $k = k_1 + k_2 + s$ . Then for any  $k$ -source  $X \in \{0, 1\}^n$ ,  $B_{TS}^\Lambda(X)$  is  $O(n \cdot 2^{-s/3})$ -close to a  $(k_1 - O(n/\Lambda), k_2)$ -somewhere-block-source.*

Now we summarize the first step:

Step 1: Set  $\Lambda = \log^{2a}(n)$ , Take  $X_2 = (X_{2,1}, \dots, X_{2,\Lambda}) = B_{TS}^\Lambda(X_1)$  as a somewhere-block-source.

► **Lemma 39.** *For any constant  $a \geq 0$ , let  $k \geq \frac{n}{\log^a(n)}$ . Then for any  $k$ -source  $X_1 \in \{0, 1\}^n$ , the somewhere-block-source  $X_2 = B_{TS}^\Lambda(X_1)$  is  $n \cdot 2^{-\frac{n}{\log^{2a} n}}$ -close to a  $(k - O(\frac{n}{\log^{2a} n}), \frac{n}{\log^{2a} n})$ -somewhere-block-source.*

The first step can be computed in  $AC^0$  with  $O(1)$  depth and  $\text{poly}(n)$  size, as it is only splitting the input into blocks.

## 5.2 Step 2: Extracting from a somewhere-block-source

In this subsection, we focus on the good block of the somewhere-block-source, and extract randomness from it. A two-block extractor is employed in this section. We use the block-extraction technique together with our extractors from Theorem 6 and Theorem 27 to extract  $O(\log^{a+c} n)$  randomness from the second block of the block source, then use it as seed for another extractor, in order to extract  $O(k)$  randomness from the first block of the block source.

## 69:16 Randomness Extractors in $AC^0$ and $NC^1$ : Optimal up to Constant Factors

For a somewhere-block-source, we may apply the two-block extractor to each segment such that the good segment is converted into a somewhere-close-to-uniform source. The source is defined as follows:

► **Lemma 40.** *Let  $X = (X_1, \dots, X_\Lambda)$  be a  $(k_1, k_2)$ -somewhere-block-source, where each segment is a source on  $\{0, 1\}^{n_1} \times \{0, 1\}^{n_2}$ . Let  $EXT: \{0, 1\}^{n_1} \times \{0, 1\}^{n_2} \times \{0, 1\}^r \rightarrow \{0, 1\}^m$  be a  $(k_1, k_2, \varepsilon)$ -strong-two-block extractor. Let  $U_r$  be a uniform random distribution on  $\{0, 1\}^r$ . Then*

$$(EXT(X_1, U_r), \dots, EXT(X_\Lambda, U_r))$$

is  $\varepsilon$ -close to a somewhere-uniform-source.

Take  $EXT_1$  from Theorem 6 and  $EXT_2$  from Theorem 27. Construct  $EXT(X_1, X_2, U_r) = EXT_1(X_1, EXT_2(X_2, U_r))$  as a strong-two-block extractor. We have the following theorem:

► **Theorem 41 (block-extraction in  $AC^0$ ).** *There exists a constant  $\gamma \in (0, 1)$ . For any constant  $a, c > 0$ , let  $k_1(n) \geq \frac{n}{\log^a(n)}$ ,  $k_2(n) \geq \frac{n}{\log^{2a}(n)}$ ,  $\varepsilon(n) \geq 2^{-\log^c(n)}$ , there exists a  $(k_1(n), k_2(n), \varepsilon(n))$ -strong-two-block extractor  $EXT: \{0, 1\}^n \times \{0, 1\}^n \times \{0, 1\}^r \rightarrow \{0, 1\}^m$ , such that  $r(n) = O(\log(\frac{n}{\varepsilon}))$ , and  $m(n) \geq (1 - \gamma)k_1(n)$ .*

Furthermore, the extractor can be implemented in  $AC^0$ , with  $O(a + c + 1)^2$  depth and  $\text{poly}(n)$  size.

We summarize the second step here:

Step 2: Take  $EXT: \{0, 1\}^n \times \{0, 1\}^n \times \{0, 1\}^{r_1(n)} \rightarrow \{0, 1\}^{m(n)}$  as a  $(\frac{n}{\log^a(n)}, \frac{n}{\log^{2a}(n)}, \varepsilon(n))$ -strong-two-block extractor, where  $r_1(n) = O(\log(\frac{n}{\varepsilon}))$  and  $m(n) \geq (1 - \gamma)k(n)$ . Take  $X_3 = (EXT(X_{2,1}, U_{r_1}), \dots, EXT(X_{2,\Lambda}, U_{r_1}))$  be  $2 \cdot \varepsilon(n)$ -close to a somewhere-uniform-source.

This step can be implemented in  $AC^0$  with  $O(a + c)$  depth and  $\text{poly}(n)$  size, as it is applying  $AC^0$  functions to each block of the input.

The source  $X_3$  is now  $\varepsilon(n)$ -close to a somewhere-uniform-source. It has  $\Lambda = \log^{2a}(n)$  segments, each of length  $m(n) \geq (1 - \gamma)k(n)$ . The next step is using the merger introduced in [9] to merge the segments into one source.

### 5.3 Step 3: Merging the segments

We use the merger introduced in [9] to merge the segments of the somewhere-uniform-source into one source. The construction of the merger is discussed in Theorem 21.

Step 3: Take  $Merge: \{0, 1\}^{\Lambda \cdot m(n)} \times \{0, 1\}^{r_2(n)} \rightarrow \{0, 1\}^{m(n)}$  be the  $(m(n), \frac{3}{4}m(n), \varepsilon(n))$ -merger from Theorem 21. Then  $X_4 = Merge(X_3, U_{r_2})$ .

As a direct consequence of Theorem 21 we have the following lemma.

► **Lemma 42.**  *$X_4$  is  $3 \cdot \varepsilon(n)$ -close to a  $\frac{3}{4}m(n)$ -source.*

Also, notice that the computation in  $AC^0$  with depth  $O(a + c)$ , with seed length  $O(\log(n/\varepsilon(n)))$ .

## 5.4 Step 4: Second extraction

The final step is as the following.

Step 4: Take  $\text{EXT}_2 : \{0, 1\}^{m(n)/2} \times \{0, 1\}^{m(n)/2} \times \{0, 1\}^{r_3(n)} \rightarrow \{0, 1\}^{m'(n)}$  be the  $(\frac{1}{8}m(n), \frac{1}{8}m(n), \varepsilon(n))$ -strong-two-block extractor from Theorem 41, where  $r_3(n) = O(\log(\frac{n}{\varepsilon}))$  and  $m'(n) \geq \frac{1-\gamma}{6} \cdot m(n)$ . Take  $X_5 = \text{EXT}_2(X'_4, X''_4, U_{r_3})$ , where  $U_{r_3}$  is a uniform random distribution on  $\{0, 1\}^{r_3(n)}$ , where  $(X'_4, X''_4) = X_4$ .

► **Lemma 43.**  $X_5$  is  $5\varepsilon(n)$  close to uniform.

The circuit depth of  $\text{EXT}_2$  is  $O(a + c + 1)^2$  by Theorem 41.

Now we prove the main theorem of this section:

► **Theorem 44.** For any constant  $a, c > 0, \gamma' \in (0, 1)$ , let  $k(n) \geq \frac{n}{\log^a(n)}, \varepsilon(n) \geq 2^{-\log^c(n)}$ . Then there exists a  $(k(n), \varepsilon'(n))$ -strong extractor  $\text{EXT} : \{0, 1\}^n \times \{0, 1\}^{r(n)} \rightarrow \{0, 1\}^{m(n)}$ , such that  $r(n) = O(\log(\frac{n}{\varepsilon(n)}))$ , and  $m(n) \geq (1 - \gamma') \cdot k(n)$ .

Furthermore, the extractor can be implemented in  $\text{AC}^0$ , with  $O(a + c + 1)^2$  depth and  $\text{poly}(n)$  size.

**Proof.** The extractor  $\text{EXT}$  is defined as  $\text{EXT}(X_1, U_{r_1}, U_{r_2}, U_{r_3}) = X_5$ , where  $X_5$  is defined through the four steps above. Detailed analysis could be found in the full version. ◀

## 6 Extractors in $\text{NC}^1$

Our method can also construct extractors in  $\text{NC}^1$  with improved parameters. The construction consists of 3 parts:

1. Apply a condenser from [19]. It behaves like the GUV condenser but is computable in  $\text{NC}^1$ . It condenses the source into a source with a constant entropy rate. We regard the output as a block source.
2. For the second block, apply our error reduction method which outputs a seed of length  $O(\log^2 n \log(n/\varepsilon))$ .
3. Apply the improved Trevisan's extractor [26] to the first block, which outputs  $\Omega(k)$  bits of randomness.

The main theorem is as follows:

► **Theorem 45.** For every constant  $\gamma \in (0, 1)$  every  $k = k(n) \geq \Omega(\log^2(n)), \varepsilon = \varepsilon(n) \geq 2^{-O(\sqrt{k(n)})}$ , there exists a strong  $(k, \varepsilon)$  extractor  $\text{EXT} : \{0, 1\}^n \times \{0, 1\}^{r(n)} \rightarrow \{0, 1\}^{m(n)}$  computable in  $\text{NC}^1$ , with  $r(n) = O(\log(n/\varepsilon))$ ,  $m(n) = (1 - \gamma)k(n)$ .

### 6.1 Condenser in $\text{NC}^1$

The first component in our construction is the condenser from [19]. A simplified version of their result is as follows:

► **Lemma 46** (condenser from [19]). For every  $k = k(n) \geq \Omega(\log^2(n)), \varepsilon = \varepsilon(n) \geq n \cdot 2^{-\sqrt{k(n)}/1024}$ , There exists  $m(n) \leq \frac{3}{2}k(n)$  and a function  $\text{Cond} : \{0, 1\}^n \times \{0, 1\}^{r(n)} \rightarrow \{0, 1\}^{m(n)}$  with  $r \leq 4 \log(\frac{n}{\varepsilon})$  such that  $\text{Cond}$  is a  $(k, k + r, \varepsilon)$ -condenser.

## 69:18 Randomness Extractors in $\text{AC}^0$ and $\text{NC}^1$ : Optimal up to Constant Factors

The condenser takes the input  $x$  as the representation of a degree  $\leq d = O(\frac{n}{\log q})$  polynomial over  $\mathbb{F}_q$  for some prime  $q \geq d, \log q \geq r$ . Denote the degree  $\leq d$  polynomial as  $f$ .

The condenser takes the seed  $y$  as a point in  $\mathbb{F}_q$ . Then the output is defined as:

$$\text{Cond}(x, y) = (y, f(y), f^{(1)}(y), \dots, f^{(s)}(y)) \quad (14)$$

for some  $s = s(n) \leq \frac{m(n)}{r(n)}$ .  $f^{(i)}$  denotes the  $i$ -th formal derivative of  $f$ .

To apply the condenser, we need to transform a source on  $\{0, 1\}^n$  to a source on  $\mathbb{F}_q$  and transform it back for the output. We use division to do the transformation, which is computable in  $\text{NC}^1$ .

The condenser itself requires two sorts of operations: polynomial evaluation and formal derivative. Denote  $f(x) = \sum_{i=0}^d a_i x^i$ . Then  $f^{(j)}(x) = \sum_{i=0}^d \frac{i!}{(i-j)!} a_i x^{i-j}$ . There are at most  $d^2$  such coefficients  $\frac{i!}{(i-j)!}$ , which can be precomputed and stored in the circuit. The multiplication of  $a_i$  and  $\frac{i!}{(i-j)!}$  can be done in  $\text{NC}^1$ . Therefore, the formal derivative is computable in  $\text{NC}^1$ .

The polynomial evaluation consists of three operations: calculating the powering  $x^{i-j}$ , multiplication and summation. The powering can be implemented with two steps:  $O(n)$ -th powering and division by  $q$ , which are computable in  $\text{NC}^1$  according to [4]. The multiplication and iterated summation are both in  $\text{NC}^1$ .

Putting it together, we can obtain the following lemma:

► **Lemma 47.** *The condenser from Lemma 46 is computable in  $\text{NC}^1$ .*

Regard the output of the condenser as  $(X_1, X_2)$ ,  $|X_1| = |X_2| = \frac{1}{2}m(n)$ . By Lemma 15,  $(X_1, X_2)$  is  $\varepsilon(n)$ -close to a  $(\frac{1}{2}m(n), \frac{1}{6}m(n), \frac{1}{2}m(n), \frac{1}{6}m(n))$ -source.

### 6.2 Error Reduction in $\text{NC}^1$

After condensing, we only need to handle an input  $(n, k)$  source  $X$  over  $\{0, 1\}^n$  with constant entropy rate  $\delta = \frac{k}{n}$ . To extract a seed of length  $O(\log n \log(n/\varepsilon))$ , we use almost the same procedure as in Section 4 despite some minor changes.

For the first step to convert the source to a somewhere source, we use the same extractors as in Section 4. We apply the extractors in parallel for  $t = \frac{\log n}{\log(1/\varepsilon)} = O(\sqrt{k})$  times. Then the output is  $\varepsilon$ -close to a somewhere  $(m_0, m_0 - \log(t))$ -source, where  $m_0 = \Omega(k)$ .

For the second step, we still apply the  $(m_0 - \log(t), 0.9m_0, \varepsilon)$ -merger from Corollary 26 to the output of the first step as in Section 4. Since  $\varepsilon \geq 2^{-O(\sqrt{k})}$  and  $t = \text{poly}(k)$ , the merger is computable in  $\text{NC}^1$ .

After applying the merger, we obtain a block-source with exponentially increasing length. We require a modification to Theorem 7 for the  $\text{NC}^1$  setting. The main difference is that the error is now  $2^{-O(\sqrt{k})}$  instead of  $2^{-\text{poly}(\log n)}$ . Also we setup the block length  $m_j = 3^j \cdot 10 \log \frac{n}{\varepsilon}$ ,  $j \in [l]$ , where  $l$  can still be  $O(\log n)$ , since  $\varepsilon = 2^{-O(\sqrt{k})}$ .

To extract from the block source, we require the following extractor in  $\text{NC}^1$ .

► **Lemma 48.** *For every constant  $\delta \in (0, 1]$  and every  $\varepsilon = 2^{-O(n)}$ , there exists an explicit  $(\delta n, \varepsilon)$ -extractor  $\text{EXT} : \{0, 1\}^n \times \{0, 1\}^d \rightarrow \{0, 1\}^m$  in  $\text{NC}^1$ , where  $d = O(\log(n/\varepsilon))$ ,  $m = \Theta(\log(n/\varepsilon))$ .*

We use the sample-then-extract technique with leftover hash lemma to construct the extractor. Detailed analysis could be found in the full version.

Using the extractor to extract from the block source as in Section 4, we obtain a seed of length  $O(\log n \log(n/\varepsilon))$ .

One can use the iteration of Section 4 to stretch the output to  $O(\log^2 n \log(n/\varepsilon))$ .

This gives us the following lemma:

► **Lemma 49.** *For every  $\delta \in (0, 1)$ ,  $k = \delta n$ ,  $\varepsilon = \varepsilon(n) = 2^{-O(\sqrt{k})}$ , there exists a strong  $(k(n), \varepsilon(n))$ -extractor  $\text{EXT} : \{0, 1\}^n \times \{0, 1\}^{r(n)} \rightarrow \{0, 1\}^{m(n)}$  computable in  $\text{NC}^1$ , with  $r(n) = O(\log(n/\varepsilon))$ ,  $m(n) = O(\log^2(n) \log(n/\varepsilon))$ .*

### 6.3 Improved Trevisan's Extractor in $\text{NC}^1$

With the seed of length  $O(\log^2 n \log(n/\varepsilon))$ , We apply the extractor from [26] to the first block of the block source. Their extractor could be implemented in  $\text{NC}^1$

► **Theorem 50 (Improved Trevisan's Extractor [26]).** *For every  $k = k(n)$ ,  $\varepsilon = \varepsilon(n)$ , there are explicit  $(k(n), \varepsilon(n))$ -extractors  $\text{EXT}_{\text{Trevisan}} : \{0, 1\}^n \times \{0, 1\}^{r(n)} \rightarrow \{0, 1\}^{m(n)}$  with  $r(n) = O(\log^2(n) \log(n/\varepsilon))$  and  $m(n) = \Omega(k(n))$ .*

*Moreover, the extractor  $\text{EXT}_{\text{Trevisan}}$  is computable in  $\text{NC}^1$ .*

### 6.4 Putting it together

Now we can prove Theorem 45.

**Proof of Theorem 45.** Take  $X$  as the input source. Let  $\text{Cond} : \{0, 1\}^n \times \{0, 1\}^{r_1(n)} \rightarrow \{0, 1\}^{m(n)}$  be the  $(k, k + r_1, \varepsilon/4)$ -condenser from Lemma 46. Take  $(X_1, X_2) = \text{Cond}(X, U_1)$ , where  $U_1$  is the seed of length  $r_1 = O(\log(n/\varepsilon))$ . By Lemma 15,  $(X_1, X_2)$  is  $\varepsilon/2$ -close to a  $(\frac{1}{2}m(n), \frac{1}{6}m(n), \frac{1}{2}m(n), \frac{1}{6}m(n))$ -source.

For  $X_2$ , apply the  $(\frac{1}{6}m(n), \varepsilon/4)$ -strong extractor  $\text{EXT}_1$  from Lemma 49 with seed  $U_2$  of length  $r_2 = O(\log(n/\varepsilon))$ . The output is  $Y = \text{EXT}_1(X_2, U_2)$  of length  $O(\log^2(n) \log(n/\varepsilon))$ .

For  $X_1$ , apply the  $(\frac{1}{2}m(n), \varepsilon/4)$ -extractor  $\text{EXT}_{\text{Trevisan}}$  from Theorem 50 with seed  $Y$ , which outputs a distribution  $W$  of length  $\Omega(k)$ .

By the property of  $\text{EXT}_1$ ,  $(X_1, Y)$  is  $3\varepsilon/4$ -close to  $(X_1, Y')$  such that  $Y'$  is a independent uniform distribution. Therefore  $W = \text{EXT}_{\text{Trevisan}}(X_1, Y)$  is  $\varepsilon$ -close to uniform.

The extractor  $\text{EXT}$  is defined as  $\text{EXT}(X, U_1, U_2) = W$ .  $\text{Cond}, \text{EXT}_1, \text{EXT}_{\text{Trevisan}}$  are all computable in  $\text{NC}^1$ . Therefore,  $\text{EXT}$  is computable in  $\text{NC}^1$ . ◀

## 7 Entropy lower bound for $\text{AC}^0$ dispersers

In the context of  $\text{AC}^0$  computation, not all sources are extractable. A well-known result of [10] shows that extracting even one bit of randomness is impossible for sources with entropy less than  $\frac{n}{\text{poly}(\log n)}$ . Similar result from [7] shows that extracting randomness with error less than  $2^{-\text{poly}(\log n)}$  is impossible for  $\text{AC}^0$  extractors.

In this section, we will extend the bound from extractors to dispersers. Dispersers are functions that take a source and a seed and output a distribution like extractors. The only difference is that the output distribution is not necessarily uniform, but rather supported on all but a small fraction of the codomain. We will show that strong  $\text{AC}^0$  dispersers for sources with entropy less than  $\frac{n}{\text{poly}(\log n)}$  do not exist.

► **Definition 51 (Disperser).** *A function  $\text{Disp} : \{0, 1\}^n \times \{0, 1\}^r \rightarrow \{0, 1\}^m$  is a  $(k, \varepsilon)$ -disperser if for every  $k$ -source  $X$  on  $\{0, 1\}^n$  and uniformly random variable  $Y$  on  $\{0, 1\}^r$ ,  $|\text{Supp}(\text{Disp}(X, Y))| \geq (1 - \varepsilon)2^m$ .*

*Furthermore,  $\text{Disp}$  is a strong  $(k, \varepsilon)$ -disperser if for every  $k$ -source  $X$  on  $\{0, 1\}^n$  and uniformly random variable  $Y$  on  $\{0, 1\}^r$ ,  $|\text{Supp}(Y, \text{Disp}(X, Y))| \geq (1 - \varepsilon)2^{r+m}$ .*

We remark that the requirement for  $X$  to have entropy  $\geq k$  can be replaced by a weaker requirement, which only requires  $\text{Supp}(X) \geq 2^k$ , without changing the definition.

Our proof is based on the new switching lemma for  $AC^0$  circuits by Rossman in [28]. Their original result says that every  $AC^0$  circuit can be reduced to a decision tree of arbitrary depth under a random restriction for all but a small fraction of the inputs. By restricting the inputs for the second time, it is reduced to a constant function.

► **Definition 52 (Restrictions).** A restriction  $\rho$  is a string on  $\{0, 1, *\}^n$ . We denote the application of  $\rho$  to  $x \in \{0, 1\}^n$  by  $\rho \circ x$ , which is defined as:

$$(\rho \circ x)_i = \begin{cases} \rho_i & \text{if } \rho_i \neq *, \\ x_i & \text{if } \rho_i = *. \end{cases} \quad (15)$$

The restriction on a function  $f : \{0, 1\}^n \rightarrow \{0, 1\}^m$  is defined as:

$$f|_\rho(x) = f(\rho \circ x). \quad (16)$$

We use  $R_p$  to denote the independent uniform random restriction with star probability  $p$ . That is, for every  $i \in [n]$ ,  $\Pr[R_p(i) = *] = p$ ,  $\Pr[R_p(i) = 0] = \Pr[R_p(i) = 1] = \frac{1-p}{2}$ .

The switching lemma for  $AC^0$  circuits is stated as follows:

► **Lemma 53 (Switching Lemma for  $AC^0$  circuits [28]).** For every  $\delta \in (0, 1)$ ,  $d > 0$ ,  $s = s(n)$ , there exists  $p = \frac{\delta}{\Theta(\log s)^{d-1}}$  such that for every  $AC^0$  circuit  $C$  of size  $s$  and depth  $d$ ,

$$\Pr_{\rho \sim R_p} [C|_\rho \text{ is not constant}] \leq \delta. \quad (17)$$

The following negative result for strong dispersers directly follows from the switching lemma.

► **Theorem 54.** For every  $d > 0$ ,  $s = s(n)$ , every constant  $\delta \in (0, 1)$ , if  $C : \{0, 1\}^n \times \{0, 1\}^r \rightarrow \{0, 1\}$  is a  $(k, \frac{1}{2} - \delta)$ -disperser that can be computed by a non-uniform  $AC$  circuit of size  $s$  and depth  $d$ , then  $k \geq \Theta(\frac{\delta n}{\log^{d-1} s})$ .

## 8 Open Questions

We mention the following open questions.

- For extractors in  $AC^0$ , can we further improve the circuit depth? The current depth is  $O(a + c + 1)^2$ . Is it possible to be linear in  $a + c + 1$ , while maintaining other parameters to be roughly the same?
- For extractors in  $NC^1$ , can we improve the plausible range of  $k$  and  $\varepsilon$ ? For example is it possible to give an  $NC^1$  construction that can work for all  $k, \varepsilon$ , matching the parameters in [13]?
- Some components of our  $NC^1$  computable extractors are actually in  $AC^0$ [2]. Is it possible to give an extractor in  $AC^0$ [2], with parameters optimal up to constant factors?
- For weak dispersers, we do not have a similar negative result to that of Section 7. The reason is that a single good seed in the seed space can make the disperser good enough, regardless of other seeds. So it remains an open question whether weak dispersers can be constructed in  $AC^0$ , specifically for sources with entropy less than  $\frac{n}{\text{poly}(\log n)}$ .

## Abstract

We consider the problem of sampling from the Ising model when the underlying interaction matrix has eigenvalues lying within an interval of length  $\gamma$ . Recent work in this setting has shown various algorithmic results that apply roughly when  $\gamma < 1$ , notably with nearly-linear running times based on the classical Glauber dynamics. However, the optimality of the range of  $\gamma$  was not clear since previous inapproximability results developed for the antiferromagnetic case (where the matrix has entries  $\leq 0$ ) apply only for  $\gamma > 2$ .

To this end, Kunisky (SODA'24) recently provided evidence that the problem becomes hard already when  $\gamma > 1$  based on the low-degree hardness for an inference problem on random matrices. Based on this, he conjectured that sampling from the Ising model in the same range of  $\gamma$  is NP-hard.

Here we confirm this conjecture, complementing in particular the known algorithmic results by showing NP-hardness results for approximately counting and sampling when  $\gamma > 1$ , with strong inapproximability guarantees; we also obtain a more refined hardness result for matrices where only a constant number of entries per row are allowed to be non-zero. The main observation in our reductions is that, for  $\gamma > 1$ , Glauber dynamics mixes slowly when the interactions are all positive (ferromagnetic) for the complete and random regular graphs, due to a bimodality in the underlying distribution. While ferromagnetic interactions typically preclude NP-hardness results, here we work around this by introducing in an appropriate way mild antiferromagnetism, keeping the spectrum roughly within the same range. This allows us to exploit the bimodality of the aforementioned graphs and show the target NP-hardness by adapting suitably previous inapproximability techniques developed for antiferromagnetic systems.

## 1 Introduction

The Ising model with a symmetric interaction matrix  $J \in \mathbb{R}^{N \times N}$  is a probability distribution  $\mu_J$  over  $\{-1, 1\}^N$  with

$$\mu_J(\sigma) = \frac{1}{Z_J} \exp\left(\frac{1}{2}\sigma^\top J\sigma\right) \text{ for all vectors } \sigma \in \{-1, 1\}^N,$$

where the normalizing constant  $Z_J = \sum_{\sigma \in \{-1, 1\}^N} \exp\left(\frac{1}{2}\sigma^\top J\sigma\right)$  is the *partition function* of the model. The most well-studied setting for the Ising model is when the underlying matrix  $J$  corresponds to the adjacency matrix of a graph  $G$ , scaled by a real parameter  $\beta$  which corresponds to the (inverse) temperature;<sup>1</sup> for  $\beta > 0$  the model is called ferromagnetic, and antiferromagnetic otherwise. The more general setting with non-uniform weights in the entries of  $J$  arises frequently in statistical learning settings, see, e.g., [9, 30, 25, 12].

The Ising model is the most fundamental example of a spin system, capturing how local interactions affect the global macroscopic behaviour, see [48, 41, 40, 33] for applications in various areas. From a computer science perspective, sampling from the Ising model plays a key role in various learning and inference problems. Understanding the limits of efficient sampling has therefore been a major focus in the literature, yielding new algorithmic techniques as well as exploring the power of classical algorithms (such as Glauber dynamics) and their connections to phase transitions in statistical mechanics; we briefly review some of the relevant literature below.

The prototypical setting where the problem of sampling for the Ising model has been studied is lattices (such as  $\mathbb{Z}^2$ ), where the landscape for Markov-chain algorithms has been well-understood [38, 39, 37]. Random graph models have also been considered more recently such as sparse random graphs [43, 13, 6, 16, 36] or the Sherrington-Kirkpatrick model [18, 17, 26]. More closely related to the setting considered in this paper is the case of general graphs. In the ferromagnetic case, where the entries of  $J$  are all nonnegative, the classical algorithm by Jerrum and Sinclair [28] gives a poly-time sampler (albeit with a relatively large running-time polynomial), see also [24, 19]. In the antiferromagnetic case, the problem is more interesting for bounded-degree graphs, where in the case of uniform weights the existence of polynomial-time algorithms is connected to the uniqueness threshold, see [46, 47, 21, 45, 35].

Recently, the development of spectral independence [4, 1] has given tight results on the performance of Glauber dynamics. This has led to nearly linear-time algorithms in various settings, see e.g., [11, 10, 18, 3, 31] and has made it possible to connect the performance of Glauber dynamics with the eigenvalues of the underlying matrix  $J$ . In this direction, [18, 3] show that Glauber dynamics is fast mixing when  $\lambda_{\max}(J) - \lambda_{\min}(J) < 1$  which significantly improves upon the standard Dobrushin's uniqueness condition (the latter only applies when  $\sum_j |J_{ij}| < 1$  for all  $i \in [N]$ ).

On the other side, the optimality of these algorithmic results in terms of the spectrum is less clear. It is known [34, 14] that Glauber dynamics mixes slowly in the complete graph for temperatures  $\beta > 1$ , which corresponds precisely to the condition  $\lambda_{\max}(J) - \lambda_{\min}(J) > 1$  by taking  $J$  to be the adjacency matrix of the  $N$ -vertex complete graph, scaled by  $\beta/N$ . This does not however translate in a straightforward way to hardness results and does not preclude the possibility that various alternative methods could potentially go beyond the 1-gap, see, e.g., [44, 31, 27] for some recent approaches using variational methods. To this

---

<sup>1</sup> Note that in this parametrization  $\mu_J(\sigma) \propto \exp(\frac{1}{2}\beta\sigma^\top A\sigma)$ , where  $A$  is the adjacency matrix of the graph.

end, Kunisky [32] gave further evidence that  $\lambda_{\max}(J) - \lambda_{\min}(J) > 1$  is hard for sampling via a reduction to hypothesis testing in a Wishart negatively-spiked matrix model that involves random matrices (which is known to resist low-degree algorithms [5]). Kunisky also posed the conjecture that in fact NP-hardness for sampling under spectral constraints should hold when  $\lambda_{\max}(J) - \lambda_{\min}(J) > 1$ . To add a bit to the mystery, it is noteworthy that the inapproximability results for the antiferromagnetic case (mentioned earlier) only apply roughly when  $\lambda_{\max}(J) - \lambda_{\min}(J) > 2$ , see also below for a more detailed discussion.

## 1.1 Our results

Our aim in this work is to address Kunisky’s conjecture and close the gap between algorithmic and NP-hardness results. In particular, we answer in the affirmative the conjecture in [32], obtaining NP-hardness results that complement the algorithmic results of [18, 3]. This completes the program initiated in [32], i.e., showing that Glauber is effectively optimal for “general-purpose” Ising model sampling, and clarifies the picture in terms of the computational complexity landscape under spectral constraints.

To formally state the result, we define the following computational problem.

*Problem:* SPECTRALISING( $\gamma$ )

*Input:* A symmetric matrix  $J \in \mathbb{R}^{N \times N}$ , with  $\lambda_{\max}(J) - \lambda_{\min}(J) < \gamma$ .

*Output:* The partition function  $Z_J = \sum_{\sigma \in \{-1, +1\}^N} \exp\left(\frac{1}{2} \sigma^\top J \sigma\right)$ .

► **Theorem 1.** *Fix any real  $\gamma > 1$ . Then, it is NP-hard to approximate SPECTRALISING( $\gamma$ ), even within an exponential factor  $2^{cN}$  for some constant  $c = c(\gamma) > 0$ .*

This confirms Conjecture 1.9 of [32] and complements the algorithm of [18, 3]. Using Theorem 1, we get the following result using the standard reduction [29] from counting to sampling (the problem is self-reducible under scaling of the matrix  $J$ ). Recall, the total variation distance between probability distributions  $\mu$  and  $\nu$  is defined as  $\text{TV}(\mu, \nu) = \frac{1}{2} \|\mu - \nu\|_1$ .

► **Corollary 2.** *For every real  $\gamma > 1$ , the following holds. Suppose there is a poly-time sampler that, on input a symmetric matrix  $J \in \mathbb{R}^{N \times N}$  with  $\lambda_{\max}(J) - \lambda_{\min}(J) < \gamma$  and  $\delta > 0$ , returns a configuration  $\sigma$  whose distribution is within TV distance  $\delta$  from  $\mu_J$ . Then NP = RP.*

As we will explain next, it is also possible to obtain a more refined version of Theorem 1, for the restricted case where each row of the interaction matrix  $J$  has at most  $d$  non-zero entries, for some fixed integer  $d \geq 4$ .

*Problem:* BOUNDED SPECTRALISING( $d, \gamma$ )

*Input:* A symmetric matrix  $J \in \mathbb{R}^{N \times N}$ , with  $\leq d$  non-zero entries per row and  $\lambda_{\max}(J) - \lambda_{\min}(J) < \gamma$ .

*Output:* The partition function  $Z_J = \sum_{\sigma \in \{-1, +1\}^N} \exp\left(\frac{1}{2} \sigma^\top J \sigma\right)$ .

► **Theorem 3.** *Fix any integer  $d \geq 4$  and real  $\gamma > \frac{1}{2} \ln\left(1 + \frac{2}{d-3}\right)(d-1 + 2\sqrt{d-2})$ . Then, it is NP-hard to approximate BOUNDED SPECTRALISING( $d, \gamma$ ), even within an exponential factor  $2^{cN}$  for some constant  $c = c(\gamma) > 0$ .*

Note that when taking the limit  $d \rightarrow \infty$  in the above bound, we recover the spectral condition  $\gamma > 1$  of Theorem 1, so asymptotically the bound is tight; we are not aware of algorithmic results that apply specifically to the  $d$ -sparse setting under the spectral condition.

We remark further that applying the results of [47, 21] would yield hardness only in the setting where  $\gamma > d \ln(1 + \frac{2}{d-2})$  (see [32, Section 1.2] for a detailed description on how to translate the results), so Theorem 3 improves on this by roughly a factor of 2 asymptotically. It should be noted however that the setting in these results is more restrictive (negative weights, which have the same value on all edges) and hence not directly comparable.

## 1.2 Techniques

Before giving the proofs, we explain briefly the main idea behind Theorem 1, the idea for Theorem 3 is almost identical, modulo the gadget used in the reduction.

The key ingredient in obtaining Theorem 1 is to exploit the slow mixing of Glauber dynamics on the complete graph in a suitable way. Recall that [34] showed exponential mixing time for Glauber dynamics on the  $N$ -vertex complete graph when the weights on the edges are ferromagnetic equal to  $\beta/N$  (entry-wise) for any  $\beta > 1$  (note that the corresponding matrix  $J$  has  $\lambda_{\max}(J) - \lambda_{\min}(J) = \beta$ ). Intuitively, the slow mixing is caused because the distribution exhibits bimodality, i.e., it is concentrated around two modes/“phases” corresponding roughly to the all-plus and all-minus configurations (see Section 2 for more details). Therefore, we would like to use the binary behaviour of the complete graph as a gadget in the reduction. The main trouble here is caused by the ferromagnetic interactions which cannot typically be related to NP-hard problems; by contrast, in the antiferromagnetic case  $\beta < 0$ , the max-probability configurations in the Ising distribution correspond to maximum cuts (when  $J$  encodes the adjacency matrix of a graph), and the respective gadgets in the constructions had bipartite structure.<sup>2</sup>

Hence, in order to get NP-hardness, we need to introduce some “mild” antiferromagnetism (small negative weights): mild to keep the spectrum unchanged and antiferromagnetic to allow us to reduce from an NP-hard problem (we will use MaxCut); this is quite different than the approach of [32] where the positive and negative entries in the constructed instance are more heavily mixed up (randomly). At this stage, the main observation is that the previous reductions used in the antiferromagnetic case [46, 47, 21] can accommodate this relatively easily; the only difference here is that we need to use small negative weights to connect disjoint copies of the gadgets, and amplify their effect using appropriately-sized matchings; conveniently, since the matchings (with the small weights on their edges) correspond to a low-rank perturbation, the spectrum of the underlying matrix is close to that of the complete graph.

The proof of Theorem 3 is almost identical. The main difference needed to make our construction sparse is to use a random  $d$ -regular graph as the gadget, which is known to exhibit slow mixing when  $\beta > \beta_d := \frac{1}{2} \ln(1 + \frac{2}{d-2})$  [22, 13, 43, 42], with a similar bimodal behaviour to that of the complete graph for  $\beta > 1$ . Relative to the spectrum, the well-known result of Friedman [20] shows that the adjacency matrix  $A$  of a random  $d$ -regular graph satisfies w.h.p.  $\lambda_{\max}(A) - \lambda_{\min}(A) \leq \lambda_d + \epsilon$  for any constant  $\epsilon > 0$ , where  $\lambda_d := d + 2\sqrt{d-1}$ . For technical reasons (see Remark 10 for details), we need to actually use a  $(d-1)$ -regular graph as a gadget in the reduction, so the argument sketched above yields NP-hardness when  $\gamma > \beta_{d-1} \lambda_{d-1}$  and  $d \geq 4$ .

---

<sup>2</sup> As a side note, we remark that the factor-2 gap from the antiferromagnetic setting (mentioned below Theorem 3) comes from the use of bipartite gadgets in these results, which have a symmetric spectrum around zero and hence effectively double the range of the eigenvalues.

### 1.3 Outline and Discussion

We give the details of the gadget in Section 2 and the reduction in Section 3.1. This gives a self-contained proof of Theorem 1; for Theorem 3 the argument is identical modulo the use of the (random)  $d$ -regular graph as the gadget, for which we need to import a couple of non-trivial results from the literature.

As a final remark before proceeding to the proofs, it would be interesting to explore whether the statistical hardness perspective from [32] (or some variant) perhaps applies to other counting/sampling problems where NP-hardness results are unlikely, such as approximating the number of independent sets in a bipartite graph [15], or approximating the partition function of the ferromagnetic Potts model [23]. Another related question is whether such statistical hardness results can be invoked on sparse random graph models where the spectral threshold  $\lambda_{\max}(J) - \lambda_{\min}(J) = 1$  (that applies to worst-case instances) is known not to be tight (see [10, 31, 36]).

## 2 The Gadget of Theorem 1

Our main gadget will be a clique graph  $K_n = (V, E)$  with  $n$  vertices, where  $V = \{1, 2, \dots, n\}$ . We will consider  $n$  to be an absolute (large) constant that we will choose later. For a small integer  $t > 0$ , let  $S \subseteq V$  be an arbitrary subset of  $V$  with  $|S| = t$ . Let  $r = n - t$ . Intuitively,  $S$  contains the nodes that will be used to connect the gadgets with each other.

We define the phase of the configuration  $\sigma \in \{-1, 1\}^n$  on  $V \setminus S$  as

$$Y_\sigma = \mathbf{1}\left\{\sum_{i \in V \setminus S} \sigma_i > 0\right\} - \mathbf{1}\left\{\sum_{i \in V \setminus S} \sigma_i \leq 0\right\}.$$

Note that the phase of a configuration is defined using only the spins in  $V \setminus S$ . For any fixed  $\beta > 0$ , consider solutions to the equation

$$\ln \frac{1 - \alpha}{\alpha} + 2\beta(2\alpha - 1) = 0 \tag{1}$$

for  $\alpha \in [0, 1]$ . It is not hard to see that for  $\beta > 1$  there are exactly three solutions  $\alpha = q^-, 1/2, q^+$  which satisfy  $q^+ - 1/2 = 1/2 - q^- > 0$ . Using these, we define the product measure  $Q_S^+$  (resp.  $Q_S^-$ ) on configurations on  $S$ , where each spin takes the value  $+1$  with probability  $q^+$ , and  $-1$  with probability  $1 - q^+$  (resp.  $q^-$  and  $1 - q^-$ ). Concretely, for  $\tau \in \{-1, +1\}^S$ , we have

$$Q_S^\pm(\tau) = (q^\pm)^{\frac{\sum_{i \in S} \tau_i + t}{2}} (1 - q^\pm)^{\frac{t - \sum_{i \in S} \tau_i}{2}} = (q^\pm(1 - q^\pm))^{t/2} \left(\frac{q^\pm}{1 - q^\pm}\right)^{\frac{\sum_{i \in S} \tau_i}{2}}. \tag{2}$$

We now state a lemma that presents the basic properties of the Ising model on our gadget graph. A similar lemma appears in the seminal results of [46, 47]. Informally, the lemma states that conditioned on the phase of the spins in  $V \setminus S$ , the spins in  $S$  behave almost *independently* from each other, with bias depending on the phase.

► **Lemma 4.** *Let  $\beta > 1$ . Then, for any real  $\epsilon > 0$  and integer  $t \geq 1$ , for all sufficiently large integers  $n = n(t, \epsilon)$  such that  $n - t$  is odd, the following holds for the Ising model with interaction matrix  $J \in \mathbb{R}^{n \times n}$  given by  $J = \frac{\beta}{n-t} \mathbf{1}\mathbf{1}^\top$ , where  $\mathbf{1}$  is the  $n$ -dimensional vector with all ones.*

Let  $S \subseteq [n]$  be a subset of the vertices with  $|S| = t$ . Then:

1. *The phases on  $V \setminus S$  appear with the same probability, i.e.,  $\Pr_{\sigma \sim \mu_J}[Y_\sigma = +] = \Pr_{\sigma \sim \mu_J}[Y_\sigma = -] = 1/2$ .*

## 70:6 On Sampling from Ising Models with Spectral Constraints

2. Conditioned on the phase, the joint distribution of the spins in  $S$  is approximately given by the product distribution  $Q_S^\pm$ , i.e.,

$$\text{for any } \tau \in \{-1, +1\}^S, \text{ it holds that } \Pr_{\sigma \sim \mu_J} [\sigma_S = \tau \mid Y_\sigma = \pm] = (1 \pm \epsilon) Q_S^\pm(\tau).$$

**Proof.** Let  $r = n - t$ . For  $r$  odd (as in the statement of the lemma), we have by symmetry that the phases appear with equal probability. So, we focus on proving the second item. For a vector  $x$  with entries  $+1$  or  $-1$ , we denote by  $|x|$  the sum of its entries.

Let  $\alpha \in [0, 1]$  be such that  $\alpha r$  is an integer. For a configuration  $\tau \in \{-1, +1\}^S$ , let  $Z^\alpha(\tau)$  be the contribution to the partition function of configurations  $\sigma$  with  $\alpha r$  spins from  $V \setminus S$  set to  $+1$ ,  $(1 - \alpha)r$  spins from  $V \setminus S$  set to  $-1$  and  $\sigma_S = \tau$ . Concretely,

$$Z^\alpha(\tau) = \sum_{\sigma \in \{-1, +1\}^V; \sigma_S = \tau, |\sigma_{V \setminus S}| = (2\alpha - 1)r} \exp\left(\frac{1}{2} \sigma^\top J \sigma\right).$$

The number of configurations  $\sigma$  with  $\sigma_S = \tau$  and exactly  $\alpha r$  of the spins in  $V \setminus S$  equal to  $1$  is  $\binom{r}{\alpha r}$ . Using that  $J = \frac{\beta}{r} \mathbf{1}\mathbf{1}^\top$ , for each such  $\sigma$ , we have  $\frac{1}{2} \sigma^\top J \sigma = \frac{\beta}{r} (|\sigma_{V \setminus S}| + |\tau|)^2 = \frac{\beta}{2r} ((2\alpha - 1)r + |\tau|)^2$ . So,

$$Z^\alpha(\tau) = \binom{r}{\alpha r} \exp\left(\frac{\beta}{2} (2\alpha - 1)^2 r + \beta(2\alpha - 1)|\tau| + \frac{\beta}{2r} |\tau|^2\right). \quad (3)$$

We use the well-known approximation of the binomial coefficient using Stirling's approximation. This yields, for any  $\alpha \in [0, 1]$ , that

$$\binom{r}{\alpha r} = \exp(rH(\alpha) + o(r)), \quad (4)$$

where  $H(\alpha) := -\alpha \ln \alpha - (1 - \alpha) \ln(1 - \alpha)$  is the binary entropy function. Asymptotically in  $r$ , we can also ignore the term  $\exp(\frac{\beta}{2r} |\tau|^2)$ , so we obtain that

$$Z^\alpha(\tau) = \exp(rf(\alpha) + o(r)) \text{ where } f(\alpha) := H(\alpha) + \frac{\beta}{2} (2\alpha - 1)^2. \quad (5)$$

The function  $f(\alpha)$  plays a key role since for large  $r$  it controls the asymptotic order of  $Z^\alpha(\tau)$ . The important point, as we will see below, is that the global maximum of  $f$  is attained for  $\alpha = q^\pm$ .

Indeed, we have

$$f'(\alpha) = -\ln(\alpha) + \ln(1 - \alpha) + 2\beta(2\alpha - 1)$$

and  $f''(\alpha) = -\frac{1}{\alpha(1-\alpha)} + 4\beta$ . Since  $f''$  has at most two zeros, we have that  $f'$  has at most three distinct zeros and hence  $f$  has at most three critical points. For  $\beta > 1$ , we have  $f'(1/2) = 0$  and  $f''(1/2) = -4 + 4\beta > 0$ , so  $f$  has a local minimum at  $\alpha = 1/2$ ; therefore, the maximum of  $f$  in the interval  $[0, 1]$  is attained at some point  $\alpha \neq 1/2$ . Using the symmetry of  $f$  around  $\alpha = 1/2$ , there must be at least two global maxima, one in the interval  $(0, 1/2)$  and  $(1/2, 1)$ . Since  $f$  has at most three critical points (and  $1/2$  is one of them), we conclude that there are exactly two critical points/maxima other than  $\alpha = 1/2$ , which must therefore be the values  $q^+, q^-$  as defined in (1).

We are now ready to establish the second item of the lemma. We will argue about the  $+$  phase, but the other phase is completely symmetric. Let  $\tau, \tau' \in \{-1, 1\}^S$  be two configurations of spins in  $S$ . We have that

$$\frac{\Pr[\sigma_S = \tau \mid Y(\sigma_{V \setminus S}) = +]}{\Pr[\sigma_S = \tau' \mid Y(\sigma_{V \setminus S}) = +]} = \frac{\sum_{\alpha > 1/2} Z^\alpha(\tau)}{\sum_{\alpha > 1/2} Z^\alpha(\tau')}. \quad (6)$$

We will show that the sums in the numerator and denominator are dominated by  $\alpha$  values that are close to  $q^+$ . First, note that since  $q^+$  is the unique global maximum of  $f(\alpha)$  in the interval  $[1/2, 1]$ , for any arbitrarily small constant  $\delta > 0$ , there is  $\eta > 0$  such that  $f(\alpha) \leq f(q^+) - 3\eta$  for all  $\alpha > 1/2$  with  $\alpha \notin [q^+ - \delta, q^+ + \delta]$ . We pick  $\delta > 0$  sufficiently small and  $r > 0$  sufficiently large so that  $\exp(4\beta t\delta + \beta \frac{t^2}{r}) < \epsilon/2$ . Since  $|\tau| \leq t$ , it follows that for  $r$  large enough it holds that

$$\sum_{\alpha > 1/2; |\alpha - q^+| > \delta} Z^\alpha(\tau) \leq \exp(r(f(q^+) - 2\eta)).$$

By the continuity of  $f$ , for  $\alpha = q^+ + O(1/r)$  we have  $f(\alpha) = f(q^+) + O(1/r)$  and therefore

$$\sum_{\alpha > 1/2; |\alpha - q^+| \leq \delta} Z^\alpha(\tau) \geq \exp(r(f(q^+) - \eta)).$$

It follows that

$$\frac{\sum_{\alpha > 1/2; |\alpha - q^+| > \delta} Z^\alpha(\tau)}{\sum_{\alpha > 1/2; |\alpha - q^+| \leq \delta} Z^\alpha(\tau)} \leq \exp(-\eta r) \leq \epsilon/2. \quad (7)$$

for all sufficiently large  $r$ . Thus,

$$\begin{aligned} \frac{\sum_{\alpha > 1/2} Z^\alpha(\tau)}{\sum_{\alpha > 1/2} Z^\alpha(\tau')} &\leq \frac{\sum_{\alpha > 1/2} Z^\alpha(\tau)}{\sum_{|\alpha - q^+| \leq \delta} Z^\alpha(\tau')} = \frac{\sum_{\alpha > 1/2} Z^\alpha(\tau)}{\sum_{|\alpha - q^+| \leq \delta} Z^\alpha(\tau)} \cdot \frac{\sum_{|\alpha - q^+| \leq \delta} Z^\alpha(\tau)}{\sum_{|\alpha - q^+| \leq \delta} Z^\alpha(\tau')} \\ &\leq (1 + \epsilon/2) \frac{\sum_{|\alpha - q^+| \leq \delta} Z^\alpha(\tau)}{\sum_{|\alpha - q^+| \leq \delta} Z^\alpha(\tau')}, \end{aligned} \quad (8)$$

where the last inequality follows from (7).

On the other hand, for any  $\alpha$  with  $|\alpha - q^+| \leq \delta$ , using (3) we get

$$\begin{aligned} \frac{Z^\alpha(\tau)}{Z^\alpha(\tau')} &= \exp\left(\beta(2\alpha - 1)(|\tau| - |\tau'|) + \frac{\beta(|\tau|^2 - |\tau'|^2)}{2r}\right) \\ &\leq \exp(4\beta t\delta + \beta \frac{t^2}{r}) \\ &\exp(\beta(2q^+ - 1)(|\tau| - |\tau'|)) \leq (1 + \epsilon/2) \exp(\beta(2q^+ - 1)(|\tau| - |\tau'|)), \end{aligned} \quad (9)$$

where the last inequality follows from the choice of  $\delta$  and  $r$ . Using the definition (2) and the fact that  $q^+$  is a solution of (1), i.e., that  $f'(q^+) = 0$ , we have that

$$\exp(\beta(2q^+ - 1)(|\tau| - |\tau'|)) = \left(\frac{q^+}{1 - q^+}\right)^{\frac{|\tau| - |\tau'|}{2}} = \frac{Q_S^+(\tau)}{Q_S^+(\tau')}.$$

Hence, from (9) we obtain that  $\frac{Z^\alpha(\tau)}{Z^\alpha(\tau')} \leq (1 + \epsilon/2) \frac{Q_S^+(\tau)}{Q_S^+(\tau')}$ . Since this holds for all  $\alpha$  with  $|\alpha - q^+| \leq \delta$ , we have

$$\frac{\sum_{|\alpha - q^+| \leq \delta} Z^\alpha(\tau)}{\sum_{|\alpha - q^+| \leq \delta} Z^\alpha(\tau')} \leq (1 + \epsilon/2) \frac{Q_S^+(\tau)}{Q_S^+(\tau')}. \quad (10)$$

Combining this with (6) and (8), we obtain that

$$\frac{\Pr[\sigma_S = \tau | Y(\sigma_{V \setminus S}) = +]}{\Pr[\sigma_S = \tau' | Y(\sigma_{V \setminus S}) = +]} \leq (1 + \epsilon) \frac{Q_S^+(\tau)}{Q_S^+(\tau')}.$$

By interchanging the roles of  $\tau, \tau'$ , we also obtain the inverse inequality, so

$$(1 - \epsilon) \frac{Q_S^+(\tau)}{Q_S^+(\tau')} \leq \frac{\Pr[\sigma_S = \tau | Y(\sigma_{V \setminus S}) = +]}{\Pr[\sigma_S = \tau' | Y(\sigma_{V \setminus S}) = +]} \leq (1 + \epsilon) \frac{Q_S^+(\tau)}{Q_S^+(\tau')}. \quad (11)$$

For  $\tau \in \{-1, 1\}^S$ , observe that we can expand the ratio

$$\frac{\Pr[\sigma_S = \tau | Y = +]}{Q_S^+(\tau)} = \frac{\sum_{\tau'} Q_S^+(\tau') \Pr[\sigma_S = \tau | Y = +]}{\sum_{\tau'} Q_S^+(\tau) \Pr[\sigma_S = \tau' | Y = +]}$$

so using that  $\min_i \frac{a_i}{b_i} \leq \frac{\sum_i a_i}{\sum_i b_i} \leq \max_i \frac{a_i}{b_i}$  for non-negative  $(a_i)_i, (b_i)_i$ , we obtain from (11) that

$$\left| \frac{\Pr[\sigma_S = \tau | Y = +]}{Q_S^+(\tau)} - 1 \right| \leq \max_{\tau'} \left| \frac{Q_S^+(\tau') \Pr[\sigma_S = \tau | Y = +]}{Q_S^+(\tau) \Pr[\sigma_S = \tau' | Y = +]} - 1 \right| \leq \epsilon.$$

This finishes the proof.  $\blacktriangleleft$

### 3 Proofs of Main Results

#### 3.1 Proof of Theorem 1

Let  $\gamma > 1$  and  $\beta = (1 + \gamma)/2 > 1$ . Following the technique in [46, 47, 21], we reduce MAXCUT on 3-regular graphs to SPECTRALISING( $\gamma$ ).

Consider a 3-regular graph  $H = (V_H, E_H)$  with  $|V_H| = m$  vertices, an instance of MAXCUT. Let  $G$  be the clique graph on  $n$  vertices, with a subset  $S$  of the vertices with  $|S| = t$  that will be used as terminals (cf. Lemma 4); for convenience, we assume that  $t > 0$  is a multiple of 3 (with  $n \gg 3t$ ). We construct an instance  $H^G$  of SPECTRALISING( $\gamma$ ) as follows:

- We replace each node  $v \in V_H$  with a distinct copy of the gadget clique graph  $G$ . In particular, for any  $v \in V_H$ , consider a copy  $G_v = (W_v, E_v)$  of the gadget  $G$ ; each edge in  $E_v$  has weight  $w_+ = \beta/r$  as in Lemma 4, where recall that  $\beta = (1 + \gamma)/2 > 1$ . For each  $v \in V_H$ , let  $S_v \subseteq W_v$  be a subset of the vertices in  $G_v$  of size  $t = n - r$ . Let  $\hat{H}^G$  be the disjoint union of the  $G_v$ 's for  $v \in H$ . Note that the number of vertices of  $\hat{H}^G$  is  $nm$ .
- We now describe how to encode the edges of  $H$  using connections between the gadgets (which will complete the construction of  $H^G$ ). Assume that the node  $u \in V_H$  has neighbors  $v_1, v_2, v_3$  in  $H$ , i.e.,  $(u, v_i) \in E_H, i = 1, \dots, 3$ . Then, we partition  $S_u$  into subsets  $S_u^i$  of size  $t/3$  each. Each subset  $S_u^i$  corresponds to one of the three neighbors of  $u$ . Then, for each  $i = 1, 2, 3$ , we add a perfect matching between  $S_u^i$  and the corresponding subset  $S_{v_i}^j$  of  $S_{v_i}$  that corresponds to  $u$ . The weight of each of these edges in the matching will be  $w_- = (1 - \gamma)/5 < 0$ , since  $\gamma > 1$ . This antiferromagnetic structure across different copies will be crucial in order to approximate  $\maxcut(H)$  by approximating the partition function of  $H^G$ .

Let  $J$  be the adjacency matrix of the weighted graph  $H^G$ . We first show that the spectrum of  $J$  has the desired properties, i.e., that  $\lambda_{\max}(J) - \lambda_{\min}(J) < \gamma$ .

▷ **Claim 5 (Structure of  $H^G$ ).** The symmetric matrix  $J = D + E \in \mathbb{R}^{nm \times nm}$ , where  $D$  is a block diagonal matrix where the matrix of each block of size  $n \times n$  is  $\frac{\beta}{r} \mathbf{1}\mathbf{1}^\top$  and  $E$  contains in each row exactly one non-zero element of magnitude  $(1 - \gamma)/5$ .

Proof. By construction since  $n$  is the number of vertices of the gadget and  $m$  is the number of vertices of the input graph.  $\blacktriangleleft$

▷ **Claim 6 (Spectrum Preservation).** For any integer  $t > 0$ , there exists  $n(t, \gamma) > 0$ , such that for  $n > n(t, \gamma)$  it holds  $|\lambda_{\max}(J) - \lambda_{\min}(J)| < \gamma$ .

*Proof.* We will use Claim 5. Using Weyl's inequality (see Chapter 3 in [7]), which controls the eigenspectrum of a matrix under small perturbations of the entries, we have that for any  $i$ , it holds that  $|\lambda_i(J) - \lambda_i(D)| \leq \|E\|$ , where  $\|E\|$  is the spectral norm of  $E$ . By definition,  $E$  has one element in each row of absolute value  $(\gamma - 1)/5$ , so  $\|E\| \leq \frac{\gamma-1}{5}$ . It follows that

$$\begin{aligned} |\lambda_{\max}(J) - \lambda_{\min}(J)| &\leq |\lambda_{\max}(J) - \lambda_{\max}(D)| + |\lambda_{\max}(D) - \lambda_{\min}(D)| + |\lambda_{\min}(D) - \lambda_{\min}(J)| \\ &\leq \frac{2(\gamma-1)}{5} + \frac{n}{r} \frac{1+\gamma}{2}. \end{aligned} \tag{12}$$

In the above we used the well-known fact that the spectrum of  $D$  is the spectrum of each of the blocks, which, in turn, is equal to

$$\lambda_{\max}(D) - \lambda_{\min}(D) = \frac{n}{r} \frac{1+\gamma}{2},$$

since each block is a rank-1 matrix. Now, recall that  $n = r + t$ , so by choosing  $r$  sufficiently large we can make  $\frac{n}{r} < \frac{6\gamma+4}{5\gamma+5}$ , which implies that the right hand side in (12) is  $< \gamma$ . ◁

We next show that if we could approximate  $Z_J$  within an arbitrarily small exponential factor in poly-time, we would obtain a PTAS for  $\text{maxcut}(H)$ . This part of the argument is largely based on the techniques of [47]; we first state the following lemma whose proof is given for completeness in the full version.

► **Lemma 7.** *It holds that*

$$(1 - 4\epsilon)^m 2^{-m} \leq \frac{Z_{H^G} / Z_{\hat{H}^G}}{A^{3mt/2} (B/A)^{\text{maxcut}(H)t/3}} \leq (1 + 4\epsilon)^m,$$

where  $B > A > 0$  are constants depending only on  $\gamma$ .

With these pieces at hand, we are now ready to complete the reduction for Theorem 1, which we restate here for convenience.

► **Theorem 1.** Fix any real  $\gamma > 1$ . Then, it is NP-hard to approximate  $\text{SPECTRALISING}(\gamma)$ , even within an exponential factor  $2^{cN}$  for some constant  $c = c(\gamma) > 0$ .

**Proof.** Assume that for any arbitrarily small constant  $\delta > 0$ , there is an oracle  $\text{approx}_\delta$  such that, for any  $J$  with  $\lambda_{\max}(J) - \lambda_{\min}(J) \leq \gamma$ , we have that, when  $F = \text{approx}_\delta(J)$ ,  $|F - \log(Z(J))| \leq \delta m$ . We will show how to obtain a PTAS for MAXCUT on 3-regular graphs, i.e., approximate MAXCUT on 3-regular graphs within an arbitrarily small factor.

Let  $H$  be a 3-regular graph  $H$  on  $m$  vertices, an instance of MAXCUT. The maximum cut of  $H$  is at least the expected value of a random cut which is equal to  $3m/4$ . We then construct  $H^G$  and  $\hat{H}^G$  as above. Observe that  $Z(\hat{H}^G)$  can be computed in poly-time since  $\hat{H}^G$  is a disjoint collection of constant-size gadget graphs. Moreover, by Claim 6,  $H^G$  is an instance of  $\text{SPECTRALISING}(\gamma)$ . So, we can use the oracle  $\text{approx}_\delta$  on  $H^G$ , which will give us an output  $F_H$  with the guarantee

$$|F_H - \log Z_{H^G}| \leq \delta mn.$$

Lemma 7 implies that

$$\frac{3 \log \left( \frac{Z_{H^G} / Z_{\hat{H}^G}}{A^{3mt/2} (1+4\epsilon)^m} \right)}{t \log(B/A)} \leq \text{maxcut}(H) \leq \frac{3 \log \left( \frac{2^m Z_{H^G} / Z_{\hat{H}^G}}{A^{3mt/2} (1-4\epsilon)^m} \right)}{t \log(B/A)}.$$

Thus, by using the output  $F_H$  we can compute upper and lower bounds for the maximum cut value, which differ by  $O((\delta n + 1)m/t)$ . Since  $m \leq 4/3 \max\text{cut}(H)$ , to show the desired PTAS for MAXCUT, it only remains to show that the quantity  $R = (\delta n + 1)/t$  can be made arbitrarily small, say less than some target value  $\zeta$ , where  $\zeta > 0$  is an arbitrary constant. We first take  $t$  to be sufficiently large, so that  $1/t < \zeta/2$  is sufficiently small. This makes  $n$  to be large, but still a constant, and hence  $n/t$  is a constant. So, by taking  $\delta$  small enough, we will have  $\delta n/t < \zeta/2$ , making  $R < \zeta$  as desired.

This yields the desired PTAS. Since MAXCUT is APX-hard [2], we conclude that it is NP-hard to approximate  $Z_J$  within some exponential factor, as wanted. ◀

### 3.2 Proof of Theorem 3

For integers  $d, n \geq 3$  with  $dn$  even, let  $G_{n,d}$  be a  $d$ -regular graph chosen uniformly at random among all such graphs with vertex set  $V = \{1, 2, \dots, n\}$ . Let  $S \subseteq [n]$  be an arbitrary subset of the vertices of size  $t$ . Consider the Ising distribution  $\mu_J$  with  $J = \beta A$  where  $A$  is the adjacency matrix of  $G$  and  $\beta > \frac{1}{2} \ln(1 + \frac{2}{d-2})$ .

The range of  $\beta$  corresponds to the so-called non-uniqueness regime on the  $d$ -regular tree; roughly, this implies that on the  $d$ -regular tree of height  $h$ , when we condition the leaves to be  $+$  and take the limit  $h \rightarrow \infty$ , the marginal probability that the root is plus converges to some value  $q^+ > 1/2$ . Similarly, when we condition the leaves to be  $-$ , the marginal probability that the root is plus converges to some value  $q^- < 1/2$ .<sup>3</sup>

It is well-known by now [13, 42] that this behaviour on the tree manifests itself on the random  $d$ -regular graph, roughly because of the tree-like neighborhoods in the latter. To make this more precise in our setting, analogously to Section 2, for a subset  $S \subseteq V$ , define the phase  $Y_S(\sigma)$  of a configuration  $\sigma \in \{-1, +1\}^V$  to be  $+$  if  $\sum_{i \in V \setminus S} \sigma_i \geq 0$ , and  $-$  otherwise. We also define the product measures  $Q_S^\pm$  on  $S$  analogously to (2), using now the values of  $q^+, q^-$  as defined above (see also Footnote 3). Then, the following lemma captures the main properties of the gadget that we need.

► **Lemma 8.** *Let  $d \geq 3$  be an integer and  $\beta > \frac{1}{2} \ln(1 + \frac{2}{d-2})$ . Then, for any real  $\epsilon > 0$  and integer  $t \geq 1$ , for all sufficiently large integers  $n = n(t, \epsilon)$  with  $n - t$  odd, the following holds with probability  $1 - \epsilon$  over the choice of  $G \sim G_{n,d}$ . Let  $S \subseteq V$  be a subset of vertices with  $|S| = t$ .*

*Consider the Ising model with interaction matrix  $J = \beta A$  where  $A$  is the adjacency matrix of  $G$ . Then:*

1.  $\lambda_{\max}(J) - \lambda_{\min}(J) \leq \beta(d + 2\sqrt{d-1}) + \epsilon$ .
2. The phases appear with the same probability, i.e.,  $\Pr_{\sigma \sim \mu_J}[Y_\sigma = +] = \Pr_{\sigma \sim \mu_J}[Y_\sigma = -] = 1/2$ .
3. Conditioned on the phase, the joint distribution of the spins in  $S$  is approximately given by the product distribution  $Q_S^\pm$ , i.e.,

$$\text{for any } \tau \in \{-1, +1\}^S, \text{ it holds that } \Pr_{\sigma \sim \mu_J}[\sigma_S = \tau \mid Y_\sigma = \pm] = (1 \pm \epsilon)Q_S^\pm(\tau).$$

**Proof.** The first item is Friedman's result [20], see also [8]. The second item is by symmetry of the configuration space (since  $n$  is odd). The third item follows by [42, Theorem 2.4], see also [13, Theorem 2.7] and [47, Proposition 4.2] for related results. Technically, there is a bit of work to translate the results here, we give the details in the full version. ◀

<sup>3</sup> To define  $q^+, q^-$  more explicitly, for  $\beta > \frac{1}{2} \ln(1 + \frac{2}{d-2})$ , let  $\tilde{q}^+ > 1 > \tilde{q}^- > 0$  be the solutions of  $x = \left(\frac{\exp(2\beta)x+1}{x+\exp(2\beta)}\right)^{d-1}$ . Then,  $q^+, q^-$  are defined from  $\frac{q^+}{1-q^+} = \tilde{q}^+ \frac{\exp(2\beta)\tilde{q}^++1}{\tilde{q}^++\exp(2\beta)}$  and  $\frac{q^-}{1-q^-} = \tilde{q}^- \frac{\exp(2\beta)\tilde{q}^-+1}{\tilde{q}^-+\exp(2\beta)}$ , see also [21, Section 3].

► **Remark 9.** We use the gadget of Lemma 8 for some large but otherwise constant value of  $n$ . So, we can find a  $d$ -regular graph  $G$  satisfying Items 1-3 of Lemma 8 in deterministic time.

We are now ready to prove Theorem 3, which we restate here for convenience.

► **Theorem 3.** Fix any integer  $d \geq 4$  and real  $\gamma > \frac{1}{2} \ln(1 + \frac{2}{d-3})(d-1 + 2\sqrt{d-2})$ . Then, it is NP-hard to approximate  $\text{BOUNDEDSPECTRALISING}(d, \gamma)$ , even within an exponential factor  $2^{cN}$  for some constant  $c = c(\gamma) > 0$ .

**Proof.** Let

$$\beta_{d-1} := \frac{1}{2} \ln\left(1 + \frac{2}{d-3}\right), \quad \lambda_{d-1} := d-1 + 2\sqrt{d-2} \tag{13}$$

and set  $\beta = \beta_{d-1} + \eta$ ,  $\lambda = \lambda_{d-1} + \eta$  where  $\eta > 0$  is a small constant so that  $\beta\lambda + 2\eta < \gamma$  (note that such an  $\eta$  exists since  $\gamma > \beta_{d-1}\lambda_{d-1}$ ).

Assume that we are given a 3-regular instance  $H$  of MAXCUT with  $m$  vertices. Let  $G$  be a  $(d-1)$ -regular gadget with  $n$  vertices for some sufficiently large  $n$ , i.e.,  $G$  satisfies Items 1-3 of Lemma 8 for degree  $d-1$  and  $\beta = \beta_{d-1} + \eta$ , see also Remark 9. So, according to Item 1 there, the interaction matrix  $J_G$  corresponding to  $G$  satisfies  $\lambda_{\max}(J_G) - \lambda_{\min}(J_G) \leq \beta\lambda$ .

Using  $G$ , the construction of the graph  $H^G$  is identical to that of Section 3.1, i.e., we have a distinct copy of  $G$  for each node of  $H$  and, for each pair of neighbouring nodes of  $H$ , we add a matching of size  $t/3$  between the corresponding gadgets using the vertices in  $S$ . Note that  $H^G$  has maximum degree  $d$ , so the interaction matrix of  $H^G$ , denoted by  $J$  henceforth, has at most  $d$  non-zero entries per row.

The weight of an edge inside the gadget is  $w_+ = \beta > 0$  and the weight of the edges that connect two gadgets is  $w_- = -\eta < 0$  (antiferromagnetic connections). Analogously to Claim 5, the symmetric matrix  $J$  can be written as  $D + E \in \mathbb{R}^{nm \times nm}$ , where (i)  $D$  is a block diagonal matrix with the matrix in each block being the  $n \times n$  adjacency matrix of  $G$  scaled by  $w_+$ , and (ii)  $E$  contains in each row exactly one non-zero element of magnitude  $w_-$ . The same argument as in the proof of Claim 6 gives that

$$\begin{aligned} |\lambda_{\max}(J) - \lambda_{\min}(J)| &\leq |\lambda_{\max}(J) - \lambda_{\max}(D)| + |\lambda_{\max}(D) - \lambda_{\min}(D)| + |\lambda_{\min}(D) - \lambda_{\min}(J)| \\ &\leq 2\eta + \beta\lambda < \gamma. \end{aligned}$$

This establishes that  $H^G$  is a valid instance of  $\text{BOUNDEDSPECTRALISING}(d, \gamma)$ .

Now, using Item 3 of Lemma 8, we obtain the exact same estimate as in Lemma 7 (with the same expressions for the constants  $A, B$  modulo the new values of  $w_+$  and  $w_-$ ), and therefore the same argument used in the proof of Theorem 1 applies verbatim to show NP-hardness of approximating the partition function within an arbitrarily small exponential factor. ◀

► **Remark 10.** Note that we could make the graph  $H^G$  to be  $d$ -regular for any integer  $d \geq 3$  by taking the gadget  $G$  to be a random  $d$ -regular graph with a matching of size  $t$  removed (and using the endpoints of the matching as the set  $S$  of terminals); this more refined construction has been used for example in the hardness results of [46, 47, 21]. While one can show the analogue of Items 2 and 3 with minor modifications (analogously to what was done in the proof of Lemma 8), the proof of Item 1 for this modified gadget seems to require more careful adaptation of the proofs in [20, 8]. It is nevertheless reasonable to expect that the same bound on the range of the eigenvalues as stated currently in Item 1 will still apply; provided this is indeed the case, one can improve slightly the parameters of Theorem 3 to  $d \geq 3$  and  $\gamma > \beta_d \lambda_d$ , where  $\beta_d, \lambda_d$  are as in (13).

## Abstract

---

Determining the approximate degree composition for Boolean functions remains a significant unsolved problem in Boolean function complexity. In recent decades, researchers have concentrated on proving that approximate degree composes for special types of inner and outer functions. An important and extensively studied class of functions are the recursive functions, i.e. functions obtained by composing a base function with itself a number of times. Let  $h^d$  denote the standard  $d$ -fold composition of the base function  $h$ . The main result of this work is to show that the approximate degree composes if either of the following conditions holds:

- The outer function  $f : \{0, 1\}^n \rightarrow \{0, 1\}$  is a recursive function of the form  $h^d$ , with  $h$  being any base function and  $d = \Omega(\log \log n)$ .
- The inner function is a recursive function of the form  $h^d$ , with  $h$  being any constant arity base function (other than AND and OR) and  $d = \Omega(\log \log n)$ , where  $n$  is the arity of the outer function.

In terms of proof techniques, we first observe that the lower bound for composition can be obtained by introducing majority in between the inner and the outer functions. We then show that majority can be *efficiently eliminated* if the inner or outer function is a recursive function.

## 1 Introduction

Representations of Boolean functions  $f : \{0, 1\}^n \rightarrow \{0, 1\}$  in terms of multivariate polynomials  $p(x)$  play a pivotal role in theoretical computer science. There are different notions of representations;

- *exact* representation:  $f(x) = p(x)$  for all  $x \in \{0, 1\}^n$ ,
- *approximate* representation:  $|f(x) - p(x)| \leq 1/3$  for all  $x \in \{0, 1\}^n$ , and
- *sign* representation:  $(1 - 2f(x))p(x) > 0$  for all  $x \in \{0, 1\}^n$ .

Arguably the most important measure associated with a polynomial is its (total) *degree*. Let  $\deg(f)$ ,  $\widetilde{\deg}(f)$ , and  $\deg_{\pm}(f)$  denote the minimal possible degree of a real polynomial *exactly*, *approximately*, and *sign* representing  $f$ , respectively. These different notions of degrees capture notions of efficiency in many different models of computation (e.g., decision trees, quantum query, perceptrons), and are thus well-studied in literature (see, e.g., [6, 7, 14] and the references therein).

For instance,  $\deg_{\pm}(f)$  (called sign degree) has strong connections to – separations among complexity classes [7], designing efficient learning algorithm [28, 27], and lower bounds against circuits, formulas, communication complexity, etc. [12, 18]. Similarly, upper bounds on  $\widetilde{\deg}(f)$  (called approximate degree), has strong connections to learning theory [25, 29, 37], approximate inclusion-exclusion [24, 43], differentially private data release [47, 17], etc. While the lower bounds on approximate degree lead to lower bounds in quantum query complexity [5, 2, 1], communication complexity [43, 38], circuit complexity [3], etc.

Despite decades of work in this area, there are many important problems that are yet to be resolved completely. One such problem pertains to the composition of approximate degrees. For any two Boolean functions  $f: \{0, 1\}^n \rightarrow \{0, 1\}$  and  $g: \{0, 1\}^m \rightarrow \{0, 1\}$ , define the *composed* function  $f \circ g: \{0, 1\}^{nm} \rightarrow \{0, 1\}$  as follows

$$f \circ g(x_{11}, \dots, x_{1m}, \dots, x_{n1}, \dots, x_{nm}) = f(g(x_1), \dots, g(x_n)),$$

where  $x_i = (x_{i1}, \dots, x_{im}) \in \{0, 1\}^m$  for  $i \in [n]$ . The function  $f$  is called the outer function and  $g$  the inner function.

Investigating the behaviour of complexity measures under composition has been a quintessential tool in our quest to gain insights into relationships among different measures. In particular, composition has been used successfully on numerous occasions to show separations between various complexity measures associated with Boolean functions, see, e.g., [36, 33, 23, 4, 46, 19]. A big open problem in this context is to understand how approximate degree behaves under composition. More formally, it asks whether for all Boolean functions  $f: \{0, 1\}^n \rightarrow \{0, 1\}$  and  $g: \{0, 1\}^m \rightarrow \{0, 1\}$ ,

$$\widetilde{\deg}(f \circ g) = \widetilde{\Theta}(\widetilde{\deg}(f) \cdot \widetilde{\deg}(g))?$$

The tilde in the  $\widetilde{\Theta}$  notation hides a factor polynomial in  $\log(n + m)$ . This problem is often referred to as the “approximate degree composition” problem.

The upper bound,  $\widetilde{\deg}(f \circ g) = O(\widetilde{\deg}(f) \cdot \widetilde{\deg}(g))$ , was established in a seminal work [42] of Sherstov. Thus to completely resolve the problem it remains to prove a matching lower bound on the approximate degree of a composed function in terms of the approximate degree of the individual functions. In other words, does the following hold for all Boolean functions  $f$  and  $g$ ,

$$\widetilde{\deg}(f \circ g) = \widetilde{\Omega}(\widetilde{\deg}(f) \cdot \widetilde{\deg}(g))?$$

In this article we will refer to the aforementioned (lower bound) question by the phrase “approximate degree composition” problem.

Numerous works, including those by [33, 4, 39, 41, 40, 13, 8, 15], actively pursued these lower bounds, leading to newer connections with several important problems in the field. However, establishing the lower bound  $\widetilde{\deg}(f \circ g) = \widetilde{\Omega}(\widetilde{\deg}(f) \widetilde{\deg}(g))$  even for specific

functions or restricted classes of functions is often very challenging. For example, consider the composed function  $\text{OR} \circ \text{AND}$ , it took a long series of work [33, 44, 4, 41, 40, 13] over nearly two decades to prove that  $\widetilde{\text{deg}}(\text{OR} \circ \text{AND}) = \Omega(\widetilde{\text{deg}}(\text{OR}) \widetilde{\text{deg}}(\text{AND}))$ . Till date we know that the approximate degree composes in the following cases:

- when the outer function  $f$  has full approximate degree, i.e.,  $\Theta(n)$  [39],
- when the outer function  $f$  is a symmetric function [8],
- when the outer function  $f$  has minimal approximate degree with respect to its block sensitivity, i.e.,  $\widetilde{\text{deg}}(f) = O(\sqrt{\text{bs}(f)})$  [15], and
- when the sign degree of the inner function is same as its approximate degree [39, 30].

This work focuses on the behavior of approximate degree when *recursive functions* are composed with other general functions (as outer or inner function). Here, by recursive functions, we mean the functions of the kind  $h^d$  ( $h$  composed with itself  $d$  times) where the arity of  $h$  is small. The function  $h$  is often called the base function and the function  $f$  is called the recursive- $h$  function.

Recursive functions are an important class of Boolean functions that are studied in various different contexts in the analysis of Boolean functions, mainly in proving various lower bounds [4, 45, 36, 33, 34, 9]. For example, the Kushilevitz's function [34] which is the only known non-trivial example of functions with low degree and high sensitivity is a recursive function of a carefully chosen base function. Recursive majority,  $\text{MAJ}_3^d$ , is another recursive function that has been studied extensively in the literature for its different properties [36, 22, 31, 32]. Boppana (see, e.g., [36]) used it to provide the first evidence that the randomized query is more powerful than deterministic query [36]. In the same article, they show a similar separation using recursive  $\text{AND}_2 \circ \text{OR}_2$  function too. In a different application of recursive  $\text{AND}_2 \circ \text{OR}_2$ , [23] show separation between deterministic tree-size complexity and number of monomials in the minimal DNF or CNF.

The approximate degree composition was not known when the outer or inner function is a recursive function, in general. For some special recursive functions, however, it was known that the approximate degree composes. For example, the OR function on  $n = 3^d$  bits is same as  $\text{OR}_3^d$ . After a series of works ([33, 4, 40, 13, 41]), it was proven that the approximate degree composition holds when the outer function is OR, and in general symmetric [8]. Similarly, from the result of [39, 30] it can be observed that the lower bound holds when either the inner or outer function is recursive PARITY. Unfortunately, these results can't be applied in general even when the base function is symmetric or it has full approximate degree.

This scenario leads to the natural question:

*Can we prove that  $\widetilde{\text{deg}}(f \circ g) = \Omega(\widetilde{\text{deg}}(f) \cdot \widetilde{\text{deg}}(g))$  when the outer function  $f$  or the inner function  $g$  is recursive?*

## 1.1 Our Results

Let  $h : \{0, 1\}^k \rightarrow \{0, 1\}$  be a function on  $k$ -bits. Let  $h^d$  denote the Boolean function represented by the complete  $k$ -ary tree of depth  $d$  such that each internal node of the tree is labelled by  $h$  and the leaves of tree are labelled by distinct variables. Our main result shows that the composition theorem holds for any  $h^d$  (except a few specific  $h$ 's), either as the outer function with any inner function or as the inner function with any outer function.

## 71:4 Approximate Degree Composition for Recursive Functions

► **Theorem 1.** *Let  $f: \{0, 1\}^n \rightarrow \{0, 1\}$  and  $g: \{0, 1\}^m \rightarrow \{0, 1\}$  be two Boolean functions and  $d \geq C \log \log n$  for a large enough constant  $C$ . Then,*

$$\widetilde{\deg}(f \circ g) = \Omega \left( \frac{\widetilde{\deg}(f) \widetilde{\deg}(g)}{\text{polylog}(n)} \right),$$

*if either of the following conditions hold:*

1.  $f = h^d$ , for any Boolean function  $h$ .
2.  $g = h^d$ , for any Boolean function  $h$  with constant arity and not equal to AND or OR.

In light of the above theorem, understanding the composition of approximate degree when inner function is OR is the central case for making progress towards the general composition question.

We would like to emphasize that there are not many results which prove composition theorem for a general class of inner functions. Theorem 1 shows that the composition property holds if the inner function is recursive irrespective of the outer function.

We further note that Theorem 1 doesn't follow from the known results even when the composition theorem is known to hold for the base function. Firstly, it is known that the composition lower bound holds when the outer function is symmetric [8]; though, a repeated composition of a symmetric function will incur the factor of  $(\log n)^d$  (because of the  $\log n$  factor hiding in the  $\widetilde{\Omega}$  notation). Secondly, while the majority function,  $\text{MAJ}_n$ , has full approximate degree  $(\Theta(n))$ ,  $\text{MAJ}_3^d$  doesn't have full approximate degree. Thus, Sherstov's result [39] that proves composition theorem holds for functions with full approximate degree cannot be applied in the case of recursive majority. The situation is similar for the inner function as well.

Moving ahead, the proof of Theorem 1 uses two ideas.

- We first prove that a similar theorem works for the specific case of  $h = \text{MAJ}_3$  and  $h = \text{AND}_2 \circ \text{OR}_2$  functions.
- Then, we use a general  $h$  to *simulate*  $\text{AND}_2 \circ \text{OR}_2$ ; hence, proving composition for the general case.

The case of recursive  $h = \text{MAJ}_3$  and  $h = \text{AND}_2 \circ \text{OR}_2$  functions is in itself very interesting. There have been several works towards exploring the approximate degree and other properties of these two functions [21, 26, 36, 23]. Given their importance, and the fact that it is a central step in our main result (Theorem 1), we state the composition theorem for these two functions separately.

► **Theorem 2.** *Let  $f$  and  $g$  be two Boolean functions. Then,*

$$\widetilde{\deg}(f \circ h^d) = \widetilde{\Omega}(\widetilde{\deg}(f) \widetilde{\deg}(h^d)) \text{ and } \widetilde{\deg}(h^d \circ g) = \widetilde{\Omega}(\widetilde{\deg}(h^d) \widetilde{\deg}(g)),$$

*where  $h$  is either  $\text{MAJ}_3: \{0, 1\}^3 \rightarrow \{0, 1\}$  or  $\text{AND}_2 \circ \text{OR}_2: \{0, 1\}^4 \rightarrow \{0, 1\}$ ,  $n$  is the arity of the outer function,  $d \geq C \log \log n$  for a large enough constant  $C$ , and  $\widetilde{\Omega}(\cdot)$  hides  $\text{polylog}(n)$  factors.*

To prove Theorem 2 we will need the following lemma. Even though the lemma can be obtained from a combination of known results (e.g., [39] and [10]) with appropriate parameters, we give a self-contained simpler proof of the lemma, inspired by the primal-dual perspective of [40].

► **Lemma 3.** *For any Boolean functions  $f: \{0, 1\}^n \rightarrow \{0, 1\}$  and  $g: \{0, 1\}^m \rightarrow \{0, 1\}$ ,*

$$\widetilde{\deg}(f \circ \text{MAJ}_t \circ g) = \Omega(\widetilde{\deg}(f) \widetilde{\deg}(g)) \tag{1.1}$$

*for  $t \geq C \log n$  for a large enough constant  $C$ .*

Note that, Lemma 3 gives a way to settle the composition question affirmatively. In particular, if  $\widetilde{\deg}(f \circ \text{MAJ}_t \circ g) = \widetilde{O}(\widetilde{\deg}(f \circ g))$ , where  $t$  is  $\Theta(\log n)$  and  $n$  is the arity of  $f$ , then it follows that the composition holds for  $f$  and  $g$ .

We also highlight that a tighter lower bound can be obtained when the middle function MAJ is replaced by an “amplifier function” in Lemma 3. Define  $H$  to be a *strong hardness amplifier function* for  $g$  if

$$\widetilde{\deg}_{\frac{1-2^{-\Omega(t)}}{2}}(H \circ g) = \Omega(\widetilde{\deg}(H) \circ \widetilde{\deg}(g)).$$

We also observe that,

$$\widetilde{\deg}(f \circ H \circ g) = \Omega(\widetilde{\deg}(f) \widetilde{\deg}(H) \widetilde{\deg}(g)), \quad (1.2)$$

when  $H$  is a strong hardness amplifier function for  $g$ . We discuss this improvement in the full version of the paper [16].

## 1.2 Proof Ideas

To address the lower bound for the composition of two Boolean functions  $f$  and  $g$ ,  $f \circ g$ , we will call  $f$  to be the “outer function” and  $g$  to be the “inner function”. In the case of three layered composed functions ( $f \circ H \circ g$ ), we will call  $H$  to be the “hardness amplifier” and  $f$  and  $g$  to be the outer and inner functions respectively.

**Primal dual approach to composition.** Our proof technique is based on the primal-dual view used by [40] for proving the composition of  $\text{AND}_n \circ \text{OR}_n$ . Here, instead of using “dual-composition method” (see [13, 14]) we will be using only the dual witness of the inner function. The primal-dual approach is to construct an approximating polynomial for  $f$  with smaller degree than  $\widetilde{\deg}(f)$  by applying a linear operator  $L$  on the assumed approximating polynomial for  $f \circ g$  (say  $p$ , with smaller degree than claimed), leading to a contradiction. The linear operator  $L$  is defined by taking the input to  $f$ , extending it to a probability distribution (which depends upon the dual of  $g$ ) over the inputs of  $f \circ g$  and outputting the expectation.

Let  $\psi$  be the dual witness of  $g$ , we get  $\mu_0$  and  $\mu_1$  by restricting  $\psi$  on support which takes positive and negative values respectively; by the properties of dual witness,  $\mu_1$  (and  $\mu_0$ ) will mostly be supported on inputs  $x$  such that  $g(x) = 1$  (and  $g(x) = 0$  respectively). The input to  $f$  is expanded bit by bit using  $\mu_0$  and  $\mu_1$ , creating a distribution on inputs of  $f \circ g$ .

Formally,  $L$  takes a general function  $h : \{0, 1\}^{mn} \rightarrow \{0, 1\}$  and gives  $Lh : \{0, 1\}^n \rightarrow \mathbb{R}$ .

$$Lh(z_1, \dots, z_n) = \mathbb{E}_{x_1 \sim \mu_{z_1}} \mathbb{E}_{x_2 \sim \mu_{z_2}} \cdots \mathbb{E}_{x_n \sim \mu_{z_n}} [h(x_1, x_2, \dots, x_n)], \quad (1.3)$$

where  $x_i \in \{0, 1\}^m$  for all  $i \in \{1, 2, \dots, n\}$ .

To complete the proof, the following two properties of  $L$  are required:

1. Showing that the polynomial  $Lp$  indeed approximates  $f$  in  $l_\infty$  norm. Intuitively this happens because the restricted distributions ( $\mu_0$  and  $\mu_1$ ) are a pretty good indicator of the value of  $g$ .
2. The degree of  $Lp$  is small, intuitively because  $L$  reduces the degree of every monomial by a factor of  $\widetilde{\deg}(g)$ .

**Problem with the primal dual approach.** Unfortunately, the recipe described above doesn't work well in general due to the error introduced by the expectation over  $\mu_0$  and  $\mu_1$  in the string  $(z_1, \dots, z_n)$ . To handle a noisy string in place of a Boolean string, the approximating polynomial  $p$  needs to be robust. A polynomial is robust to noise  $\frac{1}{3}$ , if for all inputs  $x$  and for all  $\Delta \in [-\frac{1}{3}, \frac{1}{3}]^m$ ,  $|p(x) - p(x + \Delta)| < \varepsilon$ .

While any polynomial  $p$  can be made robust up to error  $\varepsilon$  with degree at most  $\deg(p) + \log(\frac{1}{\varepsilon})$  (see Theorem 11 by [42]), such polynomials are not known to be multilinear, making the analysis of expectation difficult. [11] gives a robust multilinear polynomial for any Boolean function  $f : \{0, 1\}^n \rightarrow \{0, 1\}$ ; though, the polynomial is defined on a perturbation matrix of input  $x$  instead of  $x$  itself. We now discuss how to overcome this problem.

We give the proof ideas of Theorem 1, Theorem 2 and Lemma 3 in the reverse order, the way they are obtained from each other.

**Proof idea of Lemma 3.** We will use  $\text{MAJ}_t$  to get past this difficulty; it helps to reduce the noise in the input of  $f$  to error  $\frac{1}{n}$ . Using the fact that any multilinear polynomial on  $n$  variables is robust up to error  $\frac{1}{n}$ , we have our lower bound for the function  $\widetilde{\deg}(f \circ \text{MAJ}_t \circ g)$  where  $t = \Omega(\log n)$ .

**Proof idea of Theorem 2.** Using previously known constructions ([48, 20]),  $\text{MAJ}_{\log n}$  can be projected to  $\text{MAJ}_3^d$  and  $(\text{AND}_2 \circ \text{OR}_2)^d$ , where  $d \geq C \log \log n$ . We now replace  $\text{MAJ}_{\log n}$  in Lemma 3 with these recursive functions; by using the associativity of the composition of functions and the approximate degree upper bound [42], we finish the proof of the theorem. Note that we only lose a factor of  $\text{polylog}(n)$  in the lower bound since we only need to simulate  $\text{MAJ}_{\log n}$ .

Now we give the idea about how to replace  $\text{AND}_2 \circ \text{OR}_2$  with almost any recursive function to get our main result.

**Proof idea of Theorem 1.** Given Theorem 2, it is natural to ask, what other recursive functions satisfy the composition property. We show that almost any  $h$  can be used to replace the  $\text{AND}_2 \circ \text{OR}_2$  function. This is done by simulating  $\text{AND}_2$  and  $\text{OR}_2$  using restrictions of  $h$  and its powers. The proof of this simulation is divided into two cases: monotone  $h$  and non-monotone  $h$ .

For the monotone case (except when  $h$  is  $\text{AND}$  or  $\text{OR}$ ): We show that both  $\text{AND}_2$  and  $\text{OR}_2$  will be present as sub-cubes of the original Boolean hypercube of  $h$ .

For the non-monotone case (except when  $h$  is  $\text{PARITY}$  or  $\neg\text{PARITY}$ ): The proof requires more work here because of these two issues. First, there need not be both functions  $\text{AND}_2$  and  $\text{OR}_2$  as sub-cubes (though, we show that at least one will be present). Second, the sub-cube could be rotated. The resolution to both these issues is same. We use the non-monotonicity to construct the negation function. This allows us to rotate the sub-cube as well as construct  $\text{AND}_2/\text{OR}_2$  from the other one.

A slight technical point to note is that when  $h$  is a non-constant arity function and  $h^d$  is the inner function, then the loss in the lower bound will be larger than  $\text{polylog}(n)$ . However, even for the case when the base function  $h$  has arity that is a "slowly" growing function of  $n$  we still obtain a non-trivial lower bound composition result.

The remaining cases of Theorem 1, that is,

(i) when  $f$  or  $g$  equals  $h^d$  for  $h \in \{\text{PARITY}, \neg\text{PARITY}\}$  follows from [39], and (ii) when  $f = h^d$  and  $h \in \{\text{AND}, \text{OR}\}$  follows from [8].

## 2 Notations and Preliminaries

In this paper, we will assume a Boolean function has domain  $\{0, 1\}^n$  and range  $\{0, 1\}$ . We start with some of the important definitions.

► **Definition 4** (Generalized Composition of functions). *For any Boolean function  $f : \{0, 1\}^n \rightarrow \{0, 1\}$  and  $n$  Boolean functions  $g_1, g_2, \dots, g_n$ , define the composed function*

$$f \circ (g_1, g_2, \dots, g_n)(x_1, x_2, \dots, x_n) = f(g_1(x_1), g_2(x_2), \dots, g_n(x_n)),$$

where  $g_i$ 's can have different arities and  $x_i \in \text{Dom}(g_i)$  for all  $i \in [n]$ .

When all the copies of  $g_i$  are the same function  $g$  then the composed function is denoted by  $f \circ g$ .

► **Definition 5** (Recursive functions). *For any Boolean function  $f : \{0, 1\}^t \rightarrow \{0, 1\}$  we define recursive function  $f^d : \{0, 1\}^{t^d} \rightarrow \{0, 1\}$  by  $f^d = \underbrace{f \circ f \circ \dots \circ f}_{d \text{ times}}$ .*

► **Definition 6** (Approximate degree ( $\widetilde{\text{deg}}$ )). *For some constant  $0 < \varepsilon < 1/2$ , a polynomial  $p : \mathbb{R}^n \rightarrow \mathbb{R}$  is said to  $\varepsilon$ -approximate a Boolean function  $f : \{0, 1\}^n \rightarrow \{0, 1\}$  if for all  $x \in \{0, 1\}^n$ ,  $|p(x) - f(x)| \leq \varepsilon$ . The  $\varepsilon$ -approximate degree of  $f$ ,  $\widetilde{\text{deg}}_\varepsilon(f)$ , is the minimum possible degree of a polynomial that  $\varepsilon$ -approximates  $f$ . Conventionally we use  $\widetilde{\text{deg}}(\cdot)$  as the shorthand for  $\widetilde{\text{deg}}_{1/3}(\cdot)$ .*

Note that the constant  $\varepsilon$  in the above definition can be replaced by any constant strictly smaller than  $1/2$  which changes  $\widetilde{\text{deg}}_\varepsilon(f)$  by only a constant factor. We note this well-known fact about error reduction.

► **Lemma 7** (Error reduction). *For any  $\varepsilon > 0$ ,  $\widetilde{\text{deg}}_\varepsilon(f) = \Theta_\varepsilon(\widetilde{\text{deg}}(f))$ , where  $\Theta_\varepsilon(\cdot)$  denotes that the constant in  $\Theta(\cdot)$  depends on  $\varepsilon$ .*

► **Lemma 8** ([38, 39]). *Let  $f : \{0, 1\}^n \rightarrow \mathbb{R}$  be a function and  $\varepsilon > 0$ . Then,  $\widetilde{\text{deg}}_\varepsilon(f) \geq d$  iff there exists a function  $\psi : \{0, 1\}^n \rightarrow \mathbb{R}$  such that*

$$\sum_{x \in \{0, 1\}^n} |\psi(x)| = 1, \tag{2.1}$$

$$\sum_{x \in \{0, 1\}^n} \psi(x) \cdot f(x) > \varepsilon, \text{ and} \tag{2.2}$$

$$\sum_{x \in \{0, 1\}^n} \psi(x) \cdot p(x) = 0 \text{ for every polynomial } p \text{ of degree } < d. \tag{2.3}$$

In a seminal work, Sherstov [42] showed that the approximate degree can increase at most multiplicatively under composition.

► **Theorem 9** ([42]). *For all Boolean function  $f : \{0, 1\}^n \rightarrow \{0, 1\}$  and  $g : \{0, 1\}^m \rightarrow \{0, 1\}$ ,  $\widetilde{\text{deg}}(f \circ g) = O(\widetilde{\text{deg}}(f) \cdot \widetilde{\text{deg}}(g))$ .*

At times we will be working with inputs that are not Boolean *but* are close to Boolean. So we would also need the following notion of *robust* approximating polynomials.

► **Definition 10** ( $(\delta, \varepsilon)$ -robust approximating polynomial). *Let  $p : \{0, 1\}^m \rightarrow [0, 1]$  be a polynomial. Then, for  $\delta, \varepsilon > 0$ , a  $(\delta, \varepsilon)$ -robust approximating polynomial for  $p$  is a polynomial  $p_{\text{robust}} : \mathbb{R}^m \rightarrow \mathbb{R}$  such that for all  $x \in \{0, 1\}^m$  and for all  $\Delta \in [-\delta, \delta]^m$ ,*

$$|p(x) - p_{\text{robust}}(x + \Delta)| < \varepsilon.$$

## 71:8 Approximate Degree Composition for Recursive Functions

Sherstov [42] proved that for any Boolean function  $f : \{0, 1\}^n \rightarrow \{0, 1\}$  there exists a robust approximating polynomial with degree at most  $O(\widetilde{\deg}(f) + \log(1/\varepsilon))$ .

► **Theorem 11** ([42]). *A  $(\delta, \varepsilon)$ -robust approximating polynomial for  $p : \{0, 1\}^n \rightarrow [0, 1]$  of degree  $O_\delta(\deg(p) + \log(1/\varepsilon))$  exists. Here  $O_\delta(\cdot)$  denotes that the constant in  $O(\cdot)$  depends on  $\delta$ .*

Note that a robust approximating polynomial need not to be multilinear. For our purposes, we need a multilinear robust approximating polynomial.

► **Theorem 12** (Folklore). *Any multilinear polynomial  $p : \{0, 1\}^n \rightarrow \{0, 1\}$  is  $(\frac{\delta}{n}, \delta)$ -robust.*

A proof of the theorem above can be found at [11, Lemma 3].

► **Theorem 13** ([8]). *For any symmetric Boolean function  $f : \{0, 1\}^n \rightarrow \{0, 1\}$  and any Boolean function  $g : \{0, 1\}^m \rightarrow \{0, 1\}$ ,*

$$\widetilde{\deg}(f \circ g) = \Omega\left(\frac{\widetilde{\deg}(f)\widetilde{\deg}(g)}{\log n}\right).$$

Finally, we define projection of functions.

► **Definition 14** (Projection of functions). *Let  $f : \{0, 1\}^n \rightarrow \mathbb{R}$  and  $g : \{0, 1\}^m \rightarrow \mathbb{R}$  be two functions. We say that  $f$  is a projection of  $g$ , denoted  $f \leq_{\text{proj}} g$ , iff*

$$f(x_1, \dots, x_n) = g(a_1, \dots, a_m)$$

for some  $a_i \in \{0, 1\} \cup \{x_1, x_2, \dots, x_n\}$ . That is,  $f$  is obtained from  $g$  by substitutions of variables of  $g$  by variables of  $f$  or constants in  $\{0, 1\}$ .

We need the following theorems about computing  $\text{MAJ}_n$  using a projection of recursive functions.

► **Theorem 15** ([20]). *There exists a constant  $C > 0$ , such that  $\text{MAJ}_n : \{0, 1\}^n \rightarrow \{0, 1\}$  is a projection of  $\text{MAJ}_3^d$  where  $d = C \log n$ .*

► **Theorem 16** ([48]). *There exists a constant  $C > 0$ , such that  $\text{MAJ}_n : \{0, 1\}^n \rightarrow \{0, 1\}$  is a projection of  $(\text{AND}_2 \circ \text{OR}_2)^d$  where  $d = C \log n$ .*

### 3 Composition theorem for recursive Majority and alternating AND-OR trees

In this section we give a proof of Theorem 2. We begin with a proof highlight of Lemma 3. The missing proofs are in the full version of the paper [16].

#### 3.1 Proof of Lemma 3

► **Lemma 3.** *For any Boolean functions  $f : \{0, 1\}^n \rightarrow \{0, 1\}$  and  $g : \{0, 1\}^m \rightarrow \{0, 1\}$ ,*

$$\widetilde{\deg}(f \circ \text{MAJ}_t \circ g) = \Omega(\widetilde{\deg}(f)\widetilde{\deg}(g)) \tag{1.1}$$

for  $t \geq C \log n$  for a large enough constant  $C$ .

**Proof.** We will present a proof inspired by the primal-dual view of [40]. Fix any constant  $0 < \varepsilon < 1/2$ . Let  $h := f \circ \text{MAJ}_t \circ g$  be the composed function, and  $p_h : \{0, 1\}^{ntm} \rightarrow \mathbb{R}$  be an  $\varepsilon$ -approximating polynomial for  $h$ .

Further, define  $d := \widetilde{\deg}_{\frac{1-\varepsilon}{2}}(g)$ . Then, by Lemma 8, there exists a function  $\psi : \{0, 1\}^m \rightarrow \mathbb{R}$  such that

$$\sum_{x \in \{0, 1\}^m} |\psi(x)| = 1, \quad (3.1)$$

$$\sum_{x \in \{0, 1\}^m} \psi(x) \cdot g(x) > \frac{1-\varepsilon}{2}, \text{ and} \quad (3.2)$$

$$\sum_{x \in \{0, 1\}^m} \psi(x) \cdot p(x) = 0 \text{ for every polynomial } p \text{ of degree } < d. \quad (3.3)$$

Let  $\mu$  be the probability distribution on  $\{0, 1\}^m$  given by  $\mu(x) = |\psi(x)|$  for  $x \in \{0, 1\}^m$ . From (3.3), we have  $\sum_{x \in \{0, 1\}^m} \psi(x) = 0$ . Therefore, the sets  $\{x \mid \psi(x) < 0\}$  and  $\{x \mid \psi(x) > 0\}$  are weighted equally by  $\mu$ . Let  $\mu_0$  and  $\mu_1$  be the probability distributions obtained by conditioning  $\mu$  on the sets  $\{x \mid \psi(x) < 0\}$  and  $\{x \mid \psi(x) > 0\}$  respectively. Hence,

$$\mu = \frac{1}{2}\mu_0 + \frac{1}{2}\mu_1, \quad \text{and} \quad \psi = \frac{1}{2}\mu_1 - \frac{1}{2}\mu_0.$$

We note an important property of the distributions  $\mu_0$  and  $\mu_1$  which shows that the error between  $\text{sign}(\psi(x))$  and  $g(x)$  is low.

► **Lemma 17.**  $\mathbb{E}_{x \sim \mu_1}[g(x)] > 1 - \varepsilon$ .

► **Lemma 18.**  $\mathbb{E}_{x \sim \mu_0}[g(x)] < \varepsilon$ .

Consider the following linear operator  $L$  that maps functions  $h : \{0, 1\}^{ntm} \rightarrow \mathbb{R}$  to functions  $Lh : \{0, 1\}^n \rightarrow \mathbb{R}$ ,

$$Lh(z) = \mathbb{E}_{\substack{x_{11} \sim \mu_{z_1} \\ x_{12} \sim \mu_{z_1}}} \mathbb{E}_{\substack{x_{21} \sim \mu_{z_2} \\ x_{22} \sim \mu_{z_2}}} \cdots \mathbb{E}_{\substack{x_{n1} \sim \mu_{z_n} \\ x_{n2} \sim \mu_{z_n}}} [h(x_{11}, \dots, x_{1t}, x_{21}, \dots, x_{2t}, \dots, x_{n1}, \dots, x_{nt})]. \quad (3.4)$$

Recall  $h = f \circ \text{MAJ}_t \circ g$  and  $p_h$  be  $\varepsilon$ -approximating polynomial for  $h$ . Thus by convexity of  $L$  we have  $\|L(h - p_h)\|_\infty \leq \varepsilon$ . We will now observe some useful properties of the linear operator  $L$ .

► **Lemma 19.**  $\deg(Lp_h) \leq \deg(p_h)/d$ , where  $d = \widetilde{\deg}_{\frac{1-\varepsilon}{2}}(g)$ .

We now show that  $Lp_h$  is in fact an approximating polynomial for  $f$ .

► **Lemma 20.** Fix  $0 < \delta < 1/2$ . Recall  $p_h$  is an  $\varepsilon$ -approximating polynomial for  $h = f \circ \text{MAJ}_t \circ g$ . Let  $t = \Theta(\log n + \log(1/\delta))$  where the constant in  $\Theta(\cdot)$  depends on  $\varepsilon$ . Then,  $Lp_h$  is a  $(\delta + \varepsilon)$ -approximating polynomial for  $f$ . That is,

$$\|f - Lp_h\|_\infty \leq \|f - Lh\|_\infty + \|Lh - Lp_h\|_\infty \leq \delta + \varepsilon.$$

## 71:10 Approximate Degree Composition for Recursive Functions

**Proof.** It suffices to show  $\|f - Lh\|_\infty \leq \delta$ . To this end, consider  $Lh(z)$ .

$$\begin{aligned} Lh(z) &= \mathbb{E}_{\substack{x_{11} \sim \mu_{z_1} \\ x_{12} \sim \mu_{z_1}}} \mathbb{E}_{\substack{x_{21} \sim \mu_{z_2} \\ x_{22} \sim \mu_{z_2}}} \cdots \mathbb{E}_{\substack{x_{n1} \sim \mu_{z_n} \\ x_{n2} \sim \mu_{z_n}}} [f \circ \text{MAJ}_t \circ g(x_{11}, \dots, x_{1t}, \dots, x_{n1}, \dots, x_{nt})] \\ &\quad \vdots \\ &\quad \mathbb{E}_{\substack{x_{1t} \sim \mu_{z_1} \\ x_{2t} \sim \mu_{z_2}}} \mathbb{E}_{\substack{x_{2t} \sim \mu_{z_2} \\ x_{3t} \sim \mu_{z_3}}} \cdots \mathbb{E}_{\substack{x_{nt} \sim \mu_{z_n}}} \\ &= f \left( \text{MAJ}_t \left( \mathbb{E}_{\mu_{z_1}} [g], \dots, \mathbb{E}_{\mu_{z_1}} [g] \right), \dots, \text{MAJ}_t \left( \mathbb{E}_{\mu_{z_n}} [g], \dots, \mathbb{E}_{\mu_{z_n}} [g] \right) \right) \\ &= f(z'_1, z'_2, \dots, z'_n), \end{aligned}$$

where  $\|z - z'\|_\infty \leq \delta/n$  because  $t = \Theta_\varepsilon(\log n + \log(1/\delta))$  and Lemmas 18 and 17.

Therefore, for any  $z \in \{0, 1\}^n$ ,  $|f(z) - Lh(z)| = |f(z) - f(z')| \leq \delta$ , since  $\|z - z'\|_\infty \leq \delta/n$  and Lemma 12.  $\blacktriangleleft$

Since  $Lp_h$  is a  $(\delta + \varepsilon)$ -approximating polynomial for  $f$ , we also have  $\deg(Lp_h) \geq \widetilde{\deg}_{\delta+\varepsilon}(f)$ . We therefore have the following inequalities

$$\widetilde{\deg}_{\delta+\varepsilon}(f) \leq \deg(Lp_h) \leq \frac{\deg(p_h)}{\widetilde{\deg}_{\frac{1-\varepsilon}{2}}(g)}.$$

Rewriting we have

$$\widetilde{\deg}_\varepsilon(f \circ \text{MAJ}_t \circ g) = \deg(p_h) \geq \widetilde{\deg}_{\delta+\varepsilon}(f) \cdot \widetilde{\deg}_{\frac{1-\varepsilon}{2}}(g). \quad (3.5)$$

This completes the proof of Lemma 3.  $\blacktriangleleft$

### 3.2 Proof of Theorem 2

We note an easy to observe fact about approximate degree of projections of functions.

► **Fact 3.6.** Let  $f: \{0, 1\}^n \rightarrow \{0, 1\}$  and  $g: \{0, 1\}^m \rightarrow \{0, 1\}$  be such that  $f \leq_{\text{proj}} g$ , i.e.,  $f$  is a projection of  $g$ . Then, for any  $\varepsilon \in (0, 1/2)$ ,  $\deg_\varepsilon(f) \leq \deg_\varepsilon(g)$ .

Consider the recursive-majority function  $\text{MAJ}_3^d$  given by the complete 3-ary tree of height  $d$  with internal nodes labeled by  $\text{MAJ}_3$  and the leaves are labeled by distinct variables. Fix  $d \geq C \log \log n$  for a large enough constant  $C$ .

First, observe that  $\text{MAJ}_3^d$  is *not* a symmetric function. Secondly, it doesn't have *full* approximate degree ([35]). And finally, its approximate degree is *not* equal to  $\Theta\left(\sqrt{\text{bs}(\text{MAJ}_3^d)}\right)$  (it follows from the fact that  $\text{bs}(\text{MAJ}_3^d)$  is linear with  $\widetilde{\deg}(\text{MAJ}_3^d)$ . See the full version [16] for a proof of  $\widetilde{\deg}(\text{MAJ}_3^d) = 2^d$ ). Thus, none of the previous works [39, 8, 15] imply that approximate degree composes when one of the (inner or outer) functions is recursive-majority  $\text{MAJ}_3^d$ .

**Proof of Theorem 2.** Let  $\text{MAJ}_3^d$  be the recursive-majority function obtained by the complete 3-ary tree of height  $d$  with internal nodes labeled by  $\text{MAJ}_3$  and the leaves are labeled by distinct variables. Let  $f: \{0, 1\}^n \rightarrow \{0, 1\}$  be an arbitrary function and consider the approximate degree of the composed function  $f \circ \text{MAJ}_t \circ \text{MAJ}_3^d$  where  $t = \Theta(\log n)$ .

$$\widetilde{\deg}(f \circ \text{MAJ}_t \circ \text{MAJ}_3^d) \leq \widetilde{\deg}(f \circ \text{MAJ}_3^{C \log t} \circ \text{MAJ}_3^d) = \widetilde{\deg}(f \circ \text{MAJ}_3^d \circ \text{MAJ}_3^{C \log t}) \quad (3.7)$$

$$= O(\widetilde{\deg}(f \circ \text{MAJ}_3^d) \cdot \widetilde{\deg}(\text{MAJ}_3^{C \log t})) \quad (3.8)$$

$$= O(\widetilde{\deg}(f \circ \text{MAJ}_3^d) \cdot \text{poly}(t)). \quad (3.9)$$

The first inequality in (3.7) follows from the fact that  $\text{MAJ}_t$  is a projection of  $\text{MAJ}_3^{C \log t}$  (Theorem 15) and Fact 3.6. Then (3.8) follows from Theorem 9.

On the other hand, from Lemma 3, for  $t = \Omega(\log n)$  we have

$$\widetilde{\deg}(f \circ \text{MAJ}_t \circ \text{MAJ}_3^d) = \Omega(\widetilde{\deg}(f) \cdot \widetilde{\deg}(\text{MAJ}_3^d)).$$

Combining with (3.9), we obtain the lower bound

$$\widetilde{\deg}(f \circ \text{MAJ}_3^d) = \Omega\left(\frac{\widetilde{\deg}(f) \cdot \widetilde{\deg}(\text{MAJ}_3^d)}{\text{polylog}(n)}\right).$$

A similar argument shows the following inequalities, where in the last two inequalities we use Theorem 16 instead of Theorem 15, for  $d = \Omega(\log n)$ ,

- $\widetilde{\deg}(\text{MAJ}_3^d \circ f) = \widetilde{\Omega}(\widetilde{\deg}(f) \cdot \widetilde{\deg}(\text{MAJ}_3^d))$ ,
- $\widetilde{\deg}(f \circ (\text{AND}_2 \circ \text{OR}_2)^d) = \widetilde{\Omega}(\widetilde{\deg}(f) \cdot \widetilde{\deg}((\text{AND}_2 \circ \text{OR}_2)^d))$ , and
- $\widetilde{\deg}((\text{AND}_2 \circ \text{OR}_2)^d \circ f) = \widetilde{\Omega}(\widetilde{\deg}(f) \cdot \widetilde{\deg}((\text{AND}_2 \circ \text{OR}_2)^d))$ . ◀

## 4 Composition theorem for recursive functions

In this section we prove our main theorem (Theorem 1). It shows that the approximate degree composes when either the inner function or the outer function is a recursive function. More formally,

► **Theorem 1.** *Let  $f: \{0, 1\}^n \rightarrow \{0, 1\}$  and  $g: \{0, 1\}^m \rightarrow \{0, 1\}$  be two Boolean functions and  $d \geq C \log n$  for a large enough constant  $C$ . Then,*

$$\widetilde{\deg}(f \circ g) = \Omega\left(\frac{\widetilde{\deg}(f) \widetilde{\deg}(g)}{\text{polylog}(n)}\right),$$

if either of the following conditions hold:

1.  $f = h^d$ , for any Boolean function  $h$ .
2.  $g = h^d$ , for any Boolean function  $h$  with constant arity and not equal to AND or OR.

The following cases of Theorem 1 follows from prior works:

1.  $f$  or  $g$  equals  $h^d$  for  $h \in \{\text{PARITY}, \neg\text{PARITY}\}$  [39].
2.  $f = h^d$  and  $h \in \{\text{AND}, \text{OR}\}$  [8].

Therefore, it remains to prove Theorem 1 when  $h \notin \{\text{PARITY}, \neg\text{PARITY}, \text{AND}, \text{OR}\}$ . A crucial technical insight that makes the proof work is that when  $h \notin \{\text{PARITY}, \neg\text{PARITY}, \text{AND}, \text{OR}\}$  then  $\text{AND}_2$  and  $\text{OR}_2$  are projections of  $h^3$ . We can thus simulate MAJ using a small power of  $h$ . Thereafter, Lemma 3 is used to conclude Theorem 1. We now work out the details. We first state the main technical lemma we need for Theorem 1 and then complete the proof of the theorem. Finally, we prove the technical lemma in Section 4.1.

► **Lemma 21.** *Let  $h: \{0, 1\}^t \rightarrow \{0, 1\}$  (where  $t \geq 2$ ) be a Boolean function which depends on all  $t$  variables and is not equal to PARITY/ $\neg$ PARITY/OR/AND. The function  $\text{AND}_2$  (and similarly  $\text{OR}_2$ ) can be obtained by setting all but two variables to constants in  $h^k$  for  $k \leq 3$ .*

We now present the proof of Theorem 1 using Lemma 21.

**Proof of Theorem 1.** Let  $h: \{0, 1\}^t \rightarrow \{0, 1\}$  be any Boolean function such that  $h \notin \{\text{PARITY}, \neg\text{PARITY}, \text{AND}, \text{OR}\}$ . We know from Lemma 3 that  $\widetilde{\deg}(f \circ \text{MAJ}_k \circ h^d) = \Omega(\widetilde{\deg}(f) \widetilde{\deg}(h^d))$  where  $k = \Theta(\log n)$ . Like in the proof of Theorem 2, we will simulate  $\text{MAJ}_k$  using  $h^\ell$  for sufficiently large  $\ell$ . From Lemma 21, it follows that  $(\text{AND}_2 \circ \text{OR}_2)^\ell$  is a projection of  $h^{6\ell}$ . Therefore, we obtain from Theorem 16 that  $\text{MAJ}_k$  is a projection of  $h^{C \log k}$  for some constant  $C > 0$ . We thus have the following sequence of inequalities,

$$\begin{aligned}
 \widetilde{\deg}(f \circ h^d) &\geq \widetilde{\deg}(f \circ \text{MAJ}_k \circ h^{(d-C \log k)}) \\
 &= \Omega(\widetilde{\deg}(f) \widetilde{\deg}(h^{(d-C \log k)})) \\
 &= \Omega\left(\frac{\widetilde{\deg}(f) \widetilde{\deg}(h^d)}{t^{C \log k}}\right) \\
 &= \Omega\left(\frac{\widetilde{\deg}(f) \widetilde{\deg}(h^d)}{\text{polylog}(n)}\right).
 \end{aligned}$$

Note that the last equality above uses the fact that  $t$  is a constant. When  $h^d$  is the outer function then we don't need  $t$  to be a constant, while the rest of the argument remains the same to give

$$\widetilde{\deg}(h^d \circ g) = \Omega\left(\frac{\widetilde{\deg}(h^d) \widetilde{\deg}(g)}{\text{polylog}(n)}\right). \quad \blacktriangleleft$$

This completes the proof of the main theorem. We now present a proof of Lemma 21.

#### 4.1 Proof of the main technical lemma (Lemma 21)

We proceed by proving an intermediate result (Lemma 22) before going to the proof of Lemma 21.

Suppose we are allowed to *modify* a Boolean function by two operations: negating some of its variables, and restricting some of the variables to constant values. Lemma 22 proves that almost every Boolean function can be modified to either an AND<sub>2</sub> or an OR<sub>2</sub> function. A restriction of the variables amounts to looking at a smaller hypercube translated to a new point, and negating a variable amounts to rotating the smaller hypercube. In other words, we want to show that there is a *shifted* AND<sub>2</sub> or OR<sub>2</sub> in the Boolean hypercube of  $h$  (see Figure 1 for an example).

This shifted AND<sub>2</sub>/OR<sub>2</sub> in the Boolean hypercube of a Boolean function can be concretely defined by the concept of a sensitive block. For a block of variables  $S \subseteq [n]$  and an input  $x \in \{0, 1\}^n$ , define  $x^{\oplus S} \in \{0, 1\}^n$  to be the input which flips exactly the variables in  $S$  at the input  $x$ . Given a Boolean function  $f : \{0, 1\}^n \rightarrow \{0, 1\}$ , a block  $S$  is called sensitive on  $x$  iff  $f(x) \neq f(x^{\oplus S})$ . A block  $S$  is called *minimal sensitive* for  $x$  at  $f$ , if no subset of  $S$  is sensitive for  $x$  at  $f$ .

Notice that a shifted AND<sub>2</sub>/OR<sub>2</sub> is a square with three vertices labelled 0 and one vertex labelled 1 or vice versa. This gives us a minimal sensitive block on the vertex opposite to the unique value. It can be easily verified that the converse is also true. So, we define a function to have a shifted AND<sub>2</sub>/OR<sub>2</sub> iff it has a minimal sensitive block of size 2.

We show below that almost all functions have a minimal sensitive block of size 2.

► **Lemma 22.** *Let  $h : \{0, 1\}^t \rightarrow \{0, 1\}$  (where  $t \geq 2$ ) be a Boolean function which depends on all  $t$  variables and is not equal to PARITY/ $\neg$ PARITY. Then, there exists an  $x \in \{0, 1\}^t$  such that  $h$  has a minimal sensitive block of size 2 on  $x$ .*

**Proof.** We will prove the result using induction on the variables. The statement can be easily verified for  $t = 2$ .

Define  $g_0$  (and  $g_1$ ) to be the restrictions of  $h$  by setting  $x_t = 0$  (and  $x_t = 1$ ) respectively. Let  $e_y$  be the edge  $((y, 0), (y, 1))$  in the Boolean hypercube, and  $S_t := \{e_y : y \in \{0, 1\}^{t-1}\}$ . Color an edge  $e_y$  red if  $g_0(y) = g_1(y)$ , and blue otherwise.

■ **Figure 1** A function on 3 bits with a shifted OR marked with red edges.

Notice that not all the edges in  $S_t$  can be red, otherwise  $h$  does not depend on  $x_t$ . Suppose all the edges in  $S_t$  are blue, i.e.  $g_1 = \neg g_0$  (in other words,  $h = g_0 \oplus x_t$ ). Since  $h$  depends on all variables, then  $g_0$  depends on all variables  $x_1, x_2, \dots, x_{t-1}$ . If  $g_0$  is PARITY/ $\neg$ PARITY, then  $h$  is also PARITY/ $\neg$ PARITY. Implying that  $g_0$  is dependent on all its variables and is not PARITY/ $\neg$ PARITY. By induction, there exists a minimal sensitive block of size 2 for  $g_0$  (and hence  $h$ ).

For the rest of the proof, we can assume that there exists both a red and a blue edge in  $S_t$ .

Let  $e_x$  be red and  $e_y$  be blue, this means that  $g_0(x) = g_1(x)$  but  $g_0(y) \neq g_1(y)$ . If  $x$  and  $y$  were at Hamming distance 1, then vertices  $(x, 0), (x, 1), (y, 0)$  and  $(y, 1)$  will give us the required minimal sensitive block of size 2.

If  $x, y$  are not at Hamming distance 1, look at any path from  $x$  to  $y$  in the  $t-1$  dimensional hypercube, say  $z_0 = x, z_1, z_2, \dots, z_l = y$ . The edge  $e_{z_0}$  is red and  $e_{z_l}$  is blue. Since the color needs to switch at some point, there exist  $z_i, z_{i+1}$  at Hamming distance 1 such that  $e_{z_i}$  is red and  $e_{z_{i+1}}$  is blue. Again, the vertices  $(z_i, 0), (z_i, 1), (z_{i+1}, 0)$  and  $(z_{i+1}, 1)$  will give us the required minimal sensitive block of size 2. ◀

We are prepared to prove Lemma 21 which shows: given a Boolean function  $h$ ,  $\text{AND}_2$  (and  $\text{OR}_2$ ) can be obtained by restricting some of the variables to constants in a very small power of  $h$ . Compared to Lemma 22, we need to remove negation and simulate both  $\text{AND}_2$  and  $\text{OR}_2$  and not just one of them.

We just show how to obtain  $\text{AND}_2$ , the case for  $\text{OR}_2$  is similar. We handle the case of  $h$  being monotone and non-monotone separately.

### Monotone $h$

This case is simpler, and  $\text{AND}_2$  can be obtained as a restriction of  $h$  itself. Let a minimal 1-input be a  $x \in \{0, 1\}^t$  such that setting any 1 bit of  $x$  to 0 changes the value of  $h$ . If there is a minimal 1-input  $x$  of Hamming weight more than 2, we get a  $\text{AND}_2$  by choosing any two indices which are 1 in  $x$ . The following claim finishes the proof for monotone functions.

▷ **Claim 23.** Let  $h : \{0, 1\}^t \rightarrow \{0, 1\}$  be a monotone Boolean function which depends on all variables. If there is no minimal 1-input with Hamming weight more than 2, then  $h$  is the OR function.

■ **Figure 2** An example for constructing  $\text{AND}_2$  using a non-monotone function. Let  $h : \{0,1\}^3 \rightarrow \{0,1\}$  be 0 at  $x = 001$  and 1 otherwise. Use the shifted  $\text{OR}_2$ /minimal sensitive block at 001 with indices  $\{2,3\}$ .

Proof. By abusing the notation, let 0 denote the all 0 input. Since the function is monotone but not constant, we know that  $h(0) = 0$ . Let  $S \subseteq [t]$  capture the indices such that the corresponding Hamming weight 1-input has function value 0,

$$S = \{i : h(0^{\oplus i}) = 0\}.$$

For a  $y \in \{0,1\}^t$ , if the set of 1-indices are not a subset of  $S$ , then  $h(y) = 1$  by monotonicity. If the set of 1-indices are a subset of  $S$ , then  $h(y) = 0$  because there is no minimal 1-input with Hamming weight more than 2.

In other words,  $h$  is the OR function on the remaining  $[t] \setminus S$  variables. Since  $h$  depends on all the  $t$  variables,  $h$  is the OR function.  $\triangleleft$

### Non-monotone $h$

Since  $h$  is a non-monotone function, there exists an input  $a \in \{0,1\}^t$  and an index  $i \in [t]$  such that  $h(a) = 1$ ,  $a_i = 0$  and  $h(a^{\oplus i}) = 0$ . Restricting the variables according to  $a$  (except the  $i$ -th bit) gives  $h_1(x_i) = \neg x_i$ .

From Lemma 22, there exists a  $b \in \{0,1\}^t$  such that  $h$  has a minimal sensitive block of size 2 on  $b$  (shifted  $\text{AND}_2/\text{OR}_2$ ). The main idea of this proof is to use negation and this shifted  $\text{AND}_2/\text{OR}_2$  (Figure 2 gives an example).

For the formal proof, without loss of generality assume that the block have indices 1, 2 (that means  $h(b) = h(b^{\oplus\{1\}}) = h(b^{\oplus\{2\}}) \neq h(b^{\oplus\{1,2\}})$ ). We will finish the proof by considering the two cases  $h(b) = 0$  and  $h(b) = 1$ .

- $h(b) = 0$  (shifted  $\text{AND}_2$ ): Suppose  $b_1 = 0$  and  $b_2 = 1$  (other cases can be handled similarly). Notice that  $\text{AND}_2(x, y) = h(x, \neg y, b_3, \dots, b_t)$ , giving us  $\text{AND}_2(x, y) = h(x, h_1(y), b_3, \dots, b_t)$ .
- $h(b) = 1$  (shifted  $\text{OR}_2$ ): Suppose  $b_1 = 1$  and  $b_2 = 0$  (other cases can be handled similarly). Notice that  $\text{OR}_2(x, y) = h(x, \neg y, b_3, \dots, b_t)$ ; using De Morgan's law,

$$\text{AND}_2(x, y) = \neg \text{OR}_2(\neg x, \neg y) = \neg h(\neg x, y, b_3, \dots, b_t) = h_1(h(h_1(x), y, b_3, \dots, b_t))$$

Since  $h_1$  is also a restriction of  $h$ , the proof is complete.

## 5 Conclusion

Towards the main open problem of approximate degree composition, we have the following immediate question in light of Lemma 3. Can we upper bound  $\text{deg}(f \circ \text{MAJ}_t \circ g)$  in terms of  $\widetilde{\text{deg}}(f \circ g)$ ? Precisely,

► **Open question 24.** *Is  $\widetilde{\text{deg}}(f \circ \text{MAJ}_t \circ g) = \widetilde{O}(\widetilde{\text{deg}}(f \circ g))$ , where  $t = \Theta(\log n)$  and  $n$  is the arity of the outer function  $f$ ?*

Observe that an affirmative solution to the above question solves the composition question for approximate degree in positive. Another interesting question is to find other classes of functions for which the analogue of Equation 1.2 holds.

► **Open question 25.** *Find non-trivial classes of functions  $H$  such that  $\widetilde{\text{deg}}(f \circ h \circ g) = \widetilde{\Omega}(\text{deg}(f) \cdot \text{deg}(h) \cdot \text{deg}(g))$  for all  $h \in H$ ?*

It has the following two useful implications. First, this gives composition for functions  $h \in H$ . In particular, when one of the functions  $h$  (inner or outer) belongs to the class  $H$  then  $\widetilde{\text{deg}}(f \circ h \circ g) = \widetilde{\Omega}(\text{deg}(f) \cdot \text{deg}(h) \cdot \text{deg}(g))$  along with Theorem 9 implies

$$\widetilde{\text{deg}}(h \circ g) = \widetilde{\Omega}(\widetilde{\text{deg}}(h) \cdot \widetilde{\text{deg}}(g)) \quad \text{and} \quad \widetilde{\text{deg}}(f \circ h) = \widetilde{\Omega}(\widetilde{\text{deg}}(f) \cdot \widetilde{\text{deg}}(h)).$$

Second, a function  $h \in H$  can be used as “hardness amplifier” functions.

Another very interesting question that may provide us insights to make progress towards the main question of approximate degree composition is to prove that approximate degree composes when the inner function is  $\text{OR}$ .

► **Open question 26.** *Show that  $\widetilde{\text{deg}}(f \circ \text{OR}) = \widetilde{\Omega}(\widetilde{\text{deg}}(f) \cdot \widetilde{\text{deg}}(\text{OR}))$ .*

# Public Coin Interactive Proofs for Label-Invariant Distribution Properties

Tal Herman  

Weizmann Institute of Science, Rehovot, Israel

---

## Abstract

Assume we are given sample access to an unknown distribution  $D$  over a large domain  $[N]$ . An emerging line of work has demonstrated that many basic quantities relating to the distribution, such as its distance from uniform and its Shannon entropy, despite being hard to approximate through the samples only, can be *efficiently and verifiably* approximated through interaction with an untrusted powerful prover, that *knows* the entire distribution [Herman and Rothblum, STOC 2022, FOCS 2023]. Concretely, these works provide an efficient proof system for approximation of any label-invariant distribution quantity (i.e. any function over the distribution that's invariant to a re-labeling of the domain  $[N]$ ).

In our main result, we present the first efficient *public coin* AM protocol, for any label-invariant property. Our protocol achieves sample complexity and communication complexity of magnitude  $\tilde{O}(N^{2/3})$ , while the proof can be generated in quasi-linear  $\tilde{O}(N)$  time.

On top of that, we also give a public-coin protocol for efficiently verifying the distance a between a samplable distribution  $D$ , and some explicitly given distribution  $Q$ .

## 1 Introduction

Given sample access to a distribution, what can we learn about the distribution, and what is the complexity of learning? These questions are central to computer science and statistics and have guided a rich body of work with applications ranging many fields. An emerging line of work asks the following question:

What is the complexity of *verifying* claims about a samplable distribution?

That is, suppose there exists a powerful yet untrusted prover that claims to have drawn many samples from a distribution  $D$ , and concluded that it satisfies some condition, e.g. its support is of size at most  $K$ , its Shannon entropy is  $h$ , etc. Can a verifier interacting with the prover be convinced that the claim is (approximately) correct, while taking fewer samples and running in less time than required to compute these measures directly from samples?

This question was raised by Chiesa and Gur [5], and recently Herman and Rothblum [14] showed that a rich family of distribution properties, namely *label-invariant* distribution properties - those distribution measures that remain unchanged after permuting the domain (such as the distribution's support size and Shannon entropy) - have (*doubly*) efficient proof systems, that for natural problems, allow verification that is significantly faster than computation from samples only. These protocols are *private-coin* protocols, in which the

verifier can draw samples from  $D$ , toss random coins, and choose whether to send them to the prover, or keep them hidden from it. Indeed, the protocols in [14] rely heavily on the fact that the verifier *hides* its random coin-tosses in order to perform the verification. In this work we explore *public-coin* protocols for verifying distribution properties, in which the verifier reveals to the prover every coin it tosses immediately upon drawing it. We construct efficient *public-coin* proof systems for label-invariant distribution properties, and more.

More concretely, we follow the definition of *public-coin* proof systems for distribution properties from Chiesa and Gur [5], in which the verifier can only send random coin tosses to the prover, and the samples they draw from  $D$  are independent from the transcript of the protocol, and are drawn only after the communication phase.

Our work studies the power of public-coin proof systems in the context of verifying properties of an unknown samplable distribution. We find this to be a foundational question: indeed, the power of public-coin proof systems has been a central question since they were first introduced [10, 2]. In the classical setting (verifying the membership of a fixed and known input in a language), Goldwasser and Sipser [11] showed how to convert general protocols into public-coin ones (albeit their transformation does not preserve the honest prover’s running time [19, 1]). In our context, where the verifier only has sampling access to the unknown distribution, no such general transformation is known. Chiesa and Gur showed upper and lower bounds for public-coin interactive proofs for distribution properties. Beyond the foundational importance of public-coin protocols, they are also important for removing interaction using the Fiat-Shamir paradigm [7] and for transforming general protocol into zero-knowledge ones [9, 4]

### 1.1 This Work: Public-coin Protocols for Label-Invariant Distribution Properties

Our main result is a new *public-coin* protocol for label-invariant distribution properties. We proceed to present this result, and put it into context with the private-coin setting of [14], and the other public-coin distribution verification protocols of [5].

A distribution property  $\mathcal{P} = (\mathcal{P}_N)_{N \in \mathbb{N}}$  is an ensemble such that  $\mathcal{P}_N$  is a set of distributions over domain  $[N]$ . We consider the distance of a distribution  $D$  over domain  $[N]$  from the property by the *total variation* of  $D$  from the closest distribution to it in  $\mathcal{P}_N$ . A distribution property is said to be *label-invariant* if permuting the domain doesn’t change  $\mathcal{P}$ . This family of distribution properties contains many natural properties, such as the property of being close to uniform over some subset of the domain, or having Shannon entropy roughly  $k$ .

► **Theorem 1** (Main result: public-coin IPs for label-invariant properties, informal). *For every label-invariant distribution property  $\mathcal{P}$  with a doubly-efficient approximate decision procedure,<sup>1</sup> there exists a 2-message public-coin interactive protocol as follows. The prover and the verifier both get as input an integer  $N$  and proximity parameters  $\varepsilon_c, \varepsilon_f \in [0, 1]$  where  $\varepsilon_c < \varepsilon_f$ , as well as sampling access to an unknown distribution  $D$  over support  $[N]$ , and the following properties hold:*

---

<sup>1</sup> See Definition 28. In a nutshell, these are label-invariant properties that can be efficiently decided from the  $\tau$ -approximate bucket-histogram of the distribution, i.e. by only knowing how many elements have probability roughly  $\frac{(1+\tau)^j}{N}$  for all  $j$ , see Definition 5. [13] showed that this assumption is quite mild, and many natural distribution properties admit such a procedure, the reader is referred to [13] for a deeper exploration of this notion.

- *Completeness:* if  $D$  is  $\varepsilon_c$ -close to the property (its total variation distance from the closest distribution in the property is at most  $\varepsilon_c$ ), and the prover follows the protocol, then w.h.p. the verifier accepts.
- *Soundness:* if  $D$  is  $\varepsilon_f$ -far from the property (its total variation distance from every distribution in the property is at least  $\varepsilon_f$ ), then w.h.p. no matter how the prover cheats, the verifier rejects.
- *Doubly-efficient prover:* Taking  $\rho = \varepsilon_f - \varepsilon_c$ , the honest prover's runtime and sample complexity are  $\tilde{O}(N) \cdot \text{poly}(1/\rho)$ .
- *Efficient verification:* the communication complexity and the verifier's sample complexity and runtime are all  $\tilde{O}(N^{2/3}) \cdot \text{poly}(1/\rho)$ .

### Public-coin verification vs. testing of label-invariant distribution properties

Observe that the protocol above allows us to efficiently approximate the distance of  $D$  from  $\mathcal{P}$ , by running a binary search with different values for  $\varepsilon_c, \varepsilon_f$ . Raskhodnikova et al. [17], and Valiant and Valiant [20] showed that approximating the distance between  $D$  and natural label-invariant distribution properties, given only black-box sample access to the distribution, requires  $\Theta(N/\log N)$  samples. This includes approximating the distance from being uniform over the entire domain, from having entropy  $k$ , and more. Thus, our result demonstrates that public-coin verification can be more efficient than stand-alone computation with no access to a prover for these natural distribution problems.

### Comparison with the secret-coin setting of Herman and Rothblum [14]

Herman and Rothblum provided a *secret-coin* interactive proof for verifying membership in any label-invariant distribution property (that admits an efficient approximate decision procedure) with verifier sample complexity, runtime, communication complexity of magnitude  $\tilde{O}(\sqrt{N})$ , and only two messages. The first message in their protocol contains a tuple of elements in  $[N]$ , where each element was sampled with probability  $\frac{1}{2}$  from the distribution  $D$ , and with probability  $\frac{1}{2}$  was drawn uniformly from  $[N]$ . Crucially for their argument, the verifier doesn't share with the prover which samples were drawn according to which distribution, and later capitalizes on that fact to reject dishonest prover behavior.

In our public-coin protocol not only is the verifier required to share the random coin tosses, it also cannot send samples from  $D$  as part of the communication. Thus, Theorem 4 achieves a similar result qualitatively to theirs, but using only public coins, at the cost of more samples and communication.

### Comparison with Chiesa and Gur [5]

Chiesa and Gur provided *public-coin* protocols for any property with communication  $c = \tilde{O}(N)$ , and verifier sample complexity  $s = O(\sqrt{N})$ , by having the prover send an explicit description of the distribution, and the verifier use an *identity tester* from the distribution testing literature to check that the description matches the samplable distribution. Then, the verifier accepts if  $D$  is both close to the explicit distribution provided, and if this description is of a distribution inside the property. Moreover they also proved that for a distribution property that requires  $\Omega(t)$  samples to test, any *public-coin* proof system for this property must satisfy  $s \cdot c = \Omega(t)$ . As mentioned above, verifying the distance from uniformity or approximating the entropy of a distribution requires  $\tilde{\Omega}(N)$  samples, and so, every *AM* protocol that verifies this property must also satisfy  $s \cdot c = \tilde{\Omega}(N)$ . Our protocol for this problem achieves  $c \cdot s = \tilde{O}(N^{4/3})$ , and the question of whether there exists a more efficient *public-coin* proof system for this problem remains open.

**Obtaining approximate tags of elements in  $[N]$** 

The method through which our protocol allows the verifier to verify *any* label invariant distribution property is by having the verifier uniformly draw elements from  $[N]$ , and verifiably obtain an approximation of the probability of each element according to  $D$ , that is correct on average (we call this a *uniformly drawn approximate tagged sample*). Formally, for some accuracy parameter  $\sigma \in (0, 1)$ , and a tuple  $(z_i) \in [N]^s$ , we define:

► **Definition 2** ( $\sigma$ -approximate tags for  $(z_i)$  with respect to  $D$ ).  $\sigma$ -approximate tags for  $(z_i)$  with respect to  $D$  is a tuple  $(\pi_i)_{i \in [s]} \in [0, 1]^s$  that satisfies the following inequality:

$$\frac{1}{s} \sum_{i \in [s]} \left( 1 - \min \left\{ \frac{D(z_i)}{\pi_i}, \frac{\pi_i}{D(z_i)} \right\} \right) \leq \sigma \quad (1)$$

In other words, on *average*,  $\pi_i \in [1 \pm \sigma]D(z_i)$ . A uniformly drawn approximate tagged sample allows to approximate the probability histogram of a distribution, as explained in the following sections. Note that in [13] and [14] the authors obtain an approximate tagged sample drawn according to  $D$ , rather than from a uniformly drawn sample, and use it to approximate the probability histogram of  $D$ . Thus, upon obtaining the probability histogram, our approaches converge, and we follow these works to bridge the gap between obtaining a probability histogram of a distribution and the estimation of distance from a label-invariant property. Note that the main difficulty is obtaining the tagged sample, a task that without communication would've required  $\tilde{\Omega}(N)$  samples, and so, this paper will focus on this point.

Moreover, [13, 14] not only contain secret coins, but also rely on the fact that the verifier can send samples from  $D$  to the prover. In this work, we allow the verifier to only send random coins, not even samples from  $D$ . This choice is justified in Chiesa and Gur [5], and allows our protocol to utilize properties of public-coin protocols over other objects with different access models.

We also show that a uniformly drawn approximate tagged-sample can also be used to verify distribution properties that are *not* label-invariant. Specifically, we also show that for the well-studied problem of approximating the distance of  $D$  from an explicit distribution  $Q$ , an approximate tagged uniform sample is sufficient:

► **Theorem 3** (Tolerant Verification of Identity). *Given an explicit description of distribution  $Q$  over  $[N]$ , parameters  $0 < \varepsilon_c < \varepsilon_f <$ , and sample access to distribution  $D$  over domain  $[N]$ , there exists a 2-message public-coin protocol, with verifier sample complexity and communication complexity  $\tilde{O}(N^{2/3}) \cdot \text{poly}(\frac{1}{\varepsilon_f - \varepsilon_c})$  such that:*

- *If  $\Delta_{SD}(D, Q) \leq \varepsilon_c$ , the verifier accepts with high probability.*
- *If  $\Delta_{SD}(D, Q) \geq \varepsilon_f$ , the verifier rejects with high probability.*

**1.2 Further Related Works**

Interactive proof systems were introduced in the seminal work of Goldwasser, Micali and Rackoff [10] in the context of proving computational statements about an input that is fully known to the prover and the verifier. In our work, the distribution can be thought of as the input, but it is not fully known to the verifier, and is accessed implicitly through samples. We aim for verification without examining the distribution in its entirety, using minimal resources (samples, communication, runtime, etc.).

Our work builds on a line of work that studied the power of sublinear time verifiers, who cannot read the entire input [6, 18, 12], on verifying properties of distributions using a small number of samples [5, 13, 14], and the rich literature of distribution testing, of which

most notably, we extensively use the ideas of Batu and Canonne in [3], as explained in the technical overview. We also note that Herman and Rothblum [15] recently showed that a very rich family of distribution properties, those that can be decided by a *small* circuit from an explicit description of the distribution, can be doubly-efficiently verified with a *secret-coin* protocol.

## 2 Technical Overview

As discussed in the introduction above, the protocol behind Theorem 1 is based on obtaining verified  $\Theta(\rho)$ -approximate tags with respect to  $D$  for a sample uniformly drawn from  $[N]$ . In this section, we describe the public-coin protocol for obtaining this object. We then detail how this tagged sample can be leveraged to verify membership in label-invariant distribution properties.

► **Theorem 4 (Informal).** *There exists a 2-message public-coin interactive protocol between a verifier and a (potentially malicious) prover, where the verifier receives as input parameters  $\sigma \in (0, 0.1)$  and  $N \in \mathbb{N}$ , as well as sample access to a distribution  $D$  over domain  $[N]$ . The communication complexity, verifier sample complexity, and verifier runtime are all  $s = \tilde{O}(N^{2/3}) \text{poly}(\sigma^{-1})$ , the honest prover with the same input as the verifier has sample complexity and runtime  $\tilde{O}(N) \text{poly}(\sigma^{-1})$ . At the end of the interaction, the verifier rejects or outputs  $(S_i) \in [N]^s$  that is drawn uniformly from  $[N]$ , and  $(\pi_i) \in [0, 1]^s$  such that:*

- *If the prover is honest, for all  $i \in [s]$ ,  $\pi_i = D(S_i)$ , and with probability at least 0.75, the verifier doesn't reject.*
- *Whatever strategy a dishonest prover follows, with probability at most 0.25 over the verifier's coin tosses and samples, the verifier accepts and outputs  $(\pi_i)$  such that doesn't satisfy Inequality (1).*

We outline the protocol behind Theorem 4. We highlight that some details are swept under the rug for sake of simplicity. In particular, we assume that  $D(x) \leq \frac{1}{s}$  for all  $x \in [N]$ . After we present the protocol under this assumption, we discuss how to remove this assumption.

### The communication phase

The verifier draws an i.i.d. sample  $S = (S_i)$  of size  $s = \tilde{O}(N^{2/3}) \cdot \text{poly}(\sigma^{-1})$  uniformly from  $[N]$ , and sends the sample to the prover. For each sample  $S_i$  received, the prover replies with  $\pi_i$  such that  $\pi_i = D(S_i)$ . Note that with high probability, due to the choice of  $s$ , there doesn't exist an element in  $x \in [N]$  that was sampled more than 3 times,<sup>2</sup> and in general, the fraction of elements that were sampled twice or three times is very small with respect to  $s$ . Therefore, for sake of simplicity, assume that  $S$  contains only unique elements.

Moreover, since we assumed  $D(x) \leq \frac{1}{s}$  for all  $x \in [N]$ , by choice of  $s$ , the sample  $S$  contains with overwhelming probability *many* samples uniformly distributed inside  $\text{Supp}(D)$ .

### Verifying the prover's message

The verifier divides the samples in  $S$  into *buckets* according to their alleged probability, where inside each bucket all the samples are claimed to have roughly the same mass. Concretely, for  $\tau = O(\sigma^3)$ , and for every  $j$ , denote by  $B_j^S \subseteq [s]$  the collection of indices in  $S$  that the

<sup>2</sup> The probability that 4 samples collide is  $\sum_{x \in [N]} D(x)^4 = \frac{1}{N^3}$  while there are only  $\binom{s}{4} = O(N^{8/3})$  possible 4-tuples in the sample  $S$ .

prover claimed have probability in the range  $\left[\frac{(1+\tau)^j}{N}, \frac{(1+\tau)^{j+1}}{N}\right]$ . The verifier then tests for every such  $j$  that the *average probability* of the elements in  $B_j^S$  is indeed roughly  $\frac{(1+\tau)^j}{N}$ , and that  $D|_{B_j^S}$  is *close to uniform*:

- **Checking that the average mass is correct.** The verifier draws a fresh sample  $T$ , and checks that the empirical mass of  $B_j^S$  in  $T$  is roughly  $s \cdot |B_j^S| \cdot \frac{(1+\tau)^j}{N}$ , and rejects otherwise. Observe that for any distribution  $D$ , the true mass of  $B_j^S$  is  $\sum_{k \in B_j^S} D(S_k)$ . And so, by choice of  $s$ , since the empirical mass of  $B_j^S$  in  $T$  is strongly concentrated around its mean, if the test passes, then with high probability:

$$s \cdot \sum_{k \in B_j^S} D(x) \stackrel{\tau}{\approx} s \cdot |B_j^S| \cdot \frac{(1+\tau)^j}{N}$$

Where for  $\alpha \in (0, 1)$  we use the notation  $a \stackrel{\alpha}{\approx} b$  to indicate that  $a \in (1 \pm \alpha)b$ . We conclude that with high probability:

$$\mathbb{E}_{k \sim_{uni} B_j^S} [D(S_k)] \stackrel{O(\tau)}{\approx} \frac{(1+\tau)^j}{N} \quad (2)$$

- **Verifying that  $D|_{B_j^S}$  is close to uniform.** The verifier draws another fresh  $D$ -sample  $T'$  of size  $s$ , and counts how many *3-way collisions* occur between elements in  $B_j^S$  and the two samples  $T, T'$ , i.e. the number of 3-tuples  $(k, r, r') \in [s]^3$  satisfy  $k \in B_j^S$ ,  $S_k = T_r = T'_{r'}$ . If this quantity is far from  $s^2 \cdot |B_j^S| \cdot \left(\frac{(1+\tau)^j}{N}\right)^2$ , the verifier rejects. Similar to before, for any fixed pair of entries in  $T, T'$ ,  $(r, r') \in [s]^2$ , the true expected number of  $k \in B_j^S$  for which  $S_k = T_r = T'_{r'}$  is  $\sum_{k \in B_j^S} (D(S_k))^2$ . The total expected number of such 3-tuples is  $s^2 \cdot \sum_{k \in B_j^S} (D(S_k))^2$ . This quantity is also strongly concentrated around its mean by choice of  $s = \Theta(N^{2/3})\text{poly}(\sigma^{-1})$ . We conclude that if this test passed, then with high probability:

$$s^2 \cdot \sum_{k \in B_j^S} (D(S_k))^2 \stackrel{O(\tau)}{\approx} s^2 |B_j^S| \cdot \left(\frac{(1+\tau)^j}{N}\right)^2$$

And equivalently:

$$\mathbb{E}_{k \sim_{uni} B_j^S} [(D(S_k))^2] \stackrel{O(\tau)}{\approx} \left(\frac{(1+\tau)^j}{N}\right)^2 \quad (3)$$

We are thus left to argue that Equations (2) and (3) imply that  $D|_{B_j^S}$  is close to uniform. Following Batu and Canonne [3], observe that:

$$\text{Var}_{k \sim_{uni} B_j^S} [D(S_k)] = \mathbb{E}_{k \sim_{uni} B_j^S} [(D(S_k))^2] - \left(\mathbb{E}_{k \sim_{uni} B_j^S} [D(S_k)]\right)^2$$

And so, assuming Equations (2) and (3) hold, we get that  $\text{Var}_{k \sim_{uni} B_j^S} [D(S_k)] = O(\tau) (\mathbb{E}[D(x)])^2$ . Using Chebychev's Inequality:

$$\Pr_{k \sim_{uni} B_j^S} \left( \left| D(S_k) - \mathbb{E}_{k \sim_{uni} B_j^S} [D(S_k)] \right| \geq O\left(\sqrt{\frac{\tau}{\sigma}}\right) \cdot \mathbb{E}_{k \sim_{uni} B_j^S} [D(S_k)] \right) \leq O(\sigma) \quad (4)$$

From which we conclude all but  $\sigma$ -fraction of entries  $i \in B_j^S$  satisfy:

$$\pi_i \stackrel{O(\tau)}{\approx} \frac{(1+\tau)^j}{N} \stackrel{O(\tau)}{\approx} \mathbb{E}_{k \sim^{uni} B_j^S} [D(S_k)] \stackrel{O(\sqrt{\tau/\sigma})}{\approx} D(S_i)$$

Where the first inequality stems from the definition of  $B_j^S$ , the second from Equation (2), and the last from Inequality (4). Plugging in  $\tau = O(\sigma^3)$ , we get:  $\pi_i \stackrel{O(\sigma)}{\approx} D(S_i)$ .

We thus showed that if both verifier tests pass, then with high probability over the randomness of the verifier, it holds that for every  $j$ , the tags over  $B_j^S$  are  $\sigma$ -approximately correct, from which Inequality (1) is inferred.

### Assuming $D$ contains no heavy elements

Observe that the probability of all elements with probability larger than  $1/s$  can be well-approximated through their empirical mass in a sample of size  $\tilde{\Theta}(s)$  from  $D$ . Therefore, we can think of a verifier that estimates without need of a prover the mass of all such elements. This process is described in detail in [13], and we describe it shortly here. The reader is referred to their work for further detail. After receiving the prover's tags, the verifier performs the following step: the verifier draws a fresh  $D$ -sample, denoted  $\mathcal{H}$ , of size  $\tilde{O}(s)\text{poly}(\sigma^{-1})$  from  $D$ . With high probability, by a *coupon-collector* argument, this set contains all elements with probability at least  $\frac{1}{s}$  (if any exist).

The verifier tests the mass of  $\mathcal{H}$  by drawing a fresh sample and examining the empirical mass of  $\mathcal{H}$  in that new sample. If it is significant, i.e.  $\Omega(\sigma)$ , the verifier “learns”  $D|_{\mathcal{H}}$  up to  $\sigma$  distance by subsampling from this distribution and running a *folklore distribution learner* (see Theorem 4). This requires  $\tilde{O}(s)\text{poly}(\sigma^{-1})$  samples from  $D$ , and thus doesn't incur significant overhead to the sample complexity of the protocol. Thus, the verifier obtains an explicit description of the distribution  $P_{\mathcal{H}}$ , which is  $O(\sigma)$ -close to  $D|_{\mathcal{H}}$ . Since  $\mathcal{H}$  is a set of size at most  $s$ , and the sample  $S$  was drawn drawn i.i.d. from  $[N]$ , with overwhelming probability it holds that  $|S \cap \mathcal{H}| = O(N^{1/3}) = o(s)$ , and in order to verify the prover's answer's in the protocol described above, the verifier can just “erase” every element in  $S$  that appeared in  $\mathcal{H}$ , and run the protocol presented above over just elements guaranteed with high probability to be of probability at most  $1/s$ , without affecting the correctness of the protocol. Thus, the verifier obtains full tags for  $\mathcal{H}$ , and tags for  $S \setminus \mathcal{H}$ . Later, the verifier can “fill-in” the missing parts in  $S$  to obtain a full tagged sample. If  $D$  is entirely supported over heavy elements, then the protocol can be avoided all together by also checking the mass of  $\mathcal{H}$  is larger than  $1 - O(\sigma)$ , and ignoring the prover's message.

### Verifying label-invariant distribution properties

In order to verify *label-invariant* distribution properties, it suffices to know the *probability histogram* of the distribution, i.e., how many elements have probability  $p$  for every  $p \in [0, 1]$ . Herman and Rothblum [13] observed that for many natural properties an approximation of this histogram is sufficient, and define the  $\tau$ -bucket histogram as follows:

► **Definition 5** ( $\tau$ -bucket histogram of  $D$ ). For any  $j \in \{\dots, -1, 0, 1, \dots, \frac{\log N}{\tau}\}$ , the  $j$ 'th bucket of  $D$  over domain  $[N]$  is:

$$B_j^D = \left\{ x \in \text{Supp}(D) : D(x) \in \left[ \frac{(1+\tau)^j}{N}, \frac{(1+\tau)^{j+1}}{N} \right) \right\}$$

The  $\tau$ -bucket histogram of  $D$  is the tuple  $((j, D(B_j^D)))_{j: B_j^D \neq \emptyset}$ .

In [13] the authors focus their attention on those label-invariant distribution properties for which the information  $((j, D(B_j^D)))_{j: B_j^D \neq \emptyset}$  is sufficient in order to efficiently approximate the *distance* (in total-variation) of  $D$  from the property. They say that such properties admit an *efficient approximate decision procedure*, and show that many natural label-invariant problems are of this type, including the property of having Shannon entropy roughly  $k$ , or being close to uniform over some set of size  $M \leq N$ .

In our protocol the verifier obtains a uniformly drawn tagged sample<sup>3</sup>. We argue that this tagged sample allows the verifier to compute an approximation of the bucket histogram of  $D$ : if our protocol didn't end in rejection, then with high probability, the tags are roughly correct. In other words, for every  $j$ ,  $\frac{|B_j^S|}{s}$  is the empirical mass of  $B_j^D$  in the uniform sample  $S$ . Since we expect there to be about  $\frac{|B_j^D|}{N}$ -fraction of samples in  $S$  that landed in  $B_j^D$ , we conclude that:

$$\frac{|B_j^S|}{s} \approx \frac{|B_j^D|}{N}$$

And since  $D(B_j^D) \approx |B_j^D| \cdot \frac{(1+\tau)^j}{N}$ , if we set  $p_j = \left(\frac{|B_j^S|}{s} \cdot N\right) \cdot \frac{(1+\tau)^j}{N}$ , then  $D(B_j^D) \approx p_j$ , and we get with high probability, a  $\tau$ -histogram which is  $O(\sigma)$  close to the true histogram of  $D$  in the following sense: there exists a distribution  $D'$  with histogram exactly  $((j, p_j))$  that is  $O(\sigma)$ -close to  $D$  in total variation distance. Thus, using the decision procedure, the verifier decides whether  $((j, p_j))$  is consistent with some distribution close to  $\mathcal{P}$ , and thus, conclude whether  $D$  is far from the property, or close to it.

### 3 Preliminaries

For an integer  $n \in \mathbb{N}$ , we use  $[n]$  to denote the set  $\{1, \dots, n\}$ .

► **Definition 6.** *The total variation distance (alt. statistical distance) between distributions  $P$  and  $Q$  over a finite domain  $X$  is defined as:*

$$\Delta_{SD}(P, Q) = \frac{1}{2} \sum_{x \in X} |P(x) - Q(x)|$$

► **Theorem 7** (Folklore distribution learner [8]). *There exists an algorithm that given sample access to a distribution  $P$  over the domain  $[N]$ , and an accuracy parameter  $\alpha \in (0, 1)$ , it runs in time  $\tilde{O}(N/\alpha^2)$ , takes  $O(N/\alpha^2)$  samples, and with probability at least 0.99 outputs a full description of a distribution  $P_{approx}$  such that  $\Delta_{SD}(P, P_{approx}) \leq \alpha$ .*

► **Definition 8** (Distribution property). *We say the  $\mathcal{P} = (\mathcal{P}_N)_{N \in \mathbb{N}}$  is a distribution property if  $\mathcal{P}_N \subseteq \Delta_N$ , where  $\Delta_N$  is the set of all distributions over domain  $[N]$ .*

► **Definition 9** (Distribution tester for property  $\mathcal{P}$ ). *Let  $\mathcal{P}$  be a distribution property. A tester  $T$  of property  $\mathcal{P}$  is a probabilistic oracle machine, that on input parameters  $N$  and  $\varepsilon$ , and oracle access to a sampling device for a distribution  $D$  over a domain of size  $[N]$ , outputs a binary verdict that satisfies the following two conditions:*

1. *If  $D \in \mathcal{P}_N$ , then  $\Pr(T^D(N, \varepsilon) = 1) \geq 2/3$ .*
2. *If  $\Delta_{SD}(D, \mathcal{P}_N) > \varepsilon$ , then  $\Pr(T^D(N, \varepsilon) = 0) \geq 2/3$ .*

<sup>3</sup> Here we differ from [13] that obtain a  $D$ -sampled tagged sample, i.e.  $(z_i)$  in their case was drawn from  $D$ .

In the context of this work, the relevant distance measure is *statistical distance* as defined above. An extension of this definition, introduced by Parnas, Ron, and Rubinfeld [16] is the following:

► **Definition 10** ( $(\varepsilon_c, \varepsilon_f)$ -tolerant distribution property tester). *For parameters  $\varepsilon_c, \varepsilon_f \in [0, 1]$  such that  $\varepsilon_c < \varepsilon_f$ , a  $(\varepsilon_c, \varepsilon_f)$ -tolerant tester  $T$  of property  $\Pi$  is a probabilistic oracle machine, that on inputs  $N, \varepsilon_c, \varepsilon_f$  and given oracle access to a sampling device for distribution  $D$  over a domain of size  $N$ , outputs a binary verdict that satisfies the following two conditions:*

1. *If  $\delta(D, \Pi_N) \leq \varepsilon_c$ , then  $\Pr(T^D(N, \varepsilon_c, \varepsilon_f) = 1) \geq 2/3$ .*
2. *If  $\delta(D, \Pi_N) \geq \varepsilon_f$ , then  $\Pr(T^D(N, \varepsilon_c, \varepsilon_f) = 0) \geq 2/3$ .*

Note that a tolerant distribution test is for some property  $\Pi$  is at least as hard as a standard non-tolerant tester for the same property.

► **Definition 11** (Proof system for tolerant distribution testing problems). *A proof system for a tolerant distribution testing problem  $\mathcal{P}$  with parameters  $\varepsilon_c$  and  $\varepsilon_f$  is a two-party game, between a verifier executing a probabilistic polynomial time strategy  $V$ , and a prover that executes a strategy  $P$ . Given that both  $V$  and  $P$  have black-box sample access to distribution  $D$  over the domain  $[N]$ , and are given  $N$ , the interaction should satisfy the following conditions:*

- **Completeness:** *For every  $D$  over domain of size at most  $N$ , such that  $\Delta_{SD}(D, \mathcal{P}_N) \leq \varepsilon_c$ , the verifier  $V$ , after interacting with the prover  $P$ , accepts with probability at least  $2/3$ .*
- **Soundness:** *For every  $D$  over domain of size at most  $N$  such that  $\Delta_{SD}(D, \mathcal{P}_N) \geq \varepsilon_f$ , and every cheating strategy  $P^*$ , the verifier  $V$ , after interacting with the prover  $P^*$ , rejects with probability at least  $2/3$ .*

The complexity measures associated with the protocol are: the sample complexity of the verifier as the honest prover (strategy  $P$ ), the communication complexity, the runtime of both agents, and the round complexity (how many messages were exchanged).

► **Definition 12** (Label invariant distribution property). *A distribution property  $\mathcal{P}$  is called label invariant if for all  $N \in \mathbb{N}$ , it holds that any permutation  $\sigma$  over  $N$  elements satisfies that  $D \in \mathcal{P}_N$  if and only if  $\sigma(D) \in \mathcal{P}_N$ .*

## 4 Public Coin Protocol for Verified Tagged Sample

Using the same approach as Herman and Rothblum [13], we provide an algorithm to obtain a *tagged sample* assuming that the samplable distribution  $D$  satisfies that for every  $x \in [N]$ ,  $D(x) \leq \frac{1}{s}$ , where  $s = O\left(\frac{\log N}{\varepsilon^5} \cdot N^{2/3}\right)$ . In Section 2 we discuss why we can assume this without loss of generality.

► **Theorem 13.** *There exists 2-message AM interactive protocol between an honest verifier and a (potentially malicious) prover, where the verifier receives as input parameters  $\sigma \in (0, 0.1)$  and  $100 < N \in \mathbb{N}$ , as well as sample access to a distribution  $D$  over domain  $[N]$ . Set  $\tau = \frac{\sigma^3}{8000}$ . Assume  $D(x) \leq \frac{1}{s}$  for  $s = O\left(\frac{\log N}{\varepsilon^5} \cdot N^{2/3}\right)$ . The communication complexity, verifier sample complexity, and verifier runtime are all  $s$ . Given sample access to the distribution  $D$ , the honest prover requires with high probability  $\tilde{O}(N)$   $\text{poly}(\sigma^{-1})$  samples and runtime.*

*At the end of the interaction, the verifier rejects or outputs  $((z_i, \pi_i))_{i \in [s]}$  where  $(z_i)_{i \in [s]}$  is a sample of size  $s$  drawn uniformly i.i.d. from  $[N]$  and:*

- **Completeness.** *If the prover is honest, then with probability at least 0.75, the verifier doesn't reject, and  $((z_i, \pi_i))_{i \in [s]}$  satisfies  $\frac{1}{s} \sum_{i \in [s]: \pi_i \geq \frac{\sigma}{1000N}} \left(1 - \min\left\{\frac{\pi_i}{D(z_i)}, \frac{D(z_i)}{\pi_i}\right\}\right) = O(\tau)$ , while  $\frac{1}{s} \sum_{i \in [s]: \pi_i \leq \frac{\sigma}{1000N}} D(z_i) \leq \frac{\sigma}{50N}$ .*

## 72:10 Public Coin Interactive Proofs for Label-Invariant Distribution Properties

- **Soundness.** *Whatever strategy a dishonest prover follows, with probability at most 0.25 over the verifier's coin tosses and samples, they accept and  $((z_i, \pi_i))_{i \in [s]}$  satisfies:*

$$\frac{1}{s} \sum_{i \in [s]: \pi_i \geq \frac{\sigma}{1000N}} \left( 1 - \min \left\{ \frac{\pi_i}{D(z_i)}, \frac{D(z_i)}{\pi_i} \right\} \right) \geq \sigma \quad (5)$$

or

$$\frac{1}{s} \sum_{i \in [s]: \pi_i \leq \frac{\sigma}{1000N}} D(z_i) \geq \frac{\sigma}{10N} \quad (6)$$

Note that we use the convention that  $\min \left\{ \frac{\pi_i}{D(z_i)}, \frac{D(z_i)}{\pi_i} \right\} = 1$  if  $\pi_i = 0$  and  $D(z_i) \neq 0$ , or  $\pi_i \neq 0$  and  $D(z_i) = 0$ .

We show that Protocol 1 satisfies the conditions of Theorem 13.

### ■ Protocol 1 Public-Sample Tagged Sample Retrieval Protocol.

**Input:** parameters  $N \in \mathbb{N}$ ,  $\sigma \in (0, 1)$ , as well as sample access to distribution  $D$  over domain  $[N]$  such that for all  $x \in [N]$ ,  $D(x) \leq \frac{1}{s}$  for  $s = O\left(\frac{\log N}{\epsilon^5} N^{2/3}\right)$ .

1. V: draw  $s$  uniformly from  $[N]$ . Denote the sample  $(S_i)_{i \in [s]}$ . Reject if there exists  $x \in [N]$  such that  $x$  appears more than  $\log N$  times in  $S$ . Otherwise, send  $(S_i)$  to P.
2. P: set  $\tau = \frac{\sigma^3}{80000}$ . For every  $i \in [s]$ , if  $D(S_i) \geq \frac{\sigma}{100N}$ , send  $\pi_i$  such that  $\pi_i = D(S_i)$ , otherwise, send  $\pi_i = 0$ .
3. V: for every  $j$  set  $S^j = \left\{ i \in [s] : \pi_i \in \left[ \frac{e^{j\tau}}{N}, \frac{e^{(j+1)\tau}}{N} \right) \right\}$ . Draw two fresh samples of size  $s$  from  $D$ ,  $T = (T_i)_{i \in [s]}$  and  $T' = (T'_i)_{i \in [s]}$ . For every  $j$  such that  $|S^j| \geq e^{-j\tau} \cdot s \cdot \frac{\epsilon \cdot \tau}{100 \log N}$  and  $\frac{e^{j\tau}}{N} \geq \frac{\sigma}{1000N}$ , set:

$$\tilde{C}_j^{pair} = \left| \left\{ (k, r) \in [s]^2 : k \in S^j, S_k = T_r \right\} \right|$$

$$\tilde{C}_j^{triple} = \left| \left\{ (k, r, r') \in [s]^3 : k \in S^j, S_k = T_r = T'_{r'} \right\} \right|$$

Reject unless for all such  $j$ :

$$\left| \tilde{C}_j^{pair} - s \cdot |S^j| \cdot \frac{e^{j\tau}}{N} \right| \leq 4\tau \cdot s \cdot |S^j| \cdot \frac{e^{j\tau}}{N} \quad (7)$$

And

$$\left| \tilde{C}_j^{triple} - s^2 \cdot |S^j| \cdot \left( \frac{e^{j\tau}}{N} \right)^2 \right| \leq 4\tau \cdot s^2 \cdot |S^j| \cdot \left( \frac{e^{j\tau}}{N} \right)^2 \quad (8)$$

4. V: denote  $S^{-\infty} = \{i \in [s] : \pi_i = 0\}$ . Reject unless  $\tilde{C}_{-\infty}^{pair} \leq s \cdot |S^{-\infty}| \cdot \frac{\sigma}{50N}$ .
5. V: Output  $((S_i, \pi_i))_{i \in [s]}$

### 4.1 Protocol 1 is Complete

We first show that Step 1 of Protocol 1 does not result in rejection.

▷ **Claim 14.** With probability at least 0.99 over the choice of  $S$ , there doesn't exist an element  $x \in [N]$  that was sampled more than 3 times in  $S$ , and the verifier doesn't reject after Step 1 of Protocol 1.

Proof. Fix  $x \in [N]$  and  $i_1, i_2, i_3, i_4 \in [s]$  such that for all  $k, k' \in [\log N]$ ,  $i_k \neq i_{k'}$ . Note that:

$$\Pr_S(S_{i_1} = S_{i_2} = S_{i_3} = S_{i_4}) = \left(\frac{1}{N}\right)^4$$

There are  $\binom{s}{4}$  possible choices for  $i_1, i_2, i_3, i_4 \in [s]$ . Therefore, the probability that there exists some set of 4 indices whose respective samples equal  $x$  is at most:

$$\binom{s}{4} \cdot \frac{1}{N^4} \leq \left(\frac{s}{N}\right)^4 \leq \frac{1}{N^{4/3}}$$

Taking the union bound over all possible  $x \in [N]$  yields the desired result. ◁

Next, we argue that if the prover is honest, with high probability, the verifier collision tests don't result in rejection.

▷ **Claim 15.** Assuming the verifier didn't reject after Step 1 and that the prover is honest, then with probability at least 0.8 over the choice of  $T, T'$  the verifier doesn't reject.

Proof. For every  $j$  such that  $\frac{e^{j\tau}}{N} \geq \frac{\sigma}{1000N}$  and  $|S^j| \geq e^{-j\tau} \cdot s \cdot \frac{\varepsilon \cdot \tau}{100 \log N}$  by Propositions 30 and 31 and choice of  $s$ , it also holds that:

$$\begin{aligned} \mathbb{E} \left[ \tilde{C}_j^{pair} \right] &= s \left( \sum_{i \in S^j} D(S_i) \right) \geq s \cdot |S^j| \cdot \frac{e^{j\tau}}{N} \geq \frac{300 \log^2 N}{\tau^3} \\ \mathbb{E} \left[ \tilde{C}_j^{triple} \right] &\geq s^2 \sum_{i \in S^j} (D(S_i))^2 = s^2 \cdot |S^j| \cdot \left( \frac{e^{j\tau}}{N} \right)^3 \geq \frac{300 \log^2 N}{\tau^3} \end{aligned}$$

And so, since there are at most  $2 \log N / \tau$  buckets for which  $\frac{e^{j\tau}}{N} \geq \frac{\sigma}{1000N}$ , we conclude from Propositions 30 and 31 that with probability at least 0.8 over the choice of  $T, T'$  for all  $j$  as described in statement it holds that:

$$\left| \tilde{C}_j^{triple} - \mathbb{E} \left[ \tilde{C}_j^{triple} \right] \right| \leq \mathbb{E} \left[ \tilde{C}_j^{triple} \right] \cdot \sqrt{\frac{300 \log^2 N}{\tau \cdot \mathbb{E} \left[ \tilde{C}_j^{triple} \right]}} \leq 4\tau s^2 |S^j| \left( \frac{e^{j\tau}}{N} \right)^2$$

And similarly:

$$\left| \tilde{C}_j^{pair} - \mathbb{E} \left[ \tilde{C}_j^{pair} \right] \right| \leq \mathbb{E} \left[ \tilde{C}_j^{pair} \right] \cdot \sqrt{\frac{300 \log^2 N}{\tau \cdot \mathbb{E} \left[ \tilde{C}_j^{pair} \right]}} \leq (e^\tau - 1) s |S^j| \frac{e^{j\tau}}{N} \cdot \tau \leq 4\tau s |S^j| \frac{e^{j\tau}}{N}$$

◁

▷ **Claim 16.** If the prover is honest, with high probability over  $T$ , the final verifier test passes with high probability, and:

$$\frac{1}{s} \sum_{i \in [s]: \pi_i < \frac{\sigma}{1000N}} D(S_i) \leq \frac{\sigma}{10N} \tag{9}$$

## 72:12 Public Coin Interactive Proofs for Label-Invariant Distribution Properties

Proof. Since the prover is honest,  $\mathbb{E} [\tilde{C}_{-\infty}] = s \cdot \sum_{i \in S^{-\infty}} D(S_i) \leq s \cdot |S^{-\infty}| \cdot \frac{\sigma}{1000N}$ , and so, by Markov's Inequality, with probability at least 0.95,  $\tilde{C}_{-\infty} \leq s \cdot |S^{-\infty}| \cdot \frac{\sigma}{50N}$ , and the final test passes. Moreover, Inequality (9) holds.  $\triangleleft$

► **Remark 17 (Honest prover complexity).** For sake of simplicity we assume the honest prover in Protocol 1 knows  $D(S_i)$  exactly. However, this is not necessary. A prover that approximates this quantity for every sample up to sufficient accuracy using only  $\tilde{O}(N)\text{poly}(\tau^{-1})$  samples suffices. See Remark 4.14 in [14] for a detailed discussion.

### 4.2 Protocol 1 is Sound

Note that by Claim 14, regardless of the prover's response, the verifier rejects after Step 1 with probability at most 0.01, and so, throughout this section, we assume that Step 1 passed, and  $S$  doesn't contain elements appearing more than 4 times, even when not stated explicitly.

First, we address the *last* verifier test:

► **Claim 18.** For every index  $j$  such that  $\frac{e^{j\tau}}{N} \geq \frac{\sigma}{1000N}$  and  $|S^j| \geq e^{-j\tau} \cdot s \cdot \frac{\varepsilon \cdot \tau}{100 \log N}$ , with probability at least 0.98 over the choice of  $T$  and  $T'$ , either the verifier rejects, or it holds that:

$$\mathbb{E} [\tilde{C}_j^{pair}] \geq \frac{300 \log^2 N}{\tau^3} \quad (10)$$

and

$$\mathbb{E} [\tilde{C}_j^{triple}] \geq \frac{300 \log^2 N}{\tau^3} \quad (11)$$

Proof. Fix some  $j_0$  such that  $|S^{j_0}| \geq s \cdot \frac{\varepsilon \tau}{100 \log N}$ ,  $\frac{e^{j_0 \tau}}{N} \geq \frac{\varepsilon}{100N}$ , and also  $\mathbb{E} [\tilde{C}_{j_0}^{triple}] < \frac{300 \log^2 N}{\tau^3}$ . By Markov's Inequality, with probability at least 0.99:

$$\tilde{C}_{j_0}^{triple} \leq 100 \mathbb{E} [\tilde{C}_{j_0}^{triple}] \leq \frac{30000 \log^2 N}{\tau^3}$$

However, the verifier rejects unless:

$$\tilde{C}_{j_0}^{triple} \geq (1 - 4\tau) s^2 |S^{j_0}| \left( \frac{e^{j_0 \tau}}{N} \right)^2 \geq s^3 \cdot \frac{\tau \varepsilon^3}{2 \cdot 100^3 N^3 \log N} > \frac{30000 \log^2 N}{\tau^3}$$

Where the last inequality is justified since  $s \geq \frac{300 \log N}{\tau^{4/3 \varepsilon}} N^{2/3}$ . We thus conclude that for every  $j$  such that  $v_{j_0} \geq \frac{\varepsilon \tau}{100 \log N}$ ,  $\frac{e^{j_0 \tau}}{N} \geq \frac{\varepsilon}{100N}$ , either  $\mathbb{E} [\tilde{C}_j^{triple}] \geq \frac{300 \log^2 N}{\tau^3}$  or the verifier reject with probability at least 0.99. An analogous argument can be made w.r.t. to  $\tilde{C}_j^{pair}$ . Taking the union bound over both these events yields the required result.  $\triangleleft$

► **Claim 19.** With probability at least 0.8 over the choice of  $T$  and  $T'$ , for every  $j$  such that  $|S^j| \geq e^{-j\tau} \cdot s \cdot \frac{\varepsilon \cdot \tau}{100 \log N}$  and  $\frac{e^{j\tau}}{N} \geq \frac{\sigma}{1000N}$ , and for which Inequalities (10) and (11) hold, it further holds that:

$$\left| \tilde{C}_j^{pair} - s \sum_{i \in S^j} D(S_i) \right| \leq 4\tau \cdot s \sum_{i \in S^j} D(S_i) \quad (12)$$

As well as:

$$\left| \tilde{C}_j^{triple} - s^2 \sum_{i \in S^j} (D(S_i))^2 \right| \leq 4\tau \cdot s^2 \sum_{i \in S^j} (D(S_i))^2 \quad (13)$$

Proof. By Propositions 30 and 31 it holds that with probability 0.8 over the choice of  $T$  and  $T'$  for every  $j$  such that  $|S^j| \geq s \cdot \frac{\varepsilon \cdot \tau}{100 \log N}$  and  $\frac{e^{j\tau}}{N} \geq \frac{\varepsilon}{100N}$ , the following holds:

$$\left| \tilde{C}_j^{pair} - \mathbb{E} \left[ \tilde{C}_j^{pair} \right] \right| \leq \mathbb{E} \left[ \tilde{C}_j^{pair} \right] \cdot \sqrt{\frac{300 \log^2 N}{\tau \cdot \mathbb{E} \left[ \tilde{C}_j^{pair} \right]}}$$

$$\left| \tilde{C}_j^{triple} - \mathbb{E} \left[ \tilde{C}_j^{triple} \right] \right| \leq \mathbb{E} \left[ \tilde{C}_j^{triple} \right] \cdot \sqrt{\frac{300 \log^2 N}{\tau \cdot \mathbb{E} \left[ \tilde{C}_j^{triple} \right]}}$$

Moreover, from the same propositions we know that:

$$\mathbb{E} \left[ \tilde{C}_j^{pair} \right] = s \sum_{i \in S^j} D(S_i)$$

$$\mathbb{E} \left[ \tilde{C}_j^{triple} \right] = s^2 \sum_{i \in S^j} (D(S_i))^2$$

We thus conclude that for all the  $j$  as specified above:

$$\left| \tilde{C}_j^{pair} - s \sum_{i \in S^j} D(S_i) \right| \leq \mathbb{E} \left[ \tilde{C}_j^{pair} \right] \cdot \sqrt{\frac{300 \log^2 N}{\tau \cdot \mathbb{E} \left[ \tilde{C}_j^{pair} \right]}} \leq \tau s \sum_{i \in S^j} D(S_i)$$

Where the last inequality above stems from the assumption that Inequality (11) holds. Similarly:

$$\left| \tilde{C}_j^{triple} - s^2 \sum_{i \in S^j} (D(S_i))^2 \right| \leq \tau s^2 \sum_{i \in S^j} (D(S_i))^2 \quad \triangleleft$$

▷ **Claim 20.** Assuming the verifier didn't reject, with probability at least 0.8 over the choice of  $T$  and  $T'$ , for every  $j$  such that  $|S^j| \geq e^{-j\tau} \cdot s \cdot \frac{\varepsilon \cdot \tau}{100 \log N}$  and  $\frac{e^{j\tau}}{N} \geq \frac{\sigma}{1000N}$ , and for which Inequalities (10) and (11) hold. It further holds that:

$$\frac{1}{|S^j|} \sum_{i \in S^j} D(S_i) \in \frac{e^{j\tau}}{N} [1 - 10\tau, 1 + 10\tau] \quad (14)$$

$$\frac{1}{|S^j|} \sum_{i \in S^j} (D(S_i))^2 \in \left( \frac{e^{j\tau}}{N} \right)^2 [1 - 10\tau, 1 + 10\tau] \quad (15)$$

Proof. By Claim 19, with probability at least 0.8 over the choice of  $T$  and  $T'$ , for every  $j$  such that and  $|S^j| \geq e^{-j\tau} \cdot s \cdot \frac{\varepsilon \cdot \tau}{100 \log N}$  and  $\frac{e^{j\tau}}{N} \geq \frac{\sigma}{1000N}$ , and for which Inequalities (10) and (11) hold, Inequalities (12) and (13) hold.

Furthermore, if the verifier didn't reject, for all such  $j$ , Inequalities (7) and (8) holds as well for all such  $j$ . Putting it all together, we get that:

$$\left| s \cdot |S^j| \cdot \frac{e^{j\tau}}{N} - s \sum_{i \in S^j} D(S_i) \right| \leq \left| s \cdot |S^j| \cdot \frac{e^{j\tau}}{N} - \tilde{C}_j^{pair} \right| + \left| \tilde{C}_j^{pair} - s \sum_{i \in S^j} D(S_i) \right| \quad (16)$$

$$\leq 4\tau s \cdot |S^j| \cdot \frac{e^{j\tau}}{N} + 4\tau s \sum_{i \in S^j} D(S_i) \quad (17)$$

Rearranging Inequality (16):

$$s \sum_{i \in S^j} D(S_i) \in s \cdot |S^j| \cdot \frac{e^{j\tau}}{N} \left[ \frac{1-4\tau}{1+4\tau}, \frac{1+4\tau}{1-4\tau} \right]$$

Likewise:

$$\left| s^2 \cdot |S^j| \left( \frac{e^{j\tau}}{N} \right)^2 - s^2 \sum_{i \in S^j} (D(S_i))^2 \right| \leq +4\tau s^2 \cdot |S^j| \left( \frac{e^{j\tau}}{N} \right)^2 + 4\tau s^2 \sum_{i \in S^j} (D(S_i))^2 \quad (18)$$

Similarly, for Inequality (18):

$$s^2 \sum_{i \in S^j} (D(S_i))^2 \in s^2 \cdot |S^j| \left( \frac{e^{j\tau}}{N} \right)^2 \left[ \frac{1-4\tau}{1+4\tau}, \frac{1+4\tau}{1-4\tau} \right]$$

And through the relation  $\frac{1-4\tau}{1+4\tau} \geq 1 - 10\tau$  and  $\frac{1+4\tau}{1-4\tau} \leq 1 + 10\tau$  that holds for all  $\tau > 0$ , we get the desired result.  $\triangleleft$

► **Definition 21.** Define the distribution  $U_{S^j}$  to be the uniform distribution over  $S^j$ .

▷ **Claim 22.** Assuming the verifier didn't reject, with probability at least 0.8 over the choice of  $T$  and  $T'$ , for every  $j$  such that  $|S^j| \geq e^{-j\tau} \cdot s \cdot \frac{\varepsilon \cdot \tau}{100 \log N}$  and  $\frac{e^{j\tau}}{N} \geq \frac{\sigma}{1000N}$ , and for which Inequalities (10) and (11) hold. It further holds that:

$$\mathbb{E}_{i \sim U_{S^j}} [D(S_i)] \in \frac{e^{j\tau}}{N} [1 - 10\tau, 1 + 10\tau]$$

$$\text{Var}_{i \sim U_{S^j}} [D(S_i)] \leq 60\tau (\mathbb{E}_{i \sim U_{S^j}} [D(S_i)])^2$$

Proof. With high probability, for all  $j$  as specified in the claim statement, by Claim 20:

$$\mathbb{E}_{i \sim U_{S^j}} [D(S_i)] = \sum_{i \in S_i} \frac{1}{|S^j|} D(S_i) \in \frac{e^{j\tau}}{N} \cdot [1 - 10\tau, 1 + 10\tau]$$

Furthermore:

$$\mathbb{E}_{i \sim U_{S^j}} \left[ (D(S_i))^2 \right] = \frac{1}{|S^j|} \sum_{i \in S^j} (D(S_i))^2 \quad (19)$$

$$\leq (1 + 10\tau) \left( \frac{e^{j\tau}}{N} \right)^2 \quad (20)$$

$$\leq (1 + 10\tau) (\mathbb{E}_{i \sim U_{S^j}} [D(S_i)])^2 \frac{1}{(1 - 10\tau)^2} \quad (21)$$

$$\leq (1 + 40\tau) (\mathbb{E}_{i \sim U_{S^j}} [D(S_i)])^2 \quad (22)$$

And so, we conclude that:

$$\begin{aligned} \text{Var}_{i \sim U_{S^j}} [D(S_i)] &= \mathbb{E}_{i \sim U_{S^j}} \left[ (D(S_i))^2 \right] - (\mathbb{E}_{i \sim U_{S^j}} [D(S_i)])^2 \\ &\leq (1 + 40\tau) (\mathbb{E}_{i \sim U_{S^j}} [D(S_i)])^2 - (1 - 20\tau) (\mathbb{E}_{i \sim U_{S^j}} [D(S_i)])^2 \\ &\leq 60\tau (\mathbb{E}_{i \sim U_{S^j}} [D(S_i)])^2 \end{aligned} \quad \triangleleft$$

▷ Claim 23. Assuming the verifier didn't reject, with probability at least 0.8 over the choice of  $T$  and  $T'$ , for every  $j$  such that  $|S^j| \geq e^{-j\tau} \cdot s \cdot \frac{\varepsilon \cdot \tau}{100 \log N}$  and  $\frac{e^{j\tau}}{N} \geq \frac{\sigma}{1000N}$ , and for which Inequalities (10) and (11) hold, it further holds that:

$$\mathbb{E}_{i \sim U_{S^j}} \left[ \min \left\{ \frac{D(S_i)}{\pi_i}, \frac{\pi_i}{D(S_i)} \right\} \right] \geq 1 - \frac{\sigma}{50} \quad (23)$$

Proof. By Claim 22, for every  $j$  as specified in the claim statement, it holds that:

$$\mathbb{E}_{i \sim U_{S^j}} [D(S_i)] \in \frac{e^{j\tau}}{N} [1 - 10\tau, 1 + 10\tau]$$

$$\text{Var}_{i \sim U_{S^j}} [D(S_i)] \leq 60\tau \left( \mathbb{E}_{i \sim U_{S^j}} [D(S_i)] \right)^2$$

Therefore, through Chebychev's Inequality:

$$\Pr_{i \sim U_{S^j}} \left( |D(S_i) - \mathbb{E}[D(S_i)]| \geq \sqrt{\frac{6000\tau}{\sigma}} \cdot \mathbb{E}[D(S_i)] \right) \leq \frac{60\tau \left( \mathbb{E}_{i \sim U_{S^j}} [D(S_i)] \right)^2}{\left( \mathbb{E}_{i \sim U_{S^j}} [D(S_i)] \right)^2 \cdot 6000\tau/\sigma} \leq \frac{\sigma}{100}$$

Observe that with probability at least  $1 - \frac{\sigma}{100}$  over the choice of  $i \sim U_{S^j}$  it holds that:

$$\begin{aligned} |D(S_i) - \pi_i| &\leq |D(S_i) - \mathbb{E}[D(S_i)]| + \left| \mathbb{E}[D(S_i)] - \frac{e^{j\tau}}{N} \right| + \left| \frac{e^{j\tau}}{N} - \pi_i \right| \\ &\leq \sqrt{\frac{6000\tau}{\sigma}} \cdot \mathbb{E}[D(S_i)] + \left| \mathbb{E}[D(S_i)] - \frac{e^{j\tau}}{N} \right| + (e^\tau - 1) \cdot \frac{e^{j\tau}}{N} \\ &\leq \sqrt{\frac{6000\tau}{\sigma}} \cdot \frac{e^{j\tau}}{N} (1 + 10\tau) + 12\tau \cdot \frac{e^{j\tau}}{N} \\ &\leq \left( 2\sqrt{\frac{6000\tau}{\sigma}} + 12\tau \right) \frac{e^{j\tau}}{N} \\ &\leq e^\tau \left( 2\sqrt{\frac{6000\tau}{\sigma}} + 12\tau \right) \pi_i \\ &\leq \left( 3\sqrt{\frac{6000\tau}{\sigma}} + 12\tau \right) \pi_i \end{aligned}$$

Where the second to last inequality stems from the fact that by definition for all  $i \in S^j$ ,  $\pi_i \in \left[ \frac{e^{j\tau}}{N}, \frac{e^{(j+1)\tau}}{N} \right]$ . We conclude that for all such  $i$  it holds that:

$$\frac{D(S_i)}{\pi_i} \in \left[ 1 - 3\sqrt{\frac{6000\tau}{\sigma}} - 12\tau, 1 + 3\sqrt{\frac{6000\tau}{\sigma}} + 12\tau \right]$$

By choice of  $\tau$ , this implies that with probability at least  $1 - \frac{1}{100\sigma}$  over the choice of  $i \sim U_{S^j}$ , it holds that:

$$\frac{D(S_i)}{\pi_i} \in \left[ 1 - \frac{\sigma}{100}, 1 + \frac{\sigma}{100} \right]$$

Next, since for all  $i$  by definition  $\min \left\{ \frac{D(S_i)}{\pi_i}, \frac{\pi_i}{D(S_i)} \right\} \leq 1$ , we get that for all  $j$  as specified in the claim statement, with probability at least 0.8 over the choice of  $T$  and  $T'$  if the verifier didn't reject, it holds that:

$$\mathbb{E}_{i \sim U_{S^j}} \left[ \min \left\{ \frac{D(S_i)}{\pi_i}, \frac{\pi_i}{D(S_i)} \right\} \right] \geq \frac{\sigma}{100} + \left( 1 - \frac{\sigma}{100} \right) \left( 1 - \frac{\sigma}{100} \right) \geq 1 - \frac{\sigma}{50} \quad \triangleleft$$

## 72:16 Public Coin Interactive Proofs for Label-Invariant Distribution Properties

▷ Claim 24. Assume the prover's tags satisfy the following inequality:

$$\frac{1}{s} \sum_{i \in [s]: \pi_i \geq \frac{\sigma}{1000N}} \left( 1 - \min \left\{ \frac{\pi_i}{D(z_i)}, \frac{D(z_i)}{\pi_i} \right\} \right) \geq \sigma \quad (24)$$

Then, there exists some  $j_0$  such that  $|S^{j_0}| \geq s \cdot e^{-j_0\tau} \cdot \frac{\varepsilon \cdot \tau}{100 \log N}$  and  $\frac{e^{j_0\tau}}{N} \geq \frac{\varepsilon}{100N}$ , and:

$$\mathbb{E}_{i \sim U_{S^{j_0}}} \left[ \min \left\{ \frac{D(S_i)}{\pi_i}, \frac{\pi_i}{D(S_i)} \right\} \right] \leq 1 - 0.7\sigma \quad (25)$$

Proof. We decompose the sum in Inequality (5) according to alleged buckets as follows:

$$\begin{aligned} \sigma &\leq \frac{1}{s} \sum_{i \in [s]: \pi_i \geq \frac{\sigma}{1000N}} \left( 1 - \min \left\{ \frac{\pi_i}{D(z_i)}, \frac{D(z_i)}{\pi_i} \right\} \right) \\ &= \frac{1}{s} \sum_{j: |S^j| \neq \emptyset} \sum_{i \in S^j} \left( 1 - \min \left\{ \frac{\pi_i}{D(z_i)}, \frac{D(z_i)}{\pi_i} \right\} \right) \\ &= \sum_{j: |S^j| \neq \emptyset} \frac{|S^j|}{s} \cdot \frac{1}{|S^j|} \sum_{i \in S^j} \left( 1 - \min \left\{ \frac{\pi_i}{D(z_i)}, \frac{D(z_i)}{\pi_i} \right\} \right) \\ &= \sum_{j: |S^j| \neq \emptyset} \frac{|S^j|}{s} \cdot \mathbb{E}_{i \sim U_{S^j}} \left[ 1 - \min \left\{ \frac{D(S_i)}{\pi_i}, \frac{\pi_i}{D(S_i)} \right\} \right] \end{aligned}$$

Define  $J = \left\{ j : |S^j| \geq e^{-j\tau} \cdot s \cdot \frac{\varepsilon \cdot \tau}{100 \log N}, \frac{e^{j\tau}}{N} \geq \frac{\sigma}{1000N} \right\}$ , and denote  $\sum_{j \notin J} \frac{|S^j|}{s} = \alpha$ . Define next  $J^c = \left\{ j : 0 < |S^j| < e^{-j\tau} \cdot s \cdot \frac{\varepsilon \cdot \tau}{100 \log N}, \frac{e^{j\tau}}{N} \geq \frac{\sigma}{1000N} \right\}$ . Observe that:

$$\sum_{j \in J^c} \frac{|S^j|}{s} \leq \frac{1}{s} \sum_{j \in J^c} e^{-j\tau} \cdot s \cdot \frac{\varepsilon \cdot \tau}{100 \log N} \leq \sum_{j \in J^c} \frac{100}{\sigma} \cdot \frac{\varepsilon \cdot \tau}{100 \log N} \leq \frac{\sigma}{20}$$

Then:

$$\sum_{j \in J} \frac{|S^j|}{s} \cdot \mathbb{E}_{i \sim U_{S^j}} \left[ 1 - \min \left\{ \frac{D(S_i)}{\pi_i}, \frac{\pi_i}{D(S_i)} \right\} \right] \geq 0.7\sigma$$

Consider thus the distribution  $\mathcal{B}$  that assigns to every  $j \in J$  the probability  $\left| \frac{|S^j|}{s \cdot (1-\alpha)} \right|$ , and 0 otherwise. Then:

$$\mathbb{E}_{j \sim \mathcal{B}} \left[ \mathbb{E}_{i \sim U_{S^j}} \left[ 1 - \min \left\{ \frac{D(S_i)}{\pi_i}, \frac{\pi_i}{D(S_i)} \right\} \right] \right] \geq \sigma - \frac{\sigma}{20} \geq 0.9\sigma$$

And so it must hold that there exists some  $j_0 \in J$  such that:

$$\mathbb{E}_{i \sim U_{S^{j_0}}} \left[ 1 - \min \left\{ \frac{D(S_i)}{\pi_i}, \frac{\pi_i}{D(S_i)} \right\} \right] \geq 0.9\sigma$$

Finally, this implies that for  $j_0$ :

$$\mathbb{E}_{i \sim U_{S^{j_0}}} \left[ \min \left\{ \frac{D(S_i)}{\pi_i}, \frac{\pi_i}{D(S_i)} \right\} \right] \leq 1 - 0.9\sigma \quad \triangleleft$$

▷ **Claim 25.** With high probability over the choice of  $S, T, T'$ , if Inequality (5) holds, then, with high probability, the verifier rejects.

*Proof.* Assume the prover's response  $(\pi_i)_{i \in [s]}$  satisfies Inequality (24). Then, by Claim 24, it holds that there exists some  $j_0$  such that  $|S^{j_0}| \geq s \cdot \frac{\varepsilon \cdot \tau}{100 \log N}$  and  $\frac{e^{j_0 \tau}}{N} \geq \frac{\varepsilon}{100N}$ , and for which:

$$\mathbb{E}_{i \sim U_{S^{j_0}}} \left[ \min \left\{ \frac{D(S_i)}{\pi_i}, \frac{\pi_i}{D(S_i)} \right\} \right] \leq 1 - 0.9\sigma \quad (26)$$

Next, by Claim 18, with probability at least 0.98 over the choice of  $T, T'$ , Inequalities (10) and (13) hold for  $j_0$ . Then, assuming the verifier didn't reject, by Claim 23 it holds that with probability at least 0.8 over the choice of  $T, T'$  that:

$$\mathbb{E}_{i \sim U_{S^{j_0}}} \left[ \min \left\{ \frac{D(S_i)}{\pi_i}, \frac{\pi_i}{D(S_i)} \right\} \right] \geq 1 - \frac{\sigma}{50} \quad (27)$$

Note that Inequality (26) and Inequality (27) contradict one another, from which we conclude that if the prover's response satisfies Inequality (24), then with probability at least 0.75 over the choice of  $S, T, T'$ , the verifier should reject. ◁

Finally, concerning the final verifier test:

▷ **Claim 26.** If the prover's answer didn't result with the verifier rejecting the test in Step 4 of Protocol 1, then with probability at most 0.01, Inequality (6) holds.

*Proof.* By Proposition 30  $\mathbb{E}[\tilde{C}_{-\infty}] = s \sum_{i: \pi_i < \frac{\sigma}{1000N}} D(x)$ . Thus, assuming that Inequality (6) holds, every entry in  $T$  has probability at least  $\sum_{i \in [s]: \pi_i < \frac{\sigma}{1000N}} D(x) \geq s \cdot \frac{\sigma}{10N}$  of landing on  $S^{-\infty}$ , and by Hoeffdings Inequality, this will yield:

$$\tilde{C}_{-\infty} \in \left(1 + \frac{1}{\sqrt{s}}\right) s^2 \cdot \frac{\sigma}{10N} > s \cdot |S^-| \cdot \frac{\sigma}{50N}$$

And the verifier rejects with high probability. ◁

### 4.3 From verified uniform tagged sample to property verification

► **Lemma 27.** For every two distributions  $D, Q$  over domain  $[N]$ , and parameter  $\sigma \in (0, 1)$ . Let  $(z_i)_{i \in [s]}$  be a sample of size  $s = \tilde{O}(N^{2/3}) \text{poly}(\sigma^{-1})$  drawn uniformly from  $[N]$ . There exists an algorithm that runs in time  $O(s)$  and outputs  $\delta \in [0, 1]$ , such that  $|\delta - \Delta_{SD}(Q, D)| = O\left(\sigma + \frac{1}{\sqrt{s}}\right)$ , given the following input:

- The sample  $(z_i)_{i \in [s]}$ .
- $(\pi_i)_i \in [0, 1]^s$ , that satisfy the following two inequalities:

$$\frac{1}{s} \sum_{i \in [s]: \pi_i \geq \frac{\sigma}{1000N}} \left( 1 - \min \left\{ \frac{\pi_i}{D(z_i)}, \frac{D(z_i)}{\pi_i} \right\} \right) \leq \sigma \quad (28)$$

$$\frac{1}{s} \sum_{i \in [s]: \pi_i \leq \frac{\sigma}{1000N}} D(z_i) \leq \frac{\sigma}{10N} \quad (29)$$

- $Q(z_i)$ , for all  $i \in [s]$ .

## 72:18 Public Coin Interactive Proofs for Label-Invariant Distribution Properties

**Proof.** Consider the following algorithm: for every  $i \in [S]$ , set  $\theta'_{z_i} = \frac{|\pi_i - Q(z_i)|}{2}$ , and output  $\delta = \frac{1}{s} \sum_{i \in [s]} \theta'_{z_i}$ . We show that this algorithm satisfies the conditions of the lemma.

For every  $x \in [N]$  define  $\theta_x = \frac{|D(x) - Q(x)|}{2}$ . Observe that by definition,  $\Delta_{\text{SD}}(D, Q) = \mathbb{E}_{x \sim U_{[N]}}[\theta_x]$ . Since the sample  $(z_i)$  was drawn i.i.d., the collection  $(\theta_x)$  is independent. By Hoeffding's Inequality:

$$\Pr \left( \left| \frac{1}{s} \sum_{i \in [s]} \theta_{z_i} - \Delta_{\text{SD}}(D, Q) \right| > \frac{2}{\sqrt{s}} \right) \leq 2e^{-8} < 0.01$$

And so, with probability at least 0.99 over the choice of  $(z_i)$ :

$$\left| \frac{1}{s} \sum_{i \in [s]} \theta_{z_i} - \Delta_{\text{SD}}(D, Q) \right| \leq \frac{2}{\sqrt{s}} \quad (30)$$

By assumption over  $(\pi_i)$  and the Triangle Inequality:

$$\left| \frac{1}{s} \sum_{i \in [s]} \theta_{z_i} - \frac{1}{s} \sum_{i \in [s]} \theta'_{z_i} \right| \leq \frac{1}{s} \left| \sum_{i \in [s]} \left( \frac{|D(z_i) - Q(z_i)|}{2} - \frac{|\pi_i - Q(z_i)|}{2} \right) \right| \quad (31)$$

$$\leq \frac{1}{2s} \sum_{i \in [s]} (|D(z_i) - Q(z_i)| - |\pi_i - Q(z_i)|) \quad (32)$$

$$\leq \frac{1}{2s} \sum_{i \in [s]} |(D(z_i) - Q(z_i)) - (\pi_i - Q(z_i))| \quad (33)$$

$$= \frac{1}{2s} \sum_{i \in [s]} |D(z_i) - \pi_i| \quad (34)$$

For every  $i$  such that  $D(z_i) \neq 0$ , it holds that save for at most  $\sigma$ -fraction of  $i \in [s]$ ,  $\pi_i \in (1 \pm O(\sigma)) D(z_i)$ , and for every  $i$  such that  $D(z_i) \neq 0$ , it must hold that  $\frac{1}{s} \sum_{i \in [s]: D(z_i)=0} \pi_i \leq \sigma$ . And so:

$$\frac{1}{2s} \sum_{i \in [s]} |D(z_i) - \pi_i| \leq \frac{1}{2s} \sum_{i \in [s]: D(z_i) \neq 0} D(z_i) \left| 1 - \frac{\pi_i}{D(z_i)} \right| + \frac{1}{2s} \sum_{i \in [s]: D(z_i)=0} \pi_i \quad (35)$$

$$\leq \frac{1}{2} \left( \frac{1}{s} \sum_{i \in [s]: D(z_i) \stackrel{O(\sigma)}{\approx} \pi_i} D(z_i) \left| 1 - \frac{\pi_i}{D(z_i)} \right| + \frac{1}{s} \sum_{i \in [s]: D(z_i) \stackrel{O(\sigma)}{\not\approx} \pi_i} D(z_i) \left| 1 - \frac{\pi_i}{D(z_i)} \right| + \sigma \right) \quad (36)$$

$$\leq \frac{1}{2} (O(\sigma) + O(\sigma) + \sigma) \quad (37)$$

$$= O(\sigma) \quad (38)$$

We thus conclude that with high probability over  $(z_i)$ , the algorithm yields  $\delta$  such that:  $|\delta - \Delta_{\text{SD}}(D, Q)| = O(\sigma + \frac{1}{\sqrt{s}})$   $\blacktriangleleft$

An immediate corollary of this lemma is Theorem 3. We note here that this method can also be leveraged to achieve an efficient protocol for identity testing from an approximate tagged sample *drawn according to*  $D$ , and so, can be also implemented on the output of [14] without incurring further overhead.

We now address the question of verification of label-invariant distribution problems. First, we recall the following definition:

► **Definition 28** (Efficient approximate decision procedure, [13]). *A distribution property  $\mathcal{P}$  has a  $\mu$ -efficient approximate decision procedure if there exists a polynomial-time procedure  $A$  as follows.  $A$  gets as input the domain size  $N$ , a distance parameter  $\sigma \in (0, 1)$ , and a histogram  $(m_j)_j$  satisfying  $\sum_j |m_j - Q(B_j^Q)| \leq \mu$ . For every integer  $N$ , every distribution  $D$  over  $[N]$  and every  $\sigma > 0$ :*

- *If  $Q$  is in  $\mathcal{P}$ , then  $A$  accepts the  $(m_j)_j$ .*
- *$A$  rejects every  $(m_j)_j$  histogram that is consistent with a distribution that is not  $\sigma$ -close to  $\mathcal{P}$ .*

► **Corollary 29.** *Let  $\mathcal{P}$  be a label-invariant distribution property,  $0 \leq \varepsilon_c < \varepsilon_f \leq 1$  distance parameters, and assume  $\mathcal{P}$  admits an efficient  $\tau$ -approximate decision procedure, where  $\tau = O(\varepsilon_f - \varepsilon_c)^3$ . Given sample access to distribution  $D$  over domain  $[N]$ , there exists a 2-message public-coin protocol with verifier sample complexity and communication complexity  $\tilde{O}(N^{2/3}) \cdot \text{poly}(\tau^{-1})$ , such that:*

- **Completeness.** *If  $\Delta_{SD}(D, \mathcal{P}) \leq \varepsilon_c$ , the verifier accepts with high probability.*
- **Soundness.** *If  $\Delta_{SD}(D, \mathcal{P}) \geq \varepsilon_f$ , the verifier rejects with high probability.*

We outline how to obtain a protocol for every label-invariant distribution property admitting an efficient decision procedure from a uniform verified tagged sample. Generally, we follow [13]. The reader is referred to their work for further detail on efficient decision procedures, as well as examples for such procedures for natural label-invariant properties, such as those relating to Shannon entropy, support size, and distance from uniformity. We note that the main obstacle in the protocol behind the above corollary, addressed by this paper in a novel way, is obtaining a good approximation of the probability according to  $D$  of randomly chosen elements in the domain. Recall that without communication, this task requires  $\tilde{O}(N)$  samples and runtime from the verifier.

We provide an outline the protocol behind Corollary 29. The verifier and the prover run Protocol 1 over distribution  $D$  with distance parameter  $\sigma = \frac{\varepsilon_f - \varepsilon_c}{3}$ , and with the following addition: the prover also sends, alongside  $(\pi_i)_{i \in [s]}$ , the tags  $(q_i)_{i \in [s]}$ , such that for all  $i \in [s]$ ,  $q_i = Q(i)$ , for some distribution  $Q \in \mathcal{P}$ . The verifier performs the following checks:

1. The verifier runs the tests outlined in Protocol 1 with respect to  $(\pi_i)$ , and rejects w.h.p. if prover tags satisfy Inequalities (5) or (6).
2. The verifier uses  $(q_i)$  to compute the bucket histogram of distribution  $Q$ . The size of every bucket of significant mass  $j$  of  $Q$  can be approximated to high accuracy from a uniform tagged sample  $(q_i)$ . Then, the mass of each bucket can be approximated by the product of the size and  $\frac{e^{j\tau}}{N}$ . Note that this process yields a probability histogram for  $Q$  that is accurate with high probability up to  $\tau$  multiplicative factor. Then, the verifier runs the  $\tau$ -approximate decision procedure with distance parameter  $\sigma$ , to check that indeed  $Q \in \mathcal{P}_N$ , and reject if it's far.
3. If non of the above tests failed, the verifier estimates the distance between  $Q$  and  $D$  using  $(\pi_i)$  and  $(q_i)$  as outlined in Lemma 27, and rejects unless estimate smaller than  $\varepsilon_c + O(\tau)$ .

If the all tests passed, then with high probability it holds that  $Q$  is  $\tau$ -close to  $\mathcal{P}$ , and that  $\Delta_{SD}(Q, D) \leq \varepsilon_c + O(\tau)$ , and the conditions of Corollary 29 hold. If  $D$  is  $\varepsilon_f$  far from the property, and the tags  $(q_i)$  produce a histogram consistent with a histogram of a distribution that passes the efficient decision procedure, then by assumption, it holds that there exists some  $Q \in \mathcal{P}$  that is  $\varepsilon_f - \tau$  far from  $D$ , and so the distance test will fail. We omit further detail, as the process of verifying membership in distribution property from approximate histogram is outlined in [13].

## A Collision Tests Analysis

### A.1 Twoway Collisions

► **Proposition 30.** *Assume that for every  $x \in [N]$ ,  $D(x) \leq \frac{1}{s}$ . For every sample  $S$  such that for every  $i \in [s]$ , the element  $S_i$  appears at most  $\log N$  times in  $S$ , with probability at least  $1 - \frac{\tau}{100 \log N}$  over the choice of the sample  $T$ , it holds that:*

$$\mathbb{E} \left[ \tilde{C}_j^{pair} \right] = s \sum_{i \in S^j} D(S_i)$$

As well as:

$$\left| \tilde{C}_j^{pair} - \mathbb{E} \left[ \tilde{C}_j^{pair} \right] \right| \leq \mathbb{E} \left[ \tilde{C}_j^{pair} \right] \cdot \sqrt{\frac{300 \log^2 N}{\tau \cdot \mathbb{E} \left[ \tilde{C}_j^{pair} \right]}}$$

**Proof.** The reader is referred to the Appendix of Herman and Rothblum [14] for a detailed proof of this claim. In a nutshell, For every  $k, r \in [s]$  denote by  $C_{k,r}$  the indicator of the event  $\{S_k = T_r\}$ . Observe that  $\tilde{C}_j^{pair} = \sum_{k \in S^j} \sum_{r \in [s]} C_{k,r}$ , and that  $\mathbb{E}_T [C_{k,r}] = D(S_k)$ . By the linearity of expectation:

$$\mathbb{E} \left[ \tilde{C}_j^{pair} \right] = \sum_{k \in S^j} \sum_{r \in [s]} \mathbb{E} [C_{k,r}] = \sum_{k \in S^j} \sum_{r, r' \in [s]} D(S_k) = s \sum_{k \in S^j} D(S_k) \quad (39)$$

In order to prove concentration we show that  $\text{Var}_T \left[ \tilde{C}_j^{pair} \right]$  is small. Herman and Rothblum [14] show that the variance can be bounded by  $\log N \mathbb{E} \left[ \tilde{C}_j \right]$ . And so, the desired result is thus achieved through Chebychevs' Inequality. ◀

## A.2 Threeway Collisions

► **Proposition 31.** *Assume that for every  $x \in [N]$ ,  $D(x) \leq \frac{1}{s}$ . For every sample  $S = (S_i)_{i \in [s]}$  such that for every  $i \in [s]$ , the element  $S_i$  appears in at most  $\log N$  locations in  $S$ , with probability at least  $1 - \frac{\tau}{100 \log N}$  over the choice of the samples  $T, T'$ , it holds that for any set of bucket indices  $J$  of size at most  $2 \frac{\log N}{\tau}$ , for every  $j \in J$ :*

$$\mathbb{E} \left[ \tilde{C}_j^{triple} \right] = s^2 \sum_{i \in S^j} (D(x))^2$$

As well as:

$$\left| \tilde{C}_j^{triple} - \mathbb{E} \left[ \tilde{C}_j^{triple} \right] \right| \leq \mathbb{E} \left[ \tilde{C}_j^{triple} \right] \cdot \sqrt{\frac{300 \log^2 N}{\tau \cdot \mathbb{E} \left[ \tilde{C}_j^{triple} \right]}}$$

**Proof.** For every  $k, r, r' \in [s]$  denote by  $C_{k,r,r'}$  the indicator of the event  $\{S_k = T_r = T'_{r'}\}$ . Observe that  $\tilde{C}_j^{triple} = \sum_{k \in S^j} \sum_{r, r' \in [s]} C_{k,r,r'}$ , and that  $\mathbb{E}_{T, T'} [C_{k,r,r'}] = (D(S_k))^2$ . By the linearity of expectation:

$$\mathbb{E} \left[ \tilde{C}_j^{triple} \right] = \sum_{k \in S^j} \sum_{r, r' \in [s]} \mathbb{E}_{T, T'} [C_{k,r,r'}] = \sum_{k \in S^j} \sum_{r, r' \in [s]} (D(S_k))^2 = s^2 \sum_{k \in S^j} (D(S_k))^2 \quad (40)$$

Next, we show that for every  $j \in J$  the random variable  $\tilde{C}_j^{triple}$  is well concentrated around its mean. In order to do so, we bound the variance of  $\tilde{C}_j^{triple}$ . Note that:

$$\text{Var} \left[ \tilde{C}_j^{triple} \right] = \sum_{\substack{(k_0, r_0, r'_0) \in [s]^3 \\ (k_1, r_1, r'_1) \in [s]^3}} \text{Cov} [C_{k_0, r_0, r'_0}, C_{k_1, r_1, r'_1}]$$

And so, in order to bound the variance, consider the following case analysis for the pair  $((k_0, r_0, r'_0), (k_1, r_1, r'_1))$ :

- **Type I.**  $S_{k_0} \neq S_{k_1}$ , then: either  $r_0 \neq r_1$  and  $r'_0 \neq r'_1$  in which case  $\text{Cov} [C_{k_0, r_0, r'_0}, C_{k_1, r_1, r'_1}] = 0$  as the variables are independent; or  $r_0 = r_1$  or  $r'_0 = r'_1$ , in which case since  $S_{k_0} \neq S_{k_1}$ , it cannot be that  $C_{k_0, r_0, r'_0} = 1$  and  $C_{k_1, r_1, r'_1} = 1$  simultaneously, which means that  $\text{Cov} [C_{k_0, r_0, r'_0}, C_{k_1, r_1, r'_1}] < 0$ .
- **Type II.**  $S_{k_0} = S_{k_1}$  and  $(r_0, r'_0) = (r_1, r'_1)$ , then  $\text{Cov} [C_{k_0, r_0, r'_0}, C_{k_1, r_1, r'_1}] = \text{Var} [C_{k_0, r_0, r'_0}] \leq \mathbb{E} [C_{k_0, r_0, r'_0}]$ .

■ **Type III.:**

- **Type IIIa.**  $S_{k_0} = S_{k_1}$  and  $r_0 = r_1 = r$ , however  $r'_0 \neq r'_1$ , then:

$$\text{Cov} [C_{k_0, r, r'_0}, C_{k_1, r, r'_1}] \leq \mathbb{E} [C_{k_0, r, r'_0} \cdot C_{k_1, r, r'_1}] = (D(S_{k_0}))^3$$

- **Type IIIb.**  $S_{k_0} = S_{k_1}$  and  $r'_0 = r'_1 = r'$ , however  $r_0 \neq r_1$ , then:

$$\text{Cov} [C_{k_0, r, r'_0}, C_{k_1, r, r'_1}] \leq \mathbb{E} [C_{k_0, r_0, r'} \cdot C_{k_1, r_1, r'}] = (D(S_{k_0}))^3$$

Since all pairs of indicators of Type I do not contribute to the variance, we are left to quantify how many pairs of indicators are there of Type II and Type III. Fix  $k_0 \in [s]$ , and denote  $A_{k_0} = \{i \in [s] : S_i = S_{k_0}\}$ .

- **Type II.** By assumption over  $S$ ,  $|A_{k_0}| \leq \log N$ , and so, there are at most  $\log N$  options for  $k_1$ . Then, there are  $s^2$  ways to pick  $(r, r')$ . Therefore,  $k_0$  participates in at most  $s^2 \cdot \log N$  pairs of Type II.

- **Type III.** This type is divided into two symmetric sub-types. As above, for a fixed  $k_0$ , there are at most  $\log N$  possible values for  $k_1$ . Then, there are  $s^3$  ways to pick  $r, r'_0, r'_1$ . Therefore,  $k_0$  participates in at most  $2 \cdot s^3 \cdot \log N$  pairs of Type IIIa. Type IIIb is the symmetric where both triplets agree on  $r'$ , but have two different values  $r_0$  and  $r_1$ .

First, we calculate the contribution of all the *Type II* pairs to the variance:

$$\sum_{(k_0, r, r') \in [s]^3} \sum_{k_1 \in A_{k_0}} \text{Cov} [C_{k_0, r, r'}, C_{k_1, r, r'}] \leq \sum_{(k_0, r, r') \in [s]^3} \sum_{k_1 \in A_{k_0}} \mathbb{E} [C_{k_0, r, r'}] \quad (41)$$

$$\leq \log N \sum_{(k_0, r, r') \in [s]^3} \mathbb{E} [C_{k_0, r, r'}] \quad (42)$$

$$= \log N \cdot \mathbb{E} [\tilde{C}_j^{triple}] \quad (43)$$

As for the *Type IIIa* pairs:

$$\sum_{(k_0, r, r'_0, r'_1) \in [s]^4} \sum_{k_1 \in A_{k_0}} \text{Cov} [C_{k_0, r, r'_0}, C_{k_1, r, r'_1}] \leq \sum_{(k_0, r, r'_0, r'_1) \in [s]^4} \sum_{k_1 \in A_{k_0}} (D(S_{k_0}))^3 \quad (44)$$

$$\leq \log N \sum_{(k_0, r, r'_0, r'_1) \in [s]^4} (D(S_{k_0}))^3 \quad (45)$$

$$\leq s \cdot \log N \sum_{(k_0, r, r'_0, r'_1) \in [s]^3} (D(S_{k_0}))^3 \quad (46)$$

$$= \log N \cdot \mathbb{E} [\tilde{C}_j^{triple}] \quad (47)$$

Similarly, all *Type IIIb* contribute at most  $\log N \cdot \mathbb{E} [\tilde{C}_j^{triple}]$  to the variance as well. We thus conclude that:

$$\text{Var} [\tilde{C}_j^{triple}] \leq 3 \log N \cdot \mathbb{E} [\tilde{C}_j^{triple}]$$

Therefore, using Chebichev's Inequality:

$$\Pr_{T, T'} \left( \left| \tilde{C}_j^{triple} - \mathbb{E} [\tilde{C}_j^{triple}] \right| \geq \sqrt{\frac{300 \log^2 N}{\tau} \cdot \mathbb{E} [\tilde{C}_j^{triple}]} \right) \leq \frac{3 \log N \cdot \mathbb{E} [\tilde{C}_j^{triple}]}{\frac{300 \log^2 N}{\tau} \cdot \mathbb{E} [\tilde{C}_j^{triple}]} \quad (48)$$

$$\leq \frac{\tau}{100 \log N} \quad (49)$$

Taking union bound over all  $j \in J$  yields the desired result.  $\blacktriangleleft$

# Additive Noise Mechanisms for Making Randomized Approximation Algorithms Differentially Private

Jakub Tětek     
INSAIT, Sofia, Bulgaria

---

## Abstract

---

The exponential increase in the amount of available data makes taking advantage of them without violating users' privacy one of the fundamental problems of computer science. This question has been investigated thoroughly under the framework of differential privacy. However, most of the literature has not focused on settings where the amount of data is so large that we are not even able to compute the exact answer in the non-private setting (such as in the streaming setting, sublinear-time setting, etc.). This can often make the use of differential privacy unfeasible in practice.

In this paper, we show a general approach for making Monte-Carlo randomized approximation algorithms differentially private. We only need to assume the error  $R$  of the approximation algorithm is sufficiently concentrated around 0 (e.g.  $\mathbb{E}[|R|]$  is bounded) and that the function being approximated has a small global sensitivity  $\Delta$ . Specifically, if we have a randomized approximation algorithm with sufficiently concentrated error which has time/space/query complexity  $T(n, \rho)$  with  $\rho$  being an accuracy parameter, we can generally speaking get an algorithm with the same accuracy and complexity  $T(n, \Theta(\epsilon\rho))$  that is  $\epsilon$ -differentially private.

Our technical results are as follows. First, we show that if the error is subexponential, then the Laplace mechanism with error magnitude proportional to the sum of the global sensitivity  $\Delta$  and the *subexponential diameter* of the error of the algorithm makes the algorithm differentially private. This is true even if the worst-case global sensitivity of the algorithm is large or infinite. We then introduce a new additive noise mechanism, which we call the zero-symmetric Pareto mechanism. We show that using this mechanism, we can make an algorithm differentially private even if we only assume a bound on the first absolute moment of the error  $\mathbb{E}[|R|]$ .

Finally, we use our results to give either the first known or improved sublinear-complexity differentially private algorithms for various problems. This includes results for frequency moments, estimating the average degree of a graph in sublinear time, rank queries, or estimating the size of the maximum matching. Our results raise many new questions and we state multiple open problems.

## 1 Introduction

With the increase in the amount of available data, the problem of analyzing it in a privacy-preserving manner has become a central problem in computer science. One commonly used tool for this task is differential privacy, which is a well-established notion of privacy that is commonly used in data analysis and machine learning. However, with some notable exceptions, the literature on differential privacy has focused on the setting where the amount of data is small enough that we would be able to practically solve a given problem exactly in the non-private setting. However, in practice, this assumption is often not realistic – this is after all the reason for the existence of (among others) streaming and sublinear-time algorithms.

Our goal is thus to get very efficient (sublinear) algorithms that at the same time guarantee differential privacy. In the streaming or sublinear-time setting, the error coming from the algorithm not being exact will generally speaking be much bigger than the amount of noise that the given problem necessitates for ensuring differential privacy. The main objective in this setting is thus not to simply minimize the amount of noise we add, but rather to achieve a given level of accuracy while minimizing the complexity (e.g. space, time, or query complexity) of the algorithm. Of course, some amount of noise inherently has to be added to achieve privacy, but this is usually so small, that one would need linear complexity to get such a level of accuracy even without privacy. In the sublinear regime, we thus usually do not have to worry whether a given level of accuracy is achievable and we instead focus as our central objective on the complexity needed to achieve it.

One of the main difficulties in making sublinear algorithms private is that most sublinear-time and streaming algorithms are randomized and give only probabilistic guarantees on the quality of the output. This makes adding noise based on global sensitivity<sup>1</sup> – which is commonly used to get differentially private algorithms – unsuitable for this situation, as in the worst case the global sensitivity of the approximation algorithm<sup>2</sup> can be very large even if the global sensitivity of the function being approximated is small. In this paper, we propose a way to get around this issue by showing additive noise mechanisms that only need that (1) the function being approximated has low global sensitivity and (2) the answer of the algorithm is sufficiently concentrated around the true value.

We give two main results. The first one states that if the error has subexponential tails<sup>3</sup>, adding the Laplace distribution suffices to achieve pure differential privacy – this can be seen as a generalization of the standard Laplace mechanism. The second result shows a similar result for a different distribution, and it only assumes bounded mean deviation (or higher moments) of the error instead of being subexponential. While the first result has much stronger assumption about the error distribution, it is also stronger in that it also works for multiple adaptive queries that are *not answered independently*. This is useful for example for streaming algorithms, where multiple queries can be answered using a single sketch and are thus not answered independently. Note that the standard composition theorem would allow us to perform multiple queries only if they were answered independently.

We use our results to give new differentially private algorithms for various problems: for maximum matching under node-level privacy, frequency moments, counting connected components under edge-level privacy, and rank queries. We also show how a common

---

<sup>1</sup> Global sensitivity of a function  $g$  with respect to a relation  $\sim$  is defined as  $\sup_{x \sim x'} |g(x) - g(x')|$ .

<sup>2</sup> Here, we see the approximation algorithm as a deterministic function of the input and a string of random bits.

<sup>3</sup> A distribution is subexponential if its tails are dominated by the tail of an exponential distribution.

technique for designing relative-approximation sublinear-time algorithms – *advice removal by geometric search* – can be made differentially private. This implies an edge-differentially-private algorithm for estimating the average degree of a graph, improving upon the state of the art [5], but we think it could also be useful for many other problems. Our algorithm for maximum matching also answers an open problem from [5]. For the other mentioned problems, we give the most efficient differentially private algorithm known.

Notably, a concurrent work [7] gave a similar result. In the context of global sensitivity, their result makes weaker assumptions and results in algorithms that are less efficient since they rely on postprocessing to turn approximate differential privacy into pure differential privacy. We discuss this in detail in Section 1.3.

## 1.1 Our results

We now informally state our main technical results and then we state the results for specific results that we obtained using the technical results. We also show how to use our technical results to give algorithms for specific problems in Section 1.2. We start with a result for algorithms with subexponential error tails, which appears in Section 3:

► **Theorem 9, simplified version.** Assume we have an algorithm  $A(D)$  for  $D$  being a dataset. Assume there exists a function  $g$  with global sensitivity  $\leq \Delta_1$  w.r.t.  $D$  such that  $A(D) - g(D)$  has *subexponential diameter*<sup>4</sup>  $\leq \Delta_2$ , i.e.  $\mathbb{P}[|A(D) - g(D)| \geq t] \leq 2e^{-t/\Delta_2}$  for  $t \geq 0$ . Then releasing  $A(D) + \text{Laplace}(O((\Delta_1 + \Delta_2)/\epsilon))$  is  $\epsilon$ -differentially private for  $\epsilon \leq O(1)$ .

Moreover, with noise  $\text{Laplace}(O(k(\Delta_1 + \Delta_2)/\epsilon))$ , this also holds if we make  $k$  such releases with different algorithms  $A_1, \dots, A_k$  chosen adaptively that are executed with the same randomness.

Note that this generalizes the claim that the Laplace mechanism with noise magnitude proportional to the global sensitivity gives differential privacy (this can be seen by setting  $A(D) = g(D)$ ). Note also that in the second half, the algorithms use the same randomness, and we thus cannot get this part of the result by standard composition.

We then prove in Section 4 that in the case of a single query, it is sufficient to assume a bound on some deviation moments (multiple independently answered queries can be handled using the standard composition theorem).

► **Theorem 13, simplified version.** *Let us have an algorithm  $A$  such that there exists a function  $g$  with global sensitivity  $\leq \Delta$  and such that  $\mathbb{E}[|A(D) - g(D)|^3] \leq \Delta^3$  for any dataset  $D$ . Then for  $\epsilon \leq O(1)$  there exists a random variable  $Y$  with  $\mathbb{E}[|Y|] \leq O(\Delta/\epsilon)$ , such that  $A(\cdot) + Y$  is  $\epsilon$ -differentially private.*

We now state results which, as we show in Section 5, follow from the above technical results. For all the following results, our algorithm is the most efficient known, except for the streaming algorithm for rank queries, which is incomparable with the algorithm from [19]. With the result for maximum matching, we (together with the concurrent [7]) answer positively the open question of Blocki, Grigorescu, and Mukherjee [5], and the algorithm for estimating the number of edges improves upon the algorithm from [5]. For more detailed comparison with [7], see Section 1.3.

<sup>4</sup> The subexponential diameter of a distribution roughly corresponds to the smallest parameter  $\sigma$ , such that the tail of  $\text{Laplace}(1/\sigma)$  dominates the tails of the distribution.

► **Corollaries 16–20, simplified versions.** *There exists an  $\epsilon$ -differentially private*

1. *streaming algorithm for the frequency  $F_2$  moment problem with space complexity  $O(\frac{1}{\rho^2 \epsilon^2})$  (Corollary 16),*
2. *sublinear-time algorithm for estimating the number of connected components with time complexity  $O(\frac{1}{\rho^2 \epsilon^2} \log \frac{1}{\rho \epsilon})$  (Corollary 17),*
3. *sublinear-time algorithm for estimating the size of the maximum matching with time complexity  $d^{O(1/(\rho^2 \epsilon^2))} / (\rho \epsilon)^{O(1/(\rho \epsilon))}$  (Corollary 18),*
4. *streaming algorithm for answering  $k$  (adaptive) rank queries in space  $O(\frac{k \log^2 k}{\rho \epsilon})$  (Corollary 19),*
5. *sublinear-time algorithm for approximating the number of edges in a graph in time  $O(\frac{n}{\epsilon^2 \rho^2 \sqrt{m}})$  (Corollary 20).*

## 1.2 Our techniques

We now sketch the techniques that we use in our paper. In each part of this section, we also give a reference to the corresponding section of this paper.

### 1.2.1 Subexponential error, one query (Section 3)

Suppose we have a randomized algorithm  $A(D)$  for  $D$  being a dataset that approximates a function  $g(D)$  with global sensitivity  $\leq \Delta_1$  for some parameter  $\Delta_1$ . Define the error  $R$  as the random variable  $R = A(D) - g(D)$  and assume that it is tightly concentrated around 0, namely  $\mathbb{P}[|R| > t] \leq 2e^{-t/\Delta_2}$  for some value  $\Delta_2$  ( $\Delta_2$  is an upper bound on the “subexponential diameter” of  $R$ ). Intuitively speaking,  $\Delta_2$  determines the “scale” of  $R$ , and  $\Delta_2$  is in fact up to a constant factor an upper bound on  $\mathbb{E}[|R|]$ . Note that the tails of  $R$  decrease at least at the same rate as those of the Laplace distribution. This suggests Laplacian noise with large enough magnitude could “hide  $R$ ”. Indeed, we prove that Laplacian noise will guarantee privacy. We now sketch the proof.

**High-level view.** Assume for simplicity that both  $\Delta_1, \Delta_2 \leq 1$ . The same approach works for general values of  $\Delta_1, \Delta_2$  by simple re-scaling. Let  $Y \sim \text{Laplace}(c/\epsilon)$  for appropriately chosen value of  $c$ . We will prove that for any random variable  $X$  with subexponential diameter  $\leq 3$ <sup>5</sup> (that is  $\mathbb{P}[|X| \geq t] \leq 2e^{-t/3}$ ), the probability density functions satisfy  $f_{X+Y}(y)/f_Y(y) = e^{\pm\Theta(\epsilon)}$  for any  $y$ . We can use this to prove privacy, as we now show. For two neighboring datasets  $D_1, D_2$ , we set  $R_1 = A(D_1) - g(D_1)$  and  $R_2 = A(D_2) - g(D_1)$  (note the asymmetry in the definitions). It then holds that  $R_1$  has subexponential diameter  $\Delta_2 \leq 1$ . One can also show that the subexponential diameter of  $R_2 = (A(D_2) - g(D_2)) + (g(D_2) - g(D_1))$  is  $\leq 3$  (Lemma 5). Let  $y' = y - g(D_1)$ . It then holds for any  $y$  that

$$\frac{f_{A(D_1)+Y}(y)}{f_{A(D_2)+Y}(y)} = \frac{f_{g(D_1)+R_1+Y}(y)}{f_{g(D_1)+R_2+Y}(y)} = \frac{f_{R_1+Y}(y')}{f_{R_2+Y}(y')} = \frac{f_{R_1+Y}(y')}{f_Y(y')} \cdot \frac{f_Y(y')}{f_{R_2+Y}(y')} = e^{\pm\Theta(\epsilon)}$$

where the last equality uses the claim  $f_{X+Y}(y')/f_Y(y') = e^{\pm\Theta(\epsilon)}$  for  $X = R_1$  and for  $X = R_2$ . This implies differential privacy.

<sup>5</sup> We choose value 3 as this is the value we will need below. The claim holds also for larger constants with  $c$  chosen appropriately.

**Bounding ratios of density functions.** We now sketch why  $f_{X+Y}(y)/f_Y(y) = e^{\pm\Theta(\epsilon)}$ . Since  $Y$  is continuous, we may re-write

$$f_{X+Y}(y) = \mathbb{E}[f_Y(y - X)] = \frac{\epsilon}{2c} \mathbb{E}[e^{-\epsilon|X-y|/c}] = (*)$$

where the first equality is a standard identity [16]. We now use the inequalities  $|X - y| \leq |X| + |y|$  and  $|X - y| \geq |y| - |X|$ . This allows to bound

$$\begin{aligned} (*) &\leq \frac{\epsilon}{2c} \mathbb{E}[e^{-\epsilon(|y|-|X|)/c}] = \frac{\epsilon}{2c} e^{-\epsilon|y|/c} \mathbb{E}[e^{\epsilon|X|/c}] \\ (*) &\geq \frac{\epsilon}{2c} \mathbb{E}[e^{-\epsilon(|X|+|y|)/c}] = \frac{\epsilon}{2c} e^{-\epsilon|y|/c} \mathbb{E}[e^{-\epsilon|X|/c}] \end{aligned}$$

while it holds that  $f_Y(y) = \frac{\epsilon}{2c} e^{-\epsilon|y|/c}$ . It is thus sufficient to prove that  $\mathbb{E}[e^{\epsilon|X|/c}] \leq e^{O(\epsilon)}$  and  $\mathbb{E}[e^{-\epsilon|X|/c}] \geq e^{-O(\epsilon)}$ . While the first inequality is standard, the second is not. We will now sketch a proof for both.

**Bounding the expectation of exponentials of a subexponential random variable.** If we knew the density function of  $X$ , we could easily express the expectations as integrals. However, not only we do not have a bound on the density, but the density may even not exist. We thus use the following trick. We use the fact that for any real random variable  $Z$ , it holds that  $Z$  has the same distribution as  $F_Z^{-1}(u)$  for  $u \sim \text{Unif}(0, 1)$  where  $F_Z$  is the cumulative distribution function (CDF) of  $Z$ . This allows us to write  $\mathbb{E}[e^{-\epsilon|X|/c}] = \mathbb{E}_u[e^{-F_{\epsilon|X|/c}^{-1}(u)}]$  and similarly for  $\mathbb{E}[e^{\epsilon|X|/c}]$ .

Unlike the density function, we do have a bound on the cumulative distribution function. Specifically, we are assuming  $\mathbb{P}[|X| > t] \leq 2e^{-t/3}$  which implies that  $F_{\epsilon|X|/c}^{-1}(u) \leq -\frac{3\epsilon}{c} \log(\frac{1-u}{2})$ . Upper-bounding the CDF like this reduces the problem to computing the expectation of a function of the uniform random variable, which can be done straightforwardly. This proves the desired bounds.

### 1.2.2 Subexponential error, multiple queries (Section 3)

We would like to be able to release answers to multiple queries which are not answered independently (such as if they are answered based on the same sketch). Since the answers are not independent, we cannot use the composition theorem. We now sketch an alternative approach.

For fixed queries, the above proof goes through with minor modifications even in the multivariate case. Instead of using the inequalities  $|y - X| \leq |y| + |X|$  and  $|y - X| \geq |y| - |X|$  in the case of  $y, X \in \mathbb{R}$ , we use the analogous version for  $\ell_1$  norms in the case of  $y, X \in \mathbb{R}^k$ :  $\|y - X\|_1 \leq \|y\|_1 + \|X\|_1$  and  $\|y - X\|_1 \geq \|y\|_1 - \|X\|_1$ . We then use that if  $X$  is a vector of  $k$  subexponential random variables with diameter  $\leq \Delta$ , then  $\|X\|_1$  has subexponential diameter  $\leq 3k\Delta$  (Lemma 5).

This however gives the result only in the nonadaptive case, when the queries do not depend on the released values: the identity  $f_{X+Y}(y) = \mathbb{E}[f_Y(X - y)]$  relies crucially on  $X = (X_1, \dots, X_k)$  and  $Y = (Y_1, \dots, Y_k)$  being independent. In the case of adaptive queries,  $X_i$  could depend on  $Y_1, \dots, Y_{i-1}$  (the query that we perform – and thus also the answer to it – can be influenced by the noise we add to the previous answers). We instead use our non-adaptive version of the claim and make it adaptive in a black box fashion, by proving a claim that may be of independent interest: If we have a countable number of mechanisms such that releasing the answers of any *fixed* subset of size  $k$  is  $\epsilon$ -differentially private, then we may also pick this subset *adaptively* and it will still be  $\epsilon$ -differentially private.

### 1.2.3 Error with polynomial tails (Section 4)

In the case that the error has polynomial tails, we only consider the case of a single query. Our techniques do not seem to generalize to the multivariate case, and we conjecture that this is impossible (see Section 6). The case when multiple queries are answered independently may be still handled by the standard composition theorem.

An approach similar to the one described above can be made to work, with the difference that we use the inequality  $|x - X| \geq \max(0, |x| - |X|)$  instead of the weaker  $|x - X| \geq |x| - |X|$ . This approach, however, requires proving the following inequality for all  $y, s \geq 0, \alpha > 1, 0 \leq \epsilon \leq 1$ :

$$\int_0^1 \min \left( (1 + |y|/s)^\alpha, \left| 1 - \frac{(1 - 2^{-1/\alpha})\epsilon}{(1 + |y|/s)(1 - u)^{1/\alpha}} \right|^{-\alpha} \right) du \leq 1 + \frac{2\alpha - 1}{\alpha - 1} \epsilon.$$

This is the technically most challenging part of this paper. The trick is to bound the inside of the integral for  $u \in [0, 1 - \epsilon(1 + |y|/s)^{-\alpha}]$  by a simpler expression that can be successfully integrated. The rest of the interval  $[0, 1]$  contributes at most  $\epsilon$ , as its length is  $\epsilon(1 + |y|/s)^{-\alpha}$  and the maximum value of the function being integrated is  $\leq (1 + |y|/s)^\alpha$ .

### 1.2.4 How to use our technical results (Section 5)

#### 1.2.4.1 Error with subexponential tails

We now sketch how one can use Theorem 9 to get differentially private mechanisms for specific problems. Recall that the theorem states that if our algorithm approximates a function with global sensitivity  $\leq \Delta_1$  and the subexponential diameter of the error is  $\leq \Delta_2$ , then adding noise from  $Laplace(O(\Delta_1 + \Delta_2)/\epsilon)$  makes the algorithm  $\epsilon$ -differentially private.

We start with a randomized approximation algorithm whose error is subexponentially concentrated around zero (often, this is either known or easy to prove) that approximates a parameter with a small global sensitivity  $\Delta_1$ . This is the case for example for the YYI maximum matching algorithm [34] under node-level privacy or the KLL sketch [20] for rank queries. Suppose the complexity (such as time/space/query/sample or other complexity) of the algorithm is  $T(n, \rho)$  and has additive error of scale (i.e. with subexponential diameter)  $\rho n$ . If we want the final error with privacy to be  $O(\rho n)$ , then we run the algorithm with error parameter  $\epsilon \rho$ , making the error's subexponential diameter be  $O(\epsilon \rho n)$ . We then get from Theorem 9 that adding noise of magnitude  $O(\rho n)$  is sufficient to get  $\epsilon$ -differential privacy, assuming  $\Delta_1$  is sufficiently small, giving us the desired result. The complexity of the private algorithm will thus be  $T(n, \Theta(\epsilon \rho))$ . This allows us to achieve a given level of accuracy<sup>6</sup> under pure differential privacy, while not significantly worsening the algorithm's complexity. We describe this approach in greater detail and with general failure probabilities (not just constant) in Section 5.

To illustrate the second part of the theorem, consider for example a rank queries sketch (see Section 5.5 for details). The algorithms  $A_1, \dots, A_k$  correspond to making  $k$  adaptive queries to the sketch of a dataset (assume we are given  $k$  queries we need to perform) and the fact that the algorithms use the same randomness corresponds to us querying the same sketch (as compared to  $k$  independent sketches). Specifically, the algorithm  $A_i$  here builds

<sup>6</sup> This is true unless  $\rho$  is very small, as otherwise the global sensitivity will necessitate some level of noise. As we noted, this usually happens only when  $T(n, \epsilon \rho) \geq \Omega(n)$ , making this uninteresting for our sublinear setting.

the sketch (using the shared randomness), and then performs the  $i$ -th query. Note that the fact that we only use one sketch *prevents us from using the composition theorem* to get this from just the first part of the theorem.

### 1.2.4.2 Error with polynomial tails

If the error has polynomial tails, we can make it private in a way essentially the same as in the subexponential case using Theorem 13. Moreover, it holds that if we have  $\mathbb{E}[|A(D) - g(D)|] \leq \Delta$ , then by taking a median of 5 independent executions of  $A$ , we get an algorithm  $A'$  whose error's third moment is also bounded:  $\mathbb{E}[|A'(D) - g(D)|^3] \leq O(\Delta^3)$  [21]. This means that we can make an algorithm private even if we only have a bound on  $\mathbb{E}[|A(D) - g(D)|]$ , for  $g$  being a low-global-sensitivity function, or the mean squared error  $\mathbb{E}[(A(D) - g(D))^2]$ .

## 1.3 Related work

To the best of our knowledge, the work on differentially private approximation algorithms started with private sketches. Mir, Muthukrishnan, Nikolov, and Wright [25] gave pan-private<sup>7</sup> sketches for heavy hitters. An improved sketch has been recently given by Pagh and Thorup [27]. A private version of the deterministic Misra-Gries sketch [26] for heavy hitters has been recently given by Tětek and Lebeda [22]. Heavy hitters were also investigated in the multi-party computation setting [18], in the local differential privacy setting [3], and using cryptographic assumptions [24, 17, 18].

A sketch for fractional frequency moments  $F_p$  for  $0 \leq p \leq 1$  has been given by Wang, Pinelis, and Song [33]. After releasing this paper, Epasto, Mao, Andres, Mirrokni, Vassilvitskii, and Zhong [15] have given an algorithm general value of  $p$  in the continual release setting. A sketch for differentially private quantiles has been given by Alabi, Ben-Eliezer, and Chaturvedi [1]. A technique for stream sanitization has been given by Kaplan and Stemmer [19]; this work resulted in improved differentially private sketches for approximate quantiles. An approach for differentially privately estimating distances in euclidean spaces using private sketches has been given by Stausholm [31]. A general approach to making linear sketches differentially private was given by Zhao, Qiao, Redberg, Agrawal, Abbadi, and Wang [35].

A recent line of work has shown that many sketches already provide privacy *by themselves* or with only small modifications, without adding any noise. Blocki, Blum, Datta, and Sheffet [6] have shown that the Johnson-Lindenstrauss transform by itself ensures differential privacy. Smith, Song, and Guha Thakurta [30] have shown that this is also the case for the Flajolet-Martin sketch for counting distinct elements and a similar result is known for the LogLog algorithm [9, 11]. This was recently generalized [10] to show that this is not only the case for the two above-mentioned sketches, but in fact for a large class of sketches for counting distinct elements.

As far as sublinear-time algorithms are concerned, Sivasubramaniam, Li, and He [29] have shown a differentially private algorithm that returns a  $2 + \rho$  approximation of the number of edges in a graph in time  $\tilde{O}_{\rho, \epsilon}(\sqrt{n})$ . This has been later improved by Blocki, Grigorescu, and Mukherjee [5] to  $1 + \rho$  approximation in the same complexity. In that paper, the authors also give differentially private sublinear algorithms for approximate maximum matching and vertex cover. A sublinear time algorithm for estimating the median was recently discovered [8].

<sup>7</sup> An algorithm on an input stream is said to be pan-private if releasing the internal state of the algorithm at any point in the computation is differentially private. It is a strictly stronger notation than differential privacy of the output.

## Concurrent work

The problem of differentially private randomized approximation algorithms has been explored independently of this work by Blocki, Grigorescu, Mukherjee, and Zhou [7]. The techniques used in [7] differ significantly from those used in this paper. Specifically, in [7], the authors set the failure probability of the algorithm to be  $\leq \delta$  (for example by probability amplification), thus limiting the global sensitivity of the algorithm up to an event of probability  $\leq \delta$ . This allows them to rely on the standard result for getting differential privacy based on global sensitivity<sup>8</sup>. Specifically, if the algorithm has complexity  $T(n, \rho)$  and one uses probability amplification, then the approach of [7] gives an  $(\epsilon, \delta)$ -differential privacy in complexity  $O(T(n, \epsilon\rho) \log \delta^{-1})$ . They then show that one can post-process the output of the algorithm to achieve pure differential privacy.

In this paper, instead of relying just on global sensitivity, we instead prove privacy from first principles. At the cost of assuming that the error is sufficiently concentrated, we show that the probability amplification step is not needed, allowing us to get  $\epsilon$ -differential privacy in the better complexity of  $T(n, \epsilon\rho)$ . Our approach allows us to give more efficient algorithms than Blocki, Grigorescu, Mukherjee, and Zhou [7] for several problems: estimating the average degree of a graph, estimating the size of a maximum matching, and estimating the number of connected components.

## 2 Preliminaries

### 2.1 Differential privacy

Throughout the paper, we assume that we have a symmetric “neighbor” relation  $\sim$  on the set of all possible datasets. Intuitively speaking, in the case when we have a database of users, this should correspond to two datasets being the same except for the data of one user whose privacy we are trying to protect.

► **Definition 1** ([12]). *A randomized algorithm  $M$  with range  $S$  is  $\epsilon$ -differentially private if for any measurable  $T \subseteq S$ , it holds for any  $x \sim x'$  for a symmetric “neighbor” relation  $\sim$ , that*

$$e^{-\epsilon} \leq \frac{\mathbb{P}[M(x) \in T]}{\mathbb{P}[M(x') \in T]} \leq e^{\epsilon}$$

This definition is commonly relaxed to a notion called approximate differential privacy, with the above notion then being called pure privacy. In this paper, we will focus only on pure differential privacy.

If the output of  $M$  is a continuous random variable, then it is sufficient to prove that for any  $y$  and  $x \sim x'$  it holds  $e^{-\epsilon} \leq f_{M(x)}(y)/f_{M(x')}(y) \leq e^{\epsilon}$ , where  $f_X$  for  $X$  being a continuous random variable is the probability density function of  $X$ .

The global sensitivity [13] of a function  $g$  is defined as

$$\sup_{x \sim x'} |g(x) - g(x')|.$$

The authors have shown that if  $g$  has global sensitivity  $\Delta$ , then adding  $\text{Laplace}(\Delta/\epsilon)$  provides  $\epsilon$ -differential privacy.

<sup>8</sup> They also consider functions with low smoothed sensitivity instead of just low global sensitivity; we do not consider that in this paper.

In the context of graph problems, one often speaks of a mechanism being edge-differentially private, or node-differentially private. These terms refer to the relation  $\sim$  that is used. In the case of node-differential privacy, we have  $G \sim G'$  iff one can get  $G$  from  $G'$  by deleting one vertex and the incident edges, or the other way around. In the case of edge-differential privacy, we have  $G \sim G'$  iff one can get  $G$  from  $G'$  by deleting one edge, or the other way around.

## 2.2 Probability theory

If  $D$  is a distribution, we use  $D^{\otimes k}$  for  $k$  being a natural number, to denote the  $k$ -fold product distribution of  $D$ . For a random variable  $Z$ , we denote by  $F_Z$  its cumulative distribution function. We denote by  $F_Z^{-1}(p) = \inf\{x \in \mathbb{R} : F_Z(x) \geq p\}$  its generalized inverse. It holds that  $F_Z^{-1}(u)$  has the same distribution as  $Z$  for  $u \sim \text{Unif}(0, 1)$  [23]. We will need the following claim.

► **Fact 2** ([16]). *Let  $X, Y$  be independent random variables in  $\mathbb{R}^k$ , and assume  $Y$  has a probability density function (pdf)  $f_Y(z)$ . Then the pdf of  $X + Y$  is  $f_{X+Y}(z) = \mathbb{E}[f_Y(z - X)]$ .*

### Concentration of measure

The notions of *subexponential* random variables and *subexponential diameter*  $\sigma_{se}[X]$  are central to concentration of measure. There are several different definitions for  $\sigma_{se}[X]$ , that differ by constant factors. See for example [32, Chapter 2] for an exposition of the various definitions. In this paper, one of the definitions is especially suitable for the way we use it in our proofs, and that is the definition that we use.

► **Definition 3.** *Let  $X$  be a real random variable. We define the subexponential diameter of  $X$ , denoted by  $\sigma_{se}[X]$  as the smallest values for which for any  $t > 0$  holds*

$$\mathbb{P}[|X| \geq t] \leq 2 \exp(-t/\sigma_{se}[X])$$

A random variable  $X$  is said to be subexponential if  $\sigma_{se}[X] < \infty$ .

It holds that  $\sigma_{se}[cX] = c\sigma_{se}[X]$ . It also holds that

► **Fact 4.** *For  $X$  being a random variable and  $c \geq 0$ , it holds that  $\sigma_{se}[X+c] \leq \sigma_{se}[X] + c/\log 2$ .*

**Proof.** We can bound  $\mathbb{P}[X + c \geq t] \leq \min(1, 2e^{-(t-c)/\sigma_{se}[X]}) \leq \min(1, 2e^{-t/(\sigma_{se}[X]+c/\log 2)})$ , thus implying the claim. ◀

Finally, the following is a standard claim, but we need the constant factor, which is specific to the definition of  $\sigma_{se}$  that we are using. We thus give a proof in the full version of this paper, based on the standard proof of triangle inequality for Orlicz norms.

► **Lemma 5.** *Let us have real random variables  $X_1, \dots, X_k$ . It holds*

$$\sigma_{se}\left[\sum_{i=1}^k X_i\right] \leq 3 \sum_{i=1}^k \sigma_{se}[X_i]$$

### 3 Algorithms with subexponential error

In this section, we show how algorithms, whose error has a small subexponential diameter, can be made differentially private. We start by proving a technical lemma. We will later bound the ratios between probability densities of our mechanism's answers by the exponential expectations that we now bound and, finally, we will use that to prove privacy in Theorem 9, which is the main theorem of this section.

Note that while the second of the two inequalities is standard, the first one is not. Our proof does not follow the strategy of the standard proof of the second inequality, which is based on a Taylor expansion and does not seem to straightforwardly apply to the first inequality.

► **Lemma 6.** *Suppose  $X$  is a random variable with subexponential diameter  $\Delta \leq 1/2$ . It holds  $\mathbb{E}[e^{-|X|}] \geq \frac{2^{-\Delta}}{1+\Delta} \geq e^{-(1+\log 2)\Delta}$  and  $\mathbb{E}[e^{|X|}] \leq \frac{2^\Delta}{1-\Delta} \leq e^{3\log(2)\Delta}$ .*

**Proof.** Since  $X$  is subexponential with diameter  $\Delta$ , it holds that  $\mathbb{P}[|X| \geq z] \leq 2e^{-z/\Delta}$ . Therefore,  $F_{|X|}^{-1}(u) \leq -\Delta \log(\frac{1-u}{2})$ . We use the fact that for  $u \sim \text{Unif}(0, 1)$ , the random variable  $F_{|X|}^{-1}(u)$  has the same distribution as  $|X|$ . We can now bound

$$\begin{aligned}
 \mathbb{E}[e^{-|X|}] &= E_u[e^{-F_{|X|}^{-1}(u)}] \\
 &\geq E_u[e^{\Delta \log(\frac{1-u}{2})}] \\
 &= 2^{-\Delta} E_u[(1-u)^\Delta] \\
 &= 2^{-\Delta} \int_0^1 (1-u)^\Delta du \\
 &= 2^{-\Delta} \left[ -\frac{(1-u)^{\Delta+1}}{\Delta+1} \right]_{u=0}^1 \\
 &= \frac{2^{-\Delta}}{1+\Delta} \geq e^{-(1+\log 2)\Delta}
 \end{aligned} \tag{1}$$

where the last inequality holds because we can equivalently write  $2^{-\Delta}/(\Delta+1) \geq (2e)^{-\Delta}$ , which simplifies to  $e^\Delta \geq 1+\Delta$ , which is a standard inequality. Similarly, we can bound  $\mathbb{E}[e^{|X|}]$  as follows.

$$\begin{aligned}
 \mathbb{E}[e^{|X|}] &= E_u[e^{F_{|X|}^{-1}(u)}] \\
 &\leq E_u[e^{-\Delta \log(\frac{1-u}{2})}] \\
 &= \frac{2^\Delta}{1-\Delta} \leq e^{3\log(2)\Delta}
 \end{aligned}$$

where the second equality is by substituting  $\Delta$  with  $-\Delta$  in (1) (since as we have shown, (1) is equal to  $2^{-\Delta}/(1+\Delta)$ ). We have here used that  $\Delta < 1$  (otherwise the final expression may not be defined). The last inequality can be shown as follows: we take the ratio of the two sides resulting in  $h(\Delta) = 4^\Delta(1-\Delta)$  and we show  $h(\Delta) \geq 1$  for  $0 \leq \Delta \leq 1/2$ . The function  $h$  is concave (the second derivative is  $-2 \cdot 2^{2\Delta} \log 4 + 2^{2\Delta} \log^2 4$ , which can be easily seen to be negative), meaning that it is sufficient to check that the inequality holds at the endpoints of the interval  $[0, 1/2]$ : that  $h(0) \geq 1$  and  $h(1/2) \geq 1$ . One can easily check this holds. ◀

We are now ready to prove a lemma about the ratio of the density function of a Laplace and of Laplace shifted by a subexponential random variable. We will then use this to prove differential privacy. Note that the random variables in the lemma do not have to be independent.

► **Lemma 7.** *Let  $X_1, \dots, X_k$  be random variables with subexponential diameter at most  $\Delta$  and let  $X = (X_1, \dots, X_k)$ . Let  $Y \sim \text{Lap}^{\otimes k}(k\Delta/\epsilon)$  for  $\epsilon \leq 1/6$ . Consider  $y \in \mathbb{R}^k$ . It holds  $e^{-3(1+\log 2)\epsilon} \leq f_{X+Y}(y)/f_Y(y) \leq e^{9\log(2)\epsilon}$ . Moreover, if  $k = 1$  and  $\epsilon \leq 1/2$ , it holds  $e^{-(1+\log 2)\epsilon} \leq f_{X+Y}(y)/f_Y(x) \leq e^{3\log(2)\epsilon}$ .*

**Proof.** By Fact 2, we have

$$f_{X+Y}(y) = \mathbb{E}[f_Y(y - X)] = \left(\frac{\epsilon}{2k\Delta}\right)^k \mathbb{E}[\exp(-\frac{\epsilon}{k\Delta}\|X - y\|_1)]$$

For the sake of brevity, we let  $\gamma = \left(\frac{\epsilon}{2k\Delta}\right)^k$ . We may bound  $\|X - y\|_1 \leq \|X\|_1 + \|y\|_1$  and  $\|X - y\|_1 \geq \|y\|_1 - \|X\|_1$ . This allows us to bound

$$\begin{aligned} f_{X+Y}(y) &= \gamma E \left[ \exp\left(\frac{-\epsilon\|X - y\|_1}{k\Delta}\right) \right] \\ &\geq \gamma E \left[ \exp\left(\frac{-\epsilon(\|X\|_1 + \|y\|_1)}{k\Delta}\right) \right] \\ &= \gamma \exp\left(\frac{-\epsilon\|y\|_1}{k\Delta}\right) E \left[ \exp\left(\frac{-\epsilon\|X\|_1}{k\Delta}\right) \right] \\ &\geq \gamma \exp\left(\frac{-\epsilon\|y\|_1}{k\Delta}\right) \exp(-3(1 + \log 2)\epsilon) \end{aligned} \tag{2}$$

where the last inequality is by Lemma 6; we used that  $\frac{\epsilon\|X\|_1}{k\Delta}$  has subexponential diameter  $\leq 3\epsilon \leq 1/2$ , since we have by Lemma 5 that  $\sigma_{se}[\|X\|] \leq 3k\Delta$ . In the case  $k = 1$ , we simply have that  $\sigma_{se}[\frac{\epsilon\|X\|_1}{k\Delta}] \leq \epsilon$ , in which case the final bound on (2) is

$$\geq \gamma \exp\left(\frac{-\epsilon\|y\|_1}{k\Delta}\right) \exp(-(1 + \log 2)\epsilon)$$

At the same time,  $f_Y(y) = \gamma \exp(-\frac{\epsilon\|y\|_1}{k\Delta})$  and thus

$$\begin{aligned} \frac{f_{X+Y}(y)}{f_Y(y)} &\geq e^{-3(1+\log 2)\epsilon} && \text{if } k > 1 \\ \frac{f_{X+Y}(y)}{f_Y(y)} &\geq e^{-(1+\log 2)\epsilon} && \text{if } k = 1 \end{aligned}$$

Similarly, we can bound

$$\begin{aligned} f_{X+Y}(y) &= \gamma E \left[ \exp\left(\frac{-\epsilon\|X - y\|_1}{k\Delta}\right) \right] \\ &\leq \gamma E \left[ \exp\left(\frac{-\epsilon(\|y\|_1 - \|X\|_1)}{k\Delta}\right) \right] \\ &= \gamma \exp\left(\frac{-\epsilon\|y\|_1}{k\Delta}\right) E \left[ \exp\left(\frac{\epsilon\|X\|_1}{k\Delta}\right) \right] \\ &\leq \gamma \exp\left(\frac{-\epsilon\|y\|_1}{k\Delta}\right) \exp(9\log(2)\epsilon) \end{aligned}$$

in the case  $k > 1$  and

$$f_{X+Y}(y) \leq \gamma \exp\left(\frac{-\epsilon\|y\|_1}{k\Delta}\right) \exp(3\log(2)\epsilon)$$

in the case  $k = 1$ . Thus, we have

$$\begin{aligned} \frac{f_{X+Y}(y)}{f_Y(y)} &\leq e^{9 \log(2)\epsilon} && \text{if } k > 1 \\ \frac{f_{X+Y}(y)}{f_Y(y)} &\leq e^{3 \log(2)\epsilon} && \text{if } k = 1 \end{aligned} \quad \blacktriangleleft$$

We now state a useful technical lemma; the proof appears in the full version. This lemma states that in general, if we have a countable number of mechanisms and releasing any fixed  $k$  of them is differentially private, then picking the mechanisms adaptively will not violate differential privacy. The proof roughly follows the outline of the proof of adaptive composition [28]. In what follows, we again use the subscript  $\cdot_r$  to denote a random bitstring used as the source of randomness of the mechanisms.

► **Lemma 8.** *Let us have a countable number of mechanisms  $M_{1,r}, \dots$ , such that releasing the value  $(M_{i_1,r}(D), \dots, M_{i_k,r}(D))$  is  $\epsilon$ -differentially private for any fixed  $i_1, \dots, i_k \in [n]$ . Then the mechanism  $(M_{j_1,r}(D), \dots, M_{j_k,r}(D))$  is  $\epsilon$ -differentially private for  $j_1, \dots, j_k \in [n]$  such that  $j_\ell$  for  $\ell \in [k]$  is drawn from a distribution which is a function of  $M_{j_1,r}(D), \dots, M_{j_{\ell-1},r}(D)$ .*

We are now ready to prove the main theorem of this section. In what follows, we denote by  $A_r(\cdot)$  the algorithm  $A$  executed with randomness  $r$ . We formalize the multiple-query setting as having one algorithm which takes as part of its input a query. This differs somewhat from the presentation in the introduction which assumed we have a sequence of algorithms, which we chose there as it required less notation. Note also that while we are not assuming that the algorithm does not know which phase it is (the value of  $i$ ), we may without loss of generality assume this is passed as part of the query. Note that the condition on the queries  $x_1, \dots, x_k$  below simply states that the queries can be chosen adaptively based on the released values, and that they do not have to be deterministic. Note also that the randomness  $r$  must not be released, as the privacy also relies on that randomness.

► **Theorem 9.** *Let us have an algorithm  $A(D, x)$  for a database  $D$  and a query  $x \in U$ , where  $U$  is a countable universe. Assume there exists a function  $g(D, x)$  with its global sensitivity w.r.t.  $D$  being  $\leq \Delta_1$  for any  $x$ , and such that  $\sigma_{se}[A(D, x) - g(D, x)] \leq \Delta_2$  for any  $D, x$ .*

*Pick at random  $Y_i \sim \text{Laplace}(c(\Delta_1 + \Delta_2)k/\epsilon)$  for  $c = 3 + 12 \log 2$  and for  $\epsilon \leq c/6$  and pick  $r$  independently uniformly on  $\{0, 1\}^\infty$ . Then for queries  $x_1, \dots, x_k \in U$  where the query  $x_i$  is drawn from a distribution that is a function of  $A_r(D, x_1) + Y_1, \dots, A_r(D, x_{i-1}) + Y_{i-1}$ , releasing  $(A_r(D, x_1) + Y_1, \dots, A_r(D, x_k) + Y_k)$  is  $\epsilon$ -differentially private, with the privacy also being over the randomness of  $r$ .*

*If  $k = 1$ , then  $c = 1 + 4 \log 2$  and  $\epsilon \leq c/2$  is sufficient.*

**Proof.** Let us have two neighboring databases  $D_1, D_2$ . Let  $Y = (Y_1, \dots, Y_k)$ , and for  $x = (x_1, \dots, x_k)$ , let  $A'(D, x) = (A_r(D, x_1) + Y_1, \dots, A_r(D, x_k) + Y_k)$  for  $r$  uniform on  $\{0, 1\}^\infty$ . Similarly, let  $g(D, x) = (g(D, x_1), \dots, g(D, x_k))$ . We prove that for any fixed (non-adaptive) queries  $x = (x_1, \dots, x_k)$  it holds  $f_{A'(D_1, x)}(y)/f_{A'(D_2, x)}(y) \leq e^\epsilon$ . If we prove this, the theorem follows: the inequality  $f_{A'(D_1, x)}(y)/f_{A'(D_2, x)}(y) \geq e^{-\epsilon}$  holds by symmetry and these bounds together imply  $\epsilon$ -differential privacy. Lemma 8 then imply that  $A'$  is differentially private even for adaptive queries.

Let  $R_1 = A'(D_1, x) - g(D_1, x)$  and  $R_2 = A'(D_2, x) - g(D_1, x)$  (note the asymmetry in the definitions). We are assuming  $R_1$  has subexponential diameter  $\leq \Delta_2$ . By Fact 4, it holds that  $R_2$  has subexponential diameter  $\leq \Delta_1/\log(2) + \Delta_2$ . We now have from Lemma 7 the following bounds

$$\begin{aligned}\frac{f_{g(D_1,x)+R_1+Y}(y)}{f_{g(D_1,x)+Y}(y)} &= \frac{f_{R_1+Y}(y-g(D_1,x))}{f_Y(y-g(D_1,x))} \leq e^{9\log(2)\epsilon/c} \\ \frac{f_{g(D_2,x)+R_2+Y}(y)}{f_{g(D_1,x)+Y}(y)} &= \frac{f_{R_2+Y}(y-g(D_2,x))}{f_Y(y-g(D_1,x))} \geq e^{-3(1+\log 2)\epsilon/c}\end{aligned}$$

which in turn allows us to bound

$$f_{A'(D_1,x)}(y)/f_{A'(D_2,x)}(y) = \frac{f_{g(D_1,x)+R_1+Y}(x)}{f_{g(D_1,x)+Y}(x)} \cdot \frac{f_{g(D_1)+Y}}{f_{g(D_2)+R_2+Y}(x)} \leq e^{(3+12\log 2)\epsilon/c} = e^\epsilon$$

If  $k = 1$ , the same computation gives the desired bound for  $c = 1 + 4\log 2$ , since Lemma 7 in that case gives

$$\begin{aligned}\frac{f_{g(D_1,x)+R_1+Y}(y)}{f_{g(D_1,x)+Y}(y)} &\leq e^{3\log(2)\epsilon/c} \\ \frac{f_{g(D_2,x)+R_2+Y}(y)}{f_{g(D_1,x)+Y}(y)} &\geq e^{-(1+\log 2)\epsilon/c}\end{aligned}$$

which again results in the bound  $f_{A'(D_1,x)}(y)/f_{A'(D_2,x)}(y) \leq e^\epsilon$ . ◀

#### 4 Algorithms with bounded mean error

In this section, we show a weaker version of Theorem 9 that only requires that the error has some number of bounded moments, instead of requiring that it is subexponential. We start by defining the distribution that we will use in our additive noise mechanism.

► **Definition 10.** *Zero-symmetric Pareto distribution with shape parameter  $\alpha > 1$  and scale parameter  $s > 0$ , denoted  $ZSPareto_\alpha(s)$ , is defined by the PDF*

$$\frac{1}{2s}(\alpha - 1)(|x|/s + 1)^{-\alpha}$$

Before we can prove the main theorem of this section, we need the following technical lemma. The proof is rather technical and it appears in the full version of this paper.

► **Lemma 11.** *Let us have any  $0 \leq \epsilon \leq 1$ ,  $\alpha > 1$ , and  $x \geq 0$ . It holds*

$$\int_0^1 \min\left((1+x)^\alpha, \left|1 - \frac{(1-2^{-1/\alpha})\epsilon}{(1+x)(1-u)^{1/\alpha}}\right|^{-\alpha}\right) du \leq 1 + \frac{2\alpha-1}{\alpha-1}\epsilon \quad (3)$$

We are now ready to prove a lemma which bound the privacy loss of our mechanism. In what follows, we use the notation  $\|X\|_p$  for a random variable  $X$  to denote the  $L_p$  norm  $\sqrt[p]{\mathbb{E}[|X|^p]}$ .

► **Lemma 12.** *Let  $X$  be a real random variable such that  $\|X\|_\alpha \leq \Delta$  and let  $Y \sim ZSPareto_\alpha(s)$  for  $s = (1 - 2^{-1/\alpha})^{-1}\Delta/\epsilon$  for  $0 \leq \epsilon \leq 1$  and  $\alpha > 1$ . Consider  $y \in \mathbb{R}$ . It holds  $e^{-(1-2^{-1/\alpha})\alpha\epsilon} \leq f_{X+Y}(y)/f_Y(y) \leq e^{\frac{2\alpha-1}{\alpha-1}\epsilon}$ .*

**Proof.** Since  $\|X\|_\alpha \leq \Delta$ , it holds by the higher-order Chebyshev inequality<sup>9</sup> that  $\mathbb{P}[|X| \geq z] \leq \Delta^\alpha/z^\alpha$ . Therefore,  $F_{|X|}^{-1}(u) \leq \Delta/\sqrt[\alpha]{1-u}$ . We will use that  $|y - X| \leq |y| + |X|$  and later below also that  $|y - X| \geq \max(0, |y| - |X|)$ . We start with the simpler case of proving a lower bound.

$$\begin{aligned}
\frac{f_{X+Y}(y)}{f_Y(y)} &= \frac{\mathbb{E}[f_Y(y - X)]}{(|y|/s + 1)^{-\alpha}} & (4) \\
&= \frac{\mathbb{E}[ (|y - X|/s + 1)^{-\alpha} ]}{(|y|/s + 1)^{-\alpha}} \\
&\geq E \left[ \left( \frac{|y|/s + |X|/s + 1}{|y|/s + 1} \right)^{-\alpha} \right] \\
&= E \left[ \left( 1 + \frac{|X|/s}{|y|/s + 1} \right)^{-\alpha} \right] \\
&\geq \mathbb{E}[(1 + |X|/s)^{-\alpha}] \\
&\geq \mathbb{E}[1 - \alpha|X|/s] \\
&= 1 - \alpha\mathbb{E}[|X|]/s \\
&\geq 1 - \frac{\alpha(1 - 2^{-1/\alpha})\Delta}{\Delta} \epsilon \geq e^{-(1-2^{-1/\alpha})\alpha\epsilon} & (5)
\end{aligned}$$

where (4) holds by Fact 2, and (5) uses that  $\mathbb{E}[|X|] = \|X\|_1 \leq \|X\|_\alpha \leq \Delta$ . We now show the upper bound part. We prove an upper bound in terms of the integral which we have bounded in Lemma 11.

$$\begin{aligned}
\frac{f_{X+Y}(y)}{f_Y(y)} &= \frac{\mathbb{E}[ (|y - X|/s + 1)^{-\alpha} ]}{(|y|/s + 1)^{-\alpha}} \\
&\leq E \left[ \min \left( (1 + |y|/s)^\alpha, \left| \frac{|y|/s - |X|/s + 1}{|y|/s + 1} \right|^{-\alpha} \right) \right] \\
&= E \left[ \min \left( (1 + |y|/s)^\alpha, \left| 1 - \frac{|X|/s}{|y|/s + 1} \right|^{-\alpha} \right) \right] \\
&= E_u \left[ \min \left( (1 + |y|/s)^\alpha, \left| 1 - \frac{F_{|X|}^{-1}(u)/s}{|y|/s + 1} \right|^{-\alpha} \right) \right] \\
&\leq E_u \left[ \min \left( (1 + |y|/s)^\alpha, \left| 1 - \frac{(1 - 2^{-1/\alpha})^{-1}\epsilon}{(|y|/s + 1)(1 - u)^{1/\alpha}} \right|^{-\alpha} \right) \right] \\
&= \int_0^1 \min \left( (1 + |y|/s)^\alpha, \left| 1 - \frac{(1 - 2^{-1/\alpha})^{-1}\epsilon}{(|y|/s + 1)(1 - u)^{1/\alpha}} \right|^{-\alpha} \right) du \\
&\leq 1 + \frac{2\alpha - 1}{\alpha - 1} \epsilon \leq e^{\frac{2\alpha - 1}{\alpha - 1} \epsilon}
\end{aligned}$$

where we have proven the inequality second to last in Lemma 11. ◀

We are now ready to prove the main theorem of this section.

<sup>9</sup> The higher-order Chebyshev inequality states that for  $X$  being a real random variable, it holds  $\mathbb{P}[|X - \mathbb{E}[X]| \geq t] \leq t^\alpha/\mathbb{E}[|X - \mathbb{E}[X]|^\alpha]$  for any  $\alpha \geq 0$ .

► **Theorem 13.** *Let us have an algorithm  $A(D)$  such that there exists a function  $g(D)$  with global sensitivity  $\leq \Delta_1$  w.r.t.  $D$  for which for any input  $D$ , it holds  $\mathbb{E}[|A(D) - g(D)|^\alpha] \leq \Delta_2^\alpha$  for some  $\alpha > 1$ . Let  $Y \sim ZSPareto_\alpha(c(\Delta_1 + \Delta_2)/\epsilon)$  for  $c = \alpha + 2 + 1/(\alpha - 1)$  and  $\epsilon \leq c$ , independent of the randomness of  $A$ ; then  $A(D) + Y$  is  $\epsilon$ -differentially private with respect to  $D$ .*

**Proof.** This proof follows the strategy of the proof of Theorem 9. Let us have two neighboring databases  $D_1, D_2$ . We again prove that for any  $y$ , it holds  $f_{A(D_1)}(y)/f_{A(D_2)}(y) \leq e^\epsilon$ ; this implies the theorem. We also again set  $R_1 = A(D_1) - g(D_1)$  and  $R_2 = A(D_2) - g(D_1)$ . We are assuming  $\|R_1\|_\alpha \leq \Delta_2$  and by the triangle inequality, we have that  $\|R_2\|_\alpha \leq \Delta_1 + \Delta_2$ . Therefore, we have

$$\begin{aligned} \frac{f_{g(D_1)+R_1+Y}(y)}{f_{g(D_1)+Y}(y)} &= \frac{f_{R_1+Y}(y - g(D_1))}{f_Y(y - g(D_1))} \leq \exp\left(\frac{2\alpha - 1}{(\alpha - 1)c}\epsilon\right) \\ \frac{f_{g(D_2)+R_1+Y}(y)}{f_{g(D_1)+Y}(y)} &= \frac{f_{R_1+Y}(y - g(D_2))}{f_Y(y - g(D_1))} \geq \exp\left(-(1 - 2^{-1/\alpha})\alpha\epsilon/c\right) \end{aligned}$$

which in turn allows us to bound

$$\begin{aligned} f_{A(D_1)+Y}(y)/f_{A(D_2)+Y}(y) &= \frac{f_{g(D_1)+R_1+Y}(y)}{f_{g(D_1)+Y}(y)} \cdot \frac{f_{g(D_1)+Y}(y)}{f_{g(D_2)+R_1+Y}(y)} \\ &\leq \exp\left(\left(\frac{2\alpha - 1}{\alpha - 1} + (1 - 2^{-1/\alpha})\alpha\right)\epsilon/c\right) \leq e^\epsilon \end{aligned}$$

where we now argue the last inequality; that will conclude the proof. If we set  $c = 2 + 1/(\alpha - 1) + \alpha - 2^{-1/\alpha}\alpha$ , the last inequality would be an equality. By monotonicity, it is thus sufficient to prove that  $2 + 1/(\alpha - 1) + \alpha - 2^{-1/\alpha}\alpha \leq 2 + \log 2 + 1/(\alpha - 1)$ . This is equivalent to  $2^{-1/\alpha}\alpha \geq \alpha - \log 2$ , which in turn can be re-written as  $2^{-1/\alpha} \geq 1 - \log(2)/\alpha$ . This follows from the inequality  $e^x \geq 1 + x$  for  $x = -\log(2)/\alpha$ . ◀

## 5 Implications of our results

In this section, we give several implications of Theorem 9 and Theorem 13. This list is by no means meant to be exhaustive. We start with the more straightforward applications and focus on the more involved ones later, with one part being deferred to the full version of this paper.

Recall that, as we discussed, the goal in the sublinear setting is not to simply add small amount of noise, but rather to achieve a given level of error as efficiently as possible while guaranteeing differential privacy. This is so because in this setting, the amount of error coming from the algorithm not being exact tends to be much greater than the amount of noise needed to achieve privacy when not subject to having limited resources.

### 5.1 The general approach

In all applications, we take a known algorithm for a given problem, and use either Theorem 9 or Theorem 13 to argue that adding noise to the algorithm's answer ensures privacy.

Assume the original algorithm had complexity  $T(n, \rho)$  and assume for example that the error is of magnitude  $\rho n$ , namely that for error  $R$ , it holds  $E[R^2]^{1/2} \leq O(\rho n)$  (this can be generalized to  $\leq O(\rho f(x))$  for  $x$  being the input and  $f$  being any function). We run the algorithm with parameter  $\rho' = \epsilon\rho$  and add noise of magnitude  $O(\rho n)$  (more generally

$O(\rho f(x))$ ). By Theorem 13 with  $\alpha = 2$ , as long as the approximated function's sensitivity is  $\Delta \leq \epsilon \rho n$ , this is  $\epsilon$ -differentially private<sup>10</sup>. At the same time, the error is  $\leq O(\rho n)$  with arbitrarily high constant probability. The time complexity is  $T(n, \epsilon \rho)$ .

If we want to achieve a failure probability of  $\beta$ , we run this algorithm  $\Theta(\log \beta^{-1})$  times and take the median. By a standard probability amplification argument, the success probability will be as desired. To achieve  $\epsilon$ -differential privacy by composition, we have to divide the privacy budget between the runs, resulting in complexity  $O(T(n, \epsilon \rho / \log \beta^{-1}) \log \beta^{-1})$ . This can be summarized (and generalized with the general function  $f(x)$ ) as follows:

► **Lemma 14.** *Suppose there is an algorithm approximating a function  $g$  with global sensitivity  $\Delta$  such that  $E[(A(x) - g(x))^2]^{1/2} \leq \rho f(x)$  for some function  $f$  with time/space/query complexity  $T(n, \rho)$ . Then for  $\epsilon \leq O(1)$  there exists an  $\epsilon$ -differentially private algorithm  $A'$  such that when  $\epsilon \rho \geq \Omega(\Delta/f(x))$ , it holds  $P[|A'(x) - g(x)| > \rho f(x)] \leq \beta$  and that has complexity  $O(T(n, \epsilon \rho / \log \beta^{-1}) \log \beta^{-1})$ .*

A more efficient approach for decreasing failure probability exists in the case of subexponential error. Assume the same setting as above, except that the error's subexponential diameter is  $\rho n$  instead having only moment bounds (like above, we can generalize to  $\rho f(x)$  instead of  $\rho n$ ). We run the algorithm with parameter  $\rho' = \epsilon \rho / \log \beta^{-1}$  and add noise of magnitude  $\Theta(\rho n / \log \beta^{-1})$ . This algorithm is  $\epsilon$ -differentially private by Theorem 9, as long as  $\Delta \leq \epsilon \rho n$ . The noise has subexponential diameter  $O(\rho' n)$  and by Lemma 5, the total error will up to a constant have the same subexponential diameter. By the definition of subexponential diameter, the probability that the error is  $\geq \Theta(\rho n)$  is  $\leq \beta$  as desired. This results in complexity  $O(T(n, \epsilon \rho / \log \beta^{-1}))$  saving us one  $\log \beta^{-1}$  factor. We can summarize this as

► **Lemma 15.** *Suppose there is an algorithm approximating a function  $g$  with global sensitivity  $\Delta$  such that  $\sigma_{se}[A(x) - g(x)] \leq \rho f(x)$  for some function  $f$  with time/space/query complexity  $T(n, \rho)$ . Then for  $\epsilon \leq O(1)$ , there exists an  $\epsilon$ -differentially private algorithm  $A'$  such that when  $\epsilon \rho \geq \Omega(\Delta/f(x))$ , it holds  $P[|A'(x) - g(x)| > \rho f(x)] \leq \beta$  and that has complexity  $O(T(n, \epsilon \rho / \log \beta^{-1}))$ .*

We are now ready to give private algorithms for specific problems.

## 5.2 Frequency moment $F_2$

In their seminal paper, Alon, Matias, and Szegedy [2] show a sketch that allows one to estimate the  $F_2$  frequency moment, defined as  $F_2(x_1, \dots, x_n) = \sum_{i=1}^n x_i^2$ . In the streaming setting, the vector  $x_1, \dots, x_n$  is given through a stream of updates  $y_1, \dots, y_k$  of the form  $y_j = (\ell_j, D_j)$  where  $D$  can be negative and we define  $x_i = \sum_{j=1}^k I[\ell_j = i] D_j$ . Two inputs are then adjacent if they differ in one value  $y_j$  for some  $j$ . The algorithm from [2] uses space  $O(\frac{1}{\rho^2})$  and has mean squared error of  $\leq \rho^2 F_2^2 \leq \rho^2 n^4$ . The sensitivity of the  $F_2$  moment is  $n$ . This implies the following

► **Corollary 16.** *For  $\epsilon \leq O(1)$  and  $\rho \leq 1/(\epsilon n)$ , there is an  $\epsilon$ -differentially private algorithm that returns an additive  $\pm \rho n^2$  approximation of the frequency moment  $F_2$  with probability  $1 - \beta$ , and has space complexity  $O(\frac{\log^3 \beta^{-1}}{\rho^2 \epsilon^2})$ .*

<sup>10</sup>This upper bound on the sensitivity ensures that  $\Delta_2$  in Theorem 13 dominates.

This improves upon the concurrent work [7] which gives an algorithm with complexity  $O(\frac{\log^4 n}{\rho^2 \epsilon^2})$ . Shortly after releasing this paper, an approach also appeared with the incomparable complexity of  $O(\log(n) \log^3 \beta^{-1} / \rho^2)$  was shown (for  $\epsilon$  being not too small) that also has multiplicative approximation guarantees and works (with some loss in the complexity) in the continual release setting [15]. The setting of  $F_p$  for  $p \in [0, 1]$  has been considered in [33].

### 5.3 Connected components

An algorithm is known [4] that returns an estimate  $\hat{c}$  of the number of connected components  $c$  of a simple graph in time  $O(\frac{1}{\rho^2} \log \frac{1}{\rho})$  and has mean squared error  $\mathbb{E}[(\hat{c} - c)^2] \leq \rho^2 n^2$ . At the same time, the number of connected components has global sensitivity 1 with respect to edge additions/deletions. This gives us the following

► **Corollary 17.** *For  $\epsilon \leq O(1)$  and  $\rho \leq 1/(en)$ , there is an  $\epsilon$ -edge-differentially private algorithm that returns an additive  $\pm \rho n$  approximation of the number connected components with probability  $1 - \beta$ , and has complexity  $O(\frac{\log^3 \beta^{-1}}{\rho^2 \epsilon^2} \log \frac{\log \beta^{-1}}{\rho \epsilon})$ .*

No private sublinear-complexity algorithm for estimating the number of connected components was previously known.

### 5.4 Maximum matching

Yoshida, Yamamoto, and Ito [34] show an algorithm that can approximate the size of the maximum matching to within multiplicative  $1 + \rho$  in time  $d^{O(1/\rho^2)} (1/\rho)^{O(1/\rho)}$  for  $d$  being the maximum degree of the input graph. It works by implementing an oracle for a matching of size within factor  $1 + \rho/2$  of the maximum matching; for a specified vertex, this oracle answers whether the vertex is matched in the oracle's matching. The algorithm then samples  $\Theta(1/\rho^2)$  vertices and checks the fraction that is matched in the oracle's matching. The error coming from the oracle is  $\leq \rho n/2$  in the worst case and thus has subexponential diameter  $O(\rho n)$ . The error coming from the sampling has subexponential diameter  $O(\rho n)$  by the Hoeffding inequality. By Lemma 5, the subexponential diameter of the error is thus  $O(\rho n)$ . At the same time, the global sensitivity of the maximum matching size is  $\leq 1$  with respect to the removal of one vertex. This gives us the following

► **Corollary 18.** *For  $\epsilon \leq O(1)$  and  $\rho \leq 1/(en)$ , there is an  $\epsilon$ -node-differentially-private algorithm that returns an additive  $\pm \rho n$  approximation of the maximum matching size with probability  $1 - \beta$  in time  $d^{O(\log^2(\beta^{-1})/(\rho^2 \epsilon^2))} / (\rho \epsilon)^{O(\log(\beta^{-1})/(\rho \epsilon))}$ .*

Together with the concurrent [7], this solves the open problem posed in [5] where the authors show a hybrid  $(2, \rho n)$  approximation, while we give a purely additive  $\pm \rho n$  approximation.

### 5.5 Rank queries

Karnin, Lang, and Liberty [20] develop a sketch of size  $O(\frac{1}{\rho})$  that allows one to answer rank queries with error with subexponential diameter  $\rho n$ . We show how to use their sketch to answer range queries over an ordered universe. For small number of queries, this improves upon the work of [19] which has a logarithmic dependency on the universe size. This gives us the following corollary.

► **Corollary 19.** *There is a sketch that allows  $\epsilon$ -differentially private algorithm that returns  $k$  rank queries (potentially adaptive) for  $\epsilon \leq O(1)$  with an additive  $\pm \rho n$  error with probability  $1 - \beta$ , and has complexity  $O(\frac{k \log^2(k/\beta)}{\rho \epsilon})$ .*

**Proof.** We use the KLL sketch with error parameter  $\rho' = \rho\epsilon/(k \log(k/\beta))$ . This means that the error has a subexponential diameter of  $\leq \rho\epsilon n/(k \log(k/\beta))$ . Therefore, by Theorem 9, it holds that using for each query a Laplace mechanism with error magnitude  $\Theta(\rho n/\log(k/\beta))$  will result in  $\epsilon$ -differential privacy.

By Lemma 5, the overall subexponential diameter of the error of each answer is  $O(\rho n/\log(k/\beta))$  and therefore the probability of error  $O(\rho n)$  is  $1 - \beta/k$ . By the union bound, the overall success probability is  $\geq 1 - \beta$ .  $\blacktriangleleft$

This is in comparison to the approach of Kaplan and Stemmer [19] which results in space complexity  $O(\frac{\log |U| \log(k/\beta)}{\rho\epsilon})$ , improving by a factor of  $\log |U|$  for constant  $k, \beta$ , where  $U$  is the universe.

## 5.6 Relative approximation sublinear-time algorithms

In the full version of this paper, we show a general theorem that implies that many sublinear-time algorithms that have relative error guarantees can be made differentially private. Specifically, it applies to many algorithms that rely on a commonly used “advice removal” technique [14]. Among other things, this theorem implies the following algorithm. This improves upon the work of Blocki, Grigorescu, and Mukherjee [5] who give an algorithm with complexity  $\tilde{O}_{\epsilon, \rho}(\sqrt{n})$  under the assumption  $m \geq \Omega(n)$ .

► **Corollary 20.** *For  $\epsilon \leq O(1)$  and  $\rho \leq 1/(\epsilon n)$ , there exists an  $\epsilon$ -edge-differentially private algorithm that returns a  $1 + \rho$ -approximation of the average degree of a graph with probability  $1 - \beta$  and has complexity  $O(\frac{n \log^3 \beta^{-1}}{\epsilon^2 \rho^2 \sqrt{m}})$ .*

## 6 Open problems and conjectures

We are convinced that our results are only the beginning of the story and that there are many interesting related open problems. These include using normal noise with approximate/zero-concentrated differential privacy, generalizing our method to input-dependent error magnitudes, improving the constants, lower bounds for answering multiple queries when we have polynomial tails. For a more detailed discussion, see the full version of this paper.

## Abstract

In this paper, we study graph distances in the geometric random graph models scale-free percolation SFP, geometric inhomogeneous random graphs GIRG, and hyperbolic random graphs HRG. Despite the wide success of the models, the parameter regime in which graph distances are polylogarithmic is poorly understood. We provide new and improved lower bounds. In a certain portion of the parameter regime, those match the known upper bounds.

Compared to the best previous lower bounds by Hao and Heydenreich [19], our result has several advantages: it gives matching bounds for a larger range of parameters, thus settling the question for a larger portion of the parameter space. It strictly improves the lower bounds of [19] for all parameters settings in which those bounds were not tight. It gives tail bounds on the probability of having short paths, which imply shape theorems for the  $k$ -neighbourhood of a vertex whenever our lower bounds are tight, and tight bounds for the size of this  $k$ -neighbourhood. And last but not least, our proof is much simpler and not much longer than two pages, and we demonstrate that it generalizes well by showing that the same technique also works for first passage percolation.

## 1 Introduction and Main results

In the last years, a family of random graph models including *hyperbolic random graphs* (HRG) [26], *scale-free percolation* (SFP) [14], and *geometric inhomogeneous random graphs* (GIRG) [11], has emerged as a model for large real-world networks. They combine an

underlying geometric space with an inhomogeneous degree distribution. This combination yields many properties that occur in real-world networks across a wide range of domains, such as strong clustering, a rich community structure, ultra-small distance, small separators, compressibility, and more [11]. The networks have been used empirically and theoretically to study algorithms like local routing protocols [7, 9, 12], bidirectional search [6] or maximum flow [8], spreading processes like bootstrap percolation [21] or SI models [22–25], and they have been used to study the effectiveness of different interventions during the Covid19 pandemic [17, 20, 27].

Despite this widespread adoption, the fundamental question of graph distances has been open for some parameter regimes. In general, the models come with two parameters: the degrees follow a power-law distribution with exponent  $\tau > 1$ , i.e.,  $\mathbb{P}(\deg(v) \geq x) \sim x^{1-\tau}$  for any fixed vertex  $v$ ;<sup>1</sup> and  $\alpha > 1$  determines the number of *weak ties* [18] in the network, i.e. edges which are present although their geometric distance and degrees suggest otherwise. The parameter  $\alpha$  is also called *inverse temperature*. If  $\tau < 3$  then for two random vertices  $x, y$  in the giant component, with high probability<sup>2</sup> their graph distance  $d_G(x, y)$  is at most doubly logarithmic in their geometric distance, i.e.,  $d_G(x, y) = O(\log \log |x - y|)$ . For  $\tau \leq 2$  we even have  $d_G(x, y) = O(1)$ . These regimes are very precisely understood [1, 10, 14]. On the other hand, if  $\tau > 3$  and  $\alpha > 2$ , then it is known that the graph distance of two vertices  $x, y$  grows linearly with their geometric distance, and this is again well understood [2, 15].

However, in the *polylogarithmic regime*  $\tau > 3$  and  $\alpha \in (1, 2)$ , the picture is incomplete. It is understood in the limiting case  $\tau = \infty$ , which is known as *long-range percolation* LRP, that  $d_G(x, y) = (\log |x - y|)^{\Delta(\alpha) \pm o(1)}$  where  $\Delta(\alpha) = 1/\log_2(2/\alpha) > 1$  [2, 3]. Since graph distances can only increase with  $\tau$ , the upper bound applies for any  $\tau > 1$ , and this is the best known upper bound.<sup>3</sup> On the other hand, it is easy to see that for  $\tau > 3$  the  $k$ -neighbourhood can grow at most exponentially, so distances are at least logarithmic,  $d_G(x, y) = \Omega(\log |x - y|)$  [14]. Hence we know that distances are polylogarithmic for  $\tau > 3$  and  $\alpha \in (1, 2)$ . But the exponents of the upper and lower bound ( $\Delta$  and 1 respectively) did not match, and this gap remained open for a long time.

Very recently, Hao and Heydenreich [19] could show an improved lower bound of  $d_G(x, y) \geq (\log |x - y|)^{\Delta(\min\{\alpha, (\tau-1)/2\}) - o(1)}$ , where, as before,  $\Delta(x) = 1/\log_2(2/x)$ . This closed the gap in the case that  $\alpha < (\tau - 1)/2$ , since then  $\min\{\alpha, (\tau - 1)/2\} = \alpha$ . Their proof had 9 pages and was a complicated application of Biskup’s hierarchy argument [3]. In this paper we give a stronger lower bound with a much simpler inductive proof of only about two pages. It is inspired by ideas of Biskup for the simpler case of LRP [4], which themselves are adaptations of those in [29]. More precisely, we show that  $d_G(x, y) = \Omega((\log |x - y|)^{\Delta(\min\{\alpha, \tau-2-o(1)\})})$ . This closes the gap between upper and lower bound whenever  $\alpha < \tau - 2$ , which comprises a strictly larger portion of the polylogarithmic regime than the bound of [19]. Moreover, throughout the polylogarithmic regime, since  $\tau > 3$  implies  $\tau - 2 > (\tau - 1)/2$ , our bound is strictly stronger in all cases in which the bound of [19] is not tight.

<sup>1</sup> The distribution is often allowed to vary by constant factors or slowly varying functions, but this will not be relevant for this paper. Also, the traditional SFP parameterization uses two parameters  $\tau$  and  $\gamma$  instead of the one parameter  $\tau$ . However, one of those parameters is internal to the graph generation process and does not yield additional classes of graphs, which is why we omit the additional parameter.

<sup>2</sup> We say an event occurs *with high probability*, or w.h.p., if it occurs with probability  $1 - o(1)$ .

<sup>3</sup> An improved upper bound was claimed in [19], but the proof had an issue which we consider severe, see Appendix A for details. At submission time of the camera-ready version of this paper, the problem has not been fixed, so currently we must consider this result as unproven.

Our result is also stronger in two other aspects: Firstly, we provide strong tail bounds on the probability  $\mathbb{P}(d_G(x, y) \leq k)$ . These yield a *shape theorem* for the geometric shape of the  $k$ -neighbourhood of a fixed vertex for growing  $k$ , in the case  $\alpha < \tau - 2$  when our lower bound matches the upper bound. The shape theorem also implies that the size of the  $k$ -neighbourhood of a fixed vertex grows as  $e^{k^{1/\Delta \pm o(1)}}$  as  $k \rightarrow \infty$ , which was not known before. Secondly, due to its simplicity, we believe that our method is also potentially easier to generalize. As demonstration, we show that a similar lower bound holds not only for graph distances, but also for first passage percolation.

In the following, we will start by formally defining the graph models and stating our precise results. The heart of the paper is Section 2, where we prove our result for the SFP model. In Section 3, we extend the proof to first-passage percolation. Finally, in Appendix A we explain why the proof of the upper bound claimed in [19] is incorrect.

## 1.1 Preliminaries and Random Graph Models

Our results hold for *Scale Free Percolation* (SFP), *Geometric Inhomogeneous Random Graphs* (GIRG), and *Hyperbolic Random Graphs* (HRG). We will define LRP and GIRG formally in this section. HRG has been shown to be a special case of GIRG [11], so all results proven for GIRG automatically also hold for HRG, and we do not need to formally define HRG. A formal definition of HRG together with its connection to GIRG can be found in [11].

### 1.1.1 Scale Free Percolation (SFP)

For SFP, we start with the infinite<sup>4</sup>  $d$ -dimensional grid, which is our set of vertices. For two points  $x, y \in \mathbb{Z}^d$ , we define their distance  $|x - y|$  via the usual Euclidean norm. Moreover, each vertex draws a *weight*  $w_x$  independently identically distributed from a power-law distribution. For our purposes, this is a Pareto distribution satisfying

$$\mathbb{P}(w_x \geq z) = z^{1-\tau}$$

for  $z \geq 1$ , where the parameter  $\tau > 1$  is the *power-law exponent*.

We add edges in two different ways. First, we place the usual *grid edges*<sup>5</sup> between points that are adjacent in  $\mathbb{Z}^d$ , i.e., we place an edge between  $x = (x_1, \dots, x_d)$  and  $y = (y_1, \dots, y_d)$  if there is some coordinate  $1 \leq i \leq d$  such that  $|x_i - y_i| = 1$  and  $x_j = y_j$  for all  $j \neq i$ . Second, we randomly create long-range edges, also called *weak ties*, by placing an edge between  $x, y \in \mathbb{Z}^d$ , independently for different sets  $\{x, y\}$ , with probability  $p_{xy}$ , which is defined as<sup>6</sup>

$$p_{xy}^{(\text{SFP})} := \min \left\{ 1, \lambda \left( \frac{w_x w_y}{|x - y|^d} \right)^\alpha \right\}, \quad (1)$$

where  $\lambda > 0, \alpha > 1$  are constants. We write  $x \sim y$  if there is an edge between  $x, y \in \mathbb{Z}^d$  and  $x \approx y$  otherwise.

<sup>4</sup> Traditionally, LRP is defined on an infinite vertex set while GIRG is defined on a finite vertex set, following the tradition of mathematics for LRP and of computer science for GIRG. However, both models can be defined in either a finite or an infinite version, and this does not affect graph distances, see [25] for details.

<sup>5</sup> Some variants of SFP do not include grid edges. Since we prove lower bounds on graph distances, we make our result stronger by including grid edges.

<sup>6</sup> In the literature, the connection probability is often defined as  $1 - \exp(-\lambda|x - y|^{-\alpha d})$ . We remark that this differs from our connection probability at most by a constant factor, which does not change the model substantially.

We remark that the parameterization is slightly different from the original one used in [14] and also in [19]. Compared to our formulation, they used auxiliary weights  $w'_x := w_x^\alpha$ , which were then drawn from a power-law distribution with exponent  $\tau' = 1 + d(\tau - 1)/\alpha$ . These two parameterizations are equivalent, but our formulation has the advantage that the weights correspond, up to constant factors, to the expected degree of the vertices,  $\mathbb{E}[\deg(x) \mid w_x] = \Theta(w_x)$ . Our formulation also saves an internal parameter of the model. Moreover, we rescaled  $\alpha$  by a factor  $d$  to match it with the parameterization of GIRG. When comparing our results with the lower bounds in [19], the following transformations are needed, where the subscript “[19]” indicates notation from that paper, and parameters without subscript are from our paper.

$$\alpha_{[19]} = \alpha d \quad \text{and} \quad \gamma_{[19]} = \tau - 1. \tag{2}$$

The internal parameter  $\tau_{[19]}$  is superfluous and does not have a correspondence in our paper.

### 1.1.2 Geometric Inhomogeneous Random Graphs (GIRG)

The GIRG model is sometimes also referred to as Continuum Scale Free Percolation [16]. The main difference between SFP and GIRG is that in GIRG, the positions of vertices are randomly chosen. Namely, for some large enough  $n \in \mathbb{N}$ , we consider a cube  $\mathcal{X}$  of volume  $n$  in  $\mathbb{R}^d$ , where  $d$  is a constant. Our vertex set  $V$  then consists of  $n$  vertices, where the position  $\xi_x$  of each vertex  $x$  is picked independently at random from the uniform distribution over  $\mathcal{X}$ . The distance between two vertices  $x, y \in V$  is defined as the Euclidean norm  $|\xi_x - \xi_y|$ , as in SFP. Again similarly to SFP, each vertex  $x$  draws a weight  $w_x$  independently from the Pareto distribution satisfying

$$\mathbb{P}(w_x \geq z) = z^{1-\tau}$$

for  $z \geq 1$ , with  $\tau > 1$ . Finally, two different vertices  $x$  and  $y$  are connected by an edge with probability<sup>7</sup>

$$p_{xy}^{(\text{GIRG})} = \Theta \left( \min \left\{ 1, \left( \frac{w_x w_y}{|\xi_x - \xi_y|^d} \right)^\alpha \right\} \right), \tag{3}$$

where the hidden constants are uniform over all  $x, y$ . Formally, we require that there are two absolute constants  $c_{\text{low}}, c_{\text{upp}} > 0$  independent of  $n$  such that for all  $n$  and any two different vertices  $x, y \in V$ , conditional on their weights  $w_x, w_y \geq 1$  and positions  $\xi_x, \xi_y \in \mathcal{X}$ ,

$$c_{\text{low}} \min \left\{ 1, \left( \frac{w_x w_y}{|\xi_x - \xi_y|^d} \right)^\alpha \right\} \leq p_{xy}^{(\text{GIRG})} \leq c_{\text{upp}} \min \left\{ 1, \left( \frac{w_x w_y}{|\xi_x - \xi_y|^d} \right)^\alpha \right\}.$$

The reason for allowing constant factor deviations is that then hyperbolic random graphs (HRG) is a special case of GIRG with  $d = 1$ , where the Euclidean distance is replaced by the angular distance in hyperbolic space [11]. Hence, any statement proven for this version of GIRG also holds for HRG.

Note that the constants  $\tau$  and  $\alpha$  have an analogous role here as in SFP. A notable difference to SFP is that in GIRG there are no grid edges (since positions are no longer on the grid), but that does not significantly affect our results.

---

<sup>7</sup> The original paper [11] used a geometry that was rescaled by a factor  $n^{1/d}$ . I.e., they used a cube of volume one and had an additional factor  $n$  in the denominator of (3). Both variants are equivalent, but our scaling aligns better with the SFP scaling and allows GIRGs to be extended to infinite graphs if desired [25].

### 1.1.3 Long Range Percolation (LRP)

To put our results in an adequate context, we sometimes reference the model of *Long Range Percolation* (LRP) which is a special case and predecessor of SFP, cf. e.g. [3, 5]. We define LRP completely analogously to SFP with the only modification that every vertex has a (deterministic) weight of 1.

### 1.1.4 First Passage Percolation (FPP)

Our lower bounds on graph distances are (in a similar form) also applicable to *First Passage Percolation* (FPP) on the graph models SFP, GIRG, HRG, and also LRP. Here, each edge  $e$  of the graph draws a random length or cost  $c_e$  independently identically distributed (i.i.d.) from a distribution over the non-negative reals. For two vertices  $x, y$  we are then interested in the *minimal/infimal cost* of all paths from  $x$  to  $y$ . This can be done on an arbitrary finite or infinite underlying graph. In this work we restrict our attention to the case where each edge cost is sampled from an exponential distribution with rate 1. The formal definition is as follows.

► **Definition 1** (First Passage Percolation (FPP)). We call the following process *First Passage Percolation*, in short FPP. Given a graph  $G = (V, E)$ , assign to each edge  $e$  an i.i.d. cost  $c_e$  sampled from an exponential distribution with rate 1. For a finite path  $\pi$ , we define the *cost* of that path as

$$c(\pi) = \sum_{e \in \pi} c_e$$

Then, the *cost-distance* or *first passage time* between two vertices  $x$  and  $y$  is the minimum (or infimum) cost of any finite path connecting  $x$  and  $y$ , i.e.

$$d_G^{\text{cost}}(x, y) := \inf\{c(\pi) : \pi \in \mathcal{P}_{x,y}\} \quad \text{for } x, y \in V,$$

where  $\mathcal{P}_{x,y}$  is the set of all finite paths between  $x$  and  $y$ .

Recently, FPP on SFP, GIRG, and HRG was studied [13, 23–25]. In particular, it was shown in [23, 25] that FPP on those graphs exhibits an *explosive* behaviour if the vertex weights have infinite variance (i.e. if  $\tau < 3$ ). This means that the cost-distance between two vertices  $x, y$  converges in distribution against a random variable that is finite almost surely. In the infinite model SFP, this means that there are infinitely many vertices reachable within finite cost from a given vertex; in the finite models GIRG and HRG, a constant fraction of all vertices have cost-distance  $\mathcal{O}(1)$ . We emphasize that this is not true for *graph distances* for  $\tau \in (2, 3)$  since then degrees are finite almost surely, so the number of vertices in graph distance  $C$  is finite/constant for any constant  $C > 0$ .

We remark that a model with a similar name, *long-range first passage percolation* was introduced and studied in [13]. This is *not* FPP on LRP, but a different model with the complete graph on  $\mathbb{Z}^d$  (all edges are present, degrees are infinite), where transmission times are penalized for edges between vertices of large Euclidean distance. Despite the differences, the models are related, and our analysis of FPP uses a coupling to a similar model and is inspired by [13].

### 1.1.5 Terminology

We are interested in the typical *graph distance*  $d_G(x, y)$  between two vertices  $x, y$  in SFP, GIRG, and HRG, and the *cost-distance*  $d_G^{\text{cost}}(x, y)$  in FPP.<sup>8</sup> We are interested in the asymptotic behavior of  $d_G(x, y)$  and  $d_G^{\text{cost}}(x, y)$  in terms of the Euclidean distance  $|x - y|$ . That is, we study how  $d_G(x, y)$  and  $d_G^{\text{cost}}(x, y)$  scale as functions of  $|x - y|$  when  $|x - y| \rightarrow \infty$ . We define the function  $\Delta(\beta) := \frac{1}{\log_2(2/\beta)}$ , which will appear in the exponent governing the polylogarithmic behavior of graph distances. Throughout, we use  $\Delta = \Delta(\alpha)$  where  $\alpha$  is the long-range parameter of the relevant model.

Previous work showed that both LRP and SFP exhibit multiple phase transitions in the asymptotic behavior of  $d_G(x, y)$  depending on the model parameters, which were briefly summarized in the introduction and are further summarized (together with our results) in Table 1.

■ **Table 1** Upper and lower bounds for graph distances and cost-distances in long-range percolation (LRP), scale-free percolation (SFP) and first passage percolation (FPP) on SFP, with  $\Delta(\beta) = 1/\log_2(2/\beta)$ . The results on graph distance for SFP also hold for geometric inhomogeneous random graphs (GIRG) and hyperbolic random graphs (HRG). Our results are indicated in bold.

## 1.2 Our results

In this section, we formally state our main results. To keep the exposition simple, we state them only for SFP, not for GIRG and HRG. All results on graph distances in this section also hold for GIRG and HRG, where all constants can be chosen independently of the number  $n$  of vertices. We give details on that in the full version but omit them here due to space constraints.

We prove stronger lower bounds for graph distances in the logarithmic regimes of SFP with a much simpler proof than in [19]. Furthermore, we also obtain a *shape theorem* which sandwiches the  $k$ -neighbourhood of a given vertex between two geometric balls of similar size. The key result is a general upper bound on the probability that two vertices have graph/cost-distance at most  $k$ . For the following claims, recall that  $\Delta(\beta) = 1/\log_2(2/\beta)$ .

► **Theorem 1.1** (Tail Bound for Graph Distances in SFP). Consider SFP with parameters  $\alpha \in (1, 2), \tau > 3$  and  $\lambda$ . Fix any sufficiently small  $\varepsilon > 0$  and let  $\Delta' = \Delta(\min\{\alpha, \tau - 2 - \varepsilon\})$ . Then, there exist constants  $c_1, c_2, \beta$  depending on the model parameters as well as  $\varepsilon$  such that for any pair of vertices  $x, y \in \mathbb{Z}^d$  and any  $k \in \mathbb{N}$ , we have

$$\mathbb{P}(d_G(x, y) \leq k) \leq c_2^{-1} |x - y|^{-\alpha d} (k + 1)^{-\beta} \exp\left(c_1 k^{1/\Delta'}\right).$$

<sup>8</sup> Formally, the graph distance is also defined in Definition 1 by setting  $c(e) := 1$  for all edges  $e$ .

<sup>9</sup> In [19], the authors claim to prove an improved logarithmic upper bound with exponent  $\Delta(\min\{\alpha, \tau - 2\})$ , which would match our lower bounds. However, we show that their proof is wrong, see Appendix A.

The above bound is proved by induction over  $k$  in Section 2. We express the probability that a path of length  $\leq k$  exists recursively by decomposing the path into two parts connected by an edge which has the longest geometric distance on the original path. Applying the inductive hypothesis and integrating over all possible endpoints and weights of the endpoints of said edge then yields the desired bound. However, this actually only works if  $\alpha < \tau - 2$ , which is needed to ensure convergence of some involved integrals. We remedy this and make the theorem applicable also to the case  $\alpha \geq \tau - 2$  by using a coupling argument. Here (see Lemma 5 for the exact statement), we argue that decreasing  $\alpha$  only makes the model denser, so graph distances can only become smaller. Thus, to prove the claim for some  $\alpha \geq \tau - 2$ , we can decrease  $\alpha$  to some value  $\alpha' := \tau - 2 - \varepsilon$  without increasing distances, and then apply Theorem 1.1 for the already settled case  $\alpha'$ . This is the reason why we use the exponent  $\Delta(\min\{\alpha, \tau - 2 - \varepsilon\})$ . Using the above tail bound then directly implies a bound on typical graph distances.

► **Corollary 2** (Typical Graph Distances in SFP). *Consider SFP under the assumption  $\alpha \in (1, 2)$  and  $\tau > 3$ . Then for every sufficiently small  $\varepsilon > 0$ , there is a constant  $c > 0$  such that*

$$\lim_{|x-y| \rightarrow \infty} \mathbb{P} \left( d_G(x, y) \geq c \log(|x - y|)^{\Delta(\min\{\alpha, \tau - 2 - \varepsilon\})} \right) = 1.$$

Note that in the case  $\alpha < \tau - 2$ , the exponent is exactly  $\Delta(\alpha)$  (if  $\varepsilon$  is chosen sufficiently small), which is a slightly stronger result than the one we obtain if  $\alpha \geq \tau - 2$  and matches the known upper bounds in [5] up to only a constant factor in front of the log. The previously best lower bounds by Hao and Heydenreich [19] only matched these upper bounds if  $2\alpha < \tau - 2$  and nonetheless were only tight if we ignore an additional additive constant of  $-\varepsilon$  in the exponent. If  $\alpha \geq \tau - 2$ , we also have to account for such an  $\varepsilon$  in the exponent, but even in this case, our result strengthens the lower bounds in [19] and at the same time relies on a significantly simpler proof. The original proof heavily relied on so-called *hierarchies* as introduced in [3] and required complex combinatorial estimates for showing that certain structures w.h.p. do not exist. We avoid this by using the inductive proof strategy as described above instead. This not only simplifies and improves the existing lower bounds on graph distances, but the tail bound in Theorem 1.1 further yields a so-called *shape theorem* precisely characterizing the diameter and the cardinality of the  $k$ -neighbourhood of a vertex  $x$ , i.e., the set of vertices in graph distance at most  $k$  from  $x$ . To this end, we define  $\mathcal{B}(x, k) := \{y \in V \mid d_G(x, y) \leq k\}$  as the set of all  $k$ -hop neighbors of a given vertex  $x$ .

► **Theorem 1.2** (Shape Theorem for  $k$ -Balls in SFP). *Consider SFP with  $\alpha < \tau - 2$ . Let  $\Delta = \Delta(\alpha)$ , fix an  $\varepsilon > 0$  and let  $\mathcal{X}_{low}, \mathcal{X}_{upp}$  be the set of vertices at a geometric distance of at most  $q(k) = e^{k^{1/\Delta - \varepsilon}}$  and at most  $r(k) = e^{k^{1/\Delta + \varepsilon}}$  from a fixed vertex  $x$ , respectively. Then, we have*

$$\lim_{k \rightarrow \infty} \mathbb{P}(\mathcal{X}_{low} \subseteq \mathcal{B}(x, k) \subseteq \mathcal{X}_{upp}) = 1. \quad (\text{A})$$

In particular,

$$\lim_{k \rightarrow \infty} \mathbb{P} \left( e^{k^{1/\Delta - \varepsilon}} \leq |\mathcal{B}(x, k)| \leq e^{k^{1/\Delta + \varepsilon}} \right) = 1. \quad (\text{B})$$

The lower bound of the theorem comes from [4], while we contribute the upper bound, which is a relatively straightforward corollary of our tail bound in Theorem 1.1. For this reason, we defer the formal proof to the full version of this paper. Note that lower bounds on graph distances correspond to upper bounds for  $\mathcal{B}(x, k)$  and vice versa.

We further note that while our upper bound in Theorem 1.2 also holds for GIRG and HRG, the lower bound is not known for these models and can only hold with some caveats. Firstly, due to the lacking grid edges those graphs are not connected, and require additional constraints to ensure the existence of a giant (linear-size) connected component. Second, even if the giant component exists, a constant fraction of vertices are not in the largest component. Hence, the lower bounds in (A) and (B) can only hold conditioned on  $x$  being in the largest component, and for (A) we must intersect  $\mathcal{X}_{low}$  with the giant component. We conjecture that the lower bounds in Theorem 1.2 hold with these caveats, but this is not known.

### 1.3 First passage percolation on SFP

Using similar techniques and inspired from those in [13], we can prove similar statements for FPP on SFP. Analogous to Theorem 1.1, we obtain a tail bound on the probability that  $x, y$  have cost-distance at most  $t$ . We remark that the same result could be obtained analogously for GIRG (and thus HRG) as well, but we omit this for conciseness.

► **Theorem 1.3** (Tail Bound for Cost-Distances for FPP on SFP). Consider FPP on SFP and arbitrary vertices  $x, y$ . Fix any sufficiently small  $\varepsilon > 0$ . There exists a constant  $c$  depending only on  $\alpha, \varepsilon$  and  $\tau$  such that for  $\Delta'' = \Delta(\min\{\alpha, \frac{\tau-1}{2}\} - \varepsilon)$ ,

$$\mathbb{P}(d_G^{\text{cost}}(x, y) \leq t) \leq |x - y|^{-\alpha d} \exp\left(ct^{1/\Delta''}\right).$$

The proof of this differs from Theorem 1.1 in some significant aspects which are formally presented in Section 3. Intuitively, the main differences are as follows. Firstly, we now have two sources of randomness: the existence of edges and the cost of an existing edge. The first step towards proving Theorem 1.3 is therefore to combine these two sources into a single one. This is achieved by coupling the model to a related model called *Complete Scale Free First Passage Percolation* or CFFP for short. Here, all possible edges on the vertex set  $\mathbb{Z}^d$  exist a priori but the cost of the edge between  $x, y \in \mathbb{Z}^d$  is now drawn from an exponential distribution with rate  $w_x^\alpha w_y^\alpha |x - y|^{-\alpha d}$  instead of rate 1, i.e., in CFFP the rate of an edge depends on the vertex weights and (geometric) distances of its endpoints.

The second main difference to the proof of Theorem 1.1 is that cost-distances are continuous random variables, so we cannot union-bound over all possible cost-distances before and after the longest edge of a potential path anymore like we did for SFP (in Lemma 4). Instead, we establish a continuous analog, a so called *self-bounding inequality* that relates the expected size of a  $k$ -ball to itself recursively. Another difficulty one has to overcome is that, in principle, paths of low cost-distance do not necessarily have to correspond to low graph distance as well. It could theoretically happen that many edges have very low cost and we get a low cost path which uses many edges. In such cases, we cannot use the existence of a geometrically long edge in the path, which is very central to our proof for graph distances. However, we are able to show that paths with high graph distance are actually very unlikely to have low cost-distance (see Lemma 8). Finally, a further obstacle in adapting the proof is that we have to work with the probability that a path of a certain cost exists conditioned on the weights of its endpoints at multiple points. This impacts the probabilities of edges/paths existing and thus introduces complications. To overcome this, we relate said probabilities conditional on the involved weights to their unconditional versions by employing a coupling (Proposition 12).

As a corollary of the above tail bound, we obtain lower bounds on the typical cost-distance similar to the one established for SFP (Corollary 2).

► **Corollary 3** (Typical Graph Distances in FPP on SFP). *Consider FPP on SFP under the assumption  $\alpha \in (1, 2)$  and  $\tau > 3$ . Then, for every sufficiently small  $\varepsilon > 0$*

$$\lim_{|x-y| \rightarrow \infty} \mathbb{P} \left( d_G^{\text{cost}}(x, y) \geq \log(|x-y|)^{\Delta(\min\{\alpha, \frac{\tau-1}{2}\}-\varepsilon)} \right) = 1.$$

### 1.3.1 Asymptotics and Probability Theory

We use standard Landau notation for indicating the asymptotic growth of a function. All asymptotic statements refer to the asymptotic behavior of a function as the distance  $|x-y|$  tends to infinity, unless explicitly noted otherwise (like for the shape theorem, where we consider  $k \rightarrow \infty$ .) We further require a version of the Van den Berg-Kesten inequality (or BK-inequality) from [28], which allows us to bound the probability that there exist *disjoint* subpaths connecting a vertex  $x$  to  $u$  and a vertex  $v$  to  $y$  by the product of the probabilities of either path existing, as if they were independent. We refer the interested reader to the full version of this paper for further details.

## 2 Lower Bounds for Graph Distances in SFP

In this section, we provide the proof of our main lower bound. Our proof generally follows the structure of the proof of Theorem 3.1 in [4]. Our goal is to show that the logarithmic exponent in the distances is at least roughly  $\Delta(\min\{\alpha, \tau - 2\})$ . When  $\alpha < \tau - 2$ , this is the same as  $\Delta = \Delta(\alpha)$ . We will first give the proof under this condition, so we first show Lemma 4.

► **Lemma 4** (Tail Bound for Graph Distances in SFP). *Consider SFP with  $\alpha \in (1, 2)$  such that  $\alpha < \tau - 2$  and  $\Delta = \Delta(\alpha)$ . There exist constants  $c_1, c_2, \beta$  depending only on the model parameters, such that for any pair  $x, y \in \mathbb{Z}^d$  and any  $k \in \mathbb{N}$ ,*

$$\mathbb{P}(d_G(x, y) \leq k \mid w_x, w_y) \leq w_x^\alpha w_y^\alpha c_2^{-1} |x-y|^{-\alpha d} (k+1)^{-\beta} e^{c_1 k^{1/\Delta}}. \quad (4)$$

**Proof.** First of all, note that for fixed  $\beta, c_2$ , and  $\lambda$ , the base case ( $k = 1$ ) is true for  $c_1$  large enough. That is because the RHS of 4 is  $2^{-\beta} e^{c_1} w_x^\alpha w_y^\alpha c_2^{-1} |x-y|^{-\alpha d}$  and the actual connection probability is at most  $\lambda w_x^\alpha w_y^\alpha |x-y|^{-\alpha d}$ . For the inductive step, let  $h$  be the RHS of our induction hypothesis, i.e.,

$$h(r, k, w_x, w_y) := w_x^\alpha w_y^\alpha c_2^{-1} r^{-\alpha d} (k+1)^{-\beta} e^{c_1 k^{1/\Delta}}.$$

Assume that the induction hypothesis is true up to  $k-1$ . For  $x, y$  to be connected with at most  $k$  steps, an edge must be used with geometric distance at least  $\frac{|x-y|}{k}$ . This could either be the first or last edge on the path, or a so-called *internal* edge. Let us first bound the probability corresponding to this edge being internal. For this, we union bound over all possible endpoints  $u$  and  $v$  of said edge. Actually, we integrate, since constant factors are essentially immaterial for the proof. At a given distance  $r$ , there are at most  $c_d r^{d-1}$  vertices, for some constant  $c_d$ . Let  $w_u, w_v$  be the weights of  $u, v$ , respectively. By the BK inequality, we have

$$\begin{aligned} & \mathbb{P}(d_G(x, y) \leq k, \text{longest edge is internal} \mid w_u, w_v, w_x, w_y) \leq \\ & \sum_{i=1}^{k-2} \mathbb{P}(d_G(x, u) \leq i \mid w_x, w_u) \mathbb{P}(u \sim v \mid w_u, w_v) \mathbb{P}(d_G(v, y) \leq k-i \mid w_v, w_y) \leq \lambda w_u^\alpha w_v^\alpha \left(\frac{|x-y|}{k}\right)^{-\alpha d} \\ & \times \underbrace{\sum_{i=1}^{k-2} \left( \int_1^\infty c_d r_u^{d-1} \min\{1, h(r_u, i, w_x, w_u)\} dr_u \right)}_{\mathcal{I}(u, i)} \underbrace{\left( \int_1^\infty c_d r_v^{d-1} \min\{1, h(r_v, k-i, w_v, w_y)\} dr_v \right)}_{\mathcal{I}(v, k-i)}. \end{aligned}$$

We will now argue that there exists a constant  $C_{\text{int}}$  (depending on the model parameters) such that

$$\begin{aligned} \mathcal{I}(u, i) & \leq C_{\text{int}} \left( (i+1)^{-\frac{\beta}{\alpha}} e^{\frac{c_1}{\alpha} i^{1/\Delta}} w_u w_x c_2^{-\frac{1}{\alpha}} \right), \\ \mathcal{I}(v, k-i) & \leq C_{\text{int}} \left( (k-i+1)^{-\frac{\beta}{\alpha}} e^{\frac{c_1}{\alpha} (k-i)^{1/\Delta}} w_v w_y c_2^{-\frac{1}{\alpha}} \right). \end{aligned}$$

To this end, note that there exists a value

$$\hat{r}_u = (w_x w_u)^{\frac{1}{d}} c_2^{-\frac{1}{\alpha d}} (i+1)^{-\frac{\beta}{\alpha d}} e^{\frac{c_1}{\alpha d} (i+1)^{1/\Delta}}$$

for  $r_u$  below which the minimum inside the integral  $\mathcal{I}(u, i)$  is 1. We can thus express  $\mathcal{I}(u, i) = \int_1^{\hat{r}_u} f_1(r_u) dr_u + \int_{\hat{r}_u}^\infty f_2(r_u) dr_u$  where  $f_1(r) = c_d r^{d-1}$  and  $f_2$  is a polynomial in  $r_u$  with exponent smaller than  $-1$ . Therefore, the entire integral is dominated by the value of the antiderivative of  $f_1$  and  $f_2$  at the splitting point  $\hat{r}_u$ . Since  $f_1, f_2$  are polynomials, the antiderivative of  $f_1$  is  $\leq c r_u f_1(r_u)$  and the antiderivative of  $f_2$  is  $\leq c r_u f_2(r_u)$  for some constant  $c$ . Since the minimum is a continuous function, we have  $f_1(\hat{r}_u) = f_2(\hat{r}_u)$  and thus,  $\mathcal{I}(u, i) = \Theta(\hat{r}_u f_1(\hat{r}_u)) = \Theta(\hat{r}_u^d)$  as claimed. A similar argument holds for  $\mathcal{I}(v, k-i)$ .<sup>10</sup>

Plugging this in, we obtain

$$\begin{aligned} & \mathbb{P}(d_G(x, y) \leq k, \text{longest edge is internal} \mid w_u, w_v, w_x, w_y) \\ & \leq C_{\text{int}}^2 \lambda \cdot w_u^{1+\alpha} w_v^{1+\alpha} w_x^\alpha w_y^\alpha |x-y|^{-\alpha d} c_2^{-\frac{2}{\alpha}} \\ & \quad \times \underbrace{k^{\alpha d} \sum_{i=1}^{k-2} \left( (i+1)^{-\frac{\beta}{\alpha}} e^{\frac{c_1}{\alpha} i^{1/\Delta}} \right) \left( (k-i+1)^{-\frac{\beta}{\alpha}} e^{\frac{c_1}{\alpha} (k-i)^{1/\Delta}} \right)}_{:=S}. \end{aligned}$$

Our goal now is to show that the above term is at most  $h(r, k, w_x, w_y)$ . To this end, we show that

$$S \leq (k+1)^{-\beta} e^{c_1 k^{1/\Delta}} \tag{5}$$

for  $k$  and  $\beta$  large enough. For this, notice that for small or large  $i$ , the exponential terms in  $S$  are still quite ‘‘tame’’, due to the  $\frac{1}{\alpha}$  factor. When  $i$  is around  $\frac{k}{2}$ , their product (which is maximized for such  $i$  due to concavity) is practically

$$\exp\left(\frac{2c_1}{\alpha} \left(\frac{k}{2}\right)^{1/\Delta}\right) = \exp\left(\frac{2c_1}{\alpha} 2^{-1/\Delta} k^{1/\Delta}\right) = \exp\left(c_1 k^{1/\Delta}\right)$$

<sup>10</sup>This observation is helpful whenever we integrate a continuous and piecewise polynomial function.

as  $2^{-1/\Delta} = \alpha/2$  by definition of  $\Delta$ . In fact, for  $i = \frac{k}{2}$ , we have actual equality and for every  $1 \leq i \leq k$ , we have

$$\exp\left(\frac{c_1}{\alpha} i^{1/\Delta}\right) \exp\left(\frac{c_1}{\alpha} (k-i)^{1/\Delta}\right) \leq \exp\left(c_1 k^{1/\Delta}\right).$$

This is precisely the exponential term that appears in the statement we want to prove (5). However, we also need to account for the sum and the terms polynomial in  $k$  that appear in  $S$ . To this end, we use that – if  $i \approx k/2$  – we gain from the product of the polynomial terms in the sum to compensate overheads. On the other hand, if  $i$  is large or small, the product of the exponential terms is much smaller than what we need, so we can compensate the other terms by using the arising gap. With this in mind, we split the sum in  $S$  into the cases where  $|i - \frac{k}{2}| \leq \frac{k}{4}$  and those where this is not true. This way, we obtain

$$S \leq k^{1+\alpha d} e^{(1-\gamma)c_1 k^{1/\Delta}} + k^{1+\alpha d} ((k+1)/8)^{-\frac{2\beta}{\alpha}} e^{c_1 k^{1/\Delta}}, \quad (6)$$

where  $\gamma > 0$  is a constant depending on  $\Delta$  (and therefore on  $\alpha$ ). The first term accounts for cases where  $i$  is sufficiently far from  $\frac{k}{2}$ , making the exponential terms merge in a tame way. When  $i \in [\frac{k}{4}, \frac{3k}{4}]$ , both  $i+1$  and  $k-i+1$  are at least  $\frac{k+1}{8}$ , since  $k > 2$  (recall that we are analyzing the case where  $k$  edges allow for an internal edge), and this is how the other term is obtained.

Now, notice that since  $\alpha < 2$ , we can choose  $\beta$  large enough such that  $(\alpha d + 1) - \frac{2\beta}{\alpha} < -\beta$ . Then, the second term in 6 is at most  $(k+1)^{-\beta} e^{c_1 k^{1/\Delta}}$  as desired. For the first term, we notice that the same holds if  $k$  is large enough. Hence, for all  $k$ ,  $S$  is at most some constant  $C$  times  $(k+1)^{-\beta} e^{c_1 k^{1/\Delta}}$ . We use this to conclude that

$$\begin{aligned} \mathbb{P}(d_G(x, y) \leq k, \text{ longest edge is internal} \mid w_u, w_v, w_x, w_y) \\ \leq C C_{\text{int}}^2 \lambda c_2^{1-\frac{2}{\alpha}} w_u^{\alpha+1} w_v^{\alpha+1} w_x^\alpha w_y^\alpha |x-y|^{-\alpha d} (k+1)^{-\beta} e^{c_1 k^{1/\Delta}} c_2^{-1} \\ = C C_{\text{int}}^2 \lambda c_2^{1-\frac{2}{\alpha}} w_u^{\alpha+1} w_v^{\alpha+1} \cdot h(|x-y|, k, w_x, w_y). \end{aligned}$$

Since we assume that  $\alpha < \tau - 2$ , we can integrate  $w_u, w_v$  out such that the corresponding integrals over  $w_u$  and  $w_v$  converge and only obtain another constant factor overhead. Then, we can choose  $c_2$  large enough to compensate these constant overheads. Notice that this works since we have a factor of  $c_2^{1-\frac{2}{\alpha}}$  where the exponent is negative because  $\alpha < 2$ . In total, we have shown that we can choose the constants  $\beta, c_1$  and  $c_2$  such that the above bound is at most  $\frac{1}{3} h(|x-y|, k, w_x, w_y)$  for all  $k$ .

Now, let us also bound the probability of paths in which the longest edge is adjacent to either  $x$  or  $y$ . To this end, we sum over all possible vertices  $z$  connected to  $x$  by an edge of (geometric) length  $\geq |x-y|/k$ . Again, by the BK inequality, we have

$$\begin{aligned} \mathbb{P}(d_G(x, y) \leq k, \text{ longest edge incident to } x \mid w_x, w_z, w_y) \\ \leq \lambda w_x^\alpha w_z^\alpha \left(\frac{|x-y|}{k}\right)^{-\alpha d} \left(\int_1^\infty c_d r^{d-1} \min\{1, h(r, k-1, w_z, w_y)\} dr\right) \\ \leq C \lambda w_x^\alpha w_z^\alpha \left(\frac{|x-y|}{k}\right)^{-\alpha d} k^{-\frac{\beta}{\alpha}} e^{\frac{c_1}{\alpha} k^{1/\Delta}} w_z w_y c_2^{-\frac{1}{\alpha}} \\ \leq C \lambda w_z^{\alpha+1} \cdot (k+1)^\beta k^{\alpha d - \frac{\beta}{\alpha}} e^{c_1(\frac{1}{\alpha}-1)k^{1/\Delta}} c_2^{1-\frac{1}{\alpha}} \cdot h(|x-y|, k, w_x, w_y). \end{aligned}$$

Again, by integrating out  $w_z$ , we get another constant factor. We can now choose  $c_1$  large enough so that the term exponential in  $k$  (which has a negative exponent since  $\frac{1}{\alpha} - 1 < 0$ ) swallows the polynomial and constant terms for every  $k$ , ensuring that the factor in front

of  $h(|x - y|, k, w_x, w_y)$  is at most  $\frac{1}{3}$ , as desired. Finally, summing the three possibilities that the longest edge is internal, the first, or the last edge on the path yields that overall,  $\mathbb{P}(d_G(x, y) \leq k \mid w_x, w_y) \leq h(|x - y|, k, w_x, w_y)$  and finishes the proof.  $\blacktriangleleft$

As promised, we now deal with cases where  $\alpha \geq \tau - 2$  by coupling SFP to SFP with larger  $\alpha$  without decreasing distances using the following lemma.

**► Lemma 5.** *Let  $\alpha$  and  $\lambda$  be the long-range and percolation parameters of some instance of SFP. Fix the weights of all vertices and let  $p_{uv}$  refer to the probability that two vertices  $u$  and  $v$  are connected by an edge. Fix some  $\alpha' < \alpha$ . Then,  $p_{uv} \leq \min\{1, \lambda^{\alpha'/\alpha} w_u^{\alpha'} w_v^{\alpha'} |u - v|^{-d\alpha'}\}$ . In particular, this means that the original SFP graph (with parameter  $\alpha$ ) is a subgraph of the one with parameters  $\alpha'$  and  $\lambda' = \lambda^{\alpha'/\alpha}$ .*

**Proof.** We have

$$\begin{aligned} p_{uv} &\leq \min\{1, \lambda w_u^\alpha w_v^\alpha |u - v|^{-d\alpha}\} = \left(\min\{1, \lambda^{\frac{1}{\alpha}} w_u w_v |u - v|^{-d}\}\right)^\alpha \\ &\leq \left(\min\{1, \lambda^{\frac{1}{\alpha}} w_u w_v |u - v|^{-d}\}\right)^{\alpha'} = \min\{1, \lambda^{\frac{\alpha'}{\alpha}} w_u^{\alpha'} w_v^{\alpha'} |u - v|^{-d\alpha'}\}. \end{aligned} \quad \blacktriangleleft$$

The implication of Lemma 5 is that we can artificially ensure that  $\alpha < \tau - 2$  by setting  $\alpha' = \tau - 2 - \varepsilon$  for an arbitrarily small  $\varepsilon$  and  $\lambda' = \lambda^{\alpha'/\alpha}$ . This allows us to prove Theorem 1.1 by applying Lemma 4 to this model since here, graph distances only get shorter due to Lemma 5. We defer the proof to the full version, since it is only technical and the ideas in it are already presented.

### 3 First Passage Percolation (FPP)

In this section we study first passage percolation (FPP) on SFP. Recall that this means that we assign a cost to every edge which is drawn independently from an exponential distribution with rate 1. For conciseness, we restrict ourselves to SFP even though the same technique would also work for GIRGs/HRGs. Note that we obtain the LRP model from SFP by informally setting  $\tau = \infty$ . Formally, since SFP is an increasing model in  $\tau$  in terms of stochastic domination, the edge set of SFP with any finite  $\tau$  stochastically dominates the edge set of LRP. Hence, all lower bounds on cost-distances from SFP also transfer to LRP.<sup>11</sup> In the following, we assume for simplicity that  $\lambda = 1$ ; this does not affect our results.

In contrast to plain SFP, in FPP we have an additional source of randomness since not only the existence of an edge is random but also its cost. To prove lower bounds on cost-distances, it is therefore simpler (and sufficient) to consider a model in which there is only one source of randomness for the edges. We call this model *Complete Scale Free First Passage Percolation*, or CFFP for short. Here, all edges exist a priori, i.e., the graph is fixed to be the complete graph with vertex set  $\mathbb{Z}^d$ . However, we now draw the cost of each edge by sampling from an exponential distribution with rate  $w_u^\alpha w_v^\alpha |u - v|^{-\alpha d}$  (i.e. a rate that depends on the weights and geometric distance between the two endpoints) instead of rate 1.

We start by showing that FPP on SFP is dominated by CFFP, i.e., that cost-distances in CFFP can only become shorter as compared to FPP on SFP. To that end, we need the following lemma that will allow us to combine the randomness of two events occurring with probability  $\min\{1, \alpha\}$  and  $(1 - e^{-b})$ , respectively into an event occurring with probability  $1 - e^{-ab}$ .

<sup>11</sup>The same is true for graph-distances, but here the results for LRP were already known.

► **Lemma 6.**  $\min\{1, a\}(1 - e^{-b}) \leq 1 - e^{-ab}$  for all  $a, b \geq 0$ .

**Proof.** If  $a \geq 1$ , then the inequality is easy to see, as  $(1 - e^{-b}) \leq (1 - e^{-ab})$  in this case. So, let us assume that  $a < 1$  from now on. Consider the function

$$f(b) = a(1 - e^{-b}) - (1 - e^{-ab}).$$

Note that it suffices to show that  $f(b) \leq 0$  for all  $b \geq 0$ . We can see that  $f(0) = 0$  and also

$$f'(b) = a(e^{-b} - e^{-ab}) \leq 0.$$

This shows that the function  $f(b)$  is non-increasing and since  $f(0) = 0$ , we have  $f(b) \leq 0$  for all  $b \geq 0$ . ◀

With this, we establish a coupling between FPP on SFP and CFFP such that cost-distances in CFFP are at most as large as cost-distances in FPP on SFP.

► **Lemma 7.** Let  $u, v$  be a pair of vertices in  $\mathbb{Z}^d$ . Let further  $X_{(u,v)}$  be the cost of the edge  $\{u, v\}$  in FPP on SFP if it exists, and  $X_{(u,v)} = \infty$  if the edge does not exist, and let  $Y_{(u,v)}$  be its cost in CFFP. Then for any  $t \geq 0$ ,

$$\mathbb{P}(X_{(u,v)} \leq t) \leq \mathbb{P}(Y_{(u,v)} \leq t).$$

**Proof.** For the event on the LHS to be true, the edge  $\{u, v\}$  must exist and then *independently* the cost must be drawn to be at most  $t$ . The probability for the first event is  $\min\{1, (w_u w_v)^\alpha |u - v|^{-\alpha d}\}$  and the probability of the latter is  $1 - e^{-t}$ . For the event on the RHS, one simply needs that the cost sampled from an exponential distribution with rate  $(w_u w_v)^\alpha |u - v|^{-\alpha d}$  is at most  $t$  and the probability of this is exactly  $1 - e^{-(w_u w_v)^\alpha |u - v|^{-\alpha d} t}$ . Lemma 6 finishes the proof. ◀

Lemma 7 shows that any lower bound shown for cost-distances in CFFP will also be true for FPP on SFP. To see more clearly why this is true, note that we can couple the models in the following way. First, we sample the weights for the vertices in exactly the same way for both models. Then, conditioned on these weights, the probability space is a product space over independent one-dimensional random variables (technically, one of them can be infinite in value, but this is not a problem for our purposes) for which the inequality in Lemma 7 holds. With this in mind, we continue by establishing the lower bound for cost-distances in CFFP. We will generally follow similar arguments as the ones presented in [13], which studies a model similar to CFFP but without vertex weights. To establish an upper bound on the probability that the cost-distance between two vertices is at most  $t$ , we need a bound on the probability that the sum of exponential random variables is at most  $t$ , which is provided in the following lemma, which in turn is an adaptation of Lemma 2.1 in [13].

► **Lemma 8.** Let  $X_1, X_2, \dots, X_k$  be i.i.d. exponential random variables such that the rate of  $X_i$  is  $(w_i w_{i+1})^\alpha |u_i - u_{i+1}|^{-\alpha d}$ , for some sequence of vertices  $u_j$  with corresponding weight  $w_j$ , with  $1 \leq j \leq k + 1$ . The  $w_i$  are drawn from a power law with exponent  $\tau$ . Assume that  $2\alpha < \tau - 1$ . Then, there exists a  $c > 0$  depending only on  $\alpha, \tau$  such that for all  $t \geq 0$ ,

$$\mathbb{P}\left(\sum_{i=1}^k X_i \leq t\right) \leq \left(\frac{ect}{k}\right)^k \prod_{i=1}^k |u_i - u_{i+1}|^{-\alpha d},$$

where the above probability is taken over the randomness of the weights and the  $X_i$  values.

**Proof.** Note that each  $X_i = \frac{Y_i}{(w_i w_{i+1})^\alpha |u_i - u_{i+1}|^{-\alpha d}}$ , where  $Y_i$  is an exponential random variable with rate 1. Let us use  $\lambda_i = (w_i w_{i+1})^\alpha |u_i - u_{i+1}|^{-\alpha d}$  from now on. By Markov's inequality, we have

$$\mathbb{P}\left(\sum_{i=1}^k X_i \leq t\right) = \mathbb{P}\left(\exp\left(-\theta \sum_{i=1}^k X_i\right) \geq e^{-\theta t}\right) \leq e^{\theta t} \mathbb{E}\left[\exp\left(-\theta \sum_{i=1}^k X_i\right)\right].$$

Now, let us bound the expectation above. Once one fixes the weights  $w_j$ , each  $X_i$  is independent from each other. Moreover, for  $Y_i$  with rate one, it holds that  $\mathbb{E}[\exp(-\theta Y_i)] = \frac{1}{1+\theta} \leq \frac{1}{\theta}$  for  $\theta > 0$ . So, for a fixed realization  $w_1, w_2, \dots, w_{k+1}$  of the weights, we have:

$$\begin{aligned} \mathbb{E}\left[\exp\left(-\theta \sum_{i=1}^k X_i\right) \mid w_1, w_2, \dots, w_{k+1}\right] &= \prod_{i=1}^k \mathbb{E}\left[\exp\left(-\frac{\theta}{\lambda_i} Y_i\right)\right] \\ &\leq \prod_{i=1}^k \frac{\lambda_i}{\theta} \\ &\leq \theta^{-k} \prod_{i=1}^{k+1} (w_i)^{2\alpha} \prod_{i=1}^k |u_i - u_{i+1}|^{-\alpha d}. \end{aligned}$$

The weight terms are raised to  $2\alpha$ , since each weight  $w_i$  enters in (at most) two  $\lambda_j$  as  $w_i^\alpha$ . Integrating the weights out, we see that since they are independent, one has

$$\mathbb{E}\left[\exp\left(-\theta \sum_{i=1}^k X_i\right)\right] \leq \left[\theta^{-k} \prod_{i=1}^k |u_i - u_{i+1}|^{-\alpha d}\right] \prod_{i=1}^{k+1} \mathbb{E}[(w_i)^{2\alpha}].$$

Now, since  $2\alpha - \tau < -1$ , the expectations inside the rightmost product are all at most some constant  $c'$ . Let  $c$  be e.g. equal to  $(c')^2$  such that  $c^k \geq (c')^{k+1}$ . Collecting the above bounds, we have

$$\mathbb{P}\left(\sum_{i=1}^k X_i \leq t\right) \leq e^{\theta t} \left[\theta^{-k} \prod_{i=1}^k |u_i - u_{i+1}|^{-\alpha d}\right] c^k.$$

Setting  $\theta = \frac{k}{t}$  shows the desired bound.  $\blacktriangleleft$

With Lemma 8 at hand, we show that the expected size of the  $t$ -ball around the origin grows at most exponentially with  $t$ . We define this ball  $\mathcal{B}(x, t)$  as the set of vertices reachable from vertex  $x$  with a path of cost-distance at most  $t$ . Exponential growth is not enough by itself for our goal of showing a polylogarithmic lower bound on the distances but is a crucial step in doing so. To do this, we modify the proof of Lemma 2.6 and Theorem 1.2 (ii) in [13]. In the following, we only consider the growth of  $\mathcal{B}(0, t)$ , i.e., the  $t$ -ball around the origin, but it is easy to see that (by translation invariance) the same statements hold if we replace the origin by any vertex  $x$ .

**► Theorem 9 (Exponential Ball Growth).** *Let  $\mathcal{B}(0, t)$  denote the set of vertices reachable with a path of cost at most  $t$  from the origin in CFFP. If  $2\alpha < \tau - 1$ , we have for some  $C$  depending only on  $\alpha$  and  $\tau$ ,*

$$\mathbb{E}[|\mathcal{B}(0, t)|] \leq e^{Ct}.$$

**Proof.** We compute

$$\begin{aligned} \mathbb{E} [|\mathcal{B}(0, t)|] &= \sum_{u \in \mathbb{Z}^d} \mathbb{P} (d_G^{\text{cost}}(0, u) \leq t) \\ &\leq 1 + \sum_{\substack{u \in \mathbb{Z}^d \\ u \neq 0}} \sum_{k=1}^{\infty} \sum_{\substack{(0,u)\text{-path } \pi \\ \text{of length } k}} \mathbb{P} (\pi \text{ has cost distance at most } t) \\ &\stackrel{\text{Lemma 8}}{\leq} 1 + \sum_{\substack{u \in \mathbb{Z}^d \\ u \neq 0}} \sum_{k=1}^{\infty} \left(\frac{ect}{k}\right)^k \sum_{\substack{(0,u)\text{-path} \\ (0=u_1, u_2, \dots, u_{k+1}=u)}} \left[ \prod_{i=1}^k |u_i - u_{i+1}|^{-\alpha d} \right]. \end{aligned}$$

The constant  $c$  above is as in Lemma 8. The rightmost sum above can be bounded by  $b^k |u|^{-\alpha d}$  for some  $b$  depending only on  $\alpha$ . This is done by Lemma 2.5 (c) in [13] (the quantity bounded there is the above sum and is defined in equation (2.3) in the page previous to that of Lemma 2.5). With that in mind, we have

$$\mathbb{E} [|\mathcal{B}(0, t)|] \leq 1 + \left( \sum_{u \in \mathbb{Z}^d, u \neq 0} |u|^{-\alpha d} \right) \left( \sum_{k=1}^{\infty} \left(\frac{ecbt}{k}\right)^k \right).$$

Since  $\alpha > 1$ , the first sum above is bounded by a constant  $c_1$ . Moreover, note that

$$\sum_{k=1}^{\infty} \left(\frac{ecbt}{k}\right)^k \leq \sum_{k=0}^{\infty} \frac{(ecbt)^k}{k!} - 1 = e^{ecbt} - 1.$$

One can choose  $C$  large enough so that  $\mathbb{E} [|\mathcal{B}(0, t)|] \leq e^{Ct}$ . To see why, note that we can freely assume  $c_1 \geq 1$ . Then, setting  $C = ecbc_1$  suffices. That is because of the following. Let  $f(x) = x^{c_1} + c_1(1-x) - 1$ . This function is decreasing from 0 to 1 and increasing afterwards. Moreover, both  $f(0)$  and  $f(1)$  are non-negative, hence it is non-negative for all  $x \geq 0$ . Setting  $x = e^{ecbt}$  shows that for all  $t \geq 0$ ,

$$\mathbb{E} [|\mathcal{B}(0, t)|] \leq 1 + c_1(e^{ecbt} - 1) \leq (e^{ecbt})^{c_1} = e^{Ct}. \quad \blacktriangleleft$$

In the following, we define

$$g(t) := \mathbb{E} [|\mathcal{B}(0, t)|]$$

and note that we have already shown that  $g(t)$  grows at most exponentially. But we can do better and show that in fact it grows at most *stretched* exponentially, in particular roughly as  $\exp(t^{\frac{1}{\Delta}})$ . This intuitively corresponds to the cost-distances between two vertices  $u$  and  $v$  growing roughly as  $(\log |u - v|)^{\Delta}$ , and is then also used in proving the corresponding lower bound later.

To show this improved bound, we bound the crucial quantity

$$f(r, t) = \sup_{|u|=r} \mathbb{P} (d_G^{\text{cost}}(0, u) \leq t) \in [0, 1],$$

that is, the highest possible probability with which a vertex connects to the origin with cost at most  $t$ , given that it has geometric distance  $r$ . We only consider  $r, t > 0$ . One can show the following bound for  $f(r, t)$ .

► **Lemma 10** (Towards a Self-Bounding Inequality for  $g(t)$ ). *Consider CFFP with  $2\alpha < \tau - 1$ . There exist constants  $c_f, \delta > 0$  depending only on  $\alpha$  and  $\tau$  such that*

$$f(r, t) \leq c_f r^{-\alpha d} h(t), \text{ where } h(t) := t^{\alpha d} \int_0^t g(t-y)(g(y) - 1) dy + e^{-\delta t}.$$

This lemma can be seen as a generalization of the technique we use to prove Lemma 4: We bound the probability that two vertices at distance  $r$  are connected by a path of cost at most  $t$  by a term that is essentially  $r^{-\alpha d}$  (which is roughly the probability that the longest edge in such a path exists) times  $h(t)$  which integrates over all possible  $y$  such that said edge connects the  $(t - y)$ -ball around 0 and the  $y$ -ball around  $u$ . Using this, we can then derive a *self-bounding inequality* for  $g(t)$ , which relates  $g$  recursively to itself such that we can derive an upper bound on  $g$  by solving said recursive relation using Theorem 13 which is identical to [13, Theorem 5.3]. We derive the self-bounding inequality by summing  $f(r, t)$  over all vertices and thus express  $g(t)$  as a function of  $h(t)$ , which – in turn – depends on  $g$ . We capture this in the following lemma.

► **Lemma 11 (Self-Bounding Inequality for  $g(t)$ ).** *Consider CFFP with  $2\alpha \leq \tau - 1$ . There are constants  $c, \delta$  such that for all  $t \geq 0$*

$$g(t)^\alpha \leq c \left( t^{\alpha d} \int_0^t g(t - y)g(y)dy + 1 \right).$$

**Proof.** To derive the self-bounding inequality for  $g$  using Lemma 10, we upper bound  $g$  by an expression involving  $f(r, t)$  and then upper bound  $f(r, t)$  using Lemma 10. Specifically, we estimate the expected size of a  $t$ -ball by integrating over all vertices times the respective probability  $f(r, t)$ .

$$\begin{aligned} \mathbb{E}[\mathcal{B}(0, t)] = g(t) &\leq 1 + \int_1^\infty c_d r^{d-1} \min\{1, f(r, t)\} dr \\ &= 1 + \int_1^{(c_f h(t))^{\frac{1}{\alpha d}}} c_d r^{d-1} dr + \int_{(c_f h(t))^{\frac{1}{\alpha d}}}^\infty c_d c_f r^{d-1-\alpha d} h(t) dr \end{aligned}$$

since for  $r > (c_f h(t))^{\frac{1}{\alpha d}}$ , the minimum is smaller than 1 by definition of  $f(r, t)$  from Lemma 10. Integrating out then yields,

$$g(t) \leq 1 + c' \left( h(t)^{\frac{1}{\alpha}} + h(t)^{\frac{1}{\alpha}-1} h(t) \right) \leq 1 + ((c'' h(t))^{\frac{1}{\alpha}})$$

for some constants  $c', c''$  that depend on  $\alpha, d$  and  $\tau$ . Therefore, we infer that

$$(g(t) - 1)^\alpha \leq c'' h(t). \tag{7}$$

It can be shown that<sup>12</sup>  $g(t)^\alpha \leq 2^{\alpha-1}(1 + (g(t) - 1)^\alpha)$ . Chaining this inequality with (7) and replacing  $h(t)$  above by its definition in Lemma 10 we get the claimed recursive inequality for  $g(t)$ . In more detail, we have

$$g(t)^\alpha \leq 2^{\alpha-1}(1 + (g(t) - 1)^\alpha) \leq 2^{\alpha-1}(1 + c'' h(t))$$

Since  $h(t)$  is bounded away from zero and since  $e^{-\delta t} \leq 1$ , it follows that there exists a  $c$  such that the inequality claimed in the lemma statement holds for all  $t$ . ◀

It is through this inequality that a stronger bound on  $g(t)$  can be derived. For this, we use Theorem 5.3 from [13] directly which we restate as Theorem 13. It claims (among more general things) that for a given function  $g(t)$ , if  $1 \leq g(t) \leq e^{Ct}$  for some constant  $C$  (which we have already shown) and an inequality similar to 7 holds, then one *roughly* has  $g(t) \leq e^{t^{1/\Delta}}$ . Now that we have motivated Lemma 10, let us prove it.

---

<sup>12</sup>One simply needs to consider the function  $f(x) = 2^{\alpha-1}(1 + (x - 1)^\alpha) - x^\alpha$  restricted to  $x \geq 1$ , which has a global minimum of 0 at  $x = 2$ .

**Proof of Lemma 10.** Fix a “target” vertex  $u$ . Let us first focus on paths from 0 to  $u$  which contain at least  $\rho t$  edges (we assume that this is an integer for simplicity) for some constant  $\rho$  that will be determined later. If  $P_{\text{long}}$  is the probability that some such path has cost-distance less than  $t$ , then by a simple union bound we have

$$\begin{aligned} P_{\text{long}} &\leq \sum_{k=\rho t}^{\infty} \sum_{\substack{(0,u)\text{-path} \\ \text{of length } k}} \mathbb{P}(\pi \text{ has cost-distance at most } t) \\ &\stackrel{\text{Lemma 8}}{\leq} e^{\theta t} \sum_{k=\rho t}^{\infty} \theta^{-k} c^k \sum_{\substack{(0,u)\text{-path} \\ \text{with } u_1=0 \text{ and } u_{k+1}=u}} \prod_{i=1}^k |u_i - u_{i+1}|^{-\alpha d} \\ &\stackrel{\text{Lemma 2.5 (c) in [13]}}{\leq} e^{\theta t} |u|^{-\alpha d} \sum_{k=\rho t}^{\infty} \left(\frac{cb}{\theta}\right)^k. \end{aligned}$$

In the second line above, we used Lemma 8 but the final step where  $\theta$  is set to some value is not carried out. Furthermore, the constant  $b$  that emerges in the third line is as in Lemma 2.5 (c) of [13]. Now, setting  $\theta = \rho > ecb$ , we have

$$P_{\text{long}} \leq |u|^{-\alpha d} e^{\rho t} \frac{\left(\frac{cb}{\rho}\right)^{\rho t}}{1 - \frac{cb}{\rho}} \leq |u|^{-\alpha d} \frac{e}{e-1} e^{-\rho t \log \frac{\rho}{ecb}}. \quad (8)$$

Now, let us turn our attention to paths that use at most  $\rho t$  edges instead and let  $P_{\text{short}}$  denote the probability that such a path has cost-distance at most  $t$ . The idea here is to notice that a geometrically long edge  $(u_1, u_2)$  must be used (similarly as in the proof of Lemma 4). In particular, this edge has to cover a distance of at least  $\frac{|u|}{\rho t}$ , as there are at most  $\rho t$  edges used to cover a distance of  $|u|$ . We adapt the argumentation of the proof of Lemma 5.1 in [13], which is essentially a union bound over all the possible intermediate pairs  $(u_1, u_2)$ . More precisely, we get that

$$\begin{aligned} P_{\text{short}} &\leq \sum_{\substack{u_1, u_2 \in \mathbb{Z}^d \\ |u_1 - u_2| \geq \frac{|u|}{\rho t}}} \iint \mathbb{P}(d_G^{\text{cost}}(0, u_1) + c_{(u_1, u_2)} + d_G^{\text{cost}}(u_2, u) \leq t \mid w_{u_1}, w_{u_2}) d\mu(w_{u_1}) d\mu(w_{u_2}) \end{aligned} \quad (9)$$

where  $\mu(w) = w^{1-\tau}$  is the probability measure of the weight distribution and

$$\begin{aligned} &\mathbb{P}(d_G^{\text{cost}}(0, u_1) + c_{(u_1, u_2)} + d_G^{\text{cost}}(u_2, u) \leq t \mid w_{u_1}, w_{u_2}) \\ &\leq \int_0^t d\mathbb{P}(d_G^{\text{cost}}(0, u_1) \leq s \mid w_{u_1}) \int_0^{t-s} \mathbb{P}(d_G^{\text{cost}}(u_2, u) \leq y \mid w_{u_2}) w_{u_1}^\alpha w_{u_2}^\alpha |u|^{-d\alpha} (\rho t)^{\alpha d} dy. \end{aligned} \quad (10)$$

where we use a convolution over the cost of the left and right path segment and that the density of  $c_{(u_1, u_2)}$  is at most  $w_{u_1}^\alpha w_{u_2}^\alpha |u|^{-d\alpha} (\rho t)^{\alpha d}$ . Had there not been weights involved, the proof of Lemma 5.1 in [13] would show immediately that

$$P_{\text{short}} \leq c_{\text{short}} |u|^{-\alpha d} h(t)$$

for some constant  $c_{\text{short}}$  depending on  $\alpha$ . In our case we first need to get rid of the weights. To this end, we use the following simple proposition whose proof we defer for now.

► **Proposition 12.** For any  $u_1 \in \mathbb{Z}^d$  and any  $t > 0$ , we have

$$\mathbb{P}(d_G^{\text{cost}}(0, u_1) \leq t \mid w_1) \leq 2w_1^\alpha \mathbb{P}(d_G^{\text{cost}}(0, u_1) \leq t).$$

Applying this proposition to (10) yields

$$\begin{aligned} & \mathbb{P}(d_G^{\text{cost}}(0, u_1) + c_{(u_1, u_2)} + d_G^{\text{cost}}(u_2, u) \leq t \mid w_{u_1}, w_{u_2}) \\ & \leq 4w_{u_1}^{2\alpha} w_{u_2}^{2\alpha} |u|^{-d\alpha} (\rho t)^{\alpha d} \int_0^t d\mathbb{P}(d_G^{\text{cost}}(0, u_1) \leq s) \int_0^{t-s} \mathbb{P}(d_G^{\text{cost}}(u_2, u) \leq y) dy. \end{aligned}$$

Then, applying this to (9) and taking the sum into the integrals, we get

$$\begin{aligned} P_{\text{short}} & \leq \sum_{\substack{u_1, u_2 \in \mathbb{Z}^d \\ |u_1 - u_2| \geq |u|/(\rho t)}} \left( \iint 4w_{u_1}^{2\alpha} w_{u_2}^{2\alpha} d\mu(w_{u_1}) d\mu(w_{u_2}) \right) \\ & \quad \times \left( |u|^{-d\alpha} (\rho t)^{\alpha d} \int_0^t d\mathbb{P}(d_G^{\text{cost}}(0, u_1) \leq s) \int_0^{t-s} \mathbb{P}(d_G^{\text{cost}}(u_2, u) \leq y) dy \right) \\ & \leq \left( \int_1^\infty \int_1^\infty 4(\tau - 1)^2 w_{u_1}^{2\alpha - \tau} w_{u_2}^{2\alpha - \tau} dw_{u_1} dw_{u_2} \right) \\ & \quad \times \left( |u|^{-d\alpha} (\rho t)^{\alpha d} \sum_{u_1 \in \mathbb{Z}^d} \sum_{u_2 \in \mathbb{Z}^d} \int_0^t d\mathbb{P}(d_G^{\text{cost}}(0, u_1) \leq s) \int_0^{t-s} \mathbb{P}(d_G^{\text{cost}}(u_2, u) \leq y) dy \right) \end{aligned}$$

where we took the sum into the second set of parentheses and omitted the condition  $|u_1 - u_2| \geq |u|/(\rho t)$  from the sum and then split it into two sums. We also replaced  $\mu(w) = 1 - w^{1-\tau}$  so  $d\mu(w) = (\tau - 1)w^{-\tau} dw$ . Now, taking these sums into the integrals and recalling that  $g(x) = \sum_{v \in \mathbb{Z}^d} \mathbb{P}(d_G^{\text{cost}}(0, v) \leq x)$  yields that

$$P_{\text{short}} \leq \left( \int_1^\infty \int_1^\infty 4w_{u_1}^{2\alpha - \tau} w_{u_2}^{2\alpha - \tau} dw_{u_1} dw_{u_2} \right) \left( |u|^{-d\alpha} (\rho t)^{\alpha d} \int_0^t dg(s) \int_0^{t-s} g(y) dy \right).$$

Here, it is easy to see that the term in the second set of parentheses is at most  $c_{\text{short}} |u|^{-\alpha d} h(t)$  for some constant  $c_{\text{short}}$  as was formally shown in [13, Lemma 5.1]. The term in the first set of parentheses is some constant that only depends on  $\alpha, \tau$  since the condition  $2\alpha < \tau - 1$  ensures that the integrals converge. This constant enters into  $c_{\text{short}}$ .

If we now choose  $\rho > ecb$  and  $\delta = \rho \log \frac{\rho}{ecb}$ , then summing  $P_{\text{long}}$  from (8) and  $P_{\text{short}}$  as above yields

$$f(r, t) \leq c_f r^{-\alpha d} h(t)$$

for some constant  $c_f$  as desired. ◀

We now give the proof of the proposition deferred above.

**Proof of Proposition 12.** Recall that the statement of the proposition is that

$$\mathbb{P}(d_G^{\text{cost}}(0, u_1) \leq t \mid w_1) \leq 2w_1^\alpha \mathbb{P}(d_G^{\text{cost}}(0, u_1) \leq t)$$

We show this using a coupling argument. To this end, we consider a model  $M$  that resembles CFFP where instead of having the vertex  $u_1$  with weight  $w_1$ , we set the weight of  $u_1$  *deterministically* equal to 1. However, to decide the costs of edges adjacent to  $u_1$ , we take the minimum of  $\lceil w_1^\alpha \rceil$  many independent samples, i.e., for the edge  $(u_1, v)$  we set its cost to the minimum of  $\lceil w_1^\alpha \rceil$  independent samples from an exponential distribution with

rate  $w_v^\alpha |u - v|^{-\alpha d}$ . Alternatively, this can be seen as having  $\lceil w_1^\alpha \rceil$  copies of  $u_1$  (with weight 1) and then studying the minimal cost-distance from 0 to one of the copies  $u_1$  where the minimum is taken over all copies. Note that this description diverges from the one in the previous sentence if we are interested in paths between two arbitrary vertices, but since we are only concerned with paths from 0 to  $u_1$ , the two are equivalent.

We continue by showing that cost distances in CFFP (from 0 to  $u_1$ ) stochastically dominate those in  $M$ , i.e., that

$$\mathbb{P}(d_G^{\text{cost}}(u_1, 0) \leq t \text{ in CFFP} \mid w_1) \leq \mathbb{P}(d_G^{\text{cost}}(u'_1, 0) \leq t \text{ in } M).$$

To this end, we first show that this is the case for the cost of all edges incident to  $u_1$ . Let  $e = (u_1, v)$  be an arbitrary such edge and note that

$$\begin{aligned} \mathbb{P}(c_{(u_1, v)} \geq x \text{ in } M) &= \left( e^{-x w_v^\alpha |u_1 - v|^{-\alpha d}} \right)^{\lceil w_1^\alpha \rceil} \\ &\leq e^{-x w_1^\alpha w_v^\alpha |u_1 - v|^{-\alpha d}} = \mathbb{P}(c_{(u_1, v)} \geq x \text{ in CFFP}). \end{aligned}$$

Now, let  $\mathcal{R}$  be a fixed realization of all weights and edge costs in CFFP not associated with  $u_1$  and denote by  $[d_G^{\text{cost}}(0, v)]_{\mathcal{R}}$  the cost distance from 0 to  $v$  in this realization when  $u_1$  is removed from the underlying graph. With this, we note that – conditional on  $\mathcal{R}$  – we have

$$d_G^{\text{cost}}(u_1, 0) \leq t \iff \exists v \text{ such that } c_{(u_1, v)} \leq t - [d_G^{\text{cost}}(0, v)]_{\mathcal{R}}.$$

Since  $\mathbb{P}(c_{(v, u_1)} \geq x \text{ in } M) \leq \mathbb{P}(c_{(v, u_1)} \geq x \text{ in CFFP})$  as shown above, the probability that this occurs in  $M$  is at least as large as the corresponding probability in CFFP, and since this holds conditional on any realization  $\mathcal{R}$ , it also holds unconditionally by the law of total probability. Hence, we have shown the desired stochastic domination.

It remains to be shown that

$$\mathbb{P}(d_G^{\text{cost}}(u_1, 0) \leq t' \text{ in } M) \leq 2w_1^\alpha \mathbb{P}(d_G^{\text{cost}}(u_1, 0) \leq t \text{ in CFFP}).$$

To prove this, we again consider an arbitrary but fixed realization  $\mathcal{R}$  as in the previous paragraph and recall that  $d_G^{\text{cost}}(u_1, 0) \leq t$  if and only if there is some  $v$  such that  $c_{(u_1, v)} \leq t - [d_G^{\text{cost}}(0, v)]_{\mathcal{R}}$ . Note that by the definition of  $M$ , this occurs if and only if it happens for at least one of the  $\lceil w_1^\alpha \rceil \leq 2w_1^\alpha$  copies of  $u_1$ . Since for each copy, the probability that this happens for said copy is  $\mathbb{P}(d_G^{\text{cost}}(u_1, 0) \leq t \text{ in CFFP} \mid w_{u_1} = 1, \mathcal{R})$ , we get from a union bound and from the law of total probability that

$$\begin{aligned} \mathbb{P}(d_G^{\text{cost}}(u_1, 0) \leq t \text{ in } M) &\leq 2w_1^\alpha \mathbb{P}(d_G^{\text{cost}}(u_1, 0) \leq t \text{ in CFFP} \mid w_{u_1} = 1) \\ &\leq 2w_1^\alpha \mathbb{P}(d_G^{\text{cost}}(u_1, 0) \leq t \text{ in CFFP}) \quad \blacktriangleleft \end{aligned}$$

Finally, we will use Lemma 10 in conjunction with Theorem 5.3 from [13] to show the desired lower bound on cost-distances. We restate that theorem here, simplified for our use case.

► **Theorem 13** (Theorem 5.3 from [13]). *Let  $g(t) : [0, \infty) \rightarrow \mathbb{R}$  be a function satisfying*

$$1 \leq g(t) \leq e^{Ct}$$

and

$$g(t)^{1/\theta} \leq c_h \left( 1 + t^{\beta-1} \int_0^t g(y)g(t-y) dy \right)$$

for all  $t \geq 0$  for some constants  $C > 0$ ,  $\theta \in (\frac{1}{2}, 1)$ ,  $\beta \geq 0$ , and  $c_h \geq 1$ . Then, there exists a constant  $c_\theta > 1$  such that  $g(t) \leq G(t)$  for all  $t \geq 0$  where  $G(t)$  is defined such that

$$\log G(t) = c_\theta (2\lambda t)^{\log_2(2^\theta)} (\log(1 + t^\beta))^{\log_2(1/\theta)} (1 + o(1)).$$

We use the above theorem to prove our main lemma for FPP, which we restate here.

► **Lemma 14** (Tail Bound for Cost-Distances in FPP). *Consider FPP on SFP with  $2\alpha < \tau - 1$  and arbitrary vertices  $x, y$ . There exists a constant  $c$  depending only on  $\alpha$  and  $\tau$  such that for  $\Delta = \Delta(\alpha) = 1/\log_2(2/\alpha)$ ,*

$$\log \mathbb{P}(d_G^{\text{cost}}(x, y) \leq t) \leq c(\log(1 + t))^{1-1/\Delta} t^{1/\Delta} (1 + o(1)) - \alpha d \log |x - y| + c.$$

**Proof.** As discussed, it suffices to show the claim for CFFP. Moreover, by translation invariance, we can replace  $x$  with the origin 0 and  $y$  by  $u = y - x$ . By Lemma 11 we have

$$g(t)^\alpha \leq c_1 \left( t^{\alpha d} \int_0^t g(t-y)g(y) dy + 1 \right) \tag{11}$$

for some  $c_1, \delta > 0$  depending only on parameters of the model. We also know that  $g(t) \leq e^{Ct}$  from Theorem 9 for a  $C$  with the same dependencies. Therefore, using Theorem 5.3 from [13] (stated above the current theorem) with  $\theta = \frac{1}{\alpha}, \beta = \alpha d + 1$  and with the inequality  $1 + t^\beta \leq (1 + t)^\beta$ , we have  $g(t) \leq G(t)$ , where

$$\log G(t) = c(\log(1 + t))^{1-\frac{1}{\Delta}} t^{\frac{1}{\Delta}} (1 + o(1)),$$

where  $c$  depends only on parameters of the model. Now, by Lemma 10, we have

$$\begin{aligned} \log \mathbb{P}(d_G^{\text{cost}}(0, u) \leq t) &\leq \log f(|u|, t) \\ &\leq c' - \alpha d \log |u| + \log \left( t^{\alpha d} \int_0^t g(t-y)(g(y) - 1) dy + e^{-\delta t} \right) \end{aligned}$$

The constant  $c'$  above comes from Lemma 10. The final step is to notice that inequality (11) is satisfied as equality for  $G(t)$ , as in [13]. Then, substituting the expression for it in the resulting inequality gives the desired bound. ◀

We can use the coupling employed in Theorem 1.1 to establish the above tail bound even if  $2\alpha \geq \tau - 1$  but with  $\Delta$  replaced by  $\Delta'' = \Delta(\min\{\alpha, \frac{\tau-1}{2}\} - \varepsilon)$  for arbitrarily small  $\varepsilon$ . We then have obtained Theorem 1.3. Since the proof is almost verbatim the same as that of Theorem 1.1, we omit it. Note that one minor technical step that is required additionally to get the bound claimed in Theorem 1.3 using the one obtained from Lemma 14 is to introduce an auxiliary constant  $\varepsilon'$  in addition to the  $\varepsilon$  from the statement of the theorem. This swallows the  $(\log(1 + t))^{1-\frac{1}{\Delta}}$  factor.

### **A** On the upper bound claim in [19]

In this section, we briefly explain the mistake in the upper bound proof for graph distances in [19]. There, the authors add edges for some paths of length 2 in SFP, thus cutting graph distances at most in half. Let us call the resulting graph 2-SFP. Then they compare 2-SFP to LRP with different parameters. The 2-SFP graph does not dominate an LRP because the edges are correlated, but for every edge  $e$ ,  $\mathbb{P}(e \text{ open in 2-SFP}) \geq \mathbb{P}(e \text{ open in LRP})$ .

Then they make the argument that the correlations are positive, so that for every fixed  $x$ - $y$ -path  $\pi$ , by the FKG inequality:

$$\mathbb{P}(\pi \text{ open in 2-SFP}) \geq \mathbb{P}(\pi \text{ open in LRP}). \quad (12)$$

That is correct, but it does not imply the statement that we would want for a suitable  $k$ :

$$\begin{aligned} \mathbb{P}(\exists x\text{-}y\text{-path } \pi \text{ of length } \leq k: \pi \text{ open in 2-SFP}) \\ \geq \mathbb{P}(\exists x\text{-}y\text{-path } \pi \text{ of length } \leq k: \pi \text{ open in LRP}). \end{aligned} \quad (13)$$

Instead, (12) only implies by summing over all  $x$ - $y$ -paths of length at most  $k$ :

$$\mathbb{E}[\#\text{ of open } x\text{-}y\text{-paths of length } \leq k \text{ in 2-SFP}] \quad (14)$$

$$\geq \mathbb{E}[\#\text{ of open } x\text{-}y\text{-paths of length } \leq k \text{ in LRP}]. \quad (15)$$

However, it is not hard to see that due to the correlations the left hand side of (14) is dominated by low-probability events where the number of paths is very large. In particular, the upper bound proof for LRP is centered around the concept of *hierarchies*, and the first step of a hierarchy is to find an edge of length  $\Theta(|x - y|)$ , where the two endpoints lie respectively close to  $x$  and  $y$ . It is easy to see that for some parameters considered in [19], with high probability such edges do exist in LRP but do not exist in 2-SFP. However, the *expected number* of such edges in 2-SFP (corresponding to the left hand side of (14)) is still large because the unlikely event of a vertex of weight  $\Theta(|x - y|)$  at distance  $|x - y|$  from  $x$  induces a very large number of 2-paths in SFP, which become edges in 2-SFP.

Hence, the argument in [19] shows (14) but not (13), and this is not a minor omission but a major gap. In fact, we conjecture that the upper bound statements in [19] are false, and that the exponent  $\Delta(\alpha) = 1/\log_2(2/\alpha)$  is tight throughout the polylogarithmic regime, i.e. for all  $\tau > 3$  and  $\alpha \in (1, 2)$ . The reason for this intuition is that for  $\tau > 3$  there exists a constant  $C > 0$  such that the induced graph of vertices of weight larger than  $C$  does not percolate. However, we do not see an obvious way to leverage this property into lower bounds for graph distances.

# Derandomizing Multivariate Polynomial Factoring for Low Degree Factors

## Abstract

Kaltofen [STOC 1986] gave a randomized algorithm to factor multivariate polynomials given by algebraic circuits. We derandomize the algorithm in some special cases.

For an  $n$ -variate polynomial  $f$  of degree  $d$  from a class  $\mathcal{C}$  of algebraic circuits, we design a deterministic algorithm to find all its irreducible factors of degree  $\leq \delta$ , for *constant*  $\delta$ . The running time of this algorithm stems from a deterministic PIT algorithm for class  $\mathcal{C}$  and a deterministic algorithm that tests divisibility of  $f$  by a polynomial of degree  $\leq \delta$ .

By using the PIT algorithm for constant-depth circuits by Limaye, Srinivasan and Tavenas [FOCS 2021] and the divisibility results by Forbes [FOCS 2015], this generalizes and simplifies a recent result by Kumar, Ramanathan and Saptharishi [SODA 2024]. They designed a subexponential-time algorithm that, given a blackbox access to  $f$  computed by a constant-depth circuit, outputs its irreducible factors of degree  $\leq \delta$ . When the input  $f$  is sparse, the time complexity of our algorithm depends on a whitebox PIT algorithm for  $\sum_i m_i g_i^{d_i}$ , where  $m_i$  are monomials and  $\deg(g_i) \leq \delta$ . All the previous algorithms required a blackbox PIT algorithm for the same class.

Our second main result considers polynomials  $f$ , where *each* irreducible factor has degree at most  $\delta$ . We show that all the irreducible factors with their multiplicities can be computed in polynomial time with blackbox access to  $f$ .

Finally, we consider factorization of *sparse* polynomials. We show that in order to compute all the sparse irreducible factors efficiently, it suffices to derandomize irreducibility preserving bivariate projections for sparse polynomials.

## 1 Introduction

The problem of *multivariate polynomial factorization* asks to find the unique factorization of a given polynomial  $f \in \mathbb{F}[x_1, \dots, x_n]$  as a product of distinct irreducible polynomials over  $\mathbb{F}$ . The problem reduces to *univariate polynomial factorization* over the same field, for which a deterministic polynomial time algorithm is known over the field  $\mathbb{Q}$ . The complexity of multivariate factorization depends on the representation of input and output polynomials. If we use *dense representation* (where all the coefficients are listed including the zero coefficients), deterministic polynomial time algorithms for multivariate factoring

are known [16]. If we use *sparse representation* (where only the nonzero coefficients are listed), only randomized polynomial time (in the total sparsity of input polynomial and the output factors) algorithms are known [41, 21]. There are other standard representations like arithmetic circuits, and blackbox models (that gives the evaluations of the polynomial at any point, but the internal structure of the computation is hidden). Randomized polynomial time factorization algorithms are known in these models due to the classic results of Kaltofen [19] and Kaltofen and Trager [21]. Randomization is naturally required for these models, as the more basic question of *polynomial identity testing* (given a circuit/blackbox, test if it computes the zero polynomial) is not yet derandomized.

Towards derandomization of special cases of multivariate factoring, we are motivated by the following two questions.

► **Question 1.** Given a sparse polynomial  $f$ . Can we find all the sparse irreducible factors of  $f$  by a deterministic algorithm in polynomial/quasipolynomial/subexponential time?

Note that the factors of a sparse polynomial  $f$  might be nonsparse. Bhargava, Saraf and Volkovich [3] showed an upper bound on the sparsity of the factors of a sparse polynomial  $f$ . However, the bound is exponential in the degree of  $f$ . Therefore, instead of finding *all* the irreducible factors, we want to output only those factors that are sparse.

► **Question 2 ([41, 3]).** Given polynomial  $f = \prod_{i=1}^m g_i^{e_i}$  as a blackbox, where polynomials  $g_i$  are irreducible polynomials whose sparsities are bounded by  $s$ . Can we find the polynomials  $g_i$  in *deterministic* time  $\text{poly}(s, n, d)$  or time quasi-poly/sub-exponential in  $s, n, d$ ?

The second question can be seen as a special case of polynomial factorization, where we are *promised* that *all* the irreducible factors are sparse. To our surprise, we do not know a deterministic *subexponential*-time algorithm even for the special case of Question 2, when the given blackbox computes the product of just *two* irreducible sparse polynomials.

Derandomization of multivariate factoring (whitebox, or blackbox) reduces to (whitebox, or correspondingly blackbox) derandomization of polynomial identity testing (PIT). Kopparty, Saraf and Shpilka [27] showed this reduction in the model of arithmetic circuits. However, we do not know if sparse factorization reduces to sparse PIT or constant-depth arithmetic circuit PIT (the algorithms of [27] reduce to general arithmetic circuit PIT). Recently, there has been some progress on these questions by [28, 29]. Earlier works of Volkovich [39, 40] made progress on several special cases of sparse multivariate factoring.

Multivariate polynomial factoring has various applications, such as *low-degree testing* [1], constructions of pseudorandom generators for low-degree polynomials [6, 8], computational algebraic geometry [14] and many more. blackbox multivariate polynomial factorization is extensively used in *arithmetic circuit reconstruction* [36, 37], and polynomial equivalence testing [22, 23, 33]. Algebraic hardness vs randomness [15] results crucially use multivariate factorization. Special cases of depth-4 polynomial identity testing are related to questions about sparse polynomial factorization [12, 40, 4].

**Divisibility testing.** In a factorization algorithm, we may want to check if a candidate factor is truly a factor via *divisibility testing*. It asks to test if a polynomial  $g(\mathbf{z})$  divides a polynomial  $f(\mathbf{z})$ . Forbes [9] showed that the divisibility testing question can be efficiently reduced to an instance of a PIT question of a model that relates to both  $f$  and  $g$ ; see Lemma 9. Currently, we do not know any deterministic polynomial time algorithm even when  $g$  and  $f$  are both sparse polynomials. When  $f$  is a sparse polynomial and  $g$  is a linear polynomial, the problem reduces to polynomial identity testing of any-order read-once oblivious branching programs (ROABPs), for which polynomial time whitebox PIT algorithm [34] and quasipolynomial

time blackbox PIT algorithms are known [10, 13, 11]. We do not know a deterministic polynomial time algorithm, even for testing if a quadratic polynomial  $g$  divides a sparse polynomial.

## 1.1 Our results

We show a general result that exhibits properties of a class  $\mathcal{C}$  of polynomials, such that we can compute the *constant-degree factors* of polynomials  $f \in \mathcal{C}$ . The following theorem is an informal statement of Theorem 18.

► **Theorem 1** (Low-degree factors via divisibility). *Let  $\delta \in \mathbb{N}$  be a constant and  $\mathcal{C}$  be a class of polynomials such that there is an efficient PIT algorithm for  $\mathcal{C}$ . For any  $n$ -variate polynomial  $f \in \mathcal{C}$  of degree  $d$ , finding all its irreducible factors of degree  $\leq \delta$  reduces to solving polynomially many divisibility questions of whether a given polynomial of degree  $\leq \delta$  divides  $f$ .*

Arguably, Theorem 1 generalizes and simplifies a recent result by Kumar, Ramanathan and Saptharishi [28] about the factorization of polynomials computed by constant-depth circuits. Importantly, if  $f$  is represented in the whitebox setting, then both the required algorithms (PIT and divisibility testing) in Theorem 1 are *whitebox* algorithms, whereas [28] still requires blackbox algorithms. We compare the results in more detail in Section 1.2.

We can apply Theorem 1 in the case of (any-order) ROABPs. There are polynomial time (respectively, quasipolynomial time) whitebox (respectively, blackbox) PIT algorithms for ROABPs. Moreover, using the divisibility techniques by Forbes [9] (see Lemma 9) and the duality trick by Saxena [35], the divisibility testing question of whether a given linear polynomial divides a ROABP can be reduced to a PIT instance of a polynomial-size ROABP.

► **Corollary 2** (Linear factors of ROABPs). *Let  $f$  be an  $n$ -variate polynomial of degree  $d$ , computed by an any-order ROABP of width  $w$ . Then one can output all its linear factors, along with the exponents in time  $\text{poly}(ndw)$  in the whitebox setting, and in time  $\text{poly}(ndw^{\log \log w})$  in the blackbox setting.*

When the input  $f$  is  $s$ -sparse, this result is already known due to Volkovich [39, Theorem 4]. Note that a sparse polynomial has a trivial ROABP.

Finally, we remark that Theorem 1 can be further generalized to outputting factors from a general class  $\mathcal{D}$  (as black box) when in addition to assuming (informally speaking) efficient PIT for  $\mathcal{C}$  and the divisibility test for  $\mathcal{C}$  by  $\mathcal{D}$ , one has to assume efficient derandomization of HIT for  $\mathcal{D}$  (in the sense of finding a good bivariate projection preserving irreducibility, see Assumption 1) and an inclusion property (i.e. given  $g \in \mathcal{D}$  or not). For simplicity, in the conference version, we only assume that  $\mathcal{D}$  is the class of constant-degree polynomials.

Our second result considers the class of polynomials  $f$ , where all the irreducible factors of  $f$  are promised to have degrees bounded by  $\delta$ . For this class, there are blackbox PIT algorithms with time complexity  $\text{poly}(d, n^\delta)$  for  $n$ -variate polynomials  $f$  of degree  $d$ , see [7, 5]. Hence, by Theorem 1, the factoring problem reduces to a divisibility question. Using techniques of Forbes [9] (see Lemma 9), this can be further reduced to designing a blackbox PIT algorithm for polynomials of the form  $\sum_i \Pi_j f_{i,j}$ , where  $\deg(f_{i,j}) \leq \delta$ . However, we *do not* know better than subexponential-time PIT algorithms for this model. Thus, Theorem 1 does not yield anything fruitful in this promise setting. We show how to completely avoid divisibility testing and still find all the irreducible factors in polynomial time. The following theorem is an informal statement of Theorem 19.

► **Theorem 3** (Promise low-degree factoring). *Let  $\delta \in \mathbb{N}$  be a constant. Given a blackbox access to an  $n$ -variate polynomial  $f$  of degree  $d$  such that all its irreducible factors have degrees at most  $\delta$ , one can deterministically output all its irreducible factors along with the multiplicities in  $\text{poly}(nd)$  time.*

The above theorem can be generalized to polynomials whose irreducible factors are from a class  $\mathcal{D}$  (and we will output them as blackbox), for which efficient PIT and derandomization of HIT (in the sense of finding a good bivariate projection preserving irreducibility; see Assumption 1) is known. For simplicity, in the conference version, we only focus on the class of constant-degree polynomials.

**Related work on Theorem 3.** There have been some works when  $\delta = 1$ . In this setting, given a promise that  $f(\mathbf{z}) = \prod_{i \in [m]} \ell_i^{e_i}$ , where  $\ell_i(\mathbf{z})$  are mutually co-prime linear polynomials, we have to output  $\ell_i$ . A randomized polynomial time algorithm for this problem follows from the work of Kaltofen and Trager [21]. Recently, Koiran and Ressayre [25] gave *three* different randomized algorithms for the *non-promise* problem that can test if a given  $f$  can be completely factored into linear polynomials and output the factorization if it exists. The first algorithm assumes that  $\ell_1, \dots, \ell_m$  are *linearly independent*, while the last two do not need that assumption. Later, Koiran and Skomra [26] derandomized the first algorithm when  $\ell_i$  are linearly independent. Using a different idea and linear independence of  $\ell_i$ , Medini and Shpilka [32] gave an alternative deterministic polynomial time algorithm. All these works exploited the linearity (and sometimes randomization/linear independence) of the factors, while our algorithm neither requires linearity of the factors nor any linear independence.

Finally, we go back to Question 1 of outputting all the sparse irreducible factors of a given sparse polynomial. Can efficient sparse irreducibility testing lead to an efficient algorithm? For general multivariate factoring, an effective version of Hilbert’s Irreducibility Theorem (HIT) by Kaltofen [17] (Theorem 10) says that with high probability, an irreducible  $n$ -variate polynomial remains irreducible if we randomly project it to a bivariate polynomial. This leads to an efficient factoring algorithm, since HIT helps to preserve the *factorization pattern* (the number of distinct irreducible factors and corresponding multiplicities). The hardness of Question 1 stems from the fact that a sparse polynomial may have both sparse and non-sparse irreducible factors. Hence, preserving irreducibility for sparse polynomials will not preserve the factorization pattern, and therefore, it may be hard to get back the actual factor. However, we observe that a deterministic version of HIT for sparse polynomials can indeed solve Question 1. The following theorem is an informal statement of Theorem 20.

► **Theorem 4** (Conditional sparse factoring, Informal). *Suppose there is an efficient algorithm that finds a bivariate projection, making an  $s$ -sparse irreducible polynomial both monic (in one variable) and irreducible. Then there is a subexponential-time algorithm that outputs all its irreducible factors with sparsities  $\leq s$  along with their multiplicities.*

## 1.2 Comparison with Kumar, Ramanathan and Saptharishi [28]

**Theorem 1 implies [28, Theorem 1.1–1.2].** Let  $\Delta \geq 2$  be an arbitrary positive integer. Assume that we have a blackbox access to  $f$ , which can be computed by a  $\Delta$ -depth algebraic circuit of size  $s$ . The recent breakthrough result of Limaye, Srinivasan, and Tavenas [31] gives a subexponential time identity testing algorithm for  $f$ . Moreover, using the techniques from [9] (see Lemma 9), one can show that whether a given polynomial of degree  $\leq \delta$  divides  $f$  can be efficiently reduced to PIT for an algebraic circuit of size  $\text{poly}(sd)$ , of the

form  $\sum_i g_i h_i^{d_i}$ , where the polynomials  $g_i$  are computable by  $\Delta$ -depth algebraic circuits and  $\deg(h_i) \leq \delta$ . For a formal proof, see [28, Corollary 2.19]. The main time complexity of [28, Theorem 1.1] is also dictated by the best-known blackbox PIT algorithm for the same model as above, which runs in subexponential time [31]. This algorithm requires the underlying field to have characteristic 0.

When  $\Delta = 2$ , Theorem 1 gives a quasipolynomial time algorithm to output irreducible factors of degree  $\leq \delta$ , thus implying [28, Theorem 1.2]. We know a polynomial time identity testing for sparse polynomials, due to Klivans and Spielman [24]. Further, [9, Corollary 7.16] showed that whether a polynomial of degree  $\leq \delta$  divides a sparse polynomial, reduces to PIT for  $\Sigma m \wedge \Sigma \Pi^{[\delta]}$ ; this model computes polynomials of the form  $\sum_{i=1}^{\text{poly}(sd)} m_i h_i^{d_i}$ , where  $m_i$  are monomials, and  $\deg(h_i) \leq \delta$ . The best-known blackbox (and whitebox) PIT algorithm for this model runs in quasipolynomial time [9, Corollary 6.7], and work over fields of characteristics 0 or large.

**Whitebox vs. blackbox.** Interestingly, if the input  $f$  has a whitebox access to it (for example when  $f$  is sparse, we can use [24]), then the required PIT algorithms in Theorem 1 are also in the whitebox setting. On the other hand, the factoring algorithm in [28] requires blackbox PIT algorithms. To explain it further, let  $f(x, \mathbf{z})$  be a monic polynomial (in  $x$ ) and computed by a constant-depth circuit. Further,  $f = g \cdot h$ , where  $\deg(g) \leq \delta$  and  $\gcd(g, h) = 1$ . In the usual factoring algorithm via Hensel lifting/Newton iteration, it is important to find a good starting point  $\mathbf{a} \in \mathbb{F}^n$  such that  $\gcd(g(x, \mathbf{a}), h(x, \mathbf{a})) = 1$ . This step is usually ensured by finding a hitting set for the *Resultant* polynomial  $\text{Res}_x(g(x, \mathbf{z}), h(x, \mathbf{z}))$ . Once such a point is found, one can project to the univariate  $f(x, \mathbf{a})$ , factorize it and then do the lifting. [28] observed that  $\text{Res}(g, h) = \text{Res}(g, f/g)$ . Further, they showed that the polynomials  $f/g$  as well as  $\text{Res}(g, f/g)$  can be computed by small-size constant-depth algebraic circuits. This was enough to find a good projection using [31], and then find the true factor  $g$  via lifting. Since we do not know the factor  $g$  a priori, the polynomials  $f/g$  and  $\text{Res}(g, f/g)$  can be viewed as polynomials computable by small-size constant-depth algebraic circuits *without* having explicit access to them.

### 1.3 Proof idea

In this section, we give an overview of our algorithms. The overall idea is to project the input polynomial to a trivariate polynomial, factorize it, and recover the original factors via efficient sparse interpolation [24].

**Proof ideas of Theorem 1 and Theorem 3.** Suppose  $f(x, \mathbf{z})$  is an  $(n + 1)$ -variate degree  $d$  homogeneous polynomial computed by an  $s$ -size circuit, which is *monic* in  $x$ . The monicness property can be assumed otherwise it is well-known that a random shift can make  $f$  monic, and this step can be derandomized assuming PIT for  $f$ ; see Lemma 7. We start with the simplest scenario of  $\delta = 1$ , i.e., given  $f$ , we want to output its linear factors.

Suppose  $f = \ell^e \cdot g$ , with  $e \geq 1$ , where  $\gcd(\ell, g) = 1$  and  $\ell$  is a linear polynomial. Consider the substitution  $\phi : z_i \mapsto y^i$ , where  $y$  is a new variable. Observe that  $\phi(f) \in \mathbb{F}[x, y]$  is a nonzero monic polynomial (in  $x$ ) of total degree at most  $nd$ . Further,  $\phi(\ell)$ , remains an *irreducible* factor of  $\phi(f)$  and it is easy to identify  $\ell$  from  $\phi(\ell)$ , since the monomials  $\{z_1, \dots, z_n\}$  are assigned  $y^i$  *uniquely*. One can factorize the bivariate polynomial  $\phi(f)$  in deterministic  $\text{poly}(nd)$  time (see Lemma 11). We can apply the inverse of  $\phi$  to each factor having degree 1 in  $x$ , and there could be  $nd$  many candidates of linear factors. The actual factor  $\ell$  must be one of them. The divisibility testing makes sure that it always outputs the true linear factors.

When  $\delta \geq 2$ , we can still find small weights  $w_i$ , such that any monomial  $\mathbf{z}^e$  of degree  $\leq \delta$  gets uniquely mapped to  $y^i$ , via  $\phi : z_i \mapsto y^{w_i}$ ; see Lemma 14. Unfortunately, this map may not preserve irreducibility. On the other hand, an effective version of Hilbert's Irreducibility Theorem [20] shows that a monic irreducible polynomial  $g(x, \mathbf{z})$  remains irreducible under the substitution  $z_i \mapsto \beta_i t + \gamma_i$ , where  $\beta_i, \gamma_i$  are *randomly* chosen from  $\mathbb{F}$ ; see Theorem 10. Further, this step can be derandomized when  $g$  is a low-degree polynomial. We combine these two ideas to get small weights  $w_i$  and  $w'_i$  such that the projection  $\Psi : z_i \mapsto y^{w_i} t + y^{w'_i}$  preserves the irreducibility of *any* polynomial of degree  $\leq \delta$ , and further it is *uniquely recoverable* from the projected trivariate polynomial; see Corollary 16. Therefore, it suffices to factor the trivariate polynomial, find all its irreducible factors, and recover the original factors.

The proof of Theorem 3 uses the same trivariate projection as above. In this case, we can *avoid* divisibility because the trivariate projection preserves the factorization pattern, and one can recover the original factors uniquely from the projected ones.

**Proof idea of Theorem 4.** Kaltofen and Trager [21] gave an efficient blackbox factoring algorithm, that given a blackbox access to a polynomial  $f$ , and an arbitrary point, outputs evaluations at that point of all its irreducible factors. For simplicity, consider a monic polynomial  $f(x, \mathbf{z})$ . To get the evaluations at  $(\alpha, \mathbf{c}) \in \mathbb{F}^{n+1}$ , consider a trivariate projection  $\eta : \mathbf{z} \mapsto \beta t_1 + (\mathbf{c} - \gamma)t_2 + \gamma$  and  $x \mapsto x$ , for new variables  $t_1$  and  $t_2$ . Here  $\beta, \gamma \in \mathbb{F}^n$  was chosen such that  $\mathbf{z} \mapsto \beta t + \gamma$  *preserves* the irreducibility *all* the irreducible factors of  $f$ ; such a projection exists using Theorem 10. The map  $\eta$  preserves the factorization pattern, and hence one can find the evaluations by factoring  $\eta(f)$ , and evaluating the irreducible factors at  $x = \alpha, t_1 = 0, t_2 = 1$ .

Our algorithm is a simple adaptation of their algorithm, with the following observation. Let  $g(x, \mathbf{z})$  be an irreducible sparse factor of  $f(x, \mathbf{z})$  and let  $\beta, \gamma \in \mathbb{F}^n$  be such that  $g(x, \beta t + \gamma)$  remains irreducible. Although the map  $\eta$  does not preserve the factorization pattern,  $\eta(g)$  remains an irreducible factor of  $\eta(f)$ . Therefore,  $g(\alpha, \mathbf{c})$  can be efficiently found, via evaluating the *right* trivariate factor. For finding the right factor, one can observe that there is a unique correspondence between the bivariate  $g(x, \beta t + \gamma)$  and trivariate  $\eta(g)$ . Since,  $g$  is sparse, one can use sparse interpolation [24] to explicitly reconstruct the polynomial  $g$ , from its evaluations. Finally, whether a sparse polynomial  $g$  divides the input sparse polynomial  $f$  can be solved in deterministic subexponential time, via divisibility-to-PIT reduction of [9] (see Lemma 9) and the blackbox PIT algorithm for constant-depth circuits of [31].

## 2 Preliminaries

We take  $\mathbb{F} = \mathbb{Q}$  as the underlying field throughout the paper, although the results hold over large characteristics.

Let  $\mathcal{P}(n, d)$  be the set of  $n$ -variate polynomials of degree at most  $d$ , with variables  $\mathbf{z} = (z_1, z_2, \dots, z_n)$ . For an exponent vector  $\mathbf{e} = (e_1, e_2, \dots, e_n)$ , we denote the monomial  $\mathbf{z}^{\mathbf{e}} = (z_1^{e_1}, z_2^{e_2}, \dots, z_n^{e_n})$ . Its degree is  $\|\mathbf{e}\|_1 = \sum_{i=1}^n e_i$ .

For  $\mathbf{a} \in \mathbb{F}^n$ , we also denote  $\|\mathbf{a}\|_0 = |\{i \mid a_i \neq 0\}|$ .

$\text{sp}(f)$  denotes the *sparsity*, i.e., the number of monomials with nonzero coefficients in  $f$ .

$\text{Hom}_k[f]$  denotes the homogeneous component of  $f$  of degree equal to  $k$ .

A polynomial  $f$  is called *irreducible*, if it cannot be factored into the product of two non-constant polynomials. Polynomial  $f$  is called *square-free*, if for any non-constant factor  $g$ , the polynomial  $g^2$  is not a factor of  $f$ .

By  $\deg(f)$  we denote the total degree of  $f$ . Let  $x$  and  $\mathbf{z} = (z_1, \dots, z_n)$  be variables and  $f(x, \mathbf{z})$  be a  $(n + 1)$ -variate polynomial. Then we can view  $f$  as a univariate polynomial  $f = \sum_i a_i(\mathbf{z}) x^i$  over  $\mathbb{K}[x]$ , where  $\mathbb{K} = \mathbb{F}[\mathbf{z}]$ . The  $x$ -degree of  $f$  is denoted by  $\deg_x(f)$ . It is the highest degree of  $x$  in  $f$ . Polynomial  $f$  is called *monic in  $x$* , if the coefficient  $a_{d_x}(\mathbf{z})$  is the constant 1 polynomial, i.e.  $a_{d_x}(\mathbf{z}) = 1$ , where  $d_x = \deg_x(f)$ .

An algorithm runs in *subexponential time*, if its running time on inputs of length  $n$  is bounded by  $2^{n^\epsilon}$ , for any  $\epsilon > 0$ .

## 2.1 Computational problems, complexity measures and closure properties

For classes  $\mathcal{P}, \mathcal{Q}$  of multivariate polynomials, we define the following computational problems.

- PIT( $\mathcal{P}$ ): given  $p \in \mathcal{P}$ , decide whether  $p \equiv 0$ .
- Factor( $\mathcal{P}|\mathcal{Q}$ ): given  $p \in \mathcal{P}$ , compute all its irreducible factors in  $\mathcal{Q}$  with their multiplicities.
- Div( $\mathcal{P}|\mathcal{Q}$ ): given  $p \in \mathcal{P}$  and  $q \in \mathcal{Q}$ , decide whether  $q|p$ .

The time complexity to solve these problems we denote by  $T_{\text{PIT}(\mathcal{P})}$ ,  $T_{\text{Factor}(\mathcal{P}|\mathcal{Q})}$ , and  $T_{\text{Div}(\mathcal{P}|\mathcal{Q})}$ , respectively.

► **Remark.** Note that a decision algorithm for PIT( $\mathcal{P}$ ) also yields an algorithm that computes a point  $\mathbf{a} \in (\mathbb{F} \setminus \{0\})^n$  such that  $p(\mathbf{a}) \neq 0$ , in case when  $p \not\equiv 0$ . In the blackbox case, the queries of the decision algorithm on the input of the zero-polynomial yield a *hitting set*<sup>1</sup> for the whole class  $\mathcal{P}$ . In the whitebox case, one can search for  $\mathbf{a}$  by assigning values successively to the variables and do kind of a *self-reduction*. For each variable, one tries at most  $d$  values from  $\{1, 2, \dots, d\}$  for a polynomial of degree  $d$ . If they all give 0, definitely  $d + 1$  works because it cannot be zero at  $(d + 1)$  many values. With  $n$  variables, this amounts to  $nd$  calls to the PIT-decision algorithm. The final desired point  $\mathbf{a} \in \{1, \dots, d + 1\}^n$ , which is very explicit. The running time to compute  $\mathbf{a}$  is therefore bounded by  $nd \cdot T_{\text{PIT}(\mathcal{P})}$ .

For time complexity, we assume that the polynomials are given in some model of computation, such as circuits, branching programs, or formulas. With each model, we associate a complexity measure  $\mu : \mathbb{F}[\mathbf{z}] \rightarrow \mathbb{N}$ . For example, let  $f \in \mathbb{F}[\mathbf{z}]$ , some of the commonly used measures in the literature are:

- $\mu(f) = \text{sp}(f)$ , the number of monomials with nonzero coefficients,
- $\mu(f) = \text{size}_\Delta(f)$ , the size of the *smallest* depth- $\Delta$  algebraic circuit computing  $f$ ,
- $\mu(f) = \text{size}_{\text{ROABP}}(f)$ , the *width* of the *smallest* any-order read read-once oblivious branching program (ROABP) computing  $f$ .

We define classes of polynomials of bounded measure,

$$\mathcal{C}_\mu(s, n, d) := \{f \in \mathcal{P}(n, d) \mid \mu(f) \leq s\}. \tag{1}$$

We generally assume that all polynomials we deal with can be *efficiently evaluated* at any point  $\mathbf{a} \in \mathbb{F}^n$  within the respective measure, where we consider the unit-cost model for operations over  $\mathbb{F}$ . This holds for all the computational models usually considered in the literature.

► **Definition 5 (Closure under derivatives).** *Class  $\mathcal{C}_\mu(s, n, d)$  is closed under derivatives, if for any  $f \in \mathcal{C}_\mu(s, n, d)$ , a variable  $z \in \{z_1, \dots, z_n\}$ , and  $e \in \mathbb{N}$ , the size of the derivative  $\mu(\partial^e f / \partial z^e) = \text{poly}(snd)$ , and further it can be computed in  $\text{poly}(snd)$  time from  $f$ .*

<sup>1</sup>  $H \subseteq \mathbb{F}^n$  is a hitting set for a class  $\mathcal{P}$ , if for every nonzero  $f \in \mathcal{P}$ , there exists  $\mathbf{a} \in H$ , such that  $f(\mathbf{a}) \neq 0$ .

► **Definition 6** (Closure under highest degree). Let  $f = \sum_{k=0}^d f_k(\mathbf{z}) \in \mathcal{C}_\mu(s, n, d)$ , where  $f_k(\mathbf{z}) = \text{Hom}_k[f]$ , the homogeneous component of  $f$  of degree  $k$ . We say that  $\mathcal{C}_\mu(s, n, d)$  is closed under highest degree component if in the above,  $\mu(f_d) \leq \text{poly}(snd)$ , and further it can be computed in  $\text{poly}(snd)$  time from  $f$ .

For example, if the class contains polynomials where each is a product of constant-degree polynomials, then it is *not* closed under homogenization (i.e.  $\mu(f_k) \leq \text{poly}(snd)$  and it can be computed in polynomial time). However, the highest-degree component is still a product of constant-degree polynomials. Other classes that are closed under the highest degree are sparse polynomials, polynomials computed by polynomial size any-order ROABPs, or by constant-depth circuits.

Finally, we define  $\text{Hom}[\mathcal{C}_\mu(s, n, d)]$ , as follows:

$$\text{Hom}[\mathcal{C}_\mu(s, n, d)] := \{ f \in \mathcal{P}(n, d) \mid g \in \mathcal{C}_\mu(s, n, d) \text{ and } f = \text{Hom}_d[g] \}. \quad (2)$$

When the context and the parameters are clear, we will simply denote the classes as  $\mathcal{C}$  and  $\text{Hom}[\mathcal{C}]$ , without explicitly writing the parameters.

## 2.2 Transformation to a monic polynomial

Algorithms for factoring polynomials often assume that the given polynomial is monic. If this is not the case for the given polynomial  $f$ , we apply a transformation  $\tau$  to  $f$  that yields a monic polynomial  $\tau(f)$  that we can factor. From the factors of  $\tau(f)$  we can then reveal the factors of  $f$ . Although this is standard in the literature, we state it in terms of the symbols that we introduced above.

► **Lemma 7** (Transformation to monic). Let  $\mathcal{C}$  be a class of polynomials that is closed under highest degree component. Let  $f(\mathbf{z}) \in \mathcal{C}$  be  $n$ -variate of degree  $d$  and size  $s$ . For a new variable  $x$ , and  $\boldsymbol{\alpha} = (\alpha_1, \dots, \alpha_n) \in (\mathbb{F} \setminus \{0\})^n$ , define a linear transformation  $\tau_\alpha$  on the variables  $z_i$ :

$$\tau_\alpha : z_i \mapsto \alpha_i x + z_i,$$

where  $\alpha_i \neq 0$ , for  $i = 1, 2, \dots, n$ . Let  $f_\alpha(x, \mathbf{z})$  be the resulting polynomial.

Then we can compute  $\boldsymbol{\alpha}$  such that  $\frac{1}{f_d(\boldsymbol{\alpha})} f_\alpha(x, \mathbf{z})$  is monic in  $x$  in time  $nd \cdot \text{T}_{\text{PIT}}(\text{Hom}[\mathcal{C}]) + \text{poly}(snd)$ , where  $f_d = \text{Hom}_d[f]$ .

**Proof.** Let  $f(\mathbf{z}) \in \mathcal{C}$  be a polynomial of degree  $d$  with  $n$  variables  $\mathbf{z} = (z_1, \dots, z_n)$ .

To see what the transformation does, let

$$f = f_0 + f_1 + \dots + f_d,$$

where  $f_k = \text{Hom}_k[f]$ , the homogeneous degree- $k$  component of  $f$ . Consider the degree- $d$  component,

$$f_d(\mathbf{z}) = \sum_{|\boldsymbol{\beta}|_1=d} c_\beta \mathbf{z}^\beta.$$

Then, for  $f_\alpha$ , we have  $\deg_x(f_\alpha) = d$  and the coefficient of the leading  $x$ -term  $x^d$  in  $f_\alpha$  is  $f_d(\boldsymbol{\alpha}) = \sum_{|\boldsymbol{\beta}|_1=d} c_\beta \boldsymbol{\alpha}^\beta$ .

Hence, the PIT algorithm for the homogeneous component  $f_d$  of  $f$  yields an  $\boldsymbol{\alpha} \in (\mathbb{F} \setminus \{0\})^n$  such that  $f_d(\boldsymbol{\alpha}) \neq 0$ . Then the polynomial  $\frac{1}{f_d(\boldsymbol{\alpha})} f_\alpha(x, \mathbf{z})$  is monic in  $x$ . For simplicity of notation, assume in the following that  $f_d(\boldsymbol{\alpha}) = 1$ , so that  $f_\alpha(x, \mathbf{z})$  is monic in  $x$ . ◀

Since we work with the shifted polynomial, we need to ensure that the shift of variables does not affect the irreducibility of the factors; this is guaranteed by the following lemma. This is quite standard in the literature; for a nice proof, see [29, Lemma B7].

► **Lemma 8.** *Let  $f(\mathbf{z}) \in \mathbb{F}[\mathbf{z}]$  be an  $n$ -variate irreducible polynomial. Then, for every  $\mathbf{a} \in \mathbb{F}^n$ , the polynomial  $f(\mathbf{a}\mathbf{x} + \mathbf{z})$  is also irreducible.*

### 2.3 Divisibility testing reduces to PIT

Strassen [38] showed that if  $g \mid f$ , where both  $f$  and  $g$  can be computed by size  $s$  circuits, then  $h := f/g$  can also be computed by a circuit of size  $\text{poly}(sd)$ , where  $d = \deg(h)$ . Forbes [9] observed that this procedure can still be done, even when  $g \nmid f$ , and we will get a small size circuit computing a polynomial  $\tilde{h}$ . We can then argue that  $g$  divides  $f$  if and only if  $f = g \cdot \tilde{h}$ . The latter question is a PIT question.

► **Lemma 9** (Divisibility reduces to PIT, [9, Corollary 7.10]). *Let  $g(\mathbf{z})$  and  $f(\mathbf{z})$  be two polynomials of degree at most  $d$ . Let  $S \subseteq \mathbb{F}$  be a  $\text{poly}(d)$ -explicit set such that  $|S| = 2d^2 + 1$ . Further let  $\alpha \in \mathbb{F}^n$  such that  $g(\alpha) \neq 0$ . Then there are  $\text{poly}(d)$ -explicit constants  $\{c_{\beta,i}\}_{\beta \in S, 0 \leq i \leq d}$ , such that*

$$g(\mathbf{z}) \mid f(\mathbf{z}) \iff f(\mathbf{z} + \alpha) - g(\mathbf{z} + \alpha) \cdot \sum_{\beta \in S} f(\beta\mathbf{z} + \alpha) \sum_{0 \leq i \leq d} c_{\beta,i} \cdot g(\beta\mathbf{z} + \alpha)^i = 0$$

### 2.4 Effective Hilbert's Irreducibility Theorem

An effective version of Hilbert's Irreducibility Theorem due to Kaltofen and von zur Gathen shows how to project a multivariate irreducible polynomial down to two variables, such that the projected bivariate polynomial stays irreducible. The proof shows the existence of an *irreducibility certifying polynomial*  $G(\mathbf{a}, \mathbf{b})$  in  $2n$  variables corresponding to the irreducible polynomial  $g(x, \mathbf{z})$ . The nonzeroness of  $G$  proves the irreducibility of  $g(x, \mathbf{z})$  and also gives a way to find an irreducibility-preserving projection to bivariate (see [17, 20, 27]).

► **Theorem 10.** *Let  $g(x, \mathbf{z})$  be an irreducible polynomial of total degree  $\delta$  with  $n + 1$  variables that is monic in  $x$ . There exists a nonzero polynomial  $G(\mathbf{a}, \mathbf{b})$  of degree  $2\delta^5$  in  $2n$  variables such that for  $\alpha, \beta \in \mathbb{F}^n$ ,*

$$G(\alpha, \beta) \neq 0 \implies \widehat{g}(x, t) = g(x, \alpha_1 t + \beta_1, \dots, \alpha_n t + \beta_n) \text{ is irreducible.}$$

The certifying polynomial  $G$  immediately yields a randomized algorithm to construct the irreducible projection  $\widehat{g}$  via PIT. The derandomization of Hilbert's Irreducibility Theorem is a challenging open problem in general. We observe that it can be derandomized for constant degree polynomials.

### 2.5 Basics of factoring and interpolation

Berlekamp [2] and Lenstra, Lenstra and Lovász [30] gave efficient factorization algorithms for *univariate* polynomials over finite fields and  $\mathbb{Q}$ , respectively. Kaltofen [18] showed how to reduce the factorization of *bivariate* polynomials to univariate polynomials. In fact, the reduction works for  $k$ -variate polynomials, for any constant  $k$ . In our case, we use it for the case  $k = 3$ .

Via standard interpolation, one can assume that the input is given as a dense representation.

## 75:10 Derandomizing Multivariate Polynomial Factoring for Low Degree Factors

► **Lemma 11** (Trivariate Factorization). *Let  $f(x, y, z)$  be a trivariate polynomial of degree  $d$ . Then there exists an algorithm that outputs all its irreducible factors and their multiplicities in time  $\text{poly}(d)$ .*

The following lemma shows how to find the multiplicity of an irreducible factor  $g$  of a polynomial  $f$ . It holds when  $\text{char}(\mathbb{F}) = 0$ , or, large. For a concise proof, see [28, Lemma 4.1].

► **Lemma 12** (Factor multiplicity). *Let  $f(\mathbf{z}), g(\mathbf{z}) \in \mathbb{F}[\mathbf{z}]$  be non-zero polynomials and let  $z \in \{z_1, \dots, z_n\}$  be such that  $\partial_z(g) \neq 0$  and  $g$  is irreducible. Then the multiplicity of  $g$  in  $f$  is the smallest non-negative integer  $e$  such that  $g \nmid \frac{\partial^e f}{\partial z^e}$ .*

Klivans and Spielman [24] derandomized the isolation lemma for PIT of sparse polynomials. Their algorithm works over fields of 0 or large characteristics.

► **Lemma 13** (Sparse PIT and interpolation). *Given an  $n$ -variate  $s$ -sparse polynomial  $f$  of degree  $d$  via blackbox access, PIT for  $f$  works in time  $\text{poly}(snd)$ . Furthermore, if  $f$  is nonzero, one can find the monomials in  $f$  with nonzero coefficients in time  $\text{poly}(snd)$ .*

► **Remark.** Let  $\mathbb{F} = \mathbb{Q}$ , for the simplicity. The interpolation algorithm in [24] works by projecting  $f$  to a univariate polynomial in  $y$  via the map  $z_i \mapsto p_i y^{w_i}$ , for  $p_i$  are distinct primes, and weights  $w_i$ . They used univariate interpolation, to find the coefficients and the exponents. If the input polynomial  $f$  is not  $s$ -sparse, one can still run the algorithm. If at any moment while doing the univariate interpolation, it detects more than  $s$  many nonzero coefficients, it stops, otherwise it will continue, and indeed at the end, output a wrong  $s$ -sparse polynomial  $\hat{f}$ , such that (unfortunately) it matches at all the interpolating values. Given  $s, n, d$ , the evaluation points on which the interpolation algorithm can be thought as coming from a fixed set.

### 2.6 Isolation

Let  $M_\delta$  be the set of monomials in  $n$  variables  $\mathbf{z} = (z_1, z_2, \dots, z_n)$  of degree bounded by  $\delta$ ,

$$M_\delta = \{ \mathbf{z}^e \mid \|e\|_1 \leq \delta \}. \quad (3)$$

Note that  $M_\delta$  is polynomially bounded, for constant  $\delta$ ,

$$|M_\delta| \leq \binom{n + \delta}{\delta} \leq (n + \delta)^\delta \leq (\delta + 1) n^\delta = O(n^\delta). \quad (4)$$

There is a standard way to map the multivariate monomials in  $M_\delta$  in a injective way to univariate monomials of polynomial degree. For completeness, we describe the details.

Consider the standard *Kronecker substitution* on  $M_\delta$ . Define

$$\varphi : z_i \mapsto y^{(\delta+1)^{i-1}}. \quad (5)$$

By extending  $\varphi$  linearly to monomials  $\mathbf{z}^e \in M_\delta$ , we get

$$\varphi : \mathbf{z}^e \mapsto y^{\sum_{i=1}^n e_i (\delta+1)^{i-1}}, \quad (6)$$

Clearly,  $\varphi$  is injective on  $M_\delta$ . However, the degree of  $y$  can be exponentially large, up to  $(\delta + 1)^n$ . A way around is to take the exponents modulo some small prime number  $p$ . We have to determine  $p$  in a way to keep the mapping injective on  $M_\delta$ . Hence, for any two terms  $y^e, y^{e'}$  we get from  $\varphi$ , we have to ensure that  $e \not\equiv e' \pmod{p}$ . Equivalently  $p \nmid (e - e')$ .

We have  $|e - e'| \leq (\delta + 1)^n$  and, by (4), there are  $(\delta + 1)^2 n^{2\delta}$  many pairs  $e, e'$  we get from  $M_\delta$  via  $\varphi$ . Prime  $p$  should not divide any of these differences, and hence,  $p$  should not divide their product  $P$ . The product  $P$  is bounded by

$$P \leq ((\delta + 1)^n)^{(\delta+1)^2 n^{2\delta}} = (\delta + 1)^{(\delta+1)^2 n^{2\delta+1}}. \quad (7)$$

Hence,  $P$  has at most  $\log P \leq R = (\delta + 1)^3 n^{2\delta+1}$  many prime factors. By the Prime Number Theorem, there are more than  $\log P$  primes in the set  $[R^2]$ . Hence, we can find an appropriate prime  $p \leq R^2 = n^{O(\delta)}$ .

► **Lemma 14.** *There is a prime  $p = n^{O(\delta)}$  such that the linear extension of*

$$\varphi_p : z_i \mapsto y^{w_i}, \quad \text{where } w_i = (\delta + 1)^{i-1} \bmod p, \quad \text{for } i = 1, 2, \dots, n, \quad (8)$$

*to monomials is injective on  $M_\delta$ . Moreover, we can find such a  $p$  in time  $n^{O(\delta)}$  and compute and invert  $\varphi_p$  in time  $n^{O(\delta)}$ .*

**Proof.** We already argued about the existence of prime  $p$ . For the running time, recall that  $|M_\delta| = O(n^\delta)$ . Therefore we can search for  $p$  and check whether it works on  $M_\delta$  in time  $n^{O(\delta)}$ . At the same time we can compute pairs of exponents  $(e, k)$  such that  $\varphi_p(z^e) = y^k$ . These pairs can be used to invert  $\varphi_p$ . ◀

The mapping  $\varphi_p$  in Lemma 14 maintains factors of degree  $\delta$  of a polynomial in the following sense.

► **Lemma 15.** *Let polynomial  $f(\mathbf{z})$  factor as  $f = gh$ , where  $g(\mathbf{z})$  has degree  $\delta$ . Let  $\varphi_p$  be the map from Lemma 14. Then we have  $\varphi_p(f) = \varphi_p(g)\varphi_p(h)$ , and  $g$  can be recovered from  $\varphi_p(g)$  in time  $n^{O(\delta)}$ .*

Note that in Lemma 15, we do *not* claim that irreducibility is maintained: when  $g$  is irreducible, still  $\varphi_p(g)$  might be reducible. Consider the example  $n = \delta = 2$ . The weights  $\{1, 3\}$  make sure that each monomial  $z_1^2, z_1 z_2, z_2^2$  gets mapped to a distinct power in  $y$ . Let  $g(x, z) = x^2 - z_1 z_2$ . Observe that  $g$  is irreducible, however  $g(x, y, y^3) = (x - y^2)(x + y^2)$  is reducible.

We combine Lemma 14 and Theorem 10 to obtain a projection of a multivariate polynomial to a 3-variate polynomial that maintains irreducibility of polynomials up to degree  $\delta$ .

► **Corollary 16.** *Let  $g(x, \mathbf{z})$  be an irreducible polynomial of constant degree  $\delta$  with  $n + 1$  variables that is monic in  $x$ . There exists  $\mathbf{w}, \mathbf{w}' \in \mathbb{F}^n$  with  $w_i, w'_i = n^{\text{poly}(\delta)}$  such that*

$$\Psi(g) = g(x, y^{w_1}t + y^{w'_1}, \dots, y^{w_n}t + y^{w'_n}) \in \mathbb{F}[x, y, t] \quad (9)$$

*is irreducible. Moreover, we can compute and invert  $\Psi(g)$  in time  $n^{\text{poly}(\delta)}$ .*

**Proof.** Let  $G(\mathbf{a}, \mathbf{b})$  be the polynomial of degree  $2\delta^5$  in  $2n$  variables provided by Theorem 10 for  $g$ . Let  $\mathbf{w}, \mathbf{w}' \in \mathbb{F}^n$  with  $w_i, w'_i = n^{\text{poly}(\delta)}$  be the exponents we get from Lemma 14 for  $G$ . That is,

$$\widehat{G}(y) = G(y^{w_1}, \dots, y^{w_n}, y^{w'_1}, \dots, y^{w'_n}) \neq 0.$$

Now, suppose that  $\Psi(g)$  is reducible. Then it would also be reducible at a point  $y = \alpha$ , where  $\widehat{G}(\alpha) \neq 0$ . But then  $\widehat{g}(x, t) = \Psi(g)(x, \alpha, t)$  would be reducible too, and this would contradict Theorem 10. We conclude that  $\Psi(g)$  is irreducible.

## 75:12 Derandomizing Multivariate Polynomial Factoring for Low Degree Factors

For the complexity, we first determine prime  $p$  from Lemma 14 and then get the weights  $\mathbf{w}, \mathbf{w}'$  from above. For a given  $g(x, \mathbf{z}) = \sum_{k, \mathbf{e}} c_{k, \mathbf{e}} x^k \mathbf{z}^{\mathbf{e}}$ , we can compute  $\Psi(g)$  in time  $n^{\text{poly}(\delta)}$ . For a monomial of  $g$ , the mapping looks as follows:

$$c_{k, \mathbf{e}} x^k \mathbf{z}^{\mathbf{e}} \mapsto c_{k, \mathbf{e}} x^k \prod_{i=1}^n (y^{w_i} t + y^{w'_i})^{e_i}. \quad (10)$$

To compute  $g$  from  $\Psi(g)$ , set  $t = 0$ , i.e. consider  $\Psi(g)(x, y, 0)$ . From (10) we see that monomials then have the form

$$c_{k, \mathbf{e}} x^k y^{\sum_{i=1}^n e_i w'_i}.$$

From these we get the exponents  $k$  and  $\mathbf{e}$  similar as in the proof of Lemma 14.  $\blacktriangleleft$

► **Remark.** In Corollary 16, when we say that we *invert*  $\Psi$ , it means that for a given  $h \in \mathbb{F}[x, y, t]$  which is monic in  $x$  with  $x$ -degree  $\leq \delta$ , we either detect that  $h$  is not in the codomain of  $\Psi$ , or we compute  $g \in \mathbb{F}[x, \mathbf{z}]$  such that  $\Psi(g) = h$  in time  $n^{\text{poly}(\delta)}$ .

The inversion can be done similarly as described in the proof of Corollary 16. One can evaluate  $t = 0$ , and then for every monomial  $x^k y^j$ , try to find  $x^k \mathbf{z}^{\mathbf{e}}$  that would map to such a monomial at  $t = 0$ . By the property of the map, while mapping the  $y$ -degrees,  $\mathbf{z}$ -degree could be at most  $\delta$ , i.e.  $\deg(x^k \mathbf{z}^{\mathbf{e}}) \leq \delta$ . We will, of course, return empty if the degree of any such monomial, after inverting, becomes  $> \delta$ . Finally, once we have got a candidate  $g$  of degree  $\delta$ , we still have to check whether  $\Psi(g) = h$ , because the inversion procedure ignores the variable  $t$ . The last step can also be efficiently checked.

The polynomial  $g$  of degree  $\delta$  we considered so far can be thought to be a constant-degree factor of a given polynomial  $f$  of degree  $d$ . Our goal would be to compute  $g$ . It is now easy to extend the above results to hold for all degree- $\delta$  factors of  $f$  simultaneously.

► **Corollary 17.** *Let  $f(x, \mathbf{z})$  be a polynomial of degree  $d$  with  $n + 1$  variables that is monic in  $x$ , and let  $\delta$  be a constant. There exists  $\mathbf{w}, \mathbf{w}' \in \mathbb{F}^n$  with  $w_i, w'_i = dn^{\text{poly}(\delta)}$  such that for any irreducible factor  $g$  of degree  $\delta$  of  $f$ , we have that  $\Psi(g)$  is an irreducible factor of  $\Psi(f)$ .*

**Proof.** The proof goes along the lines of Corollary 16, but we choose the weights slightly larger so that the  $\widehat{G}(y)$  polynomials for *all* the degree- $\delta$  factors  $g$  of  $f$  are non-zero simultaneously. That is, we choose prime  $p$  in Lemma 14 as  $p = dn^{\text{poly}(\delta)}$ .  $\blacktriangleleft$

Finally, we conclude this subsection by a general remark that whenever  $n$  and  $\delta$  are fixed, these weights are fixed and can be found efficiently.

### 3 Computing the low-degree factors

For a size measure  $\mu$ , we consider a class of polynomials  $\mathcal{C} = \mathcal{C}_\mu(s, n, d) \subseteq \mathcal{P}(n, d)$  such that  $\mathcal{C}$  is closed under derivatives. Many classes  $\mathcal{C}$  in the literature fulfill this condition. Useful for us are in particular sparse polynomials, polynomials computed by poly-size any-order ROABPs or by constant-depth circuits. For a constant  $\delta \in \mathbb{N}$ , let  $\mathcal{D} = \mathcal{P}(n, \delta)$ .

Our first theorem shows that for any polynomial  $f \in \mathcal{C}$ , all the factors of  $f$  that are in  $\mathcal{D}$  can be computed in polynomial time with oracles for PIT for  $\text{Hom}[\mathcal{C}]$  and divisibility testing  $\mathcal{C}$  by  $\mathcal{D}$ .

► **Theorem 18.** *Factor( $\mathcal{C}|\mathcal{D}$ ) can be solved deterministically in time*

$$nd \cdot \text{T}_{\text{PIT}(\text{Hom}[\mathcal{C}])} + d^2 n^{\text{poly}(\delta)} \cdot \text{T}_{\text{Div}(\mathcal{C}/\mathcal{D})} + \text{poly}(s, n^{\text{poly}(\delta)}, d).$$

**Proof.** Let  $f(\mathbf{z}) \in \mathcal{C}$ . To compute the factors of degree  $\delta$  of  $f$ , we first do some transformations. The first step is to make  $f$  monic in a new variable  $x$  via Lemma 7. Let  $f_\alpha(x, \mathbf{z})$  be monic.

Then we apply Corollary 17 to  $f_\alpha(x, z)$ . That is we compute the weights  $\mathbf{w}, \mathbf{w}' \in \mathbb{F}^n$  bounded by  $dn^{\text{poly}(\delta)}$  and explicitly compute  $\Psi(f_\alpha) \in \mathbb{F}[x, y, t]$  of degree at most  $\tilde{d} = d^2 n^{\text{poly}(\delta)}$ . Note that the  $x$ -degree of  $f_\alpha$  has not changed by mapping  $\Psi$ . In the blackbox case, we can interpolate and reconstruct the polynomial in time  $\text{poly}(s\tilde{d})$ .

The next step is to factor 3-variate  $\Psi(f_\alpha)$ . This can be done efficiently Lemma 11. Finding and listing all the irreducible factors takes time  $\text{poly}(\tilde{d})$ .

Having the factors of  $\Psi(f_\alpha)$  in hand, we invert transformations  $\Psi$  and  $\tau_\alpha$  on the factors. Let  $\tilde{g}$  be a factor of  $\Psi(f_\alpha)$ . By Corollary 17, if  $g$  indeed corresponds to a  $\delta$ -degree factor of  $f$ , then  $\tau_\alpha(g)$  corresponds to a  $\delta$ -degree factor of  $\tau_\alpha(f)$ . Therefore, the inverse transformations will yield  $g$ . Formally, the factor is  $g = \tau_\alpha^{-1}(\Psi^{-1}(\tilde{g}))$ .

However  $\tilde{g}$  might also *not* correspond to a degree- $\delta$  factor of  $f$ . In this case, either the inverse transformation does not go through properly, or the degree we get is larger than  $\delta$ . In these cases, we can immediately throw away  $\tilde{g}$ ; see the remark after Corollary 16. But it could also be that we actually obtain a polynomial  $g$  of degree  $\delta$ , just that it is not a factor of  $f$ . For that reason, we finally do a divisibility check whether  $g|f$ . That way we will compute all factors of  $f$  of degree  $\delta$ .

For the time complexity of the factoring algorithm, we have  $nd \cdot \text{T}_{\text{PIT}(\text{Hom}[\mathcal{C}]})$  for transforming  $f$  to monic  $f_\alpha$  by Lemma 7. Time  $\text{poly}(dn^{\text{poly}(\delta)})$  is used for map  $\Psi$  and the factoring of  $\Psi(f_\alpha)$ . Similar time is taken to invert and get the candidate factors. Finally, we have at most  $d^2 n^{\text{poly}(\delta)}$  candidate polynomials  $g$  for which we test divisibility of  $g|f$ . ◀

► **Remark.** Theorem 18 can be applied in different algebraic models. Furthermore, if a class is closed under highest degree, one can simply assume PIT for  $\mathcal{C}$ . In particular, if we work with algebraic formulas, or algebraic branching programs (ABPs), then the above theorem along with the divisibility lemma Lemma 9 implies that we need PIT for the *same* class, to deterministically find the constant-degree factors.

The following pseudo-code summarizes the algorithm given in the proof of Theorem 18.

■ **Algorithm 1** Computing factors of degree  $\leq \delta$ .

---

**Input** :  $f(z)$ ,  $s$ , and  $\delta$ , where  $f$  is an  $n$ -variate polynomial of degree  $d$  such that  $\mu(f) \leq s$ , and  $\delta$  is a constant.

**Output** : A list of irreducible polynomials of degree  $\leq \delta$ , which are factors of  $f$ , along with the factor-multiplicities.

- 1 Set the output list  $L = \emptyset$ . Set the intermediate candidates list  $L' = \emptyset$ .
- 2 Make a monic transformation  $\tau_\alpha : z_i \mapsto \alpha_i x + z_i$ , according to Lemma 7. Let  $f_\alpha(x, z) := \tau_\alpha(f)$ .
- 3 Find weights  $\mathbf{w}, \mathbf{w}'$  bounded by  $dn^{\text{poly}(\delta)}$  according to Corollary 17 and compute  $\Psi(f_\alpha) \in \mathbb{F}[x, y]$  in dense representation.
- 4 Factorize the trivariate polynomial  $\Psi(f_\alpha)$  according to Lemma 11. Let  $S$  be the set of all  $\leq \delta$  degree factors in  $x$  of  $\Psi(f_\alpha)$  in dense representation.
- 5 **for**  $\tilde{g} \in S$  **do**
  - 6     /\* Computing candidate factors via divisibility \*/
  - 7     Compute  $\hat{g} = \Psi^{-1}(\tilde{g})$  (if the inverse exists) of degree  $\leq \delta$  by Corollary 16.
  - 8     Compute  $g = \tau_\alpha^{-1}(\hat{g})$ .
  - 9     If  $g|f$  then add  $g$  to  $L'$ .
- 9 **for**  $g \in L'$  **do**
  - 10    /\* Computing multiplicities via Lemma 12 \*/
  - 11    Let  $z \in \{z_1, \dots, z_n\}$  be any variable that  $g$  depends on, so that  $\partial_z(g) \neq 0$ .
  - 12    Find the smallest  $e \geq 0$  such that  $g \nmid \frac{\partial^e f}{\partial z^e}$ .
  - 13    **if**  $e > 1$  **then** add  $(g, e)$  to the list  $L$ .
- 13 **return**  $L$

---

#### 4 Computing the factors of a constant degree product

Now, we want to output the constant-degree irreducible factors in the promise case.

It is still an open question to test in deterministic polynomial time if a quadratic polynomial (or any non-linear polynomial whose total degree is upper bounded by a constant) divides another polynomial  $f$ , even when  $f$  is a sparse polynomial. In the above theorem  $f$  may not be sparse and we have only blackbox access to it. Thus, the proof for Theorem 2 is a bit different from Theorem 1.

► **Theorem 19.** *Given blackbox access to an  $n$ -variate degree- $d$  polynomial  $f = \prod_{i=1}^s g_i^{e_i}$ , where  $g_i$  are irreducible polynomials with  $\deg(g_i) \leq \delta$ , one can deterministically output all  $(g_i, e_i)$  in time  $\text{poly}(dn^{\text{poly}(\delta)})$ .*

**Proof.** The first step of the algorithm is to make  $f(\mathbf{z})$  monic in a new variable  $x$  via Lemma 7. One can find an  $\alpha \in (\mathbb{F} \setminus \{0\})^n$  in  $\text{poly}(d, n^\delta)$  time by using the hitting set for polynomials of degree  $\leq \delta$ ; see [7, 5].

Next step is to apply Corollary 16 to  $f_\alpha(x, \mathbf{z})$ . Find the weights  $\mathbf{w}, \mathbf{w}' \in \mathbb{F}^n$ , each bounded by  $dn^{\text{poly}(\delta)}$ . Observe that  $\Psi(f_\alpha) \in \mathbb{F}[x, y, t]$ , of degree at most  $\tilde{d} := d^2 n^{\text{poly}(\delta)}$ . By the same lemma, we know that for any irreducible factor  $g$  of  $f$ , we have that  $\Psi(g)$  is an irreducible factor of  $\Psi(f)$ .

The next step is to explicitly compute the trivariate polynomial  $\Psi(f_\alpha)$ . Since, the degree of the polynomial is at most  $\tilde{d}$ , one can interpolate and reconstruct the polynomial, from its blackbox access, in time  $\text{poly}(s\tilde{d})$ . Note that  $s \leq d$ .

The next step is to factorize  $\Psi(f_\alpha)$ . This can be done efficiently using Lemma 11. Finding and listing all the irreducible factors takes time  $\text{poly}(\tilde{d})$ .

The next step is to invert the transformation  $\Psi^{-1}$  on the factors computed in the previous step. This can be done efficiently in time  $\text{poly}(dn^{\text{poly}(\delta)})$ ; see Corollary 16 and its remark. Let  $\tilde{g}$  be a factor of  $\varphi(f_\alpha)$ . Output  $g = \tau_\alpha^{-1}(\Psi^{-1}(\tilde{g}))$ .

■ **Algorithm 2** Promise factors of degree  $\leq \delta$ .

---

**Input** : An  $n$ -variate, degree  $d$  polynomial  $f(\mathbf{z})$ , and a constant  $\delta$ , and a promise that all its irreducible factors have degree  $\leq \delta$ .

**Output** : All the irreducible factors of  $f$ , along with the multiplicities.

- 1 Set the output list  $L = \emptyset$ .
  - 2 Make a monic transformation  $\tau_\alpha : z_i \mapsto \alpha_i x + z_i$ , according to Lemma 7. Let  $f_\alpha(x, \mathbf{z}) := \tau_\alpha(f)$ .
  - 3 Find weights  $\mathbf{w}, \mathbf{w}'$  bounded by  $dn^{\text{poly}(\delta)}$  according to Corollary 17 and compute  $\Psi(f_\alpha) \in \mathbb{F}[x, y]$  in dense representation.
  - 4 Factorize the trivariate polynomial  $\Psi(f_\alpha)$  according to Lemma 11. Let  $S$  be the set of irreducible factors of  $\Psi(f_\alpha)$  along with its multiplicities as a tuple.
  - 5 **for**  $(\tilde{g}, e) \in S$  **do**
    - 6 /\* Computing the irreducible factors via inversion \*/
    - 6 Compute  $\hat{g} = \Psi^{-1}(\tilde{g})$ , by Corollary 16 and its remark.
    - 7 Compute  $g = \tau_\alpha^{-1}(\hat{g})$ , and add  $(g, e)$  to  $L$ .
  - 8 **return**  $L$
-

Now, we discuss the correctness of the output. By assumption,  $f = g_1^{e_1} \cdots g_s^{e_s}$  where  $g_i \in \mathcal{D}$ . Therefore,  $\Psi(\tau_\alpha(f)) = \Psi(\tau_\alpha(g_1))^{e_1} \cdots \Psi(\tau_\alpha(g_s))^{e_s}$ . Furthermore, by choice of  $\mathbf{w}, \mathbf{w}'$ , we know the following facts.

1. The polynomials  $\Psi(\tau_\alpha(g_i)) \in \mathbb{F}[x, y, t]$  are irreducible over  $\mathbb{F}$ , for all  $i = 1, \dots, s$ .
2.  $\Psi(\tau_\alpha(g_i)) \neq \Psi(\tau_\alpha(g_j))$ , for  $i \neq j$ .
3. One can uniquely recover  $g_i$  from  $\Psi(\tau_\alpha(g_i))$ , using Corollary 16 and its remark.

This implies that the factoring pattern of  $f$  and  $\Psi(\tau_\alpha(f))$  remain the same, and can be recovered by simply looking at the factorization of  $\Psi(\tau_\alpha(f))$ .

**Time complexity.** To make  $f$  monic, we find vector  $\alpha$  in time  $\text{poly}(dn^\delta)$ . Interpolation and trivariate factorization of a degree- $\tilde{d}$  polynomial takes time  $\text{poly}(\tilde{d}) = \text{poly}(dn^{\text{poly}(\delta)})$ , see Lemma 11. Inverting each of them to get the original factor also takes time  $\text{poly}(dn^{\text{poly}(\delta)})$ .  $\blacktriangleleft$

## 5 Finding sparse factors reduces to sparse irreducibility

Let  $f$  be an  $n$ -variate irreducible polynomial of degree  $d$ . Let  $\alpha \in (\mathbb{F} \setminus \{0\})^n$ , such that

$$f_d(\alpha) \neq 0, \text{ where } f_d = \text{Hom}_d[f] \text{ is the homogeneous degree } -d \text{ component of } f.$$

Using Lemma 7 and Lemma 8, one can conclude that  $\hat{f}(x, \mathbf{z}) := f(\alpha x + \mathbf{z})$  is a monic irreducible  $(n+1)$ -variate polynomial of degree  $d$ .

On the other hand Theorem 10 shows that for a *random*  $\beta, \gamma \in \mathbb{F}^n$ , the bivariate polynomial

$$f(\alpha x + \beta t + \gamma) = \hat{f}(x, \beta t + \gamma) \in \mathbb{F}[x, t],$$

remains irreducible. When the degree of  $f$  is a constant, such an irreducibility preserving reduction can be efficiently derandomized; see Corollary 16. Formally, we should think of it as a derandomization for the class of constant degree polynomials. In Corollary 16, one can think of evaluating  $y$  at polynomially many points to find the right  $\beta, \gamma$ , while the point  $\alpha$  comes from an efficient PIT algorithm for  $f_d$ . Note that *any*  $\alpha \in (\mathbb{F} \setminus \{0\})^n$  suffices as long as  $f_d(\alpha) \neq 0$ .

Let  $\alpha \in (\mathbb{F} \setminus \{0\})^n$ . We define a set  $S_\alpha(s, n, d)$  as follows.

$$S_\alpha(s, n, d) := \{f \in \mathcal{P}(n, d) \mid f \text{ is irreducible, } \text{sp}(f) \leq s, \text{ and } \text{Hom}_{\text{deg}(f)}[f](\alpha) \neq 0\}. \quad (11)$$

Motivated by the efficient derandomization of irreducibility preserving bivariate projections for constant degree polynomials, we assume the following.

► **Assumption 1 (Sparse irreducible projection).** Let  $\alpha \in (\mathbb{F} \setminus \{0\})^n$ , and  $S_\alpha(s, n, d) \subseteq \mathcal{P}(n, d)$  as defined in Equation (11). Then, there is a deterministic subexponential time algorithm to find an explicit set  $\mathcal{H}_\alpha \subseteq \mathbb{F}^{2n}$  of size subexponential, such that for any  $f \in S_\alpha(s, n, d)$ , there exists  $(\beta, \gamma) \in \mathcal{H}_\alpha$  such that  $f(\alpha x + \beta t + \gamma)$  remains irreducible.

► **Remark.** Assuming the above, one can decide whether an  $s$ -sparse degree- $d$  polynomial  $f$  is irreducible or not in subexponential time. To do this, one can find  $\alpha \in (\mathbb{F} \setminus \{0\})^n$  such that  $\text{Hom}_d[f](\alpha) \neq 0$ , in time  $\text{poly}(snd)$ , using [24]. Hence, one can find a set  $\mathcal{H}_\alpha$  such that  $f(\mathbf{z})$  is reducible if and only if  $f(\alpha x + \beta t + \gamma)$  is reducible, for every  $(\beta, \gamma) \in \mathcal{H}_\alpha$ . Whether a bivariate polynomial is reducible can be checked in time  $\text{poly}(d)$  (Lemma 11).

## 75:16 Derandomizing Multivariate Polynomial Factoring for Low Degree Factors

Using Assumption 1, one can design an efficient deterministic algorithm to output sparse irreducible factors of a sparse polynomial.

► **Theorem 20** (Efficient sparse factoring). *Let  $f \in \mathbb{F}[\mathbf{z}]$  be an  $s$ -sparse polynomial of degree  $d$ . If Assumption 1 holds, then there is a deterministic subexponential time algorithm that outputs all its irreducible factors with sparsities  $\leq s$ , along with the multiplicities.*

**Proof.** Assume that  $g$  is a  $s$ -sparse irreducible factor of  $f$  with multiplicity  $e$ , i.e.,  $f = g^e \cdot R$ , where  $\gcd(g, R) = 1$ . Assume that  $\deg(g) = d_1$ , and  $\deg(R) = d_2$ . We will argue that Algorithm 3 correctly outputs  $(g, e)$ . Let  $\alpha \in (\mathbb{F} \setminus \{0\})^n$ , such that  $\text{Hom}_d[f](\alpha) \neq 0$ . Observe that  $\text{Hom}_d[f] = (\text{Hom}_{d_1}[g])^e \cdot \text{Hom}_{d_2}[R]$ . Therefore, it must hold that  $\text{Hom}_{d_1}[g](\alpha) \neq 0$ , implying  $g \in S_\alpha(s, n, d)$ .

By Assumption 1, we know that there exists a subexponential time algorithm to find a set  $\mathcal{H}_\alpha$  such that  $g(\alpha x + \beta t + \gamma)$  remains irreducible for some  $(\beta, \gamma) \in \mathbb{F}^{2n}$ . We call  $(\beta, \gamma)$  a “good” point for  $g$ .

For such a good point, the set  $S$  in Line 6 of Algorithm 3 must contain  $g(\alpha x + \beta t + \gamma)$ . Pick any  $\mathbf{c} \in \mathbb{F}^n$ . Observe that  $\tilde{g}(x, t_1, t_2) := \phi_{\mathbf{c}}(g) = g(\alpha x + \beta t_1 + (\mathbf{c} - \gamma)t_2 + \gamma)$  is a monic polynomial in  $x$ . Further,  $\tilde{g}$  remains irreducible, since  $\tilde{g}(x, t, 0) = g(\alpha x + \beta t + \gamma)$  is irreducible by the choice of a good point  $(\beta, \gamma)$ . Hence,  $S'$  in Line 10 must contain the polynomial  $\tilde{g}$ .

One can find the corresponding factor in Line 12, and suppose the corresponding index is  $j$ . Note that  $\tilde{g}(0, 0, 1) = g(\mathbf{c})$ .

From the above, one can conclude that the  $L'_j$  contains  $(j, \mathbf{c}, g(\mathbf{c}))$ . One can now do the sparse interpolation using [24], to reconstruct  $g$ ; see Lemma 13. Since  $g \mid f$ , this is correctly detected and added to the list  $L'$ . This is being discussed in Line 15-16.

Further, by our choice of a good point  $(\beta, \gamma) \in \mathcal{H}_\alpha$ , the bivariate  $g(\alpha x + \beta t + \gamma)$  remains irreducible, and hence it successfully passes Line 19. Since  $g$  is a nontrivial polynomial, one can find a variable  $z \in \{z_1, \dots, z_n\}$  such that  $\partial_z(g) \neq 0$  in Line 20. Using Lemma 12, one can conclude that indeed Line 22 adds  $(g, e)$  to the list  $L$ .

From the above analysis, we know that Algorithm 3 always outputs  $g$  with the corresponding multiplicity. On the other hand, Line 15 makes sure that the candidate polynomial is indeed at most  $s$ -sparse (see Lemma 13) and Line 16, by the divisibility testing, makes sure it detects a wrong sparse factor. What could have happened is  $L'$  contains factors which are  $s$ -sparse reducible polynomials dividing  $f$ .

Line 19 again uses Assumption 1 to check if it is indeed irreducible or not. Finally, Line 20-22 make sure that the Algorithm 3 never outputs the correct multiplicity. This finishes the correctness of the algorithm.

**Running time analysis.** Since  $f$  is  $s$ -sparse, one can find an  $\alpha \in \mathbb{F}^n$ , such that  $\text{Hom}_d[f](\alpha) \neq 0$ , in  $\text{poly}(snd)$  time [24].

Line 6-10 take  $\text{poly}(d)$  time, since bivariate/trivariate interpolation and factorization can be done efficiently Lemma 11.

Line 15 can be done using the sparse interpolation algorithm in  $\text{poly}(snd)$  time [24]. Line 16 requires whether a given  $s$ -sparse polynomial  $P_j$  divides another  $s$ -sparse polynomial  $f$  or not. Using the techniques from [9] (Lemma 9), this divisibility question can be reduced to a PIT instance of a constant-depth circuit, for which there is a subexponential time algorithm [31].

Line 19 is again bivariate factorization Lemma 11 which can be done in  $\text{poly}(d)$  time.

Further,  $\frac{\partial^e f}{\partial z^e}$  is at most  $s$ -sparse. Hence, the divisibility question of whether  $P \mid \frac{\partial^e f}{\partial z^e}$  in Line 21, can be similarly done in subexponential time. Finally, since  $|\mathcal{H}_\alpha|$  is subexponentially large, the overall running time remains subexponential. ◀

■ **Algorithm 3** Computing  $s$ -sparse factors.

**Input** : An  $n$ -variate, degree  $d$  polynomial  $s$ -sparse polynomial  $f(\mathbf{z})$ .

**Output** : A list of irreducible  $s$ -sparse polynomials which are factors of  $f$ , along with the factor-multiplicities.

```

1 Set the output list  $L = \emptyset$ . Set the intermediate candidate list  $L' = \emptyset$ .
2 Use Lemma 13 to find an  $\alpha \in (\mathbb{F} \setminus \{0\})^n$  such that  $\text{Hom}_d[f](\alpha) \neq 0$ .
3 Use Assumption 1 to find a set  $\mathcal{H}_\alpha$ .
4 for each  $(\beta, \gamma) \in \mathcal{H}_\alpha$  do
5   Let  $\phi : z_i \mapsto \alpha_i x + \beta_i t + \gamma_i$ . Compute  $\hat{f} := \phi(f) \in \mathbb{F}[x, t]$ , as a dense
   representation.
6   Factorize the bivariate polynomial  $\hat{f}$  over  $\mathbb{F}$ . Let  $S = \{g_1(x, t), \dots, g_m(x, t)\}$  be
   the set of its irreducible factors.
7   Set  $m$  many interpolating lists  $L'_j = \emptyset$ , for  $j \in [m]$ .
8   Fix  $\mathbf{c} = (c_1, \dots, c_n) \in \mathbb{F}^n$ . /* These points are the evaluation points
   for which  $s$ -sparse interpolation succeeds */
9   For new variables  $t_1$  and  $t_2$ , define a new map
    $\phi_{\mathbf{c}} : z_i \mapsto \alpha_i x + \beta_i t_1 + (c_i - \gamma_i)t_2 + \gamma_i$ . Compute  $\tilde{f}_{\mathbf{c}} := \phi_{\mathbf{c}}(f) \in \mathbb{F}[x, t_1, t_2]$ , as a
   dense representation.
10  Factorize the trivariate  $\tilde{f}_{\mathbf{c}}$  over  $\mathbb{F}$ . Let  $S' = \{h_1(x, t_1, t_2), \dots, h_r(x, t_1, t_2)\}$  be the
   set of its irreducible factors.
11  for  $h_i \in S$  do
12    /* Computing the unique correspondence between bivariate and
   trivariate factors, and the evaluations */
13    Find the unique  $j \in [m]$  such that  $h_i(x, t, 0) = g_j(x, t)$ , if exists, otherwise go
   to the next factor in  $S$ .
14    Evaluate  $h_i(0, 0, 1)$ , and add  $(j, \mathbf{c}, h_i(0, 0, 1))$  to  $L'_j$ .
15  for  $j \in [m]$  do
16    /* Computing candidate sparse factors via interpolation and
   divisibility */
17    Use sparse interpolation algorithm (Lemma 13) to find an  $s$ -sparse polynomial
    $P_j$ , if exists, such that  $P_j(\mathbf{c}) = \theta$  where  $(j, \mathbf{c}, \theta) \in L'_j$ .
18    Check if  $P_j \mid f$ , or not. If yes, then update  $L' = \{P_j\} \cup L'$ .
19  return  $L'$ 
20 for each  $P \in L'$  do
21   /* Deciding irreducibility and computing multiplicities via
   Lemma 12 */
22   Check if  $P$  is irreducible, using Assumption 1 and its remark. If it is not
   irreducible, STOP, and go to the next polynomial in  $L'$ .
23   Otherwise, let  $z \in \{z_1, \dots, z_n\}$  be any variable that  $P$  depends on, so that
    $\partial_z(P) \neq 0$ .
24   Find the smallest  $e \geq 1$  such that  $P \nmid \frac{\partial^e f}{\partial z^e}$  and add  $(P, e)$  to the list  $L$ .
25 return  $L$ 

```

## ► Remarks.

1. Assumption 1 is true for constant degree polynomials and can be solved in polynomial time Corollary 16. Therefore, Algorithm 3 can be used to give an alternative proof of Theorem 18. This is because for  $f \in \mathcal{C}$ , we need to find  $\alpha$ , such that  $\text{Hom}_d[f](\alpha) \neq 0$ , which is given by the PIT oracle for  $\mathcal{C}$ . Once the  $\alpha$  is found,  $\mathcal{H}_\alpha$  can be found for the constant-degree polynomials, that preserves irreducibility; see Corollary 16. Additionally, the algorithm requires some divisibility testing by the candidate constant-degree polynomials, which is done using the divisibility testing  $\text{Div}(\mathcal{C}/\mathcal{D})$ .
2. Theorem 20 can be generalized to the input and output polynomials being computed by constant-depth circuits, by analogously changing the Assumption 1 for constant-depth circuits. In this case, we will only be able to output the factors as blackbox (because efficient reconstruction for constant-depth circuits is still unknown). Note that whether a constant-depth circuit divides another constant-depth circuit can be deterministically decided in subexponential time.

**6 Conclusion**

We conclude with some open questions.

1. Can we decide whether a given sparse polynomial is irreducible in deterministic subexponential time? The proof may already give a good bivariate projection that preserves irreducibility. Then Theorem 20 would give us a deterministic subexponential-time algorithm to find irreducible sparse factors of a sparse polynomial.
2. Can we find *bounded individual degree* sparse factors of a sparse polynomial (without any bound on the individual degree) in deterministic quasipolynomial time? Volkovich asked if multilinear factors of a sparse polynomial can be found in deterministic polynomial time [39].
3. Can one compute all the factors of a sparse polynomial/constant depth circuit by constant depth circuits of small size? At least, can one find all the factors that are computable in constant depth? The recent result in [29] gives a deterministic subexponential-time algorithm that outputs a list of circuits (of unbounded depth and possibly with division gates) that includes all such factors.
4. Given a blackbox computing the product of sparse irreducible polynomials  $f_i$  with bounded individual degree, find  $f_i$ 's in deterministic polynomial time. [3] gives a quasipolynomial time algorithm, when the input is sparse with constant individual degree and the factors are all sparse (polynomially upper bounded with respect to input polynomial's sparsity).
